Adaptation analysis of different detection methods applied to unmanned aerial dispersal

Detection Method	Feasibility	Limitations	Improvement Suggestions
Weighing Method	The feasibility is relatively strong. The load of the material box on the drone is limited and easy to plug and unplug. Pressure sensors can meet the requirements, allowing for real-time measurement.	This method mainly focuses on detecting changes in the weight of the material box, and the stress conditions of the material box have a significant impact on the detection results.	Multiple pressure sensors can be set up, using the differential principle to obtain the actual net load changes of the material box.
Coriolis Force Method	The feasibility is relatively poor. The size of the drone is limited, and most existing discharge mechanisms have compact structures, resulting in limited space for particle descent, making it difficult to generate Coriolis force.	The detection device is somewhat complex and has high installation requirements; it needs particle flow to generate Coriolis force for accurate detection.	/
Concentration-Based Method	The feasibility is relatively strong. During the drone's dispersal, the particle flow is substantial, and the signal changes based on particle volume concentration are significant and easy to obtain.	To acquire complete and accurate detection information when the particle flow is large, some methods require complex sensor arrangements, which can lead to signal redundancy and make signal processing difficult.	Improve signal processing methods and consider introducing deep learning algorithms to optimize the information processing process for faster and more accurate detection information.

Detection Method	Feasibility	Limitations	Improvement Suggestions
Velocity-Based Method	The feasibility is average. During the drone's dispersal, the distance from the material box to the dispensing mechanism is short, and the flow space for particles is limited, resulting in low speeds and making it difficult to generate noticeable signal changes.	Due to size constraints, the drone's discharge mechanism is small, and the range of particle speed variation is limited, making detection more challenging.	Optimize the signal detection circuit to amplify or convert the measured velocity-based signals to achieve significant signal changes.

Despite the existence of numerous existing seed and fertiliser particle flow quality flow detection methods, these are predominantly utilised in ground machinery with relatively slow operating speeds and small displacements. The response time and detection accuracy of these methods are generally adequate to meet requirements. However, when considering the implementation of these methods in the context of UAV seeding, it is evident that the response speed is inadequate. Furthermore, timely signal processing becomes challenging due to particle overlap and the rapid flow rate, which can result in incomplete information and increased error in the final calculated particle mass flow rate. In light of these challenges, this paper puts forward the following perspective:

1) In order to accelerate the realisation of unmanned precision operations, high-throughput dense-phase particle mass flow detection techniques applicable to agricultural UAV seeding need to be further optimised. For example, the existing unmanned aerial dispersal is divided into unconstrained diffuse dispersal and strip/shot dispersal with some constraints, and the corresponding discharge devices are mostly centralised and monolithic, which produce particle streams with different void ratios, and the installation location, mode, volume and weight of the sensors should be considered when performing the optimisation.

2) Existing sensors are typically designed for specific operating scenarios or particular types of particles, resulting in limited applicability. To address the diverse requirements of seed and fertiliser particle detection, it is necessary to explore innovative detection methods by integrating advanced technologies from various fields. For instance, flow tomography, such as X-ray imaging, can be used to obtain high-resolution, three-dimensional structural images by penetrating the material.

3) Current research has shifted from the development and performance optimisation of sensors to the integration of detection systems. How to use the existing detection information to develop an intelligent seed and fertiliser detection system and connect it to the management of smart agriculture to achieve a benign closed-loop operation system will be an important research topic in the field of smart agriculture in the future.

CONCLUSIONS

The application of unmanned aerial vehicle (UAV) spreading technology in seeding and fertiliser distribution plays a vital role in advancing agricultural precision. In precision operations, real-time information on particle mass flow is a fundamental prerequisite for effective particle displacement control and overall operation planning. Therefore, the study of high-throughput, dense-phase particle mass flow detection is crucial for achieving UAV-based precision seeding. This paper presents a comprehensive review of the principles, usage conditions, and adaptability of current mass flow detection methods for seed and fertiliser particle streams in UAV applications. The main conclusions are as follows:

Whilst the weighing and correlation methods are relatively simple to implement and have been used in UAV dispersal, the adaptability of other methods in this field remains to be investigated. For example, among the concentration-based detection methods, the electrical method is more sensitive to obvious signals. The short flow time and low velocity of particles in UAV dispersal produces relatively weak capacitance changes or electrostatic signals, which are not easily captured accurately and require signal amplification.

The application of volume concentration methods necessitates the consideration of detecting overlapping particles in high-throughput dense-phase particle flows, a consideration that extends to the expansion of the detection area of the sensor and the optimisation of the detection device. The employment of the image method requires the consideration of the accuracy of particle identification, whilst real-time image processing algorithms must be developed to meet the requirements of high-speed seeding by UAVs. The acoustic method utilised in the speed-based method primarily relies on the detection of particles impacting the detection plate sounding. However, in the context of UAV sowing operations, the high-speed rotation of the rotor wing generates significant vibrations, which can confound the distinction between particle impacts and

sound from the detection plate, thereby compromising the detection of the target signal. Consequently, the method is not particularly well-suited for utilisation in UAV sowing.

In the context of direct or indirect detection, any scenario that necessitates direct contact between the particle flow and the detection element is susceptible to damage to the detection element. Consequently, non-contact detection methods should be prioritised wherever feasible. The future of agriculture is unmanned, with intelligent seeding and fertiliser operations being a key development trend. In order to achieve this, existing mass flow detection technology needs to evolve beyond basic detection to include the ability to access data on the intelligent management platform. This will allow it to be integrated into a large database, facilitating accurate decision-making and providing data support.

Keywords: Tobacco Leaf Harvesting, Machine Vision, Robotic arm, Biomimetic flexible gripper, Kinematic Model

ABSTRACT

The efficiency and quality of tobacco leaf harvesting are crucial for the economic performance of the tobacco industry. To enhance harvesting efficiency, a non-destructive tobacco leaf harvesting robot based on machine vision and robotics technology was developed. Experimental evaluations of key components demonstrated that the biomimetic flexible gripper based on the fin ray effect has good stiffness when the clamping force is 2.5 N, ensuring stable subsequent harvesting and collection of tobacco leaves. The introduction of a 6+1-axis robotic arm significantly expands the working range compared to the original 6-axis design, effectively covering the height of the tobacco stalk. The robotic arm's speed notably affects harvesting time ($P < 0.001$), with 1.2 m/s identified as optimal for balancing recognition efficiency and success rates. Additionally, exposure time plays a critical role in success rates ($P < 0.001$), achieving peaks of 90.00% in the morning and 83.33% in the afternoon at 40000 μ s. These advancements enhance tobacco harvesting technology and provide valuable insights for intelligent crop harvesting.

摘要

烟叶采摘的效率和质量对烟草行业的经济效益至关重要。为了提高采摘效率，基于机器视觉和机器人技术开发了一种无损烟叶采摘机器人。关键部件的实验评估表明，基于鳍条效应的仿生柔性夹爪在夹紧力为 2.5 N 时具有良好的刚度确保了后续烟叶采摘和回收的稳定性。引入的 6+1 轴机械臂相比原有的 6 轴设计，显著扩展了工作范围，有效覆盖了烟草柱的高度。机械臂的速度显著影响采摘时间 ($P < 0.001$)，1.2 m/s 的速度被确定为平衡识别效率和成功率的最佳值。此外，曝光时间对成功率也有关键作用 ($P < 0.001$)，上午和下午在 40000 μ s 时成功率分别达到 90.00% 和 83.33%。这些进展提升了烟叶采摘技术，并为农作物智能采摘提供了借鉴。

INTRODUCTION

Tobacco leaves represent a significant economic crop, with a vast global market for planting and consumption (Liu S. X. et al, 2015). Harvesting tobacco leaves is a critical process in the tobacco production chain, where efficiency and quality directly influence the economic benefits of the tobacco industry (Bu L. X. et al, 2020). Currently, tobacco leaf harvesting is predominantly manual, characterized by high labor intensity, long hours, and substantial costs. Moreover, variations in subjective awareness and technical skills among workers can easily lead to damage and contamination of the leaves, adversely affecting both quality and yield (Xu Y. C. et al, 2016). The introduction of automated harvesting machinery has greatly improved efficiency. Research in this field led Li Yang et al, (2022) to develop a semi-automated tobacco harvesting machine, in which optimal parameters for the harvesting mechanism were determined through experimental trials, resulting in improved efficiency. However, the damage rate still exceeds 20%. Similarly, Ma Sijie et al, (2024), focused on designing and optimizing the key structures of automated tobacco harvesting machinery, employing experimental design methods to establish optimal harvesting parameters and successfully reducing the damage rate to below 10%, though this figure remains relatively high.

YuPei LIN, Ph.D. Eng.; GuoYong YAN, M.S. Eng.; Tao WANG, SA. Eng.; Tao BAI, M.S. Eng.; Si TANG, M.S. Eng.; JunJie CHEN, M.S. Eng.; BaoLin ZHANG, M.S. Eng.

Overall, existing bulk automated harvesting solutions often result in significant damage to tobacco leaves, limiting their practical application in production.

The integration of machine vision and robotic technology presents a promising solution for tobacco leaf harvesting (Jin Y. *et al*, 2020). Machine vision enables rapid identification and localization of leaf maturity, while robotic technology allows for precise execution of harvesting actions. This combination not only enhances the success rate of harvesting but also significantly reduces damage to the leaves, achieving an intelligent and precise harvesting process. While these technologies have been widely applied in harvesting other agricultural products (Shu Y. F. *et al*, 2024), their implementation in tobacco leaf harvesting remains rare (Zhi H.E. *et al*, 2023). The primary challenges in applying machine vision and robotics to tobacco harvesting include: 1) ensuring harvesting stability and effectiveness, which necessitates designing actuators with good enveloping characteristics and appropriate stiffness for damage-free harvesting; 2) achieving seamless integration of agronomy and machinery, requiring an organic combination of maturity identification and harvesting procedures to enhance efficiency; 3) maintaining high visual recognition success rates in complex environments, which involves breakthroughs in recognition technology, improvements in recognition efficiency, and methods for actuator matching.

To address these challenges, this study develops an intelligent, damage-free tobacco harvesting robot based on machine vision. The focus is on innovatively designing the end-effector structure for tobacco leaves, optimizing the harvesting path of the robot in conjunction with agronomy, and fine-tuning key parameters of the vision system through field tests to achieve a comprehensive solution for an efficient and stable tobacco harvesting system. This research not only advances tobacco harvesting technology, enhancing both efficiency and quality, but also provides valuable insights for the intelligent harvesting of other crops, holding significant practical application value.

MATERIALS AND METHODS

Machine structure and workflow

Machine structure

The developed intelligent, non-destructive tobacco harvesting robot, shown in Fig. 1, features a tracked mobility system, a 6+1-axis robotic arm, an end-effector, a depth camera, and a control system. The tracked mobility system ensures excellent terrain adaptability for flexible movement in complex agricultural environments, enhancing operational efficiency. The 6+1-axis robotic arm adds a vertical degree of freedom, allowing seamless integration with tobacco harvesting operations to improve efficiency. The end-effector employs a novel soft-hard gripping structure designed to maximize precision and efficiency while minimizing leaf damage. The control system integrates path planning, obstacle avoidance, and multi-task coordination, dynamically adjusting the arm's trajectory based on real-time visual feedback to ensure safety and stability. Its compact, modular design facilitates maintenance and upgrades, automating harvesting operations and enhancing intelligence through integrated vision and motion control, demonstrating significant application potential.

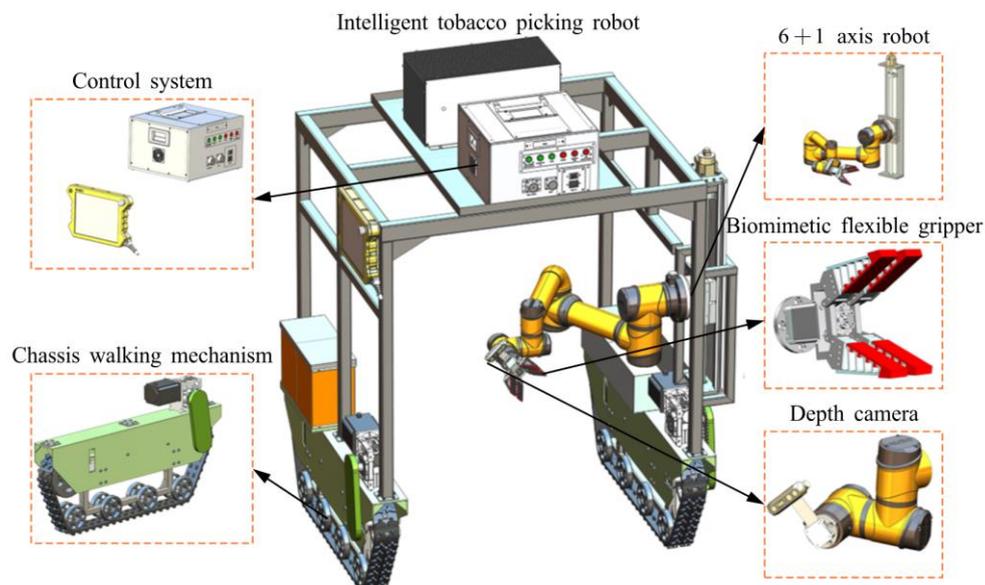

Fig. 1 – Machine Structure of the Tobacco Harvesting Robot

Workflow

The control system connects the end-effector, sliding device, robotic arm, and visual sensors via a central controller to facilitate automated and intelligent tobacco harvesting (Fig. 2). The process begins with program initiation, positioning the depth camera at the recognition point and issuing a recognition command. If obstructions are detected, the camera requests trajectory planning. The vision system identifies the petiole of the tobacco leaf, calculates the coordinates and angular orientation of the harvesting point, and transmits this data to the controller. The robotic arm then moves the end-effector to the harvesting point to complete the process. The system enters standby mode, ready to resume recognition and harvesting upon receiving new commands, concluding operations only when a stop command is issued.

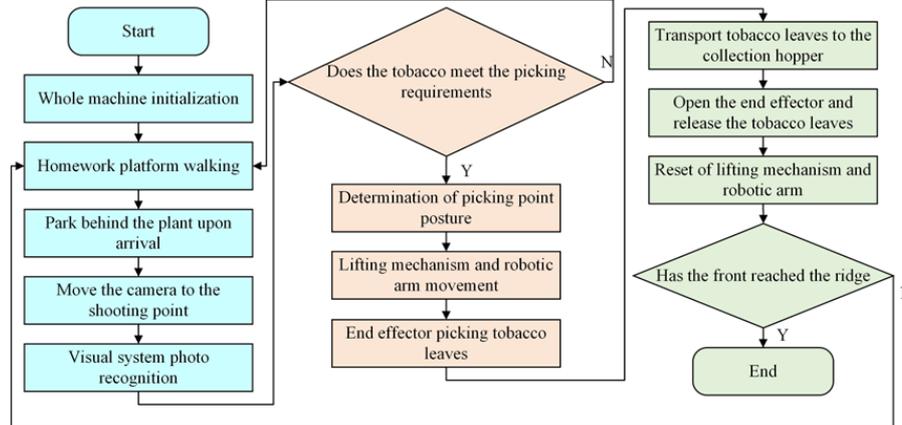

Fig. 2 – Workflow Diagram of the Tobacco Harvesting Robot

Design and Verification of the End Effector

Design of gripper structure

This study utilizes a gripper-style end-effector that combines gripping, harvesting, and transport functions. The design and optimization of the gripper structure are essential for effectively grasping and moving tobacco stems. After gripping and cutting the leaves, rapid transportation is needed, necessitating strong envelopment and structural rigidity. The fin-effect gripper must balance these functions through targeted design. An improved fin-effect gripper was developed, as illustrated in Fig. 3. The skeleton is made from thermoplastic polyurethane elastomer (TPU), which offers excellent elasticity and support, while the soft silicone contact surface securely envelops the tobacco leaves. The gripper features ribs that are thicker in the center and taper toward the edges, with outer joints designed to taper based on deformation needs and inner joints further thinned. This design aligns with the leaf stem's cross-sectional profile and the clamps' rigidity requirements.

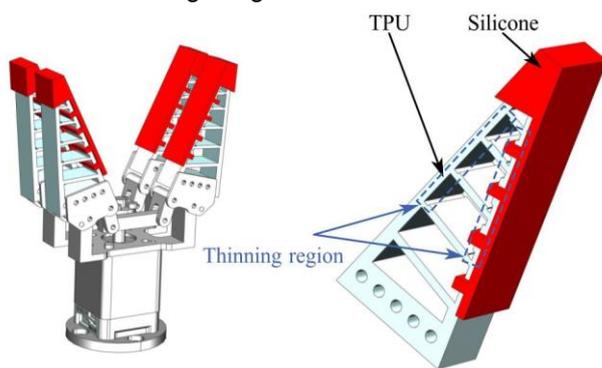

Fig. 3 – The structure design of fin gripper

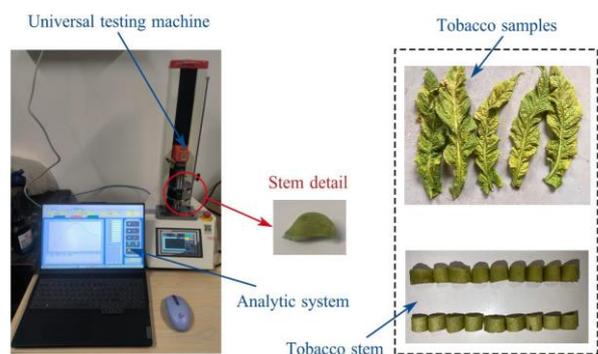

Fig. 4 – The physical properties testing of tobacco leaves and stems

The material model parameters of tobacco

The gripper structure is composed of two hyperelastic materials: TPU and silicone. The TPU material closely fits the second-order Mooney-Rivlin model, and its strain energy function is expressed as:

$$W = C_{10}(I_1 - 3) + C_{01}(I_2 - 3) \tag{1}$$

where W represents the strain energy, [MPa]; C_{10} and C_{01} are material parameters, [MPa]; I_1 and I_2 are the first and second strain invariants, respectively, with material parameters set as $C_{10}=2.101\text{MPa}$ and $C_{01}=0.105\text{MPa}$ (Guan Y. K. et al, 2023).

The second-order Yeoh model effectively characterizes silicone rubber, and its strain energy density function is expressed as:

$$W = C_{10}(I_1 - 3) + C_{20}(I_2 - 3)^2 \tag{2}$$

where C_{10} and C_{20} are material parameters set at 0.11 MPa and 0.02 MPa, respectively (Polygerinos P. et al, 2015).

The physical properties of tobacco leaf stems were determined through experimentation, with equipment and samples shown in Fig. 4. The tobacco leaves used in the experiment were collected from the Modern Tobacco Planting Demonstration Base in Malong District, Qujing City, Yunnan Province, China, and belong to the Yunyan 301 variety. Thirty mature and harvested tobacco leaves were randomly selected. The leaf blades were removed, retaining only the stems, which were cut into approximately 12 mm segments. Axial compression, radial compression, axial shear, and radial shear tests were conducted on the leaf stems using an electronic universal testing machine (ZQ-990). The density of the leaf stems was measured using the drainage method with an electronic balance (LQ-C20002) and a graduated cylinder. Due to slight variations in the shape and size of the test stems, each test was repeated 10 times, and the average value was calculated. The leaf stems were assumed to be transversely isotropic, meaning the radial and chord directions share the same modulus parameters. The final physical property parameters of the leaf stems are shown in Tab. 1, and Poisson's ratio was calculated using the following equations:

$$v_{xy} = \frac{E_x}{2G_{xy}} - 1 = v_{xz} \tag{3}$$

$$v_{yz} = \frac{E_y}{2G_{yz}} - 1 \tag{4}$$

Table 1

The physical property parameters of tobacco leaves and stems

Parameters	Elastic modulus [MPa]		Shear modulus [MPa]		Poisson's ratio		Density [kg·m ⁻³]
	E_x	E_y/E_z	G_{xy}/G_{xz}	G_{yz}	v_{xy}/v_{xz}	v_{yz}	ρ
Values	5.34	3.95	1.93	1.84	0.38	0.07	993.30

Finite element analysis of clamping force

Nonlinear static analysis was conducted using ANSYS Workbench. A simplified clamp model was imported, focusing on the clamping and wrapping behavior on the left side of the tobacco stem. Fillets and small step features were removed, and material connections were simplified to surface contact for enhanced computational efficiency. New materials were defined in the material library based on the given parameters and assigned to each part of the clamp. Friction contact was established between the silicone and the surface of the tobacco stem, while bonded contact was defined between the inner silicone surface and the TPU. A nonlinear meshing strategy was applied, generating first-order hexahedral elements to ensure computational efficiency and stability. To determine the optimal clamping force of the redesigned clamp, a fixed constraint was applied to the cylindrical hole of the clamp, while a lateral displacement constraint was added at the base of the stem. A clamping force was then applied on the opposite side of the stem, and the effects of clamping forces of 2 N, 2.5 N, and 3 N were explored. An integral solution method was used, accounting for large deformation, with nonlinear control implemented using the asymmetric Newton-Raphson method. The final solution met the force convergence criterion.

The displacement cloud diagrams of stable clamping under different forces are shown in Fig.5. It illustrates that as the clamping force increases, the enveloping capacity improves. Due to the large curvature of the outer contour of the leaf stem, achieving complete envelopment is challenging. Further modification of the clamp's size parameters to achieve full envelopment would result in excessive deformation and may cause the left and right jaws to collide. Therefore, this study improved the overall stiffness of the clamp while maximizing its envelopment of the leaf stem. Fig. 5 shows that under the studied clamping forces, the clamp envelops most of the outer edge of the leaf stem's left side, achieving overall good coverage. Additionally, because of the small transverse thickness of the leaf stem, excessive clamping force may cause the jaws to collide. At a clamping force of 2.5 N, the line connecting the top and bottom of the clamp passes through the long axis of the stem's cross-section, indicating the critical force at which the jaws might collide. Therefore, the clamping force should be kept at ≤ 2.5 N.

To further investigate the clamp’s stiffness, the equivalent strain cloud diagrams under different clamping forces were obtained, as shown in Fig.6. It illustrates that the equivalent strain distribution in the contact area is relatively uniform, with higher equivalent stress at each joint, reaching a maximum of 0.24 m/m under a 3 N clamping force. Additionally, the greater the clamping force, the larger the equivalent strain in the contact area between the clamp and the leaf stem, resulting in greater elastic recovery energy and improved clamp stiffness. Based on the maximum force limit from the above analysis, a clamping force of 2.5 N provides sufficient stiffness to ensure stable tobacco leaf harvesting and retrieval. Therefore, this clamping force of 2.5 N was selected for subsequent harvesting tests.

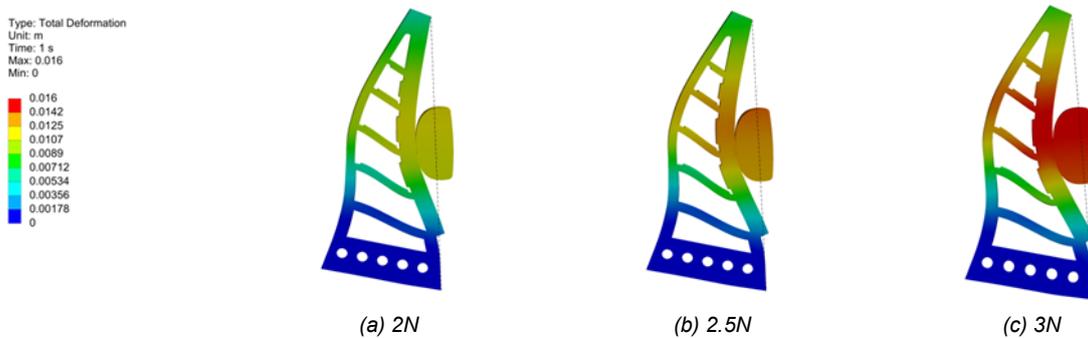

Fig. 5 – The displacement cloud diagrams of clamped leaf stems under different forces

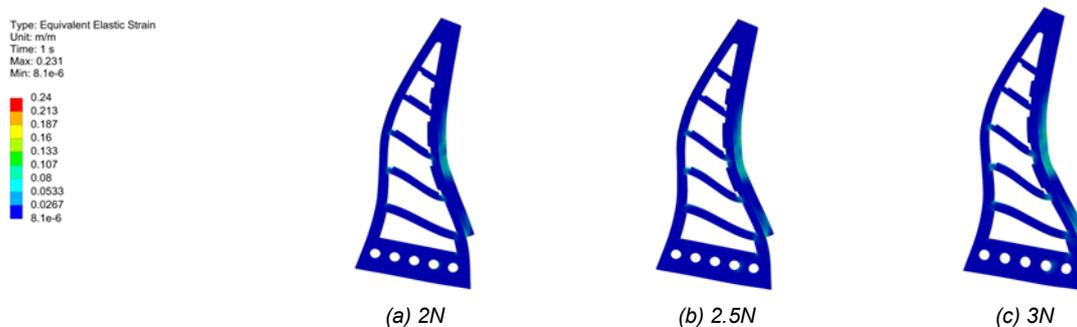

Fig. 6 – The equivalent strain cloud diagrams of clamped leaf stems under different clamping forces

The motion analysis of robotic arm

The structure and parameter design

The tobacco leaves harvesting robot uses the AUBO-I5 robotic arm, with its key parameters listed in Tab. 2. As shown in Tab. 2, the robotic arm has a working radius of 886.5 mm, while the average height of the tobacco leaves is approximately 1.5 m. Since tobacco plants mature gradually from top to bottom over 1-2 months, with only 2-3 leaves harvested at the same height during each picking cycle, a single robotic arm cannot meet agronomic needs. In this study, a 6+1 axis robotic arm solution was implemented, adding an 800 mm adjustable sliding platform at the base of the robotic arm. This setup allows the adjustment of the arm’s workspace to meet the agronomic requirements for layered tobacco leaf harvesting, while keeping the slide’s position fixed during the process.

Table 2

The parameters of the AUBO-I5 Robotic Arm

Max load	5 kg	Weight	< 24 kg	Free load ratio	< 4.8
Degrees of Freedom	6	Repeat positioning accuracy	±0.02 mm	Working radius	886.5 mm
Maximum velocity of each axis					
J₁	J₂	J₃	J₄	J₅	J₆
223 °/s	223 °/s	223 °/s	237 °/s	237 °/s	237 °/s

Workspace Analysis

The AUBO-I5 robotic arm features six degrees of freedom, with the first three controlling the end-effector’s position and the latter three its orientation. A fixed coordinate system was established for the links to describe each joint’s motion in three-dimensional space, with the joint posture represented by its coordinate system position. The kinematic model was derived using homogeneous coordinate transformation, employing the modified Denavit-Hartenberg (M D-H) method for the forward kinematic model.

$$\begin{aligned}
 {}^{i-1}T_i &= \begin{bmatrix} c\theta_i & -s\theta_i & 0 & a_{i-1} \\ s\theta_i c\alpha_{i-1} & c\theta_i c\alpha_{i-1} & -s\alpha_{i-1} & -s\alpha_{i-1}d_i \\ s\theta_i s\alpha_{i-1} & c\theta_i s\alpha_{i-1} & c\alpha_{i-1} & c\alpha_{i-1}d_i \\ 0 & 0 & 0 & 1 \end{bmatrix} & {}^0T_1 &= \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & d_1 \\ 0 & 0 & 0 & 1 \end{bmatrix} & {}^1T_2 &= \begin{bmatrix} c_2 & -s_2 & 0 & 0 \\ 0 & 0 & -1 & -0.122 \\ s_2 & c_2 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \\
 {}^2T_3 &= \begin{bmatrix} c_3 & -s_3 & 0 & 0 \\ 0 & 0 & 1 & 0.1215 \\ -s_3 & c_3 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} & {}^3T_4 &= \begin{bmatrix} c_4 & -s_4 & 0 & 0.408 \\ -s_4 & c_4 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} & {}^4T_5 &= \begin{bmatrix} c_5 & -s_5 & 0 & 0.376 \\ -s_5 & -c_5 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \\
 {}^5T_6 &= \begin{bmatrix} c_6 & -s_6 & 0 & 0 \\ 0 & 0 & 1 & 0.1025 \\ -s_6 & -c_6 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} & {}^6T_7 &= \begin{bmatrix} c_7 & -s_7 & 0 & 0 \\ 0 & 0 & -1 & -0.094 \\ s_7 & c_7 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}
 \end{aligned} \tag{5}$$

where, s_i and c_i represent $\sin\theta_i$ and $\cos\theta_i$, respectively.

Multiplying the above matrices in sequence on the right yields the robot's forward kinematics expression.

$${}^0T_7 = {}^0T_1 {}^1T_2 {}^2T_3 {}^3T_4 {}^4T_5 {}^5T_6 {}^6T_7 \tag{6}$$

Fig.7(a) illustrates the model diagram and the coordinate systems for each joint, while Tab.3 lists the corresponding D-H parameters. The M D-H method provides the coordinate transformation matrix for the homogeneous transformation from coordinate system i to system $i-1$ (Peng J. et al., 2019).

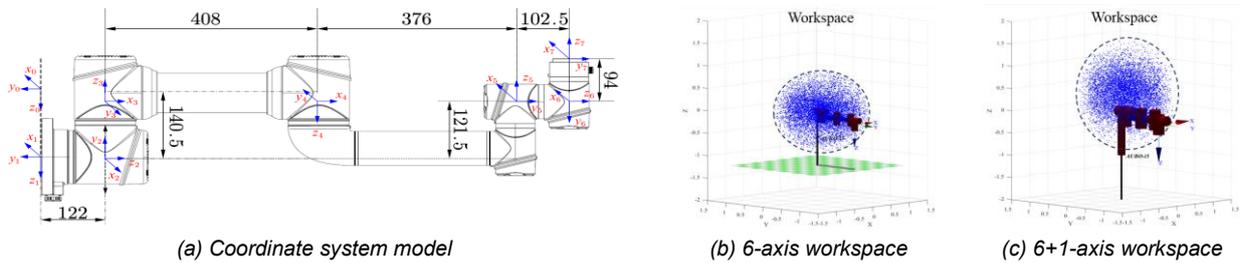

Fig. 7 – AUBO-I5 robot model and workspace

Table 3

The M D-H parameters of 6+1 axis robotic arm

Link i	a_{i-1} [mm]	α_{i-1} [°]	d_i [mm]	θ_i [°]	Variation range
1	0	0	d_1	0	0-800 mm
2	0	90	122	θ_1	$\pm 360^\circ$
3	0	-90	121.5	θ_2	$\pm 175^\circ$
4	408	180	0	θ_3	$\pm 175^\circ$
5	376	180	0	θ_4	$\pm 175^\circ$
6	0	-90	102.5	θ_5	$\pm 175^\circ$
7	0	90	94	θ_6	$\pm 360^\circ$

In Matlab, the Link and SerialLink functions were used to create a simplified model of the robotic arm's links. The simplified teaching model is shown in Fig. 7(a). The Monte Carlo method was used to simulate and analyze the robot's workspace, generating random values for each joint variable (Li J. et al, 2023):

$$\theta_i = \theta_{i_{\min}} + (\theta_{i_{\max}} - \theta_{i_{\min}}) \times \text{rand}(N,1) \tag{7}$$

Substituting the joint variables into the forward kinematics equation produces a point cloud map of the robot's workspace, as shown in Fig. 7(b) and 7(c). From the workspace point cloud, it is evident that without the sliding device, the workspace of the AUBO-I5 robotic arm is circular. With the 6+1 axis structure and the sliding device, the workspace becomes elliptical. This expanded workspace covers a larger area, meeting the height requirements for tobacco leaf picking by covering most of the plant's height. Additionally, the workspace analysis provides a theoretical basis for path planning and collision warning of the gripper.

Tobacco leaf recognition and positioning

The visual recognition system consists of an Intel RealSense D435i depth camera and an Nvidia Jetson Nano platform. The D435i camera, with a depth range of 0.1 to 10 m, captures tobacco leaf images, while the Jetson Nano, powered by a quad-core processor and CUDA GPU, handles deep learning tasks.

Fig. 8 – Visual system recognition and positioning

YOLOv7, a fast and accurate object detection algorithm, is used for real-time tobacco leaf recognition. The system captures images, processes them through YOLOv7's convolutional layers for feature extraction, and detects leaf stems using an Anchor-Free mechanism to generate bounding boxes. After non-maximum suppression, the system outputs the optimal coordinates for guiding the robot arm in precise picking. The method's high recognition accuracy and real-time performance make it suitable for complex field environments. To further enhance YOLOv7's accuracy, data augmentation, attention mechanisms, loss function refinements, and model integration were employed. The results of the visual recognition system are shown in Fig. 8.

RESULTS

Experimental conditions

The field test for tobacco leaf picking was conducted from August 14 to 16, 2024, in the modern tobacco leaf production demonstration area in Malong District, Qujing City, Yunnan Province. The test subjects were tobacco plants of the Yunyan 301 variety grown in the demonstration area. The test process is illustrated in Fig. 9.

Fig. 9 – Tobacco leaf harvesting field experiment

To evaluate the tobacco leaf picking performance of the entire machine, the time taken to fully pick a single leaf was used as a measure of overall picking efficiency. During preliminary testing, it was observed that jitter at the end of the robotic arm affected the recognition efficiency of the vision system. Therefore, the efficiency test was conducted at five speed levels: 20%, 40%, 60%, 80%, and 100% of the maximum movement speed of the robotic arm (the maximum linear speed and acceleration of the arm's end were 1.5 m/s and 1 m/s², respectively). The picking time at each speed level was recorded. To eliminate the effects of lighting variations, all tests were scheduled for the morning of the same day. Each speed level was tested by picking 10 tobacco leaves, and the average picking time was calculated over 50 tests. The picking success rate was used to evaluate the machine's reliability. Tests were conducted in both the morning and afternoon. Five camera exposure times—10000 μ s, 25000 μ s, 40000 μ s, 55000 μ s, and 70000 μ s—were selected as factors for exploration. At each exposure level, 30 tobacco leaves were picked, and the success rate was calculated over 150 tests.

Effect of robotic arm velocity on picking efficiency

The results of the tobacco leaf picking test at different robotic arm speeds are summarized in Tab. 4. As the robotic arm speed increased from 0.3 m/s to 1.5 m/s, the average picking time dropped significantly from 9.00 seconds to 2.47 seconds, indicating a clear downward trend. Variance analysis of the robotic arm speed revealed significant differences between groups ($P < 0.001$). Therefore, the speed of the robotic arm has a highly significant effect on the tobacco leaf picking time. As the robotic arm speed increases, the amplitude of vibrations at the arm’s end increases, potentially affecting the efficiency of the vision system's recognition. In practical picking, a balance must be struck between recognition efficiency and picking success rate. This is primarily because tobacco leaves near the plant may overlap or intertwine, and if the robotic arm moves too quickly, it could damage the surrounding leaves. Therefore, an efficient and relatively stable speed of 1.2 m/s was selected for subsequent experiments, ensuring maximum picking efficiency without compromising accuracy.

Table 4

The test results of tobacco leaf picking efficiency at different robot arm speeds

No.	Mechanical arm speed [m/s]	Average picking time [s]	Variance
1	0.3	9.00	0.37
2	0.6	6.75	0.13
3	0.9	5.22	0.03
4	1.2	3.71	0.01
5	1.5	2.47	0.04

Effect of exposure time on picking success rate

Exposure time is a crucial parameter for calibrating the visual recognition system. To investigate the effect of varying exposure times on picking success rates while accounting for changes in ambient light intensity during actual harvesting, experiments were conducted at 8 a.m. and 2 p.m., reflecting different ambient light conditions. The test data and pictures are shown in Tab. 5 and Fig. 10 respectively.

Table 5

Experimental results on tobacco leaf picking success rate under different exposure times

Exposure time [μs]	Picking success rate (a.m) [%]	Picking success rate (p.m) [%]
10000	33.67	43.33
25000	63.33	60.00
40000	90.00	83.33
55000	73.33	66.67
70000	53.33	46.67

Fig. 10 – Tobacco leaf harvesting picture under different exposure times

The results indicate that there are significant differences in picking success rates across various exposure times, regardless of the time of day. The variance analysis results show $P < 0.001$, indicating an extremely significant effect. In the morning, when the exposure time was set to 40000 μs, the picking success rate peaked at 90.00%. In the afternoon, under the same exposure time, the picking success rate also reached a peak of 83.33%. Overall, variations in ambient light intensity significantly influenced the picking success rates at the same exposure time. Under poor ambient lighting conditions, the upper limit of the picking success rate may be restricted. Therefore, selecting appropriate harvesting times and weather conditions is crucial. In conclusion, selecting an appropriate exposure time can significantly enhance the system’s ability to identify tobacco leaves, ultimately improving the picking success rate. The tobacco leaf picking robot system developed in this study, based on machine vision, demonstrates excellent picking performance.

CONCLUSIONS

This study developed an intelligent, non-destructive tobacco leaf picking robot utilizing machine vision. The research focused on the design and analysis of key components, with field experiments conducted to assess the machine's overall picking performance. This research yielded the following conclusions:

(1) The clamping jaw structure was redesigned based on the fin-ray effect. Finite element analysis revealed that increasing the clamping force improves the jaw's wrapping capability. To prevent collisions while maintaining sufficient rigidity and stability during tobacco leaf picking and collection, the clamping force was set to 2.5 N.

(2) The working space of the robot arm without the sliding table is circular, while the 6+1-axis arm with the sliding table has an elliptical workspace. This larger range covers most of the tobacco plant height, meeting the operational requirements for leaf picking.

(3) The speed of the robotic arm significantly impacts the picking time ($P < 0.001$). At 1.5 m/s, the average picking time was minimized to 2.47 seconds. A speed of 1.2 m/s was found to balance efficiency and picking success rate.

(4) Exposure time significantly affects the picking success rate ($P < 0.001$). A 40000 μs exposure achieved a peak success rate of 90.00% in the morning and 83.33% in the afternoon. Overall, changes in ambient light intensity noticeably impacted success under the same exposure conditions.

ABSTRACT

This study focused on an in-depth analysis of the cam motion process of the seedling clamp within the automatic seedling-picking device for tomato pot seedlings. Key influencing factors, including spring stiffness coefficient, seedling needle holding angle, and seedling-picking frequency, were selected for investigation. Evaluation indicators included substrate loss rate, pot seedling drop rate, and seedling-picking success rate. A three-factor, three-level, second-order rotational orthogonal combination test was conducted. Using Design-Expert V13.0.5 software for data analysis, the theoretical optimal parameter combination was identified: a spring stiffness coefficient of 376.8 N/m, a seedling needle holding angle of 15.6°, and a seedling-picking frequency of 89 plants per minute. Under this parameter combination, the substrate loss rate was reduced to 3.94%, the pot seedling drop rate to 2.01%, and the seedling-picking success rate reached 94.05%. A verification test conducted on the seedling-picking device test bench showed that the experimental results closely aligned with the optimized theoretical values. These findings provide a valuable reference for the structural optimization and performance improvement of seedling-picking devices in fully automatic tomato transplanters and contribute significantly to the advancement of automation in tomato transplanting operations.

摘要

本研究聚焦于番茄钵苗自动取苗装置中的夹苗器凸轮运动过程展开深入分析。在研究过程中，选定弹簧刚度系数、苗针夹持角度以及取苗频率作为关键影响因素，并将基质损失率、钵苗脱落率和取苗成功率确定为评价指标，进而开展三因素三水平二次旋转正交组合试验。借助 Design-Expert.V13.0.5 软件对试验数据进行分析处理，最终获取理论上的最优参数组合，即弹簧刚度系数为 376.8 N/m，苗针夹持角度为 15.6°，取苗频率为 89 株/min。在该参数组合条件下，基质损失率低至 3.94%，钵苗脱落率仅为 2.01%，而取苗成功率高达 94.05%。随后，在取苗装置上进行验证试验，试验结果与优化所得理论结果基本相符。本研究所得的相关成果，能够为番茄全自动移栽机取苗装置的结构优化改进以及作业参数的精准控制提供有益的参考借鉴，对于推动番茄移栽作业的自动化发展具有重要意义。

INTRODUCTION

Ningxia serves as a pivotal production region for processing tomatoes in China. The tomato - related industry holds a place of considerable importance in Ningxia's agricultural production landscape (Niu et al., 2022). In recent years, Ningxia has predominantly employed seedling transplanting technology in tomato cultivation. With the continuous expansion of the planting scale, the annual demand for transplanting machinery during the spring season has also been on the rise (Liu et al., 2013). At present, the transplanting machinery in use is predominantly semi - automatic. The seedling-picking operation still needs to be completed manually, which is characterized by low automation, high labor intensity, low efficiency, and high operating costs.

Fukang Zhou M.S. Stud. Eng.; Mengqi Zhang M.S. Stud. Eng.; Weichen Yan M.S. Stud. Eng.; Shijun Song M.S. Stud. Eng.; Yi Niu M.S. Stud. Eng.; Tao Fan M.S. Stud. Eng.; Bolong Wang, As. Ph.D. Eng; Fangyuan Lu, As. Ph.D. Eng;; Guohai Zhang, Prof. Ph.D. Eng.

These factors are significantly hindering the advancement of seedling transplanting technology (Yu *et al.*, 2014; Zhang *et al.*, 2013; Hu *et al.*, 2014). Therefore, the automatic transplanting machine has become an inevitable development trend for achieving efficient and large-scale crop transplanting in Ningxia. It is imperative to advance the research and development of fully automatic transplanting machines equipped with automatic seedling-picking and seedling-dropping functions. The core of automatic transplanting machine research and development lies in automatic seedling picking technology. At present, both domestic and international research on mechanical automatic seedling-picking methods for automatic transplanting machines primarily focus on two approaches: the clamping (folder-picking) type and the ejecting type. Automatic transplanting machines developed using these two methods have already been applied in foreign countries (Dixit, 2010; Manjunatha *et al.*, 2009; Sakaue, 1996). Although this type of fully automatic transplanting machine offers high working efficiency and a high degree of automation, it is expensive, structurally complex, and primarily designed for bare-soil transplanting. As a result, it does not meet the agronomic requirements for transplanting on mulch film making it unsuitable for introduction and widespread adoption (Huang *et al.*, 2023). Domestic research on transplanting machinery started relatively late; however, several semi-automatic transplanting machine models have already been developed, applied, and promoted (Xue *et al.*, 2013; Jin, 2014). In recent years, several domestic universities and research institutes have conducted extensive research on automatic seedling extraction mechanisms, which are core components of automatic vegetable transplanters. Their work has focused on the mechanical properties of pot seedlings (Chen *et al.*, 2024; Hu *et al.*, 2023), the structural design of seedling extraction claws (Han *et al.*, 2013; Liang *et al.*, 2018; Han *et al.*, 2015), the optimization and simulation analysis of key components in the seedling extraction mechanism (Hai *et al.*, 2025; Wang *et al.*, 2015), and experimental studies on key parameters (Gao *et al.*, 2015; Zhang *et al.*, 2016; Zhang, 2014). However, despite this progress, no mature technology has yet been successfully applied in actual agricultural production.

This paper focuses on a tomato pot seedling automatic extraction device developed by the research group. A seedling extraction test bench was established to support experimental analysis. The seedling extraction mechanism employs a planetary gear-linkage system combined with an irregular slide drive to control the clamping motion and achieve the desired trajectory and posture for automatic seedling extraction. A cam-toggle mechanism is used to control the opening and closing of the seedling clamping needles, enabling both clamping and seedling releasing actions. Using the test bench and applying response surface method, the study optimizes key operating parameters of the device to enhance operational quality. The findings aim to provide a reference for the structural optimization and design improvement of automatic seedling extraction devices.

MATERIALS AND METHODS

Structure and working principle of automatic seedling picking device

The seedling extraction device is the core component of the automatic seedling extraction test bench. It is primarily composed of a rackmount, planetary gearbox, connecting rod, seedling needle, seedling pushing ring, cam, slide, etc., as illustrated in Fig. 1.

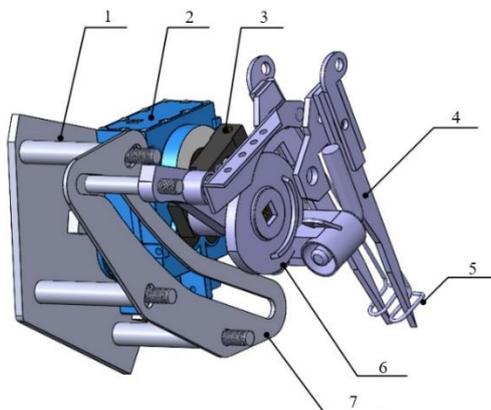

Fig. 1 – Overall system architecture Figure

Schematic diagram of tomato pot seedling automatic picking device

1. Rackmount; 2. Planetary gearbox; 3. Connecting rod; 4. Seedling needle; 5. Seedling pushing ring; 6. Cam; 7. Slide

According to the requirements of seedling picking and dropping operation (Li et al., 2015; Ye et al., 2014), the cam's working stroke is divided into four working phases: preparation for seedling picking, seedling clamping, seedling holding and seedling releasing, as shown in Fig. 2. To prepare the seedling clamping section AB, the two seedling needles are fully opened, the push ring slides upward along the seedling needles under the action of the cam, and the seedling needles approach the holes at a fixed angle. In the seedling clamping section BD, the seedling needles were inserted into the holes at a fixed angle, and when they reached point C, the distance between the tip points of the two seedling needles was gradually reduced to clamp the root plug, and the distance between the tip points of the seedling needles remained unchanged after the root plug was clamped. In the seedling holding section DF, the seedling needles vertically pull the pot seedling out from the tray holes. During this stage, the seedling pushing ring remains stationary. As the mechanism moves along the cam profile to point F, the seedling holding stage ends and the seedling needles begin to open. At this point, the pot seedling assumes a vertically downward posture. In the seedling release section FA, as the mechanism progresses to stage GA, the seedling pushing ring slides downward along the seedling needles. When it reaches point A, the pushing ring completes its stroke, pushing the seedling vertically downward to release it. Simultaneously, the seedling needles open and return to their initial angle, completing one full cycle of seedling extraction and release.

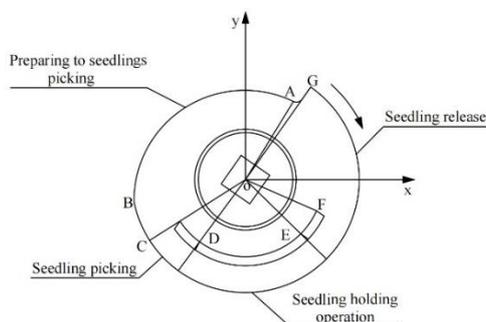

Fig. 2 – Cam working stroke

Principle of system operation

In order to investigate the effects of spring stiffness coefficient, clamping angle of seedling needle and seedling picking frequency on the performance of seedling picking device and the optimal combination of parameters, a three-factor and three-level quadratic rotary optimization experiment was carried out with the indicators of substrate loss, seedling shedding rate and seedling picking success rate. The spring stiffness coefficients X_1 were set at 300, 400 and 500 N/m, and the clamping angles X_2 were set at 14, 16 and 18°, respectively, the seedling picking frequency X_3 was set at 60, 90 and 120 plants/min. The quadratic rotary orthogonal combination scheme was designed, 20 groups of automatic seedling extraction device performance tests were conducted, each group of experiments was repeated three times and the average of the three test results was taken as the experimental results. Design-Expert.13.0.5 software was used to design the experimental scheme and analyze the results, as shown in Table 1.

Experimental results and analyses

Quadratic polynomial regression models were established between spring stiffness coefficient, clamping angle of seedling-picking needle, frequency of seedling picking and substrate loss rate, pot seedling shedding rate and seedling picking success rate. The regression equations were obtained by eliminating the insignificant factors.

$$Y_1 = 4.57 + 2.98X_1 - 2.45X_2 + 2.34X_3 - 0.80X_1X_2 + 0.98X_1X_3 - 0.58X_2X_3 + 1.56X_1^2 + 1.96X_2^2 + 1.43X_3^2 \tag{1}$$

$$Y_2 = 0.21 - 0.62X_1 + 2.13X_2 + 1.48X_3 - 0.78X_1X_2 + 0.38X_1X_3 - 0.78X_2X_3 + 1.35X_1^2 + 1.34X_2^2 + 1.07X_3^2 \tag{2}$$

$$Y_3 = 93.34 - 2.36X_1 + 0.32X_2 - 3.82X_3 + 1.58X_1X_2 - 1.36X_1X_3 + 1.36X_2X_3 - 2.90X_1^2 - 3.30X_2^2 - 2.49X_3^2 \tag{3}$$

The results showed that the regression equation models for substrate loss rate, pot seedling shedding rate, and seedling removal success rate were $P < 0.0001$, indicating that the three regression equation models were significant, suggesting that the regression models fitted well within the experimental range.

Table 2

Variance analysis of regression models						
Indexes	Variance source	Sum of squares	Degree of freedom	Mean square	F value	P value
Y_1	Model	393.75	9	43.75	102.39	< 0.0001
	Residual	4.27	10	0.4273

	Pure Error	1.84	5	0.3677		

RESULTS

Effect of interaction factors on the substrate loss rate

The substrate loss rate's response surface is illustrated in Fig. 3. As shown in Fig. 3(a), when the seedling picking frequency is 90 plants/min, the substrate loss rate exhibits an upward trend with the increasing needle clamping angle, while it shows a downward trend with the rising spring stiffness coefficient. The response surface demonstrates a relatively rapid change in the direction of the needle clamping angle, whereas the change in the direction of the spring stiffness coefficient is relatively slow. At a certain seedling picking frequency, the impact of the needle clamping angle on the substrate loss rate is more pronounced than that of the spring stiffness coefficient. A lower substrate loss rate was observed at a spring stiffness coefficient of approximately 400 N/m and a needle clamping angle of around 16°.

As depicted in Fig. 3(b), when the clamping angle of the seedling needle is set at 16°, an increase in the spring stiffness coefficient leads to a higher rate of substrate loss. Similarly, as the frequency of seedling extraction rises, the rate of substrate loss also shows an upward trend.

The response surface analysis reveals that the substrate loss rate is more sensitive to changes in the spring stiffness coefficient, exhibiting a relatively rapid variation along this direction. In contrast, its change along the direction of seedling extraction frequency is comparatively slower.

As shown in Fig. 3(c), when the spring stiffness coefficient is fixed at 400 N/m, the substrate loss rate initially rises and then declines with increasing seedling extraction frequency, while it consistently increases with an increasing needle clamping angle. The response surface exhibits a more pronounced change in the direction of the needle clamping angle compared to the direction of the seedling extraction frequency. This indicates that, for a given spring stiffness coefficient, the needle clamping angle has a more significant impact on the substrate loss rate than the seedling extraction frequency.

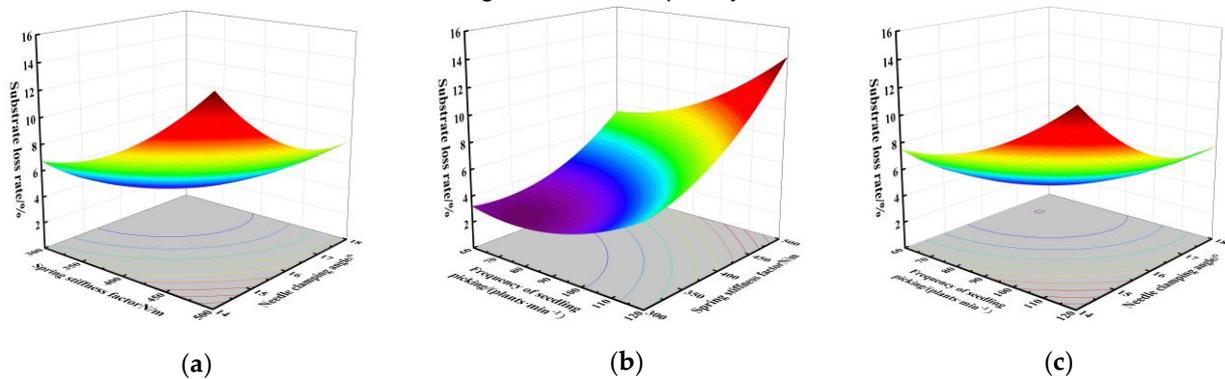

Fig. 3 – Effect of interaction factors on substrate loss rate

Effect of interaction factors on the pot seedling shedding rate

The response surface of the seedling shedding rate is presented in Fig. 4. As depicted in Fig. 4(a), when the seedling picking frequency is 90 plants/min, the seedling shedding rate increases with the increasing seedling needle clamping angle and first decreases and then increases with the rising spring stiffness coefficient. The response surface analysis indicates that the seedling shedding rate changes along the direction of the spring stiffness coefficient, but the rate of change is faster along the direction of the needle clamping angle. At a given picking frequency, the influence of the needle clamping angle on the seedling shedding rate is more significant than that of the spring stiffness coefficient.

As illustrated in Fig. 4(b), when the clamping angle of the seedling needle is 16°, the pot seedling shedding rate increases with the increasing spring stiffness coefficient. Meanwhile, it first decreases and then increases with the rising seedling picking frequency. The response surface exhibits a slower rate of change along the direction of seedling picking frequency and a faster rate of change along the direction of spring stiffness coefficient. When the seedling picking frequency is approximately 90 plants/min and the spring stiffness coefficient is around 400 N/m, the pot seedling shedding rate is relatively lower.

As depicted in Fig. 4(c), when the spring stiffness coefficient is approximately 400 N/m, the seedling shedding rate rises with the increasing seedling picking frequency and also increases with the increasing needle clamping angle. The response surface analysis indicates that the rate of seedling shedding varies more rapidly in the direction of the needle clamping angle and more slowly in the direction of the seedling picking frequency. Under a certain spring stiffness coefficient, the influence of the needle clamping angle on the seedling shedding rate is more significant than that of the seedling picking frequency.

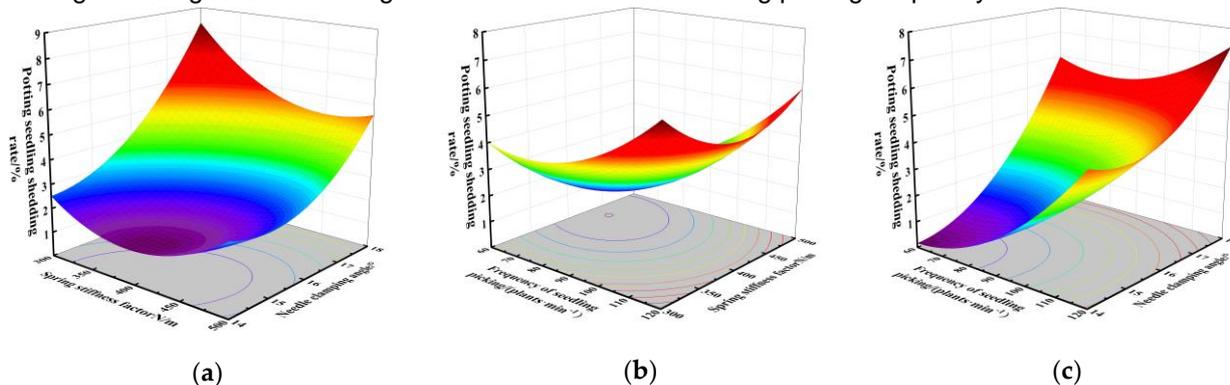

Fig. 4 – Effect of interaction factors on pot seedling shedding rate

Effects of interaction factors on seedling extraction success

The response surface of the seedling extraction success rate is presented in Fig. 5. As depicted in Fig. 5(a), when the seedling extraction frequency is 90 plants/min, the seedling extraction success rate decreases with the increasing seedling needle clamping angle and initially increases and then decreases with the rising spring stiffness coefficient. The response surface analysis reveals that the seedling extraction success rate exhibits a more rapid change along the direction of the spring stiffness coefficient and a relatively slower change along the direction of the needle clamping angle.

As shown in Fig. 5(b), when the clamping angle of the seedling needle is 16°, the success rate of seedling extraction increases with the increasing spring stiffness coefficient. Meanwhile, it initially increases and then decreases with the increasing seedling extraction frequency. The response surface analysis indicates a more rapid change in the direction of seedling extraction frequency and a relatively slower change in the direction of spring stiffness coefficient.

As depicted in Fig. 5(c), when the spring stiffness coefficient is set at 400 N/m, the success rate of seedling extraction initially increases and then decreases with the increasing seedling extraction frequency. Similarly, it first rises and then falls with the increasing needle clamping angle. The response surface analysis shows that the seedling extraction success rate varies gradually in the direction of the needle clamping angle, while it exhibits a relatively rapid change in the direction of the seedling extraction frequency. Given a certain spring stiffness coefficient, the impact of the seedling extraction frequency on the seedling extraction success rate is more pronounced than that of the seedling needle clamping angle.

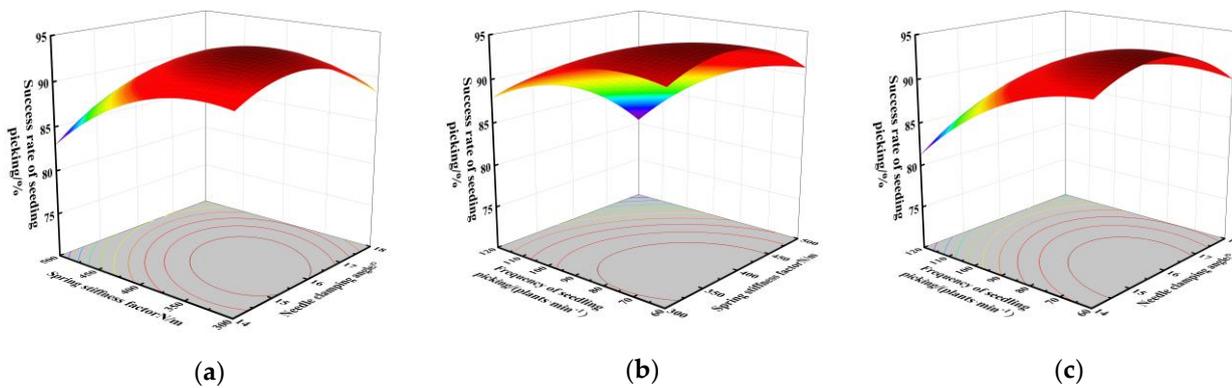

Fig. 5 – Effect of interaction factors on seedling extraction success

Parameter optimization

To enhance the operational performance of the seedling extraction device, an optimization of its working and structural parameters is conducted. This optimization is aimed at achieving three primary goals: reducing the substrate loss rate, decreasing the seedling dropout rate, and increasing the success rate of seedling extraction. The optimization process employs the Optimization-Numerical module in Design-Expert V13.0.5 software to determine the optimal parameter settings. The objective functions and constraints for this optimization are outlined as follows:

$$\begin{cases} \min Y_1 \\ \min Y_2 \\ \max Y_3 \\ X_1 \in [-1, 1] \\ X_2 \in [-1, 1] \\ X_3 \in [-1, 1] \end{cases} \quad (4)$$

The optimal parameter combinations were selected by the software Design-Expert.V13.0.5: spring stiffness coefficient of 376.81 N/m, a clamping angle of 15.6° and a seedling picking frequency of 89 plants/min. The model predicted the substrate loss rate of 3.94%, the pot seedling shedding rate of 2.01%, and a seedling-picking success rate of 94.05%.

Experimental validation

Using the optimized parameters (spring stiffness coefficient of 376.81N/m, seedling needle clamping angle of 15.6°, seedling picking frequency of 89 plants/min), the model validation experiments were carried out on the automatic seedling picking performance experimental table in the laboratory of agricultural machinery and equipment of Shandong University of Science and Technology, as shown in Fig. 6.

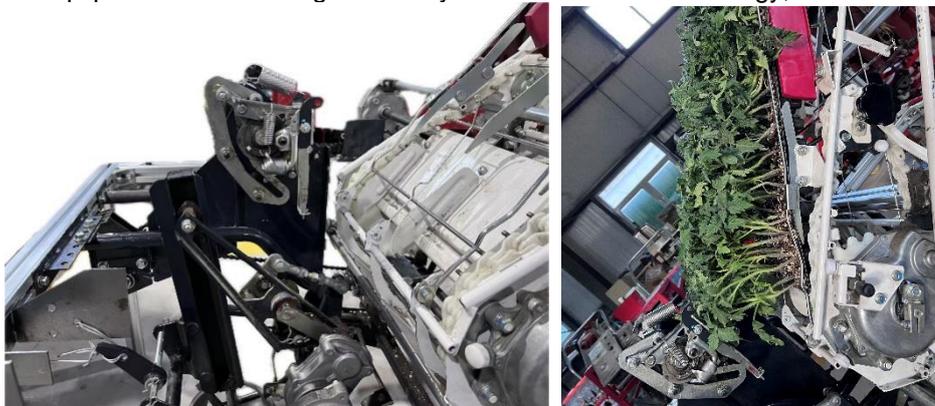

Fig. 6 – Automatic Seedling Picking Device Laboratory

To eliminate random errors and ensure the reliability of the results, five repeated tests were conducted, and the average values were calculated. Each test involved removing 72 seedlings from the entire tray, with the results summarized in Table 3. As can be seen, the average values of the substrate loss rate, pot seedling shedding rate, and seedling extraction success rate are 4.09%, 1.97%, and 93.94%, respectively. Notably, the error between the test value of the seedling extraction success rate and the optimized parameter value from the software is a mere 0.11%. This minimal discrepancy indicates that the selection of influencing factors on the quality of seedling extraction is reasonable and well - justified. Therefore, it can be concluded that the established performance optimization model of the automatic seedling picking device is correct and valid. Moreover, the obtained working and structural parameters fully meet the requirements for automatic seedling picking in tomato pot seedling machinery, ensuring both practical applicability and operational effectiveness.

Table 3

Results of seedling picking experiment under optimized conditions			
Test No.	Substrate loss rate $Y_1/\%$	Pot seedling shedding rate $Y_2/\%$	Success rate of seedling picking $Y_3/\%$
1	3.41	0.83	95.76
2	3.53	1.21	95.26
3	4.26	1.95	93.79
4	4.71	2.75	92.54
5	4.54	3.13	92.33
Average value	4.09	1.97	93.94

CONCLUSIONS

1) This study investigated the cam motion process of the seedling gripper in a tomato pot seedling automatic extraction device, enabling the precise determination of cam movement parameters. By conducting a theoretical analysis of the forces acting on the root plug during the seedling-picking process, combined with the planting frequency of duckbill planting, a one-factor experiment was carried out using spring stiffness coefficient, seedling needle clamping angle, and seedling-picking frequency as the variables. The results indicated that these parameters had significant effects on the substrate loss rate, pot seedling shedding rate, and seedling-picking success rate.

2) A second - order rotary orthogonal combination test was performed on the seedling - picking device. Regression models between each factor and index were established, and the parameters were optimized using the response surface methodology. The optimal parameter combinations for the automatic seedling - picking device were determined as follows: the spring stiffness coefficient was 367.8 N/m, the clamping angle of the seedling needles was 15.6°, and the picking frequency was 89 plants per minute. Under these parameter combinations, the average substrate loss rate was calculated to be 4.09%, the average pot seedling shedding rate was 1.97%, and the average seedling extraction success rate was 93.94%. The results of the bench - top validation test were found to be in close agreement with the optimization results.

Keywords: tomato detection; YOLOv8n; fruit maturity detection; EMA attention mechanism; C2f-Faster module

ABSTRACT

The detection of tomatoes for automatic picking is challenging due to the dense distribution of fruit and severe occlusions. To address this, a dataset is developed using tomato images captured in a greenhouse environment, and an enhanced model for tomato fruit maturity detection based on YOLOv8n is proposed, which incorporates the EMA attention mechanism and the C2f-Faster module for multi-scale feature fusion. These additions not only improve detection accuracy but also enhance detection speed, thereby boosting the model's robustness and generalization ability. Experimental results demonstrate that the proposed ECF-YOLOv8n model achieves detection accuracies of 93.8%, 94.7%, 92.5% and 94.1% for immature, nearly mature, ripe tomatoes and mean average precision in a greenhouse setting, respectively. The model's size is 4.7 MB, with GFLOPs of 6.5G. Compared to advanced models like RT-DETR, YOLOv5, YOLOv7 and YOLOv11, the ECF-YOLOv8n model outperforms them in both detection accuracy and speed. This work provides valuable insights for the research, development and optimization of tomato picking robots.

摘要

针对目前番茄自动化采摘目标检测中因果实密集、遮挡严重等导致目标检测难度大的问题，本研究基于温室大棚环境下的番茄图像，构建了数据集，提出了一种基于 YOLOv8n 的番茄果实成熟度检测的改进模型，并添加引入了 EMA 注意力机制和 C2f-Faster 模块，以实现多尺度特征融合，在保证检测精度较高的情况下，有效提高了番茄果实检测速度，从而进一步提高了模型的鲁棒性和泛化能力。试验结果表明：提出的 ECF-YOLOv8n 模型对温室大棚环境下未成熟、将要成熟、成熟番茄检测精度和均值平均精度分别为：93.8%、94.7%、92.5% 和 94.1%，模型大小为 4.7 MB，GFLOPs 为 6.5G，与 RT-DETR、YOLOv5、YOLOv7、YOLOv11 等先进模型进行比较，该模型实现了较高的检测精度和更快的检测速度，本研究可为番茄采摘机器人的研发和优化提供重要参考。

INTRODUCTION

Tomato is one of the important economic crops in greenhouses. In recent years, the area of greenhouse tomato cultivation has continued to expand. However, tomato harvesting is still primarily carried out by humans, which is inefficient and costly. In addition, since the harvesting window for tomatoes is short, failing to pick the ripe fruits in time directly affects both fruit quality and economic benefits (Malik et al., 2018; Lawal et al., 2021). To achieve efficient and rapid automated tomato picking, accurate target detection is crucial. Target detection technology provides precise information for mechanized picking, enabling the automation of the harvesting process. Therefore, enhancing the accuracy of target detection is key to improving picking efficiency and reducing costs (Tsai et al., 2022; Li R et al., 2023; Miao, et al., 2023).

In recent years, convolutional neural networks (CNNs) based on deep learning have become a major research focus and have been widely applied to the identification of greenhouse tomatoes (Gao et al., 2022; Zeng et al., 2024). Target detection algorithms are generally categorized into two main types: one-stage and two-stage. Typical representatives of one-stage object detection algorithm include the YOLO series. The typical representative of the two-stage object detection algorithm is the RCNN series, including Fast R-CNN, Faster R-CNN and Mask R-CNN (Bai et al., 2024; Yin et al., 2024; Babu et al., 2024).

HongBo Wang, Professor, Correspondent author

This algorithm first generates a series of candidate boxes for samples and then classifies the samples through a convolutional neural network. Compared with the one-stage algorithm, the two-stage algorithm has a slower detection speed, and a higher algorithm complexity.

In the field of fruit and vegetable maturity detection, numerous experts and scholars both domestically and internationally have conducted relevant research. In terms of one-stage algorithm, *Fengjun et al.*, (2024), addressed the issue of occlusion of *Camellia oleifera* fruits in natural environments by improving the original YOLOv7 model. They proposed a maturity detection method for *Camellia oleifera* fruits, providing a theoretical basis for the intelligent harvesting of these fruits. To improve the accuracy of surface defect detection in pinewood while maintaining detection speed, *Jiwen et al.*, (2024), proposed an improved RT-DETR model, RIC-DETR. Experimental results demonstrated that the RIC-DETR model achieved an accuracy of 95.4%, offering technical support for surface defect detection in pinewood. *Zheng et al.* (2022) constructed a new backbone network, R-CSPDarknet53, based on YOLOv4 by integrating a residual neural network to establish skip connections between the front and back layers, thereby preventing the loss of low-dimensional small target features. In addition, by replacing the maximum pool in the original SPP network with the deep separable convolution model, C-SPP is proposed to realize feature information reuse and multi-scale fusion. On this basis, a tomato detection model RC-YOLOv4 is constructed, which improves the detection accuracy of tomato in natural environment. The test results show that the tomato detection accuracy and recall rate of RC-YOLOv4 model in natural environment are 88% and 89% respectively, the average detection accuracy is 94.44%. *Appel et al.*, (2023), proposed an improved YOLOv5 tomato detection algorithm. By adding CBAM convolutional attention mechanism to the YOLOv5 model, feature extraction and target recognition were carried out to improve the accuracy of the model. Non-maximal suppression and distance union ratio (DIoU) were APPLIED to enhance the recognition of overlapping objects in the image. The results showed that the average accuracy of the CAM-YOLO algorithm for the detection of overlap and small tomatoes was 88.1%.

Li P. et al. (2023), based on the requirements of the tomato maturity grading task, adopted the MHSA attention mechanism to improve the YOLOv8 backbone, enhancing the network's ability to extract diverse features. The Precision, Recall, F1-score, and mAP50 of the tomato fruit maturity grading model constructed based on MHSA-YOLOv8 were 0.806, 0.807, 0.806, and 0.864. *Solimani et al.*, (2024), proposed a new data balancing method in order to overcome the problem of data imbalance. A squeezing and exciting (SE) block attention module is integrated into the head structure of YOLOv8 model, which significantly improves the algorithm's ability to detect objects of different sizes in complex environments, and can effectively detect flowers and fruits in tomato plants.

In terms of two-stage algorithm, *Gao et al.*, (2020), addressed the issue of occlusion in apples during the harvest period by applying the Faster R-CNN model for detecting occluded apples. Experimental results showed that the model achieved an average detection accuracy of 80%-90% for occluded apples. *Chen et al.*, (2022), integrated Gabor features into Faster R-CNN and proposed a two-stage training method based on a genetic algorithm and backpropagation to train a new Faster GG-R-CNN model, achieving an average precision of 94.57%. *Seo et al.*, (2021), developed a real-time robotic detection system based on Faster R-CNN, utilizing hue values to establish an image-based ripeness standard for tomatoes, with a recognition accuracy of 90.2%. *Fang et al.*, (2024), proposed a multi-target identification and localization method for tomato plants based on the VGG16-UNet model. The average intersection and pixel accuracies of the VGG16-UNet model after introducing the pretrained weights were 85.33% and 92.47%, respectively, which were 5.02% and 4.08% higher than those of the VGG16-UNet without pretrained weights, achieving the identification of main branches, side branches, and axillary bud regions.

In a greenhouse environment, factors such as lighting, occlusion, and the density of plants can complicate the accurate identification of tomato ripeness (*Huiqin et al.*, 2024), leading to low detection efficiency. To improve the detection accuracy and speed of tomato ripening in greenhouse, this study proposes an enhanced YOLOv8n object detection algorithm. By incorporating the EMA attention mechanism, the model reduces sensitivity to noise and outliers, while the C2f-Faster module enables multi-scale feature fusion, thus improving both detection accuracy and speed for tomatoes. To account for the complexity of greenhouse tomato scenes, images of tomatoes are captured under various weather conditions, lighting angles, and shooting perspectives, ensuring the dataset's richness and diversity. Additionally, preprocessing and image augmentation techniques are applied to enhance dataset quality, making it better suited for tomato fruit detection in greenhouse environments. This research provides valuable target information for tomato-picking robots and offers a theoretical foundation for automated harvesting.

MATERIALS AND METHODS

DATA SAMPLE COLLECTION AND DATASET CREATION

Data Sample Collection

The tomato image data were collected from a tomato picking garden located in the suburbs of Hohhot, where standardized cultivation techniques are applied. To ensure the diversity of the dataset, enhance the model's robustness, and improve its generalization ability, images of tomatoes were captured at different times of day, across various stages of ripeness, from different angles, at varying distances, and under different lighting conditions (Wang *et al.*, 2024). A total of 2,080 images, each with a resolution of 640×640, were selected for the dataset, as shown in Figure 1.

Fig. 1 - Images of tomatoes in a greenhouse in different scenes

Dataset Preparation

The creation of the dataset primarily involved two key processes: image annotation and dataset categorization. The Labellmg annotation tool was used for manual labelling of the image data, following the YOLO dataset annotation format. According to the national standard GH/T1193-2021, the maturity of tomatoes can be divided into unripe stage, green ripe stage, colour change stage, early red ripe stage, mid-red ripe stage and late red ripe stage. Specifically, tomatoes in the mid-red ripe stage and late red ripe stage have a red surface coverage of 40%-60% and 70%-100%, respectively. In the greenhouse, only mid-red and late-red ripe tomatoes are harvested (Zhao, 2024).

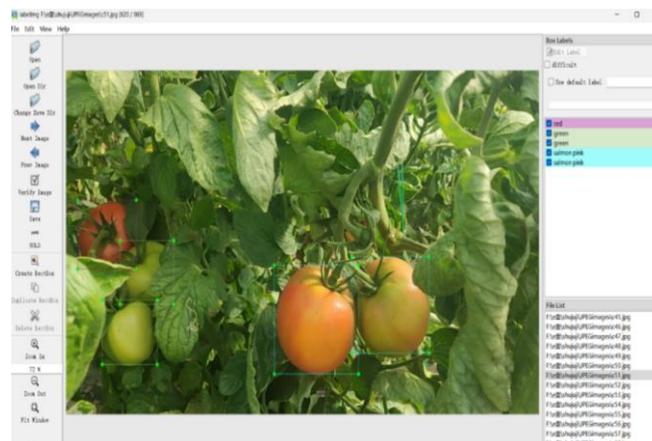

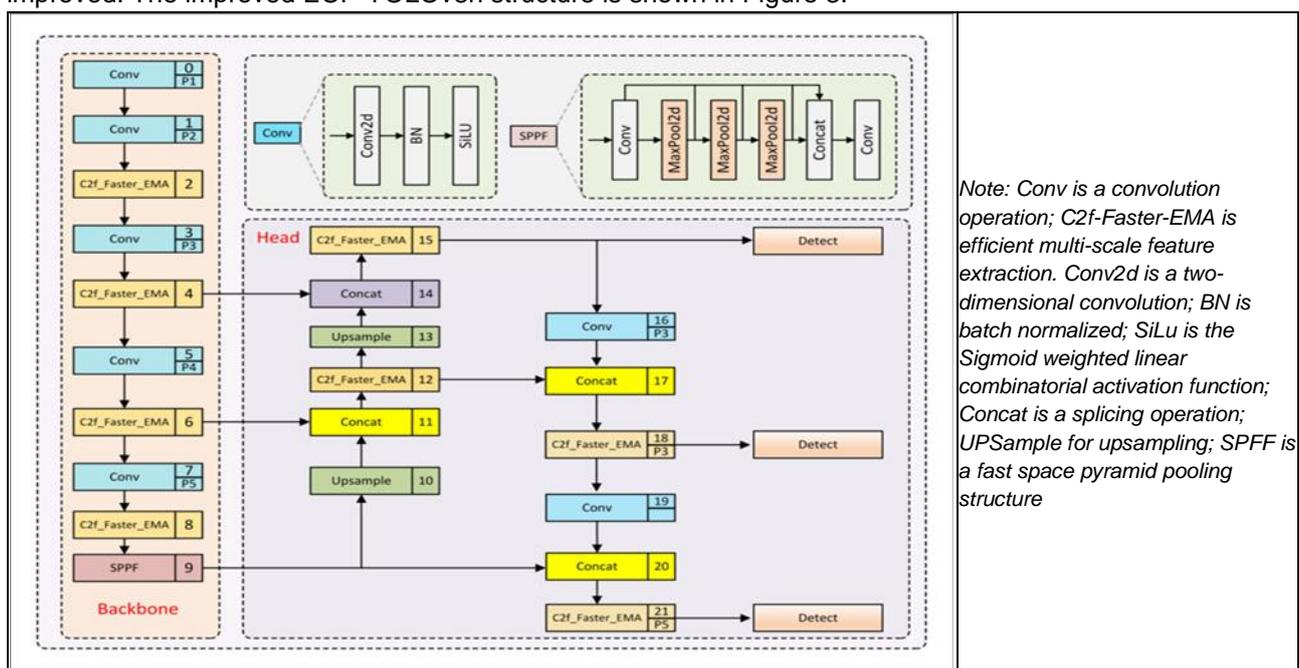

Fig. 2 - Tomato image annotation

In this paper, the labelled targets, i.e. the tomato fruits to be detected, are divided into three categories: Tomato fruits in the unripe, green-ripe, colour-changing, and early red-ripe stages, i.e. tomatoes with less than 40% red surface coverage, are classified as unripe and labelled as green; mid-ripe tomatoes with 40% to 60% red colouring on the fruit surface are classified as almost ripe and are labelled as salmon pink; late-ripe tomatoes with 70% to 100% red colouring on the fruit surface are classified as mature and labelled as red. The image annotations are illustrated in Figure 2. Upon completion of the annotation process, a corresponding text file (*.txt) for each image was generated, linking the image name with the txt file name. The labelled dataset was then split into training, validation, and test sets in a 7:1:2 ratio, with 1456 images for training, 208 images for validation, and 416 images for testing.

FRUIT MATURITY DETECTION MODEL OF TOMATO

YOLOv8 algorithm is the Yolo series target detection algorithm launched by Ultralytics. It is an upgrade based on the historical version of the Yolo series. The network composition of YOLOv8 mainly includes four parts: Input, Backbone, Neck and Head. Backbone is the network part used to extract image features in YOLOv8. It uses a series of convolution and deconvolution layers to extract features, and also uses residual connections and bottleneck structures to reduce the size of the network and improve performance. The neck part plays a role in feature fusion in YOLOv8. It uses multi-scale feature fusion technology to fuse feature maps from different stages of the backbone to enhance feature representation capabilities. The head part is responsible for the final target detection and classification tasks.

YOLOv8 has five different structures, namely YOLOv8m, YOLOv8l, YOLOv8x, YOLOv8n, and YOLOv8s. These models differ only in depth and width. The basic structure of these models is four parts. In order to meet the requirements of lightweight and real-time detection, while ensuring high detection accuracy and detection speed, YOLOv8n which has a relatively low complexity is chosen as the base model. It can achieve faster recognition speed and smaller storage occupancy while ensuring high detection accuracy, which is conducive to deployment on mobile devices (Hussain et al., 2023). Based on YOLOv8n, an improved ECF-YOLOv8n network model structure is proposed, and the EMA attention mechanism is introduced. By reconstructing some channels into batch dimensions and grouping the channel dimensions into multiple sub-features, the EMA attention mechanism can reduce information loss while keeping the tensor size unchanged, and enhance the model’s ability to capture spatial semantic features. The C2f-Faster-EMA module is also responsible for fusing feature maps of different scales to generate more representative feature representations. This feature fusion process may be achieved through upsampling, downsampling, splicing and other operations to ensure that the model can fully utilize multi-scale information to improve detection performance. While keeping the YOLOv8n model lightweight, the detection performance and speed of the model are improved. The improved ECF-YOLOv8n structure is shown in Figure 3.

Note: Conv is a convolution operation; C2f-Faster-EMA is efficient multi-scale feature extraction. Conv2d is a two-dimensional convolution; BN is batch normalized; SiLu is the Sigmoid weighted linear combinatorial activation function; Concat is a splicing operation; UPSample for upsampling; SPPF is a fast space pyramid pooling structure

Fig. 3 - Structural diagram of the improved YOLOv8n

EMA Attention Mechanism

EMA attention mechanism is a new type of efficient multi-scale attention method, which focuses on retaining information on each channel and reducing the amount of computation, as shown in Figure 4.

EMA is an attention weight descriptor that uses three parallel paths to extract grouped feature maps. Two of the parallel routes are located in the 1x1 branch, and the third parallel route is located in the 3x3 branch. In order to reduce the amount of computation and obtain the dependencies between channels at the same time, cross-channel information interaction is established in the channel direction.

In this structure, output represents the output plane of the input features, input represents the input plane of the input features, and k represents the kernel size. Accordingly, the G group is reshaped to the batch dimension and the input tensor is redefined as C//GxHxW. The two encoded features are connected in the height direction of the image and share the same 1x1 convolution without dimensionality reduction 1x1 branch (Xu et al., 2024). After decomposing the output of the 1x1 convolution into two vectors, two nonlinear sigmoid functions are used to fit the 2D Binomial distribution on the linear convolution. In order to realize the different cross-channel interaction features between the two parallel paths in the 1x1 branch, the attention maps of the two channels are aggregated within each group by a simple multiplication. On the other hand, the 3x3 branch captures the local cross-channel interaction through 3x3 convolution to expand the feature space. In this way, EMA not only encodes inter-channel information to adjust the importance of different channels, but also embeds the precise spatial structure information into the channel (Yang et al., 2024).

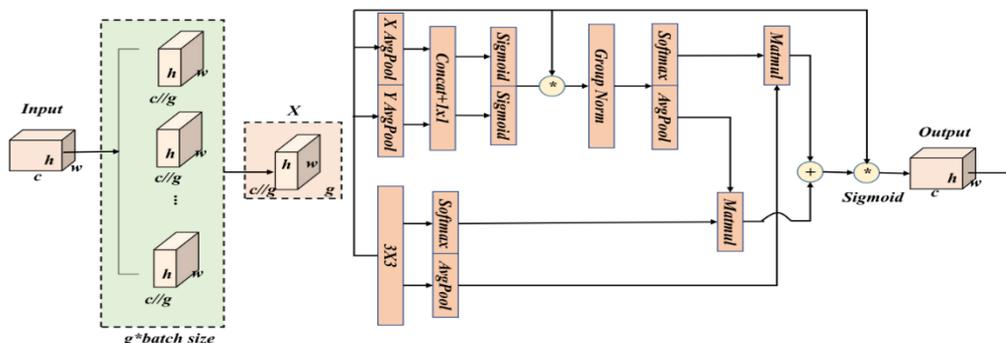

Fig. 4 - EMA module

C2f module

C2f module consists of a convolution block, which receives the input feature map and generates an intermediate feature map. The C2f module structure diagram is shown in Figure 5. The generated intermediate feature map is split into two parts, one part is directly passed to the final "Concat block", and the other part is passed to multiple "Bottleneck blocks" for further processing. The feature map input to the "Bottleneck block" is processed through a series of convolution, normalization and activation operations, and the final feature map is concatenated with the directly passed feature map in the "Concat block". In the C2f module, the number of "Bottleneck modules" is defined by the "depth multiple" parameter of the model, that is, the depth and computational complexity of the module can be adjusted according to the needs. The concatenated feature maps are input into a final convolutional block for further processing to generate the final output feature map.

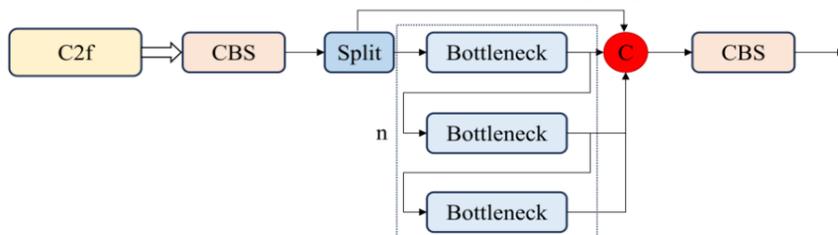

Fig. 5 - C2f module

C2f-Faster Module

In the target detection task, due to the relatively simple structure of the C2f module and the lack of a dedicated acceleration mechanism, it exhibits a low detection speed when processing large-scale data sets or performing real-time detection. In order to solve this performance bottleneck, a new neural network, FasterNet, was introduced. FasterNet has shown significant advantages in achieving fast target detection due to its excellent running speed and optimized design.

There is a new partial convolution (PConv) in the FasterNet module, as shown in Figure 6 (c). The core function of partial convolution (PConv) lies in its flexibility and adaptability to data missing. Compared with traditional convolution, partial convolution does not mechanically apply the same convolution kernel to all parts of the input data. Instead, it dynamically determines the scope of the convolution kernel based on the validity of the data, that is, whether the data points are missing or damaged.

When partial convolution (PConv) processes a convolution window, it first checks the data points within the window. For valid, non-missing data points, PConv applies the convolution kernel like a regular convolution operation. However, for missing or invalid data points, PConv will choose to ignore them and not include them in the convolution calculation. This flexibility means that the actual area of action of the convolution kernel may be different in each convolution window. This depends entirely on the completeness and distribution of the data in the window. In this way, partial convolution not only improves the robustness to missing data, but also more effectively extracts and utilizes the remaining valid information. By reducing redundant computation and memory access at the same time, spatial features can be extracted more efficiently. Each FasterNet (FasterBlock) module has a PConv layer followed by two Conv1x1 layers. Together, they are shown as an inverted residual block, where the intermediate layers have an expanded number of channels and shortcut connections are placed to reuse input features.

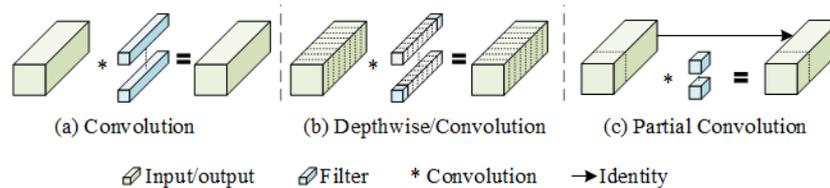

Fig. 6 - Three different convolution structures

The intermediate feature map generated by the fusion of the C2f module and FasterNet is split into two parts, one part is directly passed to the final Concat block, and the other part is passed to multiple FasterBlock blocks for further processing. The C2f-Faster module structure diagram is shown in Figure 7. The feature map input to the FasterBlock is further processed through a series of partial convolution, normalization and activation operations. At this time, the FasterBlock is more efficient and faster than the Bottleneck due to the existence of the partial convolution layer. The final feature map will be concatenated with the directly transmitted feature map in the Concat. The concatenated feature map will be input to a final convolution block for further processing to generate the final output feature map.

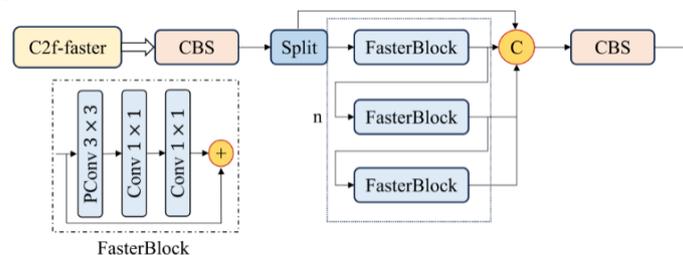

Fig. 7 - C2f-Faster module

C2f-Faster-EMA Module

Although C2f-Faster speeds up the detection speed, some convolution operations will cause some information loss, resulting in a decrease in detection accuracy, which cannot meet the requirements of tomato maturity detection in a greenhouse. Therefore, the EMA (Efficient Multi-scale Attention) attention mechanism is integrated in the C2f-Faster module, forming the C2f-Faster-EMA module, as shown in Figure 8.

The C2f-Faster-EMA module enhances the model's focus on key features, allowing it to more accurately identify target objects during detection, thereby improving overall detection accuracy. At the same time, the acceleration characteristics of FasterNet enable the C2f-Faster-EMA module to significantly reduce computational complexity and time consumption during target detection, speeding up the detection process. The FasterEMA module consists of a partial convolution layer (PConv) followed by a Sequential module comprising a multi-layer perceptron (MLP). This Sequential module includes a CBS module and a convolution layer (Conv2d). To further enhance the model's generalization ability and effectively prevent overfitting, DropPath regularization strategy is introduced. Specifically, DropPath randomly selects a subset of paths within each feature map and sets the weights of these paths to zero. This reduces the number of effective paths, thereby decreasing the model's parameter count and improving its robustness.

The Droppath operation can be applied to each feature map of every convolutional layer, with the pruning probability dynamically adjusted during training to control the extent of pruning. Finally, the EMA attention mechanism, incorporated into the C2f-Faster-EMA, enhances the feature fusion capability of the C2f module. By introducing a more complex network structure and attention mechanism, the model is able to learn more rich and comprehensive feature representations. These representations not only improve detection accuracy but also contribute to the model's robustness in more complex scenarios.

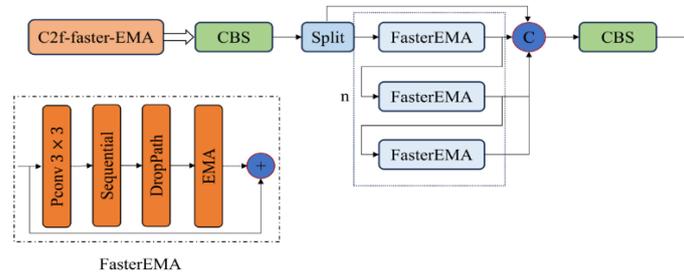

Fig. 8 - C2f-Faster-EMA module

Test environment

The operating system used for trial and training is Windows 11, the CPU is 12th Gen Intel(R) Core(TM) i5-12500H 3.10 GHz, the GPU is NVIDIA GeForce RTX 3060 Laptop GPU, and the running memory is 16G. CUDA version is 12.0, and is implemented using Python 3.10.14 under the PyTorch2.1.0 deep learning framework.

Evaluation indicators

Seven indicators were used to evaluate the maturity detection model of tomato fruit, namely precision (P), recall (R), average precision (AP), and mean average precision (mAP), model parameters, detection speed and memory usage. The calculation formulas of P, R, AP and mAP are as follows.

$$P = \frac{T_P}{T_P + F_P} \times 100\% \tag{1}$$

$$R = \frac{T_P}{T_P + F_N} \times 100\% \tag{2}$$

$$AP = \int_0^1 P(R) dR \tag{3}$$

$$mAP = \frac{\sum_{i=1}^m AP(n)}{3} \tag{4}$$

$$t = \frac{t_N}{N} \tag{5}$$

where, T_P represents the number of positive samples predicted as positive samples, that is, the number of correctly predicted tomato ripening levels; F_P represents the number of negative samples predicted as positive samples, that is, the number of falsely predicted tomato ripening levels; F_N represents the number of negative samples predicted as negative samples, that is, the number of tomato ripening level is incorrectly predicted; AP represents the P(R) curve made by using the Recall value as the X axis and the Precision value as the Y axis. The area of the measurement is the accuracy of identification of a certain category; mAP represents the average value of each category of AP, and measures the average quality of all categories.

RESULTS

IMPROVED TEST RESULTS OF YOLOV8N MODEL

In order to verify the effect of the improved YOLOv8n model, the accuracy P of the improved YOLOv8n model reached 93.7%, the recall R was 83.7%, and the average accuracy mean mAP was 94.1% for the 416 tomato fruit images divided into the test set. Some of the detection results are shown in Figure 9.

Fig. 9 - Improved YOLOv8n model detection results

COMPARISON OF IMPROVED YOLOV8N ABLATION EXPERIMENT PERFORMANCE

In order to better analyse the detection performance of the improved YOLOv8n model on tomato fruit maturity, ablation test was performed using YOLOv8n as the basic model to verify the optimization effect of each improved module. The optimization effect of each improvement point is evaluated using precision (P), recall (R), mean average precision (mAP), parameter quantity, floating point operations per second (FLOPs) and memory usage. The results of the ablation test are shown in Table 1.

Table 1

Model	Green mature (P)/%	Colour change (P)/%	Red mature (P)/%	MAP50 /%	Parameter quantity /M	FLOPs /G	Memory usage /MB
YOLOv8n	94.5	89.6	91.9	91.9	3.0	8.1	5.6
v8n-C2f-Faster	92.2	90.5	95	92.9	2.3	6.3	4.6
v8n-C2f-Faster-CGLU	93.2	92.7	87.1	93.2	2.2	6.2	4.5
v8n-C2f-Faster-EMA	93.8	94.7	92.5	94.1	2.3	6.5	4.7

The analysis results show that the proposed ECF-YOLOv8n model with the C2f-Faster-EMA module has significantly reduced the parameters, floating point operations amount and memory usage of the model compared with the YOLOv8n basic model, which improves the computing and storage efficiency. The detection precision (P) has also been increased, with the average of the mean average precision (mAP) increased by 2.2 percentage points, and the parameter quantity, floating point operations per second (FLOPs), and memory usage have been reduced by 23.33%, 19.75%, and 21.52%, respectively. This shows that the ECF-YOLOv8n model is maintaining high detecting rate, the model is lightweighted. Although the proposed ECF-YOLOv8n model with fusion C2f-Faster-EMA module has slightly increased the mean average precision (mAP) compared with the model with fusion C2f-Faster and C2f-Faster-CGLU. The average value has increased by 1.3 and 0.9 percentage points respectively, with a valuable increase, which can achieve accurate and efficient identification of tomato fruits by picking robots in greenhouse, and is more conducive to the picking of tomato picking robots.

COMPARATIVE TEST RESULTS OF IMPROVING YOLOV8N MODEL

In order to evaluate the detection effect of the ECF-YOLOv8n model proposed in this paper on tomato fruit maturity, three algorithms, YOLOv5, YOLOv7, YOLOv11, and RTDETR, were selected for performance comparison under the premise of consistent experimental conditions. The comparison results are shown in Table 2.

Table 2

Model	Precision (P) / %	Recall (R) / %	Mean average precision (mAP) / %	Frames per second (FPS)	Parameter quantity / M	FLOPs / G	Memory usage / MB
RT-DETR	87.5	82.1	87.6	87.0	19.9	56.9	40.5
YOLOv5	90.0	85.0	88.7	263.6	7.1	15.8	14.4
YOLOv7	91.5	87.2	94.3	145.8	37.9	104.1	73.8
YOLOv11	90.1	87.9	93.3	107.5	2.58	6.3	4.6
Ecf-YOLOv8n	93.7	83.7	94.1	335.1	2.3	6.5	4.7

As shown in Table 2, the ECF-YOLOv8n model achieved a precision (P) of 93.7%, a recall (R) of 83.7%, and a mean average precision (mAP) of 94.1%. Compared to other detection models, the ECF-YOLOv8n model demonstrates improved performance in greenhouse tomato maturity detection. Compared with the mean average precision (mAP), the RT-DETR, YOLOv5 and YOLOv11 models were improved by 6.5%, 5.4% and 0.8%. respectively, indicating that ECF-YOLOv8n has higher precision in the detection of tomato maturity in greenhouses. The ECF-YOLOv8n model has decreased by 0.2% compared with the YOLOv7 model in terms of the mean average precision (mAP), but the parameter quantity and memory usage of ECF-YOLOv8n are much smaller than that of YOLOv7, and the detection rate is faster.

The average frame of ECF-YOLOv8n reaches 335.1 frames/s, which is far higher than YOLOv7, showing that it has better efficiency and better real-time detection capabilities. Overall, ECF-YOLOv8n has shown balanced and excellent performance in detection performance, resource use and detection rate, and has better effect on the detection of tomato maturity in greenhouses.

Test verification

Owing to the constraints of test conditions, time, and other factors, a laboratory-based experiment was conducted to evaluate the detection performance of the enhanced ECF-YOLOv8n model for tomato maturity recognition. The results indicated that the average recognition accuracy of the improved ECF-YOLOv8n model for tomatoes reached 91%, which satisfies the requirements for greenhouse tomato harvesting. Future testing will be conducted in real-world greenhouse environments to improve the model's adaptability in complex scenarios, thereby better aligning it with the requirements of intelligent agriculture.

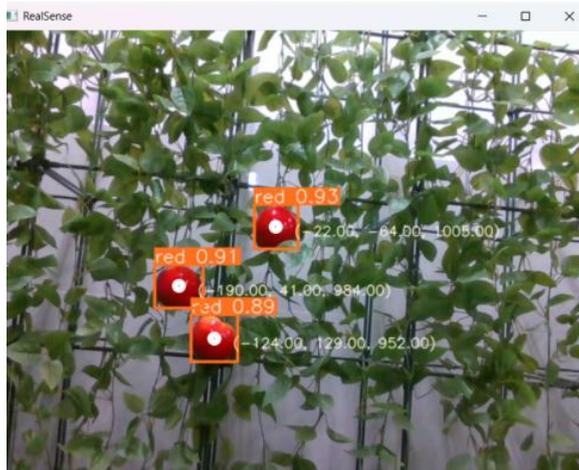

Fig. 10 - Tomato ripeness identification results

CONCLUSIONS

This paper improves the tomato maturity model based on the Yolov8n model, and realizes rapid and accurate detection of the tomato maturity in greenhouses. The main conclusions are as follows:

1) This paper proposes an ECF-YOLOv8n model based on the Yolov8n model. The precision (P) of this model for detecting the maturity of tomato is 93.7%, the recall (R) is 83.7%, and the mean average precision (mAP) is 94.1%. Through the ablation test results, it can be seen that the improved ECF-YOLOv8n model has a mean average precision (mAP) increase of 2.2% compared with the original YOLOv8n model, and has decreased by 23.33%, 19.75%, and 21.52% respectively in terms of parameter quantity, floating point operations per second (FLOPs), and memory usage, respectively. This indicates that the method proposed in this paper, which integrates the EMA attention mechanism and introduces the C2f-Faster module for multi-scale feature fusion, improves the speed of tomato maturity detection while maintaining high detection precision. It enables fast and accurate assessment of tomato maturity in greenhouse.

2) The C2f-Faster-EMA module is introduced into the backbone and head parts of the Yolov8n model to improve the network feature extraction capability. Compared with mainstream models such as RT-DETR YOLOv5 and YOLOv11 models, the mean average precision (mAP) is increased by 6.5%, 5.4% and 0.8%, respectively, and the experimental results show that the improved ECF-YOLOv8n model has a fast detection speed and high precision, which basically meets the real-time and efficient work of picking robots, and provides a theoretical basis for tomato picking technology.

3) In the laboratory environment, the detection performance of the enhanced ECF-YOLOv8n model for tomato ripeness identification was evaluated. The results demonstrated that the improved model achieved an average identification accuracy of 91%, meeting the requirements for greenhouse tomato harvesting.

SEMI-SUPERVISED WHEAT EAR DETECTION ALGORITHM BASED ON THE MODIFIED YOLOv8

/ 基于改进 YOLOv8 的半监督麦穗识别算法

Yu ZHANG ¹⁾, Zihui XU ¹⁾, Fuzhong LI ¹⁾, Xiaoying ZHANG ^{*1)}, Xiao CUI ^{*1)}¹⁾ School of Software, Shanxi Agricultural University, Shanxi/China;Tel: +86-15803449361; E-mail: xiaoyingzhang@sxau.edu.cn; cuixiaocuilu@163.comDOI: <https://doi.org/10.35633/inmateh-75-54>**Keywords:** wheat spike, object detection, semi-supervised learning, YOLOv8**ABSTRACT**

In contemporary agricultural practices, the use of image and video acquisition technologies, such as drones and cameras, has become increasingly common for capturing and monitoring crop growth in agricultural fields. The reliance on visual data for analyzing farm management conditions and facilitating decision-making processes is gaining significant traction. However, in practical applications, image acquisition tools often face challenges in maintaining optimal distance and angle during data capture, which can negatively impact the detection accuracy of existing object detection methods. Semi-supervised learning plays a crucial role in improving object detection. In this study, a semi-supervised algorithm for wheat spike recognition was developed based on an optimized YOLOv8n model. The model incorporates SPDCConv and PSA attention modules after the SPPF layer, effectively reducing computational and memory demands while enhancing model performance. The proposed model achieved an accuracy of 94.2%, outperforming YOLOv5s, Efficient Teacher, and the baseline YOLOv8n by 10.9%, 4.5%, and 6.1%, respectively—demonstrating its strong potential for practical agricultural applications.

摘要

当今农业，使用无人机或摄像头这样的图像视频采集工具拍摄或监控农田作物生长情况变得常见，依靠这些图像分析农田管理情况和辅助决策也会变得越来越有市场。但在实际生产中，图像采集工具在拍摄时很难保持合理的距离和角度，这使得现有的目标检测方法检测精度低。而半监督学习对提高物体检测至关重要。我们开发了一种用于麦穗识别的半监督学习算法，使用了改进的 YOLOv8n，并在 SPPF 之后集成了 PSA 注意力机制和 SPDCConv。这些改进减少了计算和内存需求，提升了模型性能。我们的模型达到了 94.2% 的准确率，分别比 YOLOv5s、Efficient Teacher 和 YOLOv8n 高出 10.9%、4.5% 和 6.1%，展示了其实际潜力。

INTRODUCTION

Wheat, recognized as a globally cultivated food crop, has maintained its status as the third most extensively sown crop in terms of both area and total production since the 1940s. It serves as a staple food for approximately one-third of the global population and is cultivated across an estimated 224 million hectares, thereby supporting around 30 percent of the world's inhabitants (Eversole et al., 2014; Li et al., 2018a). Enhancing wheat yield per unit area remains a primary objective of contemporary breeding efforts. The implementation of automated detection and counting of wheat ears facilitates the rapid and precise assessment of ear numbers, which subsequently allows for the estimation of yield per plant, yield per unit area, and overall production. This advancement significantly aids researchers in optimizing breeding efficiency. With continuous advancements in artificial intelligence technologies, various approaches, including image processing, machine learning, and deep learning, are increasingly being applied to wheat yield prediction and phenotypic identification.

The methodologies employed for counting wheat ears through traditional image processing techniques can be broadly classified into three distinct categories (Fu Jingbo, 2021; Liu et al., 2019): curve fitting segmentation, image-based fractal segmentation, and pixel-based area estimation (Liu Tao, 2014). These approaches typically utilize color features or grain characteristics to extract images of wheat ears, followed by morphological operations such as corrosion expansion, cavity filling, and refinement processing. This sequence of operations facilitates the enumeration of wheat spike skeleton images through angular point detection methods. Moreover, Li et al., (2018b), implemented a technique that involved color space

transformation, utilizing a custom device to capture RGB images of wheat in natural field conditions, which were subsequently converted to HSV space.

The saturation component (S) was subjected to binary conversion, resulting in a binary image. An adhesion object segmentation algorithm was then applied to the wheat ear images, followed by the implementation of a concave point detection method for segmentation and counting, ultimately enabling the calculation of grain numbers and yield prediction. Furthermore, *Fernandez-Gallego et al., (2018)*, introduced a wheat ear counting method based on an enhanced K-means clustering algorithm, which relies on color feature clustering. In this approach, each sub-region identified through clustering is interpreted as representing a wheat ear, with the total number of sub-regions serving as an estimate of the wheat ear count. While traditional machine learning techniques for wheat ear counting significantly reduce the labor required compared to manual counting and enhance efficiency and accuracy to some extent, the complexity of field environments presents challenges in maintaining consistent image quality and limits the versatility of these methods.

The continuous advancements in deep learning within the domain of agricultural research have prompted certain scholars to integrate YOLOv5 with semi-supervised learning methodologies, culminating in the creation of a semi-supervised target detection algorithm that is applicable across various contexts. In their study, *Zhou et al., (2023)*, presented an innovative semi-supervised adaptive algorithm, named SSDA-YOLO, which combines a YOLOv5-based semi-supervised framework with a knowledge distillation approach. This algorithm enhances the quality of pseudo-labels through improved view refinement and global view filtering. Furthermore, *Lyu et al., (2022)*, reported a notable enhancement in the recognition accuracy of citrus bagging by incorporating a strip attention module into the YOLOv5 backbone and employing additional semi-supervised learning techniques.

Despite the advancements made in the aforementioned studies, which have enhanced the algorithm from various perspectives and yielded certain outcomes, significant challenges persist when applying these methods to single-stage target detection models, such as YOLO. In particular, the detection of wheat ears presents several critical issues. Firstly, there is an inconsistency in the scale of wheat spike targets. As wheat ears progress from the heading stage to maturity throughout their growth cycle, the size of individual wheat plants varies temporally. Additionally, certain weeds exhibit morphological similarities to wheat ears, thereby complicating the accurate differentiation and identification of these targets based solely on visual characteristics. Secondly, the samples of wheat spikes are frequently densely clustered. In areas where wheat plants are closely spaced, occlusion of wheat ears is a prevalent issue. The dataset contains a substantial number of samples, which not only affects the accuracy of target identification but also complicates the labeling process. Finally, the extensive volume of data within the wheat spike dataset results in high labor costs associated with large-scale annotation.

In response to the challenges previously outlined, this study proposes a semi-supervised algorithm for the detection of wheat spikes, which is based on an enhanced version of YOLOv8. The algorithm integrates Spatial Depth Conversion Convolution (SPDConv) to improve the detection of small objects in low-resolution images, thereby augmenting the feature extraction capabilities for such targets (*Sunkara and Luo, 2023*). Additionally, the PSA attention mechanism is incorporated to reduce the computational and memory demands associated with self-attention in visual tasks, ultimately resulting in enhanced detection accuracy. Furthermore, this paper presents improvements derived from the modified Efficient Teacher framework (*Xu et al., 2023*), which effectively increases the detection accuracy of the algorithm by utilizing valuable information from unlabeled images, all while preserving the model's original size.

MATERIALS AND METHODS

Data collection and data processing

To enhance the generalization performance of the model, this study employed two distinct datasets for training. One of these datasets, known as the Wheat Detect (WD) dataset, consists of images of wheat captured at the Yang Jia Zhuang Village experimental base of Shanxi Agricultural University. The specific wheat variety used for this dataset is Agricultural University 212. The images were systematically collected from April to June 2024, with a frequency of every three days, to comprehensively cover the filling and maturation stages of the wheat.

The shooting process involved a variety of weather conditions, encompassing both sunny and overcast scenarios. The iPhone 15 Pro Max was employed as the primary photographic equipment, leading to the

acquisition of over 6,500 images of wheat canopies, of which 3,011 were selected for further analysis. All images were stored in JPG format, ensuring a consistent resolution of 3648x2736 pixels.

The Labellmg software was utilized for image annotation, with the sole category label assigned being "wheat." The resulting annotation data were subsequently saved as "txt" files in the YOLO format.

The second data set is the Global Wheat Head Detection (GWHD) from the global wheat public database (David et al., 2021). This data set pooled 6,422 RGB images with a resolution of 1,0,24x1,024 pixels, and 275,187 labeled ears of wheat. The images were collected from Europe, North America and Asia, covering a variety of varieties, planting conditions, climate types, as well as collection methods, thus ensuring the diversity of the data set in terms of genotype and environment. These characteristics of GWHD data sets help improving the accuracy and reliability of wheat ear detection and positioning. Fig.1 shows some examples of images generated from data obtained from the Yang Jia Zhuang Experimental Base.

Fig. 1 - Images of wheat at different growth stages

YOLOv8ps structure

As depicted in Fig.2, Efficient Teacher, which is constructed on YOLOv5, introduces several enhancements to the network. Efficient Teacher proposes three modules to implement a scalable and effective SSOD framework. The Dense Detector module improves the quality of pseudo labels with dense input and offers better inference efficiency; the Pseudo Label Assigner module categorizes pseudo labels into two types to mitigate the issue of pseudo labeling.

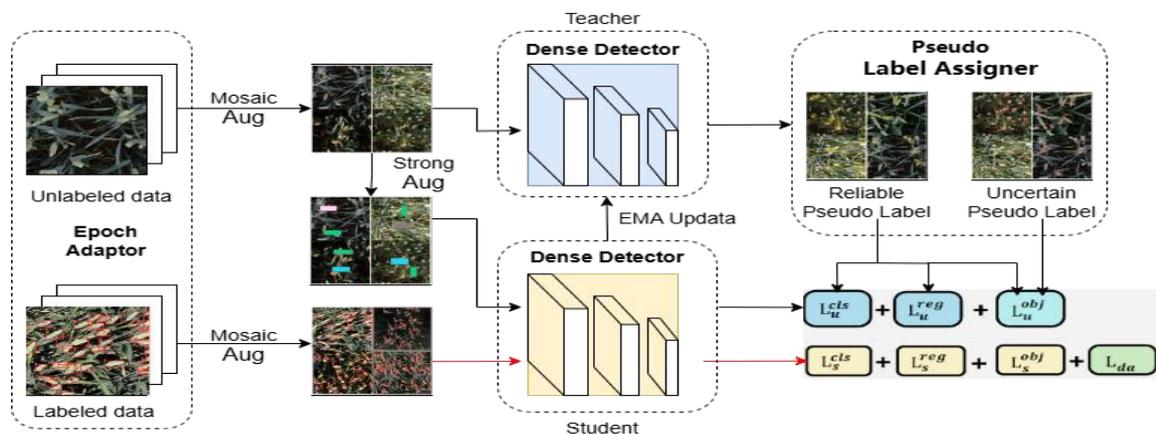

Fig. 2 - Semi-supervised training framework

Inconsistency problem, Epoch Adaptor reduces training time and the inconsistency of features. Although Efficient Teacher shows significant improvement in detection accuracy compared to SSOD and one-stage anchor-based detectors, it still faces significant challenges in the accuracy of small object detection. These challenges mainly stem from the fact that small objects occupy fewer pixels in images, making feature extraction difficult and thus affecting the accuracy of detection. To address these challenges, this study proposes a small object detection network architecture based on YOLOv8. The main innovations include: in the initial stage of the study, the YOLOv8ps model was proposed. By adopting this strategy, it was expected to capture the detailed features of small objects more accurately, thereby improving the overall detection performance. Subsequently, this study delved in to the efficiency of convolution (SPDCConv) within CNN architectures and introduced four layers of SPDCConv after the Conv layers in the YOLOv8 backbone network.

This method effectively maintains the detail information of the input image by transforming the spatial dimensions into depth dimensions, significantly enhancing the feature extraction performance for small objects.

Furthermore, to reduce the computational burden on the YOLOv8n network, Partial Self-Attention (PSA) was integrated, as proposed in YOLOv10. PSA addresses the high computational complexity and memory consumption associated with traditional self-attention mechanisms in visual tasks, thereby significantly enhancing the model's performance and capability.

As shown in Fig 3, the lightweight network architecture proposed in this study mainly consists of three core components: the backbone network, the neck structure, and the head module. The primary function of the backbone network is to extract feature information from the input image data and output feature maps at three different scales. During this feature extraction process, the study introduces the SPDConv module, which aims to take the feature maps produced by the previous convolution operation as input, process them through the SPD layer, and then perform further feature extraction through consecutive convolution layers. Additionally, the study integrates the PSA attention mechanism to address the inherent high computational complexity and significant memory consumption issues of traditional self-attention mechanisms in visual tasks.

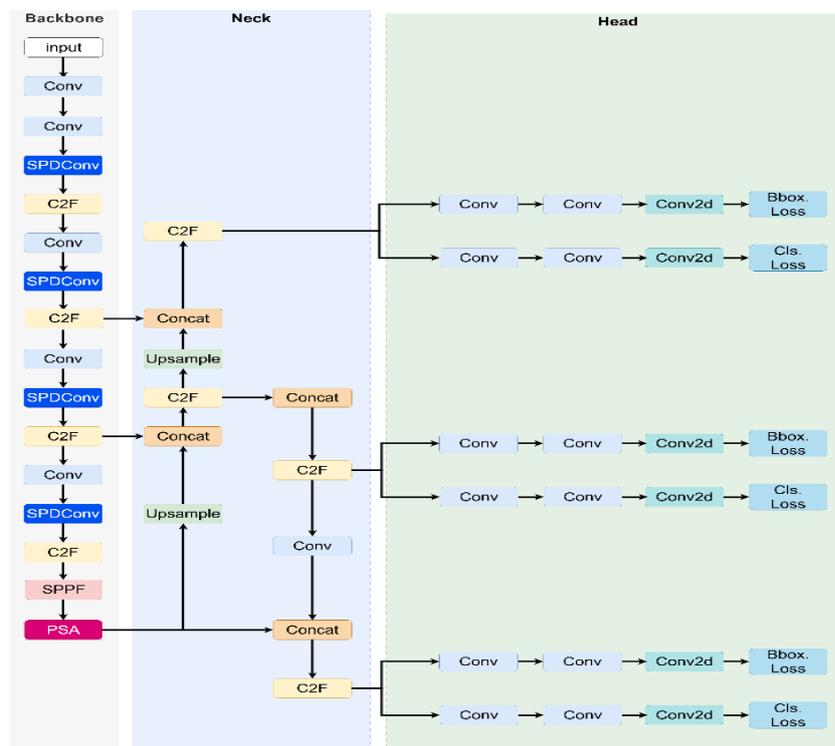

Fig. 3 - Network structure of improved YOLOv8 algorithm

The neck design of the network is used to enhance the ability to detect objects of different sizes by fusing feature maps from the backbone network at different scales, and then outputs three different scale feature maps. Similarly, both PSA and SPDConv are utilized for feature extraction and downsampling. Three independent and decoupled header structures are designed at the network's front, each responsible for predicting and analyzing feature maps of three distinct scales. This design allows each header structure to concentrate on processing feature information of a particular scale, thereby enhancing the network's capacity to capture and predict features across various scales. Consequently, this significantly improves the model's performance in visual tasks involving small objects. The darkened section in Fig. 3 represents the structural improvement module.

SPDConv The structure is composed of space to depth (SPD) layer and no convolutional step size (Conv) layer, replacing the pooling operation and convolution operation with step size in a similar way, and using scientific parameters to reduce the number of channels, which is suitable for a variety of convolutional neural network (CNN) architectures. In the traditional CNN architecture, the direct application of step convolution and pooling layer will lead to the gradual decrease of the spatial resolution of images with the deepening of the deepening of the network level, resulting in the loss of details of small objects, which makes the network encounter difficulties in accurately identifying these small objects. However, the combination of using SPD layers with step-free convolution layers enables the CNN to more effectively handle the challenges

posed by small objects and low-resolution images, thus improving the performance and robustness of the model in these complex scenarios.

For a specific feature plot X , the down sampling was performed by the scaling factor. Fig.4b shows the space-to-depth operation, where the spatial information is reorganized into the depth channel. When the scale factor is set to 2, the four feature subgraphs shown in Fig.4c can be obtained, and the shape of each subgraph is $(S/2, S/2, C)$, which realizes the effect of subsampling the feature graph X by 2 times. Subsequently, the four feature sub-maps are successively connected along the channel dimension to form the feature map in Fig.4d $(S/2, S/2, 4C)$. After completing the feature transformation in the SPD layer, the dimensions change from Fig. 4d $(D, 4C)$ to $(S/2, S/2, D)$. The detailed procedure is shown in Figure Fig.4.

In this study, four SPDConv layers were introduced after the Conv convolution layer. This move aims to take the feature graph generated by the convolution operation of the previous layer as input, and to transform the spatial dimension of the input image into depth dimension, so as to improve the depth of the feature graph without losing information. Subsequently, the convolution processing through the continuous Conv layer realizes the feature extraction without reducing the feature graph size, which effectively maintains the detailed information of the image. Compared with the traditional convolution operation, this insertion method is more efficient in retaining the information in the channel, which significantly enhances the feature extraction performance for small targets (Fig 3).

Despite the self-attention mechanism, its computational amount and memory footprint are high. To solve this problem, YOLOv10 proposed an efficient local self-attention mechanism (Wang et al., 2024), namely the PSA module. As shown in Fig.3, this module first divides the feature graph into two parts by channels after the convolution operation, one of which is sent to the N_PSA module composed of multi-head self-attention module (MHSA) and feedforward network (FFN). Subsequently, the two parts are reconnected and fused through a convolution operation. The PSA module is only placed after the lowest resolution stage, effectively avoiding the excessive consumption of resources caused by the squared computational complexity of the self-attention mechanism. Through this design, the PSA module can solve the high computational complexity and memory footprint problems faced by the self-attention mechanism in visual tasks, thus significantly improving the performance and capability of the model (Fig 5).

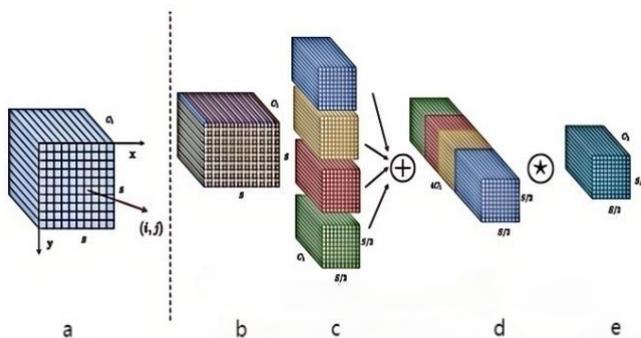

Fig. 4 - Illustration of SPDConv with a Scale Factor of 2

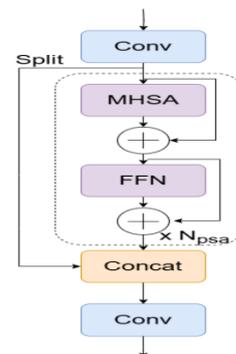

Fig. 5 - The partial self-Attention module (PSA)

Experimental Environment

The operating system used in this experiment is Windows 11, and the development environment of the model is Python 3.8, CUDA 11.1.0 and PyTorch 1.11.0. The training process was performed on the NVIDIA GeForce RTX 4060 graphics card. During the training process, YOLOv8n was used as the basic model, the size of the input image was set to 640×640 pixels, the batch size was set to 32, and the weight attenuation coefficient was set to 0.0005. In the fully supervised learning mode, the initial learning rate is set to 0.01, the minimum learning rate is set to 0.002, and the adjustment strategy of the learning rate adopts the cosine annealing method for a total of 40 training cycles (epochs). In the semi-supervised learning mode, the learning rate maintained a fixed value of 0.01, with a total of 300 training cycles.

Evaluation indexes of the model

A range of accepted evaluation measures in the field of target detection were used, including precision (Precision, P), recall (Recall, R), mean precision (mean Average Precision, mAP50) mAP50 at the IoU threshold of 0.5. Determine the integral of the precision-recall (P-R) curve.

In this study, only a single category of wheat ears was involved, with a sample size of $n=1$. Precision (P) is defined as the ratio of the number of correctly identified wheat ear samples to the total number of predicted

wheat ear samples, while Recall (R) is the ratio of the number of correctly identified wheat ear samples to the total number of actual wheat ear samples.

Model Detection Accuracy Analysis

In this research, a 50 cm x 50 cm plastic board was used to contain the samples during each shooting session, after which manual counting was performed. Subsequently, image capture was conducted, as illustrated in Figure 6. All images that had been manually counted were then utilized as a training set to assess the model's accuracy in identifying real-world scenarios and to compare it with other models.

Fig. 6 - Wheat image

RESULTS

In this study, our goal is to develop an efficient wheat spike detection algorithm by improving the original YOLOv8 network. These improvements include adjusting the network architecture of YOLOv8, incorporating SPDCConv and PSA attention mechanisms, and embedding them into a semi-supervised algorithm. To elucidate the impact of each improvement on the network, ablation experiments were conducted under the same training environment and hyperparameters. The YOLOv8n model served as the baseline, against which the previously mentioned improvements were sequentially implemented.

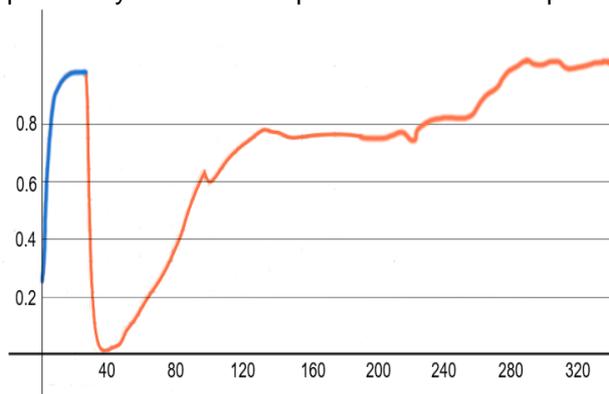

Fig. 7 - Changes in mAP50 metric during semi-supervised training stage

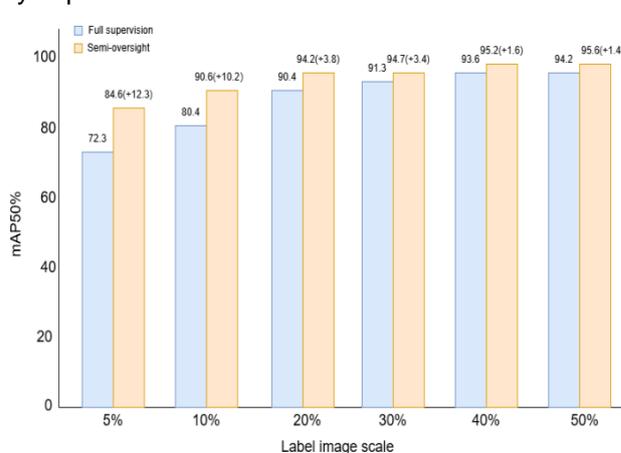

Fig. 8 - mAP50 metric of different annotation sample ratios

To verify the effectiveness of the proposed improvement strategy in improving the model accuracy, the ablation experiment was conducted based on the YOLOv8n algorithm. The experimental results are detailed in Table 1. Among them, A represents the introduced SPDCConv module, and B represents the PSA attention mechanism added after SPPF, while C represents the semi-supervised object detection method mentioned in this article.

According to the data in Table 1, the detection performance is significantly improved with the gradual integration of the improved module YOLOv8n. However, the proposed algorithm did not achieve the best performance in recall rates. The reason for this phenomenon is that the algorithm improves the extraction ability of the small target features, but also optimizes the computational complexity and memory footprint. Nevertheless, a slight decrease in recall is acceptable because the algorithm's accuracy and average accuracy have peaked, given the mutual constraints between accuracy (P) and recall (R).

Table 1

Results of the ablation experiment

For the fully supervised training, a ratio of 0.2 and 1400 samples were used, after which 5600 images were introduced as unannotated samples to perform the semi-supervised training. Fig 7 illustrates the evolution of mAP50 values during fully supervised versus semi-supervised training. As can be seen from the figure, after the full supervised training, the mAP50 index of the algorithm has basically reached the fitting state, with the accuracy of 90.4%. Then, 3200 unlabeled samples were added for semi-supervised training. At this time, the mAP50 index of the model went through the process of first reducing and then rising, and finally achieved further improvement with an accuracy rate of 94.2%. The reason for the decrease lies in the early stage of the semi-supervised training, where the accuracy of the model is low and the quality of the pseudo-labels generated by the teacher model is not high. However, as the training continues, the quality of the pseudo-labels gradually improves, and the detection accuracy of the model is correspondingly enhanced.

Table 2

Comparative experiments on object detection algorithms						
Model	Size	P	R	mAP50	mAP50:95	
YOLOv5s	640	0.867	0.754	0.833	0.473	
YOLOv5l	640	0.899	0.776	0.825	0.466	
Faster R-CNN	640	0.898	0.846	0.910	0.486	
SSD	640	0.901	0.834	0.905	0.481	
YOLOv8n	640	0.891	0.732	0.881	0.493	
YOLOX	640	0.902	0.859	0.921	0.528	
Efficient Teacher	640	0.890	0.827	0.897	0.502	
V8	640	0.904	0.852	0.914	0.494	
V8ps	640	0.957	0.865	0.942	0.487	

Subsequently, this study compared the effects of fully supervised and semi-supervised training methods under different annotated sample proportions, and the experimental results are shown in Fig 8. In the figure, blue area on the left represents the mAP50 values obtained from the fully supervised training with the entire annotated samples, while the orange area on the right shows the mAP50 values obtained after the further semi-supervised training. Since the total number of samples used in the training is 7000, the annotated ratio of 20% corresponds to 1400 annotated samples and 5600 unannotated samples, and so on.

To further verify the performance advantages of the algorithm proposed in this paper on the wheat spike detection dataset, comparative experiments were conducted with other mainstream lightweight object detection models, including YOLOv5s (Jocher, 2020), YOLOv5l, Faster R-CNN (Ren et al., 2017), SSD (Liu et al., 2016), YOLOv8n, YOLOX (Z Ge et al., 2021) and Efficient Teacher. For fairness, their default resolutions were not adjusted. The experimental results are detailed in Table 2.

In this experiment, Efficient Teacher uses the YOLOv5s detector, while V8ps represents the semi-supervised training results with the improved YOLOv8n as the baseline model, and V8 represents the semi-supervised training results with YOLOv8n as the baseline model.

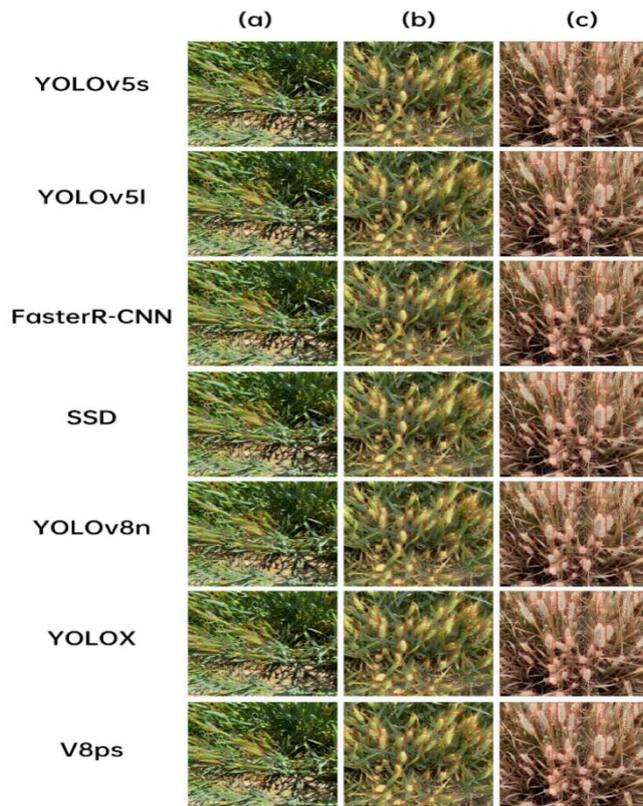

Fig. 9 - Comparison of V8ps and fully supervised models in wheat spike detection effectiveness

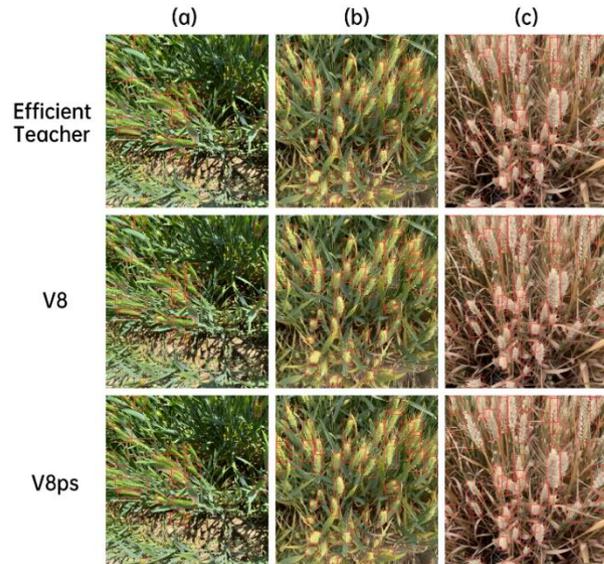

Fig. 10 - Comparison of V8ps and semi-supervised models in wheat spike detection effectiveness

The fully supervised target detection algorithms listed in the table were all obtained with 300 epochs without pre-training weights. According to the data in Table 2, using the improved YOLOv8n as the base model, the mean accuracy (mAP50) reached 94.2% under the semi-supervised training condition, and the performance improved by 4.5% compared with the semi-supervised base model Efficient Teacher. Its precision exceeds all other algorithms in the table compared to the fully supervised model. If the base model is changed from an improved YOLOv8n to an unimproved YOLOv8n, the improved YOLOv8n achieves a performance improvement of 2.8% on the mAP50 index.

Table 3

Comparative experiments on object detection algorithms					
Model	Manual count	Model count	Number of missed detection	Omission factor	Precision ratio
YOLOv5s	359	321	38	10.63%	89.37%
YOLOv5l	421	379	42	10.06%	89.94%
Faster R-CNN	433	391	42	9.68%	90.32%
SSD	217	196	21	9.59%	90.41%
YOLOv8n	189	172	17	9.15%	90.85%
YOLOX	285	259	26	8.98%	91.02%
Efficient Teacher	295	269	26	8.83%	91.17%
V8	311	285	26	8.28%	91.72%
V8ps	354	331	23	6.43%	93.57%

The manually counted images were randomly categorized into nine groups, each consisting of ten images, and the model was evaluated. As shown in Table 3, the enhanced model demonstrated significantly higher accuracy in real-world situations compared to other popular models, achieving a detection accuracy of 93.57% in the tests.

Furthermore, Fig.9 and Fig.10 respectively present a comparative analysis of the wheat spike detection effects of the improved model compared to the fully supervised model and the semi-supervised model at different growth stages. In these images, (a) represents Heading stage, (b) represents Filling stage, and (c) represents Harvesting period. Accordingly, it can be concluded that the improved model in this study is more suitable for the application scenario of wheat ear detection in the field.

CONCLUSIONS

To address the challenges of small target sizes, severe occlusion, and high annotation costs in wheat spike detection, a semi-supervised wheat spike detection algorithm, named YOLOv8ps, was proposed. It is based on YOLOv8. Our main contributions are summarized as follows: wheat spike images are sourced from wheat field environments and the global wheat public database. After annotating the images, data augmentation was performed to create the final dataset. YOLOv8ps was developed by integrating the SPDCConv module, which mitigates the adverse effects of processing small objects and low-resolution images, thereby enhancing the model's performance and stability in complex scenarios. Simultaneously, the introduction of the PSA attention mechanism further optimizes the model's performance. Ultimately, the combination of an improved semi-supervised learning method significantly enhances the model's detection accuracy. First, ablation experiments were conducted in a consistent training environment to analyze the independent impact of each improvement on the model. Subsequently, comparative experiments were carried out using both full-supervision and semi-supervision training methods under varying proportions of annotated samples to verify the effectiveness of the newly proposed YOLOv8ps in semi-supervised training. Finally, the model was compared with other existing models in terms of performance. Experimental results indicate that, compared to Efficient Teacher, the improved model's mean average precision (mAP50) increased by 4.5%, reaching 94.2%. In comparison to the full-supervision baseline model YOLOv8n, it increased by 6.1%, achieving excellent detection accuracy. Although model lightweighting and other optimization techniques have not yet been considered, future research will focus on expanding the dataset and exploring how to integrate these techniques with more advanced and efficient technologies to achieve a higher level of wheat detection performance.

ABSTRACT

During the warm season, when ambient temperatures exceed +28 °C, the tunnel ventilation system is predominantly used in poultry facilities. This system effectively removes excess heat from the environment. However, under conditions of high ambient temperatures and high humidity, specialized systems were required to cool the incoming air and create a controlled microclimate within the poultry house. In ventilation systems, various types of cooling methods are employed to reduce the temperature of incoming air during the summer. Most commonly, these involve water spray systems. The core objective of this study is to conduct theoretical research on regulating heat and mass transfer processes in poultry houses, considering both internal dynamics and interactions through external barriers. This study proposes an innovative approach to cooling incoming air in poultry house ventilation systems. The method utilized water sourced from underground wells and heat exchangers-recovery units (recuperators) to efficiently cool the incoming air. As a result of the numerical modeling, the temperature distribution within the service zone of the poultry house was determined. When heat exchangers were used, the inlet air temperature in the facility was maintained at +20 °C. The temperature increase along the length of the facility was clearly observed in the provided diagrams. The outlet temperature of the cooled air is +27.89 °C, which was attributed to heat generated by the poultry and the warming of the poultry house walls by external air. Thus, the air temperature within this cooling system did not exceed permissible limits. Analyzing the numerical modeling results at a height of 0.7 m from the floor level, it was concluded that no more than 2% of the poultry would experience discomfort under the proposed cooling system. The average air velocity was 0.83 m·s⁻¹, and the air temperature was +23.64 °C.

INTRODUCTION

A conventional method for maintaining a regulated microclimate in poultry houses is direct evaporative cooling (DEC) using cassette-type systems (Hoff, 2018; Liang et al., 2020; Boltyanska et al., 2022). However, this method has significant drawbacks, such as high aerodynamic resistance and installation costs. Another disadvantage is the clogging of cassette channels with dust during operation (Hui et al., 2018). Notably, mold formation on the clogged cassette surfaces can introduce harmful components into the incoming air, which, under high humidity conditions, may lead to various poultry diseases (Kim et al., 2008).

Direct evaporative cooling is a typical ventilation system used in poultry houses in hot climates (James, 2012; Czarick & Fairchild, 2014). As mentioned earlier, this cooling method becomes ineffective in conditions of relatively high humidity, resulting in reduced thermal comfort and degraded air quality for poultry.

Studies have examined two advanced ventilation systems designed for hot and humid climates to improve poultry housing conditions (Harrouz et al., 2021; Rozenboim et al., 2007). System I integrates a conventional direct evaporative cooler with an adsorption dehumidifier containing a packed bed, while System II combines a dew point indirect evaporative cooler with a packed-bed dehumidifier. These models were optimized using a genetic algorithm to evaluate and compare their performance. The findings revealed that System II met the heat and air quality requirements of poultry houses with 35% lower operational costs compared to System I over the entire cooling season.

One of the modern cooling systems that has gained attention in recent years and has proven to be a successful replacement for DEC is the indirect evaporative dew point cooler (IDPC) (Mahmood *et al.*, 2016). The IDPC is capable of significantly cooling the incoming air to its dew point without adding moisture (Tariq *et al.*, 2017). Many studies have examined the performance of IDPCs with various configurations of working airflow (in wet channels) and product airflow (in dry channels). They found that the crossflow IDPC has the lowest pressure drop, the lowest investment cost, and the highest energy efficiency ratio (Zhan *et al.*, 2011; Pandelidis *et al.*, 2019).

Al-Assaad *et al.* (2021) compared the performance of two cooling systems combining DEC or crossflow IDPC with tunnel ventilation for a poultry house in the hot and semi-arid climate of the Bekaa Valley in Lebanon. They demonstrated that the IDPC better met heat and air quality constraints while reducing system costs by 6.8%. This is due to the IDPC's ability to provide a lower supply air temperature, which reduces water consumption and, consequently, water and electricity usage.

All of the aforementioned cooling systems have their drawbacks, which ultimately lead to reduced productivity in poultry farms. Thus, the development of new and improved cooling systems for poultry houses remains a relevant issue. The aim of this study is to explore new ways to improve the poultry house cooling system by installing heat exchange equipment with evaporative cooling cassettes, as well as by implementing a non-traditional placement of exhaust fans on the side wall of the poultry house.

MATERIALS AND METHODS

A tunnel cooling system is proposed for poultry facilities during the hot season when the outside air temperature reaches +40 °C. The poultry house has dimensions of 120x21 meters and a height of 5.3 meters, the total volume of the poultry house is 5,234.4 m³. On the side walls, where evaporative cooling cassettes are typically located near the front end wall, heat exchange units are installed instead. The number of units is 3 pcs, each with dimensions of 5.3 × 1.0 m and a total capacity of 35.52 m³·s⁻¹ (42.8 kg·s⁻¹) for half of the poultry house. The heat exchangers for this system were developed in the study by Trokhaniak *et al.* (2023a). They ensure an outlet air temperature of +20 °C when the inlet air temperature is +40 °C. The warm outside air is cooled using water from underground wells.

Additionally, considering the authors' previous studies (Trokhaniak *et al.*, 2023b), exhaust fans are installed: 4 pcs on the side wall and 1 on the rear end wall, with a total capacity of 35.52 m³·s⁻¹ (42.8 kg·s⁻¹). This airflow volume is sufficient to remove excess heat from the poultry house.

The floor is made of concrete with a thickness of 0.1 m on the top and bottom, separated by a 0.05 m layer of polystyrene insulation. In areas 2 m from the walls, the thickness of the insulating material is increased to 0.1 m. The assumed temperature for the floor is +10 °C. The walls are constructed as three-layered structures, with concrete layers 0.06 m thick on both sides and a 0.1 m polystyrene layer in between. For simplification, the ceiling is modeled as a three-layer structure with concrete layers on both sides and an insulating material, Izovat 30, in between with a thickness of 0.1 m. For all external walls and the ceiling, third-kind boundary conditions (Fig. 1) were applied, with an external temperature of +40 °C and a heat transfer coefficient of 10 W·(m²·K)⁻¹, assuming low wind speeds were observed at the poultry house location.

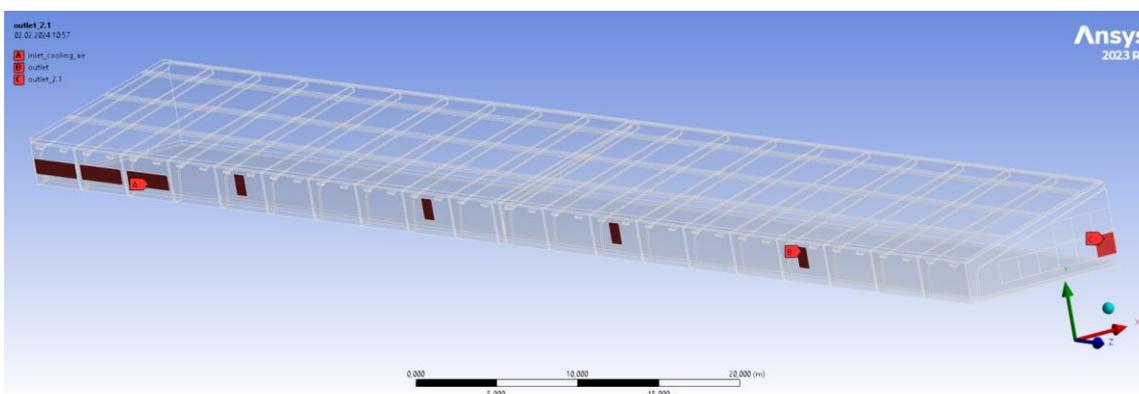

Fig.1 - 3D model of poultry house

The geometry of the poultry house was created using ANSYS Design Modeler 2023 R1, with boundary conditions applied. The geometry was then transferred to ANSYS Meshing 2023 R1 for mesh generation. The mesh was constructed using the CutCell method. The minimum face size was set to 0.015 m, and the maximum face size to 0.12 m. For the supply air inlets and exhaust fans, the mesh was refined with minimum element sizes of 0.01 m and 0.04 m, respectively. This refinement was implemented to achieve more accurate simulation results at the poultry house's inlet and outlet. As a result, the mesh quality indicator, orthogonal quality, was 0.214. The total number of elements was 4,485,116 pcs, and the total number of nodes was 4,854,992 pcs.

The numerical modeling was carried out directly in ANSYS Fluent 2023 R1. The model used the Navier-Stokes equations (Schneiderbauer & Krieger, 2014), the standard k- ϵ turbulence model, and the Discrete Ordinates radiation model (ANSYS, 2023). The tunnel effect of turbulent flows is also discussed in detail in Azhar *et al.*, (2022). The development of mathematical models in the technical field of crop and livestock farming is the focus of works by Bulgakov *et al.*, (2017, 2020a, 2020b), Ivanovs *et al.*, (2020). Specific aspects of the methodology presented in these works were used in the current study.

RESULTS AND DISCUSSION

In Fig. 2–3, the results of numerical modeling of the poultry house are shown at four locations along the length of the room: 10.25 m, 43.25 m, 74.75 m, and 109.25 m along the xy axis. The first location is the outlet of the second heat exchanger. The third is the third exhaust fan. The second and fourth are the third section of the poultry house and the end, respectively.

Fig. 2 shows the airflow lines in the poultry house at different locations. The airflow, exiting from the heat exchangers ($2.24 \text{ m}\cdot\text{s}^{-1}$, 3.080 Pa), covers a quarter of the poultry house's width and, due to heating, rises sharply upwards (Fig. 2a). Flowing over the ceiling, it meets the neighboring flow from the opposite side of the poultry house and descends towards the birds. A large air vortex is formed, which moves deeper into the poultry house. Such a gas-dynamic flow can be observed in Fig. 2b and 2d. As seen, the tunnel effect is formed. A similar phenomenon, but with more turbulent flows, can be seen in (Raza *et al.* 2020; Trokhaniak *et al.*, 2023b). In the middle at the top near the ceiling, a small stagnant air zone is formed. The average velocity in the poultry house is $0.58 \text{ m}\cdot\text{s}^{-1}$.

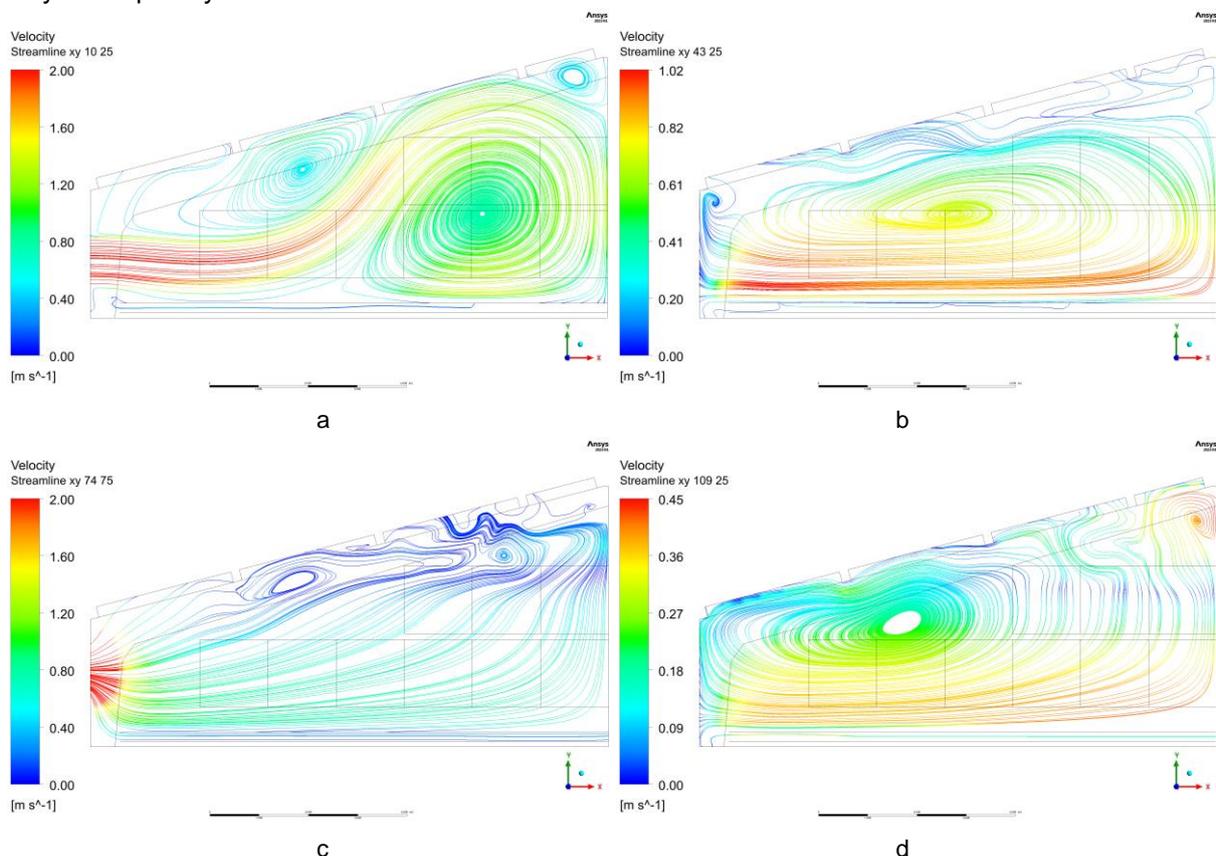

Fig. 2 - The air flow lines ($\text{m}\cdot\text{s}^{-1}$) in the poultry house along the xy axis at different distances from the front end wall

a – 10.25 m; b – 43.25 m; c – 74.75 m; d – 109.25 m

In turn, at the exhaust fans (Fig. 2c), located on the side wall, the air speed is $5.11 \text{ m}\cdot\text{s}^{-1}$. The air is evenly removed from the poultry house. The pressure at the outlet is -2.72 Pa . The fan on the rear end wall showed the following results: speed $-5.06 \text{ m}\cdot\text{s}^{-1}$; pressure -2.27 Pa .

Fig. 3 shows the temperature distribution in different sections of the poultry house. As seen, the cooled air from the heat exchangers, with a temperature of $+20 \text{ }^\circ\text{C}$ (Fig. 3a), enters the poultry house. After passing about 3.5 m and absorbing heat from the birds, the air heats up and rises. The average temperature in this section ranges from $+20 \text{ }^\circ\text{C}$ to $+22 \text{ }^\circ\text{C}$. Through the stagnant zones of the air flow at the top of the poultry house, the temperature increases, but as it approaches the birds, it cools down (Fig. 3b-3d). This thermal barrier has a size from 1.3 m to 1.6 m , with temperatures ranging from $+40 \text{ }^\circ\text{C}$ to $+24.1 \text{ }^\circ\text{C}$. Fig. 3c shows the temperature field at the level of the third exhaust fan. The temperature in this section is slightly higher, ranging from $+24.17 \text{ }^\circ\text{C}$ to $+25.83 \text{ }^\circ\text{C}$. This is due to the intense air mixing and high turbulence. The heated air enters the fan's exhaust field, where the temperature at the outlet is $+25.74 \text{ }^\circ\text{C}$.

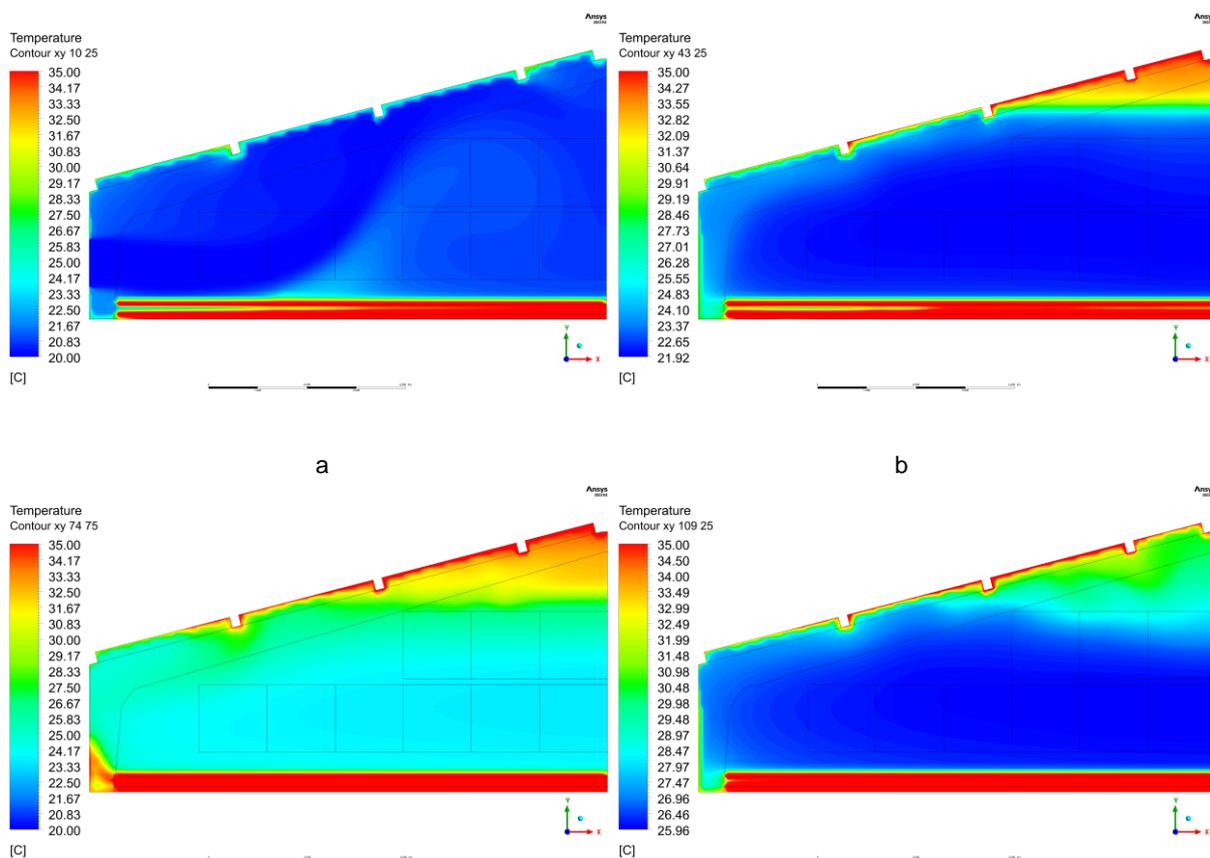

Fig. 3 - The air temperature field ($^\circ\text{C}$) in the poultry house along the xy axis at different distances from the front end wall

a – 10.25 m; b – 43.25 m; c – 74.75 m; d – 109.25 m

Fig. 4 shows the velocity field (Fig. 4a) and temperature field (Fig. 4b) at a height of 0.7 m from the floor level. These results are the most interesting and important, as the birds are kept on the floor. According to the technical norms for poultry housing, the air velocity near the birds should not exceed $2 \text{ m}\cdot\text{s}^{-1}$. As seen in Fig. 2a, the airflow from the heat exchangers enters the poultry house. It is slightly above $2 \text{ m}\cdot\text{s}^{-1}$, but this affects only 0.25% of the birds near the heat exchangers. An obvious and simultaneously interesting turbulent flow created by the first exhaust fan is also observed. Between the third heat exchanger and the first exhaust fan, a stagnant zone is observed (Fig. 4a). Due to this zone, an increase in temperature levels near the wall is noticeable (Fig. 4b). The model assumes that the birds are not placed within 0.5 m of the wall. Therefore, the birds will not experience discomfort. The average air velocity at a height of 0.7 m from the floor (Fig. 4a) is $0.83 \text{ m}\cdot\text{s}^{-1}$, and the pressure is 0.430 Pa .

The air temperature near the birds during the hot period of the year should not exceed +28 °C. Considering the results of the numerical simulation (Fig. 4b), the air temperature exceeding +28 °C occupies no more than 2% of the area. This indicates the sufficient effectiveness of the poultry house cooling system. On the rear side of the poultry house, where the exhaust fan is located, slightly higher air temperatures are observed, approaching +28 °C. This is due to the stagnant zone from the fourth exhaust fan on the side wall to the rear side of the poultry house. The average temperature across the entire area of the poultry house at a height of 0.7 m from the floor level is +23.64 °C.

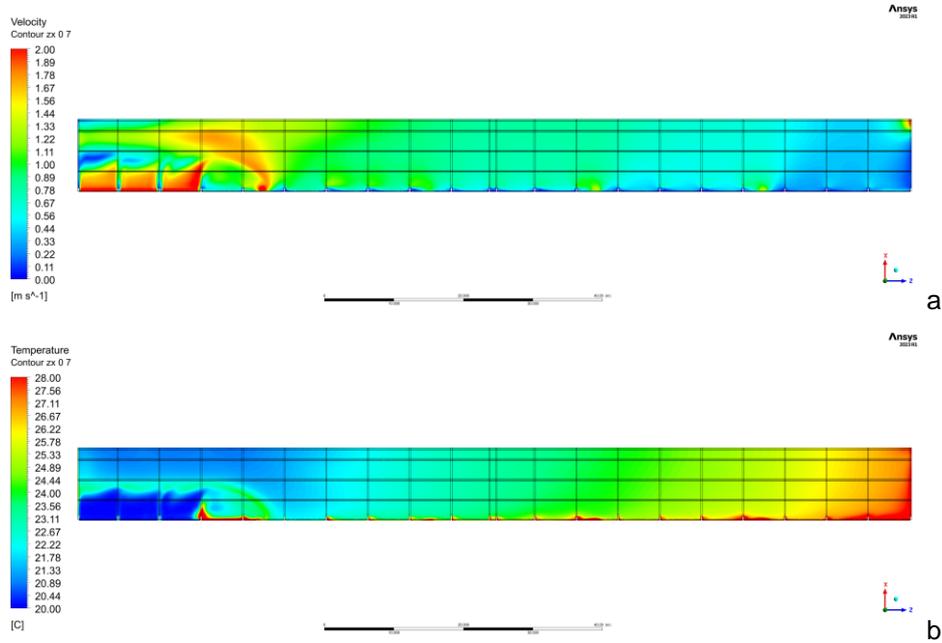

Fig. 4 - The air velocity field, m·s⁻¹ (a), and temperature field, °C (b), in the poultry house along the zx axis at a height of 0.7 m from the floor level

Fig. 5 shows the distribution of air temperature in the 3D poultry house, ranging from +20 °C to +35 °C. It can be seen that in the center of the poultry house, near the ceiling, the air temperatures are higher. With the tunnel-side ventilation system, the air gradually heats up along its length. As the air moves through the poultry house, part of it reaches the exhaust fan on the rear end wall with a temperature of +27.89 °C.

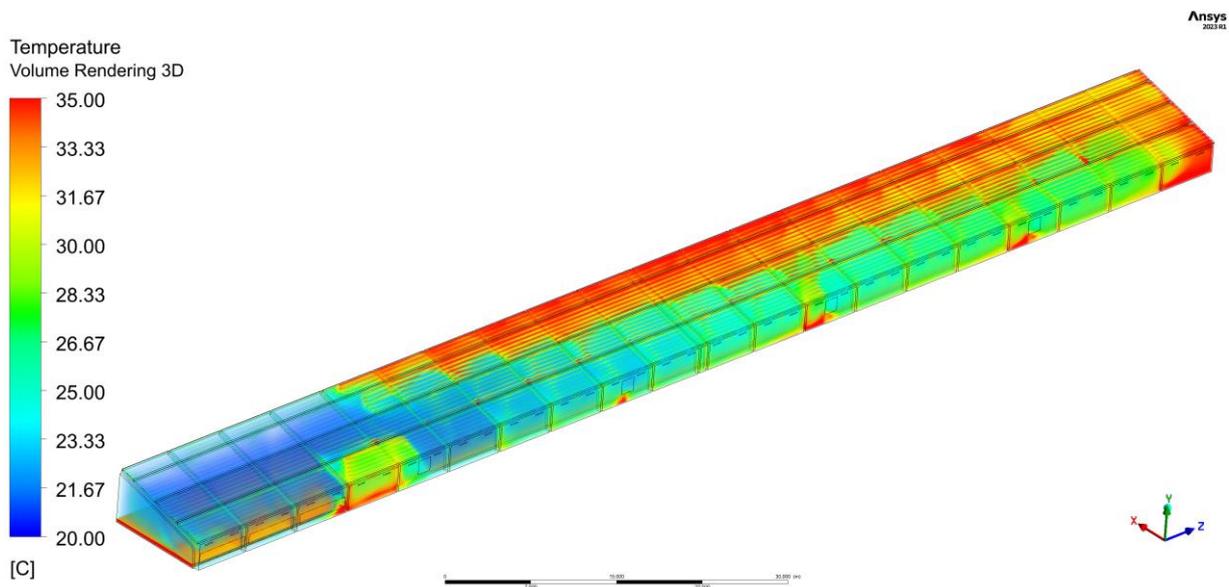

Fig. 5 - The visualization of the air temperature in the poultry house ranges from 20°C to 35°C

Considering Fig. 6, it can be concluded that due to the tunnel effect and the decrease in air velocity near the ceiling (Fig. 6a), the temperature rises in this area (Fig. 6b). To avoid such heat and mass transfer processes, the authors recommend relocating the exhaust fan on the rear wall of the poultry house, with its center positioned 4.45 m from the side wall. This would prevent stagnant airflow and thermal zones within the poultry house.

In the study by *Trokhaniak et al. (2024)*, the use of heat exchange equipment achieved a lower air temperature at the outlet (20 °C). However, this approach may require significant energy costs and the use of groundwater, which limits the applicability of this technology. In contrast, the system proposed in this article is less energy-intensive, ensuring uniform temperature and air velocity distribution with minimal discomfort for the poultry, though in some areas the temperature may slightly exceed 28 °C. Both studies confirm the effectiveness of the proposed cooling systems for poultry houses during the hot period of the year, but the approaches to implementing cooling are different.

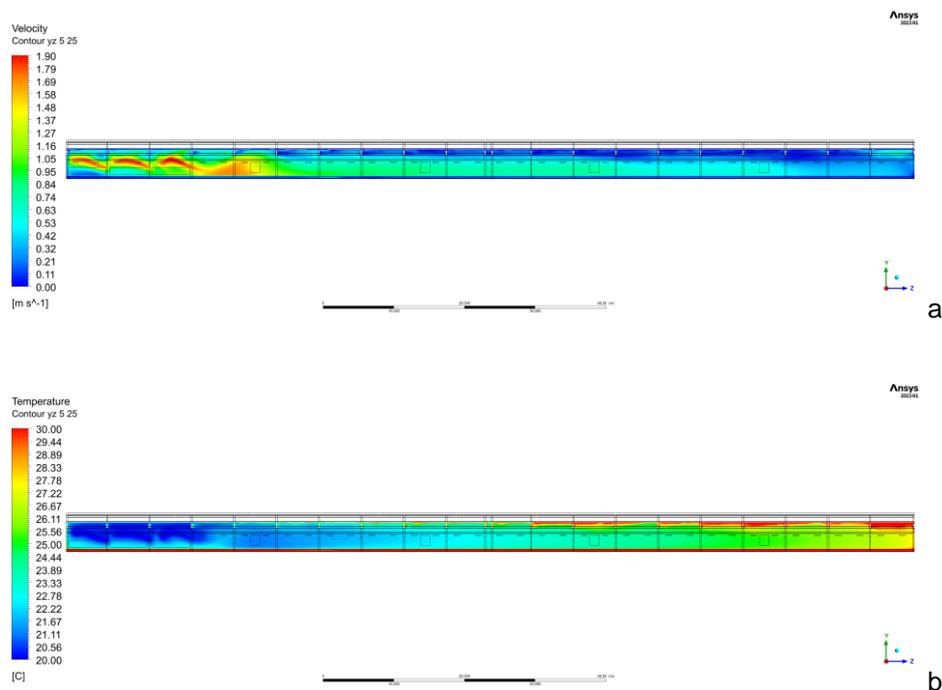

Fig. 6 - The air velocity field, m·s⁻¹ (a), and temperature field, °C (b), in the poultry house along the zy axis at 5.25 m from the side wall

Additionally, the study by *Trokhaniak et al. (2024)* demonstrated that with an air velocity of 14.36 m·s⁻¹ at the outlet of the ventilation openings, the airflow effectively reached the center of the room, ensuring uniform temperature distribution. In this case, the average air temperature in the poultry housing area was 26.56 °C, exceeding 28 °C only in certain locations. Discomfort was experienced by no more than 7.8% of the birds at an average air velocity of 0.74 m·s⁻¹. In this article, it is shown that the airflow velocity ensured uniform temperature distribution within a range that did not exceed critical values. Thermal comfort was achieved through the optimal placement of ventilation openings and the use of spoilers.

According to the numerical modeling results in the study by *Trokhaniak et al. (2024)*, the use of heat exchange equipment with groundwater as the cooling medium reduced the air temperature from 30 °C to 20 °C at the system outlet. This result demonstrates the high efficiency of the proposed cooling technology. In this article, the maximum temperature inside the poultry house did not exceed 28 °C, and the average temperature was within the range of 24.44–27.35 °C. These values confirm that the proposed cooling system also successfully maintains comfortable conditions for poultry during the hot period of the year. However, the cooling system relies on a combination of ventilation openings and directional elements (spoilers), which may require less energy compared to active heat exchange.

CONCLUSIONS

1. Using numerical modeling, the cooling system for the hot season with an outdoor air temperature of +40°C was investigated in 3D for half of the poultry house. A new cooling system for poultry houses is proposed, utilizing heat exchange equipment, with an outlet temperature of +20°C. Groundwater from underground wells is suggested as the cooling agent.
2. Air velocity fields were obtained at various sections of the poultry house. The effectiveness of the placement of heat exchange units and exhaust fans was demonstrated. The fresh air flow, exiting the heat exchangers with a speed of 2.24 m·s⁻¹ and a pressure of 3.08 Pa, passes a quarter of the width of the poultry house and, due to heating, rises sharply. The temperature in these sections averages from +20°C to +27.9°C, not exceeding the standard of +28°C during the hot season. Analyzing the results of numerical modeling at a height of 0.7 m from the floor level, it was concluded that no more than 2% of the birds would experience discomfort with the proposed cooling system. The average velocity is 0.83 m·s⁻¹, and the air temperature is +23.64°C.
3. To avoid the decrease in air velocities near the ceiling where the temperature rises, and similar heat and mass transfer processes, the authors recommend relocating the exhaust fan to the rear wall of the poultry house, with its center positioned 4.45 m from the side wall. This will prevent stagnant airflow and thermal zones in the poultry house.

Keywords: Licorice root, Shear test, mechanical properties, physical and mechanical characteristics

ABSTRACT

The process of slicing is a vital component in the preliminary treatment of licorice roots. The physical properties and shear mechanical attributes of licorice root are of considerable importance for the development and optimization of machinery intended for slicing licorice root. In this research, four-year-old mature licorice roots were selected as the experimental specimens, and shear strength evaluations were conducted on these roots by means of a universal testing machine (Instron 3344 series). The experimental design utilizes a blend of univariate and multivariate orthogonal testing techniques. Within this design, moisture content, shear speed, and shear angle are identified as the independent variables, while the maximum cutting force is defined as the primary assessment criterion. The experimental results reveal that the primary and secondary factors influencing the shear strength of licorice root follow the order: moisture content > shear speed > shear angle. The optimal conditions for the slicing pretreatment process are identified as a moisture content of $50 \pm 2\%$, a shear speed of 0° , and a shear speed of $90 \text{ mm} \cdot \text{min}^{-1}$.

摘要

切片是甘草根预处理流程中的关键环节之一。甘草根的物理参数和剪切力学特性对于甘草根切片设备的研发和工艺优化具有重要意义。本研究选取四年生的成熟期甘草根作为试验材料，利用万能试验机（Instron3344系列）开展甘草根剪切性能试验。试验设计采用单因素和多因素正交试验，将含水率、剪切角度、剪切速度设定为试验因素，以最大剪切力作为评价指标。结果表明，影响甘草根剪切力的主次因素为：含水率>剪切速度>剪切角度。当含水率为 $50 \pm 2\%$ ，剪切角度为 0° ，剪切速度为 $90 \text{ mm} \cdot \text{min}^{-1}$ 时，进行切片预处理工序最为适宜。

INTRODUCTION

Licorice, alternatively known as Gan Cao, sweet grass, or sweet root, acquires its name due to the sweet flavor of its root. Licorice is taxonomically classified within the Fabaceae family, specifically residing in the subfamily Faboideae, the tribe Galegeae, and the subtribe Glycyrrhiza. It is a perennial herbaceous plant that is grouped under the genus Glycyrrhiza. Licorice, which is widely acknowledged as one of the earliest plant species enlisted in China's inventory of medicinal and edible resources, also serves as a significant natural resource in arid and semi-arid regions (He et al., 2024). Licorice is mainly distributed in arid and semi-arid areas around 40° north latitude. The major cultivation areas are concentrated in Central Asia, North America, and Eastern Europe. In China, licorice is one of the major economic crops. It has a relatively large cultivation area that is mainly spread across the northeastern, northern, and northwestern provinces. The key production areas encompass Xinjiang, Inner Mongolia, Ningxia, and Gansu (Li et al., 2015). The cultivation of licorice spans a period of two to four years from planting to harvesting. And it is generally necessary to conduct pretreatment on the roots prior to their utilization in medicinal applications. The cutting procedure is essential in the pretreatment stage, as it enhances the surface area interaction between the substrate and the solvent, thereby promoting the extraction of the drug and its subsequent delivery.

Shear strength, as one of the critical mechanical properties of agricultural materials, can provide theoretical foundations and effective parameters for the design, manufacturing, and optimization of licorice cutting devices and harvesting machinery.

Currently, relevant research focuses on the shear mechanical properties of various plant organs and crops, covering the main roots of *Panax notoginseng* (Yang *et al.*, 2016) and the rhizomes of *Coptis chinensis* (Li *et al.*, 2023) as medicinal plants, the root systems of maize (Zhao *et al.*, 2021; Guo *et al.*, 2016) as a food crop, as well as common categories such as fruits (Wu *et al.*, 2022), seeds (Bao *et al.*, 2022; Huang *et al.*, 2021; Guo *et al.*, 2016), vegetables (Yang *et al.*, 2022) and crop stalks (Yang *et al.*, 2016; Li *et al.*, 2020). Moreover, the shear mechanical properties of tea tree new shoots (Wang *et al.*, 2022) also fall within the scope of research. In contrast, studies concerning the shear characteristics of *Glycyrrhiza uralensis* are notably scarce.

Therefore, this study opts for the roots of licorice harvested at the appropriate time as the research object, with cutting force serving as the evaluation criterion. It dissects the influences of moisture content, root diameter, shear speed, and other factors on the cutting force of licorice roots. Through the application of orthogonal experimental methodologies, the predominant influencing factors during the licorice cutting process are pinpointed, and the fluctuations in its shear mechanical properties are investigated. This offers a requisite theoretical groundwork for the design and optimization of the preliminary processing techniques and equipment for licorice.

MATERIALS AND METHODS

Materials

This study focuses on *Glycyrrhiza uralensis* as the principal experimental subject. The samples were obtained from a comprehensive demonstration practice base specialized in *Glycyrrhiza uralensis* cultivation in the Northeast region. The selected *Glycyrrhiza uralensis* plants were of four-year-old age and possessed a root system composed of both vertical and horizontal roots (as depicted in Figure 1). The vertical roots of the *Glycyrrhiza uralensis* (hereinafter denoted as *Glycyrrhiza uralensis* roots) had diameters spanning approximately from 1.5 to 3 cm, and their epidermis exhibited a coarse texture. Solely healthy *Glycyrrhiza uralensis* roots, demonstrating optimal growth status and being free from pests and diseases, were selected for this study. The lateral roots were trimmed and all residual debris was removed. The *Glycyrrhiza uralensis* roots are illustrated in Figure 2.

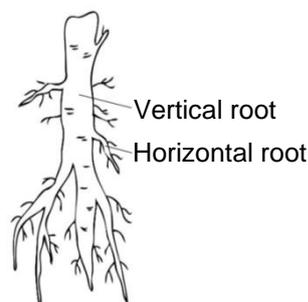

Fig. 1 - Schematic Diagram of the Structure of Licorice Root

Fig. 2 - *Glycyrrhiza uralensis* root

Equipment

The experimental apparatuses and implements employed in this study comprise a Model 101 electric blast drying oven (with a temperature range of 0 - 300°C and a voltage of 220 V), an Instron 3344 series microcomputer-controlled electronic universal testing machine, a stereo electron microscope (Nexcope NSZ606), a digital vernier caliper (having a measuring range of 150 mm and an accuracy of 0.01 mm), an electronic balance (with a capacity of 500 g and an accuracy of 0.001 g), an angle square, scissors, and sealing bags, among other items.

Experimental Methods

Determination of Physical Parameters and Tissue Structure

The simple random sampling method was adopted to randomly select samples of licorice roots for testing purposes. For each individual root, its length was measured three times, and then the average value was calculated. Subsequently, the licorice root was sectioned into five discrete portions, specifically designated as the upper, upper-middle, middle, lower-middle, and lower segments. The diameter measurements corresponding to each segment are presented in Figure 3. The average diameter of the licorice root was computed using Formula (1), which is as follows:

$$d_j = \frac{1}{6} \sum_{i=1}^2 (d_{1i} + d_{2i} + d_{3i}) \quad (1)$$

where:

d_j represents the mean diameter of the cross-sectional area of the licorice root, mm;

d_{1i} represents the length of the major axis of the cross-section of the licorice root recorded during the i -th measurement, mm;

d_{2i} represents the length of the minor axis of the cross-section of the licorice root recorded during the i -th measurement, mm;

d_{3i} represents the length of the shortest axis of the cross-section of the licorice root recorded during the i -th measurement, mm.

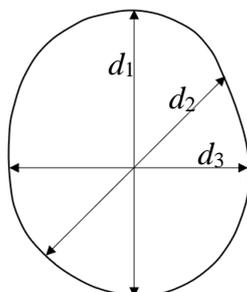

Fig. 3 - Schematic diagram of measurement positions for the diameter of licorice root cross-sections

Scissors and a scalpel were utilized to obtain cross-sectional specimens of licorice root with differing moisture content levels. The moisture content levels were adjusted by subjecting the licorice roots to different drying durations in a controlled environment. Subsequently, high-quality digital microscopy was employed to examine the tissue architecture within the cross-sections of the licorice root, focusing particularly on features such as the cell arrangement, vascular bundle structure, and parenchyma tissue morphology.

Determination of moisture content and density

The entire licorice roots were cut with scissors to determine of the moisture content of freshly harvested licorice and were then grouped accordingly. An electronic balance was employed to weigh each group of licorice roots separately, and the measurements were recorded. After weighing, the samples were placed in a drying box and then transferred into a vacuum drying oven, as depicted in Figure 4. The temperature was set at 110°C, and the weight was recorded every 2 hours until the mass stabilized with a relative change of less than 0.1% between consecutive measurements, indicating the end of the experiment. The average of the weights recorded every 2 hours during the drying process was calculated. Upon the completion of the drying process, the samples were weighed again to calculate the absolute moisture content using the following formula:

$$M = \frac{m_1 - m_2}{m_1} \times 100\% \quad (2)$$

where: M represents the moisture content of licorice root, %;

m_1 is the wet mass of the sample before drying, g;

m_2 is the dry mass of the sample after drying, g.

Fig. 4 - Licorice root drying test

The freshly harvested licorice roots were meticulously cleaned to remove any adhered soil and debris. After allowing the roots to air-dry for 30 minutes, until the surface appeared dry to the touch, a utility knife was used to cut the licorice roots into numerous small fragments. These fragments were then randomly divided into ten groups to ensure sample diversity and representativeness for subsequent measurements. The mass of each group was precisely measured using an electronic balance and denoted as M . A 500-milliliter beaker was selected, and 300 milliliters of water were initially added. The licorice root samples were then weighed and carefully placed into the beaker, ensuring complete submersion in the water. At this point, the change in water level was meticulously observed and recorded. The density of the licorice roots was subsequently calculated using formula (3), as follows:

$$\rho_g = \frac{M_g}{V_g} \quad (3)$$

where: ρ_g represents the density of licorice root, g/cm^3 ; M_g is the total mass of licorice root obtained through direct weighing, g; V_g is the total volume measured by the pycnometer method, mL.

Shear testing methodology

To explore the impacts of shear angle, shear speed, and moisture content of licorice root on its shear strength, based on preliminary investigations, licorice roots with a diameter of approximately 15 mm were selected and samples with a length of 80 mm were fabricated to ensure the representativeness and uniformity of samples for subsequent shear tests. Figure 5 clearly illustrates the schematic diagram of the sample.

Fig. 5 - Licorice root cutting test sampling

Single-factor experiment

The moisture content of the licorice root was adjusted to $(50 \pm 2)\%$, and the shear speed was set at 60 mm/s. The shear angles were arranged as shown in Figure 6, which were divided into 0° , 15° , 30° , 45° , and 60° . The 0° angle represents the shear test carried out on the transverse section of the licorice root. Five sets of repeated tests were performed for each shear speed, and the results were averaged.

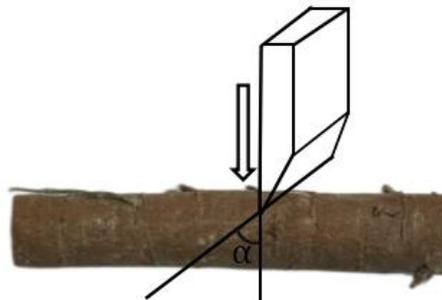

Fig. 6 - Cutting diagram

The shear speed was set to 60 mm/s and the shear angle to 0° . The moisture content of licorice was selected as $(50 \pm 2)\%$, $(40 \pm 2)\%$, $(30 \pm 2)\%$, $(20 \pm 2)\%$, and $(10 \pm 2)\%$ for the cutting tests. Five sets of replicated experiments were conducted for each moisture content, and the average of the results was obtained.

For licorice root with a moisture content of $(50 \pm 2)\%$ and a shear angle of 0° , the shear speeds were adjusted to 30 mm/min, 60 mm/min, 90 mm/min, 120 mm/min, and 150 mm/min for the cutting tests. Five sets

of replicated experiments were performed at each shear speed, and the average of the results was calculated. The cutting process is depicted in Figure 7.

Fig. 7 - Cutting process

Multifactorial experiment

By incorporating single-factor experiments, multifactorial orthogonal tests taking into account moisture content, shear angle, and shear speed were conducted. The multifactorial orthogonal test scheme is presented in Table 1.

Table 1

Experimental factors and levels

Test No.	Moisture content / %	Shear angle / °	Shear speed / (mm/min)
1	20±2	0	30
2	30±2	15	60
3	40±2	30	90
4	50±2	45	120

Evaluation indicators

During the experiment, the licorice root specimen was precisely positioned on the testing platform of a universal testing machine. The sampling frequency was meticulously set to 50 Hz, and the base span was accurately configured to 30 mm. A 1000 N sensor in conjunction with its corresponding shear fixture was employed, featuring a double shear surface. The research primarily focused on investigating the effects of shear angle, moisture content, and shear rate on the maximum cutting force of licorice root stems. The computer software interfaced with the testing machine automatically recorded the data and generated a cutting force - displacement curve.

RESULTS AND ANALYSIS

The physical parameters and structural characteristics

The mean length of four-year-old Ural licorice root was determined to be 41.78 mm, and the average diameter was measured as 15.054 mm. The direct measurements for each section are tabulated in Table 2.

Table 2

The physical parameters of Licorice root

Sampling location	Diameter / mm	Average diameter / mm	Average length / mm
Upper section	20.41	15.054	41.78
Upper-middle section	17.73		
Middle section	14.39		
Lower-middle section	12.72		
Lower section	10.02		

Figures 8 (a) and (b) depict the microscopic structural organization of licorice root under two distinct moisture content conditions, namely 52% and 11.6%. It is conspicuous that the principal constituents of the licorice root comprise the periderm, phloem rays, secondary phloem, xylem rays, secondary xylem, cambium, and fiber bundles. With a reduction in moisture content, the texture of the periderm becomes more pronounced and compact, the interstices between the phloem rays are marginally reduced, the secondary phloem displays

wrinkling, the xylem rays undergo a darkening in coloration, and the lignification of the secondary xylem is enhanced.

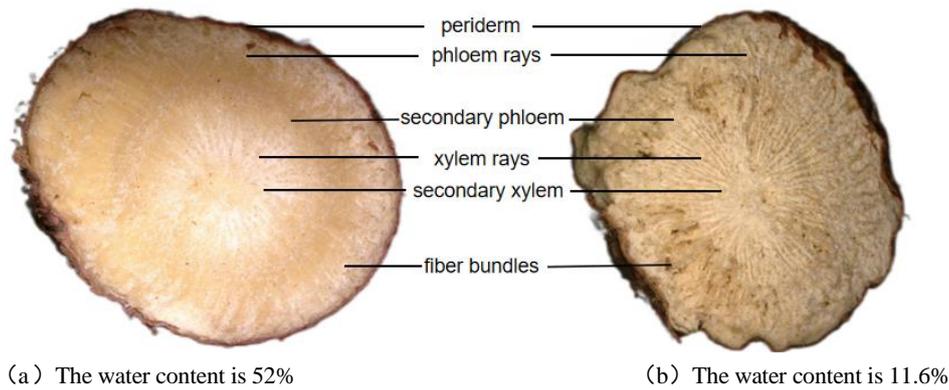

Fig. 8- Structure of cross-section of the internode of corn stalk

Moisture content and density

Based on the in-depth analysis of the experimental outcomes, the quality of ten groups of fresh licorice roots was found to stabilize subsequent to being dried for 12 hours at a temperature of 120°C. The initial moisture content of the fresh licorice roots was precisely measured and calculated, with a resultant moisture content of 52.36%. Moreover, the density of the licorice roots was ascertained by means of the specific gravity bottle method. Upon averaging the results, the final density of the fresh licorice roots was determined to be 1031 kg·m⁻³.

Analysis of the cutting process

When the moisture content was within the range of $(50 \pm 3)\%$, the loading speed was set at 60 mm/min, and the shear angle was 0°. The cutting force-displacement curve of licorice root is presented in Figure 9. The cutting process of licorice root can be categorized into three distinct phases. In the initial phase (segment OA), the licorice root is in a compressive state, and the cutting force displays an approximately linear increment with respect to the displacement. In the intermediate phase (segment AB), as the displacement continuously augments, the cutting force exhibits a fluctuating upward trend. With further progression of displacement, the load surges sharply, attaining a peak value, which signifies the critical state at which the licorice root is severed. In the final phase (segment BC), the licorice root stem is entirely severed by the tool, leading to a rapid attenuation in cutting force until it approaches zero. Research findings suggest that although substantial differences exist in cutting force under diverse moisture contents, loading rates, and shear angles, the overall tendency of the cutting force - displacement curve for licorice root invariably shows an initial increase, subsequent fluctuations, and ultimately a precipitous decrease.

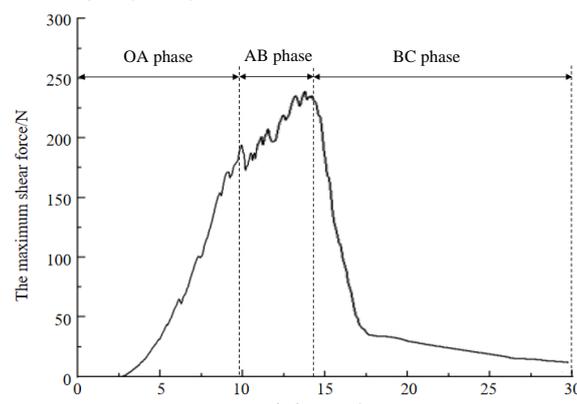

Fig. 9 - Cutting force-displacement curve

Analysis of Single-Factor Experimental Results

Analysis of the Influence of Moisture Content on the Maximum Shear Strength of Licorice Root

The variation in the impact of moisture content on shear strength is depicted in Figure 10. At a moisture content of $(50 \pm 2)\%$, the average maximum shear force was measured as 240.23 N. When the moisture content was adjusted to $(40 \pm 2)\%$, the average maximum shear force escalated to 312.87 N; at $(30 \pm 2)\%$, it

further augmented to 357.95 N. At $(20 \pm 2)\%$, the average maximum shear force attained 397.65 N, and at $(10 \pm 2)\%$, the maximum shear force peaked at 447.87 N.

These data show a trend of increasing shear force as the moisture content in licorice root decreases. It can be inferred that at a moisture content of $(50 \pm 2)\%$, the shear force reaches its minimum, indicating that this moisture level is optimal for preprocessing operations such as slicing and root trimming.

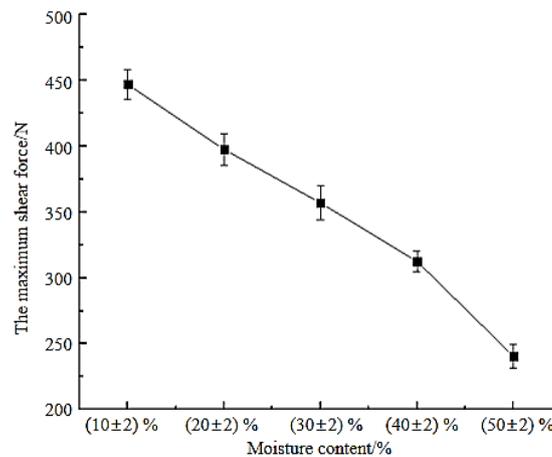

Fig. 10 - The effect of different moisture contents on cutting force

Analysis of the Influence of Shear Angle on the Maximum Shear Strength of Licorice Root

The variation in the impact of shear angle on shear strength is depicted in Figure 11. When the shear angle was set at 0° , the average value of the maximum shear force was measured as 292.398 N. Subsequently, when the shear angle was adjusted to 15° , the average value of the maximum shear force increased to 318.262 N. At a shear angle of 30° , the average value of the maximum shear force was 385.41 N. When the shear angle reached 45° , the average value of the maximum shear force was 426.366 N. And when the shear angle was set to 60° , the maximum shear force was 468.32 N. Within the range of shear angles from 0° to 60° , it was observed that the maximum shear force of licorice root exhibited a gradually increasing trend with the augmentation of the shear angle.

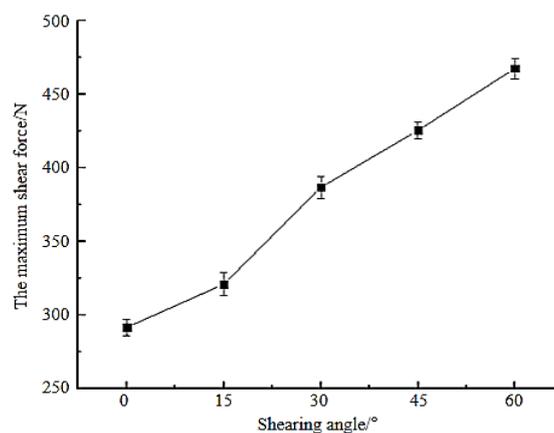

Fig. 11 - The effect of different shear angles on cutting force

Analysis of the Influence of Shear Speed on the Maximum Shear Strength of Licorice Root

The variation in the impact of shear speed on shear strength is depicted in Figure 12. When the shear speed was set at 150 mm/min, the average value of the maximum shear force of licorice root was measured as 290.398 N. Subsequently, when the shear speed was adjusted to 120 mm/min, the average value of the maximum shear force increased to 322.262 N. At a shear speed of 90 mm/min, the average value of the maximum shear force was 387.21 N. When the shear speed was reduced to 60 mm/min, the average value of the maximum shear force was 426.166 N. And when the shear speed was further decreased to 30 mm/min, the average value of the maximum shear force reached 476.32 N. It can be clearly seen that within the range

of shear speed s set in the experiment, the shear force of licorice root exhibited a decreasing trend with the increase of the shear speed.

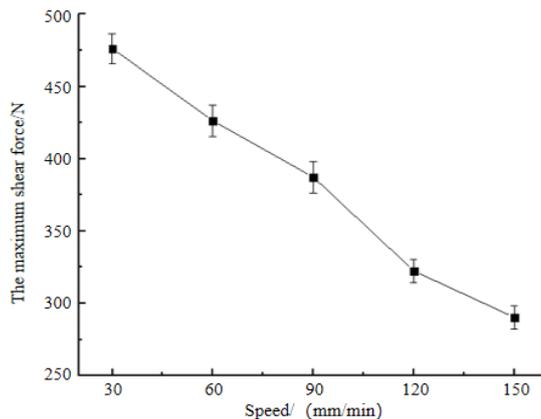

Fig. 12 - The effect of different shear speeds on cutting force

Multifactorial test analysis

After performing a univariate analysis of moisture content, shear angle, and shear rate, it is crucial to take into account the possible interactive effects among these factors, since they might have a cumulative influence on the shear strength of licorice root. Hence, combining these three factors for a multifactorial comprehensive analysis is justified. In this research, moisture content, shear angle, and shear rate were chosen as experimental variables, with the maximum shear strength as the experimental parameter. An orthogonal experiment was designed and carried out accordingly. The specific experimental protocol and corresponding results are shown in Table 3.

Table 3

Experimental factors and levels

Test No.	Moisture content A/%	shear angle B/°	shear speed C/(mm/min ⁻¹)	Maximum cutting Force /N
1	1	1	1	487.36
2	1	2	2	439.35
3	1	3	3	470.25
4	1	4	4	397.24
5	2	1	2	488.75
6	2	2	1	290.22
7	2	3	4	300.55
8	2	4	3	491.22
9	3	1	3	450.33
10	3	2	4	400.11
11	3	3	1	268.45
12	3	4	2	481.06
13	4	1	4	308.55
14	4	2	3	331.39
15	4	3	2	277.19
16	4	4	1	266.13

Analysis of variance, as an effective statistical method, allows for an in-depth examination of the fluctuations in experimental indicators caused by variations in the levels of experimental factors, thereby determining the significance of each factor's impact on the experimental outcomes. Data from Table 3 indicates that among the experimental factors considered in this study, the order of significance affecting the maximum shear force is as follows: moisture content, shear rate, and shear angle. The variation in moisture content of licorice has a highly significant effect on the shear force of licorice roots, dominating the entire influence framework. Additionally, the shear rate also significantly impacts the shear force of licorice roots, exhibiting a clear pattern of change with varying shear rates. In contrast, while the shear angle does have some effect on the shear force of licorice roots, its significance is relatively weak, suggesting a secondary role within the

multifactorial interaction system. Nevertheless, its influence should not be entirely disregarded when conducting precise analyses and optimizing the shear processing of licorice roots.

Table 4

Analysis of Variance						
Sources	SS	df	MS	F	P-value	Significance
Moisture content/A	49096.228	3	16365.409	7.704	0.018	*
shear angle/B	25835.984	3	8611.995	4.054	0.068	
shear speed/C	33104.015	3	11034.672	5.195	0.042	*
Error	12745.125	6	2124.188			
Total sum	120781.352	15				

Note: *, significance level $0.01 < P < 0.05$; **, significance level $P < 0.01$.

From Table 5, it can be observed that the influence of various experimental factors on the maximum shear force follows a descending order of significance: $A > C > B$, which translates to moisture content > shear rate > shear angle. The intuitive analysis results regarding the maximum shear force are in strong agreement with the results of the variance analysis.

Table 5

Intuitive analysis results			
Index	A	B	C
mean 1	448.6	433.7	328
mean 2	392.7	365.3	421.6
mean 3	400	329.1	435.8
mean 4	295.8	408.9	351.6
Range	152.7	104.6	107.8
Primary and secondary factors	$A > C > B$		
A relatively optimal combination	$A_4B_3C_1$		

For the determination of the optimal combination of factor levels, the present study endeavors to minimize the experimental index of maximum shear force. Via a visual analysis of the maximum shear force of licorice root, the level associated with the minimum value of the evaluation index was chosen. The optimal factor level combination with respect to maximum shear force was determined as $A_4B_3C_1$, which represents a moisture content of $50 \pm 2\%$, a shear angle of 0° , and a shear rate of $90 \text{ mm} \cdot \text{min}^{-1}$. This optimal factor level combination offers a critical reference for the optimization of the licorice root shearing process and bears substantial guiding significance for subsequent related research and practical applications.

CONCLUSIONS

This study systematically analyzes the physical parameters, structural organization, and shear characteristics of four-year-old licorice, thereby providing a theoretical foundation for optimizing post-harvest treatment and processing techniques. The specific conclusions are as follows:

(1) Measurements demonstrate that the average length of the roots of four-year-old Ural licorice is approximately 41.78 mm, with an average diameter of around 15.054 mm. The diameters at the upper, upper-middle, middle, lower-middle, and lower sections are approximately 20.41 mm, 17.73 mm, 14.39 mm, 12.72 mm, and 10.02 mm, respectively. Moreover, the moisture content of fresh licorice roots is determined to be 52.36%, and the density is $1031 \text{ kg} \cdot \text{m}^{-3}$.

(2) Shear tests on licorice roots disclose that the shear process mainly comprises three distinct stages: compression, shear, and unloading. This process reflects the mechanical response characteristics of licorice roots under shear forces, which is essential for a more profound understanding of their shear resistance.

(3) Results from single-factor experiments suggest that the shear force of licorice roots rises with increasing moisture content and shear angle, whereas it declines with a growing shear speed. Multi-factor experiments reveal the relative impact of various factors on the shear force of licorice roots in the following order: moisture content > shear speed > shear angle. The optimal combination of shear factors is identified as

A₄B₃C₁, corresponding to a moisture content of 50 ± 2%, a shear angle of 0°, and a shear speed of 90 mm·min⁻¹.

Keywords: Peanut parameters; Peanut flip; Experiment; Simulation

ABSTRACT

Aiming at the problem that there are few studies on the turnover device in the current peanut laying operation equipment and lack of simulation parameters, this study measured the characteristic parameters of upright peanut plants and tested the feasibility of conveying the turnover device to flip the vine. By studying the mechanical properties of peanut plants, the suitable clamping height range of plants was determined. By studying the size, mass parameters and distribution of peanut plants, the possibility of plant flipping and falling was analyzed, and the main structure and working principle of the conveying flipping device were determined. Based on the RECURDYN-EDEM coupling, the joint simulation of the conveying and overturning device was carried out to complete the dynamic analysis of the plant conveying and overturning process, and the simulation parameters were further optimized. The test results show that the device can achieve 95.1 % plant turnover completion and improve the quality of field drying, which can meet the requirements of peanut laying and harvesting operation. It can provide a theoretical basis for the design of two-stage peanut harvesting device in the future.

摘要

针对目前花生铺放作业机具中翻转装置相关研究较少且缺乏仿真参数的问题，本研究对直立型花生植株特性参数进行测定，试验输送翻转装置翻转秧蔓的可行性。通过研究花生植株力学特性，确定植株适宜夹持高度范围；通过研究花生植株的尺寸、质量参数及其分布规律，分析植株翻转掉落的可能性，确定输送翻转装置的主要结构与工作原理。基于 RECURDYN-EDEM 耦合开展输送翻转装置联合仿真，完成植株输送以及翻转过程的动态分析，进一步优化了模拟参数。试验结果表明，该装置可实现植株翻转完成度 95.1%，田间晾晒质量提高，能够满足花生铺放收获作业要求，可为今后两段式花生收获作业装置的设计提供理论依据。

INTRODUCTION

Peanut is the most important oil crop and economic crop in China and even in the world (*China statistical yearbook, 2023*). At present, the mechanized harvesting methods of peanut are mainly divided into combined harvesting and two-stage harvesting (*Gao et al., 2017*). The first section of the two-stage harvest is mostly operated by digging and laying machines. After digging and removing the soil, the plants are laid in the field for drying for 3 to 5 days, and then the second section is collected. However, the field drying after the traditional two-stage harvest will result in a large difference in the moisture content of the upper and lower pods, which will greatly affect the subsequent picking and harvesting operations (*Chen et al., 2017*).

Domestic and foreign scholars have made some progress in the research of two-stage peanut harvester (*Guo et al., 2020*). *Bader et al., (2009)*, analyzed the mass distribution characteristics of peanut plants and the movement characteristics during the inversion of vines, and realized the inversion of the elevated peanut vines on the ground. AMADAS company developed belt and rod conveyor structure, through the combination of large conveyor and vibration table roller, to ensure the quality of the harvest, but for the domestic peanut planting mode and farmers purchasing power it does not match (*Amadas Industries, 2022*). Pearman company has produced a peanut harvester, which uses clamping chain to lift peanut plants to remove soil, and realizes inertial lateral laying by laying guide rods, but it has poor adaptability to peanut planting mode (*Pearman corporation, 2022*).

In recent years, the research progress of two-stage peanut harvesting in China has been rapid. Gao Lianxing *et al.* proposed the 'flip-sliding fence' type laying method and designed the flip laying device of chain-stick peanut picker, which realizes the orderly laying of peanut plants 'head-to-tail' through the flip wheel device and the sliding fence-type plant gathering device. This is conducive to the subsequent operation after drying in the field (Gao *et al.*, 2016). Zheng Jinsong, (2022), developed a peanut digging and inverted laying machine that uses a vibration digging mechanism, soil-conveying system, and turning-laying mechanism to complete the harvesting operation in a single pass. While the machine achieves a high degree of inverted placement, the harvested peanut plants contain more impurities, which can easily cause conveyor belt clogging and consequently reduce harvesting efficiency. Zhou Quan *et al.*, (2022), proposed a shovel-chain low-laying peanut picker and harvester, which employs an extruding and dialing roller at the end of the digging device to lift and transport the peanut plants. Soil is then removed through shaking and vibration, ultimately achieving longitudinal laying with the roots positioned behind the seedlings.

To achieve the placement of peanut pods above the leaves after harvest, Su, (2024), investigated the turning behavior of peanut plants by studying their physical and mechanical properties, combined with conveyor turning device bench tests and discrete element simulation experiments. The objective was to explore the key factors and influencing mechanisms involved in successful peanut plant turning. He *et al.*, (2024), further verified the optimal working performance of the conveyor turning device, aiming to provide a theoretical and technical reference for the development of two-stage peanut harvesting technology and equipment.

MATERIALS AND METHODS

Overall Structure and Parameters of The Test Rig

The overall structure of the conveying and tipping device is shown in Fig.1.

Fig. 1 – 3D Conveying and tipping device test platform model

The conveying and tipping device consists of components such as a rounding wheel, tensioning sprocket, vibrating wheel, guide grid, rounding grid, clamping chain, and others. During the clamping and lifting process, root-soil separation and final throwing of the peanut plants are achieved. The plants are first collected by the guide grid and then gradually lowered and laid down under their own weight as they pass through the collection grid.

Table 1

Main Technical Data	
Parameter	Value
Overall dimensions (length × width × height) (mm)	1940×540×710
Harvest method	Two-part
Horizontal inclination angle of clamping chain (°)	20°
Clamping height (mm)	140~170
Clamping and conveying speed (km·h ⁻¹)	1.4

Experiment Material Selection

The representative peanut variety "Huayu No. 25," commonly grown in Jiaozhou, Shandong Province, was selected as the experimental material. The crop was harvested in September 2024. The collected peanut plants were sealed in bags and brought back to the laboratory to prevent moisture loss. To better simulate the harvesting environment, the local planting pattern was measured, as shown in Fig.2.

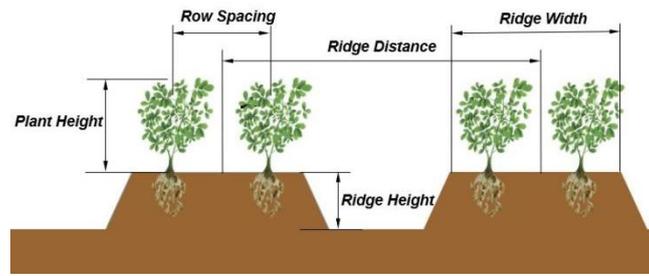

Fig. 2 - Peanut planting pattern diagram

Size parameters and their distribution rules

The three-axis size parameters of peanut plants are necessary for the motion analysis of peanut plants and the establishment of discrete element simulation models of peanut plants. The three-axis dimensions of 50 peanut test samples were measured using a ruler, as shown in Fig. 3, and processed through data analysis software. The results are shown in Table 1.

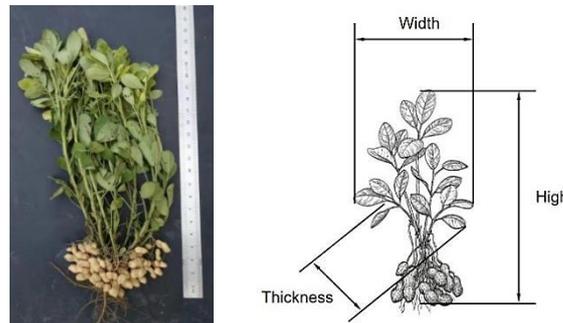

Fig. 3 - Three-axis dimension calibration of peanut plant samples

Table 2

Peanut sample three-axis size data statistics

Name	Average value	Standard deviation	95% confidence interval of mean		Minimum value	Medium number	Maximum value
			Upper limit	Lower limit			
Peanut plant height	464.79	3.15	465.69	463.9	457	463.35	482
Peanut plant width	262.24	9.77	265.02	259.46	232	261	287
Peanut plant thickness	78.92	7.31	81	76.85	65	77.43	96

The normal distribution diagram is obtained based on the measurement results, as shown in Fig.4.

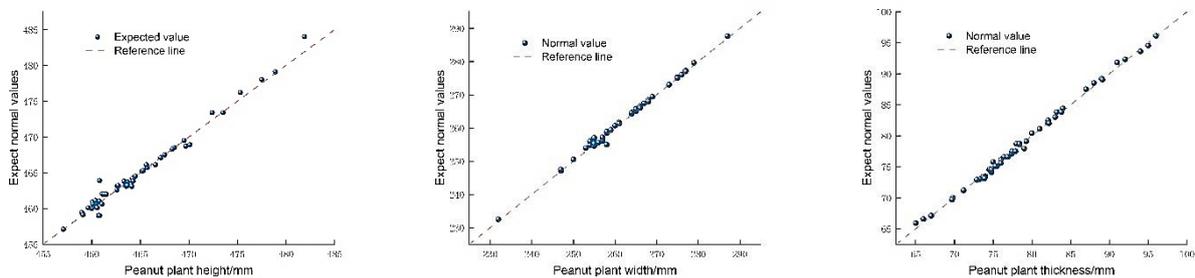

Fig. 4 - Size distribution rules of peanut plant samples

According to the above measurement results and statistical analysis, the height range of peanut plants is between 457 and 482 mm, with an average length of 464.79 mm. According to the statistical results, the standard deviation of the height of peanut plants is 3.15; the width of peanut plants ranges from 261 to 287 mm, with an average width of 262.24 mm. According to the statistics, the standard deviation of the width of peanut plants is 9.77; the thickness range of peanut plants is between 65 and 96 mm, with an average thickness of 78.92 mm. According to the statistics, the standard deviation of peanut plants is 7.31.

Study on the material characteristics of peanut plants

In order to study the flipping rules of peanut plants, it is necessary to analyze and determine the center of mass of peanut plants to provide data reference for the design of the conveying flip device.

Considering that in the actual peanut harvesting process, the peanut stalk, the pod, and the soil carried by the pod are a whole, a holistic study is conducted. In order to determine the position of the center of mass, the entire structure is assumed to be symmetrical, meaning the overall center of mass is located along the central axis of this symmetrical structure. The formula for calculating the centroid of peanut plants at harvest time was obtained, as shown in Figure 5.

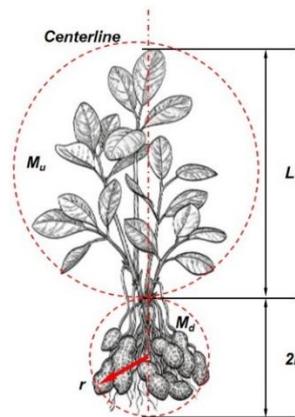

Fig. 5 - Schematic diagram of the overall center of mass of peanut plants

$$\bar{Y} = \frac{\sum M_n \cdot L_n}{\sum M_n} = \frac{M_u \cdot (L_1 + 2r) + M_d \cdot 2r}{M_u + M_d} \tag{1}$$

In the formula, \bar{Y} represents the distance from the root of the seedling to the center of mass along the central axis of the peanut plant during the harvest period. M_u denotes the mass of the above-ground portion, while M_d represents the mass of the underground portion. L_1 is the height of the above-ground part of the peanut plant, and r is the radius of the growth contour of the underground section of the plant.

In order to determine the above-ground part mass, underground part mass, above-ground part height and underground part growth profile radius during the harvest period, the sample needs to be measured multiple times to obtain an average value to explore the mass distribution of the above-ground peanut plants. The test results are shown in the Table 3.

Table 3

Peanut sample three-axis size data statistics

Sample serial number	L ₁ (mm)	M _u (g)	M _d (g)	r(mm)	\bar{Y} (mm)
1	342	335.6	290.1	59	301.43
2	338	340.3	298.4	56	292.09
3	324	320.8	291.5	63	295.75
4	360	352.1	315.6	50	289.83
5	346	327.5	322.7	52	278.28
Mean	342	335.26	303.6	56	291.48

Since the majority of a peanut plant's mass is concentrated in the underground portion, the center of mass is located closer to the rhizome. Based on the data in the table, the center of mass during the harvest period is found to be in the middle to lower part of the plant, near the rhizome. To ensure smooth flipping of the peanut plants when they come into contact with the bar, the seedling clamping height is controlled within the range of 140–180 mm.

Determination of friction coefficient of peanut seedlings

During the simulation analysis of the conveying and flipping motion of peanut plants, the friction coefficient plays a crucial role in determining the interaction between the peanut plants and both the clamping chain and the guide bar. The peanut plant serves as the primary subject of study; therefore, measuring its friction coefficient is of significant importance. (Liu, 2022).

The rolling friction and static friction of peanut seedlings characterize their friction properties when in contact with solid surfaces. In the study, the material in contact with peanut seedlings was Q235 steel. The rolling friction and static friction between the seedling vines and the guide bar were measured.

This test uses the inclined method to measure the friction coefficient of peanut seedlings, and the test diagram is shown in Fig. 6.

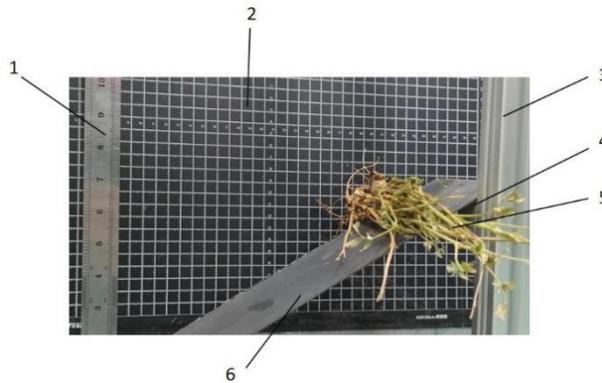

Fig. 6 - Friction coefficient bench test

1. Scale ruler; 2. Square scale board; 3. Bench frame; 4. Lift platform; 5. Peanut seedling sample; 6. Contact material

During the measurement test, the peanut seedlings are subjected to the support force F_1 , the static friction force f and their own gravity G that is obliquely facing the seedlings. When the component force along the inclined direction is greater than the static friction force it is subjected to, the stem slides down along the inclined surface. From this, the static friction factor μ_1 of the seedling and steel material can be obtained:

$$\mu_1 = \frac{f}{F_1} = \frac{G \sin \alpha_1}{G \cos \alpha_1} = \tan \alpha_1 \tag{2}$$

where α_1 is the inclination angle of the test material.

Similarly, when determining the static friction coefficient μ_2 between peanut seedlings, it is only necessary to replace the test material with peanut seedlings. Finally, the static friction coefficient μ_1 between the peanut seedlings and Q235 steel is 0.44, and the static friction coefficient μ_2 between peanut seedlings is 0.32.

Rolling friction coefficient determination

The tool used to measure the rolling friction coefficient of peanut seedlings is the same as that used for measuring static friction. The peanut seedling sample is approximated as a cylindrical object, and it is assumed that the resistance encountered during the rolling process arises solely from rolling friction. During rolling, the rolling friction torque M_1 is proportional to the normal force F_2 exerted on the contact surface. As the inclination angle of the slope gradually increases, the sample begins to roll. When rolling occurs, the stress conditions are illustrated in Fig. 7. The formula for calculating the rolling friction coefficient ε is:

$$\varepsilon = \frac{M_1}{F_2} = \frac{G_1 r_1 \sin \beta}{G_1 \cos \beta} = r_1 \tan \beta \tag{3}$$

where G_1 is the gravity of the peanut seedling sample, β is the angle at which the peanut seedling starts to roll on the contact material, and r_1 is the cross-sectional radius of the peanut seedling cross-section.

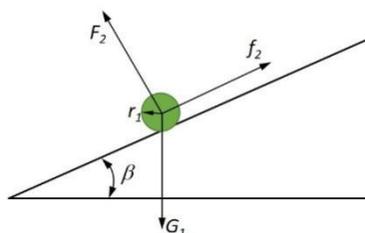

Fig. 7 - Schematic diagram of stress during rolling of seedlings and vines

The seedlings sample was placed on the inclined surface of the contact material of Q235 steel and the peanut seedlings for multiple tests, and the inclined angles β_1 and β_2 of the seedlings rolling were measured and recorded. The rolling friction between the peanut seedlings was calculated. The factor is 0.25, and the rolling friction coefficient between the peanut seedlings and steel is 0.13.

Determination of shear modulus and Poisson's ratio in peanut plants

A compression test was conducted using the XTC-18 Mass Composition Tester to determine the shear modulus and Poisson's ratio of peanut seedling samples. The test setup is shown in Fig. 8. The test parameters were as follows: test distance of 25 mm, loading speed range of 0.001~45 mm/s, test type set to downward pressure, trigger point type set to force, with a trigger point value of 5.000 gf. The target modes included pressure, displacement, and deformation. Prior to testing, the platform holding the sample was height-calibrated. The instrument was set to displacement mode, and the probe was programmed to press downward by a specified distance. After reaching the target value, the probe returned to its original position. The displacement value was set to exceed the height of the sample to ensure complete compression. A total of 30 peanut seedling samples were selected and divided into two groups of 15. One group was used for lateral compression tests, while the other group was used for longitudinal compression tests. Before testing, the transverse and longitudinal dimensions of all samples were measured and recorded.

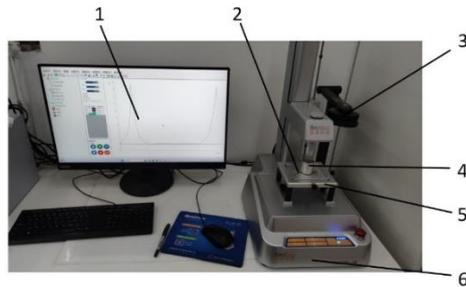

Fig. 8 - Test bench for mechanical properties of peanut seedlings

1. Program interface; 2. Seedling sample; 3. Sensor; 4. Planar probe; 5. Platform; 6. XTC-18 mass composition tester

The elastic modulus and Poisson's ratio calculation formulas of peanut seedling samples are:

$$\begin{cases} G_2 = \frac{E}{2(1 + \mu_3)} \\ \mu_3 = \left| \frac{\Delta \varepsilon_x}{\Delta \varepsilon_y} \right| = \left| \frac{\Delta d_x d_y}{\Delta d_y d_x} \right| \end{cases} \quad (4)$$

where: μ_3 is the Poisson ratio of peanut seedlings sample, G_2 is the shear modulus, ε_y is the longitudinal strain, d_y is the original longitudinal size, Δd_x is the lateral deformation, Δd_y is the longitudinal deformation, ε_x is the lateral strain, d_x is the original transverse size, and E is the elastic modulus.

The calculation method of elastic modulus of peanut seedlings is:

$$E = \frac{\sigma}{\varepsilon_y} \quad (5)$$

where σ is the stress of the peanut seedling sample.

The compression test of peanut seedlings was repeated 15 times, and the results were statistically analyzed and averaged. The shear modulus interval of peanut seedlings was 18.13~18.15 MPa, and the Poisson ratio interval of peanut seedlings was 0.33~0.35.

Dynamic simulation optimization analysis

According to the above analysis, the peanut plants were simulated and a geometric model was established for conveying and flipping device (Zhao et al., 2021). However, the actual structure of the device was relatively complex. In order to save simulation calculation time, components that did not affect the simulation operation results were omitted, as shown in Fig. 9a.

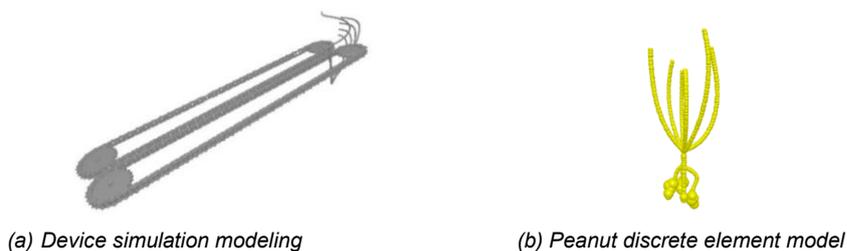

Fig. 9 - Emulation modeling

Through the RECURDYN-EDEM coupling simulation optimization analysis, the specific setting parameters are shown in Table 4. The peanut plant particles were generated in EDEM, and the particles were imported into RECURDYN software to set the position and speed, and then the flip process was simulated and analyzed by the device in RECURDYN. The plant model is shown in Fig. 9b (Zuo *et al.*, 2022).

Table 4

Peanut discrete element modeling simulation parameters					
Maximum feeding amount (kg/s)	Material generation rate (g/s)	Peanut plant height (mm)	Width (mm)	Result depth (mm)	Peanut plant size distribution
4	1.95	460	260	95	0.9 ~ 1.1

The Hertz-Mindlin (non-slip) contact model was adopted in order to study the regularities of peanut plant turnover and drop at the back end of the conveyor turnover device. During this process, peanut plant and peanut plant, peanut plant and clamp chain, peanut plant and guide rod were considered to be non-adhesive. (Hao *et al.*, 2021). The materials and contact mechanical parameters related to peanuts and conveying and flipping devices are shown in Table 5.

Table 5

Simulation material and mechanical parameters		
Item	Parameter	Numerical value
Peanuts	Shear modulus (Pa)	1.8×10^7
	Densities ($\text{kg} \cdot \text{m}^{-3}$)	450
	Poisson's ratio	0.35
Steels	Shear modulus (Pa)	7.9×10^{10}
	Densities ($\text{kg} \cdot \text{m}^{-3}$)	7865
	Poisson's ratio	0.3
Peanuts - Peanuts	Coefficient of restitution	0.5
	Static friction coefficient	0.32
	Rolling friction coefficient	0.25
Peanuts - Steel	Coefficient of restitution	0.42
	Static friction coefficient	0.44
	Rolling friction coefficient	0.13

The movement parameters of the conveying and flipping device include the conveying speed, the gripping height of the seedlings and the impact angle between the seedlings and the bar (Chen *et al.*, 2023). A one-factor test was performed on each motion parameter. The RECURDYN-EDEM coupling simulation process is shown in Fig.10. The impact angle between the seedlings and the bar is 18°, 19°, 20°, 21°, 22°; the conveying speed is 1.2, 1.3, 1.4, 1.5 and 1.6 m/s; the clamping height of the seedlings is 140 mm, 150 mm, and 160 mm , 170 mm and 180 mm.

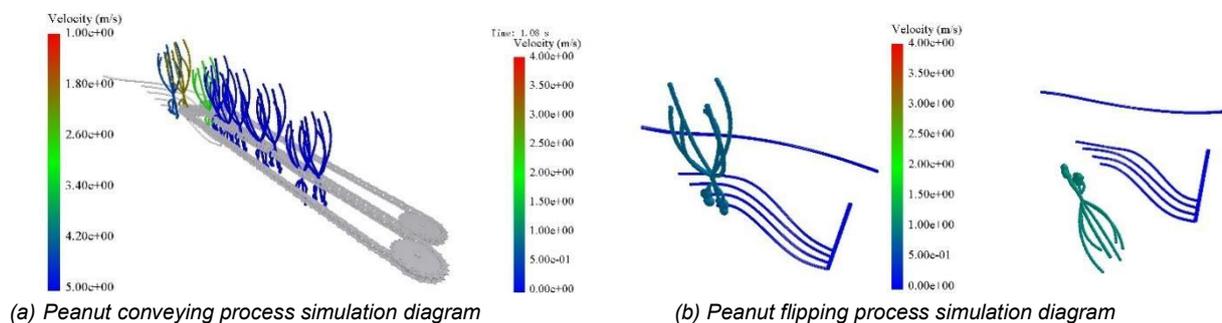

Fig. 10 - Directional turnover peanut harvest device simulation flow chart

Analysis of data results

According to the analysis of simulation process, the gripping height of peanut plant X1, the impact Angle of peanut plant X2 and the conveying speed X3 were tested by experimental factors. The degree of peanut flipping completion Y was used as the evaluation index. A 3-factor, 3-level orthogonal testing method was employed to design the experiments (Xie *et al.*, 2024). The factor coding is shown in Table 6.

Table 6

Test factor coding table			
Encodings	Factor		
	X ₁ (mm)	X ₂ (°)	X ₃ (m·s ⁻¹)
-1	140	18	1.2
0	160	20	1.4
1	180	22	1.6

The test scheme and results are shown in Table 7.

Table 7

Test factor coding table				
Encodings	Factor			Peanut flip completion
	X ₁ (mm)	X ₂ (°)	X ₃ (m·s ⁻¹)	
1	140	18	1.4	93
2	180	18	1.4	91.4
3	140	22	1.4	93.4
4	180	22	1.4	90.2
5	140	20	1.2	91.9
6	180	20	1.2	88.2
7	140	20	1.6	89.1
8	180	20	1.6	88.5
9	160	18	1.2	94.8
10	160	22	1.2	95.2
11	160	18	1.6	94.6
12	160	22	1.6	93.2
13	160	20	1.4	97.4
14	160	20	1.4	97.6
15	160	20	1.4	97.7
16	160	20	1.4	97.1
17	160	20	1.4	97.9

The response surface analysis of the test results was carried out by Design-Expert13.0.1.0 software, and the influence of each test factor on the completion degree of peanut flipping was obtained, as shown in Fig.11. It can be seen that when the clamping height is 156.8 mm, the conveying speed is 1.47 m / s, and the impact angle is 20.24 °, the peanut flipping completion degree is up to 98.1% (Zhang et al., 2024). With the increase of the impact angle between the vine and the grid, the chain clamping peanut vine is more unobstructed, which is convenient for the smooth turnover of the plant. With the increase of vine clamping height, the peanut flip completion degree showed a trend of increasing first and then decreasing, and the influence was the most obvious among the three factors. With the increase of conveying speed, the completion degree of peanut flipping showed a trend of increasing first and then decreasing (Zhang et al., 2022).

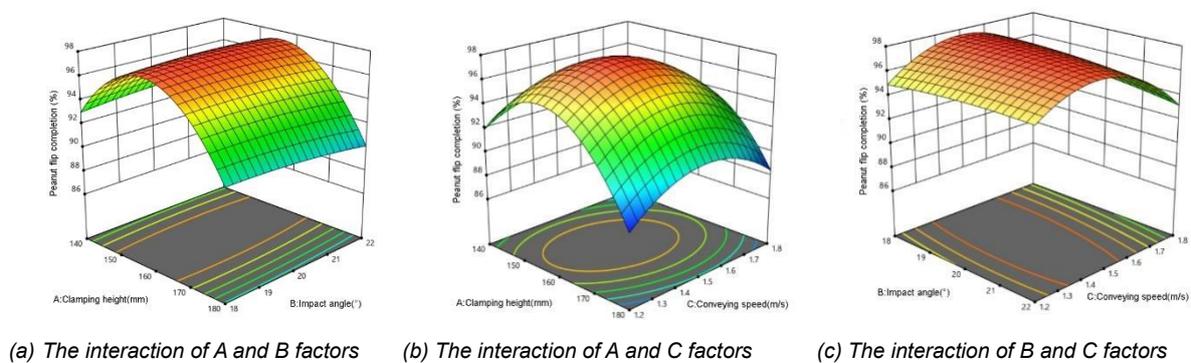

Fig. 11 - Response surface analysis of peanut turnover completion

According to the harvest demand of peanut turnover completion degree and the boundary of test factors, combined with the analysis results of related models, the constraints of the optimal solution are as follows:

$$\begin{cases} \min Y_1(x_1, x_2, x_3) \\ s.t \begin{cases} 140mm \leq x_1 \leq 180mm \\ 1.2m/s \leq x_2 \leq 1.6m/s \\ 18^\circ \leq x_3 \leq 22^\circ \end{cases} \end{cases} \quad (6)$$

Through the optimization scheme, when the clamping height is 160 mm, the clamping and conveying speed is 1.4 m/s, and the impact angle between the vine and the grid is 20°. It is the optimal combination parameter, and the peanut turnover completion degree is 96.1% (Zhang et al., 2022).

RESULTS

Field test of the device

The installation structure diagram of the conveying and flipping device bench is shown in Fig.12a.

Fig. 12 - Directional flipping peanut harvesting device test diagram

The feasibility of bench test design is established. After the data is optimized, it is installed on the whole machine for field testing, as shown in Fig. 12b. According to the theoretical prediction value of each factor and the actual operation situation, the vine clamping height was 160 mm, the conveying speed was 1.4 m/s, and the impact angle was 20°. Under the same test conditions of the quadratic multiple regression analysis test, three repeated tests were performed and the average value was taken. By counting the completion of peanut flipping and analyzing the moisture content of peanut pods in the field after flipping, the feasibility of peanut flipping and whether the quality of drying after flipping was improved were tested (Chen et al., 2024).

Compared with the traditional peanut unidirectional lateral orderly placement machine, it is better to realize the turnover and placement of peanuts on the ground after harvest, allowing for more thorough drying in the field. The higher the degree of peanut turnover, the better the field drying effect, and the lower the moisture content of peanut pods. The peanut flip completion degree and prediction results are basically the same as shown in Table 8, which is more in line with the requirements of two-stage peanut harvest.

Under identical drying conditions, the moisture content of peanut pods from the two different laying methods was compared after three days of drying.

Table 8

Comparison of peanut flipping completion	
Parametric	Peanut flip completion
Projected value	96.1%
Experimental value	95.1%

The peanut moisture content data of the experiment were visualized to form a line chart, as shown in Figure 13.

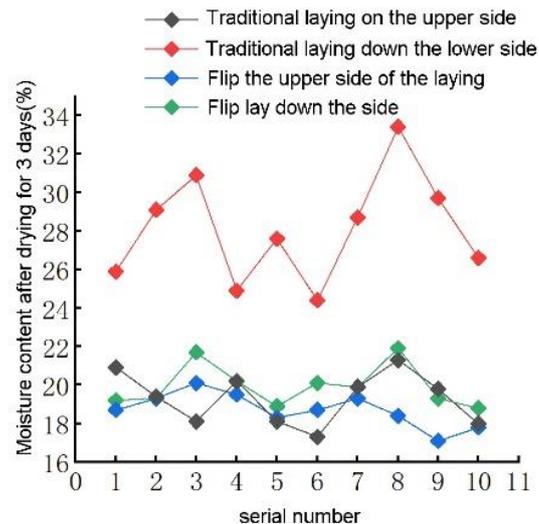

Fig. 13 - Peanut pod moisture content comparison chart

According to the experimental results, the highest value of peanut flip completion is 96.9 %, the lowest value is 92.7 %, and the average value is 95.1%. After 3 days of drying, the highest moisture content of the upper peanut pod was 19.8%, the lowest was 16.7%, and the average was 18.1%. After 3 days of drying, the highest moisture content of the lower peanut pod was 20.9%, the lowest was 18.5% and the average was 19.1%. Compared with the traditional peanut harvester, the harvesting efficiency and the drying quality of peanut in the field were further improved.

CONCLUSIONS

(1) Aiming at the problems of poor field drying quality and long harvest cycle of traditional two-stage peanut after harvest, an optimized laying method was proposed, and a conveying and turning device was designed. Peanut plants were turned down and laid on the ground to improve the quality of field drying.

(2) Through the analysis of the physical and mechanical properties of peanut plants, the feasibility of flipping was assessed. After the measured parameters were brought into the coupling simulation, the mathematical model of the relationship between test factors and indicators was established by Design-Expert software. The response surface method was used to study the law of peanut turnover completion.

(3) The performance of the equipment was tested. Under the optimal parameter combination, the harvest efficiency and harvest quality of the field experiment were tested.

ABSTRACT

Optimizing parameters is a crucial step in designing mechanical structures and a primary means of raising equipment efficiency. This paper proposes a multi-parameter optimization technique that combines an improved genetic algorithm (IGA) and ensemble machine learning (EML) to optimize a licorice harvester's work and structure parameters. The EML model is trained using a small sample dataset built on the coupled DEM-MBD (Multi-body Dynamics Coupled Discrete Element Method) simulation model. The impact of base learner diversity and quantity on the model's prediction accuracy is investigated. Using EML and IGA, the parameters of a licorice harvester are optimized. It is also contrasted with conventional response surface model (RSM) parameter optimization techniques. The study results show that the EML with KNN + lightGBM + catBoost as the base learner and linear as the meta-learner has an R^2 of 0.959, MAE of 0.048, and RMSE of 0.06. In comparison to the RSM, EML-IGA reduces resistance by 18.16% and specific power consumption by 21.33%; in comparison to the EML and Pre-improvement genetic algorithm (PIGA), it reduces resistance by 11.36% and specific power consumption by 11.19%. It provides a reference for intelligent parameter optimization methods.

摘要

参数优化是机械结构设计过程中必不可少的环节，也是提高机械工作效率的主要途径之一。本研究通过集成学习与改进遗传算法结合提出一种多参数优化方法对甘草收获机的结构和工作参数进行优化。基于 DEM-MBD 耦合仿真模型构建小样本数据集对集成学习模型进行训练，并探究基学习器的数量与多样性对集成学习模型预测精度的影响。利用集成学习结合改进遗传算法对甘草收获机的多个参数进行优化。并与传统的响应面参数优化方法进行对比。研究表明，以 KNN+lightGBM+catBoost 为基学习器，线性拟合为元学习器的集成学习模型，其 R^2 为 0.959，MAE 为 0.048，RMSE 为 0.06。其相较于改进前的遗传算法的优化结果，阻力降低 11.36%，比功耗降低 11.19%，相较于传统的响应面分析法，阻力降低 18.15%，比功耗降低 21.33%，为智能化参数优化方法提供参考。

INTRODUCTION

The main component of the licorice harvester is the digger device, whose work and structure parameters directly impact the machine's resistance and power consumption. Both domestically and internationally, researchers have conducted a great deal of study on the optimization of the parameters of the harvesting device for deep root crops to address the issues of high digging resistance and high power consumption in deep root crops. Zhang et al., (2024), optimized three working parameters of a residual film recycler using RSM to improve its pick-up rate. Awuah et al., (2022), optimized the parameters of the vibratory digging shovel based on DEM and RSM, significantly reducing the working resistance. The RSM utilized in the previously mentioned parameter optimization techniques is primarily useful for optimization variables fewer than or equal to 4. An excessive number of optimization variables might result in issues such as local optimal solutions and inaccurate fitting. As machine learning advances, more academics are using it to predict regression using multivariate inputs. Huang Lvwen et al, (2023), utilized 40 feature values as inputs into the LSTMED-MLP model to forecast the soluble solids content of apples. Ge et al., (2023), trained eight machine learning algorithms by multiple input features with different importance. It can be seen that machine learning is suitable for the nonlinear fitting of multivariate inputs for prediction.

However, most of the research has generally focused on the predictive performance of individual machine-learning models. Single models' limited adaptability makes them frequently unable to handle complex problems completely (Cao *et al.*, 2024).

On the other hand, by combining the benefits of several models, EML can successfully enhance the generalization performance of prediction models and lower prediction errors. Liu Tan *et al.* (2024), used EML to estimate the photosynthetic rate of greenhouse tomatoes, which increased the prediction's accuracy and stability. Zongquan, (1997), researched the predictive accuracy of Stacking's EML for cracking in reinforced concrete against that of a single machine learning model; it was discovered that the model performed better. Consequently, it is now worthwhile to research how to fully utilize the benefits of a single learner in order to enhance the model's generalization performance and prediction accuracy. Researchers have started combining machine learning and simulation modeling techniques to solve various real-world problems since numerical simulation techniques have become more popular. Yu *et al.*, (2023), trained BP neural networks using datasets obtained from numerical simulations. Liao *et al.*, (2021), combined DEM and deep learning methods to predict particle flow behavior in a wedge-shaped hopper.

An intelligent optimization technique, genetic algorithm (GA), is utilized to find the objective function's optimal solution (Aote *et al.*, 2023). Although it has a straightforward structure, it has limitations on local search capability and population variety. A few academics started enhancing GA. NING Fanghua *et al.* (2024), combined the NEH and random generation to produce high-quality first populations as an alternative to the conventional technique of randomly generating starting populations. Wei *et al.* (2024), introduced simulated annealing algorithm into the genetic algorithm, which improved the local search ability of the traditional genetic algorithm. The crossover and mutation probabilities of GA should be adjusted adaptively; however, this is rarely done by academics. Doing so would increase the genetic algorithm's capacity for global search and speed of convergence.

The EML model is trained using a small dataset built on the coupled DEM-MBD simulation model. The impact of base learner diversity and quantity on the model's prediction accuracy is investigated. EML-IGA was possible to predict licorice harvester performance indicators quickly and accurately. A uniform distribution of the initial population and adaptive adjustment of crossover and mutation probabilities are achieved by improving upon some of the shortcomings of conventional genetic algorithms. Subsequently, the optimization results of the response surface analysis method are compared with the EML - IGA to obtain a method suitable for complex multi-parameter optimization problems. The combination of structural and working parameters was also optimized to achieve the licorice harvester's minimum resistance and power consumption.

MATERIALS AND METHODS

Small sample dataset construction

- Physical structure of the licorice harvester

The structure of the licorice harvester is shown in Fig.1, which is mainly composed of digging device, suspension system, vibration system, excitation device and frame. Fig.2 shows the main structural parameters, digging inclination α , dispersal inclination β , dispersal length L , dispersal spacing D , and working width d . Working speed V , harvesting depth H , vibration frequency f , and crank amplitude A are the primary operating parameters.

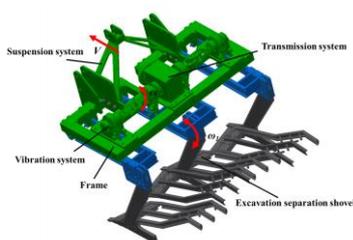

Fig. 1 - Physical structure of the licorice harvester

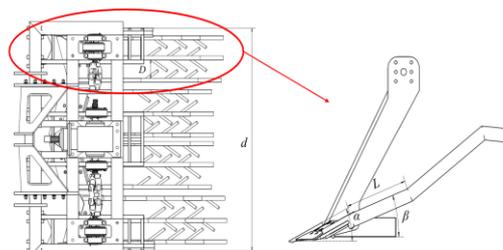

Fig. 2 - Main structural parameters of excavating shovel

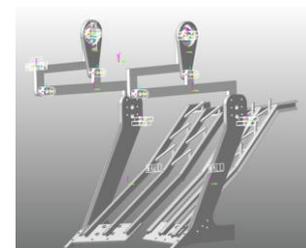

Fig. 3 - Multi-body dynamics simulation model of the licorice harvester

● MBD Simulation Model Building

The licorice harvester is first structurally simplified. Parts of the frame, gearbox, vibration system, etc. that do not affect the simulated motion setup are removed, and only half of the digging shovel structure of the original unit is retained. It accomplishes the objective of reducing the simulation time for model coupling and ensuring that the model moves by the working principle. The working width of the simplified unit is 840 mm. Fig. 3 shows the multi-body dynamics simulation model of the licorice harvester. Import the simplified 3D model into RecurDyn in .sat format and add motion and drives between parts. Two drives in total are added to the model. The first adds a forward drive with the drive function $V*time$ to the frame for linear motion. The other adds a vibration drive to the eccentric block for rotational motion with a drive function of $\frac{f*360}{57.3^\circ} * time$ ($time$ is the total simulation time).

● DEM simulation model construction

The soil's calibration and the soil particle interaction model selection are crucial to producing a DEM model. The soil samples calibrated were brown loam soils in Beijing. The density of the soil was 2130 kg/m^3 , shear modulus 0.96 MPa , Poisson's ratio 0.36 (Song Jiannong et al., 2021). The soil has a sticky texture and a high degree of bonding between soil particles. The Hertz-Mindlin with JKR Cohesion contact model was selected for parameter calibration because it takes the influence of bonding force into account and works well with cohesive soils with high adhesion forces (Junwei et al., 2019). The static repose angle of the soil served as an indicator for calibrating the target soil. The actual soil repose angle test was repeated five times and then averaged to obtain the actual soil repose angle $\theta = 31.42^\circ$. The natural soil static repose angle values were obtained by processing the raw photos of the static repose angle test using PyCharm software, which allowed for determining the soil repose angle. The processing is shown in Fig. 4.

Using soil-soil collision recovery coefficient $X1$, soil-soil static friction factor $X2$, soil-soil rolling friction factor $X3$, and JKR surface energy $X4$ as the test factors and soil repose angle as the test index, Box-Behnken simulation test was conducted to determine soil-soil contact parameters. The DEM model for the calibration test is shown in Fig. 5. The soil particles were defined as spherical, measuring 6 mm in size, and their distribution followed a conventional normal distribution with a 0.05 variance. Table 1 displays the range of JKR surface energies as well as the range of soil-soil contact coefficients needed for calibration, together with the organic glass intrinsic parameters needed for the tests and the soil-organic glass contact coefficients that have been observed in the literature (Fangping et al., 2020). The software Design-Expert 13 carried out the Box-Behnken simulation test program and optimized the results. Optimal parameter combinations of contact parameters are obtained: $X1=0.39$, $X2=0.4$, $X3=0.05$, $X4=7.22$. The combination of contact parameters is effective since the simulated value of the repose angle is 30.64° , and the relative error with the observed value is 2.48% , indicating the relative error is less than 5% . The digging shovel's material is 65Mn , its density is 7865 kg/m^3 , its Poisson's ratio is 0.3 , and its shear modulus is $7.9 \times 10^7 \text{ MPa}$ (Song Jiannong et al., 2021). The contact parameters of soil and digging shovel are as follows: the collision recovery coefficient e is 0.5 , the static friction factor μ_s is 0.3 , and the dynamic friction coefficient μ_r is 0.1 (Zhang et al., 2017).

For the excavation shovel to operate normally, the DEM simulation model needs to be configured as an earth slot since the shovel's real operating environment is a complete field. The length of the soil box was set at 3500 mm , the width at 950 mm , and the height at 800 mm , based on the excavation shovel's working width and speed.

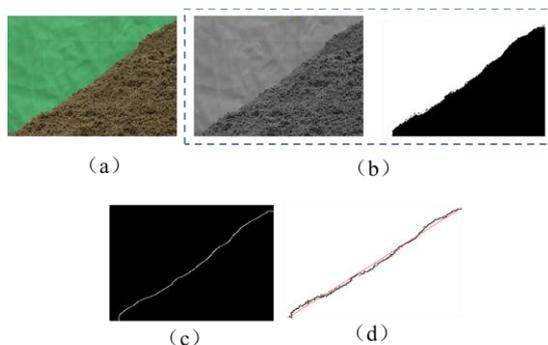

Fig. 4 - The process of soil repose angle processed by Pycharm

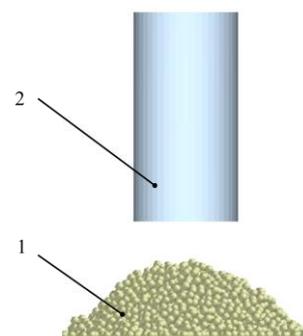

Fig. 5 - DEM model of calibration test

Table 1

Calibration model simulation parameters	
Parameter	Value
Poisson's ratio of soil particles	0.36
Density of soil particles /(kg/m ³)	2130
Shear modulus of soil particles /MPa	0.96
Poisson's ratio of organic glass	0.37
Density of organic glass/(kg/m ³)	2.5×10 ³
Shear modulus of organic glass /MPa	100
Soil-organic glass Recovery coefficient ball and steel	0.3
Soil-organic glass static friction coefficient<	0.41
Soil-organic glass rolling friction coefficient<	0.01
soil-soil collision recovery coefficient	0.35 ~ 0.7
Soil-soil static friction	0.4 ~ 1.1
Soil-soil rolling friction	0.05 ~ 0.25

● Coupled DEM-MBD simulation model of licorice harvester

The two digging shovels from the MBD simulation model are exported in WALL format and then loaded into the EDEM2020 software to establish the model. The time step of the MBD simulation was set to 15 samples per vibration cycle. In summary, the STEP design equation for the MBD model is $f^*15*time$, where time is the overall simulation duration. The DEM's time step is 20%, and the save interval is 0.005 s.

● Design of dataset construction methods

This study proposes using a small sample-based simulation dataset for machine learning training to increase design efficiency. The resistance F_q and the power consumption P_{wk} (power consumption per unit volume of soil handled by the licorice harvester) that the harvester experiences while in operation were utilized as optimization indications. F_q is extracted in the DEM model simulation results.

The driving torque T_q is extracted directly by the result function in RecurDyn. P_{wk} was calculated using Equation (1).

$$P_{Wk} = \frac{\bar{F}_q}{1000DBt} + \frac{\bar{T}_q R}{9550VDBt} \quad (1)$$

where:

\bar{F}_q is the average of resistance in the effective range, N;

\bar{T}_q is the average of driving torque with the value greater than 0, N.m;

R is the crank speed, r/min;

t is the working time, s;

V is the forward speed, m/s;

B is the working width, mm;

D is the digging depth, mm.

However, F_q and P_{wk} are calculated as a combined performance index Z utilizing linear weighting in accordance with the Entropy technique in order to simplify the genetic algorithm optimization. The entropy method is more objective, assigning weights based on sample data sets (de Blas et al., 2021). According to the calculations, the weight of P_{wk} is 0.757, and the weight of F_q is 0.243. The licorice harvester's primary structure and operating parameters have been described above. In this study, the parameters significantly affecting the composite indicator Z were screened by the Plackett-Burman test. Six design factors significantly impacted the composite index Z : vibration frequency f , crank amplitude A , harvesting depth H , operating speed V , digging inclination angle α , and dispersal inclination angle β . To summarize, this study generates a small sample dataset by utilizing the composite index Z as the optimization index and the licorice harvester's six structural and operating characteristics as the optimization variables. The dataset was produced by a 6-factor Box-Behnken test with 54 groups, created with the software Design-Expert 13.

Ensemble Machine Learning Model Building

● Building Methods for Ensemble Machine Learning

Ensemble Machine Learning (EML) is one of the more advanced machine learning paradigms (Ribeiro *et al.*, 2022). The main principle is to use one of the three strategies—Boosting, Bagging, or Stacking—to aggregate the prediction result of several learners (base learners) to achieve more excellent prediction performance than a single learner. Stacking has the flexibility to take full advantage of different base learners, as well as the ability to select meta-learners based on specific problems and samples. Therefore, a stacking integration strategy was selected for this study. There are two layers in the stacking integration model: Level 1, which comprises several base learners, each of which produces individual predictions. The meta-estimator, present in Level 2, used inputs of predictions from several base learners in Level 1 to learn more and generate the final integrated predictions. The base learner selects the eight machine learning models—Random Forest (RF), Decision Tree (DT), K Nearest Neighbors (KNN), Ridge Regression (RR), AdaBoost, lightGBM, catBoost, and XGBboost—that are commonly employed for regression prediction. The meta-learner selects a more straightforward linear regression to avoid overfitting and improve the model's generalization performance.

Evaluation index of Ensemble Machine Learning

The accuracy of the EML model is assessed in this work using three indices: the root mean square error (RMSE), the mean absolute error (MAE), and the coefficient of determination (R^2) (Wu *et al.*, 2022). The model's quality of fit is shown by the R^2 , which has a value range of 0 to 1. The closer the value is to 1, the better the model. The MAE and RMSE values represent the model's prediction error; the lower the number, the smaller the prediction error and the higher the model's fitting accuracy.

Improvement methods for genetic algorithms

● Improvements in initialization of populations

The population of the traditional genetic algorithm is not uniformly distributed and is initialized with a random distribution within the optimization range of the independent variables. This could lead to the algorithm finding a local optimum solution (Qiao *et al.*, 2022). Therefore, rather than using random distribution, Circle Chaotic Mapping is used in this work. Circle mapping can improve the algorithm's capacity for global search and offer a proper exploratory mechanism. The mapping form is indicated in Equation (2).

$$D_{i+1} = \text{mod}(D_i + a - \frac{b}{2\pi} \sin(2\pi D_i), 1) \quad (2)$$

where: D_i denotes the current mapping state value, located in the interval (0,1); D_{i+1} is the next state value. a and b are the control parameters, which usually take the values of $a=0.5$ and $b=0.2$. The mod function guarantees that the mapping's outcome stays inside (0, 1).

● Adaptive improvement for crossover and mutation probability

The Gompertz function is a mathematical model that Gompertz initially proposed. It is typically used to represent a system or process that increases in speed at the rate of the first fast change rule followed by a slow one (Yin *et al.*, 2021). The crossover, mutation probability, and function curve change rules are similar. Consequently, this study refines the Gompertz function to create an adaptive adjustment formula for the crossover and mutation probabilities. The general form of the Gompertz function is shown in Equation (3). An evolutionary coefficient R must be proposed to characterize the population's degree of evolution to satisfy the requirement that the probability of crossover mutation is by the population's degree of evolution. Individual fitness values are small and discrete during the early stages of genetic algorithm population evolution. However, as the population ages and approaches the ideal solution, its fitness values become more concentrated. The notions of expectation and variance are introduced to represent the change in fitness values. The population fitness value increases throughout the evolutionary process while the variance decreases. Therefore, the evolutionary coefficient R expression can be designed as Equation (4). To satisfy the adaptive features, the general form of the Gompertz function was combined with the evolutionary coefficients R to form the crossover and mutation probability adaptive adjustment formulas in Equation (5) and (6), where the a , b , and c coefficients are used to set the range of crossover mutation probability values and their trends.

$$f(x) = ae^{-be^{-cx}} \quad (3)$$

$$R = \frac{EX+1}{\sqrt{DX}} \quad (4)$$

$$f(x) = 0.9e^{-0.05e^{0.4R}} \tag{5}$$

$$f(x) = 0.1e^{-0.05e^{0.8R}} \tag{6}$$

where: x is the independent variable; a , b , c are positive real parameters. a denotes the maximum value; b controls the initial growth rate; and c controls the steepness of the growth curve. P_c is the crossover probability, ranging from (0,0.9); P_m is the variation probability, ranging from (0,0.1); and R is the evolutionary coefficient, ranging from (0, $+\infty$).

Design of multi-parameter optimization methods

Three optimizing strategies will be developed to optimize the licorice harvester's six structures and operating parameters. The first is based on traditional response surface analysis; the second is EML combined with a genetic algorithm for optimization; and the third is EML combined with the improved genetic algorithm for multi-parameter optimization. All three methods are based on the same dataset.

RESULTS

Exploration of the influence of structural working parameters on Z

To guide the actual design and optimization, the impact of operational and structure parameters on the performance indices was examined independently. Fig 6 shows the pattern of influence of single factors on Z. The remaining factors are at intermediate levels when examining the pattern of influence of individual components.

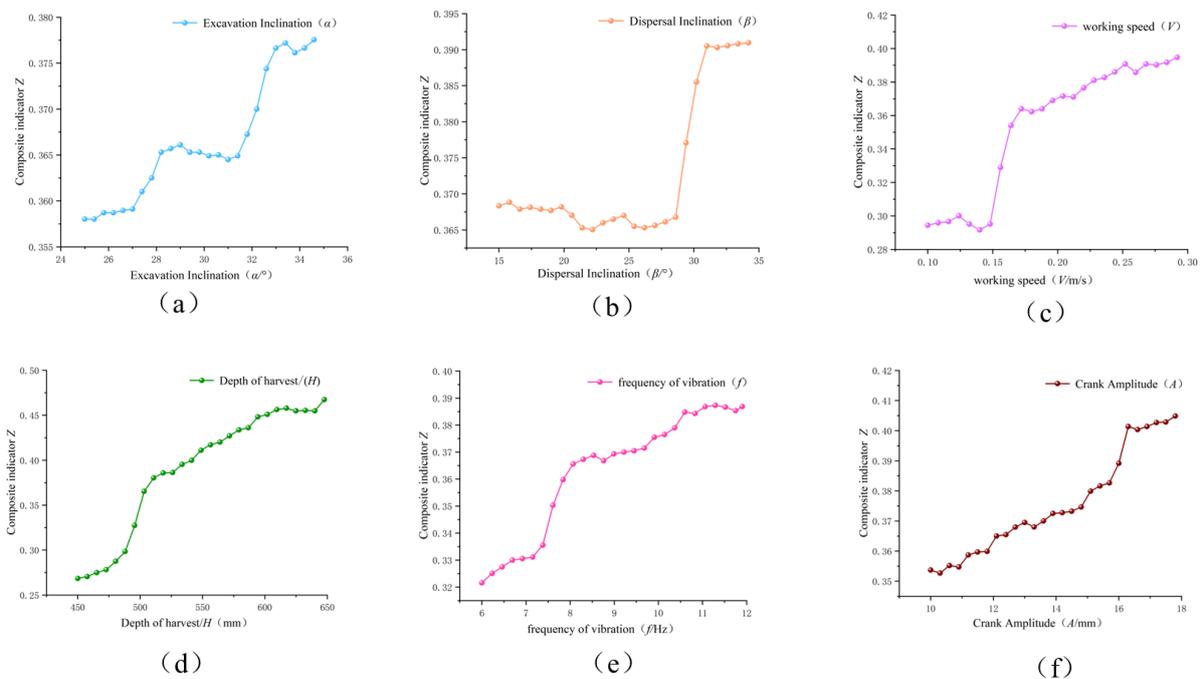

Fig. 6 - Single-factor influence pattern diagram

(a) Laws of influence of α on Z; (b) Laws of influence of β on Z; (c) Laws of influence of V on Z; (d) Laws of influence of H on Z; (e) Laws of influence of f on Z; (f) Laws of influence of A on Z

Fig. 6(a) shows the pattern of excavation inclination angle on Z. As α increases, Z is gradually increasing. However, when α is at $28-31^\circ$, Z is unchanged and tends to decrease slowly. Beyond 32° , Z increases rapidly before stabilizing. Thus, resistance and power consumption might quickly surge when the digging inclination is too high. Fig. 6(b) shows the law of β on Z. Z is nearly constant between 15 and 29° of β ; however, above 29° , Z climbs quickly to a higher level and then stays nearly constant. Consequently, the design of β should be smaller than 29° . Fig. 6(c) is the law of the effect of V on Z. When V exceeds 0.15 m/s, Z climbs quickly before rising slowly. In general, resistance and power consumption rise with V . Consequently, the deep-rooted crop harvester's working speed should be limited to roughly 0.15 m/s. The impact of H on Z is shown in Fig. 6(d). Resistance and power consumption rise with increasing H . 500 mm of H causes a spike in resistance and power consumption.

Therefore, not only will resistance and power consumption increase with increasing H (more than 500 mm), but the operation will also become increasingly challenging. (e) is the law of the effect of f on Z . There is an increase in power consumption with increasing f . Power consumption rises in proportion to the f . There is a spike in power consumption at 7.5 Hz. However, the power consumption is nearly constant and somewhat steady when the frequency is at 8-10 Hz. (f) is the law of A on Z . As the A increases slowly, the power consumption increases slowly.

In conclusion, there is a positive correlation between each factor's laws of impact over resistance and power consumption. It is important to keep each aspect within a narrow range when designing.

Comparative evaluation of different combinatorial basis learners' prediction effects for ensemble machine learning

The choice of base learners is the most crucial step in training ensemble machine learning models. This section investigates how the quantity and kind of base learners affect the model's prediction accuracy. Alternatives for the base learner, RF, DT, KNN, RR, AdaBoost, lightGBM, catBoost, and XGBboost, have been selected. Fig X displays the prediction results received after the model has been trained. As the Fig. 7 illustrates, all five of the prediction models—AdaBoost, lightGBM, catBoost, XGBboost, and RF—have good robustness, with R^2 values over 0.9 and RMSE and MAE errors hovering around 0.08, indicating excellent prediction accuracy. By comparison, R^2 was less than 0.8, and MAE and RMSE errors were more significant than 0.12, indicating lower prediction accuracy for KNN and ridge regression compared to the other models. The more accurate base learners—AdaBoost, lightGBM, catBoost, XGBboost, and RF—are chosen in order to guarantee the predictive capacity of ensemble machine learning. Because unlike the five model-building procedures mentioned above, KNN was also used as the primary learner to ensure the diversity of the underlying learners.

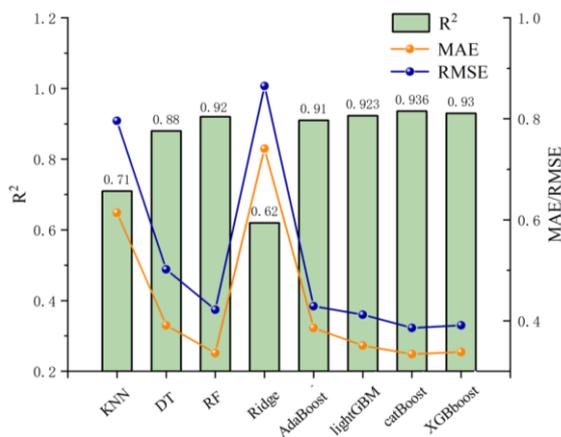

Fig. 7 - Base Learner Prediction Accuracy Graph

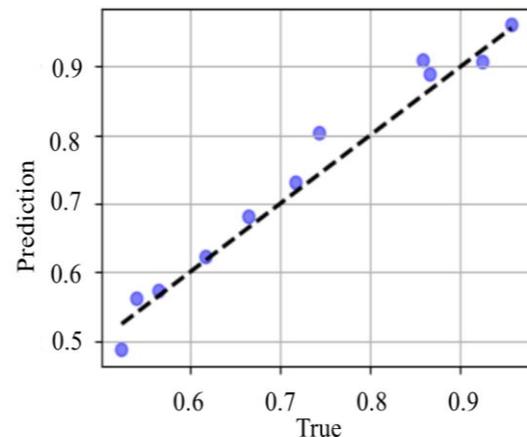

Fig. 8 - Robust graph of prediction accuracy

This study will use two-by-two, three-by-three, four-by-four, five-by-five, and six-by-six combinations to systematically analyze the impact of the set of base learners in different configurations on the model performance in order to investigate the impact of the number and diversity of base learners on the prediction accuracy of the integrated learning model. A linear model is used to fit the meta-learner in order to prevent the ensemble machine learning model from overfitting. Fig.9 displays the prediction accuracy of the ensemble machine learning using various base learner combinations. (a) displays the primary learner's two-by-two combination model's prediction performance. The model with the highest prediction accuracy is model 8-KNN+catBoost. The prediction performance of the three combined basic learner models is displayed in (b). Model 6-KNN+lightGBM+catBoost has the best robustness and lowest error. 0.959 is the R value, 0.048 is the MAE, and 0.06 is the RMSE. The prediction performance of the four combined basic learner models is displayed in (c). Models 4 and 5 both have an R^2 of 0.949, an MAE of 0.05, and an RMSE of 0.066, indicating higher accuracy and fewer prediction mistakes. The prediction performance of the five combined base learner models is displayed in (d). The three models have similar and strong prediction abilities. The error is approximately 0.066, and the R^2 approach is 0.95. The final model is a combination of six, and it has an RMSE of 0.068, an MAE of 0.052, and an R^2 of 0.939.

In conclusion, it was discovered that when the essential learners are merged two by two, the KNN+catBoost model performs best across all combinations. The models with three and four combinations have comparable predictive power, whereas those with six have less predictive power. Also, it was discovered that KNN models were included in the two-by-two model 8-KNN+catBoost, three-by-three model 6-KNN+lightGBM+catBoost, and four-by-four model 4-KNN+AdaBoost+lightGBM+catBoost combinations. Model KNN has the lowest predictive power R^2 , at just 0.71, as the preceding section has shown. This means that in addition to models with high individual predictive ability, models of various types are also needed to select base learners. Ensemble machine learning's prediction accuracy rarely increases appreciably once the base learner count reaches a certain point. Thus, the option of base learners is 2 or 3, given the combination of the arithmetic cost and the need for model prediction accuracy.

Therefore, in this study, ensemble machine learning with KNN+lightGBM+catBoost, which has the best prediction accuracy, as the base learner and linear fitting as the meta-learner was chosen as the prediction model for the performance index of the licorice harvester. As shown in Fig. 8, the prediction robustness plot of this model indicates its strong prediction ability.

Comparative analysis of optimization capabilities of different methods

From the above, the ensemble machine learning model identified in this study has KNN+lightGBM+catBoost as the base learner in the first layer and linear regression as the meta-learner. Pre- and post-improved genetic algorithms will be coupled with the ensemble machine-learning model to optimize the licorice harvester's operating and structure parameters. H was fixed at 600 mm during the optimization process, and the other parameters were optimized. The pre-improved optimization algorithm optimized the parameter combinations as $\alpha=26^\circ, \beta=27^\circ, V=0.1\text{ m/s}, f=6\text{ Hz}, A=11\text{ mm}$. The improved optimization algorithm optimized the parameter combinations as $\alpha=25^\circ, \beta=25^\circ, V=0.1\text{ m/s}, f=6\text{ Hz}, A=11\text{ mm}$. The findings of an ANOVA based on response surface analysis for Z optimization are displayed in Table 2. The response surface model's R^2 of 0.86 is less than the ensemble machine learning model's R^2 of 0.959, even though the response surface model is highly significant ($p < 0.01$) and the misfit term is not significant ($p > 0.05$). The response surface model was optimally solved with the same H of 600 mm. The optimized parameter combinations obtained were $\alpha=27^\circ, \beta=22^\circ, V=0.1\text{ m/s}, f=6\text{ Hz}$, and $A=13\text{ mm}$.

Pure error	0.0037	5	0.0007		
Total sum	2.74	53			

Table 3 shows the performance results of the licorice harvester optimized by the three methods. The EL-IGA's optimization outcome considerably lowers resistance and power consumption. In comparison to the RSM, it reduces resistance by 18.16% and specific power consumption by 21.33%; in comparison to the EML-PIGA, it reduces resistance by 11.36% and specific power consumption by 11.19%.

In conclusion, RSM is less useful for solving intricate multi-parameter optimization issues, but the study's EML-IGA can efficiently locate the global optimal solution. The low-order data fitting method, which is prone to falling into local optimal solutions due to its inability to capture the complex relationship between the data, limits the RSM when solving most complex multi-parameter optimization issues. However, EML is good at fitting complex nonlinear relationships, providing an accurate, objective function for the ensuing genetic algorithm optimization, overcoming the limitations of traditional RSM methods, and providing high-precision fitting of design variables and performance metrics. Fast convergence in the optimization process is made possible by combining the IGA method, ensuring that the dominating populations down the population iteration are not killed while maintaining population variety.

Table3

Comparative analysis table of optimization results of different methods		
	Resistance /N	Power consumption /KJ
RSM	7411.99	74.4
EML-PIGA	6843.22	65.91
EML-IGA	6065.52	58.53

CONCLUSIONS

This paper uses DEM-MBD coupling simulation, ensemble learning, and an improved genetic algorithm to optimize the licorice harvester's structure and working parameters. It is found that the optimization results of EML-IGA are better than those of traditional RSM, which provides some ideas and methods for multi-parameter optimization.

(1) A coupled DEM-MBD simulation model of the licorice harvester was constructed, which could simulate the actual working condition of the licorice harvester in the soil. The correctness of the simulation model was demonstrated by the DEM model's error of 2.48%, with a relative error of less than 5%, when calibrated using the static soil accumulation angle.

(2) The EML model, trained using a small sample dataset from the simulation model, provides valuable insights into the impact of the quantity and variety of base learners on prediction accuracy. The findings suggest that a diverse range of base learners, in addition to a single model with strong predictive ability, can significantly enhance the predictive capacity of EML.

(3) With a model R^2 of 0.959, an MAE of 0.048, and an RMSE of 0.06, the model has the highest prediction accuracy and accurately represents the mapping relationship between the optimization variables and the optimization metrics when the first layer of the model is KNN + lightGBM + catBoost and the second layer is linear regression.

(4) In comparison to the RSM, EML-IGA reduces resistance by 18.16% and specific power consumption by 21.33%; in comparison to the EML-PIGA, it reduces resistance by 11.36% and specific power consumption by 11.19%. According to the study comparison, EML-IGA is appropriate for solving difficult multi-parameter optimization issues and addresses the shortcomings of RSM.

DOI: <https://doi.org/10.35633/inmateh-75-59>**Keywords:** YOLOX; CBAM; EIoU; millet ear detection; UAV; deep learning**ABSTRACT**

Rapid and accurate detection of millet ears is essential for yield estimation and phenotypic studies. However, traditional detection methods primarily rely on manual observation, which are both subjective and labor-intensive. To address this issue, this study employed Unmanned Aerial Vehicle (UAV) for image data collection of millet ears and proposed the YOLOX-CBAM-EIoU model to facilitate real-time detection, focusing on challenges such as small millet ears size, dense distribution, and severe occlusion in the dataset. Firstly, the Mosaic data augmentation technique was employed to enhance the diversity of the dataset. Subsequently, the CBAM attention mechanism was incorporated between the Neck and Prediction layers of YOLOX, enabling the reallocation of channel weights to enhance the extraction of fine-grained features and deeper semantic information. Additionally, EIoU Loss was utilized as the loss function for bounding box regression to mitigate missed detections in dense scenes. The improved model achieved an average precision (AP) of 90.30%, a 6.44 percentage point increase over the original YOLOX model, significantly enhancing detection performance for densely distributed millet ears. The improved model also demonstrated a Precision of 91.01%, Recall of 89.45%, and F1-score of 90.22, highlighting strong robustness and generalization capabilities. These findings substantiate the efficacy of the YOLOX-CBAM-EIoU model in improving detection performance under dense distribution and occlusion conditions, providing valuable technical reference for further UAV-based analyses of millet ears phenotypes and yield predictions.

摘要

小米穗的快速准确检测对于产量估计和表型研究至关重要。然而，传统的谷穗检测主要依靠人工观察，不仅主观性强且耗时耗力。为此，本研究通过无人机进行谷穗图像数据采集，主要针对数据集中谷穗体积小、分布密集、遮挡严重等问题提出了 YOLOX-CBAM-EIoU 模型对谷穗进行实时检测。该模型首先在 YOLOX 的颈部层和预测层之间引入了 CBAM 注意力模块，通过重新分配不同通道的权重，获得了更浅层的细粒度特征和更深层的语义信息，以提高对谷穗表型的特征提取能力；其次，采用 EIoU 函数作为回归损失函数，以改善密集场景下谷穗目标的漏检问题。结果表明，改进后的模型检测平均精度 (AP) 达到 90.30%，与原 YOLOX 模型相比提高了 6.44 个百分点，显著提高了密集分布的谷穗目标检测性能。改进后模型的精确率达到 91.01%，召回率达到 89.45%，F1 分数达到 90.22，表现出较强的鲁棒性和泛化能力。结果充分证明了 YOLOX-CBAM-EIoU 模型能显著提高谷穗在密集分布及遮挡条件下的检测效果，为进一步使用无人机分析谷穗表型和产量预测提供了技术参考。

INTRODUCTION

Millets are highly drought-resistant and can thrive in poor soils, making it an important coarse grain crop globally. China's millet planting area accounts for about 80% of the world, and its production accounts for about 90% of the world's total output (Li et al., 2021). Millet ears are crucial agronomic indicators for assessing yield and quality, playing a key role in breeding, nutritional diagnosis, and growth period monitoring. Therefore, research and management of millet ears could improve millets yield and quality, providing scientific basis for agricultural production.

The traditional method for detecting millet ears primarily relies on manual observation, which is labor-intensive, subjective and inefficient. In recent years, with the advancement of computer technology, the integration of computer vision technology with agricultural production has deepened, demonstrating significant application potential in the field of crop detection. *Zhao et al., (2014)*, proposed a method for wheat ear detection that integrated color information with the AdaBoost algorithm, achieving automated recognition and counting of wheat ears. *Liu et al., (2014)*, proposed a wheat ear counting method based on image analysis technology. By integrating color and texture features for image segmentation, the method achieved counting accuracies of 95.77% and 96.89% under broadcast and row-seeding conditions, respectively. *Li, (2016)* applied binarization and morphological processing to raw wheat images, incorporating the Harris corner detection algorithm to extract the wheat ear skeleton. This method effectively enabled the automatic assessment of wheat ear density per unit area. *Li et al., (2018)*, converted RGB images of wheat ears to binary images through color space transformation. They then applied boundary and regional feature parameters to identify fused regions. Subsequently, a line-matching technique based on concavity point detection was employed to segment these fused regions, enabling accurate quantification of the wheat ears. *Meng et al., (2019)*, utilized the improved K-means algorithm to cluster wheat texture features and achieve the recognition of wheat ears. When the traditional image processing methods shown above were used for target detection of cereal crops, it was found that the traditional methods had strong dependence on texture and color, making them highly susceptible to variations in background, lighting, and foliage. Additionally, these methods often required manual adjustment of feature thresholds, which could introduce subjective bias and lead to poor generalization across diverse environments and conditions.

Given the limitations of traditional machine learning technology, crop object detection methods based on deep learning technology have gradually emerged as the mainstream solution. Current research primarily concentrates on the application of deep learning to wheat, rice, and other crops, focusing on improving the accuracy and efficiency of detection models (*Yang et al., 2022; Huang et al., 2022; Liu et al., 2023; Xiong, 2018; Yang et al., 2021*). *Duan et al., (2018)*, proposed a rice panicle segmentation network model based on SegNet, which effectively addressed the challenges to segmentation accuracy posed by the irregular panicle edges, substantial variations in appearance across different rice varieties and growth stages, and occlusions. *Zhang et al.* proposed a convolutional neural network model for the identification of winter wheat ear. By incorporating non-maximum suppression technology, this model achieved the rapid and accurate detection of wheat ear in field conditions (*Zhang et al., 2019*). *Bao et al.* proposed a wheat ear recognition model based on convolutional neural network. This model incorporated an image pyramid to construct multi-scale sliding windows and utilized non-maximum suppression techniques to eliminate overlapping bounding boxes, ultimately achieving efficient counting of wheat ears (*Bao et al., 2019*). *Zhang et al., (2021)*, proposed an improved wheat ear detection method based on the feature pyramid network, which weighed the underlying high-resolution feature map to enhance the useful information channel. *Zhang et al., (2021)*, proposed a rice panicle detection model based on Faster R-CNN, which enhanced the model's performance in detecting small objects by incorporating dilated convolution. In 2023, *Bao et al.* proposed a wheat ear detection model based on TPH-YOLO, which effectively localized the wheat ear in high-density environments (*Bao et al., 2023*). In the same year, *Cai et al. (2023)*, made adaptive improvements to the YOLOv5l model to enable precise detection of rice panicles in field environments. By incorporating the Efficient Channel Attention mechanism before the spatial pyramid pooling layer of the original YOLOv5l model, this study effectively enhanced the model's accuracy and speed in detecting small targets. *Cai et al., (2023)*, proposed a method to reduce the training data for sorghum panicle detection through semi-supervised learning. The results indicated that this approach achieved performance comparable to supervised methods while using only 10% of the original training data.

However, the application of deep learning techniques in crop detection has primarily focused on wheat, rice, and other crops, while research on millet ear detection remained limited. On the other hand, the small size, dense distribution, and frequent occlusions of millet ears in field environments present significant challenges to accurate detection. To address these issues, this study employed UAV to capture images of millet ears in field environments and constructed a dataset of millet ears. Additionally, a millet ear detection model based on YOLOX was proposed. Specifically, (1) the CBAM attention mechanism was introduced to improve the YOLOX model's ability to extract detailed features of millet ears; (2) the original IoU loss function was replaced with the EIoU loss function, further improving the model's performance in detecting small, densely distributed millet ear targets.

MATERIALS AND METHODS

Data acquisition and processing

Data acquisition

The millet images used in this study were acquired from an experimental field located on the southern side of Shanxi Agricultural University, Jinzhong City, Shanxi Province (37°42'45" N, 112° 59' 27" E). The millet cultivar employed was Jingu21. Data collection was conducted between July and August 2022, during the heading stage of the millet. A DJI MAVIC AIR 2 portable UAV, equipped with a 48-megapixel visible light camera, was utilized for image acquisition. The camera was oriented vertically, at a 90° angle to the ground. The UAV was flown at an altitude of 3 m and a speed of 5 m/s during the image capture process. Representative images of the millet are presented in Fig. 1.

Fig. 1 - Images collected by UAV

Data Preconditioning

To ensure the high quality of the dataset, video footage was recorded under optimal conditions, specifically during clear weather and adequate lighting, between 9:30 AM and 10:30 AM. The raw videos were processed through frame extraction, with the elimination of images that were either highly similar or blurry, which culminated in the selection of 117 images, each with dimensions of 3840 pixels by 2160 pixels. However, the pixel proportion occupied by millet ears in these original images was found to be insufficient, presenting challenges for effective model training. Additionally, processing the original images at this resolution resulted in excessively long times. To address these concerns, each original image was subdivided into six smaller images using a 3×2 grid, yielding a total of 702 images, each with a resolution of 1280 pixels by 1080 pixels. An illustration of this image segmentation process is provided in Fig. 2.

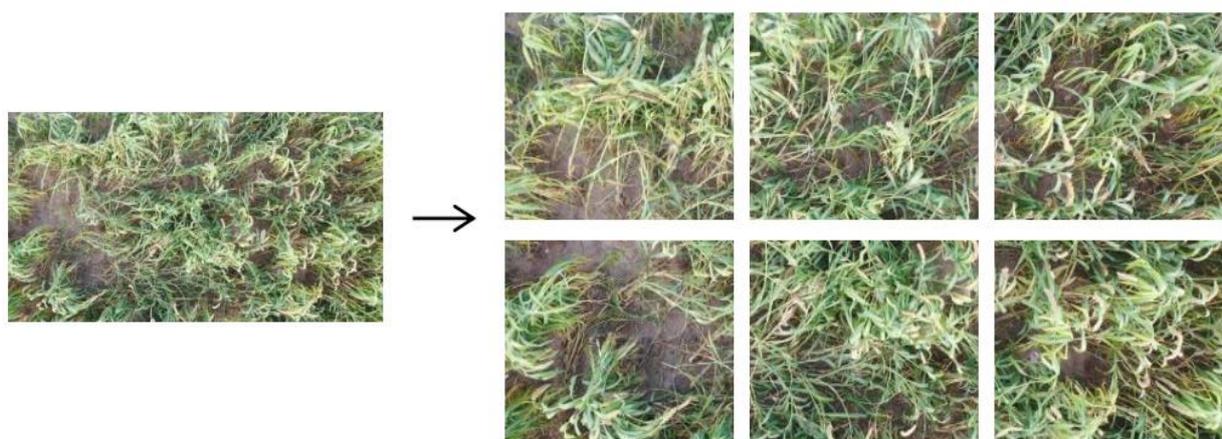

Fig. 2 - Image cutting example diagram

The millet ears in the images were annotated using Labeling software, and the annotation result is shown in Fig. 3.

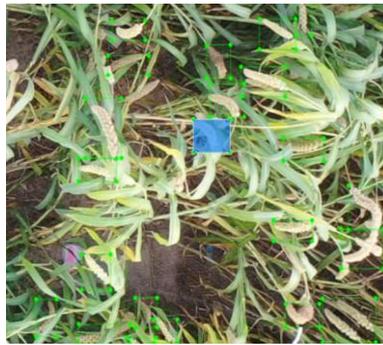

Fig. 3 - Data annotation results

In this study, the Mosaic data augmentation technique was employed to enhance the diversity of the dataset. The Mosaic data augmentation method involved a series of operations, including random scaling, rotation, and stitching. The newly generated image was created by stitching four original images after applying the transformations, as illustrated in Fig. 4. A total of 2,106 images of millet ears were obtained and divided into training, validation, and test sets in an 8:1:1 ratio.

Algorithm introduction

YOLOX-CBAM-EIoU network architecture

In this study, an improved model named YOLOX-CBAM-EIoU was proposed for millet ear detection. Firstly, a Convolutional Block Attention Module (CBAM) was integrated between the Neck and Prediction layers of the YOLOX model. Secondly, the EIoU function was introduced as the model's loss function. These modifications were found to effectively improve the stability of the bounding box regression and mitigate the scattering of IoU loss during training, thereby improving the overall detection performance. The network architecture of the improved model is illustrated in Fig. 5.

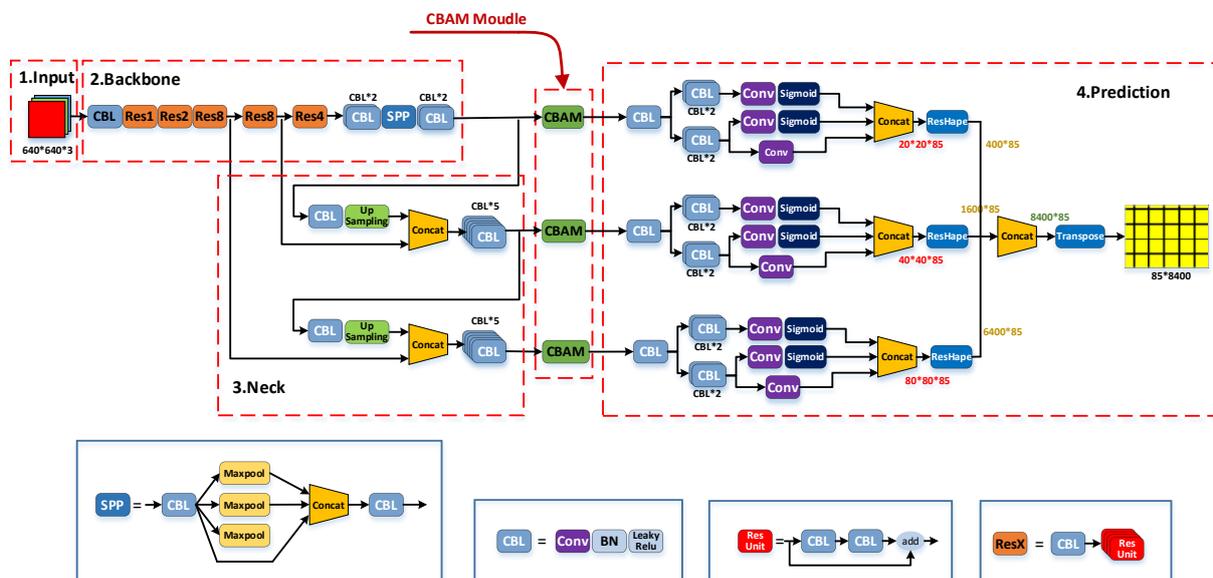

Fig. 5 - YOLOX-CBAM-EIoU network architecture

YOLOX network architecture

The YOLOX network architecture is mainly composed of four parts: the Input, the Backbone, the Neck, and the Prediction (Ge et al., 2021). In the Input stage, the image undergoes scaling, enhancement, and normalization processes to prepare it for further analysis. The Backbone utilizes CSPDarknet53 (Cross-Stage Partial Darknet53) for feature extraction, incorporating Spatial Pyramid Pooling (SPP) to effectively capture multi-scale feature information. The Neck component incorporates the Path Aggregation Network (PANet) structure, which enhances the generation of high-quality feature maps crucial for subsequent prediction tasks. In the Prediction stage, the network comprises three decoupled heads, each characterized by a unique configuration of convolutional layers and activation functions. This architecture provides a robust and efficient solution for object detection and localization across diverse scales and contexts.

CBAM attention mechanism

The CBAM is composed of a Channel Attention Module (CAM) and a Spatial Attention Module (SAM) (Woo et al., 2018). As illustrated in Fig. 6, the architecture of CBAM integrates two modules to enhance the network's representational power. Traditional convolutional neural network-based attention mechanisms primarily focus on channel-wise interactions, concentrating on the analysis of channel dimensions. In contrast, CBAM incorporates attention mechanisms in both channel and spatial dimensions, thus implementing a sequential attention structure that progresses from channel to spatial dimensions. The spatial attention mechanism enables the network to concentrate on pixel regions critical for image classification while disregarding less important areas. Simultaneously, the channel attention mechanism manages the distribution of channels within the feature maps. The synergistic combination of these two attention dimensions significantly improves the model's performance.

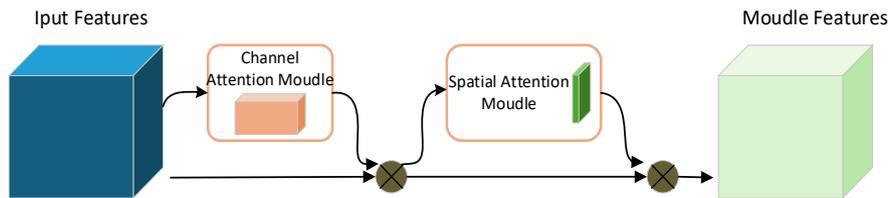

Fig. 6 - Structure of CBAM attention mechanism

EIoU loss function

In this study, the EIoU loss function (Zhang et al., 2022) was employed to replace the original IoU loss function in the YOLOX model. The definition of EIoU loss is shown in Equation (1):

$$L_{EIoU} = L_{IoU} + L_{dis} + L_{asp} = 1 - IoU + \frac{\rho^2(\mathbf{b}, \mathbf{b}^{gt})^2}{(w^c)^2 + (h^c)^2} + \frac{\rho^2(w, w^{gt})^2}{(w^c)^2} + \frac{\rho(h, h^{gt})}{(h^c)^2} \tag{1}$$

where:

\mathbf{b} and \mathbf{b}^{gt} denote the central points of anchor box and target box; $\rho^2(\cdot) = \|\mathbf{b} - \mathbf{b}^{gt}\|$ indicates the Euclidean distance; w and w^{gt} denote the weight of anchor box and target box; h and h^{gt} denote the height of anchor box and target box; w^c and h^c are the width and height of the smallest enclosing box covering the two boxes.

Evaluation indicators

In this study, the evaluation indicators for the model included Precision (P), Recall (R), F1-score, and Average Precision (AP). The formulas for these metrics are as follows:

$$P = \frac{TP}{TP + FP} \tag{2}$$

$$R = \frac{TP}{TP + FN} \tag{3}$$

$$F1 = 2 \times \frac{P \times R}{P + R} \tag{4}$$

$$AP = \int_0^1 P(R) dR \tag{5}$$

where:

P denotes accuracy; R denotes recall; FI denotes FI -score; AP denotes average precision; TP indicates the number of instances where the model correctly identifies the grain bounding box, matching the actual category label; FP denotes the number of instances where the model incorrectly identifies the grain bounding box, resulting in a mismatch with the actual category label; FN represents the instances where the model fails to detect any millet ears.

Parameter settings

The experimental equipment and configuration are shown in Table 1.

Table 1

Experimental Configuration	
Parameter	Configuration
Operating System	Windows 10
CPU	11th Gen Intel(R) Core (TM) i7-11800 H
GPU	RTX 3080 Ti
Memory	16 GB
Programming Language	Python 3.8
Development Environment	PyCharm
CUDA Driver	11.7

In the comparative experiments conducted in this study, all detection models were configured with identical hyperparameters and trained on the same dataset. Specifically, the training was conducted for 200 epochs, with a momentum of 0.9 and a weight decay regularization coefficient of 0.005. A learning rate decay strategy was adopted, with an initial learning rate set to 0.0001.

RESULTS AND ANALYSIS

Comparison of detection performance of different models

In this section, three comparative experiments were designed and conducted under identical experimental conditions to identify the millet ear detection model that yields the best performance. The details of the experimental procedures and the resulting analyses were presented below.

In the first set of comparative experiments, classical detection models including EfficientDet (*Tan et al., 2020*), YOLOv4 (*Bochkovskiy et al., 2020*), YOLOv5, and YOLOX were selected for millet ear detection. The detection results are presented in Table 2.

Table 2

Comparative experimental results of different models				
Model	Precision (%)	Recall (%)	F1 (%)	AP (%)
EfficientDet	78.11	52.04	62.46	70.50
YOLOv4	82.18	66.90	73.76	81.90
YOLOv5	83.13	62.73	71.50	81.76
YOLOX	88.07	54.95	67.68	83.86

Based on the comparison results presented in Table 2, it could be seen that the YOLOX model achieved an AP of 83.86%. Compared to the EfficientDet, YOLOv4, and YOLOv5 models, YOLOX demonstrated improvements in AP of 13.36%, 1.96%, and 2.1%, respectively. The results demonstrated the superior performance of the YOLOX model in millet ear detection tasks.

In the second set of comparative experiments, attention mechanisms including SE, BAM, NAM, and CBAM were selected to enhance the YOLOX model. These modified models were subsequently compared with the original YOLOX model to evaluate their performance improvements. The detection results are presented in Table 3.

Table 3

Results of attentional mechanism comparison experiments				
Model	Precision (%)	Recall (%)	F1 (%)	AP (%)
YOLOX	88.07	54.95	67.68	83.86

Model	Precision (%)	Recall (%)	F1 (%)	AP (%)
YOLOX-SE	81.59	79.95	80.76	85.66
YOLOX-BAM	83.79	76.24	79.84	84.63
YOLOX-NAM	84.75	75.38	79.79	85.37
YOLOX-CBAM	82.09	79.12	80.58	86.24

Based on the comparison results presented in Table 3, the introduction of CBAM significantly enhanced model performance compared to other attention mechanisms. Specifically, the YOLOX-CBAM model achieved a 12.9% improvement in the F1 and a 2.38% increase in AP relative to the baseline YOLOX model. Furthermore, in comparison to YOLOX models that incorporated SE, BAM, and NAM modules, the YOLOX-CBAM model demonstrated improvements in AP of 0.58%, 1.61%, and 0.87%, respectively. The superior performance of CBAM could be attributed to its dual-channel and spatial attention architecture, which enriched feature representations across both dimensions by integrating max pooling and average pooling. This design significantly enhanced the model's capacity to capture critical details in millet ear images. The results indicated that the integration of the CBAM attention mechanism into the YOLOX framework facilitated more accurate and reliable detection of millet ears.

In the third set of comparative experiments, the loss functions including GloU, CioU, DloU and EloU were employed to replace the IoU loss function in YOLOX. The detection results are presented in Table 4.

Table 4

Loss function comparison experiment results

Model	Precision (%)	Recall (%)	F1 (%)	AP (%)
YOLOX	88.07	54.95	67.68	83.86
YOLOX-GIoU	77.94	42.67	55.15	64.03
YOLOX-CIoU	79.93	49.52	61.15	69.43
YOLOX-DIoU	70.97	47.89	57.19	62.16
YOLOX-EIoU	92.04	56.56	70.06	86.06

Based on the comparison results presented in Table 4, the experiments demonstrated that the YOLOX-EIoU model exhibited superior performance over all other models, as evidenced by both AP and F1. Specifically, the F1 of the YOLOX-EIoU model surpassed that of the YOLOX, YOLOX-GIoU, YOLOX-CIoU, and YOLOX-DIoU models by 2.38%, 14.91%, 8.91%, and 12.87%, respectively. Additionally, the AP of the YOLOX-EIoU model surpassed that of the YOLOX, YOLOX-GIoU, YOLOX-CIoU, and YOLOX-DIoU models by 2.2%, 22.03%, 16.63%, and 23.9%, respectively. The results indicated that the EloU loss function serves as the optimal alternative to the IoU loss function in the original YOLOX model.

Ablative test performance comparison

To validate the improvement method proposed in this study, ablation experiments were conducted focusing on the CBAM and the EloU loss to assess the effectiveness of each enhancement. CBAM and EloU were sequentially integrated into the original YOLOX model while employing the same parameter configuration throughout the training process. The experimental results are presented in Table 5. The introduction of CBAM resulted in significant performance enhancement, with a 2.38% increase in AP. Furthermore, the utilization of both CBAM and EloU led to improvements in F1 and Recall, culminating in a 6.44% increase in AP. It could be concluded that the incorporation of the attention mechanism CBAM enabled the model to selectively emphasize informative features, thereby enhancing its representational capacity, as evidenced by the marked improvement in detection accuracy. Additionally, the EloU loss function enhanced sensitivity to the position and size of bounding boxes by introducing an extra penalty term, which further contributed to the improvement in detection precision.

Table 5

Results of ablation experiment

Model	Precision (%)	Recall (%)	F1 (%)	AP (%)
YOLOX	88.07	64.95	74.76	83.86
YOLOX-CBAM	82.09	79.12	80.58	86.24
YOLOX-EIoU	92.04	56.56	70.06	86.06
YOLOX-CBAM-EIoU	91.01	89.45	90.22	90.30

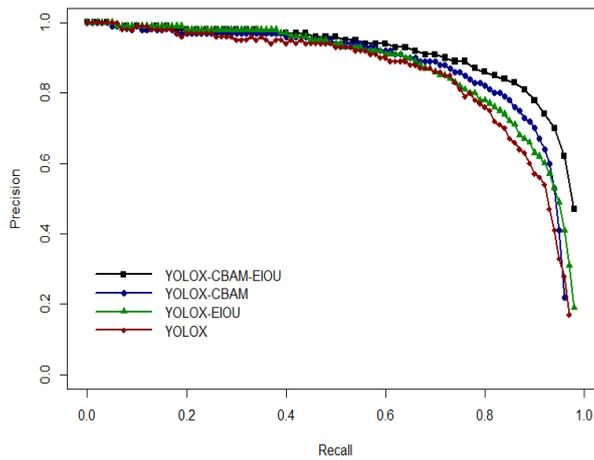

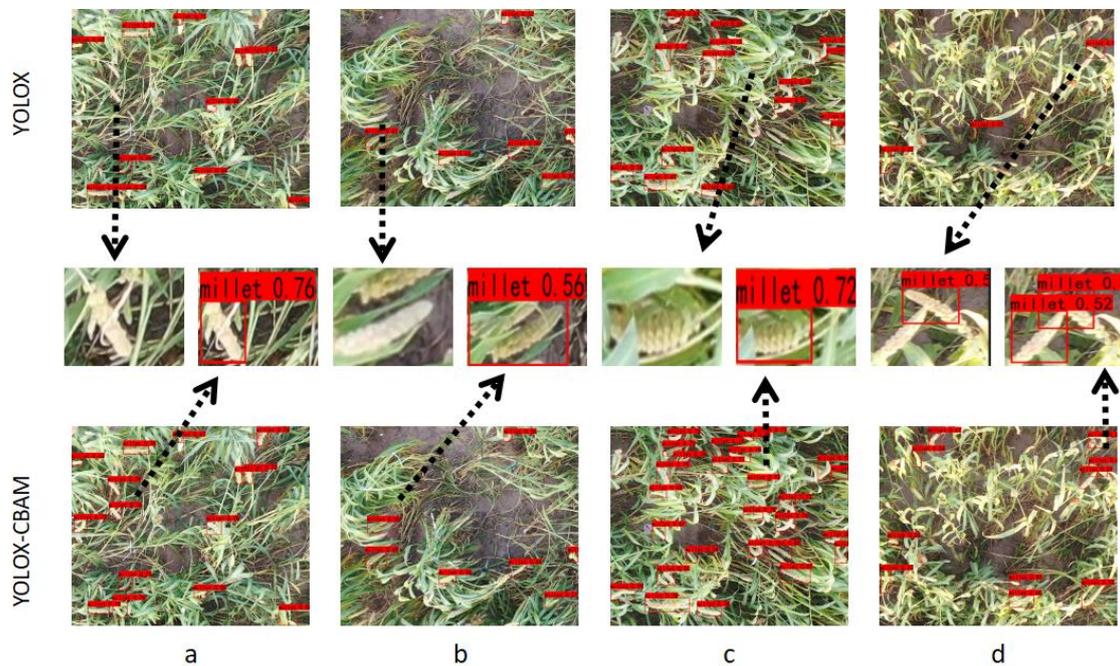

Fig. 7 - P-R curve of ablation experiment

To provide a more intuitive demonstration of the performance of the proposed YOLOX-CBAM-EIoU model, the P-R curves for the four different models mentioned in the ablation experiments were plotted, as shown in Fig. 7. In comparison to the other three models, the P-R curve of the YOLO-CBAM-EIoU model consistently lies at the top, and the area under the curve is the largest. The result indicates that the model achieves the highest AP, demonstrating superior performance in the task of millet ear detection.

Visualization analysis of detection results

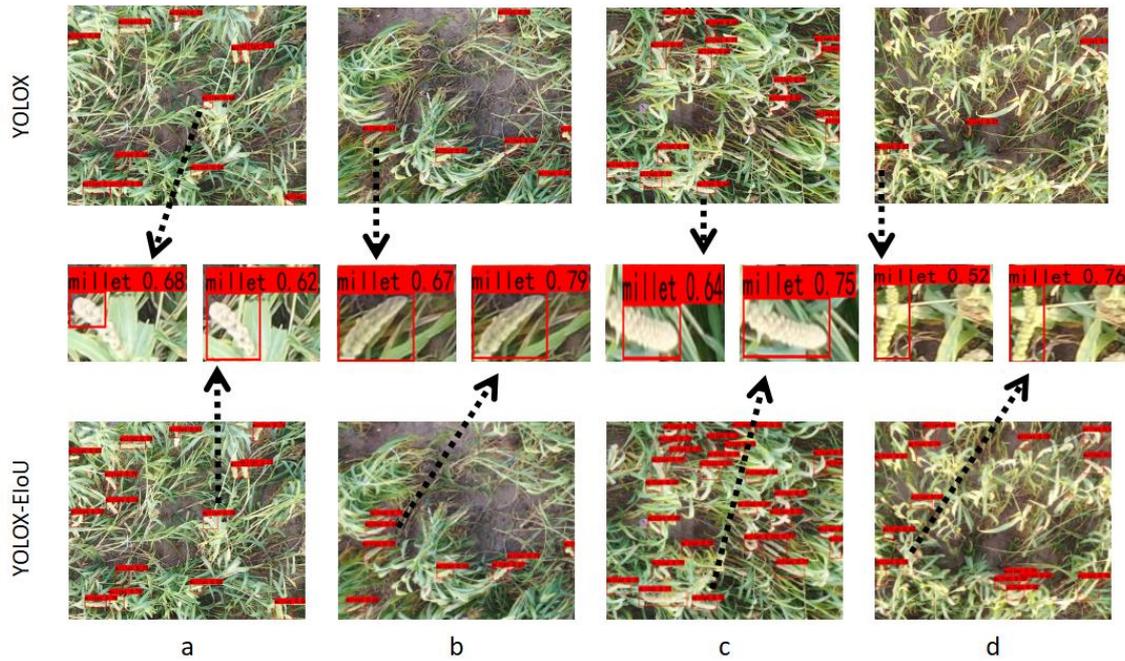

To provide a more intuitive evaluation of model performance, YOLOX, YOLOX-CBAM, YOLOX-EIoU, and YOLOX-CBAM-EIoU were tested and visually analyzed under identical experimental conditions. In the visualization results shown below, Fig. 8a and 8b represent cases where the millet ears are relatively dispersed, Fig. 8c and 8d correspond to cases where the millet ears are relatively dense and occluded. The red boxes in the figure indicate the detected millet ears.

(Note: the upper layer is YOLOX visualization result diagram; The middle layer is the enlarged image of the contrast effect; The lower layer is the YOLO-CBAM visual result chart)

Fig. 8 - Comparison of the detection performance before and after using the CBAM module

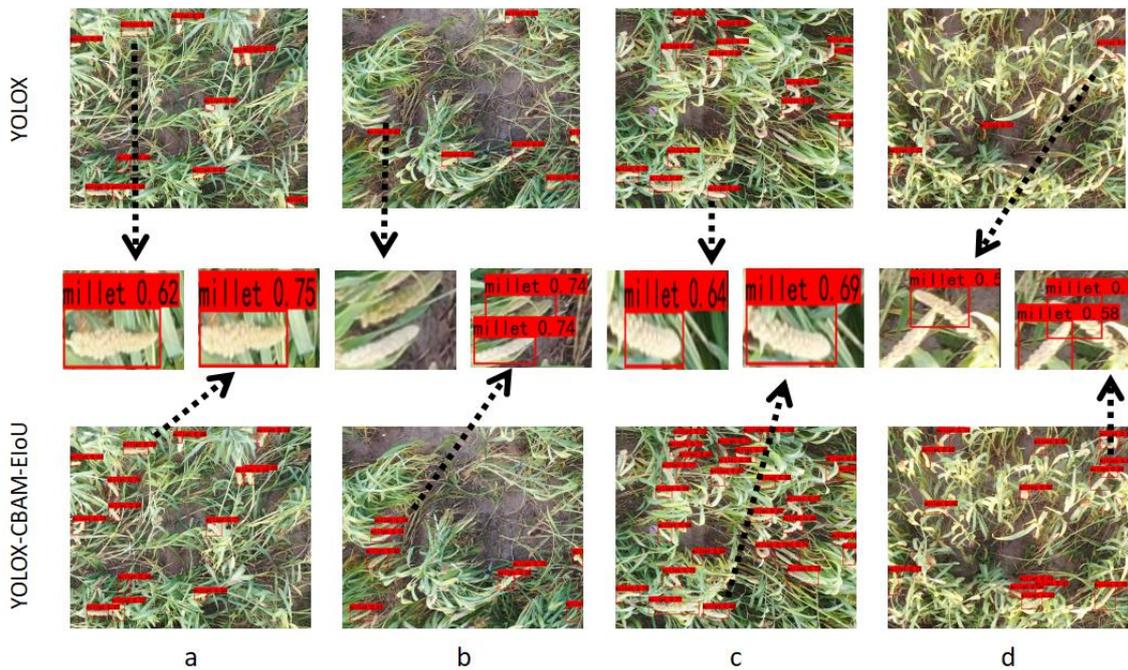

The detection results of the YOLOX-CBAM model are shown in Fig. 8. It can be observed that the millet ears in UAV images are small and subject to occlusion both among the ears and between ears and leaves. This causes considerably missed detection with the original YOLOX model. The incorporation of the CBAM attention mechanism can significantly reduce these missed detections, as evidenced in Fig. 8a and 8b. Moreover, the CBAM attention mechanism can effectively mitigate the issue of missed detection resulting from occlusion between millet leaves and ears, as shown in Fig. 8c and 8d.

(Note: the upper layer is the YOLOX visualization result diagram; The middle layer is the enlarged image of the contrast effect; Below is the YOLO-EIoU visualization result chart)

Fig. 9 - Comparison of detection performance before and after using the EIoU loss function

The detection results of the YOLOX-EIoU model are shown in Fig. 9. It can be observed that the YOLOX model exhibits instances of missing detections, along with relatively low confidence scores. Conversely, the improved YOLOX-EIoU model has fewer occurrences of missed detections, and a notable enhancement in the confidence of the predicted bounding boxes.

(Note: the upper layer is YOLOX visual result diagram; The middle layer is the enlarged image of the contrast effect; The lower layer is the YOLO-CBAM-EIoU visual result chart)

Fig. 10 - Comparison of detection performance before and after combining CBAM with EIoU

The detection results of the YOLOX-CBAM-EIoU model are shown in Fig. 10. It can be observed that our improved model can significantly reduce the occurrence of false negatives when detecting small-sized millet ear targets and partially occluded millet ear targets.

Furthermore, the discrepancy between the predicted bounding boxes and the actual bounding boxes is markedly minimized, with confidence levels achieving the highest standards among all tested models.

CONCLUSIONS

To address the current challenges in millet ear detection, such as the small size of millet ears, their dense distribution, and severe occlusion, this study proposed an improved model based on the YOLOX model. The proposed model achieved improvements of 2.94% in precision, 24.5% in recall, 15.46% in F1-score, and 6.44% in average precision. The following improvements were made in this study:

(1) CBAM attention mechanism was added to the neck of the YOLOX model to enhance its ability to extract detailed features of millet ears.

(2) The IoU loss function was replaced with the EIoU loss function. This refinement enhanced the precision of box dimensions and positions, leading to improved detection accuracy and reduced issues with low confidence and misalignment between ground truth and predicted boxes.

(3) The YOLOX-CBAM-EIoU model was proposed. Experiments demonstrated that integrating the CBAM attention mechanism with the EIoU loss function achieved the highest detection performance. The proposed improvement method could address issues observed in real-world application environments, including missed detections, false positives, significant discrepancies between ground truth and predicted boxes, as well as low confidence in detection boxes.

The experiment results demonstrate that this model could effectively solve the problem and accurately detect millet ears in the UAV image in the field environment, which provides a way for realizing intelligent management of large-scale millet planting. Furthermore, the model would be used in the planting and management of more cereal crops, and further research would be conducted on the calculation of crop density to provide a reference for the construction of intelligent farms.

Keywords: sugarcane harvester, cutting damage, vibration transmission, dynamic optimization, parametric modeling

ABSTRACT

The hilly terrain where sugarcane harvesters travel, the harvest object of rough and tough stalks, and the perennial cultivation property are all different from those of other straw crops. In order to reduce the cutting damage of cane stalks caused by complex excitation in field conditions, a method for optimizing dynamic characteristics of vibration transmission system based on implicit parametric modeling of harvester frame was proposed. First, the impact damage effect of the cutter on the cut section of stalk was analyzed by high-speed images. Accordingly, the cutter amplitude RMS and impact velocity (V_I) were proposed as parameters to characterize the damage inducibility. Subsequently, a 5-DOF dynamic model of the whole machine was established covering 21 dynamic parameters. With the measured excitation of road spectrum, cane cutting force and engine, the virtual prototype simulation showed that the frame stiffness was the most sensitive to vibration response. Through topology optimization and implicit parametric modeling of such load-bearing frame, a high-rigidity design was derived to improve the vibration transmission characteristics. Comparison of testing results before and after frame optimization illustrated that the bending stiffness and torsional stiffness were increased by 1.95% and 2.84% respectively, and the RMS of operating frequency-response functions with road and engine as path sources were decreased by 21.7% and 27.2% respectively. As a result, the output amplitude RMS and impact velocity V_I were reduced by 35.9% and 5.9% respectively, implying corresponding improvements in the cutting quality of cane stalks. This study provided a reference for the development of harvester dynamic systems based on harvesting quality optimization.

摘要

甘蔗收获机的丘陵行进地形、粗韧茎秆割收对象及其宿根种植性状与其它秸秆作物条件不同。为降低蔗地工况复杂激励所致的蔗秆切割损伤，本文提出了一种基于机架隐式参数化建模对蔗秆切割损伤进行优化的方法。首先利用高速摄像图像剖析了刀盘-茎秆互作的冲击损伤效应。据此提出了采用刀盘振幅 RMS 和冲速 (V_I) 作为诱损性表征参量。随后，基于实测路谱建立了整机 5 自由度动力学模型，解析发现机架刚度对动力响应的敏感性最大。进而筛选出可映射机架承载式结构特征的 21 个设计变量，从而建立其隐式参数化模型，并通过拓扑优化衍生出机架高刚性的优化设计。优化前后的对比测试结果表明，其弯曲、扭转刚度分别提高 1.95% 和 2.84%，以路面、发动机为路径源的传振频响函数 RMS 各降低 21.7% 和 27.2%。综合引起致损振幅 RMS 和冲速 V_I 降低了 35.9% 及 5.9%，意味着蔗秆切割质量获得相应的改进。该研究可为收获机械的动力学系统开发及收割质量优化提供参考。

INTRODUCTION

Sugarcane is a perennial crop whose post-harvest residual stumps germinate, emerge and grow up at cane nodes under suitable environmental conditions (Liu *et al.*, 2018). At present, the planting area of ratoon sugarcane accounts for more than 70% of the total sugarcane area (Yang *et al.*, 2021; Wu *et al.*, 2022), so the germination rate directly affects the yield and efficiency of the next year. Since the main sugarcane-producing regions, such as Guangxi and Yunnan Provinces, are widely distributed across the hilly areas of South China, sugarcane harvesters often operate on uneven ridge-furrow terrain. Furthermore, due to the thick and highly fibrous nature of cane stalks, harvesters typically adopt a low-position cutting method, inserting the cutter deep into the soil to improve cutting efficiency (Mo *et al.*, 2013). The above compound working conditions are obviously different from the harvesting conditions of other straw crops such as corn and cotton, and have a

significant impact and instability on the key high-speed rotary cutter (Zou *et al.*, 2018). In the coupled environment of sugarcane fields, harvesters, and sugarcane plants, the harvester experiences vertical oscillations as it moves along uneven terrain. Influenced by multiple excitation sources, the cutting tool undergoes severe vibration, which can easily lead to damage of the budding nodes on the remaining cane stumps. These cutting quality issues significantly hinder the germination of ratoon sugarcane and have become a major bottleneck limiting sustainable and efficient sugarcane cultivation cycles.

So far, from the perspective of factors contributing to stalk cutting damage, Gupta *et al.* (1992), Razavi *et al.* (2010), and Wang *et al.* (2019) have experimentally analyzed the effects of structural and operational parameters - such as disc cutter configuration, blade layout, and rotational speed - on sugarcane harvest damage. Kroes *et al.* (1995) developed a model which described the base-cutter kinematics of the dual base-cutter sugarcane harvester. By using the model, the maximum permissible velocity ratio (forward speed/disc rotational speed) was calculated, which improved the cutting quality. Silva *et al.* (2008) evaluated the sugarcane root damage degree caused by cutting height differences through experiments. Peloso *et al.* (2021) studied effects of the cutter rotating speed and the sugarcane harvester moving speed on the cutting quality of sugarcane harvesters. Li *et al.* (2017) and Ma *et al.* (2006) analyzed the role relationship of system design elements on the cracking damage rate from perspectives of blade edge angle, travel speed and embedded depth. However, the cutting action of the blade is characterized by high speed, strong intermittent, short duration and invisible contact interface, making it difficult to use visual testing methods to effectively and accurately monitor the cutting process and damage evolution. In this regard, Liu *et al.* (2007) used high-speed cameras to experimentally test the splitting caused by the smooth blade cutting, and simulated the damage behavior of sugarcane under different load forms of tension, compression, bending and torsion (Liu *et al.*, 2007). Kroes *et al.* (1996) measured and predicted the force, energy, bending strength and splitting of sugarcane stalk during impact cutting. Mello *et al.* (2001) and Momin *et al.* (2017) studied the effects of the angle and serrated blades on the damage, force and energy and verified them by indoor high-speed camera and field test. In order to intuitively reveal the dynamic relationship and local structural characteristics of their interactions. Lv *et al.* (2008) and Yang *et al.* (2017) respectively established digital models of stem-plants based on structure-function, and simulated the damage process in the cutting motion by finite element method (FEM). The factors affecting the cutting state and extrusion of the cane head, as well as their interaction on the damage process, were quantitatively studied through virtual experiments.

Based on previous studies (Zhou *et al.*, 2017; Fan *et al.*, 2012), it has been confirmed that the cutting damage of sugarcane is significantly correlated with the amplitude of cutter, and the damage degree deepens as the amplitude increases. The vibration response output of the cutter is actually related to the imbalance caused by its own manufacturing and installation errors. It also interacts with the alternating loads on the whole vehicle generated by field road spectrum, engine, cutting force and other excitation sources. It itself is closely related to the dynamic characteristics of the vibration transmission system consisting of the frame, power gearbox, hydraulic lifting device, tires and other components. The system dynamics parameters involved include component mass and stiffness, connection stiffness and damping, power mounting position, etc. Therefore, from the perspective of a multi-source and multi-component coupled system, an in-depth analysis of the dynamic characteristics of such vibration transfer system from the excitation source to the response point is conducive to establishing the influence relationship between dynamic parameters and responses (Hou *et al.*, 2021; Xu *et al.*, 2017). Thus, the insensitive factors can be eliminated, the dynamical parameters of the dominant factors can be improved, and the characteristics of components can be optimized in terms of modal, lightweight and so on. Further, on the basis of considering the dynamic response, the forward design of the whole machine is guided to achieve the purpose of improving the sugarcane cutting quality.

Regarding the problem of cutting damage caused by vibration, this paper first analyzed the characteristics of excitation sources experienced by the sugarcane harvester under working conditions, and improved the response vibration evaluation from the perspective of cutting damage mechanism. Then, a dynamic analytical model of the vibration transmission system under action of multiple vibration sources was established. On this basis, a rigid-flexible coupling virtual prototype model was established to solve the nonlinear response, and the influence and correlation of multiple dynamic parameters on the response were analyzed. After screening, implicit parametric modeling and topology optimization design were carried out on the frame. Finally, the system dynamic characteristics were experimentally tested using the frequency-response function of the frame structure and the vibration characteristics of the response target to estimate the improved degree in sugarcane cutting damage.

MATERIALS AND METHODS

Principle of sugarcane cutting damage

Analysis of excitation Sources

Observation of damage morphology

During the operation of sugarcane harvester, the high-speed rotating cutterhead is subjected to various excitation in the process of cutting and conveying sugarcane, resulting in obvious axial vibration. Through observation, this vibration effect is usually accompanied by the splitting damage effect of ratoon cane stumps, as shown in Figure 1. The main forms of damage are penetrating tears and splitting notches along longitudinal stem-nodes. It is inferred that such damage is mainly attributed to the action of squeezing impact force when the blade comes into contact with cane material. Therefore, it is necessary to trace the sources of axial vibration of the cutter from the entire harvesting machine, including the forced vibration caused by field road spectrum, the second-order unbalanced inertial force of engine, and the self-excited vibration caused by sugarcane cutting.

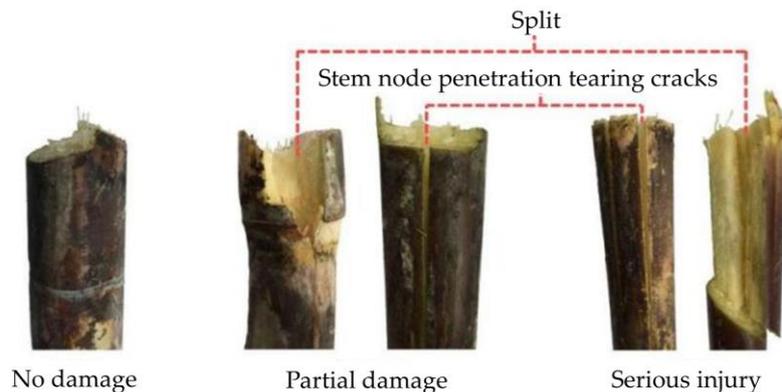

Fig. 1 - Cutting damage of sugarcane stubble

Measurement of field road spectrum

Using a portable data acquisition front end and PCB three-axis acceleration sensors, under a constant speed condition of $0.8 \text{ m}\cdot\text{s}^{-1}$, the Z-direction acceleration signal of a typical sugarcane field in the hilly area of Guangxi was collected as a road spectrum. The timing signal was then denoised through the MATLAB wavelet packet, and its amplitude-frequency curve was obtained using Fourier transform, as shown in Figure 2. It can be seen that road excitation is a low-frequency and high-amplitude displacement load, with frequencies concentrated within 10 Hz and the peak value appearing at 2.5 Hz.

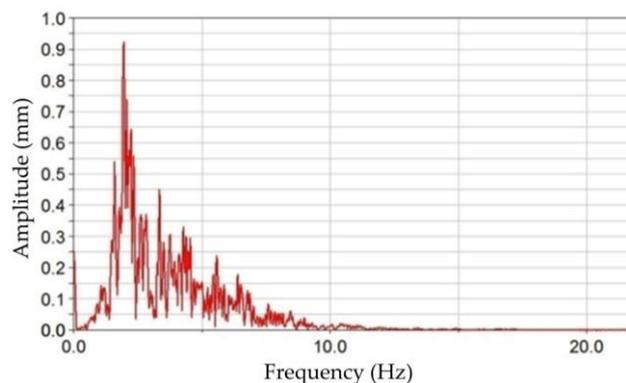

Fig. 2 - Amplitude-frequency curve of hilly field road spectrum

Calculation of engine excitation force

For the second-order reciprocating inertia force caused by the eccentricity of the engine cylinder, the calculation formula is as follows (Gu *et al.*, 2013):

$$F_{2nd} = 4 \cdot m_o \cdot r \cdot \omega^2 \left(\lambda + \frac{3}{2} \lambda^3 \psi^2 \right) \cos 2\alpha \quad (1)$$

where: m_o is the cylinder weight, kg; r is the crankshaft crank radius, m; ω is the angular velocity, rad/s; λ is the ratio of connecting rod; ψ is the eccentricity; α is the crank angle. In addition, the vertical vibration frequency of the engine follows:

$$f = \frac{Qn}{60} \tag{2}$$

where: Q is the proportional coefficient, which takes a value of 2 under the second-order inertia force; n is the engine speed, r/min.

Referring to the recorded cylinder parameters and the engine speed range of 1500~2000 rpm under working conditions (Zhou et al., 2018), it can be calculated that the excitation force from the engine is approximately 2493 N and the f is about 50~66.7 Hz.

Measurement of sugarcane cutting force

During the experimental sugarcane cutting process, a quartz three-phase dynamometer was used to collect the axial cutting force at a sampling frequency of 20 kHz. The data after using Matlab wavelet package to denoise the time-series signal is shown in Figure 3. At the same time, in order to understand the instantaneous cutting process of cane, an industrial camera was employed to focus on the cutting position of the stalk and record the frame images at four sequential cutting moments of the blade during cutting off a single cane, as shown in Fig. 4.

Based on Figure 3 and Figure 4, it can be seen that there were four equidistant peaks in the cutting force signal, indicating that the rotating blades of the cutter cut off a single cane after four repeated cuts. This was consistent with the results of high-speed photographic images. By calculating the sampling frequency and the number of sampling points, it was found that the cutting action time of single blade was extremely short, approximately 0.0023 s, and thus the cutting excitation frequency was about 434.8 Hz, which was a high-frequency self-excited vibration.

(d) Image at 2100 ms

Fig. 4 - Sequential high-speed images of repeated cuts of a single stalk

Vibration evaluation index based on sugarcane damage process

Figure 5 shows the axial vibration of the working cutterhead sampled using a laser displacement sensor. Since the periodic displacement change of the cutter affects the cutting position of the stalk, the root mean square (RMS) of the amplitude was first used as the response index. In addition, within a single cutting duration of about 0.0023 s, a positive pressure (F_N) of about 246 N (taken from the average of the peak values in Figure 3) acted on the sugarcane cross-section, so the impulse (I) generated at the instant of cutting was calculated to be about 0.57 N·s, causing the cane material to crack. Further, since there was a certain interval of about 0.013 s between two consecutive cuts, as the cutting depth gradually increased, the second to fourth cuts can produce a certain bending moment (M), causing cracks to continue to expand:

$$M = F_N \cdot \Delta s \cdot i \quad (3)$$

where Δs is the feeding depth for a single cut, which is related to the harvester driving speed; $i=2, 3, 4$.

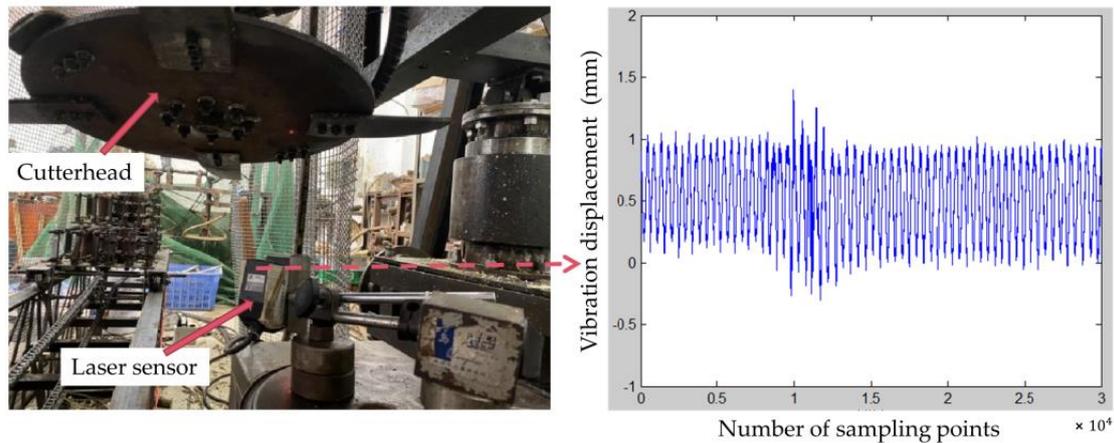

Fig. 5 – Cutter vibration signal measurement

Based on the above analysis, it can be known that the joint action of F_N , I and M lead to the damage of sugarcane nodes. Considering the spatial-temporal observation of instantaneous cutting, the single cutting time (Δt) of the blade is close to zero, and the corresponding axial relative displacement (Δu) is formed. Therefore, the impact velocity (V_I) can be defined to characterize the impact strength of the cutter on the section:

$$V_I = \lim_{\Delta t \rightarrow 0} \frac{\Delta u}{\Delta t} \quad (4)$$

In summary, based on the analysis of the damage mechanism of sugarcane cutting, the indicators of cutter amplitude *RMS* and impact velocity were proposed, thus forming a comprehensive response evaluation covering macroscopic vibration energy and local impact intensity. It was helpful to comprehensively evaluate the relationship between the cutter vibration responses and cutting damage.

Dynamic modeling of vibration transmission system

Dynamic model

The main vibration excitation devices installed on the frame include front guide wheels, rear drive wheels, cutting system and engine. Therefore, it is necessary to study the impact of the combined effects of ground roughness, engine cycle excitation force and cutting force on the dynamic characteristics of the whole machine, especially reflected in the impact on cutter vibration. The sugarcane harvester was simplified as a mass-spring-damping system (Mo et al., 2022), in which the four wheels were simplified into spring coupled damping. The dynamic theoretical model established is shown in Figure 6 (a). Based on the Z-direction sensitivity to cutting damage, this model only considered the degrees of freedom (DOF) in the three directions of vertical vibration (along the Z direction), transverse torsional vibration (around the Y-axis) and longitudinal torsional vibration (around the X-axis). Thus, the model contains 5-DOF, which are the vertical displacement of frame centroid (X_1), the rotation angle around X-axis (θ_1), the rotation angle around Y-axis (θ_2), and the vertical displacement of engine centroid (X_2) as well as the vertical displacement of cutting system (X_3).

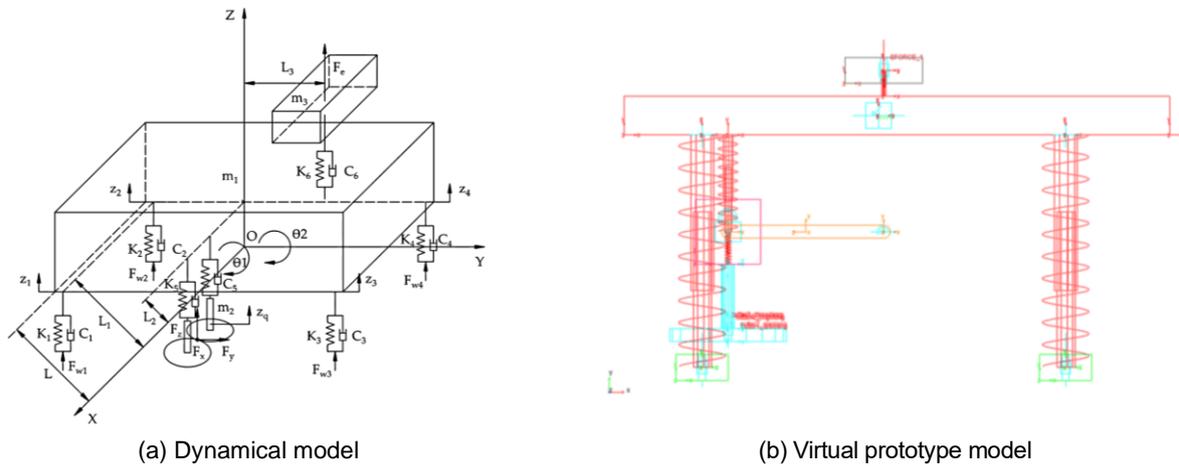

Fig. 6 - The frame model

Note: m_1 , m_2 and m_3 are masses of frame, power gearbox and engine, kg; K is stiffness, N/m; C is damping, N/(m/s); K_1 , K_2 , C_1 and C_2 are stiffness and damping of the front wheels; K_3 , K_4 , C_3 and C_4 are stiffness and damping of the rear wheels; K_5 and C_5 are stiffness and damping of the lifting hydraulic cylinder between gearbox and frame; K_6 and C_6 are stiffness and damping of the engine suspension; $F_{w1} \sim F_{w4}$ are road spectrum excitation loads on four wheels; F_e is vertical excitation force from the engine, N; F_x , F_y and F_z are respectively the radial, tangential and axial cutting force, N; L is half the length of frame, m; L_1 is the distance from front wheel or rear wheel to frame centroid, m; L_2 is the distance from gearbox to frame centroid, m; L_3 is the distance from engine to frame centroid, m; z_i is the vertical displacement of each wheel, m; z_q is the vertical displacement of cutting system, m.

Virtual prototyping simulation

Since the analytical model is a complex multi-DOF nonlinear system, the ADAMS 2020 software was used to establish a virtual prototype simulation model to solve the correlation coefficients between the above 21 dynamic parameters and the cutter vibration response (Zhang et al., 2023; Han et al., 2022). As shown in Figure 6 (b), a total of 11 components were created. The frame and engine parts were flexibly processed and then assembled with other rigid body parts, to reflect their stiffness characteristics, i.e. elastic modulus E_1 and E_2 respectively. Moreover, the required constraints, including global Y-direction translation, rotations around Z-direction and X-direction, were applied. The measured field road spectrum excitation (Fig. 2), the measured cane cutting force (Fig. 3) and the engine excitation force, modeled as a sine wave, were applied as loads to simulate real driving conditions.

Experimental testing of frame dynamic characteristics

Modal testing

The experimental bench model of the sugarcane harvester is shown in Figure 7, which includes the key operating assemblies.

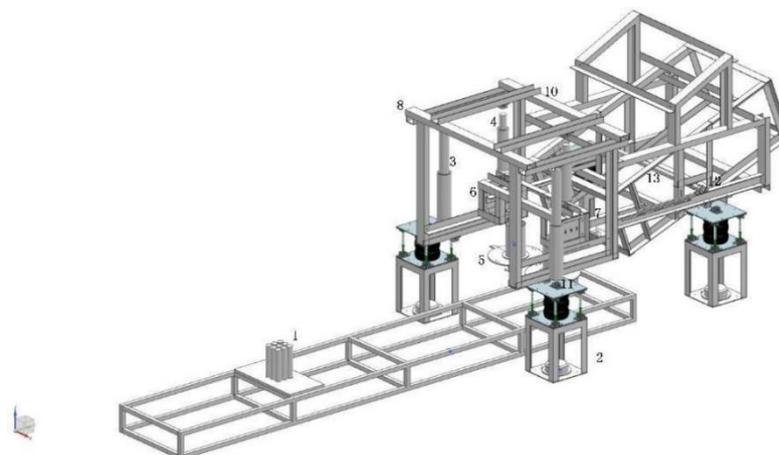

Fig. 7 - General assembly of the whole machine system

- 1- sugarcane clamping conveying device; 2- road spectrum exciter; 3- overall lifting hydraulic cylinder; 4- hydraulic cylinder for partial lifting of the cutting system; 5- cutter; 6- gearbox; 7- cantilever; 8- frame; 9- conveying rack; 10- motor for engine excitation; 11- exciter hinge; 12- logistics hinge; 13- pin shaft

The excitation devices involve mechanical road exciters, a triple-phase asynchronous motor, frequency converters and an infrared photoelectric speedometer for calibration. With these, low-frequency road excitation, engine excitation of 50 Hz and high-frequency cutting force excitation can be achieved in experiments. As the main rigid component that supports various parts of cane cutting system, the beam-structure frame bears the dynamic loads under working conditions. The purpose of modal analysis is to find the weak points of the frame under the excitation loads based on its natural vibration forms, so as to provide a reference for subsequent optimization.

The modal testing was performed using an LMS data acquisition system, PCB three-axis acceleration sensors, and an excitation hammer. With the single-point excitation and multi-point response method, the PCB sensors were arranged at 66 measuring points on the whole machine, as shown in Figure 8. In this way, constrained modal frequencies and vibration modes can thus be analyzed to search for locations of weak dynamic stiffness while avoiding frequency resonances.

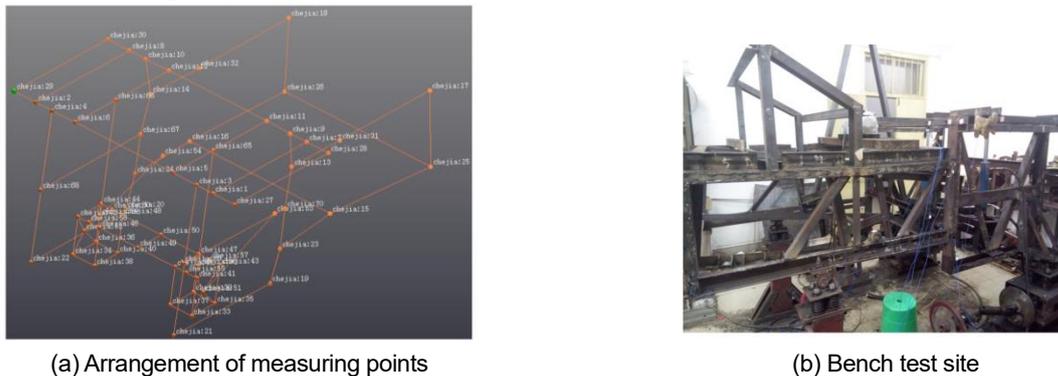

Fig. 8 - Modal Testing

Frequency-response function testing

Since the frame is the main transfer path from vibration sources to the cutter, it is necessary to test the vibration transfer function (VTF) before and after structural modifications. When the RMS of VTFs decreases and the peak frequency is far away from the excitation frequency, it means that the vibration isolation performance of the frame on the vibration transmission path is improved, and the response caused by the same excitation intensity is reduced. In addition, since the axial vibration of the cutter is most sensitive to the vertical vibration of the frame, the vertical VTF should be adopted.

With the road and engine vibration sources activated, a PCB acceleration sensor was arranged at the critical gearbox where the cutter was installed, as shown in Figure 9. Similarly, the LMS data acquisition system was employed to collect the response data of this target point of interest under multi-source vibration. Thus, the processed vertical frequency-response functions (FRF) from the two excitation sources to this response output location can be calculated as follows:

$$H(\omega) = \frac{t(\omega)}{f(\omega)} \tag{5}$$

where:

$t(\omega)$ is the frequency-related response at the target point, taking 0~100 Hz as the frequency analysis range; $f(\omega)$ is the hammer excitation force. In addition, the real time-domain signal of the cutter displacement before and after the frame optimization was also tested using the Laser vibration testing system, and its amplitude RMS was used as an indicator to verify the final optimization effect.

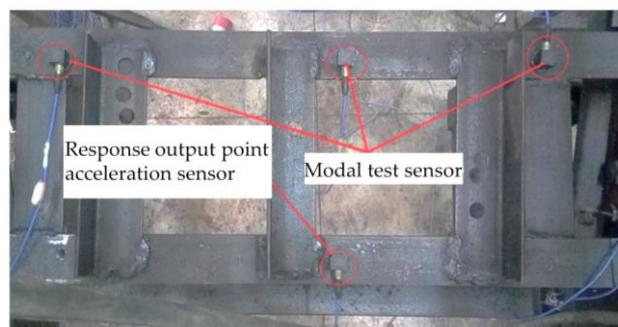

Fig. 9 - Response output signal acquisition

Optimized Design of Frame Structure

Multi-objective Topology Optimization

Considering the requirements of static Z-direction stiffness and dynamic vibration frequency, a comprehensive multi-objective optimization function combined compromise planning method with average frequency method was adopted for the frame structure (Liu et al., 2022):

$$\min F = \left\{ \omega^2 \left(\frac{C(\rho) - C_{\min}}{C_{\max} - C_{\min}} \right)^2 + (1 - \omega)^2 \left(\frac{\Lambda_{\max} - \Lambda(\rho)}{\Lambda_{\max} - \Lambda_{\min}} \right)^2 \right\}^{1/2} \tag{6}$$

where:

$C(\rho)$ and $\Lambda(\rho)$ are objective functions of flexibility and average frequency; ω is the weight of flexibility. Thus, the optimal material distribution capable of comprehensively improving stiffness and dynamic frequency can be suggested in the design domain to guide the frame shape design.

Besides, in ANSYS 14.5 software, the beam elements in the non-optimized region were set to SOLID92 and the shell elements in the optimized region were set to SHELL93. Dynamic single-step load conditions were applied simultaneously with the simple harmonic forces of the field road and the engine on the frame. Then, taking ω as 0.4, the iterative control of optimization objectives was implemented based on APDL language programming.

Implicit parametric modeling

In order to solve the problem of steel specification selection of the main load-bearing beams in the frame structure, an implicit parameter-based modeling of the frame was carried out to further obtain a better beam structure design scheme in terms of inherent dynamic characteristics (Chen et al., 2016). For the main force deformation forms of the beam, bending and torsion, its moment of inertia and polar moment of inertia depend on its cross-sectional shape and size. Hence, several stressed beams with large bending and torsion degrees were extracted based on the modal results, and their cross-sectional dimensions were used as parametric design variables (V_i). The ANSYS command flow was actually employed to create these beams to be optimized. The beam element used Beam188, which was a two-node three-dimensional linear element suitable for linear, large-angle or large-strain nonlinear analysis of slender to medium-thick short beam structures. As a result, an implicit parameterized model of the frame containing material properties, solder joints, constraints and other information was obtained, as shown in Figure 10.

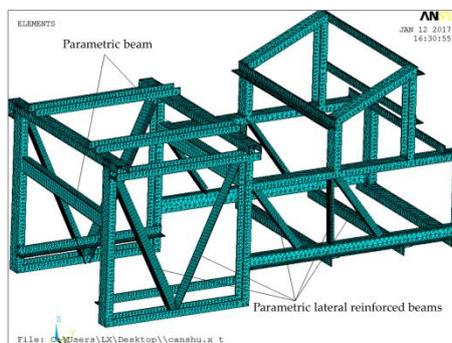

Fig. 10 – Implicit parametric model

Taking the reduction of the frame mass and moving the dangerous natural frequency out of the resonance frequency band as constraints, and aiming to increase the first to four-order natural frequencies as the goal, a mathematical model for beam section size optimization was established:

$$\begin{cases} \min F(V_i) = 1/f_{av} \\ s. t. \begin{cases} V_{i\min} \leq V_i \leq V_{i\max} \\ (50 - f_5) \cdot (66.7 - f_5) \geq 0 \\ m \leq m_o \end{cases} \end{cases} \tag{7}$$

where:

f_{av} is the low-order average frequency, Hz; V_i is the i -th design variable, $i=1,2...10$; f_5 is the 5th-order dangerous resonance frequency, Hz; m_o is the initial mass of frame, kg. Based on the conditions, a parametric optimization design was carried out using a zero-order algorithm with a maximum number of iterations of 30 (Yan et al., 2020).

RESULTS

Correlation analysis of cutter vibration

Under the joint action of road spectrum excitation, periodic excitation of engine and cane cutting pulse excitation, the simulated vibration response of the cutter is shown in Figure 11. It can be seen that the RMS of the cutter displacement response is 2.64 mm, and the RMS of the vibration velocity is 74.6 mm·s⁻¹. The average displacement during a single cutting is 0.17 mm, which can produce an impulse on the cut surface. The average displacement during the interval between two cuts is 0.97 mm, which could cause obvious bending moments to promote crack expansion.

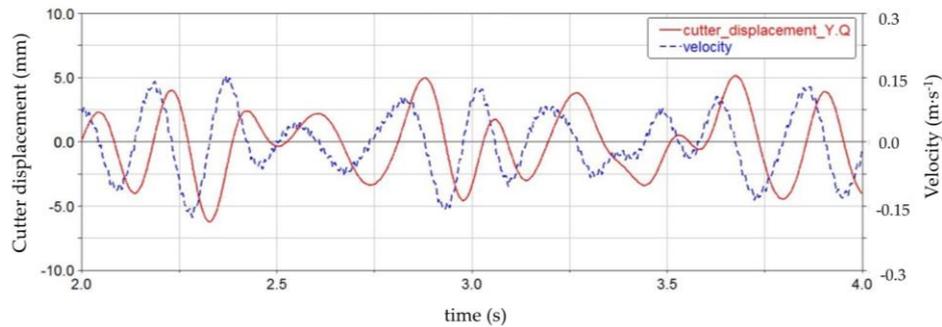

Fig. 11 - Nonlinear response of vibration

The correlation between dynamic parameters and cutter vibration was analyzed, and the results are shown in Table 1. It was found that the stiffness and mass (E_1 & m_1) of the frame had a higher impact on vibration, which was related to the fact that the frame structure accounted for the largest proportion and was the most widely distributed in the harvester. Therefore, the frame should be the main object of structural dynamics optimization where computing resources are concentrated.

Table 1

Correlation analysis results			
Dynamic parameters	Amplitude correlation	Impact velocity correlation	
m_1	-0.073	0.134	
m_2	0.022	-0.055	
K_1	0.051	-0.020	
K_3	-0.010	0.074	
K_5	-0.016	0.019	
K_6	0.009	-0.023	
L_1	0.026	-0.055	
L_2	0.006	-0.014	
L_3	-0.008	0.013	
E_1	0.168	-0.122	
E_2	0.091	-0.027	

Analysis of frame dynamic characteristics

The simulated and measured low-order frequency results below 50 Hz are shown in Table 2, and the corresponding vibration modes are shown in Figure 12. The errors between the finite element simulation results and the actual values are all less than 5%. Taking into account the errors in bench processing and assembly, it is believed that the accuracy requirements can be met. This suggests that further dynamic optimization can be carried out for the finite element model of frame. At the same time, it was found that the 5th-order natural frequency was close to the engine excitation frequency range, indicating that a dangerous resonance frequency currently existed.

Table 2

Comparison of modal results from finite element simulation and actual testing				
Order	Simulated frequency (Hz)	Tested frequency (Hz)	Description of vibration modes	
1	21.1	20.5	X-direction oscillation	
2	25.9	25.0	Z-direction oscillation	
3	40.0	38.6	X-direction first-order torsion	
4	47.6	45.3	Z-direction first-order bending	
5	53.0	51.2	X-direction second-order torsion	

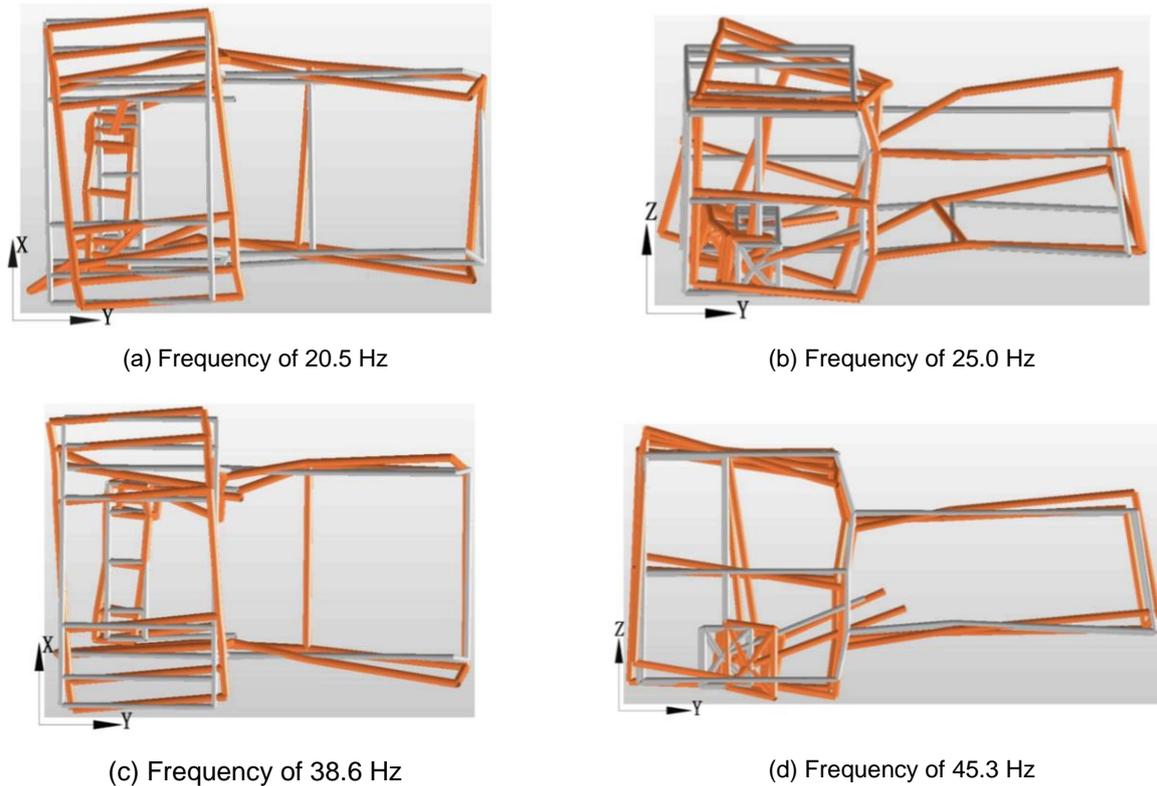

Fig. 12 - Vibration modes for modal testing

From the constrained modal results in Figure 12, the vibration modes and their frequencies were consistent with the finite element results. The combination of the four vibration modes showed that the dynamic stiffness of the frame was insufficient in the lateral and vertical directions, especially the open structure at the front end lead to severe lateral oscillations. Therefore, it was judged that the supporting structure located on the sides of the frame and the beam structures with right-angle bends were weak links and should be regarded as optimization focus.

Analysis of frame optimization

Figure 13(a) shows the density cloud diagram obtained by topology optimization of the frame under the condition of material removal rate of 50%. It has gradually evolved from the initial full-coverage plate-shell elements to a specific structural distribution composed of support beams. After extracting and simplifying the features of material-concentrated area, the reconstructed frame model is shown in Figure 13(b). The comparison results between the natural frequencies of the reconstructed model and the original values after topology optimization are shown in Table 3. The low-order frequencies have been increased by 17.91% to 86.37%, indicating that the dynamic characteristics have been further improved.

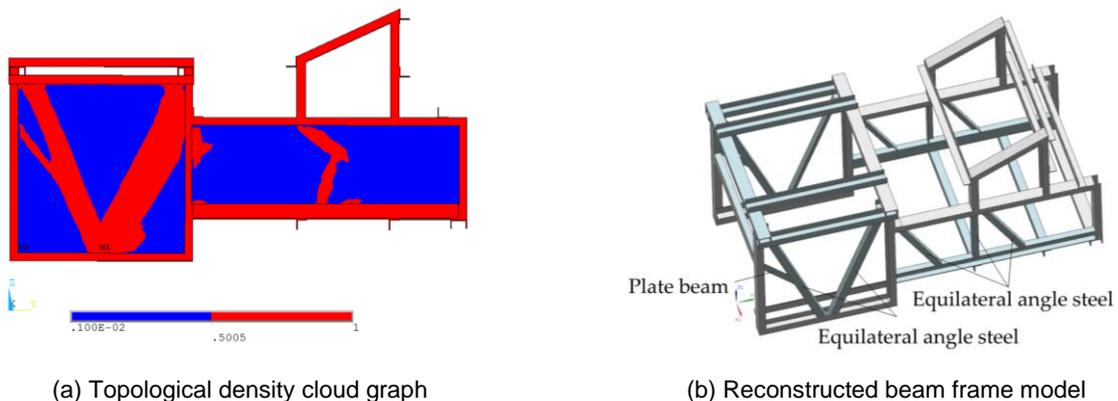

Fig. 13 - Multi-objective topology optimization results

Table 3

Comparison of natural frequencies before and after reconstruction

Natural frequency	Topology optimized	Reconstructed	Rate of change (%)
f_1 (Hz)	19.77	23.31	17.91
f_2 (Hz)	25.04	36.10	44.17
f_3 (Hz)	25.46	47.45	86.37
f_4 (Hz)	36.09	47.89	32.70

The initial values, constraints and parameter optimization results for parameterized variables and multi-objectives are shown in Table 4. Comparing the dynamic performance before and after optimization shows that without increasing the mass of the frame, the low-order frequencies of the frame were increased and the dangerous fifth-order natural frequency was moved out of the engine's resonance frequency band, achieving the expected optimization effect. Besides, the specification combination of steel dimensions for the main load-bearing beams was determined.

Table 4

Parameterized optimization results

Variables	Definition	Initial	Constraint	Optimized
V_1 (mm)	Front crossbeam channel steel width	80	50 ~120	85.3
V_2 (mm)	Front crossbeam channel steel height	43	35 ~55	48.9
V_3 (mm)	Front crossbeam channel steel thickness	5	4~6	4.3
V_4 (mm)	Middle crossbeam rectangular steel width	60	40~80	47.7
V_5 (mm)	Middle crossbeam rectangular steel height	90	70~120	70.8
V_6 (mm)	Middle crossbeam rectangular steel thickness	4	3~5	3.3
V_7 (mm)	Front side beam angle steel edge length	50	40~60	56.7
V_8 (mm)	Front side beam angle steel thickness	5	3~6	3.0
V_9 (mm)	Rear side beam angle steel edge length	40	30~50	46.2
V_{10} (mm)	Rear side beam angle steel thickness	5	3~5	3.2
m_1 (kg)	Frame mass	195.7	≤ 195.7	195.5
f_1 (Hz)	1 st -order frequency	28.5		29.2
f_2 (Hz)	2 nd -order frequency	31.1		32.7
f_3 (Hz)	3 rd -order frequency	38.9		39.2
f_4 (Hz)	4 th -order frequency	49.1		49.9
f_5 (Hz)	5 th -order frequency	58.3	≤ 50 or ≥ 66.7	66.9

Analysis of frequency-response characteristics

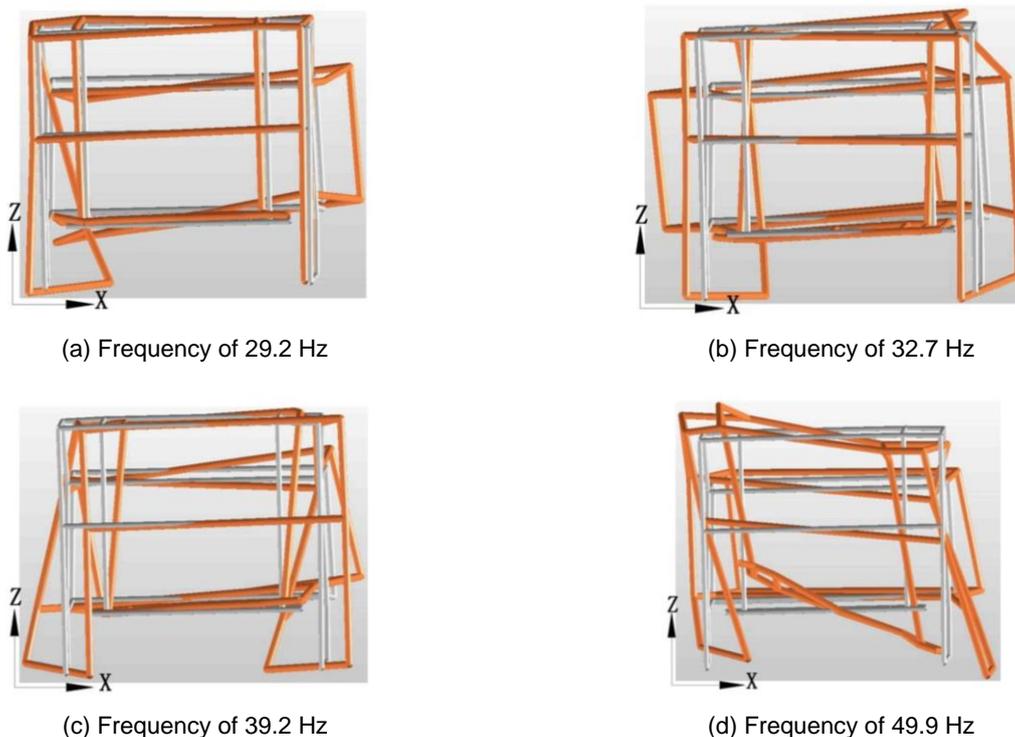

Fig. 14 - Vibration modes of optimized frame structure

It can be seen from the test results (Fig.14) that the vertical vibration mode of the optimized frame disappears, indicating that the vertical stiffness of the frame structure has been enhanced.

Figure 15 shows the vertical FRFs along different vibration transmission paths tested for the optimized frame. The frequency-response characteristics under multiple operating conditions can be extracted from it. In comparison, the response amplitude RMS ($2.3 \text{ e}^{-3}\text{g}\cdot\text{N}^{-1}$) excited by the road spectrum was larger than that ($2.2 \text{ e}^{-3}\text{g}\cdot\text{N}^{-1}$) of the engine. Among the two excitation sources, road excitation was the dominant factor. The peak value of frequency of excited by the road spectrum was close to the engine excitation frequency, which may cause dangerous resonance. The test results of the optimized frame were shown in Table 5. The response amplitude RMS excited by the road spectrum and engine were decreased by 21.7% and 27.2% respectively. In addition, the excitation frequencies that can produce significant amplitudes avoided two operating frequency ranges, i.e. 1~5 Hz for the road spectrum and 50~66.7 Hz for the engine.

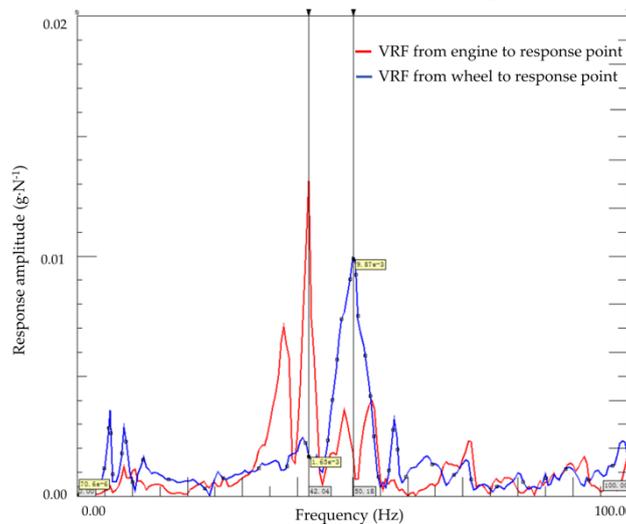

Fig. 15 - Tested frequency-response functions

Table 5 summarizes the comparison results extracted from the measured FRFs before and after frame optimization. It was found that bending and torsional stiffness of the optimized frame increased slightly, and throughout the range of 0~100 Hz, the amplitude RMS and variance values from the engine or road to the response point (P_e & P_r) were reduced to varying degrees (21.7%~46.6%), indicating that the response characteristics of these transmission paths have been improved and the system robustness has become more stable. It was comprehensively verified that the frame achieved dynamic characteristics optimization through topological and implicit parameter optimization processes. Moreover, the vertical vibration amplitude and VI output at the cutter position were ultimately reduced by 35.9% and 5.9% respectively. Based on the positive correlation between vibration response and cutting damage, the improvements of these two indicators were obviously beneficial to reducing the cutting damage level of sugarcane.

Table 5

Comparison of VRF index before and after frame optimization

FRF Index	Initial value	Optimized value	Rate of change
Bending stiffness ($\text{kN}\cdot\text{mm}^{-1}$)	11.80	12.03	1.95%
Torsional stiffness [$\text{kN}\cdot\text{m}\cdot(\text{N})^{-1}$]	11.98	12.32	2.84%
RMS of P_e ($\text{e}^{-3}\text{g}\cdot\text{N}^{-1}$)	2.2	1.6	-27.2%
Variance of P_e ($\text{e}^{-6}\text{g}^2\cdot\text{N}^{-1}$)	3.2	2.2	-31.3%
RMS of P_r ($\text{e}^{-3}\text{g}\cdot\text{N}^{-1}$)	2.3	1.8	-21.7%
Variance of P_r ($\text{e}^{-6}\text{g}^2\cdot\text{N}^{-1}$)	3.0	1.6	-46.6%
Vertical amplitude (mm)	0.64	0.41	-35.9%
V_l ($\text{mm}\cdot\text{s}^{-1}$)	101.2	95.2	-5.9%

CONCLUSIONS

(1) This paper presented a method for optimizing cutting damage of cane stalk based on implicit parametric modeling of frame. The excitation sources under the working conditions of sugarcane harvester were analyzed qualitatively and quantitatively by combining theory and experiment. Based on the analysis of the damage mechanism of sugarcane cutting, vibration amplitude and impact velocity were proposed as dynamic indicators to characterize damage inducibility.

(2) Through the constructed dynamic model and rigid-flexible coupled virtual prototype model, the parameters with the greatest influence on the nonlinear cutter response were selected from 21 dynamic parameters by correlation analysis. The results showed that the frame stiffness and mass had the greatest correlation with responses, which pointed out the target for subsequent optimization.

(3) Combined with topological and implicit parametric optimization, the dynamic characteristics of the frame were improved. Comparison of testing results before and after optimization showed that the bending and torsional stiffness were increased by 1.95% and 2.84%, and a dangerous natural frequency was moved out of the engine's operating frequency band. The RMS of FRFs with road and engine as path sources were reduced by 21.7% and 27.2% respectively, which comprehensively improved the frequency-response characteristics of such vibration system. Finally, the output amplitude RMS and impact velocity were decreased by 35.9% and 5.9% respectively, which was beneficial to reduce the level of damage to cane stalks. This study provided a reference for the development of harvester dynamic systems based on harvesting quality optimization.

Keywords: Grain combine harvester, threshing device, intelligent detection, intelligent control

ABSTRACT

This paper reviews the progress in innovative design and intelligent technology applications of threshing devices in combine harvesters for staple crops. To address the issues of poor adaptability and low intelligence in traditional threshing systems, researchers have significantly improved threshing performance by optimizing threshing components and drum structures. Meanwhile, machine vision and deep learning have achieved important breakthroughs in feed rate monitoring, breakage and impurity rate detection, and intelligent control. This review aims to provide a reference for research and applications in threshing system structural optimization and operational parameter control.

摘要

本文综述了主粮作物联合收获机脱粒装置的创新设计与智能化技术应用进展。针对传统脱粒装置适应性差和智能化程度低的问题，研究者通过优化脱粒元件和滚筒结构显著提升了脱粒性能。同时，机器视觉和深度学习在进料速度监测、破碎率与含杂率检测及智能控制方面取得了重要突破。综述旨在为脱粒系统结构优化、作业参数控制等研究与应用提供参考。

INTRODUCTION

With the rapid growth of the population and the increasing demand for food, food security plays a crucial role in economic and social development. Achieving efficient and low-loss mechanized harvesting is a key approach to increasing grain yield (Shahbazi et al., 2025). The combine harvester is a large-scale harvesting machine that integrates multiple functions (Fu et al., 2018; Ni et al., 2021; Yin et al., 2024), including cutting, threshing, and cleaning. While ensuring operator comfort (Marin et al., 2024; Vlăduț et al., 2023), the performance of the threshing system directly determines the quality and efficiency of grain crop harvesting. With the gradual application of emerging technologies such as sensor technology and automatic control in agricultural machinery for navigation (Xie et al., 2023; Yao et al., 2024), path planning (Chen et al., 2024), and operation quality monitoring (Guo et al., 2025), there is significant potential for the innovative design and intelligent upgrading of combine harvester threshing devices. These advancements lay the foundation for achieving clean, low-loss, and highly efficient intelligent harvesting with combine harvesters (Mandal et al., 2024).

The threshing system of a combine harvester primarily consists of a threshing drum, concave, transmission, and adjustment mechanisms (Miu et al., 2008b, 2008a). By adjusting operational parameters such as drum speed and feed rate, optimal threshing quality can be achieved (Vlăduț et al., 2023). Based on the different conveying directions of crops within the drum, various structural forms of threshing devices have been developed, including tangential threshing devices (Hussain et al., 2024), axial threshing devices (Srison et al., 2016; Vlăduț et al., 2022), and hybrid tangential-axial threshing devices (Chai et al., 2020).

Currently, threshing systems meet the requirements for harvesting various staple crops; however, challenges remain, including high grain breakage rates, high impurity and loss rates, and a lack of precise control (Guo *et al.*, 2019). In particular, under challenging harvesting conditions such as high humidity, threshing devices are prone to clogging and entanglement (Tang *et al.*, 2019). In terms of operational parameter and quality monitoring, installing quality detection sensors on key working components (Liu *et al.*, 2025) has enabled the monitoring of breakage rates and loss rates (Chen *et al.*, 2024).

However, due to environmental interferences such as vibration, dust, high humidity, and high temperatures, sensors often suffer from low real-time performance, stability, and accuracy (Li *et al.*, 2024; Liu *et al.*, 2024). Additionally, the lack of standardized communication protocols among various sensors and actuators leads to difficulties in integrating, sharing, and monitoring multi-source heterogeneous data (Qiu *et al.*, 2022). Furthermore, although machine learning- and deep learning-based operation quality detection methods (Hasan *et al.*, 2023) have achieved significant advancements, challenges remain in acquiring large-scale datasets, manual data annotation, and the high cost of training data (Ahmed *et al.*, 2025).

In terms of intelligent control strategies and algorithms, a state-space model of the threshing system has been established, and expert systems based on empirical rules have been integrated into the control module (Omid *et al.*, 2010). Additionally, associative models such as neural networks have been introduced to capture nonlinear relationships, while methods like fuzzy control (Craessaerts *et al.*, 2010) and adaptive regulation strategies (Zhu *et al.*, 2025) have been employed to achieve dynamic adjustment of operational parameters. However, due to limitations in sensor detection accuracy, the generalizability of algorithm models, and insufficient machine-wide coordination, modeling the complex, dynamic, and nonlinear relationships between operational parameters and crop attributes over time remains challenging. As a result, real-time responsiveness is poor, and the threshing control system lacks deep adaptive capabilities and multi-parameter decoupling (Zhang *et al.*, 2022a).

In summary, due to the variations in planting patterns and harvesting environments of different staple crops, existing data acquisition and information fusion methods still face challenges related to models and algorithms in practical applications. These issues significantly hinder the real-time control capability of threshing systems in adjusting operational parameters. Given this context, this study systematically reviews recent research progress in the structural design, operational performance optimization, and integration of intelligent technologies in combine harvester threshing devices for staple crops. Furthermore, potential future research directions and development trends are explored to provide insights and references for the continuous innovation and practical application of threshing devices.

INNOVATIVE DESIGN OF THRESHING DEVICE STRUCTURE

The primary operating targets of staple crop combine harvesters include maize, soybeans, and cereals (wheat and rice), necessitating the design of threshing devices tailored to the specific properties of different crops. Therefore, in the structural innovation of threshing devices, key operational components should be interchangeable and adjustable to accommodate various crop characteristics. Additionally, the combined application of multiple threshing structures, the flexibility of critical components, and lightweight design are fundamental principles in the innovative structural design of threshing devices (Dong *et al.*, 2023; Zhao *et al.*, 2023).

Corn Threshing Devices

For maize crops, the maize ear has a large volume, hard kernels, high adhesion strength between kernels and the cob, and a high moisture content. Therefore, maize grain harvesting requires a threshing system with sufficient throughput and high processing efficiency. To ensure low breakage while maintaining effective threshing, high-intensity impact or rubbing mechanisms are commonly employed (Qian *et al.*, 2017; Steponavičius *et al.*, 2023). By adjusting the threshing drum diameter, various variable-diameter and variable-speed threshing drum designs have been developed. For instance, Wang *et al.*, (2021), designed a conical variable-diameter threshing drum (Figure1), which enhances the ear-holding capacity in the threshing section, loosens the interaction forces between kernels and between kernels and the cob, and enables efficient threshing and conveying of maize ears with different diameters.

Traditional concaves in maize combine harvesters are typically designed with a fixed radius and are mostly rectangular or arcuate in shape, making it difficult to meet the diverse harvesting requirements of different crops and moisture levels. To address this limitation, Pužauskas *et al.*, (2017), proposed the concept of "inclined beam and variable-radius concaves" and found that when the working surface of the inclined beam was set at 45°, maize kernel separation efficiency, breakage rate, and threshing losses were optimized. By innovating the operational mechanism of threshing drums and the structural design of threshing components,

Hou et al., (2023), developed a novel low-damage, high-efficiency threshing drum. Additionally, Tang et al., (2024), designed a low-loss threshing device equipped with a "rotatable concave sieve" (Figure 2), in which the concave rotates in the opposite direction to the drum, significantly increasing the residence time of maize ears in the threshing space. The concave is designed as an adjustable structure, enabling high threshing efficiency without the need for a substantial increase in drum speed, while simultaneously reducing mechanical damage to the kernels.

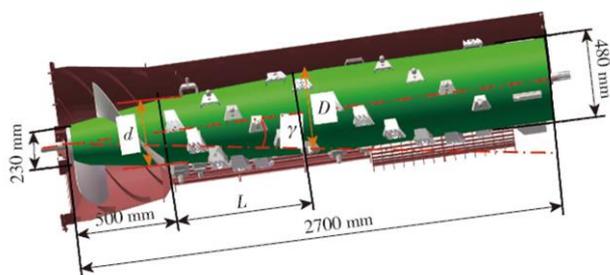

Fig. 1 - Variable diameter threshing drums (Wang et al., 2021)

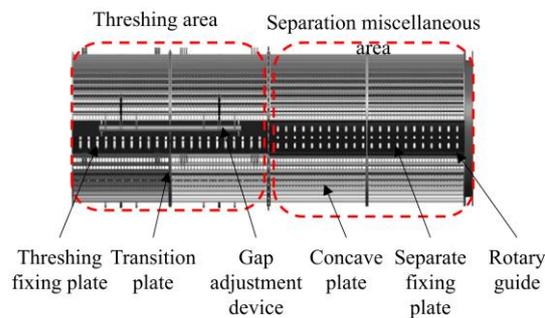

Fig. 2 - Schematic of rotary concave screen (Tang et al., 2024)

Traditional threshing devices typically employ rigid spike-tooth or short rasp-bar threshing elements, which often result in either "high impact and high breakage" or "insufficient threshing." Consequently, the concept of flexible threshing elements has been introduced. For instance, Li et al., (2020), found that rubber composite spike-tooth elements significantly improved the threshing performance of high-moisture maize ears. Similarly, Chen et al., (2020), demonstrated that a combination of "flexible spike-tooth and dual-torsion spring-loaded short rasp bars" effectively reduced impact damage to kernels. Building on these findings, Song et al., (2022), proposed a flexible threshing device featuring "front-end flexible spike-tooth elements and rear-end elastic short rasp bars with pressure springs" (Figure 3). This design balances maize ear grasping, helical conveying at the front end, and flexible impact and rubbing-based threshing at the rear end, thereby minimizing kernel damage.

For high-moisture maize threshing, Li et al., (2023), introduced a flexible threshing element composed of variable-stiffness conical springs and impact tooth bars, which can appropriately rebound or yield upon contact with maize ears. Similarly, Li et al., (2023), designed a novel threshing drum incorporating a combination of rasp bars, separation rods, and impurity-removal bars. Compared to conventional spike-tooth drums, the increased contact area between the rasp bars and kernels reduces impact and clamping-induced breakage, particularly under high-moisture conditions.

Additionally, Gong et al., (2024), drew inspiration from torsion spring structures to develop a variable-stiffness maize flexible threshing element composed of conical springs and short rasp bars. Furthermore, Xing et al., (2024), designed a threshing element with helically arranged rasp-bar blocks installed in the threshing section (Figure 4). The improvements in threshing elements mainly focus on the alternating arrangement of different threshing components or the adoption of novel flexible threshing elements to minimize maize kernel breakage.

Fig. 4 - Spirally arranged rasp bar threshing elements (Xing et al., 2024)

In summary, through concave adjustment, flexible improvements in threshing elements, and optimization of variable-diameter drum structures in maize threshing devices, the contradiction between incomplete threshing and high kernel breakage rates can be effectively mitigated. These advancements enhance the adaptability of threshing devices to varying feed rates and moisture conditions, thereby improving overall threshing efficiency and grain quality.

Grain threshing devices

For cereal threshing, the adhesion force between the grain and the husk (or pod) is relatively low, the grain size is small, and the moisture content is lower. Additionally, cereal crop stems are relatively thin and brittle. As a result, threshing elements in cereal harvesters predominantly utilize arc-tooth and spike-tooth structures to achieve threshing through friction and rubbing (Abdeen et al., 2021; Hu et al., 2024). For example, the application of a rigid-flexible coupled arc-tooth design has been shown to reduce stem clogging and decrease grain breakage rates.

For concave adjustment, the perforation design must ensure high screening efficiency, typically utilizing hydraulic or electronically controlled adjustment mechanisms (Su et al., 2020). For instance, Yuan et al., (2024), adopted a rod-tooth threshing drum (Figure 5) combined with an adjustable concave clearance design, demonstrating excellent adaptability to uneven wheat feeding and moist crops.

Based on the segmented axial-flow threshing and separation device for rice and wheat, Kang et al., (2022), designed a symmetrically adjustable concave, allowing for dual-sided threshing gap adjustments to enhance threshing performance across varying moisture conditions. Furthermore, Kang et al., (2025), developed an independently adjustable concave system comprising long concave sieves, short concave sieves, electric cylinders, and a control system. This system modifies the internal rubbing intensity of the material, thereby improving threshing efficiency.

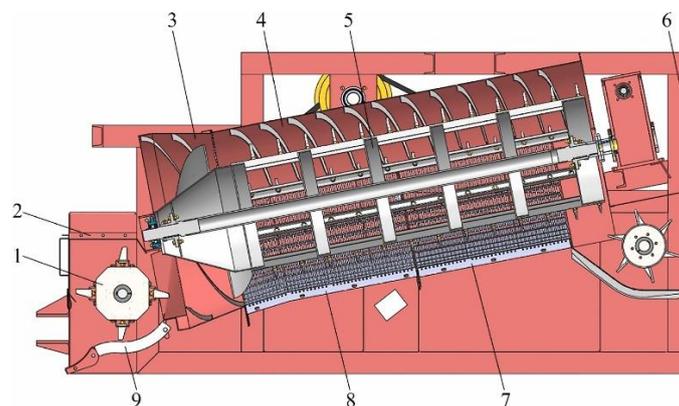

Fig. 5 - Tangential and longitudinal-axial threshing and separating unit (Yuan et al., 2024)

1. Tangential drum; 2. Tangential cover; 3. Conical cylinder; 4. Longitudinal axial cover; 5. Axial-flow drum;
6. Frame; 7. Rear axial concave; 8. Front axial concave; 9. Tangential concave

For the optimization of threshing drum structures, the primary approach involves using variable-diameter and variable-speed threshing drums to address the adaptability limitations of fixed-diameter drums in the threshing and separation zones. Typically, the threshing zone adopts a larger diameter, while the separation zone utilizes a smaller diameter conical drum. For instance, Abdeen et al., (2025), evaluated and optimized the performance of a longitudinal axial-flow threshing device using a conical threshing drum. Similarly, Zhang et al., (2022b), designed an axial threshing and separation device incorporating a front-end rasp bar and a rear-end spike-tooth structure, demonstrating that the combination of rasp bars and spike teeth meets the operational requirements for both threshing and separation.

Additionally, differential-speed threshing drums can be designed to enhance crop feed rate adaptability. Examples include a segmented threshing drum with an adjustable rotational speed difference between the front and rear sections (Kang et al., 2023) (Figure 6) and a coaxial differential-speed threshing drum with a spiral plate-tooth axial threshing system (Zhou et al., 2022). Furthermore, Wang et al., (2022), developed a combination threshing device with independently rotating inner and outer drums, effectively reducing grain breakage during threshing. For rice threshing, Liu et al., (2022), Wang et al., (2023), designed a variable-diameter rice threshing drum (Figure 7), which improves adaptability to varying feed rates and effectively reduces stem clogging issues.

In summary, the innovative design of cereal threshing devices enhances crop throughput capacity through concave adjustments, reduces grain breakage by incorporating flexible threshing elements, and improves multi-crop adaptability with variable-diameter and variable-speed drum designs. These advancements provide a critical foundation for enhancing the threshing performance and intelligent control of combine harvesters, offering significant engineering application value.

INTELLIGENT TECHNOLOGY FOR THRESHING SYSTEMS

The primary objective of the intelligent technology applied to threshing and separation in combine harvesters is to enhance threshing efficiency, reduce loss and breakage rates, and ensure optimal operational quality across different crops and field conditions. This paper reviews research progress in key areas, including feed rate detection, breakage and impurity content monitoring, entrainment loss detection, and intelligent control. It explores the application of machine vision technology, deep learning models, and intelligent optimization algorithms in threshing systems, providing a reference for the integration of intelligent perception, decision-making, and control in threshing system operations.

Intelligent feed rate detection

In traditional combine harvesters, the grain feed rate is typically estimated based on the forward speed and cutting width, which results in low accuracy since the feed rate is influenced by multiple factors, including crop density, header height, cutting width, grain moisture content, and forward speed (Zhang et al., 2018). In recent years, with the application of sensor technology and deep learning in data detection, significant advancements have been made in grain feed rate detection technology. Furthermore, multi-sensor data fusion techniques have further improved detection accuracy.

Mechanical sensor detection technology

Mechanical sensor detection technology estimates the feed rate based on pressure variations as grain material passes through the auger, feeder house, and threshing drum. Typically, pressure sensors are installed on the feeder house bottom plate, while torque sensors are mounted on the auger drive shaft, concave, and drum bearings to measure pressure and torque fluctuations during harvesting. By integrating these measurements with the power consumption and operating speed of the threshing system, the feed rate can be calculated.

For instance, *Liang et al., (2013)*, developed an online monitoring system for feed rate estimation based on drum torque, rotational speed, grain flow, and the straw-to-grain ratio. However, the system exhibited a certain degree of data latency. To investigate the relationship between feed rate and header torque, *Zhang Z. et al., (2019)*, designed a feed rate monitoring system based on the torque of the header drive shaft, revealing a strong correlation between header torque and feed rate. *Abdeen et al., (2022)*, constructed a longitudinal axial-flow rice threshing platform and designed a threshing drum cover stress monitoring system using force-sensitive resistors. Their results showed that the force signals collected by the thin-film sensors were significantly correlated with drum rotational speed and feed rate. Additionally, by installing vibration acceleration sensors at the bottom of the inclined conveyor (Figure 8), *Liang et al., (2024)*, investigated the impact of feed rate on the vibration characteristics of the combine harvester's inclined conveyor.

Fig. 8 - Installation positions of the vibration acceleration sensor (*Abdeen et al., 2022*)
 (a) Position of the inclined conveyor in the combine harvester; (b) Sensor placement on the inclined conveyor

With the advancement of multi-sensor fusion technology, the integration of multiple parameters—such as header torque, inclined conveyor torque, and crop properties—has significantly improved the accuracy of feed rate detection. *Zhang et al., (2022)*, proposed a feed rate detection method based on multi-sensor decision-level fusion (Figure 9) and developed a feed rate monitoring system for grain combine harvesters. Their study analyzed the correlation between operating speed, crop density, auger torque, conveyor torque, and cylinder torque with feed rate. The results demonstrated that the proposed detection system exhibited high monitoring accuracy and stability.

To further enhance detection precision, *Sun et al., (2022)*, developed a neural network-based feed rate detection method by incorporating multiple parameters, including header drive shaft torque, header height, and grain moisture content. Among these approaches, torque and pressure measurements provide more direct and precise assessments. However, due to the distance between measurement points and the header, these methods exhibit a certain degree of data latency.

To address this issue, a feed rate monitoring system based on the reel force at the header position was developed (Figure 10). This system utilizes force sensors and angle sensors to detect variations in forward speed, reel rotational speed, header height, and plant bending force, enabling an accurate estimation of the combine harvester's feed rate (*Chen et al., 2025*).

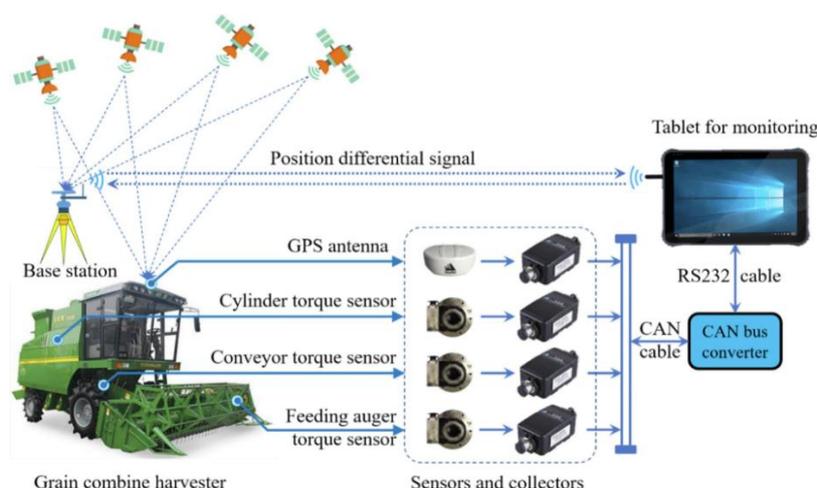

Fig. 9 - Multi-sensor fusion-based crop feed rate detection method (*Zhang et al., 2022*)

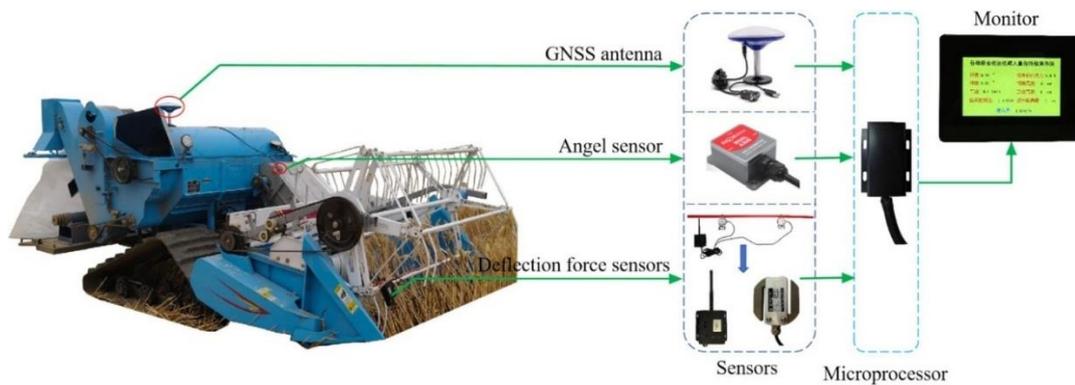

Fig. 10 - Design of the feed rate monitoring system (Chen *et al.*, 2025)

Intelligent detection technology

In addition to estimating feed rate based on material pressure measurements during harvesting, advanced intelligent detection technologies such as machine vision and LiDAR can be used for crop perception, enabling crop information collection and prediction. These technologies can estimate crop density and height, thereby indirectly predicting the relationship between crop feed rate and threshing performance.

The measurement principle of a LiDAR system is based on the constant speed of light to calculate the distance between the collision point and the emitted pulse (Rivera *et al.*, 2023). This allows for the determination of target object distance and depth, generating high-precision 3D point cloud data. Studies have shown that two LiDAR sensors can be used for real-time measurement of wheat crop density before harvesting with a combine harvester (Saeys *et al.*, 2009), as well as for analyzing the effects of LiDAR installation angle and height on crop height and density detection (Blanquart *et al.*, 2020).

To enhance LiDAR detection range and efficiency, LiDAR and spectral sensors can be mounted on unmanned aerial vehicles (Liu *et al.*, 2024), allowing for the integration of different data sources to develop a maize canopy height detection method. UAV-mounted spectral sensors offer the advantage of high-speed and efficient crop density detection; however, challenges remain, including high costs, blind spots in small target detection, and susceptibility to adverse environmental factors such as lighting conditions and dust.

With the continuous advancements in machine vision and deep learning technologies, deep learning is not only used for in-field crop and weed density detection (Adhinata *et al.*, 2024) but also for crop density assessment during the harvesting period. By equipping harvesters with machine vision technology, crop height and density data can be collected. Additionally, attention mechanisms can be introduced to optimize the backbone structure of neural networks, allowing for image segmentation and object detection of crops. This data, combined with field area measurements, can be used to estimate crop density. Zhang *et al.*, (2024), proposed a wheat crop density detection method based on an improved YOLOv5s model (Figure 11), which estimates the height of individual stubble-free wheat plants. Similarly, Sun *et al.*, (2024), developed a real-time rice panicle density detection method based on YOLOv5n (Figure 12). By applying coordinate transformation, this approach matches actual crop size with pixel area to calculate rice panicle density, thereby enhancing the harvester's crop state perception capabilities. Machine vision-based crop feed detection offers high accuracy and real-time performance; however, challenges remain, including the high computational cost of deep learning models, difficulties in field deployment, and the requirement for large-scale dataset training.

(a) acquisition location; (b) sample

In summary, using mechanical sensors for indirect feed rate detection can provide insights into the material flow status within the harvester to a certain extent. However, the collected data lacks predictive capability, requires longer processing times, and is insufficient for providing real-time parameter adjustments for threshing operations. The integration of machine vision-based crop height and density detection methods with YOLO object detection models has proven effective in improving crop feed detection accuracy. Therefore, for crop feed rate detection, a multi-sensor fusion approach incorporating mechanical sensors, machine vision, and LiDAR can enhance environmental adaptability. Additionally, adopting lightweight neural network models combined with transfer learning techniques can reduce reliance on large-scale datasets, improve detection speed, and enhance model generalization capabilities.

Intelligent detection of breakage rate and impurity content

Traditional grain detection methods primarily rely on manual inspection, which is characterized by low efficiency, high error rates, and poor real-time performance. Machine vision and deep learning technologies, with their advantages of non-contact detection, high efficiency, and precise image recognition, provide new approaches for detecting grain breakage rate and impurity content. Machine vision analyzes grain morphological features based on image processing techniques, while deep learning, leveraging the powerful feature extraction capabilities of convolutional neural networks (CNN), integrates object detection, image segmentation, and classification regression methods. These approaches have demonstrated significant superiority in breakage rate and impurity content detection.

Machine vision-based intelligent detection

Machine vision-based grain breakage rate detection primarily relies on morphological, color, and texture feature extraction, as well as spectral imaging analysis, to distinguish between intact and broken grains. In terms of color feature extraction, image processing and feature extraction techniques have been used to calculate the impurity rate of maize kernels, cobs, and husks (Liu *et al.*, 2022). Similarly, Momin *et al.*, (2017), performed image segmentation and detection to identify different types of split soybeans, contaminated beans, defective beans, and stems/pods, achieving an identification accuracy of 96% for split beans, 75% for contaminated beans, and 98% for defective beans and stems/pods. Figure 13 illustrates the image processing workflow for grain and impurities in harvested soybeans.

To improve real-time breakage and impurity detection, Jin *et al.*, (2020), proposed an online rice breakage rate detection system for combine harvesters based on machine vision. This system identifies broken and intact grains by extracting the chromaticity of kernel images in the color space. Similarly, Chen *et al.*, (2021), developed a soybean image acquisition system based on machine vision, achieving a precision rate of 86.45% for breakage rate detection and 85.19% for impurity detection.

Regarding spectral imaging analysis, multi-spectral vision sensors have been employed to obtain spectral bands of pure maize kernels, husks, and straw based on pixel proportions (Wallays *et al.*, 2009). Additionally, by extracting impurity images and spectral features of wheat at different terahertz frequencies, a CNN classification model was developed to process and classify the imaging data, leading to the construction of the V2 CNN wheat image detection model (Shen *et al.*, 2021).

Fig. 13 - Image processing process of soybean harvested seeds with impurities (Momin *et al.*, 2017)

Machine vision-based impurity content detection primarily relies on object detection and classification, combined with hyperspectral imaging technology. By utilizing differences in reflectance between grains and impurities across the hyperspectral range, grain impurity detection can be effectively achieved. For instance, Liu *et al.*, (2023), introduced a standardized attention mechanism and employed the NAM-EfficientNetV2 network as the grain feature extraction structure. They applied fully convolutional pixel segmentation techniques to segment rice grains and impurities. Similarly, Zhang *et al.*, (2024), proposed a wheat breakage rate and impurity rate detection method based on the DeepLab-EDA semantic segmentation model and developed a wheat quality image acquisition system (Figure 14). The DeepLab-EDA model achieved mean intersection over union (MIoU), mean precision (MP), and mean recall (MR) values of 89.41%, 95.97%, and 94.83%, respectively, demonstrating a significant improvement in the accuracy of grain breakage and impurity segmentation.

Additionally, Chen *et al.*, (2025), integrated hyperspectral imaging with a random forest (RF) model to achieve rapid and accurate classification of soybean components. The RF classification model achieved optimal prediction accuracy during training, demonstrating its effectiveness in hyperspectral-based impurity detection.

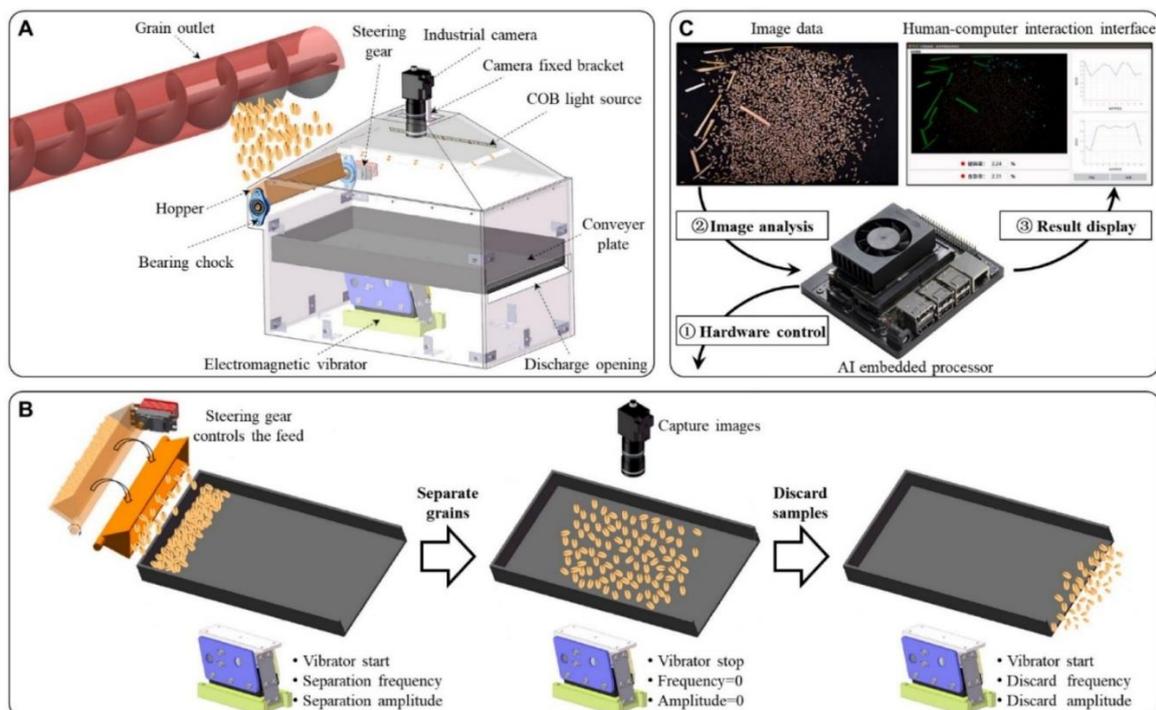

Fig. 14 - Wheat broken rate and impurity rate detection system (Qi *et al.*, 2024)

Deep learning-based intelligent detection

Deep learning-based grain breakage rate detection primarily utilizes YOLO or Faster R-CNN for object detection, U-Net or Mask R-CNN for image segmentation, and ResNet or VGGNet for feature extraction. These models are used to identify intact and broken grains, accurately segment breakage regions, and extract key features such as the edges, texture, and color of broken grains.

Traditional machine learning methods have relatively weak generalization capabilities for breakage detection. To address this, *Wu et al., (2022)*, proposed a maize impurity and breakage rate detection method using feature thresholds and a backpropagation (BP) neural network optimized with a genetic algorithm. The improved Mask R-CNN method demonstrated advantages such as fast detection speed and high accuracy, achieving a maize kernel breakage rate detection time of only 76 ms. *Wang et al., (2023)*, enhanced the YOLOv7 model by integrating a transformer encoding block and a coordinate attention mechanism, proposing the BCK-YOLOv7 model for maize kernel breakage detection. Similarly, *Fan et al., (2024)*, developed a breakage rate prediction model based on machine vision and machine learning algorithms. In another study, *Wang et al., (2025)*, utilized deep learning and sliding window techniques to propose a quantitative model for maize kernel breakage rate detection, named BCK-YOLOv7 (Figure 15). After model deployment, the system achieved a processing speed of 22 FPS, meeting the real-time detection requirements for maize kernel breakage rates. To reduce the computational complexity of detection models, *Wu et al., (2024)*, developed a lightweight impurity content and breakage rate detection system based on the Mask R-CNN model (Figure 16). The improved model increased segmentation accuracy for broken particles and impurities by 6.13% and 9.19%, respectively.

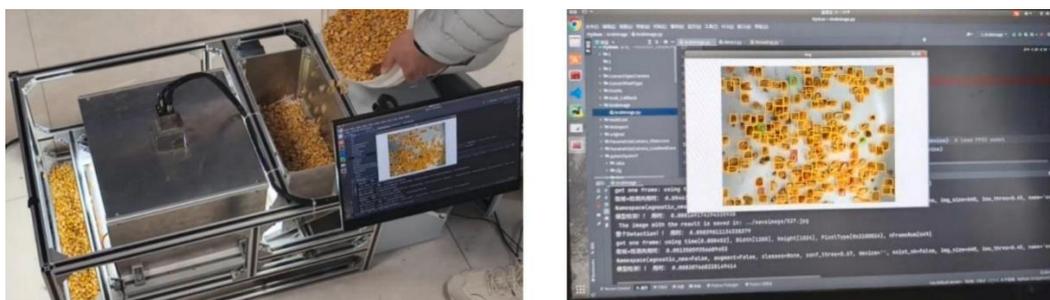

Fig. 15 - Dynamic detection of maize kernels based on BCK-YOLOv7 (*Wang et al., 2025*)

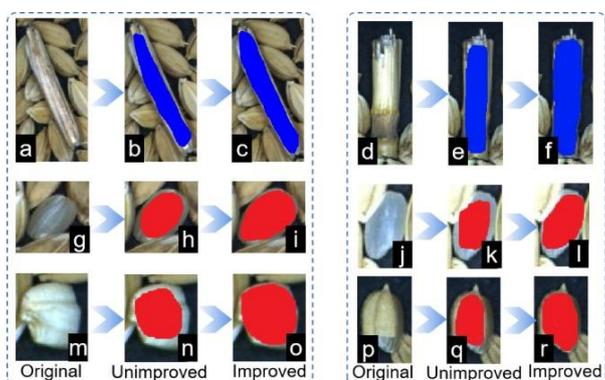

Fig. 16 - Comparison of Detection Performance Before and After Improvement Based on the Mask R-CNN Model (*Wu et al., 2024*)

Deep learning-based impurity content detection primarily employs ResNet or MobileNet for classification, combined with hyperspectral imaging and attention mechanisms to enhance impurity detection accuracy (*Yu et al., 2023*). *Zhang et al., (2023)*, evaluated rice impurity and breakage rates using an improved DeepLabv3+ and YOLOv4 model, achieving higher recognition accuracy compared to existing DeepLabv3+, YOLOv4, U-Net, and BP models. Similarly, *Niu et al., (2024)*, developed a lightweight YOLOv8 quality detection model to address issues of fine-grained information loss and low feature representation learning efficiency in YOLOv8, achieving an average recognition speed of 163.9 FPS per image, which is 5.2 FPS faster than the standard YOLOv8 model. *Zhang et al., (2024)*, proposed an improved YOLOv8n-based lightweight detection method tailored for small, high-density target detection, achieving impurity and breakage detection accuracies of 95.33% and 96.15%, respectively. Additionally, *Zhang et al., (2025)*, introduced a dual-attention diffusion model (DADM) based on a denoising diffusion probabilistic model, which demonstrated superior detection performance on maize, rice, and soybean datasets. This model effectively addresses challenges in agricultural image acquisition caused by seasonal, climatic, and environmental variations, further advancing the integration of deep learning applications in the agricultural sector.

In summary, significant progress has been made in grain breakage rate and impurity content detection using machine vision and deep learning. However, challenges remain, including high data annotation costs, poor real-time performance, and insufficient environmental adaptability. Future research should focus on lightweight deep learning models for integration into harvesters, enabling real-time processing. Additionally, the fusion of multimodal sensors should be explored to enhance the accuracy of grain and impurity recognition.

Intelligent detection of entrainment loss rate

The detection of entrainment loss in the threshing system is primarily used to evaluate threshing quality. Current research on entrainment loss monitoring mainly involves installing entrainment loss monitoring sensors beneath the threshing drum to analyze the correlation between the number of maize kernels detected by the sensors and the actual entrainment loss (Bomoi *et al.*, 2022). This approach enables indirect monitoring of entrainment loss. For entrainment loss detection, the YT-5L piezoelectric ceramic element is commonly used as a sensing component to develop grain loss monitoring sensors. The performance of these sensors is evaluated by analyzing the voltage amplitude and signal attenuation time of grain impact events. Additionally, operational parameters such as feed rate and drum speed influence the proportional relationship between sensor measurements and actual entrainment loss.

Liu *et al.*, (2023), designed an entrainment loss detection system for direct maize grain harvesting based on an embedded microcontroller. The system exhibited a maximum detection error of 9.96% and an average error of approximately 6.52%. Similarly, Dong *et al.*, (2024), symmetrically installed two entrainment loss monitoring sensors along the radial direction of the threshing drum and developed a maize entrainment loss monitoring model using a multiple linear regression machine learning algorithm. Figure 17 illustrates the structure and signal processing workflow of the entrainment loss monitoring sensor.

Furthermore, Dong *et al.*, (2024), designed another entrainment loss detection system (Figure 18) and implemented a random forest machine learning algorithm to construct a loss prediction model, significantly improving entrainment loss estimation accuracy. To further enhance detection precision and practical application, Yu *et al.*, (2025), identified that the optimal placement of the detection sensor was at the left tail end of the concave sieve, with a minimum distance of 58 mm between the sensor plate centerline and the concave sieve, and an installation angle of 65° relative to the horizontal plane, achieving the highest detection accuracy.

In summary, current entrainment loss detection models are relatively simplistic, often neglecting dynamic operating conditions such as feed rate and drum speed variations. This limitation results in significant fluctuations in sensor measurement errors, reducing detection accuracy. Additionally, the adaptability of sensor installation positions and structures remains insufficient, and the vibration characteristics of combine harvesters during field operations significantly impact sensor performance. With the accumulation of entrainment loss detection data, the integration of multi-sensor fusion and deep learning models can enhance noise suppression and real-time analysis capabilities, enabling the development of a more precise and reliable loss monitoring system.

Intelligent threshing control

Based on the structural innovations of threshing devices, the detection of operational parameters such as rotational speed, vibration, and torque, as well as machine vision-based detection of breakage rate and impurity content, a solid structural and data foundation has been established for intelligent control of the threshing system. Intelligent control technologies leverage algorithms such as fuzzy control, neural networks, and reinforcement learning to achieve dynamic adjustment of parameters including drum speed, concave clearance, and feed rate (Wang et al., 2025), thereby enhancing the threshing system's adaptability to multiple crops and improving threshing efficiency.

For intelligent control of maize threshing systems, the primary objective is to address the challenges of high grain breakage and entrainment loss rates during high-moisture maize harvesting under complex and time-varying operating conditions. Li et al., (2023), developed an automatic low-loss maize grain harvesting control system and optimized a control model for drum speed, concave clearance, and driving speed using an improved particle swarm optimization algorithm.

Additionally, some researchers have designed optimal control models based on feed rate and threshing gap. For instance, Fan et al., (2022), developed a threshing device equipped with an automatic gap adjustment system based on feed rate. Their results showed that the variable-gap threshing system outperformed fixed-gap systems in terms of efficiency under random feed rate fluctuations.

Moreover, variations in field conditions and crop density can cause fluctuations in the combine harvester's feed rate. To address this, Fan et al., (2023), proposed a multi-parameter maize threshing control structure and method based on feed rate (Figure 19). By applying intelligent algorithms, a control model was developed for drum speed, threshing gap, and cover vane angle, which enhanced the adaptability of the threshing system to different crop conditions.

1. Angle sensor; 2. Hydraulic cylinder; 3. Displacement sensor; 4. Guide vane; 5. Dynamic torque sensor; 6. Hydraulic motor drive; 7. Concave; 8. Rotor

For intelligent control of cereal threshing systems, machine learning models have been applied to construct predictive models, effectively addressing the challenges of time variability, delay, and multi-parameter coupling in cereal threshing. These models provide a foundation for intelligent control of the threshing process. For example, *Ma et al., (2023)*, developed an artificial neural network (ANN) model to predict the performance of a flexible threshing device. Similarly, *Li et al., (2024)*, proposed a fusion approach combining particle swarm optimization and wavelet neural networks to optimize the state-space model of the threshing system. They employed model predictive control (MPC) to regulate multiple threshing parameters. The resulting state-space and adaptive control models demonstrated strong adaptability and stability for threshing system operation.

In summary, control technologies for intelligent threshing systems are developed based on structural innovations in threshing devices and the detection of operational parameters, providing both structural and data support for intelligent regulation. Methods such as fuzzy control and neural networks have been widely applied for the dynamic adjustment of threshing system operating parameters.

THRESHING SYSTEM DEVELOPMENT TRENDS

Multi-sensor fusion and intelligent detection

The multi-sensor fusion used for detecting operating parameters and operation quality in threshing systems still faces numerous challenges, including spatiotemporal synchronization, accuracy and robustness, real-time performance, and compatibility, making it difficult to provide stable and precise data. Therefore, for intelligent threshing systems, it is necessary to construct a multi-sensor fusion detection network utilizing various sensors such as infrared, laser, ultrasonic, and spectral sensors to enhance data accuracy.

Additionally, data synchronization mechanisms should be introduced, and intelligent filtering algorithms as well as deep learning methods should be applied to further improve data analysis and processing capabilities. Standardization of sensor data formats and communication protocols should also be established, along with the development of large-scale datasets for crop harvesting operations, to enhance the generalization capability of intelligent detection models.

Deep learning and intelligent algorithm optimization

Deep learning technology has demonstrated exceptional pattern recognition capabilities in the optimization of threshing operation parameters and quality detection. It significantly enhances the automation of key tasks such as grain loss prediction, breakage rate detection, impurity identification, and operational condition optimization. However, challenges remain, including limited availability of harvesting data samples, high data annotation costs, poor adaptability to different crops and field environments, and difficulties in integrating deep learning with threshing system control strategies.

Therefore, under the premise of multi-sensor fusion, the adoption of lightweight deep learning models is essential to enhance edge computing capabilities. In addition, the application of transfer learning and related techniques can promote the development of threshing operations toward higher precision, intelligence, and adaptability.

Intelligent control of threshing systems

Intelligent threshing control systems for combine harvesters still face core challenges such as difficulties in real-time control, poor crop adaptability, and complex multi-parameter coupling. Traditional control methods, including PID and fuzzy control, struggle to achieve precise regulation under complex and dynamically changing threshing conditions, often resulting in high levels of threshing loss, grain breakage, and impurity content.

Deep learning, through data-driven approaches, can predict optimal adjustment strategies for threshing parameters. When integrated with physical modeling, it enables the construction of reinforcement learning-driven intelligent adaptive control systems that autonomously adjust control parameters based on different crops and field environments. In the future, with the advancement of technologies such as digital twins, threshing control systems will become more precise and intelligent, further promoting the development of agricultural machinery toward unmanned operation and autonomous optimization.

CONCLUSIONS

The structural design of threshing devices in combine harvesters has been significantly optimized by fully considering crop characteristics and variations in operating conditions, resulting in enhanced multi-crop adaptability, improved threshing efficiency, and greater operational stability. At the same time, real-time monitoring technologies based on multi-sensor fusion, machine vision, and deep learning models have achieved major breakthroughs in key aspects such as feed rate detection, grain breakage rate analysis, impurity content assessment, and entrainment loss identification, providing high-precision data support for the intelligent regulation of threshing systems.

Moreover, adaptive control strategies based on fuzzy logic have laid the foundation for developing data-driven control systems with multiple inputs and outputs for threshing systems. Reinforcement learning methods are increasingly being adopted to enable real-time adjustment of threshing parameters in response to changing environmental conditions, ensuring that the system operates under optimal conditions—an emerging and important direction in the intelligent development of combine harvesters.

However, despite substantial technological progress, challenges remain in the online monitoring and dynamic regulation of threshing system operation parameters and quality indicators. In the future, with the further integration of artificial intelligence and deep learning into combine harvester threshing systems, the capabilities of intelligent perception, decision-making, and control will be significantly enhanced, ultimately enabling the construction of a low-loss, high-efficiency intelligent threshing system.

Tel: +86-13222725599; E-mail: 758128332@qq.comDOI: <https://doi.org/10.35633/inmateh-75-62>**Keywords:** Wheat Impurity Detection, YOLOv8, Multi-scale Feature Fusion, Lightweight Design**ABSTRACT**

To achieve fast and accurate detection of wheat impurities, this study proposes an improved YOLOv8-based algorithm that targets three typical impurity types: bran, straw, and spike. The original C2f module is replaced with the C2f_UIB structure from MobileNetV4 to reduce model complexity, and a High-level Screening Feature Pyramid Network (HS-FPN) is integrated to enhance multi-scale feature fusion. Additionally, a Generalized IoU loss function is adopted to improve detection robustness in dense impurity scenarios. The optimized model is deployed on an embedded Jetson Nano platform for real-time inference, coupled with an industrial camera and LED lighting system. To validate its practical effectiveness, an indoor experimental setup was constructed to simulate field conditions. A total of 30 wheat samples were tested, and results demonstrate high consistency between system detection and manual annotation, with minimal deviation across all impurity types. The proposed algorithm exhibits excellent accuracy, lightweight characteristics, and strong potential for deployment in intelligent agricultural equipment.

摘要

为实现对小麦杂质的快速准确检测, 本文提出一种基于改进 YOLOv8 的杂质识别算法, 主要针对三类典型杂质: 麦麸、秸秆和麦穗。该算法将 YOLOv8 中的 C2f 模块替换为 MobileNetV4 的 C2f_UIB 结构, 以降低模型复杂度, 并引入高级筛选特征金字塔网络 (HS-FPN) 以提升多尺度特征融合能力。此外, 采用广义 IoU 损失函数以增强高密度杂质场景下的检测鲁棒性。优化后的模型部署于 Jetson Nano 嵌入式平台, 并结合工业相机与 LED 面光源构建图像采集系统, 实现了模型的实时推理。为验证其实际应用效果, 搭建室内试验平台模拟田间作业环境, 对 30 组小麦样本进行了检测实验。结果显示, 系统识别结果与人工标注高度一致, 各类杂质检测误差极小, 表明所提算法具备良好的检测精度、轻量化特性及农业装备部署应用潜力。

INTRODUCTION

Wheat is one of the most important staple crops globally, playing a critical role in food security and economic development. However, the presence of impurities such as straw, wheat bran, and other foreign materials during the harvesting process significantly affects the quality and market value of wheat. Traditional methods for impurity detection rely heavily on manual labor, which is not only time-consuming but also prone to human error. With the aging agricultural workforce and rising labor costs, there is an urgent need for automated and precise impurity detection systems to improve the efficiency and quality of wheat harvesting.

In early research on visual impurity detection in agriculture, traditional image processing techniques such as color thresholding and morphological filtering were commonly used.

Chen *et al.* (2020) proposed a machine vision-based real-time impurity detection system for rice combine harvesters, employing decision tree algorithms to classify grain morphological features (A1-A6). The integrated lateral illumination system and decision tree model achieved 76% classification accuracy on training datasets, establishing a foundation for real-time parameter optimization in harvesting machinery.

Marjanović *et al.* (2018) developed a rainfall-triggered landslide prediction model using decision tree algorithms to analyze precipitation data from 2001-2014. Critical thresholds of 30 mm rainfall in 2-3 days and 140 mm cumulative rainfall over 30 days were identified, revealing dominant mechanisms of medium-term rainfall impacts on landslides in Western Serbia.

Ok *et al.* (2012) applied random forest with parcel-based analysis to SPOT5 imagery crop classification, achieving 85.89% overall accuracy (8% improvement over maximum likelihood methods), demonstrating superiority in multispectral interpretation.

Mavridou et al. (2019) systematically reviewed agricultural machine vision technologies across seven domains (fruit grading/yield estimation/disease detection), analyzing multi-sensor integration strategies to guide precision agriculture implementation.

These traditional methods are limited by their reliance on handcrafted features, low adaptability to complex environments, and difficulty in handling high-density impurity scenarios. In contrast, deep learning techniques have shown great potential by leveraging convolutional neural networks (CNNs) to automatically extract multi-level semantic features.

Deep learning overcomes these limitations by leveraging convolutional neural networks (CNNs) to automatically extract multi-level features.

Shen and Zhao (2021) proposed a lightweight YOLOv3-based detection model for peanut sorting systems, solving missed detection problems while ensuring real-time inference on CPUs.

Qi et al. (2023) designed a GhostNet-based pest detection model with attention-guided receptive field fusion, achieving high mAP and FPS under lightweight constraints.

Shi et al. (2023) developed a DCGA-YOLOv8 system for multi-crop navigation line extraction, achieving 98.9%-100% correct clustering rates for cabbage/kohlrabi/rice. The integration of threshold-optimized DBSCAN and B-spline curve modelling enabled safe agricultural machinery path planning.

Jia et al. (2024) proposed ADL-YOLOv8 for weed detection, incorporating AKConv networks and DySample upsampling. The model improved mAP@0.5 by 3.07% while maintaining 15.77% compression rate, providing lightweight high-precision solutions for smart weeding devices.

Zhang et al. (2024) built HR-YOLOv8 for crop growth monitoring using dual self-attention mechanisms and parallel feature fusion. The model enhanced detection accuracy by 5.2% for oil palm and 0.6% for strawberries, enabling high-resolution feature preservation.

Jiang et al. (2022) optimized YOLOv7 with CBAM attention modules for Muscovy duck flock counting, achieving 98.6% accuracy and 2.3% mAP@0.5 improvement over baseline models, supporting automated density monitoring in poultry farming.

Wang et al. (2022) streamlined YOLOv5s for real-time apple calyx/stem recognition via detection head search and channel pruning. The compressed model achieved 25.51 FPS on CPUs with 93.89% accuracy, enabling efficient automated sorting.

Mathew and Mahesh (2022) deployed YOLOv5 for bell pepper bacterial spot detection, implementing whole-image feature extraction to identify micro-lesions, providing early disease warnings for mobile agricultural systems.

These studies highlight that deep learning not only supports real-time multi-target recognition in complex scenes, but also enables flexible model design through end-to-end training.

In the domain of wheat impurity detection, several notable deep learning-based methods have emerged recently.

Zhou et al. (2023) proposed WheNet, an Inception-v3-based CNN that achieved 98.59% Top-1 accuracy for classifying wheat and five impurity types.

Li et al. (2023) combined terahertz 3D imaging with a metaheuristic RetinaNet model (AHA-RetinaNet-X), obtaining over 95% accuracy for impurity classification in non-destructive testing.

Chen et al. (2022) developed Ro-YOLOv5 based on rotated bounding boxes and Circular Smooth Labels, significantly improving impurity detection in wheat CT images.

However, many of these approaches rely on complex imaging systems (e.g., THz, CT), large-scale models, or lack the ability to run in real-time on resource-limited embedded devices. In addition, some methods focus on image classification rather than instance-level detection and localization, which limits their deployment in actual harvesting scenarios.

To address these challenges, this study proposes a lightweight wheat impurity detection algorithm based on an improved YOLOv8 architecture, integrating a Universal Inverted Bottleneck (UIB) module for computational efficiency, a High-level Screening Feature Pyramid Network (HS-FPN) for multi-scale fusion, and a GloU-based loss function for robust object localization. The model is deployed on a Jetson Nano embedded platform with industrial camera input, and validated through indoor experiments simulating real-world conditions. Compared with existing methods, our approach achieves high accuracy, fast inference, and low computational cost, making it highly suitable for intelligent agricultural equipment in modern farming environments.

MATERIALS AND METHODS

The wheat used in this study was provided by the Xizhai Agricultural Machinery Cooperative in Tianzhuang Town, Pingdu City, Qingdao, Shandong Province. The wheat was harvested using a combine harvester. The main impurity categories included wheat bran, straw, and spikes, which are the most common and representative types of impurities during the wheat harvesting process.

Wheat bran refers to fragments of the outer shell and germ produced during threshing. It is typically yellow or brown and has a regular shape. Straw is the residual stem of wheat plants with a smooth surface and varying thickness, appearing yellow or light yellow in color. Spikes are yellow or brown and usually consist of multiple unthreshed wheat kernels adhered together. Sample images of these impurities are shown in Figure 1.

Fig. 1 - Partial Wheat Impurity Samples

The image acquisition system used a Hikvision MV-CS060-10GC industrial camera equipped with a Hikvision MVL-HF0828-6MPE lens. The camera supported a maximum resolution of 3072×2048 pixels. During image capture, an acrylic tray was used to hold the wheat samples, and the shooting distance was fixed at 95 mm. The output image resolution was set to 2048×2048 pixels to ensure clarity and preserve the visual characteristics of the impurities. This also helped improve the precision of the subsequent labeling process. In total, 720 wheat images were collected.

The dataset was annotated using the X-AnyLabeling-GPU software and saved in YOLO format. To improve the model's generalization and robustness, the dataset was augmented through operations such as mirror flipping, 30° rotation, and brightness adjustment. A total of 2,140 images were selected for training, with the training and validation sets divided at a ratio of 8:2. The Mosaic augmentation function of YOLOv8 was also enabled during training to further enhance model robustness.

During wheat harvesting, the straw and spike impurities vary significantly in size and shape. Moreover, the relatively small sample size for these two categories makes accurate detection more difficult. While existing object detection algorithms can barely meet basic requirements, they often suffer from high complexity and large model parameters. Therefore, this study chose to improve the YOLOv8 model to better suit the task.

To enhance computational efficiency while maintaining accuracy and better utilize the computing power of the device, the Bottleneck module in the YOLOv8 C2f module was replaced with the Universal Inverted Bottleneck (UIB) module from MobileNetV4, forming a new structure named C2f_UIB. To improve the extraction of impurity features with diverse scales and shapes, the original PANet feature fusion network was replaced by the High-level Screening Feature Pyramid Network (HS-FPN). Compared with PANet, HS-FPN achieved better multi-scale feature fusion with fewer parameters. The network structure of the improved YOLOv8 model is illustrated in Figure 2.

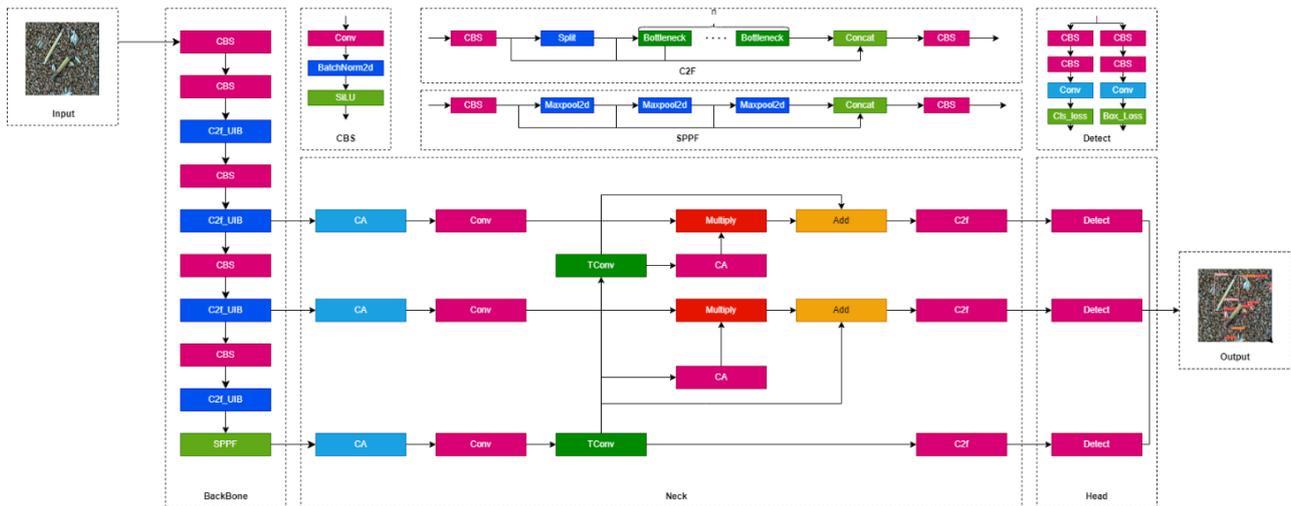

Fig. 2 - Improved YOLO v8 Lightweight Network Model

Universal Inverted Bottleneck

The Universal Inverted Bottleneck (UIB) was a lightweight network architecture introduced by MobileNetV4 to improve the efficiency of object detection (Qin et al., 2024). The UIB module significantly reduced the number of parameters and computational load by incorporating two optional depthwise convolutions (DW) into the Inverted Bottleneck (IB). Its core idea was to treat deep convolution as a variable structure by sharing common components such as pointwise expansion and projection. This design effectively reduced computational redundancy and optimized resource utilization efficiency.

Compared with the conventional Bottleneck structure used in the C2f module, the UIB module offered greater efficiency under limited computing resources. By replacing the Bottleneck in the C2f module with the UIB, an improved module named C2f_UIB was constructed. Experimental results demonstrated that the new module greatly reduced computation and memory usage without sacrificing performance. This improvement was of practical significance for large-scale deep learning tasks, especially in resource-constrained environments such as edge devices or mobile applications. The application of the C2f_UIB module further confirmed the potential and practical value of lightweight design for efficient object detection.

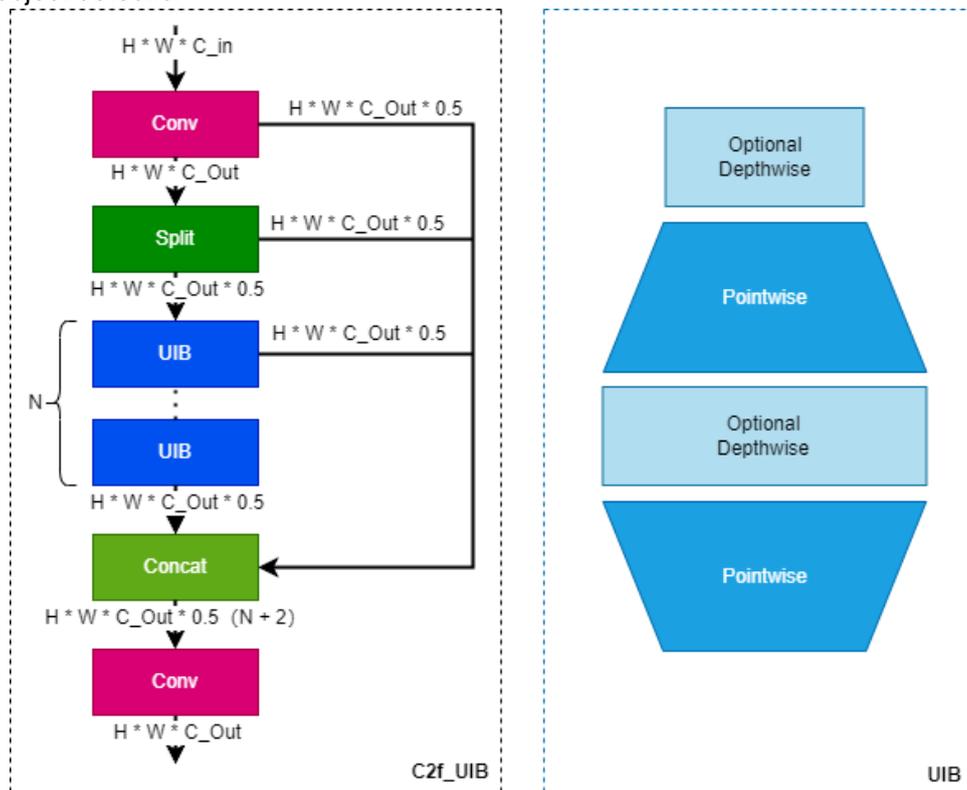

Fig. 3 - UIB Module Structure Diagram

Feature fusion network HS-FPN

The High-level Screening Feature Pyramid Network (HS-FPN) was a multi-scale feature fusion structure designed to enhance the attention and semantic understanding capabilities of the model when detecting impurities of different sizes, particularly straw and spikes. The HS-FPN framework consisted of two major components: a feature selection module and a feature fusion module (Chen et al., 2023). These modules worked together to aggregate features of varying semantic depths and spatial resolutions, thus providing more accurate and informative representations for impurity detection. The improved HS-FPN structure adapted to the YOLOv8 backbone is shown in Figure 4.

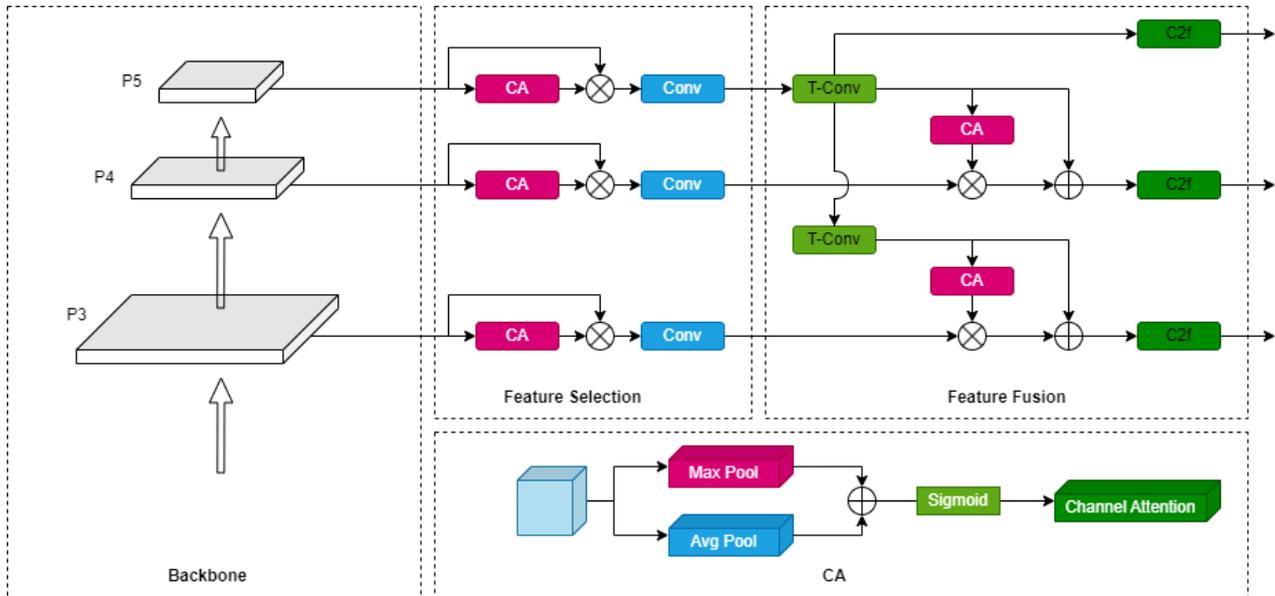

Fig. 4 – HS-FPN Structure Diagram

The feature selection module aimed to filter and reweight the multi-scale feature maps using a channel attention (CA) mechanism. As shown in the figure, the CA module first processed the input feature map using global average pooling and global max pooling to calculate the weights of each channel. These weights were then passed through a Sigmoid activation function to determine their importance. The weighted values were used to enhance the original feature map, emphasizing the most relevant feature channels for detection.

The feature fusion module served as the core component of HS-FPN. It combined feature maps of different resolutions to enhance the model's representational ability. Within this module, the Selective Feature Fusion (SFF) mechanism was used to selectively merge feature information.

The fusion process included two SFF blocks. Firstly, the high-level features with a size of $f_{high} \in R^{C \times H \times W}$ was up sampled via transposed convolution (T-Conv) to obtain $f_{high-T} \in R^{C \times 2H \times 2W}$ matching the scale of lower-level features. The channel attention module generated a weight vector $f_{CA} \in R^{C \times 1 \times 1}$, which was used to reweight the low-level feature f_{low} . The final fused feature output was calculated by the weighted addition of both:

$$f_{out} = f_{low} \times f_{CA} + f_{high-T} \quad (1)$$

This process enabled the model to leverage both detailed and abstract features. The transposed convolution and CA module jointly reconstructed the high-level features and facilitated their integration with low-level semantics. The optimization of this fusion strategy improved multi-scale feature utilization and overall detection performance.

Optimize loss function

The original YOLOv8 model employed the Complete IoU (CIoU) loss function for bounding box regression. However, CIoU suffered from ambiguity in aspect ratio representation and was not well-suited for high-density target detection. To overcome these limitations, this study adopted the Generalized IoU (GIoU) loss, which introduced the concept of an inclusion box.

GIoU not only measured the overlap between predicted and ground truth boxes but also quantified their spatial relationship when no intersection existed, thus providing richer gradient information for optimization (Zhang *et al*, 2022).

In high-density impurity scenes, GIoU utilized the surrounding region to enhance robustness under occlusion and tight target spacing. Moreover, its simplified formulation reduced normalization overhead and lowered computational complexity. These advantages made GIoU better suited for detecting varied-scale impurities under dense distribution, offering a more stable optimization path.

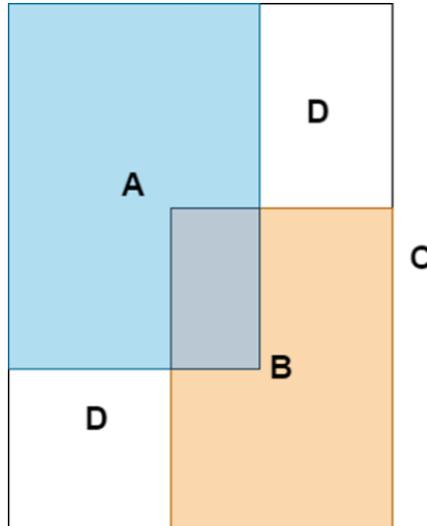

Fig. 5 – GIoU Loss Function

The GIoU is defined as:

$$GIoU = IoU - \frac{|C \setminus (A \cup B)|}{|C|} \quad (2)$$

where: $IoU = \frac{|A \cap B|}{|A \cup B|}$: represents the intersection and union ratio of the prediction box and the real box. C : It's the minimum closure rectangle containing the prediction box and the real box $|C \setminus (A \cup B)|$: It's the area in the closure rectangle that does not belong to the union of the prediction box and the real box. $|C|$: It's the area of the closure rectangle.

The corresponding GIoU-based loss function is:

$$L_{GIoU} = 1 - GIoU \quad (3)$$

This design not only reduced computational cost but also improved detection reliability in dense impurity scenarios.

Indoor Experimental Setup

To evaluate the proposed impurity detection model under practical conditions, an indoor experimental system was constructed to simulate the post-harvest wheat impurity collection environment. The system consisted of a sampling box, an industrial camera (Hikvision MV-CS060-10GC), a rectangular LED light source, and a Jetson Nano embedded processor for real-time inference, as shown in Figure 6.

Fig. 6 - Structure of the indoor impurity detection system.

The camera was fixed at a certain height above the observation window to ensure clear imaging of the wheat samples. The interior of the sampling box was coated with matte material to reduce light reflection and background interference. During each test, wheat samples were spread fully across the sampling area, and the system automatically captured images under stable lighting conditions. The collected images were then processed in real time by the YOLOv8 detection model deployed on the Jetson Nano platform.

This setup replicated key aspects of a combine harvester's impurity output environment and enabled controlled validation of the model's detection accuracy. A total of 30 samples were tested in this configuration, forming the basis for performance evaluation described in the Results section.

RESULTS

Test environments and parameter configuration

The experimental environment is Windows10 operating system, the CPU is AMD EPYC 7402 24-Core Processor, the main frequency is 2.79 GHz, the Python 3.9.7 development environment is used, the deep learning framework is Pytorch1.12.1, the GPU uses NVIDIA GeForce RTX 3090 for computing acceleration, and the GPU runs memory of 24 GB. The software environment is configured as CUDA12.2. The input image size is 640 pixels × 640 pixels, the training rounds are set to 300 rounds, the batch size is set to 16, and the optimizer is SGD.

Evaluating indicator

In the task of wheat impurity detection, it is essential to consider the model's accuracy, size, and deployment feasibility on edge devices. To objectively evaluate the performance of the target detection algorithms, this study employs a series of standardized evaluation metrics, including precision (P), recall (R), and mean average precision (mAP), alongside the model's memory usage and parameter count for a comprehensive performance comparison. These metrics collectively provide a thorough quantitative assessment of the model's precision, efficiency, and resource consumption in practical applications.

The calculation formula is as follows:

$$P = \frac{T_p}{T_p + F_p} \quad (4)$$

$$R = \frac{T_p}{T_p + F_n} \quad (5)$$

$$mAP = \frac{\sum_{i=1}^N AP_i}{N} \quad (6)$$

Precision measures the proportion of correctly predicted positive samples among all predicted positives, where T_p is the number of correctly detected positive samples and F_p is the number of false positives; Recall measures the proportion of actual positive samples detected by the model, where F_n is the number of missed positive samples; mean Average Precision is the average of the precision-recall curve area across all classes, with N being the total number of classes, and mAP comprehensively reflects the overall performance of the model in multi-class detection tasks.

Comparative test analysis of different algorithms

To evaluate the effectiveness of the proposed improved YOLOv8 model, it was compared with mainstream detection models, including Faster R-CNN, YOLOv5s, YOLOv7-Tiny, and the original YOLOv8n. As shown in Table 1, the improved model achieved the highest accuracy rate, recall rate, and average accuracy, outperforming all baseline models. Specifically, compared to YOLOv8n, the improved model increased accuracy by 1.0%, recall by 0.9%, and average accuracy by 1.3%. Notably, the model size was reduced by 46.7%, and parameter quantity decreased by 28.4%. This demonstrates that the lightweight design and multi-scale fusion effectively balance performance and efficiency. While YOLOv7-Tiny achieved comparable accuracy, its recall rate and average accuracy were inferior, and its parameter count remained higher. Traditional models like Faster R-CNN exhibited significantly lower performance and excessive resource consumption, highlighting the superiority of the proposed lightweight improvements.

Table 1

Models	Model Performance Comparison				
	accuracy rate	recall rate	average accuracy	model memory usage	parameter quantity
	[%]	[%]	[%]	[MB]	x 10 ⁹ [FLOPS]
Faster R-CNN	79.6	82.1	45.3	315.6	137.2
YOLOv5s	92.3	93.8	96.7	13.7	16.5
YOLOv7-Tiny	93.5	94.6	96.6	11.7	13.2
YOLO v8n	93.2	93.6	97.4	6.0	8.1
YOLO v8n+UIB+HSFPN+GIOU	94.2	94.5	98.7	3.2	5.8

Figure 7 shows the comparison between the improved model and YOLOv8n in terms of accuracy, recall and average accuracy. On the whole, our method performs better than YOLOv8n on all indicators.

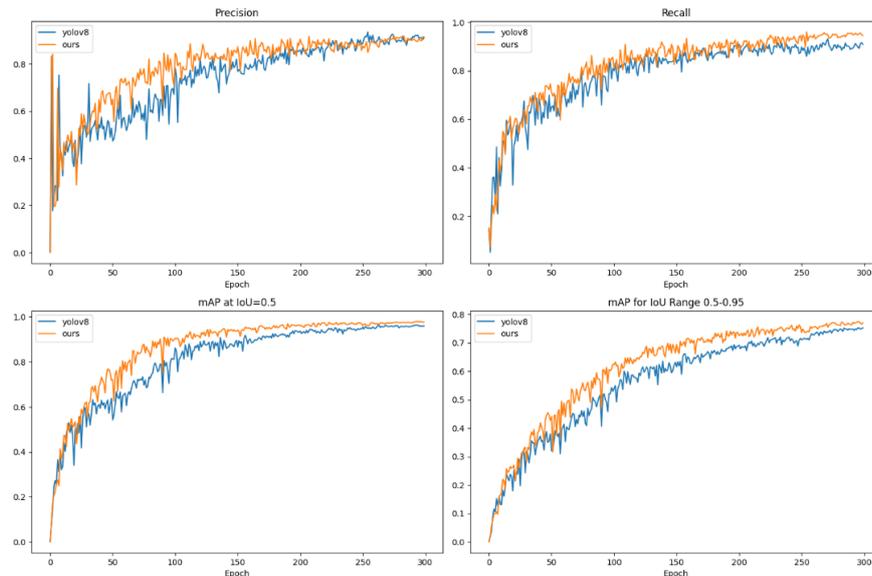

Fig. 7 – Performance curves of YOLOv8 model and improved YOLOv8 model

As demonstrated in Figure 8, the enhanced YOLOv8 model exhibits superior detection performance relative to the original architecture, with notable improvements in impurity recognition capability. The optimized model achieves reduced occurrence of both missed detections and false positives, while demonstrating higher confidence scores in accurate impurity identification.

Fig. 8 – Comparison of model detection effects

Ablation test

Ablation experiments were conducted to validate the contribution of each proposed improvement. As shown in Table 2, the baseline YOLOv8n achieved 93.2% accuracy, 93.6% recall, and 97.4% mAP. Introducing the UIB module alone slightly improved accuracy but reduced model memory usage by 11.7% and parameters by 13.6%. Replacing PANet with HS-FPN yielded more significant gains: accuracy increased to 93.7%, recall to 94.6%, and mAP to 97.8%, with a 33.3% reduction in memory. Using GloU loss alone improved recall and mAP without affecting model size. Combining UIB+HSFPN achieved 93.8% accuracy, 94.4% recall, and 98.3% mAP, while reducing memory to 3.2 MB. Finally, integrating all three improvements achieved optimal performance: 94.2% accuracy, 94.5% recall, and 98.7% mAP, confirming the synergistic effect of lightweight design, multi-scale fusion, and loss optimization.

Table 2

Models	Ablation experiment				
	Accuracy rate	Recall rate	Average accuracy	Model memory usage	Parameter quantity
	[%]	[%]	[%]	[MB]	$\times 10^9$ [FLOPS]
YOLOv8n	93.2	93.6	97.4	6.0	8.1
YOLOv8n+UIB	93.4	93.5	97.4	5.3	7.0
YOLOv8n+HSFPN	93.7	94.6	97.8	4.0	6.9
YOLOv8n+GIoU	93.6	94.3	97.7	6.0	8.1
YOLOv8n+UIB+HSFPN	93.8	94.4	98.3	3.2	5.8
YOLOv8n+UIB+HSFPN+GIoU	94.2	94.5	98.7	3.2	5.8

Indoor Test and Validation

To evaluate the practical performance of the proposed wheat impurity detection algorithm, an indoor test was conducted under simulated harvesting conditions. The experimental setup was described in detail in the Materials and Methods section.

A total of 30 wheat samples were tested. For each sample, the system automatically captured images and detected three impurity types: wheat spike, bran, and straw. The recognition results were displayed in real-time and recorded for statistical analysis. Figure 9 shows the indoor test platform, and Figure 10 presents representative detection results.

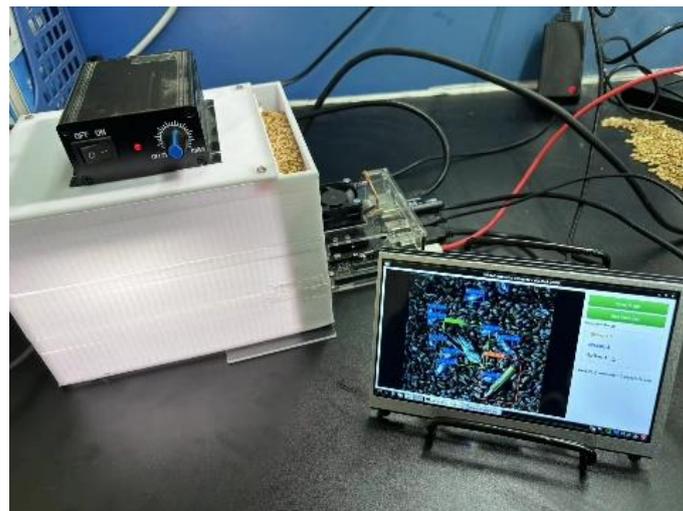

Fig. 9 – The indoor test

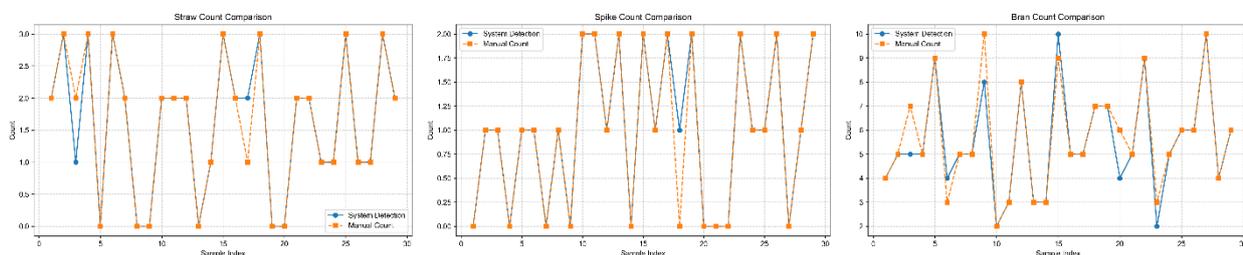

Fig. 10 – Comparison of impurity counts for systematic detection and manual annotation

According to the statistics, the model achieved high detection consistency. Only one sample had a single-object deviation in spike detection, and two samples had minor deviations in straw detection. Among the 162 bran targets, only six samples showed a one-object difference. These results validate the model's detection accuracy and robustness under realistic lighting and target distribution conditions.

The experimental outcomes further demonstrate the model's deployment potential in embedded platforms for intelligent agricultural equipment.

CONCLUSIONS

This study proposed an improved YOLOv8-based wheat impurity detection algorithm, focusing on lightweight design, multi-scale feature fusion, and enhanced loss function. By integrating the Universal Inverted Bottleneck (C2f_UIB), High-level Screening Feature Pyramid Network (HS-FPN), and GloU loss, the model achieved a significant reduction in computational cost while maintaining high detection accuracy.

The detection system was deployed on a Jetson Nano embedded platform and validated through indoor experiments simulating post-harvest impurity collection conditions. The experimental results demonstrated high recognition consistency and robustness, with most impurity categories exhibiting only minimal detection deviation.

Compared with existing mainstream detection models, the proposed approach offers a balanced trade-off between accuracy and efficiency, making it well-suited for real-time deployment in intelligent agricultural machinery. This work provides a practical reference for the application of deep learning in grain impurity detection, and lays a foundation for future field experiments and system integration.

ABSTRACT

This research addresses the axisymmetric problem in the theory of granulation of porous bodies, with practical application in calculating the forces involved in the granulation of dispersed bulk materials such as chips, granules, and other agricultural and woodworking waste. For such materials, the shape of the particles (structural elements) is generally irregular and not geometrically well-defined. This characteristic served as the basis for adopting a continuum model of porous media. In this model, the material is treated as a continuous substance that fills all available layers of bulk space, allowing for the mechanical behavior of materials with internal pores or voids to be accurately described. The pores within the material are considerably smaller compared to other characteristic dimensions of the material's properties. In the continuum model, the mechanical characteristics of the material, such as stress, strain, and compaction, are described by mathematical equations that account for the material's physical properties and its behavior under loading. By reducing this model to a two-dimensional spatial form, a closed-form analytical solution was obtained using a general method for solving the differential equations of equilibrium along with the Huber–Mises energy condition for plasticity. The following assumptions were adopted as working hypotheses: radial and tangential stresses are equal, and the lateral pressure coefficient is equal to the proportional granulation density. Given that the problem is solved in a general form, the solution should be regarded as methodological, that is, it can be applied to any loading scheme exhibiting axial symmetry. Transcendental equations were derived to describe the deformation compaction process of a porous body. These equations account for both the ideal granulation process and the influence of contact friction forces. As a result of developing a solution method for these equations, dependencies were obtained for calculating the local characteristics of the stress state during granulation, as well as for integral parameters of the process, such as compaction and deformation work.

АНОТАЦІЯ

Дане дослідження присвячене вирішенню вісе-симетричної задачі теорії гранулювання пористих тіл з практичним застосуванням у вигляді силового розрахунку процесів гранулювання дисперсних сипучих матеріалів: стружкових, гранульованих та інших відходів сільськогосподарського виробництва і деревообробки. Для таких матеріалів форма частинок (структурних елементів) не є геометрично правильною або взагалі визначеною. Це служило підґрунтям для того, що в основу вирішення була покладена континуальна модель пористого тіла, яка дозволяє описувати механічну поведінку матеріалів, які мають пори або порожнини в своїй структурі. В даній моделі матеріал розглядається як неперервна речовина, що заповнює усі доступні шари сипкого простору. Пори у матеріалі вважаються невеликими в порівнянні зі значеннями інших властивостей матеріалу.

У континуальній моделі, механічні характеристики матеріалу, такі як напруження, деформація та тиск, описуються математичними рівняннями, що враховують фізичні властивості матеріалу та його поведінку під навантаженням. Ця модель застосовується для аналізу різних видів механічних деформацій та взаємодії матеріалів, включаючи стискання, розтягування, згин, обертання тощо. В результаті зведення даної моделі до двовимірної просторової моделі отримано замкнене аналітичне рішення методом спільного вирішення диференціальних рівнянь рівноваги та енергетичної умови пластичності Губера-Мізеса. В якості робочих гіпотез прийняті наступні припущення: радіальне і тангенціальне напруження рівні, коефіцієнт бічного тиску рівний пропорційній щільності гранулювання. З огляду на те, що задача вирішена у загальному вигляді, саме рішення слід розглядати як методологічне, тобто може бути використано для будь-якої схеми навантаження, яка виявляє осьову симетрію. Були отримані трансцендентні рівняння, які описують процес деформаційного ущільнення пористого тіла. Ці рівняння враховують як ідеальний процес гранулювання, так і вплив сил контактного тертя. Внаслідок розробки методу розв'язання цих рівнянь були отримані залежності для обчислення локальних характеристик напруженого стану в процесі гранулювання, а також для інтегральних параметрів цього.

INTRODUCTION

Porous bodies include materials that can be granular or other bulk substances (Pisarenko & Mozharovsky, 1981; Bertram, 2012; Hashiguchi & Yamakawa, 2012; Haupt, 2002; Lubliner, 1990; Zhou et al., 2021; Aruffo et al., 2024; Zheng et al., 2017; Uniyal et al., 2020). Zhou et al., (2021), present the shear strength behavior of glass beads with two particular sizes under the influence of 0-5% liquid and hydrated lime (HL) contents. Experimental work was performed to analyze the influence of liquid-powder mixture ratios on a wet granular system under various loading stresses. Hence, evaluating bulk density and shear resistance is crucial for assessing the growth and strength of agglomerated products (Aruffo et al., 2024; Zheng et al., 2017; Uniyal et al., 2020).

In the classification according to the physical and mechanical properties of particles (structural elements), these materials belong to the category of structurally heterogeneous (Landau, & Lifshits, 2013; Gurson, 1977; Bettinotti et al., 2017; Aruffo et al., 2022). Usually, the shape of the particles does not have a geometrically correct structure or may even be undefined, which casts doubt on the possibility of using the contact-discrete model of deformation compaction for such materials. In such situations it is more appropriate to use a model that treats the material as a compressible continuum and takes into account rheological characteristics, such as the yield strength (Lu & Li, 2017; Bratishko, 2020; Bratishko, 2014; Boltyanska, 2018; Salman et al., 2007; Probst & Ileleji, 2016).

Probst & Ileleji, (2016), presented a laboratory-scale batch drum granulation process used to produce granules from dried distillers grains with solubles (DDGS). This was achieved by adding condensed distillers solubles (CDS) as a binder to wet distillers grains (WDG), both of which are coproducts of the corn dry-grind ethanol process, under varying formulation and process conditions. A full factorial experimental design was employed to test all combinations of factor levels, including the amount of CDS binder, CDS solids content, screen size opening, and residence time. These characteristics allow for the assessment of the material's resistance to deformation.

Even though several studies have described the impact of granulation process parameters on granule size distribution, granules density, and flowability (Benali et al., 2009; Liu et al., 2013; Mangwandi et al., 2013), no systematic investigation has yet reported how these variables influence the granule hardness and compression properties of granules. Granule hardness could be one of the important properties in tablet formulation because granules having insufficient hardness are extremely fragile leading to compromise on quality. On the other hand, if the granules are extremely hard, this may compromise the compressibility. Meanwhile, compression behavior of granules might be altered by process variables. However, detailed studies are very limited on how process variables influence the compression behavior of granules. Heckle plot analysis can be commonly used for the analysis of compression behavior of pharmaceutical excipients. Therefore, one of the objectives of the present study was to investigate the impact of process variables on granule hardness and compression behavior of granules.

MATERIALS AND METHODS

The solution of the axisymmetric problem in the granulation theory of porous bodies involves determining the local characteristics of the stress state during granulation as a function of spatial coordinates, as well as key integral parameters such as compression, force, and deformation work (Pisarenko & Mozharovsky, 1981; Bertram, 2012; Hashiguchi & Yamakawa, 2012; Haupt, 2002; Lubliner, 1990). For modeling purposes, the porous body is represented as a solid, compressible, rigid-plastic material with a defined yield point. The granulation process of the porous material is carried out within a die, as illustrated in Fig. 1.

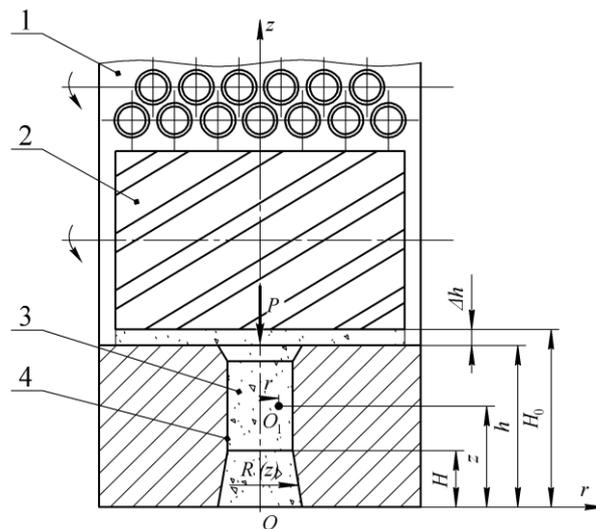

Fig. 1 – Technological scheme of granulation of a porous body in a die spinneret

1 – die; 2 – roller; 3 – porous material; 4 – spinneret

During the granulation process, the side surface of the die is modeled as a body of revolution. At any given moment under axisymmetric loading, it can be described by the equation $R=R(z)$. In the first stage of analysis, force calculations are performed without accounting for contact friction forces.

The following notations are used in this research: H_0, H – initial and final granulation height; h – current granule formation height; Δh – deformation path (compaction); R – radius of granule formation at a given section z ; ρ_0 – current material density; ρ_m – maximum material density (granules); $\mu = \rho_0/\rho_m$ – relative granule density; μ_0, μ_k – initial and final values of relative density; $\varepsilon = 1-\mu$ – relative porosity; σ_m – yield strength of the material; η – plasticity constant; f – coefficient of friction.

For any point in the deformation process the differential equations of equilibrium in cylindrical coordinates are written as follows (Pisarenko & Mozharovsky, 1981; Hashiguchi & Yamakawa, 2012; Landau & Lifshits, 2013; Bettinotti et al., 2017; Lu & Li, 2017):

$$\frac{\partial \sigma_R}{\partial R} + \frac{\partial \tau_{Rz}}{\partial z} + \frac{\sigma_R - \sigma_\varphi}{R} = 0 \tag{1}$$

$$\frac{\partial \tau_{zR}}{\partial R} + \frac{\partial \sigma_z}{\partial z} + \frac{\tau_{zR}}{R} = 0 \tag{2}$$

The plasticity condition is applied in the following form (Landau & Lifshits, 2013; Bratishko, 2020):

$$(\sigma_R - \sigma_\varphi)^2 + (\sigma_\varphi - \sigma_z)^2 + (\sigma_z - \sigma_R)^2 + 6 \cdot \tau_{Rz}^2 = 2 \cdot \sigma_m^2 \tag{3}$$

An elementary volume of a granule with the corresponding stress tensor components is shown in Fig. 2. Under axisymmetric loading conditions in meridional planes passing through the z -axis, the tangential stresses are zero, and the stress components are independent of the coordinate φ .

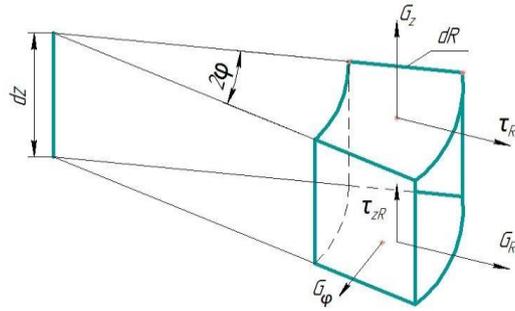

Fig. 2 – Schematic diagram of the elementary volume of the deformation element together with the components of the stress tensor during the granulation process

According to the Haar-Karman condition of full plasticity (Pisarenko & Mozharovsky, 1981; Salman et al., 2007; Payne et al., 2016), when the movement of the material in the radial direction is limited by the die wall, and tangential movement is kinematically prohibited due to the symmetrical separation of the surface in the planes φ, it can be assumed that $\sigma_\phi = \sigma_R$. In addition, the normal radial stress σ_R is directly proportional to the density of the material during the granulation process and within the limits $\mu = 1$ reaching value σ_z (Bratishko, 2014; Boltjanskaya, 2018; Pietsch, 2002):

$$\sigma_\phi = \sigma_R = \mu \cdot \sigma_z \tag{4}$$

Under conditions of fully-sided non-uniform compression, where the spherical component of the stress tensor significantly dominates the deviatoric component, a relationship is established between the normal axial (or radial) stress and the deviatoric stress. The relationship between the tangential and normal radial stresses is linear. In practice, the relative density of granules during the granulation process μ is approximately equal to the lateral pressure coefficient.

Relative density, as well as the deformation path or time, are common variables of the granulation process. However, for the studied fixed moment it is considered a constant when calculating the stress state.

Taking into account the proposed assumption (4), the law of paired tangential stresses $\tau_{Rz} = \tau_{zR} = \tau$ and the corresponding designation, $\sigma = \sigma_z$ the system of equations (1) – (3) can be expressed as follows:

$$\mu \frac{\partial \sigma}{\partial R} + \frac{\partial \tau}{\partial z} = 0 \tag{5}$$

$$\frac{\partial \tau}{\partial R} + \frac{\partial \sigma}{\partial z} + \frac{\tau}{R} = 0 \tag{6}$$

$$(1 - \mu)^2 \cdot \sigma^2 + 3 \cdot \tau^2 = \sigma_m^2 \tag{7}$$

The plasticity condition (Aruffo et al., 2024) establishes the following relationship between the components of the stress tensor:

$$\sigma = \varepsilon^{-1} \cdot (\sigma_m^2 - 3 \cdot \tau^2)^{0.5} \tag{8}$$

$$\tau = 0.58 \cdot (\sigma_m^2 - \varepsilon^2 \cdot \sigma^2)^{0.5} \tag{9}$$

For the following calculations we will create a table of derivatives of these expressions, using the concept, known in mathematics, of taking the derivative of an implicitly defined function and, taking into account (Lublinter, 1990), we will obtain:

For the subsequent calculations, a table of derivatives of these expressions will be will constructed using the mathematical concept of taking the derivative of an implicitly defined function. Taking into account the approach described in Lubliner (1990), it is obtained:

$$\dot{\sigma}_R = 3 \cdot \varepsilon^{-1} \cdot \tau \cdot \dot{\tau}_R \cdot (\sigma_m^2 - 3 \cdot \tau^2)^{-0.5} = -3 \cdot \tau \cdot \dot{\tau}_R \cdot \varepsilon^{-2} \cdot \sigma^{-1} = -\dot{\tau}_z \cdot \mu^{-1} \tag{10}$$

$$\dot{\sigma}_z = 3 \cdot \varepsilon^{-1} \cdot \tau \cdot \dot{\tau}_z \cdot (\sigma_m^2 - 3 \cdot \tau^2)^{-0.5} = -3 \cdot \tau \cdot \dot{\tau}_z \cdot \varepsilon^{-2} \cdot \sigma^{-1} \tag{11}$$

$$\dot{\tau}_R = -0.58 \cdot \varepsilon^2 \cdot \sigma \cdot \dot{\sigma}_R \cdot (\sigma_m^2 - \varepsilon^2 \cdot \sigma^2)^{-0.5} \tag{12}$$

$$\dot{\tau}_R = -0.58 \cdot \varepsilon^2 \cdot \sigma \cdot \dot{\sigma}_R \cdot (\sigma_m^2 - \varepsilon^2 \cdot \sigma^2)^{-0.5} = 0.33 \cdot \varepsilon \cdot \mu^{-1} \cdot \dot{\tau}_z \cdot \tau^{-1} \cdot (\sigma_m^2 - 3 \cdot \tau^2)^{0.5} \quad (17)$$

Equation (6) may be expressed as follows:

$$0.33 \cdot \varepsilon \cdot \tau^{-1} \cdot \mu^{-1} \cdot (\sigma_m^2 - 3 \cdot \tau^2)^{0.5} \cdot \frac{\partial \tau}{\partial z} - 3 \cdot \varepsilon^{-1} \cdot \tau \cdot (\sigma_m^2 - 3 \cdot \tau^2)^{-0.5} \cdot \frac{\partial \tau}{\partial z} + \frac{\tau}{R} = 0 \quad (18)$$

By performing the procedure of separation of variables and summing up the integration, the following is obtained:

$$0.6 \cdot \varepsilon \cdot \mu^{-1} \cdot \int \left(\frac{(0.3 \cdot \sigma_m^2 - \tau^2)^{0.5}}{\tau^2} \right) d\tau - 1.7 \cdot \varepsilon^{-1} \cdot \int (\sigma_m^2 - \tau^2)^{-0.5} d\tau + R_1^{-1} \cdot \int dz = 0 \quad (19)$$

$$0.33 \cdot \varepsilon \cdot \mu^{-1} \cdot \tau^{-1} \cdot (\sigma_m^2 - 3 \cdot \tau^2)^{0.5} + [0.58 \cdot \varepsilon \cdot \mu^{-1} + 1.73 \cdot \varepsilon^{-1}] \cdot \sin^{-1} [1.73 \cdot \tau \cdot \sigma_m^{-1}] - z \cdot R_1^{-1} = C \quad (20)$$

or considering (8):

$$\sigma \cdot \omega^{-1} \cdot \tau^{-1} + \chi \cdot \beta - z \cdot R_1^{-1} = C \quad (21)$$

where:

$$\chi = 0.58 \cdot \varepsilon \cdot \mu^{-1} + 1.73 \cdot \varepsilon^{-1}; \beta = \sin^{-1} [1.73 \cdot \tau \cdot \sigma_m^{-1}]; \omega = 3 \cdot \mu \cdot \varepsilon^{-2} \quad (22)$$

The integration constant C can be found by taking into account the initial and the limiting conditions. At the beginning of plastic deformation on the contact surface between the die and the roller during the granulation process, that is, at $z = h = H_0$ and $R = R_1$, the tangential stress reaches a value equal to the plasticity constant: $\tau = \eta = 0.58 \sigma_m$, and, taking into account condition (7), it is established that the normal stress becomes zero: $\sigma = 0$. Therefore:

$$C = 0.5 \cdot \chi \cdot \pi - H_0 \cdot R^{-1} \quad (23)$$

Then the solution (21) is expressed in the following way:

$$\sigma \cdot \omega^{-1} \cdot \tau^{-1} + \chi \cdot \beta - z \cdot R_1^{-1} = 0.5 \cdot \chi \cdot \pi - H_0 \cdot R^{-1} \quad (24)$$

By substituting $R = R(z)$ into expression (24), the marginal conditions can be satisfied. For a cylindrical die $R = \text{const}$, the value remains constant.

Equation (24) defines the equation of deformation compaction of a porous body, which connects all parameters of the process. To determine stresses σ and τ , this equation must be solved together with the plasticity condition (7), namely, by substituting expressions (8), (9):

$$(\sigma_m^2 - 3 \cdot \tau^2)^{0.5} \cdot \omega^{-1} \cdot \tau^{-1} \cdot \varepsilon^{-1} + \chi \cdot \beta - z \cdot R_1^{-1} = 0.5 \cdot \chi \cdot \pi - H_0 \cdot R^{-1} \quad (25)$$

$$1.73 \cdot (\sigma_m^2 - \varepsilon^2 \cdot \sigma^2)^{-0.5} \cdot \omega^{-1} \cdot \sigma + \chi \cdot \beta - z \cdot R_1^{-1} = 0.5 \cdot \chi \cdot \pi - H_0 \cdot R^{-1} \quad (26)$$

Equations (24)–(26) are transcendental, but functions $\sigma(z, R)$ and $\tau(z, R)$ are given implicitly. Their solution is possible only with the help of numerical methods. However, these equations are a closed solution for the problem of axisymmetric granulation theory of porous bodies under the condition of plasticity.

Let us represent the first term in equation (6) as function of σ and its derivative, using expressions (10), (12), (13):

$$\begin{aligned} \dot{\tau}_R &= -0.58 \cdot \varepsilon^2 \cdot \sigma \cdot \dot{\sigma}_R \cdot (\sigma_m^2 - \varepsilon^2 \cdot \sigma^2)^{-0.5} = \\ &= -0.58 \cdot \varepsilon^2 \cdot \sigma \cdot \dot{\tau}_z \cdot \mu^{-1} \cdot (\sigma_m^2 - \varepsilon^2 \cdot \sigma^2)^{-0.5} = \\ &= -0.33 \cdot \varepsilon^4 \cdot \sigma^2 \cdot \dot{\sigma}_z \cdot \mu^{-1} \cdot (\sigma_m^2 - \varepsilon^2 \cdot \sigma^2)^{-1}. \end{aligned} \quad (27)$$

Equation (6) can be rewritten as follows:

$$-0.33 \cdot \varepsilon^4 \cdot \sigma^2 \cdot \mu^{-1} \cdot (\sigma_m^2 - \varepsilon^2 \cdot \sigma^2)^{-1} \cdot \frac{\partial \sigma}{\partial z} + \frac{\partial \sigma}{\partial z} + \frac{\tau}{R} = 0 \quad (28)$$

Both parts of the equation are divided by τ , using the substitution of expression (9):

$$-0.33 \cdot \varepsilon^4 \cdot \sigma^2 \cdot \mu^{-1} \cdot \tau^{-1} \cdot (\sigma_m^2 - \varepsilon^2 \cdot \sigma^2)^{-1} \cdot \frac{\partial \sigma}{\partial z} + \tau^{-1} \cdot \frac{\partial \sigma}{\partial z} + R^{-1} = 0 \quad (29)$$

$$-0.58 \cdot \varepsilon \cdot \sigma^2 \cdot \mu^{-1} \cdot \left(\left[\frac{\sigma_m}{\varepsilon} \right]^2 - \sigma^2 \right)^{-1.5} \cdot \frac{\partial \sigma}{\partial z} + 1.73 \cdot \varepsilon^{-1} \cdot \left(\left[\frac{\sigma_m}{\varepsilon} \right]^2 - \sigma^2 \right)^{-0.5} \cdot \frac{\partial \sigma}{\partial z} + R^{-1} = 0 \quad (30)$$

By separating variables and integrating, it is obtained:

$$-0.58 \cdot \varepsilon \cdot \mu^{-1} \cdot \int \left[\sigma^2 \cdot \left(\left[\frac{\sigma_m}{\varepsilon} \right]^2 - \sigma^2 \right)^{-1.5} \right] d\sigma + 1.73 \cdot \varepsilon^{-1} \cdot \int \left(\left[\frac{\sigma_m}{\varepsilon} \right]^2 - \sigma^2 \right)^{-0.5} d\sigma + \int R^{-1} dz = 0 \quad (31)$$

$$-0.58 \cdot \varepsilon \cdot \mu^{-1} \cdot \left[\sigma \cdot \left(\left[\frac{\sigma_m}{\varepsilon} \right]^2 - \sigma^2 \right)^{-0.5} - \sin^{-1} \left[\varepsilon \cdot \sigma \cdot \sigma_m^{-1} \right] \right] + 1.73 \cdot \varepsilon^{-1} \cdot \sin^{-1} \left[\varepsilon \cdot \sigma \cdot \sigma_m^{-1} \right] + z \cdot R^{-1} = C \quad (32)$$

$$\left[0.58 \cdot \varepsilon \cdot \mu^{-1} + 1.73 \cdot \varepsilon^{-1} \right] \cdot \sin^{-1} \left[\varepsilon \cdot \sigma \cdot \sigma_m^{-1} \right] - 0.58 \cdot \varepsilon^2 \cdot \mu^{-1} \cdot \sigma \cdot (\sigma_m^2 - \varepsilon^2 \cdot \sigma^2)^{-0.5} + z \cdot R^{-1} = C \quad (33)$$

Or, taking into account (9) and (12):

$$\chi \cdot \alpha - \sigma \cdot \omega^{-1} \cdot \tau^{-1} + z \cdot R_1^{-1} = C \quad (34)$$

The constant of integration C can be determined using the initial and marginal conditions, for example, when $z = h = H_0$ and $R = R_1$. During the start of plastic deformation when $\tau = \eta = 0.58 \sigma_m$, $\sigma = 0$, the value of C will be equal to H_0 / R . The resulting solution (34) takes the following form:

$$\chi \cdot \alpha - \sigma \cdot \omega^{-1} \cdot \tau^{-1} + z \cdot R_1^{-1} = H_0 \cdot R^{-1} \quad (35)$$

Comparing Equations (24) and (35), it can be concluded that they essentially express the same equation, differing only in the angles α and β , as shown in (Fig. 3). By adding their left and right parts, the plasticity condition is obtained (7), which is expressed by the angles α and β :

$$\sin^{-1} \left[1.73 \cdot \tau \cdot \sigma_m^{-1} \right] + \sin^{-1} \left[\varepsilon \cdot \sigma \cdot \sigma_m^{-1} \right] = \alpha + \beta = \pi / 2 \quad (36)$$

Equation (35) can also be obtained from equation (24) by replacing β angle with angle $\alpha: \beta = \alpha - \pi / 2$.

The presence of trigonometric functions of angles in the equation of deformation compaction is a result of the relationship between normal and tangential stresses σ and τ according to the algebraic dependence (7).

To find stresses σ and τ using simple formulas, the specifics of axisymmetric loading are used. Let us turn again to Fig. 3. The nominal cross-section in the granulation channel, as well as the plasticity circle, have the shape of a circle with radius R . The point under consideration O_1 is located on a circle with radius R_1 . The section of this circle with diagonal OO_2 of triangle OO_2B_2 yields point O_1 that has the same coordinates z and R_1 , and is also in the same stress state as point O_1 . The projection of radius $R_1(OO_1)$ onto axis $\tau(R)$ forms segment $R_2(OB_1)$ and creates a coordinate triangle OO_1B_1 . Right triangles OO_2B_2 and OO_1B_1 with the same angles α and β have geometric similarities, that is:

$$\begin{aligned} \zeta = \sin \beta &= \frac{R_2}{R_1} = 1.73 \cdot \tau^{-1} \cdot \sigma_m^{-1} \\ \cos \beta &= \varepsilon \cdot \sigma \cdot \sigma_m^{-1} = \frac{\sqrt{R_1^2 - R_2^2}}{R_1} = \sqrt{1 - \left[\frac{R_2}{R_1} \right]^2} = \sqrt{1 - \zeta^2} \\ \sigma \cdot \tau^{-1} &= 1.73 \cdot \varepsilon^{-1} \cdot [\tan \beta]^{-1} \cdot 1.73 \cdot \varepsilon^{-1} \cdot \beta^{-1} \\ \sigma &= \sigma_m \cdot \varepsilon^{-1} \cdot \sqrt{1 - \zeta^2}; \quad \tau = 0.58 \cdot \zeta \cdot \sigma_m \end{aligned} \quad (37)$$

To calculate stresses σ and τ using formulas (37), it is sufficient to find the value of angle β and coefficient ζ . Let's substitute ratio σ/τ from formula (37) into (24), After minor transformations, a quadratic three-term equation is obtained, from which angle β is determined, and then coefficient ζ :

$$a \cdot \beta^2 + b \cdot \beta + c = 0; \beta_{1,2} = \frac{-b \pm \sqrt{b^2 - 4 \cdot a \cdot c}}{2 \cdot a}$$

where:

$$a = \chi \cdot \omega \cdot \varepsilon; b = -\eta \cdot \omega \cdot \varepsilon; c = 1.73; \eta = \chi \cdot \frac{\pi}{2} - \frac{H_0}{R} + \frac{z}{R_1}; \zeta = \sin\beta \quad (38)$$

The coefficient ζ is a complex function of the coordinates of the points within the elementary volume undergoing deformation, the relative density of the granules, and the yield strength of the material being deformed at a given temperature and granulation speed mode.

The system of equations (37), (38) is a closed analytical solution to the equation of deformation compaction of a porous body. In addition to calculations and analysis of local characteristics of the stress state of the granulation process, these equations allow determining the integral parameters of this process: of pressure, the force and deformation work.

The force calculation of the granulation process will be carried out by constructing force diagrams and determining the deformation work, which are related to the determination of the average integral value of pressure on the contact surface between the material and the die during the granulation process S at $z=h$, $R = R_1$. The average pressure, without taking into account the contact friction forces, is calculated using the following formula:

$$\begin{aligned} g_i &= \frac{1}{S_i} \cdot g_i(S) \cdot dS = \frac{1}{S_i} \cdot [\sigma_z + \tau_{zR}] \cdot dS = \frac{1}{\pi \cdot R_1^2} \int_0^R \left[\frac{\sigma_m}{\varepsilon} \cdot \sqrt{1-\zeta^2} + \frac{\zeta \cdot \sigma_m}{\sqrt{3}} \right] d(\pi \cdot R^2) = \\ &= \frac{2 \cdot \sigma_m}{R_1^2} \int_0^R \left[\frac{1}{\varepsilon} \cdot \sqrt{1-\zeta^2} + \frac{\zeta}{\sqrt{3}} \right] \cdot R \cdot dR. \end{aligned} \quad (39)$$

Based on the results of numerical integration (39), a diagram of the granulation process $g_i(\mu)$ is constructed, considering that $\varepsilon = 1-\mu$. It is important to note here that plastic deformation of the material does not occur at a zero value of the average pressure during the granulation process, calculated on the contact area. At the beginning of the process, the average pressure has a clearly defined value, which was taken into account when determining the initial and the marginal conditions and which can be calculated using formula (39).

The formula for the calculation of the force of the granulation process is as follows (Pisarenko & Mozharovsky, 1981; Bratishko, 2014; Bratishko, 2014):

$$P_i = g_i \cdot S_i = 2 \cdot \pi \cdot \sigma_m \cdot \int_0^R \left(\left[\varepsilon^{-1} \cdot \sqrt{1-\zeta^2} + \frac{\zeta}{\sqrt{3}} \right] \cdot R \right) dR \quad (40)$$

The impact of the contact friction forces is considered taking into account the efficiency of granulation processes of porous materials, which largely depends on the interaction of the lateral surface of granulation with the wall of the die, especially when the movement occurs. The speed of the movement of the material particles along the height of the spinneret during the granulation process decreases from the maximum value \mathcal{G} to zero, this means that the roller moves at a constant speed \mathcal{G} . This results in a lateral friction force that consistently counteracts the effective force exerted by the roller on the material during the granulation process. This interaction positively influences the process flow by reducing deformation resistance and lowering the energy required for deformation work.

The average value of the normal lateral pressure is calculated as (Zhou et al., 2021; Probst & Ileleji, 2016):

$$g_R = \frac{1}{h} \cdot \int_0^h [\sigma_R(z) + \tau_{Rz}(z)] dz = \sigma_m \cdot h^{-1} \cdot \int_0^h \left[\mu \cdot \varepsilon^{-1} \cdot \sqrt{1-\zeta^2} + \frac{\zeta}{\sqrt{3}} \right] dz \quad (41)$$

The Amonton-Coulomb law shows that the frictional force between the surfaces is proportional to the lateral pressure (Pisarenko & Mozharovsky, 1981; Bratishko, 2014; Bratishko, 2020):

$$\tau = f \cdot g_R = f \cdot \sigma_m \cdot h^{-1} \cdot \int_0^h \left[\mu \cdot \varepsilon^{-1} \cdot \sqrt{1 - \zeta^2} + \frac{\zeta}{\sqrt{3}} \right] dz \quad (42)$$

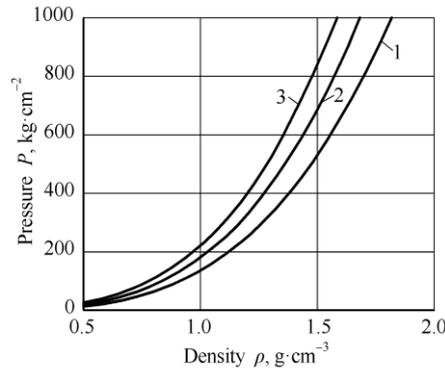

Fig. 4 – Dependence of specific pressing pressure P on the density of the material ρ for various values of the physical and mechanical properties of the material mixture

1 – $\delta = 141.4$; 2 – $\delta = 183.2$; 3 – $\delta = 220.6$

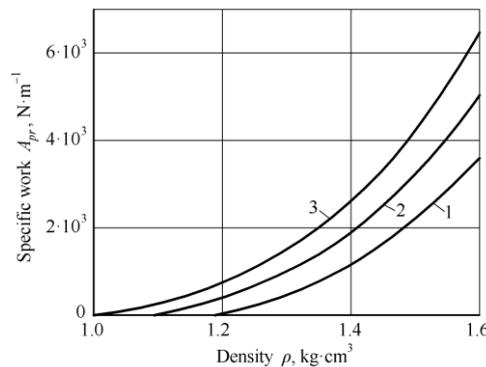

Fig. 5 – Dependence of the specific work A_{pr} of the granulation process on the density ρ of the material for various values of the physical and mechanical properties of the material mixture:

1 – $\delta = 141.4$; 2 – $\delta = 183.2$; 3 – $\delta = 220.6$

The lateral friction force is defined as the result of multiplying the specific friction force by the area of the lateral contact surface of the die during the granulation process. This ratio shows how the friction force depends upon the contact area and the magnitude of the specific friction force:

$$F_T = \tau \cdot S_R = 2 \cdot \pi \cdot R \cdot f \cdot \sigma_m \cdot \int_0^h \left[\mu \cdot \varepsilon^{-1} \cdot \sqrt{1 - \zeta^2} + \frac{\zeta}{\sqrt{3}} \right] dz \quad (43)$$

With this conclusion it can be claimed that the lateral friction force is determined by the contact area between the granulation surface and the bulk material that is supplied for granulation. This is of great importance in the analysis and calculation of the force parameters of the granulation process and the reduction of deformation resistance.

To take into account the impact of the contact friction forces during the granulation of a porous body in the moving die, the following calculation expression is used:

$$P = P_i - F_T = 2 \cdot \pi \cdot \sigma_m \cdot \left[\int_0^R \left(\left[\varepsilon^{-1} \cdot \sqrt{1 - \zeta^2} + \frac{\zeta}{\sqrt{3}} \right] \cdot R \right) dR - R \cdot f \cdot \int_0^h \left[\mu \cdot \varepsilon^{-1} \cdot \sqrt{1 - \zeta^2} + \frac{\zeta}{\sqrt{3}} \right] dz \right] \quad (44)$$

The displacement of deformation and the relative density of granules during the granulation process are related by the following relationship:

$$\Delta h = H_0 - H \cdot \mu^{-1} \quad (45)$$

Accordingly, the expressions for calculating the current value of the deformation work and the total work have the following form:

$$A_p = \int_0^{\Delta h} P(\Delta h) d(\Delta h) = \int_{\mu_0}^{\mu} P(\mu) d\mu \quad (46)$$

$$A_z = \int_0^{H_0-H} P(\Delta h) d(\Delta h) = \int_{\mu_0}^{\mu_k} P(\mu) d\mu \quad (47)$$

The above equations and formulas facilitate the calculations and analysis of the force parameters of the granulation process of porous bodies. They allow taking into account the impact of contact friction forces upon the process, which helps to determine the efficiency of the proposed process flow diagram and energy costs for deformation.

It should be noted that granulated materials have several advantages over the bulk materials. One of the main limiting factors for the widespread use of granulation is the low energy efficiency of the existing granulators. For example, the ring die granulators with a capacity of up to $1 \text{ t}\cdot\text{h}^{-1}$ are equipped with drive electric motors with a power of 90-110 kW.

Based on our calculations, innovative energy-efficient granulators are being developed from the original design of the press rollers and the annular die. A possibility to obtain granules from some types of both agricultural and wood processing raw materials has been experimentally proven. The research is carried out on a specially created experimental setup, which is shown in Fig. 6. Taking into account that the parameters of granulation processes influence a number of input factors, the granulation processes must be described by multifactorial dependencies that can be obtained on the basis of the theory of planning multifactorial experiments. To formulate the planning task correctly, it is necessary to conduct preliminary studies of the impact of individual factors.

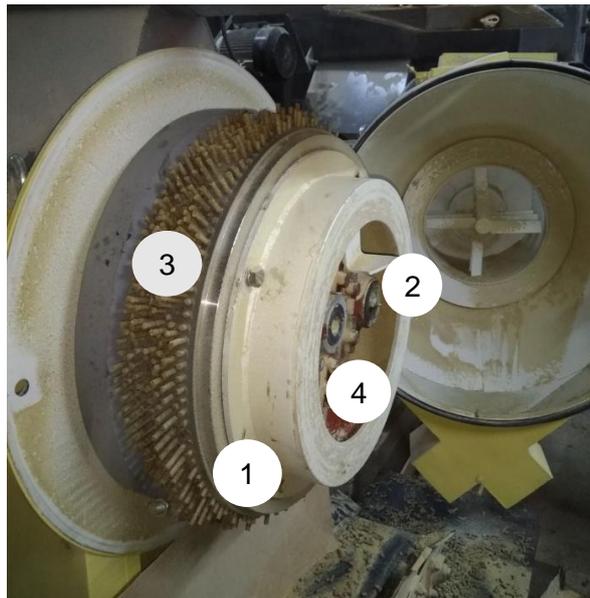

Fig. 6 – Experimental setup for granulating agricultural waste
1 – die; 2 – roller; 3 – granulate material; 4 – spinneret

During the experiments, the granulation system was used to process agricultural waste as well as wood-processing raw materials. The raw material was fed using a screw conveyor with adjustable drive shaft speed. The input parameters identified as influencing pellet quality and production efficiency were: temperature, raw material moisture content, the rotational speed of the gear transmission pinion, n , (rpm), and the screw shaft speed, n_w , (rpm). The raw material temperature was measured using a pyrometer-thermometer (model AZ-8838), and moisture content was measured with a Greisinger GMK100 non-contact moisture meter. The diameter of the die holes was 8 mm. Granulation productivity Q and pellet density ρ were selected as the main evaluation criteria. Productivity was determined using the well-known formula $Q = m \tau^{-1}$ ($\text{kg}\cdot\text{h}^{-1}$), where m is the mass of granules, obtained over time t .

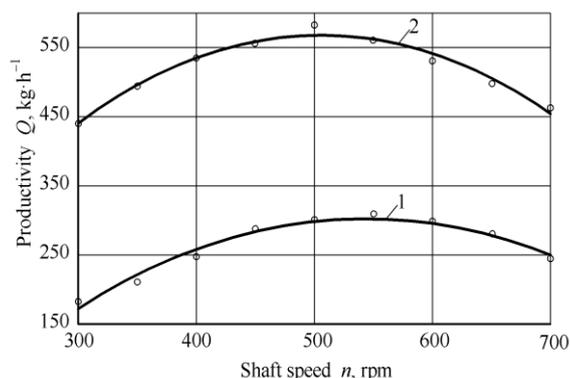

Fig. 7 – Dependence of granulation productivity of agricultural raw materials on the number of revolutions of granulator’s leading shaft ($d = 8 \text{ mm}$; $n_w = 20 \text{ rpm}$; $T = 14^\circ\text{C}$; $W = 34.8\%$)
 1 – two-roller granulation system; 2 – three-roller granulation system

Fig. 7 shows dependence of granulation productivity of agricultural raw materials on the number of drive shaft revolutions. It is evident that the dependencies have an optimum in the range of 500 – 550 rpm. In addition, it was found that when the material sticks to the die, the productivity decreases by 1.5-2.0 times. It is necessary to determine the factors that influence the nature of the free (without sticking) exit of granules through the holes of the die. During granulation of the raw materials its humidity and temperature were taken into account.

Fig. 8 presents the graphical dependence of the granulation productivity of woodworking raw materials on the number of revolutions of the granulator’s leading shaft.

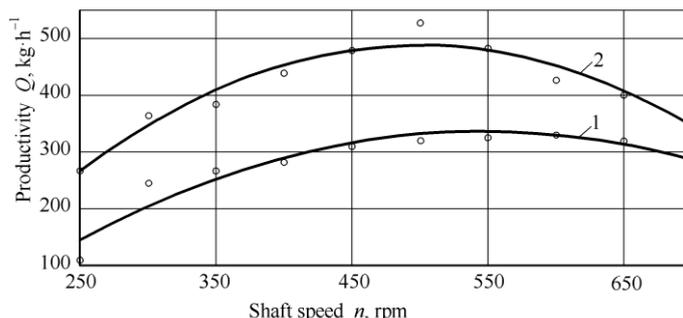

Fig. 8 – Dependence of granulation productivity of woodworking raw materials on the number of revolutions of the granulator’s leading shaft ($d = 8 \text{ mm}$; $n_w = 20 \text{ rpm}$; $T = 14^\circ\text{C}$; $W = 25.4\%$)
 1 – two-roller granulation system; 2 – three-roller granulation system

It has been established that dependence $Q(n)$ is also of an extreme nature. Maximum productivity (over $320 \text{ kg}\cdot\text{h}^{-1}$) is observed in the range of rotational speeds of the granulator’s leading shaft – from 600 to 700 rpm.

One of the key quality indicators of granules is their density, which was measured both immediately after production and after cooling. To determine granule density, samples with identical moisture content and temperature were taken, but produced at varying screw conveyor shaft speeds $n_w = 10 - 70 \text{ rpm}$, while maintaining a constant rotational speed of the granulator’s leading shaft $n = 500 \text{ rpm}$. The tests were conducted at different initial raw material moisture contents: 15.1%, 25.4%, and 34.8%.

The data, obtained during the experiment, are presented in Table 1.

Table 1

Density of granules of the agricultural raw materials depending on the number of revolutions of the screw conveyor "before cooling" / "after cooling" at different humidity of the raw materials

Number of screw revolutions n_w , rpm	Density of granules ρ , kg·m ⁻³ at various raw material moisture					
	15.1%		25.4%		34.8%	
	before cooling	after cooling	before cooling	after cooling	before cooling	after cooling
10	1252.2	1181	1140.3	1120.1	1011.2	951.8
20	1181.8	1123.4	1157.4	1120.9	1065.4	1023.2

Number of screw revolutions n_w , rpm	Density of granules ρ , kg·m ⁻³ at various raw material moisture					
	15.1%		25.4%		34.8%	
	before cooling	after cooling	before cooling	after cooling	before cooling	after cooling
30	1142.4	1078.9	1131.7	1102.6	1053.2	987.2
40	1210.2	1157.1	1110.2	1113.4	1034.4	974.5
50	1194.6	1078.5	1109.9	1100.5	1036.1	967.4
60	1248.3	1167.7	1134.4	1137.5	1011.5	996.6
70	1242	1185.9	1140.3	1120.4	1030.1	950.7

A graphical representation of the results of the experiment with a change in the granule density from the number of revolutions of the screw conveyor before and after cooling is shown in Fig. 9. It can be seen that the density remains almost constant, changing within 10%.

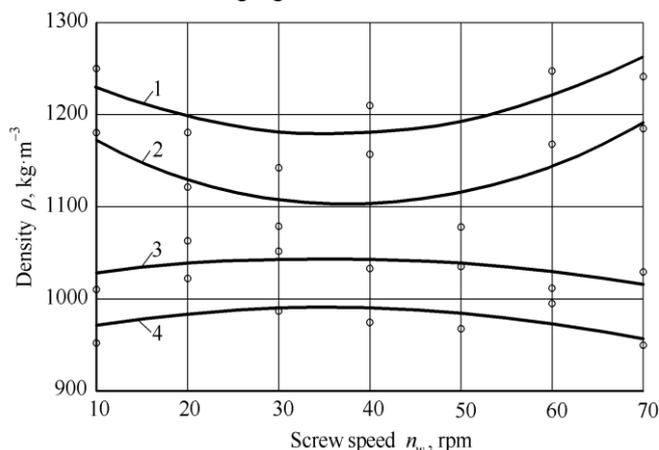

Fig. 9 – Graphic dependencies of the change of the granule density before and after cooling
 1 – granules before cooling; 2 – granules after cooling; ($d = 8$ mm; $T = 140^\circ\text{C}$; $W = 15.1\%$); 3 – granules before cooling;
 4 – granules after cooling; ($d = 8$ mm; $T = 140^\circ\text{C}$; $W = 34.8\%$)

The graphs presented in Fig. 9 show that the density of the granules, regardless of the initial moisture content of the raw material (from 15% to 35%), is practically independent of their cooling but depends on the feed rate of the raw material into the granulation zone. Thus, with an initial raw material moisture content of 34.8% an extreme value may be observed at the screw speed of $n_w = 20$ -30 rpm (Fig. 9).

Under the condition of lower initial raw material moisture content (15.1%) the granules obtained have a denser structure ($\rho \approx 1200$ kg m⁻³), and with high initial raw material moisture content (more than 35%), the density of the obtained granules decreases to $\rho \approx 950$ kg·m⁻³. In addition, it should be said that in the operating mode of the granulator ($n = 500$ rpm and $n_w = 50$ rpm), in which the highest productivity is observed, the density of the granules is the lowest.

A series of preliminary experimental studies showed that the selected input factors have a significant impact on the initial parameters of the granulation process, which allows constructing correctly a plan for conducting multifactorial studies and identifying mathematical dependencies that describe the granulation process.

CONCLUSIONS

The application of the continuum model to the force calculation of the granulation process of porous bodies made it possible to obtain a comprehensive analytical solution for an axisymmetric problem. Application of the continuum model to the force calculation of the granulation process of porous bodies made it possible to obtain a complex analytical solution for an axisymmetric problem. The obtained mathematical dependencies take into account the differential equations of equilibrium and the plasticity condition. Since this solution applies to bodies of revolution of general shape and setting, it can be used for any axisymmetric loading scheme.

Equations for deformation compaction of a porous body have been obtained, both for an ideal granulation process and taking into account the forces of contact friction.

A method has been developed for calculation of local parameters of the stress state during the granulation process, using the coordinates of the plastic deformation point, as well as integral process parameters, such as pressure, force and the deformation work.

It was established that under the conditions of initial raw material moisture content (15.1%), the granules obtained have a denser structure ($\rho \approx 1200 \text{ kg m}^{-3}$), and with high initial raw material moisture content (more than 35%), the density of the obtained granules decreases to $\rho \approx 950 \text{ kg m}^{-3}$. In addition, it should be said that in the operating mode of the granulator ($n = 500 \text{ rpm}$ and $n_w = 50 \text{ rpm}$), in which the highest productivity is observed, the density of the granules is the lowest.

Keywords: Rotary tilling blades, High frequency quenching, Hardness, Parameter optimization

ABSTRACT

The high-frequency quenching technique can enhance the surface hardness of 65Mn rotary tilling blades, thereby improving their wear resistance. This approach addresses common issues found in conventional rotary tilling blades, such as severe wear failure, short service life, and reduced operational efficiency due to frequent replacements. The quenching position was determined through finite element simulation. Based on orthogonal rotation combination tests using ternary quadratic regression, quenching temperature, tempering temperature, and tempering time were identified as key test factors. Using blade hardness as the evaluation index, the optimal parameters were determined to be a quenching temperature of 852 °C, tempering temperature of 171 °C, and tempering time of 85 minutes. Under these conditions, the blade hardness reached 57.5 HRC, meeting the national standard. Blades treated with these optimal quenching parameters were tested under actual soil conditions over a total operating area of 67 hm². The results showed that the average wear of the quenched blades was 11.9 g, and their wear resistance was 3.13 times higher than that of blades treated with conventional heat treatment. This represents a significant improvement in abrasion resistance and provides a solid experimental foundation for the reliability assessment of rotary tilling blades.

摘要

针对目前市面上旋耕刀工作过程中磨损失效严重, 使用寿命低, 耕作时需要频繁更换刀具影响作业效率等问题。采用高频淬火技术, 对 65Mn 旋耕刀表面进行强化处理从而提高其耐磨性。通过有限元仿真确定淬火位置, 基于三元二次回归正交旋转组合试验。确定了淬火温度, 回火温度和回火时间为关键试验因素, 以旋耕刀的硬度为试验指标, 得出最优试验参数淬火温度为 852 °C, 回火温度为 171 °C, 回火时间为 85min, 此条件下旋耕刀的硬度值为 57.5HRC, 符合国家标准。采用最优工艺参数对 65Mn 旋耕刀进行高频淬火, 在实际土壤环境中进行田间试验, 总作业面积 67hm²。结果表明: 经淬火处理后的旋耕刀平均磨损量为 11.9g, 与传统热处理后的旋耕刀相比耐磨性提高了 3.13 倍, 磨损程度得到极大改善, 为旋耕刀的可靠性研究提供了试验基础。

INTRODUCTION

With the rapid development of agricultural mechanization, the service life of the key parts of agricultural machinery and equipment is expected to get longer and longer (Hao *et al.*, 2021). Rotary tillers are essential agricultural machinery that significantly influence the quality and efficiency of soil tillage. Their supporting rotary tilling blades are responsible for critical operations such as ploughing, soil crushing, and land preparation, resulting in a flat and soft surface suitable for sowing (Xiao *et al.*, 2022). Therefore, the performance and service life of the blades directly affect the overall quality and effectiveness of the rotary tiller.

Most rotary tilling blades just operate in the open air, and interact with sand grains and crop stubble for a long time, resulting in serious wear and tear and a low service life, frequent failure and damage. According to incomplete statistics, more than 80% of the soil parts of agricultural machinery operation are scrapped due to the wear and failure of grinding particles, which not only increases the operation cost of agricultural machinery, but also seriously affects the operation quality and efficiency (Yadav *et al.*, 2020; Zhu *et al.*, 2022; Zhao *et al.*, 2024; Kaur *et al.*, 2011; Temesgen *et al.*, 2009; Valboa *et al.*, 2015; Sun *et al.*, 2022; Li, 2018).

In recent years, how to effectively improve the wear resistance and corrosion resistance of rotary tillage blade surface, reduce the energy consumption and reduce the loss is an urgent problem to be solved for agricultural machinery (Wang *et al.*, 2013; Shen *et al.*, 2022). In the past, to enhance the surface hardness of rotary tilling blades, many researchers both domestically and internationally have employed various coating preparation techniques to create wear-resistant layers on the blade surface, achieving significant research

outcomes (Xiao et al., 2013; Falalu et al., 2020; Wang et al., 2022; Xie et al., 2021; Dariusz et al., 2017; Huang et al., 2015; Lee et al., 2006; Satit et al., 2007). However, these methods often involve high equipment costs, complex procedures, and expensive materials, making them difficult to implement on a wide scale and limiting their practical applicability.

In order to reduce the cost, this study adopts partial high-frequency quenching technique, compared with the traditional heat treatment technique, which has the advantages of extremely fast heating speed, easy depth control of quenching layers, uniform heating and high production efficiency. Moreover, only the surface of a certain depth of the workpiece is reinforced, while the core parts basically maintain the organization and performance before treatment, so that the combination of high strength, high wear resistance and high toughness can be obtained. Because 65 Mn materials have better friction performance and better economy, the 65 Mn rotary tilling blades were selected to analyze the significance of the influence of each factor on the hardness of rotary tilling blades. Finally, the field test was carried out to verify the actual working effect of partial high frequency quenching, so as to provide a reference for improving the wear resistance of the surface of rotary blades.

MATERIALS AND METHODS

Partial high-frequency quenching technique of rotary tilling blades

High-frequency quenching is a rapid surface treatment technique characterized by controllable quenching depth and uniform heating. It selectively hardens the surface of the workpiece to a specific depth while preserving the original microstructure and mechanical properties of the core. As a result, it achieves an optimal combination of high strength, excellent wear resistance, and good toughness. Additionally, the method offers numerous advantages, including a high start-up success rate, high efficiency, precise control, smooth and continuous power adjustment (10–100% of rated power), reliable operation, advanced technological integration, and ease of operation.

The partial high-frequency quenching technique of rotary tilling blades is: first start the power supply, the machine begins to work; operate the partial high-frequency quenching device through the control panel of the equipment; hold the rotary tilling blades in the clamp device on the bench and clamp it; transfer the rotary tilling blades to the induction coil by the turntable automatically changing positions; heat the blade by moving the high-frequency induction coil to the blade position; use the infrared high-temperature sensor to collect the temperatures; and give feedback to the PLC control system. When heated to the set temperature range, the system automatically stops heating and returns to the original position; clamp the cylinder and loosen the blade; the return cylinder pushes the blade into the quenching fluid to cool it quickly; complete the quenching of a blade. Replace the rotary tilling blades in turn with the rotation of the turntable and repeat the high frequency quenching technique, as shown in Fig. 1.

Fig. 1 - Flow chart of high-frequency partial quenching technique of rotary tilling blades

Test materials and equipment

Type IT245 rotary tilling blade was selected, as shown in Fig. 2 below, the material is 65 Mn steel, and its chemical composition is shown in Table 1. According to the shape of the rotary tilling blade selected, the electromagnetic induction coil used was bent to a fixed shape, as shown in Fig. 3 below.

Table 1

65 Mn Steel Chemical Composition (wt.%)

C	Si	Mn	P	S	Cr	Ni	Cu
0.62~0.70	0.17~0.37	0.90~1.20	≤0.035	≤0.035	≤0.25	≤0.25	≤0.25

Fig. 2 - The rotary tilling blades of choice

Fig. 3 - Electromagnetic induction heating coils

The high frequency quenching device is used to quench the rotary tilling blade, and SX2-15-12 box resistance furnace to temper the blades, FLIR-T440 infrared thermal imager to measure the temperature, and HR-150A Roche hardness tester to measure the hardness.

The partial high-frequency quenching device is mainly composed of control system, cooling device, heating device, power supply, clamping device and working table, as is shown in Fig. 4.

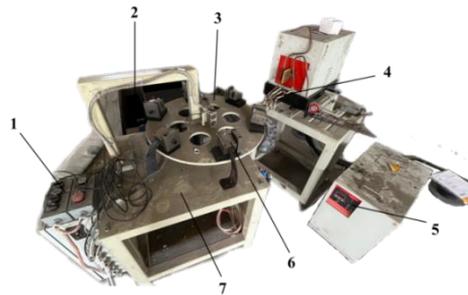

Fig. 4 - Rotary tilling blades high-frequency partial quenching device

 5 – Power supply; 6 – Clamping device; 7 – Working table

Experiment indicators and methods

Each set of tests was conducted indoors with all doors and windows closed, maintaining a constant temperature of 15 °C. The rotary tilling blades underwent partial quenching. The quenching frequency was set to 20 kHz, resulting in an effective quenching depth of approximately 0.8–1.5 mm. After quenching, the blades were cooled using No. 20 mechanical oil at room temperature, then tempered in an SX2-15-12 box resistance furnace and allowed to cool to room temperature following tempering. The surface of each specimen was cleaned, and one side was polished using No. 800 corundum sander to remove the oxide layer. Hardness measurements were performed using an HR-150A Rockwell hardness tester. Each blade's surface hardness was measured three times, and the average was taken as its final hardness value. Each test level was repeated three times, and the average of these three repetitions was used as the final hardness value for that level.

Finite element simulation of rotary tilling blades

To determine the optimal partial quenching position of the rotary tilling blade, the blade was modeled in SolidWorks and analyzed using ANSYS Workbench. The test focused on the right-side machete blade of the IT245 rotary tiller. The 3D model was created in SolidWorks using operations such as stretching, bending, scanning and cutting, as illustrated in Fig. 5 and Fig. 6.

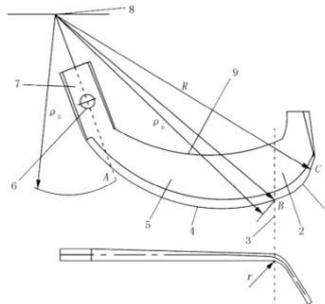

Fig. 5 - Schematic diagram of the structure of the rotary tilling blades

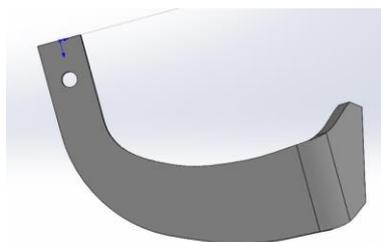

Fig. 6 - Geometric solid model

65 Mn is often adopted as the model material, and the main mechanical properties are shown in Table 2.

Table 2

65 Mn mechanical properties table

Material	Density / kg·m ⁻³	Elastic modulus / GPa	Poisson's ratio	Yield strength / MPa	Allowable stress / MPa
65Mn	7850	210	0.3	800	340

To improve the grid quality, the tetrahedral mesh was used to automatically divide the geometry, and the size of the grid was set to 6 mm to generate 2398 tetrahedral units, 10378 nodes, with a good grid quality of 0.7, as shown in Fig. 7.

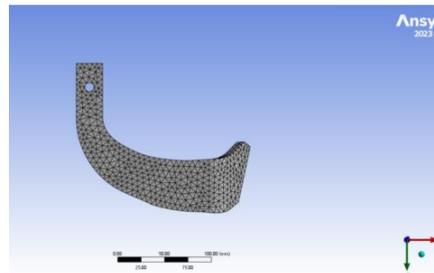

Fig. 7 - Meshing the model

Loads and boundary conditions were applied to the rotary tilling blades based on actual working conditions. Fixed constraints were assigned to the inner surfaces of the circular mounting holes. A force of 500 N, perpendicular to the surface, was applied to the side cutting edges, main cutting edges, and transition surface cutting edges for simulation and analysis.

Analysis of simulation results

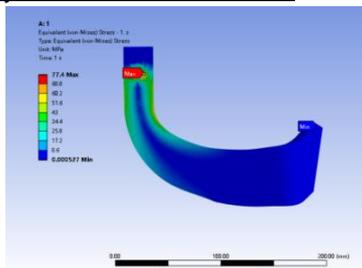

Fig. 8- Stress contour diagram

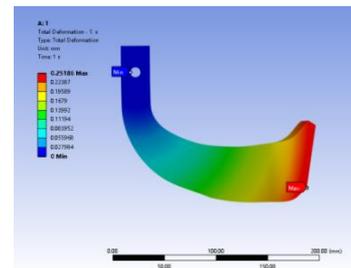

Fig. 9 - Total deformation contour diagram

Fig. 8 and Fig. 9 show the results of the static simulation analysis. The stress is concentrated at the mounting hole of the blade handle, as the rotary tilling blade acts as a single-degree-of-freedom rigid body. The section of the blade furthest from the constraint exhibits lower rigidity and greater deformation. Conversely, the area near the constraint, the handle, experiences the highest stress concentration due to the restriction at the tie point, with a maximum stress value of 77.4 MPa. The maximum displacement occurs at the main and side cutting edges and gradually decreases symmetrically toward both sides. The maximum total deformation is 0.25 mm, indicating that the simulation results meet the mechanical strength requirements for steel. Furthermore, the results are consistent with the actual fracture-prone areas observed in the field. Based on this analysis, the optimal quenching position is identified as the main cutting edge.

Analysis of influencing factors

Uni-variate test

The test aims to identify the factors that influence the wear resistance of the blade, specifically quenching temperature, tempering temperature, and tempering time. By varying one factor while keeping the others constant, the significance of each factor's impact on the test index can be assessed. If a factor has a significant effect, a reasonable value range is determined and later used as an input in the multi-factor optimization test. The quenching temperature is preset at 9 levels ranging from 800°C~880°C; the tempering temperature at 9 levels from 170°C~250°C; and the tempering time at 9 levels from 80 min~160 min.

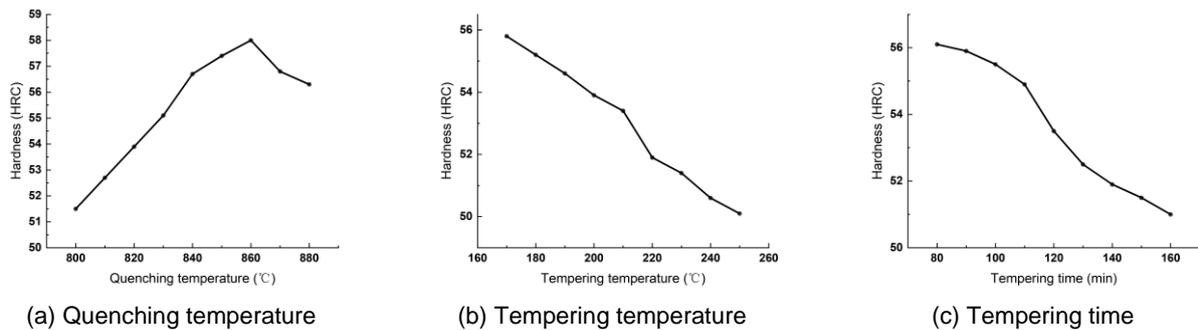

Fig.10 - Statistical graph of single factor examination results

With a tempering temperature of 210°C and a tempering time of 120 minutes, the rotary tilling blades were subjected to quenching to investigate the influence of quenching temperature on hardness. The results indicate that quenching temperature significantly affects the hardness of the rotary tilling blade, making it a critical parameter in the quenching process. According to the test data, a clear relationship between quenching temperature and hardness is observed (as shown in Fig. 10a). Specifically, the hardness of the rotary tilling blade initially increases with rising quenching temperature, reaches a maximum at 840°C, and then gradually decreases. As quenching temperature increases, the dissolution of carbon and alloying elements in the 65Mn steel into the austenite phase becomes more pronounced, promoting the formation of martensite during cooling. Since the hardness of quenched steel is primarily determined by the martensite content, this leads to a peak in hardness at the optimal temperature. However, higher temperatures do not always yield better results. Due to the high sensitivity of 65Mn steel to overheating, temperatures exceeding 840°C cause the austenite grains to coarsen, which diminishes the strength and toughness of the resulting martensite. This, in turn, leads to a reduction in quenching hardness and increased hardness loss during subsequent tempering.

The rotary blades were quenched at a quenching temperature of 840°C and a tempering time of 120 min. According to the test data, the tempering temperature and hardness relationship curves are shown in Fig. 10b. The hardness of rotary blades decreases with the increase of tempering temperature mainly because the tempering of 65 Mn steel is a diffusion and transition process from sub-stable martensite and residual austenite structure to ferrite and carbide. When the tempering temperature is low, the internal stress generated in the quenching process cannot be fully released, resulting in a slight hardness decrease. If the internal stress cannot be fully alleviated, cracking or deformation problems will arise. When the tempering temperature reaches 210°C, it is a more suitable tempering temperature for 65 Mn steel blades; within this temperature range, the internal stress can be effectively released and the hardness can be moderately reduced; customarily, a higher comprehensive hardness and toughness can be obtained, thus meeting the requirements of rotary blades. However, when the tempering temperature is too high, the martensite structure will be further decomposed (converting to bainite or ferrite). As a result, the hardness will be greatly reduced, which will also reduce the abrasive resistance and impact resistance of the blades.

The rotary blades were quenched at a quenching temperature of 840°C and a tempering temperature of 210°C. According to the test data, the relationship curves of tempering time and hardness are shown in Fig.10c. The change trends and principles of hardness with the tempering time are consistent with those of the tempering temperature. When the tempering time is too short, the internal stress cannot be released. The residual stress will affect the service life and safety of the blades. The hardness decrease is small, and the ideal comprehensive performance cannot be obtained. When the tempering time reaches 120 min, it can fully release the internal stress and reduce the hardness appropriately, which can maintain a high hardness level, but also improve the toughness and impact resistance of the blades. When the tempering time is too long, the martensite structure will be further decomposed to the more stable bainite or ferrite transition, which will not only lead to a great decrease in hardness, but also reduce the wear resistance and blade retention ability.

Combination trial

Based on the effects of the three factors (quenching temperature, tempering temperature and tempering time) on the hardness of rotary tilling blades, the test adopts Box-Behnken response surface trial design. With the quenching temperature being x_1 , tempering temperature being x_2 , tempering time being x_3 , the hardness response value being Y , the ternary quadratic regression orthogonal rotation combination test is carried out.

Regression analysis is conducted with Design-Expert 12.0 software, and significance verification test and variance analysis are performed on the basis of the test results. The levels of test factors and their coding are shown in Table 3.

Table 3

Level	Parameter		
	Quenching temperature	Tempering temperature	Tempering time
	[°C]	[°C]	[min]
-1	820	170	80
0	840	210	120
1	860	250	160

RESULTS

Test scheme and results

Based on a ternary quadratic regression orthogonal rotation combination test, a total of 17 test groups were conducted. Using blade hardness as the response variable Y , and quenching temperature x_1 , tempering temperature x_2 , and tempering time x_3 as influencing factors, a multiple regression analysis was performed. The regression equation for hardness Y was derived from the test data using Design-Expert 12.0 software, and its statistical significance was subsequently evaluated. The experimental design and corresponding results are presented in Table 4.

Table 4

Combined test protocols and results				
No.	Quenching temperature / [°C]	Tempering temperature / [°C]	Tempering time / [min]	Hardness / [HRC]
1	-1	-1	0	50.6
2	-1	1	1	57.6
3	1	0	1	47.4
4	-1	0	-1	53.1
5	0	1	-1	48.5
6	1	0	-1	56.9
7	0	0	0	48.7
8	1	0	-1	54.5
9	0	0	0	57.9
10	0	0	0	55.9
11	0	0	0	57.4
12	0	-1	1	52.3
13	0	0	0	55.5
14	-1	1	0	54.5
15	1	-1	0	54.7
16	0	0	0	54.5
17	0	1	1	54.1

The input data were analyzed using the Box-Behnken design in Design-Expert software to fit the regression model. Based on the results of the analysis of variance (ANOVA), a quadratic polynomial model was selected to best represent the relationship between the variables. The resulting regression equation describes the relationship between quenching temperature, tempering temperature, and tempering time with respect to blade hardness, and is given as follows:

$$\hat{Y} = 54.66 + 3.36X_1 - 1.85X_2 - 0.7875X_3 - 0.325X_1X_2 - 0.65X_1X_3 - 0.775X_2X_3 - 3.11X_1^2 + 0.62X_2^2 + 0.595X_3^2 \quad (1)$$

The significance test of the coefficients in the regression equation obtained the ANOVA results as shown in Table 4; the significance test coefficient of the hardness Y regression model being $p < 0.0001$, the equation can be deduced to be more significant. The regression equation can better reflect the practical problems. On account of $p = 0.4905 > 0.05$ of the mismatch term (Lack of Fit), the model fitting loss is not significant and fits well with the actual situation, which can be used to analyze and predict the optimal process parameters of high frequency quenching (Wang et al., 2024).

The coefficient of determination R^2 of the model was 0.9892, indicating that the model had high significance, while $R^2_{Adj} = 0.9754$ was able to explain 97.54% of the response value variation in the trial and was also close to the predicted correlation coefficient R^2_{pred} . Therefore, this model can better describe the relationship between hardness and each response factor, and this secondary regression model can be used to analyze and predict the optimal process parameters of high-frequency quenching.

As shown in Table 5, quenching temperature, tempering temperature, and tempering time (based on one-factor trials) all have significant effects on the hardness of the rotary tilling blade. The order of influence is as follows: quenching temperature > tempering temperature > tempering time. Regarding interaction effects between two factors, the following were found to significantly affect hardness: the interaction between quenching temperature and tempering time, tempering temperature and tempering time, as well as the quadratic terms of quenching temperature, tempering temperature, and tempering time. In contrast, the interaction between quenching temperature and tempering temperature did not show a significant effect on hardness.

Table 5

Analysis of variance of hardness

Source of variation	Sum of square	Degree of freedom	Mean square	F value	P value	Significance
Model	169.67	9	18.85	71.35	< 0.0001	**

Analysis and discussion of factor interaction

The images generated in the Model Graphs visually reflect the effects of each factor on the response value. The influence of each factor is clearly demonstrated through the changes in factor levels. To investigate whether the interaction between factors significantly affects the hardness of the rotary blades after quenching, response surface analysis was employed. This analysis involved fixing one factor and examining the interaction between the other two factors. Fig. 11 presents a three-dimensional graph of quenching temperature, tempering temperature, and tempering time, which provides a clear visual representation of how each factor influences the quenching performance of the rotary blades. It also demonstrates how these factors interact and jointly affect the evaluation indexes.

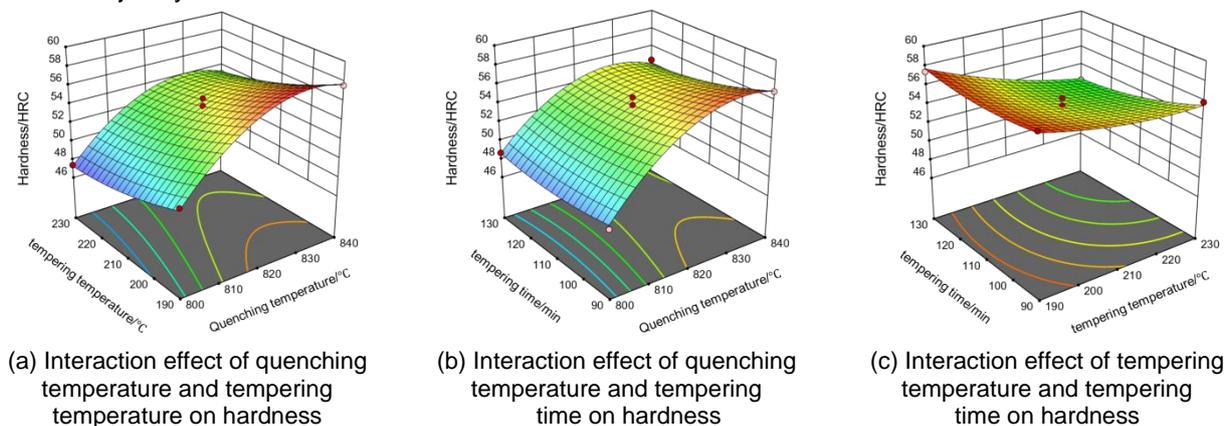

Fig. 11 - The effects of the interaction of various factors on the hardness of rotary tilling blades

Fig. 11a illustrates the response surface diagram showing the interaction effects between quenching temperature and tempering temperature on the hardness of rotary blades, with tempering time fixed at 120 minutes (0 level). The analysis reveals that when the quenching temperature is held constant at a low level, the change in hardness with increasing tempering temperature is minimal. However, at higher quenching temperatures, the hardness value decreases consistently as the tempering temperature increases. When the tempering temperature is held constant, the hardness response value increases within a certain range as the quenching temperature rises. However, once the quenching temperature reaches 840°C, any further increase leads to a gradual decline in the hardness of the rotary blades. This behavior is attributed to the growth of austenite grains: initially, the grains are fine, but as the quenching temperature increases, they begin to coarsen significantly. The higher the temperature, the more pronounced this grain growth becomes. In the case of 65Mn steel, excessive grain coarsening reduces the material's hardness, thereby diminishing the effectiveness of the heat treatment.

Fig. 11b presents the response surface diagram illustrating the interaction between quenching temperature and tempering time on the hardness of rotary blades, with tempering temperature fixed at 210°C (0 level). The analysis shows that within the tested range, when the quenching temperature is held constant, the effect of tempering time on hardness is not significant at lower quenching temperatures. However, at higher quenching temperatures, the hardness gradually decreases with increasing tempering time. Conversely, when tempering time remains constant (regardless of whether it is at a high or low level) the hardness initially increases as the quenching temperature rises, but then slowly goes down when the quenching temperature reaches 840°C. This is because the tempering process is a diffusion and transition process from sub-stable martensite and martensite and residual austenite tissues to ferrite and carbide. As tempering time extends, internal stresses are gradually relieved, leading to a moderate reduction in hardness.

Fig. 11c illustrates the response surface diagram showing the interaction effects between tempering temperature and tempering time on the hardness of rotary blades, with the quenching temperature fixed at 840°C (0 level). The analysis indicates that within the tested range, when the tempering temperature is held constant, the change in hardness with increasing tempering time is minimal at lower tempering temperatures. However, at higher tempering temperatures, the hardness gradually decreases as tempering time increases. Similarly, when tempering time is held constant (regardless of whether it is at a high or low level) the hardness decreases with increasing tempering temperature, with the decline being more pronounced at higher levels. This trend results from the interaction between tempering temperature and tempering time: during tempering, the transformation of martensite and retained austenite into ferrite and carbide occurs. The atomic diffusion along grain boundaries promotes grain growth, which increases the material's fracture toughness. However, this grain coarsening simultaneously leads to a reduction in hardness.

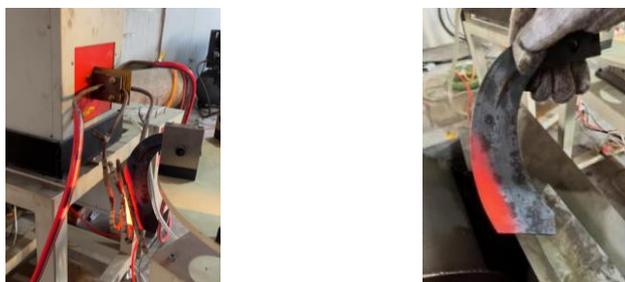

Parameter optimization and validation tests

The optimal combination of quenching process parameters was determined by analyzing the experimental data and optimizing the influencing factors. Based on the quenching performance requirements of rotary tilling blades and the boundary conditions of the key parameters, an optimization model was established. Using quenching temperature X_1 , tempering temperature X_2 , and tempering time X_3 as constraint variables, and hardness Y as the optimization target, a mathematical model for the rotary blade quenching process was developed. The computational method for this model is described in Equation (2) (Wang *et al.*, 2023).

$$\begin{cases} \max Y \\ 820 \leq X_1 \leq 860 \\ 170 \leq X_2 \leq 250 \\ 80 \leq X_3 \leq 160 \end{cases} \quad (2)$$

The target parameter was set to be maximized in the optimization module of Design-Expert 12.0 software. Each process variable was constrained within the ranges specified in Table 3. The optimized combination of process parameters was identified as follows: quenching temperature of 852.2°C, tempering temperature of 171.4°C, and tempering time of 84.7 min. Under this combination, the rotary tilling blade is predicted to achieve optimal quenching performance, with a hardness value of 57.9 HRC. To verify the reliability of the model, the optimized process parameters were tested under the same experimental conditions. The test specimens, both before and after quenching, are shown in Fig. 12.

For improved operability in practical applications, the optimized values were rounded to quenching temperature of 852°C, tempering temperature of 171°C, and tempering time of 85 min. Under these conditions, the measured average hardness was 57.5 HRC, with a relative error of only 0.81%, confirming the accuracy and credibility of the regression model and optimization analysis. It is worth noting that the optimized tempering temperature lies at the boundary of the test parameter range, indicating that low-temperature tempering effectively eliminates quenching stress while avoiding deformation or cracking. This ensures dimensional stability during operation and maintains the high hardness and wear resistance of the blade after heat treatment.

Field testing

When tilling with the rotary blades, the actual soil environment is often very complicated, as a result the soil tank test bench in the laboratory cannot fully simulate the field test conditions. In order to further verify the correctness of the above quenching test conclusions, the rotary blades are quenched under the above optimal process parameters to verify the wear resistance of the high-frequency quenching technique. Before the test, all the rotary blades were washed and dried, weighed with a balance with an accuracy of 0.1 g, and the original mass was recorded. The 10 rotary blades were quenched with the optimal parameter combination, and the other 10 were not treated, as shown in Fig.13.

(a) Unquenched rotary tilling blades (b) Quenched rotary tilling blades
Fig. 13 - Heat treatment before field trials

Then, the rotary blades quenched with the optimal combination parameters and the original blades without being quenched are installed on the shaft of the rotary blades alternately for a contrast test, as shown in Fig. 14. Field test site lies in the corn planting field of Yi County, Jinzhou City, Liaoning Province (Fig.15): the soil was sand soil, the average moisture content of the test soil was 19.8%, and the total working area was 67 hm². After the tillage, all rotary blades were removed and the surface soil was wiped off the friction loss was weighed and measured. The quality changes of rotary tilling blades before and after the field test are shown in Table 6.

Fig. 14 - Schematic diagram of rotary tilling blades installation

Fig. 15 - Field trials

Table 6

Title	The amount of wear and tear of the rotary tilling blades									
	Test blade number									
	1	2	3	4	5	6	7	8	9	10
The amount of wear on the rotary tilling blades after quenching/(g)	11.3	12.5	11.7	10.9	12.6	12.8	11.4	11.7	11.4	13.1
The amount of wear on the rotary tilling blades after not quenching/(g)	37.6	38.1	36.9	36.7	36.8	37.9	37.6	35.9	36.8	37.4

Discussion

From the table data, the average abrasion of 10 quenched blades is only 11.9 g, while the average abrasion of the other 10 without being quenched is as high as 37.2 g. In contrast, the wear resistance of the blades after being quenched increase by 3.13 times, which demonstrates that the high frequency quenching can effectively improve the wear resistance of the blades.

In order to improve the wear resistance of rotary tilling blades, many scholars at home and abroad used various coating preparation techniques to prepare wear resistance layer on the surfaces of rotary tilling blades. *Amardeep et al (2012)* compared three different kinds of explosive spraying coatings on high strength steel rotary tillers, namely WC-Co-Cr, Cr₃C₂NiCr and Stellite-21, and the following field tests showed that the three coated rotary blades show excellent wear resistance, helping to extend the service life of rotary tillers. *Zhan (2022)* prepared Fe/WC/CeO₂ stack welding layer on Q235 matrix by using plasma stack welding technology. In the field comparison test, it was found that the grinding crack of the cutting edge of the 65 Mn rotary tillers was dense and the abrasion was obvious, while the Fe/WC/CeO₂ stack welding layer carried no obvious wear marks, and the stack welding layer did not fall off, and the wear quality was reduced by about 65%. *Long et al (2022)* took 65 Mn rotary tillage blades as the matrix, selected BNi-2 brazing material and the carbide as the brazing coating material, studied the influence of heat treatment process after brazing coating on the tissue evolution and hardness of nickel base alloy, and the results showed that the hardness of the coating was high in the state of brazing coating. However, through comprehensive comparison, it is evident that although thermal spraying, plasma stack welding, and brazing coating technologies can enhance the microstructure of materials and improve the wear resistance of rotary tilling blades, these methods are associated with complex processes, high costs, and technical challenges. If not precisely controlled, the desired improvement in wear resistance may not be achieved, making these methods less practical for widespread application in agricultural settings. Compared with these surface strengthening processes, the high-frequency quenching technology adopted in this paper has the advantages of uniform heating, rapid heating-up and simple processing. The induction heating principle only heats the surface of the material to achieve the effect of hard outside and tough inside, which just meets the needs of rotary tilling blades.

CONCLUSIONS

In this study, 65 Mn steel, a commonly used material of rotary blades was selected, and based on the existing heat treatment research and combined with the characteristics of agricultural production, a partial high-frequency quenching technique with low cost and excellent performance was adopted to solve the wear and failure problem of 65 Mn rotary blades. In the quenching test, the hardness of rotary blades was taken as the technical index of partial high frequency quenching, and the appropriate parameter range of high frequency quenching was explored under the preliminary quantitative condition. Then, the following conclusions were drawn:

(1) The finite element static solution result shows that the maximum total deformation of rotary blades is 0.25 mm, located at the positive cutting edge position, and the maximum stress of rotary blades is 77.4 MPa, located at the upper half of the back edge curve. The solution result is in line with the actual situation, and the quenching position is determined. Single factor test preliminarily determined the value range of the parameters as follows: the quenching temperature is 820°C ~860°C, the tempering temperature is 170°C ~250°C, and the tempering time is 80min~160min; under these conditions, the hardness of the rotary blades is above 48, and the quenching effect is good.

(2) A regression model expressing the hardness of rotary blades was established by ternary quadratic regression orthogonal rotation combination test, and the influence pattern of each parameter was analyzed by using Design-Expert 12.0 software, and the fitting and significance tests were performed by ANOVA.

The effects of each factor on the hardness of rotary blades is as follows: quenching temperature>tempering temperature>tempering time. The interaction between quenching temperature and tempering time, between tempering temperature and tempering time both have a more significant effect. The optimized parameters bring about the best quenching conditions: quenching temperature 852°C, tempering temperature 171°C, and tempering time 85min, when the hardness of rotary blades is 57.5 HRC, which not only meets the national standard, has good wear resistance and corrosion resistance, but also provides a test basis for the study of high-frequency quenching technique and supporting equipment design.

(3) Through comparative analysis between the 10 blades quenched using the optimal quenching parameter combination and the 10 unquenched original blades, the average wear of the quenched blades was found to be only 11.9 g, whereas the unquenched blades exhibited an average wear of 37.2 g. This indicates that the wear resistance of the blades improved by 3.11 times after high-frequency quenching, thereby confirming the effectiveness and feasibility of the high-frequency quenching technique for enhancing the durability of rotary tilling blades.

(4) High-frequency quenching, as an emerging surface treatment technology, effectively enhances the surface wear resistance of metal components and offers considerable economic benefits. This study presents a preliminary investigation into the application of high-frequency quenching on 65Mn rotary tilling blades, demonstrating a notable improvement in their wear resistance. However, to further facilitate the adoption of this technique in agricultural production, more in-depth and systematic research is required. Importantly, the high-frequency quenching method is not limited to 65Mn steel; it holds promise for optimizing the surface treatment of other soil-contact parts in agricultural machinery. To expand its applicability, a comprehensive database of quenching parameters for various metal materials should be established, providing a valuable reference for enhancing the wear resistance of metallic components. It is worth noting that this study focused primarily on surface hardness and wear performance. To gain a more comprehensive understanding of the material behavior post-quenching, future research will explore the internal microstructural changes of the treated materials, thereby enabling more accurate and reliable evaluations of the high-frequency quenching process.

ABSTRACT

Precision agriculture requires accurate and efficient crop yield distribution information. However, both traditional field-based yield measurement methods and existing combine harvester yield monitoring systems face significant limitations. Traditional methods, such as direct weighing or sampling, are time-consuming and inefficient, and they only provide average yield values - insufficient for large-scale farming needs. Meanwhile, current monitoring systems often suffer from high measurement errors, low spatial resolution, and limited generalizability. For this reason, this study designs a new type of grain yield monitoring system, which corrects the photoelectric sensor data through the load cell data, realizes the calibration of the photoelectric sensor, avoids the influence of external factors, and improves the accuracy of measurement. Firstly, tests were carried out at three rotational speeds of 10 Hz, 20 Hz and 25 Hz of the motor inverter setting, respectively, to determine the positive proportionality coefficient between the photoelectric signal and the grain mass, and the overall error of the system was measured to be less than 6.44%. For the load cell, a model of the relationship between tilt angle and weighing accuracy was established and a compensation algorithm was proposed, the weighing error data in different directions and at different tilt angles were measured and analyzed, and a mathematical model between the corrected angle and the weighing error was established. Through the tilting experiment, the feasibility of the modified angle compensation model is verified, and the overall error after compensation is less than 0.25%, and the systematic error of measurement and production after the intervention of the feedback system is less than 0.74%. The experimental results demonstrate that the system significantly enhances the accuracy and stability of yield measurement. It holds substantial potential for widespread application, provides strong support for the advancement of precision agriculture, and is expected to drive agricultural production toward greater efficiency and sustainability.

摘要

精准农业需要准确且高效的作物产量分布信息，但传统的田间作物产量获取方法以及现有的联合收割机产量监测系统存在诸多问题。传统方法，如直接称重或抽样，不仅耗时且效率低下，而且只能获取平均产量，难以满足大面积种植的需求，而现有的系统测量误差大、空间分辨率低且通用性差。为此，本研究设计了一种新型的谷物产量监测系统，该系统通过称重传感器数据对光电传感器数据进行校正，实现了对光电传感器的校准，避免了外部因素的影响，提高了测量精度。首先，分别在电机变频器设定的10赫兹、20赫兹和25赫兹这三种转速下进行测试，以确定光电信号与谷物质量之间的正比例系数，经测量该系统的整体误差小于6.44%。对于称重传感器，建立了倾斜角度与称重精度之间关系的模型，并提出了一种补偿算法，测量并分析了不同方向和不同倾斜角度下的称重误差数据，建立了校正角度与称重误差之间的数学模型。通过倾斜实验，验证了修正后的角度补偿模型的可行性，补偿后的整体误差小于0.25%，反馈系统介入后测量和生产的系统误差小于0.74%。实验结果表明，该系统有效地提高了产量测量的准确性和稳定性，具有广泛的应用价值，为精准农业的发展提供了有力支持，有望推动农业生产朝着更高效、更可持续的方向发展。

INTRODUCTION

Precision agriculture, also known as smart agriculture, is an agricultural management method that integrates modern information technologies such as geographic information system (GIS), global positioning system (GPS), remote sensing technology, and Internet of Things (IoT) (Luo *et al.*, 2001; Maldaner *et al.*, 2021; Maldaner *et al.*, 2022; Price *et al.*, 2017; Sirikun *et al.*, 2021; Wang *et al.*, 2021; Yin *et al.*, 2024). It realizes precise control of the agricultural production process, including precise fertilization, irrigation, and harvesting, through real-time monitoring and data analysis of the farmland environment, crop growth, and soil conditions. In the process of crop cultivation and production management, obtaining the information of crop yield distribution in the farmland in an online, real-time, and effective method is the main starting point for the implementation of precision agriculture (Li *et al.*, 2004; Lou *et al.*, 2006). The traditional method of obtaining field crop yields is through direct weighing or sampling, which is not only time-consuming and inefficient, but also can only obtain the average yield of crops, so it is not suitable for obtaining the yields of field crops planted over large areas. The use of remote sensing technology to collect crop images or establish crop growth condition models are extracted crop characteristic values to establish the relationship with crop yield, but the collected data are affected by environmental factors (Choi *et al.*, 2018; Martello *et al.*, 2022; Taylor *et al.*, 2016). In field harvesting operations, real-time information on crop yield distribution in large fields can be accurately obtained through instantaneous yield monitoring of the combine harvester operation process. Through the drawn spatial distribution map of farmland yield, subsequent field management, rational use of agricultural resources, regulation of input-output ratio, improve yield, reduce pollution, is the basic guarantee of sustainable development of agricultural production (Wang *et al.*, 2021).

Currently, grain yield monitoring techniques mainly include impact measurement, volumetric measurement, dynamic weighing measurement, and radiation measurement, etc. Zandonadi *et al.*, (2009), verified the correlation between the tension on the tension side of the bin chain, shaft torque, and yield by setting a torque sensor in the bin of a harvester. The maximum error of the yield monitoring system designed in this way was 4.9%. Geng *et al.*, (2021), developed an on-line monitoring system for on-board grain yield based on the principle of grain flow pressure, guided by the mathematical model of grain yield and grain flow pressure. They built a grain yield monitoring test bed and investigated the effects of the number of sensors, the sensor installation position, and the horizontal inclination angle of the monitoring device on the yield measurement error of the grain yield monitoring system. The results showed that the indoor test error of the grain yield monitoring system was 3.27% and the field yield measurement error was 5.28%. Fang *et al.*, (2024), designed a convex surface grain mass flow sensor to compare the errors of different grain types and flow rates on the experimental measurements, and the measurement error was less than 5% after calibrating the zero point and coefficient of the sensor. Cheng *et al.*, (2023), constructed a corn seed yield model based on low-potential signals by adding three pairs of photoelectric sensors to a scraper—type elevator of a corn kernel harvester and achieved real-time monitoring of yield. The average error of the measured yield was 3.72%. Navid *et al.*, (2015), utilized a laser line scanner to measure material flow. In the system, the laser line scanner measures the distance between the sensor and the object according to the time-of-flight principle. Grain flows from a stationary bin, and a sliding door at the bottom of the bin is used to regulate the mass flow rate of grain. The results showed that the grain flow rate and the laser scanning signal are linearly related. This method is one of the yield measurement methods. Overall, the study shows that there is no significant difference in the measurement errors of different yield measurement methods, and the main sources of error include: non—calibration error, sensor response error, grain moisture content measurement error, and error due to uneven distribution of grain flow.

Existing combine harvester yield monitoring systems usually employ impact grain flow sensors, photoelectric volumetric flow sensors, or γ -ray technology-based grain photoelectric yield sensors. These sensors require continuous dynamic measurements and are affected by various factors, such as the moisture content of grains, species, yield differences, harvesting speed, and variations in flow rate due to vehicle adjustments at the ground level. These factors can lead to large measurement errors (De *et al.*, 2020; Jensen *et al.*, 2019; Sun *et al.*, 2022; Liu *et al.*, 2022). At the same time, these yield detection methods need to be calibrated before operation. Conventional calibration methods require correction by weighing on the ground for comparison. Moreover, with the change of time and space, frequent calibration is also necessary. Calibration difficulties cause detection inaccuracies. This system combines sensor strengths: load cells for large masses, photoelectric sensors for small ones. It calibrates photoelectric sensors with load cell data, improving per - unit yield measurement accuracy.

MATERIALS AND METHODS

Yield Monitoring System Principle

The principle of yield measurement using weighing method is to add a pressure transducer directly underneath the grain tank of the harvester and convert the weight of the grain applied to the transducer into an electrical signal (Hong *et al.*, 2019).

The working principle of the load cell is shown in Figure 1(b), where R_1, R_2, R_3 and R_4 are resistive strain gauges. When the load cell is subjected to gravity, it undergoes slight deformation. The strain gauges also deform under external force, leading to changes in their resistance values. These changes follow a specific relationship with the applied force. By measuring the variation in resistance, the magnitude of the external force can be accurately determined.

$$U = \frac{R_1 R_3 - R_2 R_4}{(R_1 + R_2)(R_3 + R_4)} U_0 \quad (1)$$

where U_0 is the DC supply voltage, and U is the output voltage. In the formula above, the resistance values of the four resistors are the same. When the sensor strain gauge is subjected to external forces, the resistance values change, and the output voltage will also change. Therefore, the amount of change in the voltage can be taken as an indication of the change in the resistance values, as a way to determine the force acting on the elastic element.

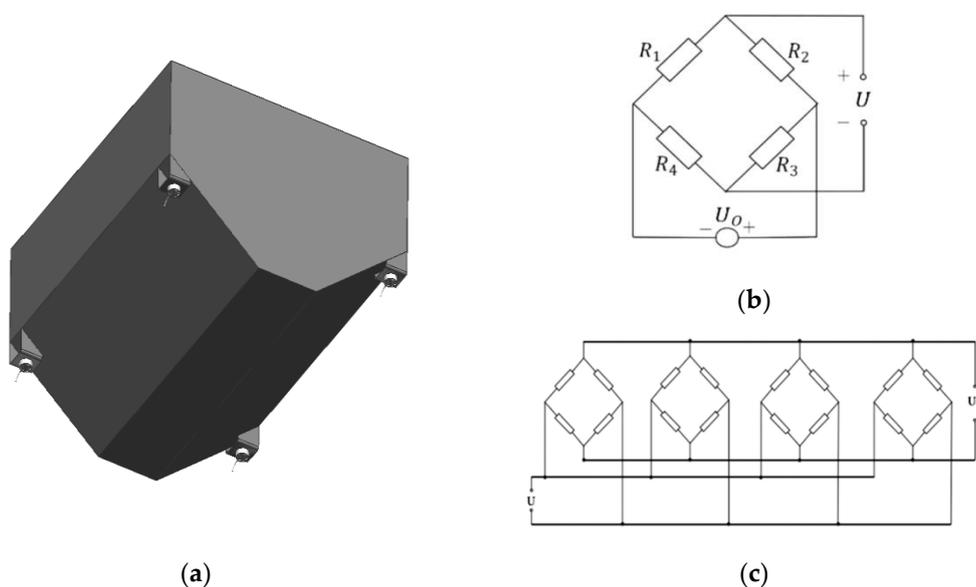

Fig. 1 - Installation position of the four load cells at the bottom of the grain tank

Designed according to the volume and shape of the harvester's grain tank, a weighing structure uses four load cells to measure the weight of the wheat in the tank. Each load cell needs to be placed on the same level during installation, otherwise the measurement quality will be inaccurate. Multiple load cells will output multiple signals, in order to streamline the wiring and the controller, a weighing structure only needs to collect one weighing signal, which can be connected to four load cells in series or in parallel (Marangoni *et al.*, 2017). Due to the poor stability of the series connection, the system uses the parallel connection for the 4 load cells, as shown in Figure 1(c). After connecting the pressure sensor with the transmitter, the RS485 to USB converter is used to connect the transmitter with the host computer, and the host computer data acquisition software receives, displays, stores and analyzes the collected data.

The light transmitter and light receiver of the opposed-radiation photoelectric sensor are on the same axis installed on both sides of the scraper lifter, respectively, and when the grain passes through the photoelectric path of the sensor, the photoelectric path is blocked, which causes the output voltage of the light receiver to change potentiometrically (Jin *et al.*, 2022). Therefore, the thickness of the grain on the scraper is determined by recording the duration of the output pulse signal of the photoelectric sensor, and the measurement of the grain mass is finalized based on the bottom area of the scraper and the grain capacity weight. The principle is shown in Figure 2(b).

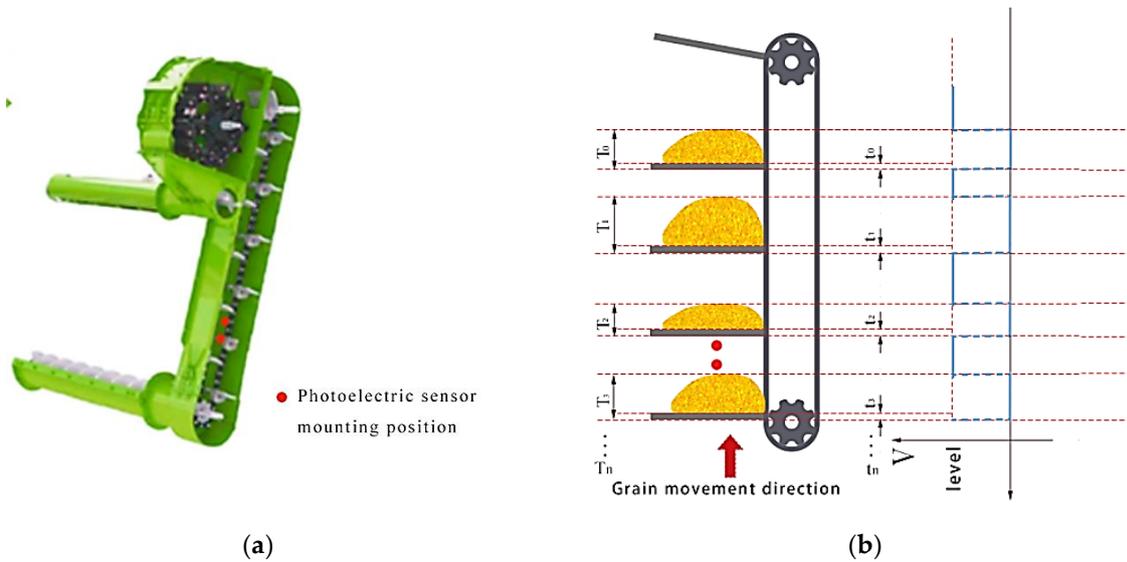

Fig. 2 - Photoelectric Sensor Yield Measurement Principle

where T_n is the time when the infrared rays of the opposed-beam photoelectric sensor are blocked by the grain and the scraper, and t_n is the time when the scraper blocks the sensor, and the sensor outputs a low-level signal. By counting the time of the low-level signal output from the opposed-beam photoelectric sensor, the yield estimation model constructed in this paper is used to obtain the weight of the grain entering the bin in the combine harvester.

When the combine harvester is operating under normal working conditions, the wheat yield M_1 is measured by the photoelectric yield monitoring system. Once it reaches the preset threshold, the load cell weighs the wheat in the grain tank to obtain M_2 , and the feedback unit calculates the calibration coefficient K .

$$K = \frac{M_2}{M_1} \tag{2}$$

where: K is the photoelectric metering calibration coefficient; M_1 is the mass measured by the photoelectric sensor; M_2 is the mass measured by the load cell. After the load cell weighs the grain in the tank, it calculates the new photoelectric metering coefficient. The system then updates the old coefficient with the newly calculated one and stores it for use in the next yield measurement.

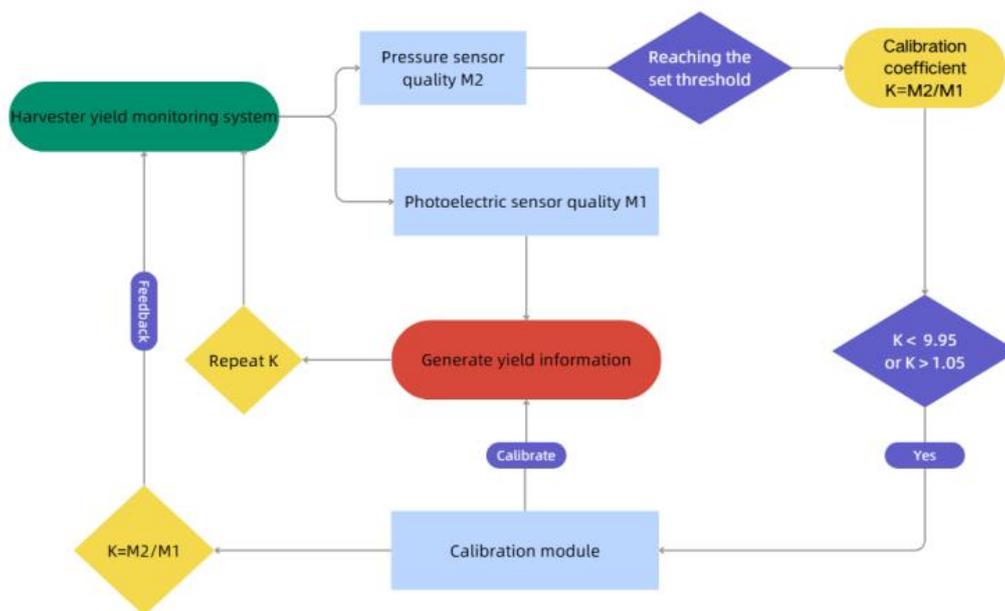

Fig. 3 - Workflow of the yield monitoring calibration system

Yield Monitoring System Hardware Selection

The yield monitoring system is installed on the grain combine harvester, which mainly collects crop yield information in real time. It mainly includes main control module, sensor module, data transmission module, digital signal processing and model conversion module, power supply module, data storage and display unit, etc., as shown in Figure 4.

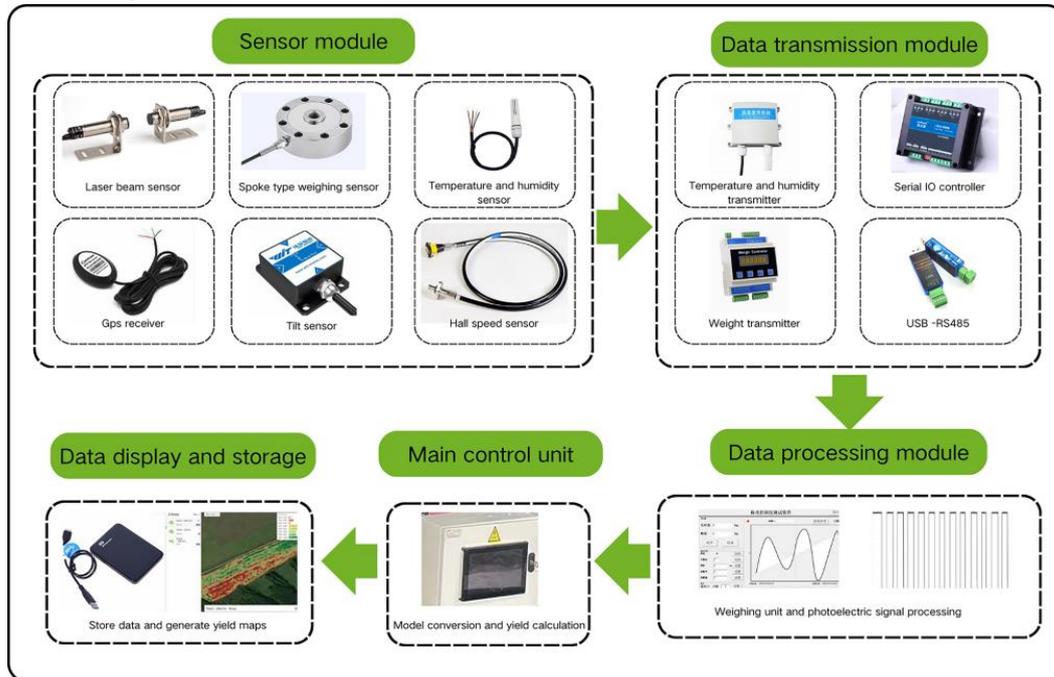

Fig. 4 - Schematic diagram of the harvester yield monitoring system

After passing through the harvester cleaning device, wheat grains are conveyed by a screw conveyor at the harvester's bottom to a scraper - type elevator. The scraper elevator, composed of a scraper, chain, and shell, uses the chain - moving scraper to lift grains to the harvester's grain tank. To study grain quality in the tank and the relationship between photoelectric sensor output and grain quality, a yield monitoring test bed was designed based on the 4YZL - 6S harvester elevator (Figure 5). The test bench includes a bottom screw conveyor, scraper elevator, top screw conveyor, grain tank, drive mechanism, and control system. The elevator is at a 72° angle to the ground. During operation, harvested wheat reaches the scraper elevator after cleaning. Photoelectric sensors at the elevator bottom estimate grain quality by recording pulse - signal durations from wheat shading, combined with scraper parameters. Pressure sensors under the grain bin convert grain weight to electrical signals, and data is sent to the host computer. When the photoelectric yield monitoring system reaches a set threshold, the pressure sensor weighs, calculates calibration coefficients, calibrates the photoelectric sensor, and generates yield information for real - time crop yield monitoring.

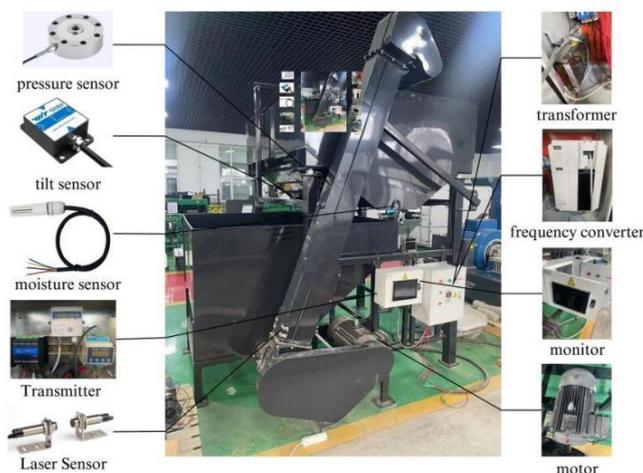

Fig. 5 - Yield monitoring system test bench structure

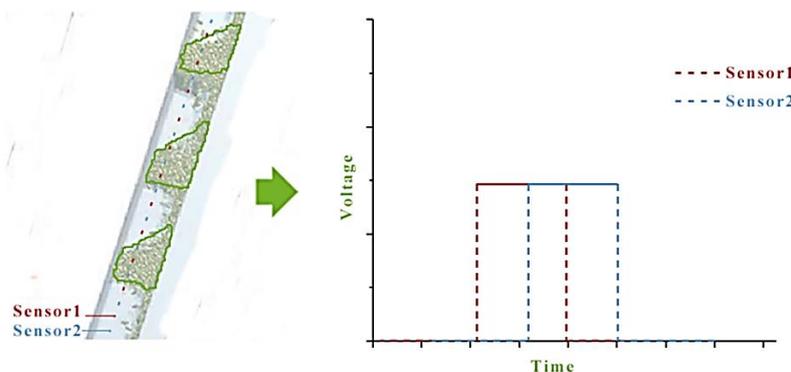

In order to obtain the relationship between the duration of photoelectric signal and the quality of grain, as well as the load pressure of the grain box on the counterweight sensor, this paper carries out the selection of hardware for the test bench. Two counter-reflective photoelectric sensors, specifically the E2F-20C2 (NPN) type, were selected and placed at the bottom of the scraper lifter. These sensors, manufactured by Wenzhou Mingxun Electronics Co., Ltd. (Wenzhou, China), have a supply voltage range of 6 – 36 V and a response time of ≤ 2 ms. The photoelectric sensors' data transmission module is selected to be the serial IO controller of LangHande, with a supply voltage of 9–24 V, and adopts the standard Modbus- RTU protocol of the relay. The load cell used is the SLLF-74 spoke-type load cell, manufactured by Shenglong Machinery Co., Ltd. (Wenzhou, China), with a measurement range of 1 T and a power supply requirement of 5–12 V. The load cell transmitter is the XSF4-channel digital transmitter from Bengbu Zhongnuo Sensors Technology Co., Ltd. (Bengbu, China), which operates with a 10–30 V power supply, has a sampling frequency of 500 Hz, supports the Modbus-RTU protocol, and offers an accuracy of 0.0003%. The transmitter is connected to the host computer via an RS-485 to USB converter. The power supply unit provides 12 V through a transformer to power both the sensors and the transmitters.

Photoelectric Sensor Yield Measurement Model

Since the photoelectric sensor cannot directly obtain the grain quality, it is necessary to construct the relationship between the photoelectric signal and the quality model. For NPN-type sensors, the transmitter emits light, and when an object enters the detection area to block the light, the amount of light received by the receiver changes, and the detection circuit produces an electrical signal change according to this change. When there is no obstruction, the sensor outputs a low level; when an object blocks the light, the sensor outputs a high level, thus realizing the detection of the object. Thus, the relationship between wheat volume and the photoelectric signal can be established by calculating the cumulative generation voltage time. In order to avoid the large error data generated by a single sensor, two photoelectric sensors were selected for the experiments in this paper. However, in the process of photoelectric sensors being blocked by wheat, the scraper of the grain bin will also block the photoelectric sensors at the same time, which will have an impact on the results of yield calculation, so the time of shielding wheat particles during the accumulation of photoelectric sensors eliminates the influence of the scraper on the total accumulation time, the calculated formula is:

$$T = \sum \left(\frac{T_{an} + T_{bn}}{2} - t_n \right) \tag{3}$$

The time at which photoelectric sensor No. 1 accumulates the generated potential is denoted as T_{an} , and the time at which photoelectric sensor No. 2 accumulates the generated potential is denoted as T_{bn} . The time at which the photoelectric sensor monitors the accumulation of each scraper is represented as t_n . Additionally, T signifies the average accumulated time during which the photoelectric sensor monitors the wheat. These time parameters are critical for analyzing the sensor's response and the accumulation process of the wheat. Looking at the analysis of the accumulation of wheat on the elevator by EDEM 2022.2 software, it can be approximated that the accumulation pattern of wheat on each scraper is close to a trapezoidal shape, as shown in Figure 6.

(a)

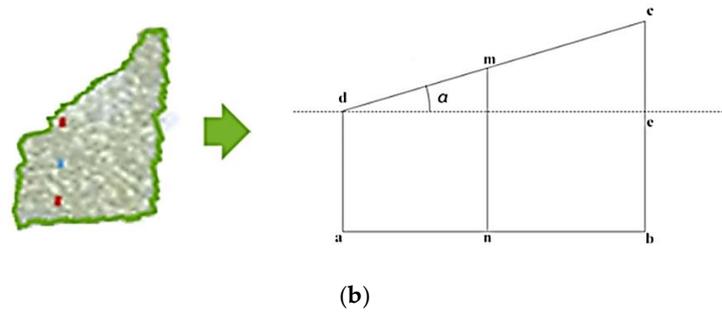

Fig. 6 - Relationship between wheat volume and potential

Since the scrapers are rigidly connected to the elevator chain, the spacing between each scraper is nearly identical. Given that the length and width of each scraper are fixed, a linear relationship exists between the volume of grain on each scraper and the stacking height of the grain. Therefore, the mass of grain on each scraper can be estimated by monitoring the duration for which the wheat obstructs the photoelectric sensors and combining this information with the elevator's speed. The volume of grain on a scraper is calculated as:

$$V = L_{ab}L_{mn} + \left(\frac{L_{nb}^2 \tan \alpha}{2} - \frac{L_{an}^2 \tan \alpha}{2} \right) L_1 \tag{4}$$

where L_{ab} is the width of the scraper, L_1 is the length of the scraper, L_{mn} is the photoelectric sensor monitoring line, which can be understood as the effective length of the grain that can be monitored by the photoelectric sensor during the scraper lifting process. L_{an} is the length from the sensor monitoring line mn to the upper edge of the scraper, L_{nb} is the length from the sensor monitoring line mn to the lower edge of the scraper, α is the angle of the top of the grain pile relative to the scraper. From Equation (5), it can be seen that there is a linear relationship between the stacked volume of grain and the measured value of photoelectric sensor L_{mn} under the ideal model. However, the yield monitoring system in this paper is calibrated to the thickness of the scraper after idling, when L_{mn} is 0 the volume V of the grain is also 0, and the value of the constant term in Equation (4) is 0. Therefore, the mass m of the grain measured in the system is positively proportional to the cumulative voltage time corresponding to L_{mn} and the mass of the wheat is given in the Equation (5):

$$m = kL_{mn} \tag{5}$$

where k is the coefficient of positive proportionality of the cumulative voltage generation time to m .

Weighing System Correction Model

To address errors from uneven terrain in field operations, a mathematical model between tilt angle and weighing error is established. Nonlinear regression fits experimental data, and a compensation algorithm for tilted grain bins is proposed. The photoelectric sensor data model is better calibrated by enhancing load cell stability. When the grain box is stationary on the ground (0°), the sensor output equals the actual wheat mass. When the grain box is tilted, the load cell is in a tilt - weighing state. As shown in Figure (7), the force on the sensor at this time is:

$$\begin{cases} F_2 = W_m \cos \alpha \\ F_3 = W_m \sin \alpha \end{cases} \tag{6}$$

where F_2 is the load of the load cell along the vertical direction of the grain tank, and F_3 is the load of the load cell along the horizontal direction of the grain tank, F_2 is the main direction force of the load cell, which is perpendicular to the pressure sensor and has a good linear relationship, while F_3 is the parallel direction force of the load cell, whose output is affected by the tilt direction of the grain tank, the mass of the wheat W_m , the angle of inclination α and other factors. From equation 7, the output of the load cell at this time is:

$$W_s = F_2 + f(F_3) = W_m \cos \alpha + f(W_m \sin \alpha) \tag{7}$$

where: W_s is the output value of the pressure transducer, $f(F_3)$ is the nonlinear function that affects the output of the pressure transducer. According to equation (6) and (7), it can be inferred that:

$$W_e = W_m - W_s = W_m(1 - \cos\alpha) - f(F_3) \tag{8}$$

Fig. 7 - Grain box force analysis

When the grain bin is at a certain angle to the ground, Equation (8) is decomposed by the Taylor's equation:

$$W_e = W_m \left(\frac{1}{2}\alpha^2 + o(\alpha^2) \right) - f(F_3) \tag{9}$$

In this equation, $o(\alpha^2)$ represents the second order infinitesimal quantity of α . Since the effect of $o(\alpha^2)$ in Equation (9) on the load weight value is very small, it can be neglected. Based on this, the weighing error compensation equation can be derived:

$$W'_m = W_s + W_e = W_m \left(1 + \frac{1}{2}\alpha^2 \right) - f(F_3) \tag{10}$$

where W'_m is the weight compensated according to the algorithm. Due to the complexity of the change of the force plane of the load cell and the insensitivity of the force F_3 in the horizontal direction of the sensor to the action of the load cell, Equation (11) can be simplified as follows.

$$W'_m = K_2 \cdot W_s \cdot \alpha^2 + B \tag{11}$$

where K_2 is the tilt compensation coefficient, B is the model correction value. Due to the insensitivity of the weighing pressure sensor to lateral stress. In this paper, simplifying the model, correcting the tilt direction according to the change of tilt angle of the load cell caused by the load of the grain tank, and then compensating the weighing accuracy according to the corrected tilt angle are considered.

RESULTS

Determination of the coefficient of proportionality

To get the positive coefficient k between cumulative potential generation time and wheat quality, experiments were done on a designed bench. Shandong Luzhong's Qimin 13 hulled wheat (moisture 12 - 14%, purity 98%) was used. Instruments included Yingheng T1 scale, Shandong Huali motor, and Shandong Shenchuan inverter. Test photos are shown in Figure 9.

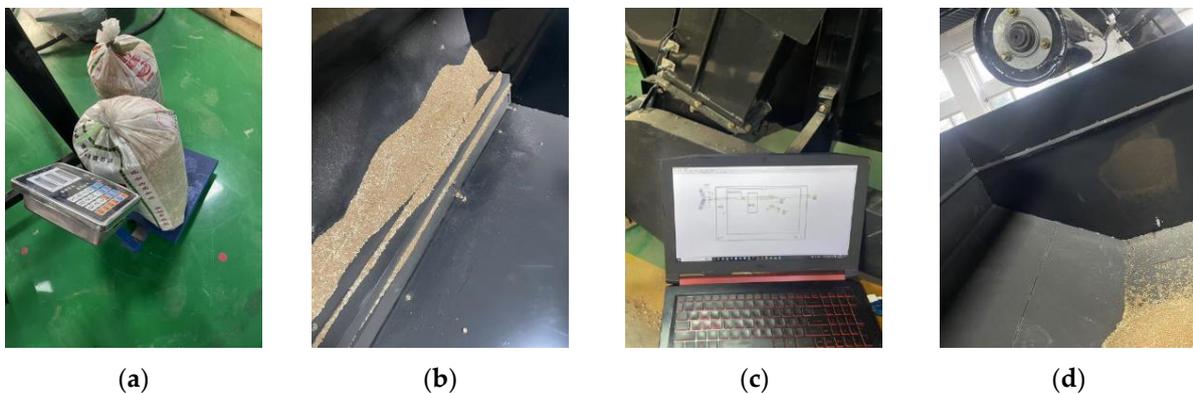

Fig. 8 - Indoor bench experiment site

To determine the proportionality coefficient under different scraper lifter speed conditions, 30 sets of tests were conducted at motor frequency converter settings of 10 Hz (approximately 150 r/min), 20 Hz (approximately 300 r/min), and 25 Hz (approximately 375 r/min). For each test, the system recorded the accumulated photoelectric signal duration along with the actual grain mass measured by a bench scale. The results are shown in Figure 9.

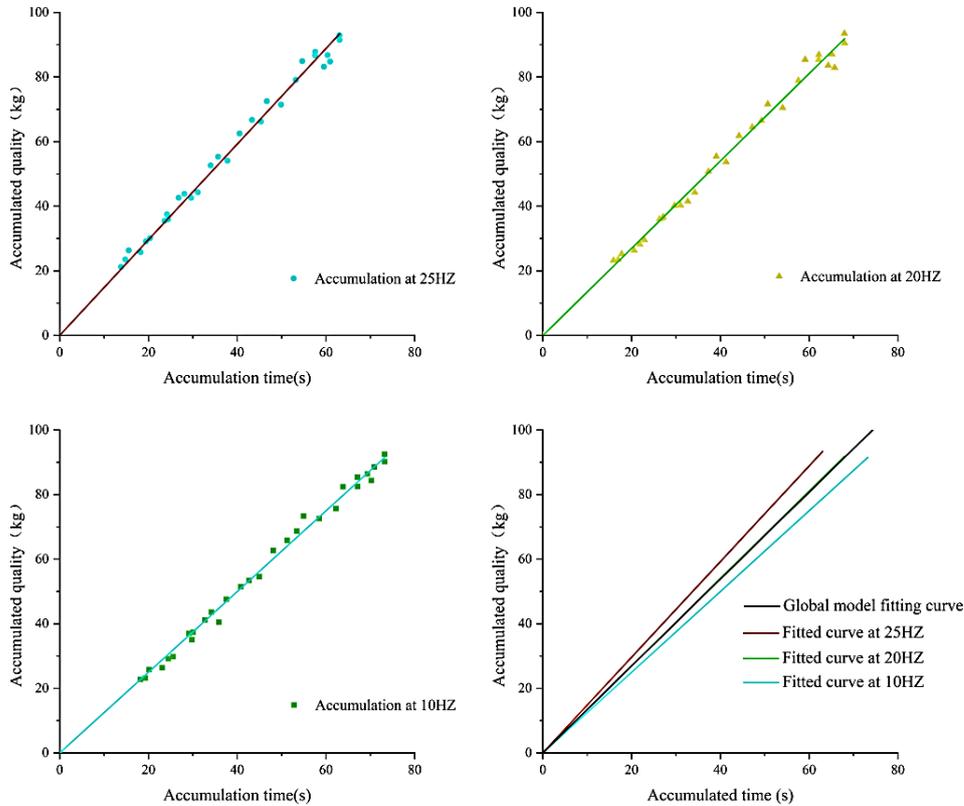

Fig. 9 - Fitted straight line between cumulative time and mass at different rotational speeds

Since the experiment has been calibrated for the cumulative time of the scraper pair in the unloaded state of the scraper lifter at each frequency, each frequency has the constraint that the constant term of the fitted curve is 0. Based on the experimental results, the cumulative time was fitted to the actual weighing mass of the grain by linear regression using Origin2024 software, and the following positive scale factors were obtained, respectively:

The positive proportionality coefficient at 25 Hz (approx.375 r/min) is:

$$M = 1.370(T_1 + T_2) \tag{12}$$

The positive proportionality coefficient at 20 Hz (approx.300 r/min) is:

$$M = 1.362(T_1 + T_2) \tag{13}$$

The positive proportionality coefficient at 10 Hz (approx.150r/min) is:

$$M = 1.349(T_1 + T_2) \tag{14}$$

Positive scale factor for global model:

$$M = 1.355(T_1 + T_2) \tag{15}$$

where $T_1 + T_2$ represents the total duration of the output signals from the two photoelectric sensors. Based on this relationship, the positive scale factor k is determined to be 1.355. The fitted model achieved correlation coefficients of 0.998, 0.992, 0.994, and 0.994.

Weighing error compensation

To study the impact of load cell weighing errors in the grain bin under different tilt angles, this research adjusted the yield test stand using a manual forklift to angles of 0.5°, 1°, and 1.5°. A total of 1000 kg of grain was loaded into the test stand, with sampling points set every 200 kg to calculate the error at each point. Before the experiment, the grain box was leveled using the HWT901B tilt angle sensor from Witte Intelligent Technology Co., Ltd. (Shenzhen, China). The motor frequency was set to 20 Hz, and 200 kg of wheat was added to the bottom grain bin. The cumulative time of the potential generated by the photoelectric sensor was recorded to determine the actual mass of wheat using a model conversion factor. After the wheat was transferred to the top grain bin, the mass measured by the load cell was collected. Due to gaps between the scraper elevator and screw conveyor, the measured mass was less than 200 kg, requiring manual replenishment until the load cell reading reached 200 kg.

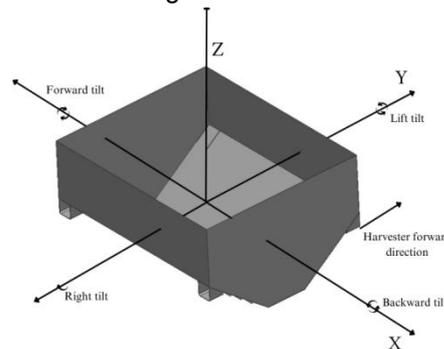

Fig. 10 - Schematic diagram of the adjustment direction of the laboratory bench

In practice, grain distribution in the bin is non-uniform. When the harvester tilts, the thickness of the grain pile and the position of the center of gravity shift in the left, right, or forward/backward directions. These variations, along with the mechanical structure of the harvester and sensor placement, influence the measurements. The harvester's structure may exhibit varying stiffness and flexibility in different directions, leading to differential deformation around the load cell when tilted. Additionally, despite precise mounting, slight variations in the sensitivity or response characteristics of the load cells in different directions may persist. These combined factors contribute to discrepancies in readings when tilted in various directions.

To address this, a forklift was used to fill the test stand from all four directions, adjusting it to the appropriate angles to collect weight and angle data from the grain bin. The weighing error under tilted conditions was determined by comparing the sensor-measured mass of wheat with the actual mass loaded. After completing the experiment at one sampling point, the process was repeated for the remaining points. The experimental results are presented in Figure 11.

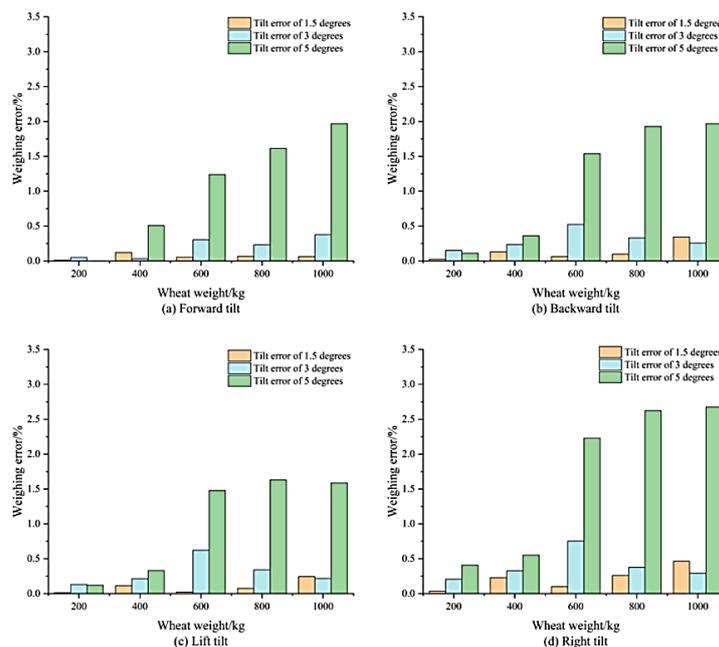

Fig. 11 - Weighing errors in different directions and at different angles of inclination

The experimental results show that the weighing error of the bin is almost negligible when the tilt angle is 0.5° . However, when the tilt angle reached 1.5° , the weighing errors in the four directions increased significantly, far exceeding the error levels of 0.5° and 1° . The analysis shows that the weighing accuracy of the bin under the left tilt condition is slightly higher than that of the other directions, which may be related to the inhomogeneity of wheat distribution in the bin. When the grain bin is tilted to the right, the grains on the left side may become more densely packed due to gravity, while the right side remains relatively loose. This causes the force on the right-side sensor to increase. Conversely, when the bin is tilted to the left, the inlet located on the right side promotes a more uniform grain distribution within the bin, thereby reducing the measurement error. For forward and backward tilts, the feeding port remains aligned with both directions, resulting in relatively similar errors in both cases. To improve weighing accuracy under inclined ground conditions, this paper proposes a corresponding error compensation algorithm for the grain bin.

To determine the tilt compensation coefficient K_2 and the model correction value in Equation (11), and to correct for the influence of inclination on the model, this study utilizes load cell weighing data collected under tilted conditions. The model parameters are fitted using the least-squares algorithm.

$$S = \sum_{i=1}^n (y_i - f(x_i))^2 \quad (16)$$

where S is the sum of squared errors, representing the total of the squared differences between the model's predicted value y_i and the true observed value $f(x_i)$. The objective of the least squares method is to minimize S in order to determine the optimal parameters of the model. Here, y_i is the observed value of the i -th sample, based on the model function f , when the input is the independent variable x_i of the i -th sample.

Considering that the measurement error is small and close to the accuracy error of the load cell itself when the tilt angle is 0.5° and 1° , this paper only compensates the weighing error for the weighing data with tilt angle of 1.5° under single-axis tilt condition. Where $K_2 = 0.44$, $B = -1.93$. The fitting accuracy is 0.818. In addition, the error plots for both corrected and uncorrected tilt angles are compared in this paper, as shown in Figure 12.

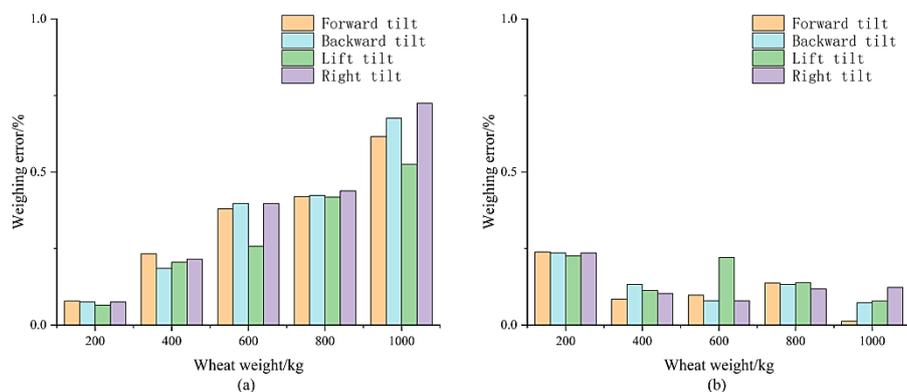

Fig. 12 - Plot of uncorrected model vs corrected model

From the comparison, it can be observed that the compensation accuracy and consistency of the model without tilt angle correction decrease as the loading load increases. In contrast, the compensation performance of the model with tilt angle correction improves progressively with increasing load. The overall error after compensation remains below 0.25%, and the accuracy of the corrected model consistently surpasses that of the uncorrected model. Overall, the compensation effect of the corrected model is significantly better than that of the uncompensated approach.

Experimental Results of a Self-Feedback Labor Monitoring System

In order to verify the accuracy of the model based on the improved photoelectric yield monitoring system, this paper simulates the harvester field operation by indoor bench test. The data of the photoelectric yield monitoring system and weighing system were obtained by manually inputting wheat into the bottom grain bin, and the test was conducted by inputting in batches of 200 kg into the grain inlet of the test stand. The calibration accuracy of the pressure sensing was set to 200 kg, and the yield quality corresponding to the global fitting coefficients was used to measure the yield. The excellence with the self-feedback system was contrasted, and the results of the experiments are shown in Table 1.

The yield monitoring system with the addition of the self-feedback module is clearly shown by the experimental results to have a certain compensation effect at all three frequencies, and the before and after comparison with the error without the feedback module is shown in Figure 13.

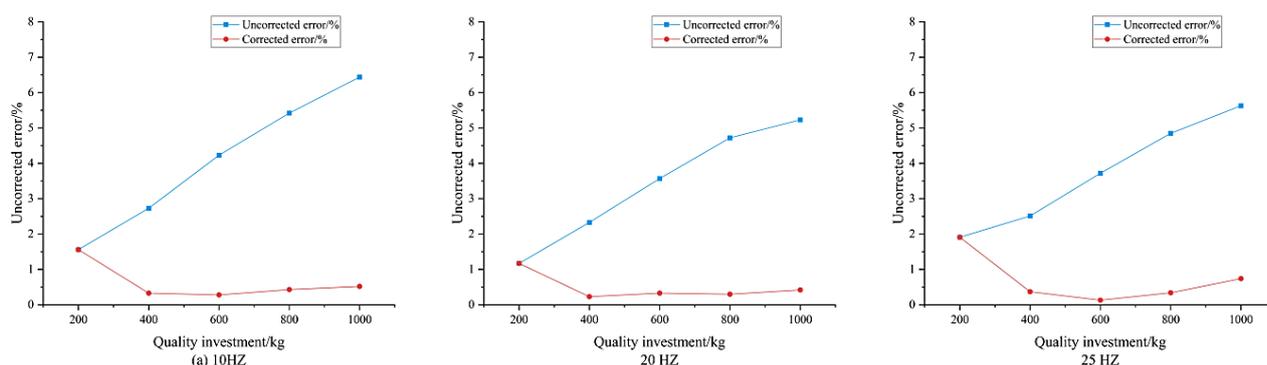

Fig. 13 - Comparison of yield data with and without calibration system

As shown by the results, the error is relatively large when the input is 200 kg. This is because the load cell's calibration accuracy is set for 200 kg, and the threshold for calibration had not yet been reached, meaning the feedback module had not been activated. At this stage, the photoelectric measurement coefficient remains at its initial value. Once the input reaches 400 kg, the system's self-feedback module begins functioning, correcting the photoelectric measurement coefficient. Observations from the 2nd to 5th tests show that the system's yield measurement error gradually stabilizes, with errors ranging from 0.23% to 0.74%. The optimal

calibration occurs at a frequency converter setting of 20 Hz, where the overall error remains below 0.42%, indicating strong accuracy and stability of the system. In contrast, the standalone photoelectric yield measurement system exhibits a larger error fluctuation range, between 1.17% and 6.44%, with a tendency for errors to increase over time. The self-feedback calibration system effectively performs dynamic calibration, keeping the error within a stable range. This significantly reduces system fluctuations and measurement errors, thereby ensuring the accuracy and stability of the system.

CONCLUSIONS

In this study, a multi-sensor fusion-based yield monitoring system for grain harvesters was successfully designed and validated, and a series of results of significant value were obtained. The positive proportionality coefficients between the photoelectric signal and the grain mass at different rotational speeds were determined through experiments, and the overall error of the system was less than 6.44% in the initial test. The established model of the relationship between tilt angle and weighing accuracy and the compensation algorithm were effective, with the overall error less than 0.25% after compensation and less than 0.74% after system intervention. The self-feedback calibration system played a key role in keeping the system error low under different loads, and the best calibration effect was achieved at 20 Hz, with the overall error less than 0.42%. The system provides an efficient and reliable yield monitoring solution for agricultural production, which strongly promotes the development of precision agriculture and helps to improve resource utilization efficiency and economic benefits. However, considering the complexity of practical applications, more field trials are needed in the future to further optimize the adaptability of the system to different environments and crops, and to improve the sensor parameters and algorithms, so as to give full play to the potential of the system in agricultural production and help agriculture achieve higher quality development.

Keywords: Methane detection; rice field; DFB laser diode; infrared absorption

ABSTRACT

A methane gas detection system has been developed based on the infrared absorption method. The system can be deployed in dry rice field for real-time detection. It consists of self-developed circuits and essential optical parts. A distributed feedback laser has been chosen as the optical source of the system. Hollow-core photonic crystal fibre is also applied as a part of the gas cell. The major circuit boards include laser driver circuit, laser temperature control circuit, digital lock-in amplifier circuit and linear power circuit. The laser diode can be effectively controlled by using the above circuits. The laser driving current step is 1 mA and the temperature fluctuation is less than ± 0.02 °C. Based on the TDLAS technique, spectroscopy test shows that the proposed laser driving circuits has accurate control capability. The detection error is about 2.3% by performing the full-scale detection experiments. Further gas detection experiments using standard gas under 600 ppm also demonstrate the effectiveness and stability of the proposed system. By replacing the optical source and essential driving circuits of the system, the system can be applied to detect other trace gases.

摘要

开发了一种基于红外光谱吸收法的甲烷气体检测系统。研制的系统能够应用在早稻田中进行实时气体检测。它由自主开发的电路和相关光学部件组成。分布式反馈激光器作为光源，空心光子晶体光纤作为气室的一部分。系统中主要电路板包括激光器的驱动电路、激光器的温度控制电路、数字锁向放大器电路和线性电源电路。使用上述电路可以有效地控制激光二极管。激光驱动电流步长为 1 mA，其温度波动可以限制在 ± 0.02 °C 的范围内。基于 TDLAS 技术，光谱测试表明，所提出的激光驱动电路具有精确的控制能力。通过进行全量程的气体检测实验，检测误差约为 2.3%。进一步使用 600 ppm 以下的标准气体进行气体检测实验也证明了文章中提出系统的稳定性、有效性。通过更换系统的光源和基本驱动电路，该系统可以应用于其他痕量气体的检测。

INTRODUCTION

Rice as an important food crop is widely cultivated in China and many regions around the world. However, in recent years, the methane gas released from paddy fields has attracted the attention of many researchers (Jikun H. et al., 2014; Mujiyo M. et al., 2017; Xie B.H. et al., 2010). It is widely researched that CH₄ is a kind of important greenhouse gas and it is 28 times higher than carbon dioxide with a global warming potential (Ma J.L. et al., 2019; Palmer P.I. et al., 2021; Rajasekar P. et al., 2022; Rizzo et al., 2015). According to studies in the past years, the methane gas released from rice fields are increasing for numerous reasons (Bai Y. et al., 2023; Xu X.Y. et al., 2020). In this way, it is important to develop advanced and reliable sensors for monitoring methane gas in rice fields for purposes including environmental protection and sustainability.

Traditional methods of methane detection in rice field such as chamber technique has some drawbacks. The measurement accuracy of chamber technique is good. And this method is widely used for many years. However, it is not efficient in the real-time detection and monitoring of large areas of rice fields. Other traditional methods such as micrometeorological technique and isotope method, also have drawbacks including unstable accuracy and complex requirements in the sensing process (Arianti F.D. et al. 2023; Gao Z.R. et al., 2018; Zhang G.B. et al., 2014; Zhang G.B. et al., 2015). Therefore, it is essential to apply advanced methods for high-precision and large-scale monitoring of methane gas in rice fields.

¹ Bin Li, Prof.; Ruotong Liu, Stud.; Guangfei Shang, Stud.; Lihui Zhang, Prof.; Chenghao Han, Prof.; Yitong Huang, Stud.

The infrared spectral absorption method is an advanced optical technique to monitor trace gases which has been studied by many researchers. In 2021, Catia L. etc. proposed their work with an immunosensor for achieving fast and highly sensitive detection of cortisol based on plasmonic tilted fiber (Catia L. et al., 2021). In 2023, Maxime L. etc. proposed an electro-plasmonic biosensor for attracting cells and proteins by migration of controlled biomolecular. The sensor is on the surface of a probe linked with fiber (Maxime L. et al., 2023). Compared with traditional detection methods, the infrared spectral absorption method is characterized by high precision and rapid response. At the same time, this method has strong selectivity and is capable of monitoring specific gases for a long time in an open space. Different types of optical fibers are widely used in these detection systems (Bai Y.R. et al., 2021; Dar S.A. et al., 2020; Davis N.M. et al., 2016; Jiao Y.X. et al., 2021). Hollow-core photonic crystal fiber (HC-PCF) can be used not only for the transmission of optical signals but also as a part of the gas cell, enabling the target gas to come into contact with the light beam so as to achieve spectral absorption. It has been applied to replace gas chambers to achieve effective detection of target gas. Meanwhile, distributed feedback (DFB) laser diode has the characteristics of narrow linewidth and wavelength tunability. It can be linked with HC-PCF and commercial communication fiber to achieve the transmission of optical signals over long distances. Therefore, HC-PCF and DFB laser diode are suitable for the detection system based on infrared spectral absorption method.

In this paper, a highly integrated CH₄ sensing system is proposed. In the system, DFB laser diode and HC-PCF have been applied with other self-developed key modules. The TDLAS technique has been adopted as the core detection method in this system to perform gas sensing experiments. In this way, DFB laser diode has been chosen as the optical source in this system with other relevant optical parts such as fiber optic beam splitter and photodiodes. Compared to other commercial light sources such as QCL lasers, DFB laser diode has the advantage including effective tunable ability and lower heat generation. Therefore, remote detection of target gas can be achieved by its working features. The emitting light beam can be controlled and be modulated to meet the requirements of the TDLAS technique. Compared to our earlier research (Bin L. et al., 2018), the hardware part has been upgraded by using more powerful chips. And the software part has been upgraded by optimizing the control algorithm especially for laser temperature controlling circuit. This part has been updated in many ways. The photoelectric conversion circuit uses InGaAs photodiodes with a higher cost-performance ratio, which reduces the cost while ensuring the conversion performance. Meanwhile, second harmonic signals can be extracted for gas detection by using the technique of wavelength modulation spectroscopy (WMS). The proposed system can be deployed to perform CH₄ detection in large-scale rice fields remotely.

SYSTEM STRUCTURE AND DETECTION THEORY

System structure

The functional diagram of the proposed CH₄ sensing system is shown in Fig. 1. On the left side of Fig. 1 is the independently integrated detection system, which includes optical devices and electronic devices. The acrylic box on the right side of Fig. 1 is the gas cell of the detection system. It is placed in a dry paddy field for detection. Firstly, the detection system on the left side is integrated in an instrument case and can be placed near the measured area, and then communicates with the measured area through an optical fiber. This instrument has been proposed in our previous work. Then, the HC-PCF allows target gas spreads inside the fiber in order to be irradiated by the near infrared light beam. In this way, the gas absorption phenomenon can occur. The optical signal after coming into contact with the measured gas returns to the integrated detection instrument through the optical fiber, and the lost optical signal can be used to calculate the concentration of the gas.

The proposed detection instrument contains many key electrical and optical modules. All the calculation work is completed by the main control chip which is a Digital Signal Processor (DSP), including generating modulation signals, generating laser control instructions, and calculating the gas concentration, etc. The modulation signal includes ramp wave and sine wave. After the modulation signal of the laser is output by the DSP, the laser is driven by a ramp wave signal. It is generated by a high-performance Digital-to-Analog (DAC) chip which type is AD5541. Meanwhile, a Direct-Digital-Synthesizer (DDS) chip is applied to generate sine wave signal and the chip type is AD9851. With the signal modulation, a fiber optic beam splitter (FOBS) is used to divide the output signal of the DFB laser into two equal parts. One part enters the gas cell and undergoes an absorption reaction, and the other part has its light intensity reduced by an optical attenuator (OA). After photoelectric conversion which uses two InGaAs photodiodes, the difference between the two signals contains the information about the gas concentration. In this way, the subtraction of the absorbed signal

and the reference signal can be performed. In this system, it is sent digitally to the DSP by using an Analog-to-Digital (ADC) chip. Finally, the result of detection can be displayed or processed for further applications. The calculated data can be sent to a laptop via the UART port. And the gas information can be received by using software developed by LabVIEW to perform further analysis.

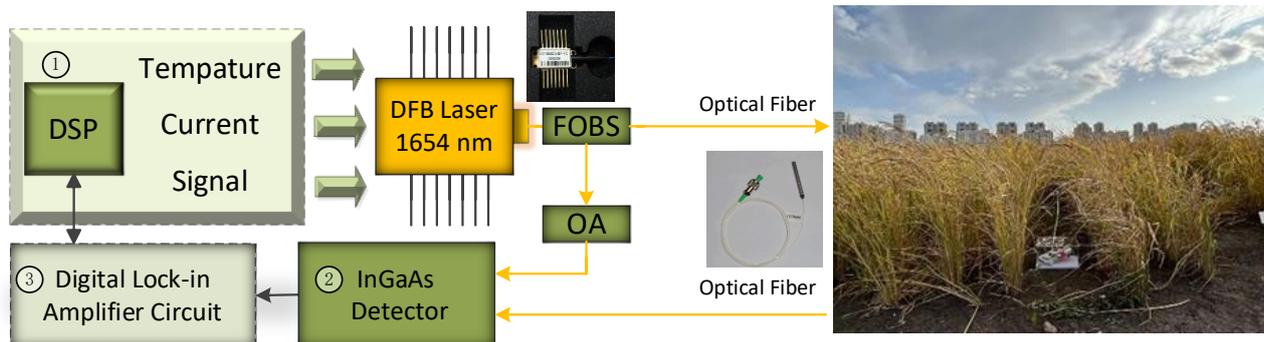

Fig. 1 - Block diagram of rice field methane gas detection system using TDLAS technique

Detection theory

Based on the TDLAS technique, the absorption line of CH₄ must be scanned across periodically in order to detect the optical loss. Fig. 2(a) shows the absorption spectrum of CH₄ around 1654 nm. And its absorption intensity is at the level of 10⁻²¹ cm⁻¹/(molecule cm⁻²). Therefore, in order to meet the requirement of detection, the selection of the laser is very important. In this system, a DFB laser is applied as the main light source of the detection system. Both DFB lasers and Quantum Cascade Laser (QCL) lasers are widely used in the field of gas detection. Compared with QCL lasers, DFB lasers are more likely to use optical fibers for long-distance signal transmission, which is applicable for the remote detection of methane gas in paddy fields. At the same time, DFB lasers are cheaper than QCL lasers, which also helps to carry out relevant experiments. The applied DFB laser has the center wavelength around 1654 nm as shown in Fig 2(d). In this infrared region, there are interfering gases such as H₂O and CO₂, which are also shown in Fig. 2 to demonstrate their absorption lines. It can be seen that their absorption intensity is much weaker than the intensity of CH₄. Their absorption intensity are 4 orders of magnitude lower than that of methane as shown in Fig. 2(b) and Fig. 2(c). Therefore, when detecting methane in this interval, water and carbon dioxide in the atmosphere hardly cause any interference. High selectivity is an advantage of the infrared spectroscopy method. When using traditional gas detection methods, it is very easy to be affected by interfering gases.

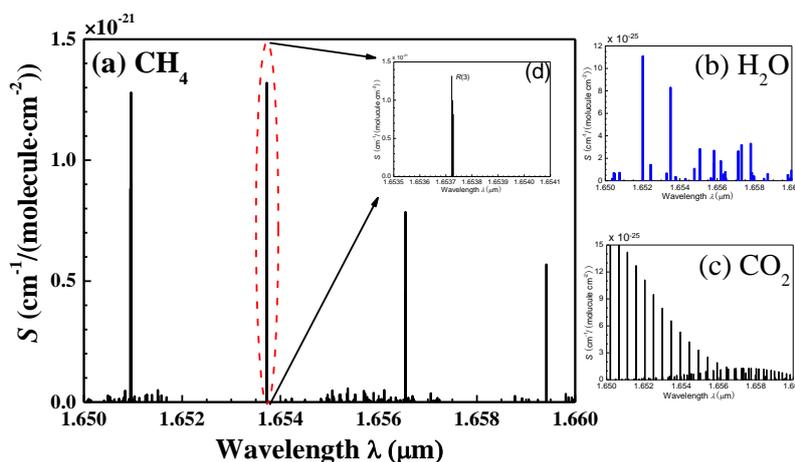

Fig. 2 - Absorption line selection of CH₄ (a) (d) and the absorption intensity of the interfering gas H₂O (b) and CO₂ (c) in this infrared region

The detection theory of absorption spectroscopy is governed by the Beer-Lambert law. The calculation is determined by the optical loss of spectral intensity (W/m²) while radiation interacts with gas molecules. The expression of the coefficient $\tau(\nu, t)$ is shown in Eq. (1). The transmitted intensity and the initial light intensity can be expressed as $I(\nu)$ and $I_0(\nu)$ respectively. The relationship can be seen as follows:

$$\tau(\nu, t) = \frac{I(\nu)}{I_0(\nu)} = \exp[-\alpha(\nu, t)LC] \tag{1}$$

where $\alpha(v, t)$ (cm^{-1}) in Eq. (1) is the absorption coefficient at frequency v (cm^{-1}). In this equation, C is the mole fraction of the target gas and L is the effective optical path length. Based on TDLAS and WMS technique, the DFB laser is tuned by a low-frequency repetitive ramp waveform with the period of T_{ramp} . Meanwhile, a high-frequency sine wave signal is added to the ramp wave. Its angular frequency is expressed as ω_{sin} . The expressions of the above signals and the strength of the light source can be represented in Eq. (2), Eq. (3) and Eq. (4), respectively:

$$u_{ramp}(t) = a + \frac{a}{T_{ramp}}(t - T_{ramp}) \quad (2)$$

$$u_{sin}(t) = b \sin(\omega_{sin}t) \quad (3)$$

$$I(t) = I_0[1 + mu_{ramp}(t) + mu_{sin}(t)] \quad (4)$$

In above equations, $u_{ramp}(t)$ and $u_{sin}(t)$ are the voltage of ramp signal and sine signal, a , b , m and T_{ramp} are the amplitude of ramp signal, the amplitude of sine signal, the intensity modulation coefficient and the cycle of ramp signal, respectively. The waveform of a standard ramp wave rises in a straight line, then falls sharply in one cycle period. In this paper, the cycle period of the modulating ramp wave was set as 10 Hz. The sine wave signal was set as 5 kHz. The sine wave signal is also set as the modulating signal and it is mounted on the ramp signal for modulation.

Therefore, the relationship of gas concentration and 2f harmonic signal of system can be calculated according to the equations. The ramp signal and the sine signal in above equations can be generated by DFB lasers which are under the control of the self-developed circuits.

MATERIALS AND METHODS

Laser driving circuit

According to the TDLAS technique, laser diode must be linearly controlled to scan across the gas absorption line. The driving current and operating temperature of laser diodes were precisely regulated using self-developed control circuits. Compared to the previous design, the main controller chip of the laser driving circuit was upgraded from TMS320F28335 to TMS320C28346. The main computing frequency reaches 300 MHz, with a cycle time of approximately 3.33 ns, resulting in a processing performance nearly twice that of the previous design. In this way, the floating-point performance has been enhanced and the algorithm for the detection system can be processed effectively especially for the digital lock-in part which involves complex real-time computing. Meanwhile, the TMS320C28346 also has abundant on-chip peripherals including six 32-bit timers, nine 16-bit timers, 258K 16-bit SARAM and serial port peripherals. However, there is also a problem of the new MCU in the system. Its package type is 256-ball plastic ball grid array (BGA) which is not convenient for hand soldering. After several attempts, the chip was successfully soldered on the board by using a hot air gun. The board has four layers as shown in Figure 3(a) which are top layer, bottom layer and two internal power layers. The completed board is shown in Figure 3(b).

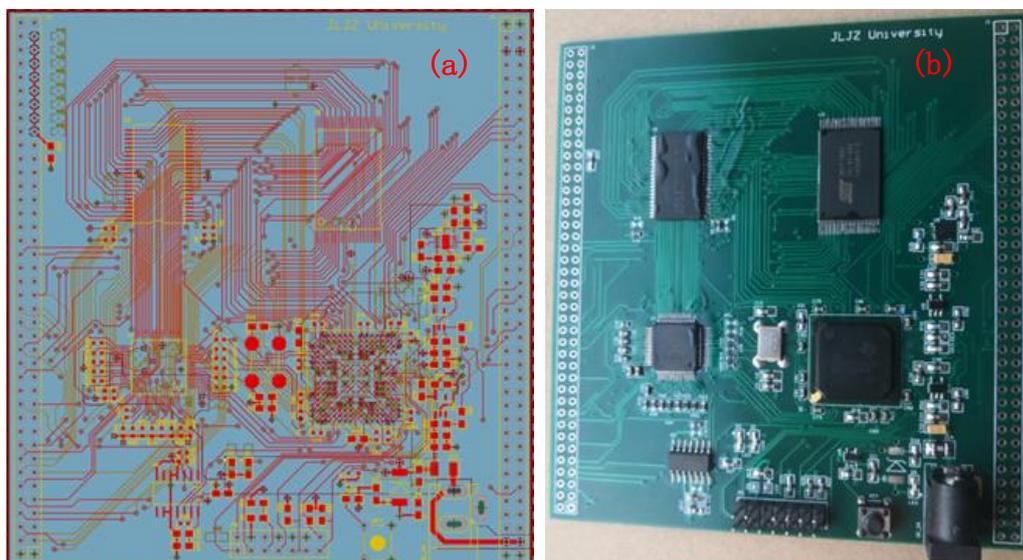

Fig. 3 – Self-developed PCB drawing (a) and soldered circuit board of the main controller

Laser temperature controller

The DFB laser has the characteristic that its output wavelength changes with the change of its operating temperature. Therefore, it is very important to control its operating temperature. On the one hand, if the temperature of the laser is too high, it may shorten its lifespan or cause damage to it. On the other hand, controlling the output wavelength of the laser by changing its temperature is very effective, especially in the detection system using TDLAS technology. Therefore, in this paper, a temperature control circuit for the DFB laser is developed based on the Thermoelectric Cooler (TEC) control circuit. The DFB laser used in the system has a built-in TEC module. Therefore, through the TEC control circuit, real-time and precise control of the laser's temperature can be achieved, thus enabling effective control of its output wavelength. The TEC control chip used in the system is the ADN8831. This chip can effectively control the TEC built into the laser based on the Analog PID algorithm. It can achieve a temperature fluctuation of no more than 0.01 degrees Celsius at the minimum. The photo of the developed circuit is shown in the figure. It is a four - layer PCB. The inner layer is the power layer, and the top and bottom layers are the signal layers. The compensation network of the laser diode is shown in Fig. 4. The resistors of R_{LOW} , R_{MID} and R_{HIGH} can be obtained in datasheet. The voltage V_{SET} , which decides the value of laser temperature, can be obtained by Eq. (5) - (8), as:

$$V_{SET} = \left(\frac{R_3}{R_{TH} + R_2} - \frac{R_3}{R_1} + 1 \right) \times \frac{V_{REF}}{2} \tag{5}$$

$$R_1 = R_{MID} + \frac{R_{MID}(R_{LOW} + R_{HIGH}) - 2R_{HIGH}R_{LOW}}{R_{HIGH} + R_{LOW} - 2R_{MID}} \tag{6}$$

$$R_2 = R_1 - R_{MID} \tag{7}$$

$$R_3 = \frac{R_1(R_1 + R_{LOW} - R_{MID})}{R_{LOW} - R_{MID}} \tag{8}$$

where V_{SET} is the output voltage for setting the temperature and it is can be set by DSP. The resistors of R_{LOW} , R_{MID} and R_{HIGH} set the temperature range which can be determined by specific characters of the laser diodes according to its datasheet, R_{TH} is the resistance of thermistor which is inside the DFB laser diode, V_{REF} is the reference voltage which is 2.5 V generated by the TEC controller chip, R_1 and R_2 are calculated by Eq. (6) and Eq. (7), R_3 represents the compensation resistor and can be calculated by Eq. (8). By using the above equations, as the resistors are chosen, the controlling voltage can be calculated and be generated to control the laser temperate.

The temperature controlling circuit is shown in Figure 4. In this circuit, the resistors and capacitors set the compensation network based on Analog PID. The temperature compensation network composed of these components can effectively approximate the actual value to the set value of temperature. The compensation network in the lower right corner can change the values of these resistors and capacitors by changing the jumper caps as shown in Fig. 4. The main controller chip of ADN8831 is placed on the center location of the board as shown in the photo. The left zone which is selected by the red lines is the temperature setting zone. The temperature value can be set by using serial resistors after calculation. The bottom area of the board is the compensation zone. The resistors and capacitors can be selected by using the jumper cap. According to the Analog PID algorithm, if the response time of the temperature controlling for DFB laser is extremely fast, the stability of the temperature fluctuation will be impacted. Therefore, it is necessary to achieve the balance of stability and response speed by adjusting the components.

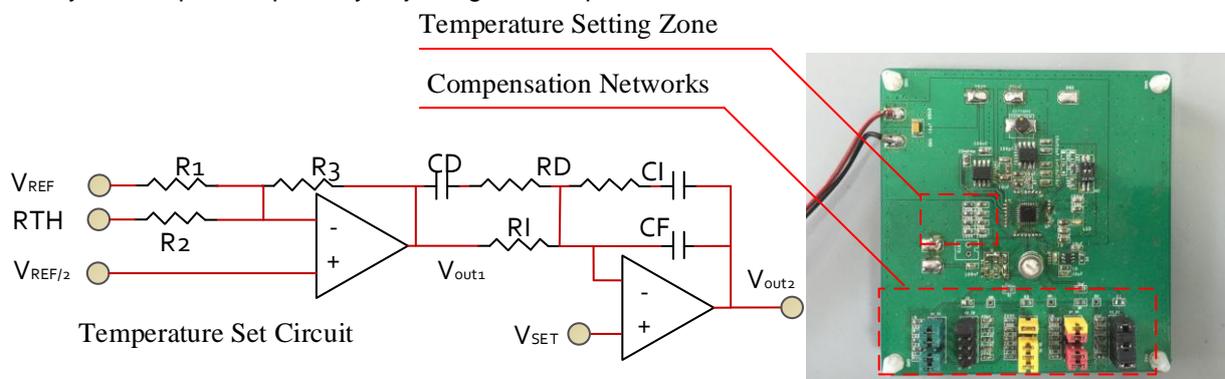

Fig. 4 – Temperature control circuit for DFB laser diode based on Analog PID algorithm

Experiments were carried out to investigate the temperature control performances by using the developed circuit. The stability test of the temperature control module is shown in Fig. 5.

The laser's temperature was stabilized at 24.55 °C within 15 hours. The laser temperature was sampled by an Analog-to-digital circuit. During the experiment, a random period of 100 minutes was selected to show the detailed fluctuation. Then, temperature data was transmitted by the serial port circuit from the DSP board to a computer. The fluctuation of temperature can determine the stability of the laser. The relationship between laser temperature and its output spectroscopy can be determined by carrying out experiments and be expressed as fitting formulas. The small temperature fluctuation within the range of ± 0.02 °C will not affect the stability of the output wavelength. Therefore, the fabricated laser temperature control circuit can effectively control the output wavelength of the laser.

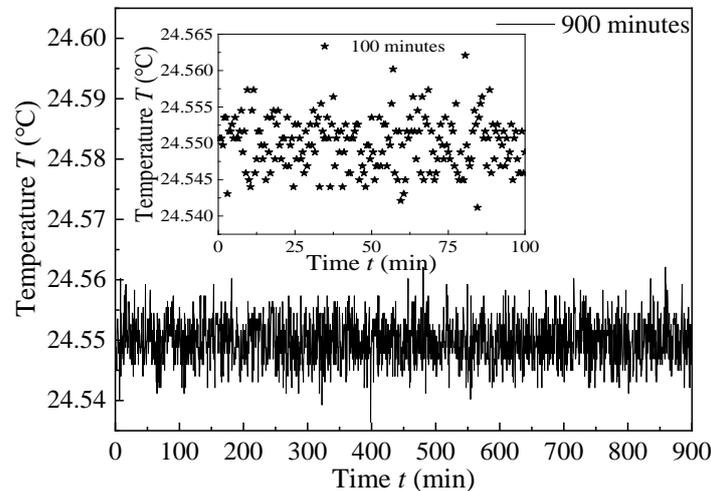

Fig. 5 – Temperature stability test of the proposed control circuit during 15 hours

HC-PCF characteristics

The Hollow-core photonic crystal is applied in this system. It can be used not only for signal transmission but also as a gas cell. The effective wavelength range of the HC-PCF used in the system is 1490-1680. Since the absorption peak of the gas to be measured in the system is around 1654 nm, the optical signal output by the laser can pass through the HC-PCF almost without loss. The transmission loss is only 25 dB/km. Its cross-section of the optical fiber is shown in Fig. 6(a). The center-to-center distance of the holes is 3.8 micrometers. Due to its 95% hollow structural characteristics, the gas to be measured can be filled inside, so that it can fully come into contact with the optical signal. The diameter of the fiber is about 70 μm . Its coating material is acrylate which has a single layer.

The gas diffusion performance of the HC-PCF has been tested in the system. Place the HC-PCF in a gas chamber with dynamic gas mixing, and inject methane gas with a concentration of 2000 ppm into the gas chamber through the method of dynamic gas mixing. Through observation, it can be seen that after approximately 69 minutes, the methane concentration inside the optical fiber is consistent with the external concentration. The speed of gas diffusion is acceptable for experiments such as long-term outdoor monitoring of methane. If it is necessary to increase the diffusion speed, laser drilling can be used to make holes in the outer sheath of the optical fiber. However, it is also necessary to re-evaluate the loss rate of its optical signal at the same time.

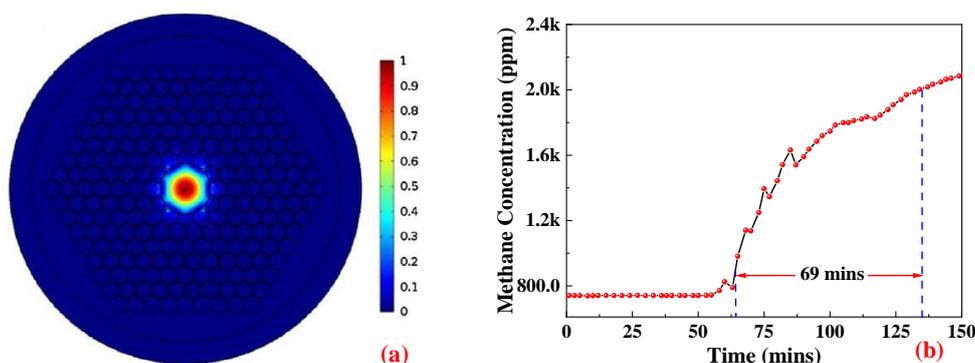

Fig. 6 – Simulation test of the optical structure (a) and the diffusion test of standard gas (b)

RESULTS AND DISCUSSIONS

Spectroscopy test

In order to meet the detection requirements of the detection system, the output spectrum of the laser must be stable and controllable. The output spectrum of the laser is determined by its control temperature and current. Therefore, it is important to evaluate the output spectral characteristics of the laser by changing its control temperature and driving current. The control temperature of the laser can greatly affect the output spectrum of the DFB laser, which is determined by the internal structure of the DFB laser. In contrast, the change in wavelength caused by the control current of the DFB laser is smaller than that caused by the control temperature. Therefore, during the experiment, it is usually the case that the output wavelength is first positioned at the absorption peak of the gas by changing the control temperature of the laser. Then, the wavelength position is finely adjusted by regulating the current of the DFB laser, so as to meet the requirements of the TDLAS detection technology.

In this paper, the proposed circuit controls the wavelength and the wavelength was tested by using an infrared spectrometer as shown in Fig.7. As can be seen in Fig.7(a), when the driving current of the laser is constant and the control temperature of the laser is changed, its central wavelength changes linearly. The injection current of the laser is set to 70 mA, and the adjustment coefficient between the temperature and the wavelength is approximately 0.115 nm/°C. In contrast, when the control temperature of the laser is kept constant, the driving current is changed, and the five sets of measured data are shown in Fig.7(b). The DFB circuit controls its current, which is increased from 40 mA to 80 mA with a step size of 10 mA. As shown in the figure, when the temperature of the laser is constant, the current of the laser is changed, and the adjustment coefficient between the current and the wavelength is measured to be approximately 0.014 nm/mA. Therefore, the control circuit proposed in this paper can effectively control the temperature and current of the laser, thus achieving effective control of its output wavelength and meeting the requirements of the detection system.

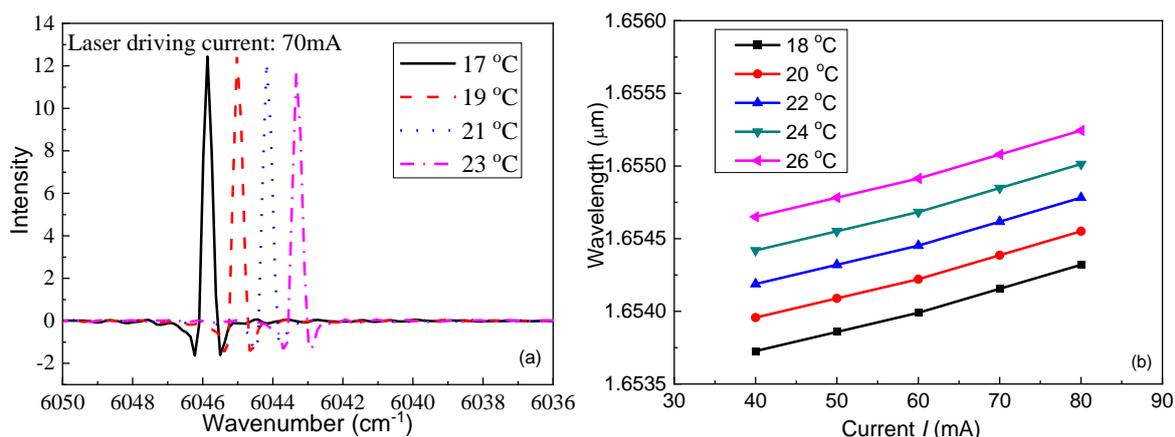

Fig. 7 – Spectroscopy test under the condition of constant temperature (a) and constant current (b)

Response time test

Since the detection and processing speed of infrared gas detection is very fast, the response time of the system is mainly determined by the volume of the gas chamber and the flow rate of the gas distribution. The detection system can detect the change of the concentration in the gas chamber in real time, so the data acquiring time of the DSP chip can be considered as the response time of the system. The calculation time of the DSP chip is very fast and the key signal which can be represent gas concentration can be obtained instantly. Compared to the traditional sensors, TDLAS technique has the advantage of fast response. This TDLAS based detection system performs an average calculation on the measured gas concentration, and the obtained average gas concentration is displayed on an LCD screen every 2 seconds. When the gas concentration in the gas chamber is changed, the fluctuation of the gas concentration will cause the detected second harmonic to fluctuate, as shown in Figure 8.

A gas mass flowmeter is applied in the system and it is required to manually adjust the knob to change the concentration during the process of gas detection. By adjusting the concentration, there is a certain slope at the rising edge of the concentration. Compared to the traditional method of gas distribution, dynamic gas distribution is the method that has better accuracy. The specific gravities of different gases need to be calculated and used to adjust the mass flowmeter in the experiment. When the target concentration is quickly

reached, the gas concentration in the gas chamber fluctuates as shown in Figure 8. Continuing to adjust the concentration when the concentration is not yet stable will cause the concentration of the gas chamber to oscillate. By measuring the Peak-to-Peak Voltage (PPV) value of the second harmonic, real-time fluctuations in gas concentration can be obtained.

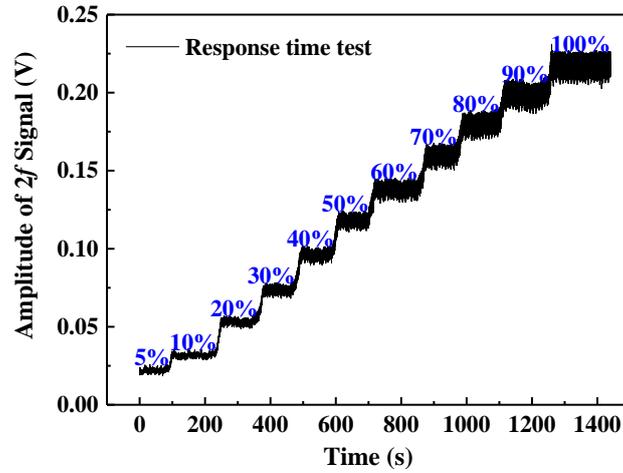

Fig. 8 – Response time test of the proposed detection system using 2f harmonic signal

Error test

The detection error of the detection system can be evaluated by using the dynamic gas mixing method. The dynamic gas mixing method can keep the gas concentration in the gas chamber approximately constant, and can change the gas concentration in the gas chamber within a short period of time. In the experiment, the high-concentration range and the low-concentration range were tested respectively, as shown in Fig. 9. For the experiments using high concentration of methane gas, the N₂ and pure CH₄ gas was mixed together after calculation of their relative height and volume. For the low concentration experiments, the pure liquid methane will be replaced by 1% standard gas to guarantee accuracy. In the high-concentration range, the error is relatively small, which is because the concentration inside the gas chamber using the dynamic gas mixing method is relatively stable, as shown in Fig. 9(a). In the low-concentration range, the error increases as shown in Fig.9(b). By calibrating the gas concentration with the second harmonic, the detection sensitivity can be further enhanced.

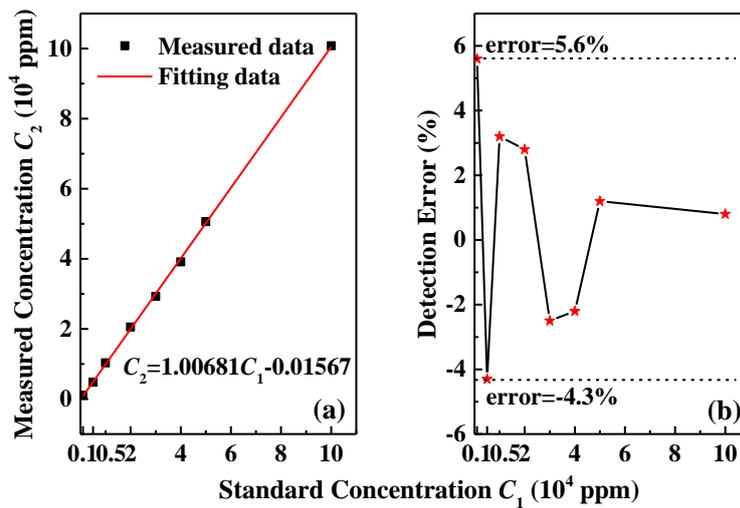

Fig. 9 – Error test of the measured methane gas using standard gas

Detection limit test

In combination with the WMS technology, detection sensitivity can be further improved. Through the sine wave and square wave of the same frequency and phase generated by the DDS, the first harmonic and the second harmonic after gas absorption can be obtained. Among them, the second harmonic can more effectively characterize the gas concentration, and the experiment carried out is shown in Fig.10.

In Fig.10(a), it can be seen that within the detection range, the second harmonic can be effectively extracted and is still clearly visible at 600 ppm. In Figure (b), when the gas chamber is filled with pure nitrogen, the fluctuation of the second harmonic can be evaluated, which is within the range of 1748 - 1754 mV. By increasing the effective absorption optical path, the detection lower limit of the system can be further reduced. In subsequent experiments, by using HC-PCF, the effective absorption optical path can be greatly increased, thereby improving the detection sensitivity of the system.

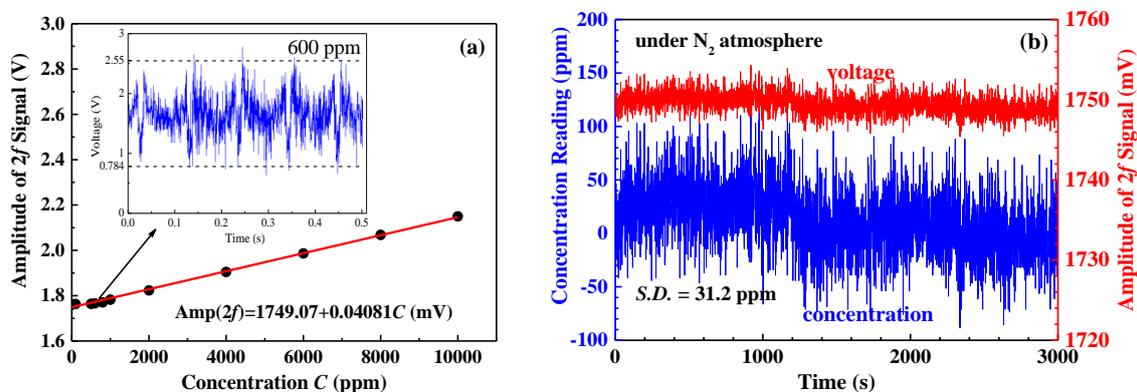

Fig. 10 – Detection limit test using 2f harmonic signal (a) and mixed standard gas (b)

CONCLUSIONS

The proposed methane detection system involves a DFB laser, InGaAs photodiodes, HC-PCF and updated circuits such as the DSP28346 circuit for laser controlling. By using the key components, the detection system has the ability to perform accurate remote detection of target gas. Through spectral testing, the stability of the laser's control temperature and driving current was verified, and the respective control coefficients were obtained. By conducting a variety of gas detection experiments, the effectiveness and stability of the detection system for detecting methane gas were developed. In subsequent research work, the use of HC-PCF will be increased to further improve the detection sensitivity of the detection system. Combined with this new type of optical fiber, the developed system can be used for large-scale methane gas monitoring in paddy fields.

Keywords: Corn Kernel, Object Detection, Light Angle, YOLOv8n

ABSTRACT

To enhance real-time detection of corn breakage rate under dim conditions, this study designed a dual-light (top/backlight) sampling system. By comparing four datasets (top-scattered, top-clustered, backlight-scattered, backlight-clustered), the algorithm optimized with backlight-scattered data achieved optimal accuracy (79.6%). A lightweight YOLOv8n_gcd model was proposed, integrating Ghost convolution in the backbone to reduce redundancy, attention mechanisms for feature enhancement, and depthwise separable convolutions in the neck. The optimized model reduced FLOPs by 24% and increased FPS by 165%, offering an efficient, low-cost solution for agricultural quality inspection with theoretical and practical value.

摘要

为了增强在昏暗条件下玉米破损率的实时检测，本研究设计了一种双光（顶部/背光）采样系统。通过比较四个数据集（顶光-籽粒分散、顶光-籽粒聚集、背光-籽粒分散、背光籽粒聚集），得出背光籽粒分散的数据优化的算法达到了最佳（79.6%）之后利用该数据集训练出一种轻量级的 YOLOv8n_gcd 模型，将 Ghost 卷积集成在骨干网中以减少冗余，将注意力机制用于特征增强，并在颈部进行深度可分离卷积。优化后的模型将 FLOP 降低了 24%，FPS 提高了 165%，为农业质量检测提供了一种高效、低成本的解决方案，具有理论和实践价值。

INTRODUCTION

Corn holds the position as the largest - scale grain crop in China (Cui *et al.*, 2019). With the progressive development of agricultural mechanization, the mode of corn harvesting in China is undergoing a significant transition from ear - based harvesting to direct kernel – harvesting (Li, 2017; Zhao *et al.*, 2020). This shift in the harvesting method represents a crucial step in modernizing corn production, enabling a more efficient and cost-effective approach. It has thus become an inevitable trend in the mechanized production of corn in the country (Zhu *et al.*, 2021). The operational quality of corn harvesting exerts a profound impact on both its yield and economic value. The breakage rate and impurity content serve as pivotal metrics for evaluating the performance of direct - kernel harvesters (Zhao *et al.*, 2025; Cui Y.S., 2024; Yang *et al.*, 2018). However, the traditional manual detection method is fraught with limitations. It is characterized by high labor intensity and low detection efficiency, which not only burdens the workforce but also fails to provide real-time and accurate feedback of the breakage rate and impurity content to the automatic control system of the harvester. As a result, timely adjustments to the operation parameters cannot be made, leading to potential substantial harvesting losses (Xu *et al.*, 2021; Wu *et al.*, 2024). This in turn has significantly impeded the advancement of intelligent harvesting technologies for domestic corn direct - kernel harvesters.

Convolutional Neural Networks (CNvolutional Neural Networks, CNNs) in deep learning have demonstrated exceptional performance improvements in cutting-edge fields such as object recognition, image classification, and image segmentation.

Liu *et al.* showed significant advantages in training multi-scale image input models compared to single-scale scene classification strategies (Liu *et al.*, 2018). Since the introduction of ResNet, residual networks have successfully addressed the long-standing vanishing gradient problem enabling unrestricted network depth and garnering widespread attention in computer vision (He *et al.*, 2016). However, deep learning-based image classification tasks often suffer from excessive parameters and bulky models, posing challenges for deployment on mobile devices. To address this, Andrew *et al.* proposed MobileNets, a lightweight convolutional neural network that achieves efficient computation on mobile and embedded systems while reducing memory consumption, thereby streamlining model parameters and computational load (Howard *et al.*, 2017). However, this simplification comes at the cost of some accuracy loss. In MobileNetV2, Mark *et al.* introduced an inverted residual structure, achieving higher accuracy with the same computational cost while minimizing information loss (Sandler *et al.*, 2018).

In the field of damaged corn kernel identification, Velesaca *et al.* proposed a two-stage static detection algorithm for corn kernel breakage (Velesaca *et al.*, 2020). This method first segments individual kernels from clustered corn images using Mask R-CNN, then classifies them via a custom-designed network (CK-CNN). Han *et al.* introduced an independent component analysis (ICA)-based method for germ feature detection, selecting germ-representative components from RGB color space and integrating nine additional germ-area features, yielding a minimal area error of 0.7% compared to manual inspection (Han *et al.*, 2010). Li *et al.* developed an image acquisition device and an improved YOLOv4-tiny model for broken kernel detection, achieving 93.5% and 93% precision for intact and damaged kernels, respectively, with lower detection error than manual methods, demonstrating real-time applicability (Li *et al.*, 2021). Xu *et al.* selected corn varieties Denghai 518, Xundan 20, and Zhengdan 958, constructing a CNN model using the Keras deep learning framework, achieving an average recognition rate of 95.49% (Xu *et al.*, 2020). Quan *et al.* investigated corn kernel selection and classification, developing a lightweight convolutional neural network. By optimizing prototype parameters, they achieved optimal performance with a detection accuracy of 96.50% and an effective sorting rate of 97.51% for four categories of kernels (high-quality, rejected, germ-side, and endosperm-side) (Quan *et al.*, 2020).

As mentioned earlier, it is necessary to research an algorithm that is adaptable to dark conditions and is lighter and easier to deploy on mobile devices.

DUAL LIGHT DEVICE DESIGN

Lighting System Design

To address image acquisition challenges in low-light environments, this study designed a dual-light system with engineered multi-angle coordination (upper and lower illumination). Comparative experiments were conducted using datasets under distinct lighting conditions to evaluate optimal angles for image capture. Hybrid-angle lighting (simultaneous upper/lower illumination) was excluded to ensure experimental comparability. The core light source is the Leichu Lighting 600×600 direct-emitting LED panel which named Model LZ-600D, whose technical specifications are compared with industry standards in Table 1.

Table 1

Comparison of Main Light Source Technical Parameters and Industry Standards

Parameter	Light emission type	Rated power [W]	Luminous flux [lm]	Illuminance uniformity [%]	Color temperature [K]	Color Rendering Index (CRI)
Leichu 600×600 LED Panel	COB-integrated direct/edge-lit	80	9,600	92 (at 0.5 m distance)	6,500 ± 200	Ra ≥ 96
Industry Standard (Industrial Grade)	Direct/edge-lit	50–100	8,000–12,000	≥85	5,000–6,500 (recommended)	Ra ≥ 90 (for precision inspection)

Mechanical Structure and Optical Layout

A modular dark chamber (80 cm × 50 cm × 50 cm) was constructed to simulate post-threshing conditions (ambient light <10 lux). The chamber's interior was coated with black light-absorbing paint (reflectivity <2%), and labyrinthine light seals (attenuation >99%) were installed at joints to eliminate stray light interference. A circular aperture (8 cm diameter) was integrated at the top for imaging.

The lighting system comprised two configurations (Fig. 2):

Top Lighting: A ring-shaped array of 24 COB LED modules (3W each) with a three-layer homogenizing structure (diffuser plate, micro-prism film, anti-glare mesh) to reduce illuminance gradients to <5%.

Backlighting: An identical LED array and homogenizer positioned at the chamber base to create a planar light source.

A co-axial optical path (light source–camera–sample alignment) was implemented to minimize edge shadows and ensure accurate kernel morphology recognition.

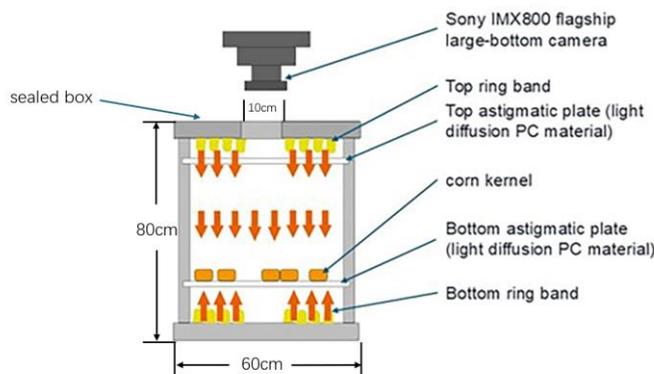

Fig. 2 – Schematic layout of the sampling device

Imaging System Design

The imaging system featured:

1) Camera: A Sony IMX800 image sensor (1/1.49", 54 MP) with 82% quantum efficiency at 550 nm, readout noise of $2.3e^-$, and dynamic range of 73 dB.

2) Lens: A Computar MLH-10X fixed-focus lens (25 mm focal length, f/2.8 aperture).

3) Stage: A three-axis precision stage with ± 50 mm horizontal range, <0.01 mm repeatability, and vertical electric focusing (0–100 mm travel). A laser rangefinder (0.1 mm accuracy) and dual-axis gimbal (15° pitch, 10° roll correction) were integrated to mitigate mechanical misalignment and vibration-induced imaging errors.

MATERIALS AND METHODS

Target Materials

The corn kernels harvested in the Northeast region of China during late September 2024 were chosen as the representative samples for this study. Two distinct types of corn kernels were the focus of detection: intact corn kernels, as illustrated in Fig. 3 (a), and damaged corn kernels, as shown in Fig. 3 (b).

Fig. 3 – Types of corn kernels

a) Complete corn kernels; b) Damaged corn kernels

During the corn - threshing process, kernel damage can occur due to multiple factors. Mechanically, the use of certain threshing machines, such as those equipped with round - headed spike - tooth mechanisms, can cause physical damage to the kernels. Additionally, improper operational practices, including sub-optimal moisture content levels (either too high or too low) and uneven feeding of corn materials into the threshing machine, can also contribute to kernel breakage.

Image Acquisition

Image collection was conducted within the established image - acquisition system. Initially, the enclosure of the system was opened, and the corn kernels designated for imaging were carefully placed inside. Subsequently, the enclosure was sealed to create a controlled, relatively dark environment that mimics the real-world conditions of post-threshing. Depending on the experimental setup, either the top - light or the back - light was activated. The height of the camera was then adjusted until the entire area of the corn kernels was within the field of view. For each batch of corn kernels, two images were captured: one with the top - light illumination and another with the back - light illumination. After image acquisition, the corn kernels were replaced, and the process was repeated. In total, 684 image pairs were collected.

Typically, the quality of the dataset significantly influences the predictive performance of subsequent deep - learning algorithms. To enhance the generalization and robustness of the network model, conventional data - augmentation techniques, such as noise injection, exposure adjustment, horizontal and vertical flipping, and random rotation, are often employed. However, in this experiment, the primary objective was to compare the efficacy of top - light and back - light illumination for detecting damaged corn kernels. Therefore, data - augmentation techniques were not applied to maintain the integrity of the original lighting - condition data.

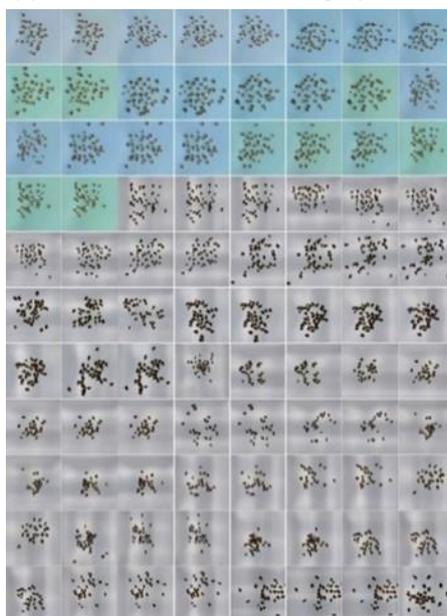

Fig. 4 – Sample images collected during the experiment

Image Calibration and Processing

After image acquisition, the datasets were categorized into four classes: top-scattered, top-clustered, backlight-scattered, and backlight-clustered. Subsequently, images within each subfolder were partitioned into training, validation, and test sets at a ratio of 6:2:2 to ensure balanced data distribution.

The images in each set were then imported into the Labelling software, a widely - used tool in the field of image recognition for manual annotation. In this study, the only objects of interest were intact and damaged corn kernels. Therefore, only these two types of kernels were annotated within the images, enabling the training of the subsequent detection algorithm.

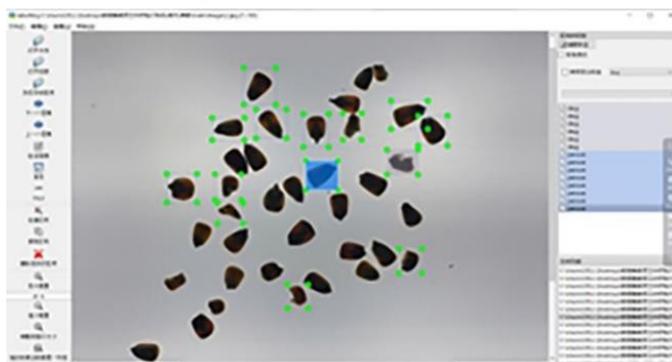

Fig. 5 – Example of an image being annotated in the Labelling software

ALGORITHM OPTIMIZATION AND TRAINING

YOLOv8 Model

Given the real-world application scenario of detecting damaged corn kernels, the YOLOv8n algorithm was selected for this study.

Renowned for its high - speed and efficient object - detection capabilities, YOLOv8n has found extensive applications across various domains. It is a component of the YOLOv8 network model, which supports multiple computer - vision tasks, including image classification, object detection, and instance segmentation. The YOLOv8 architecture consists of five main components: Input, Backbone, Neck, Head, and Output.

Compared to the full - scale YOLOv8 model, YOLOv8n has a more streamlined architecture with fewer model parameters and reduced computational requirements. This makes it particularly suitable for deployment in resource - constrained environments while still maintaining a relatively high detection speed. Despite its lightweight design, YOLOv8n can achieve competitive accuracy in object - detection tasks.

GhostNet

The backbone network architecture of the YOLOv8 model utilizes CSPDarknet. The significant depth and width of this backbone network, while suitable for high precision, incur high computational costs that degrade YOLOv8's overall detection speed. To address this limitation, this chapter introduces the lightweight network GhostNet, replacing the CSPDarknet in YOLOv8 with the hierarchical structure of GhostNet.

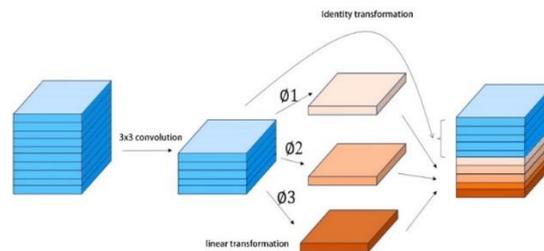

Fig. 6 – Ghost Convolution Process

CBAM Attention Mechanism

When detecting damaged corn kernels, the input images often contain not only the target objects but also substantial complex background information. The deep architecture of YOLOv8, after undergoing multiple convolutional layers, tends to neglect critical target feature information while disproportionately focusing on background features. To address this issue, this chapter integrates a spatial-channel combined attention mechanism—Convolutional Block Attention Module (CBAM) (Woo et al., 2018)—into the backbone network of YOLOv8. This mechanism aims to enhance the network's ability to precisely localize regions of interest (ROIs) and suppress the influence of background noise in remote sensing images. The core principle of the attention mechanism lies in dynamically amplifying the saliency of specific spatial and channel-wise features within input images, thereby refining the extraction of key discriminative features for improved detection accuracy.

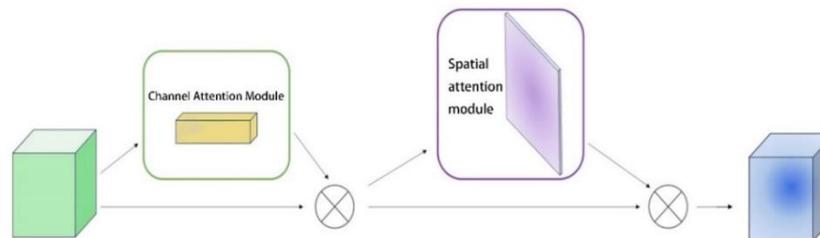

Fig. 7 – CBAM Attention Mechanism

Depthwise Separable Convolution

To further enhance the detection accuracy of the model, an attention mechanism can be introduced in the backbone of the original network. However, the attention mechanism may negatively impact inference speed. Therefore, Depthwise Separable Convolution (DWConv) is incorporated into the neck for localized optimization (Woo et al., 2018).

In the modified YOLOv8 model, standard convolutions in the backbone network are replaced with DWConv. The computation is divided into two steps: depthwise convolution (applying a single filter per input channel) followed by pointwise convolution (combining outputs across channels via 1×1 convolutions). Compared to standard convolutions, this approach drastically reduces computational complexity and accelerates model inference speed. The structure of this modification is illustrated in Fig. 8.

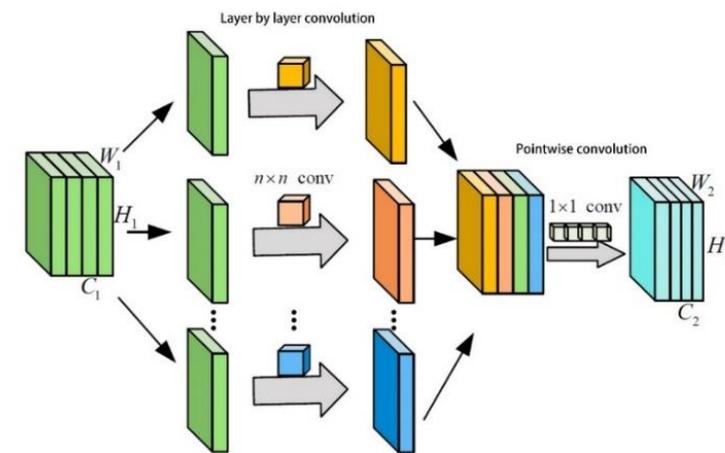

Fig. 8 – Depth Separable Convolutional Structure

MODEL TRAINING AND RESULT ANALYSIS

Training Environment

The experimental setup was configured with a 64-bit Windows 10 operating system. The hardware specifications included a 12th-generation Intel(R) Core (TM) i7-12700KF CPU operating at a base frequency of 3.61 GHz, 32 GB of RAM, and an NVIDIA 3080Ti graphics processing unit (GPU) with 12 GB of dedicated video memory. The deep-learning framework employed was Python 3.11.0, in conjunction with Cuda 12.4 for GPU-accelerated computations. Python 3.8.0 was used as the programming language, and the development environment was PyCharm Community Edition.

Evaluation Indicators

In the process of model training, two key performance indicators, precision and recall, play a vital role in assessing the algorithm's effectiveness. Precision measures the proportion of correctly identified positive samples among all samples predicted as positive, while recall represents the proportion of correctly identified positive samples among all actual positive samples. The mathematical formulas for calculating precision (P) and recall (R) are as follows:

$$P = \frac{TP}{TP+FP} \quad (1)$$

$$R = \frac{TP}{TP+FN} \quad (2)$$

where: *TP* (True Positive) refers to positive samples that are correctly classified as positive; *TN* (True Negative) represents negative samples that are correctly classified as negative; *FP* (False Positive) denotes negative samples that are incorrectly classified as positive; and *FN* (False Negative) indicates positive samples that are incorrectly classified as negative.

Mean Average Precision (*MAP*) is another crucial metric for evaluating the overall performance of the network model. It provides a comprehensive measure of the model's accuracy across different confidence thresholds. The formula for calculating *MAP* is as follows:

$$AP = \int_0^1 p(r) dr \quad (3)$$

$$MAP = \frac{\sum_{i=1}^k AP_i}{k} \quad (4)$$

where: *AP* (Average Precision) represents the average precision for a specific class of objects; and *k* is the total number of classes in the dataset.

In this experiment, four evaluation metrics were utilized to analyze the experimental results and compare them with the baseline network performance. These metrics include MAP_{b50 - 95}, MAP_{m50 - 95}, computational complexity, and inference time. The notation 50 - 95 represents the average MAP calculated at different Intersection over Union (IoU) thresholds, ranging from 50% to 95% with a step size of 5%.

Comparative experiment of datasets from different perspectives

To determine which lighting angle, top - light or back - light, is more suitable for detecting damaged corn kernels in real-world scenarios, the YOLOv8n algorithm was trained using four different datasets: top-scattered, backlight-scattered, top-clustered, and backlight-clustered. All training was conducted under identical experimental conditions, using the hyperparameters tuned from the original model and maintaining consistent training epochs and learning rates. The experimental verification results are presented in Table 2.

Table 2

Verification results of algorithms trained with different datasets

datasets	Precision/%	Recall/%	mAP _{0.5~0.95} (%)	FPS/F-s-1
<i>Top-scattered</i>	89.8	67	70.7	35
<i>Top-clustered</i>	76.6	77.7	61.4	39
<i>Backlight-scattered</i>	85.7	70.6	79.6	31
<i>Backlight-clustered</i>	80.6	74.1	75.4	30

As indicated by the data in Table 2, the Dispersal in the Backlight dataset performs the best, along with the fastest recognition speed. Through horizontal comparison, it was evident that discrete-kernel datasets were more conducive to training, resulting in more accurate models. Moreover, back-light-illuminated datasets generally outperformed top-light-illuminated datasets in terms of training efficiency and model accuracy. Therefore, backlight-scattered dataset was used to train the improved algorithm model.

Data Enhancement

After identifying the backlight-scattered dataset as the optimal training dataset, data preprocessing was performed to enhance sample diversity and enable the network to learn features from multiple perspectives before feeding it into the training pipeline. This process improves the model's ability to analyze feature data and strengthens its generalization capability. Data augmentation techniques—such as rotation, flipping, blurring, and brightness adjustment—were performed on the dataset samples, as illustrated in Fig. 9.

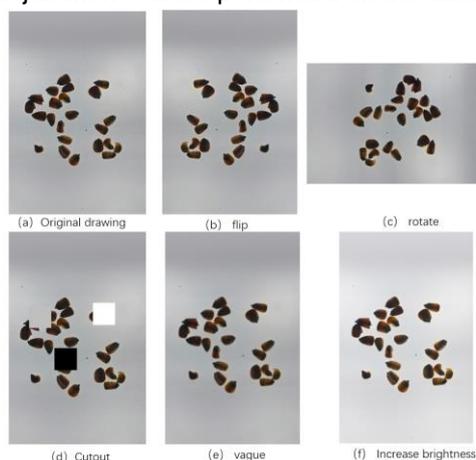

Fig. 9 – Data enhanced image

RESULTS

Ablation Experiment

To verify the effectiveness of the improvements proposed in this article, ablation experiments were conducted to validate the effectiveness of each part. The experimental results are shown in Table 3, where YOLOv8n_g represents the use of Ghost convolution on the basis of YOLOv8n, YOLOv8n_gc represents the use of attention mechanism on the basis of YOLOv8n_g, and YOLOv8n_gcd represents the addition of depthwise separable convolution on the basis of YOLOv8n_gc. Compared to YOLOv8n GFLOPS, YOLOv8n_g has decreased from 8.1 to 5.9, the model's accuracy mAP has decreased from 86.6% to 84.6%, and FPS has increased from 43 to 68. Although using Ghost convolution can significantly improve the model's detection efficiency, it will result in a loss of accuracy.

Compared to YOLOv8n_g, YOLOv8n_gc showed a 0.9 percentage point increase in accuracy and an 8% decrease in FPS with a 0.2 increase in GFLOPs. The attention mechanism can enhance the model's feature extraction ability for targets and improve detection accuracy. Compared to YOLOv8n_gcd, YOLOv8n_gcd reduces computational complexity by 7.97%, increases detection speed by 11fps, and reduces mAP value by 1.05%. Compared to YOLOv8n, YOLOv8n_gcw significantly improves FPS by 60% while slightly reducing model accuracy.

Table 3

Results of ablation experiment

Model	Ghost	CBAM	DWConv	GFLOPs	FPS	mAP
YOLOv8n	-	-	-	8.1	43	86.6%
YOLOv8n_g	√	-	-	5.9	68	84.6%
YOLOv8n_gc	√	√	-	6.1	60	85.5%
YOLOv8n_gcd	√	√	√	6.1	71	84.95%

The specific training dynamics of the YOLOv8n_gcw model are illustrated in Fig. 10. By observing the mAP@50 and mAP@50-95 metrics in Figure 10, it is evident that the model's average precision values stabilize around the 200th epoch, with no significant improvement thereafter. This indicates that the model has converged to its optimal state and does not benefit from further training iterations.

Concurrently, the evaluation metrics for Precision and Recall also exhibit stable and unchanging trends at this stage, suggesting that the model has achieved an optimal balance between detecting true positives and minimizing false positives/negatives. Therefore, additional training epochs are unnecessary, as they would not yield meaningful performance gains.

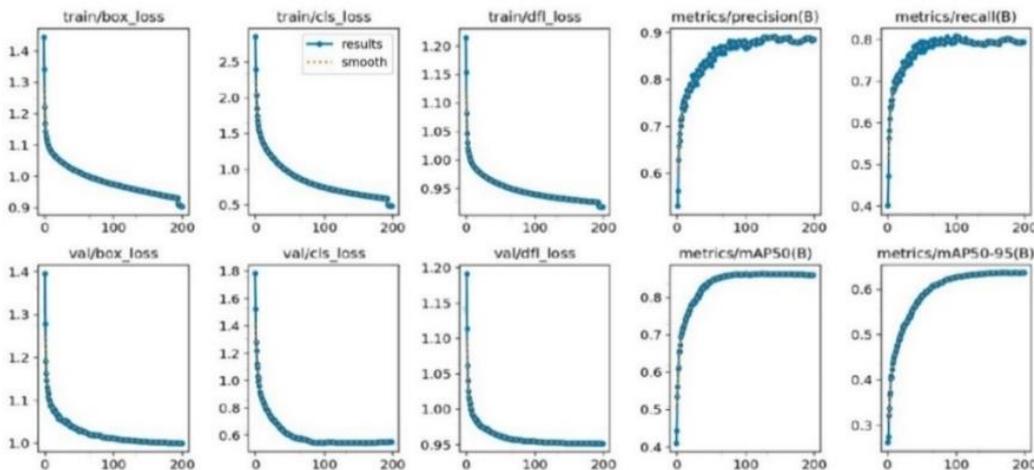

Fig. 10 – YOLOv8n_gcd Training Process Diagram.

Contrast Test

To further demonstrate the effectiveness of the algorithm presented in this chapter, comparative experiments were conducted against classical deep learning object detection algorithms, including Faster R-CNN, SSD, and YOLOv7 (Wang et al., 2023). The experimental results are shown in Table 4.

Table 4

Comparative experiment of different object detection algorithms

Model	GFLOPs	mAP@0.5	Precision	Recall
Faster-RCNN	227.8	80.6%	81.8%	74.6%
SSD	63.14	78.6%	79.1%	70.9%
YOLOv7	105.4	81.5%	82.4%	73.5%
YOLOv8n_gcd	6.1	84.95	84.8%	76.2%

The experimental results in Table 4 clearly demonstrate that the optimized model proposed in this study achieves significantly superior performance in reducing floating-point operations (FLOPs), with its FLOPs far lower than those of the other three benchmark models. In other aspects, compared to Faster R-CNN, SSD, and YOLOv7, the optimized model exhibits improvements in precision by 3%, 5.7%, and 2.4%, respectively; recall by 1.6%, 5.3%, and 2.7%, respectively; and mean average precision (mAP@0.5) by 4.35%, 6.35%, and 3.45%, respectively. Notably, the YOLOv8n_gcd model maintains a compact architecture with reduced computational demands, enabling rapid deployment on resource-constrained platforms. These enhancements collectively validate the superior performance and broad applicability of the proposed improved model in real-world applications.

CONCLUSIONS AND DISCUSSIONS

This study designed a dual-light device to collect datasets, generating four distinct datasets: top-lighting-dispersed, top-lighting-aggregated, backlighting-dispersed, and backlighting-aggregated, which were used to train the same algorithm. The results revealed that the backlighting-dispersed dataset achieved the highest accuracy and was most suitable for training. Building on this, an optimized YOLOv8-based model, termed YOLOv8n_gcd, was proposed. This model integrates Ghost convolutions into the backbone network to minimize redundant computations, incorporates attention mechanisms to enhance feature extraction for damaged regions, and replaces standard convolutions with depthwise separable convolutions in the Neck section. These localized optimizations achieve a balance between accuracy and lightweight efficiency. Comparative experiments demonstrated that the YOLOv8n_gcd model outperforms Faster R-CNN, SSD, and YOLOv7, with precision improvements of 3%, 5.7%, and 2.4%, recall improvements of 1.6%, 5.3%, and 2.7%, and mAP@0.5 gains of 4.35%, 6.35%, and 3.45%, respectively. Notably, the optimized YOLOv8s model retains a compact architecture with significantly reduced computational demands, enabling rapid deployment on resource-limited platforms. These advancements in precision, speed, and robustness validate the superiority and broad applicability of the proposed model in practical agricultural scenarios, offering a high-performance solution for real-time quality inspection tasks while maintaining adaptability to industrial constraints.

ABSTRACT

To address challenges in developing the rice-wheat harvester cutting platform controller—such as sensitivity to working conditions, long development cycles, and cumbersome performance testing—a semi-physical simulation platform is designed. Based on the functional requirements of the cutting platform, Simulink is used to build a mathematical model of the controller and its I/O hardware model. A hardware-in-the-loop simulation test platform is developed using the TC377ECU controller. By integrating the Whale Optimization PID algorithm, overshoot is reduced by 3.5%, and rise time improves by 0.303 s compared to conventional PID. Testing in both simulation and real environments shows a maximum absolute error of 10.58 mm for cutting height and a correlation coefficient of 0.9474. The rotational speed errors for the reel and auger have expectations of 0.106 rad/min and 0.101 rad/min, with standard deviations of 0.165 rad/min and 0.172 rad/min. This validates the controller's feasibility, shortens development time, and lowers costs.

摘要

针对稻麦收获机割台控制器开发过程受工况影响较大, 传统开发过程周期长, 测试控制器性能过程繁琐等问题, 设计了一套稻麦收获机割台自动调控系统半实物仿真平台。以稻麦收获机割台功能需求作为开发指标, 利用 simulink 搭建控制器数学模型以及 I/O 硬件模型, 基于 TC377ECU 控制器搭建硬件在环仿真测试平台。结合鲸鱼优化 PID 算法对控制策略进行了优化, 相较于普通 PID, 超调量降低了 3.5%, 上升时间提升了 0.303s。通过仿真平台与真实环境进行试验对比, 割台高度的最大绝对误差是 10.58mm, 相关系数为 0.9474; 拨禾轮和搅龙转速误差的数学期望依次为 0.106 rad/min 和 0.101 rad/min, 标准差为 0.165 rad/min 和 0.172 rad/min, 测试了控制器和仿真平台的可行性, 缩短了开发周期, 降低了开发成本。

INTRODUCTION

As one of China's major food crops, ensuring the production of rice and wheat is of primary importance. In 2024, 23,090.7 thousand hectares of wheat were sown, marking an increase of 31.7 thousand hectares, or 0.1%. With the growing prevalence of machine harvesting across the country, the automation level of agricultural machinery has reached a point where higher standards are required. This makes the development and optimization of agricultural machinery functions increasingly significant. To overcome the limitations of using joysticks for regulating the cutting platform parameters in traditional harvesters, researchers have increasingly focused on developing automatic regulation systems for the cutting platform of grain combine harvesters. Ji *et al.*, (2023), employed the polar filling method to model the rigid and flexible discrete elements of reed stalks, and conducted a three-point bending test in EDEM software to calibrate the bonding parameters. The optimal parameter combinations for the cutting table were identified through simulation analysis and later verified by field tests, confirming their alignment with the simulation results. Yao *et al.*, (2023), investigated the impact of harvester forward speed, transverse cutter cutting height, and longitudinal cutter cutting speed on the cutting table loss rate in rapeseed combine harvesting, addressing the issue of high loss rates. The analysis revealed that the significance order of these factors was: cutting speed > forward speed > cutting height. Optimal parameter combinations were determined through response surface analysis and regression model optimization, with the results experimentally verified for reliability.

Aiming to address the issues of low gripping capacity, poor cutting quality, and easy damage of existing harvester tools, *Zhao et al.*, (2024), designed a bionic knife blade inspired by the maxillary teeth of ants. They investigated the effects of parameters such as blade tooth pitch, constructed edge angle, and tilt angle on the stress field and deformation through finite element analysis. The results confirmed that optimizing the knife edge design significantly enhances its performance, providing a theoretical foundation for the design of harvester knives.

Chen et al., (2018), addressed the low automation levels in cutting platform parameter regulation by using a PLC as the controller to design an automatic adjustment device for the rice combine harvester's cutting platform. In their system, the response time for controlling the rotational speed of the reel was ≤ 0.8 s, with a control accuracy of 91.5%.

Liu et al., (2022), designed an adaptive profiling cutting table to ensure the stubble height remains within an optimal range during harvesting. The table could adjust its height and level adaptively, using a PLC controller and a fuzzy PID method for regulation. The cutting table's rising speed was 0.216 m/s, and its descending speed was 0.244 m/s.

Ji et al., (2022), aimed to improve harvesting quality by designing a cutting table with a response time of ≤ 0.8 s and control accuracy of 91.5%. They also developed a device to match the rotational speed of the reel with the forward speed using an STM32 controller and fuzzy PID control strategy. This system could adapt to different crops, with a rotational speed-to-vehicle speed ratio between 1.4 and 1.8, yielding better harvesting results.

Shi et al., (2024), designed an adaptive control system for the cutting platform to address the inefficiency and inaccuracy of manual adjustments. Using a PLC as the controller, the system achieved an average response time of 2.3 s for height control. These studies demonstrate that factors such as the height of the cutting platform, reel height, rotational speed of the reel, and auger speed directly affect the harvesting loss rate of rice and wheat. However, most of the research primarily focuses on optimizing the regulation process of the reel using fuzzy PID methods for height and speed control. The optimization of cutting platform regulation strategies remains under developed. Moreover, the process of controller development and testing requires numerous experiments for validation. This not only increases the risk of actuator burnout due to errors in control strategies but also raises testing costs and demands frequent mounting, dismounting, and optimization operations. Additionally, given the growth cycles of rice and wheat, continuous field experiments are necessary for verification, resulting in a lengthy development cycle. HIL simulation allows for effective testing of controllers by simulating realistic controlled objects. While HIL simulation has been widely applied in industries such as automotive and aviation, *Shahir et al.*, (2021), uses HIL to test complex algorithms in electric vehicle propulsion architectures, validating the correctness of the proposed theoretical concepts.

Abboush et al., (2024), applies semi-physical simulation techniques for fault injection, testing the safety of automobiles. *Klionovska et al.*, (2021), utilizes the HIL technique for spacecraft rendezvous simulation testing. Its application in agriculture has only emerged relatively recently, primarily for tractor steering control and gearshift simulation, *Hang et al.*, (2024), improves the steering control strategy for tractors and develop HIL testbeds. *Cevallos et al.*, (2022), applies the HIL technique to validate a hybrid control method for a greenhouse model.

Wu et al., (2023), uses HIL technology for an electric tractor seeding unit, building a hardware-in-the-loop simulation testbed to compare and validate proposed improvement strategies. *Zhu et al.*, (2022), applies the HIL technique to a corn harvester threshing unit, creating a low loss intelligent control simulation platform for corn.

Zhai et al., (2023), establishes a semi-physical simulation test platform for the tractor electro hydraulic suspension control system, verifying the performance of the designed controller in this system. It is evident that the introduction of semi-physical simulation technology has accelerated the development of automation in the agricultural sector, yet its application in the development of cutting table regulation systems remains limited.

Therefore, this paper aims to optimize the cutting platform's automatic regulation system, addressing the gap in current research regarding the optimization of cutting platform height control strategies. By combining the Whale Optimization Algorithm (WOA) with a PID based control strategy for height regulation, this approach reduces overshoot by 3.5% compared to traditional PID control, thereby enhancing system stability. Additionally, the rise time is improved by 0.303 seconds, which boosts the system's response speed. Agricultural automation systems are often influenced by environmental changes and the aging of equipment, which can impact response speed.

However, the WOA-optimized controller demonstrates strong adaptability to these variations, enhancing the system's robustness. In terms of reel and auger speed regulation, this study integrates findings from existing research to ensure that the speed ratio between the reel and vehicle speed remains within an optimal range. The TC377 is selected as the control center for the system, offering better compatibility with the harvester. To address the long testing cycles in traditional development processes, a semi-physical simulation platform for the cutting platform's automatic control system is constructed. The feasibility of the platform is evaluated in comparison with traditional methods, providing a solid foundation for the continued development of the cutting platform control system.

MATERIALS AND METHODS

Simulation platform overall structure

The overall structure of the simulation platform should have the function of simulating the environment of the real vehicle, so it is necessary to analyze the overall architecture of the cutting platform first; as shown in Figure 1, the whole simulation platform consists of on-board controllers, driver operating system, hydraulic model, actuator model, operation interface, information processing system, and power supply module, the on-board controller as the core component of the whole system. The simulation platform board issues its input to simulate the voltage signal of the sensor so that the controller mistakenly thinks that the current working environment is the real machine, to achieve the purpose of testing the controller function. The data transmission between the controller and the simulation platform is via I/O hardware. The CAN communication bus and the current value of each data can be monitored in real-time via telegrams. The operator interface interacts with the information processing system to send user operation data and controller feedback results. Its functional design mainly includes the working mode selection of the whole machine, the height of the cutting platform, the height of the reel, the speed regulation and monitoring of the reel, and the entire regulation process is realized by the controller sending out PWM pulse signals to control the openness of the solenoid valve.

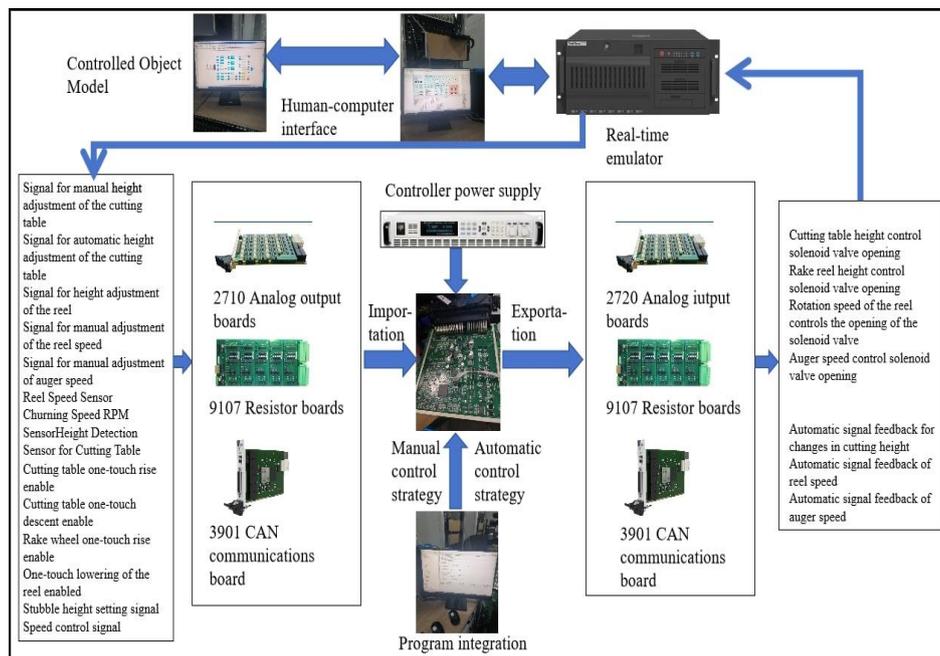

Fig. 1 - Block diagram of grain harvester cutting platform control system components

A complete grain harvester cutting table model is established using existing experimental data and formulas to create a realistic test environment for the controller. This includes simulating the conventional vehicle voltage signals required by the controller, the voltage signals from the cutter sensors, the control signals from the receiver controller, and the feedback status signals. The input and output signals of the entire system are regulated by the real-time simulator, and the regulation strategy is implemented based on the established I/O model. The controlled variables include the cutting platform height, the reel's height and rotational speed, and the auger's rotational speed. Modeling of the actuator based on the hydraulic system, with its schematic diagram shown in Figure 2.

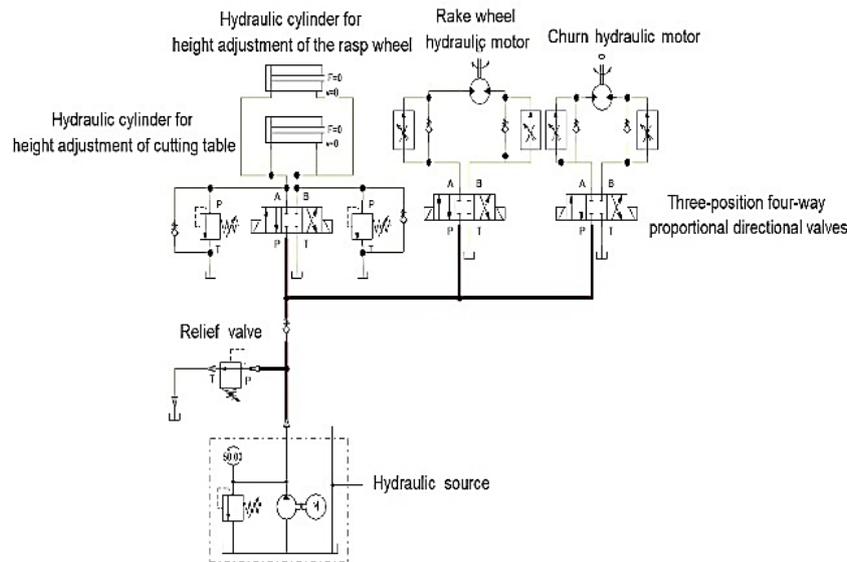

Fig. 2 - Hydraulic system schematic

The complete model must account for the following considerations: ①The hydraulic element’s power source is the pressure generated by fluid flow, requiring incorporation of the nonlinear relationship between flow rate and pressure. ②Assuming the hydraulic oil is compressible, the mechanical analysis must include the elastic resistance of the liquid. ③To ensure compatibility with the controller and minimize computational burden, the model must be discretized.

The height regulation of the cutting platform is primarily achieved by controlling the expansion and contraction of the hydraulic cylinder. The hydraulic cylinder’s power is derived from the conversion of hydraulic oil flow, and the displacement of the hydraulic cylinder is determined through the mathematical relationship between pressure and acceleration. A piston pump model is selected as the power source for the entire hydraulic system, with its displacement formula given by:

$$V = \frac{\pi}{4} d^2 D z \eta_v \tan \delta \tag{1}$$

where d is the plunger diameter, m; D is the diameter of the distribution circle of the plunger on the cylinder body, m; z is the number of plungers; η_v is the pump volumetric efficiency; δ is the inclination of the swashplate, rad.

Find the flow rate produced by the pump based on the displacement of the piston pump:

$$Q = nV \tag{2}$$

where:

Q is the output flow rate of the piston pump, m³/s; n is the engine speed of the piston pump, r/min; V is the displacement of the piston pump, L/rev.

Hydraulic oil exits the hydraulic pump, with one path flowing through the relief valve into the tank and the other passing through the check valve into the solenoid directional valve. During this process, a localized fixed capacity cavity is formed. Assuming the liquid is compressible, if the volume of the fixed-capacity cavity is V and the initial internal pressure is P_0 , then as the liquid continues to flow into the cavity at a changing rate of ΔQ , the pressure inside the cavity can be expressed as follows:

$$P = P_0 + B \int \frac{\Delta Q}{V} dt \tag{3}$$

where:

P is the hydraulic chamber pressure in Pa; P_0 is the initial pressure of the hydraulic chamber in Pa; B is the bulk modulus of elasticity of the hydraulic fluid in Pa; ΔQ is the amount of flow change in m³/s; V is the volume of a fixed volume in m³.

The hydraulic fluid output from the check valve serves as the input to the three-position four-way proportional directional valve. The position and opening of the proportional directional valve are controlled by a PWM signal from the controller. Given that the valve port opening is not strictly linear, the flow rate output from each valve port, based on the valve port characteristics, can be expressed as follows:

$$Q=C_d A_0 \sqrt{\frac{2\Delta p}{\rho}} \tag{4}$$

$$A_0 = \begin{cases} 0, & x < x_0, \\ Kx, & x > x_0. \end{cases} \tag{5}$$

C_d is the flow coefficient, dimensionless; A_0 is the cross sectional area of the hole, m^2 ; ρ is the density of the liquid, kg/m^3 ; Δp is the pressure difference between the inlet and outlet of the small hole, m^2 ; x_0 denotes the deadband flow rate, m^2 ; K is the gain coefficient, dimensionless.

The hydraulic oil output by the reversing valve flows to the hydraulic cylinder, and the flow of hydraulic oil realizes the reciprocating motion of the hydraulic cylinder push rod; according to the relationship between the force and acceleration can be calculated the displacement of the hydraulic bar, and its kinetic equation can be expressed as:

$$F_i - F_o - F_c - F_k - F_{load} = ma \tag{6}$$

F_i is the inlet chamber pressure, N; F_o is the outlet pressure, N; F_c is the liquid damping force, N; F_k is the liquid elastic force, N; F_{load} is the model load force, N; m is the mass of the piston rod, kg; a is the piston rod acceleration, m/s^2 .

The RPM model hydraulic circuit is similar to the height model, with the key difference being that the actuator in the RPM model is a hydraulic motor. This motor converts the pressure of the hydraulic fluid into mechanical energy to drive the rotation of the reel. The moment balance equation for the hydraulic motor and the load can be expressed as (Lu et al., 2023):

$$D_m(p_H + p_L) = J_t \frac{d^2\theta_m}{dt^2} + B_m \frac{d\theta_m}{dt} + G\theta_m + T_l \tag{7}$$

p_H and p_L are the hydraulic motor inlet chamber pressure and return chamber pressure, respectively, Pa; D_m is the displacement of the hydraulic motor, m^3/s ; J_t is the total inertia of the hydraulic motor and load, $kg \cdot m^2$; B_m is the viscous damping coefficient, kg/s ; G is the load spring stiffness, $N \cdot m$; T_l is any unintentional load moment acting on the hydraulic motor shaft, N; θ_m is the motor rotation angle, rad.

As the command processing center of the entire platform, the controller's control strategy plays a pivotal role, directly impacting the functionality of the cutting table and the overall effectiveness of the test. Among the various control tasks, height regulation of the cutting table is particularly critical. To achieve fast, stable, and precise control, a PID control strategy optimized using the Whale Optimization Algorithm (WOA) has been selected. WOA is an innovative bio-inspired intelligence algorithm modeled after the foraging behavior of humpback whales (NadimiShahraki et al., 2021; Miao et al., 2025; Wei et al., 2025). In the WOA optimization process, each humpback whale represents a candidate solution. These whales utilize a distinctive hunting technique known as the bubble-net predation strategy, which serves as the foundation for the algorithm's search and exploitation mechanisms.

In the encircling prey phase, the current best candidate solution is assumed to be the optimal solution for the target prey, or at least close to it (Yan et al., 2022). The humpback whale then moves around this best candidate solution, continuously updating its position. The mathematical model for this phase is represented as:

$$X(t+1) = X^*(t) - A \times |CX^*(t) - X(t)| \tag{8}$$

t is the number of iterations for the current update position, dimensionless; $X^*(t)$ is the current optimal position vector, m; $X(t)$ is the current position vector of the whale, m; A and C are position vector coefficients which operate as follows:

$$A = \frac{2T_{max}}{T_{max} + t} (2r_1 - 1) \tag{9}$$

$$C = 2r_2 \tag{10}$$

r_1 and r_2 is a random vector in the range (0,1), dimensionless; T_{max} is the iteration maximum, dimensionless.

During the prey search phase, humpback whales update their position in an upward spiral and keep approaching their prey, its hunting model is:

$$X(t+1) = X^*(t) + e^{bl} \cos(2\pi l) |X^*(t) - X(t)| \tag{11}$$

b is the whale spiral path coefficient and l is a (0,1) random number conforming to a uniform distribution, dimensionless.

From this, two behaviors of whales when catching prey are derived, assuming that the probability of both behaviors is the same.

$$X(t+1)=\begin{cases} X^*(t)-A\times|CX^*(t)-X(t)|, p<0.5 \\ X^*(t)+e^{bl}\cos(2\pi l)|X^*(t)-X(t)|, p\geq 0.5 \end{cases} \quad (12)$$

where p is the probability of the two behaviors, dimensionless.

When attacking the prey, the difference between the iteration value t and the maximum iteration value gradually decreases, causing the range of values of A to decline. When the value of A is within $[-1, 1]$, the next position of the whale can be any position between it and the prey, and at $A < 1$, the attack is launched at the prey.

To ensure that all humpback whales can perform a thorough search in the solution space, they must randomize their targets based on each other's positions. When the value of A is outside the range of $[-1, 1]$, the algorithm randomly selects a whale's position to modify the position vectors of other whales. This helps them locate suitable prey and enables global search capabilities.

$$X(t+1)=X_{random}(t)-A\times|CX_{random}(t)-X(t)| \quad (13)$$

where $X_{random}(t)$ is a vector of randomly selected whale positions, m .

Based on PID control of the cutting table elevation, the system error is used as the evaluation function for the whale optimization algorithm. The fitness function value is calculated, and the proportional, integral, and derivative parameters are adjusted according to the fitness to optimize the PID controller, thereby achieving optimal control.

To reduce the computational load of the simulation platform and facilitate test sampling, the model must be discretized. The Simulink tool is used to automatically solve the discrete model using the forward Euler method, which can be expressed as follows:

$$x(k+1)=x(k)+Tf(x(k),t(k)) \quad (14)$$

where $x(k)$ is the state variable at the current moment k , m ; $x(k+1)$ is the state variable at the next moment $k+1$, m ; T is the sampling time, s ; $f(x(k),t(k))$ is the derivative of the system, m/s .

RESULTS AND ANALYSIS

The simulation platform functionality test primarily includes the simulation function test of the controller signals and the hardware-in-the-loop (HIL) test.

Taking the cutting platform height regulation signal as an example, the controller adjusts the lift of the hydraulic cylinder based on the detection signal from the profiling device. The profiling device's source is the angle detected by the angle sensor, which sends out a voltage signal. This process can be used as the basis for analog signal testing. The voltage signal value can be set on the control panel, and a multimeter can be used to measure the voltage signal output from the corresponding board to conduct the test.

For the selection of an angle measurement sensor in a cutting table profiling device, the GT-B type Hall angle sensor is a suitable choice. This sensor features an output voltage range of 0-3.3 V, which corresponds linearly to an angular range of 0-360°.

The relationship between the measured angle and the simulated angle value follows the equation:

$$V=a\times\frac{3.3}{360} \quad (15)$$

where: V is the simulation platform voltage setting, V ; a is the angle value measured by the true angle sensor, °.

$$\theta=V\times\frac{360}{3.3} \quad (16)$$

where θ is the simulation platform angle analog input value, °.

Based on the measured angle value, the required voltage parameter V can be determined and set on the platform, allowing for the calculation of the corresponding angle input. A comparison between the measured sensor values and the platform's angle measurement values was conducted, with the test results presented in Table 1.

The results indicate that the maximum absolute error between the simulation platform and the measured sensor angle is 0.98°, while the maximum relative error is 0.08°. This discrepancy arises because, after setting the voltage parameter V , the board card outputs the voltage according to the set value, but minor deviations exist in the actual output. This conclusion is further validated by measuring the board card's output voltage using a multimeter.

Table 1

Sensor and simulation platform angle measurements

The CAN signal test uses VBA software to monitor real-time changes in message transmission data, assessing the accuracy and timeliness of signal transmission. Figure 3 displays the screen of real-time monitoring during the test. The CAN message monitoring screen displays real-time data transmission between the platform and the controller. The current value of each signal θ is updated in real-time, simulating an environment where CAN communication is active.

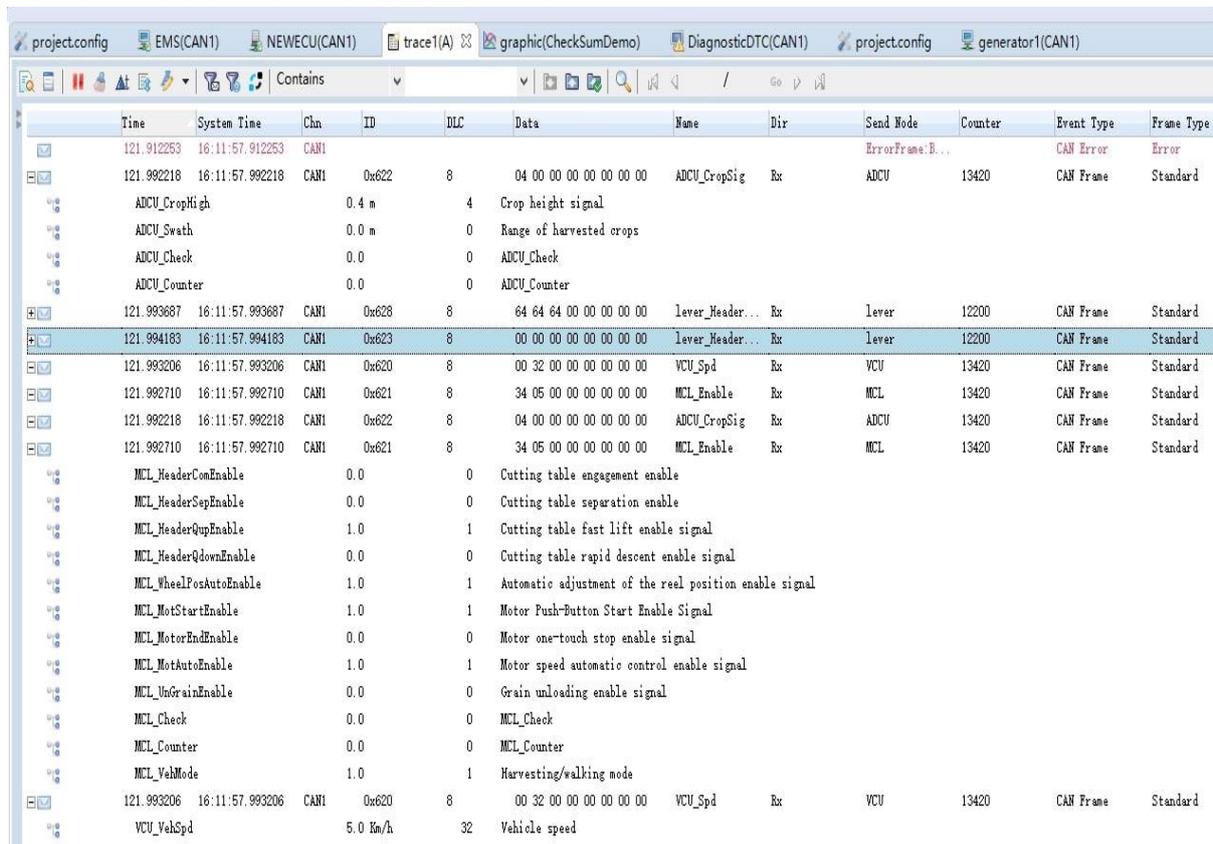

Fig. 3 - CAN communication real-time monitoring messages

To verify the optimization effect of the whale optimization PID and traditional PID control in regulating the lift of the cutting table, the dynamic response of the system will be observed. The mathematical transfer function for the lift of the cutting table is established. The opening of the reversing valve directly influences the speed of the hydraulic cylinder's lifting. The hydraulic cylinder's speed changes in accordance with the variation in the valve opening. The acceleration and deceleration, as well as the expansion and contraction of the hydraulic cylinder, are considered inertial elements (Qin et al., 2009). The transfer function for this process can be expressed as follows:

$$G(s) = \frac{1}{Ts+1} \tag{17}$$

where s is the Laplace operator, s^{-1} ; T is the hydraulic cylinder inertia constant, s , here take 0.83.

The simulation model of the control strategy is built in Matlab/Simulink environment and its model diagram is shown in Figure 4.

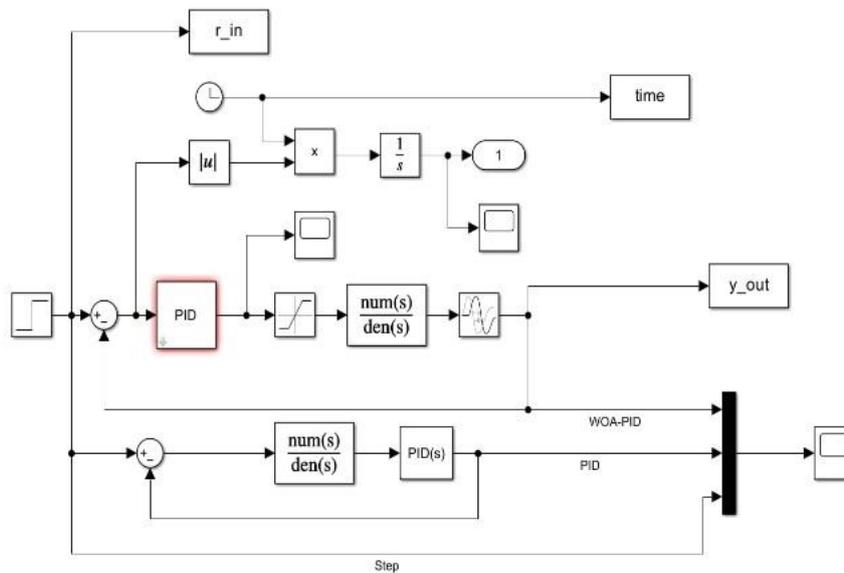

Fig. 4 - WOA-PID Simulink model

A step signal is used as the input to the system. After 10 iterations of the whale optimization algorithm, the optimal solution is obtained, yielding the corresponding values of K_p , K_i , and K_d . A comparison curve between the results of the optimized PID and the standard PID is then generated, and the resulting graph is shown in Figure 5.

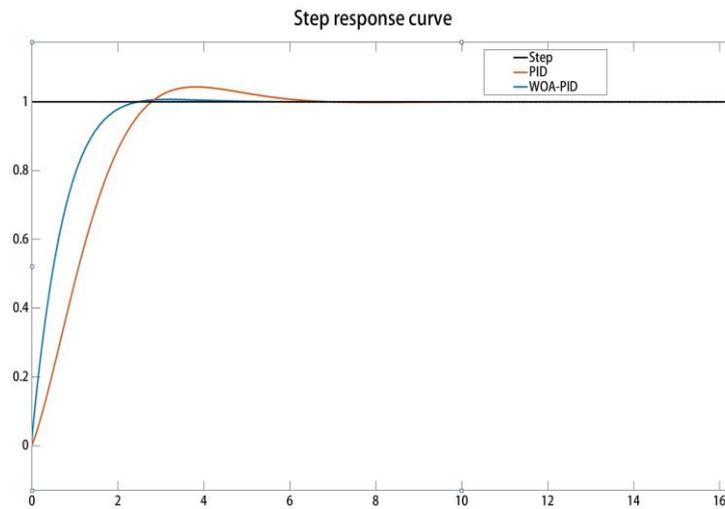

Fig. 5 - Control strategy step response comparison curve

From the dynamic response curve, it can be observed that the regulation effect of the whale optimized PID is significantly improved compared to the standard PID. The overshoot is reduced by 3.5%, and the rise time is improved by 0.303 seconds, enhancing the system's speed and stability.

To verify the feasibility of the semi-physical simulation platform for controller testing, a control experiment was conducted using the platform to simulate the working process of the rice and wheat harvester. The experimental indices included vehicle speed, cutting platform height, reel height and rotational speed, and auger rotational speed. These parameters were used to assess the accuracy and feasibility of the platform. The experiment was conducted in Junan County, Linyi City, Shandong Province, in a field of wheat to be harvested. The wheat had a grain height of approximately 450 mm, row spacing of about 300 mm, and a ground undulation of around 60 mm, with a uniform crop density across the field. The actual field measurements are shown in Figure 6. Based on the field conditions, the stubble height was set to 200 mm, and both the field experiment and semi-physical simulation platform experiment were carried out sequentially. According to the actual situation in the field, the stubble height was set to 200 mm, and the field experiment and semi-physical simulation platform experiment were carried out in turn.

Fig. 6 - Control strategy step response comparison curve

During field experiments, the harvester is set to harvesting mode, with the stubble height adjusted to 200 mm. The driving speed is increased to 12 km/h and maintained at a steady pace. As the terrain changes, the height of the cutting platform dynamically adjusts based on the detection values from the mimic device. The cutting platform's height is continuously recorded and using the mathematical relationship between the platform height and the angle sensor of the mimic device, the corresponding angle values are derived in response to terrain variations.

After harvesting a certain distance, the vehicle speed is reduced to 8 km/h. In harvesting mode, the rotational speeds of the reel and auger vary with the vehicle speed; therefore, the changes in rotational speed during acceleration and deceleration are recorded. The simulation platform parameters are configured based on the recorded angle values and vehicle speed from the field experiment. In the human-computer interaction interface, real-time monitoring is conducted to track the variations in cutting platform height in response to terrain changes, as well as the fluctuations in reel and auger rotational speeds corresponding to vehicle speed adjustments. The experimental results are presented in Table 2, Figure 7 and Figure 8.

As shown in Table 2, during the field test, the cutter height was recorded every 10 seconds from the actual vehicle and converted into the corresponding angular change as an input to the simulation platform. Throughout this process, the maximum absolute error in cutter height was 10.58 mm, which primarily resulted from conversion inaccuracies and voltage output errors from the platform. To evaluate the linear relationship between the actual cutter height and the simulated cutter height output from the platform, Pearson correlation analysis was conducted. The calculated Pearson correlation coefficient was 0.9474, indicating a strong correlation between the two. This result confirms that the simulation platform effectively replicates the cutter lifting and lowering process of the test vehicle.

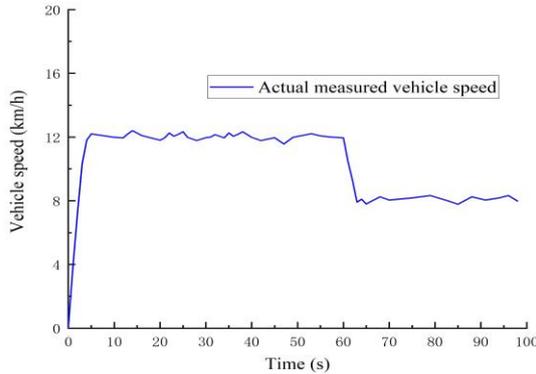

The experimental results show that the rotational speeds of the reel and auger vary with the vehicle speed. Directly adjusting their speeds through the platform alone cannot fully ensure consistency with field measurements. To accurately control a single variable, the vehicle speed curve is pre-sampled and used as an input to the control strategy. However, the output speed curve from the simulation platform is influenced by factors such as the simulation step length and refresh period. Therefore, the generated curve must be exported for comparison with the actual speed curve. Compared to the harvester, the mathematical expectation of the rotational speed error for the reel and auger is 0.106 rad/min and 0.101 rad/min, respectively, with standard deviations of 0.165 rad/min and 0.172 rad/min. These results indicate that the control strategy meets the actual harvesting requirements. Moreover, the simulation platform provides an accurate evaluation of the controller's functionality, making it a valuable reference for functional testing in the early stages of controller development.

CONCLUSIONS

(1) To enhance the output response characteristics of the cutter height regulation strategy, the cutter controller is optimized by combining the Whale Optimization Algorithm with PID control. The simulation results demonstrate that the optimized PID controller reduces the overshoot by 3.5% compared to the conventional PID controller and improves the rise time by 0.303 seconds. These improvements indicate that the optimized control strategy can effectively regulate the cutter height with both stability and rapidity.

(2) To effectively evaluate the controller's performance under real physical signals, hardware-in-the-loop (HIL) tests were conducted on a semi-physical simulation platform. Angle sensor variations caused by terrain undulations were used as input variables, while the output height values of the platform and the field-measured cutter height values served as comparison control experiments. The results showed that the maximum absolute error between the simulated and measured height variations was 10.58 mm. This indicates that the developed cutting platform model has a strong correlation with the actual cutting platform mechanism and can serve as a reliable basis for pre-testing the cutting platform controller.

(3) When testing control strategies for reel speed and auger speed, the speed values are influenced by the vehicle speed. First, the vehicle speeds, along with the corresponding reel and auger speeds, are recorded during the field experiment. These recorded speeds are then used as input variables for the semi-physical simulation platform, which outputs the corresponding reel and auger speeds. By comparing the deviation between the actual values and the output values of the platform under the same vehicle speed input, it is found that the mathematical expected error for the reel speed is 0.106 rad/min, and for the auger speed, it is 0.101 rad/min. The standard deviations are 0.165 rad/min and 0.172 rad/min, respectively. These results validate the reliability and feasibility of the simulation platform and provide a theoretical foundation for the development and testing of the cutting platform control system.

Keywords: head-feed combine harvester, threshing and separating unit, segmented-differential, physical design, test study

ABSTRACT

To address the issues of incomplete threshing, separation loss, and grain breakage during the harvesting of super hybrid rice with conventional threshing and separating units in head-feed combine harvesters, a segmented-differential threshing and separating unit was developed. This unit mainly consists of a coaxial segmented-differential threshing drum and a rotary concave screen. Its structure and working principle are described in detail. A three-factor quadratic regression orthogonal rotation combination test was conducted, with the rotational speed of the segmented-differential drum, the linear velocity of the rotary concave screen, and the clamping chain speed as test factors. The grain loss rate, breakage rate, and impurity rate were taken as performance indicators. The test results were analyzed using Design-Expert 8.0.6 software to establish a mathematical model for the performance indicators and to determine the optimal combination of working parameters. Additionally, a comparative test was carried out between the segmented-differential unit and a conventional single-speed unit. The results showed that when the rotational speed of the low-speed/high-speed drum in the segmented-differential unit was 520/630 r·min⁻¹, the linear velocity of the rotary concave screen was 1.20 m·s⁻¹, and the clamping chain speed was 1.10 m·s⁻¹, the grain loss rate, breakage rate, and impurity rate were 1.95%, 0.20%, and 0.56%, respectively.

摘要

为解决半喂入联合收割机脱粒分离装置在超级杂交稻收获过程中脱粒不全、分离损失和断粒率的矛盾，研制了半喂入联合收割机分段差动脱粒分离装置。该装置主要由同轴分段-差动脱粒滚筒和旋转凹筛组成。阐述了分段式差动脱粒分离装置的结构和工作原理。以分段差动滚筒转速、旋转凹筛线速度、夹紧链速度为试验因素，以籽粒损失率、破碎率、杂质率为性能指标，进行三因素二次回归正交旋转组合设计试验。本文利用 Design-Expert8.0.6 软件对试验结果进行分析，建立脱粒分离装置性能指标数学模型，确定最佳工作参数组合。此外，本文还对分段脱粒分离装置与常规单速脱粒分离装置进行了对比试验。结果表明：当分段装置低速/高速滚筒转速为 520/630 r·min⁻¹，转凹筛线速度为 1.20 m·s⁻¹，夹紧链速度为 1.10 m·s⁻¹ 时，籽粒损失率、破碎率和杂质率分别为 1.95%、0.20% 和 0.56%。

INTRODUCTION

Rice is one of the main crops in China, accounting for about 65% of all the grain consumption (Xin et al., 2018). In recent years, the planting area of super hybrid rice has been gradually expanded, and the yield has been continuously increased. Compared with conventional rice, the biological characteristics of super hybrid rice are significantly different, such as high yield per unit area, thick stems, large grain-grass ratio, and high moisture content of stems (Xu et al, 2019; Hao et al, 2018; Wei et al, 2018). These characteristics bring new problems to the conventional threshing and separating unit for a head-feed combine harvester (Gao et al, 2017).

To improve operational efficiency and reduce losses, combine harvester manufacturers at home and abroad mostly take action to increase power, increase the threshing drum length and so on. The power of Kubota PRO888 head-feed combine harvester is 66.1 kW, its threshing drum length is 1000 mm, and its maximum operating efficiency is 0.67 hm²/h. The parameters of other foreign and domestic machines are similar.

These measures have improved the operational efficiency but failed to solve the problem that the super hybrid rice is incompletely threshed and has large losses during harvest. The current threshing and separating unit for the head-feed combine harvester is mostly composed of a single-speed drum with a fixed concave plate. For super hybrid rice or when feeding thick rice stalks, a low threshing drum speed results in insufficient threshing capacity, leading to incomplete threshing, separation losses, and even potential blockages within the drum. If the drum's rotation speed is increased, it may lead to a higher grain breakage rate and more broken stems, causing the operation quality to fall short of national standards for the three key indicators: loss rate, breakage rate, and impurity rate. To reduce incomplete threshing losses in super hybrid rice, *Wang (2016)* and *Chen et al. (2011)* studied the application of differential threshing drums for head-feed combine harvesters. *Wang, Xie & Li, (2019)*, designed a threshing drum with an adjustable diameter, enabling threshing clearance adjustment by varying the drum's diameter. Also, as a part of the combine harvester, the grid concave plate has a significant influence on the performance of the threshing and separating unit. *Wang et al., (2017)*, studied the threshing and separating units (with concave plate) of different structures and established the motion model of threshed materials. *Ding, (1987)*, established a mathematical model for the separation rate and hole size of grid concave plate. *Li et al, (2018)*, developed an adjusting mechanism for concave plate clearance to adjust the threshing clearance through a hydraulic cylinder. *Liu et al., (2018)*, studied a threshing and separating unit equipped with a single-speed drum and rotary concave plate. Its operational efficiency and performance were significantly improved compared to the unit with a fixed concave plate. However, the studies were limited to units with either a single-speed drum and fixed concave plate, or a single-speed drum combined with a rotary concave plate.

To address the issues of incomplete threshing, separation loss, and high grain breakage during the harvest of super hybrid rice using conventional threshing and separating units in head-feed combine harvesters, a segmented-differential threshing and separating unit was developed. This unit consists of a segmented-differential threshing drum and a rotary grid concave plate. This paper details the structure and working principle of the new unit, evaluates its performance through a multi-factor optimization experiment, and investigates its overall efficiency. The goal is to enhance threshing effectiveness and reduce losses, thereby providing a theoretical foundation for the innovative design of key components in head-feed combine harvesters.

MATERIALS METHODS

Main structure and working principle

The segmented-differential threshing and separating unit for a head-feed combine harvester is mainly composed of low-speed threshing drum, drum linkage, high-speed threshing drum, threshing drum shaft. The threshing drum consist of a leading-in spiral, rotary grid concave plate, belt wheel for high-speed drum, belt wheel for low-speed drum, and the driving wheel for grid concave plate, etc., as shown in figure 1 (the fairing cap on threshing and separating unit is not shown). The power of the machine is transferred from a driving wheel to each mechanism through a belt. In the segmented-differential threshing drum, the high-speed threshing drum and the low-speed threshing drum share the same draft and diameter. The high-speed and low-speed threshing drums are connected with the drum linkage and driven respectively by the belt wheel for high-speed/low-speed drums. The rotary grid concave plate is installed in the arc-shaped concave screen frame. The concave plate grid strips are also in the arc-shaped concave screen frame. They are driven by the driving wheel for the grid concave plate to rotate. Meanwhile, this guarantees the threshing clearance between the high-speed/low-speed threshing drum and the rotary concave plate to be 20 mm (*Wang & Ge, 1982*).

When the head-feed combine harvester operates, cut rice plants are clamped by the feeding chain into the threshing area through the leading-in spiral. The rice plants are firstly threshed and separated by carding and impact effect in the low-speed threshing drum, then threshed and separated by the high-speed threshing drum. The threshed grains afterwards fall onto the vibrating screen surface through the rotary grid concave plate, and will be put into subsequent cleaning operation. During the threshing process, most grains with small connection force are threshed and separated in the low-speed drum, which reduces the grain breakage rate. A few grains with large connection force are threshed and separated in the high-speed drum, which increases threshed rate and separation rate and reduces the grain loss rate. The rotary grid concave plate rotates, and the linear velocity direction of the upper grid surface is the same as that of the threshing drum. The rotary grid surface can thresh the ears of rice plants got to the grid concave plate and prevent blockage in the threshing drum.

5. Leading-in spiral; 6. Threshing drum shaft

Threshing drum

The structure of the threshing drum is closed, mainly composed of a coaxial straight high/low-speed threshing drum, drum linkage, threshing arcuate teeth, low-speed drum shaft, high-speed drum shaft, leading-in spiral, grass cutter, etc., as shown in figure 2. The leading-in spiral and the low-speed threshing drum are firmly attached, and two spiral guiding blades are set to comb and push the rice ears (Wang, Lv & Chen, 2017). The high-speed and low-speed threshing drums are connected by a linkage, which rotates with the low-speed threshing drum. The low-speed drum shaft is a hollow shaft, which is driven by the low-speed belt wheel and drives the low-speed threshing drum simultaneously. The high-speed drum shaft is set in the low-speed drum shaft through a bear, which is driven by the high-speed belt wheel and drives the high-speed threshing drum simultaneously. The high-speed and low-speed belt wheels are set on the left side of the drum shaft and driven respectively by the belt wheel of the machine power-output shaft with different drive ratios. The threshing arcuate teeth are helically arranged on the drum surface with an equal pitch, featuring a 4-start thread, a helical angle of 50°, and a total of 15 rows of threshing arcuate teeth.

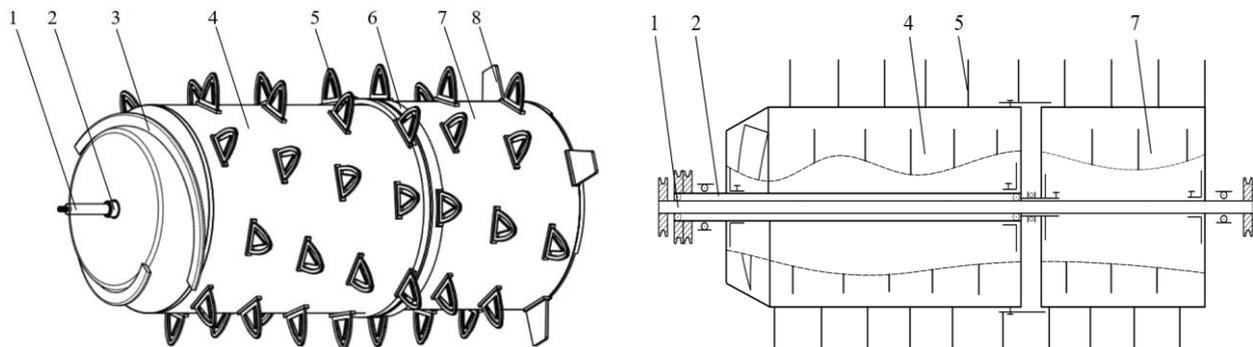

Fig. 2 - Threshing drum

1. High-speed drum shaft; 2. Low-speed drum shaft; 3. Leading-in spiral; 4. Low-speed threshing drum;
5. Threshing arcuate teeth; 6. Drum linkage; 7. High-speed threshing drum; 8. Grass cutter

The segmented-differential rotary threshing and separating unit for the head-feed combine harvester mainly utilize the carding and impact of threshing arcuate teeth on the ears of rice, so that the grains get the energy to fall off from the ears, thus achieving threshing and separation. Threshing drum length determines the threshing process. Generally, the longer the drum is, the longer the rice ears stay in the threshing chamber, and the longer the threshing arcuate teeth act on the rice ears, but it increases the threshing power consumption. According to the overall structure of the segmented-differential threshing and separating unit and the research results of the distribution law of threshed materials in the early stage (Peng et al, 2016), the total length of the threshing drum is determined to be 1000 mm, and the length of low-speed threshing drum (that is, the length of the grid concave plate in low-speed section) can be obtained from formula (1).

$$L = \frac{\varepsilon Q}{\eta \gamma R_1} \quad (1)$$

where: L – length of grid concave plate in the section of low-speed threshing drum (length of low-speed threshing drum), m; ε – ratio of the feeding rate undertaken by the low-speed threshing drum, taken as 0.85.

By substituting the relevant values into equation (1), L is 0.682 m, 2/3 (that is, 0.667 m) of the threshing drum length is taken as the low-speed threshing drum, and the remaining 1/3 is the high-speed threshing drum.

Rotary grid concave plate

The structure of the rotary grid concave plate is as shown in figure 3. Several grid strips are set in three groups of A12 type sleeve roller chain pin holes at two ends and the middle part to form a flexible screen surface consisting of grid strips. The two ends of the roller chain are connected to form a semicircular grid strip concave screen with a width of 800 mm. The width of each grid hole (that is, the spacing of grid strips) is 11 mm, and the length of grid holes is 50 mm. The inner core of the concave grid strip is a steel wire with a diameter of 5 mm, and fit together with steel tube with a diameter of 8 mm outside. The steel tube can rotate around the inner core. The screen surface can vibrate, making the threshed materials separate quickly and preventing blockage in the threshing drum. Concave plate grid strips use the upper and lower shaping platen as rotary track, using the threshing drum belt wheel to drive the grid concave plate driving wheel, and using a coaxial driving chain wheel with the driving wheel to drive the concave plate grid strip chain, so that the grid concave plate rotates around the driven chain wheel along the rotary track.

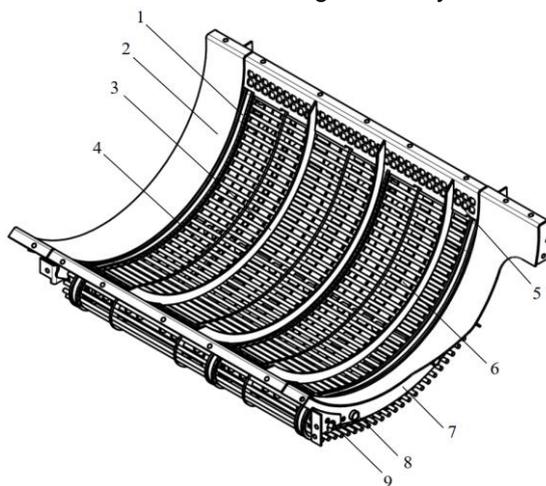

Fig. 3 - Rotary grid concave plate

5. Multi-hole side plate; 6. Lower shaping platen; 7. Grid strip; 8. Horizontal axis; 9. Driven shaft

The operation efficiency of the Segmented-differential rotary threshing and separating unit is related to the action area of the grid concave plate (the surrounding area of rotary grid concave plate) (Jin & Liu, 1980).

$$S = \frac{Q}{\eta} = E \cdot R_1 \cdot \gamma \quad (2)$$

where: S – surrounding area of rotary grid concave plate, m^2 ;
 η – productivity per unit area of grid concave plate, taken as $2.0 \text{ kg}/(m^2 \text{ s})$;
 Q – feeding quantity (i.e. working flow), taken as 1.5 kg/s ;
 E – width of head-feed grid concave plate, taken as 0.8 m ;
 R_1 – radius of rotary grid concave plate, taken as 0.295 m ;
 γ – wrap angle of rotary grid concave plate, rad.

By substituting the relevant values into equation (2), the surrounding area of the rotary grid concave plate is 0.75 m^2 , and the wrap angle is rounded to 180° .

TEST APPARATUS

Based on theoretical analysis and practical experience in the threshing and separating operations of head-feed combine harvesters, this study investigates how the working parameters of the segmented-differential threshing and separating unit, including the rotational speeds of the high-speed and low-speed threshing drums, the linear velocity of the rotary grid concave plate, and the clamping chain speed, affect the grain loss rate, breakage rate, and impurity rate. A segmented-differential threshing and separating test bench was designed for the head-feed combine harvester, and performance tests were conducted using a three-factor quadratic regression orthogonal rotation combination design.

Test bench

The segmented-differential threshing and separating test bench for the head-feed combine harvester includes: rice plants conveying platform, segmented-differential threshing and separating unit (high-speed/low-speed threshing drum, clamping chain, rotary grid concave plate, and cleaning vibrating screen), adjustable-speed motor and control box, etc., as shown in figure 4. The rice plant conveying platform consists of two conveyors connected in series, with adjustable height and a stepless variable conveying speed ranging from 0 to 2 m·s⁻¹. The power of the threshing drum adjustable-speed motor is 15kW, and the rotational speed of the high-speed/low-speed threshing drum is stepless speed changing. The power of the clamping chain driving motor is 7.5 kW, and the power of the rotary grid concave plate driving motor is 2 kW. The motor speed is adjusted by the frequency converter and the relevant data are recorded.

1. Low-speed threshing drum; 2. High-speed threshing drum

Test material

The selected test material is "Yongyou 15#", which is widely planted in Zhejiang province, China. The basic characteristic parameters of rice are as shown in table 1.

Table 1

Basic characteristic parameters of rice	
Items	Parameters
Height of plants / cm	95 ~ 110
Length of ears / cm	18.5 ~ 25.5
Moisture content of grains / %	23.2~24.6
Moisture content of stems / %	66.4
Grain-grass ratio (stubble height 15 cm)	2.56:1
Thousand kernel weight / g	28.9
Yield per unit area / kg / ha	9890

RESULTS AND ANALYSIS

Performance indicators

Before the test, the conveyor speed was set according to the set feeding rate (working flow) of 1.5 kg/s. In each group of tests, rice plants were evenly spread in the designated range of conveyor. The lengthwise direction of rice plants was perpendicular to the conveying direction, and the rice ears were toward the threshing drum. Based on "Thresher-Testing method" (GB/T 5982-2017), the test was carried on.

According to the feeding rate and grain-grass ratio, the total grain weight obtained in each test was calculated and denoted as W . The total weight of grains sampled at the grain receiving port was denoted as W_1 . The broken grains and impurities were picked by hand and weighed respectively, and denoted as W_p and W_z . In the discharges collected at the cleaning chamber outlet and straw outlet, the broken ears containing grains and the unthreshed grains were picked and weighed, which were denoted as the cleaning loss W_q and separation loss W_j . Thus, the loss rate y_1 , breakage rate y_2 and impurity rate y_3 can be calculated by the following formulas.

$$y_1 = \frac{W_q + W_j}{W} \times 100\% \quad (3)$$

$$y_2 = \frac{W_p}{W_1} \times 100\% \quad (4)$$

$$y_3 = \frac{W_z}{W_1} \times 100\% \quad (5)$$

Test scheme

To explore how the parameters such as the rotational speed of high-speed/low-speed threshing drum, the linear velocity of rotary grid concave plate and the clamping chain speed influence the threshing and separating performance, the parameter variation range was controlled properly according to the production practice and single-factor test, and the three-factor quadratic regression orthogonal rotation combination design test was performed. The levels of individual factors are shown in table 2.

Table 2

Levels of test factors			
Coded value	Rotational speed of low-speed / high-speed drum	Linear velocity of rotary concave plate	Clamping chain speed
	$x_1 / (\text{r} \cdot \text{min}^{-1})$	$x_2 / (\text{m} \cdot \text{s}^{-1})$	$x_3 / (\text{m} \cdot \text{s}^{-1})$
-1.682	480/590	0.40	0.60
- 1	500/610	0.72	0.80
0	530/640	1.20	1.10
1	560/670	1.68	1.40
1.682	580/690	2.00	1.60

According to 23 groups of quadratic regression orthogonal rotation combination design tests, the test scheme and results are shown in table 3. Where y_1 is the loss rate, y_2 is the breakage rate and y_3 is the impurity rate.

Table 3

Test scheme and results						
Test no.	Test factors			Test indicators

23	530/640	1.20	1.10	1.88	0.31	0.78

To apply the Expert8.0.6 software to the regression analysis of test data, the rotational speed of low-speed threshing drum x_1 , the linear velocity of rotary concave plate x_2 and clamping chain speed x_3 were selected as parameters, and the corresponding regression equation was obtained.

$$\begin{cases} y_1 = 70.31 - 0.28x_1 - 2.15x_2 + 9.24x_3 + 0.0003x_1^2 + 0.86x_2^2 + 1.63x_3^2 - 0.02x_1x_3 \\ y_2 = 41.54 - 0.16x_1 - 0.37x_2 + 0.82x_3 + 0.0002x_1^2 + 0.17x_2^2 + 1.64x_3^2 - 0.01x_1x_3 \\ y_3 = 60.23 - 0.21x_1 - 4.51x_2 - 3.93x_3 + 0.0002x_1^2 + 1.57x_2^2 + 0.009x_1x_2 \end{cases} \quad (6)$$

Test results and analysis

To intuitively analyze the relationship between individual parameters and the threshing and separating performance indicators, the Design-Expert8.0.6 software was used to obtain the response surface, as shown in figure 5.

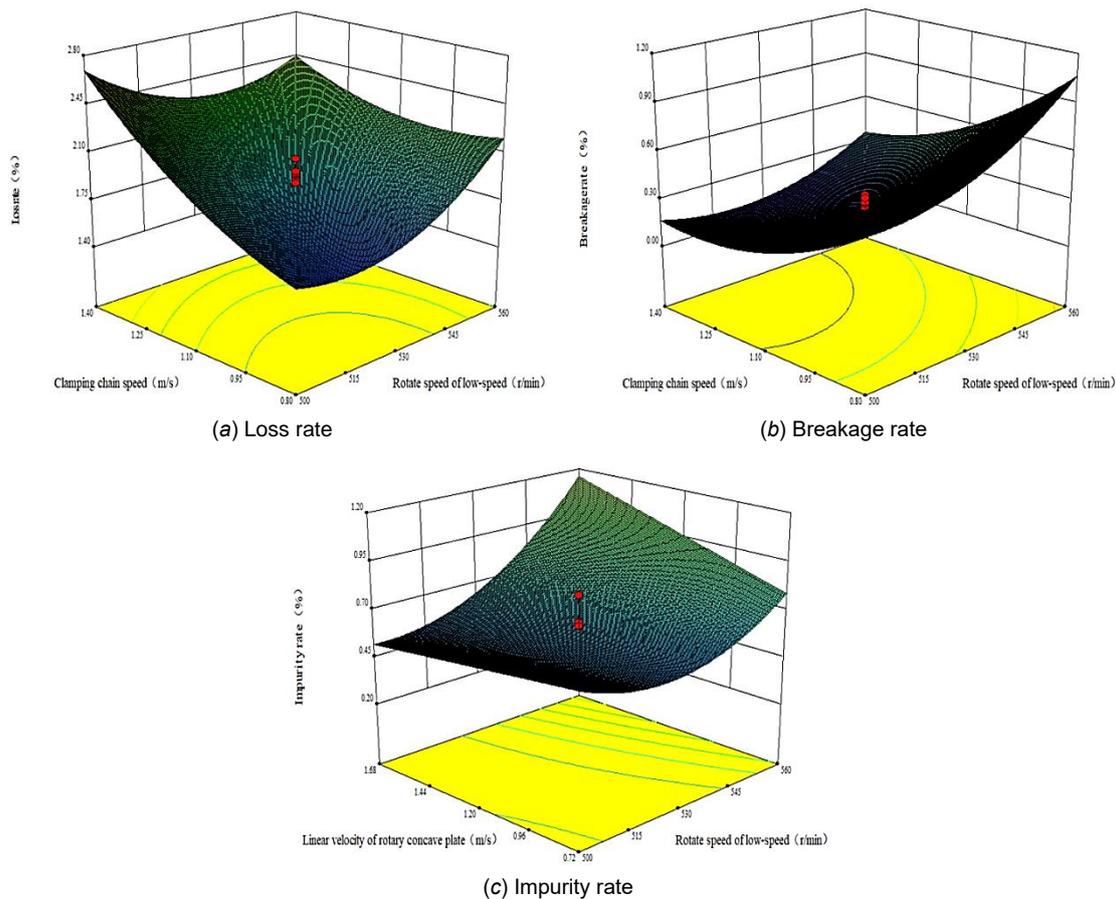

Fig. 5 - Response surfaces of individual factor's influence on performance indicators

According to the analysis of equation (6) and figure 5, it can be seen from figure 5(a) that in the interaction between the rotational speed of high-speed/low-speed threshing drum x_1 and clamping chain speed x_3 , the rotational speed of high-speed/low-speed threshing drum influences the loss rate more significantly. As the rotational speed of the high-speed/low-speed threshing drum increases, the clamping chain speed increases, and the loss rate of the threshing and separating unit increases gradually. It can be seen from figure 5(b) that in the interaction between the rotational speed of high-speed/low-speed threshing drum x_1 and clamping chain speed x_3 , both of them have a significant impact on the breakage rate of threshing and separating unit, indicating that when the clamping chain speed is low, the activation times of threshing drum on grains in rice ears increases, and the higher the rotational speed of the drum is, the higher the grain breakage rate is. It can be seen from figure 5(c) that in the interaction between the rotational speed of high-speed/low-speed threshing drum x_1 and the linear velocity of rotary concave plate x_2 , the rotational speed of high-speed/low-speed threshing drum has a significant impact on the impurity rate. As the rotational speed of the threshing drum increases, the broken stems and leaves in the threshing chamber increases, causing that the grain impurity rate gradually increases.

The grain loss rate, breakage rate and impurity rate are important indicators to evaluate the performance of the segmented-differential threshing and separating unit, and should be minimized under their individual constraint conditions. To obtain the optimal combination under the constraint conditions, the multi-objective variables optimization method is adopted to establish the nonlinear model by combining the boundary conditions of each factor, as follows:

$$\begin{cases} \min y_1 \\ \min y_2 \\ \min y_3 \\ \text{s. t. } (480/590)r/\text{min} \leq x_1 \leq (580/690)r/\text{min} \\ 0.4\text{ m/s} \leq x_2 \leq 2.0\text{ m/s} \\ 0.6\text{ m/s} \leq x_3 \leq 1.6\text{ m/s} \\ 0 \leq y_i(x_1, x_2, x_3) \leq 1 \end{cases} \quad (7)$$

Formula (7) was used to optimize multi-objective parameters based on the Optimization module of Design-Expert6.0.10 software. It was found that when the rotational speed of the high-speed/low-speed threshing drum was 518/626 r·min⁻¹, the linear velocity of rotary grid concave plate was 1.21 m·s⁻¹ and the clamping chain speed was 1.10 m·s⁻¹, the corresponding grain loss rate, breakage rate and impurity rate were 1.87%, 0.18% and 0.56%, respectively.

Discussion and analysis

To verify the performance of the segmented-differential threshing and separating unit and contrast it to the conventional single-speed threshing and separating unit, the boundary dimension and structure of the two units are basically the same, which are "two-speed drum (arcuate-tooth) + rotary concave plate" and "single-speed drum (arcuate-tooth) + fixed concave plate" respectively. The rice variety for the contrast test is YongyouNo.15, and the characteristic parameters are shown in table 1. The feeding rate of the two units is both 1.5 kg/s, which is artificial feeding. The rotational speed of the high-speed/low-speed threshing drum in the segmented-differential threshing and separating unit is set to 520/630 r·min⁻¹, and the rotational speed of the threshing drum in single-speed threshing and separating unit is set to 600 r·min⁻¹. After threshing, the threshed materials are collected and counted by a sampling tray. The sampling tray is divided into 6 grids along the axial direction of the threshing drum with each grid length of 167 mm, of which 4 grids are located under the low-speed threshing drum and 2 grids are located under the high-speed threshing drum.

Performance analysis of two kinds of threshing and separating units

In terms of the grain loss rate, breakage rate and impurity rate in the front 2/3 part of the threshing drum in the axial direction, the conventional single-speed threshing and separating unit was higher than the segmented-differential threshing and separating unit in the axial direction, indicating that the rotational speed of threshing drum had a significant influence on the three indicators of threshing and separating performance. In the back 1/3 part of the threshing drum in the axial direction, although the rotational speed of high-speed threshing drum is higher than that of single-speed threshing drum, the breakage rate and impurity rate of the conventional single-speed threshing and separating unit were still higher than those of the segmented-differential threshing and separating unit. The reason is that the broken grains produced in the forepart of the single-speed threshing and separating unit were mixed up with the stem layer to the posterior to separate. The impurities in the forepart of the conventional single-speed threshing and separating unit were not separated enough, which caused that the posterior impurity rate was higher than that of the segmented-differential threshing and separating unit. This also indicated that the posterior drum played an important role to threshing and separating.

Through determination, the contrast of performance indicators between the segmented-differential threshing and separating unit and the conventional single-speed threshing and separating unit is shown in table 4. It can be seen that the performance of the segmented-differential threshing and separating unit is significantly better than that of conventional single-speed threshing and separating unit.

Table 4

Comparison of grain breakage rate, impurity rate and loss rate

Threshing and separating unit	Breakage rate / %	Impurity rate / %	Loss rate / %
Single-speed drum + fixed concave plate	0.38	0.70	2.07
Two-speed drum + rotary concave plate (segmented-differential)	0.20	0.56	1.95

CONCLUSIONS

Taking the segmented-differential threshing and separating unit of a head-feed combine harvester as the research focus, a model describing the grain stress and movement within the unit was developed, and the structure and working principle of the unit were thoroughly analyzed. By effectively utilizing the dual-speed threshing drum and the rotary grid concave plate, the performance of the head-feed threshing mechanism and the operational efficiency of the head-feed combine harvester were significantly improved.

(1) With the rotational speed of high-speed/low-speed drum, the linear velocity of rotary grid concave screen, and the clamping chain speed as the test factors, the grain loss rate, breakage rate and impurity rate as the performance indicators, three-factor quadratic regression orthogonal rotation combination design method was used to establish the mathematical model between the factors and indicators. The results of the test were processed using the Design-Expert8.0.6 software and showed that the rotational speed of the high-speed/low-speed threshing drum was 518/626 r·min⁻¹, the linear velocity of rotary grid concave plate was 1.21 m·s⁻¹ and clamping chain speed was 1.10 m·s⁻¹. The grain loss rate, breakage rate and impurity rate were 1.87%, 0.18% and 0.56%, respectively.

(2) The loss rate is significantly affected by the rotational speed of the high-speed/low-speed threshing drum. The loss rate will increase gradually with the increase in the rotational speed of the high-speed/low-speed threshing drum. Both the rotational speed of the high-speed/low-speed threshing drum and clamping chain speed significantly affect the breakage rate. The grain breakage rate would increase when the clamping chain speed decreases or the rotational speed of the drum increases. The rotational speed of high-speed/low-speed threshing drum has a significant impact on the impurity rate. The grain impurity rate will gradually increase with the increase in the rotational speed of the threshing drum.

(3) The performances contrast test between the segmented-differential threshing and separating unit and the conventional single-speed threshing and separating unit showed that: the drum speed of the segmented-differential threshing and separating unit was 520/630 r·min⁻¹, the linear velocity of rotary grid concave plate was 1.20 m·s⁻¹ and clamping chain speed was 1.10 m·s⁻¹. The grain loss rate, breakage rate and impurity rate were 1.95%, 0.20% and 0.56%, respectively. The performance indicators were better than the regulations of the industry standard.

(4) This study was conducted using the Yongyou No.15 rice variety, with a moisture content ranging from 23.3% to 24.5%. Future research will evaluate the performance of the segmented-differential threshing and separating unit when processing other rice varieties. Additionally, the impact of higher throughput on the unit's threshing and separating performance will also be investigated.

Keywords: tobacco harvester, hydraulic drive, steering wheel control, chassis design

ABSTRACT

In order to solve the problems of inconvenient operation and easy loss of control levers in traditional tracked harvesters, this paper designs a hydraulic-driven chassis based on steering wheel control, and the structure and working principle of the chassis are described. The parameters such as track grounding length and drive wheel diameter are calculated; the design of the hydraulic drive system of the chassis is completed, and the driving control strategy is proposed. The test results show that the maximum speed of the chassis is 0.79 m/s, the minimum turning radius is 766 mm, and the failure rate tobacco rod clamping in field tests is only 4.37%. This design meets the needs of field operations, with high operability, stability, and ability, providing theoretical and practical basis for the development of tracked tobacco leaf harvesters.

摘要

为解决传统履带式收获机底盘操控不便、操纵杆易失位等问题, 本文设计了一种基于方向盘控制的液压驱动底盘, 并阐述了底盘结构、工作原理。对履带接地长度、驱动轮直径等参数进行了计算; 完成了底盘液压驱动系统的设计, 并提出了行驶控制策略。试验结果表明, 底盘最高速度为 0.79 m/s, 最小转弯半径为 766 mm, 田间试验烟杆夹持失效率仅为 4.37%。该设计满足田间作业需求, 具备较高操控性、稳定性和适应性, 为履带式烟叶收获机的发展提供了理论与实践依据。

INTRODUCTION

The tobacco industry occupies an important position in China's national economy (Liu et al., 2024), and the tobacco growing areas in China are mainly concentrated in 20 provinces and cities in the south (Tan et al., 2023). At present, the harvest of tobacco leaves mainly relies on manual labor, with high labor intensity, high cost and low operation efficiency, which restricts the rapid development of tobacco industry (Xue et al., 2024; Zhou et al., 2024). Therefore, the realization of mechanized tobacco harvesting is of great significance to the development of the industry.

Hydraulic crawler chassis is a key component of harvesting machinery (Wang B et al., 2024; Xi et al., 2024). Its outstanding advantages lie in strong traction and adaptability, low ground specific pressure, excellent obstacle crossing and load carrying capacity, and can work efficiently under complex conditions (Pan et al., 2024; Xiao et al., 2024; Du et al., 2023). By directly connecting the hydraulic pump and hydraulic motor, the hydraulic system eliminates transmission components such as transmission and differential, greatly improving transmission efficiency. Based on the growth characteristics of sweet sorghum, Wu L et al., (2018), designed a hydraulic driven harvester chassis, which uses dual pumps to drive the motor and can adjust the operation speed according to the density of plants. Wang P et al., (2022), designed 4CJZ-1000 self-propelled crawler tea picker. The crawler chassis controlled the power output of the gasoline engine through a pull-press joystick to realize movement and stopping. Xiao Wenying et al. (2023), designed a tractor hydraulic drive system and verified its applicability under large loads through field tests. Li et al., (2024), designed a fully hydraulic tracked power chassis, which uses a closed triple plunger pump to provide power for the driving and operating mechanism. Wang et al., (2023), designed a special chassis for the Chinese sugarcane harvester, and the hydraulic system realized the steering function by controlling the steering cylinder valve core.

At present, the variable pump displacement adjustment of most hydraulic systems is still achieved by turbine rack drive or joystick control valve, which has some problems such as inflexible control, out of position and unstable oil supply, which seriously affects the handling performance and safety of tracked vehicles.

Aiming at the above problems, a hydraulic driven tobacco leaf harvesting machine chassis is designed in this paper. The steering wheel control mechanism is used instead of the traditional joystick to realize the straight running and turning control of the chassis. Prototype production and performance verification were carried out to provide equipment support for tobacco leaf harvest in hilly and mountainous areas of South China.

MATERIALS AND METHODS

Structure of tobacco harvester

In order to meet the requirements for baking the upper leaf belt stalks after harvesting the lower leaves, the tobacco leaf harvester is primarily designed to perform two tasks: harvesting the upper leaves of the tobacco stalk and crushing the remaining stalk. The harvester consists of a chassis, control cabinet, soil excavation mechanism, clamping transmission mechanism, cutting mechanism, crushing and collection mechanism, guide collection mechanism, and collection box, as shown in Figure 1.

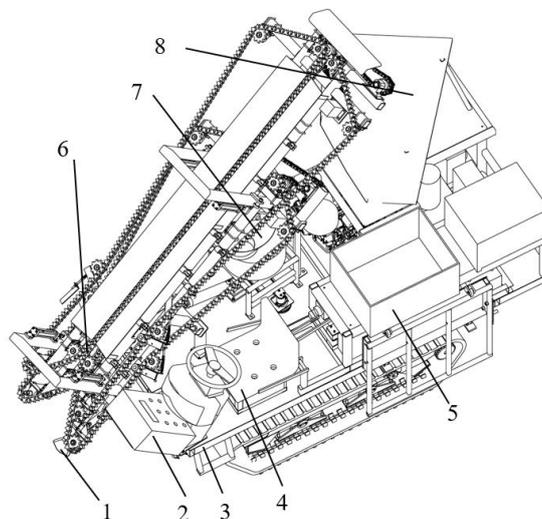

Fig. 1 - Schematic diagram of tobacco leaf harvester

1. Soil Loosening Mechanism; 2. Control Cabinet; 3. Rack; 4. Chassis; 5. Collection Box; 6. Clamping Conveying Mechanism; 7. Crushing Collection Mechanism; 8. Guiding Collection Mechanism

The tobacco harvester sequentially performs digging, conveying, cutting, crushing, and collecting of tobacco stalks. After starting the machine by pressing the control button on the control cabinet, the operator adjusts the position of the entire machine so that the tobacco stalks enter the feeding inlet of the clamping transmission mechanism. During operation, the stalks are excavated and pulled upward, moving backward and upward along the clamping chain. When the stalks reach the feed inlet of the crushing mechanism, the cutting mechanism separates the upper stalk (with leaves) from the lower root. The lower root falls into the crusher for crushing, while the upper stalk carrying the tobacco leaves continues to move backward and upward along the clamping chain. The staff on the platform assist in collecting the falling tobacco leaves and guide them into the collection box via the guide bend plate, completing the harvesting process.

Hydraulic drive chassis structure of tobacco leaf harvester

The hydraulic drive chassis structure of the tobacco leaf harvester is shown in Figure 2. The chassis is powered by a diesel engine, and the engine's output is distributed in two ways via a transfer box: one output is connected to a series variable piston pump to drive the tracked chassis for movement and steering; the other is connected to a gear pump to power the operational mechanisms. The output shaft of the travel hydraulic motor is directly coupled to the drive wheel, eliminating traditional transmission components such as the gearbox, clutch, and drive shaft. This design enables efficient power transmission and reduces energy loss. The vehicle body is also equipped with a complete power supply system, hydraulic oil tank, diesel tank, hydraulic seat valve, radiator, and a steering wheel control system.

Working principle of hydraulic drive chassis

The chassis of the tobacco harvester is hydraulically driven, powered by a diesel engine and a series variable piston pump. The series variable piston pump in this system is equipped with two valves and is connected to the stepper motors K1 and K2 by coupling. When operating the steering wheel, the Angle encoder monitors the steering Angle in real time and feeds the signal back to the STM32 microcontroller. According to the received Angle signal, the MCU controls the stepper motor to rotate at a predetermined Angle, thus adjusting the opening of the two valves of the plunger pump. The valve can be rotated to neutral, forward, or reverse positions. When the valve is in the neutral position, the hydraulic oil flows directly back to the tank. When the valve is shifted to the forward or reverse position, the direction of the hydraulic oil flow changes accordingly, thereby controlling the forward or reverse rotation of the hydraulic motor. The size of the valve opening determines the speed of the hydraulic motor, so as to achieve the forward, backward and steering of the tobacco harvester chassis. In addition, through the shift lever, the driver can switch between different gear positions to achieve high, medium and low speed conversion. The outline of the series variable piston pump is shown in Figure 3, and the overall technical parameters of the chassis are shown in Table 1.

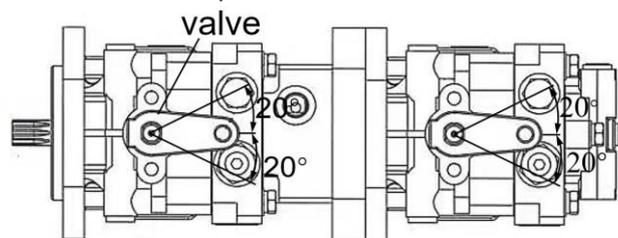

Fig. 3 - Outline of series variable piston pump

Table 1

Design parameters of hydraulic drive chassis of tobacco leaf harvester	
Parameters	Numerical value
Dimensions (Length x Width x Height) / mm	1500x3000x2500
Travel mode	Crawler type
Crawler width / mm	230
Crawler ground contact length / mm	1300
Full load weight / kg	2000
Engine power / kW	31
Steering method	Differential steering
Track gauge / mm	1200

Calculation of track parameter

Compared with the wheeled device, the crawler chassis shows better stability, obstacle crossing ability and smaller ground specific pressure when facing the undulating road surface and complex working environment. Therefore, the crawler type traveling device is selected and its key parameters are calculated.

The ratio of track grounding length L to track gauge B has an important effect on the driving performance of the chassis. When the L/B value is large, steering becomes more difficult; When the L/B value is small, the driving stability will be reduced (Wu et al., 2024; Chen et al., 2010).

The empirical formula for calculating the track grounding length is shown in equation (1):

$$L = (1.15 \sim 1.39) B \quad (1)$$

where L is the grounding length of the track, [mm]; B is the gauge, [mm].

The value range of the ratio of track width to ground length is shown in equation (2):

$$0.18 < \frac{b}{L} < 0.24 \quad (2)$$

where b is the width of the track, [mm].

The drive wheel diameter is calculated using the following formula:

$$D = \frac{t}{\sin(\pi/n)} \quad (3)$$

where D is the diameter of the drive wheel, [mm]; t is the track pitch, [mm]; n is the number of teeth on the drive wheel.

To ensure no rolling damage to the ridge body in tobacco fields, appropriately increasing the track width helps reduce ground pressure and enhances traction and adhesion performance (Ding et al., 2020; Li Qingjiang et al., 2024). Based on calculations and available market track specifications, the track grounding length was determined to be 1300 mm, the width 230 mm, and the pitch 72 mm. The diameter of the drive wheel is 270 mm.

Principle of hydraulic system

The chassis of the crawler tobacco harvester adopts a double pump (series variable piston pump) double motor drive scheme, and each hydraulic pump controls a hydraulic motor to drive a single track. In this way, the track can be independently driven on both sides, and the hydraulic oil circuits on both sides are independent of each other, effectively avoiding the interference and coupling phenomenon between the systems. Its single-side track hydraulic system is shown in Figure 4, and the engine drives a series variable plunger pump to provide pressure oil, converting the mechanical energy into the pressure energy of the hydraulic oil. The pressure oil rotates by driving the hydraulic motor, thus driving the movement of the track driving mechanism. The hydraulic system adopts volumetric speed regulation technology, which has high working efficiency and good load adaptability. The traveling hydraulic motor is a bidirectional variable motor, and the speed and rotation direction of the hydraulic motor can be controlled by adjusting the valve opening and direction of the plunger pump. The safety relief valve in the system plays a load protection role to ensure that the working pressure of the hydraulic system is always maintained within the safe range. Finally, the hydraulic oil flows through the loop back to the radiator for cooling and then back to the tank.

Selection of hydraulic motor

In the process of tobacco field operation, the chassis has the greatest resistance when running on the ramp, which mainly includes rolling resistance, slope resistance and acceleration resistance. In the tobacco leaf harvest operation, because the chassis is usually in a uniform motion state, the influence of acceleration resistance can be ignored. Therefore, the formula for calculating slope resistance is as follows:

$$F_a = Mgf \cos \alpha + Mg \sin \alpha \quad (4)$$

where F_a is the slope resistance, [N]; M is the mass of the whole machine, taken as 2000 kg; g is the acceleration of gravity, which is 9.8m/s^2 ; f is the operating resistance coefficient, which ranges from 0.08 to 0.12, and 0.12 is taken in this paper (Mei *et al.*, 2024). α is the climbing angle, which is 20° .

The torque of the traveling hydraulic motor is shown in equation (5):

$$T = \frac{F_a r}{k\eta_1} \quad (5)$$

where T is the required torque of a single traveling hydraulic motor, [N·m]; r is the radius of the drive wheel, which is 0.134m; k is the number of traveling hydraulic motors, 2; η_1 is the efficiency of the track travel device, which is 0.9.

The theoretical displacement of traveling hydraulic motor is shown in equation (6):

$$V_c = \frac{2\pi T}{P\eta_2} \quad (6)$$

where V_c is the displacement of the traveling hydraulic motor, [ml/r]; P is the maximum working pressure of the hydraulic system, taking 15 MPa; η_2 is the mechanical efficiency of the traveling hydraulic motor and is taken as 0.9 (Li *et al.*, 2024).

According to the driving speed of the chassis, the required speed of the hydraulic motor can be calculated, and the specific calculation formula is shown in equation (7):

$$n_c = \frac{1000v}{60 \times 2\pi r} \quad (7)$$

where n_c is the maximum speed of the traveling hydraulic motor, [r/min]; v is the maximum driving speed of the chassis, which is 3 km/h.

By substituting the relevant design parameters into equations (4)~(7), it is calculated that the maximum resistance of the whole machine is 8914 N, the torque of a single traveling hydraulic motor is 664 N·m, the theoretical displacement is 309 ml/r, and the required speed is 60 r/min. Since the output shaft of the traveling hydraulic motor is directly connected to the drive wheel, the hydraulic motor needs to bear radial, axial and impact loads from the drive wheel (Liu *et al.*, 2022), which puts higher requirements on the durability and torque capacity of the hydraulic motor. Therefore, after comprehensive evaluation, the BM5-400 hydraulic motor was finally selected. Its main technical parameters include: maximum displacement of 400 mL/r, output torque of 715 N·m, maximum output speed of 178 r/min, working pressure of 15 MPa, maximum input flow of 75 L/min.

Selection of hydraulic pump and engine

Hydraulic pump output flow is shown in equation (8):

$$Q_h = \frac{zKV_c n_c}{1000\eta_3} \quad (8)$$

where Q_h is the output flow rate of hydraulic pump, [L/min]; z is the number of hydraulic motors, taken as 2; K is the leakage coefficient of the hydraulic pump, taken as 1.1; η_3 is the volumetric efficiency of the traveling hydraulic motor, which is 0.9.

Hydraulic pump theoretical displacement is shown in equation (9):

$$V_h = \frac{1000Q_h}{n_h\eta_4} \quad (9)$$

where V_h is the theoretical displacement of hydraulic pump, ml/r; n_h is the speed of hydraulic pump, taken as 3000 r/min; η_4 is the volumetric efficiency of the hydraulic pump, which is 0.9.

By substituting the relevant parameters into equations (8) and (9), it is calculated that the output flow rate of the hydraulic pump is 46 L/min, and the theoretical displacement is 17 mL/r. According to the requirements of the system, two plunger pumps are installed in series, so the HAZE-21 series variable plunger pump is selected as the traveling hydraulic pump. The main technical parameters of the hydraulic pump include: maximum displacement of 21 mL/r, rated pressure of 17 MPa, rated speed of 3600 r/min. Each plunger pump will provide the required hydraulic energy for a traveling hydraulic motor.

According to the maximum flow required by the hydraulic system of the whole machine in the working process, the engine selection is further carried out. The calculation formula of engine power is as follows:

$$P_j = \frac{QP_h}{60\eta_s} \quad (10)$$

where P_j is the engine power, [KW]; Q is the required flow rate of the hydraulic system of the whole machine, [L/min]; P_h is the working pressure of the hydraulic pump, taken as 15 MPa; η_s is the engine mechanical efficiency, which is 0.9.

The total flow required by the machine's hydraulic system is the sum of the flow demands of both the driving mechanism and the working mechanism. Based on calculations, the hydraulic system requires a flow rate of 100 L/min under maximum working conditions. According to Equation (10), the required engine power P_j is 28 kW. Taking into account engine size and output performance, the 4L22B diesel engine from Shandong Huayuan Laidong Internal Combustion Engine Co., Ltd. was selected. This engine provides a good performance match, with a rated power of 31 kW and a rated speed of 3300 r/min.

Control structure

The steering wheel operation mechanism is illustrated in Figure 5. When the steering wheel rotates, it drives the pinion via the steering shaft, with the pinion and large gear engaging through meshing teeth. A limiting gear mounted on the large gear restricts the pinion's rotation to one and a half turns in both directions, thereby limiting the steering wheel's total rotation range to ± 540 degrees from the central position. As the steering wheel turns, the steering shaft and the angle encoder rotate synchronously, with the encoder capturing and transmitting the rotation angle data to the controller. The controller then calculates the required pulse count based on this angle data and adjusts the operation of stepper motors K1 and K2 accordingly. These stepper motors control the first and second flow control valves of the series variable piston pump, regulating the speed of hydraulic motors K1 and K2. The speed differential between the two motors enables the tracked vehicle to steer. The structure of the flow control valve mechanism is shown in Figure 6.

Control System Integration

The steering wheel control system comprises a steering wheel, shift lever, stepper motors, and an angle encoder, as illustrated in Figure 7. The shift lever, adapted from an automotive automatic gear selector, includes five gear positions: forward fast (D3), forward medium (D2), forward slow (D1), park (P), and reverse (R). It is connected to the controller via five DuPont wires, transmitting five signals that enable the controller to synchronize the rotation angles of the two stepper motors. The angle encoder records the steering wheel’s rotation angle and updates the rotation of the stepper motors accordingly. The system’s controller is based on the STM32F103 core board, with the angle encoder connected through RS485 serial communication. A RS485-to-TTL chip is used to convert signals for compatibility. The controller’s GPIO pins are linked to the motor driver board, which receives PWM pulse signals to control the stepper motors’ movement. By adjusting the gear position and rotating the steering wheel, the chassis of the tobacco harvester can perform both linear and steering movements.

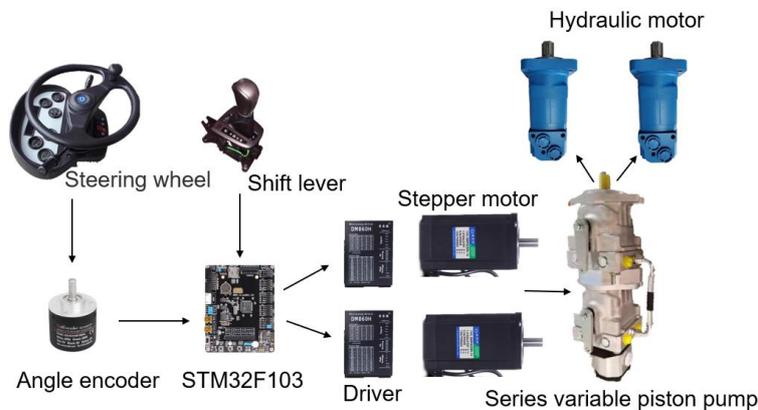

Fig. 7 - Schematic diagram of steering wheel system

Driving control strategy

(1) The controller determines the gear control signal of the straight-line operating mechanism:

The maximum rotation angle of the positive and negative direction of the flow control valve of the series variable piston pump is θ degree, and the number of pulses required by the rotation shaft of the motor to rotate 360 degrees is N , and the calculation formula is as follows:

$$N = \frac{360\partial}{\theta} \tag{11}$$

where θ is the step angle, measured in degrees; ∂ is a subdivision multiple and has no dimension.

The shift lever is equipped with n gears, each corresponding to a rotation angle α_n of the flow control valve (where $n = 1, 2, 3, \dots$, and $\alpha_n \leq \theta$). Each gear position is associated with an external interrupt in the controller, and each external interrupt triggers a specific interrupt function. The number of pulses generated by the interrupt function is calculated using the formula: $\alpha_n * N / 360$.

According to the selected gear position, the controller simultaneously sends the corresponding number of pulses to both the first and second stepper motors. These two motors respectively control the first volume control valve and the second flow control valve to rotate to a predetermined angle. At this point, both hydraulic motors rotate in the same direction and at the same speed, thereby enabling the chassis to move in a straight line.

(2) After determining the gear position in step (1), the controller evaluates the steering signal from the steering wheel control mechanism:

Set the maximum steering wheel rotation angle in both clockwise and counterclockwise directions from the center (neutral) position to the limit stop as β . Let the angle γ be the current rotation angle of the steering wheel from the center position, as detected by the angle encoder, where $\gamma \leq \beta$. For a given gear, the rotation angle of the flow control valve is α_n , corresponding to the steering wheel's rotation angle γ . Thus, for each 1° of steering wheel rotation from the center, the flow control valve must rotate by $\beta_n = 2\alpha_n/\beta$.

When the steering wheel is turned clockwise by γ degrees, the stepper motor K1 remains stationary, and the controller commands the stepper motor K2 to rotate in the opposite direction by $|\gamma\beta_n|$ degrees. When the steering wheel is returned to its neutral position by γ degrees, the stepper motor K1 remains stationary, and the controller commands the stepper motor K2 to return to its original position by $|\gamma\beta_n|$ degrees;

When the steering wheel is turned counterclockwise by γ degrees, the stepper motor K2 remains stationary, and the controller commands the stepper motor K1 to rotate in the opposite direction by $|\gamma\beta_n|$ degrees. When the steering wheel is returned to its neutral position by γ degrees, the stepper motor K1 remains stationary, and the controller commands the stepper motor K2 to return to its original position by $|\gamma\beta_n|$ degrees.

By controlling the stepper motors K1 and K2, a speed difference is generated between the hydraulic motors K1 and K2, thereby controlling the steering of the track vehicle.

Analysis of steering performance

During operation, the steering system of the track chassis achieves directional control through differential movement. In the steering process, the tobacco harvester turns with a specific turning radius toward the side with the lower track speed. The diagram of differential steering is illustrated in Figure 8.

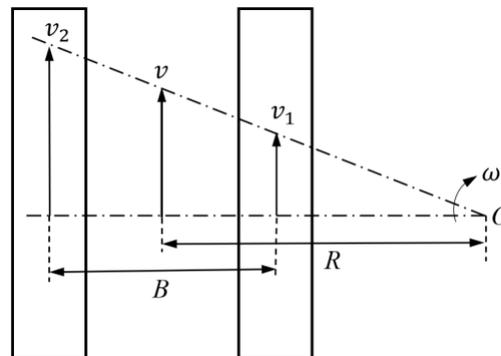

Fig. 8 - Diagram of differential right turn

Under ideal conditions, assuming that track slip and skid are negligible, the turning radius can be calculated using the following formula:

$$R = \frac{B(v_1 + v_2)}{2(v_2 - v_1)} \quad (12)$$

where R is the turning radius, [mm]; v_1 is the linear speed of the right track, [m/s]; v_2 is the linear speed of the left track, [m/s].

When the linear speeds of the right and left tracks are the same and in opposite directions, the tobacco harvester will achieve in-place turning of the chassis.

Test methods

The average plant spacing in the test field was approximately 400 cm, with row spacing ranging from 105 cm to 115 cm, and plant height ranging from 80 cm to 120 cm. The machine operated in slow gear mode, and three tobacco ridges were selected for harvesting, with each ridge having about 60 tobacco stalks. During the trial, the operation of the entire machine was observed, and the failure rate of tobacco stalk clamping for each ridge was calculated.

The calculation formula is as follows:

$$C = \frac{A_1}{A_2} \times 100\% \tag{13}$$

where C is the rate of tobacco rod clamping failure, [%]; A_1 is the number of tobacco rods not harvested in a single ridge; A_2 is the total number of tobacco rods in a single ridge.

RESULTS

Whole Machine Performance Test

The processing and trial production of the tobacco harvester chassis were completed at Guilin Maike Machinery Co., Ltd., and the upper working parts were successfully mounted. In order to comprehensively evaluate the performance and agronomic adaptability of the whole machine, performance tests were carried out in various aspects, mainly including driving speed test, steering performance test, and field harvesting effect test. The test instruments and equipment include tape measure, stopwatch, etc.

Driving Speed

The tobacco harvester is equipped with three forward speed gears, which are slow gear, medium gear, and fast gear, corresponding to the flow control valve rotation angles of 6 degrees, 12 degrees, and 20 degrees, respectively. The driving speed test was conducted according to the standard GB/T 10394.3-2002 “Feed Harvesters Part 3: Test Methods”, as shown in Figure 9(a). The test selected a flat field road with a length of more than 50 meters. The driver, by operating the gear shift lever, used a stopwatch to measure the time required for the machine to travel 50 meters at the highest speed in a straight line at different gears. Each gear measurement was repeated 3 times and the average was taken, and then the highest driving speed at different gears was calculated. The test results are shown in Table 2.

(a) Driving speed

(b) Turning radius

Fig. 9 - Steering turning test

Table 2

Test results for driving speed

Gear	Times	Time/s	Average time/s	Driving speed / (m·s ⁻¹)
Slow gear	1	200.69	198.79	0.25
	2	197.23		
	3	198.46		
Medium gear	1	105.16	105.44	0.47
	2	103.83		
	3	107.33		
Fast gear	1	62.36	63.37	0.79
	2	64.28		
	3	63.47		

As can be seen from Table 2, the driving speeds of the tobacco harvester at different gear settings are 0.25 m/s, 0.47 m/s, and 0.79 m/s, respectively, with the maximum driving speed being close to the predetermined target speed (3 km/h).

The machine is capable of driving at medium to high speeds in the field or on the road. Due to the power loss of the entire machine and the slippage of the track chassis on the field road surface (Wu *et al.*, 2024), the actual driving speed is slightly lower than the target speed.

Steering Test

The turning performance of the chassis is characterized by the turning radius. During the steering process, the maximum circular radius drawn by the track on the ground is the turning radius. When the steering wheel is fully turned to the left or right, the rotation angles of the two flow control valves of the series piston pump are the same but opposite in direction, causing the tracks to move at the same speed but in opposite directions, thus achieving the pivot turn of the tobacco harvester chassis. According to the standard GB/T 3871.5-2006 "Steering Circle and Passing Circle Diameter", the turning radius test was conducted on an open area of the processing plant. During the test, the machine was driven in slow gear, then the steering wheel was turned fully to the left or right, the machine rotated 360 degrees and the steering wheel was returned to the center, and then driven out of the test area. The diameters at the 0, 120, and 240-degree positions of the turning circle were measured, and the mean value and minimum turning radius were calculated. The test process is shown in Figure 9 (b), and the test results are shown in Table 3.

Table 3

Test results for minimum turning radius

Steering direction	Measurement location	Diameter/mm	Mean Diameter/mm	Turning radius/mm
Left turn	0°	1593	1552	776
	120°	1566		
	240°	1496		
Right turn	0°	1483	1532	766
	120°	1536		
	240°	1576		

As can be seen from Table 3, the minimum turning radius of the whole machine is 766 mm, which meets the design requirements for tobacco leaf operation and transfer. Compared with the track gauge, the measured value is slightly larger, mainly due to the overall weight of the machine and the presence of certain track slip and skid during turning.

Field experiment

To further verify the agronomic compatibility of the chassis, field harvesting trials were conducted at a tobacco planting base in Chenzhou, Hunan Province, as shown in Figure 10.

Fig. 10 - Field harvesting experiment

The experimental results indicate that the tobacco harvester operates smoothly with sufficient power. The failure rates for tobacco stalk clamping on three rows of tobacco were 4.91%, 3.38%, and 4.83% respectively, with a low overall clamping failure rate. The chassis has good agronomic compatibility and can complete the tobacco harvesting task relatively smoothly.

For the cases of tobacco stalk clamping failure, the analysis suggests that the cause may be related to the tobacco stalks being deeply rooted in the soil, which leads to the chisel-shaped spade of the soil loosening mechanism failing to effectively lift the stalks out of the soil. This affects the normal conveyance of the clamping chain, resulting in clamping failure. To further improve the success rate of clamping, subsequent optimizations to the design of the soil loosening mechanism will be made, enhancing the penetration power and soil adaptability of the spade head to ensure effective digging and clamping of tobacco stalks under various soil conditions. This will improve overall operational efficiency and the quality of tobacco leaf harvesting.

CONCLUSIONS

(1) To address the issues of difficult control and easy dislocation of control levers when tracked vehicles turn while traveling, this paper designs a tobacco harvester hydraulic drive chassis based on steering wheel control. This design can solve the problems of insufficient accuracy and complex operation inherent in traditional control methods. Through the design of the chassis structure and the selection of key components, and the performance test of the prototype, its applicability in tobacco harvesting has been verified.

(2) The chassis adopts a hydraulic drive system, with a power of 31 kW and a tracked drive mode. A steering strategy for straight steering control with the steering wheel is proposed, by adjusting the opening of the flow control valve of the series variable plunger pump, thus achieving control over the speed of the left and right tracks.

(3) The test results show that the tobacco harvester chassis can achieve three-speed gear shifting in actual work, with the highest travel speeds of 0.25 m/s, 0.47 m/s, and 0.79 m/s respectively, meeting different travel speed requirements; the minimum turning radius is 766 mm; field harvesting test results show that the machine runs smoothly during operation, the power system is sufficient, and can effectively cope with complex terrain and irregular crop planting environments. The average tobacco rod clamping failure rate is 4.37%, with a low overall clamping failure rate, meeting the requirements of field operations.

Keywords: head-forming vegetables, root-cutting device, virtual simulation, experiment

ABSTRACT

In response to the current low level of mechanized harvesting for heading vegetables in China and the unsatisfactory harvesting results, this study focuses on the root-cutting operation during the harvesting process. A double-disk root-cutting device was designed to achieve low-power consumption and high-efficiency root cutting. Through LS-DYNA simulation experiments, the root-cutting process of the root-cutting device was simulated, and the cutting force and internal cutting energy of three different cutter combinations are compared. The simulation results show that the maximum cutting force of the double-serrated blade was the smallest, while the combination of a smooth blade and a serrated blade had the lowest internal cutting energy. Compared to smooth blades, serrated blades exhibited better clamping effects on the roots of head-forming vegetables. Considering both cutting force and internal cutting energy, the combination of a serrated blade and a smooth blade was found to be optimal. The quadratic rotary orthogonal combination test method was used to analyze the relationship between the main influencing factors of the root cutting device performance (rotational speed of the cutter, conveying speed, inclination angle of the cutter, and overlapping amount of the cutter) and the performance index (root cutting power) of the root cutting device. The bench test program was designed by applying regression analysis, response surface and multi-objective variable optimization methods. The bench test results show that the optimal parameter combination of the designed root cutting device were: cutter speed of 200 rpm, conveying speed of 0.3 m/s, cutter inclination angle of 10°, and cutter overlap of 20 mm. The predicted cutting power of the model was 51.19 W.

摘要

针对现阶段我国结球类蔬菜机械化收获水平低下，收获效果不理想等问题。本文重点研究结球类蔬菜收获过程中的切根作业，设计一种双圆盘切根装置，可实现低功耗、高效率切根。过 LS-DYNA 仿真实验，模拟了切根装置的切根工作过程并比较了三种切刀组合的切根力和切根内能，仿真实验结果双锯齿刀的最大切根力最小，光刀与锯齿刀的组合切根内能最小。光刀与锯齿刀相比，锯齿刀对结球类蔬菜根的钳持效果更好，综合切根力和切根内能，选择锯齿刀加光刀的组合更优。采用二次旋转正交组合试验方法，分析切根装置性能的主要影响因素（切刀转速、输送速度、切刀倾角、切刀重叠量）与性能指标（切根功率）的关系，应用回归分析、响应曲面和多目标变量优化方法设计了台架试验方案。台架试验结果表明，所设计切根装置的最优参数组合为：切刀转速 200r/min，输送速度 0.3m/s，切刀倾角 10°，切刀重叠量 20mm；模型预测的切根功率为 51.19W。

INTRODUCTION

Heading vegetables is one of the important vegetables consumed by the Chinese residents, which is important for ensuring the balanced supply of vegetable market, balancing the price of vegetables and ensuring the income of farmers (Sheng et al., 2021; Yan et al., 2024). The relevant agronomic data show that in the whole process of heading vegetable production, the harvesting operations accounted for more than 40% of the entire heading vegetable production operations (Li, 2020). At present, China's heading vegetable mechanized harvesting level is low, still completely rely on manual completion, harvesting process farmers need to constantly bend down and cut vegetables from the roots. Then remove the package and picking up the vegetable bulb. Finally load, with trucks. Thus, harvesting operations is a long time, labor-intensive process (Li et al., 2023; Wen et al., 2024).

Heading vegetables mechanized harvesting can reduce the labor intensity for vegetable farmers, eliminating the constantly bending over to cut and pick up of the manual processes. With the promotion of China's urbanization process and the rural labor force to the city to transfer, it is imperative to improve the level of mechanized harvesting for heading vegetables (Wang *et al.*, 2018; Zhou, 2013; Wang *et al.*, 2014).

Heading vegetables belong to a class of vegetables harvested without root, the quality of its cut root (whether the cut is flat, whether the cut is biased, whether there is damage, etc.) has a great impact on its subsequent storage. Therefore, many experts and scholars have conducted a lot of research on disk cutting device, most of them focus on the mechanical properties of crops, crop cutting mechanism, slip cutting theory, cutting device structure and other aspects of the study. (Jang *et al.*, 2021; Jing *et al.*, 2021).

El *et al.*, (2020), developed and tested a cabbage root cutting device and investigated the effects of cutter shape, cutter speed and cutter angle on the performance of the harvester. Xu *et al.*, (2009), investigated the shear characteristics of cabbage roots and stems using different conditions such as cutting speed, blade curve, blade thickness and blade smoothness. The effect of cutting speed, blade shape and blade smoothness on the shear force was tested. Li *et al.*, (2020), designed an adjustable root-cutting device, and obtained the influence law of individual factors on root-cutting reaction force through one-factor test and orthogonal test; then they conducted second-order orthogonal rotary combination multifactorial test to study the influence of cutter speed, cutting position, walking speed, cutter overlap and pitch angle on the maximum root-cutting reaction force, and at the same time, they used the response surface method for the optimization of the parameters to obtain the best parameter combination. Du *et al.*, (2017), carried out the cutting part test, cutting force orthogonal test, cutting and splitting breakage test and stem using the universal material testing machine. The test results showed that both the maximum cutting force and the average cutting force were linearly related to the crude fiber content, and the interval of 30-35 mm in diameter of kale rhizome was the optimal root cutting area.

Based on the above research, this paper designs a root cutting device for heading vegetables, applies LS-DYNA software to simulate and analyze the root cutting characteristics of different blade combinations, confirms the blade combinations according to the results, and optimizes the structure and working parameters of the root cutting device.

MATERIALS AND METHODS

Design of key components

Root cutting mechanism is an important part of the root cutting operation of heading vegetables. While operating, the root cutting mechanism needs to clamp and excise the roots of heading vegetables. Its performance will directly affect the results of the root cutting operation. Root cutting mechanism diagram is shown in Figure 1 and it mainly consists of: cutter, 4; cutter plate, 5; bracket, 1; cutter shaft, 6; universal joint coupling, 2; T-type commutator, 7; hexagonal shaft, 8 and hydraulic motor and other components, 3.

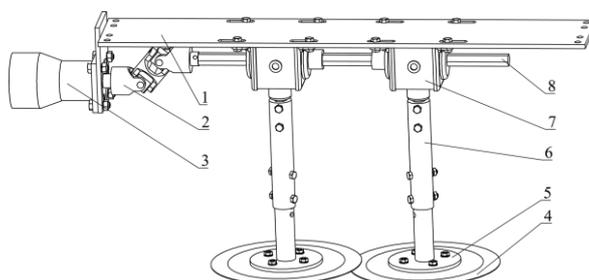

Fig. 1 – Structure diagram of heading vegetables root cutting mechanism

The design of the root cutting mechanism in this paper mainly focuses on the selection of the cutter and the design of the main parameters of the two cutters. There are generally two types of cutting mechanisms used for crop harvesting: the reciprocating type and the disk type. The reciprocating type is typically employed for harvesting crops with relatively fine stems, such as rice and wheat, while the disk type is commonly used for harvesting crops with thicker stems, such as sugarcane and cabbage. Since the roots of heading vegetables are relatively thicker, the type of cutter designed in this paper utilizes the disk type cutter.

According to the number of cutters used in the cutting process is divided into single disk cutting mechanism and double disk cutting mechanism.

Among them, the single disk cutting mechanism cutter needs a larger diameter, the rotational speed set is also relatively high. This situation can unbalance the force of the root cutting process; while the diameter of the double disk knife does not need to be too large, the rotational speed does not need to be too high, you can reduce the energy consumption in the work process, eliminate the force imbalance during root cutting. Therefore, the cutting mechanism designed in this paper selects double disk cutter. In order to ensure the integrity of the cut root, there is a certain overlap area between the double disk cutter. Common disk cutter shape mainly has a smooth edge type, serrated type and extra-blade type three types, as shown in Figure 2 (Li, 2018; Liu et al., 2021).

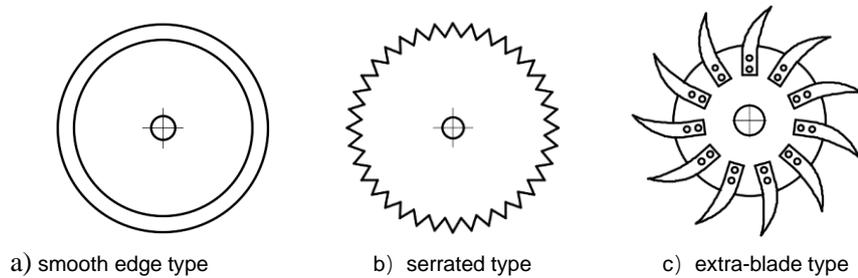

Fig. 2 – Different style cutters

Under the same working conditions, the cutting effect and power consumption of the disk cutter with different edges and structures are different. The smooth-edge cutter has the lowest power consumption and small force, while the extra-blade-type disk cutter is subject to the largest force and the highest cutting power consumption. Du Dongdong found that it was difficult to clamp cabbage roots for stable cutting by a separate smooth-edged disk cutter through mechanical analysis, therefore, this paper chooses the combination of smooth-edged and serrated cutter for root cutting (Du et al., 2011; Du et al., 2015; Du et al., 2017).

The root cutting device designed in this paper has overlapping upper- and lower-disk knives, and during the root cutting process, the double disk knives will clamp and cut off the heading vegetable roots. As the clamping force and shear force are in the rotating plane of the disk knives, only the force on the heading vegetable roots in the rotating plane of the disk knives is analyzed. The force on the heading vegetable roots is shown in the schematic diagram in Fig. 3:

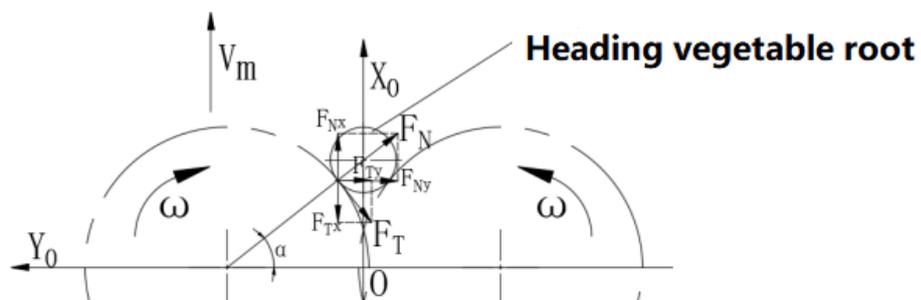

Fig. 3 – Stress analysis of heading vegetable root during root cutting process

The force analysis leads to the equation (1):

$$\begin{cases} F_C = F_{Ty} + F_{Ny} = F_T \sin \alpha + F_N \cos \alpha \\ F_S = F_{Tx} + F_{Nx} = F_T \cos \alpha - F_N \sin \alpha \\ F_T = f F_N \end{cases} \quad (1)$$

F_C - clamping force, N;

F_S - shear force, N;

F_N - normal reaction force of the disk cutter acting on the heading vegetable root, N;

α - angle between F_N and Y_0 axis direction, (°);

F_T - friction force of the disk cutter on the heading vegetable root, N;

f - friction coefficient between the disk cutter and the heading vegetable root, generally take 0.4~0.7.

From the force analysis, it can be seen that the disk cutter can clamp the heading vegetable root under the condition that: $F_T \cos \alpha > F_N \sin \alpha$, therefore, at $f > \tan \alpha$, the disk cutter can clamp the heading vegetable root.

$$\alpha = \sin^{-1} \frac{A_1/2}{(D+d)/2} = \arccos \frac{A_1}{D+d} \quad (2)$$

A_1 - center distance between two disk cutters, mm;

D - diameter of the disk cutter, mm;

d - diameter of cabbage root cutting place, generally take 25~35 mm.

When A_1 increases or D decreases, α decreases, which is beneficial for the two disk blades to clamp the root of heading vegetables for cutting. However, due to structural constraints such as the center distance A_1 between the two disk blades and the disk cutter diameter D , the angle α is typically limited to a range of 35° to 40°. Additionally, the friction coefficient f between the root of heading vegetables and the blade edge generally ranges from 0.4 to 0.7. As a result, it is difficult for two smooth-edged disk blades to effectively clamp the root of heading vegetables for cutting. In this paper, the ability of the cutter to clamp the root is improved by using a combination of a smooth-edged disk cutter and a serrated disk cutter.

According to the analysis results, in the case of the root cutting mechanism, conveying mechanism and frame do not interfere with each other, while meeting the requirements of the two pieces of the cutter have a partial overlap, the diameter of the outer end of the cutter is set to 270 mm, the diameter of the inner hole in the middle is set to 25 mm, and the design of the cutter parameters is shown in Figure 4.

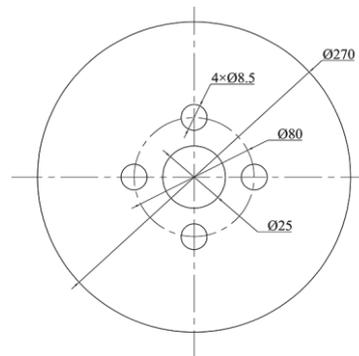

Fig. 4 – Design diagram of cutting tool structure

MATERIALS AND METHODS

Simulation experiment

In order to study the effect of different knife combinations on the maximum root cutting force and internal energy of root cutting, three knife combinations of double smooth-edged knife, double serrated knife and smooth-edged knife + serrated knife were simulated and analyzed using LS-DYNA software, and the root cutting characteristics of different knife combinations were analyzed according to the simulation results.

SolidWorks was used to establish three kinds of root cutting model, and then the model mesh was imported to Workbench/LS-DYNA in order to reduce the amount of calculation. In this study, the disk cutter will be defined as a rigid body. The mesh at the contact area between the roots of heading vegetables and the disk cutter in the root cutting process was finely divided, and the mesh size could be coarsened in other positions. The meshed root-cutting model is shown in Figure 10, and the number of nodes of the knotty vegetable root and disk cutter meshes are 42036 and 12960, the number of cells are 39510 and 6199, respectively.

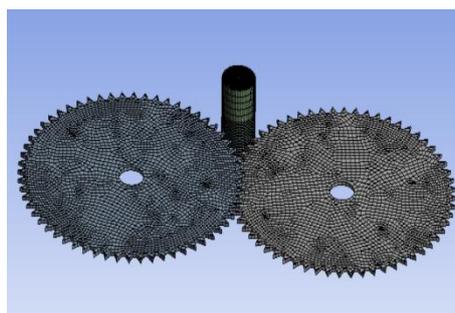

Fig. 5 – Grid division results

In the simulation model, the relative motion between the heading vegetable root and the cutter is used to simulate the actual root-cutting process. Select the upper end surface of the heading vegetables as fixed; the movement of the cutter is divided into forward motion and rotary motion around the axis, therefore, when constraining the cutter, it is necessary to set the X, Y, Z direction of the velocity component and X, Y, Z direction of the angular velocity component. The end time depends on the distance between the root of the heading vegetables and the cutter and the rotational speed of the cutter; the default safety factor of the time step is 0.9, and in the case of cutting simulation where the unit will be destroyed, it is possible to generate a negative volume, at this time, you can change the safety factor to a smaller one and set it to 0.6, and at the same time, the Minimum Time Step should be greater than 10^{-10} s (Li, 2013; Mohammad et al., 2019).

Bench Test

In order to optimize the key structural parameters and working parameters of the root cutting device, the root cutting performance test was carried out. The quadratic rotary orthogonal combination test method was adopted to analyze the relationship between the main influencing factors of root cutting performance (rotational speed of the cutter, conveying speed, inclination angle of the cutter, and the overlap amount of the cutter) and the performance index of the root cutting (cutting power). Regression analysis, response surface, and multi-objective variable optimization were applied to optimize the performance index of the root cutting device (cutting power).

The test is carried out on an independently designed double-disk heading vegetables root cutting test bench. This bench is mainly composed of double-disk cutting device, root cutting motor, clamping and conveying device, conveying motor, dynamic torque sensor, elastic pin coupling, frame, control and information acquisition system, etc. The test is carried out on a double-disk heading vegetables root cutting test bench. During the working process, the heading vegetable is stably clamped by the clamping and conveying device and conveyed in the direction of the cutting device, and the root of the heading vegetable is removed by the high-speed rotating double-disk cutter at the bottom.

Test Indicators

Referring to the national standard General Provisions on Measurement Methods for Test Conditions of Agricultural Machinery (GB/T 5262-2008) and the agricultural industry standards Test Methods for Sugar Beet Harvesting Machinery (JB/T 6276-2007) and Operational Quality of Sugar Beet Harvester (NY/T 1412-2007), the root cutting power P during the cabbage root cutting process was used as the test index.

$$P = \frac{(T_1 - T_0) \cdot n}{9550} \tag{3}$$

- P - cutting power, W;
- T_1 - total working torque, N·m;
- T_0 - idling torque, N·m.

Test Design

According to the previous experimental research, the factors that have a greater impact on the performance of root cutting mainly include the rotational speed of the cutter, conveying speed, inclination angle of the cutter, and overlap of the cutter. Therefore, in order to obtain a better combination of root cutting parameters, this experiment refers to the results of simulation tests and related literature, with the rotational speed of the cutter (A), conveying speed (B), cutter inclination (C) and the amount of overlap of the cutter (D) as the test factors, and with the root cutting power (R) as the response index, to carry out a four-factor, three-level quadratic rotary orthogonal test, the four factors of the Chinese cabbage cutting test level coding as shown in Table 1.

Table 1

Factors and level of orthogonal test				
Level	Factors			
	A. The rotational speed of the cutter (rpm)	B. Conveying speed (ms ⁻¹)	C. Cutter inclination (°)	D. Cutter overlap (mm)
1	200	0.3	5	15
2	300	0.4	10	20
3	400	0.5	15	25

RESULTS

Analysis of simulation test results

According to the above operation steps, the root cutting process in three types of cutting combinations was simulated and analyzed, and the root cutting process and the change curve of root cutting force were obtained through simulation analysis, as shown in Figure 6.

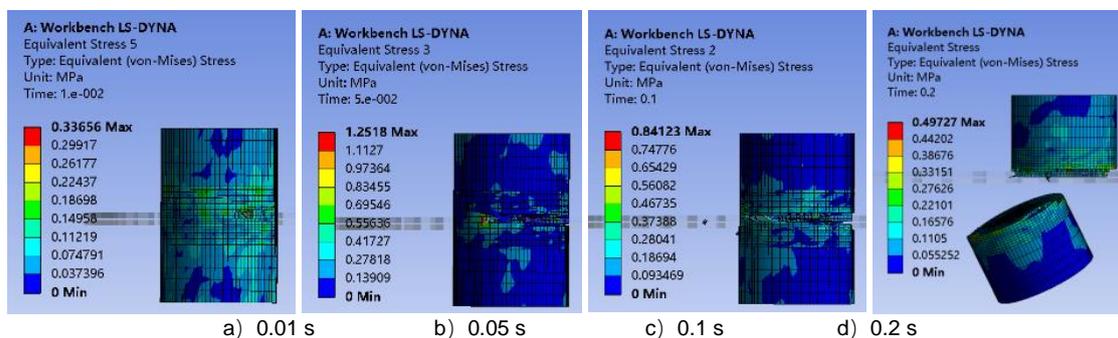

Fig. 6 – Simulation process of root cutting

The heading vegetables root and the cutter began to contact, the cutter approached the heading vegetables root and contacted the outer skin of the cabbage root, and the outer skin of the heading vegetables root was gradually deformed, as shown in Figure 6a. As the cutter continued to go deeper into the interior of the heading vegetables root, the cutter exerted a vertically acting cutting and friction force on the root resulting in the cutting of the root as shown in Figure 6b. The cutter continued to penetrate deeper into the root, and the root started to fracture, as shown in Figure 6c. Eventually, the cutter severed the cabbage root, as shown in Figure 6d.

The effects of different cutter combinations on the maximum root cutting force and internal energy of root cutting during root cutting were further analyzed and the statistical simulation results are shown in Table 2.

Table 2

Data of maximum root cutting force and internal energy under different cutter types		
Cutter types	Maximum root cutting force (N)	Internal energy (mJ)
Double smooth blade	22.797	1854.56
Double serrated blade	20.499	1751.4
Smooth + serrated blade	20.97	1653.53

From the data in Table 2, it can be concluded that the maximum root cutting force of the double serrated knife is the smallest, and the root cutting internal energy of the combination of smooth knife and serrated knife is the smallest. Compared to the smooth knife, the serrated knife has a better clamping effect on the cabbage root. The combination of serrated knife and smooth-edged knife is more optimal by combined analysis of the results of maximum root-cutting force and internal energy.

Analysis of bench test results

The experiments were designed in accordance with the BBD experimental design method, and the experimental program and results are shown in Table 3.

The quadratic polynomial response surface regression model of the root cutting power (R) on the rotational speed of the cutter (A), conveying speed (B), cutter inclination (C) and the amount of overlap of the cutter (D) was established by using Design-Expert 8.06 to fit the multivariate regression to test results in Table 4. In this table, df means degree of freedom. F-value is the ratio of the variance between the group means to the variance within the groups. A higher F-value indicates a greater difference between group means relative to the variation within the groups. The P-value is the probability of obtaining an F-value as extreme as the one calculated, assuming the null hypothesis is true. A small P-value (typically < 0.05) suggests that the observed differences between group means are statistically significant, leading to the rejection of the null hypothesis.

Table 4

Results of variance analysis of orthogonal test

Source	Root cutting power					
	Sum of Squares	df	Mean Square	F value	P value	Significant
Model	8324.53	14	594.61	63.97	<0.0001	**
A	5646.34	1	5646.34	607.45	<0.0001	**
B	2197.81	1	2197.81	236.45	<0.0001	**
C	14.30	1	14.3	1.54	0.2352	
D	0.27	1	0.27	2.9E-2	0.8671	
AB	44.89	1	44.89	4.83	0.0453	*
AC	22.56	1	22.56	2.43	0.1415	
AD	57.76	1	57.76	6.21	0.0258	*
BC	85.56	1	85.56	9.21	0.0089	**
BD	2.5E-3	1	2.5E-3	2.7E-4	0.9871	
CD	13.32	1	13.32	1.43	0.2511	
A2	73.92	1	73.92	7.95	0.0136	*
B2	19.04	1	19.04	2.05	0.1743	
C2	99.89	1	99.89	10.75	0.0055	**
D2	3.29	1	3.29	0.35	0.5617	
Residual	130.13	14	9.3			
Lack of Fit	93.3	10	9.33	1.01	0.5424	
Pure Error	36.83	4	9.2			
Cor Total	8454.66	28				

Note: ** indicates a highly significant effect ($P < 0.01$) and * indicates a significant effect ($P < 0.05$)

As can be seen from Table 4, the root cutting power regression model $P < 0.01$ and the misfit term $P > 0.05$, indicating a high degree of goodness of fit and a highly significant fitting effect.

From the value of F-value in Table 4, it can be seen that the factors affecting the root cutting power (R) of the root cutting device are, in order of priority: the rotational speed of the cutter (A), conveying speed (B), cutter inclination (C), the amount of overlap of the cutter (D). From the value of P in Table 3, it can be seen that the effect of A, B, BC, and C2 on the root cutting power is highly significant, the effect of AB, AD, and A2 on root cutting power is significant, and the rest of the items do not have a significant effect on the root cutting power.

In summary, the optimized regression fitting equation about root cutting power obtained after eliminating the insignificant terms is shown in equation (4), and the optimized model is reliable with $P < 0.01$ and the out-of-fit term with $P > 0.05$.

$$R = 87.61 + 21.69A + 13.53B - 1.09C - 0.15D + 3.35AB + 3.8AD - 4.63BC - 3.22A^2 + 4.08C^2 \quad (4)$$

Discussion

In order to further explore the factors affecting the experimental results and the degree of influence, this paper chooses to use the response surface method to analyze the influence of the rotational speed of the cutter (A), conveying speed (B), cutter inclination (C) and the amount of overlap of the cutter (D) on the root cutting power (R). The design of the root-cutting device is based on a set of objective function and constraints. By establishing the objective function and constraints, the optimal parameter combinations of the designed root cutting device are found.

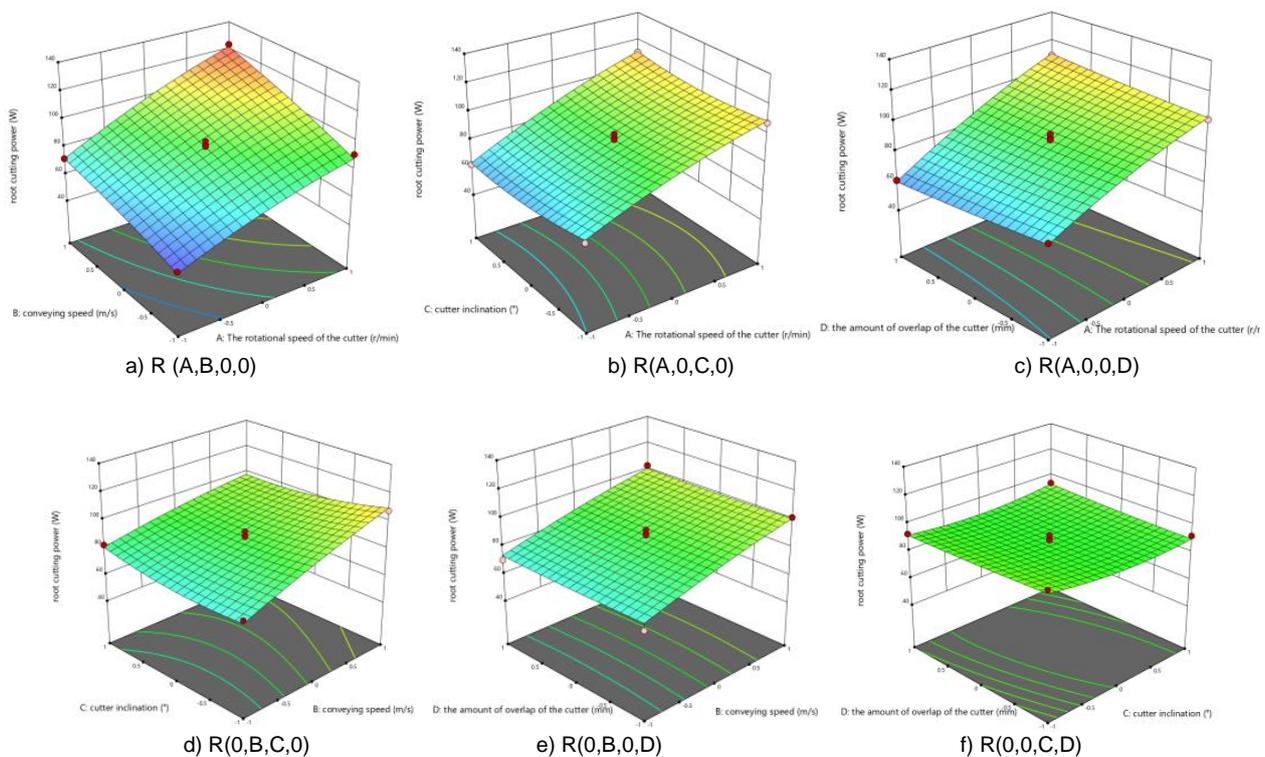

Fig. 7 – Three-dimensional response surface analysis of root cutting power interaction factors

As can be seen from Figure 7, the rotational speed of the cutter (A) and other factors response surface slope is larger, that is, the rotational speed of the cutter (A) on the root cutting power R has the greatest impact, conveying speed (B) is the next largest, while cutter inclination (C) and the amount of overlap of the cutter (D) on the root cutting power R has a smoother impact, that is, the interaction factors in the C and D have the smallest impact on the root cutting power.

In order to achieve low-power and high-efficiency root cutting, this paper takes the root cutting power as the optimization index, and carries out parameter optimization analysis on the influencing factors such as the rotational speed of the cutter, conveying speed, tilting angle of the cutter, and overlapping amount of the cutter. The regression model is optimized and solved using the optimization module in Design Expert 8.0.6 software, and the established optimization model is shown in equation (5).

$$\begin{aligned} & \min R \\ & s. t. \begin{cases} 200 \leq A \leq 400 \\ 0.3 \leq B \leq 0.5 \\ 5 \leq C \leq 15 \\ 15 \leq D \leq 25 \end{cases} \end{aligned} \quad (5)$$

CONCLUSIONS

(1) In order to improve the efficiency of mechanized harvesting of heading vegetables, a root cutting device for heading vegetables was designed. Through the LS-DYNA simulation experiments, the root cutting process of the root cutting device was simulated and the root cutting force and root cutting internal energy of three knife combinations were compared. The simulation results of the maximum root cutting force of the double serrated knife is the smallest, and the combination of the smooth-edged knife and the serrated knife has the smallest root cutting internal energy. Compared with the smooth-edged knife and serrated knife, the serrated knife has a better clamping effect on the heading vegetables root. The combination of serrated knife and smooth-edged knife is more optimal by combined analysis of the results of maximum root-cutting force and internal energy.

(2) In order to obtain the optimal structural parameters and operating parameters of the root cutting device, a quadratic rotary orthogonal combination test method was used to analyze the relationship between the main factors affecting the performance of the root cutting device (rotational speed of the cutter, conveying speed, inclination angle of the cutter, and overlap amount of the cutter) and the performance index (root cutting power), and the regression analysis, response surface, and multi-objective variable optimization methods were applied to design the bench test program. The results of the bench test showed that the optimal parameter combinations of the designed seed dispenser were: cutter speed of 200 rpm, conveying speed of 0.3 ms⁻¹, cutter inclination angle of 10°, and cutter overlap volume of 20 mm; and the model-predicted root-cutting power was 51.19W.

Keywords: Grain harvesting, Cleaning device, Design, Semi-physical simulation system

ABSTRACT

To address the long development cycle of the grain air-screen cleaning device, a semi-physical simulation platform for the grain cleaning control system was designed. The platform was used to simulate the actual operational process, conducting both open-loop and closed-loop tests, with results compared to actual tests. In the open-loop test, the speed error had a mathematical expectation of 0.8387 rpm, with a standard deviation of 2.75 rpm, and the fish-scale sieve opening error had a mathematical expectation of -0.0117 mm, with a standard deviation of 0.038 mm. In the closed-loop test, the speed error had a mathematical expectation of 0.679 rpm, with a standard deviation of 1.815 rpm. The experimental results demonstrate that the simulation platform can effectively replicate the actual operating conditions of the grain cleaning device and validate the effectiveness of the TC377 controller's control algorithm, thereby improving the development efficiency.

摘要

针对谷物风筛式清选装置开发周期长的问题, 设计出一套谷物清选调控系统半实物仿真平台。利用半实物仿真平台模拟实际作业过程, 进行开环与闭环测试, 与实际测试进行对比。其中, 开环测试转速误差数学期望为 0.8387rpm, 标准差为 2.75rpm, 鱼鳞筛开度误差数学期望为 -0.0117mm, 标准差为 0.038mm。闭环测试转速误差数学期望为 0.679rpm, 标准差为 1.815rpm, 试验结果表明了该仿真平台能够模拟谷物清选装置的实际工况以及 TC377 作为控制器控制算法的有效性, 能够提高开发效率。

INTRODUCTION

China, as a major agricultural country, has high demands on the quality and efficiency of grain production due to its socio-economic context. During the processes of growth, harvesting, transportation, and storage, grains are susceptible to various adverse factors, leading to the presence of impurities, damaged kernels, and certain harmful substances. These factors not only impact the quality and nutritional value of the grains but may also pose potential health risks to consumers. Therefore, grain cleaning and sorting equipment plays an indispensable role in agricultural production (Qu et al., 2024; Wang et al., 2022).

The wind-sifting cleaning and sorting device is the primary equipment used by combine harvesters for grain cleaning operations. It offers advantages such as high cleaning efficiency and a high kernel cleaning rate. During operation, the wind-sifting cleaning device has multiple adjustable working parameters. The precision and automation of these adjustments are key factors that influence its cleaning efficiency and performance in field operations (Ning et al., 2018).

In the practical development of harvesting machine cleaning devices, limitations such as harvest season and test field conditions make it difficult to conduct extensive field trials under various operational conditions. Before conducting real-world vehicle tests, extensive iterative experimental research is required to obtain optimal test results, which, to some extent, impacts the development process of cleaning devices. Many research institutions have designed and manufactured various testing rigs, but these rigs are expensive, and the testing process requires large amounts of crops, which still presents certain constraints. Under these conditions, the concept of semi-physical simulation technology has been proposed (Jiang et al., 2022; Xu et al., 2024; Liu et al., 2018).

Semi-physical simulation technology is an important simulation technique, currently widely used in various fields such as aerospace engineering, military applications, automotive engineering, diesel engine electronic control systems, and medical applications (Cheng et al., 2022).

Hardware-in-the-loop simulation is a simulation method targeting specific research objects. Its core lies in introducing a portion of the simulation object system into the simulation environment in the form of a physical model, while the remaining components are described through mathematical modeling methods and further developed into corresponding simulation computation models. Based on this, leveraging the actual effects generated by the physical model, real-time joint simulation tests can be conducted, integrating the collaborative work of mathematical and physical models. At present, the semi-physical simulation technology is not widely used in the field of agricultural machinery, and it is mainly used for the steering control and gear shift simulation of tractors (Wu et al., 2023; Wu et al., 2019; Li et al., 2024). Semi-physical simulation technology provides strong support for the integration of control systems in the development of agricultural machinery. By combining virtual models with actual hardware, it allows for the validation of the system's overall performance at an early stage of agricultural machinery development, enabling the timely identification of potential issues and optimization of system design. Furthermore, this simulation technology can real-time simulate the performance of agricultural machinery during actual operation. Through interaction with physical hardware, developers can more precisely adjust control system parameters, thus optimizing the performance of the grain cleaning device and ensuring that the machinery operates efficiently and stably (Zhu et al., 2022).

Zhu Xiaolong et al. in China developed a semi-physical simulation platform for a low-loss threshing intelligent control system. Through signal simulation testing and automatic control strategy simulations, they demonstrated that the platform can be used for the development of intelligent control systems for corn grain harvesters. This platform has provided an experimental foundation for the development of intelligent control systems for corn grain harvesters. Through a comparison of simulation and experimental tests, the semi-physical simulation platform was successfully validated for the development of the intelligent control system, shortening the development cycle (Zhu et al., 2022). Xie Bin et al. designed the mechanical structure of the electric tractor's drive system and built a prototype, which was then downloaded to the controller for hardware-in-the-loop (HIL) experiments. Actual data from previous field tests on plowing and rotary tilling were used as the load for the HIL experiments, which were conducted on a personal computer. Through multiple simulations and experiments on the semi-physical simulation platform, the traditional drive system was successfully improved, enhancing ploughing and rotary tilling efficiency (Xie et al., 2022).

Therefore, this paper focuses on the development of a grain cleaning test bench and designs a semi-physical simulation platform, applying semi-physical simulation technology to the grain cleaning device. The aim is to address the issues of long development cycles and high development costs. By reviewing relevant literature and utilizing appropriate software, mathematical models of the key operating components of the grain cleaning system were established. The platform was equipped with various components that generated the necessary signals for the testing process, achieving the conversion between physical values and signal values, thereby enabling successful signal transmission between different circuit boards. Finally, before conducting actual experiments, the control effects were verified through simulation testing of the controller.

MATERIALS AND METHODS

The overall structure of the hardware-in-the-loop simulation platform is shown in Fig. 1. Its structure is mainly divided into three parts: the hardware platform, the up-per-level computer software, and the real-time simulation model.

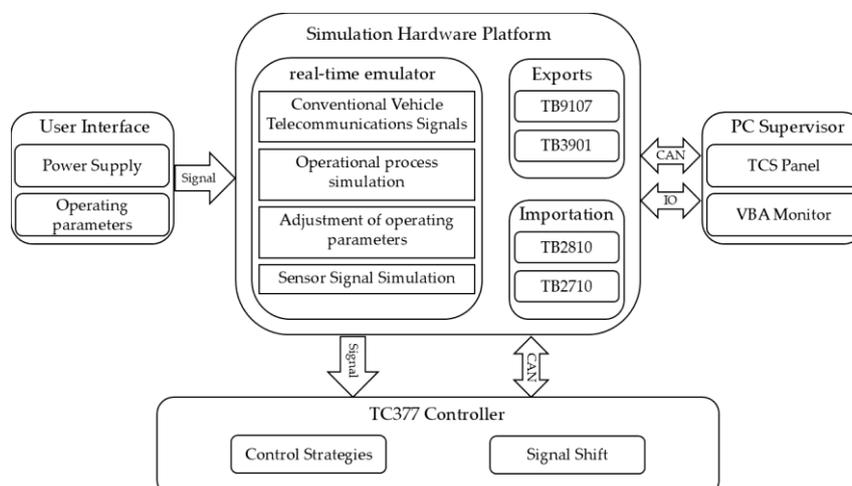

Fig. 1 - Overall Flow Chart

The specific requirements are as follows: (1) Simulate the electrical signals generated during the operation of the grain cleaning test bench, as well as the signals transmitted by the sensors. These signals are received through various boards located within the cabinet and transmitted to the controller via the ODU port. (2) It should be capable of simulating the actual working conditions, detecting variations in signals such as voltage and current during the control process, and performing data processing and transmission via hard-wire I/O signals and CAN communication. (3) Develop a model of the grain cleaning test bench and construct the mathematical model using the Simulink simulation platform. The controlled object receives the control signals from the controller and generates corresponding feedback signals to return to the controller, thus forming a complete closed-loop system. (4) The system is equipped with a human-machine interface, allowing for more intuitive and convenient adjustment and monitoring of the frequency variations of the inverter control cabinet, motor speed, fan speed, and other key components. The working status is monitored in real-time through CAN messages.

The components of the cabinet used for testing include devices such as PDU, programmable power supplies, regulated power supplies, PSM, function boards, general-purpose IO boards, and real-time processing systems, as shown in Fig. 2. The PDU primarily performs AC power control, distribution, and equipment protection functions. The real-time simulator ensures the simulation model operates in real-time, facilitates data interaction with the host-computer test software, and enables online parameter adjustment and monitoring. It also transmits the signals required by the controller through various IO boards and collects all signals transmitted by the controller.

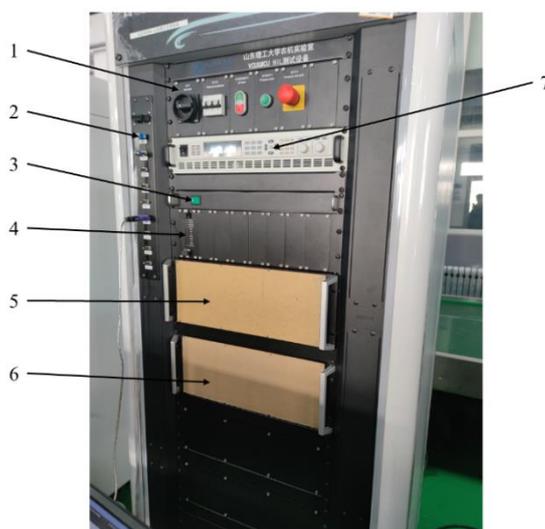

Fig. 2 - Cabinet Composition

1 - PDU Power Management, 2 - CAN interface, 3 - Signal conditioning power supply, 4 - Power switching, 5 - ODU connection draw box, 6 - Load draw box, 7 - Programmable power supply

The host computer software primarily includes Real-time Simulation Test Management Software (TCS), Automated Testing Software (TAE), Bus Monitoring Software (VBA), IO Model Generation Software (TB_IOModel_Gen), and Fault Injection Software (TB_EFI). The experimental management software oversees the management of model files and hardware resources. The bus monitoring software directly monitors messages on the CAN bus and functions as the bus monitor during the interaction between the HIL device and the controller. The fault injection software directly controls the fault injection board to introduce faults, thereby simulating real-world scenarios. The automation management software facilitates the invocation of the aforementioned software via the corresponding software interfaces, setting the execution sequence to achieve an automated testing process.

The drive motor selected is a squirrel-cage three-phase asynchronous motor, which drives the corresponding components through belt transmission. The motor speed is adjusted by varying the frequency using a frequency converter. A simulation model is built to simulate the corresponding frequency-controlled speed regulation system and output the corresponding motor speed. The motor speeds of the driving and driven wheels are detected by the VEMSEE speed sensor. Wind speed is measured by installing a wind speed sensor at the fan outlet and inside the sieve box. An impact plate sensor is used behind the sieve box to record the number of grains lost at the impurity discharge outlet during the grain cleaning process.

In actual operation, the size of the motor-driven load also affects the variation in motor speed. Therefore, to simplify the process, it is assumed that the motor's speed transmission is ideal. Mathematical models for the centrifugal fan, fish-scale sieve opening, spiral drill, and other components were established based on the agricultural machinery manual and relevant literature. The mathematical models were not optimized in this paper but are used to simulate the adjustment process of the test bench during actual operation. The physical values obtained during operation are converted into signal values and output through the circuit boards. The simulation of vehicle electrical signals and sensor signals is achieved through the IO conversion board and CAN communication board integrated into the simulation platform.

Table 1

The Main Technical Parameters of the Grain Cleaning Device	
Item	Parameter
Belt width	1000 mm
Feed motor speed	0~100 rpm
Fan speed	400~1200 rpm
Vibrating screen crank speed	0~280 rpm
Fish scale sieve opening	7~22mm
Rotating speed of the elevator	0~500rpm

This paper takes the air-screen grain cleaning device as the development object. The tuning ranges for the working components are based on the equipment settings provided by the grain cleaning device manufacturer, as well as the professional instructions from the training personnel. The tuning ranges comply with the manufacturer's technical specifications and usage recommendations, ensuring standardization and consistency during the experimental process. Additionally, the device was delivered at the end of last year and, under the guidance of trained personnel, the operational ranges for each component parameter were confirmed, thereby enhancing the reliability of the experiment.

The wind separation system of the grain cleaning device employs a volute centrifugal fan, consisting primarily of components such as the fan casing, air regulation plate, fan shaft, blade connection plate, and blades. This centrifugal fan features a relatively wide design, provides adequate airflow, and ensures a uniform distribution of air within the screening box, thereby meeting the cleaning and selection requirements. The airflow speed and direction within the system can be adjusted through the air regulation plate based on actual conditions, enabling the attainment of the desired cleaning and selection effect.

The cleaning airflow V is given by Equation (1).

$$V = \frac{\beta Q}{\mu \rho} \quad (1)$$

where: β is the proportion of impurities in the mixture, taken as $\beta=16\%$, for full feeding, the typical values for wheat range from 0.15 to 0.2, and for rice, from 0.1 to 0.15; for partial feeding, wheat typically ranges from 0.1 to 0.15, and rice from 0.08 to 0.12; Q is the machine's feeding rate, with a minimum value of 10 kg/s; μ is the concentration ratio of the airflow carrying impurities, taken as 0.25; ρ is the air density, taken as 1.29 kg/m³.

Outlet air velocity, v , is given by Equation (2).

$$v = \frac{V}{BH} \quad (2)$$

where B is the outlet width, mm; H is the outlet height, mm.

The variation in the fish-scale sieve opening corresponds to the vertical spacing between adjacent sieve plates is given by Equation (3). The airflow through the cross-sectional gap between adjacent sieve plates per unit time is given by Equation (4).

$$S_1 = l \cdot l_1 = l_0 \sin \alpha l_1 \quad (3)$$

$$N = 3600 S_1 v = 3600 l_0 \sin \alpha l_1 v \quad (4)$$

where: N is the airflow through the cross-sectional area of the gap between adjacent sieve plates per unit time, in m³/s; v is the airflow velocity, in m/s; S_1 is the cross-sectional area of the gap between adjacent sieve plates, in m²; l_0 is the length of the connecting plate between adjacent sieve plates, in m; l_1 is the width of the sieve plate, in m; l is the opening of the fish-scale sieve, in m.

v, l_0, l_1 is a fixed value, therefore, the change angle α of the sieve sheet determines the cross sectional ventilation N of the adjacent sieve sheet gap per unit time. From $l=l_0 \sin\alpha$, it follows that $0^\circ \leq \alpha \leq 90^\circ$, so $0 \leq \sin\alpha \leq 1$, when $\alpha = 90^\circ$, $\sin\alpha = 1$, at this point, the opening l of the fish scale sieve is at its maximum value and equal to l_0 .

The horizontal winch seed conveying speed is given by Equation (5).

$$v_{d1} = \frac{P_1 w_{d1}}{60\pi} \tag{5}$$

where v_{d1} is the axial conveying speed of the material, in m/s; p_1 represents the pitch of the helical blade, full-face blade $p_1 = 0.8D_1$, in m; D_1 represents the diameter of the helical blade, in m; w_{d1} represents the rotational speed of the screw shaft, in rpm.

Vertical winch seed conveying speed is given by Equation (6).

$$v_{d2} = \frac{w_{d2} R_{d2} \sin\alpha \sin\beta}{30 \sin(\alpha + \beta)} \tag{6}$$

where w_{d2} is the rotational speed of the screw shaft, in rpm; R_{d2} is the radius of the auger, in m; β represents the angle between the direction of grain movement and the horizontal, in degrees ($^\circ$); α represents the helical angle of the blade, in degrees ($^\circ$).

The simulation model built in MATLAB/Simulink consists of multiple modules. TestBaseIO: Cabinet Basic Control Module. This section primarily controls the output of the programmable power supply and its feedback. The programmable power supply is turned off by adjusting the high or low level of DO1. Additionally, the output voltage values of AO1 and AO2 are used to achieve the specified voltage and current settings in the model.

The IO model serves as the interface between the simulation model and external hardware. As shown in Fig. 3, the left-side module, MDL Data to Controller, transmits hard-wired signals from the model to the cabinet board, which are then sent to the controller. Conversely, the right-side module, Controller Data To MDL, collects hard-wired signals from the controller via the cabinet board and delivers them to the model.

In particular, the MDL Soft ECU Data to Bus module categorizes various messages, as shown in Fig. 4, which are centrally monitored and managed by VBA. Each signal is ultimately transmitted to the RTSE output interface, then forwarded to the CAN communication board, and finally sent to the controller under test.

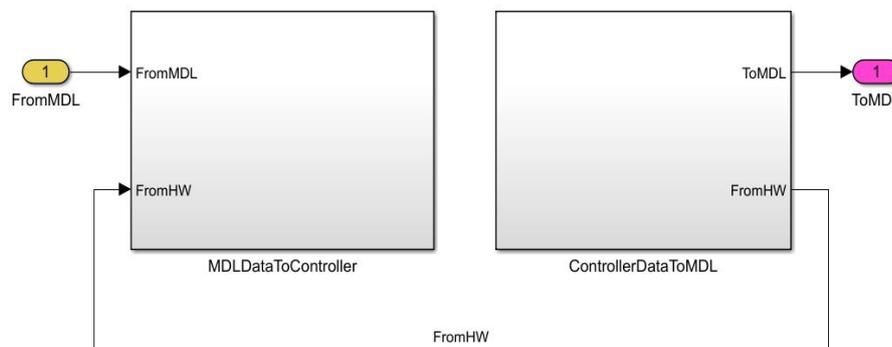

Fig. 3 - I/O model

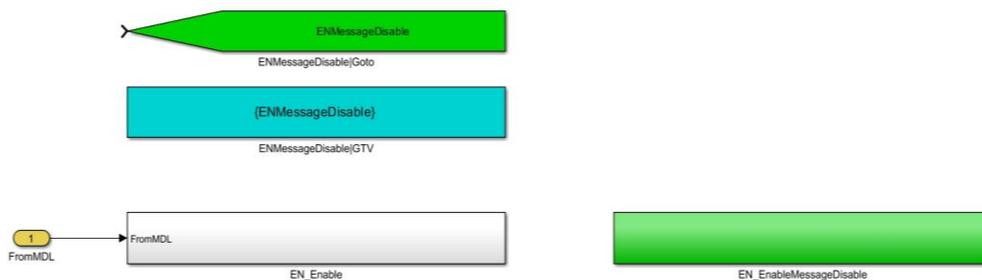

Fig. 4 - MDL Soft ECU Data to Bus

Test Bench Model: This model is used to simulate the virtual controlled object of the controller under test. The model is divided into three parts: the control cabinet, virtual controller, and test bench. The input to the model comes from signals transmitted by the IO model. The Maneuver module replaces the control cabinet and is primarily responsible for starting and stopping the test bench as well as regulating the motor speed. The virtual controller is not used in this model. The test bench model includes the motor model and the working components model. The specific setup is shown in Fig. 5.

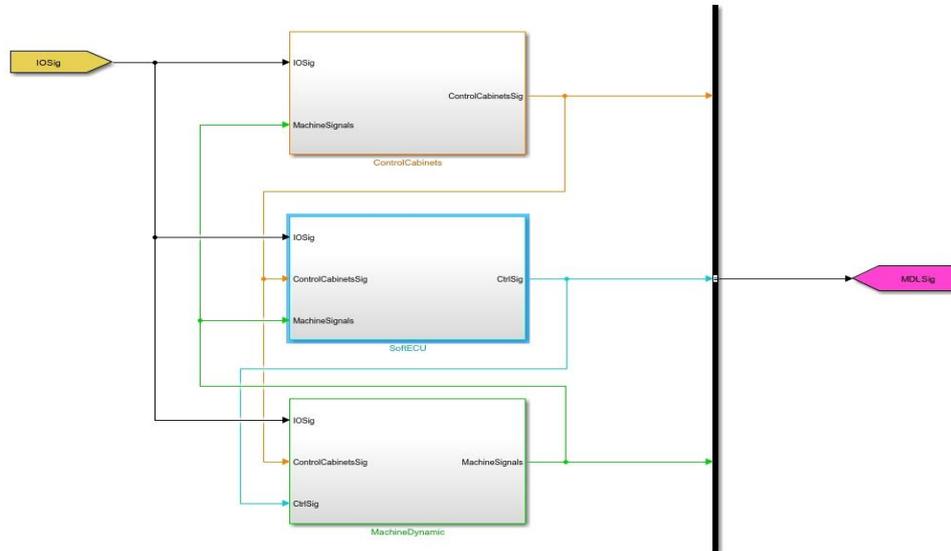

Fig. 5 - Test Bench Model

A 3D model of the grain cleaning test bench was built using SolidWorks software, based on the geometric and mass parameters of the working mechanism, as shown in Fig. 6 and Fig. 7. The model primarily includes components such as the shaker plate, vibrating screen, fan, and screw conveyor. The mass, moment of inertia, and connection parameters for each component are carefully set to ensure accuracy.

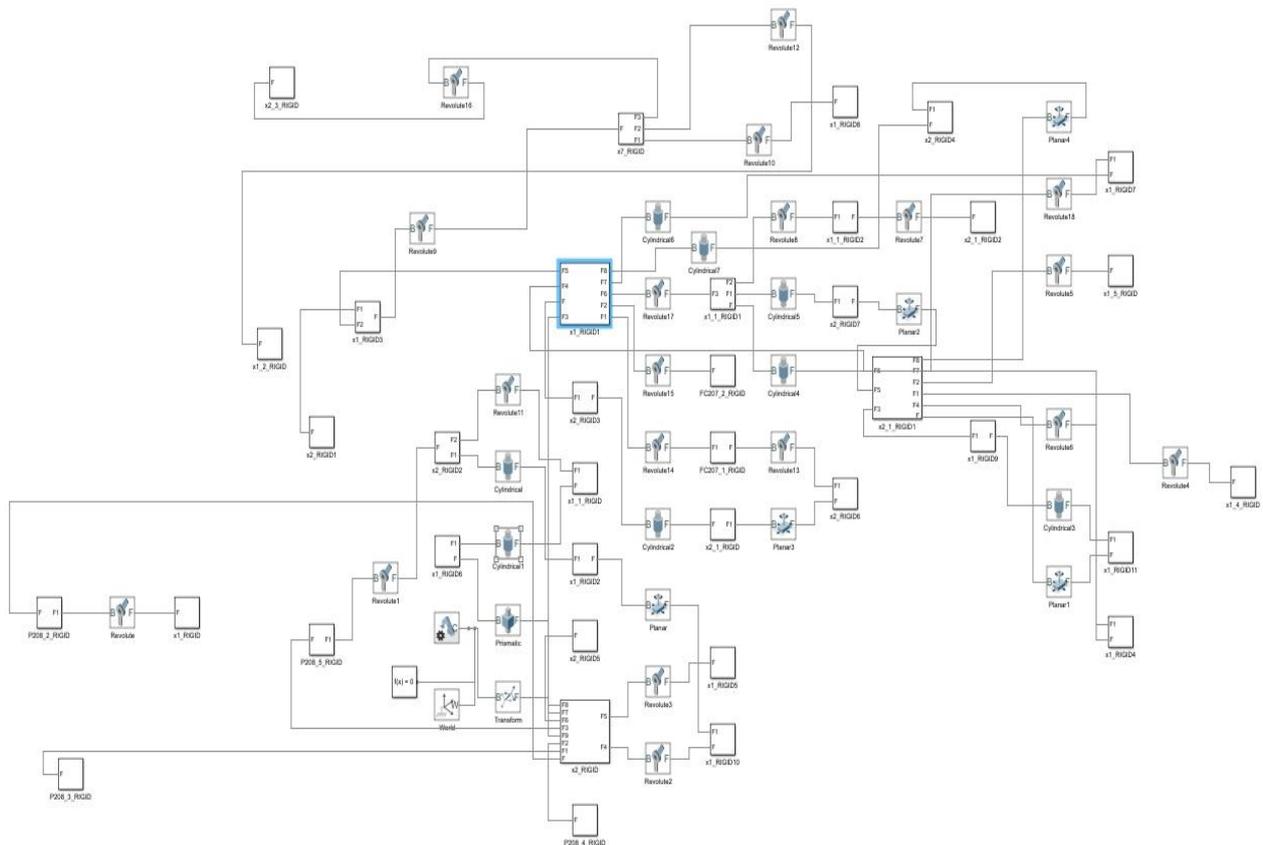

Fig 6 - Models in Simulink

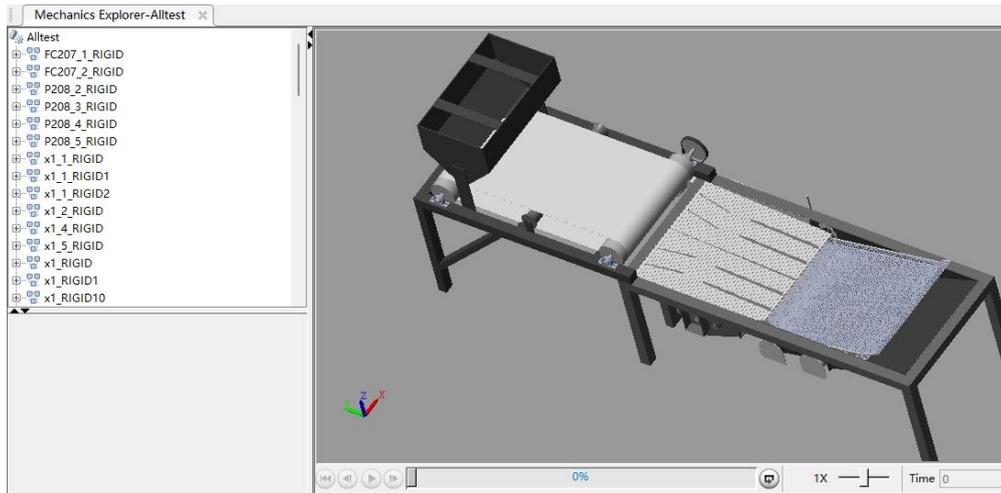

Fig. 7 - The mechanical operation diagram generated by Simscape

The TCS software control interface is shown in Fig. 8. The left side is configured for controlling the PDU and programmable power supply, enabling power cycling of the cabinet and controller as well as the corresponding voltage and current variations. The right side displays the operating parameters of each component, which need to be manually set. The basic control elements in the layout are connected to the relevant signals, reflecting the values detected by the sensors.

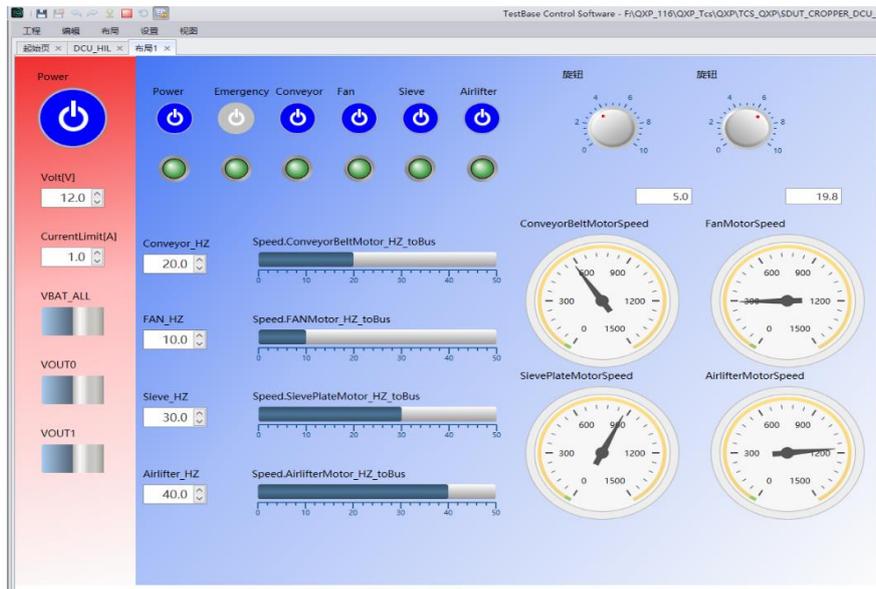

Fig. 8 - TCS Operator Interface

The VBA monitoring software is shown in Fig. 9. The cabinet is connected to the controller and successfully powered on. After running via TCS, the software reads the DBC file and displays multiple messages on the CAN bus. It intuitively shows whether the current components have started operating and the current operating frequency of the motor. The names assigned to these messages in the software provide a clearer view of the relationship between each message. This software effectively monitors whether CAN communication is running successfully.

Fig. 9 - VBA Monitor Interface

Automatic Control Strategy: An automatic control strategy is built within the controlled object model and the TC377 controller, with predefined goals to be achieved. During simulation, the TC377 controller periodically uses data feedback from sensors to assess the current operating status. By determining the deviation between the current state and the target parameters, it sends corresponding signals to drive the controlled object further, continuing until the parameters fall within the set range.

RESULTS

Operational parameter tests are conducted on both the simulation platform and the grain cleaning test bench. Under the assumption of no load, motor speed adjustment and fish-scale sieve opening adjustment experiments are carried out. The actual adjustment process of the operational parameters is compared with the simulation adjustment process to verify the effectiveness of the controlled object model within the simulation platform. To ensure that the control processes on both the simulation platform and the grain cleaning test bench are identical, the adjustment time and steps for both should be consistent during the experiments.

(1) Open-loop control test procedure:

Actual Test: Operate the control panel on the frequency converter control cabinet to adjust the motor's operating frequency to 41 Hz within 10 seconds. After the motor speed reaches 1200 rpm, it will continue to run, with detection and recording conducted through the speed sensor installed on the motor's drive wheel.

The adjustment range of the fish-scale sieve screen piece angle α is from 15° to 40°, and the screen opening l ranges from 7 mm to 22 mm. The fish-scale sieve adjustment device measures and records every 5° adjustment. The data record of the fish-scale sieve screen piece angle variation is presented in Table 2.

Table 2

Fish-Scale Sieve Screen Piece Angle Variation					
Angle of change	Fish Scale Sieve Opening	Emulate / mm Practice / mm		Relative error / mm	
α (°)	l / mm				
15	7	7.17	7.2	-0.4167	
20	10	9.56	9.6	-0.4167	
25	13	11.94	11.9	0.3361	
30	16	14.33	14.4	-0.4861	
35	19	16.72	16.7	0.1198	
40	22	19.11	19.1	0.0524	

Simulation platform test: Input the same control signals as those on the test bench into the upper-level TCS control interface, complete the input of the corresponding parameters and the adjustment of control knobs, and record the data generated by the controlled object during operation.

Comparison of the experimental results shown in Fig. 10 and Fig. 11 reveals that there is a discrepancy between the simulation results on the simulation platform and the actual test results of the grain cleaning machine. The main reason for this is the presence of numerous uncontrollable factors in the actual experiment, which cause deviations in the motor speed. In contrast, the simulation platform may experience voltage or current instability during transmission, leading to deviations in the simulated motor speed.

The actual measurement of the scalper screen opening contains errors due to manual measurement. The tool used was a standard vernier caliper with a precision of 0.1 mm. The mathematical expectation of the speed error is 0.8387 rpm, with a standard deviation of 2.75 rpm. The mathematical expectation of the speed error is positive, with the simulation results generally being 1 rpm higher than the actual measured results. Additionally, the motor speed does not remain completely stable at a specific value but exhibits some random fluctuations, which are caused by the instability in the actual measurements. The mathematical expectation for the fish-scale sieve is -0.0117 mm, with a standard deviation of 0.0380 mm. The measurement data shows some fluctuation, but the range of variation is small, which is within an acceptable range for the actual machine. Therefore, the controlled object model in the simulation platform can reasonably simulate the actual operating conditions of the grain cleaning test bench.

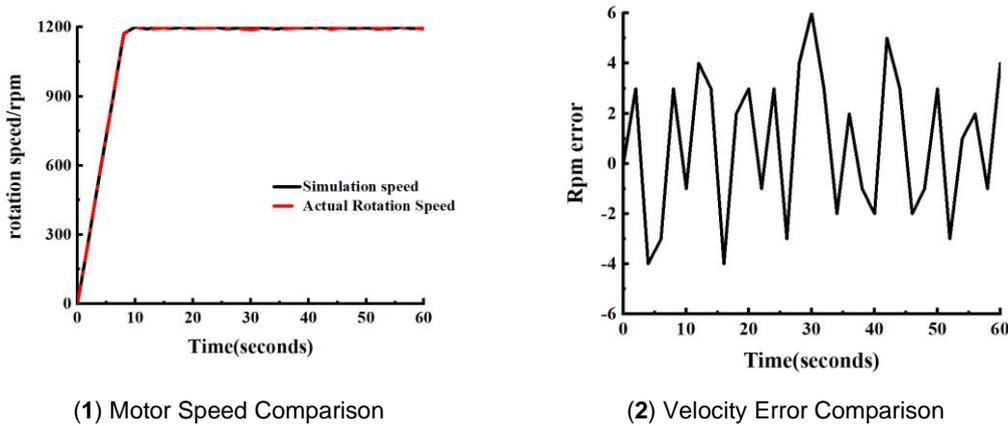

Fig. 10 - Open Loop Test Comparison and Error

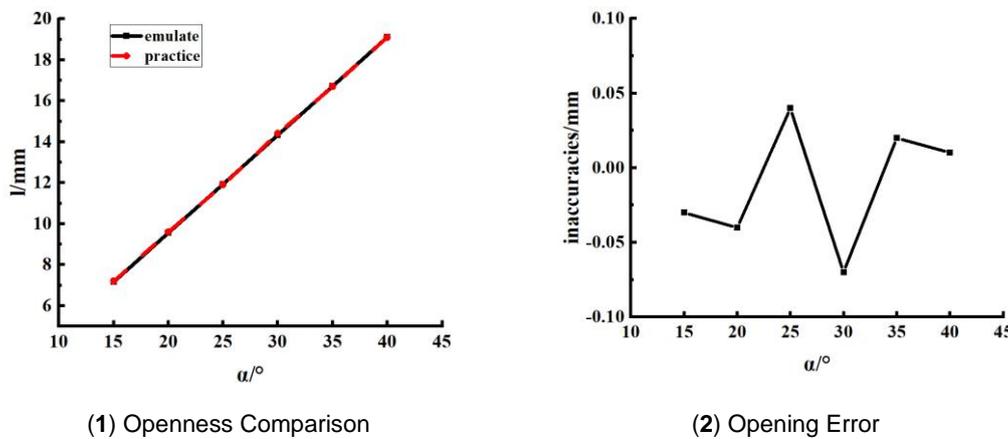

Fig. 11 - Fish Scale Sieve Opening Test Comparison

(2) Closed-loop control of the test process:

The TC377 development board, based on AutoSAR, is used as the controller. This controller is employed for both simulation and real-world experiments, with the results compared.

Actual test: Through the control panel on the frequency converter cabinet, the fan motor is stabilized to operate at around 400 rpm for a small amount of grain cleaning. After 20 seconds, the feeding rate is increased, and 20 seconds later, the initial feeding rate is restored. The experiment shows that the motor speed changes with the feeding rate. When the feeding rate suddenly increases, the controller receives the instruction for the change and sends a signal to increase the fan speed, thereby ensuring the normal operation of the cleaning process.

Simulation platform test: Design the same control signals as in the actual test. Adjust the input parameters in the initial state to stabilize the model at the corresponding speed. Then, increase the feeding rate by adjusting the control knob and restore the initial state after 20 seconds.

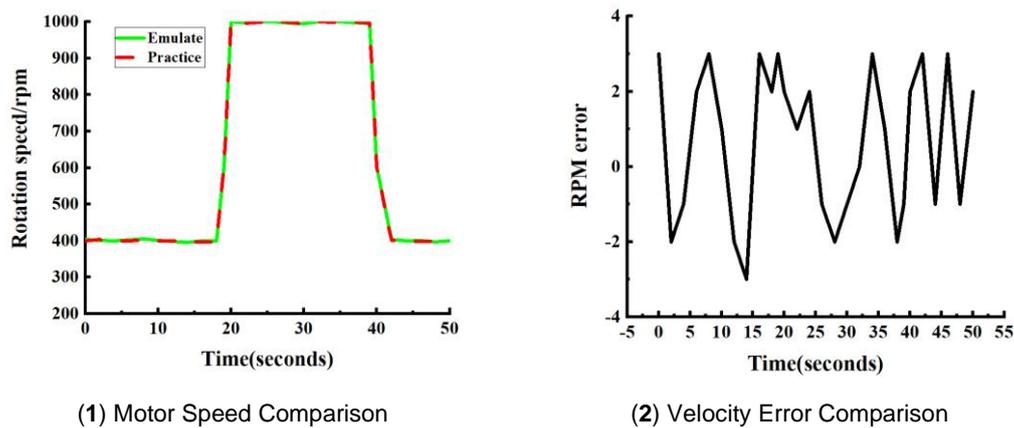

Fig. 12 - Closed Loop Test Comparison and Error

Due to deviations in the actual feeding weight and differences in bulk density, there is a slight error between the comparison tests. The experimental results are shown in Fig. 11. The mathematical expectation of the error during the speed adjustment process is 0.679 rpm. It can be observed that the simulation platform is capable of testing the controller and that the controller demonstrates strong control capability over the actual machine.

This paper takes the air-screen grain cleaning device, a common type of agricultural machinery, as the development object and applies semi-physical simulation technology to the grain cleaning device. By building a model on the semi-physical simulation platform, experimental results demonstrate that the simulation model can effectively replicate the actual operating conditions of the machine, with errors within an acceptable range. This provides a testing platform for the subsequent controller development, preventing potential damage to the grain cleaning device during the actual testing phase, and eliminating the need for multiple experiments, thus saving significant operational time.

CONCLUSIONS

(1) Due to the lengthy development process, cumbersome testing, and high development costs of the grain cleaning test bench, a hardware-in-the-loop simulation platform for grain cleaning control was designed. This platform is linked to the actual machine through the establishment of mathematical models for key components during operation. It provides the necessary hardware platform and corresponding upper-level control software for the development of the intelligent grain cleaning control system.

(2) Based on the practical influence of seasonal and site factors on the development of the grain cleaning device, a semi-physical simulation platform for the grain cleaning device control system was designed. This platform provides the hardware foundation and simulation test object for the development of the grain cleaning control system.

(3) The TC377 development board is used as the controller for both the actual machine and the controlled object on the simulation platform. A comparative experiment between simulation and real-world testing was conducted. The open-loop test verified the validity of the model and the successful transmission of signals, while the closed-loop test demonstrated the effectiveness of the controller algorithm and the actual control performance. This confirms that the simulation platform can significantly shorten the development cycle and reduce development costs.

(4) Hardware-in-the-loop simulation technology has achieved initial success in the field of grain cleaning. However, at present, its application objects are relatively simple, and there may be some errors in the development process. It is hoped that, in future development, improvements can be made to expand the applicability of this technology to various types of cleaning equipment.

Keywords: agricultural machinery, skeletonization, image stitching, corn interplant recognition

ABSTRACT

To address the challenges associated with high interrow weeding difficulty and seedling damage in corn fields, a weed removal machine based on crop spacing recognition was designed. It captures crop images at variable speed intervals, obtains corn seedling centroid coordinates via image stitching and skeleton extraction, calculates actual plant spacing through pixel-to-real coordinate transformation, and enables real-time control of the weeding device. Key components were analyzed for motion trajectories and critical parameters. Field tests revealed optimal performance at 0.45 m/s, namely, a 92.6% weed removal rate with 2.05% seedling damage, meeting operational requirements. This research provides technical and equipment support for interrow weeding.

摘要

针对大田玉米株间除草难度大、伤苗率高的问题，设计了一种基于作物株距信息识别的杂草清除机。依据车速信息变化间隔拍摄作物图像，通过图像拼接与骨架提取获取玉米苗质心坐标，结合像素坐标系与实际坐标系之间的转换原理计算出两作物实际株距，控制系统根据株距信息实时控制除草装置；对关键部件除草装置进行设计分析，分析除草运动轨迹，明确影响运动轨迹的关键参数。在设计分析的基础上进行田间试验，试验结果表明，当前进速度为0.45m/s时，除草效果较好，除草率为92.6%，伤苗率为2.05%，满足作业要求，该研究可为株间除草提供技术和装备支撑。

INTRODUCTION

Weeds compete with crops for nutrients and space for growth, severely affecting crop yield and quality (Uehleke et al., 2024; Zheng et al., 2024). Efficient weed control is a key link in agricultural production. At present, field weeding is performed via three main methods: manual weeding, chemical weeding, and mechanical weeding (Wang et al., 2021). Manual weeding is characterized by a high labor intensity, low efficiency, and high operating costs (Fang et al., 2022); chemical weed control poses problems such as environmental pollution and harm to the health of workers (Ji et al., 2023); and mechanical weeding has the advantages of reduced labor and high efficiency and is an inevitable choice for the development of modern agriculture (Lai et al., 2023). Improving the accuracy of crop center distance recognition in field operation environments is a key prerequisite for achieving interplant weed control operations.

Domestic and foreign scholars have conducted extensive research on interplant mechanical weed control for field crops. Pérez Ruiz et al. (2014) designed an interplant weed control device with a cylinder-driven opening and closing for hoes, which requires human-machine collaboration. Jiao et al. (2023) developed a device for weed control between rows in paddy fields and conducted field experiments.

Quan et al. (2021) designed a weed control mode based on corn root protection to address the problem of crop root damage in weed control with mechanical actuators. They also designed an intelligent plant weed control robot system to detect corn seedlings and weeds through YOLOv4 and conducted field experiments. The above research yielded several useful conclusions, but owing to issues such as work speed and performance limitations, there are currently no mature products available on the market (Xing et al., 2022).

A crop center recognition method is proposed to address the problems of high computational complexity and low efficiency in intelligent weed control algorithms. The proposed method uses machine vision to obtain the crop centroid and coordinate system transformation to obtain the actual distance between two crops. Image stitching technology is used to continuously obtain crop plant distance information, and the control system controls the rotation speed of the weed control device in real time on the basis of the plant distance information, thereby achieving interplant weed control in corn fields.

MATERIALS AND METHODS

Structure and working principle of the weed removal machine

The overall structure of the machine, which is shown in Figure 1, includes a self-propelled chassis, industrial cameras, weed control devices, etc. The overall structure is based on the self-propelled chassis, and the weed control device is installed at the lower middle position of the chassis.

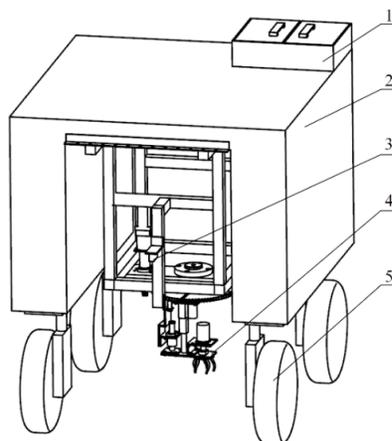

Fig. 1 - Structural diagram of the weed control device test prototype

1. Control system; 2. Self-propelled chassis; 3. Industrial camera; 4. Weed removal device; 5. Wheel hub motor

Table 1

Main technical parameters of the weed removal device

Parameters	Value
Size of whole machine (lengthxwidthxlength)/(mmxmmxmm)	1,000x800x400
Power/kW	25.2
Work speed/(m/s)	0.45
Control width/mm	240
Speed range of the weed removal device/(r/min)	30-40

Identification and localization methods for corn sprouts

The overall structure of algorithm used in the weed removal and machine plant spacing recognition system is shown in Figure 2. Plant images are taken at intervals on the basis of vehicle speed information, and a feature point matching mechanism and the fusion of different frequency bands are used to preserve details for image stitching. According to traditional machine vision methods, the image is processed, and the plant centroid is obtained by refining the skeleton and comparing the skeleton intersection points with the contour centroid. Finally, the plant spacing information is obtained by converting between the global coordinate system and the pixel coordinate system.

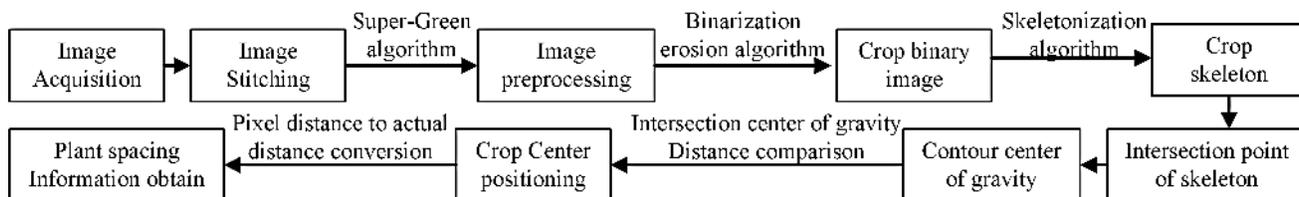

Fig. 2 - Overall algorithm structure

Original image acquisition

By continuously capturing images of seedlings through a vehicle-mounted industrial camera and adjusting the shooting time according to changes in vehicle speed, plant images are obtained, as shown in Figure 3.

Fig. 3 - Example seedling images captured with the device's camera

Image mosaicking

The scale-invariant feature transform (SIFT) algorithm is used to detect key points in the images and generate scale-invariant and rotation-invariant descriptors. A BFMatcher object is created, the KNN-Match method is utilized to match the feature descriptors between two images, the parameter $K=2$ is set, and the Euclidean distance for each feature point is returned.

$$d = v_1, v_2 = \sqrt{\sum_{i=1}^{128} v_{1i} - v_{2i}^2} \tag{1}$$

Here, v_1 and v_2 are 128-dimensional SIFT descriptor vectors.

A ratio test is applied to filter reliable matching points if the first-best match distance d_1 and the second-best match distance d_2 of a feature point satisfy:

$$\frac{d_1}{d_2} < 0.75 \tag{2}$$

In this case, the match is considered valid. Figure 4 shows the process of stitching two images together.

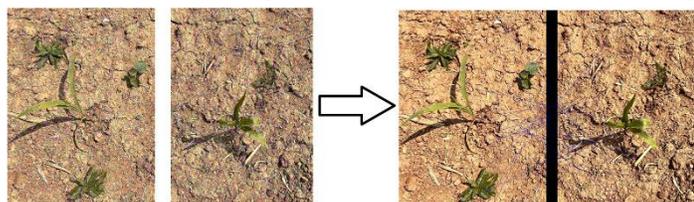

Fig. 4 - Stitching of two images

a. Feature points; b. Feature point matching

The homography matrix H is computed by matching point pairs, and the second image is projected to the coordinate system of the first image.

The homography transformation is defined as follows:

$$\begin{bmatrix} x' \\ y' \\ 1 \end{bmatrix} = H \begin{bmatrix} x \\ y \\ 1 \end{bmatrix} = \begin{bmatrix} h_{11} & h_{12} & h_{13} \\ h_{21} & h_{22} & h_{23} \\ h_{31} & h_{32} & h_{33} \end{bmatrix} \begin{bmatrix} x \\ y \\ 1 \end{bmatrix} \tag{3}$$

The optimal homography matrix H is iteratively estimated via the RANSAC algorithm by minimizing the reprojection error, defined as:

$$\arg \min_H \sum_i \|x_i - Hx_i\|^2 \tag{4}$$

After alignment is complete, the second image undergoes perspective rotation to match the angular orientation of the first image. The final image stitching result is shown in Figure 5.

Fig. 5 – Result of image stitching

Image preprocessing

Figure 6 shows the image preprocessing process for a single crop. The collected images are preprocessed via an ultragreen algorithm and area threshold segmentation. The corrosion algorithm is used for weed and plant seedling recognition, weed images are removed, and agricultural plant seedling images are extracted.

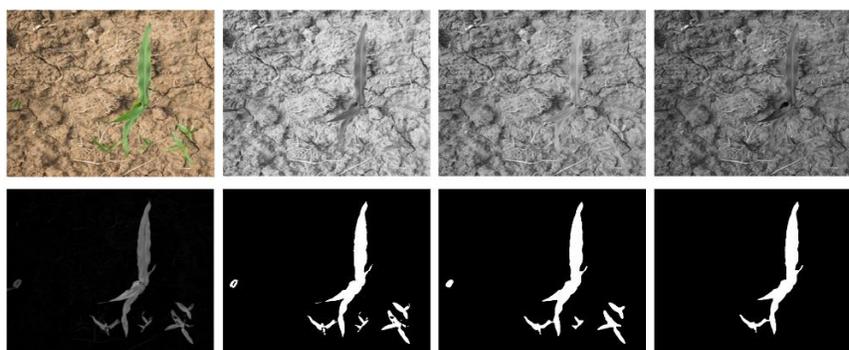

Fig. 6 - Image preprocessing

a. Original image; b. blue channel; c. green channel; d. red channel; e. excess green (ExG); f. binarization; g. morphological opening/closing; h. area threshold segmentation

Skeletonization

The principle of skeleton refinement is shown in Figure 7. First, the image is converted into a binary image by setting a threshold to retain only the contour regions of crop seedlings. The contour information is extracted via the findContours function in the OpenCV library, and the bounding box of each contour is calculated with its center coordinates expressed as:

$$c_x, c_y = \left(\frac{x_{\min} + x_{\max}}{2}, \frac{y_{\min} + y_{\max}}{2} \right) \tag{5}$$

where $(x_{\min}, x_{\max}, y_{\min}, y_{\max})$ are the extreme coordinates of the contour’s bounding box

Starting from the center, the radius is iteratively expanded in increments of ΔR to verify the tangency condition between the circle and the contour.

$$\sum_{(x,y) \in \partial M} \delta \left(\sqrt{x - c_x^2 + y - c_y^2} - R_k \geq 2 \right) \tag{6}$$

In the equation, δ represents the Dirac delta function, which is applied to determine the number of points on the contour where the distance equals the current radius R_k . At least two points must satisfy the tangency condition for this criterion to hold.

The process is further refined via the Zhang–Suen thinning algorithm (Wu et al., 2022) to iteratively erode edge pixels layer by layer, preserving a single-pixel skeleton. The pixel deletion conditions of the algorithm are as follows:

$$\begin{cases} N_p = \sum_{i=1}^8 p_i \text{ (Total number of pixels in the domain)} \\ B_p = \sum_{i=1}^8 |p_i - p_{i+1}| \text{ (Number of boundary transitions)} \end{cases} \quad (7)$$

If the following conditions are met,

$$2 \leq N(p) \leq 6 \text{ and } B(p) = 2 \quad (8)$$

the pixel p is deleted to preserve the centerline. All circles within the contour are detected, and their center coordinates are connected to ensure that the skeleton maintains a single-pixel width. The trajectory formed by linking these circle centers constitutes the crop contour skeleton.

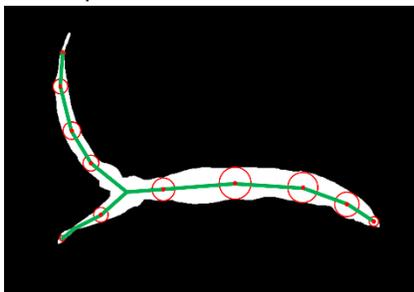

Fig. 7 - Skeleton thinning

Crop contour centroid acquisition

The matching process combines skeleton junction points and contour centroids. For each pixel $p(x,y)$ in the skeleton image, its 8 neighborhood pixels are examined, and the neighborhood coordinates are defined as:

$$\begin{cases} d_x = -1, 0, 1, 1, 1, 0, -1, -1 \\ d_y = 1, 1, 1, 0, -1, -1, -1, 0 \end{cases} \quad (9)$$

with 8-neighborhood traversal in a clockwise order.

A pixel p is identified as a junction point if its neighborhood contains at least three skeleton pixels. The mathematical condition is defined as follows:

$$\sum_{i=1}^8 S_{x+d_{xi}, y+d_{yi}} \geq 3 \quad (10)$$

In the equation, $S(x,y)$ represents the pixel value of the skeleton image at coordinates (x,y) , where 1 denotes the skeleton and 0 corresponds to the background.

The centroid coordinates (c_x, c_y) of the contour are calculated via image moments via the following formula:

$$c_x = \frac{M_{10}}{M_{00}}; c_y = \frac{M_{01}}{M_{00}} \quad (11)$$

where the image moment M_{pq} is defined as:

$$M_{pq} = \sum_x \sum_y x^p y^q I_{x,y} \quad (12)$$

In the equation, $I(x,y)$ represents the binary image, M_{00} corresponds to the contour area, and M_{10} and M_{01} are the first-order moments.

The skeleton junction point closest to the contour centroid is selected as the stem centroid. The Euclidean distance is calculated as follows:

$$d^* = \min_{x,y \in \text{set of Intersection Points}} \sqrt{(x_i - c_x)^2 + (y_i - c_y)^2} \quad (13)$$

The final localization result is illustrated in Figure 8.

Fig. 8 - Identification results for individual seedlings

a. Skeleton refinement results; b. junction points of the skeleton; c. contour centroid; d. plant centroid positioning results

Acquisition of plant spacing information

The camera is calibrated to obtain the intrinsic parameter matrix, which includes the focal length (f_x, f_y) and the principal point (C_x, C_y). The camera intrinsic parameter matrix is expressed as:

$$Z = \begin{bmatrix} f_x & 0 & C_x \\ 0 & f_y & C_y \\ 0 & 0 & 1 \end{bmatrix} \tag{14}$$

The centroid pixel coordinates of two corn plants are converted into coordinates in the image coordinate system. This conversion is based on the camera's intrinsic matrix and requires subtracting the principal point coordinates from the x and y values of the pixel coordinates and then dividing by the focal length to obtain the u and v values in the image coordinate system.

$$\begin{cases} u = \frac{x - C_x}{f_x} \\ v = \frac{y - C_y}{f_y} \end{cases} \tag{15}$$

where (x, y) represents the centroid's pixel coordinates and (u, v) represents the coordinates in the image coordinate system.

Furthermore, given that the depth information for the camera in the corn field is d , with d , the points in the image coordinate system are converted into points in the camera coordinate system, and the actual distance between the two corn plants in three-dimensional space is calculated. The coordinate calculation formula in the camera coordinate system is as follows:

$$\begin{cases} X = u \cdot d \\ Y = v \cdot d \\ Z = d \end{cases} \tag{16}$$

where d represents depth information, which is the distance from the camera to the corn plants in the vertical direction.

The actual distance between two corn plants is calculated via the distance formula between two points in three-dimensional space:

$$D_L = \sqrt{X_2 - X_1^2 + Y_2 - Y_1^2 + Z_2 - Z_1^2} \tag{17}$$

where (X_1, Y_1, Z_1) and (X_2, Y_2, Z_2) are the global coordinate sets of two adjacent seedlings.

The final positioning result is shown in Figure 9.

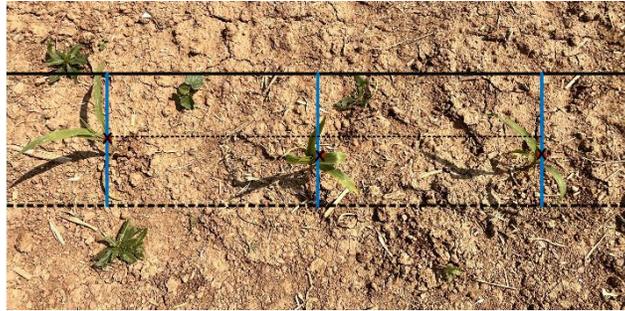

Fig. 9 - Results of interplant seedling identification and localization

Design and analysis of weeding devices

Weeding device design

The weeding device consisted of a support frame, a power transmission device, and a gear set, as shown in Figure 10. The weeding device is attached to the support frame, with the power transmission device acting as the core power provider for the weeding device. Power is transmitted to the small gear via coupling, and the small gear drives the large gear to rotate. The control system, which is based on the plant spacing information from the recognition system and the forward speed, controls the rotation speed of the weeding device in real time. Under the combined action of the rotation of the weeding device and the movement of the self-propelled chassis, the weeding tines form a cycloid trajectory on the ground (Huang *et al.*, 1979), ensuring that the center of the crop canopy is located at the center of a single cycloid trajectory, thus weeding without damaging the seedlings.

Weed removal trajectory analysis

The maximum major axis value L (defined as the distance between points A and B) and the maximum minor axis value S (defined as the distance between points C and D) were set to approximately 1. This configuration enabled effective prevention and removal of interrow weeds, and the trajectory variation of the cutting tool was the primary focus of the optimization analysis.

Optimization of parameter L

As shown in Figure 11, assuming that the intersection point of circle O and the y -axis is F , a perpendicular extension line passing through point F intersects the cycloid at point E , and a perpendicular extension line passing through point E intersects the x -axis at point E' . If the time taken for point E to complete a rotation is t , according to the theory of cycloids, the time required for point B to rotate is the same as that of point B' , and the time required for point B' to rotate is $t/2$.

Thus, it can be obtained:

$$t = \frac{2\pi R}{\lambda u_x} \Rightarrow \frac{t}{2} = \frac{\pi R}{\lambda u_x} \tag{18}$$

where t - rotation time of point F around the circle, [s];
 R - the radius of circle O , [mm];
 λ - the ratio of forward speed u to rotational speed v ;
 u_x —velocity of circle O in the x-axis direction, [m/s];

The abscissa value of point B is the same as that of point A' ; therefore,

$$l_{OA'} = u_x \frac{t}{2} = u_x \frac{\pi R}{\lambda u_x} = u_x \frac{\pi R}{\lambda} \tag{19}$$

The intersection circle O of BO and AO is connected to two points D and C . Let the arc length CK be l_1 and the arc length KD be l_2 . From the arc length formula, it can be obtained:

$$l_1 = \theta_1 R \Rightarrow \theta_1 = \angle COK = \frac{l_1}{R}, \left(0 < \theta_1 < \frac{\pi}{2}\right), \quad l_2 = \theta_2 R \Rightarrow \theta_2 = \angle KOD = \frac{l_2}{R}, \left(0 < \theta_2 < \frac{\pi}{2}\right) \tag{20}$$

According to the Pythagorean theorem:

$$AA' = l_{OA'} \cdot \tan \theta_1 = l_{OA'} \cdot \tan \left(\frac{l_1}{R}\right); \quad A'B = l_{OA'} \cdot \tan \theta_2 = l_{OA'} \cdot \tan \left(\frac{l_2}{R}\right) \tag{21}$$

Then,

$$AB = l_{OA'} \tan \theta_1 + \tan \theta_2 = l_{OA'} \left(\tan \left(\frac{l_1}{R}\right) + \tan \left(\frac{l_2}{R}\right) \right) \tag{22}$$

where

$$l_{OB} = \sqrt{l_{OA'}^2 + l_{OA'}^2 \tan^2 \theta_2} = \sqrt{l_{OA'}^2 (1 + \tan^2 \theta_2)}; \quad l_{OA} = \sqrt{l_{OA'}^2 + l_{OA'}^2 \tan^2 \theta_1} = \sqrt{l_{OA'}^2 (1 + \tan^2 \theta_1)} \tag{23}$$

Let $\theta_1 + \theta_2 = \theta_J$, ($0 < \theta_J < \pi$), and $AB=L$. According to the sine theorem:

$$L = \frac{l_{OB}}{\sin 90^\circ + \theta_2 - \theta_J} \tag{24}$$

Notably, L is an increasing function with respect to θ_J within $(0, \pi/2)$ and a decreasing function with respect to θ_J within $(\pi/2, 0)$.

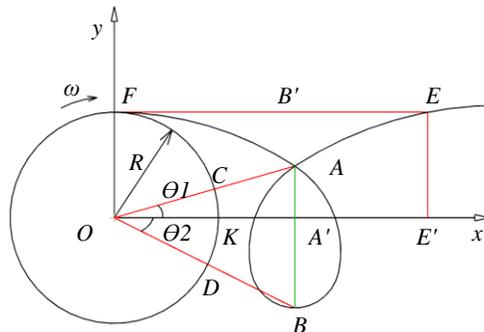

Fig. 11 - Optimization of parameter L

Optimization of parameter S

As shown in Figure 12, from $\omega t = \theta$ and $x = vt + R \sin \omega t$, it can be obtained:

$$x = \frac{v}{\omega} \theta + R \sin \theta \tag{25}$$

With respect to x , the derivative of θ is obtained:

$$\frac{dx}{d\theta} = \frac{v}{\omega} + R \cos\theta, \theta_J < \theta < \pi \tag{26}$$

When $dx/d\theta=0$, the extremum is:

$$\cos\theta_{\max} = -\frac{v}{\omega R} \tag{27}$$

$$\theta_{\max} = \arccos\left(-\frac{v}{\omega R}\right), \theta_J < \theta_{\max} < \pi \tag{28}$$

The maximum transverse chord value is as follows:

$$S = 2\left(\frac{v}{\omega}\theta_{\max} + R \sin\theta_{\max} - l\right) \tag{29}$$

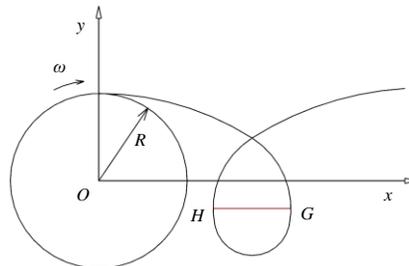

Fig. 12 - Optimization of parameter S

According to formulas (24) and (29), the values of parameters L and S are related to the turning radius, turning speed, and forward speed of the equipment. After image recognition analysis yields the plant spacing value, the turning speed and turning radius are adjusted in a timely manner in combination with the forward speed.

Design principles of the weed control machine control system

The controller detects the distance information between the weeding tines and the ground through a distance sensor and drives the weeding motor to ensure the high-speed rotation of the tines. A speed encoder and the NVIDIA Jetson TX2 microprocessor work in a loop to monitor the chassis travel speed and the crop center distance for the controller. After the relative position information of the seedlings is obtained, the controller adjusts the speed of the weeding device by controlling the stepper motor to achieve precise weeding.

Control system hardware and circuit design

The hardware circuit design of the control system is shown in Figure 13. The hardware circuit consists of encoders, STM32F103 microcontrollers, stepper motors, cameras, NVIDIA Jetson TX2 microprocessors, and other components.

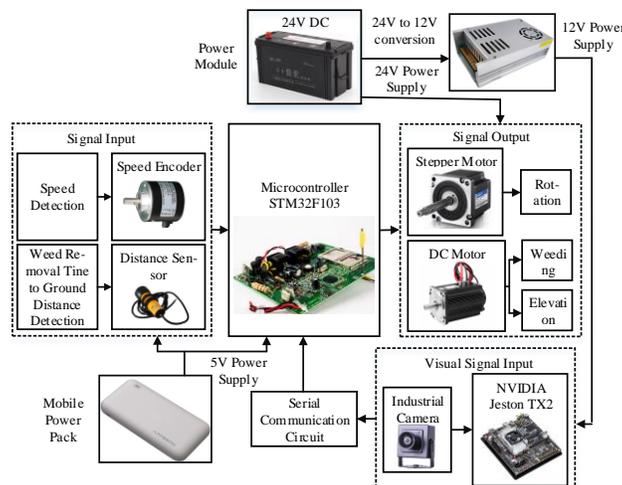

Fig. 13 - Hardware composition of the control system

The working process of the whole machine is as follows: as the chassis advances, the NVIDIA Jetson TX2 microprocessor begins to receive images captured by the camera and recognizes seedlings and weeds. The STM32F103 microcontrollers calculate the center coordinate position of the seedlings and the lateral and longitudinal deviations between the material center and the center of the weeding teeth in the pixel plane. When the seedlings are in the center position of the weeding teeth, the STM32F103 microcontrollers send a start signal to rotate the stepper motor. The microcontroller provides the alpha, beta, and gamma values of the host via a feedback loop on the basis of the recognition image and adjusts the speed of the stepper motor. After the hardware system was assembled, field experiments were conducted to verify the operation of all components of the entire machine.

RESULTS

Experimental conditions

The experiment was conducted on September 8, 2024, at the corn experimental base in Zhangqiu District, Jinan city, using a Nonghaha 2BYQF-3 air suction corn precision seeder with a row spacing of 0.65 meters. For the field performance test, corn seedlings at the 19-day-old and 3-4-leaf stage were selected, with an average stem thickness of approximately 16 mm and a plant height of approximately 25 cm. Five independent experiments were repeated at each forward speed (0.3, 0.4, 0.45, and 0.55 m/s), with a test area length of 16 m. Additionally, the weed control rate and seedling damage rate were recorded for each experiment.

Experimental indicators

In the experiment, weeding efficiency and the seedling damage rate were used as evaluation indicators.

$$P_C = \left(1 - \frac{R_S}{R_H}\right) \times 100\% ; P_D = \frac{R_D}{R_E} \times 100\% \quad (30)$$

In the formula, P_C represents the weed control rate, %; P_D represents the rate of seedling damage, %; R_S represents weeds that have not been removed after interplant weeding; R_H represents the total number of weeds before weeding; R_D represents the number of injured seedlings; and R_E represents the total number of experimental seedlings.

The experiment was set up with three test areas, each 20 m long. The forward speed of the self-propelled chassis was controlled at a constant speed with a remote controller, with the speed settings ranging from low to high. The starting preparation area was 2 m long, and the test area was 16 m long. The weeds in the test area included naturally occurring *Portulaca oleracea*, *Eleusine indica*, *Capsella bursa-pastoris*, etc. (Wang et al., 2021), with the depth of the weed roots being approximately 30 mm. Each test area was marked in advance with prepared signs, and the number of effective corn plants in each area was recorded. The experimental method refers to the "Practical Manual for Field Experiments of Crops," and the field experiment is shown in Figure 14.

Fig. 14 - Experimental scenario

1. Battery; 2. Laptop; 3. Self-propelled chassis; 4. Weeding unit; 5. Hub motor; 6. Weeding tines; 7. DC motor (weeding); 8. Lifting motor (DC); 9. Distance sensor; 10. Gear assembly; 11. Industrial camera; 12. Stepper motor (steering)

Analysis of experimental results

During the bench test analysis of the motion trajectory, a high seedling damage rate was observed. The analysis indicated that the cause was the jerking of the conveyor belt during operation, which led the control system to detect seedlings prematurely, causing a change in the speed of the weeding device and early entry to the weeding area, resulting in seedling damage. In the field test, flat land was chosen, and the self-propelled chassis was moved at a constant speed to avoid the aforementioned situation.

Table 2

Statistics for weeding performance indicators

Test No.	Forward speed/(m/s)	Weeding rate/%	SD (Weeding)	Seedling injury Rate/%	SD (Injury)
1	0.30	91.2 ± 1.5	1.5	2.21 ± 0.18	0.18
2	0.40	91.9 ± 1.2	1.2	2.15 ± 0.15	0.15
3	0.45	92.6 ± 0.9	0.9	2.05 ± 0.10	0.10
4	0.55	90.6 ± 0.9	1.8	2.35 ± 0.25	0.25

The field experiment results (Table 2) revealed that as the advancing speed increased from 0.3 to 0.55 m/s, the weed control rate first increased but then decreased, whereas the seedling damage rate gradually increased. At a speed of 0.45 m/s, the weed removal rate was the highest (92.6%), and the seedling damage rate was the lowest (2.05%). One-way analysis of variance (ANOVA) revealed that different forward speeds had a statistically significant effect on the removal of fast-growing seedlings ($F=4.32$, $p=0.023$) and the seedling injury rate ($F=3.89$, $p=0.035$) ($\alpha=0.05$). Multiple comparisons revealed that the weed control rate at a speed of 0.45 m/s was significantly greater than that in the other groups ($p<0.05$), whereas the seedling injury rate was not significantly different from that in the other groups ($p>0.1$). The variability analysis of the experimental data revealed that the standard deviation range of the weed control rate was 0.9–1.8%, and the standard deviation range of the seedling damage rate was 0.10–0.25%, indicating high repeatability of the control scheme. The coefficients of variation (CVs) at a speed of 0.45 m/s were 1.6% (weed control rate) and 7.8% (seedling damage rate), indicating stable and reliable machine performance under these operating conditions.

CONCLUSIONS

(1) A corn weeding machine was designed to meet the needs of weeding in corn fields. By using a camera to capture images of plants in the field and applying skeleton extraction algorithms and image stitching techniques to obtain real-time distances between plants, the control system accurately controls the speed of the weed control device on the basis of the distance information between plants.

(2) The key components of the weed control device were designed, and the motion trajectory of the cycloid of the weed control device was analyzed. The turning radius, turning speed, and forward speed were determined to be the key parameters affecting weed control.

(3) In field experiments, the chassis moved at a constant speed, and the results revealed that at a travel speed of 0.45 m/s, the weed control effect was good, with a weed control rate of 92.6% and a seedling damage rate of 2.05%, meeting the agronomic requirements for weed control in corn fields.

Future directions and applications:

To further enhance the practicality and impact of the proposed technology, future research could focus on the following tasks:

Algorithm Optimization: Deep learning models (e.g., convolutional neural networks) could be integrated into the proposed approach to improve real-time weed recognition accuracy under complex field conditions, including overlapping foliage and variable lighting.

Multi-crop adaptability: The system could be extended to other row crops (e.g., soybeans and cotton) by adjusting the plant spacing recognition algorithm and mechanical structure to accommodate diverse growth patterns.

These advancements could accelerate the adoption of intelligent weeding systems in sustainable agriculture, thus supporting the transition toward fully automated and eco-friendly farming practices while addressing global challenges related to food security and environmental conservation.

Keywords: agricultural stone picker, spiral cutter drum, EDEM, soil trench test

ABSTRACT

This study aimed to solve the inefficiency and high-energy-consumption problems of current agricultural stone pickers. It introduced a novel spiral cutter tooth design. Dynamic and kinematic analyses determined the key components' parameters and performance-influencing factors. With EDEM software, discrete element simulations using a three-factor, five-level quadratic regression orthogonal design were carried out. Stone-picking efficiency and power consumption were the evaluation metrics. Regression analysis and significance tests clarified the impact of forward speed, drum speed, and tilt angle. Multi-objective optimization of the regression model found the optimal parameters: 0.18 m/s forward speed, 260 rpm drum speed, and 30° tilt angle. Field tests with this setup achieved a 93.71% stone-picking rate and 4.63 kW stable power, validating the design's effectiveness. These results offer a theoretical basis and reference for stone picker design and optimization.

摘要

针对现有农田捡石机捡石效率低, 消耗功率大等问题, 提出了一种螺旋刀齿式农田捡石机, 通过动力学和运动学分析, 确定了关键部件的结构参数和运动参数范围, 以及影响工作性能的主要因素。利用 EDEM 软件开展了离散元仿真试验, 采用三因素五水平二次回归正交旋转中心组合试验方法, 以捡石效率和消耗功率为评价指标, 对机具前进速度、螺旋刀辊转速和螺旋刀辊侧倾角进行回归分析和显著性检验, 明确了各因素对评价指标的影响及主次顺序, 通过对回归模型进行多目标函数优化求解, 得出最佳参数组合为机具前进速度 0.18 m/s、螺旋刀辊转速 260 r/min、螺旋刀辊侧倾角 30°。使用最佳参数组合进行了土槽试验, 试验结果表明: 捡石效率为 93.71%, 稳定作业时的功率为 4.63 kW, 螺旋刀齿式捡石机作业稳定, 满足农田捡石作业要求。

INTRODUCTION

Arable land forms the cornerstone of agricultural development, with soil quality enhancement being paramount for sustainable farming practices (Zhan *et al.*, 2023). In northwestern China's newly developed Gobi farmlands, stony soils present a critical challenge. Elevated stone content restricts root proliferation, exacerbates soil desiccation, reduces seed germination rates, and ultimately compromises crop yields (Yu *et al.*, 2007; Zhang *et al.*, 2024). Furthermore, stone interference during mechanized operations accelerates equipment wear and impedes agricultural modernization.

Current stone removal strategies predominantly employ mechanical methods over manual collection (Li *et al.*, 2024; Bu *et al.*, 2022). Existing machinery—including comb-tooth shovels, tooth rakes, and shovel-chain systems—has been extensively studied. For example, Yu *et al.* developed a chain-tooth stone picker demonstrating high efficiency through dynamic analysis of soil-tool interactions, though limited by shallow excavation depth (Yu *et al.*, 2007). Ma *et al.* (2007) achieved shallow-layer stone removal (≤ 100 mm) using a wheel-tooth rake, yet faced challenges of excessive energy consumption and suboptimal collection rates. Niu *et al.*, (2007), advanced the field with a shovel-sieve design, employing discrete element modeling to analyze stone-soil separation dynamics. While functional, these systems universally exhibit energy inefficiency and inconsistent performance.

Jia Zhang, Assoc. Prof.; Heng Qu, Student; Ping Xiao, Assoc. Prof.; Shaoteng Ma, Lecturer; Weisong Zhao, Lecturer

To address these limitations, a novel spiral cutter tooth stone picker is introduced. Through kinematic analysis of stone-cutter interactions, critical operational parameters governing collection efficiency are identified. EDEM simulations and field trials validate the optimized design, demonstrating enhanced performance while reducing power demands. This work establishes a theoretical framework for advancing stone-picking technology, offering practical insights for agricultural equipment innovation.

MATERIALS AND METHODS

Overall structure and working principle

The spiral cutter tooth stone picker for agricultural fields primarily comprises a frame, gearbox, spiral cutter rollers, cutter teeth, and deflector plates. The spiral cutter rollers are symmetrically mounted on the frame at specific angles on either side, and the cutter teeth are arranged in a double helical line extending outward. The structure is illustrated in Fig 1.

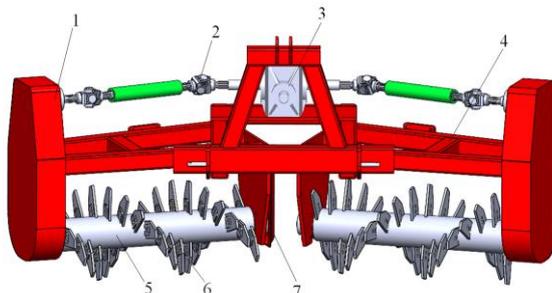

Fig. 1 – Schematic diagram of the overall structure
 1. transmission device; 2. universal shaft; 3. gearbox; 4. frame; 5. spiral cutter rollers;
 6. cutter teeth; 7. deflector plate

During operation, the machine connects to the tractor via a three-point hitch. The tractor provides power that is transmitted through the gearbox to the universal shaft and then through the internal transmission chains of the drive devices on both sides to the spiral blade roller. The rotational speed of the spiral blade roller aligns with the forward direction of the machine, effectively lifting stones from the surface and from certain soil depths. The lifted stones are conveyed toward the center, where the inner guide plates on the frame align them into rows, completing the stone-picking process. This machine not only picks stones but also tills and effectively loosens the soil. A schematic of the stone picker operation is shown in Fig. 2, and the main technical parameters are listed in Table 1.

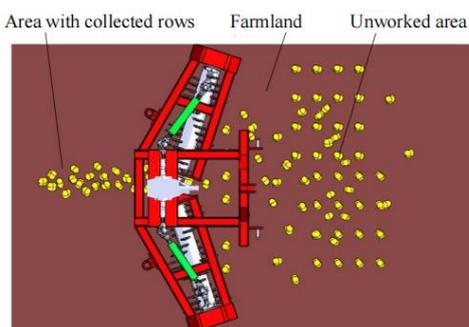

Fig. 2 – Schematic diagram of the operating principle of the stone picker

Table 1

Main technical parameters of the stone picker	
Parameter	Value
Connection type	Suspension type
Overall dimensions (lengthxwidthxheight) (mm)	2500x1105x1210
Working width (mm)	2100
Working depth (mm)	55
Spiral blade roller speed (r/min)	150~350
Traction power (kW)	≥40

Tooth structure design

The installation type of the teeth significantly affects the performance of the stone picker. Depending on the angle between the tangent at the point of contact between the tooth blade and the tooth shaft, the teeth can be classified as radial, forward-leaning, or backward-leaning. A force analysis is conducted at initial contact with the stone and when the stone is lifted off the ground for various tooth types to compare their effectiveness in stone picking. The force analysis for the three types of teeth is illustrated in Fig 3.

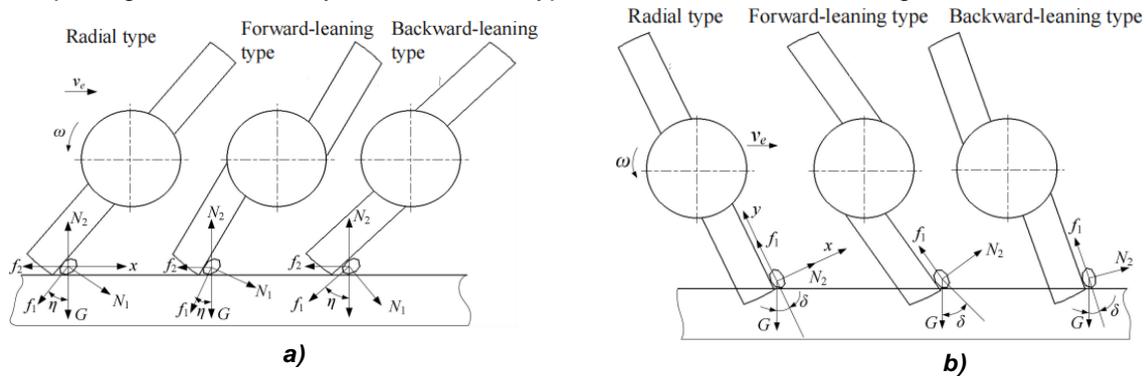

Fig. 3 – Force analysis of stones during operation

a) Force analysis of the stone at initial contact with the tooth; b) Force analysis of the stone during lifting by the tooth

As shown in Figure 3a, a coordinate system is established with the center of the stone as the origin, where the x-axis is parallel to the ground and the y-axis is perpendicular to it. When the tooth contacts the stone, there is no vertical movement relative to the ground; instead, the stone primarily undergoes horizontal displacement. The velocity along the x-axis is determined by the horizontal resultant force. The expression for this resultant force is given by:

$$F_{xa} = N_1 \cos \eta - f_1 \sin \eta - f_2 \tag{1}$$

where:

F_{xa} is the resultant force of the tooth in the horizontal direction, [N]; N_1 is the support force exerted by the tooth on the rock, [N]; η is the angle of entry into the soil, [°]; f_1 is the frictional force of the tooth on the rock, [N]; f_2 is the frictional force of the ground on the rock, [N]; G is the gravitational force of the rock, [N].

The derivative of equation (1) yields:

$$F'_{xa} = -N_1 \sin \eta - f_1 \cos \eta \tag{2}$$

where:

$$\eta < \pi/2 \tag{3}$$

This resultant force is derived from equations (2) to (3). The analysis reveals that as the entry angle η increases, the horizontal resultant force F_{xa} decreases, reducing the tooth's tendency to move forward at initial contact with the stone. Therefore, the preferred sequence for selecting tooth types is: forward-leaning, radial, and backward-leaning.

As shown in Figure 3b, a coordinate system is established with the center of the stone as the origin, where the direction perpendicular to the tooth contact surface serves as the x-axis and parallel to it serves as the y-axis. At the moment the tooth lifts the stone off the ground, no force is exerted on the stone by the ground. At this instant, the velocity in the direction perpendicular to the tooth contact surface is determined by the resultant force in that direction. The expression for the vertical resultant force acting on the working surface of the tooth is as follows:

$$F_{xb} = N_1 - G \sin \delta \tag{4}$$

where:

F_{xb} is the resultant force of the tooth in the direction perpendicular to the contact surface, [N]; δ is the angle of extraction from the soil, [°].

The derivative of equation (4) yields:

$$F'_{xb} = -G \cos \delta \tag{5}$$

where:

$$\delta < \pi/2 \tag{6}$$

Analysis of equations (5) to (6) reveals that as the extraction angle increases, the horizontal resultant force along the x-axis decreases, resulting in a reduced tendency for the stone to be lifted off the ground and diminishing the effectiveness of stone picking. When lifting the stone off the ground, the preferred sequence for selecting tooth types is: backward-leaning, radial, and forward-leaning teeth.

Balancing overall performance, radial teeth excel in continuously moving stones forward compared to backward-leaning teeth and are more effective in lifting stones off the ground than forward-leaning teeth. Therefore, selecting radial teeth maintains the stability of stone picking operations and can enhance the operational efficiency of the stone picker.

To facilitate the replacement of worn teeth, the teeth are designed to be detachable. The base of each tooth is curved to match the spiral blade roller, which enhances operational stability. To reduce soil resistance against the teeth, they are designed with a trapezoidal shape and sharpened tips. As shown in Fig. 4, the sharpened teeth have a reduced contact area at the tip, which lowers resistance during soil entry, enhances penetration ability, and reduces energy loss during contact (Gao *et al.*, 2023). When the tooth lifts the stone from the ground, the sharpened teeth cause the stone's weight and the angle of contact along the surface to decrease. Analysis of equations (5) and (6) shows that the sharpened teeth enhance the tendency to lift the stone off the ground along the tooth's vertical contact surface, thereby improving the stone-throwing effect.

The depth of stone extraction in farmland typically ranges from 0 to 50 mm below the surface; therefore, the chosen penetration depth for the teeth is set at 55 mm. The average profile length of stones is about 90 mm. To avoid excessive torque and power consumption from overly long teeth and inadequate stone-picking performance from overly short teeth, the length of the teeth is set at 140 mm. The diameter of the spiral blade roller is determined based on factors such as depth of penetration, size, and arrangement of the teeth. Considering all factors, the working diameter of the teeth (D) is set at 430 mm, while the diameter of the spiral blade roller (d) is 75 mm.

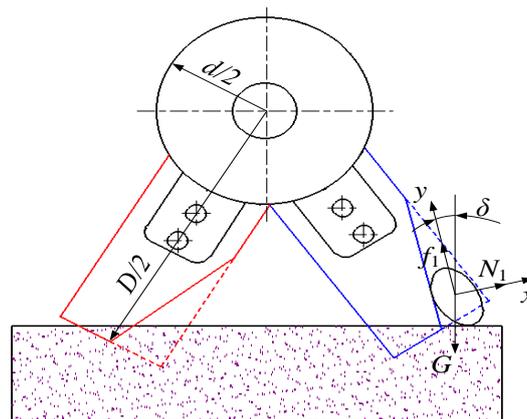

Fig. 4 - Comparison of tooth design before and after optimization

Design of tooth arrangement

An appropriate tooth arrangement can significantly enhance the stone-picking rate of the machine and reduce the occurrence of missed stones. Drawing on the principles of spiral cover implements (Zheng *et al.*, 2021; Yang *et al.*, 2023), the teeth are arranged in a spiral pattern. Increasing the number of spiral lines reduces the rotational speed of the spiral blade roller, which decreases the velocity and kinetic energy exerted on the stones, thus reducing their tendency to be thrown from the ground. To avoid issues such as excessively high rotational speeds with a single spiral head, excessive power consumption, and poor stone-picking performance with multiple spiral heads, a dual spiral line arrangement is employed.

Stones with a maximum profile length exceeding 50 mm can adversely affect crop growth; therefore, the spacing between two adjacent teeth on the spiral blade roller is set at 50 mm, and the pitch is set at 800 mm. The spiral rise angle (α) is calculated using formula (7) to be 30.5° . The spiral blade rollers on the left and right sides are installed in opposite directions, forming a symmetrical structure. An illustrative diagram of tooth installation and arrangement is shown in Fig. 5.

$$\alpha = \arctan \frac{P}{\pi d} \quad (7)$$

where:

α is the angle of the spiral ascent, [$^\circ$]; P is the pitch, [mm].

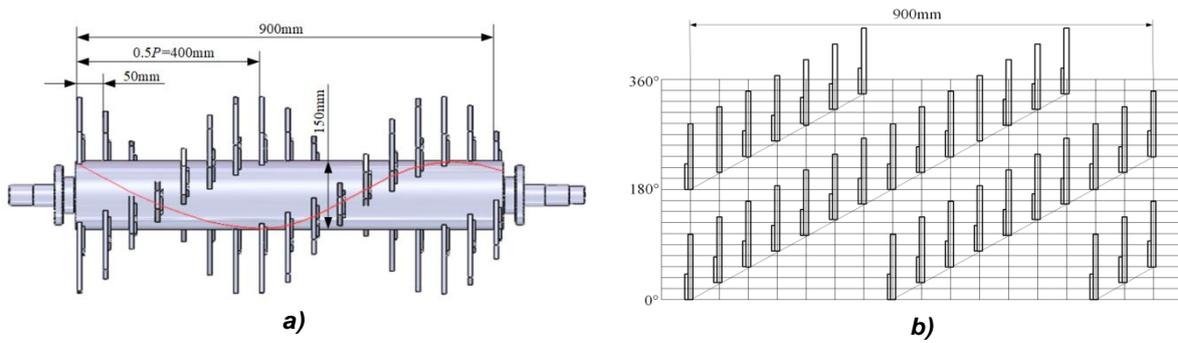

Fig. 5 – Schematic diagram of tooth installation and arrangement
 a) Tooth installation diagram; b) Double-helix arrangement diagram

Kinematic analysis of the tooth stone-picking process

When the stone picker moves at a uniform speed, the teeth rotate synchronously with the spiral blade roller. For analytical convenience, a spatial coordinate system O_{xyz} is established, as shown in Fig. 6. Here, the angle between the spiral blade roller and the x -axis is referred to as the side tilt angle γ . The x -axis indicates the direction of stone clearing, the y -axis is the forward direction of the equipment, and the z -axis is perpendicular to the ground. Using the centroid of the stone as the origin O_1 the component velocities of the tooth tip along the x , y , and z axes are as follows:

$$\begin{cases} v_x = R\omega \sin(\omega t) \sin \gamma \\ v_y = v_e + R\omega \sin(\omega t) \cos \gamma \\ v_z = R\omega \cos(\omega t) \end{cases} \quad (8)$$

where:

$$\omega = 2\pi n / 60 \quad (9)$$

v_e is the forward speed of the machinery, [m/s]; ω is the angular velocity of the spiral cutting roller, [rad/s]; n is the rotational speed of the spiral cutting roller, [r/min]; R is the radius of rotation of the tooth, [mm]; γ is the inclination angle of the spiral cutting roller, [°].

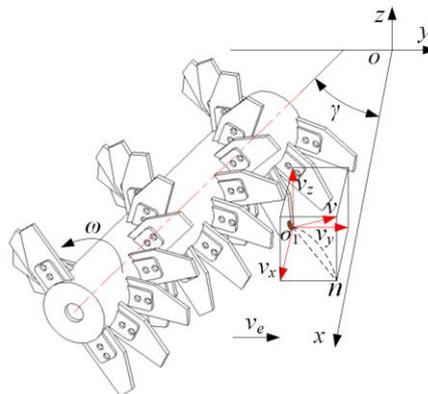

Fig. 6 – Kinematic analysis of the tooth

In the coordinate system O_{1xyz} , the absolute velocity of the tooth tip can be derived from equation (8):

$$|v| = \sqrt{v_x^2 + v_y^2 + v_z^2} = \sqrt{v_e^2 + R^2\omega^2 + 2v_eR\omega \sin(\omega t) \cos \gamma} \quad (10)$$

Based on equations (8) to (10), the factors affecting the absolute velocity of the tooth include the forward speed of the equipment v_e , the rotational speed of the spiral blade roller n , and the side tilt angle γ of the spiral blade roller. When the side tilt angle γ exceeds 45° , the lateral force on the tooth increases, making it prone to bending and damage, which reduces the effectiveness of the stone-picking operation. Therefore, the side tilt angle γ should be less than 45° . Since the lateral velocity v_{xy} and the dislodging velocity v_{yz} of the tooth directly affect the stone dislodgement distance and the soil disturbance coefficient (Yao *et al.*, 2022), the range for the side tilt angle γ is chosen to be between 20° and 40° . The operational process must ensure that the absolute velocity of the tooth is greater than the forward speed of the equipment v_e . The field operational speed of the stone picker v_e is set between 0.1 and 0.5 m/s. Through pre-experimental analysis, it was found that the stone-picking effect is optimal when the rotational speed n of the spiral blade roller is between 150 and 350 r/min.

Discrete element simulation analysis

EDEM simulation modeling

Establishing a realistic stone model is crucial for ensuring the accuracy of simulation data. Stones found in fields are typically rod-shaped, block-shaped, or slab-shaped, with particle sizes related to their shapes and contour lengths. Based on data from basic soil and stone experiments, stone particles are modeled using multi-sphere representations in the discrete element software. The average profile length is set at 90.0 mm, with stone sizes ranging from 50.0 mm to 120.0 mm. The size distribution parameter settings vary from 0.56 to 1.30, with a representative stone model illustrated in Fig. 7.

Fig. 7 – Discrete element model of the stone

During the operation of the stone picker, various contacts occur among tooth-soil particles, tooth-stone particles, soil-soil particles, soil-stone particles, and stone-stone particles. By combining initial parameter calibration with relevant literature, the physical and mechanical parameters of materials and the contact coefficients are determined (Deng et al., 2022; Chen et al., 2024; Hao et al., 2023). The mechanical characteristic parameters for each material particle, along with the contact coefficients for other objects, are detailed in Tables 2 and 3. The simulation models for soil-soil and soil-stone contacts are based on the Hertz-Mindlin with JKR model, while the Hertz-Mindlin (no slip) model is used for other contact types (Li et al., 2022; Shi et al., 2024; Zhang et al., 2022).

Table 2

Item	Parameter	Value
Stone-Tooth	Coefficient of restitution	0.2
	Static friction coefficient	0.5
	Dynamic friction coefficient	0.01

To simplify the EDEM simulation computation and considering the symmetry of the entire machine with no mutual influence, the simulation focuses solely on one side. The length of the single spiral blade roller is reduced to 530 mm and features 0.65 turns. A virtual soil trough model is established with dimensions of 1500 mm (length) × 1100 mm (width) × 160 mm (height). Due to the large size of the soil trough, soil particles are modeled as single spheres with a radius of 5 mm, while stones are placed on the surface of the soil.

Simulation parameter settings

Using SolidWorks software, the model is created to scale and saved in .stp format for import into EDEM for preprocessing, as shown in Fig. 8. The spatial coordinates of the initial motion state are aligned with those of the soil trough model. The penetration depth is set to 55 mm, along with the correct rotation direction, angular velocity, machine advance direction, and forward speed. Based on the forward speed, the simulation time is set, with a mixing timestep of 20% and a target save interval of 0.01 s.

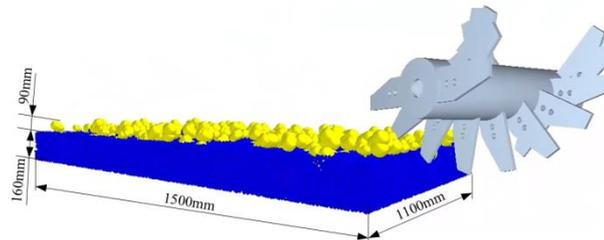

Fig. 8 – Modelling of stone-soil-knife-tooth interactions

Experimental design and methods

The method employed is a three-factor, five-level second-order regression orthogonal rotation central composite design. The experimental factors include the machine's forward speed, the rotational speed of the spiral blade roller, and the side tilt angle of the spiral blade roller, with the stone-picking rate and power consumption as the experimental indicators. The coding of the experimental factors is presented in Table 4.

Table 4

Experimental factors and codes

Coded Values	Factors		
	Forward speed/ (m·s ⁻¹)	Roller speed/ (r·min ⁻¹)	Roller side tilt angle/ (°)
1.682	0.5	350	40
1	0.42	321	36
0	0.3	250	30
-1	0.18	179	24
-1.682	0.1	150	20

Determination of Stone-Picking Rate: The stone-picking rate Y_1 is calculated using the Selection module in EDEM's post-processing analysis options. This module outputs the number of stones within the grid area before and after operation, as illustrated in Fig. 9. The formula for calculating the stone-picking rate Y_1 is as follows:

$$Y_1 = \left(1 - \frac{W_1}{W}\right) \times 100\% \tag{11}$$

where: W is the number of rocks in the soil trench before operation; W_1 is the number of rocks missed in the soil trench after operation.

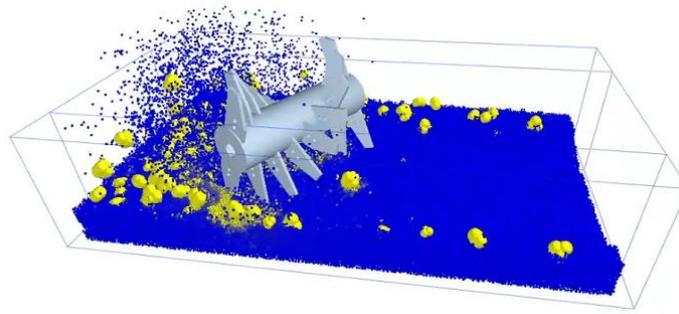

Fig. 9 – Simulation of the stone picker's operational process

Determination of Power Consumption: After the simulation is complete, torque data is exported using the EDEM post-processing module. The power consumption Y_2 of the spiral blade roller is calculated using the following formula:

$$Y_2 = P = \frac{T \times n}{9550} \quad (12)$$

where:

P is consumed power [kW]; T is the average torque of the spiral knife roller during operation [N·m].

Soil trough experiment

To validate the accuracy of the discrete element simulation results and the performance of the optimized stone picker, an indoor soil trough experiment was conducted on August 1, 2024, at the Key Laboratory of Intelligent Equipment at Xinjiang Agricultural University. The equipment used included the TCC-III computer-monitored soil trough test vehicle, stones, the spiral tooth-type stone picker, and a measuring tape.

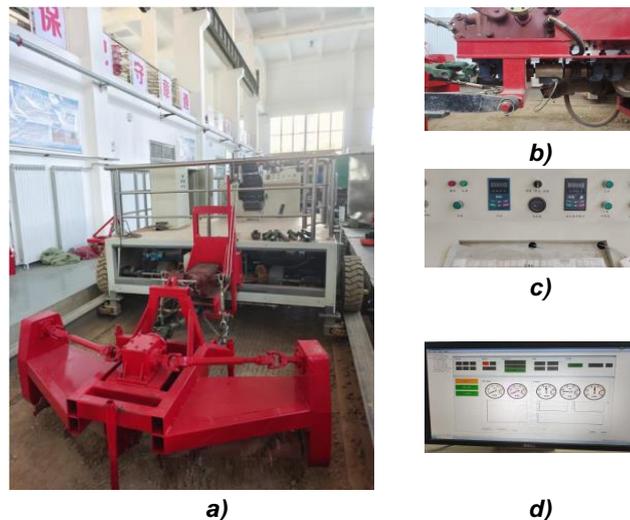

Fig. 10 – Soil trench test

a) Experimental prototype; b) Power monitoring sensor; c) Parameter adjustment system; d) Data monitoring system

The equipment was connected to the soil trough test vehicle via a three-point hitch. The experimental setup is shown in Fig. 10. The trough contained original sandy soil, with stones randomly placed on the 2m×10m soil surface before operation. Soil moisture and compaction were measured using a soil moisture meter and a soil compaction tester. The results indicated a soil moisture content of 12.7% and a compaction of 4094.57 kPa. Based on the simulation results, the experimental conditions were set as follows: roller speed $n=260$ r/min, forward speed $v_e=0.18$ m/s, tilt angle of 30° , and a working depth of 55 mm for a travel distance of 10 m in the soil trough.

RESULTS

Analysis of simulation experiment results

A total of 20 experiments were conducted, with the results presented in Table 5, where X_1 , X_2 and X_3 represent the coded values of the experimental factors.

Table 5

Experimental design and results					
Test No.	Factors			Response Value	
	X ₁	X ₂	X ₃	Y ₁ /%	Y ₂ /%
1	-1	-1	-1	87.27	2.17

19	0	0	0	93.66	3.45
20	0	0	0	93.27	3.92

The experimental data were processed using Design-Expert 13.0 to perform regression analysis and significance testing on the simulation results. Based on the analysis of variance (ANOVA), model significance, lack of fit, and correlation were evaluated, with results presented in Table 6. The ANOVA results indicate that both regression models for the stone-picking rate and power consumption are significant ($P < 0.01$), while lack-of-fit terms are non-significant ($P > 0.05$), demonstrating a good fit of the regression model equations. Thus, these models can be effectively used for the analysis and optimization of the experimental indicators. The order of influence of each factor on the stone-picking rate is as follows: machine forward speed, spiral blade roller rotational speed, and side tilt angle. For power consumption, the order of influence is: spiral blade roller rotational speed, side tilt angle, and machine forward speed. An F -test at a 0.05 confidence level was conducted, with non-significant terms removed to obtain the final regression model as follows:

$$\begin{cases} Y_1 = 92.68 - 2.53X_1 + 2.39X_2 + 1.69X_3 - 1.07X_1X_2 - 0.33X_1^2 - 1.05X_2^2 - 1.39X_3^2 \\ Y_2 = 3.74 + 0.78X_1 + 1.26X_2 + 0.93X_3 + 0.19X_1X_2 + 0.15X_1^2 + 0.84X_2^2 + 0.27X_3^2 \end{cases} \quad (13)$$

Response surfaces were created to illustrate the effects of interactions among factors on the stone-picking rate and power consumption. Fig. 11a shows that, at a central level of the spiral blade roller's side tilt angle, the stone-picking rate is positively correlated with both the forward speed and the rotational speed of the spiral blade roller. When the roller's rotational speed is constant, an increase in forward speed results in a decrease in the lateral push speed of the tooth, which may prevent stones from being directed to one side within a limited distance. This increases the likelihood of missed stones and reduces the picking rate. Conversely, at a constant forward speed, increasing the roller speed enhances the lateral displacement of the stones and the frequency of stone lifting per unit time, thereby increasing the stone-picking rate.

Fig.11b indicates that, at a central tilt angle and constant forward speed, power consumption initially decreases and then increases with an increase in roller speed. Excessively high roller speeds lead to more frequent stone-lifting events, which ultimately increases power consumption. When the roller speed is constant, power consumption rises with increasing forward speed due to the increased contact distance between the teeth and the soil, which heightens resistance and increases operational torque. Increased power consumption reduces the lifespan of the teeth and raises strength requirements. To enhance stone-picking efficiency while minimizing power consumption, the structural and operational parameters of the equipment should be optimized.

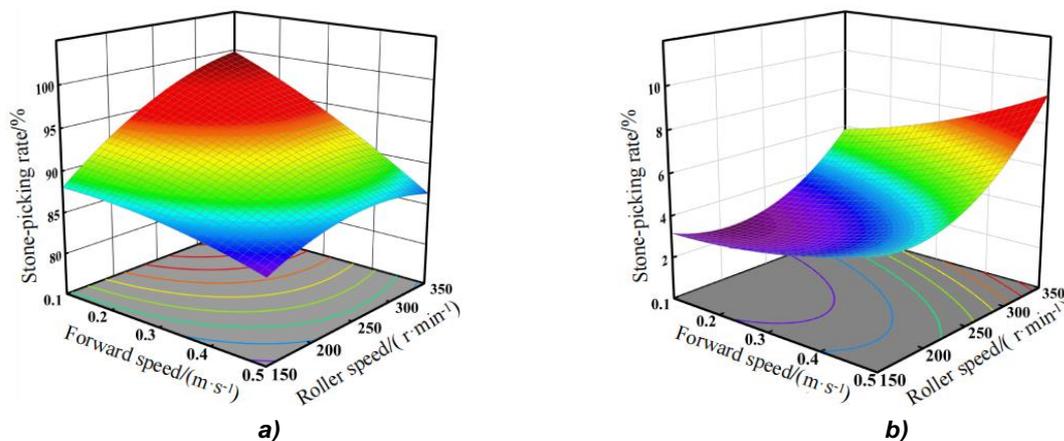

Fig. 11 – Response surface of the effect of factor interactions on each indicator

a) Effect of interaction factors on the stone-picking rate; b) Effect of interaction factors on power consumption

Parameter optimization

To achieve optimal performance, the Optimization module of Design-Expert software was used to perform constrained optimization of the regression model. The aim was to maximize stone-picking efficiency while minimizing power consumption. The objective function and constraints were defined as follows:

$$\begin{cases} \max Y_1(X_1, X_2, X_3) \\ \min Y_2(X_1, X_2, X_3) \\ \text{s.t.} \begin{cases} -1.682 \leq X_1 \leq 1.682 \\ -1.682 \leq X_2 \leq 1.682 \\ -1.682 \leq X_3 \leq 1.682 \end{cases} \end{cases} \quad (14)$$

When analyzing simulation parameters in the optimization module, the importance levels for the evaluation indicators were set, prioritizing the stone-picking rate as "+++" and power consumption as "+." The optimal parameter combination obtained was a forward speed of 0.18 m/s, a spiral blade roller speed of 274.71 r/min, and a side tilt angle of 30.28°. To account for the difficulty of setting exact speed ratios in the machine, the roller speed was rounded to 260 r/min and the tilt angle to 30°.

Analysis of the results of the soil trough experiment

Stone-picking rate measurement

The experiment included five repeat tests, with the average value taken as the verification result. The soil trough experiment setup is shown in Fig. 12. When operating under the optimal parameter combination, the average stone-picking rate achieved was 93.71%, with a deviation of 3.2% from the theoretical value. This indicates a close alignment between the experimental results and the model predictions. This outcome demonstrates that the designed stone picker performs well and meets the requirements for farmland stone-picking operations.

Fig. 12 – Prototype operation effect

Power consumption measurement

Once the equipment achieved stable operation, sensors recorded the real-time rotational speed and torque of the soil trough test vehicle’s output shaft. A dynamic torque sensor transmitted the torque data in real time to the digital display. Torque data for the 2–4 second interval is shown in Fig.13.

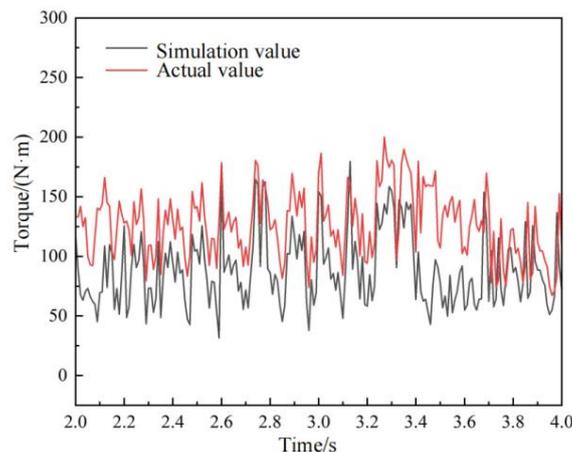

Fig. 14 – Power consumption verification

The average power consumption of the spiral blade roller was calculated using the torque formula. The average operational power consumption was 4.63 kW, which is slightly higher than the theoretical value. This discrepancy is likely due to the complex actual operating environment, the lower real speed compared to the theoretical speed, and the presence of numerous small stones.

CONCLUSIONS

(1) In response to the low stone-picking rate and high power consumption of existing stone pickers, a spiral tooth-type farmland stone picker was designed. A mechanical analysis of different tooth shapes for stone picking identified the optimal tooth type, followed by structural optimization of the teeth. A kinematic analysis of the stone-lifting process was conducted to establish the structural and operational parameters of the main components.

(2) Using EDEM discrete element simulation software, an interaction model among stones, soil, and teeth was developed. A three-factor, five-level, second-order regression orthogonal rotation central composite design was employed, with machine forward speed, spiral blade roller speed, and side tilt angle as factors, and stone-picking rate and power consumption as performance indicators. The effects of factor interactions on these performance indicators were analyzed.

(3) Design-Expert software was utilized to optimize the operating parameters of the stone picker. Optimal performance was achieved at a forward speed of 0.18 m/s, a spiral blade roller speed of 260 r/min, and a side tilt angle of 30°. Under these optimized conditions, the soil trough test demonstrated an average stone-picking rate of 93.71% and a power consumption of 4.63 kW. The spiral tooth-type stone picker exhibited stable operational performance, providing valuable insights and a reference framework for future optimization and design improvements of stone-picking machines.

Keywords: Discrete element, Cotton stalks, Rubber belts, Parameter calibration, Harvesting efficiency

ABSTRACT

This study aims to accurately calibrate the interaction between cotton stalks and rubber belts in agricultural machinery using the Discrete Element Method (DEM). Through physical experiments, key parameters such as the collision recovery coefficient, static friction, and rolling friction were measured and validated through simulations in EDEM. Optimal values were identified as 0.446, 1.146, and 0.0194, respectively. Full-factorial analysis revealed significant effects on repose angle. Repeated trials confirmed a deviation of only 0.72% from experimental results, validating the calibration method. These findings provide a foundation for improving cotton stalk harvesting and transportation efficiency.

摘要

本研究旨在通过离散元法(DEM)准确标定棉秆与橡胶带在农业机械中的相互作用。通过物理实验,测得关键参数如碰撞恢复系数、静摩擦系数和滚动摩擦系数,并在EDEM中进行仿真验证,最佳值分别为0.446、1.146和0.0194。全因子分析显示这些参数对堆积角的影响显著。重复实验结果与实际实验值偏差仅为0.72%,验证了标定方法的准确性。本研究为优化棉秆收获和运输效率提供了理论基础。

INTRODUCTION

Cotton stalks, a major by-product of cotton production, hold significant value in industries ranging from bioenergy to materials manufacturing. In agricultural machinery, the interaction between cotton stalks and rubber belts is crucial, as these belts play a key role in efficiently pulling and transporting cotton stalks from the field during harvesting operations. However, calibrating key parameters like collision restitution, static friction, and rolling friction remains challenging, often leading to discrepancies between simulations and real-world performance, affecting key metrics such as uprooting efficiency, breakage rate, and missed uprooting rate, thereby causing inefficiencies in machine design.

The previous research on the calibration of cotton stalks has focused primarily on simulating individual mechanical properties or interactions with other materials. For instance, Zhang *et al.* (2022) and Zhang *et al.* (2024) advanced the calibration of cotton stalk parameters using Discrete Element Method (DEM) and response surface methods, improving the accuracy of simulations. Similarly, Jiang *et al.* (2023), expanded on this by incorporating cotton stalk-soil mixtures, enhancing the potential for improving harvesting performance. However, while these studies significantly improve the understanding of cotton stalk simulations, they still fall short of offering practical guidance for optimizing the design of flexible cotton stalk harvesting equipment.

Further contributions have come from studies that addressed the interaction between plant materials and rubber belts, such as Jin *et al.* (2022), who calibrated contact parameters between corn seeds and rubber belts, and Sun *et al.* (2019), who studied the contact parameters between wheat and conveyor belts. These studies helped enrich the field of plant-rubber belt interface research, yet they do not fully address the complexities involved in cotton stalk harvesting machinery design. Li *et al.* (2022) also conducted detailed DEM analyses to improve simulation accuracy in complex systems, but similar to the other studies, this

^{1,2} Yasenjiang Baikeli, M.S.Stud.Eng.; ^{1,2} Haodong Xu, M.S.Stud.Eng.; ^{1,2} Jiayi Zhang, Prof.Ph.D.Eng.; ^{1,2} Rensheng Xing, M.S.Stud.Eng.; ^{*1,2} Yong Yue, Prof.Ph.D.Eng.

research does not provide a complete framework for optimizing the design of rubber belt cotton stalk harvesting equipment. On the other hand, the calibration of rubber materials and their interactions with agricultural materials has received significant attention. *Rossow et al. (2021)* and *Zhao et al. (2023)* examined the interaction between rubber conveyor belts and various materials, contributing valuable insights into friction and wear behaviors. *Nattino et al. (2014)* also refined rubber material calibration through statistical models to improve predictive accuracy. While these studies do not directly address the optimization of rubber belt cotton stalk harvesting equipment, highlighting a clear gap in research.

Most existing studies have concentrated either on the mechanical properties of cotton stalks or on the contact characteristics of rubber with other materials. This study fills that gap by focusing on the dynamic interaction between cotton stalks and rubber belts, providing a more holistic view that directly contributes to the optimization of harvesting equipment.

MATERIALS AND METHODS

Test material

Cotton Stalks: The primary test material was Xinluzao 66 cotton stalks, sourced from Anning Town, Urumqi City (43°58'N, 87°30'E) in Xinjiang, China. The stalks were selected for uniform size and moisture content, crucial for accurate results. They were cut to 25 mm lengths, with key properties like density (1.08 g/cm³) and moisture content standardized using a drying oven at 105°C for 24 hours.

Rubber Belts: A standard EP100-640 × 3(4+2) rubber belt, widely used in agricultural machinery, was chosen for the tests. The belt measures 300 mm × 350 mm × 8 mm and features a polyester (EP) fabric core, providing high tensile strength and durability.

Test method

Contact coefficient calibration experiment: Physical experiments and EDEM 2022 software were used to calibrate the contact coefficient between cotton stalks and rubber belts, including collision recovery coefficient, static friction coefficient, and rolling friction coefficient. Single-factor experiments were employed to optimize each parameter, using average area count, slip angle, and rolling distance as metrics. Lastly, the Angle of Repose was measured using the Cylinder Lifting Method, which evaluated the pile angle of the cotton stalks on the rubber belts.

Full Factorial Experimental Design: A full factorial experimental design was implemented using Design Expert 10.0 to analyze the significance of the cotton stalk-rubber belt contact parameters and their interactions. This provided insight into both individual and combined parameter effects.

Box-Behnken test Design: The parameters were optimized through a Box-Behnken Design (BBD) and response surface analysis. A binary regression equation was derived, targeting the Angle of Repose, and the optimal parameter values were determined based on this analysis.

The coefficient of variation (CV) was 1.01%, indicating good reliability of the test, and the binary regression equation is shown in equation (2):

$$\theta = 43.04 + 0.8A + 0.225B - 1.25C - 0.625AB + 1.775AC + 0.375BC - 1.8325A^2 - 2.3325B^2 - 1.7825C^2 \quad (1)$$

By using the Design-Expert software constraint solving tool to find the minimum extreme value of the error point for equation (2), the angle of repose is used as the target to find the best value of parameters, and the collision recovery coefficient (A), static friction coefficient (B), and rolling friction coefficient (C) between cotton stalk and rubber belt are 0.446, 1.146, and 0.0197.

Cotton stalk-rubber belt contact parameter calibration experiment

Using EDEM 2022, contact parameters were simulated to enhance the accuracy of physical tests, focusing on single-factor experiments for optimal parameter isolation. The Hertz-Mindlin no-slip contact model was applied to simulate cotton stalk-rubber belt interactions during the angle of repose test, given the minimal bonding forces between particles (*Hu et al., 2022*). To replicate the cylindrical shape of cotton stalk shown in Figure 1(a), models were created with a diameter of 10 mm and lengths of 25 mm (*Zhang et al., 2024*), as shown in Figure 1(b), ensuring accurate calibration of the interaction.

Fig. 1 - Cotton stalk model

The results from the physical tests, combined with a review of relevant literature, provide the characteristic contact parameters for cotton stalks and rubber belts, as summarized in Table 1. A review of the literature (Zhang et al., 2024; Jiang et al., 2021) identified a range of values for the angle of repose, bending, and fracture characteristics, along with other key contact parameters for cotton stalks.

Table 1

Simulation parameters of materials in contact with cotton stalks

Materials	Parameter	Value	Units
Cotton stalk	Poisson's ratio	0.35	-
Cotton stalk	Shear modulus	0.69	GPa
Cotton stalk	Density	1080	kg/m ³
Rubber Belt	Poisson's ratio	0.48	-
Rubber Belt	Shear modulus	1 × 10 ⁹	GPa
Rubber Belt	Density	1.38	kg/m ³
Stalk-Rubber Belt	Collision recovery coefficient	0.35~0.5	-
Stalk-Rubber Belt	Static friction factor	0.5~1.5	-
Stalk-Rubber Belt	Rolling friction factor	0.015~0.025	-

Collision Recovery Coefficient

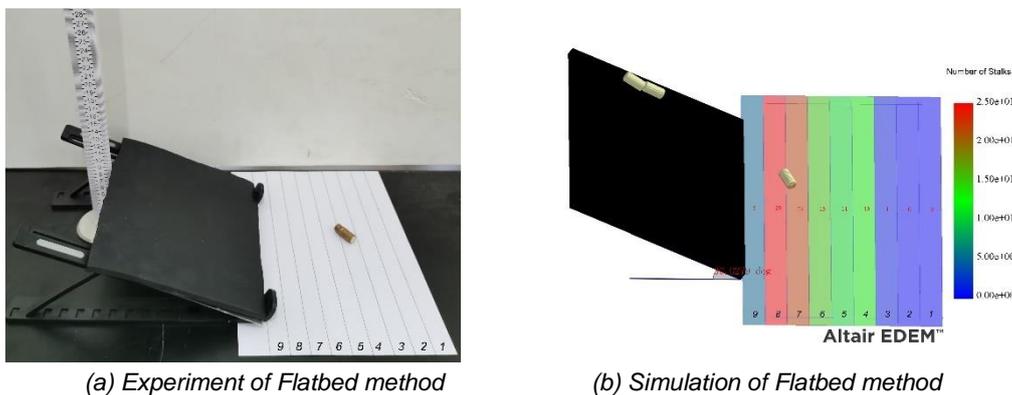

Fig. 2 - Measurement of Collision Recovery Coefficient for cotton stalk and rubber belt

To accurately measure the collision recovery coefficient between cotton stalks and a rubber belt using the Flatbed method (Zhang et al., 2024), a simple yet effective apparatus was designed as shown in Figure 2(a). The apparatus featured an inclined rubber belt plate, measuring 180 mm by 200 mm, set at a 30° angle. This setup allowed cotton stalk particles, each 25 mm in length, to be released from a height of 300 mm, enabling free fall onto the plate. Below the plate, a 9-grid paper with 25 mm spaced grids was placed to record the landing positions.

To facilitate the subsequent calculation of the area count, the method from (Niu et al., 2022) for measuring the collision recovery coefficient of feed was referenced. Using the average area as the target value and applying the equation as follow:

$$K = \frac{1}{N_{total}} \sum_{k=1}^n (kN_k) \tag{1}$$

where:

- K - the average number of areas;
- N_{total} - the total number of cotton stalk models;
- n - the total number of areas;
- N_k - the number of models in area k , where k is the area number.

The results of the collision recovery coefficient experiment are shown in Table 2. According to the aforementioned equation (1), the average area count was calculated to be 7.01. By measuring the average area count from particle landing positions, an accurate representation of the stalks' rebound behavior was obtained.

Table 2

Experimental Results of Collision Recovery Coefficient Measurement

Serial number	1	2	3	4	5	6	7	8	9
Number of stalks	0	0	2	2	5	16	37	35	3

To determine the optimal collision recovery coefficient between cotton stalks and the rubber belt in simulations, as shown in Figure 2(b), the coefficient was varied from 0.35 to 0.5, with a step size of 0.03. Six experiments, as shown in Table 3, were conducted to assess how changes in this coefficient affect the spatial dispersion of cotton stalks particles upon contact. The results in Table 3 showed that as the coefficient increased, the mean number of regions decreased, with the optimal value of 0.44 yielding the lowest error rate of 0.7%. This suggests that a coefficient of 0.44 most accurately replicates the interaction for further simulations.

Table 3

Simulation Results of Collision Recovery Coefficient Measurement

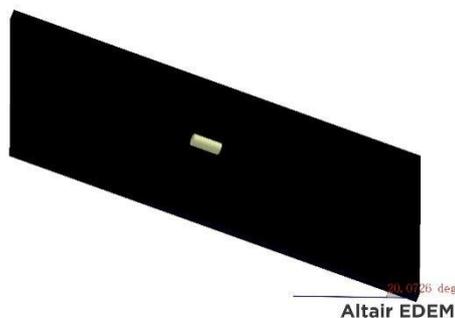

Serial number	Collision recovery coefficient	Mean number of regions	Error
1	0.35	7.85	12.0%
2	0.38	7.58	8.1%
3	0.41	7.53	7.4%
4	0.44	7.06	0.7%
5	0.47	6.76	3.6%
6	0.50	6.52	7.0%

Static Friction Coefficient

To measure the static friction coefficient between cotton stalks and the rubber belt, an inclined plane method was used (Du et al., 2012). A rubber belt (300 mm x 350 mm x 8 mm) was fixed onto a board, and a cotton stalk was placed on the belt, as shown in Figure 3(a). The belt was gradually lifted until the stalk began to slide, and the angle (θ) between the belt and the horizontal plane was measured. This process was repeated 10 times, as shown in Table 4, yielding an average θ of 53.7°.

(a) Experiment of Inclined Plane Method

(b) Simulation of Inclined Plane Method

Fig. 3 - Measurement of Static friction coefficient for cotton stalk and rubber belt

Table 4

Static Friction Measurement of Experimental Cotton Stalk Slip Angle

Serial number	1	2	3	4	5	6	7	8	9	10
1	69°	48°	45°	47°	74°	53°	61°	49°	46°	48°
2	64°	52°	47°	50°	65°	51°	52°	50°	49°	55°
3	44°	55°	46°	69°	54°	70°	44°	59°	49°	47°
Mean	59°	51.6°	46°	55.3°	64.3°	58°	52.3°	52.6°	48°	50°

A simulation experiment was conducted to measure the static friction coefficient between cotton stalks and the rubber belt using the inclined plane sliding test as shown in Figure 3(b). The collision recovery coefficient between the cotton stalks and the rubber belt was set at 0.4, while the dynamic friction coefficient was set to 0.

The static friction coefficient was tested over a range of 0.5 to 1.5, with a step size of 0.1, resulting in a total of 11 simulation experiments. The results of each simulation, along with the corresponding levels of the static friction coefficient, are summarized in the Table 5.

Table 5

Static Friction Measurement of Cotton Stalk Slip Angle Simulation

Serial no.	Coefficient of static friction	Slipping angle	Error
1	0.5	30.4°	43.4%
2	0.6	34.5°	35.6%
3	0.7	38.8°	27.7%
4	0.8	44.4°	17.3%
5	0.9	47.1°	12.3%
6	1.0	48.3°	10.1%
7	1.1	52.1°	3.0%
8	1.2	53.1°	1.1%
9	1.3	54.5°	1.5%
10	1.4	58.2°	8.4%
11	1.5	61.2°	14.0%

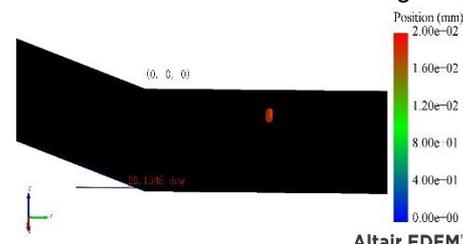

Based on the static friction measurement results shown in Table 5, the slipping angle of cotton stalks increases as the coefficient of static friction increases. The error percentage, however, decreases as the static friction coefficient increases, reaching its lowest point (1.1%) at a coefficient of 1.2. This suggests that a friction coefficient between 1.0 and 1.2 offers the most accurate prediction of the cotton stalk's slip angle in simulations, with minimal error.

The Rolling Friction Coefficient

To assess the rolling friction between cotton stalks and the rubber belt, the Oblique Rolling Method was employed (Liang et al., 2022), two rubber belt sections were mounted onto iron plates with dimensions of 350 mm x 300 mm x 8 mm and 600 mm x 500 mm x 8 mm, as shown in Figure 4(a). Preliminary tests revealed that when the angle of the first belt exceeded 25°, cotton stalks would bounce upon reaching the second belt, disrupting the smooth rolling motion. To prevent this, the belt was inclined at a consistent angle of 20°.

(a) Experiment of Oblique Rolling Method

(b) Simulation of Oblique Rolling Method

Fig. 4 - Measurement of Rolling Friction Coefficient for cotton stalk and rubber belt

During the main experiment, cotton stalks were released from a height of 100 mm above the second belt to measure the rolling distance on the horizontal section. If a cotton stalk rolled off the belt, the test was repeated to ensure accuracy.

After conducting 10 valid trials, the average rolling distance was found to be 190.5 mm, as shown in Table 6, indicating a smooth interaction between the cotton stalk and the rubber belt at the given conditions.

Table 6

Rolling friction determination of experimental cotton stalk rolling distance

Serial number	1	2	3	4	5	6	7	8	9	10	Mean
Rolling distance (mm)	138	249	218	204	198	181	219	134	153	211	190.5

Figure 4(b) shows the Simulation of Oblique Rolling Method in EDEM, the results of the rolling friction simulation experiment for cotton stalks are summarized in Table 7. In this experiment, the rolling friction coefficient was incrementally varied from 0.015 to 0.025, with a step size of 0.002. The findings demonstrate that as the rolling friction coefficient increases, the rolling distance of the cotton stalks decreases correspondingly. Notably, a coefficient of 0.019 was identified as the optimal value, yielding the smallest error of 1.6%, making it the most accurate for simulating the rolling motion of cotton stalks on the rubber belt. Consequently, this coefficient is recommended as the most suitable parameter for modelling cotton stalk-rubber belt interactions in discrete element simulations.

Table 7

Rolling friction determination of cotton stalk rolling distance simulation

Serial number	Rolling Friction Coefficient	Rolling distance (mm)	Error
1	0.015	212.6	11.6%
2	0.017	210.2	10.3%
3	0.019	193.6	1.6%
4	0.021	186.7	2.0%
5	0.023	163.6	14.1%
6	0.025	155.9	18.2%

Angle of Repose

The angle of repose is a macroscopic parameter that reflects the flow and friction characteristics of granular materials (Zhang et al., 2022), directly linked to contact parameters and the material's inherent physical properties. In this study, the angle of repose of cotton stalks on a rubber belt was measured to verify the accuracy of the contact parameters between the stalks and the rubber belt.

For the experiment, cotton stalks with diameters of 10 mm were cut to a uniform length of 25 mm, with 340 particles being used, as shown in Figure 5(a). A cylindrical rubber tube was placed vertically on the rubber belt, and the stalks were released at a uniform speed of 0.03 m/s (Wang et al., 2022), allowing them to naturally accumulate on the belt. The image of the cotton stalk's angle of repose was first binarized using MATLAB software to differentiate between the stalks and the background, as shown in Figure 5(b). Photoshop was then employed to extract the edge lines of the binarized image, as shown in Figure 5(c). Finally, the least squares method was applied to fit the boundary curve, as shown in Figure 5(d). In this figure, the x and y axes represent the width and heights of stalks, respectively. The experiment was repeated five times, with an average angle of repose measured at 43.04°.

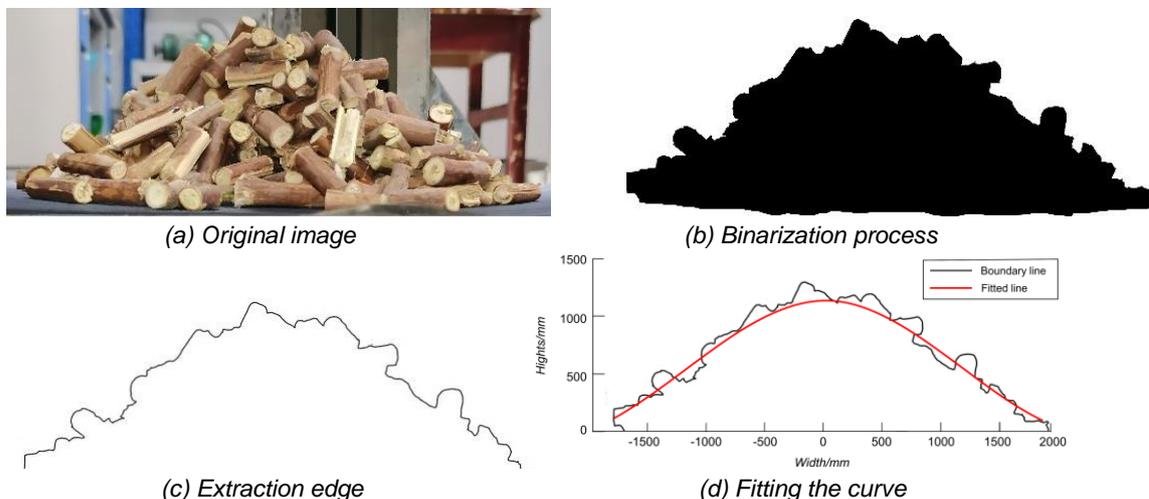

Fig. 5 - Image processing

In the EDEM simulation experiments, conducted under the same conditions as the physical tests, the Hertz-Mindlin contact model was utilized to simulate the interactions between particles. The particle factory, positioned 100 mm above the simulation base, generated cotton stalk particles at a rate of 114 particles per second, ensuring consistency with the stalk diameter. Figure 6(a) shows the static state of cotton stalk particles after generation, while Figure 6(b) shows the state of cotton stalk particles after the cylinder is lifted and the flow stops.

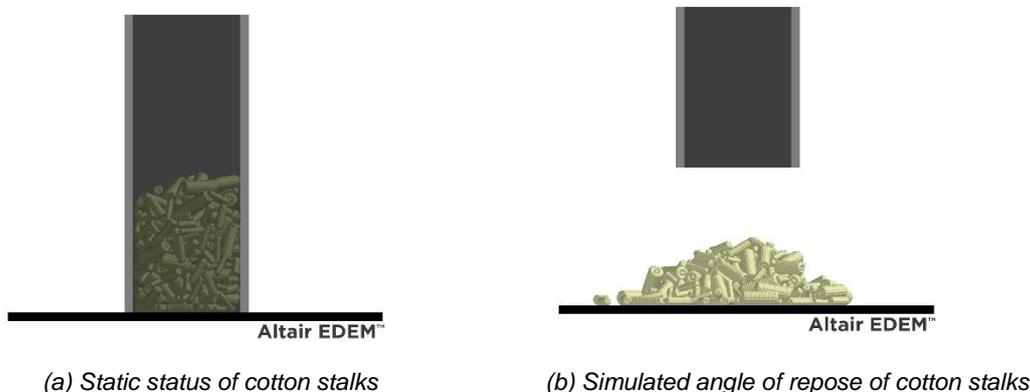

Fig. 6 - Cotton Stalks simulation stacking angle experiment

From these experiments, it was observed that the selected parameters closely replicated the physical behavior of the cotton stalks, providing reliable data for further analysis. Therefore, this setup and parameter configuration proved effective for accurately modeling the mechanical interactions of cotton stalk particles in discrete element simulations.

RESULTS AND ANALYSIS

A full factorial experiment was designed to investigate the factors affecting the angle of repose (θ) in the contact parameters between cotton stalks and the rubber belt. The experiment considered three factors: the collision recovery coefficient (A), static friction coefficient (B), and rolling friction coefficient (C), designed in Table 8. Since it was unclear whether each factor had a significant effect on the angle of repose, the experiment aimed to identify significant factors influencing θ .

The design also included three central points to ensure accuracy in the analysis. The levels of each factor are detailed in Table 9, with a total of 11 experimental designs established.

Table 8

Experimental factor level design

Experimental factor	-1	0	1
A	0.41	0.44	0.47
B	1.0	1.20	1.40
C	0.017	0.021	0.025

Table 9

Experimental design of contact parameters

Serial number	A	B	C	θ (°)
1	-1	-1	-1	40.9
2	1	-1	-1	41.2
3	-1	1	-1	42.8
4	1	1	-1	38.9
5	-1	-1	1	33.8
6	1	-1	1	40.7
7	-1	1	1	36.5
8	1	1	1	40.5
9	0	0	0	43.6
10	0	0	0	42.8
11	0	0	0	43.3

Table 10

Parameter significance analysis

Parameter	Effect	Sum of square	Mean square	F Value	P-Value	Significance ranking
A	1.825	6.66	6.66	37.15	0.009	3
B	0.525	0.55	0.55	3.07	0.178	6
C	-3.075	18.91	18.91	105.47	0.002	2
AB	-1.775	6.3	6.3	35.14	0.01	4
AC	3.625	26.28	26.28	146.57	0.001	1
BC	0.725	1.05	1.05	5.86	0.094	5

Based on the results shown in Table 10, a significance analysis of the parameters was conducted to evaluate their impact on the angle of repose. The interaction between the rolling friction coefficient and the static friction factor (AC) has the highest significance, as shown by its P-value of 0.001 and F value of 146.57, making it the most influential factor. In addition, the rolling friction coefficient (C) also plays a crucial role, with a P-value of 0.002 and an F value of 105.47, ranking second in significance. This highlights its strong independent effect on the angle of repose. Therefore, the analysis indicates that rolling friction (C) and its interaction with static friction (AC) should be prioritized for tuning in future simulations, as they exhibit the most significant effects on the simulation results, particularly in modeling the behavior of cotton stalks in discrete element simulations.

BBD response surface test results and analysis

To determine the optimal contact parameters between cotton stalks and the rubber belt, the Box-Behnken Design (BBD) was applied (Coetzee et al., 2017). In this study, A three-factor, three-level combination design test was established with 17 test simulations and five sets of tests at the central level in Table 11, and the BBD response surface test analysis of variance is shown in Table 12.

Table 11

BBD Response surface design

Serial number	A	B	C	$\theta(^{\circ})$
1	-1	-1	0	37.4
2	1	-1	0	40.0
3	-1	1	0	39.0
4	1	1	0	39.1
5	-1	0	-1	41.8
6	1	0	-1	40.1
7	-1	0	1	35.2
8	1	0	1	40.6
9	0	-1	-1	40.0
10	0	1	-1	39.8
11	0	-1	1	37.3
12	0	1	1	38.6
13	0	0	0	42.6
14	0	0	0	43.2
15	0	0	0	43.3
16	0	0	0	42.8
17	0	0	0	43.3

Table 12

BBD Response surface analysis of variance

Source	Freedom Degrees	Mean Square	F Value	P-Value Prob
Model	9	9.89	59.56	<0.0001
A	1	5.12	30.84	0.0009
B	1	0.41	2.44	0.1623

Source	Freedom Degrees	Mean Square	F Value	P-Value Prob
C	1	12.5	75.3	<0.0001
AB	1	1.56	9.41	0.0181
AC	1	12.6	75.92	<0.0001
BC	1	0.56	3.39	0.1082
A ²	1	14.14	85.18	<0.0001
B ²	1	22.91	138	<0.0001
C ²	1	13.38	80.59	<0.0001
Residual	7	0.17	-	-
Lack of Fit	3	0.25	2.43	0.257
Pure Error	4	0.1	-	-
Cor Total	13	-	-	-

Analysis of the response surface test variance data revealed that factors (B) and (BC) had no significant effect on the angle of repose. The regression model yielded a coefficient of determination R^2 of 0.9871, indicating a high level of model fit. Additionally, the lack-of-fit P-value was greater than 0.05, confirming that the model was statistically significant and the lack of fit was not significant.

Compared with other studies, this research advances calibration efforts beyond the traditional focus on isolated parameters, such as the mechanical properties of cotton stalks or individual interactions between rubber belts and materials, as seen in *Zhang et al. (2024)*, which improved the accuracy of simulations for chopped cotton stalks. Building on that foundation, this study incorporates a more comprehensive set of parameters, including the coefficients of collision recovery, static friction, and rolling friction. These parameters are further validated through real-world experimental data, enhancing the accuracy and realism of the simulation models. Regarding device design optimization, this study differs from works like those by *Zhang et al. (2023)* and *Li et al. (2022)*, which primarily concentrated on simulation accuracy and material-specific calibration.

This study provides a more refined, practical approach to simulating cotton stalk-rubber belt interactions, addressing a gap in the current literature by providing valuable insights for the optimization of flexible cotton stalk harvesting equipment. The innovation of this research lies in its practical application for optimizing the design of harvesting equipment.

CONCLUSIONS

(1) Through physical experiments, such as the flatbed method and the inclined plane method, the contact parameters between cotton stalks and rubber belts were calibrated. The flatbed method measured the average area count was calculated to be 7.01, while the inclined plane method yielded an average sliding angle of 53.7° and an average rolling distance of 190.5 mm for the cotton stalks. Using the average area count, sliding angle, and rolling distance as evaluation indicators, simulations of single-factor experiments based on EDEM 2022 software determined the optimal contact parameters between cotton stalks and rubber belts: a collision recovery coefficient of 0.44, a static friction coefficient of 1.2, and a rolling friction coefficient of 0.019.

(2) The full-factorial experimental analysis revealed that both the collision recovery coefficient and the rolling friction coefficient significantly affected the repose angle. Furthermore, the interaction between the collision recovery coefficient and the static friction coefficient, as well as between the collision recovery coefficient and the rolling friction coefficient, had a considerable impact on the repose angle.

(3) Using Design Expert 10.0 software, the response surface analysis, contour plots, and regression equations identified the optimal cotton stalk-rubber belt contact parameters: a collision recovery coefficient of 0.446, a static friction coefficient of 1.146, and a rolling friction coefficient of 0.0194. Repeated experiments (n=5) resulted in an average repose angle of 42.73°, with a deviation of 0.72% from the actual experimental results.

Keywords: Basal Stem Rot, GIS, IoT, Machine Learning, Oil Palm Plantation, Remote Sensing, Automated Disease Detection

ABSTRACT

Basal Stem Rot (BSR) disease attacks in oil palm plantations are still the most significant cause of losses in oil palm plantations. The leading cause of BSR disease in oil palm plants is the *Ganoderma Boninense* fungus. The spread of BSR in an oil palm area can be massive due to transmission through root contact, airborne, and sporophores spread on the soil and in dead plant debris. The application of advanced technologies to mitigate and prevent the spread of BSR disease can be carried out considering that the nature of the spread and characteristics of this disease infection are well known. Advanced technologies such as the Internet of Things (IoT) are suitable for real-time monitoring of large areas. The key to successfully detecting BSR disease in oil palm plants is the selection of sensor technologies for monitoring and machine learning (ML) models used for segmenting and classifying infected plant characteristics. This paper comprehensively summarizes the spread of BSR disease and then describes various technologies and ML models for monitoring and preventing BSR disease in oil palm plantations. The use of ML can be potentially used for early detection of BSR. Finally, this paper can complement and provide a basis for developing technology to prevent the spread of BSR disease.

ABSTRAK

Penyakit Busuk Pangkal Batang (BSR) pada perkebunan kelapa sawit masih menjadi penyebab utama kerugian di perkebunan tersebut. Penyebab utama penyakit BSR pada tanaman kelapa sawit adalah jamur *Ganoderma boninense*. Penyebaran BSR pada area kelapa sawit dapat berlangsung masif karena penularannya melalui kontak akar, udara, dan penyebaran sporofor pada tanah serta sisa-sisa tanaman yang mati. Aplikasi teknologi canggih untuk mengurangi dan mencegah penyebaran penyakit BSR dapat dilakukan mengingat sifat penyebaran dan karakteristik infeksi penyakit ini sudah dikenal. Teknologi canggih seperti Internet of Things (IoT) sangat cocok untuk pemantauan secara real-time pada area yang luas. Kunci keberhasilan dalam mendeteksi penyakit BSR pada tanaman kelapa sawit adalah pemilihan teknologi sensor untuk pemantauan dan model pembelajaran mesin yang digunakan untuk segmentasi dan klasifikasi karakteristik tanaman yang terinfeksi. Makalah ini merangkum secara komprehensif penyebaran penyakit BSR, kemudian mendeskripsikan berbagai teknologi dan model pembelajaran mesin untuk pemantauan dan pencegahan penyakit BSR di perkebunan kelapa sawit. Diharapkan, artikel ini dapat melengkapi dan memberikan dasar bagi pengembangan teknologi dalam mencegah penyebaran penyakit BSR.

INTRODUCTION

Palm oil is a competitive and efficient commodity for vegetable oil production, particularly when considering production costs and the ratio of planting area to oil yield (Destiarni & Jamil, 2021). Apart from that, palm oil commodities have been proven to improve the welfare of small farmers if they follow the principles of correct cultivation methods (Thoumazeau et al., 2024). The economic prospects for palm oil commodities are increasing due to the diversification of derivative products in biomaterials, biofuels, and bioenergy, which can become a powerful new bioeconomic force (Sakai et al., 2022). The main derivatives of palm oil products are food ingredients such as margarine, spreads, ice cream, confectionery fats, emulsifiers, and vanaspati

(Ximenes *et al.*, 2022). Apart from that, methyl ester compounds from palm oil can be the primary alternative material for burning diesel engines. Even diesel fuel with a 20% mixture of palm oil (B20) has been proven to produce almost the same axial flame temperature as pure diesel fuel but with lower NO_x and CO₂ emissions (Pourhoseini *et al.*, 2021). Palm oil produces oil derivative products; even its leaves, stems, empty bunches, kernel shells, and mesocarp fibers can be used as asphalt hardeners and construction materials (Al-Sabaeei *et al.*, 2022). In developing countries like Indonesia, this commodity has proven to be an industrial sector that drives the economy by fostering entrepreneurship, enhancing village development, and supporting household income (Hariyanti *et al.*, 2024).

BSR disease reduces crop yields and destroys the lignin in cell walls. BSR disease symptoms are absent in the early stages and only emerge later. Although the infection develops slowly, it can spread across thousands of hectares of oil palm plantations (Naheer *et al.*, 2013). It also spreads very fast through contact with infected roots and basidiospores. This fungus can also spread and live in felled stems and remaining wood fibers in the soil (Rees *et al.*, 2012). BSR spreads rapidly, affecting oil palm of all ages but is most severe in plants over 25 years old. It is most prevalent in laterite, coastal, inland, and peat soils (Ibrahim *et al.*, 2020).

Currently, BSR detection in oil palm plantations relies on manual observation and laboratory analysis, as the fungi primarily inhabit the trunk and roots. Given its rapid and invasive nature, advanced technologies such as IoT, ML, and remote sensing offer faster detection. IoT integrates sensors, including soil, temperature, and leaf sensors, with single-board microcontrollers, aiding crop monitoring, irrigation, pest control, soil mapping, and disease detection, making it increasingly popular in agriculture (Rudrakar & Rughani, 2023). For large-scale plantations, remote sensing is the most effective method, with data acquired via satellites or UAVs in formats such as RGB images, spectroradiometer, multispectral, and hyperspectral data. Remote sensing has proven reliable for monitoring oil palm health (Santoso *et al.*, 2019), and advancements in imaging sensors with varying spatial, temporal, and spectral resolutions enhance its capabilities. Multispectral and hyperspectral imaging datasets enable detailed analysis of land cover changes, including plant canopy and soil characteristics, with prior studies confirming remote sensing's effectiveness in early plant disease detection (Abdullah *et al.*, 2023).

Early BSR detection requires fast, accurate data processing for timely decisions. Machine learning (ML) enhances disease detection accuracy, efficiently handling large datasets for data-driven decision-making. (Ennaji *et al.*, 2023). ML explores data by building estimation models and relationships between parameters. It processes structured datasets to predict trends. Supervised learning handles known classifications, while unsupervised learning finds patterns. Model development includes classification, regression, clustering, dimensionality reduction, reinforcement learning, and deep learning (Sarker, 2021). Applying ML in the agricultural sector usually goes through data extraction and classification stages to produce output (Kipli *et al.*, 2023). ML is widely used in agriculture for planting, harvesting, and post-harvest stages. It supports disease detection, soil analysis, plant age estimation, population counting, and yield classification (Meshram *et al.*, 2021).

This study aims to elucidate the opportunities for advanced technologies to detect BSR disease spreading in oil palm plantations. The presence of *G. Boninense* can be detected by the appearance of basidioma in the planting medium and changes in leaf color on oil palm seedlings under 1 year old. In addition, environmental factors such as temperature, duration, and intensity of rainfall, dew levels, soil temperature and water content, soil fertility, soil organic matter content, wind, herbicide history, and air pollution also influence the spread of pathogens. It also highlights the strengths and limitations of these technologies. By highlighting the strengths and limitations of existing technologies, this article proposes a novel approach that combines advanced sensor fusion with real-time processing to provide more reliable, cost-effective, and scalable solutions for early BSR detection in diverse environmental conditions.

MASSIVE DAMAGE DUE TO THE SPREAD OF BSR DISEASE IN OIL PALM PLANTATIONS

BSR is a severe threat to oil palm plantations and has been proven to cause severe economic losses for palm oil-producing countries. The fungus *Ganoderma boninense* (*G. Boninense*) is the main cause of BSR disease, which can result in economic losses of up to 43% over 6 months due to reduced oil palm yields (Assis *et al.*, 2016). BSR infection in oil palm plantations can reduce plant yields between 50% and 80% (Corley & Tinker, 2015). BSR disease is the biggest threat to oil palm plantations caused by the *Ganoderma Boninense* (*G. Boninense*) fungus which attacks the roots to the base of the plant stem. Without early detection or control, infected plants die within 6–12 months of symptom onset, with an 80% mortality rate in productive-age plants.

In Johor, Malaysia, the BSR infection rate rose from 1.51% in 1994 to 3.71% in 2009, averaging a 10.3% annual increase (Roslan & Idris, 2012).

Studies using the Bayesian Model Averaging (BMA) model approach show that the level of economic loss is estimated to reach 68% of the yield of all infected plants (Assis *et al.*, 2020). In 2009, BSR disease spread across 151,208 hectares in Malaysia, causing an estimated loss of US\$ 351 million (Parthiban *et al.*, 2016). By 2040, if uncontrolled, it could destroy 860,610 ha of productive oil palm plantations, leading to job losses and rising palm oil prices (Olaniyi & Szulczyk, 2020). Indonesia is also estimated to experience losses of US\$ 38 million for every 1% of oil palm plantation areas that experience BSR attacks based on calculations using commodity prices in 1996. It is estimated that losses due to oil palm plantations attacked by BSR in Southeast Asia could reach 500 million US\$ per year (Ahmadi *et al.*, 2017). The first convincing discovery of *G. Boninense* infection was in gardens owned by private corporations in North Sumatra, with an attack rate of 22% of the plant population per hectare in 2017 (Haryadi *et al.*, 2019). Losses due to the spread of BSR disease have not only hit Malaysia and Indonesia; in fact it was recently discovered that several oil palm plantations in Papua New Guinea experienced BSR infection rates of up to 50% (Murphy *et al.*, 2021). Statistics of losses due to BSR can be seen in Table 1.

Table 1

The summary on BSR-related losses

Metric	Value	Source
Yield losses	Can reduce yield by 50% to 80%	(Murphy <i>et al.</i> , 2021; Zakaria, 2022)
Annual economic losses	Estimated between US\$ 38 million to US\$ 351 million.	(Parthiban <i>et al.</i> , 2016; Paterson, 2023)
Environment Impact	CO ₂ and CH ₄ emissions from decomposition; soil pollution from chemical treatments.	(Jazuli <i>et al.</i> , 2022)
Agricultural Implication	Increased replanting costs; challenges in disease management.	(Paterson, 2023)

SPREAD OF BSR IN OIL PALM PLANTATIONS

The disease triangle concept highlights the interaction between the host, pathogen, and environment, all of which influence disease spread. Infectious diseases emerge when susceptible hosts, virulent pathogens, and favorable environmental conditions align (Mead *et al.*, 2022). Several types of ganoderma, such as *G. Boninense*, *G. Miniotacinctum*, *G. Chalceum*, *G. Tornatum*, *G. Zonatum*, and *G. Xylonoides*, can be the cause of the spread of BSR disease. However, *G. Boninense* is the main cause of BSR infection in oil palm plants (Zakaria, 2022). Several types of seeds are claimed to be more susceptible and more resistant to disease. Progenies from palm oil seeds PK 2724 and PK 2567 were detected as seeds that were susceptible to infection. AVROS oil palm seeds are also more vigorous than the Ekona and Calabar varieties (Chong *et al.*, 2012). In the latest study, 31 oil palm progenies had partial resistance to Ganoderma attacks in peatlands, but further confirmation and testing in the nursery were needed to ensure their performance (Amiruddin, 2022). Environmental factors can also influence pathogen behavior, such as germination speed, spread of inoculum, ability to survive and penetrate pathogens, and the potential for infection.

Stages Development of Ganoderma Boninense

The development phases of *G. Boninense* are the same as fungi in general as seen in Fig. 1(a). The mature fruiting body will produce basidiospores. Basidiospores can spread through the air or with the help of insects and then germinate into monokaryotic mycelia. This mycelium is not yet pathogenic to oil palm plants (Khoo & Chong, 2023). Pathogenic properties for oil palm plants only appear in dikaryotic mycelia after fusion or mating occurs. Dikaryotic mycelia are more commonly found on the surface of stems and roots than on the interior of oil palm stems (Pilotti *et al.*, 2018). The dikaryotic mycelia grows into mycelium, which eventually develops into an infectious inoculum. Mycelium will continue to develop into a fruiting body if it is infected with the suitable medium. The base of the stem of an oil palm plant that is injured or has been pruned is the medium most easily infected by mycelium *G. Boninense* (Jazuli *et al.*, 2022). This *G. Boninense* fungus colony has a characteristic white color on the surface and a dark color on the reverse side. On infected stems, fruiting bodies often appear to contain spores with layers varying in color from yellow to brown (Khoo & Chong, 2023).

Dikaryotic mycelia form rapidly in favorable conditions. *In vitro* studies show *G. boninense* spores germinate within 1–2 days in darkness. Monokaryotic mycelia grow 4–5 days after transfer to potato dextrose agar (PDA), with clamp cell formation observed 5–7 days post-mating, indicating successful fusion (Pilotti *et al.*, 2003). The development of dikaryotic mycelia, which infects the base of the oil palm stem, is characterized by the appearance of a slightly raised white button which changes shape into a dome structure within 2 days. This structure develops into a slender white column with a length of 1.1 cm and a width of 1.1 cm. Within 14 days, the structure of the column becomes harder and starts to turn brown, except for the apical tissue, which remains white. The apical tissue eventually stops growing and forms a growth cap. The longer it grows, the color of the cap becomes browner, and the size also increases. Its size can reach a length of 17.8 cm and a width of 14.6 cm at 14 weeks after infection (Ho & Nawawi, 1986a).

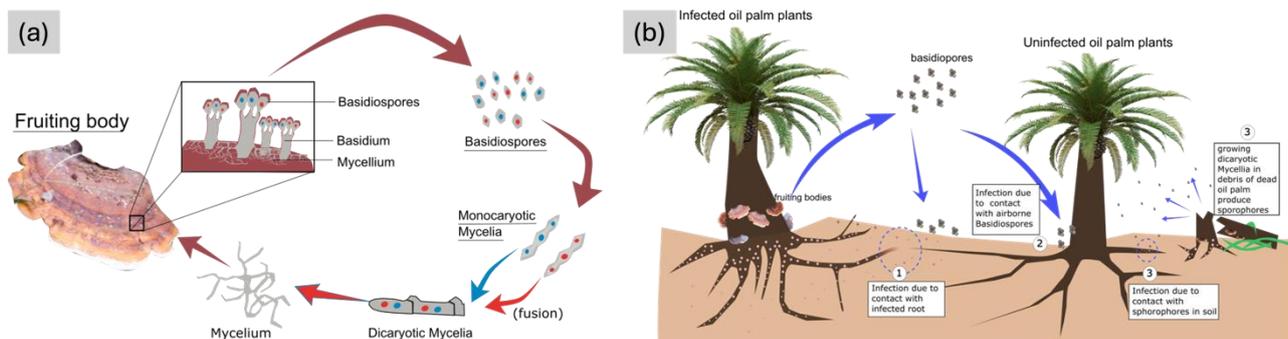

Fig. 1 - *G. boninense* and BSR transmission: (a) Life cycle of *G. boninense*. (b) Transmission via root-to-root contact, basidiospores, and free sporophores in debris and soil.

The spread of BSR in oil palm plants can be seen in Fig. 1(b). The spread of BSR is mainly due to the invasion of the *G. Boninense* pathogen in the roots. *G. Boninense* has the ability to spread through soil (soil-borne) and basidiospores in massive numbers with the help of wind or insects. The spread of *G. Boninense* basidiospores is not only influenced by one environmental factor but a combination of several factors (Ho & Nawawi, 1986b). Airborne basidiospores will develop on the surface of oil palm stems that are injured or have been pruned. Basidiospores that fall to the soil surface can be carried by water or insects, moving to the root area and colonizing oil palm roots. In addition, dikaryotic mycelia in the remaining roots and stems of dead oil palms can continue to grow and produce sporophores which can infect healthy plants (Pilotti *et al.*, 2018).

Symptoms of Infection in Oil Palm Plants

In the initial phase of the inoculum infecting oil palm plants, no symptoms can be observed directly with the naked eye (Siddiqui *et al.*, 2021). Based on recent observations, morphological symptoms on leaves only appear if the development of BSR disease on plants is severe or reaches 60-70% (Chong *et al.*, 2017). The initial characteristics of infected plant roots include changes in metabolism, characterized by the discovery of fatty acid compounds and steroidal compounds in large quantities in roots infected with *G. Boninense* (Isha *et al.*, 2020). The first morphological symptom that appears is chlorosis on oil palm leaves. This phase shows that *G. Boninense* has colonized the roots. Then, there is characteristic necrosis in the roots at the beginning of the infection, which then spreads to the base of the stem. Apart from that, stunted growth and curled leaves are symptoms in infected oil palm plants. This stage of infection indicates that the infection has reached the base of the oil palm plant stem.

Other symptoms that often appear on infected plants include the appearance symptoms of drought stress on the plant, spots appearing on the plant canopy on one side, a flat crown, many buds that should have opened but have not yet opened, the appearance of basidiocarp at the base of the lower stem, leaves unopened spears, and palm stems breaking and falling in cases of severe infection (Parthiban *et al.*, 2016). If fruiting bodies appear on oil palm plants, this indicates that the infection stage is severe. There has been massive degradation of plant stems. Old oil palm plants will die in 6 to 24 months, while young plants will die 2 to 3 years after the first symptoms of infection are detected (Siddiqui *et al.*, 2021).

Environmental Factors Support the Spread of BSR Disease

BSR disease can spread in various conditions and types of soil, even in oil palm plantations on peatlands, cases of BSR infection have been found (Midot *et al.*, 2019). Based on a survey conducted in

Malaysia, the most cases of BSR infection were found in lateritic soils and the least in peatlands. Lateritic soil is soil that has high aluminum and iron content. Usually, lateritic soils are formed in wet and hot tropical areas and are characterized by a red color (A. R. Mareddy, 2017). Land use history can also influence the spread of BSR infection. BSR disease can develop more massively in oil palm plantations located in coastal areas where the oil palm land was previously coconut plantation land. The spread of BSR disease has been shown to be more severe in areas with higher plant densities (Jazuli et al., 2024).

The chance of plants being infected with *G. Boninense* is greater in oil palm plantations that have undergone more than three replantings. Also, old plants have a greater chance of being infected than plants that have not yet produced fresh fruit bunches (Priwiratama et al., 2020). BSR infection can occur in various life cycles of oil palm plants. In cases found in Indonesia, the infection attack rate in 4 years old oil palm plants was between 1.42% and 4.28%. The attack rate on 17 years old oil palm plants is 50%. Meanwhile, in plantations with 33 year old oil palm plants, the infection rate was 0.71% (Lisnawita et al., 2016).

Tabel 2

The behavior of *Ganoderma Boninense* in each environmental parameter

No.	Parameter	Remarks
1.	Temperature	<ul style="list-style-type: none"> Optimal growth at 27–30°C; inhibited below 15°C and above 35°C; o growth at 45°C (Chong et al., 2017; Nawawi & Ho, 1990).
2.	Relative Humidity (RH)	<ul style="list-style-type: none"> Optimal at 50–60%; reduced growth above 60%.
3.	Soil pH	<ul style="list-style-type: none"> Best growth at pH 3–5.5 (Chong et al., 2017) pH 6 reduces BSR growth and supports seedlings (Rahman & Othman, 2020).
4.	Sunlight	<ul style="list-style-type: none"> Higher infection risk in shaded seedlings (Rees et al., 2007).

Molecular Testing Methods for BSR Disease

BSR infection can be detected by direct observation and molecular detection. The molecular detection approach is the fastest way to detect BSR infection (Bahari et al., 2024). Detection can also be done simpler, namely by observing pathogenic fungi directly at both macro and microscopic levels. However, this method takes a long time and has low resolution and sensitivity. Several molecular approaches to detect *G. Boninense* infection are real-time polymerase chain reaction (PCR) testing on fungal samples obtained in the field. The fruiting bodies or basidiomata part of the fungus is the most sensitive part for detecting the presence of pathogen DNA compared to the stem and root tissue of the fungus *G. Boninense* (Hilmi et al., 2022). Another commonly used early detection method for spreading BSR is a multiplex PCR-DNA kit using oil palm plants' root and stem tissue samples (Idris et al., 2010).

The enzyme-linked immunosorbent assay (ELISA) application can detect *G. Boninense* infection. This technique uses polyclonal antibodies to detect the presence of *G. Boninense* serologically. Detection can also be done by detecting the presence of typical ergosterol produced by the fungus *G. Boninense*. This method is carried out by making an extraction solution from samples suspected of being exposed to *G. Boninense* spores or mycelia. Ergosterol is detected if there is thin layer chromatography (TLC) in the extract solution and can then be quantified using high-performance liquid chromatography (Muniroh et al., 2014). However, this molecular method is quite complicated and expensive, so it is not appropriate to carry out in large areas with lots of samples (Siddiqui et al., 2021).

Many detection procedures can be done, but there is no truly effective way to stop the spread of BSR unless the biomarkers of *G. Boninense* have been detected (Mohd Hilmi Tan et al., 2023). Biomarkers are changes in cells, biochemistry, or molecules that can objectively measure normal biological processes, pathogenic processes, and pharmacological responses to treatment to control the development of infection. Biomarkers are technological tools that can help understand the causes, distribution status, diagnosis, and treatment response to a disease. The search for appropriate biomarkers to detect *G. Boninense* is currently being developed, but none are ready to be applied in the field. One of the biomarker developments being developed is the Oil palm extract medium (OPEM) model. This model is still being developed to produce a faster and non-invasive method for diagnosing *Ganoderma* in oil palm plantations (Santiago et al., 2023). The mRNA marker *EgPIN5* is a promising biomarker for early *G. Boninense* detection, identifying infection as early as 11 days post-inoculation before symptoms appear. LFA strips with ssDNA aptamers targeting *EgPIN5* RNA fragments offer a low-cost, visual detection method. While this approach shows potential, its sensitivity remains limited due to the low RNA copy numbers in field samples (Bahari et al., 2024).

Management of the Current Spread of BSR Disease

Management of the spread of *G. Boninense* can currently be done physically, chemically, and by biocontrol. Cleaning infected plantation areas must be done in detail. Clean clearing and windrowing procedures can be carried out to minimize the spread of inoculum. Infected oil palm plants must be chopped, crushed, and stacked between planting rows, although it cannot be guaranteed that the pathogen will not spread and infect healthy plants if this is done. Using fungicides to control the spread of *G. Boninense* is not very effective because this fungus is soil-borne. Fungicides will first be degraded in the soil before reaching their target. Injection of 90 ml of hexaconazole with 10 liters of water into the stems of infected oil palm plants can increase the survival rate by up to 70% and the ability to produce for several years to come (Mohammed et al., 2014). The use of biocontrol agents to control the spread of infection has been widely developed and shows reasonable success rates. Use of fungi *Trichoderma* spp., *Aspergillus* spp., and *Penicillium* spp. They were proven antagonistic to *G. Boninense* through in vitro experiments (Naher et al., 2013).

A mixture of *Trichoderma* spp, namely *Trichoderma aspergillum*, *Trichoderma harzianum*, and *Trichoderma virens*, as a biocontrol agent, can reduce symptoms of disease infection between 83% and 89%. The *Trichoderma* spp mixture can be applied in the nursery three months before planting the seeds (Musa et al., 2018). Application of *Trichoderma aspergillum* strain T76-14 is known to be able to respond to oil palm seedlings to control and limit pathogen colonization in host tissue and inhibit the distribution of *G. Boninense* in the soil (Samlkamnoed et al., 2023). Three bacterial strains, namely, *Pseudomonas aeruginosa* strain JQ-41, *Serratia marcescens* strain S16, and *Stenotrophomonas rhizophila* strain CASMBAUDAL2, together with one fungal strain, *Trichoderma* sp., and one actinomycetes strain, *Streptomyces* sp., have been proven to be able to prevent the growth of *G. Boninense* with inhibition levels between 70% - 88.5% (Rupaedah et al., 2024). Currently further studies are being carried out to formulate integrated control through a deeper understanding of the influence of physical, chemical and biological factors on the spread of *G. Boninense* infection. Temperature treatment, administration of boron and potassium, and application of the fungicide Manzoceb are known to reduce the specific metabolic rate of *G. Boninense* and have no effect on the development and metabolism of *Trichoderma virens* (Anothai et al., 2023).

THE POTENTIAL OF IoT UTILIZATION TO DETECT THE SPREAD OF BASAL STEM ROT DISEASE

Molecular infection testing can provide accurate confirmation of whether a plant has been infected with *G. Boninense* and how severe the infection is because it directly tests DNA sequences. However, this method requires complex lab tests, high expertise, is costly, and challenging for large-scale application. Therefore, advanced technologies like sensors and IoT have been developed for faster early detection of *G. Boninense* in oil palm fields. Imaging sensors, including RGB, multispectral, hyperspectral, thermal, fluorescence, and 3D, are widely used in precision agriculture. They can be applied in microscopes for cellular analysis, mounted on vehicles for plant imaging, deployed on UAVs for aerial monitoring, or placed on satellites for large-scale ecosystem assessment (Mahlein, 2016). High-resolution aerial images from UAVs can classify oil palm conditions based on tree crowns using image processing, ML, and deep learning. Hyperspectral imaging detects infection characteristics by combining absorption, reflectance, and fluorescence data into a hypercube (Vasefi et al., 2016). Non-imaging sensors like portable GC-MS, electronic noses, biosensors, and nuclear magnetic resonance (Wei et al., 2021). Table 3 summarizes sensor technologies tested for BSR detection in oil palms.

Table 3

Sensor Technology for BSR Detection in Oil Palm

Technology	Sensor	Measurement Technique	Pros	Cons	Ref.
Imaging	High-resolution RGB	UAV with 12.1 MP RGB camera	Low cost, easy to use	Sun bias, low infection correlation	(Izzuddin et al., 2019)
	Multispectral Imaging	UAV with multispectral camera	Full spectrum for classification, NIR effective for BSR	Accuracy depends on segmentation and sample size	(Ahmadi et al., 2022)
	Hyperspectral Imaging	Hyperspectral sensors on canopy	Detailed spectral-spatial models, low cost	Expensive instruments, complex data processing	(Kurihara et al., 2022)

Technology	Sensor	Measurement Technique	Pros	Cons	Ref.
	FLIR Thermal Imaging	FLIR cameras placed around trees	Easy to use, clear thermal stats	Narrow measurement spectrum, difficult infection suspicion	(Hashim et al., 2021)
Spectroscopy	Mid-infrared Spectroscopy	FTIR spectrometer in lab	High accuracy, detects biochemical compounds	Complicated sampling and analysis, expensive tools	(Liaghat et al., 2014)
	NIR Spectroscopy	NIRscan Nano spectrometer on leaves	Simple, rapid, non-destructive	Low sensitivity, complex calibration	(Mohd Hilmi Tan et al., 2023)
	Dielectric Spectroscopy	Measures dielectric properties of leaves	Rapid, detects health levels	Hard to pinpoint disease cause	(Khaled et al., 2022)
Satellite	WorldView-3 Satellite	Pixel value analysis of palm crown reflectance	Can classify infection symptoms	Requires expertise, accuracy depends on model selection	(Santoso et al., 2019)
	Sentinel-2 Satellite	Vegetation indices from multispectral data	Comprehensive data, low cost	No thermal band, influenced by cloud cover	(Handrian et al., 2022)
Sensor	Intelligent Electronic Nose	32 sensor elements detect compounds in soil, stem, and leaves	Classifies healthy and infected plants, estimates infection area	Reduced sensitivity in humid conditions, calibration challenges	(Markom et al., 2009)
	E-Nose MOS Gas Sensor	MOS sensors in the lab detect chemical properties	Quick detection, affordable	Sensitive to temperature/humidity	(Marhaenanto et al., 2025)
	Terrestrial Laser Scanning	3D laser scanning around oil palm trees	Effective at detecting unopened spears in infected plants	Time-consuming setup, requires trained staff for data extraction	(Husin et al., 2020)
	Electrical Resistance Sensor	Measures electrical resistance in stems/soil	Rapid, easy, and low-cost	Data highly influenced by temperature, humidity, and other factors	(Aziz et al., 2019)
Imaging with consumer-grade camera	Camera Canon 600D	Mounted to DJI phantom 3 to capture area	Low-cost, easy to use, large area	Data highly influenced by light intensity	(Hermantoro et al., 2023)
	Canon SX240 HS	Mounted to Turnigy 9XR Octocopter UAV	Low-cost, large area	Light-sensitive	(Bejo et al., 2018)

The IoT extends beyond sensor technology for data acquisition and can be developed into an integrated system for managing plant pests and diseases. This includes data traffic management, big data processing, sensor-CPU interfaces, and machine-user interaction design (Nayagam et al., 2023). Architectures integrating all components of an IoT system continue to evolve to simplify the integration of diverse systems and hardware. Lysis, a cloud-based architecture platform, has four key functions: integrating IoT with social networks, enabling virtual objects and device communication, storing sensor data while controlling sensor behavior, and allowing data requests from the same sensor across different IoT systems (Girau et al., 2016). The Lysis platform integrates sensors for real-time plant detection, classifies data using the Model Builder Micro Engine, and displays results via a smartphone app. The basic framework of the IoT layer architecture should have sensors and actuators, connectivity and communication paths, edge devices

and gateways, Cloud Platform, Data Analytics (machine and deep learning), mobile and web applications, decision support systems, and finally security and privacy (Dhaka et al., 2023). The IoT is not only limited to sensor technology for data acquisition but can also be developed into an integrated system for managing plant pests and diseases. This can include data traffic management, big data processing, sensor and CPU interfaces, and machine-user interaction design (Nayagam et al., 2023). Architectures that integrate all parts of an IoT system continue to evolve to bridge the complexity of integrating dissimilar systems and hardware. Lysis is an example of a cloud-based architecture platform that has 4 essential functions, namely social network integration with IoT, creating virtual objects and communication between devices, features for storing data from sensors and controlling sensor behavior, and the ability to request data from the same sensor but from different IoT systems. The Lysis platform can be developed into a plant detection system capable of connecting various collocated sensors and sending the data in real-time to a dataset management platform. The collected dataset is classified and modeled in the Model Builder Micro Engine, the results of which are displayed in the app on the user's smartphone (Delnevo et al., 2022). The basic framework of the IoT layer architecture should have sensors and actuators, connectivity and communication paths, edge devices and gateways, Cloud Platform, Data Analytics, mobile and web applications, decision support systems, and finally security and privacy.

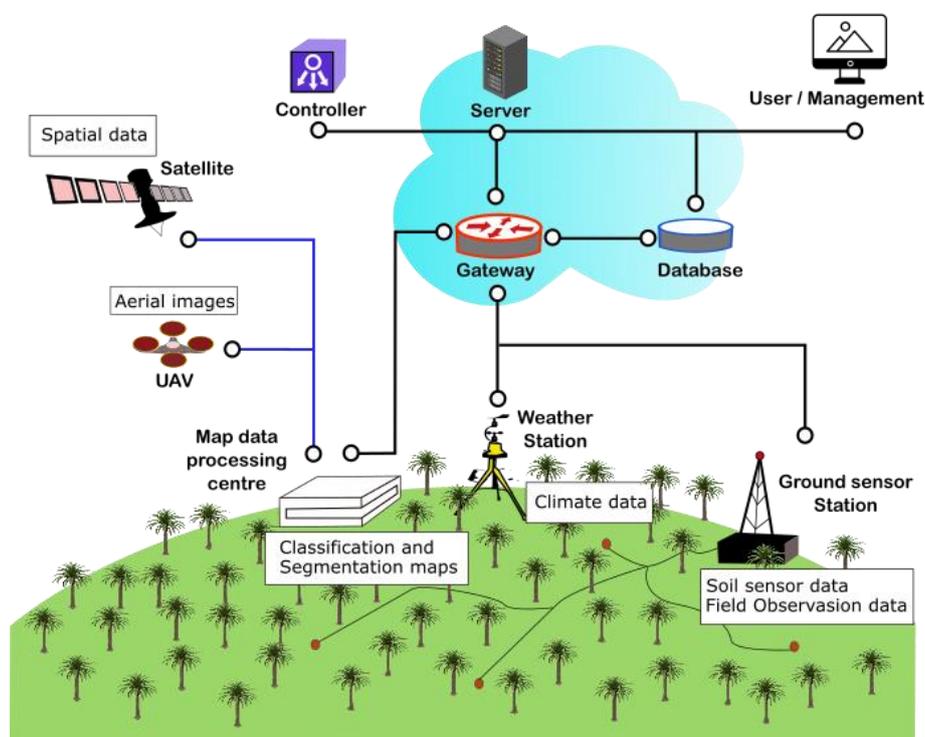

Fig. 2 - Concept of applying IoT for developing a BSR outbreak warning system

IoT technology makes it possible to apply it in building an early warning system for the spread of BSR disease in oil palm plantations. An initial overview of the concept of early warning for BSR disease using IoT can be seen in Fig. 2. Detection via imagery from UAVs and satellites can detect the characteristics of BSR infection, especially through monitoring the condition of the oil palm plant canopy. Satellite data containing multispectral information such as Sentinel-2, Landsat, and WorldView-3 are possible to use because they have many spectra to be analyzed either through modeling the spectral values or through converting the spectral values to obtain vegetative indices or surface temperature (Handrian et al., 2022). A UAV can capture aerial images for clearer analysis. Hyperspectral cameras offer high accuracy in segmenting and classifying BSR-infected oil palms but are costly. Monitoring often includes high-resolution aerial maps to enhance segmentation and classification. Hyperspectral data detects early BSR infection as mycelium develops on bark or fragile wood (Kurihara et al., 2022).

However, the characteristics of the plant canopy cannot wholly describe the spread of infection due to *G. Boninense* attacks the roots and base of oil palm plant stems. It has been proven with prior reports that the average accuracy of remote sensing in classifying the severity is around 80%, and in classifying healthy and

unhealthy trees is around 86.67% (Siddiqui *et al.*, 2021). So, field observations are still necessary to provide information about the presence of infected plants and confirm the monitoring result from remote sensing and sensors. These field observations can be carried out simultaneously with plant maintenance work. *G. Boninense* is also a fungus that can spread through airborne and direct contact, so it is also necessary to monitor environmental conditions by acquiring weather and climate data and soil conditions. Weather and climate data can be taken from weather stations, and soil condition data can be monitored using soil sensors or manual measurements. Meanwhile, data on soil electroconductivity distribution on land can be used to monitor soil conditions. Apart from carrying out analysis to predict disease outbreaks, steps to verify the results of predictions also need to be taken to control the spread of disease infections. Manual verification approaches and molecular detection can be carried out as further steps to verify the BSR outbreak warning system results. (Wang *et al.*, 2023). Manual verification approaches and molecular detection can be carried out as further steps to verify the BSR outbreak warning system results.

MODEL DEVELOPMENT FOR DETECTING BSR

Detection models are crucial factors other than data acquisition techniques and methods determining detection success. ML applications in precision agricultural systems can be used to detect plant pests and diseases. ML integrated into IoT is very powerful for real-time detection systems. ML has a role in predicting and detecting the spread of epidemics by studying datasets containing information about pathogen behavior, demographics, population, information about biology and biodiversity. Many models can be used to predict and detect the spread of disease infections, ranging from regression models neural networks to deep learning. Apart from that, the types of datasets used also vary, starting from spatial, epidemiological, meteorological, and remotely sensed data (Alfred & Obid, 2021). ML construction can be divided into several parts: dataset preparation, data preprocessing, data correlation analysis, determining the suitable model, and testing and verifying the selected model. The final stage is implementation (An *et al.*, 2024). Many statistical models and ML models can be used to prepare an early detection system for evaluating the spread of a disease. The model choice depends on the dataset type and the purpose of data processing. For example, if the goal is to obtain the relationship between spatial and temporal data in the spread of disease, spatio-temporal models can be used. If the goal is to detect climate data indicating what disease outbreak will occur, you can use Bayesian ML (Haque *et al.*, 2024). Several ML models that can be used to detect BSR disease in oil palm plantations are presented in Table 4.

Tabel 4

Several ML models for classifying the level of BSR disease infection in oil palm plants.

Models	Dataset Type	Purpose	Pros	Cons	Ref.
Kernel Naive Bayes	3D plot data from laser scans	Detect unopened spears, classify infection	Can classify with small datasets	Biased by poor data, not for continuous features	(Husin <i>et al.</i> , 2020)
ANN Backpropagation	VIS-NIR spectral data	Identify best wavelength for BSR	No parameter tuning, versatile	Sensitive to noise, slow training	(Ahmadi <i>et al.</i> , 2017)
PLS Discriminant Analysis	Hyperspectral images	Classify plant disease infection levels	Handles high variable-to-sample ratios	Requires deep statistical understanding	(Lelong <i>et al.</i> , 2010)
Support Vector Machine	Hyperspectral crown images	Classify infection using top fronds	Good for high-dimensional data	Needs large memory, struggles with large datasets	(Khaled <i>et al.</i> , 2018)
K-Nearest Neighbor	Hyperspectral frond samples	Classify BSR infection levels	Simple, no need for training model	Needs data smoothing, K-value affects accuracy	(Liaghat <i>et al.</i> , 2014)
Random Forest	Multispectral data from Sentinel 2A	Map plant infection distribution	Robust, handles imbalanced data	Complex interpretation, long prediction time	(Handrian <i>et al.</i> , 2022)
Multilayer-Perception NN	Hyperspectral drone images	Separate healthy/diseased plants	Handles non-linear problems	Slow computation, reliant on training data quality	(Lee <i>et al.</i> , 2022)

Models	Dataset Type	Purpose	Pros	Cons	Ref.
M-CR U-Net	Aerial RGB images	Classify infection severity via image segmentation	Robust for pixel-level segmentation	Downsampling reduces spatial accuracy, overfits on small datasets	(Win Kent <i>et al.</i> , 2023)

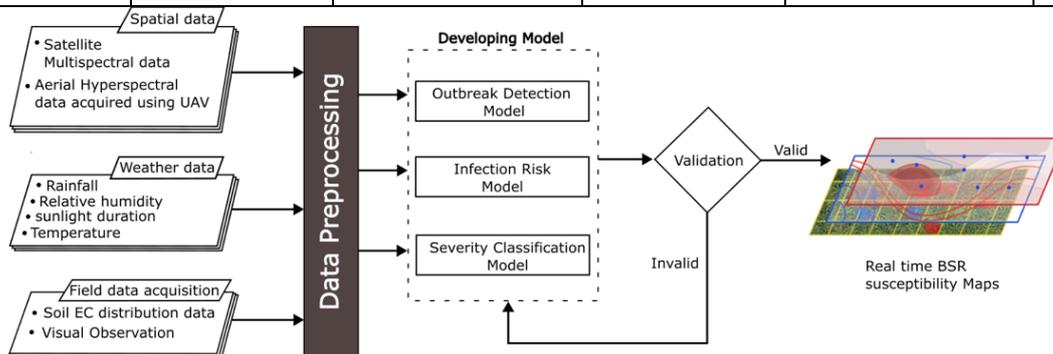

Fig. 3 - Proposed dataset and ML model development for real-time BSR susceptibility mapping

Models for segmentation and classification are not limited to those shown in Table 3, there are many more advanced models, especially deep learning models, which can be used for segmentation and classification but have not been widely used to detect the spread of BSR disease. For example, ML systems such as the YOLO (You Only Look Once) series can be used for image recognition and recognizing pest habitat environments. There are 3 models that can be developed to create a BSR outbreak warning system, namely the outbreak detection model, infection risk model, and severity classification model. The severity classification model aims to detect the presence of BSR infection in an oil palm plantation, which can classify infected and healthy plants and the level of infection. Meanwhile, the outbreak detection model is used to detect distribution patterns that may occur and need to be anticipated in the future. The resulting output is an integrated map that can show the existing and potential distribution of BSR infection, as shown in Fig.3. (Chen *et al.*, 2020). There are 3 models that can be developed to create a BSR outbreak warning system, namely the outbreak detection model, infection risk model, and severity classification model. The severity classification model aims to detect the presence of BSR infection in an oil palm plantation, which can classify infected and healthy plants and the level of infection. Meanwhile, the outbreak detection model is used to detect distribution patterns that may occur and need to be anticipated in the future. The resulting output is an integrated map that can show the existing and potential distribution of BSR infection, as shown in Fig. 3.

CONCLUSIONS

The Basal Stem Rot disease that attacks oil palm plantations is mainly caused by *Ganoderma Boninense*, a fungus that can spread via airborne spores, through root contact, or spread by its sporophores in the soil and plant debris. The ability of very fast and massive spread and transmission must be overcome quickly to reduce losses from the loss of potential fresh fruit bunch (FFB) harvests than they should. Advanced technologies can be a solution because of their ability to detect in real time through a precise classification and segmentation system and are able to cover large areas through geospatial data acquisition techniques either via satellite or drone. With the current advances in sensors, IoT, AI technologies, it is very possible to build a monitoring system and early warning system that integrates the results of data acquisition through direct observation, sensors, and dynamic and real-time geospatial data for the next future studies. The key to the success of this system lies in selecting a classification and segmentation model that can detect and assess the level of infection of *G. Boninense* on oil palm plants in oil palm plantations.

ABSTRACT

This study aims to construct digital fruit trees with high-precision geolocation and high-quality canopy phenotypic details, supporting the development of digital fruit tree technology and the establishment of smart orchards. The Neural Radiance Fields (NeRF) theory was integrated with georeferencing technology. Firstly, multiple ground control points were placed around the tree, and their WGS-84 coordinates were recorded using an RTK surveying instrument. Next, a drone captured multi-view images of the fruit tree, recording the camera poses during the image acquisition. The multi-view fruit tree images undergo ray casting, hierarchical sampling, and high-frequency position encoding before being input into a Multilayer Perceptron (MLP). The MLP was then supervised through volume rendering to obtain a convergent radiance field that reflects the true form of the fruit tree, resulting in the generation of a fruit tree point cloud. Finally, by establishing correspondences between the points in the fruit tree point cloud and the ground control points in the real world, a rigid transformation matrix was computed to convert the point cloud from a local coordinate system to WGS-84 coordinates, yielding a geographically informed digital fruit tree. The experiments demonstrate that the constructed digital fruit tree exhibits excellent phenotypic details and accurately represents multi-scale characteristics. The accuracy of tree morphology indicators, such as tree height, crown length, and width, reached 99.12%, 99.34%, and 99.22%, respectively. Compared to point clouds generated by traditional Structure from Motion-Multi View Stereo (SfM-MVS) methods, the root mean square errors were reduced by 61.24%, 73.48%, and 62.32%, respectively. Additionally, the georeferencing accuracy achieved millimeter-level precision, with registration errors generally below 2 mm. The proposed method can construct digital fruit trees with high geolocation accuracy, detailed phenotypic information, and scale consistency, overcoming key barriers in the development of digital fruit tree technology. It can provide comprehensive data for various production operations in smart orchards.

摘要

本研究旨在构建具有高水平地理定位精度与高品质叶冠表型细节的数字果树，支持数字果树技术体系与智慧果园建设。将神经辐射场 (Neural Radiance Fields, NeRF) 理论与地理坐标配准 (Georeferencing) 技术相结合，以初果期的桃树作为研究对象。首先，在果树周围地面上布设多个地面控制点并通过 RTK 测量仪记录地面控制点中心位置的 WGS-84 坐标；其次，使用无人机环绕拍摄果树多视角图像并记录拍摄时相机位姿；然后，将多视角果树图像进行光线投射法分层采样和高频位置编码后输入多层感知机 (Multilayer Perceptron, MLP)，通过体积渲染 (Volume Rendering) 监督训练过程以获取收敛且能反映果树真实形态的辐射场并导出果树点云；最后，通过果树点云中与现实世界中地面控制点的对应关系，计算刚性变换矩阵，将果树点云从局部坐标系转换至 WGS-84 坐标系，得到具有地理信息的数字果树。试验表明，本研究构建的数字果树具有良好的表型细节，可准确表征果树多尺度表型细节。该方法构建的果树点云在树高、冠层长度与宽度等树形指标方面的精度分别达到 99.12%、99.34%、99.22%，相较于传统的运动恢复结构-多视图立体匹配 (Structure from motion-Multi View Stereo, SfM-MVS) 方法构建的果树点云，均方根误差分别减小 61.24%、73.48%、62.32%。同时，其地理坐标配准精度达到毫米级，配准误差普遍小于 2mm。该研究提出的方法能构建具有高地理坐标定位精度、高表型细节与高尺度一致性的数字果树，突破了制约数字果树技术体系发展的关键瓶颈，能够为智慧果园的数字化果树表型组学研究、数字化树形管理、数字化生长监测等领域提供关键技术支撑。

INTRODUCTION

In the intelligent orchard production model of all-weather, all-process, and all-space unmanned operations, the digital fruit tree technology system plays a crucial role (Wu *et al.*, 2021). It provides comprehensive spatial perception capabilities for unmanned agricultural machinery, guiding autonomous tasks such as pruning (Yang *et al.*, 2017), thinning (Zhang *et al.*, 2020), and harvesting (Zhao, 2022). Simultaneously, in fields such as digital phenomics research (Hu *et al.*, 2019), digital tree management (Jiménez-Brenes *et al.*, 2017), and digital growth monitoring (Bdulridha *et al.*, 2019), the digital fruit tree finds extensive application, holding significant importance for the construction and management of smart orchards (Zhou *et al.*, 2019).

The acquisition of phenotypic information from fruit trees is a critical step in constructing digital fruit trees (Narvaez *et al.*, 2019). The main approaches for obtaining three-dimensional phenotypes of fruit trees are laser scanning systems (Zhang *et al.*, 2020; Colaço *et al.*, 2017) and stereo vision systems. Laser scanning provides high accuracy but is costly and lacks color information. In contrast, stereo vision systems, represented by the Structure from Motion-Multi View Stereo (SfM-MVS) method, have lower costs and can simultaneously capture both the structure and color information of fruit trees.

Notably, Dongyu Ren *et al.* achieved the reconstruction of peach tree branches and crowns using the Kinect v2 camera (Ren *et al.*, 2022),

Gatziolis *et al.* planned various aerial trajectories for SfM-MVS in tree 3D reconstruction (Gatziolis *et al.*, 2015), and Miller *et al.* reconstructed potted trees using handheld cameras (Miller *et al.*, 2015). However, for fruit tree canopies with complex topological structures and multi-scale high-frequency details, traditional stereo vision systems struggle to accurately capture their three-dimensional phenotypes, posing a critical scientific challenge to the development of digital fruit trees.

Mildenhall *et al.* introduced the theory of Neural Radiance Fields (NeRF) (Mildenhall *et al.*, 2021), an implicit neural rendering (Tewari *et al.*, 2022) for three-dimensional reconstruction. It achieves finer three-dimensional representations of complex phenotypes through sparse input image sets and a Multilayer Perceptron (MLP). With research and improvements to the NeRF theory, there has been a significant leap in both speed and quality (Barron *et al.*, 2021; Martin-Brualla *et al.*, 2021; Tancik *et al.*, 2023; Müller *et al.*, 2022).

The foundation of digital fruit trees lies in obtaining phenotypic information from fruit trees, and further applications rely on accurate geographical information (Zhang *et al.*, 2013). Geographical information supports automated agricultural practices in smart orchards and allows the integration of geographical, environmental, and meteorological data to build a comprehensive digital fruit tree management system. However, the fruit tree point clouds generated by stereo vision systems are limited to local coordinate systems, unable to provide global geographical information. Real-Time Kinematic (RTK) positioning systems, leveraging real-time differential GNSS technology, achieve centimeter-level high-precision geographical coordinate positioning. Therefore, combining the RTK positioning system with fruit tree point clouds allows for georeferencing, integrating digital fruit trees into a global geographical spatial framework. Extensive research has been conducted on the alignment and fusion of point clouds.

Nistér *D.*, (2004), extracted feature points from point cloud data for feature point matching after acquiring the data using a stereo camera, thereby efficiently solving the traditional five-point relative pose problem.

Konolige *et al.*, (2008) and Akbarzadeh *et al.*, (2006), utilized the ICP (Iterative Closest Point) algorithm to align point cloud data from multiple scenes. The ICP algorithm has shown considerable promise in recent years. However, the alignment in this study requires the matching and fusion of two ground point clouds with significant overlap, using image control points. For aligning fruit tree point clouds and georeferenced ground point clouds, this study refers to the four-point fast matching algorithm proposed by Aiger *D et al.*, (2008).

In addressing the challenges of stereo vision 3D reconstruction technology in accurately representing multi-scale complex phenotypic details of fruit trees and the lack of geographical location information in generated fruit tree point clouds, this study combined the Neural Radiance Fields theory with georeferencing technology. Focusing on peach trees, a method for constructing digital fruit trees based on the Neural Radiance Fields theory and georeferencing technology is proposed. The aim is to leverage the NeRF's excellent representation capabilities for high-frequency details and complex topological structures and the RTK's centimeter-level high-precision geographical coordinate positioning ability to build a digital fruit tree with high-level geospatial positioning accuracy and high-quality canopy phenotypic details.

MATERIALS AND METHODS

The experimental site for this study is the peach orchard at Shandong University of Technology, with the experimental subjects being individual peach trees in the early fruiting stage. Firstly, multiple ground control points were positioned around the fruit tree, and their WGS-84 coordinates were meticulously recorded using an RTK surveying instrument. Subsequently, a drone was employed to capture multi-perspective images of the fruit tree while simultaneously recording the camera poses during image acquisition. Following this, a Neural Radiance Field for the fruit tree was trained using image data augmented with additional pose information, and a point cloud was generated as an output. Lastly, through establishing correspondences between ground control points in the real world and points within the fruit tree point cloud, a rigid transformation matrix was computed. This facilitated the conversion of the fruit tree point cloud from local coordinate systems to the WGS-84 coordinate system, resulting in the generation of a geospatially informed digital fruit tree.

The equipment for fruit tree image acquisition and geographical coordinate measurement is illustrated in Figure 1. The image acquisition device utilized is the DJI "Mavic 2" unmanned aerial vehicle, while the geographical coordinate measurement device consists of the Qianxun SR2 high-precision Real-Time Kinematic (RTK) surveying instrument and ground control points.

Fig. 1 - Experimental equipment

1. Ground control point; 2. UAV; 3 RTK receiver 4. RTK display terminal; 5. RTK positioning rod

The individual peach tree selected for the experiment measured 2.18 m in height with a crown width of 2.17 m. The data collection was conducted between 4:30 and 4:45 p.m. under cloudy weather conditions, with a light breeze and no direct sunlight. The drone used for image acquisition operated with a focal length of 26 mm and a resolution of 1920 × 1080 pixels. The setup for fruit tree image acquisition and geographical coordinate measurement is shown in Figure 2. Four ground control points (GCPs) were placed around the tree, clearly marked at the base of the trunk, the top of the canopy, and along its edges. Using an RTK surveying instrument, the WGS-84 coordinates of these GCPs were recorded. Following the calibration of the intrinsic parameters of the UAV-mounted camera, the drone captured multi-view images by circling the tree along a spiral trajectory, also illustrated in Figure 2. The flight trajectory was designed based on the experimental protocol outlined by *Tewari et al. (2022)*, featuring a circumferential radius of approximately 3 m, a pitch of 0.5 m, and a rotation speed of around 2 RPM. This process resulted in the collection of 284 images with roughly 50% overlap. Finally, a 3D reconstruction dataset consisting of the fruit tree images and their corresponding camera pose data was compiled, serving as input for the subsequent neural radiance field-based 3D reconstruction of the fruit tree.

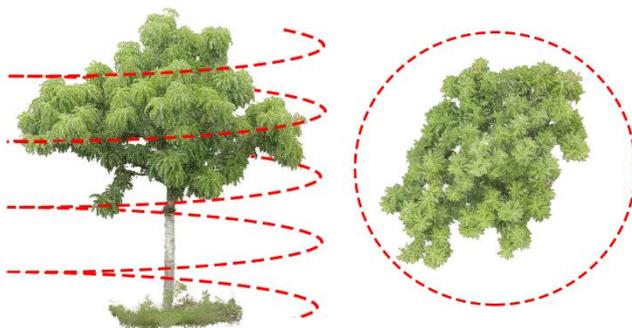

Fig. 2 - UAV aerial photography path

The Neural Radiance Fields (NeRF) were trained using two-dimensional fruit tree images and corresponding pose data to transform the two-dimensional images into a three-dimensional spatial structure of the fruit tree. The NeRF utilized an implicit function to record color and volume density information of sampled points in the scene. This function is approximated by a Multilayer Perceptron (MLP) and converges during the training iterations. The experimental hardware configuration for training included: CPU: i9-10850K; GPU: NVIDIA GeForce RTX3090; RAM: 64GB. The software programs used in the point cloud measurement and visualization process were Cloud compare and Metashape.

Initially, camera rays were projected from the camera origin toward specific pixel directions on the image plane using the ray casting method (Kajjya J et al., 1984). Each ray traverses the fruit tree scene to capture visual information along its path. The camera ray D , originating from the camera center and passing through a given pixel, can be mathematically expressed as:

$$D(m,n) = \frac{1}{\left\| K^{-1} \begin{bmatrix} m \\ n \\ H \\ 1 \end{bmatrix} \right\|_2} \begin{bmatrix} m \\ W \\ n \\ H \\ 1 \end{bmatrix} \tag{1}$$

The variable (m,n) represents the pixel coordinates through which the camera ray passes, with the pixel plane dimensions denoted as W for width and H for height. The camera intrinsic matrix is denoted as K .

Subsequently, sampling along the camera ray was conducted, where each sampled point was represented by a vector comprising five parameters: the coordinates of the points sampled along the ray (x,y,z) and the direction of the camera ray (θ,ϕ) . After encoding the sampled points, the vector was input into the Multilayer Perceptron (MLP). The MLP, a fully connected deep neural network, consisted of two parts, as illustrated in Figure 3. The first part of the MLP comprises eight fully connected layers with 256 dimensions each, taking the sampled point coordinates (x,y,z) as input. To address potential issues such as gradient explosion and vanishing gradients in deep neural networks, a residual connection structure (Rahaman N et al., 2019) is introduced in the fourth layer of the network. This involves concatenating the output of the fourth layer with the input signal (x,y,z) before inputting it into the fifth layer, thereby breaking network symmetry and enhancing the representational capacity of the MLP. The MLP outputs the volume density w and a 256-dimensional feature vector.

The second part, denoted as cMLP, takes the feature vector outputted by the w MLP and a 24-dimensional high-frequency signal representing the direction of the camera ray $f(\theta,\phi)$ as input. After concatenation, this combined input is passed through a 256-dimensional fully connected layer, and the output from the cMLP layer produces the color $C=(R,G,B)$.

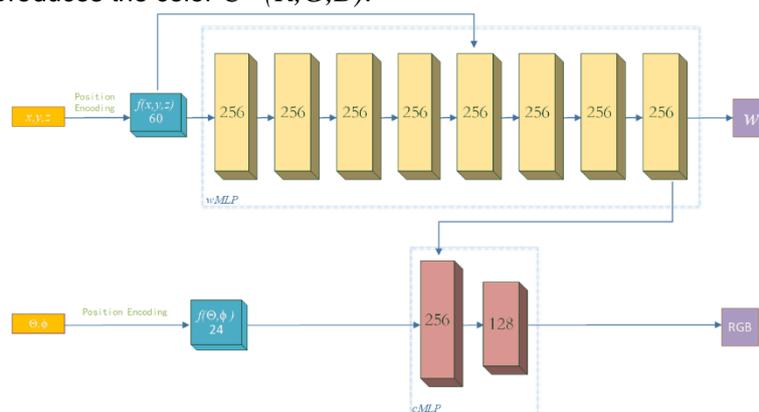

Fig. 3 - Neural radiance field MLP illustration

The fruit tree scene was approximated as a neural radiance field describing the volume density and color of all sampled points in the scene through the two components of the Multilayer Perceptron (MLP). The initial neural radiance field generated exhibits a discrete, cloud-like form, lacking accurate representation of the tree's morphology. Therefore, it is necessary to perform volume rendering on the volume density and color of the sampled points outputted by the MLP. Subsequently, the MLP's weights were updated in reverse to facilitate training.

Integral to this process is the direction along the camera ray, where each sampled point is integrated, and the volume density w serves as the weighting factor. Based on the volume density w , a weighted sum of colors C at each sampled point along the ray is computed. This calculation determines the color of the pixel point traversed by the camera ray. Higher volume density w corresponds to lower transparency, thus greater influence of the color C of the sampled point on the pixel color. This computation process is known as volume rendering, and the formula for the calculation is as follows:

$$\begin{cases} C_c(r) = \pi \int_{t_n}^{t_f} T(t)w(r(t))C(r(t), d)dt \\ T(t) = \exp(-\int_{t_n}^t w(r(s))ds) \end{cases} \quad (2)$$

The variable $C_c(r)$ represents the pixel color, $T(t)$ denotes the cumulative transmittance coefficient, $w(r(r(t)))$ is the volume density of the sampled point at position $r(t)$, $w(r(r(s)))$ is the volume density of the sampled point at position $r(s)$, $C(r(t))$ represents the color of the sampled point at position $r(t)$, t_n is the near point of the view frustum, and t_f is the far point of the view frustum.

Subsequently, to achieve high-quality rendering results with a reduced number of sampled points and simultaneously decrease computational complexity, coarse-fine two-level granularity stratified sampling and rendering were performed along the rays. This involves using the volume density distribution of coarse-grained sampled points as a reference to sample more fine-grained points in regions with higher volume density along the rays.

In the coarse-grained rendering phase, N_c points were uniformly sampled along the camera ray, input into the MLP, and subjected to coarse-grained volume rendering. The resulting coarse-grained rendering pixel color $\hat{C}_c(r)$ was obtained. Following this, N_f fine-grained sampled points, based on the volume density distribution of coarse-grained sampled points, are input again into the MLP for fine-grained volume rendering, yielding the fine-grained rendering pixel color $\hat{C}_f(r)$.

$$\begin{cases} \hat{C}_c(r) = \sum_{g=1}^{N_c} w_g C_g \\ \hat{C}_f(r) = \sum_{l=1}^{N_c+N_f} w_l C_l \end{cases} \quad (3)$$

The variables w_g and w_l represent the cumulative volume density of coarse-grained and fine-grained sampled points, respectively, while C_g and C_l denote the colors of coarse-grained and fine-grained sampled points. N_c and N_f are the respective quantities of coarse-grained and fine-grained sampled points.

After computing the coarse-grained rendering pixel color $\hat{C}_c(r)$ and the fine-grained rendering pixel color $\hat{C}_f(r)$, a comparison was made between each of them and the pixel color $C(r)$ at the pixel (m, n) traversed by the camera ray. This process results in the derivation of the training loss, followed by the computation of the squared sum of the L norm of the loss. Iterating over all pixels for a given viewpoint V , the loss function L for that viewpoint is obtained.

$$L = \sum_{r \in V} [\|\hat{C}_c(r) - C(r)\|_2^2 + \|\hat{C}_f(r) - C(r)\|_2^2] \quad (4)$$

The variables $\hat{C}_c(r)$ and $\hat{C}_f(r)$ represent the pixel colors computed through coarse-grained and fine-grained rendering, respectively, while $C(r)$ is the color of the pixel along the ray direction. O encompasses all pixels in a given view. Subsequently, the network weights of the MLP are updated in reverse based on the loss function, iteratively adjusting the scene to gradually approximate the real morphology of the tree. This process continues until convergence conditions are met, completing the training of the neural radiance field for the tree. The final outcome is the NeRF scene of the tree, which characterized the three-dimensional spatial structure and realistic color information. By mapping the coordinates and color information of each sampled point in the scene to the local coordinate system and recording it, the three-dimensional real-world point cloud of the tree is obtained, thus achieving the three-dimensional reconstruction of the tree.

The fruit tree point cloud obtained from the three-dimensional reconstruction exists in a local coordinate system. To establish a geospatially informed digital representation of the fruit tree, it is imperative to perform georeferencing on the fruit tree point cloud, thereby transforming it from the local coordinate system to the WGS-84 geographic coordinate system. In this study, ground control points (GCP) serve as registration benchmarks. Four ground control points were positioned around the fruit tree. Subsequently, using an RTK, the WGS-84 coordinates at the center of each ground control point were recorded. The simultaneous reconstruction of both the fruit tree and ground control points is illustrated in Figure 4, where the identification numbers of the ground control points are distinctly discernible in the point cloud.

Fig. 4 - Comparison of ground control point cloud and photo

Consider the point cloud representing the fruit tree as Point Cloud A. Select the coordinates of four ground control points' centers as matching points, and designate them as the Point Cloud B, with the WGS-84 geographic coordinates recorded by the RTK surveying instrument for these four ground control points as the corresponding matched points. For each matching point and its corresponding matched point, perform centering, and calculate the covariance matrix H using the decentered coordinates of the matching points.

$$\begin{cases} \Delta A_i = A_i - \phi A \\ \Delta B_i = B_i - \phi B \end{cases} \quad (5)$$

$$H = \sum_{i=1}^4 (\Delta B_i) \cdot (\Delta A_i)^T \quad (6)$$

Where ϕA represents the average coordinates of matching points in Point Cloud A, and ϕB represents the average coordinates of matching points in Point Cloud B. A_i and B_i denote the i -th matching points in Point Cloud A and B, respectively. ΔA_i and ΔB_i represent the decentered coordinates of the matching points. H stands for the covariance matrix. Subsequently, perform singular value decomposition on H and calculate the scaling factors. The calculation formula is as follows.

$$H = U \Sigma V^T = [u_1 \quad u_2 \quad u_3] \begin{bmatrix} \sigma_1 & 0 & 0 \\ 0 & \sigma_2 & 0 \\ 0 & 0 & \sigma_3 \end{bmatrix} \begin{bmatrix} v_1^T \\ v_2^T \\ v_3^T \end{bmatrix} \quad (7)$$

$$s = \frac{\sqrt{\sigma_1^2 + \sigma_2^2 + \sigma_3^2}}{\sigma_1} \quad (8)$$

Where U and V are the left and right singular vector matrices, respectively. Σ represents the singular value matrix, and u_i ($i=1,2,3$) denotes the column vectors of matrix U . Similarly, v_i ($i=1,2,3$) represents the row vectors of matrix V , and σ_i ($i=1,2,3$) denotes the singular values, indicating the scaling factors in different directions for the matching points. Through the left and right singular vector matrices and the scaling factor, calculate the rotation matrix R and translation vector t to transform Point Cloud A from the local coordinate system to the WGS-84 coordinate system. These components constitute the rigid transformation matrix that aligns Point Cloud A with Point Cloud B.

$$\begin{cases} R = VU^T \\ t = \phi B - s \cdot R \cdot \phi A \end{cases} \quad (9)$$

$$T = \begin{bmatrix} sR & t \\ 0 & 1 \end{bmatrix} \quad (10)$$

Where ϕA and ϕB represent the average coordinates of matching points in Point Cloud A and B , respectively. U and V are the left and right singular vector matrices, R is the rotation matrix, t is the translation vector, s is the scaling factor, and T is the rigid transformation matrix. Applying the rigid transformation matrix T to all points in Point Cloud A aligns Point Cloud A with the coordinate system of Point Cloud B . As a result, each point in the tree point cloud obtains its coordinates in the WGS-84 geographical coordinate system, establishing a digital tree with geographical coordinate information.

RESULTS AND ANALYSIS

The dataset for the three-dimensional reconstruction of the tree consists of a total of 284 images, with 21 images in the training dataset and 263 in the testing dataset. The training process of the tree NeRF scene spans 30,000 steps, taking 17 minutes and 16 seconds, with a generation rate of 1.14×10^5 training rays per second. As illustrated in Figure 5, after reaching 15,000 steps, the scene representation stabilizes, and parameters such as learning rate, training loss, distortion loss, RGB loss, among others, gradually converge. The learning rate is a critical component in the optimization of machine learning models. It is employed to regulate the step size of the update process, which is progressively reduced through the implementation of an exponential decay strategy. The training loss functions as the overarching objective function for model optimization, thereby guiding the direction of parameter updates. RGB loss serves as the primary supervisory signal of NeRF, reflecting the model's performance in color reconstruction and geometric rationality. Aberration loss, on the other hand, leads to a more rational volume density distribution, thereby enhancing geometric coherence and rendering quality.

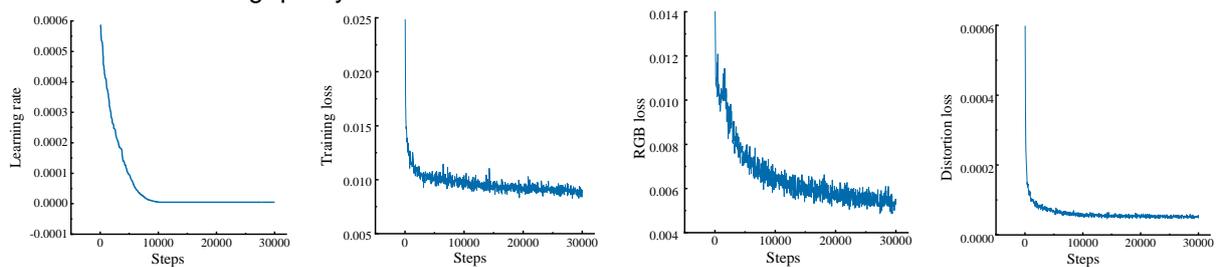

Fig. 5 - Neural radiance field training parameters

The reconstructed three-dimensional NeRF scene of the fruit tree is depicted in Figure 6, juxtaposed with corresponding depth maps and photographs of the fruit tree. The fidelity of the reconstructed fruit tree in terms of color and texture is exceptional, closely resembling the photograph of the fruit tree taken at the same pose, thereby achieving a representation effect at the level of real scenes. The contours of the canopy in the NeRF scene depth map are sharp and well-defined, with clear delineation of branches and leaf layers, providing distinct hierarchical depth information. This underscores the commendable three-dimensional representation efficacy of the NeRF scene.

Fig. 6 - Comparison between fruit tree photo and fruit tree NeRF scene and depth map

In order to assess the three-dimensional scene representation efficacy of the NeRF method, fruit tree images from the test dataset were compared with corresponding NeRF scene images captured at identical poses. Structural Similarity Index (SSIM) (Rahaman *N et al.*, 2019) and Learned Perceptual Image Patch Similarity (LPIPS) (Zhang *R et al.*, 2018) were introduced as two image quality assessment metrics to gauge the scene reconstruction capability of the NeRF method. Figure 7 illustrates the evolution of these evaluation metrics during the training process. The LPIPS metric stabilizes within the range of 0.2 to 0.3 after 25,000

steps, with a minimum value of 0.2050. The SSIM metric stabilizes within the range of 0.6 to 0.7 after 25,000 steps, reaching a maximum value of 0.7215.

Both evaluation metrics consistently reside within the high-quality range (Wang Z et al., 2004), indicating the NeRF method's proficient recovery capability for high-frequency detailed scenes.

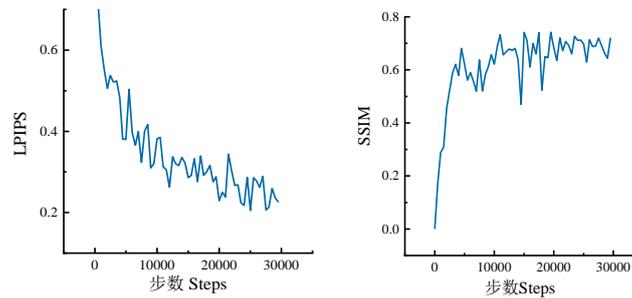

Fig. 7 - Neural radiance field quality assessment metrics

Due to the inherent nature of the NeRF scene for fruit trees, which is essentially a representation by an implicit function approximated using Multilayer Perceptrons (MLP), direct editing of the scene is not feasible. Consequently, it becomes imperative to convert the NeRF scene into a three-dimensional point cloud model for subsequent research and applications. The fruit tree point cloud model, derived from the NeRF scene, is depicted in Figure 8, where features such as the fruit tree, ground control points, and yellow markers at the base of the trunk are distinctly reconstructed within the point cloud model.

Fig. 8 - Comparison between NeRF scene of fruit tree and Point cloud model of fruit tree

The ground control points play a pivotal role as essential links establishing the connection between the local coordinate system and the WGS-84 coordinate system for the fruit tree point cloud. Four ground control points were deployed for this experiment, denoted as points 2, 13, 20, and 28. The centroids of these four points were utilized as matching points to compute the rigid transformation matrix. Consequently, the ground control points in the fruit tree point cloud model were aligned with their corresponding positions in the WGS-84 coordinate system. In the geospatial coordinate registration process of this experiment, the scaling factor s was determined to be 1.00809. The rigid transformation matrix T applied is expressed as follows:

$$T = \begin{bmatrix} 0.921 & -0.409 & 0.014 & 28.185 \\ 0.409 & 0.919 & -0.058 & -12.497 \\ -0.011 & -0.058 & -1.006 & 58.429 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

To validate the accuracy of geospatial coordinate registration, the right upper corner points of each ground control point and the vertices of the triangular yellow markers at the base of the trunk were selected as test points. An RTK surveying instrument was employed to measure the WGS-84 coordinates of these test points as actual values. Subsequently, the WGS-84 geographical coordinates at the corresponding positions in the fruit tree point cloud after registration were measured as experimental values. A comparison was then conducted between the measured and actual values. The geospatial coordinate registration accuracy, as depicted in Table 1, indicates registration errors within a 2 mm range, attaining accuracy at the millimeter level.

To assess the quality of the NeRF fruit tree point cloud, a set of fruit tree point clouds was reconstructed using the classical stereo vision algorithm SFM-MVS as a control, based on the same dataset. A detailed analysis was conducted to compare the reconstruction effects and reconstruction scale consistency between the two types of fruit tree point clouds.

Regarding the reconstruction effects, as illustrated in Figure 9, a thorough comparison was made at the scales of tree, canopy, and organ for the phenotypic reconstruction of fruit trees using the two methods. At the tree scale, the NeRF method produced a fruit tree point cloud with sharp contours, clear crown textures, and well-defined branch hierarchy. In contrast, the SFM-MVS fruit tree point cloud exhibited blurred contours, abundant noise in the crown, and difficulties in texture recognition. At the canopy scale, the NeRF fruit tree point cloud accurately restored the morphology of branches and leaves. Details such as internal branches, clustered peach tree fruits, and diseased and withered leaves were clearly visible in Figure 9g, highlighting the NeRF method's outstanding recovery capability for high-frequency canopy details. In contrast, the SFM-MVS method at the canopy scale could hardly identify any fruit tree organs. At the organ scale, despite the clustering of immature peach fruits due to non-thinning, the NeRF method could still distinctly reconstruct each fruit, providing a clear, well-organized, and highly recognizable structure. This level of detail is sufficient to guide unmanned agricultural machinery in thinning and harvesting operations. Conversely, the SFM-MVS fruit point cloud at the organ scale exhibited a mosaic-like pattern, rendering it incapable of identifying any details.

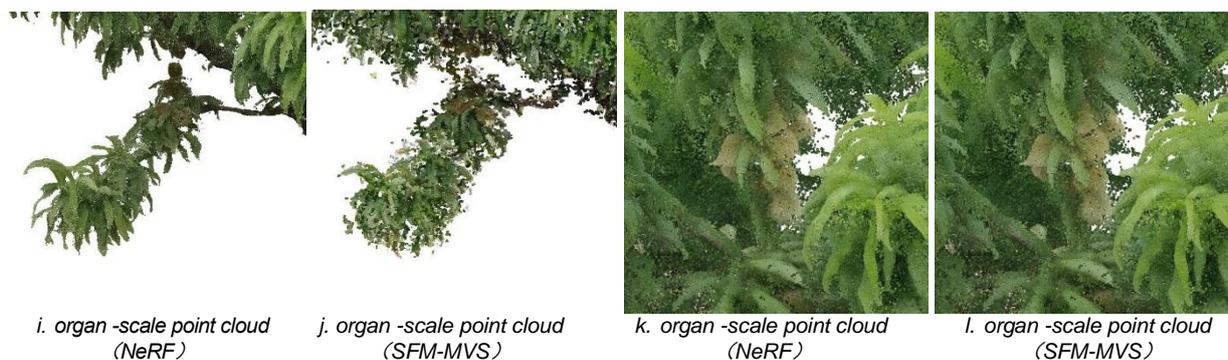

Fig. 9 - Comparison of NeRF fruit tree point cloud and MVS fruit tree point cloud

In terms of scale consistency, prior to the experiment, marker points were placed throughout the canopy of the fruit tree, as depicted in Figure 10. Tree height, crown length, and width were measured at these marker points and served as actual values. Additionally, the trunk diameter at 1.3 meters above the ground level was measured as an actual value for breast height.

Within the fruit tree point cloud, the distances were calculated for the corresponding measurement parameters by selecting marker points. Both actual and experimental values were measured 10 times, and the averages were taken as the true values.

Fig. 10 - Comparison between photo of tagged point and point cloud of tagged point

As indicated in Table 2, both methods exhibit comparable accuracy levels, with a root mean square error of 0.0047 m, when reconstructing the morphology of objects characterized by regular shape and simplicity, such as breast diameter. They both demonstrate a high-level reconstruction accuracy at the millimeter scale. However, in the reconstruction of the fruit tree canopy, which involves intricate details and complex phenotypic information, the reconstruction accuracy of the NeRF method significantly surpasses that of the SFM-MVS method. The scale consistency accuracy for tree height, crown major axis, and crown minor axis achieved by the NeRF method are 99.12%, 99.34%, and 99.22%, respectively. In comparison to the SFM-MVS method, the root mean square errors are reduced by approximately 61.24%, 73.48%, and 62.32%, respectively.

Table 2

3D Reconstruction scale consistency Evaluation Indexes

Parameter	measured value	NeRF tested value	NeRF Root Mean Square Error	NeRF Mean Accuracy	SFM-MVS tested value	SFM-MVS Root Mean Square Error	NeRF Mean Accuracy
Tree Height /m	2.1850	2.2030	0.0193	99.12%	2.1412	0.0495	97.73%
Canopy Length /m	2.1760	2.1845	0.0143	99.34%	2.1157	0.0637	97.07%
Canopy Width /m	1.6420	1.6456	0.0128	99.22%	1.6123	0.0340	97.93%
Breast Diameter /m	0.0680	0.0643	0.0047	93.09%	0.0645	0.0047	93.09%

CONCLUSIONS

This study, focusing on peach trees in the initial fruiting stage, addressed the scientific challenges associated with the limitations of stereoscopic vision-based 3D reconstruction techniques in representing multiscale complex phenotypic details of fruit trees and the absence of geographic information in generated

fruit tree point clouds. By integrating neural radiative fields with georeferencing technology, a digitally reconstructed fruit tree was successfully created with high-level geographic positioning accuracy and superior leaf canopy phenotypic details, thereby overcoming the technical bottlenecks that have hindered the development of the digital fruit tree technology system.

Experimental results demonstrated that Neural Radiance Fields (NeRF) could capture the intricate topological structure of fruit trees at multiple levels, including tree scale, canopy scale, and organ scale, accurately characterizing morphological features of tree branches, fruits, and even leaves. During the NeRF scene training process, the LPIPS metric reached a minimum value of 0.2050 and stabilized within the range of 0.2 to 0.3, while the SSIM metric achieved a maximum value of 0.7215 and stabilized within the range of 0.6 to 0.7. The scale consistency accuracy of NeRF fruit tree point clouds in tree height, canopy length, and width reached 99.12%, 99.34%, and 99.22%, respectively. Compared to Structure-from-Motion Multi-View Stereo (SFM-MVS) fruit tree point clouds, the root mean square errors were reduced by 61.24%, 73.48%, and 62.32%, respectively. The geographic coordinate registration accuracy of the fruit tree point cloud reached millimeter-level, with registration errors generally less than 2 millimeters.

The digitally reconstructed fruit tree established in this study possesses accurate geographic information and high-resolution phenotypic details at multiple scales. It can provide precise spatial data for unmanned agricultural machinery in the WGS-84 geographic coordinate system, endowing it with global perception capabilities to guide tasks such as pruning, thinning, and harvesting. Additionally, with its high-quality leaf canopy phenotypic details, the digitally reconstructed fruit tree lays a solid technical foundation for research in digital phenomics of fruit trees, digital lighting simulation, digital production management, digital yield estimation, digital growth monitoring, and digital agricultural technology training, thereby holding significant implications for the development of smart orchards.

ABSTRACT

One of the essentials of intelligent prosthetics design is to recognize the wearer's movement intention, to provide the wearer with the corresponding control strategy and movement assistance. The 11 independent gait patterns and 5 transformed gait patterns are recognized by the self-designed human lower limb motion data measurement system. The human gait pattern is classified by the linear discriminant analysis (LDA) classifier, and the recognition accuracy is evaluated by K-fold Cross Validation(K-CV). The average recognition accuracy of independent gait patterns is 90.91%. In the independent gait pattern, the lowest recognition accuracy of DS1 gait phase is 90.53%, and the highest recognition accuracy of SS2 gait phase is 91.36%. The overall average recognition accuracy of the transformed gait pattern is 92.67%, the lowest recognition accuracy of DS1 gait phase is 91.93%, and the highest recognition accuracy of SS1 gait phase is 93.31%. The main reason affecting the recognition accuracy is that some gait patterns have similar motion characteristics. The method proposed in this study can accurately predict the wearer's locomotion mode and serves as a reference for gait pattern recognition, prediction, and control strategies in intelligent prosthetic devices.

摘要

智能假肢设计的关键之一是识别佩戴者的运动意图，为佩戴者提供相应的控制策略和运动辅助。通过自主设计的人体下肢运动数据测量系统对11种独立步态模式和5种变换步态模式进行识别。采用线性判别分析(LDA)分类器对人体步态模式进行分类，并采用K-fold交叉验证(K-CV)对识别精度进行评价。独立步态模式的平均识别准确率为90.91%。在独立步态模式下，DS1步态相位的识别准确率最低为90.53%，SS2步态相位的识别准确率最高为91.36%。变换步态模式的整体平均识别准确率为92.67%，DS1步态相位的最低识别准确率为91.93%，SS1步态相位的最高识别准确率为93.31%。影响识别精度的主要原因是某些步态模式具有相似的运动特征。本文提出的方法可以准确预测佩戴者的运动模式，为智能假肢的步态模式识别、预测和控制策略提供参考。

INTRODUCTION

Lower limb amputation affects daily life. Although passive prostheses can meet the basic daily use of amputees, the wearer presents asymmetrical gait patterns in performing daily activities (Zhu et al., 2014; Windrich et al., 2016; Dey et al., 2020). To compare with the able-bodied individuals, the amputees need to consume 20-30% extra metabolic energy in movement (Au et al., 2009). Intelligent prostheses, as a medical device that can simulate the human-machine relationship between amputee and prosthesis to the maximum extent, are attracting more and more attention (Tucker et al., 2015; Silva Júnior et al., 2015; Yang et al., 2016; Hernandez and Yu, 2022; Yue et al., 2023).

The study of locomotion mode is one of the important contents of intelligent prostheses. By collecting and analyzing relevant signals, the basic information of human movement can be extracted, and then different control strategies can be selected by judging the movement to ensure the smooth and labor-saving of the wearer. At present, the signals used for the study of locomotion mode are mainly divided into mechanical signals (such as gyroscopes, accelerometers, goniometers and magnetometers) (Bisio et al., 2016; Quintero et al., 2016) and bioelectric signals (electromyography (EMG) is a widely used bioelectric signal) (Bakina et al., 2018; Chen et al., 2015; Wang et al., 2016).

Cuihong Liu, Prof. Ph.D. Eng.; Yanbo Han, Xiangwen Song, Shipeng Zhang, Na han, M.S. Stud. Eng.; Meng Zou and Liyan Wu, Prof. Ph.D. Eng.

Nazarpour et al. recognized the locomotion mode based on EMG signals, utilized higher order statistics of EMG signal to classify four primitive motions, i.e., elbow flexion, elbow extension, forearm supination, and forearm pronation. The results indicated that the proposed approach provided higher identification rates (Nazarpour et al., 2007). Liu et al. collected the EMG signals of two able-bodied subjects and two unilateral transfemoral amputees during normal walking, compared and evaluated three kinds of adaptive classifiers off-line (Liu et al., 2017). The entropy-based adaptation was implemented for real-time human-in-the-loop prosthesis control. The online evaluation showed that the developed novel adaptive strategy may further enhance the reliability of neurally controlled prosthetic legs. Wang et al. proposed a wearable plantar pressure measurement system, which identified five locomotion modes through four force sensors mounted on insoles, and the average recognition errors of four phases of the five patterns were 19.6%, 12.6%, 5.2%, and 6.3% respectively (Wang et al., 2012). Young et al. used mechanical sensors to identify five motion modes of walking on level ground, ramp and stairs, with an overall accuracy of 93.9% (Young et al., 2013). Meng et al. collected EMG signals and linear acceleration of 10 able-bodied subjects in seven locomotion activities, such as sitting, standing and walking horizontally. By comparing four classifiers, the results show that the SVM model with a sliding window size of 80ms has the best recognition performance. EMG signal fusion not only improves the recognition accuracy of steady-state motion from 90% (only using acceleration data) to 98% (using data fusion), but also can predict the next steady-state motion (Meng et al., 2021).

EMG signal will change with the change of electrode conductivity, electrophysiology, space, user and other factors, and the myoelectric decoding algorithms is very demanding (Sensing et al., 2009; Jain et al., 2012; Young and Ferris, 2016; Fan et al., 2024). Compared with bioelectric signals, mechanical signals are more mature, smaller in size and highly integrated (Ambrozic et al., 2014; Gorsic et al., 2014; Yuan et al., 2017). The acquisition of mechanical signals is mainly through accelerometers, gyroscopes, pressure sensors and other devices (Adapala et al., 2013; Parri et al., 2017; Hussain et al., 2019). For example, Hartmann et al. proposed an online human activity recognition (HAR) system, in which wearable sensors (such as inertial measurement units) acquire data and identify activities through hidden Markov models (Hartmann et al., 2022). On the other hand, data provided by multiple sensors is superior to data provided by a single sensor in theory (Khaleghi et al., 2013). Multi-sensing technology can reduce the power consumption while achieving more abundant functions, because of the development of microcomputer system and electronic technology. Hartmann et al. proposed a multi-sensor data collector (CSL-SHARE) for HAR. sensors used include triaxial accelerometers, triaxial gyroscopes, sEMG sensors, biaxial electrogoniometer, and airborne microphone. The accuracy of the CSL-SHARE dataset reached 96.1% (Liu et al., 2021; Hartmann et al., 2022). Smart knee bandage is a new method, sensors are fixed inside knee bandages and socks, and evaluates the movement posture of patients through IMU and pressure sensors, so as to obtain the movement and rehabilitation of patients (Haladjian et al., 2017; Haladjian et al., 2018). It is worth noting that Hartmann et al. defined six High-Level Features of the subjects, obtained the information base by deploying different sensor carriers, and learned the relationship between the characteristic values of each activity and the sensor data through classification algorithms, so as to carry out pattern recognition. This method is a relatively advanced research content, and the recognition accuracy rate based on the CSL-SHARE and UniMiB SHAR datasets reaches 89.7% and 67.3%, respectively (Hartmann et al., 2023). In conclusion, the study of locomotion mode based on multi-sensor fusion has received more attention and development (Varol et al., 2010; Huang et al., 2011; Luo et al., 2023). Linear Discriminant analysis (LDA), also known as Fisher Linera Discriminant (FLD), is a classic algorithm for pattern recognition. It was introduced into the field of pattern recognition and artificial intelligence by Belhumeur in 1996. It is an effective feature extraction method. By this, the interclass dispersion matrix of projected pattern samples can be maximized, while the intra-class dispersion matrix is minimized (Tharwat et al., 2017). This method has been successfully applied to HAR. Hartmann et al. also compared the differences between the methods. The research showed that the poor recognition performance when it was used in a single read, but its transformation helped to improve the overall recognition performance, which was conducive to identifying most activities (Hartmann et al., 2021), and the evaluation performance of LDA based on HMM could be improved by 4 percentage (Hartmann et al., 2020). Therefore, the LDA method is adopted in this paper.

This study aims to accurately recognize human lower limb locomotion mode through the method of multi-sensor fusion. First a human lower limb motion data measurement system was developed. The measurement system consists of two inertial measurement units (IMUs) and a plantar pressure measurement system (PPS, containing three force sensors for each foot). The kinematic and dynamic parameters of the human motion are measured by IMU and PPS, respectively.

Linear discriminant analysis (LDA) was used to identify 11 independent gaits and 5 transformed gaits. Gait recognition helps to provide the right control strategy for the intelligent prosthesis, thus activating the corresponding drive mode to assist the amputee's movement. On the basis of ensuring the recognition accuracy, the number of motion patterns increased in this study. Outcomes covers the daily use of subjects, providing a reference for HAD and intelligent wearable devices.

MATERIALS AND METHODS

Human lower limb motion data measurement system

The key to accurately recognize locomotion mode is the reliability and stability of measurement system. The human lower limb motion data measurement system is presented, and its reliability and environmental adaptability is also verified.

The daily movement of human lower limbs includes the kinematic information of legs and the dynamic information between the sole and the ground. Only by collecting this information comprehensively, can the motion state of lower limbs be accurately described. The spatial motion information of human lower limbs is complicated, and it is difficult to cover the daily activity posture with a single sensor. Therefore, the composition of motion data measurement system designed in this paper needs two sensors, inertial measurement unit (IMU) and plantar-pressure measurement unit, which can make up for each other's shortcomings and facilitate us to analyze human lower limb gait more comprehensively. Secondly, due to the complexity of human movement, the data collected by the same type of single sensor can't completely reflect the information contained in the movement to a certain extent. To sum up, the composition of the human lower limb motion data measurement system is shown in Fig. 1. The system consists of two inertial measurement units (IMUs), six thin-film force sensors, an Analog to digital conversion module (A/D Mod) and a computer. The information detected by IMUs and plantar pressure sensors enables comprehensive analysis and recognition of lower limb gaits.

The IMU is an MTi-30 AHRS (Attitude and Heading Reference System) produced by Xsens of the Netherlands (fig. 1b). Motion capture of human lower limbs can be realized by IMU sensor. However, it is difficult for a single IMU sensor to accurately judge the movement with the gait cycle. Two IMU sensors are selected and fixed on the thigh and shank, which can reflect the complete information of the movement. The MT Manager software is used to display in real-time the three-dimensional motion information of the human lower limbs collected by the IMU, and it can also store the experimental data.

In this paper, the force sensor, FlexiForce A401, is a thin film sensor (fig. 1d), which is produced by Tek scan of America. This sensor integrates the measurement signal and processing circuit and obtains drift-free signal data through its built-in low-power processor.

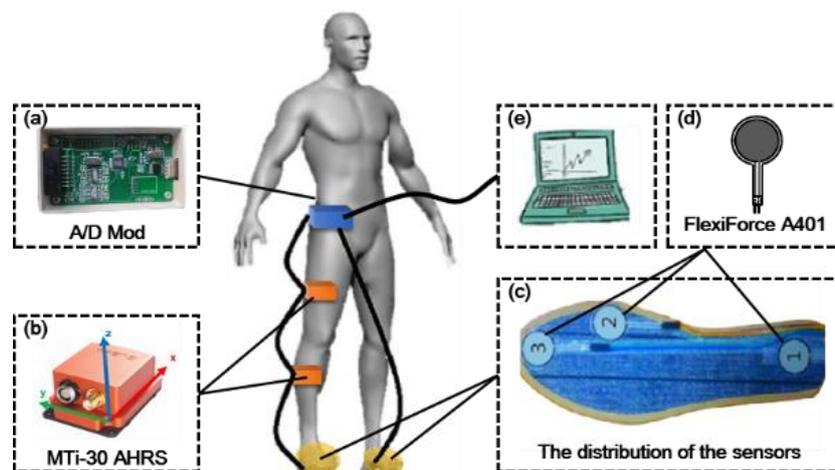

Fig. 1 - Human lower limb motion data measurement system

A single sensor cannot completely measure the pressure change of the entire plantar during the movement, and if the pressure sensing area is small or the location is inappropriate, it will inevitably cause the loss of the plantar pressure information. In this paper, the pressure test system (fig. 2a) is used to test the plantar pressure. In the experiment, three healthy volunteers walked through the plantar pressure test bench with bare feet. After collecting the data of the changes of plantar pressure, the plantar region was partitioned and the stress situation of each region was analyzed. The placement position of the plantar region sensor was determined by observing several zones with the largest strain (fig. 2b).

Fig. 2 - Position of the plantar region sensor
(a) Pressure test system; (b) Volunteer plantar pressure

Three sensors are attached to each insole to form a plantar pressure measurement system (PPS), the distribution of the sensors is shown in Figure 1c, the calcaneus tuberosity (sensor 1), the first metatarsal bone (sensor 2) and the hallux toe (sensor 3).

A/D Mod is installed on the waist of the wearer to process and convert the signals output by the sensor. To reduce the delay of data transmission, the transmission cable is used, and the computer is connected by USB to realize the transmission and storage of sensor data, and the analysis and visualization of IMU and force sensor data are realized.

Plantar pressure system calibration

IMU realizes data conversion through its built-in low-power processor. But the force sensor (FlexiForce A401) is a tiny thin force-sensitive resistor which varies with the vertical pressure. To ensure the accuracy of the value, it is necessary to carry out calibration.

Weight of 1-10 kg is used in the calibration. The weight is increased in increments of 1 kg and the corresponding force is 9.8 N. In the test, to ensure full contact between the weight and the force sensor, the weight is placed vertically, while the applied pressure value and the output value are recorded. The linear fitting was carried out by Matlab and the resulting calibration equation is shown in Equation 1:

$$V_{out} = 0.0028 \times F + 1.1128 \quad (1)$$

where V_{out} is the output value of the force sensor, F is the applied pressure. The residual norm of linear fitting is 0.0101, and the residual norm is < 0.05 . The results show that there is a good linear relationship between the output value and the applied pressure value (fig. 3). In order to identify various gaits more intuitively, the calibration equation was used to convert the voltage output of the sensors into the pressure value, and then the test results were analyzed.

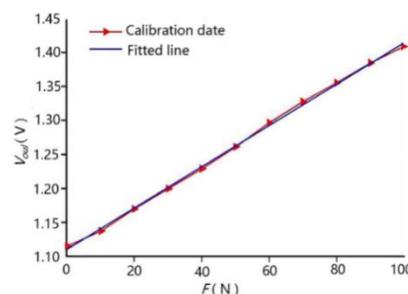

Fig. 3 - The fitting details

Adaptability to different ground surfaces

The contact force that is obtained by the plantar pressure measurement system may be affected by the type of surface. To ensure the output stability of different surfaces, the adaptability of 6 mm rubber floor, 3 mm carpet floor and 9 mm wood floor is carried out. The experiment process is described in Fig. 4.

Fig. 4 - The experiment process
(a) Rubber floor; (b) Carpet floor; (c) Wood floor

The experiment is carried out by an able-bodied subject, 25 years old, male, with weight of 75 kg and height of 1.72 m. The subject is asked to walk at a normal, comfortable pace across three different surfaces under laboratory conditions. The subject walks for 3 complete gait cycles each time, and the pressure between the foot and the ground is collected during the walking. The pressure data are shown in Fig. 5.

Fig. 5 shows the data collected by three force sensors of a plantar pressure measurement system, and data of different ground types are represented by curves of different colors. The maximum signal difference of each force sensor in three different ground types is 6.6%, 4.5% and 7.9%, respectively. And the maximum signal difference is always around the peak of the signal. These results indicate that the signals of three force sensors in different areas of the same foot have similarities on different ground. In other words, the plantar pressure measurement system adapts to different surfaces.

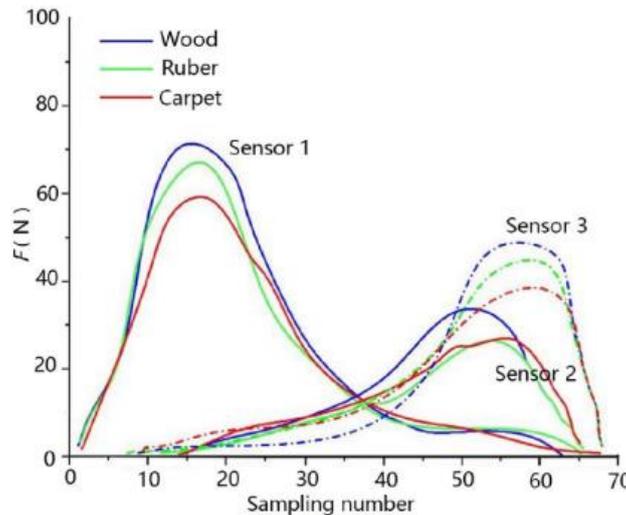

Fig. 5 - The pressure data on three surface types

The process of experiment

In our study, 10 able-bodied subjects are recruited. Their average age is 24.7 ± 1.4 years, average weight is 69.4 ± 10.7 kg, average height is 1.773 ± 0.054 m, and average foot size is 26.1 ± 0.5 cm. The positions of the sensors are shown in Fig. 1 10 able-bodied subjects are given adaptive exercises after wearing the device.

In this paper, 11 independent gait patterns and 5 transformed gait patterns are designed to study the locomotion mode. The number of experiment groups in each gait pattern is 15. The type of gait pattern and gait cycles are shown in Table 1.

Table 1

The number of trials for each pattern and gait cycles for each trial			
Type	Gait patterns	Trial number	Gait cycles
Independent gait patterns	Sitting (SI)	15	–
	Standing (ST)	15	–
	Level-Walking (LW)	15	5
	Level-Fast Walking (LFW)	15	5
	Soil Walking (SW)	15	5
	Stair Ascending (SA)	15	2
	Stair Descending (SD)	15	2
	Ramp Ascending (RA)	15	2
	Ramp Descending (RD)	15	2
	Soil Ramp Ascending (SRA)	15	2
	Soil Ramp Descending (SRD)	15	2
Transformed gait patterns	Level-Walking - Ramp Ascending (LW - RA)	15	4
	Level-Walking - Stair Ascending (LW - SA)	15	4
	Level-Walking - Stair Descending (LW - SD)	15	4
	Soil Walking - Soil Ramp Ascending (SW - SRA)	15	4
	Standing - Sitting (ST-SI)	15	–

The requirements of the test of independent gait are as follows. For the pattern of SI, the subjects are asked to sit on a 42 cm high chair in a normal, comfortable position (Fig. 6a). For the ST test, the subjects are asked to stand still on the ground, and the subjects are relatively relaxed, and maintain a steady body (Fig. 6b). The LW and LFW require subjects to walk 5 steps on a straight hard surface, the speed is scheduled walking speed and slightly higher than daily walking speed respectively (Fig. 6c). The walking conditions of SW are the same as LW.

The difference is that the road surface of SW is soft soil, and the soil needs to be turned over before and after walking (Fig. 6d). The test environment of SA and SD is four steps, the width of the step is 0.4 m, and the height is 0.15 m. The subjects need to walk at a comfortable pace and posture (Fig. 6e). RA and RD are tested on the hard floor on the ramp, and the slope on the hard floor slope is 5 m in length, 1 m in width and 18.5° in inclination angle. To maintain normal walking speed and posture (Fig. 6f). The difference between SRA and SRD and RA and RD is that the road surface of SRA and SRD is soft soil, the soil needs to be turned over before and after walking to ensure the soft soil (Fig. 6g).

Fig. 6 - Test of independent and transformed gait pattern

(a) SI; (b) ST; (c) LW and LFW; (d) SW; (e) SA and SD; (f) RA and RD; (g) SRA and SRD; (h) LW-RA; (i) SW-SRA

The requirements of the test of transformed gait are as follows. The walking conditions of LW-RA mode (Fig. 6h), LW-SA mode, LW-SD mode and SW-SRA mode (Fig. 6i) are consistent. The subjects are advised to walk 2 steps on each road. The difference between them is that the two types of pavements are different from each other. See independent gait for a detailed description. In ST-SI, the subjects stand up at first and then sit on a chair in a way that is normal for them.

During the experiment, 10 subjects perform only one gait pattern each time, and each gait pattern is done in 15 groups. After each group of experiments, subjects are given a certain rest time. This method eliminates the impact of muscle fatigue on the data.

Data filtering processing

The Matlab software is employed, and statistical analysis methods are utilized for data processing. Moreover, algorithms such as time-domain analysis and principal component analysis are applied for eigenvalue extraction and other processing.

One of the keys of preprocessing is to remove the noise in the acquisition and transmission stages from the data. The data information necessary for the test can be obtained by data filtering. The data information comes from IMU and force sensor. In this paper, the IMU has a built-in classical Kalman filtering algorithm to filter the signals in real time. Kalman filter is a common algorithm for sensor data processing in the navigation field. Based on the linear system state equation, the Kalman filter optimally estimates the current state of the system by updating the collected data and the previous state estimation data. Compared with other filtering algorithms, it can process data in the time domain. The filter algorithm can be directly used to process sensor data in the actual power assisted control, and the algorithm uses less storage space and is easy to implement in the system.

Take the ADC (Analog-to-Digital Converter) curve of the original pressure at the position of the first metatarsal bone (Fig. 1c-sensor2) from RD gait pattern as an example (Fig. 7). The subjects start walking downhill from a stationary state, the initial pressure value was about 28 N, and began to decline with the right foot gradually raised. With the heel landing again, the pressure tended to peak again, and then the value changed periodically.

There is noise impact in the data of Fig. 7 The noise source mainly has 3 aspects: One is the body shake, then because of the signal conversion process, the last one is the friction between the sole and the insole. To eliminate the periodic interference in the data and effectively suppress the high-frequency jitter, the ADC value of plantar pressure was filtered by Savitzky-Golay sliding filter in this paper.

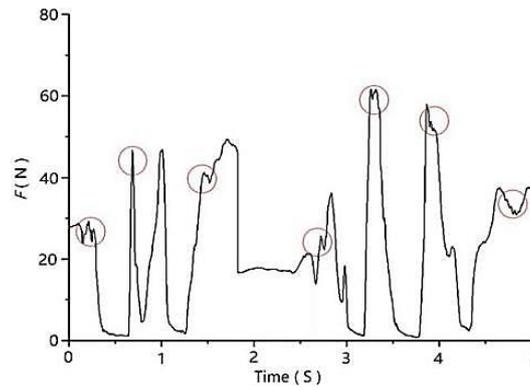

Fig. 7 - The value of the first metatarsal bone in RD gait patterns (before the filtering)

The core idea of Savitzky-Golay sliding filter is to fit the data in the window by the least squares method based on polynomials in the domain. Assume that the gait action data in a window of length p is $x(i)$, $i = -m, \dots, 0, \dots, m$, same as $2m+1=p$. In this window, K -order polynomials (Equation 2) are used to fit the original data.

$$f(i) = a_0 + a_1i + a_2i^2 + \dots + a_ki^k = \sum_{n=0}^k a_ni^n \tag{2}$$

The residual of the least squares fitting ε is calculated through Equation 3.

$$\varepsilon = \sum_{i=-m}^m (f(i) - x(i))^2 = \sum_{i=-m}^m \left(\sum_{n=0}^k a_ni^n - x(i) \right)^2 \tag{3}$$

To minimize the residual, the partial derivative of each polynomial coefficient needs to be 0, the derivative of it can be obtained through Equation 4.

$$\frac{\partial \varepsilon}{\partial a_r} = \sum_{i=-m}^m 2(f(i) - x(i))i^r = 0 \tag{4}$$

where $r=0, 1, \dots, k-1, k$.

The result after processing is shown in Equation 5.

$$\sum_{i=-m}^m \left(\sum_{n=0}^k a_ni^{n+r} \right) = \sum_{i=-m}^m x(i)i^r = \sum_{n=0}^k a_n \left(\sum_{i=-m}^m i^{n+r} \right) \tag{5}$$

where $r=0, 1, \dots, k-1, k$, The linear system of equations on the fitting coefficients can be obtained by derivation, which can be expressed by the following matrix (Equation 6).

$$A^T A a = A^T X \tag{6}$$

where, $a = [a^0, a^1, \dots, a^n]^T$, $X = [x(-m), \dots, x(0), \dots, x(m)]^T$,

The matrix A is defined as shown in Equation 7:

$$A = \begin{bmatrix} (-m)^k & (-m)^{k-1} & \dots & (-m)^0 \\ \dots & \dots & \dots & \dots \\ m^k & m^{k-1} & \dots & m^0 \end{bmatrix} \tag{7}$$

Finally, he result can be obtained as shown in Equation 8:

$$a = (A^T A)^{-1} A^T X \tag{8}$$

According to the coefficients, the results of k -order polynomial fitting to the original data can be obtained, and the filtering results can be obtained after discretization. After several tests, the best filtering effect with $p=6$ and $k=1$ is obtained. The ADC value of the first metatarsal bone in RD gait pattern after Savitzky-Golay filtering is shown in Fig. 8.

The gait segmentation

Gait Phase (GP) refers to the different states that a foot presents during a gait cycle. A gait cycle can be divided into several gait phases (Wang and Hou, 2007). Gait phase is usually composed of two parts: Stance Phase and Swing Phase (Fig. 9). The phases of the gait cycle are relatively fixed during normal motion. It is believed that the stance phase takes up 60 – 65% of the time in a gait cycle (Anwary et al., 2018).

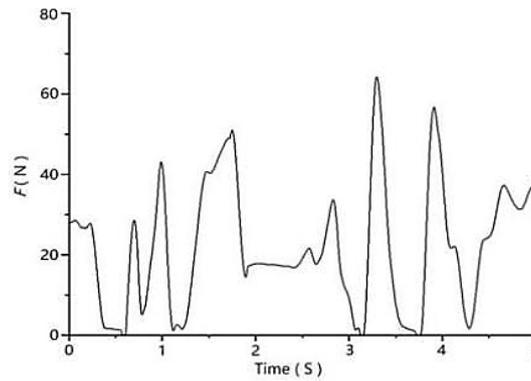

Fig. 8 - The value of the first metatarsal bone in RD gait patterns (after the filtering)

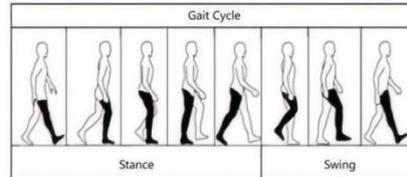

Fig. 9 - Gait cycle

If a gait cycle is effectively segmented, the effective and invalid data can be greatly reduced, and the real-time performance and accuracy of recognition can be obtained. In this paper, the plantar pressure and threshold are used to segment gait phase effectively. The threshold is finally determined as 1/3 of the pressure sum when the user stands still.

Based on previous research on gait, in this paper, two gait events are defined to divide the gait phase. The two gait events are Foot Contact (FC) and Foot Off (FO). FC is the gait event when the pressure rises below a defined threshold reaches the threshold; FO is a gait event when the pressure above the defined threshold drops to a threshold.

Take Fig. 10 as an example to explain a gait cycle. The black curve represents the sum of the three plantar pressure signals, dark blue represents Sensor 1, red represents Sensor 2, and light blue represents Sensor 3. When humans walk on flat ground, they start with the heel off the ground and move forward until the tip of the foot is off the ground. Through the proposed gait segmentation method, a complete gait cycle is divided into four stages by FC and FO: two-station 1 (DS1) and single-station 1 (SS1), two-station 2 (DS2) and single-station 2 (SS2). DS1 is the process of the left foot touching the ground to the right foot leaving the ground, DS2 is the opposite of DS1. SS1 is defined as when the sole of the left foot leaves the ground to when the sole of the left foot touches the ground. Again, SS2 is the opposite of SS1.

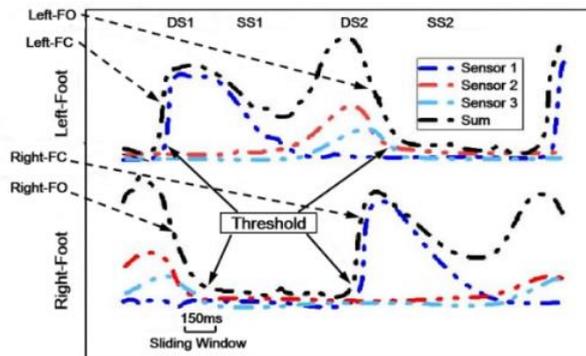

Fig. 10 - Gait segmentation in a gait cycle

Eigenvalue extraction and classifier

Signal eigenvalues are important parameters in locomotion mode recognition and are typically analyzed using window-based analysis and incremental steps. The detailed process is illustrated in Figure 11. During locomotion mode recognition, the eigenvalue of the signal is calculated within each analysis window of duration R. The window then shifts backward by a time interval t, and the eigenvalue for the next analysis window is computed.

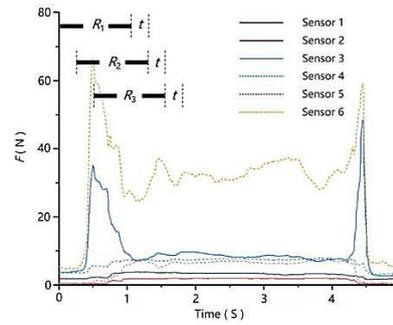

Fig. 11 - The process of eigenvalue extraction

In theory, the duration of the analysis window affects the length of recognition time and whether the current gait pattern is accurately reflected. The increment of the window will also affect the computation amount and recognition delay. The eigenvalue extraction of the signal is related to the sensor signals.

In this paper, a 150 ms sliding window is used to extract the eigenvalue of a total of 14 channels of sensing data (including two IMU sensing signals, each IMU has 4 channels) and pressure data (6 channels).

The sensor type in this paper is a mechanical sensor, the time-domain analysis method is used to extract signal eigenvalues. This method does not need signal transformation, and the calculation is easy and time-consuming. It mainly includes: maximum value, minimum value, mean value, standard deviation, and waveform length (the sum of absolute values of signal changes every 10 ms), where:

Waveform length (WL) is calculated by Equation 9.

$$l_0 = \sum_{k=1}^N |\Delta x_k| \tag{9}$$

Standard deviation (STD) is calculated by Equation 10.

$$STD = \sigma = \sqrt{\frac{1}{N-1} \sum_{k=1}^N (x_k - \bar{x})^2} \tag{10}$$

In summary, this paper constructs a sliding window of 15x14 matrix through Matlab and extracts the maximum value, minimum value, mean value, standard deviation and waveform length of each signal channel under this sliding window. LDA is a linear discriminant analyzer, which requires relatively low computational complexity and can better reflect the differences between samples by using prior knowledge of categories. Therefore, LDA is selected as the classification method.

The performance of LDA is the important target, its model is constructed and explained. In general pattern recognition, the goal of classification is to pursue the minimum error rate. By using the Bayes rule, the classification decision can be made to minimize errors. When the probability density in Bayes rule is a normal distribution condition, the expression of statistical decision-making is given in Equation 11.

$$P(x|c_i) = \frac{1}{(2\pi)^{d/2} |\Sigma_i|^{1/2}} \times e \left\{ -\frac{1}{2} (x - \mu_i) \Sigma_i^{-1} (x - \mu_i)^T \right\} \tag{11}$$

where $x = [x_1, x_2, \dots, x_d]$, x_i is the eigenvalue of the input, x is the corresponding feature vector, that is, the new sample formed after extracting the feature value from the original data. In this paper, the dimension of the feature vector is 1x30, that is, $d=30$. $\mu = [\mu_1, \mu_2, \dots, \mu_d]$, μ is the mean of the sample of eigenvalues, Σ_i is the covariance matrix of each class (symmetric nonnegative definite matrix).

For binary problems, it is only necessary to compare the numerator parts of the above formulas. If the two types of samples are separated, a decision surface exists, and the equation of the decision surface can be expressed as shown in Equation 12.

$$g(x) = \ln P(C_i|x) - \ln P(C_j|x) \\ g(x) = -\frac{1}{2} \left[(x - \mu_i) \Sigma_i^{-1} (x - \mu_i)^T - (x - \mu_j) \Sigma_j^{-1} (x - \mu_j)^T \right] - \frac{1}{2} \ln \frac{|\Sigma_i|}{|\Sigma_j|} + \ln \frac{P(C_i)}{P(C_j)} \tag{12}$$

Assuming that the covariance matrices of each class are equal, i.e., $\Sigma_i = \Sigma_j = \Sigma$, the decision surface equation $g(x)$ can finally be expressed as shown in Equation 13.

$$g(x) = \omega x^T + \omega_0 \\ \omega = (\mu_i + \mu_j) \Sigma^{-1} \\ \omega_0 = -\frac{1}{2} (\mu_i + \mu_j) \Sigma^{-1} (\mu_i - \mu_j)^T + \ln \frac{P(C_i)}{P(C_j)} \tag{13}$$

where ω and ω_0 are the model parameters. After obtaining the training model, they are directly used in the subsequent online identification test, and the model parameters do not change in the test.

Evaluation method

In our study, K-fold Cross Validation (K-CV) method is used to evaluate the recognition accuracy. In the K-CV method, 10-fold Cross Validation is used. The data of each gait pattern at each gait phase are divided into 10 parts, among which 9 parts are used for classifier training and the remaining one part is used for test data. This process is repeated 10 times to make the 10 parts used as one test data respectively.

Recognition Accuracy (RA) is defined by Equation 14.

$$RA = \frac{N_{cor}}{N_{total}} \times 100\% \tag{14}$$

where N_{cor} represents the number of correctly identified data groups, and N_{total} indicates the total number of test data groups.

To describe the recognition effect in more detail, a confusion matrix was used, as shown in Eq.15.

$$C = \begin{bmatrix} r_{11} & r_{12} & \dots & r_{1n} \\ r_{21} & r_{22} & \dots & r_{2n} \\ \dots & \dots & \dots & \dots \\ r_{n1} & r_{n2} & \dots & r_{nn} \end{bmatrix} \tag{15}$$

where each element is described as shown in Equation 16.

$$r_{ij} = \frac{n_{ij}}{n_i} \times 100\% \tag{16}$$

where n_{ij} is the number of gait patterns i recognized as j in the test. n_i denotes the number of gait patterns i in the test. r_{ij} represents the probability that gait pattern i is recognized as j . When $i=j$, r_{ij} represents the recognition accuracy of gait pattern i .

RESULTS AND DISCUSSIONS

Independent gait pattern recognition performance

The average recognition accuracy of the independent gait pattern is 90.91%, and the recognition accuracy of DS1, DS2, SS1 and SS2 are 90.53%, 91.18%, 90.59% and 91.36%, respectively. The independent gait pattern has 11 gaits pattern in total and contains gaits pattern with similar motion characteristics. Overall, the experimental results are satisfactory. It should be noted here that the SI and ST do not have gait phase, but they are lumped together for the brevity of the confusion matrix. The detailed results are shown in Fig. 12.

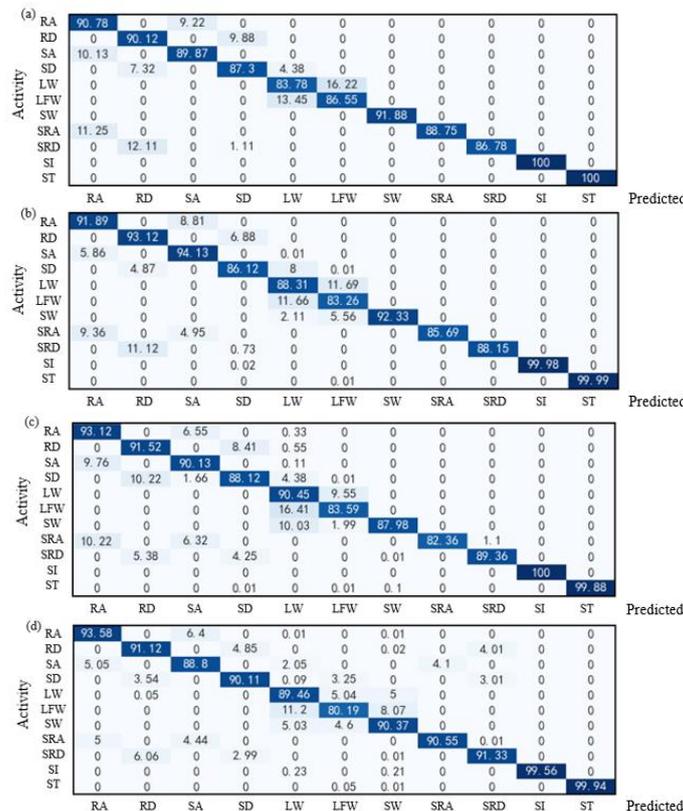

Fig. 12 - The detailed results of the independent gait pattern
 (a) DS1 phase; (b) DS2 phase; (c) SS1 phase; (d) SS2 phase

In the above results, the lowest recognition accuracy of the independent gait pattern is 80.19%, which is LFW in SS2 phase. Three flat walking modes are tested: LW, LFW, and SW. By comparing the curves of the plantar pressure system of the three gait patterns (Fig. 13), it can be seen that they have similar motion characteristics, which leads to the identification error. Although the recognition accuracy of LFW in SS2 phase is about 10% different from the average recognition accuracy, the accuracy of 80.19% is acceptable.

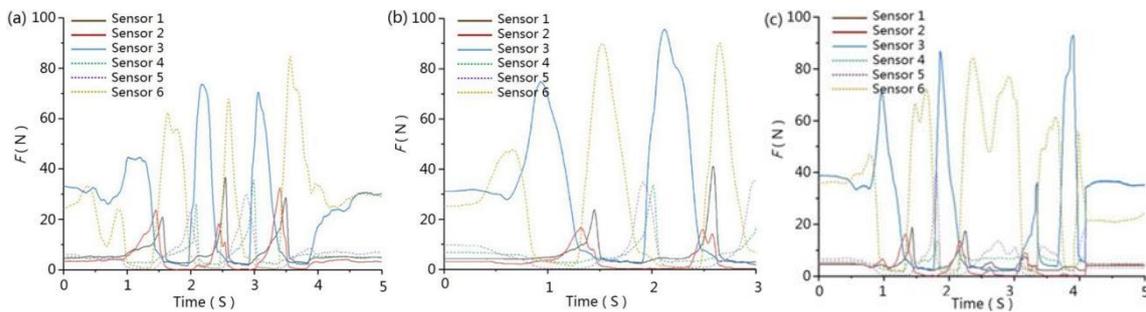

Fig. 13 - The curves of the plantar pressure system of the LW, LFW and SW
(a) LW; (b) LFW; (c) SW

Transformed gait patterns recognition performance

The results of the transformed gait pattern are similar to the independent gait pattern (Fig. 14). Its average recognition accuracy is 92.67%, and the recognition accuracy of DS1, DS2, SS1 and SS2 are 91.93% , 92.79%, 93.31% and 92.65%, respectively.

The lowest recognition accuracy is 85.47%, which is LW-SD in DS1 phase. In DS1, the two highest false recognition rates are LW-SA and SW-SRA, which are 7.20% and 4.02%, respectively. The three gaits pattern have similar motion characteristics. The higher false recognition rate is also due to these similar motion characteristics.

Discussion

Independent gait has been studied relatively early, and the common human locomotion modes are: level walking, ramp ascent, ramp descent, stair ascent and stair descent. At present, the recognition rate of independent gait can reach above 95%. Compared with independent gait, the research time of transformed gait is relatively late, and the recognition is more difficult. At present, most types of gait recognition are less, about 5 – 8, and the road is mostly standardized (Table 2) (Gao et al., 2020; Liu et al., 2020; Young et al., 2013). Because the increase in the number of patterns will affect the recognition accuracy.

Table 2

Reference	Independent gait		Transformed gait	
	Number	Accuracy	Number	Accuracy
Gao et al. (2020)	5	98.46%	—	—
Liu et al. (2020)	5	95.8%	—	—
Young et al. (2013)	5	84.5%	8	93.9%
Our Method	11	90.91%	5	92.67%

In this paper, the number of locomotion modes has been increased. 11 independent gaits and 5 transformed gaits are studied. In addition, the road conditions are much closer to reality. The walking condition in the soil is added, which is more significant in application. The overall accuracy of pattern recognition for both independent and transformed gait is above 90%. This is a relatively satisfactory result.

At present, the main locomotion modes with similar motion curves have affected the accuracy. This may be related to the number of sensor and data processing. The increase in the number of sensor helps with pattern recognition, but it puts an extra burden on amputees' bodies and affects their movement. On the premise of ensuring the recognition accuracy, the use of sensors should be reduced. The recognition rate of the measurement system proposed in this work is above 90%, which achieves the expected goal.

CONCLUSIONS

In this paper, a human lower limb motion data measurement system, which has good environmental adaptability, was presented. Based on data filtering and gait segmentation, LDA classifier is used to analyze the data, and K-CV method is used to judge the accuracy of the results.

The average recognition accuracy of the independent gait pattern is 90.91%, and the highest accuracy of SS2 pattern is 91.36% among the four gait phases. The average recognition accuracy of the transformed gait pattern is 92.67%, and the highest accuracy among the four gait phases is 93.31% of SS1.

This method can accurately predict the locomotion mode of human lower limbs. Intelligent prostheses help lower limb amputees move by controlling joints, they can perform various activities more easily. Since the dynamics and kinematics required by the prosthesis are different in different locomotion modes, it is of great significance to accurately identify the user's locomotion mode for the operation of the prosthesis. Therefore, the method in this paper can provide a reference for the gait recognition, prediction and control strategy of intelligent prostheses.

ABSTRACT

Ensuring the reliability and efficiency of agricultural machinery is critical for modern farming operations. Traditional maintenance strategies, including corrective and preventive approaches, often lead to unexpected downtime or excessive servicing costs. This study explores the application of machine learning-based predictive maintenance for agricultural equipment, focusing on the hydraulic system of a Massey Ferguson 7700 S tractor. Real-time sensor data was collected, with hydraulic pressure selected as the primary diagnostic metric for detecting early signs of mechanical degradation. A predictive maintenance framework was developed using seven machine learning models: Isolation Forest, One-Class SVM, KMeans, DBSCAN, Autoencoders, Convolutional Neural Networks (CNNs), and XGBoost. These models were individually applied to identify pressure anomalies indicative of potential failures. To enhance detection accuracy, a "Council of the Wise" ensemble approach was introduced, where an anomaly was validated only if at least four of the seven models agreed on its presence. This consensus-based method reduced false positives and improved fault identification reliability. Results demonstrated that integrating multiple models effectively distinguished significant anomalies from noise, capturing both transient mechanical instabilities and gradual wear-related failures. The findings highlight the potential of machine learning-driven predictive maintenance in optimizing maintenance schedules, reducing unplanned downtime, and extending equipment lifespan. This study establishes a scalable, data-driven maintenance approach that enhances the operational resilience of agricultural machinery, ensuring greater efficiency and sustainability in farming operations.

REZUMAT

Asigurarea fiabilității și eficienței utilajelor agricole este esențială pentru agricultura modernă. Strategiile tradiționale de mentenanță, inclusiv abordările corective și preventive, conduc adesea la perioade neprevăzute de indisponibilitate sau la costuri excesive de întreținere. Acest studiu investighează posibilitatea aplicării unui sistem de mentenanță predictivă pentru echipamentele agricole bazat pe învățarea automată, analizând date achiziționate din sistemul hidraulic al tractorului Massey Ferguson 7700 S. Datele au fost colectate în timp real, presiunea din instalația hidraulică fiind selectată ca parametru principal pentru detectarea timpurie a eventualelor defecțiuni. A fost dezvoltat un sistem de mentenanță predictivă bazat pe șapte modele de învățare automată: Isolation Forest, One-Class SVM, KMeans, DBSCAN, Autoencoders, Convolutional Neural Networks (CNNs) și XGBoost. Aceste modele au fost aplicate individual pentru a identifica anomaliile ale presiunii, fapt care ar putea scoate în evidență posibile defecțiuni. Pentru a îmbunătăți acuratețea detecției, a fost introdusă o abordare de tip „sfatul înțelepților”, în care o anomalie a fost validată doar dacă cel puțin patru dintre cele șapte modele au confirmat prezența acesteia. Această metodă bazată pe consens a redus numărul de alarme false și a îmbunătățit fiabilitatea identificării defecțiunilor. Rezultatele au demonstrat că integrarea mai multor modele a permis diferențierea eficientă a anomaliilor semnificative de zgomot, evidențiind atât instabilitățile mecanice tranzitorii, cât și degradările progresive. Concluziile evidențiază potențialul mentenanței predictive bazată pe învățarea automată în optimizarea programelor de întreținere, reducerea timpilor neplanificați de oprire și prelungirea duratei de viață a echipamentelor. Metoda propusă pentru mentenanța utilajelor agricole este scalabilă și poate îmbunătăți semnificativ reziliența operațională, eficiența și sustenabilitatea în sectorul agricol.

INTRODUCTION

Maintenance strategies in industrial and agricultural machinery have evolved to address operational reliability and cost efficiency. Traditional approaches include corrective maintenance, which involves repairing equipment only after a failure has occurred, often leading to unexpected downtime and high repair costs. Preventive maintenance seeks to mitigate these risks by scheduling routine inspections and servicing at fixed intervals, regardless of the actual condition of the equipment. While this approach reduces the likelihood of failures, it may result in unnecessary maintenance and higher operational costs.

Predictive maintenance, powered by machine learning and real-time data, proactively detects early signs of wear or malfunction, replacing fixed schedules and reactive repairs. By identifying subtle anomalies and degradation patterns, it optimizes maintenance scheduling, reducing unnecessary interventions while preventing costly breakdowns. Advanced algorithms enhance precision in fault detection, ensuring efficient resource allocation and extending equipment lifespan. Increasingly adopted in the agriculture and food industries, predictive maintenance improves equipment reliability, minimizes downtime, and lowers maintenance costs. Conventional methods, such as corrective maintenance, addressing failures after they occur, and preventive maintenance, based on predefined schedules, can lead to inefficiencies and unexpected failures. Machine learning models provide a more intelligent, data-driven approach, enhancing fault prediction accuracy and overall system performance.

This paper explores the application of machine learning (ML) models in predictive maintenance for biotechnical systems, evaluating their effectiveness in improving system reliability and efficiency. By examining the capabilities of various machine learning techniques in failure prediction and early fault detection, the study highlights the advantages of a data-driven approach in minimizing downtime and reducing maintenance costs. The potential of predictive maintenance extends beyond cost savings, it enhances operational resilience, ensuring that agricultural and food production systems remain sustainable and efficient in the face of growing industry demands (Lima *et al.*, 2021).

Agricultural machinery, such as the Massey Ferguson 7700 S tractor, operates under demanding conditions that require continuous performance monitoring to ensure efficiency and longevity. During various soil operations, including plowing, tillage, and planting, as well as harvesting corn or other crops, the hydromechanical systems of agricultural machinery, including the hydraulic system, engine, and drivetrain, experience dynamic mechanical stresses. Modern real-time condition monitoring systems integrated into such equipment collect high-frequency operational data, capturing parameters such as engine temperature, hydraulic pressure, vibration levels, fuel consumption, and mechanical load fluctuations. These data streams, when processed using machine learning models, allow for the early identification of potential failures, preventing costly breakdowns and minimizing downtime.

Ouadah *et al.* (2022) evaluates various supervised machine learning algorithms for predictive maintenance, focusing on their classification and regression capabilities. Key algorithms analyzed include Random Forest, Decision Trees, and k-Nearest Neighbors (KNN), tested on both real-world and simulation datasets. The findings indicate that:

- Random Forest and Decision Trees perform similarly in small datasets and excel in regression-based reliability prediction;
- KNN proves to be more effective for classification tasks, particularly in handling large volumes of data;
- the use of vibration analysis and reliability evaluation enhances failure detection accuracy, supporting early fault diagnosis in industrial equipment.

Furthermore, the study highlights vibration analysis as one of the most reliable PdM techniques, particularly for detecting faults in rotating machinery such as misalignment, imbalance, and bearing degradation. Additional monitoring methods include infrared thermography, acoustic analysis, lubricant analysis, and ultrasonic testing, all of which contribute to data collection for ML models. The results emphasize that PdM strategies, when combined with ML techniques, can reduce system downtime, optimize maintenance scheduling, and minimize costs. However, challenges such as data quality, model interpretability, and real-time deployment constraints remain critical factors in PdM implementation. The study concludes that while ML-based predictive maintenance provides a more dynamic and cost-effective approach than traditional methods, continued research is needed to refine models, improve scalability, and enhance real-time decision-making.

Predictive maintenance (PdM) is an essential component of modern industrial operations, aiming to optimize maintenance actions by predicting failures before they occur. Traditional PdM strategies rely on statistical models and machine learning (ML) techniques, but reinforcement learning (RL) has emerged as a promising approach for designing autonomous and adaptive maintenance strategies.

Siraskar et al. (2023) explores how reinforcement learning is applied to predictive maintenance across various industrial contexts, from early fault detection to health index modeling and maintenance scheduling. Unlike conventional ML techniques, which often require large amounts of labeled historical data, RL-based approaches learn optimal maintenance policies dynamically through interaction with the system.

A contribution of this work is the development of a taxonomy of RL-based predictive maintenance strategies, distinguishing between model-based RL, model-free RL, Markov Decision Processes (MDP), Partially Observable MDPs (POMDPs), and Semi-Markov Decision Processes (SMDPs). The paper highlights the advantages of RL over traditional PdM methods, including its ability to handle dynamic, non-stationary environments, optimize maintenance decisions in real time, and reduce overall maintenance costs. The review also outlines practical challenges in applying RL to PdM, including data quality issues, real-time deployment constraints, and the need for robust edge computing solutions. Additionally, the study emphasizes the importance of reward function design, exploration-exploitation trade-offs, and agent training efficiency in ensuring successful RL-based maintenance systems.

Meddaoui et al. (2024) focuses on remaining useful life (RUL) estimation, a key metric in predictive maintenance that determines the expected time before a component or system fails. Various ML models, including support vector machines (SVM), random forests (RF), k-nearest neighbors (KNN), and artificial neural networks (ANN), are evaluated to determine their effectiveness in predicting RUL. The findings indicate that:

- KNN and ANN models achieve the highest classification accuracy, with KNN reaching 95.92% accuracy in failure prediction;
- Random forests (RF) and principal component analysis (PCA) provide the best results for regression-based RUL estimation, demonstrating lower prediction error rates;
- feature engineering and data preprocessing techniques, including normalization, principal component analysis (PCA), and attribute selection methods, significantly impact model performance by reducing data dimensionality and improving predictive accuracy.

Recent advancements in artificial intelligence have revolutionized predictive maintenance strategies, enabling more efficient fault detection, failure prediction, and maintenance optimization (*O'Neil et al., 2022*). A study on deep learning-driven architectures for predictive maintenance highlights how machine learning techniques, particularly convolutional neural networks (CNNs), deep recurrent neural networks (DRNNs), stacked autoencoders (SAEs), and deep belief networks (DBNs), have evolved to address the complex challenges of reliability engineering in industrial systems. *Li et al. (2024)* systematically reviews deep learning-driven architectures applied to PdM, examining their advantages, limitations, and adaptability across various industrial scenarios.

The authors highlight how Industry 4.0 advancements and IIoT (Industrial Internet of Things) have enabled PdM models to process vast industrial datasets in real time. CNNs and autoencoders outperform traditional ML techniques by automatically extracting critical degradation patterns from raw sensor signals. LSTMs and DRNNs are particularly effective in failure prediction and RUL estimation, capturing long-term dependencies in machinery operations. Long Short-Term Memory (LSTM) networks, trained on historical operational data, provided fault predictions with an accuracy exceeding 95 percent. As a result, repair response time was reduced by 40 percent, and maintenance costs were lowered by 20 percent.

Serradilla et al. (2021) provide a comprehensive review of deep learning (DL) applications in predictive maintenance (PdM), addressing challenges in selecting suitable architectures for industrial use cases. Given the increasing volume of industrial data in the Industry 4.0 era, the study highlights how advanced DL techniques can optimize maintenance strategies by predicting failures before they occur, thus minimizing downtime and reducing costs. The authors categorize and analyze various state-of-the-art (SotA) deep learning architectures, including Self-Organizing Maps (SOM), One-Class Neural Networks (OCNN), and Generative Models, examining their adaptability to real-world industrial maintenance scenarios. The paper also systematically evaluates PdM data characteristics, reviews statistical and traditional ML techniques as baselines, and compares DL approaches against benchmark datasets. A key contribution of this work is the comparison of DL models on a turbofan engine degradation dataset, providing insights into performance, adaptability, and reproducibility in PdM applications.

Zhang et al. (2023) explores an optimized approach to configuring maintenance service vehicles for agricultural machinery operations. It presents a method for resource allocation that minimizes costs while enhancing the efficiency of maintenance services. Using a service coverage model, the research optimizes vehicle positioning and dispatch to ensure timely repairs while reducing overall operational expenses. An

improved genetic algorithm is implemented to address the challenge of optimizing service vehicle deployment, incorporating enhanced selection, crossover, and mutation techniques to refine resource distribution.

Wang et al. (2023) show that autoencoders, a type of neural network designed for unsupervised learning, can effectively extract meaningful fault-related features from large datasets. This approach enables the mapping of failure causes to observed fault phenomena, such as cutter winding, roller clogging, bridge blockage, chain wear, and excessive tool clearance. The results show that autoencoders outperform traditional rule-based and statistical models by dynamically learning complex patterns from sensor data, rather than relying on fixed analytical equations. A key advantage of ML-based predictive maintenance is its ability to identify anomalies before they lead to critical failures. For instance, when analyzing historical harvester failure data, an ML model trained on normalized and preprocessed sensor inputs achieved a prediction accuracy of over 93%, significantly outperforming support vector machines (SVMs), Bayesian classifiers, and sparse self-coding networks. The confusion matrix analysis confirmed that autoencoder-based models exhibited the lowest false-positive and false-negative rates, making them highly reliable for real-time predictive applications. In predictive modeling for refrigeration systems, sensor fusion techniques have been used to combine vibration, temperature, and pressure sensor data. ML algorithms process these multi-source inputs, allowing for early fault detection by recognizing subtle deviations from normal operating conditions. Experimental results indicate that deep learning models reduce false alarm rates by 27% compared to traditional threshold-based monitoring methods, providing a significant improvement in predictive accuracy.

To assess the effectiveness of ML models in predictive maintenance, Wang et al. (2023) have conducted comparative analyses of different approaches: self-coding neural networks (autoencoders), sparse self-coding networks, a variant of traditional autoencoders, and RotGBM, a hybrid gradient-boosting model.

Reliability is a fundamental concern in agricultural machinery, as failures in critical components can lead to significant productivity losses, increased maintenance costs, and operational inefficiencies. Traditional failure analysis methods rely on Failure Mode, Effects, and Criticality Analysis (FMECA) to identify high-risk components. However, these approaches often suffer from subjectivity and difficulty in data acquisition. By utilizing data mining techniques, researchers have been able to systematically analyze large datasets of operational faults, extract meaningful failure patterns, and enhance predictive maintenance strategies (Yang et al., 2022). The study of failure data collected from grain harvesters has identified the cutter component as the most failure-prone, with blade degradation being a dominant failure mode. Excessive clearance, misalignment, and improper installation contribute to high failure rates, requiring frequent inspections and maintenance interventions. Data-driven failure analysis has enabled the classification of failure causes into four primary categories: failures due to mechanical wear, accidental failures, operational errors, and failures caused by insufficient maintenance.

Risk assessment methodologies have been refined using machine learning models, allowing for a more precise evaluation of failure probabilities and severity. The use of risk matrix analysis, analytic hierarchy process (AHP), and FMECA data visualization has improved the accuracy of risk categorization. Machine learning models trained on failure history have successfully identified patterns in risk distribution, revealing that blockages in the header, speed mismatches between working parts, and cutter malfunctions pose the highest operational risks. The application of these models in predictive maintenance enables real-time fault detection, reducing downtime and optimizing repair schedules (Kammerer et al., 2021).

Challenges remain in implementing machine learning-based predictive maintenance at scale. The accuracy of predictions relies heavily on the quality and availability of sensor data, which can be affected by environmental conditions and sensor noise. Additionally, real-time decision-making requires low-latency processing, particularly in remote agricultural locations with limited connectivity. Advances in edge computing and federated learning are expected to address these limitations by enabling decentralized data processing, reducing dependence on cloud-based infrastructure.

Table 1 summarizes the key machine learning methods discussed in the recent studies, highlighting their specific applications in predictive maintenance and the advantages they offer in improving reliability, reducing downtime, and optimizing maintenance schedules.

Table 1

AI Methods for Predictive Maintenance

Method	Application in Predictive Maintenance	Advantages
Convolutional Neural Networks (CNNs)	Analyzes vibration and temperature data to detect faults like bearing degradation, misalignment, and lubrication failures.	Extracts both time-domain and frequency-domain features, improving predictive accuracy.

Method	Application in Predictive Maintenance	Advantages
Deep Recurrent Neural Networks (DRNNs)	Tracks component degradation over time, improving failure prediction in conveyor belts, gearboxes, and hydraulic systems.	Captures complex degradation trends that traditional methods miss.
Long Short-Term Memory (LSTM) & Gated Recurrent Units (GRUs)	Handles long-term dependency modeling, predicting remaining useful life (RUL) in time-series maintenance data.	Enables robust prediction of maintenance needs for systems requiring long-term analysis.
Stacked Autoencoders (SAEs)	Enhances feature extraction from high-dimensional sensor data, reducing reliance on manual feature selection.	Automates feature learning, enhancing predictive model efficiency.
Deep Belief Networks (DBNs)	Offers a probabilistic framework for modeling uncertainty in sensor-based failure prediction models.	Handles noisy sensor data effectively, increasing reliability of predictions.
Transfer Learning	Adapts models trained in one environment to new industrial conditions with minimal retraining.	Reduces the need for extensive labeled datasets, improving model adaptability.
Reinforcement Learning	Optimizes maintenance scheduling by dynamically learning from equipment performance data.	Continuously refines maintenance strategies based on real-time feedback.
Digital Twin Technology	Creates virtual representations of physical assets to simulate operational conditions and improve failure prediction accuracy.	Enhances predictive modeling by reducing reliance on physical testing, optimizing resource use.

Liu et al. (2024) provide a comprehensive overview of predictive maintenance, integrating Industry 4.0 concepts such as IoT, big data, and AI. The book highlights predictive maintenance as a key advancement over traditional methods, emphasizing real-time condition monitoring, fault diagnosis, and predictive analytics to enhance equipment performance and reliability. A major focus is the shift from conventional maintenance to AI-driven models using sensor data, digital twins, and machine learning for early fault detection. Digital twin technology enables real-time simulations and failure forecasting, while predictive algorithms optimize maintenance schedules, reducing unplanned downtime and improving spare parts management.

A case study on Vestas illustrates how SCADA systems and predictive maintenance enhance wind turbine performance through real-time data analysis. The book also explores applications in agriculture and food processing, where IoT-enabled sensors anticipate failures in farm machinery, irrigation systems, and food processing equipment. AI-driven monitoring of refrigeration units and conveyor belts ensures food safety and reduces spoilage risks.

Additionally, the book examines AI-based automation techniques, including genetic algorithms, particle swarm optimization, and neural networks, for optimizing repair schedules. Challenges such as multi-source data fusion and sensor integration are addressed, emphasizing the need for robust predictive models. The work underscores the role of Industry 4.0 in advancing predictive maintenance, making industrial systems smarter, more reliable, and cost-efficient. The Table 2 provides a summarized overview of key insights from Liu et al. (2024). This summary captures the essential aspects of predictive maintenance methodologies, including its integration with Industry 4.0, applications of AI and machine learning, the role of digital twins, sensor technologies, and industry-specific implementations in agriculture and food processing. Additionally, the table highlights the primary challenges and future directions of AI-driven predictive maintenance.

Table 2

Extended Summary of Intelligent Predictive Maintenance

Topic	Key Insights
Predictive Maintenance Concept	Transition from reactive and preventive maintenance to AI-driven predictive strategies.
Integration with Industry 4.0	Use of Cyber-Physical Systems (CPS), Industrial IoT (IIoT), and big data for real-time monitoring.
AI and Machine Learning Models	Implementation of deep learning, Bayesian networks, fault tree analysis, and neural networks for failure prediction.
Digital Twin Applications	Creation of virtual replicas for failure forecasting, operational simulations, and process optimization.
Sensor Technologies	Integration of vibration sensors, acoustic emission monitors, and temperature sensors for real-time anomaly detection.

Topic	Key Insights
Applications in Agriculture (Extended Insight)	Additional insights on predictive maintenance applications in farm equipment, including IoT-enabled sensors on combine harvesters, irrigation systems, and agricultural processing equipment, reducing failures and optimizing performance.
Applications in Food Industry (Extended Insight)	Beyond the book's scope: AI-driven predictive maintenance for monitoring refrigeration units, conveyor belts, and packaging automation, ensuring food safety, reducing spoilage, and minimizing production disruptions.
Challenges and Future Directions	Challenges in data integration, sensor reliability, and computational resource requirements; advancements in edge computing and federated learning proposed as solutions.

Bala et al. (2024) explore the integration of artificial intelligence (AI) with edge computing for predictive maintenance in industrial machines, addressing key challenges in data processing and model deployment. The study categorizes existing approaches into three main architectures: cloud-based training with edge deployment, edge-based training for enhanced data privacy, and hybrid cloud-edge training. The review highlights the advantages of edge computing, such as reduced latency and improved availability, while also acknowledging challenges like limited computational power and the need for lightweight AI models. Additionally, the paper discusses emerging research directions, including synthetic data generation, transfer learning applications, and secure communication protocols for edge AI. This work contributes to the evolving landscape of AI-driven predictive maintenance by assessing the trade-offs between centralized and distributed learning architectures.

Glock et al. (2024) introduce a novel unsupervised CPD framework, Predict and Compare (P&C), which integrates predictive machine learning models with statistical validation methods to improve anomaly detection reliability. Their approach aligns closely with ensemble-based strategies, such as the "Council of the Wise" framework employed in this study, which aggregates multiple model outputs to enhance detection accuracy. Using both deep learning models (LSTM) and statistical models (ARIMA), the Predict and Compare method successfully identifies structural shifts while mitigating false positives caused by long-term trend variations. The insights from *Glock et al. (2024)* reinforce the importance of combining predictive modeling with statistical validation in predictive maintenance applications. Their findings serve as a valuable reference point for enhancing multi-model anomaly detection frameworks, further supporting the scalability and adaptability of predictive maintenance strategies across diverse industrial settings.

MATERIALS AND METHODS

The predictive maintenance analysis was conducted using data collected from a Massey Ferguson 7700 S tractor, a widely used model in modern precision agriculture. Data acquisition took place in May 2023, focusing on the tractor's hydraulic system, which plays a crucial role in various agricultural operations, including plowing, lifting, and operating auxiliary implements. Given that hydraulic systems in agricultural machinery are subject to high operational loads and varying environmental conditions, they are critical components for predictive maintenance assessment.

The Massey Ferguson 7700 S series is known for its high-performance engine, advanced transmission options, and robust hydraulic capabilities, making it an ideal candidate for predictive maintenance analysis. This model is typically equipped with a 6.6L AGCO Power engine, delivering 140 to 280 horsepower, depending on the variant. Its Dyna-VT continuously variable transmission (CVT) allows for smooth and efficient power delivery, enhancing fuel efficiency and reducing mechanical stress. However, the hydraulic system is one of the most stressed components in the tractor, as it directly influences the performance of attached implements and overall machine efficiency (<https://www.masseyferguson.com/en/product/tractors/mf-7700-s.html>).

The hydraulic system of the 7700 S series operates within a pressure range of 140 to 200 bar, providing the necessary force for lifting and operating various implements. This system consists of variable displacement pumps, pressure relief valves, hydraulic cylinders, and control units that regulate fluid flow and pressure. Given that hydraulic failures are often attributed to fluid contamination, wear in seals and valves, pressure fluctuations, and overheating, predictive maintenance techniques are crucial in detecting early signs of degradation before failures occur.

This study evaluates predictive maintenance strategies in agriculture using AI-driven failure prediction and sensor-based diagnostics. By integrating these methodologies, the objective was to reduce unplanned downtime, optimize maintenance schedules, and enhance the operational lifespan of the tractor's hydraulic system, ultimately contributing to increased agricultural productivity.

The predictive maintenance framework for agricultural and food industry machinery, specifically for the Massey Ferguson 7700 S tractor's hydraulic system, operates through an integrated process of data acquisition, processing, analysis, and decision-making.

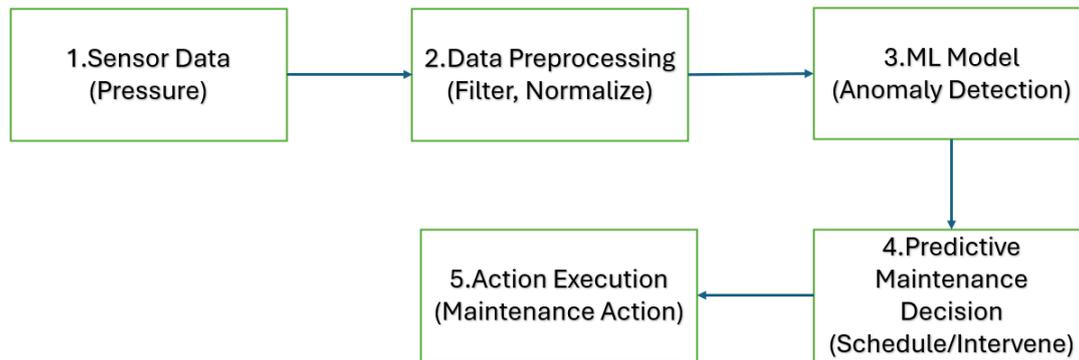

Fig. 1 - Data flow from sensor data collection through data preprocessing, ML model analysis (e.g., anomaly detection, failure prediction), maintenance decision-making, and action execution

The diagram in figure 1 follows a structured workflow that ensures early failure detection, optimizes maintenance scheduling, and improves equipment longevity.

1. **Sensor Data Collection.** The system begins with real-time data acquisition from multiple IoT-enabled sensors embedded in the hydraulic system of the tractor. These sensors continuously monitor key performance indicators (KPIs) such as:
 - hydraulic pressure fluctuations detect inefficiencies or valve blockages;
 - fluid temperature variations identify overheating risks or cooling inefficiencies;
 - vibration levels in hydraulic actuators and pumps indicates mechanical wear or imbalance;
 - operational workload and duty cycle variations determines stress levels on the system.
2. **Data Transmission and Preprocessing.** The collected sensor data is transmitted via wireless communication to an edge computing unit or cloud-based storage system. Here, the raw data undergoes preprocessing, including:
 - noise filtering – removes irrelevant fluctuations caused by environmental interference;
 - feature extraction – selects the most relevant sensor parameters for analysis;
 - data normalization – ensures consistency in input values across different operating conditions.
3. **Machine Learning Models for Anomaly Detection.** The processed data is then analyzed using machine learning (ML) models trained to recognize normal vs. abnormal operating patterns. Additionally, moving average and moving median filters were used as comparative statistical methods to smooth noisy sensor readings and identify abrupt fluctuations. While these are not machine learning techniques, they serve as baseline references to validate the anomaly detection models. Key AI techniques used include:
 - Time-Series Forecasting (LSTM, ARIMA – not applied in this study) to detect deviations from expected trends;
 - Isolation Forest and One-Class SVM for detecting anomalies by isolating rare and abnormal sensor readings;
 - K-Means and DBSCAN clustering to categorize different failure modes and identify outliers indicative of early-stage mechanical degradation;
 - Autoencoders for feature extraction and unsupervised anomaly detection, reconstructing normal operational states and identifying anomalies when deviations exceed a predefined threshold;
 - Convolutional Neural Networks (CNNs) to analyze spatial-temporal correlations in sensor data, particularly useful for identifying nonlinear relationships in hydraulic system degradation;
 - XGBoost for failure prediction, leveraging gradient-boosted decision trees to analyze feature importance and classify high-risk operational states.
4. **Predictive Maintenance Decision Making.** Based on the analysis, the system provides predictive alerts regarding potential failures before they occur. The maintenance strategy includes:
 - immediate alerts for critical failures when a component is on the verge of breakdown;
 - scheduled maintenance recommendations to address wear before it escalates;
 - spare parts inventory management ensuring the availability of necessary components based on predicted failure rates.

5. Action Execution and Maintenance Action Optimization. The system integrates with farm management software (FMS) or maintenance dashboards, allowing technicians to access real-time condition reports and historical performance logs. This enables:

- proactive intervention rather than reactive maintenance;
- minimized downtime by repairing components before catastrophic failure;
- cost reduction by avoiding unnecessary replacements and optimizing resource allocation.

To evaluate the performance of the hydraulic system, real-time sensor data was collected, encompassing pressure measurements, flow rates, temperature variations, and vibration levels. These parameters were continuously tracked to detect potential anomalies associated with seal wear, pump inefficiencies, valve obstructions, or hose degradation.

For this study, output pressure was selected as the primary diagnostic metric due to its critical role in assessing the health and efficiency of hydraulic pumps. Variations in pressure readings can reveal early signs of degradation, helping maintenance teams anticipate failures before they lead to system breakdowns. Several aspects of hydraulic pump performance can be inferred by closely monitoring pressure fluctuations, making it a valuable tool for predictive maintenance. One of the most critical insights that output pressure provides is an indication of internal component wear. A gradual drop in pressure over time may signal wear in essential components such as pistons, vanes, or gears, reducing overall efficiency and leading to performance losses. Additionally, monitoring pressure allows for the early detection of cavitation, a damaging condition where vapor bubbles form due to pressure inconsistencies and collapse violently, causing internal damage to the pump. While output pressure is an effective parameter for diagnosing hydraulic pump health, relying solely on it may not provide a complete picture of the system's condition. It is best used in combination with other parameters, such as flow rate, temperature, and vibration analysis, to create a more comprehensive predictive maintenance strategy. A multi-sensor approach helps improve diagnostic accuracy, allowing for a deeper understanding of the system's overall health and facilitating early anomaly detection (*Herrera-Granados et al., 2024*).

In this stage of the research, output pressure was selected as the primary health indicator of the hydraulic pump, with data recorded under constant torque conditions. The decision to maintain a constant torque setting provided a controlled operational environment, ensuring that any fluctuations in pressure readings could be attributed to internal factors within the pump or hydraulic system, rather than variations in external load or torque. By isolating pressure as the key variable, this study aimed to enhance the reliability of pressure-based diagnostics. Any deviations detected in the output pressure were more easily linked to specific mechanical issues such as component wear, cavitation, sealing degradation, or hydraulic resistance variations. These pressure anomalies act as early warning signals, allowing maintenance teams to take preventive action before critical failures occur.

The moving average is a widely used technique that smooths data by calculating the mean value over a predefined window of time. By averaging out short-term fluctuations, it provides a clearer representation of gradual changes in system behavior. For instance, if hydraulic pressure readings are recorded every second, applying a moving average over one minute interval can reveal long-term trends while minimizing the impact of transient noise. Large deviations from the moving average, such as sudden spikes or drops, can serve as early indicators of abnormal conditions. A sustained upward drift in temperature, for example, may suggest the gradual failure of a cooling system, while a sharp pressure drop could point to a hydraulic leak or valve malfunction. The moving median, in contrast, calculates the median value within a chosen time window, making it particularly effective at handling data sets with sudden, irregular spikes or short-lived anomalies. Unlike the moving average, which smooths all fluctuations evenly, the moving median focuses on the central tendency of the data, filtering out outliers that could distort the analysis. This property makes it highly valuable in predictive maintenance scenarios where sensor noise, electrical interference, or momentary load changes can create misleading spikes in the data. By emphasizing typical values rather than being influenced by extreme variations, the moving median helps in identifying genuine trends without overreacting to temporary fluctuations.

Combining the moving average and moving median offers a more comprehensive approach to anomaly detection. While the moving average is useful for identifying long-term trends and gradual deviations, the moving median ensures that brief, isolated spikes do not lead to false alarms. When applied together, these techniques provide a balanced perspective, helping maintenance teams distinguish between short-term disturbances and sustained changes that require intervention. This dual approach enhances predictive maintenance by allowing for early detection of subtle shifts in equipment behavior, ensuring that emerging faults can be addressed proactively before they lead to failures.

By incorporating both techniques into predictive maintenance strategies, organizations can optimize their ability to monitor system performance, improve failure prediction accuracy, and reduce the risk of unexpected breakdowns. These statistical smoothing methods serve as valuable tools in data preprocessing, supporting more advanced machine learning models by ensuring that input data remains stable, interpretable, and free from misleading noise. When integrated with real-time monitoring systems, moving averages and moving medians contribute to a more robust and reliable maintenance framework, ultimately improving operational efficiency and reducing downtime across industrial and agricultural applications.

One of the most valuable findings was that the most significant anomaly patterns were not necessarily extreme values, but rather subtle deviations that did not conform to typical operational trends. These nuanced anomalies, often overlooked by traditional threshold-based methods, reinforce the importance of leveraging multiple machine learning techniques to gain a more comprehensive perspective on system health. Given that no single model can be expected to detect every relevant anomaly with absolute accuracy, a more effective approach involves a form of ensemble learning inspired by the "wisdom of the crowd" principle.

This study proposes a method for estimating anomaly detection points, referred to as the "Council of the Wise." This approach relies on an ensemble decision-making system, where an odd number of models independently analyze incoming sensor data and "vote" on whether a given point should be classified as an anomaly requiring maintenance intervention. This method ensures a more balanced and reliable assessment, reducing the likelihood of false positives and false negatives. By aggregating the decisions of multiple diverse models, this ensemble approach enhances predictive accuracy and increases confidence in maintenance recommendations. For instance, if five out of the seven models flag a particular data point as anomalous, the system classifies it as an anomaly and triggers an alert for maintenance action. If only a minority of models detect an issue, the system may either discard the anomaly or mark it as a lower-priority concern for further observation. This voting mechanism mitigates the risk associated with the limitations of any single model, creating a more resilient and adaptive predictive maintenance framework.

By combining different models, each with distinct strengths in identifying various types of anomalies – whether based on density, clustering, reconstruction errors, or decision trees – the "Council of the Wise" approach maximizes the effectiveness of predictive maintenance. It reduces dependency on any single algorithm, ensuring a more robust and interpretable decision-making process. Ultimately, this proposed method enhances anomaly detection accuracy, optimizes maintenance scheduling, reduces downtime, and extends equipment lifespan, making it a valuable contribution to predictive maintenance strategies.

The "Council of the Wise" framework, where seven machine learning models independently analyze sensor data and "vote" to determine anomalies, shares conceptual similarities with the Digital Twin paradigm while serving a distinct function within predictive maintenance (*Pulcini and Modoni, 2024*). Both approaches leverage real-time data-driven decision-making and advanced computational models to enhance predictive accuracy and optimize system performance. A Digital Twin is a virtual replica of a physical system, continuously updated with sensor data to enable real-time monitoring, fault prediction, and operational optimization. In contrast, the "Council of the Wise" operates as an ensemble anomaly detection mechanism, where multiple machine learning models process the data independently and reach a consensus on potential failures. This ensemble approach enhances reliability by reducing false positives and ensuring that only significant deviations from normal operational patterns are flagged for maintenance interventions. Integrating the "Council of the Wise" within a Digital Twin framework could enhance predictive maintenance strategies by providing an additional decision-making layer. While the Digital Twin maintains a real-time simulation of system behavior, the ensemble-based "voting" mechanism would refine anomaly detection, improving failure prediction accuracy and ensuring more confident maintenance recommendations. This hybrid methodology would combine the benefits of continuous situational awareness and high-confidence anomaly detection, leading to proactive and precise intervention strategies, minimizing downtime, and optimizing resource allocation in industrial and agricultural applications.

In the field of predictive maintenance, accurately identifying early signs of mechanical degradation is essential to minimizing unplanned downtime and optimizing maintenance schedules. One of the key challenges in this domain is distinguishing genuine system anomalies from natural operational variations, particularly in complex industrial environments where data trends are influenced by multiple factors. Change point detection (CPD) techniques play a crucial role in this process, enabling systems to identify transitions between different operational states without being misled by normal fluctuations.

To develop a robust predictive maintenance framework, this study employed eight machine learning models: Isolation Forest, One-Class SVM, KMeans, DBSCAN, Autoencoders, Convolutional Neural Networks

(CNNs), XGBoost, and Gaussian Naïve Bayes. Each model was selected based on its ability to detect anomalies in hydraulic system pressure data, leveraging different approaches such as unsupervised learning, clustering, deep learning, and probabilistic classification. The following sections provide a detailed examination of how each model was applied and its effectiveness in identifying potential failures.

Isolation Forest is a powerful and efficient tool in predictive maintenance, particularly suited for detecting anomalies in systems where deviations in sensor data can indicate early signs of equipment wear, malfunction, or inefficiencies. It is an unsupervised machine learning algorithm designed to differentiate normal operating conditions from rare, abnormal events, making it highly effective in identifying potential failures before they escalate. Unlike One-Class SVM, which constructs a boundary around normal data points, Isolation Forest isolates anomalies by assessing how quickly a given data point can be separated from the majority of the dataset. This method works on the principle that anomalies are typically sparse and differ significantly from normal data, making them easier to isolate (Murphy, 2002; Xiao, 2022).

Isolation Forest is based on Isolation Trees (iTrees), which recursively divide data points by selecting random features and split values. For a given dataset X with n samples, an Isolation Tree is built using the following recursive function:

$$Partition(X) = \begin{cases} X, & \text{if } |X| = 1 \text{ (single point left)} \\ Partition(X_L) \cup Partition(X_R), & \text{otherwise} \end{cases} \quad (1)$$

where X_L and X_R are the left and right subsets after a random split on a randomly chosen feature. The height $h(x)$ of a data point x in an Isolation Tree represents the number of splits required to isolate x .

The key idea behind Isolation Forest is that anomalies are easier to isolate than normal points, so they tend to have shorter average path lengths in the Isolation Trees.

$$E(h(x)) = 2H(n-1) - \frac{2^{(n-1)}}{n} \quad (2)$$

where $H(n)$ is the harmonic number, approximated as:

$$H(n) \approx \ln(n) + 0.5772156649 \text{ (Euler - Mascheroni constant)} \quad (3)$$

Since anomalies tend to be isolated faster, their expected path length $E(h(x))$ is smaller than that of normal points.

To quantify how anomalous a point is, Isolation Forest computes an anomaly score $s(x)$ based on the path length:

$$s(x) = 2^{-\frac{E(h(x))}{c(n)}} \quad (4)$$

where $c(n)$ is an adjustment factor for normalizing path lengths:

$$c(n) = 2H(n-1) - \frac{2^{(n-1)}}{n} \quad (5)$$

The anomaly score $s(x)$ falls within the range $[0,1]$. If we have a high $s(x)$ ($s(x) \sim 1$) is likely an anomaly (isolated quickly). If we have a low $s(x)$ ($s(x) \sim 0$) is likely normal data (requires many splits to isolate). A typical threshold for anomaly classification is $s(x) > 0.6$ or $s(x) > 0.7$ based on empirical tuning.

One-Class Support Vector Machine (One-Class SVM) is a kernel-based anomaly detection model that learns a boundary around normal data and identifies points outside this boundary as anomalies. Unlike traditional SVMs used for classification, One-Class SVM is an unsupervised algorithm that operates on a single class of data (Murphy, 2002; Xiao, 2022).

One-Class SVM finds a hyperplane or hypersphere that best encloses normal data, separating it from potential outliers. The optimization problem is formulated as:

$$\min \frac{1}{2} \|w\|^2 + \frac{1}{\nu n} \sum_{i=1}^n \xi_i - \rho \quad (6)$$

where w is the normal vector defining the hyperplane, $\xi_i \geq 0$ are slack variables allowing some flexibility for soft margins, ρ is the decision boundary threshold, ν is the hyperparameter controlling the fraction of outliers allowed in the dataset (typically between 0 and 1), n is the number of training samples. The goal is to maximize the margin while allowing a small fraction of the training points to be considered anomalies.

Once trained, One-Class SVM uses the following decision function to classify new data points:

$$f(x) = \text{sign}(w \cdot \phi(x) - \rho) \quad (7)$$

where $\phi(x)$ is a feature transformation function (applied via a kernel), ρ is the threshold learned from the training data. A new point x is classified as normal if $f(x) \geq 0$ or anomalous if $f(x) < 0$.

One-Class SVM is a widely used tool in predictive maintenance, particularly effective for detecting anomalies in systems where normal operating behavior dominates, but occasional deviations may indicate potential faults, wear, or system degradation. Its ability to model normal conditions and identify unexpected variations makes it a valuable method for early fault detection, allowing maintenance teams to intervene before

minor issues develop into costly failures. In predictive maintenance applications, data is continuously collected from sensors monitoring critical parameters and other performance indicators. One-Class SVM is trained exclusively on this normal operating data, constructing a mathematical boundary that encapsulates expected values. Once trained, the model evaluates new sensor readings by determining whether they fall within or outside this learned boundary. Any data point that significantly deviates from the norm is flagged as an anomaly, signaling potential irregularities in the system.

KMeans is a widely used clustering technique that partitions data into a predefined number of clusters based on similarity. In predictive maintenance, this method is particularly effective for analyzing historical sensor data to identify typical operating states. By defining clusters that represent normal working conditions, KMeans can evaluate new data points in real-time. If a new observation falls significantly outside the boundaries of these predefined clusters, it is flagged as an outlier or anomaly. This approach is well-suited for relatively stable systems where operational patterns remain consistent (Murphy, 2002; Xiao, 2022).

The goal of K-Means is to minimize the total variance within clusters, defined as:

$$J = \sum_{i=1}^k \sum_{x \in C_i} \|x - \mu_i\|^2 \quad (8)$$

where J is the total sum of squared distances (cost function), k is the number of clusters, C_i is the set of points assigned to cluster i , x is a data point in cluster C_i , μ_i is the centroid of cluster i , $\|x - \mu_i\|^2$ represents the squared Euclidean distance between a point and its cluster center. The algorithm seeks to find the optimal centroids μ_i that minimize this cost function.

Each data point is assigned to the closest centroid using the Euclidean distance:

$$c(x) = \arg \min_i \|x - \mu_i\| \quad (9)$$

where $c(x)$ is the cluster index assigned to x . The function finds the centroid μ_i that minimizes the distance to x .

The algorithm iterates until centroids no longer change significantly or the decrease in cost function is below a threshold:

$$\mu_i^{(t+1)} - \mu_i^{(t)} < \epsilon \quad (10)$$

where t is the iteration index, ϵ is a small predefined tolerance level.

DBSCAN (Density-Based Spatial Clustering of Applications with Noise) offers a more flexible approach to anomaly detection by clustering data points based on density rather than predefining a fixed number of clusters. Unlike KMeans, which assumes that all data points should belong to a cluster, DBSCAN labels low-density points as noise or anomalies. This makes it particularly effective in handling complex sensor data where operating conditions may fluctuate, and anomalies do not necessarily conform to a fixed pattern (Xiao, 2022).

DBSCAN uses two important hyperparameter: ϵ (neighborhood radius) that defines the maximum distance within which points are considered neighbors and min_pts – minimum points – that defines the minimum number of points required within a neighborhood of radius ϵ for a point to be considered a core point.

To measure similarity between points, DBSCAN typically uses the Euclidean distance:

$$d(x_i, x_j) = \sqrt{\sum_{k=1}^d (x_{ik} - x_{jk})^2} \quad (11)$$

where $d(x_i, x_j)$ is the Euclidean distance between two points x_i and x_j , d is the number of dimensions, x_{ik} and x_{jk} are the k -th features of points i and j . Other distance metrics like Manhattan distance or Cosine similarity can be used depending on the application.

A point x in the dataset is classified into one of three categories:

- core point, if it has at least min_pts neighbors within distance

$$|\{x_j \in D \mid d(x_i, x_j) \leq \epsilon\}| \geq min_pts \quad (12)$$
- border point, if point lies within ϵ -distance of a core point but has fewer than min_pts neighbors;
- noise (outlier), if it is not a core point and does not lie within the ϵ -radius of any core point.

In predictive maintenance, DBSCAN is useful for identifying irregular or infrequent operating states that might not fit within predefined categories. For example, in rotating machinery, vibration readings often exhibit natural fluctuations due to varying loads and speeds (Laaradj et al., 2023; Popescu et al., 2022). DBSCAN can distinguish between expected variations and truly anomalous behavior, such as imbalance, misalignment, or excessive friction, by detecting low-density, outlier points in the data. Since DBSCAN does not require prior knowledge of the number of clusters, it is particularly advantageous for monitoring systems with variable operating conditions, where unexpected failures may arise in non-uniform patterns.

Both KMeans and DBSCAN contribute to a proactive maintenance strategy by enabling early detection of anomalies and potential faults. KMeans is best suited for systems with predictable and well-structured operational states, where deviations from established clusters can reliably indicate anomalies. In contrast, DBSCAN excels in complex and noisy environments where system behavior is more variable, allowing for greater adaptability in detecting rare but significant failures. By combining these clustering techniques with other anomaly detection methods, maintenance teams can improve predictive maintenance accuracy, optimize intervention timing, and extend the lifespan of critical machinery.

Convolutional Neural Networks (CNNs) are becoming increasingly valuable in predictive maintenance, particularly for detecting anomalies in sensor data that exhibit spatial or temporal patterns. While CNNs are traditionally known for their success in image processing, they have also proven to be highly effective in analyzing sequential data, making them a powerful tool for identifying irregularities in time-series sensor readings. Their ability to capture local dependencies within complex datasets allows them to recognize subtle variations that may indicate early signs of equipment degradation (Abo-Habaga et al., 2024; Subburaj et al., 2025; Yun et al., 2024; Zhang et al., 2024; Taner et al., 2024).

The fundamental operation in CNNs is convolution, which is applied between an input feature map and a set of learnable filters (kernels). Mathematically, the convolution operation for a 2D input (e.g., sensor data) is:

$$Z(i, j) = \sum_m \sum_n X(i - m, j - n)K(m, n) \quad (13)$$

Where:

$X(i, j)$ is input feature map (e.g., sensor data), $K(m, n)$ convolution kernel (filter), $Z(i, j)$ output feature map after convolution, (m, n) is kernel size (height and width). This convolution operation slides the kernel over the input and computes weighted sums, capturing local patterns like edges, trends, or changes in sensor data (Murphy, 2002; Xiao, 2022).

In predictive maintenance applications, CNNs are trained on historical sequences of normal operating data collected from sensors monitoring key parameters. By applying convolutional layers, CNNs extract patterns from these sequences, learning what constitutes normal fluctuations under different operating conditions. Unlike traditional anomaly detection methods that rely on manually defined thresholds, CNNs autonomously learn meaningful features from raw sensor data, enhancing their ability to detect deviations that signal emerging faults. Once trained, a CNN continuously processes new sensor data, comparing it to previously learned patterns. When it identifies abnormal trends – such as unexpected pressure spikes, sudden drops, or irregular variations in vibration frequency – it flags them as potential anomalies. These deviations may indicate developing issues such as wear in mechanical components, internal leaks in hydraulic systems, or imbalances in rotating machinery. By detecting these early-stage anomalies, CNNs enable maintenance teams to investigate and address potential failures before they escalate into severe damage or system downtime.

One of the primary advantages of CNNs in predictive maintenance is their ability to handle multidimensional data, making them particularly useful in systems where multiple sensor inputs need to be analyzed simultaneously. For example, in industrial machinery equipped with an array of sensors measuring different parameters, CNNs can correlate fluctuations across these variables, identifying complex patterns that may not be apparent through single-variable analysis. This capability allows for a more comprehensive assessment of equipment health, improving failure prediction accuracy.

Autoencoders, a specialized type of neural network, are highly effective in predictive maintenance for detecting anomalies in complex and nonlinear data patterns. Their primary function is to learn a compressed representation of normal operating data and then attempt to reconstruct it as accurately as possible. Any significant differences between the reconstructed output and the original data indicate deviations from expected patterns, which may signal the onset of equipment faults or mechanical degradation (Xiao, 2022).

An autoencoder aims to encode input data into a lower-dimensional representation and then reconstruct it as accurately as possible. It consists of two main parts: encoder that compresses input data into a latent space representation and decoder that reconstructs the original input from the latent space (Hajgató et al., 2022). Given an input x , an autoencoder learns two functions:

1. encoding function $z = f_{\theta}(x)$, where z is the latent representation (compressed encoding) and f_{θ} is the encoder function (usually a neural network with parameters θ);
2. decoding function $\hat{x} = g_{\phi}(z)$ where \hat{x} is the reconstructed input, g_{ϕ} is the decoder function (another neural network with parameters ϕ).

The goal of an autoencoder is to minimize the reconstruction error between x and \hat{x} .

Using XGBoost in combination with Isolation Forest creates a highly effective approach to anomaly detection in predictive maintenance, leveraging the strengths of both algorithms to enhance the accuracy and reliability of fault identification. This hybrid strategy takes advantage of Isolation Forest's ability to quickly isolate outliers while utilizing XGBoost's advanced pattern recognition to refine anomaly detection, reducing false positives and ensuring maintenance teams focus on critical system issues. Isolation Forest serves as the initial anomaly detection mechanism, analyzing historical sensor data – in this study, but could be also pressure, temperature, and vibration readings – to establish a model of normal operating behavior. By isolating outliers, it effectively flags deviations that may indicate potential failures. However, because Isolation Forest does not differentiate between minor fluctuations and critical anomalies, it can sometimes generate false positives, triggering unnecessary alerts. To refine these results, XGBoost is introduced as a second layer of analysis.

XGBoost optimizes a regularized loss function:

$$L = \sum_{i=1}^N l(y_i, \hat{y}_i) + \sum_{k=1}^K \Omega(f_k) \quad (14)$$

where $l(y_i, \hat{y}_i)$ is loss function (e.g., Log Loss for classification, MSE for regression), $\Omega(f_k)$ is regularization term to prevent overfitting, K number of trees, f_k prediction function for tree k .

Each XGBoost tree predicts the anomaly probability by using gradient boosting, where each new tree corrects the previous errors (Murphy, 2002):

$$g_i = \frac{\partial L}{\partial \hat{y}_i}, h_i = \frac{\partial^2 L}{\partial \hat{y}_i^2} \quad (15)$$

where g_i is gradient (first derivative of loss function), h_i is hessian (second derivative of loss function). These terms adjust tree weights for better classification of anomalies.

For each tree leaf, the new score is updated as:

$$w_j = -\frac{\sum g_i}{\sum h_i + \lambda} \quad (16)$$

where w_j is weight assigned to leaf j , λ is a regularization parameter.

The final anomaly score is a combination of Isolation Forest's anomaly score and XGBoost's refined classification probability:

$$S_{final}(x) = \alpha \cdot s_{IF}(x) + (1-\alpha) \cdot P_{XGB}(x) \quad (17)$$

where $s_{IF}(x)$ is Isolation Forest anomaly score, P_{XGB} is XGBoost probability of being an anomaly and α a weight parameter (controls importance of each method). A higher $S_{final}(x)$ means a higher likelihood of an anomaly.

Gaussian Naïve Bayes is a probabilistic classification model widely applied in predictive maintenance, particularly for anomaly detection and failure prediction in industrial systems. It operates based on Bayes' theorem, modeling each feature as following a Gaussian distribution (Murphy, 2002; Xiao, 2022).

The fundamental formula is:

$$P(C_k|X) = \frac{P(X|C_k)P(C_k)}{P(X)} \quad (18)$$

where $P(X|C_k)$ is the posterior probability of class C_k given the feature vector X , $P(X|C_k)$ is the likelihood, the probability of observing X given class C_k , $P(C_k)$ is the prior probability of class C_k , $P(X)$ is the marginal probability of the feature vector X , serving as a normalizing constant.

The assumption of Gaussian distribution allows the model to estimate the likelihood of different operating conditions based on historical sensor data, making it well-suited for systems where key parameters such as temperature, pressure, and vibration fluctuate within predictable ranges. Naïve Bayes assumes conditional independence of features, meaning:

$$P(X|C_k) = \prod_{i=1}^n P(X_i|C_k) \quad (19)$$

The predicted class is the one that maximizes the posterior probability:

$$C^* = \arg \max_{C_k} P(C_k|X) \quad (20)$$

Despite its strengths, Gaussian Naïve Bayes has limitations that must be considered when applying it to predictive maintenance. The model assumes independence between features, which may not always hold true in complex industrial systems where multiple variables interact. This simplification can lead to misclassifications, particularly when the underlying data distribution deviates significantly from a normal Gaussian pattern. Additionally, the model does not capture intricate dependencies between parameters as effectively as more advanced machine learning methods such as tree-based models or deep learning approaches.

Each of these eight machine learning models contributed with insights into anomaly detection, leveraging different mathematical approaches to identify deviations from normal operating conditions. Interestingly, some of the models identified similar patterns of abnormal behavior, reinforcing their reliability in predictive maintenance and suggesting consistency in detecting potential failures.

An important observation in this study was that Gaussian Naïve Bayes failed to detect any anomalies, making it unsuitable for inclusion in the final anomaly “voting” process. This is most likely due to the fact that Naïve Bayes relies on well-defined probability distributions and requires a larger dataset or extended training time to accurately learn the underlying patterns in the data. Given the complexity and variability of hydraulic pressure fluctuations, its assumptions about feature independence and Gaussian distribution may not have aligned well with the dataset, leading to an inability to effectively distinguish anomalies from normal operating conditions. This outcome underscores a broader challenge in artificial intelligence: the difficulty in predicting why certain models perform effectively in specific contexts while others fail to recognize meaningful patterns. Given its inability to identify anomalies in this dataset, Gaussian Naïve Bayes was excluded from the final decision-making process, ensuring that only models capable of reliably detecting deviations contributed to the “Council of the Wise voting” framework.

The implementation of all machine learning models was carried out using Python 3.9. The experiments were conducted using widely adopted open-source libraries, including Scikit-learn, TensorFlow, Keras, XGBoost, NumPy, and Matplotlib. Model training and evaluation were performed on a workstation equipped with an Intel Core i7 processor, 32 GB of RAM, and the Ubuntu 20.04 LTS operating system. This configuration provided sufficient computational resources to train the models efficiently and ensured the reproducibility of results in a controlled and stable software environment.

The dataset used in this study was recorded during real-life plowing operations in May 2023, using a Massey Ferguson 7700 S tractor equipped with a hydraulic pressure sensing system. In order to minimize external variability and isolate equipment behavior, an approximately constant torque level was maintained throughout the entire recording period, regulated by the onboard electronic control system. The dataset includes measurements sampled at a frequency of 20 Hz and later aggregated using harmonic means calculated over one-minute intervals, providing a stable temporal structure suitable for anomaly detection models. The models based on unsupervised learning, such as Isolation Forest, One-Class SVM, K-means, and Autoencoder, were trained using data presumed to represent normal system behavior, as no labeled anomalies were available at the time of analysis. For the deep learning models (Autoencoder and 1D CNN), the training was performed exclusively on segments of data identified as non-anomalous, with model evaluation conducted by observing reconstruction errors and deviation from learned representations. No separate validation dataset was required in the traditional supervised sense, as the focus of the analysis was on outlier and anomaly detection in time-series sensor data using models that learn from normal conditions. The detection results were cross-referenced with expert knowledge and system behavior to verify the correctness of anomaly localization.

The decision to average the pressure values was based on the operational characteristics of hydraulic systems, where most mechanical degradation processes and failure precursors evolve over extended periods rather than instantaneously. High-frequency fluctuations, while relevant in some cases, can introduce unnecessary noise in anomaly detection models, potentially leading to false positives. By computing one-minute mean values, we retained essential variations indicative of progressive component wear, valve inefficiencies, or pressure instabilities while minimizing the impact of momentary perturbations caused by sensor noise or minor operational transients. Additionally, reducing the data dimensionality improved computational efficiency. Despite this averaging process, the dataset still captured meaningful pressure variations associated with the hydraulic system’s health, ensuring that predictive maintenance insights were not compromised.

RESULTS

To comprehensively assess anomalies in the hydraulic system of the Massey Ferguson 7700 S tractor, seven machine learning models were applied: Isolation Forest, One-Class SVM, KMeans, DBSCAN, Autoencoders, CNNs, and XGBoost. Each of these models independently analyzed the sensor data, identifying deviations from normal operating conditions.

Figure 2 presents a comparative analysis between Moving Average, Moving Median, and the anomalies detected by Isolation Forest in the hydraulic pressure data. The Moving Average smooths out short-term fluctuations by averaging data points within a defined window, providing a clearer trend of pressure variations. Similarly, the Moving Median filters out transient spikes and noise, making it particularly effective in handling abrupt outliers that might distort the overall trend. A significant portion of the anomalies flagged by Isolation Forest aligns with points where the Moving Average and Moving Median exhibit noticeable deviations or sudden shifts, suggesting that the system experienced abnormal fluctuations in hydraulic pressure. However, while the Moving Average and Moving Median indicate general pressure trends, they do not inherently classify anomalies, unlike Isolation Forest, which explicitly isolates unusual patterns.

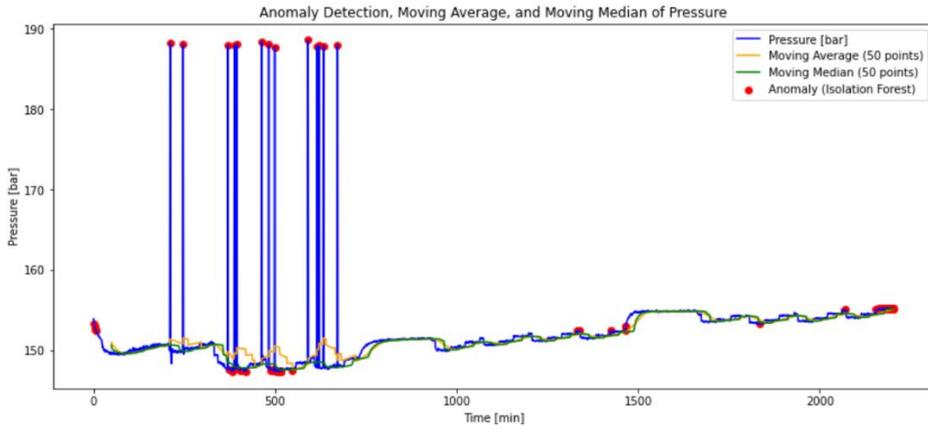

Fig. 2 – Moving Average and Moving Median compared with the anomalies detected by Isolation Forest in the hydraulic pressure data

This comparison highlights that statistical smoothing techniques like Moving Average and Moving Median can aid in visually interpreting pressure fluctuations, but they lack the ability to proactively detect anomalies with the same precision as machine learning-based models. The observed correlation between some of the Isolation Forest anomalies and deviations in the statistical trends reinforces the effectiveness of machine learning models in predictive maintenance, as they can effectively differentiate between normal system variations and potential faults.

The following figures (Figure 3 to 9) present the results of each machine learning model, showcasing their performance in detecting anomalies over time within the hydraulic pressure data. Each plot highlights pressure fluctuations and flagged anomalies, allowing for a comparative analysis of detection performance.

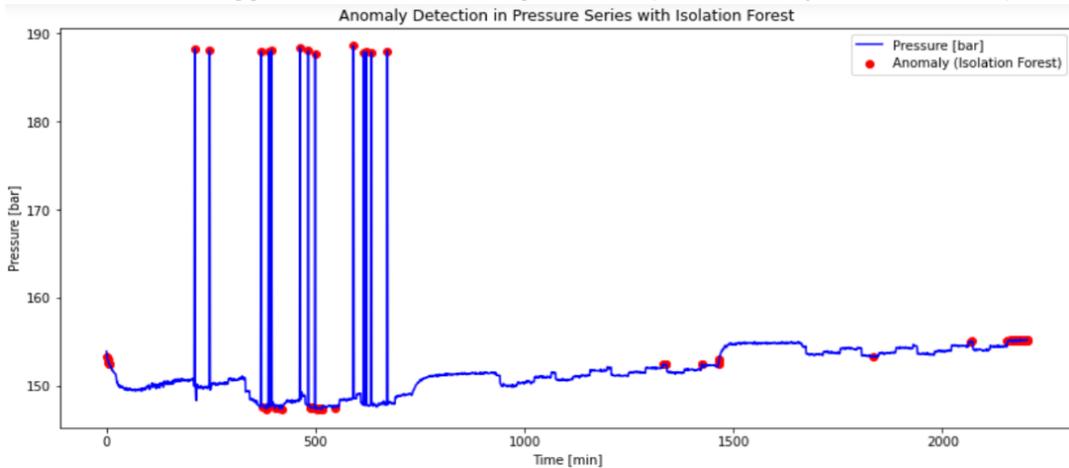

Fig. 3 – Isolation Forest results

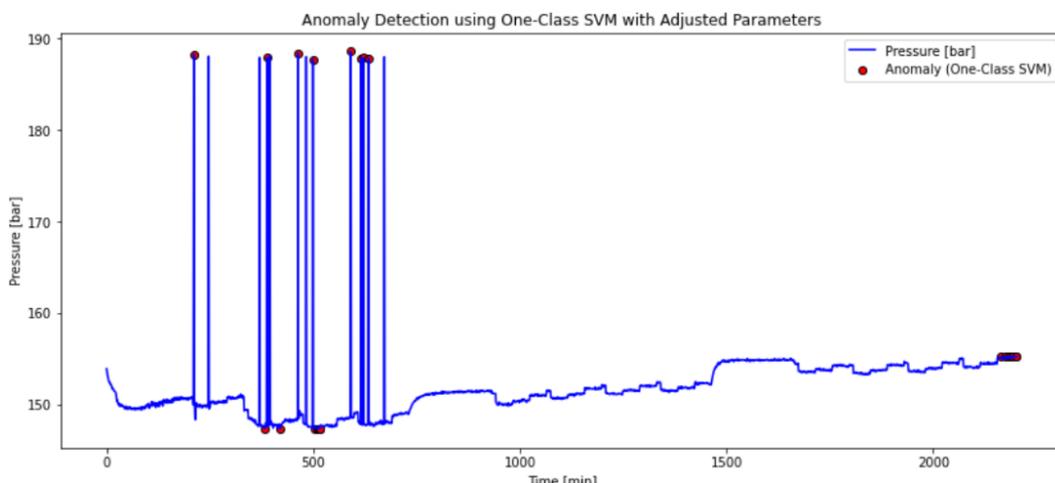

Fig. 4 – One-Class SVM results

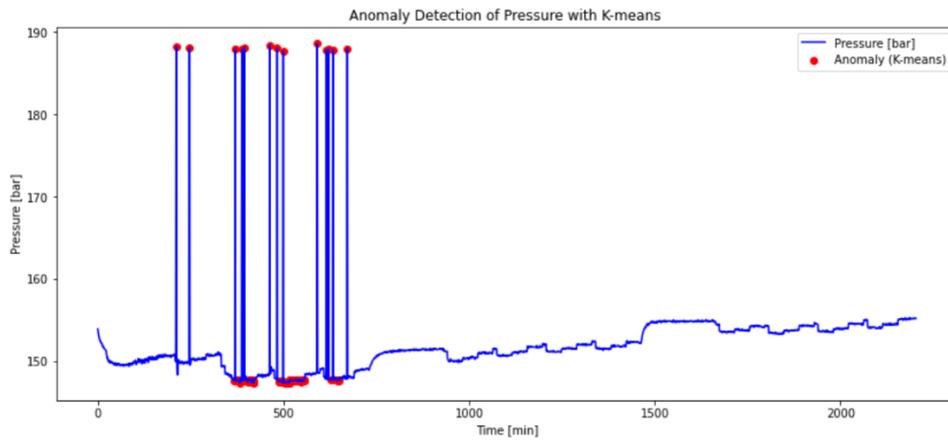

Fig. 5 – KMeans clustering results

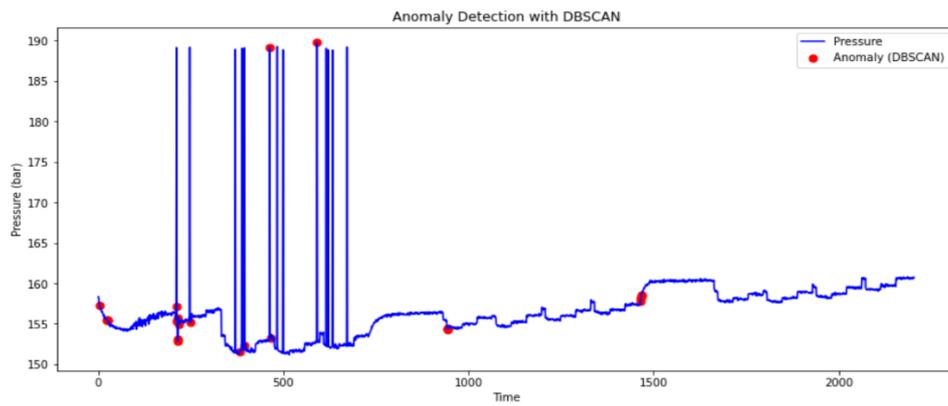

Fig. 6 – DBSCAN results

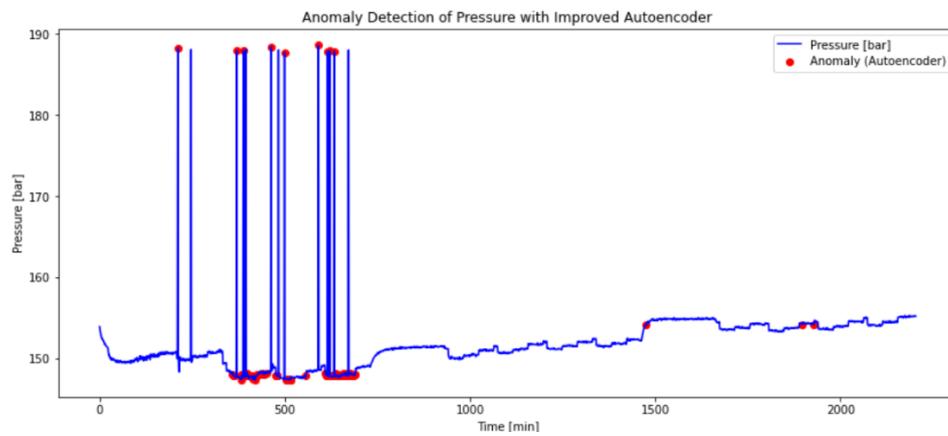

Fig. 7 – Autoencoder results

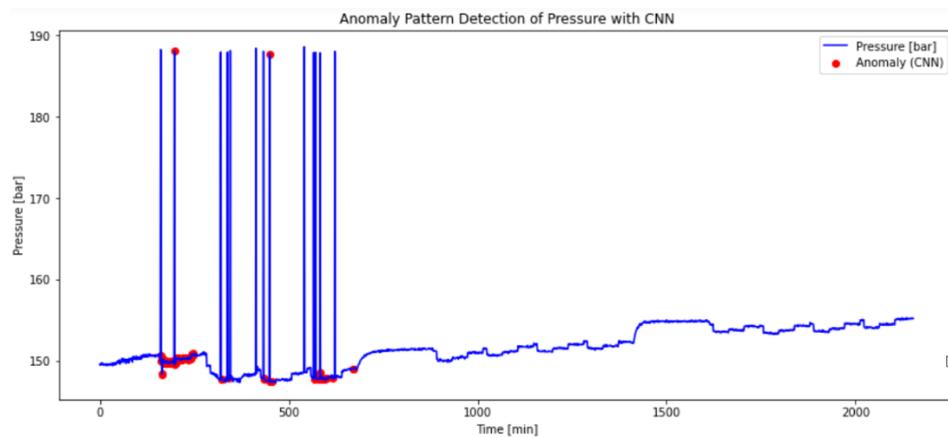

Fig. 8 – CNN results

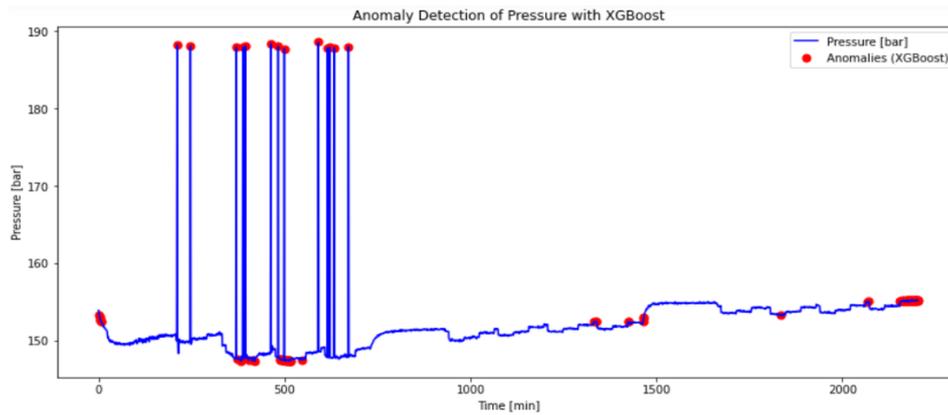

Fig. 9 – XGBoost results

Each figure provides a visual representation of how each algorithm performed in identifying anomalies, offering insights into their sensitivity, reliability, and potential limitations. The final anomaly decision (Table 3 and Figure 10), however, was determined using the "Council of the Wise" method, where an anomaly was validated only if at least four out of the seven models concurred on its presence. This consensus-based approach enhances the robustness of anomaly detection by reducing false positives and ensuring that flagged anomalies are significant deviations from normal operating conditions. By integrating these machine learning models, a robust anomaly detection framework was developed, ensuring greater accuracy in predictive maintenance. The results demonstrate that while some models are more sensitive, others provide a higher precision in detecting real faults.

Table 3 presents critical pressure anomalies identified through a consensus-based approach, where multiple machine learning models independently flagged specific points as outliers. These anomalies, identified under the specified experimental conditions, represent deviations from normal operational behavior in the hydraulic system of the Massey Ferguson 7700 S tractor. "The Council of the Wise" method, proposed in this study, combines the outputs of seven anomaly detection models (Isolation Forest, One-Class SVM, KMeans, DBSCAN, Autoencoders, CNNs, and XGBoost). Instead of relying on a single detection method, the approach ensures robustness by requiring that at least four models agree on an anomaly before it is classified as an outlier. This majority "voting" mechanism helps mitigate false positives and enhances detection accuracy.

Each entry in the table corresponds to a timestamp (Time, in minutes) and a recorded pressure value (Pressure, in bar), which has been identified as anomalous. These anomalies may indicate incipient mechanical degradation, hydraulic system inefficiencies, or potential faults, such as: valve malfunctions, leading to sudden pressure drops or spikes; cavitation or fluid instability, which can create short-term fluctuations in pressure; internal component wear, affecting system performance.

Since pressure variations in hydraulic systems are inherently dynamic, the use of this "voting"-based ensemble method significantly could improve reliability in predictive maintenance. These flagged anomalies warrant further inspection and maintenance intervention before they evolve into critical failures, thereby reducing downtime and improving system longevity.

Table 3

Final anomalies

Time (s)	Pressure (bar)
2164	151.71
2175	151.81
2186	151.81
2203	151.83
211	188.71
247	188.62
370	188.50
378	145.43
381	145.40
483	188.52
499	188.34
500	145.03
502	144.98
504	145.13
505	145.08
507	145.05
509	144.95
515	144.95
516	144.95
591	188.80
621	188.36
633	188.34
672	188.62

While this study focuses primarily on hydraulic pressure as a key indicator for predictive maintenance, additional sensor data – such as vibration, temperature, and load variation – were also collected during the experimental phase. However, to ensure clarity, reproducibility, and focus in this first phase of model evaluation, only pressure-based analysis was presented. These additional sensor signals are currently being processed and will be integrated into a multi-sensor anomaly detection framework in future work. The inclusion of multiple sensor streams is expected to enhance the robustness of the models and allow more nuanced fault detection and diagnostics.

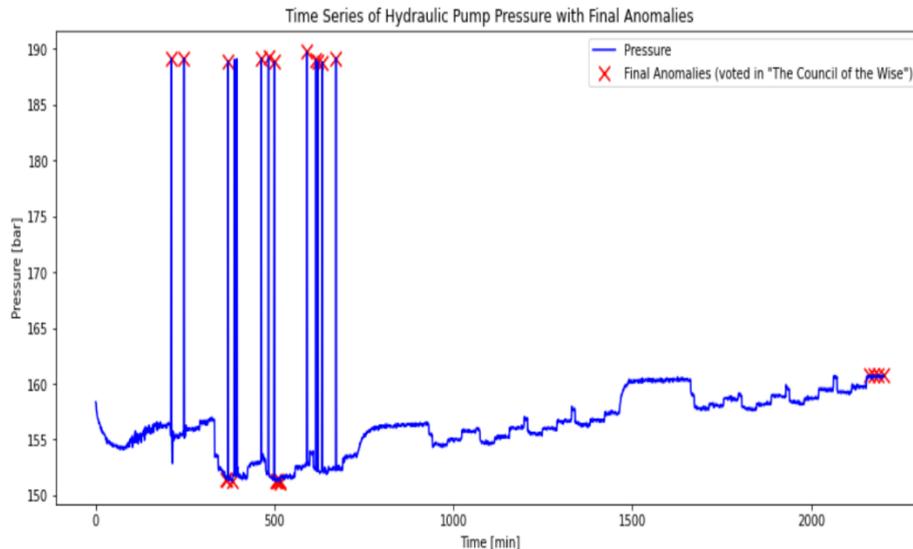

Fig. 10 – Final "voted" anomalies

CONCLUSIONS

The final results, summarized in Table 3, confirm the effectiveness of the "Council of the Wise" approach in identifying critical anomalies in the hydraulic system of the Massey Ferguson 7700 S tractor. The detected anomalies indicate significant deviations from normal operating conditions, with pressure values fluctuating beyond expected ranges. This validates the robustness of the multi-model "voting" framework, which successfully filtered out noise, reduced false positives, and preserved the most relevant anomalies.

The temporal distribution of anomalies reveals two key insights. Clusters of anomalies occurring within short intervals suggest transient mechanical instabilities, possibly due to sudden pressure surges, valve malfunctions, or localized hydraulic inefficiencies. In contrast, isolated anomalies at different time points indicate gradual wear or intermittent system irregularities that may not be detected by traditional threshold-based monitoring. By using seven machine learning models, this ensemble-based approach improves predictive maintenance reliability by incorporating diverse detection capabilities. The ability to reduce false alarms while capturing early indicators of mechanical degradation enhances its practical applicability for agricultural machinery maintenance. While this study highlights the potential of the approach, future research could further refine adaptive sampling techniques to enhance data utilization. Retaining raw high-frequency sensor data where beneficial, alongside dynamic aggregation methods, may improve both detection accuracy and computational efficiency. Additionally, optimizing the data preprocessing pipeline could help achieve a better balance between real-time responsiveness and long-term trend analysis. This study focused primarily on hydraulic pressure as an indicator, but incorporating additional sensor data – temperature fluctuations, vibration analysis, mechanical load variations, and fuel consumption metrics – could provide a more comprehensive failure prediction framework. Expanding monitored parameters would enhance fault detection accuracy, root cause analysis, and predictive capabilities.

It is acknowledged that under typical agricultural operations, torque is not constant and may vary due to factors such as soil resistance, implement load, or maneuvering dynamics. In the current experimental setup, torque was intentionally held approximately constant in order to isolate the effects of internal system behavior on hydraulic pressure, and to validate the ability of machine learning models to detect anomalies under controlled conditions. Future stages of this research will involve data collection under variable torque conditions, representing more realistic operating environments. This will allow the models to learn and adapt to fluctuations caused by load dynamics, and assess the robustness of anomaly detection under more complex field conditions.

Overall, these findings demonstrate that the multi-model “voting” framework is a promising predictive maintenance methodology, offering a reliable, automated, and proactive solution for identifying failures before they escalate into costly breakdowns. Future research should explore its adaptability to different agricultural machinery types and operational conditions, refining the approach through advanced AI techniques and real-time deployment.

Keywords: tea sorting; Dynamic Snake Convolution module; Multi-Head Self-Attention mechanism; YOLOv8

ABSTRACT

In this paper, an improved intelligent sorting algorithm for YOLOv8 white tea fresh leaves is proposed to solve the problems of unclear tea grades and uneven product levels caused by mechanical picking. The algorithm introduces the Dynamic Snake Convolution module (DsConv) for feature enhancement and adds an attention mechanism module, the Multi-Head Self-Attention mechanism (MHSA). Experiments show that the YOLOv8-DsConv-MHSA algorithm has an average accuracy of 96.4% and an average detection rate of 126.6 FPS per second, which is the best algorithm for white tea fresh leaf sorting in the comprehensive comparison. After deploying the proposed YOLOv8-DsConv-MHSA algorithm onto the developed tea sorting machine and conducting experimental comparisons with existing tea sorting machines, it is evident that the screening rate has been enhanced by 10.7%, and the operational efficiency has increased by 20%.

摘要

本文提出了一种改进的 YOLOv8 白茶鲜叶智能分拣算法，以解决机械采摘造成的茶叶等级划分不清和产品层次不齐的问题。该算法引入了动态蛇形卷积模块 (DsConv) 进行特征增强，并且添加了注意力机制模块--多头自我注意力 (MHSA)。实验表明：YOLOv8-DsConv-MHSA 算法的平均准确率为 96.4%，平均检测率为每秒 126.6 FPS，是综合比较中白茶鲜叶分选效果最好的算法。将所提出的 YOLOv8-DsConv-MHSA 算法部署到研发的茶叶分选机上，与现有茶叶分选机进行实验对比可知，筛分率提升了 10.7%，作业效率提升了 20%。

INTRODUCTION

Tea is an important economic crop in China, and the area under tea cultivation is one of the largest in the world, with a total production value of more than 600 billion yuan (\$86.6 billion). Scientific studies have shown that tea has great benefits for human health, and the demand for high-quality tea is gradually increasing (Ruxton *et al.*, 2013). Due to the huge production of tea, the picking method is gradually transitioning from labor to mechanization (Zheng *et al.*, 2011). The cost of tea picking through machinery has been greatly reduced, and the efficiency has been improved, but through the mechanical way of tea picking, the tea leaves picked will be mixed with leaf stems and debris, which need to be further sorted out to realize the tea grading of the high-quality fresh tea leaves (Yuan *et al.*, 2016).

Research on grading of machine-picked tea can improve the quality of machine-picked tea and is an effective way to solve the problem of high-quality tea picking. At present, most of the common tea grading devices are mechanized grading, mainly roller (Wang *et al.*, 2016), vibrating screen (Lv *et al.*, 2022), air flow sorting - mesh belt sieving (Wang *et al.*, 2019). These methods separate the normal tea leaves, broken buds and leaves, leaf stalks and other debris of fresh tea, but the grading effect is still a certain distance from the high-quality fresh tea. Achieving the standard of high-quality tea and improving the quality and economic value of tea is an urgent problem for the tea industry.

In recent years, with the continuous emergence of machine vision and artificial intelligence algorithms, it provides many new possibilities in the field of agricultural production and processing, and of course there are some scholars who have achieved research results in the intelligent sorting of fresh tea leaves.

Chen *et al.* (2010) from Nanjing Institute of Mechanical and Agricultural Research (NIMAR) applied BP neural network to classify fresh leaves of tea and achieved good results by extracting a variety of geometric features and texture parameters.

Liu et al. (2016) used artificial neural network to categorize and analyze the geometrical features and image characteristics of tea leaves, and identified them with various neural networks such as radial basis, BP neural network, Hopfield neural network, and so on. *Gao et al. (2017)* built a 7-layer convolutional neural network recognition model to realize automatic identification and sorting of fresh tea leaves by sharing weights and adjusting the learning rate. *Song et al. (2018)* took Keemun black tea as the research object, constructed an image acquisition system, extracted six absolute shape features and two relative shape features to construct a feature histogram, and identified it with various classification models such as BP neural network, Extreme Learning Machine (ELM), Support Vector Machine (SVM), Least Squares Support Vector Machine (LS-SVM), which provided experimental data and reference methods for the realization of the digital grade appraisal of tea leaves.

Zhu et al. (2019) designed a convolutional neural network (CNN) model with three convolutional layers, two pooling layers and one fully connected layer, the model recognized Huoshanhuangya tea correctly by 95.3% through the training and testing of real-time captured Huoshanhuangya tea images. *Yang et al. (2019)* proposed an improved (You Only Look Once) YOLO-v3 deep convolutional neural network algorithm for recognizing the picking point of young tea buds, which achieves end-to-end target detection and recognition of different poses of high-quality buds, taking into account both efficiency and accuracy. *Chen et al. (2020)* extracted the features of tea by determining the topology of the tea and used SVM to sort and recognize the tea with 94% recognition accuracy. *Gao et al. (2021)* constructed a tea sample dataset and completed the image recognition of tea by building a convolutional neural network, and the correct rate of the trained image recognition model was 96%.

Chen et al. (2021) designed a lightweight convolutional neural network model (MobileNetV2-Tea), and by improving the MobileNetV2 network, the MobileNetV2-Tea model obtained has 99% accuracy in fresh tea image recognition, with a model size of only 28.86M and an average recognition time of 45ms.

Gan et al. (2022) investigated feature classification methods using improved genetic algorithms to screen features with the best combination of three different classifiers with optimal dimensionality, and finally Support Vector Machines (SVMs) achieved 97% recognition accuracy on a 28-dimensional feature set.

Pi et al. (2023) applied YOLO-v5 to the task of intelligent detection of tea buds, and added the structure of bidirectional feature pyramid network (BiFPN) in Neck to optimize the structure of the network, which provided an effective detection model for the sorting of high-quality tea leaves.

Cao et al. (2023) proposed a novel fresh tea sorting system, which uses a tea recognition model based on YOLOv5 deep learning model for fast, high-precision multi-channel sorting of four grades of tea, with a model recognition accuracy of 88.8%. At the same time, the YOLO deep learning algorithm has demonstrated remarkable effectiveness in the detection of numerous crops, covering various types of crops such as cucurbits' fruits (*Zhao et al., 2022*), young apple fruits (*Du et al., 2024*), potato (*Pan et al., 2024*), grapes (*Tao et al., 2024*), wheat (*Bi et al., 2024*).

Although the above research has made some achievements in machine-picked fresh tea leaf sorting, there is still space for improvement in the precision and speed of sorting, especially considering the large-volume and larger-scale fresh tea leaf sorting scenarios. Therefore, this paper takes Anji white tea as the research object, and establishes a database of fresh tea samples containing one bud and one leaf, one bud and two leaves, one bud and three leaves, one bud and four leaves, broken leaves, and single bud in six forms. The state-of-the-art YOLOv8 deep learning algorithm is applied to the fresh tea leaf classification and recognition task to perform deep feature extraction and fresh tea leaf grade classification. On this basis, the Dynamic Snake Convolutional Kernel (DSConv) (*Qi et al., 2023*) is used to carry out the improved replacement of the convolutional kernel in the C2f module, and Multi-Head Self-Attention mechanism (MHSA) (*Vaswani et al., 2017*) is added to enhance the feature representation capability and extract more representative semantic information.

MATERIALS AND METHODS

Dataset collection

The fresh tea leaves dataset collected in this study was obtained from Anji County, Huzhou City, Zhejiang Province. The collected Anji white tea was brought back to the laboratory, video shooting was performed by Canon 6D II camera, and then the pictures of fresh tea leaves were serialized and extracted by frames, obtaining 2537 usable pictures of fresh tea leaves of different grades, which was used to obtain to the tea leaf sorting dataset. The details of the dataset are shown in Fig. 1.

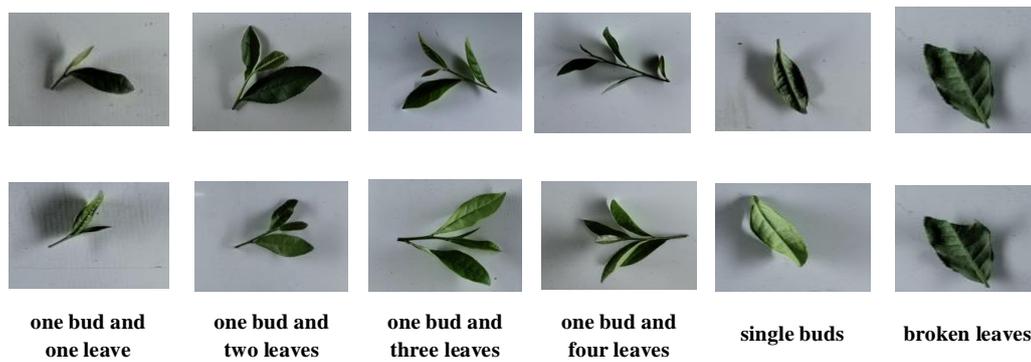

Fig. 1 - Specific types of fresh white tea leaves

Dataset expansion

The amount of data in the realistic fresh white tea leaf sorting scenario is huge. In order to adapt to the realistic demand as well as to meet the training requirements of the YOLOv8 deep learning algorithm, the fresh white tea leaves dataset is expanded to 18 times of the original dataset by rotating the angle, mirroring, sizing, changing the brightness, changing the chromaticity, changing the contrast, changing the sharpness, and so on. Fig. 2 shows a detailed illustration of the expansion of the fresh tea leaf dataset. The expanded dataset was obtained as 45,666 sheets, including 17,388 sheets of one bud and one leaf, 10,674 sheets of one bud and two leaves, 5,742 sheets of one bud and three leaves, 1,836 sheets of one bud and four leaves, 7,236 sheets of single buds, and 2,790 sheets of broken leaves. The fresh white tea leaf dataset of each category was divided into train and test sets in the ratio of 8:2, and the detailed dataset information is shown in Table 1.

Table 1

Number of specific images in the fresh white tea leaf dataset				
category	original	expansion	train	test
one bud and one leaf	966	17388	13910	3478
one bud and two leaves	593	10674	8539	2135
one bud and three leaves	319	5742	4594	1148
one bud and four leaves	102	1836	1469	367
single buds	402	7236	5789	1447
broken leaves	155	2790	2232	558

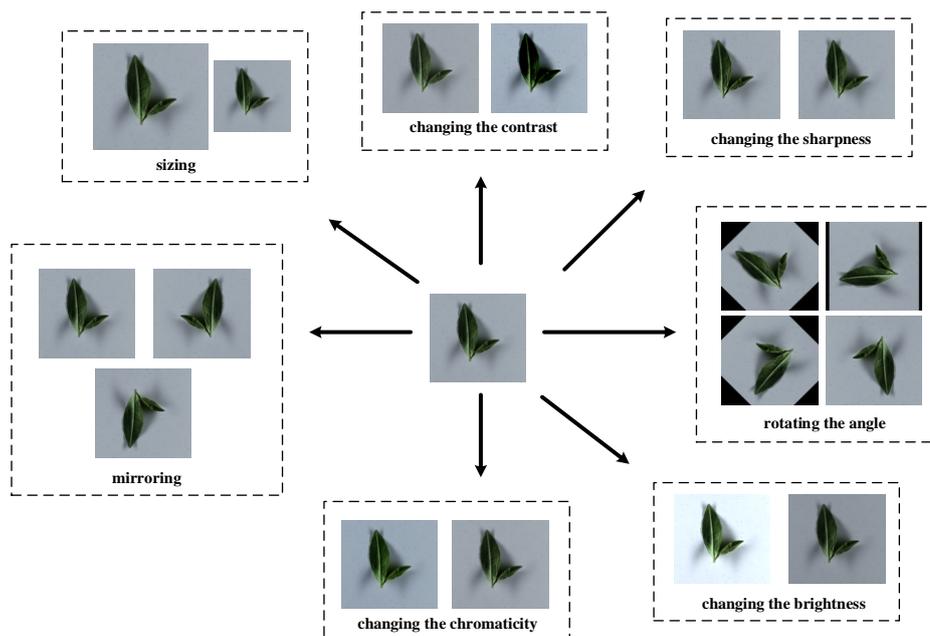

Fig. 2 - Example diagram of fresh white tea leaf dataset expansion

The YOLOv8 deep learning algorithm

The YOLOv8 model is a deep neural network-based target detection algorithm that supports tasks such as image classification, object detection and instance segmentation. Combining the YOLOv8 algorithm with fresh tea leaf sorting can quickly realize end-to-end intelligent grading of fresh tea leaves, which provides a good idea for fresh tea leaf sorting. The specific algorithm implementation process is as follows.

Firstly, from the captured video taken, fresh white tea leaf images are extracted by frame, and the fresh white tea leaf dataset is constructed according to multiple data expansion methods. Then the YOLOv8 deep learning network model is constructed. The recognition ability of the pre-trained YOLOv8 network model is mainly focused on the categories in the ImageNet dataset (the ImageNet dataset covers more than 1,000 image categories that are common in life), so the parameters of the YOLOv8 deep learning network model are dynamically adjusted according to the fresh tea leaves dataset. The model internally undergoes deep feature extraction and sorting, and is finally able to complete sorting of fresh tea leaves.

As shown in Fig.3, the YOLOv8 model applied to the intelligent sorting of fresh tea leaves mainly consists of a backbone network (Backbone) and a predictive output network (Head). The backbone network mainly uses the convolutional kernel to extract multi-scale features from the fresh white tea leaf contour, and operates the fresh tea leaf image layer by layer with multiple Conv, C2f and SPPT modules, so that the proposed features can be more representative. The predicted output network computes probability scores based on the extracted deep feature representations for intelligent sorting of different categories of fresh white tea leaves.

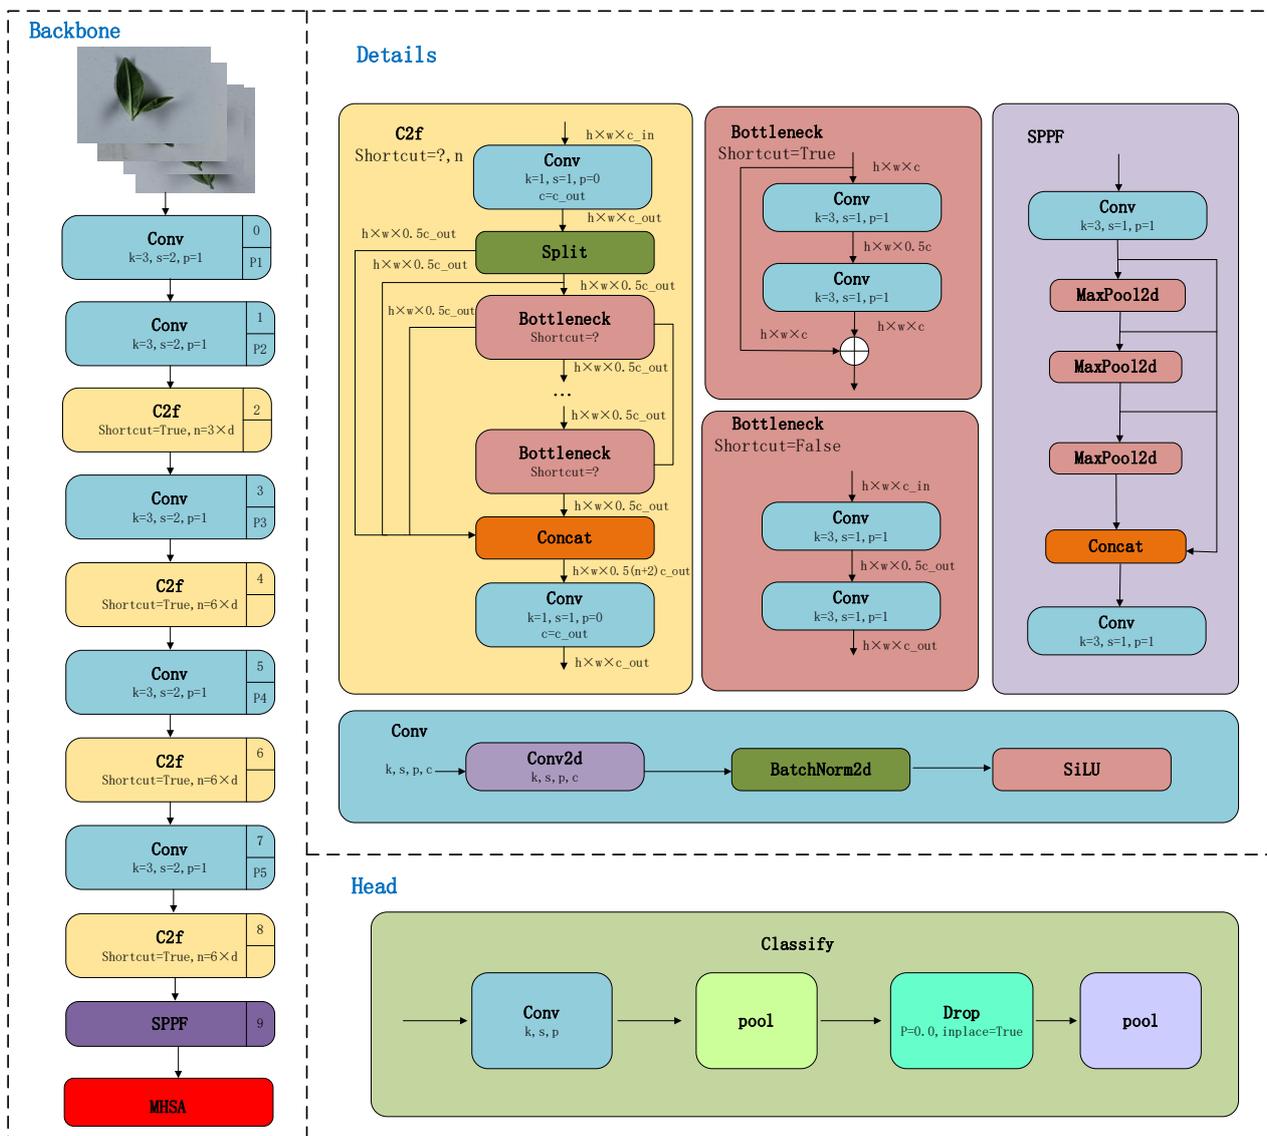

Fig. 3 - Flowchart of YOLOv8 sorting of fresh white tea leaves

Dynamic Snake Convolution Module (DSCConv)

The convolution Conv module in the YOLOv8 model performs convolutional computation for the entire region of the input fresh white tea leaf image, in order to be able to focus the convolution kernel on the target features of interest and reduce feature interference in the surrounding region, it is proposed that the dynamic snake convolution kernel (DSCConv) be introduced to the fresh white tea leaf feature extraction. The feature extraction process of the Dynamic Serpentine Convolution Kernel (DSCConv) is shown in Fig. 4. The next convolution position is calculated by extrapolating from the previous convolution position, starting from the center of the whole image $K_i=(x_i,y_i)$. By iterating continuously, it ensures that the extracted features are concentrated in the region where the fresh tea leaves are located, reduces the bias of the convolutional computation, and improves the accurate representation of the extracted features.

$$K_{i\pm c} = \begin{cases} (x_{i+c}, y_{i+c}) = (x_i + c, y_i + \sum_i^{i+c} \Delta y) \\ (x_{i-c}, y_{i-c}) = (x_i - c, y_i + \sum_{i-c}^i \Delta y) \end{cases} \quad (1)$$

The computational operation of convolution kernel actually starts from the center point and makes convolution computation in x-axis and y-axis directions sequentially, in x-axis direction, as shown in Equation (1), $K_{i\pm c}$ denotes any convolution computational position in the grid, $c=\{0,1,2,3,4\}$ denotes the distance from the center point, and the bias $\Delta=\{\delta|\delta\in[-1,1]\}$ is the offset of the next convolution position K_{i+1} relative to the previous one K_i . Since the convolution operation is a non-stop iterative process, \sum needs to be added outside the bias to perform a linear accumulation.

$$K_{j\pm c} = \begin{cases} (x_{j+c}, y_{j+c}) = (x_j + \sum_j^{j+c} \Delta y, y_j + c) \\ (x_{j-c}, y_{j-c}) = (x_j + \sum_{j-c}^j \Delta y, y_j - c) \end{cases} \quad (2)$$

Equation (2) represents the y-axis direction to do the convolutional computation operation.

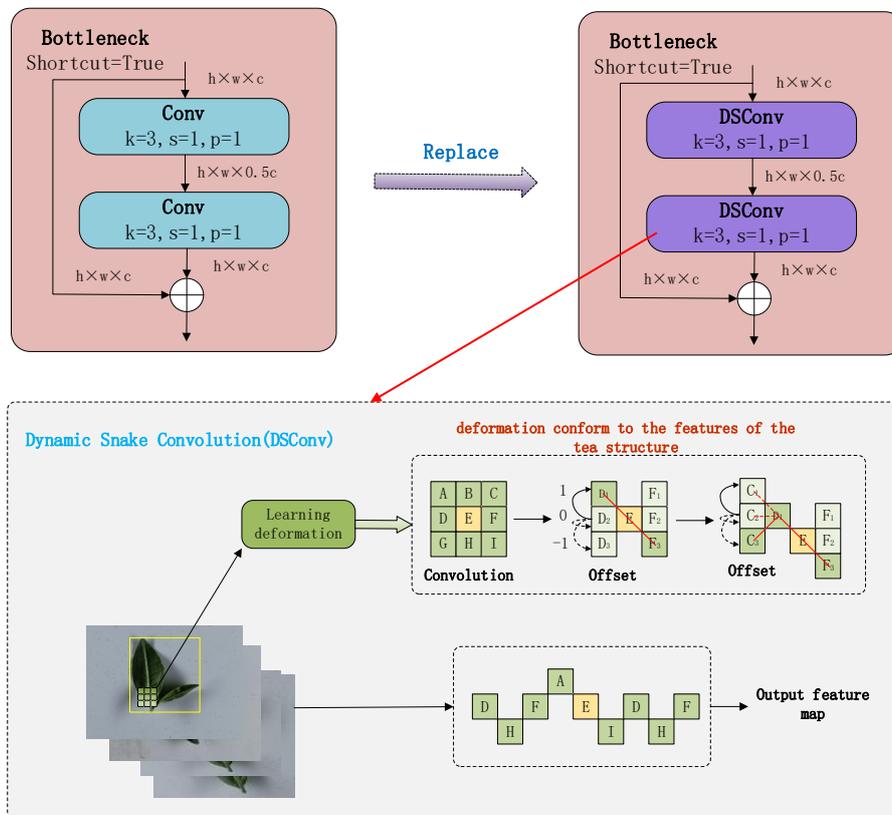

Fig. 4 - Flowchart of dynamic snake convolution kernel feature extraction

The Multi-Head Self-Attention mechanism (MHSA)

In the intelligent sorting of fresh tea leaves, the completeness of the extracted feature information is directly related to the subsequent performance of fresh tea leaves sorting and identification. To further enhance the feature representation capability, the multi-head self-attention mechanism (MHSA) is added to the YOLOv8 network model as a way to ensure the completeness and accuracy of the proposed features. As shown in Fig. 5, in the self-attention layer, all the keys K , values V , and query operations Q come from the feature parameters of the last fresh tea leaves, and the mapping calculation can make each position in the self-attention layer pay attention to all the positions in the previous layer, which increases the completeness of feature extraction. Each self-attention mechanism focuses on different subspace information of different positions, and the results of multiple attention mechanism calculations are fused and then linearly mapped to obtain the final feature representation.

$$A(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right) V \tag{3}$$

where A denotes the Attention computation operation, d_k denotes the vector dimension computed by the input key and the query. The keys K , values V , and query operations Q computed from the previous layer are matrices.

$$MH(Q, K, V) = \text{Concat}(h_1, \dots, h_i) w^o \tag{4}$$

$$h_i = A(W_i^Q, KW_i^K, VW_i^V) \tag{5}$$

where $W_i^Q \in R^{d_{model} \times d_k}$, $W_i^K \in R^{d_{model} \times d_k}$, $W_i^V \in R^{d_{model} \times d_v}$, $W_i^O \in R^{hd_v \times d_{model}}$ are composed of parameter matrices of the corresponding dimensions. d_{model} denotes the unity parameter dimensions of the model, h denotes the number of attention heads, which is set to $h=4$ in this model. Multiple self-attention mechanisms are spliced and fused, where MH denotes multi-head self-attention mechanism and h_i denotes one of the $head_i$ attention mechanisms.

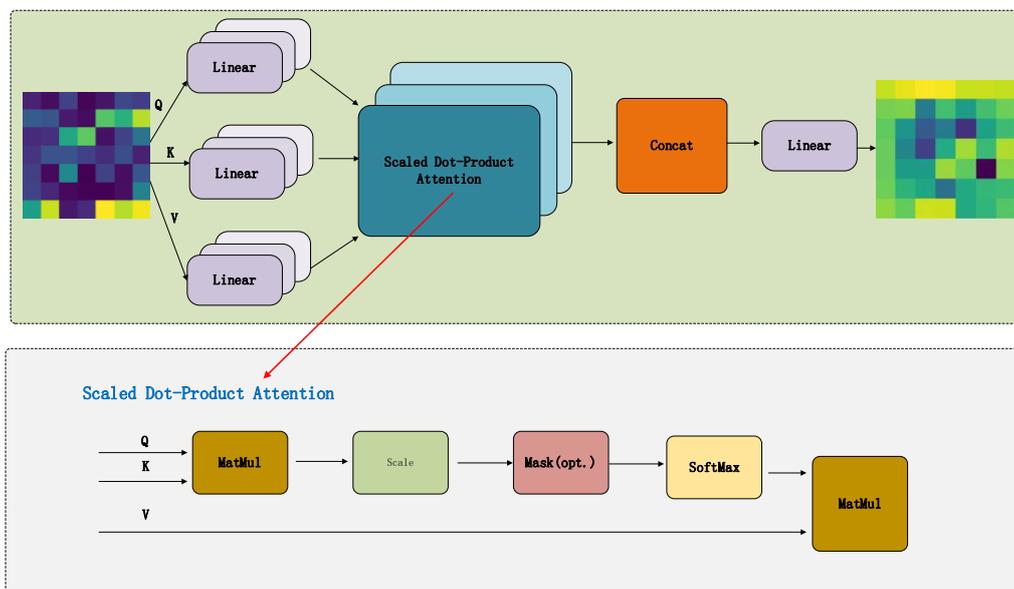

Fig. 5 - Flowchart of feature extraction for Multi-head Self-Attention Mechanism

Improving the network structure parameters of YOLOv8

The Dynamic Snake Convolution Module (DSConv) and Multi-head Self-Attention Mechanism (MHSA) are added into the YOLOv8 deep learning algorithm model to obtain the improved YOLOv8 model. In order to more clearly visualize the specific parameters of the model, the parameters of the improved YOLOv8 network structure are listed in Table 2.

Table 2

Network structure parameters of the improved YOLOv8						
Layers	From	n	Params	Module	Arguments	
0	-1	1	464	Conv	[3, 16, 3, 2]	
1	-1	1	4672	Conv	[16, 32, 3, 2]

Experimental equipment and parameterization

The specific parameters of the computer used for the experimental training in this study are: the operating system is Windows 11, the CPU is i9, the GPU is NVIDIA RTX A4000, the deep learning modeling framework used is PyTorch 1.12.0, and the programming version is Python 3.9, and the specific parameter settings at the time of model training are shown in Table 3.

Table 3

Parameter settings for model training	
Parameters	Value
Image-size	224
Epochs	60
Batch	30
Momentum	0.937
Workers	8
Optimizer	Auto
Lr	0.01
Loss	VFL Loss

The improved YOLOv8 deep learning algorithm model built in this study is a classification problem, and the accuracy rate is mainly utilized as an evaluation metric when performing model evaluation (Li *et al.*, 2023).

$$ACC = \frac{TP+TN}{TP+TN+FP+FN} \quad (6)$$

$$mACC = \frac{\sum_{i=1}^N ACC_i}{N} \quad (7)$$

where ACC denotes accuracy, TP denotes the number of positive samples correctly identified, TN denotes the number of negative samples correctly identified, FP denotes the number of negative samples misreported, FN denotes the number of positive samples omitted, ACC_i denotes the accuracy of classification of the i th class of fresh white tea leaves, N denotes the type of fresh white tea sorting, which was six in this study, and $mACC$ denotes the mean accuracy.

RESULTS

Comparison of the impact of improved modules

In this study, the Dynamic Snake Convolution module (DSCConv) was replaced and the Multi-head Self-Attention Mechanism (MHSA) module was added in order to further improve the sorting of fresh white tea leaves. In order to validate the usefulness of the improvements that had been made, the test images were randomly selected from the database of fresh white tea leaves and experiments were conducted, and the extracted comparative plots are shown in Fig. 6.

As can be seen in Fig. 6, after replacing the dynamic snake convolution module in the C2f module, the features extracted from each channel are clearer and crisper. Taking the 10th channel as an example (as shown in the red box in Fig. 6), after the dynamic serpentine convolution module, the extracted features more closely match the contour map of fresh white tea leaves. This is due to the fact that the dynamic serpentine convolution kernel (DSCConv) is able to accurately extract adaptive features based on the overall external shape and structure of the tea leaves, focusing on the shape of the white tea fresh leaves themselves, which effectively improves the accuracy of the features.

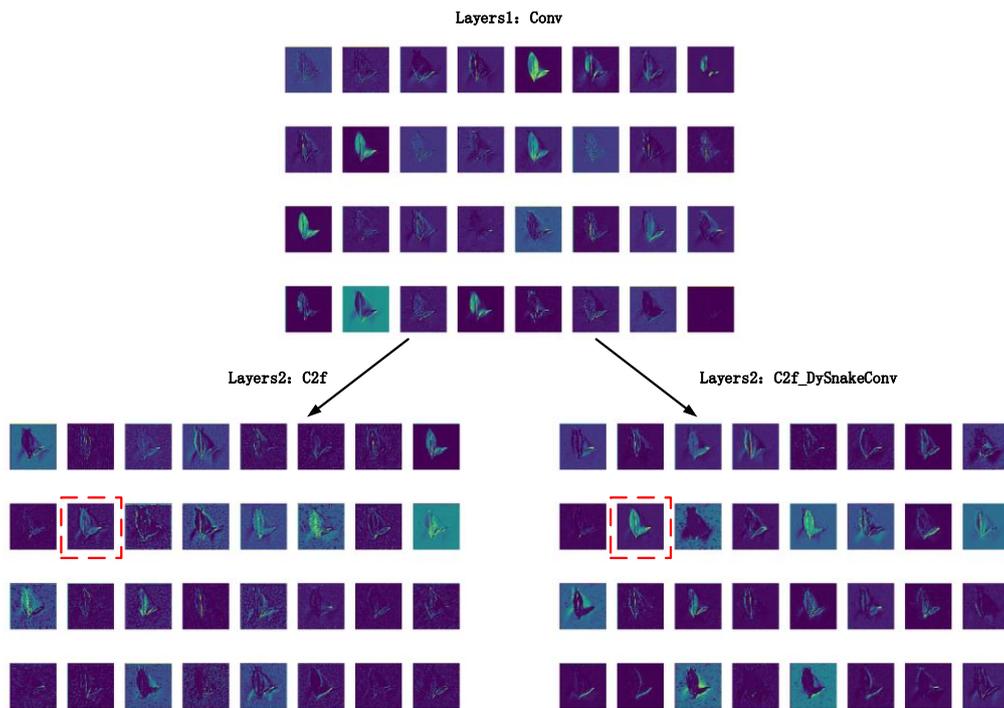

Fig. 6 - Comparison of features before and after replacing the dynamic snake convolution

In the YOLOv8 deep learning algorithm model, with the depth of the network layers, the deep network will focus more on abstract features, and for the Multi-head Self-Attention Mechanism (MHSA), it is added after the SPPF layer. As it can be seen from Fig.7, the multi-head self-attention mechanism (MHSA) focuses more on the detail region of fresh white tea leaves, which can effectively capture the robust features in the image of fresh tea leaves and realize the accuracy and completeness of the feature extraction, at the same time, it helps to further improve the recognition rate of the intelligent sorting of fresh white tea leaves.

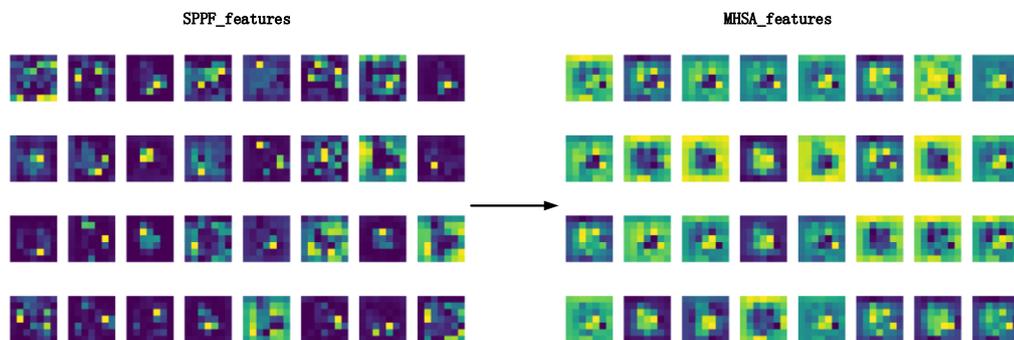

Fig. 7 - Comparison of features before and after the addition of the Multi-head Self-Attention Mechanism (MHSA) module

Comparison of Sorting Performance between Different Models

In this study, in order to verify the effectiveness of the proposed algorithms, YOLOv5, YOLOv7, YOLOv8, YOLOv8-DsConv, YOLOv8-MHSA and our algorithm (YOLOv8-DsConv-MHSA) are used in this study for comparative verification. In white tea fresh leaf sorting, the algorithm speed and sorting accuracy are two indicators that need to be considered in practical applications, so these two indicators are used for comparative analysis.

Table 4

Sorting effect of fresh white tea leaves with different algorithms

Model	ACC						mACC	FPS
	OL	TwL	ThL	FL	SiB	BrL		
YOLOv5	93.6	92.9	90.5	89.9	95.5	96.2	92.9	138.9
YOLOv7	94.1	93.4	90.9	90.6	95.2	96.5	93.4	147.1

Model	ACC						mACC	FPS
	OL	TwL	ThL	FL	SiB	BrL		
YOLOv8	95.2	94.6	93.5	91.8	96.2	97.1	94.6	161.3
YOLOv8-DsConv	96.5	95.7	94.1	93.2	97.9	97.5	95.7	137.0
YOLOv8-MHSA	96.3	96.1	94.9	93.6	97.3	97.4	95.9	140.9
Ours	97.4	96.4	94.9	94.8	97.0	97.8	96.4	126.6

As can be seen from Table 4, under the same experimental conditions, the YOLOv8-DsConv-MHSA algorithm proposed in this study is far ahead of the other algorithms in terms of accuracy, with an average of 96.4%, followed by the YOLOv8-MHSA algorithm with an average of 95.9%, the YOLOv8 algorithm, with an average of 94.6%, and the YOLOv8-DsConv algorithm with an average accuracy of 95.7%. From the processing speed of each model for white tea fresh leaves, YOLOv8 algorithm has the best recognition frame rate of 161.3 FPS, while YOLOv8-DsConv-MHSA algorithm has a certain degree of decline in recognition speed due to the increase in the parameters of the model, which is 126.6 FPS. Combining the results of the above data measured results, it can be seen that the proposed YOLOv8-DsConv-MHSA algorithm has the highest accuracy and the recognition speed of each fresh leaf can meet the requirements of practical applications. Among the various types of white tea fresh leaves, the sorting recognition effect of broken leaves is the best, up to 97.8%. The sorting effect of one bud and one leaf, one bud and two leaves, single bud is also more satisfactory, while the sorting effect of one bud and three leaves, one bud and four leaves is obviously poorer, which indicates that the task of recognizing the complex structure still has some difficulty.

Practical Application

Through continuous research and testing, our research team has successfully deployed the proposed algorithm model onto a developed tea sorting machine and conducted application debugging. The components of this tea sorting machine include sensors, a control cabinet, machine vision cameras, a server, robotic arms, and more. The implemented algorithm model is the proposed YOLOv8-DsConv-MHSA. First, the trained model is deployed on the server. When the tea leaves pass through the sensor on the conveyor belt, the sensor sends a signal to the control cabinet. The control cabinet then triggers the machine vision camera to capture an image. The captured image is transmitted to the server, where the fresh tea leaf image is input into the model to complete the sorting and recognition task. Subsequently, the robotic arm controls a vacuum suction cup to pick up the fresh tea leaves that do not meet the requirements and moves them to a parallel secondary conveyor belt for placement, thereby achieving automatic sorting of the fresh tea leaves.

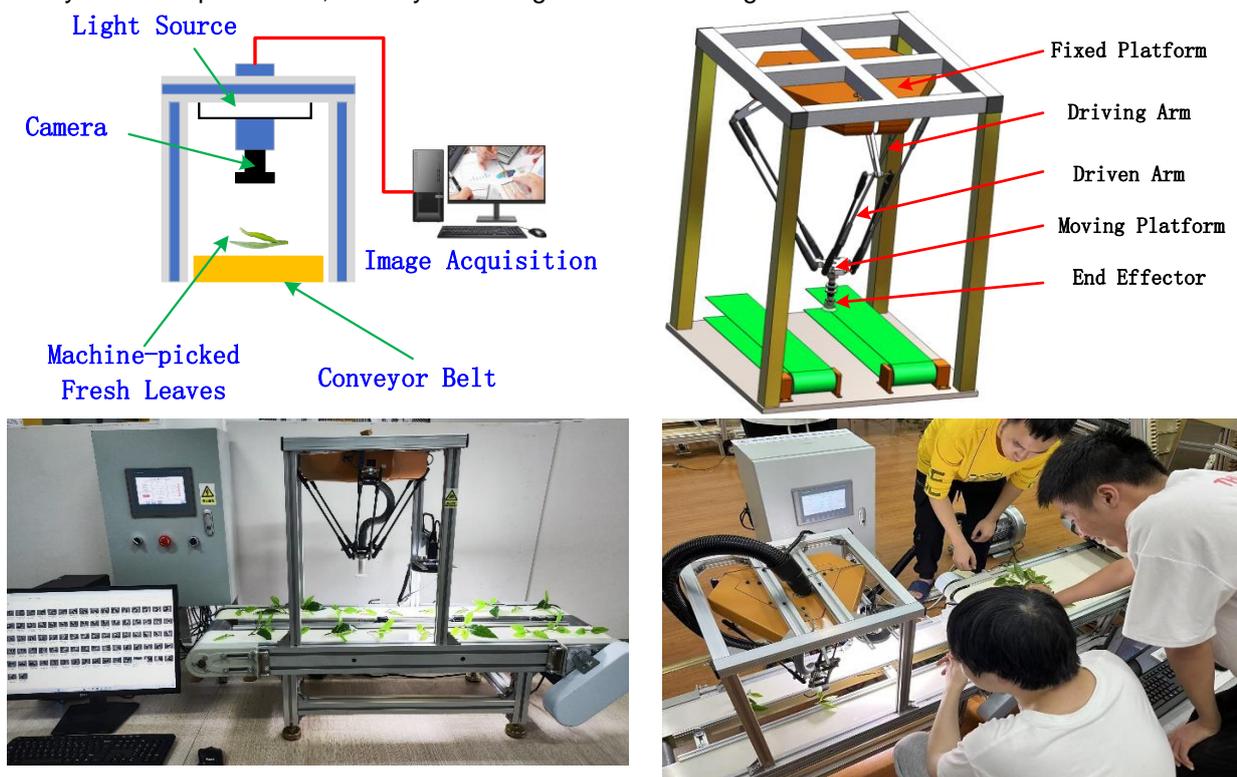

Fig. 8 - Research and Development Process of the Tea Fresh Leaf Sorting Machine

After the successful development of our tea sorting machine, a comparative analysis between the tea sorting machine developed by our team and existing tea sorting machines available on the market was conducted. Three tea sorting machines were identified for comparison: the YJY-2 developed by the Tea Research Institute of the Chinese Academy of Agricultural Sciences, the DJFJ developed by Zhejiang Sci-Tech University, and the 6CXF-70 developed by Zhejiang Chunjiang Tea Machinery Co., Ltd. Our analysis primarily focused on two key metrics: screening rate and operational efficiency. The screening rate is defined as the percentage of the weight of sorted tea leaves relative to the total weight of tea leaves, while operational efficiency refers to the amount of tea that can be processed per unit of time. As shown in Table 5, compared to the most advanced tea sorting machines currently available, our equipment achieved a 10.7% improvement in screening rate and a 20% increase in operational efficiency.

Table 5

Performance Comparison Analysis of Different Tea Sorting Machines				
Sorting Machine	YJY-2	DJFJ	6CXF-70	Ours
Sorting Grade	4	4	5	6
Screening Rate	62.4%	81.6%	76.5%	92.3%
Operational Efficiency	78kg/h	115kg/h	150kg/h	180kg/h

CONCLUSIONS

This paper investigates the problems encountered in sorting fresh white tea leaves and proposes an intelligent sorting algorithm for them using an improved YOLOv8. The algorithm introduces the DSConv and MHSA to enhance the accuracy of feature characterization and enable intelligent sorting of the established fresh white tea leaves dataset. The main results of this study are presented below:

1) A complete dataset of fresh white tea leaves and an improved YOLOv8 deep learning algorithm model were established. The accuracies for one bud and one leaf, one bud and two leaves, one bud and three leaves, one bud and four leaves, single bud, and broken leaves were 97.4%, 96.4%, 94.9%, 94.8%, 97.0%, and 97.8%, respectively, resulting in an average accuracy of 96.4%.

2) The comparison experiments demonstrate that the improved YOLOv8 deep learning model performs much better in intelligent sorting, with an improved average accuracy of 0.7% over YOLOv8-DsConv, 0.5% over YOLOv8-MHSA, 1.8% over YOLOv8, and 3.5% over YOLOv5;

3) In the improved YOLOv8 deep learning algorithm model, the DSConv is able to extract adaptive feature representations based on the shape structure of fresh white tea leaves, and the proposed features are concentrated in the region where the fresh white tea leaves are located, which reduces the bias of the convolutional computation, and improves the accurate representation of the extracted features;

4) In the improved YOLOv8 deep learning algorithm model, each self-attention mechanism in the MHSA focuses on different subspace information at different locations, and fuses the computation results of multiple attention mechanisms to make the captured image features of the fresh white tea leaves more robust, and to realize the accuracy and completeness of feature extraction.

5) The proposed YOLOv8-DsConv-MHSA was deployed on the server for the development of the tea sorting machine. Comparative analysis with existing tea sorting machines revealed that the screening rate improved by 10.7%, and the operational efficiency increased by 20%.

The experimental results show that the algorithm proposed in this study has broad application prospects in the intelligent sorting and recognition of tea leaves, providing a good solution for the subsequent sorting of mechanically harvested fresh white tea leaves. Additionally, the proposed YOLOv8-DsConv-MHSA was deployed on the server and the practical application development of the tea sorting machine was carried out. Of course, there are some limiting factors in the intelligent sorting of fresh tea leaves, such as mutual shading between tea leaves and the influence of light intensity. These issues need to be addressed in subsequent research, and the performance of the tea sorting machine should be further optimized.

DOI: <https://doi.org/10.35633/inmateh-75-81>**Keywords:** YOLOv5; Apple; Attention mechanism; Apple fruit recognition**ABSTRACT**

This study addressed the practical problems of complex picking environments, difficult image recognition, and low picking efficiency in apple harvesting, combined with China's agricultural requirements and picking systems. An improved apple fruit recognition method based on attention mechanisms and YOLOv5 was proposed. A dataset was created by collecting 3,600 apple images under front-light, side-light, and backlight conditions at different coloring stages in natural environments. The SENet and CBAM attention mechanisms were used to enhance YOLOv5's feature extraction network, and the model was trained to improve detection accuracy. Experimental verification showed that the YOLOv5x model embedded with the CBAM module achieved the highest mean average precision (mAP) of 98.3%. The CBAM module outperformed the SENet module. Actual tests of the apple-picking robot's vision system prototype showed that when the IOU threshold was set at 0.5 and 0.3, the average detection accuracy was over 85% in both cases. The results demonstrated that the improved YOLOv5 model exhibited robustness to light intensity variations. This approach provides a technical reference for developing apple picking robot vision systems.

摘要

针对苹果采摘存在采摘环境复杂、图像准确识别困难、采摘效率低下等实际问题，结合我国苹果采摘农艺要求及采摘体系。本文提出了一种基于注意机制和改进的 YOLOv5 的苹果果实识别方法。该方法通过收集 3600 张自然环境中顺光、侧光和背光的不同着色天数的苹果图像，创建了一个数据集，注意机制 SENet 和 CBAM 用于改进 YOLOv5 的特征提取网络，并对模型进行训练以提高模型的检测精度。经过实验验证，嵌入 CBAM 模块的 YOLOv5x 的平均检测精度最高，mAP 为：98.3%。CBAM 模块的性能优于 SENet 模块。结果表明：改进的 YOLOv5 模型对光强变化具有良好的鲁棒性。通过采摘机器人视觉识别系统样机的实际试验验证，当 IOU 阈值设为 0.5 和 0.3 时，该系统样机平均检测精度均在 85% 以上。改进后的 YOLOv5 模型可为苹果采摘机器人视觉系统的开发提供参考。

INTRODUCTION

China is the largest producer and consumer of apples, with a large cultivation area and high yield. However, the mechanization level of apple harvesting is relatively low (Lu et al., 2020). Apple-picking robots can improve harvesting efficiency and save costs, but the complex working environment and various uncertain factors make apple picking challenging. Rapid detection of fruits in complex natural environments is the primary task in research on apple-picking robots (Wang et al., 2021). Only when the visual system recognizes the target can the robotic arm and end effector be driven to complete fruit picking (Tian et al., 2020; Liu et al., 2019; Zhao et al., 2021). The accuracy of fruit recognition directly affects the efficiency and quality of robot harvesting.

Traditional target recognition methods for apple-picking robots mainly rely on the color and grayscale threshold of the fruits (Felzenszwalb et al., 2010). They require manual extraction of target features and are greatly influenced by natural light intensity, as well as branch and leaf occlusion. The robustness of the algorithm is poor. Target detection based on machine learning requires predetermined parameters, and the parameter size significantly affects the classification results.

Currently, deep learning-based detection algorithms are divided into single-stage algorithms and two-stage algorithms based on the different ways of predicting target categories and positions (Luo et al., 2020).

Since 2014, *Girshick et al., (2016)*, have successively proposed a series of two-stage algorithms, such as R-CNN, Fast R-CNN, Faster R-CNN, and Mask R-CNN.

The calculation area generation in the two-stage detection algorithm improves the detection accuracy, but increases the calculation amount, training difficulty and parameter quantity of the algorithm, reduces the prediction speed of the algorithm, and is difficult to meet the real-time detection requirements. To solve the problem of algorithm efficiency, *Redmon J et al., (2016)*, have successively proposed single-stage object detection algorithms represented by the YOLO series since 2016. Single-stage algorithms regress the position and class of bounding boxes in a single output layer, resulting in a significant improvement in detection speed compared to two-stage algorithms. Among them, the YOLOv5 algorithm is currently a more advanced object detection algorithm, surpassing YOLOv4 in both detection accuracy and speed. Therefore, this model has a significant advantage in hardware deployment and is suitable for rapid detection of apples in natural environments.

In this study, an improved YOLOv5 object detection method based on attention mechanisms is proposed to optimize the apple fruit detection process. The goal is to overcome errors and influences caused by environmental factors and enhance the detection performance of the visual system for fruits.

MATERIALS AND METHODS

Data acquisition and pre-processing

This study focuses on the Red Fuji apple in Yantai. The data collection was conducted at the Le Feng apple plantation in Linqu, Weifang. Figure 1 shows images of apples at different stages of maturity. Collecting images of apples at different coloring stages facilitates testing the impact of different maturity stages on the detection performance of the network model.

Fig. 1 – Apple images collected at different coloring periods

1. Coloring for 5 days; 2. Coloring for 10 days; 3. Coloring for 15 days

Fig. 2 – Images of an apple under different lighting angles

1. Front-lighting; 2. Side-lighting; 3. Backlighting

To ensure the diversity of collected image samples, apple images were captured under different weather conditions (sunny and cloudy) at the time range of 8:00-17:00. The captured images were taken in three lighting modes: front-light, side-light, and backlight. Figure 2 shows apple images captured under different lighting angles.

Data pre-processing

The labelling software was used to annotate the apple fruits in the collected 3600 images. Figure 3 shows the distribution of sample attributes in the dataset.

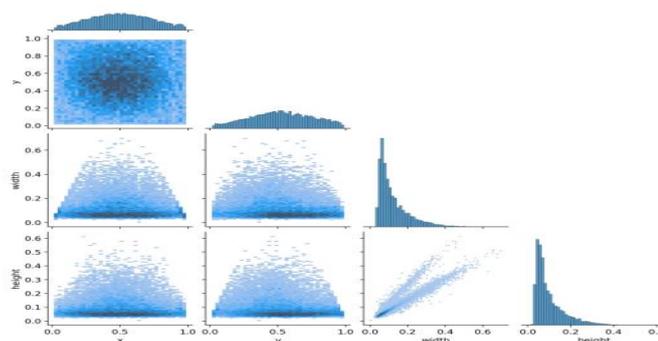

Fig. 3 – Distribution of sample attributes in the dataset

To ensure the randomness and rationality of dataset partition, manual partitioning was conducted on the collected apple images in this study. A total of 300 images were randomly selected from the original dataset to create Test Set 1, which consists of 100 images taken in front-lighting conditions, side-lighting conditions, and backlighting conditions, respectively. Additionally, Test Set 2 was created by randomly selecting 100 images of apples that were 5 days, 10 days, and 15 days old, respectively, while the remaining images were used as training data for the model. The number of samples in each dataset and the corresponding number of target boxes are shown in Table 1.

Table 1

Factors and level of orthogonal test						
Datasheet	Training sets		Test set 1		Test set 2	
	Number of pictures	Number of target boxes	Number of pictures	Number of target boxes	Number of pictures	Number of target boxes
Coloring for 5 days	1000	12038	100	1314	100	1328
Coloring for 10 days	1000	13117	100	1248	100	1196
Coloring for 15 days	1000	12864	100	1293	100	1159
Grand total	3000	38019	300	3855	300	3683

The 3600 original apple images collected in this study are not sufficient to cover all the factors such as lighting intensity, weather, noise, and clarity in natural environments. Therefore, data augmentation is performed on the original images to enhance the generalization ability of the object detection model and prevent overfitting. This study mainly adds random brightness, random contrast, random Gaussian noise, random saturation, and random flipping to the collected apple images to simulate various states of fruit trees in natural environments as much as possible. The augmented apple images are five times more than the original data. Figure 4 shows some examples of the apple images after augmentation.

Construct an apple recognition model based on improved YOLOv5

The YOLOv5 algorithm added modules such as image compression and Mosaic data augmentation at its input end (Yonghui et al., 2022). Mosaic utilized random scaling, cropping, and arrangement of four images to generate a new image, achieving data augmentation (Chen et al., 2022).

There were four different versions of the YOLOv5 algorithm: YOLOv5x, YOLOv5l, YOLOv5m, and YOLOv5s. The structural principles of the YOLOv5 versions were similar, with differences only in network width and depth (Liu et al., 2020, Yongpeng et al., 2024). The network structure of the YOLOv5 algorithm mainly consisted of modules such as Focus, CBL, CSP_1, CSP_2, and SPP, as shown in Figure 5.

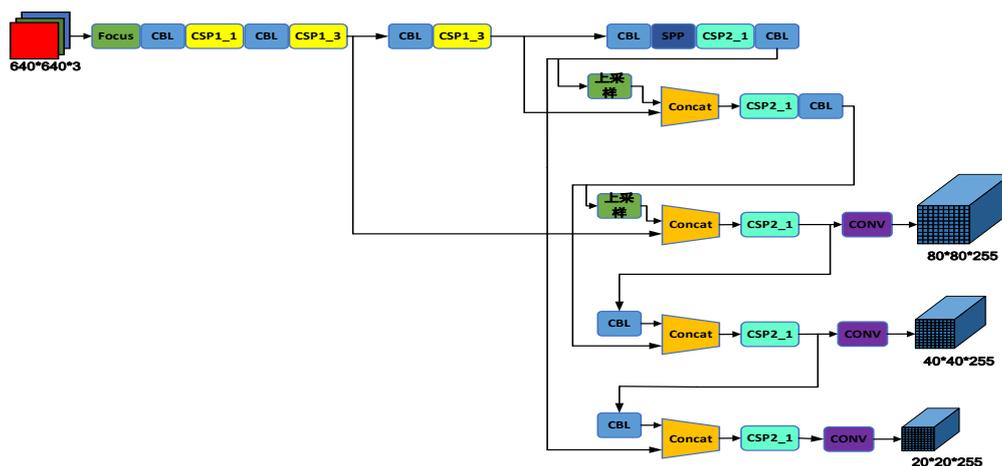

Fig. 5 – The network structure of YOLOv5

The CBL module consists of Convolutional layers, Batch Normalization (BN) layers, and Leaky ReLU (LR) layers. The CBL module plays a role in downsampling and helps reduce information loss in the downsampling process. The computational cost of the Focus module in YOLOv5 is approximately three times higher than that of downsampling with convolution, but it helps reduce information loss in the downsampling process.

The feature extraction network in the YOLOv5 algorithm consists of various functional modules such as Focus, CBL, CSP, and SPP. The deep network layers ensure the network's ability to extract features. The YOLOv5 algorithm utilizes convolutional operations to perform feature re-extraction on the output feature maps. The algorithm takes in input image data of size 640x640x3 and outputs three feature maps of sizes 80x80x18, 40x40x18, and 20x20x18, respectively. The feature map with a higher resolution is used for predicting smaller objects, while the ones with lower resolutions are used for predicting larger objects. Using feature maps of different resolutions helps improve the accuracy of object recognition for objects of different sizes.

Attention mechanism

The introduction of attention mechanisms in computer vision can effectively enhance the feature extraction capability of networks, thereby improving the accuracy of object recognition. Currently, widely used attention mechanisms in deep learning include SENet and CBAM.

SENet attention mechanism

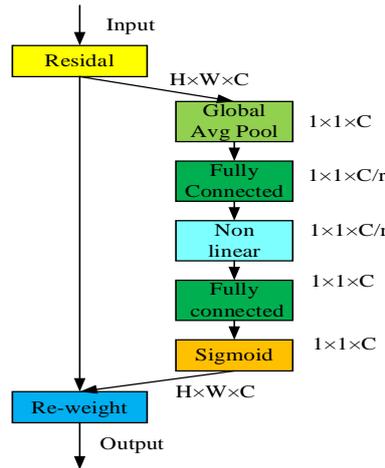

Fig. 6 – Schematic diagram of the seNet attention mechanism structure

Figure 6 shows the structure of the SENet network. The SENet takes an $H \times W \times C$ feature map as input, with C channels (Bai et al., 2022; Lin et al., 2021; Peng et al., 2022). First, the input feature map is globally average pooled, reducing the height and width of the feature map to 1×1 , as shown in Eq.(1). Then, two fully connected layers are applied, followed by the sigmoid activation function to normalize the values. This process obtains the weights for each channel in the input feature map. By multiplying these weights with the input feature map, a new calibration of the input feature map using channel attention is achieved, as shown in Eq.(2).

$$z_c = F_{sq}(u_c) = \frac{1}{H \times W} \sum_{i=1}^H \sum_{j=1}^W u_c(i, j) \tag{1}$$

$$\hat{X} = X \cdot \sigma(z) \tag{2}$$

- z_c : the c -th element of z ;
- H : the height of the feature map;
- W : the width of the feature map;
- $u_c(i, j)$: the (i, j) -th element of the c -th channel of u ;
- $\sigma(\hat{z})$: channel weight.

After passing through the first fully connected layer, the dimension of the feature map decreases, significantly reducing the model's parameters and computational complexity. After passing through the second fully connected layer, the dimension of the feature map is restored to the same as the input, establishing correlations between channels. This increases the weights of effective feature map channels and decreases the weights of other feature map channels, allowing the model to achieve better training performance.

CBAM attention mechanism

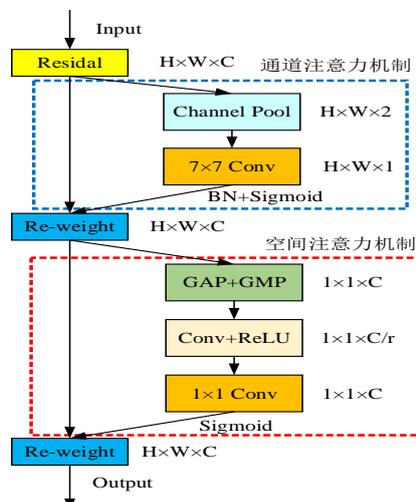

Fig. 7 – Schematic diagram of the structure of the CBAM attention mechanism

The structure shown in Figure 7 is the Convolutional Block Attention Module (CBAM), which consists of a Channel Attention Module and a Spatial Attention Module (Liu et al., 2021; Xia et al., 2023; Huang et al., 2021). The input feature map first goes through the Channel Attention Module, where the feature map's height and width are globally averaged and globally max-pooled. The resulting values are then passed through a Multi-Layer Perceptron (MLP) to obtain the channel attention weights. These weights are then added to the original input feature map through a multiplication and addition operation. This completes the calibration of the original input feature map using channel attention, as shown in Equation (3).

$$\begin{aligned} M_c(F) &= (MLP(AvgPool(F)) + MLP(MaxPool(F))) \\ &= \sigma(W_1(W_0(F_{avg}^c)) + W_1(W_0(F_{max}^c))) \end{aligned} \quad (3)$$

σ : Sigmoid function;

C : Number of channels;

W_1, W_0 : Input shared weights;

F_{avg}^c : Feature mapping generated by average pooling in space;

F_{max}^c : Feature mapping generated by maximum pooling in space.

After passing through the CBAM module, the feature map generates new feature maps with channel and spatial attention weights, enhancing the relationship between image features in both spatial and channel dimensions. This is beneficial for extracting typical features of the target (Su et al., 2021, Lingqing et al., 2024).

Loss function

In the target detection task, the loss function can better reflect the gap between the predicted value and the real value of the data, and then reflect the detection effect. The loss function used in this paper consists of three parts, they are Loss of confidence (L_{con}), Positioning loss (L_{GIOU}) and Classification loss (L_{class}). The total loss function (L_{total}) can be obtained by accumulating the three, as shown in Equation (4).

$$L_{total} = L_{con} + L_{GIOU} + L_{class} \quad (4)$$

In the formula, the confidence loss measures the confidence level of the prediction box, with the calculation shown in Equation (5). The calculation method of the function is cross entropy error, which determines whether the predicted bounding boxes contain the predicted target. If there is a predicted target in the current bounding box, the value of I_{ij}^{obj} is 1. If there is no predicted target in the current bounding box, the value of I_{ij}^{obj} is 0. The confidence values are weighted and summed to obtain the value of L_{con} .

$$\begin{aligned} L_{con} &= \lambda_{obj} \sum_{i=0}^{S^2} \sum_{j=0}^B I_{ij}^{obj} \left[-\hat{C}_i \ln C_i - \left(1 - \hat{C}_i\right) \ln \left(1 - \hat{C}_i\right) \right] \\ &\quad + \lambda_{no} \sum_{i=0}^{S^2} \sum_{j=0}^B I_{ij}^{no} \left[-\hat{C}_i \ln C_i - \left(1 - \hat{C}_i\right) \ln \left(1 - \hat{C}_i\right) \right] \end{aligned} \quad (5)$$

λ_{obj} : there is a target weight coefficient in the grid;

λ_{no} : no target weight coefficient in the grid;

S^2 : number of grids;

I_{ij}^{obj} : to determine whether the j -th bounding box in the i -th grid needs to be predicted,

I_{ij}^{no} : to determine whether the j -th bounding box in the i th grid has a target that does not need to be predicted,

C_i : predict the target confidence value;

\hat{C}_i : the actual target confidence value.

L_{class} is the classification loss, which is used to calculate the difference between the predicted value and the actual value of the category. The calculation is shown in Equation (6).

The calculation of L_{class} is similar to that of L_{con} . The values of I_{ij}^{obj} and I_{ij}^{obj} are the same as shown in Equation (7). The calculated probability value is weighted and summed to obtain the value of L_{class} .

$$L_{class} = \sum_{i=0}^{S^2} \sum_{j=0}^B \sum_{c \in class} I_{ij}^{obj} \left[-\hat{p}_i(c) - \ln \left(\hat{p}_i(c) \right) - \left(1 - \hat{p}_i(c) \right) \ln(1 - \hat{p}_i(c)) \right] \tag{6}$$

c : Boundary box prediction category;

$p_i(c)$: The probability that the target is predicted to be c in the i -th grid;

$\hat{p}_i(c)$: The actual probability that the target is c in the i -th grid.

In object detection tasks, IoU is often used to calculate the coordinate differences between predicted bounding boxes and ground-truth bounding boxes, and can more directly reflect the detection performance of the algorithm. The calculation formula is shown in (7) ~ (9).

$$IoU = \frac{A \cap B}{A \cup B} \tag{7}$$

$$GIoU = IoU - \frac{|C - (A \cup B)|}{|C|} \tag{8}$$

$$L_{GIoU} = \sum_{i=0}^{S^2} \sum_{j=0}^B (1 - GIoU) \tag{9}$$

A : Real box area;

B : Predicting box area;

C : A and B minimum circumscribed rectangle area.

RESULTS

The effect of adding attention mechanism on the test results

To verify the detection performance of the YOLOv5 algorithm after adding the attention mechanism module, a comparative experiment was conducted between the YOLOv5 algorithm with the added attention mechanism module and the original YOLOv5 algorithm. The performance was tested using a dataset composed of samples mixed from different maturity stages. Table 2 shows the experimental results of apple detection before and after adding the attention mechanism module to the YOLOv5 algorithm.

Table 2

Test results of Apple detection before and after the improvement of the YOLOv5 algorithm

Algorithm	Number of network parameters (MB)	Examination speed (ms)	mAP (%)
YOLOv5s	13.7 (0.00)	31.5 (0.00)	92.3 (0.00)
YOLOv5s-SENet	14.8 (+8.03%)	31.9 (+1.26%)	93.5 (+1.30%)
YOLOv5s-CBAM	15.1 (+10.22%)	32.1 (+1.9%)	94.2 (+2.06%)
YOLOv5m	40.2 (0.00)	80.2 (0.00)	93.1 (0.00)
YOLOv5m-SENet	42.8 (+6.47%)	81.4 (+1.50%)	94.4 (+1.40)
YOLOv5m-CBAM	43.6 (+8.46%)	82.3 (+2.62%)	95.6 (+2.69%)
YOLOv5l	88.5 (0.00)	148.3 (0.00)	95.6 (0.00)
YOLOv5l-SENet	92.8 (+4.86%)	149.8 (+1.01%)	96.9 (+1.36%)
YOLOv5l-CBAM	94.2 (+6.44%)	151.8 (+2.36%)	97.8 (+2.30%)
YOLOv5x	171.6 (0.00)	304.2 (0.00)	96.4 (0.00)
YOLOv5x-SENet	179.1 (+4.37%)	308.4 (+1.38%)	97.7 (1.35%)
YOLOv5x-CBAM	181.2 (+5.59)	311.7 (+2.47%)	98.3 (+1.97%)

According to Table 2, it could be seen that in the original YOLOv5 algorithm, YOLOv5x had an average detection accuracy of 96.4%, higher than the other three networks, but it had a longer detection time.

After separately embedding the SENet attention mechanism module, the average detection accuracy of YOLOv5s increased by 1.3% to 93.5%. YOLOv5m, YOLOv5l, and YOLOv5x also showed some improvements in average detection accuracy. The parameter count of YOLOv5s-SENet increased by 8.03% compared to the original version, resulting in a 1.26% increase in detection time. Compared to the original version, the parameter count of YOLOv5m-SENet, YOLOv5l-SENet, and YOLOv5x-SENet increased by 4.37% to 6.47%, with the highest increase being only 7.5MB. However, all versions achieved more than 1% improvement in accuracy, demonstrating good detection performance.

When the CBAM module was embedded in all four different network structures of the YOLOv5 algorithm, the parameter count of YOLOv5s, YOLOv5m, YOLOv5l, and YOLOv5x increased by 10.22%, 8.46%, 6.44%, and 5.59% respectively. The lighter the network, the greater the increase in parameter count. The actual detection results of YOLOv5 model before and after adding the attention mechanism modules were shown in Figure 7.

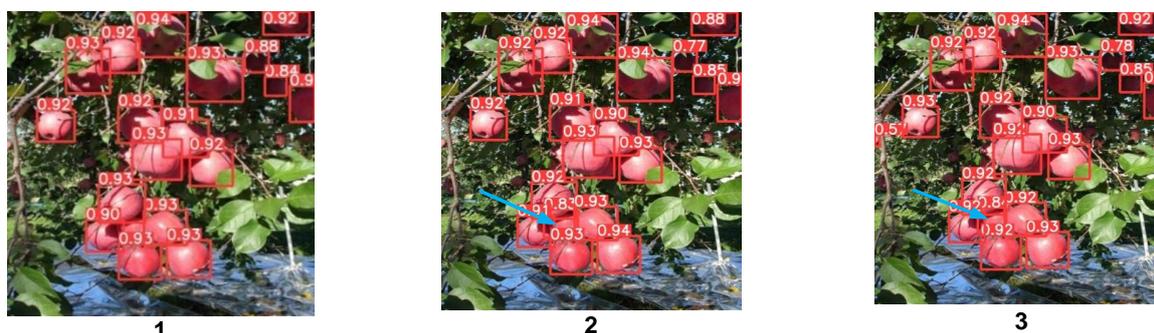

Fig. 8 – YOLOv5 test effect before and after improvement
1. Unimproved YOLOv5, 2. YOLOv5+SENet, 3. YOLOv5+CBAM.

From Figure 8, it could be seen that compared with Figure (a), the occluded fruits in Figure (b) and Figure (c) were successfully recognized, indicating that the YOLOv5 network model with the added attention mechanism module had improved accuracy in identifying small and occluded targets. Figure (c) showed that the improved YOLOv5-CBAM model successfully detected the small target fruit on the left, while the other two algorithms failed to detect this target. Taking into account various factors, embedding the attention mechanism module helped improve the model's accuracy in recognizing difficult samples, and the performance of the SENet module was slightly lower than that of the CBAM module.

Impact of different lighting intensity on experimental results

In natural environments, different lighting intensities have some influence on the brightness of captured images. Images captured in direct light are clearer, images captured in side-light have some variations in lighting and shadows, while images captured in backlight are darker, all of which can affect the accuracy of fruit detection. To further validate the detection performance of the proposed attention mechanism-based improved YOLOv5 algorithm, this section conducted relevant experiments using YOLOv5s, YOLOv5s-SENet, and YOLOv5s-CBAM as examples.

The test sets were then evaluated using different weight files before and after the addition of the attention mechanism, and the experimental results were shown in Table 3.

Table 3

Average detection accuracy at different light intensity datasets

Data set	YOLOv5s	YOLOv5s-SENet	YOLOv5s-CBAM
Front-lighting	94.3%	95.1%	95.6%
Side-lighting	92.6%	93.7%	94.3%
Backlighting	91.4%	92.5%	92.8%

According to Table 3, the average accuracy of the original YOLOv5s algorithm on the front-light dataset was 94.3%. The YOLOv5s - SENet and YOLOv5s - CBAM algorithms achieved average accuracies of 95.1% and 95.6%, respectively.

This indicated that embedding attention mechanism modules in the YOLOv5 algorithm improved the average detection accuracy across different lighting intensities, with the YOLOv5s - CBAM algorithm achieving the best detection performance. The YOLOv5s - CBAM algorithm achieved the highest average accuracy of 95.6% on the front-light dataset, which was 1.38% higher than that of YOLOv5s. Both the original and improved YOLOv5 algorithms achieved average accuracies above 94% on the front-light dataset. On the backlight dataset, YOLOv5s - CBAM achieved an average detection accuracy of 92.8%, while YOLOv5s achieved only 91.4%, a difference of 1.4%. Furthermore, the average accuracy of YOLOv5s - CBAM on the backlight dataset was 2.93% lower than that on the front-light dataset. This also explained why the average detection accuracy of both the original and improved YOLOv5 algorithms was lowest on the backlight dataset. On the side-lighting dataset, the average accuracy of YOLOv5s, YOLOv5s - SENet, and YOLOv5s - CBAM was 92.6%, 93.7%, and 94.3%, respectively, all of which fell between the average detection accuracy of the front-lighting and backlighting datasets.

The average accuracy of YOLOv5s on datasets with different lighting intensities differed by only 2.9%, indicating that both the original and improved YOLOv5 algorithms had good robustness to changes in lighting intensity. The detection results were shown in Figure 9.

Prototype testing of a robotic target recognition system based on the proposed algorithm

As shown in Figure 9, the prototype of the vision recognition system for the picking robot was designed in this paper. The system was composed of a JETSON NANO embedded development board, a 5V4A power supply, a USB camera, and an HDMI touch display. Figure 9 presents the scene when the system prototype was functioning properly, with the recognition object being a simulated apple tree in a real - world scenario. As can be seen in Figure 9, the system could normally detect the fruit targets in the field of view, and the detection speed was stable at 30 frames per second.

Fig. 10 – Prototype of target recognition system for harvesting robot

Experimental verification showed that when the IOU threshold was set at 0.5 and 0.3, the average detection accuracy of the system prototype was over 85% in both cases, with a detection speed of 30 frames per second.

Fig. 11 – Actual testing results of Apple

CONCLUSIONS

This article proposed an apple detection method using attention mechanisms and improved YOLOv5 to facilitate picking robots' detection. Firstly, SENet and CBAM mechanisms enhanced YOLOv5's feature extraction network, improving model accuracy.

Experimental results showed that after embedding the attention mechanism module, the mAP of the YOLOv5m-CBAM model was 95.6%, which was improved by 2.69%, with an increase in detection time of 2.62%. Among the YOLOv5x models with embedded CBAM module, the average detection accuracy was the highest, with an mAP of 98.3%, and the performance of the CBAM module was superior to that of the SENet module. The improved YOLOv5s model achieved apple recognition accuracy ranging from 91.4% to 95.6% under different lighting conditions, with a difference in fruit recognition accuracy within 3% for the same model. These results demonstrated that the improved YOLOv5 model had good robustness to changes in light intensity. The improved YOLOv5 model could provide reference for the development of the visual system of apple picking robots. Actual tests of the apple-picking robot's vision system prototype showed that when the IOU threshold was set at 0.5 and 0.3, the average detection accuracy was over 85% in both cases.

Keywords: corn peeling, high-moisture corn cobs, high-speed camera, scratching device, friction peeling

ABSTRACT

To address the challenges of high moisture content and the difficulty of peeling corn cobs in certain regions during harvest, a novel peeling device was developed. The device uses directional friction to peel the cob after introducing scratches on the bracts. Mechanical and kinematic analyses were conducted to study the peeling process, along with the design of the scratching mechanism. High-speed camera technology was employed to observe the peeling process, confirming that the peeling rollers effectively gripped the bracts at the scratched points. A three-factor, three-level response surface optimization experiment was carried out, using peeling roller speed, pressing wheel speed, and the distance between the pressing wheel and the peeling roller as independent variables, with bract peeling rate and grain shedding rate as the response indicators. The results showed that at a peeling roller speed of $353.2 \text{ r}\cdot\text{min}^{-1}$, a pressing wheel speed of $81.42 \text{ r}\cdot\text{min}^{-1}$, and a distance of 37.16 mm between the pressing wheel and the peeling roller, the bract peeling rate reached 95.67% with a grain shedding rate of 1.45%. Validation tests under these conditions yielded a bract peeling rate of 93.33% and a grain shedding rate of 1.56%, meeting the operational requirements for efficient corn peeling.

摘要

针对部分地区大田玉米在收获时其含水率高剥皮困难等问题,设计了一款在果穗苞叶上划痕后定向摩擦去皮的剥皮装置。对果穗剥皮过程进行力学与运动学分析,并对划痕装置进行设计。采用高速摄像技术对果穗剥皮过程进行研究并验证了剥皮辊在苞叶划痕处能有效的抓取到苞叶。以剥皮辊转速、压送器转速和压送器距剥皮辊间距作为试验因素,以苞叶剥净率和籽粒损失率作为试验指标,进行三因素三水平响应曲面优化试验。结果表明:当剥皮辊转速为 $353.2 \text{ r}\cdot\text{min}^{-1}$ 、压送器转速为 $81.42 \text{ r}\cdot\text{min}^{-1}$ 、压送器距剥皮辊间距为 37.16mm 时,此时苞叶剥净率为 95.67%,籽粒损失率为 1.45%。在该条件下开展验证试验,得到苞叶剥净率、籽粒损失率分别为 93.33%、1.56%,满足玉米剥皮要求。

INTRODUCTION

In some regions, the high moisture content of corn cobs at maturity, generally ranging from 30% to 40%, is primarily due to the local climate and environmental conditions (Chen *et al.*, 2014; Li *et al.*, 2024). As a result, directly harvesting kernels often leads to a higher kernel breakage rate. Consequently, the standard method involves harvesting the entire cob, followed by drying, peeling, and threshing (Chen *et al.*, 2023). Given the high moisture content at harvest, if the cobs are not dried and peeled promptly, they are prone to deterioration and germination, which significantly affects their value (Zhao *et al.*, 2024; Barnwal *et al.*, 2012). Therefore, the development of an efficient method for peeling corn cobs with high moisture content is of paramount importance.

In recent years, numerous scholars have focused on improving the material properties of corn cobs and optimizing the structure of key components involved in the peeling process, to enhance the operational efficiency of peeling devices (Xie *et al.*, 2018; Liu *et al.*, 2020). Plett *et al.* (1994) conducted a study on various corn cob varieties to assess kernel crushing and found that the lowest kernel crushing rate occurred when the moisture content was between 16.7% and 22.1%.

Bang Ji, Lect. Ph.D.; Long Pan, M.S. Stud.; Yusong Xie, M.S. Stud.; Hao Zhou, M.S. Stud.; Yongkang Li, M.S. Stud.; Pu Li, Lect. M.S.

Li Zhenye *et al.* (2021) investigated the physical and tensile properties of corn cob bracts throughout the harvest period, developing a mathematical model that correlates bract tensile properties with moisture content and thickness.

Liu Lei *et al.* (2022) established a discrete element method (DEM)-based simulation model to analyze the corn peeling process, focusing on kernel crushing and shedding. Their study provided insights into the cob peeling process and highlighted the extent of kernel damage to light cobs during interaction with the peeling roller. The Kubota PRO1408Y-4 self-propelled corn cob harvester, produced by Kubota Agricultural Machinery Co., Ltd. in Japan, features an extended peeling roller (1.1 m in length), which ensures a high peeling rate even at elevated speeds. Additionally, the spacing between the pressing wheel and the peeling roller can be adjusted via a handle, allowing the device to accommodate different corn cob sizes (Shirly., 2015). Although these studies demonstrate effective peeling performance at low moisture content, they are less suited for high-moisture corn cobs. When corn cobs have high moisture content, the bracts and kernels bond more tightly, which prevents the peeling rollers from effectively gripping the bracts and performing an efficient peeling operation.

To address these challenges, the present study designs a peeling device specifically for the directional friction peeling of corn cob bracts after initial scratching. This design is based on an analysis of the physical properties and peeling requirements of the bracts from high-moisture corn cobs. Through theoretical analysis of the peeling process and the design of key components, the study also employs high-speed camera technology to verify that the peeling rollers can effectively grip and peel the bracts. Finally, through bench testing, relevant parameters are optimized to facilitate the efficient peeling of high-moisture corn cobs.

MATERIALS AND METHODS

Machine structure and working principle

The high-moisture-content corn cob peeling device consists of two main components: the scratching device and the peeling device, as illustrated in Fig. 1. During operation, the cob initially passes through the scratching device, where it is guided along a semi-circular rail. The rail is situated below the blade. As the cob progresses along the guide rail, it passes beneath the blade, which creates scratches on the bracts. Following this, the cob enters the peeling device. The rollers continuously grasp the bracts at the locations of the scratches (Zhao *et al.*, 2012).

Modeling of corn cob-mechanics

Cob bracts scratch force analysis

In the semicircular guide scratching process, the force conditions are illustrated in Fig. 2.

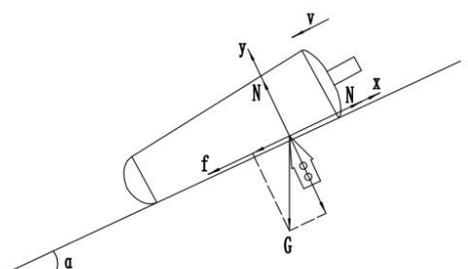

Fig. 2 – Force analysis diagram for cob bracts scratching process

When the cob is fed into the scratching device, it moves downward along the guide rail with a specified acceleration α , and the blade scratches the cob bracts under the action of the pressing force F . The force equation of the scratching process is given in Eq. (1) and (2).

$$mg \sin\alpha + f - F = ma \tag{1}$$

$$\begin{cases} N = mg \cos\alpha \\ f = \mu_1 N \end{cases} \tag{2}$$

From Equations 1 and 2, will result:

$$a = g(\sin\alpha + \mu_1 \cos\alpha) - \frac{2F}{m} \tag{3}$$

where:

m is the unpeeled cob mass, [kg]; g is the acceleration due to gravity, [$m \cdot s^{-2}$]; f is the frictional resistance of the guide rail acting on the cob, [N]; N is the support force of the guide rail on the cob, [N]; μ_1 is the friction factor between the guide rail and the cob; α is the guide rail inclination angle, [$^\circ$].

When the Corn cob moves within the guide rail at a uniform linear velocity, then:

$$S = v_0 t + \frac{1}{2} a t^2 \tag{4}$$

where:

S is the length of the guide rail, [m]; V_0 is the initial feeding speed of the corn cob [$m \cdot s^{-1}$]; t is the cob peeling time, [s].

Substituting Eq. (3) into Eq. (4), the required force F for cob scratching is obtained, as shown in Eq. (5).

$$F = \frac{m[gt^2(\sin\alpha + \mu_1 \cos\alpha) - 2(S - v_0 t)]}{2t^2} \tag{5}$$

Equation (5) shows that the scratching process is influenced by the inclination angle of the guide rail, α . Based on the peeling device's inclination angle, the value of α can range from 10° to 20° .

Conditions required for cob bracts peeling

As shown in Fig. 3, consider the peeling process of the bracts from point A to point B. The length of the bract from point A to point B is denoted as C. Treating the bract as an elastomer, a mechanical model for bract peeling is established to study the peeling process. During the bract peeling process, the action of the peeling force F on the bracts can be divided into three distinct components (Rivlin et al., 1997; Kendall et al., 1975).

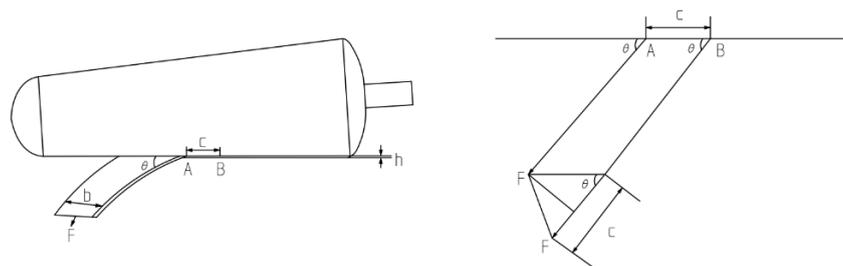

Fig. 3 – Schematic diagram of bracts peeling

Surface energy W_s refers to the energy generated when the peeling force F peels the upper bracts from the lower bracts as seen in Eq. (6):

$$W_s = -b c R \tag{6}$$

Potential energy W_p denotes the energy generated by the movement of the peeling force F from point A to point B as seen in Eq. (7):

$$W_p = c(1 - \cos\theta)F \quad (7)$$

Elastic potential energy: W_e refer to the energy produced by the peeling force F as it stretches the bracts. This energy comprises two components:

The first component is the work W_{e1} done by the constant force F in the stretching region:

$$W_{e1} = F \Delta c \quad (8)$$

It is known that $E = \frac{F/bh}{\Delta c/c}$, $\Delta c = \frac{Fc}{Ebh}$, thus:

$$W_{e1} = \frac{F^2 c}{Ebh} \quad (9)$$

The second component is the elastic strain energy W_{e2} :

$$W_{e2} = \frac{1}{2} F \Delta c \quad (10)$$

$$W_{e2} = \frac{F^2 c}{2Ebh} \quad (11)$$

where:

F is the peeling force of peeling bracts, [N]; E is the modulus of elasticity, [MPa]; θ is the peeling angle, [°]; b is the bract peeling width, [mm]; h is the bracts thickness, [mm]; R is the unit peeling energy, bract peeling energy consumption per unit area of bract peeling, [J].

According to the law of conservation of energy, the following equation is established:

$$-bcR + c(1 - \cos\theta)F + \frac{F^2 c}{2Ebh} = 0 \quad (12)$$

By solving this equation, the formula for the bract peeling force F is obtained as shown in Eq. 13:

$$F = Ehb \sqrt{\sqrt{(1 - \cos\theta)^2 + \frac{2R}{Eh}} + \cos\theta - 1} \quad (13)$$

From Eq. (13), it is clear that the peeling force F during bract peeling depends on several factors such as the peeling angle θ , the bract peeling width b , the bract thickness h , the bract elastic modulus E , and the energy consumption R required for peeling each unit area.

Design of the key components

Scratching device

When the moisture content of corn cobs is high, the pores of the bracts become saturated with water (Mandang et al., 2018), causing the bract layers to stack tightly and wrap around the bare cob. As a result, the peeling rollers cannot effectively grip the bracts, leading to difficulties in the peeling process. Scratching the surface of the bracts can cause them to split at the point of contact, as shown in Fig.4d, allowing the peeling roller to better grip the bracts at the scratched location.

The scratching device as illustrated in Fig.7. The blade is welded to the bottom of the guide rail through the knife frame. The blade extends approximately 2 mm into the notch, ensuring it scratches a sufficient depth into the bracts without damaging the seeds. The operation principle is as follows: the cob passes through the semi-circular guide rail, which is set at a certain angle, and slides down the guide rail due to its gravity and the force from the pressing wheel (Fig.7a).

When the cob reaches the tip of the blade, the pressing wheel exerts both downward and forward forces on the cob, causing the cob to move over the blade (Fig.7b).

This action effectively scratches the bracts (Fig.7c). Furthermore, the semi-circular guide causes the corn cob to enter the peeling device in a vertical orientation, reducing the likelihood of clogging within the peeling device. This improvement enhances both the peeling efficiency and overall working performance.

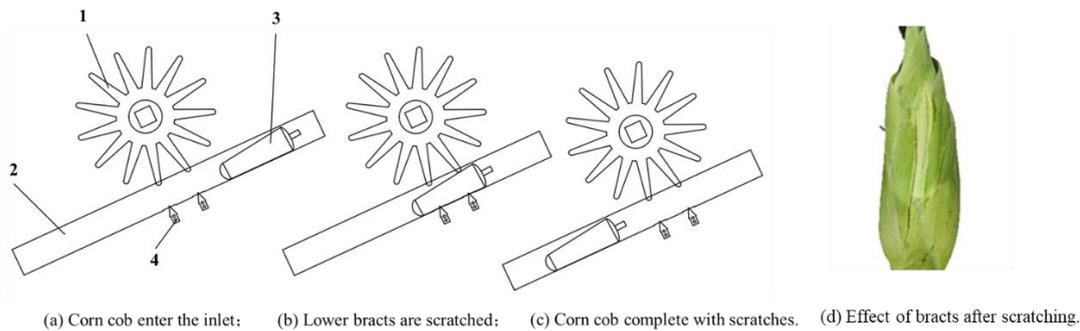

Fig. 4 – Schematic diagram of corn cob scratching and effect of bracts after scratching
 1 - Pressing wheel; 2 - Semi-circular guide rail; 3 - Corn cob; 4 Blade.

Peeling device

The peeling device is illustrated in Fig.5. During the corn cob peeling process, the peeling roller maintains continuous frictional contact with the bracts, which is a critical mechanism underlying the device’s operation (Fu et al., 2020; Gorad et al., 2019). The device's configuration incorporates both high and low rollers, making it particularly well-suited for cobs with tightly wrapped bracts. The surface of the peeling roller is designed with both fish scale rollers and double spiral rollers. The fish scale rollers, positioned as the high rollers, exert friction on the bracts, effectively gripping them. The low rollers are equipped with double spiral rollers, whose helical pattern promotes the cob's continuous forward movement. Furthermore, the height difference between the high and low rollers creates varying friction torques on the cob. This torque disparity not only aids in correcting the cob's position but also induces rotational motion around its axis, thus increasing the number of contact points between the bracts and the peeling roller (Yang et al., 2021).

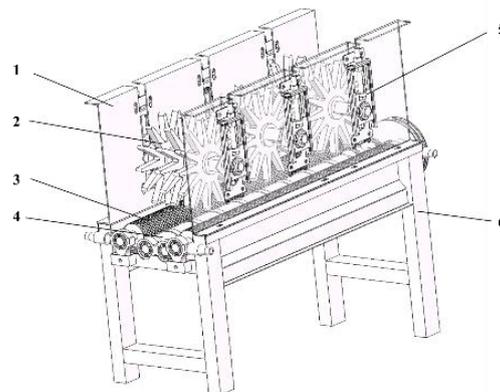

Fig. 5 – Peeling device

High-speed camera experiment design

To verify the ability of the peeling roller to effectively grasp and remove bracts during the peeling of corn cobs with high moisture content, a high-speed camera peeling test platform was constructed, consisting of a high-speed camera and the peeling device (Fig.6). Before the test, the shooting frame rate set to 3000 frames/s and resolution set at 1920×1080. (Zhu et al., 2015).

Fig. 6 – Test device

Peeling performance test design

The test samples used in this study were the Denghai 605 corn variety and were harvested in Liuyang City, Hunan Province, China. Samples exhibiting optimal cob length and undamaged bracts were selected, with moisture content maintained at approximately 35%. The test materials and device are illustrated in Fig. 7.

Fig. 7 – Test materials and device

Based on a theoretical mechanical analysis of the corn peeling process and preliminary pre-tests, three primary factors—peeling roller speed, pressing wheel speed, and the distance between the pressing wheel and peeling roller—were chosen for response surface test. Following JB/T11907-2014 standards, two evaluation metrics were selected: the bract peeling rate (Y_1) and the grain shedding rate (Y_2). The respective calculation formulas are given below:

$$Y_1 = \left(1 - \frac{n_b}{n}\right) \times 100\% \quad (14)$$

$$Y_2 = \frac{G_s}{G + G_s} \times 100\% \quad (15)$$

where:

n is the total number of corn cobs of the measurement sample, [one]; n_b is the number of corn cobs without peeling bracts, [one]; G is the total mass of sample grains, [g]; G_s is the total mass of lost grains, [g].

Design of the one-way test

Based on both preliminary pre-tests and relevant research conducted by scholars domestically and internationally, the peeling roller speed was set within the range of 300–500 r·min⁻¹, the pressing wheel speed was set within the range of 40–120 r·min⁻¹, and the distance between the pressing wheel and peeling roller was set between 30 and 50 mm (Li, 2023). As detailed in Table 1.

Table 1

Single-factor test levels			
Level	Factor		
	The peeling roller speed [r·min ⁻¹]	The pressing wheel speed [r·min ⁻¹]	The distance between the pressing wheel and the peeling roller [mm]
1	300	40	30
2	350	60	35
3	400	80	40
4	450	100	45
5	500	120	50

Response surface test

Based on the results of the one-way test, the following parameter ranges were selected: peeling roller speed of 300–400 r·min⁻¹, pressing wheel speed of 60–100 r·min⁻¹, and the distance between the pressing wheel and peeling roller set at 35–45 mm. The factor levels are presented in Table 2.

Table 2

Factor coding of peeling test			
Encodings	Factor		
	Peeling roller speed [r·min ⁻¹]	Pressing wheel speed [r·min ⁻¹]	Distance between the pressing wheel and the peeling roller [mm]
-1	-1	-1	-1
0	0	0	0
1	1	1	1

RESULTS AND DISCUSSION

Results and analysis of the high-speed camera

Figure 8 presents the high-speed camera's capture of the cob bracts removal process post-scratching. Analysis of the high-speed footage revealed that the peeling process can be divided into two distinct stages: Firstly, due to the height difference between the high and low rollers, the friction torque acting on the cob varies, causing the cob to rotate around its axis. Simultaneously, the bracts' surface becomes puckered after being scratched. The pressing wheel intermittently applies pressure to the cob, which increases the friction between the peeling rollers and the scratched bracts. When this friction exceeds the bond between the layers of the bracts, the peeling rollers effectively grip the bracts (Fig. 8a–c). Secondly, once the peeling rollers grasp the bracts, they are continuously pulled. As the area of the bracts engaged between the two peeling rollers increases, the bracts break along the longitudinal veins, completing the peeling process (Fig. 8 d–f). Once the upper layer of bracts is peeled, the lower layers continue to be pulled by the combined forces of the peeling rollers and pressing wheel. Meanwhile, the cob continues to rotate around its axis, allowing each successive layer of bracts to be grasped and peeled until all the bracts are removed, as depicted in (Fig. 8 g–h). Thus, in the corn cob peeling process, increasing the friction between the peeling rollers and appropriately adjusting the difference in friction torque between the high and low rollers can facilitate the cob's rotation around its axis. This increases the contact time between the bracts and the peeling rollers, thereby improving the efficiency of bract removal.

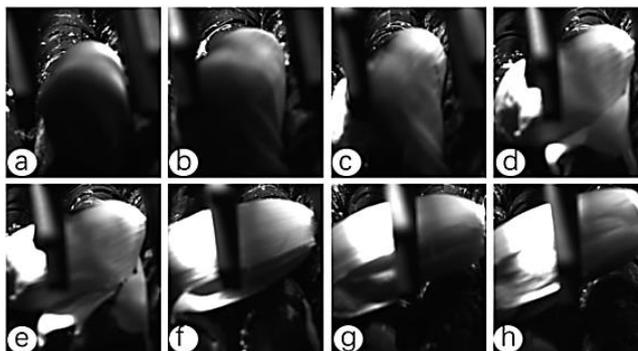

Fig. 8 – High-speed camera capture of bracts peeling process

Results and analysis of the one-way test

The results of the single-factor tests are presented in Fig. 9. As illustrated in Fig. 9, an increase in peeling roller speed, pressing wheel speed, and the distance between the pressing wheel and the peeling roller initially led to an increase in the bract peeling rate, followed by a subsequent decrease. In contrast, the grain shedding rate initially decreased and then increased. Specifically, when the peeling roller speed ranged from 300 to 400 r·min⁻¹, the maximum bract peeling rate reached 95%, and the minimum grain shedding rate was 1.45%. Similarly, when the pressing wheel speed varied between 60 and 100 r·min⁻¹, the maximum bract peeling rate increased to 96.67%, with a minimum grain shedding rate of 1.47%. When the distance between the pressing wheel and the peeling roller was adjusted to 35–45 mm, the maximum bract peeling rate was 95%, and the minimum grain shedding rate was 1.65%. Consequently, the optimal settings for the response surface test were determined to be a peeling roller speed of 300–400 r·min⁻¹, a pressing wheel speed of 60–100 r·min⁻¹, and a distance between the pressing wheel and the peeling roller of 35–45 mm.

Significance analysis

The analysis of significance for the bract peeling rate (Y₁) and grain shedding rate (Y₂) is shown in Table 4. Both regression models for Y₁ and Y₂ were found to be statistically significant, with P-values less than 0.01. This indicates that the models effectively describe the relationship between the experimental factors and the response variables. Moreover, the regression equations were not found to be significantly out of fit, suggesting a strong quadratic relationship between the test parameters and the factors within the tested range. The coefficients of determination (R²) for Y₁ and Y₂ were 0.9195 and 0.9558, respectively, demonstrating high consistency between the predicted and actual values. Based on the results, the regression terms X₃, X₁², and X₂² significantly influence Y₁ (P < 0.01). The interaction terms X₁, X₁X₂ and X₃² also showed a significant effect on Y₁ (0.01 < P < 0.05). Conversely, the regression terms X₂, X₁X₃, and X₂X₃ did not significantly affect Y₁ (P > 0.05). The corresponding regression equation for the bract peeling rate is provided in Eq. (16). For the grain shedding rate (Y₂), the regression terms X₃, X₁², and X₂² were found to have a very significant effect (P < 0.01). The interaction terms X₁, X₁X₂, X₁X₃, and X₃² were significantly associated with Y₂ (0.01 < P < 0.05). However, the terms X₂ and X₂X₃ had no significant impact on Y₂ (P > 0.05). The regression equation for the grain shedding rate is presented in Eq. (17).

$$Y_1 = 95 + 1.25X_1 - 1.67X_3 + 1.66X_1X_2 - 2.92X_1^2 - 2.92X_2^2 - 1.25X_3^2 \tag{16}$$

$$Y_2 = 1.47 - 0.055X_1 + 0.085X_3 + 0.08X_1X_2 - 0.095X_1X_3 + 0.2335X_1^2 + 0.1735X_2^2 + 0.0835X_3^2 \tag{17}$$

Response surface analysis

Based on the regression equations and response surface analysis (see Fig. 10), an interaction was observed between the peeling roller speed, the pressing wheel speed, and the distance between the pressing wheel and the peeling roller. As the peeling roller speed increased, the bract peeling rate initially increased and then decreased, with the maximum rate observed in the range of 340~360 r·min⁻¹. Similarly, the bract peeling rate increases and then decreases with increasing pressing wheel speed, reaching its maximum in the range of 70~85 r·min⁻¹. Moreover, as the distance between the pressing wheel and the peeling roller increases, the bract peeling rate initially increases slowly and then decreases, with the maximum rate observed between 37 and 41 mm. In summary, the optimal bract peeling rate for corn cobs with high moisture content occurs when the peeling roller speed is between 340 and 360 r·min⁻¹, the pressing wheel speed ranges from 70 to 85 r·min⁻¹, and the distance between the pressing wheel and the peeling roller lies between 37 and 41 mm.

Based on the regression equation and response surface analysis (Fig. 11), an interaction was observed between the peeling roller speed, the pressing wheel speed, and the distance between the pressing wheel and the peeling roller. As the peeling roller speed increased, grain shedding initially decreased and then increased, with the minimum shedding rate occurring in the range of 340~360 r·min⁻¹. Similarly, grain shedding decreased and then increased with an increase in pressing wheel speed, with the minimum rate observed between 75 and 85 r·min⁻¹. Furthermore, as the distance between the pressing wheel and the peeling roller increased, grain shedding decreased and then increased, with the minimum shedding rate occurring within the interval of 35~39 mm. In summary, the optimum peeling rate for corn cobs with high moisture content was achieved when the peeling roller speed was between 340 and 360 r·min⁻¹, the pressing wheel speed was between 75 and 85 r·min⁻¹, and the distance between the pressing wheel and the peeling roller was between 35 and 39 mm, simultaneously minimizing the grain shedding rate.

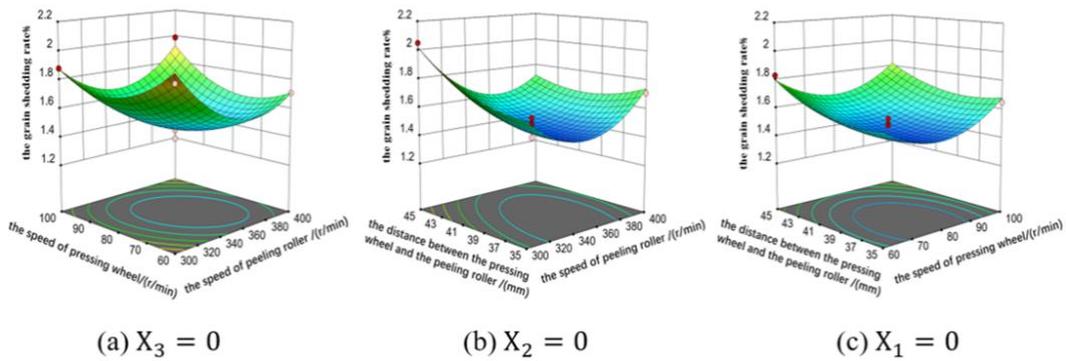

Fig. 11 – Effect of factor interactions on grain shedding rate

Validation test

Using the optimization module of Design-Expert 13 software, the quadratic regression models for Y_1 and Y_2 are optimized and solved, with the objective function and constraints defined as follows:

$$\left\{ \begin{array}{l} \max Y_1 \\ \min Y_2 \\ 300r \cdot \text{min}^{-1} \leq X_1 \leq 400r \cdot \text{min}^{-1} \\ 60r \cdot \text{min}^{-1} \leq X_2 \leq 80r \cdot \text{min}^{-1} \\ 35\text{mm} \leq X_3 \leq 45\text{mm} \end{array} \right\} \quad (18)$$

It led to the identification of the optimal parameter combination: peeling roller speed of 353.2 r·min⁻¹, pressing wheel speed of 81.42 r·min⁻¹, and a distance of 37.16 mm between the pressing wheel and the peeling roller. The bract peeling rate and grain shedding rate were found to be 95.67% and 1.45%, respectively.

The optimized test conditions were adjusted as follows: peeling roller speed of 353 r·min⁻¹, pressing wheel speed of 80 r·min⁻¹, and a distance between the pressing wheel and the peeling roller of 37 mm. To validate these conditions. Three repetitions were performed, resulting in an average bract peeling rate of 93.33% and an average grain shedding rate of 1.56%. These results, as presented in Table 5, fulfil the machine design specifications.

Table 5

Test validation results		
Test number	Bract's peeling rate	Grain shedding rate
1	95%	1.55%
2	90%	1.59%
3	95%	1.54%
Average value	93.33%	1.56%

CONCLUSIONS

(1) A peeling device was designed to remove the skin through friction, following the initial scratching of the surface of the cob bracts. Additionally, the design of the scratching mechanism ensured that the surface of the cob bracts was scratched to a specific depth without damaging the seeds. The semi-circular guide rail was incorporated to position the corn cob vertically as it entered the peeling device.

(2) A peeling test platform, comprising a high-speed camera and the peeling device, was established to investigate the cob peeling process and verify that the peeling rollers can effectively grip the bracts at the points where the surface was scratched.

(3) Using Design-Expert 13 software to process the experimental data, the optimal parameter combination for the peeling device was identified as follows: peeling roller speed of 353.2 r·min⁻¹, pressing wheel speed of 81.42 r·min⁻¹, and a distance of 37.16 mm between the pressing wheel and the peeling roller. Under these conditions, the bract peeling rate was 95.67%, while the grain shedding rate was 1.45%. In the verification test, the bract peeling rate was 93.33%, the grain shedding rate was 1.56%, and the device met the design requirements.

ABSTRACT

Plowing is recognized as an essential agricultural task that cannot yet easily be substituted with alternative soil processing methods due to its significance. However, it is also one of the most fuel-intensive operations. The main objective of this paper is to determine the optimal operational parameters (working speed and working width) of a plowing aggregate composed of a 180 HP tractor and a 5-moldboard plow, which ensures the full utilization of the tractor engine's power and the use of the aggregate at its maximum working capacity, respectively, achieving an optimal power balance.

REZUMAT

Lucrarea de arat este recunoscută ca fiind una încă greu de înlocuit de alte lucrări de pregătire a patului germinativ datorită importanței și utilității acesteia. În același timp, lucrarea de arat este una dintre cele mai mari consumatoare de combustibil din întreg ciclul de cultivație. Obiectivul principal al lucrării constă în determinarea parametrilor de operare optimi pentru un agregat de arat compus dintr-un tractor de 180 CP și un plug cu 5 trupițe, care să asigure utilizarea în întregime a puterii motorului tractorului și folosirea agregatului la capacitatea maximă de lucru, respectiv, realizarea un bilanț de putere optimal.

INTRODUCTION

Plowing is a crucial agricultural operation that demands significant fuel consumption. To reduce the significant amount of fuel required for seedbed preparation operations, particularly for plowing, the tractor-implement aggregates must be properly configured, and the operating parameters must be selected to ensure the full utilization of the tractor engine's power (Șandru *et al.*, 1983; Croitoru *et al.*, 2017). Additionally, the soil processing equipment should operate at its maximum working capacity while maintaining an optimal power balance (Hunt, 1986).

Studies on soil-machine interaction aim to provide scientific insights into the dynamics between tillage tools, traction devices, and the terrain they operate on. Key variables examined include the forces needed to operate tillage tools, vertical and lateral forces acting on them, patterns of soil failure, displacement of soil particles, forces at the wheel-soil interface, wheel sinkage, rolling resistance, contact area of wheels, and soil stress at various depths (Ani *et al.*, 2018; Ghereș *et al.*, 2013).

The resistance force to the movement of agricultural aggregates arises from the friction between the wheels and the soil surface, the friction of the axles in the wheel bearings, and the deformation of the soil by the aggregate's wheels (Dobrescu, 1981). This force is influenced by the type and construction of the driving and supporting wheels, the weight of the aggregate, and the properties of the soil on which it operates. On loose, highly moist, or uneven soils, the resistance to movement is higher compared to operating on compacted, smooth-surfaced soils. Soil surface irregularities increase rolling resistance due to additional soil deformation, deviation of the machines in the aggregate from the forward direction, and the emergence of additional inertial forces (Gill, Vanden Berg, 1968; Kheiralla *et al.*, 2004).

Rolling resistance is also affected by the relaxation time of the soil and the tires after their mutual deformation at the point of contact. As relaxation time increases, soil deformation decreases, and vice versa (Koolen *et al.*, 1983). Low-pressure tires, typical for agricultural machines, have a larger contact area with the soil, resulting in lower specific pressure and reduced soil deformation. Consequently, rolling resistance on

deformable soil surfaces is lower, but the tires undergo more significant deformations, reducing their service life. On loose soils, aggregates equipped with low-pressure tires or tracks exhibit lower resistance to movement compared to those with metal wheels or high-pressure tires (Bennett et al., 2019; Jun et al., 2024).

The traction resistance of agricultural machines, like other aggregate parameters, exhibits a pronounced random nature (Ghereș et al., 2013). Several factors influence the variability characteristics, the most important being soil type, soil compaction, moisture, non-uniformity, texture, and structure of the processed soil, as well as certain variations occurring at the drive wheels and articulation points of the aggregate. These factors have a more pronounced effect on aggregates with high-powered tractors and at high working speeds (Abo et al., 2011; Biriș et al., 2017).

The variation in the working resistance of agricultural machines also leads to the tractor engine operating under unstable conditions. Depending on this variation and the engine load coefficient, power losses of up to 10-15% can occur. The load regime of the aggregate machines induces random dynamic processes in all aggregate components (Dobrescu, 1981; Md-Tahir et al., 2021).

The random nature of the engine torque further affects the tractor's traction characteristics. A negative impact can be observed on the adhesion force and the slippage of the driving wheels. At equal traction forces, higher dispersion in their value leads to increased tractor slippage. Additionally, when the frequency of traction resistance variation is high, significant power losses occur due to slippage (Md-Tahir et al., 2021; McKyes, 1985). The traction resistance value of agricultural machines considered in calculations is the average value obtained from statistical processing of traction diagrams recorded during operation (Trendafilov et al., 2023; Varani et al., 2023). As the working speed increases, the working resistance of agricultural machines also increases. The rate of this increase depends on the type of working parts of the machine and the nature of the working process (Cardei et al., 2023).

It is imperative to determine the optimal operating parameters for agricultural implements designed for seedbed preparation, ensuring full utilization of the tractor engine's power and operating the implement at maximum working capacity, thereby achieving an optimal power balance (Legay, 1988; Vlăduț et al., 2018). Currently, this can be accomplished using analytical and numerical calculation algorithms, which can be implemented on modern agricultural tractors and are presented within this study (Vlăduțoiu et al., 2017; Simionescu et al., 1995).

The main objective of the paper is to determine the optimal operational parameters of a plowing aggregate composed of a 180 HP tractor and a 5-moldboard plow, specifically: v - working speed and B - working width, which ensure the full utilization of the tractor engine's power and the use of the aggregate at its maximum working capacity. As will be further shown, the power balance equation can be used as an objective function for optimizing the power balance.

MATERIALS AND METHODS

The study presented in this paper was conducted for an aggregate consisting of a 180 HP tractor (A 1800-A) and a variable working width plough with 5 moldboards (PP5VM), designed to perform plowing operations on flat terrain or slopes with a maximum inclination of 6° (figure 1).

Fig. 1 - The 180 HP tractor and a plough with variable working width with 5 moldboards

The aggregate requires power for movement and power for performing the plowing operation. The tractor's drive wheels generate the power necessary to operate the aggregate. As a constraint, the coefficient of utilization of travel time, τ_d , can be considered, knowing that its level is proportional to the working capacity of the aggregate (Dobrescu, 1981).

The power balance of a plowing aggregate can be expressed by the following equation:

$$P_M \cdot \tau_M = \frac{f_l \cdot G \cdot v + f_v \cdot G \cdot v^2 + k \cdot a \cdot B \cdot v + \varepsilon \cdot a \cdot B \cdot v^3}{\eta_T \cdot (1 - \delta_p)} \quad (1)$$

where: P_M - is the power developed by the engine, (W); η_M - the engine power utilization coefficient, η_p - the efficiency of the transmission at the power take-off and the driving wheels; f_l - proportionality coefficient; f_v - coefficient of resistance increase due to speed growth, (s/m); δ_p - tractor slippage; G - the weight of the aggregate, (N); v - the working speed (m/s); B - the working width, (m); a - the working depth, (m); k - the resistance to deformation and crumbling of the soil furrow, (N/m²); ε - the coefficient characterizing the shape of the crown and the properties of the soil, (N·s²/m⁴).

The terms in the first fraction of equation (1) represent the power required for moving the aggregate, while the terms in the second fraction represent the power required for plowing. If the coefficient k is determined without considering the friction between the working parts and the furrow, then the last two terms correspond to Goriacichin's formula (Cardei et al., 2023). These frictions are accounted for when determining the coefficients f_l and f_v .

If it is considered that there is a relationship between the weight of the aggregate and the working width in the form of $G_B = \alpha \cdot B$, where α is the specific weight of the aggregate per working width, (N/m), the objective function becomes:

$$P_M \cdot \eta_M \cdot \eta_T \cdot (1 - \delta_p) = f_l \cdot \alpha \cdot B \cdot v + f_v \cdot \alpha \cdot B \cdot v^2 + k \cdot a \cdot B \cdot v + \varepsilon \cdot a \cdot B \cdot v^3 \quad (2)$$

The optimal parameters B and v are those that ensure maximum productivity at the engine power level. Since the technical productivity of plowing aggregates is related to the level of the time utilization coefficient of travel, τ_d , this constitutes the constraint:

$$\frac{v_g \cdot L}{v_g \cdot L + v \cdot (\Omega + m_l \cdot B)} - \tau_d = 0 \quad (3)$$

The optimal solution can be found using the Lagrange multiplier and the constraint (Simionescu et al., 1995):

$$\begin{cases} \frac{\partial P_M}{\partial v} + \lambda \cdot \frac{\partial \tau_d}{\partial v} = 0 \\ \frac{\partial P_M}{\partial B} + \lambda \cdot \frac{\partial \tau_d}{\partial B} = 0 \end{cases} \quad (4)$$

and the constraint:

$$\frac{m}{m + v \cdot (\Omega + m_l \cdot B)} - \tau_d = 0 \quad (5)$$

in which m and m_l are operating parameters dependent on the idle travel speed of the aggregate (v_g), the plot length (L), the length of the path travelled without working (S_g), the plot width (C), ($m = v_g \cdot L$, $m_l = S_g \cdot C$).

The terms in the system of equations (4) are determined using (Dobrescu, 1981):

$$\frac{\partial P_M}{\partial v} = f_l \cdot \alpha \cdot B + 2 \cdot f_v \cdot \alpha \cdot B \cdot v + k \cdot a \cdot B + 3 \cdot \varepsilon \cdot a \cdot B \cdot v^2 \quad (6)$$

$$\frac{\partial P_M}{\partial B} = f_l \cdot \alpha \cdot v + f_v \cdot \alpha \cdot v^2 + k \cdot a \cdot v + \varepsilon \cdot a \cdot v^3 \quad (7)$$

$$\frac{\partial \tau_d}{\partial v} = \frac{m \cdot (\Omega + m_l \cdot B)}{[m + v \cdot (\Omega + m_l \cdot B)]^2} \quad (8)$$

$$\frac{\partial \tau_d}{\partial B} = \frac{m_l \cdot m \cdot v}{[m + v \cdot (\Omega + m_l \cdot B)]^2} \quad (9)$$

A system of three equations with three unknowns is obtained:

$$\begin{cases} f_l \cdot \alpha \cdot B + 2 \cdot f_v \cdot \alpha \cdot B \cdot v + k \cdot a \cdot B + 3 \cdot \varepsilon \cdot a \cdot B \cdot v^2 - \lambda \cdot \frac{m \cdot (\Omega + m_l \cdot B)}{[m + v \cdot (\Omega + m_l \cdot B)]^2} = 0 \\ f_l \cdot \alpha \cdot v + f_v \cdot \alpha \cdot v^2 + k \cdot a \cdot v + \varepsilon \cdot a \cdot v^3 - \lambda \cdot \frac{m_l \cdot m \cdot v}{[m + v \cdot (\Omega + m_l \cdot B)]^2} = 0 \\ \frac{m}{m + v \cdot (\Omega + m_l \cdot B)} - \tau_d = 0 \end{cases} \quad (10)$$

The variable λ is eliminated by equating its value from the first equation of the system (10) with the value obtained from the second equation, resulting in:

$$3 \cdot v^2 + 2 \cdot v \cdot \left[\frac{m \cdot (1 - \tau_d)}{\tau_d \cdot \Omega} - \frac{\alpha \cdot f_v}{\varepsilon \cdot a} \right] + \frac{f_1 \cdot (f_v \cdot \alpha + k \cdot a \cdot \Omega)}{\varepsilon \cdot a \cdot \Omega} = 0 \tag{11}$$

from which the expression for the optimal speed is obtained:

$$v_{opt} = \frac{1}{3} \cdot \left[\frac{m \cdot (1 - \tau_d)}{\tau_d \cdot \Omega} - \frac{\alpha \cdot f_v}{\varepsilon \cdot a} + \sqrt{\left(\frac{\alpha \cdot f_v}{\varepsilon \cdot a} \right)^2 + \left(\frac{m \cdot (1 - \tau_d)}{\tau_d \cdot \Omega} \right)^2 + \frac{\alpha \cdot f_v \cdot m \cdot (1 - \tau_d)}{\varepsilon \cdot a \cdot \tau_d \cdot \Omega} - \frac{3 \cdot (\alpha \cdot f_1 + k \cdot a)}{\varepsilon \cdot a}} \right] \tag{12}$$

From the third equation of the system (10), it results:

$$B_{opt} = \frac{m \cdot (1 - \tau_d) - \tau_d \cdot \Omega \cdot v_{opt}}{\tau_d \cdot m_1 \cdot v_{opt}} \tag{13}$$

The productivity of the aggregate is:

$$U_{\tau_d} = v_{opt} \cdot B_{opt} \cdot \tau_d \tag{14}$$

The power required to operate the aggregate is calculated using the following equation:

$$P_{min} = f_1 \cdot \alpha \cdot B_{opt} \cdot v_{opt} + f_v \cdot v^2 \cdot \alpha \cdot B_{opt} + B_{opt} \cdot v_{opt} \cdot a \cdot k + \varepsilon \cdot a \cdot B_{opt} \cdot v_{opt}^3 \tag{15}$$

The above calculation can be applied when studying the parameters of a new implement or when forecasting the development of plowing aggregates.

For existing aggregates, the relationship between the weight of the aggregate and its components is established using the following formula:

$$G = G_0 + G_B = G_0 + \alpha \cdot B \tag{16}$$

where: G_0 - represents the constant weight of the aggregate (the weight of the tractor and the carrying device), and α - is the specific weight of the part that changes with the working width B .

In this case, the mathematical model takes the form of:

$$P_M \cdot \eta_M \cdot \eta_T \cdot (1 - \delta) = f_1 \cdot G_0 \cdot v + f_1 \cdot \alpha \cdot B \cdot v + f_v \cdot G_0 \cdot v^2 + f_v \cdot \alpha \cdot B \cdot v^2 + k \cdot a \cdot B \cdot v + \varepsilon \cdot a \cdot B \cdot v^3 \tag{17}$$

and:

$$\frac{m}{m + v \cdot (\Omega + m_1 \cdot B)} - \tau_d = 0 \tag{18}$$

By deriving the objective function and the constraints, the following is obtained:

$$\left\{ \begin{aligned} \frac{\partial P_M}{\partial v} &= f_1 \cdot (G_0 + \alpha \cdot B) + 2 \cdot f_v \cdot v \cdot (G_0 + \alpha \cdot B) + k \cdot a \cdot B + 3 \cdot \varepsilon \cdot a \cdot B \cdot v^2 \\ \frac{\partial P_M}{\partial B} &= f_1 \cdot \alpha \cdot v + f_v \cdot \alpha \cdot v^2 + k \cdot a \cdot v + \varepsilon \cdot a \cdot v^3 \\ \frac{\partial \tau_d}{\partial v} &= \frac{m \cdot (\Omega + m_1 \cdot B)}{[m + v \cdot (\Omega + m_1 \cdot B)]^2} \\ \frac{\partial \tau_d}{\partial B} &= \frac{m_1 \cdot m \cdot v}{[m + v \cdot (\Omega + m_1 \cdot B)]^2} \end{aligned} \right. \tag{19}$$

A system of three equations with three unknowns is formulated using the coefficient λ :

$$\left\{ \begin{aligned} f_1 \cdot G + f_1 \cdot \alpha \cdot B + 2 \cdot f_v \cdot v \cdot G + 2 \cdot f_v \cdot \alpha \cdot B \cdot v + k \cdot a \cdot B + 3 \cdot \varepsilon \cdot a \cdot B \cdot v^2 - \lambda \cdot \frac{m \cdot (\Omega + m_1 \cdot B)}{[m + v \cdot (\Omega + m_1 \cdot B)]^2} &= 0 \\ f_1 \cdot \alpha \cdot v + f_v \cdot \alpha \cdot v^2 + k \cdot a \cdot v + \varepsilon \cdot a \cdot v^3 - \lambda \cdot \frac{[m + v \cdot (\Omega + m_1 \cdot B)]^2}{m_1 \cdot m \cdot v} &= 0 \\ \frac{m}{m + v \cdot (\Omega + m_1 \cdot B)} - \tau_d &= 0 \end{aligned} \right. \tag{20}$$

By eliminating the variable λ and performing the simplifications, the following is obtained:

$$f_1 \cdot \alpha \cdot \Omega + f_v \cdot \alpha \cdot v \cdot \Omega + k \cdot a \cdot \Omega \cdot v^2 - f_1 \cdot G \cdot m_1 - 2 \cdot f_v \cdot v \cdot \Omega \cdot B \cdot m_1 - 2 \cdot \varepsilon \cdot a \cdot B \cdot v^2 \cdot m_1 = 0 \tag{21}$$

If B is replaced in the last equation of the system (20), the result is:

$$3 \cdot v^2 + 2 \cdot v \cdot \left[\frac{f_v \cdot (\alpha \cdot \Omega \cdot G \cdot m_1)}{\varepsilon \cdot a \cdot \Omega} - \frac{m \cdot (1 - \tau_d)}{\tau_d \cdot \Omega} \right] + \frac{f_1 \cdot (\alpha \cdot \Omega \cdot G \cdot m_1 + k \cdot a \cdot \Omega)}{\varepsilon \cdot a \cdot \Omega} - \frac{f_v \cdot \alpha \cdot m_1 \cdot (1 - \tau_d)}{\varepsilon \cdot a \cdot \tau_d \cdot \Omega} = 0 \tag{22}$$

from which the expression for the optimal speed results:

$$v_{opt} = \frac{1}{3} \cdot \left[\frac{m \cdot (1 - \tau_d)}{\tau_d \cdot \Omega} - \frac{f_v \cdot (\alpha \cdot \Omega \cdot m_1 \cdot G)}{\varepsilon \cdot a \cdot \Omega} + \sqrt{\left(\frac{m \cdot (1 - \tau_d)}{\tau_d \cdot \Omega} \right)^2 + \frac{f_v \cdot m \cdot (1 - \tau_d) \cdot (\alpha \cdot \Omega + 2 \cdot m_1 \cdot G)}{\varepsilon \cdot a \cdot \tau_d \cdot \Omega^2} \left(\frac{\alpha \cdot f_v}{\varepsilon \cdot a} \right)^2 - \frac{3 \cdot f_1 \cdot (\alpha \cdot \Omega \cdot m_1 \cdot G) + 3 \cdot k \cdot a \cdot \Omega}{\varepsilon \cdot a \cdot \Omega}} \right] \tag{23}$$

The optimal working width, B_{opt} , is determined by the relationship of the maximum working capacity of the aggregate:

$$B_{opt} = \frac{m \cdot (1 - \tau_d) - \tau_d \cdot \Omega \cdot v_{opt}}{\tau_d \cdot m_1 \cdot v_{opt}} \tag{24}$$

If the maximum loading of the tractor is desired, the following relation (25) results:

$$B_{opt} = \frac{P_a \cdot f_l \cdot G_0 \cdot v_{opt} \cdot f_v \cdot G_0 \cdot v_{opt}^2}{f_l \cdot a \cdot v_{opt} + f_v \cdot a \cdot v_{opt}^2 + k \cdot a \cdot v_{opt} + \varepsilon \cdot a \cdot v_{opt}^3} \quad (m) \quad (25)$$

If in equation (23) of the working speed, $G_B = \alpha \cdot B = 0$ is assumed, equation (12) is obtained. If it is assumed that the weight of the entire aggregate is constant, i.e., $\alpha = 0$, the following results:

$$v_{opt} = \frac{1}{3} \cdot \left[\frac{m \cdot (1 - \tau_d)}{\tau_d \cdot \Omega} + \frac{f_v \cdot m_l \cdot G}{\varepsilon \cdot a \cdot \Omega} + \sqrt{\left(\frac{m_l \cdot G \cdot f_v}{\varepsilon \cdot a \cdot \Omega} \right)^2 + \left(\frac{m \cdot (1 - \tau_d)}{\tau_d \cdot \Omega} \right)^2} + \frac{2 \cdot m_l \cdot G \cdot f_v \cdot m \cdot (1 - \tau_d)}{\varepsilon \cdot a \cdot \tau_d \cdot \Omega^2} + \frac{3 \cdot f_v \cdot m_l \cdot G \cdot 3 \cdot k \cdot a \cdot \Omega}{\varepsilon \cdot a \cdot \Omega} \right] \quad (26)$$

By applying equation (25) and the corresponding computational algorithm, a Python code was developed, allowing the calculation and plotting of the optimal values for the plow's total working width (figure 2.a), as well as the 3D generation of this dependency on the working speed and the utilization coefficient of the displacement time (τ_d) (figure 2.b).

Fig. 3 – Python code for determining the traction force of a plow with 5 plowshares

For the plowing work, the traction resistance force of the plow can be estimated using the following relation:

$$R_p = k_0 \cdot a \cdot B_l \quad [N] \quad (27)$$

in which: k_0 represents the specific soil resistance to plowing, $(2 - 10) \cdot 10^4$ [N/m²]; a is the working depth [m]; B_l is the total working width of the plow [m].

In figure 3.a, a Python code is presented that allows the calculation and graphical plotting of the dependency of the plow's draft resistance on the working depth for different working speeds, and in figure 3.b, the same dependency is shown, but for various total working widths of a plow with 5 plowshares and a variable working width.

In figure 4.a, a Python code is presented that allows the calculation and 3D plotting of the plow's traction resistance as a function of working depth and working speed for a single soil type, while in figure 4.b, the same dependence is shown for four soil types with different specific resistances to tillage in the case of a plow with 5 plowshares and a variable working width.

<pre>import numpy as np import matplotlib.pyplot as plt from mpl_toolkits.mplot3d import Axes3D G_pl = 30000 # N f_pl = 0.35 k_0 = 50000 # N/m^2 eps = 1000 # N/m^3 B = 1.5 # Constanta B (poți ajusta această valoare) v_pl_values = np.linspace(0.5, 3.5, 100) # Interval pentru v_pl a_values = np.linspace(0.1, 0.3, 50) # Interval pentru a V_PL, A = np.meshgrid(v_pl_values, a_values) R_pl_values = G_pl * f_pl + k_0 * A * B + eps * A * B * (V_PL)**2 fig = plt.figure(figsize=(10, 7)) ax = fig.add_subplot(111, projection='3d') surf = ax.plot_surface(V_PL, A, R_pl_values, cmap='viridis') cbar = fig.colorbar(surf, ax=ax, shrink=0.5, aspect=10) cbar.set_label("\$R_{pl}\$ (N)") ax.set_title("3D Surface Plot of \$R_{pl}\$ as function of \$v_{pl}\$ and \$a\$") ax.set_xlabel("\$v_{pl}\$ (m/s)") ax.set_ylabel("\$a\$ (m)") ax.set_zlabel("\$R_{pl}\$ (N)") plt.tight_layout() plt.show()</pre>	<pre>import numpy as np import matplotlib.pyplot as plt from mpl_toolkits.mplot3d import Axes3D from matplotlib.lines import Line2D import matplotlib.colors as colors G_pl = 30000 # N f_pl = 0.35 eps = 1000 # N/m^3 B = 1 # Constanta B v_pl_values = np.linspace(0.5, 3.5, 100) a_values = np.linspace(0.1, 0.3, 50) V_PL, A = np.meshgrid(v_pl_values, a_values) k_0_values = [30000, 50000, 70000, 90000] all_R_pl_values = [] for k_0 in k_0_values: R_pl = G_pl * f_pl + k_0 * A * B + eps * A * B * (V_PL)**2 all_R_pl_values.append(R_pl) min_val = min(np.min(R) for R in all_R_pl_values) max_val = max(np.max(R) for R in all_R_pl_values) fig = plt.figure(figsize=(12, 9)) ax = fig.add_subplot(111, projection='3d') norm = colors.Normalize(vmin=min_val, vmax=max_val) cmap = plt.get_cmap('viridis') surf_list = [] for i, k_0 in enumerate(k_0_values): R_pl_values = G_pl * f_pl + k_0 * A * B + eps * A * B * (V_PL)**2 surf = ax.plot_surface(V_PL, A, R_pl_values, cmap=cmap, alpha=0.6, norm=norm) surf_list.append(surf) custom_lines = [Line2D([0], [0], color=cmap(i / len(k_0_values)-1), lw=4) for i in range(len(k_0_values))] ax.legend(custom_lines, ["\$k_0\$ (N/m^2)" for k_0 in k_0_values], title="Values of \$k_0\$") cbar = fig.colorbar(surf_list[0], ax=ax, shrink=0.5, aspect=10) cbar.set_label("\$R_{pl}\$ (N)") ax.set_title("3D Surface Plot of \$R_{pl}\$ as function of \$v_{pl}\$ and \$a\$ for different \$k_0\$") ax.set_xlabel("\$v_{pl}\$ (m/s)") ax.set_ylabel("\$a\$ (m)") ax.set_zlabel("\$R_{pl}\$ (N)") plt.tight_layout() plt.show()</pre>
a)	b)

Fig. 4 – Python code for determining the 3D variation of the draft force of a plow with 5 plowshares

The power required to pull the plow during the plowing process is calculated:

$$P_t = k_0 \cdot a \cdot B_l \cdot v_l \quad [W] \quad (28)$$

where v_l represents the working speed of the tillage aggregate [m/s].

The energy consumption per unit of processed surface is calculated using the following relation:

$$E_{ha} = \frac{P_t}{S_h} \quad [Wh/ha] \quad (29)$$

where S_h represents the working capacity of the plowing aggregate [ha/h].

In figure 5.a, a Python code is presented which, based on relation (29), allows for the calculation and graphical plotting of the dependence of energy consumption per unit of worked surface for a plow with 5 moldboards with variable working width, for different working depths according to the specific resistance to plowing, and in figure 5.b, the same dependence is calculated and plotted in 3D.

<pre>import numpy as np import matplotlib.pyplot as plt B_l = 1.5 v_l = 2 W_h = 0.25 k_0_values = np.linspace(2e4, 10e4, 500) a_values = [0.15, 0.175, 0.2, 0.215, 0.25, 0.275, 0.3] plt.figure(figsize=(8, 6)) for a in a_values: P_t = k_0_values * a * B_l * v_l E_ha = P_t / W_h plt.plot(k_0_values, E_ha, label=f"a = {a}") plt.title("Graph of \$E_{ha}\$ vs \$k_0\$ for Different \$a\$ values") plt.xlabel("\$k_0\$ [N/m^2]") plt.ylabel("\$E_{ha}\$ [Wh/ha]") plt.legend() plt.grid(True) plt.show()</pre>	<pre>import numpy as np import matplotlib.pyplot as plt from mpl_toolkits.mplot3d import Axes3D B_l = 1.5 v_l = 2 W_h = 0.25 k_0_values = np.linspace(2e4, 10e4, 500) a_values = np.linspace(0.15, 0.3, 6) K0, A = np.meshgrid(k_0_values, a_values) E_ha = (K0 * A * B_l * v_l) / W_h fig = plt.figure(figsize=(10, 8)) ax = fig.add_subplot(111, projection='3d') surf = ax.plot_surface(K0, A, E_ha, cmap='viridis') ax.set_title("Graph of \$E_{ha}\$ vs \$k_0\$ and \$a\$") ax.set_xlabel("\$k_0\$ [N/m^2]") ax.set_ylabel("\$a\$ [m]") ax.set_zlabel("\$E_{ha}\$ [Wh/ha]") cbar = fig.colorbar(surf, ax=ax, shrink=0.5, aspect=5) cbar.set_label("\$E_{ha}\$ [Wh/ha]") plt.show()</pre>

RESULTS

Through classical analytical calculation, applying the mathematical models embodied in equations (25) and (26), for a plowing unit operating under the conditions given in the first column of Table 1, the optimal parameters are obtained, which are found in the second column of the same table.

Fig. 6 – Graphical representation of the dependency of the optimal plowing width on the working speed and the travel time utilization coefficient for a plow with 5 moldboards

Using the calculation algorithms and Python codes presented in figure 2, the optimal values for the plow's total working width were calculated and plotted (figure 6.a), as well as the 3D variant of this dependency on working speed and the travel time utilization coefficient (τ_d) (figure 6.b). In addition, figure 6.c shows the 3D graph of the dependency of the optimal working width on the working speed - with values in the range of 0.5 - 2.5 m/s - and on the travel time utilization coefficient - with values in the range of 0.7–0.9.

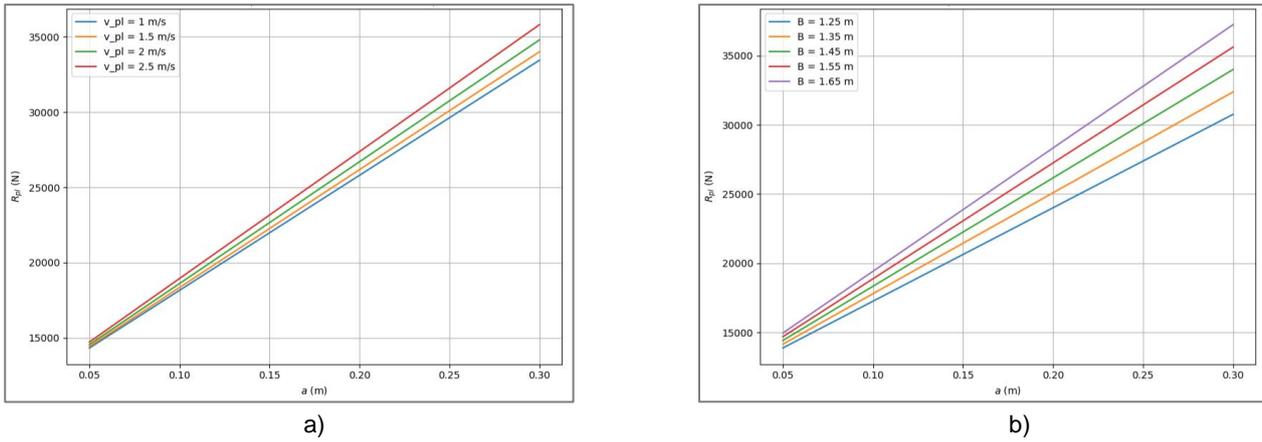

Fig. 7 – Graphical representation of the dependence of the draft force of a plow with 5 moldboards at working depth for different working speeds and different total working widths

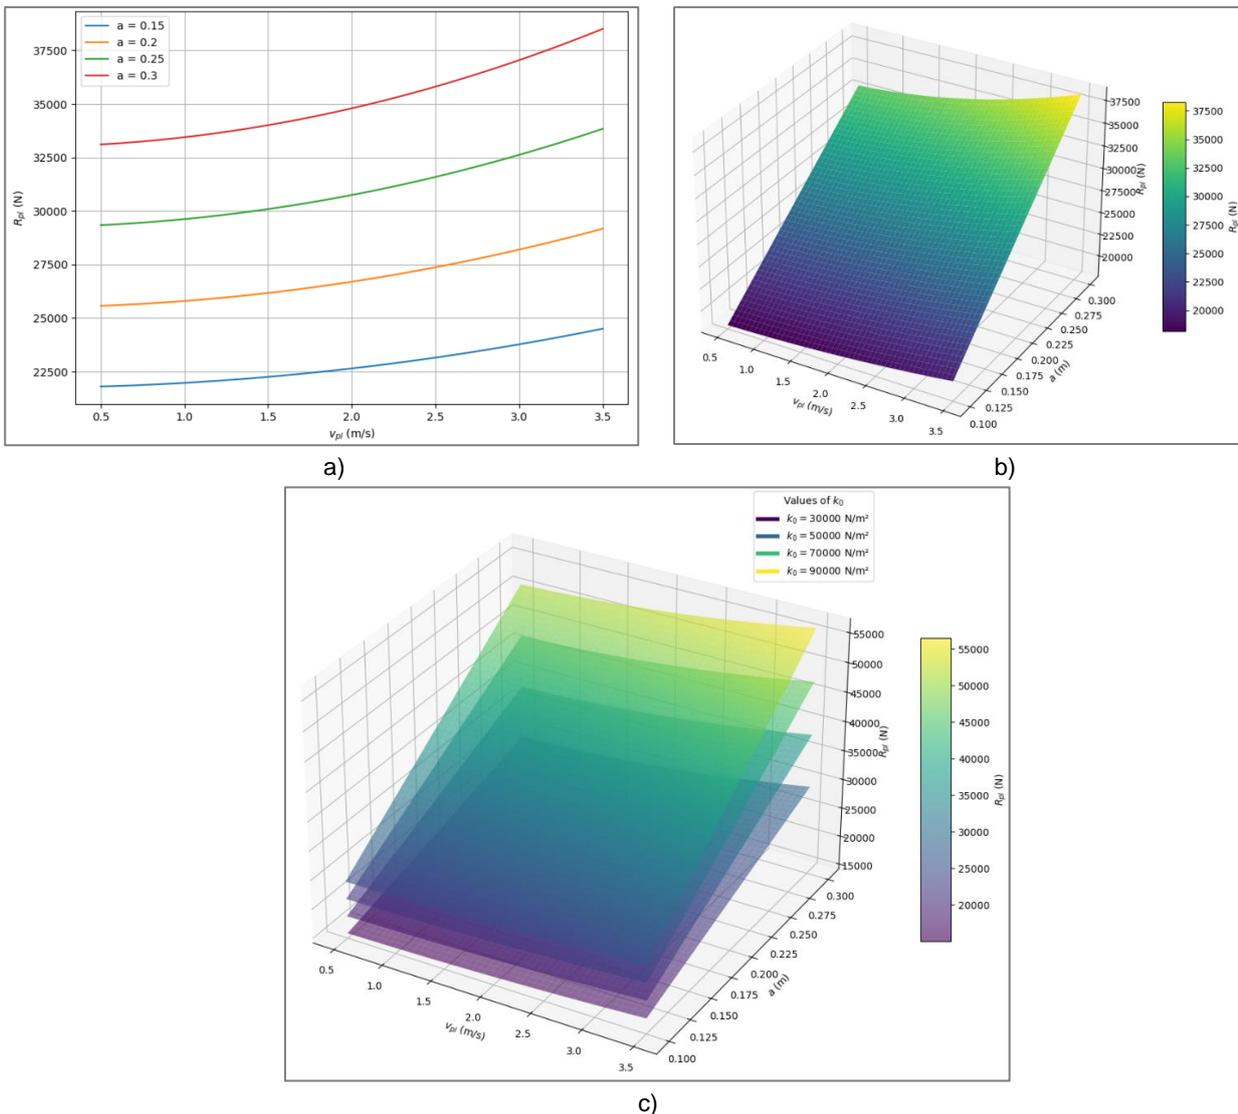

Fig. 8 – Graphical representation of the dependency of the traction force of a plow with 5 plowshares on working speed for various working depths and operating speeds

Using the calculation algorithms and Python codes presented in figure 3.a and figure 3.b, the dependence of the plow's draft resistance on working depth was calculated and plotted for different working speeds (figure 7.a), as well as the same dependence for various total working widths of a 5-furrow plow with variable working width (figure 7.b). It is easy to observe that the plow's draft resistance increases with the increase in working depth, for the different working speeds and various total working widths.

The draft force of the plow as its traveling speed increases, with the dependency $R_{pl}=f(v_{pl})$ being nonlinear (figure 8.a). The increase in draft force is smaller at lower speeds (0.5–2 m/s) and much more significant at higher working speeds (2–3.5 m/s).

In figure 8.b, the 3D graphical representation of the plows's draft force is shown, with working depth and working speed as the independent parameters, for a single type of soil. This was generated using the calculation algorithm and the Python program presented in figure 4.a. In figure 8.c, the same dependency is displayed, but for four different types of soil, using the calculation algorithm and Python code presented in figure 4.b.

Using the computational algorithms and the Python code presented in figure 5.a, the dependence based on relation (29) of the energy consumption per unit worked area for a plow with 5 moldboards of variable working width has been calculated and plotted, for different working depths as a function of the specific tillage resistance (different soil types) (figure 9.a). In figure 9.b, the 3D dependence of the energy consumption per unit worked area is presented as a function of the independent variables: working depth and specific tillage resistance, calculated and generated using the Python code presented in figure 5.b. The energy consumption per unit worked area for a plow with 5 moldboards of variable working width increases with an increasing working depth. The soil category and its physico-mechanical properties (specific tillage resistance) have a significant influence on the mechanical energy consumption.

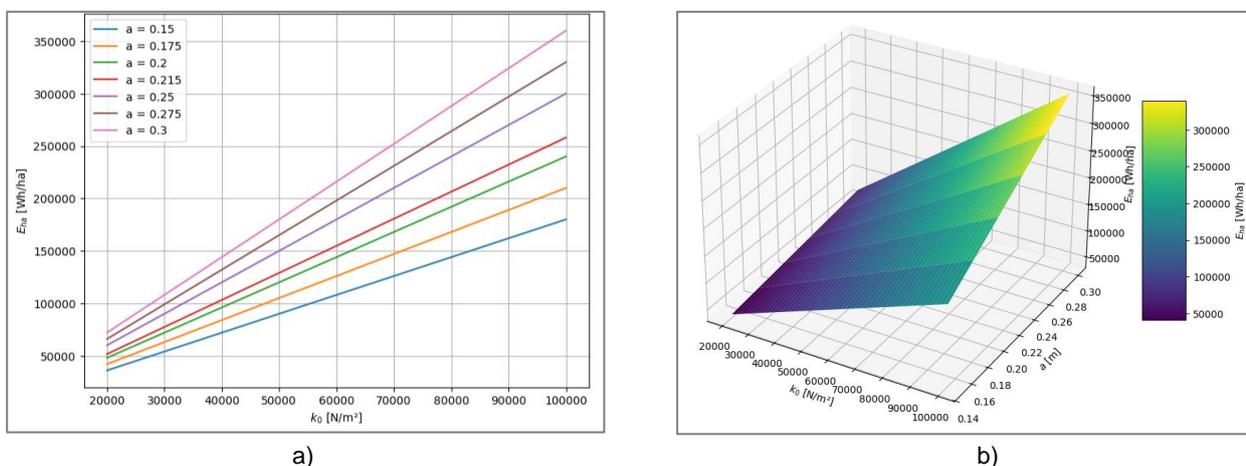

Fig. 9 – Graphical representation of the dependency of the traction force of a plow with 5 plowshares on working speed for different working depths and operating speeds

CONCLUSIONS

Optimal operation of the implements used for plowing is essential for efficient resource use and cost reduction. Fully utilizing the tractor's engine power and operating the plowing implement at its maximum capacity enables an optimal power balance. The optimal operating regime can be determined through numerical algorithms based on Lagrange multipliers, using computing programs (Python code in this case). To achieve maximum productivity at the engine power level, it is necessary to calculate the optimal working speed and optimal working width, depending on the coefficient of utilization of the plowing implement's transit time.

Keywords: agricultural machinery, tobacco leaf picking, bionic, low damage

ABSTRACT

To address the issues of high damage rate and low harvesting efficiency during the tobacco leaf picking process, this study analyzed the separation mechanics of tobacco stems and leaves. A low-damage bionic picking device was designed by imitating the manual method of harvesting tobacco leaves. Based on theoretical analysis of the device and its key components, the structure and parameters of the complete system were determined. The picking process was simulated using ADAMS software, focusing on the contact force between the rigid and flexible components at various picking rod speeds. This analysis yielded the optimal combination of structural and operational parameters. Field experiments were subsequently conducted, and a response surface mathematical model was established using Design-Expert software to evaluate the relationship between key factors and performance indicators. The optimal parameter combination was found to be: a picking rod speed of 0.8 m/s, a device inclination angle of 30°, a picking rod spacing of 90 mm, and a forward speed of 0.69 m/s. Under these conditions, the tobacco leaf damage rate was minimized, meeting the requirements for low-damage harvesting. Further experimental validation showed consistency with simulation results, confirming the model's reliability and demonstrating the practical feasibility of the device for tobacco field operations. This provides a valuable reference for the development of low-damage tobacco leaf harvesting equipment.

摘要

为解决目前烟叶采摘装置在采收过程中烟叶破损率高、采净率低的问题，对烟叶的茎叶分离进行分析，模仿人手采摘烟叶方式，设计了一种低损伤烟叶仿生采摘装置。通过对该装置及关键部位的理论分析，确定整体装置的结构和参数。利用 ADAMS 软件对烟叶采摘过程进行仿真，分析不同采摘手速度和茎秆送料速度下刚性结构与柔性缓冲结构之间的接触力，得到了最佳参数组合。最后进行了田间试验，使用 Design-Expert 软件，建立各因素与指标的响应面数学模型，分析了各因素与评价指标之间的关系，得到参数优化组合，采摘杆转速为 0.8m/s，装置倾斜角为 30°，采摘指间距为 90mm，前进速度为 0.69m/s，该组合下烟叶破损率最低，满足低损伤采摘的条件。结果基本与仿真结果一致，证明了模型的可靠性。最后进行了田间试验，试验结果表明此装置在实际烟叶田间采摘工作的可行性，为低损伤烟叶收获装置的研发提供了参考。

INTRODUCTION

In the tobacco harvesting process, picking is the most fundamental and challenging operation. The quality of harvested tobacco leaves directly influences the effectiveness of post-harvest grading. As the core component of the harvesting machinery, the picking device plays a crucial role. Therefore, the design of the tobacco leaf picking device is key to ensuring high-quality tobacco leaf harvesting.

Early tobacco leaf harvesting devices have been categorized into three primary types (Papusha S.K, 2022). The first type, a serrated harvesting device, employs a saw-toothed blade to sever the entire tobacco stalk at its base, achieving high operational efficiency. The second type, a chain-and-hole harvesting device, incorporates a series of spaced chains with apertures sized to accommodate the stalk diameter. During operation, the stalk is guided through these apertures, thereby completing the detachment process. Both serrated and chain-and-hole methods are exclusively suitable for fully matured tobacco plants. The third and most widely utilized type is the mechanical striking harvester, which induces leaf detachment by applying downward force on the petiole through controlled mechanical impact. Although these methods demonstrate operational efficiency, they exhibit elevated leaf damage rates (12–18%) and variable collection efficiency (67–82% across field trials). Further design refinements are therefore required to mitigate these limitations, particularly through enhanced stalk-gripping mechanisms and impact force modulation.

With the continuous advancement of modern agricultural technology, the mechanization and intelligentization of tobacco harvesting have become inevitable trends to enhance production efficiency and quality. In recent years, significant achievements have been made by scholars both domestically and internationally in the field of tobacco harvesting machinery and intelligent recognition. Sun C. (2024) and colleagues designed and tested key components of a comb-type tobacco harvester, providing valuable insights for optimizing tobacco harvesting equipment. Liu J. (2012) and Yu J. (2019) leveraged virtual manufacturing technology to design and simulate a tobacco harvesting system, further advancing the intelligence and automation of harvesting processes. Zhu H. (2014) developed a floating harvesting platform based on the advantages and disadvantages of tobacco leaf harvesting processes. This platform enables selective harvesting by determining the relative position of leaves and the harvesting device using sensor rods, while hydraulic systems control the platform's lateral movement and elevation. Gan W. (2018) and colleagues designed a tobacco leaf harvesting device featuring left and right curved blades connected via a rotating axis. This design effectively harvests mature leaves while protecting unripe ones, ensuring efficient and low-damage harvesting.

Bionic picking machinery is designed and improved by studying biological mechanisms and imitating the shape, structure, or function of organisms. Currently, bionic mechanical design has been widely applied in fields such as sensors and new materials, with numerous studies (Luo, Y. et al., 2024.) published in this area. Beyond developing cutting end effectors with low cutting resistance, bionic optimization of these effectors is achieved by mimicking the fingers and claws of natural organisms. Research in this field primarily focuses on crops such as fruits (Malekzadeh, 2019; He Z., 2022; Kurbah F., 2022), tea (Kurbah F., 2022; Nie Y.C., 2022) and vegetables (Du Z., 2021), with tomatoes (Gao J. et al., 2022; Gao J. et al., 2024; Guo T. et al., 2022; Hou Z. et al., 2021; Wang M. et al., 2022; Zhao L. et al., 2012) being the most extensively studied. For high-stalk crops like corn and tobacco, scholars have conducted significant research on bionic ear-breaking mechanisms for corn (Xu W.T. et al., 2018; Zhang L.P. et al., 2015). A notable example is the work of Zhang Liping and Chen Meizhou (Zhang L.P. et al., 2015. Chen M.Z. et al., 2018), who addressed issues such as high impurity rates in plate-type ear picking, gnawing in roller-type ear picking, and significant grain loss. They proposed a bionic ear-breaking hand-type mechanism for corn harvesting, providing valuable insights for the development of low-damage corn harvesting techniques. In contrast, research on bionic picking for tobacco leaves remains limited. Li Zhiguang (2016) designed a self-propelled intelligent bionic picking system for tobacco leaves. This system mimics the entire process of manual tobacco harvesting by controlling a bionic picking hand to perform actions such as extending, grasping, picking, releasing, and retracting, thereby reducing damage to both tobacco leaves and stems.

On the basis of drawing lessons from the existing automatic picking machinery of tobacco leaves and other crops, this paper intends to combine modern bionic technology, imitate the action of human hand picking, and apply force to tobacco leaves from top to bottom to make tobacco leaves fall. This paper verifies the possibility of low-loss harvesting of this bionic picking method, which can solve the problems of high crushing rate and low picking rate in the process of automatic picking of tobacco leaves, in order to provide theoretical basis and technical basis for low-damage automatic tobacco leaf picking technology.

ANALYSIS OF THE MANUAL HARVESTING PROCESS AND DESIGN OF BIONIC STRUCTURES

Analysis of Manual Harvesting Actions

Stem-leaf separation constitutes the initial critical stage in flue-cured tobacco harvesting. During mechanized operations, this process exhibits complex mechanical stress distributions due to heterogeneous stalk-foliage interactions.

Such dynamic force conditions frequently induce mechanical injuries to leaves, including surface abrasions, midrib fractures, and lamina tearing, as documented in field studies. Consequently, minimizing mechanical damage rates during automated stem-leaf separation has emerged as a pivotal technical challenge that must be resolved to enable fully mechanized tobacco production systems.

This paper analyzes the motion of manual tobacco leaf harvesting and designs a bionic harvesting device to achieve the purpose of reducing damage and increasing efficiency. Manual harvesting typically involves using the thumb and index finger (the "tiger mouth" position) to grip the leaf stem, pressing straight down until the leaf detaches from the stalk. The following Figure 1 is the manual harvesting process and the force diagram of tobacco leaves.

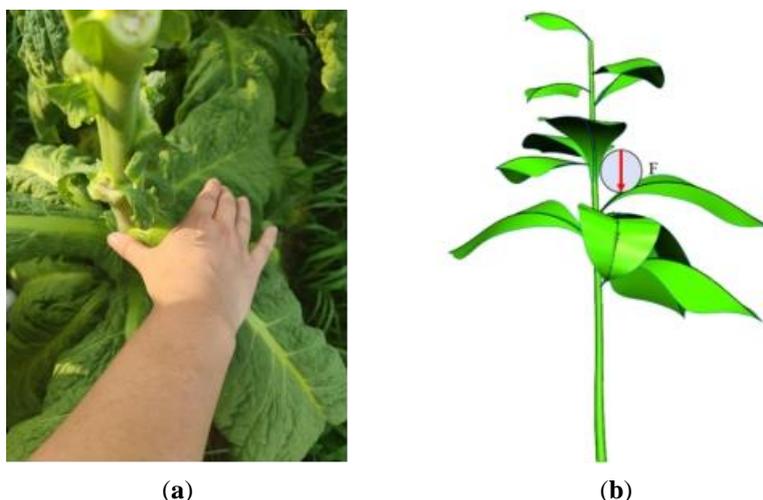

Fig. 1 - Manual harvesting action and force diagram of tobacco leaves
(a) Artificial harvesting method; (b) Harvesting force diagram.

Bionic Design Principles

The crucial part of the bionic tobacco leaf harvesting machine is the bionic picking rod, which acts as the executive mechanism to directly sever the leaves from the stem. The stability of the picking rod's operation directly impacts the performance of the harvester and the quality of the picked tobacco leaves. This study designs the bionic picking rod by mimicking the action of human fingers when picking tobacco leaves, considering that tobacco leaves grow in various directions around the stalk during their growth in the field. Auxiliary rods are therefore positioned vertically along the picking rod, and the two picking rods, in conjunction with the auxiliary rod, form a picking frame that ensures all leaves can be collected. The following Figure 2 is a bionic design.

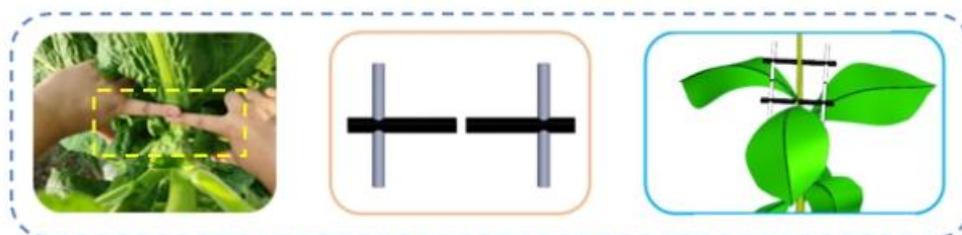

Fig. 2 - Bionic picking principle diagram

Design and Working Principle of Bionic Tobacco Leaf Harvesting Structure

The low-damage bionic tobacco leaf harvesting machine is structured vertically with a collection box at the top, followed by a transmission section, and a harvesting unit at the bottom, as shown in Figure 3. The harvesting unit consists of two oppositely positioned harvesting modules, with a gap reserved between them. The height and tilt angle of the harvesting unit are adjustable to accommodate tobacco plants of varying heights. The transmission section includes a series of rollers positioned below the harvesting unit and a conveyor belt that transports harvested leaves upward toward the collection box. The divider, designed in a triangular conical shape, is mounted at the front of the harvesting mechanism and positioned between two parallel bionic harvesting units, serving as the leading component of the entire apparatus.

This design can complete the layered mechanized picking of tobacco leaves, with low breakage rate and high harvesting efficiency. At the same time, it can greatly reduce the damage to tobacco plants and ensure the normal growth of tobacco plants in the future.

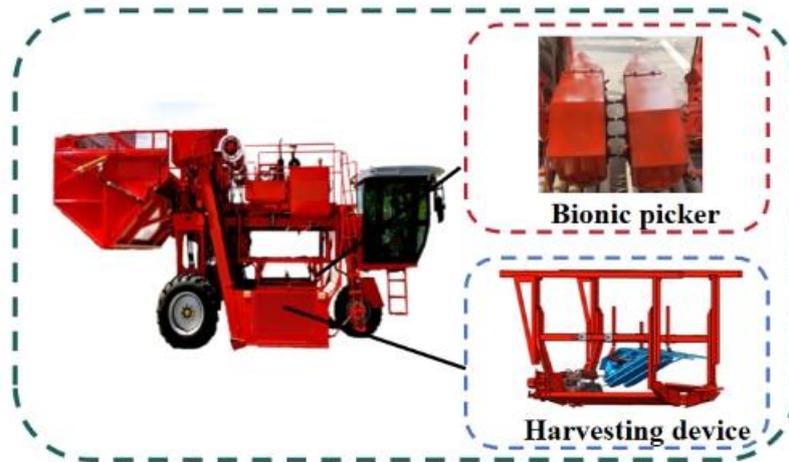

Fig. 3 - The overall structure of tobacco leaf harvester

Working Principle

When the tobacco leaf picking machine starts to harvest tobacco leaves, the tobacco plants are first introduced by the upper and lower pairs of dividers at the front end, and then the tobacco plants enter the bionic picking frame composed of picking rods and auxiliary rods on both sides. The picking frame is fixed on the chain and rotates around the picking frames on both sides, and the back end of the chain plane is tilted downward to ensure that the tobacco leaves within the preset height range can be harvested. The picking frame rotates downward and backward, and the picking machine moves forward. The petiole is subjected to a downward force. When the force is greater than the connection force between the tobacco leaf and the stem, the petiole breaks. After the tobacco leaves are removed, they fall on the conveyor belt below and are then transmitted to the collection box. The picking machine continues to move forward, and the flexible picking rod contacts and bends with the tobacco rod. The tobacco rod enters the next picking frame and carries out the tobacco leaf picking at the next height until the tobacco plant passes through all the picking frames to complete the tobacco leaf picking in the preset height range. The harvesting operation of the whole device imitates the action of rolling tobacco leaves down along the stem during manual picking through the motion synthesis of the picking frame and the whole machine, so as to realize the low-loss picking of tobacco leaves. The schematic diagram of the harvesting process is shown in Figure 4.

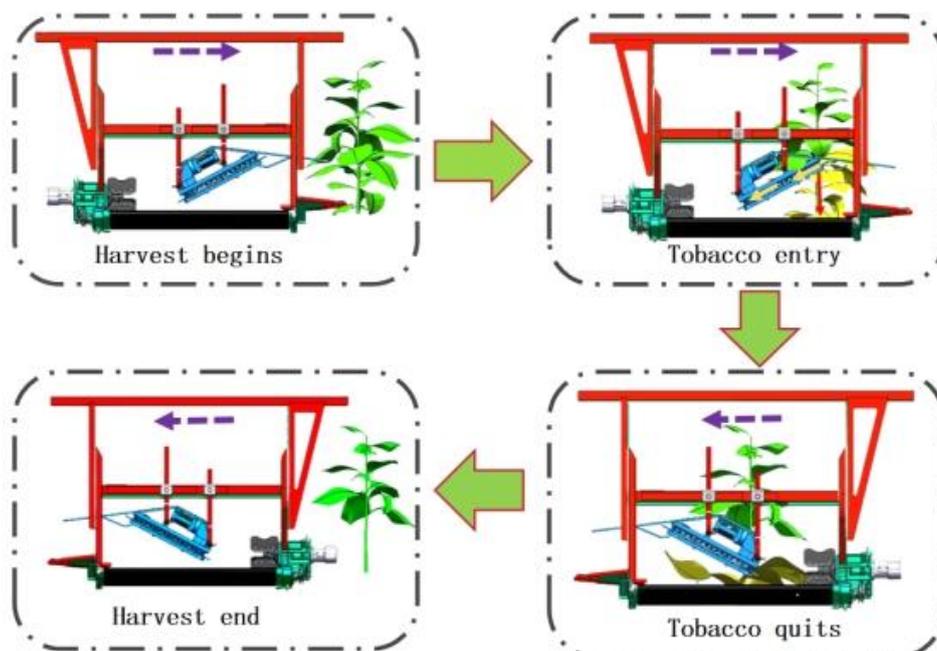

Fig. 4 - Tobacco leaf harvesting process

Analysis of Mechanical Properties in Tobacco Leaf Harvesting Process

Characteristics of Tobacco Leaf Harvesting

The growth characteristics of tobacco leaves and the connection strength of stems and leaves are important basis for the design of bionic picking device. The experiment was conducted in the tobacco fields of Xiangcheng County, Henan Province. The height of tobacco plant is moderate, the oil of tobacco leaf is large, the toughness is good, and it is suitable for mechanized harvesting. As shown in Figure 5, 20 tobacco plants were randomly selected as test objects, and steel ruler, electronic tension meter and protractor were used to measure the trait characteristics of tobacco leaves, the angle between petiole and stem, the position of picking force and the fracture force between stem and petiole. After removing extreme data, the average value of the measurement results was taken: length 58 cm, width 34 cm, stem diameter 3.6 cm, stem leaf angle 46°, petiole fracture force 34 N, which provided data support for the design of bionic picking device.

Fig. 5 - Measurement of tobacco leaf characteristics

Analysis of the Collision Process in Tobacco Leaf Harvesting

In the process of tobacco leaf picking, the collision between the picking device and the tobacco leaf will produce a large impact force. Assuming that the external force impulse is constant, the length of the collision time Δt will seriously affect the peak impact force. Prolonging the collision time can reduce the collision impact force, thereby reducing the damage rate of tobacco leaves. The tobacco leaf is regarded as a particle, and its collision process conforms to the impulse-momentum theorem:

$$I = \int_{t_0}^{t_0 + \Delta t} ma(t)dt \tag{1}$$

Where: I is the impulse of tobacco leaves, N·s; m is the quality of tobacco leaves, kg; a is acceleration, m/s²; t is time, s.

It can be seen from Equation (1) that the impulse of tobacco leaves during picking is not only related to its own weight, but also affected by collision time and collision acceleration.

Let y be the coordinate of the middle part of the tobacco leaf in the vertical direction, then the motion equation of the single degree of freedom system is:

$$m \ddot{y} + c \dot{y} + (k + k_o)y = 0 \tag{2}$$

$$y(0) = 0, \dot{y}(0) = v_0$$

In the case of underdamping, the solution of Equation (2) is:

$$y = Ae^{-\lambda \omega_i t} \sin \omega_s t \tag{3}$$

where:

$$\lambda = \frac{c}{2m\omega_i} \tag{4}$$

$$A = \frac{v_0}{\omega_s} \tag{5}$$

$$\omega_s = \sqrt{1 - \lambda^2} \omega_i \tag{6}$$

$$\omega_i = \sqrt{\frac{k + k_0}{m}} \quad (7)$$

In the formula, λ is viscous damping ratio, $\lambda < 1$; A is amplitude, mm; ω_s is damped natural frequency, Hz; ω_i is undamped natural frequency, Hz.

With an initial displacement of 0, the collision time is determined by the smallest positive root of Eq. (8):

$$f(t) = c \dot{y} + ky = 0 \quad (8)$$

The available collision time is:

$$\Delta t = \frac{\pi + \arctan \lambda_2}{\omega_i \sqrt{1 - \lambda^2}} \quad (9)$$

It can be seen from Equation (9) that the impact time is related to the tobacco leaves mass, picking mechanism stiffness coefficient, damping coefficient, and other parameters of the system, and these inherent parameters depend on its structure and materials.

As mentioned above, in the design of the next bionic picking device, the stiffness coefficient can be reduced and the damping coefficient can be increased by changing the structure and contact material of the picking mechanism, thereby reducing the collision acceleration, reducing the impact force at the moment of collision, and finally reducing the damage rate of tobacco leaves.

Bionic Harvesting Device Parameter Design

Harvesting Rod Parameter Design

The bionic picking rod and the auxiliary rod are fixed on the chain, and the chain and the motor are installed on both sides of the frame. The two chains are driven by the motor to rotate around the two sides of the frame. In the process of field operation, as the picking machine moves forward, the tobacco stem enters the picking frame composed of picking rod and auxiliary rod through the guidance of the front divider, as shown in the following Figure 6.

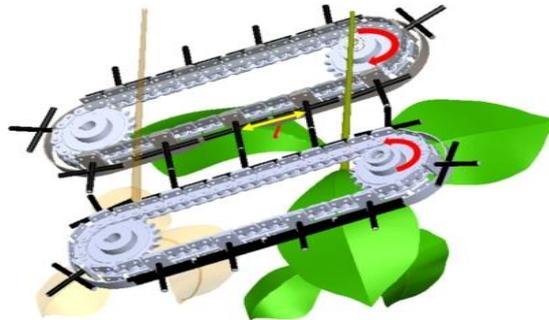

Fig. 6 - Picking rod structure diagram

If the picking frame is set too small, the stem pass ability is reduced, which is likely to cause damage to the stem and seriously affecting the picking effect; if the picking frame is too large, the torque of the tobacco leaves increases, and completing the picking operation requires greater force, resulting in an increase in the power consumption of the picking machine. Secondly, if the picking frame is too large, it will lead to the contact being not with the petiole but with the more fragile blade, resulting in an increase in the picking damage rate. Through field experiments, it has been determined that the distance between two adjacent picking rods on the same side of the transmission chain needs to be optimized:

$$l \times \cos \alpha = l_0 + d \quad (10)$$

where, l is the distance between the two picking rods in the same side, mm; α is the angle between the plane and the horizontal plane of picking rod, °; d is diameter, mm; l_0 is tobacco leaf picking position to the distance from the stem pole, mm.

According to the previous measurement and statistics of tobacco stems, d is 35 mm, the angle between the plane of the picking rod and the horizontal plane is 30, and the picking force of the tobacco petiole is tested. The distance from the picking force position to the stem is 70 mm, and it is reasonable to take 92 mm by calculation.

Harvesting Rod Rotation Speed Design

The picking rod rotates with the chain around the frame. It can be seen from the previous calculation that the greater the instantaneous speed of contact between the picking rod and the blade, the greater the impact force on the tobacco leaf, so the excessive speed of the chain will cause the damage rate of the tobacco leaf to increase. If the chain speed is simply reduced, the tobacco stem bent by the picking frame will cause damage to the tobacco stem because it does not pass through the flexible picking frame in time. According to the design principle of the picking device and the agronomic requirements of the layered picking of tobacco leaves, as shown in Figure 7, the speed of the picking frame needs to match the speed of the picking machine to achieve the expected effect of the picking rod relative to the downward movement of the tobacco stem. The speed of the two needs to meet:

$$v_1 = k \frac{v}{\cos \alpha} \quad (11)$$

where, v is picking machine forward operating speed, m/s; k is empirical coefficient; v_1 is the chain rotation speed of picking rod, m/s; α is the angle between the picking mechanism and the horizontal plane, °.

After many field experiments, the value of the empirical coefficient k is 1.0-1.1, the picking frame plane and the horizontal plane are 25°-35°, the integrity of the tobacco leaf is high, the damage to the tobacco stem is low, and the expected operation effect can be better realized. At the same time, in order to ensure the harvest efficiency of 1 to 1.3333 hectares per day, the operating speed v of the tobacco picking machine in the field is 1.5 km/h-4 km/h. When the angle α between the plane of the picking mechanism and the horizontal plane is set to 30°, substituting this value into Equation (11) yields a calculated range for the chain rotation speed v_1 of the picking rod between 0.48 m/s and 1.28 m/s.

Fig. 7 - Velocity relation diagram

Design of Grain Divider

The divider, as the core front-end component of the harvester, primarily serves to upright fallen tobacco plants and guide them into the harvesting mechanism while separating upper and lower leaves to prevent damage during harvesting. Its simple yet critical design directly impacts overall harvesting performance. Featuring symmetrical triangular-cone structures, the divider's effectiveness depends on its angle (β) and front height (l_1). Based on field data, it is designed to handle plants with up to 20° of lodging. For example, in central Henan, where mid-stem leaves grow 0.5–0.9 meters above ground, the front height (l_1) is calculated using the formula:

$$l_1 = 0.9 \cos \gamma \quad (12)$$

where, l_1 is the height of the front end of the layered device from the ground, cm; γ is tobacco lodging angle, °, $\gamma = 0 \sim 20^\circ$.

Because the maturity of tobacco leaves is from bottom to top, the design of the divider only considers the uppermost part of the picking layer. The distance from the front end of the divider to the ground is 84.5 ~ 90 cm, and the inclination angle of the divider should be satisfied.

$$\beta = \arcsin \frac{l_2 - l_1}{l_3} \quad (13)$$

where, β is angle of inclination of the divider, °; l_2 is the height from the rear end of the divider to the ground, cm; l_3 is length of divider, cm.

Through the comprehensive analysis of the characteristics of tobacco field planting in Henan and the agronomic requirements of picking, combined with the design experience, the distance from the front end of the divider to the mechanism is determined to be 46.5 cm, and the height from the connection position of the divider and the mechanism to the ground is 100 cm.

The data is brought into the formula (13) to calculate and sort out the value range of the inclination angle of the divider is about $12.4^\circ \sim 20.7^\circ$. The smaller the inclination angle of the divider, the better the effect of the divider and the passing ability. Considering that the picking machine needs to adapt to different heights of tobacco leaves, in order to ensure the picking effect, the inclination angle of the divider should be smaller on the basis of calculation. In summary, the inclination angle of the divider is 10° .

Tobacco Harvest Simulation

Model Establishment

Based on field measurements of tobacco plant dimensions, the stalk height is set to 1700 mm, the stalk diameter to 4 mm, and the overall leaf dimensions to 600×350 mm. A thin-shell structure is created based on the leaf shape. As shown in Figure 9(a), a tobacco plant model is established using SolidWorks software. To clearly illustrate the harvesting process, the plant model is simplified, as shown in Figure 9(b). The simplified model consists of two components: the stalk and the leaf. The leaf is positioned 1000 mm above the ground, and the angle between the leaf stalk and the plant stalk is 50° .

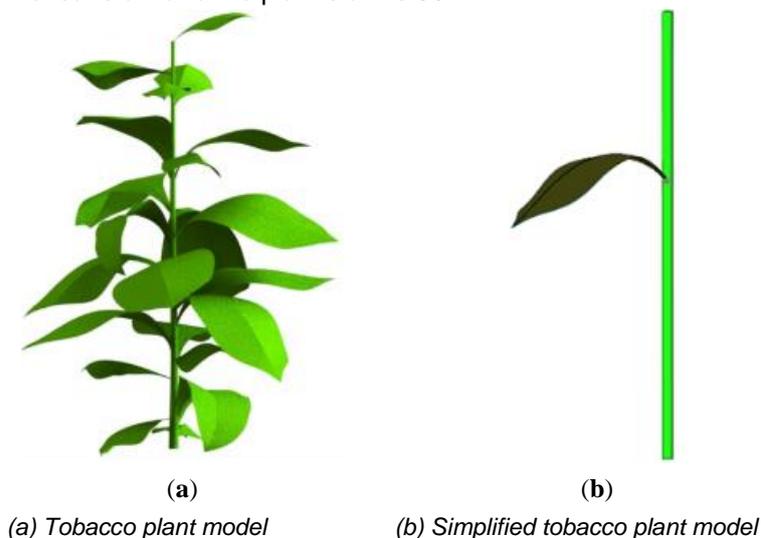

Fig. 9 - Whole tobacco and simplified model

Analysis of Tobacco Leaf Dropping Conditions

By applying an external force to the tobacco leaf, the change of the flexible connection force between the tobacco leaf and the tobacco stem under different forces is analyzed, so as to determine the condition of the

tobacco leaf falling from the tobacco plant, and lay the foundation for the simulation of the next tobacco leaf picking process.

Simulation Parameter Settings

The simplified tobacco plant model built in SolidWorks is imported into ADAMS. The file format is "Parasolid" format, which is relatively stable after conversion and is not easy to lose graphic information. Because the materials provided by the system do not meet the actual needs, the actual tobacco plant materials are created by inputting parameters such as tobacco plant density, tensile modulus and Poisson 's ratio. Combined with relevant literature (Zhang T. et al., 2018; Han M. et al., 2024; Zhang L., 2015) and data collected in the field, the model parameters of tobacco plants were selected in Table 1.

Table 1

Tobacco plant material parameters		
Density (Kg·mm ⁻³)	Tensile modulus (N·mm ⁻²)	Poisson's ratio
4.5E-0.7	1.1E+0.4	0.33

In order to accurately reflect the change rule of the flexible connection force between tobacco stems and tobacco leaves, it is necessary to add a fixed connection between tobacco stems and the earth to make it unable to move in any direction when analyzing the falling conditions of tobacco leaves in tobacco.

The connection between tobacco stems and leaves is modeled using a bushing force. Due to the numerous and complex parameters involved in flexible sleeve connections, there is currently limited literature and few relevant case studies available. Therefore, based on previously measured physical and chemical properties, as well as the shedding force of tobacco plants in the early stage (Qu Z. et al., 2024; Zhang H. et al., 2022), the parameters for the flexible sleeve force were defined as shown in Table 2. The central point at the junction between the tobacco stem and leaf was selected as the connection point for applying the flexible bushing force, labeled Bushing1.

Table 2

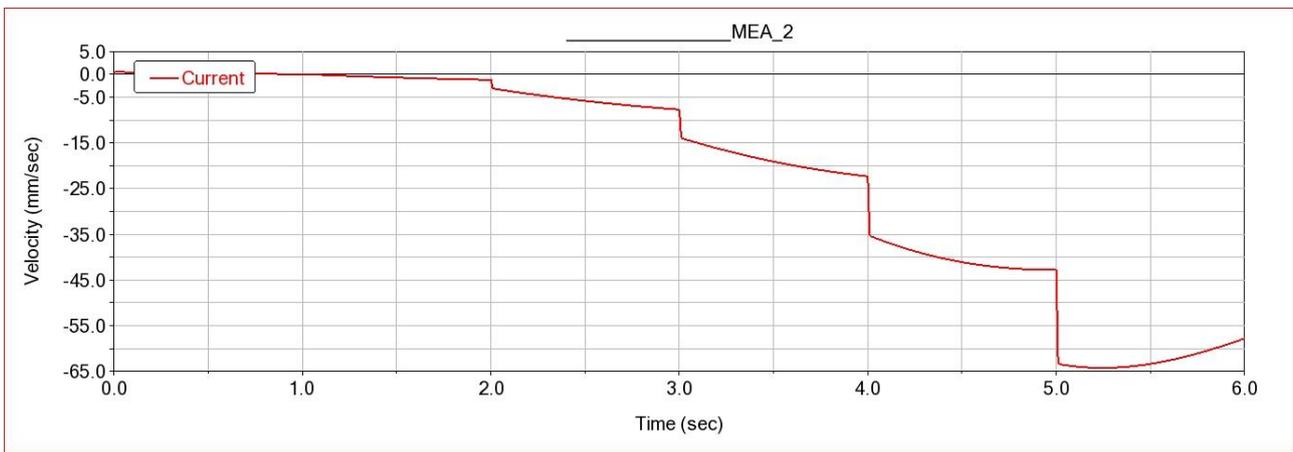

Flexible connection sleeve force parameters					
Connection force	Translation characteristics (x, y, z)		Rotation characteristics (x,y,z)		remark
	stiffness coefficient (N·mm)	damping coefficient (N·s·mm ⁻¹)	stiffness coefficient (N·mm/deg)	damping coefficient (N·mm·s/deg)	
Bushing 1	1.8	10	30	100	Connection between tobacco stem and leaf

Step function was used to apply increasing external load to tobacco leaves in ADAMS software, and the separation conditions of tobacco stems and leaves were analyzed. By referring to the relevant literature (Wen, B., 2010) and combining with the fracture force of tobacco petiole measured above, the external load range was set to 5-50 N, and the direction of external load was set along the negative direction of Y axis. The initial external load was set to 5 N, and then 10 N was added every 1 second. The functional equation is written as: + 5 + STEP (time, 1, 0, 1.01, 5) + STEP (time, 2, 0, 2.01, 10) + STEP (time, 3, 0, 3.01, 10) + STEP (time, 4, 4, 0, 4.01, 10) + STEP (time, 5, 0, 5.01, 10). The simulation time is set to simulate the falling process of tobacco leaf.

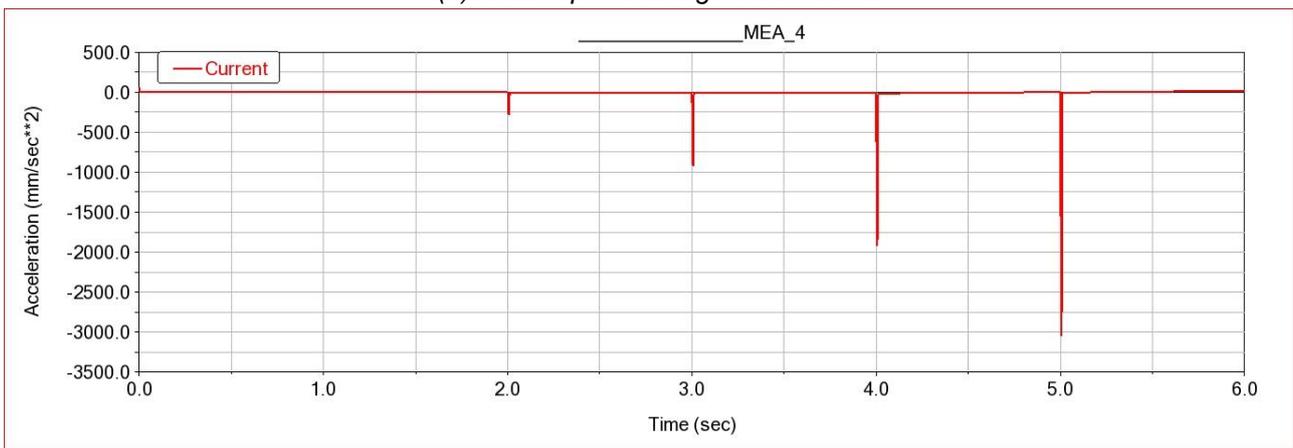

RESULTS AND DISCUSSIONS

Simulation Results Analysis

Figure 10 shows the velocity and acceleration curves of tobacco leaves in the X direction when subjected to external forces. As shown in the figure, since the tobacco leaves are only subjected to external loads in the negative Y direction, there is almost no velocity in the X direction, and the acceleration is also zero between 0s and 2 s. This indicates that when the external load is between 5 N and 15 N, the connection force (Bushing1) between the tobacco leaves and the tobacco stalk has not reached the breaking point. After 2 s, when the external load suddenly increases to 25 N, there is a significant change in velocity in the X direction, and the acceleration is no longer zero. This is because when the connection force reaches the breaking limit and the external load continues to increase, Bushing1 needs to transfer the received energy through lateral vibration. This shows that when the external force reaches 25 N, it has met the breaking condition of Bushing1.

(a) X axis speed change curve of leaf

(b) X axis acceleration curve of leaf

Fig. 10 - Curves of X-axis velocity and acceleration of tobacco leaf

The flexible connecting sleeve force Bushing1 between tobacco leaf and stem exceeded the bearing limit when the external force reached 25 N at the end of the second. Figure 11 illustrates the displacement curve of the flexible sleeve force. At the end of 2 seconds, the displacement of the Y axis reached 1.2981 mm. This indicates that the shedding condition for the tobacco leaf occurs when the Y-axis displacement of the flexible connection (Bushing1) reaches 1.2981 mm.

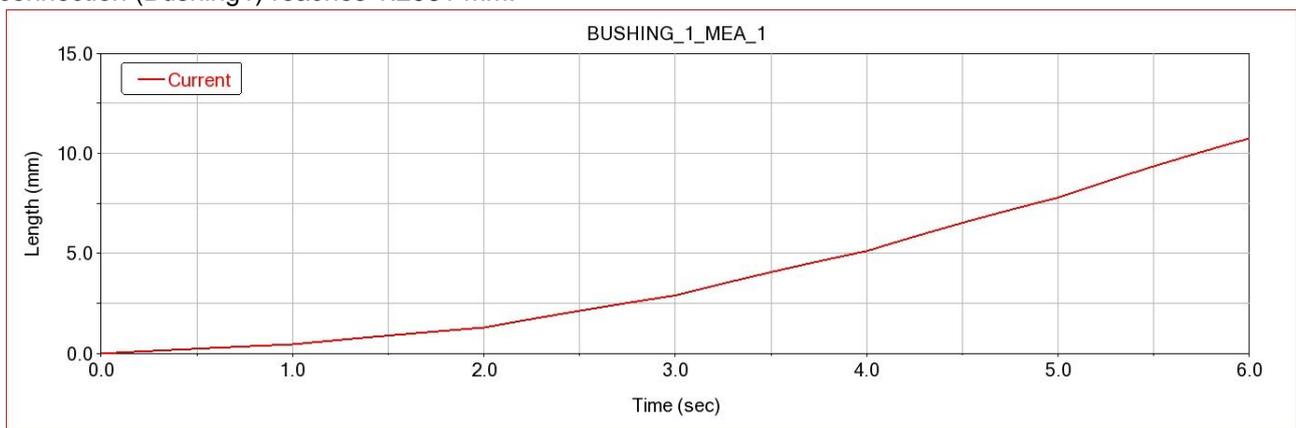

Fig. 11 - Flexible connection force displacement curve

Harvesting Process Simulation

The virtual prototype simulation analysis of the tobacco leaf picking process is to study the force change of the tobacco leaf during the picking process of the picking device, and to compare the force of the flexible picking mechanism and the rigid picking mechanism on the tobacco leaf. In this paper, the tobacco leaf picking device is taken as the research object. Because the picking process of a tobacco leaf is only affected by a picking rod, the number of picking rods is simplified to 1.

Import the model and set the material properties

The three-dimensional model of tobacco and picking rod is saved as "Parasolid" (*.x_t) format, and then imported into ADAMS to construct the simulation picking system of tobacco plant-picking rod. The relative position of picking rod and tobacco stem is adjusted. The axis direction of tobacco stem coincides with the Y axis, the vein of tobacco leaf is parallel to the X-Y plane, and the picking rod is parallel to the Z axis and placed above the tobacco leaf. The materials of picking rod are steel and rubber respectively. The relevant performance parameters of steel and rubber (Hou J. et al., 2022) are shown in Table 3.

Table 3

Physical performance parameters of picking rod			
Material type	Elastic modulus (N·mm ⁻²)	Density (Kg·mm ⁻³)	Poisson's ratio
Steel	2.06 E+05	7.85 E-06	0.3
Rubber	7.84	1.5 E-06	0.47

Adding Constraints, Drivers, and Sensors

Add constraints

The flexible connection between the two parts of the tobacco is still based on the data listed in Table 2. The picking rod is added with a negative moving pair relative to the earth along the Y axis, and the tobacco stem and the earth are fixed by a fixed pair.

Add driver

According to the previous calculation, when the rotation speed of the picking rod is 1.73 km/h ~ 5.08 km/h, the vertical downward combined speed is 0.865 km/h ~ 2.54 km/h, and the slip drive is added to the negative slip pair of the shaft to be 0.24 m/s, 0.4 m/s, 0.55 m/s and 0.71 m/s.

Define contact

The research on the contact parameters between tobacco and other materials in the literature is limited. Referring to the wood which is close to the physical and chemical properties of tobacco, combined with the relevant data measured above, and consulting the relevant references (Jin C. et al., 2023), the specific contact parameters are shown in Table 4.

Table 4

Contact parameters of different materials					
Material type	Stiffness coefficient (N·mm ⁻¹)	Force index	Damping coefficient (N·s·mm ⁻¹)	Static friction factor	Dynamic friction coefficient
Steel-Wood	2855	1.5	0.57	0.3	0.25
Rubber-Wood	2855	1.1	0.57	0.5	0.36

Define the sensor

Based on the previous analysis, Sensor1 is configured to monitor the displacement of the flexible connection bushing force (Bushing1) along the Y-axis. When the displacement exceeds 1.2981 mm, it is determined that the connection between the tobacco stem and leaf has fractured. At this point, both Sensor1 and Bushing1 are considered to have failed, indicating that the tobacco leaf has detached and fallen, completing the picking process. The sequence of the picking process is illustrated in Figure 12.

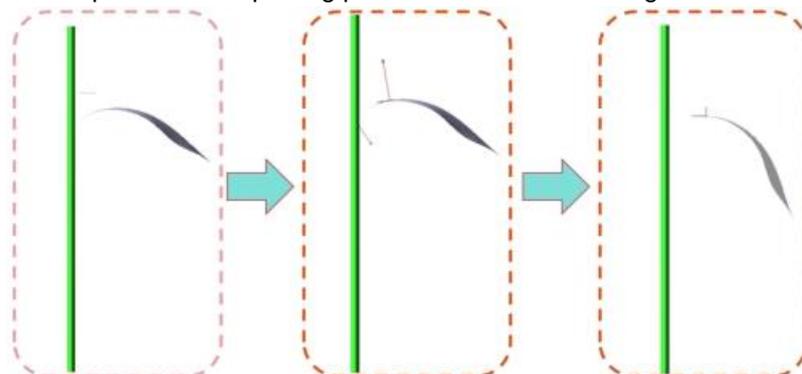

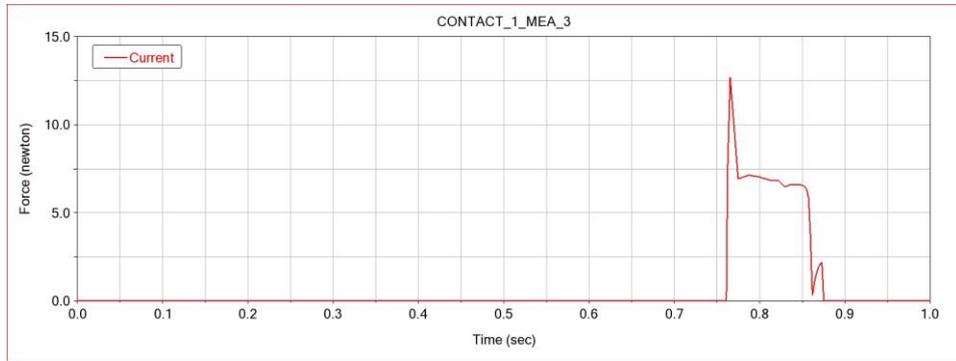

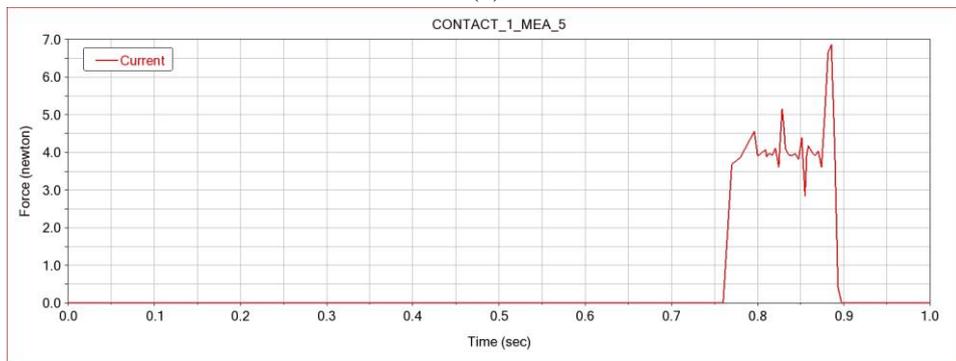

Fig.12 - Simulation of tobacco picking process

Simulation Results Analysis

The speed of the picking rod along the negative direction of the Y axis is 0.24 m/s, 0.4 m/s, 0.55 m/s, 0.71 m/s, respectively. As shown in Figures 13 ~ 16, the left side is the contact force change curve when the rigid picking rod collides with the tobacco leaf, and the right side is the contact force change curve when the flexible picking rod collides with the tobacco leaf.

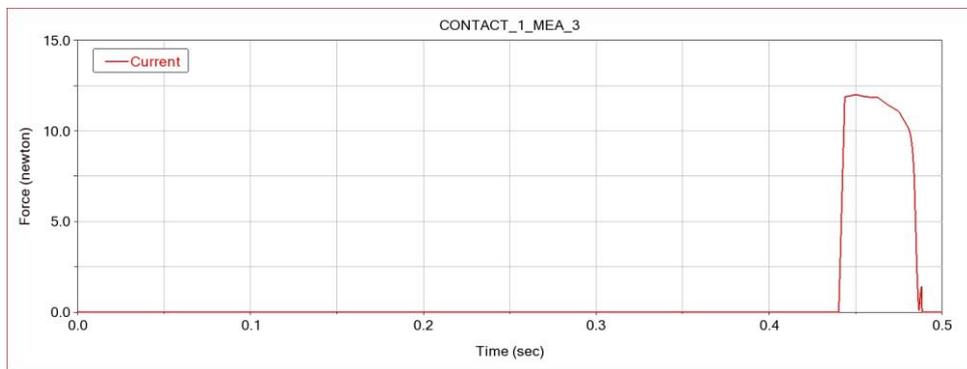

(a)

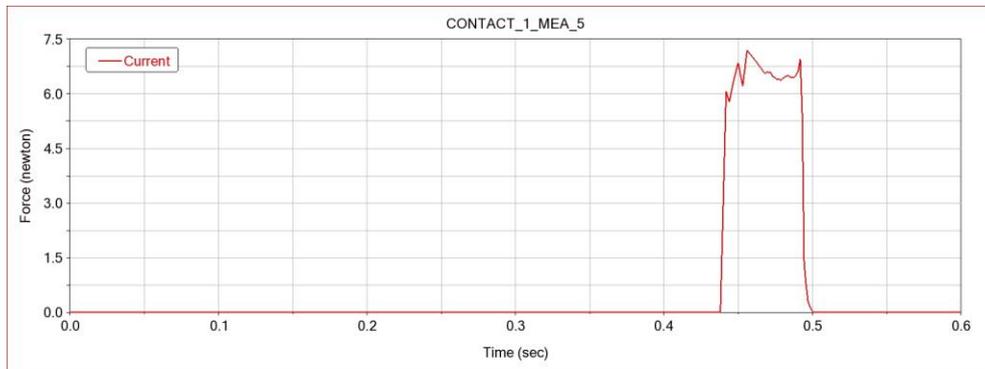

(b)

Fig. 16 - Impact force on tobacco leaves when the speed of picking rod is 0.71 m/s

(a) Rigid picking rod contact force; (b) Contact force of flexible picking rod

The comparative analysis of test data shows that:

By comparing the simulation test data on the left and right sides, it is found that the change rule of the overall curve of the two is similar, but it is relative to the rigidity. For the picking rod, the action time of the flexible rubber picking rod on the tobacco leaves is prolonged, and the effect of reducing the collision force is obvious.

Comparing the four groups of different picking rod speeds, it is found that when the picking rod speed is 0.4 m/s, the corresponding flexible picking rod collision force in Figure 16(b) is the smallest.

In summary, combined with the comprehensive consideration of tobacco picking efficiency and collision damage, when the vertical speed of the picking rod is 0.4 m/s, the picking effect of the flexible rubber picking rod is the best.

Field Trials

Test Conditions and Equipment

The field experiment was conducted in a tobacco field located in Xuchang, Henan Province, focusing on the harvesting of middle-position tobacco leaves. The experimental setup is illustrated in Figure 17. The instruments and equipment used included the custom-built tobacco leaf bionic picking machine, a computer, and a high-speed camera system. This experiment was performed outdoors. During the trials, trained operators operated the bionic picking machine, adjusting its forward operating speed to perform straight-line picking operations under varying conditions.

Fig. 17 - Field experiment plot

Experimental Design

The test materials and contents are shown in Table 5. According to the working principle analysis and pre-experimental analysis of the tobacco simulation picking device, it is concluded that the rotation speed of the picking rod, the inclination angle of the picking plane, the spacing of the picking rod, and the material of the picking rod have a great influence on the efficiency and harvesting quality of the picking device. The damage rate and operating efficiency of tobacco leaves are selected as test indicators. Each test sample group consisted of two rows of tobacco plants, with a total length of approximately 150 m.

After each test group, the harvested tobacco leaves in the collection box were gathered for evaluation. Each leaf was examined to determine whether the main stem was broken and whether the area of leaf loss exceeded the predefined damage threshold. The classification criteria for harvested tobacco leaves are illustrated in Figure 18. The number of damaged and intact tobacco leaves was recorded separately, and the damage rate was calculated using the following formula.

Table 5

Tobacco plant material parameters				
Project	Test equipment	Test site	Experiment variables	Test metrics
elements	The processed tobacco leaf bionic picking machine, computer and high-speed camera system.	Xu chang, Henan Provinc	The picking rod, the inclinatio angle of the picking table and the picking rod spacing	The damage rate and operation efficiency

Fig. 18 - Classified tobacco leaves

$$Z_s = \frac{W_s}{W_i + W_s} \times 100\% \tag{14}$$

where: Z_s is the leaf damage rate, %; W_s is number of damaged tobacco leaves; W_i is number of intact tobacco leaves.

According to the ADAMS simulation results, the picking effect of the picking rod with flexible rubber material is better than that of the steel picking rod. The test factors were determined to be the rotation speed of the picking rod, the inclination angle of the picking table and the picking rod spacing, which were expressed by A, B and C respectively. The damage rate and operation efficiency of the test index tobacco leaves were expressed by W_1 and W_2 . The quadratic orthogonal rotation combination analysis method with three factors and three levels was used in the experiment. The factor coding was shown in Table 6, and a total of 17 groups were carried out. Design-Expert software was used to analyze the test results. The test results are shown in Table 7.

Experimental Results Analysis

The regression model of tobacco leaf breakage rate was established

The regression mathematical model of tobacco leaf damage rate W₁ was obtained by regression fitting of the test results:

$$W_1 = 18.26 + 0.74A + 0.35B + 0.73C + 0.29AB + 0.00AC + 0.065BC + 1.00A^2 + 3.44B^2 + 3.58C^2 \quad (15)$$

The determination coefficient of the regression equation is R² = 0.9892, and the fitting degree is high. The regression model was analyzed by variance analysis, and the results are shown in Table 8.

Available: P < 0.0001 of the model, indicating that the regression equation is significant; a, C, A², B², C² P < 0.01, the results were significantly affected; other factors and interaction terms P > 0.05, had no significant effect on the test index.

The significance of the influence of each factor on the damage rate of tobacco leaves is the rotation speed of the picking rod > the picking rod spacing > the inclination angle of the picking table. The interaction of each factor is shown in Figure 19.

Table 8

Note: P<0.01 (extremely significant, **); p < 0.05 (significant, *)

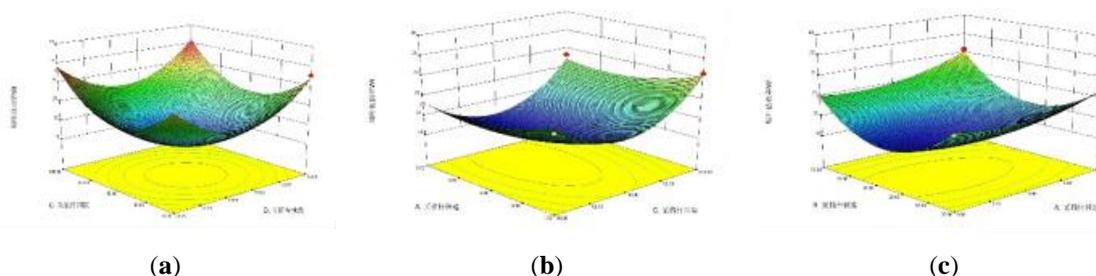

Fig. 19 - Effect of interaction of 21 factors on damage rate of tobacco leaf

- (a) The interaction between the picking rod spacing and the inclination angle of the picking table;
- (b) The interaction between the rotation speed of the picking rod and the picking rod spacing;
- (c) The interaction between the rotation speed of the picking rod and the inclination angle of the picking table.

When the rotation speed of the picking rod is fixed, the effect of the interaction between the picking rod spacing and the inclination angle of the picking table on the damage rate of tobacco leaves is shown in figure 19(a). When the interval of the picking table is fixed, the inclination angle of the picking table is too large or too small, it will lead to the increase of the damage rate of tobacco leaves. When the inclination angle of the picking table is constant, the damage rate of tobacco leaves increases with the increase of the picking rod spacing.

When the inclination angle of the picking rod is fixed, the influence of the interaction between the picking rod spacing and the rotation speed of the picking table on the damage rate of the tobacco leaf is shown in Figure 18(b). When the picking rod spacing is constant, the damage rate of tobacco leaves increases with the increase of the rotation speed of the picking rod. When the picking rod speed is constant, the damage rate increases slowly with the increase of the picking rod spacing.

When the picking rod spacing has a fixed value, the effect of the interaction between the inclination of the picking table and the rotation speed of the picking rod on the damage rate of tobacco leaves is shown in figure 18(c). When the rotation speed of the picking rod is constant, the inclination angle of the picking table is too large or too small, which leads to the increase of the damage rate of tobacco leaves. When the inclination angle of the picking table is constant, the damage rate of tobacco leaves increases slowly with the increase of the rotation speed of the picking rod.

Establishment of a regression model for working efficiency

The regression mathematical model of working efficiency W2 is obtained by regression fitting of the test results:

$$W_2 = 2.51 + 0.81A - 0.16B - 0.001C + 0.019AB + 0.0001AC - 0.01BC - 0.19A^2 - 0.04B^2 + 0.033C^2 \quad (16)$$

The coefficient of determination for the regression equation was R2 = 0.9978, indicating an excellent degree of fit. The regression model was evaluated using analysis of variance, with the results presented in Table 9. The model's P-value was less than 0.0001, confirming its statistical significance. The quadratic terms of variables A, B and A2 had P-values less than 0.01, indicating a significant influence on the results. Additionally, B2 had a P-value less than 0.05, suggesting it also had a significant effect on the response variable. Other factors and interaction terms had P-values greater than 0.05, indicating no significant effect on the test indices. The ranking of the factors based on their influence on operational efficiency was as follows: picking rod speed > picking table inclination > picking rod spacing. The interaction effects among these factors are illustrated in Figure 20.

Table 9

Analysis of variance of operation efficiency						
Source	Sum of Squares	df	Mean Squares	F Value	P Value	
Model	5.65	9	0.63	354.73	<0.0001

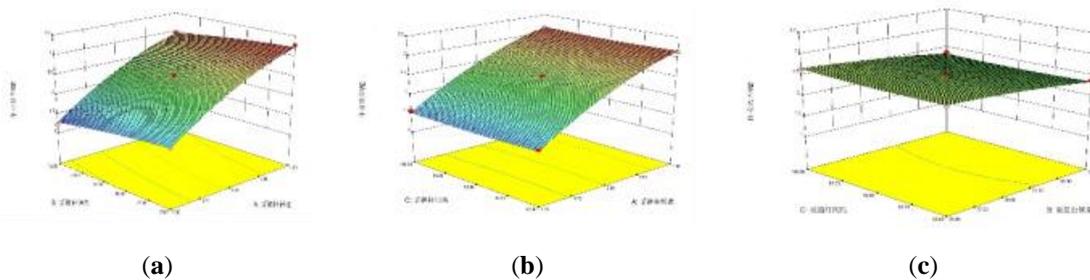

Fig. 20 - The effect of factor interaction on work efficiency

(a) The interaction between the rotation speed of the picking rod and the inclination angle of the picking platform;

(b) The interaction between the rotation speed of the picking rod and the picking rod spacing;

(c) The interaction between the inclination angle of the picking platform and the picking rod spacing.

When the picking rod spacing is a fixed value, the effect of the interaction between the picking rod speed and the inclination angle of the picking table on the operating efficiency is shown in Figure 20(a). When the inclination angle of the picking table is constant, with the increase of the rotation speed of the picking rod, the working efficiency gradually increases, and the change is more obvious. When the rotation speed of the picking rod is constant, the working efficiency increases with the decrease of the inclination angle of the picking table.

When the inclination angle of the picking table is fixed, the influence of the interaction between the picking rod speed and the picking rod spacing on the working efficiency is shown in Figure 20(b). When the picking rod speed is constant, the operating efficiency increases slightly with the decrease of the picking rod spacing, and the change is not obvious. When the picking rod spacing is constant, the working efficiency gradually increases with the increase of the rotation speed of the picking rod.

When the picking rod speed is constant, the influence of the interaction between the inclination angle of the picking table and the picking rod spacing on the working efficiency is shown in Figure 20(c). When the picking rod spacing is constant, the working efficiency gradually increases with the decrease of the inclination angle of the picking table. When the inclination angle of the picking platform is constant, the working efficiency increases slightly with the decrease of the picking rod spacing, and the change is not obvious.

In order to achieve better picking effect, the optimization module is used to optimize the regression model. By analyzing the constraints, the optimal parameter combination is obtained in the optimal combination of multiple parameters: picking rod speed 0.8 m/s, picking table angle 30° , picking rod spacing 90 mm, the tobacco leaf damage rate is 18.35%, the operation efficiency is 2.51 km/h, and the test index effect is the best.

The optimized parameter combination was tested and verified. The rotation speed of the picking rod was set to be 0.8 m/s, the inclination angle of the picking table was 30° , and the picking rod spacing was 90 mm. The average value of multiple tests was obtained. The damage rate of tobacco leaves was 18.32%, and the operating efficiency was 2.483 km/h, which verified the reliability of the model.

CONCLUSIONS

(1) To address the issues of low efficiency and high damage rates in the current tobacco harvesting process, the rotation speed of the picking rod, the dimensions of the picking frame, and the angle of the holding device were theoretically calculated and analyzed. Based on this analysis, a bionic tobacco leaf harvesting device was designed. The proposed device significantly enhances harvesting efficiency while effectively reducing the damage rate associated with mechanical picking.

(2) The tobacco leaf picking process was simulated using ADAMS software, focusing on analyzing the contact forces between rigid and flexible picking rods at different speeds. The optimal combination was identified as a vertical speed of 0.4 m/s using a flexible picking rod.

(3) Preliminary processing of the bionic harvester was completed, followed by field experiments to evaluate its performance. Design-Expert software was used to optimize and analyze the experimental data. The optimal combination of parameters for each experimental factor was determined as follows: the rotation speed of the picking rod was 0.8 m/s, the inclination angle of the picking table was 30° , and the picking rod spacing was 90 mm. Under these conditions, the tobacco leaf damage rate was 18.35%, and the operational efficiency reached 2.51 km/h.

(4) Using the optimized parameter combination, a follow-up harvesting test was conducted. The tobacco leaf breakage rate was 18.32%, with a relative error of only 0.1% compared to the predicted value. The operational efficiency reached 2.483 km/h, with a prediction error of 0.11%. These results confirm the reliability

of the optimized model. This study successfully achieved low-damage mechanized harvesting of tobacco leaves and provides a valuable reference for the development of bionic tobacco leaf harvesters designed to minimize leaf damage.

(5) The current harvesting equipment and experimental program are still in the preliminary stages of development, and the cost of the designed harvesting device remains relatively high. Future research will focus on investigating the effects of tobacco leaf surface properties on harvesting efficiency, with the aim of further optimizing the structural design to improve cost-effectiveness. Additionally, integration of a harvesting quality inspection system is planned to ensure consistent and reliable performance in real-world applications.

Keywords: multidimensional cleaning method; rapeseed; CFD-DEM; combined harvester

ABSTRACT

Searching for and identifying methods to reduce grain cleaning loss, grain impurity, and improve cleaning efficiency is crucial for processing threshed rapeseed outputs in uneven conditions. Leveling a single-degree-of-freedom cleaning sieve becomes particularly challenging under terrain undulations and limited cleaning space. Based on spiral theory and mechanical design principles, this study explores a multi-degree-of-freedom cleaning sieve capable of vertical movement along the horizontal plane and rotation around its center. This design allows the sieve to adjust its relative angle, enabling a more uniform distribution of threshed outputs. A CFD-DEM coupling method was used to simulate the movement of these outputs. The cleaning sieve inclined forward and to the right served as the experimental group, while a horizontal cleaning sieve functioned as the control group. Compared to the control, the experimental group showed a 14.6% reduction in grain loss and a 2.3% decrease in impurities. Furthermore, the centroid motion of the rapeseed was enhanced prior to sieving, facilitating more effective separation, while the movement speed of impurities outside the cleaning shoe increased, aiding impurity removal.

摘要

针对丘陵地区地形起伏，小型收获机清选空间有限的难题，多自由度的清选装置开发是相当具有挑战性的。文章基于螺旋理论和机械设计方法，探索了一种可以在水平方向上垂直移动并绕其中心旋转的多自由度清选筛。该清选筛通过调整筛面角度实现脱出物均布，实现清选性能和清选效率的提升。基于 CFD-DEM 耦合方法模拟脱出物运动，将清选筛前倾和向右倾斜状态设置为实验组，清选筛水平状态设置为对照组。结果表明，对比对照组，试验组籽粒损失和含杂分别减少了 14.6% 和 2.3%。同时，在筛分前，油菜籽、杂质的质心运动速度明显增强，这有利于去除含杂和提高筛分效率。该研究方法对于收获装备转型升级具有重要的实际意义。

INTRODUCTION

Rapeseed is the largest source of edible vegetable oil in China. Accelerating the development of rapeseed mechanization, supporting the upgrading of the oil industry, and reducing China's heavy dependence on imported raw materials for vegetable oil are among the country's most pressing priorities. Hilly and mountainous areas account for 1/3 of the country's crop cultivation area. Between the hills and low mountains there are many river valley basins. The four seasons are distinct, the land is fertile, suitable for rape planting. The primary crops of wheat and corn differ substantially in their agronomic and physical attributes compared to rapeseed (Zhao et al, 2022; Zhang et al, 2024; Li et al, 2024), making it impractical to directly apply their harvesting design methods and equipment to rapeseed. Hilly and mountainous regions typically experience abundant rainfall and sufficient sunshine, leading to robust rapeseed growth. In these areas, rapeseed plants usually range from 220 mm to 250 mm in height, and the grass-to-grain ratio is significantly higher than in the plains—often reaching as much as 4–5:1. After threshing and separation, the grain volume in the rapeseed material fed into the cleaning shoe accounts for only about 8%, while the volume of impurities is considerably higher. These impurities are diverse in composition, and the small, spherical rapeseed grains are mixed with various irregular residues.

¹ Xiaoyu Chai (Lecturer), Pengtao Zhang (M. Eng. student), Xinting Liu (Engineer), Lizhang Xu (Professor), Liyuan Chen (Doctor), Qiang Li (Engineer), Longhai Wang (Doctor).

This complex mixture makes stratification and separation difficult, resulting in a portion of the grains being discharged along with the impurities, thus increasing grain loss. Additionally, some impurities may fall into the grain auger, further raising the impurity content of the harvested product.

Unlike traditional field harvesting equipment, threshing and cleaning systems must account for variations in terrain (Vlăduț et al., 2023; Zhang et al., 2024). In hilly and mountainous regions, rapeseed suitable for mechanized harvesting is often cultivated on sloped lands, with inclines ranging from 6° to 15° in hilly areas and 15° to 25° on terraced slopes. For combine harvester manufacturers, incorporating components, or even designing entire machines, with the capability to adapt to uneven surface topography is essential for improving harvesting adaptability in these challenging environments. The IDEAL 10T combine harvesters (Fendt, 2025) are equipped with multiple guide strips and multi-layer vibrating sieves, enabling uniform material distribution during multi-crop harvesting. Technologies such as header contouring devices and 3D multi-layer vibrating sieves have been implemented (MF, 2025; Claas, 2025) to automatically adjust to varying slope angles, maintaining a level threshing and cleaning system. Experts and researchers have been actively engaged in developing small-scale harvesting machinery tailored for hilly and mountainous regions. To address the accumulation of threshed material on the sieve surface, caused by the topography of hilly and mountainous regions, technologies for threshed material dispersion and the analysis of particle movement trajectories have become particularly critical. A three-stage vibrating sieve equipped with guide strips and a cross-flow fan (Case, 2025) was employed to achieve more uniform airflow across the entire sieve, thereby improving the even distribution of materials on the sieve surface. The CFD-DEM coupling method has been increasingly applied to simulate two-phase flow performance in complex agricultural systems (Wang et al., 2024; Shen et al., 2024; Tanneru et al., 2024). Korn et al. utilized this method to simulate the separation process of threshed materials within the cleaning unit of a combine harvester. The CFD-DEM coupling method has been employed to simulate the movement of jojoba and flax threshing materials within an airflow-sieve cleaning device, enabling the prediction of grain separation performance under specific design conditions (El-Emam, 2021). Similarly, CFD-DEM has been used to study the movement of corn and rapeseed threshed outputs during the sieving process (Wang et al., 2021), helping determine optimal parameters such as sieve hole sidewall angle, airflow velocity, and airflow direction angle. These studies demonstrate that CFD-DEM simulations are highly effective for analyzing particle motion, offering clear insights into grain dynamics. As a result, the advantages of the CFD-DEM method will be applied in this study to enhance the analysis of threshed material behavior and cleaning performance.

Based on the above, current gas-solid coupling simulations in the cleaning process typically focus only on the primary components present on the cleaning sieve. However, in real-world conditions, particularly in hilly regions, rapeseed accumulation is often severe, and traditional simulations rarely account for the accumulation state of separated materials or the complex interactions between them. Furthermore, many simulations consider only a single particle type, overlooking the uneven distribution of different particle types across various regions. This simplification results in a significant deviation from the actual separation process. Therefore, it is essential to study the movement trajectories of separated particles under conditions of inclined accumulation and to further explore the underlying sieving mechanisms in order to enhance separation performance and overall cleaning efficiency.

MATERIALS AND METHODS

Multidimensional motion theory of the cleaning device

When a combine harvester operates in hilly and mountainous terrain, changes in surface topography can cause the entire cleaning device to tilt both in the forward-backward direction and the left-right direction. Moreover, the centrifugal force acting on threshed outputs in the longitudinal axial flow threshing and separation device typically causes the threshed outputs to distribute unevenly, with higher concentrations on both sides and lower concentrations in the middle (Liu et al., 2022; Li et al., 2022). This uneven distribution leads to threshed output accumulation on both sides of the sieve surface, negatively affecting the sieving efficiency. Therefore, it is necessary to develop a multidimensional cleaning device that can adapt to varying terrain conditions and dynamically regulate the distribution of threshed outputs. To minimize the impact of external factors such as terrain on the cleaning device, it is essential to eliminate the influence of forward-backward and left-right tilting on the cleaning system. Let the forward direction of the combine harvester be defined as the positive x-axis. In the following descriptions, "forward," "backward," "left," "right," "up," and "down" correspond to the positive x-axis, negative x-axis, positive y-axis, negative y-axis, positive z-axis, and negative z-axis, respectively.

The designed multidimensional cleaning device compensates for the effects of terrain on the cleaning shoe in both the forward-backward and left-right directions. This device features three degrees of freedom, including rotation around the x-axis and y-axis to adjust the uneven distribution of threshed outputs in the left-right direction.

Additionally, movement along the z-axis ensures that the relative position of the sieve surface remains constant within the adjustment range when the terrain has significant vertical undulations. The primary technical specifications are detailed in Table 1.

A combination of the SPS/RPS-UP parallel stable platform and the 2PSS-U parallel stable platform was selected to achieve multidimensional adjustment of the sieve surface within the confined space. The principle diagram of the multidimensional adjustment mechanism for the sieve surface is shown in Fig. 1.

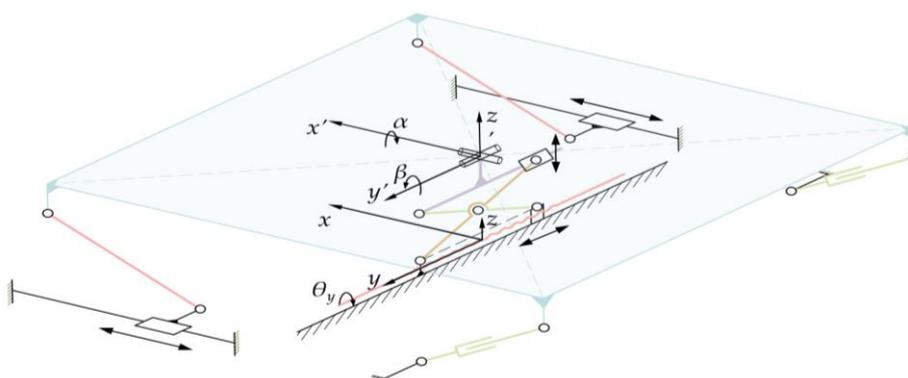

Fig.1 - Prototype of the multi-dimensional cleaning mechanism

The 2PSS-U parallel stable platform serves as the core of the design, with its U-branches modified to PU-branches. To accommodate the longitudinal movement, range of the mechanism, a retractable linear drive device is incorporated into the middle PU branch of the sieve surface. Additionally, two support points are added at the vertices of the platform to maintain dynamic stability during the adjustment process.

Table 1

Performance specifications of the multidimensional cleaning device

No.	Performance	Value	Remarks
1	Adjust the limit position around the x-axis	$+8^{\circ} \pm 0.5^{\circ}$, $-8^{\circ} \pm 0.5^{\circ}$	Angle with the horizontal direction
2	Adjust the limit position around the y-axis	$+8^{\circ} \pm 0.5^{\circ}$, $-8^{\circ} \pm 0.5^{\circ}$	Angle with respect to the horizontal direction
3	Range of longitudinal movement for the mechanism	≤ 65 mm	The limit position of the movement space must ensure a certain distance between the vibration plate and the fish scale sieve
4	Load capacity of the mechanism	≥ 2 kg	Mass flow rate of the threshed outputs stream
5	Rotation angle around the x-axis	$\leq 5^{\circ}$	Angle with the horizontal direction
6	Rotation angle around the y-axis	$\leq 5^{\circ}$	Angle with the horizontal direction

Structural design of multi-dimensional cleaning device

The multi-dimensional cleaning device, designed to adapt to terrain variations and the distribution state of separated materials, features a perforated sieve at its output end, positioned between the fish-scale screen and the vibrating plate. The structural principle of the adjustable cleaning device is illustrated in Fig. 1, while the designed multi-dimensional cleaning device is shown in Fig. 2. The system consists of a frame, an upper platform, a screw, a screw nut, connecting rods, and sliding blocks mounted on the upper platform. To enable folding motion, connecting rods with spherical joints at both ends are installed on either side of the upper sieve surface. At the center of the sieve, an "X"-shaped retractable cross-link mechanism serves as a linear actuator. The rotation of the screw, which is arranged along the y-axis, causes the screw nut to move along the y-axis. This screw also results in changes in the angle between the cross-links, which drives the upper platform to move up and down along the z-axis. At the two rear vertices of the platform, spherical joints and damping slide rods are used for connection. The damping slide rods are moving pairs with damping characteristics, and their other ends are connected to the frame via spherical joints.

These two damping slide rods act as driven components and enhance the stability of the mechanism's movement without affecting its degrees of freedom. Forward drive slider is fixed on the power guide rail on the side wall of the cleaning shoe, with a certain gap introduced between it and the spherical joint to reduce the probability of interference with the side wall during platform movement.

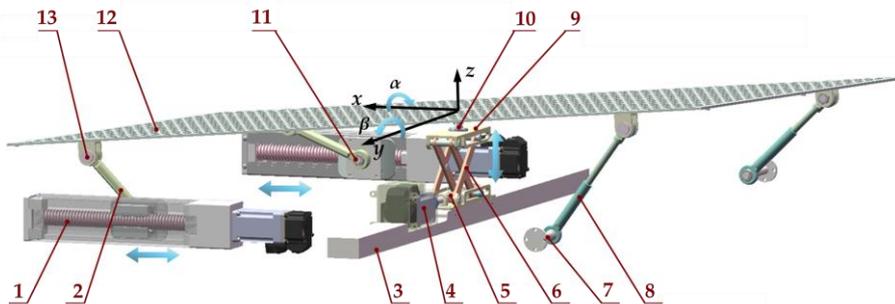

Fig. 2 - Schematic diagram of multi-dimensional cleaning device structure.

1. Screw sliding table; 2. Double spherical hinge connecting rod; 3. Support beam; 4. Lifting platform drive motor; 5. Drive screw; 6. Lifting platform connecting rod; 7. Damping rod support; 8. Damping rod; 9. Upper platform of the lifting platform; 10. Hook hinge; 11. Lower spherical hinge; 12. Movable screen surface; 13. Upper spherical hinge

The fixed end of the lifting platform is mounted to the bottom of the support beam, while its movable end is connected to the bottom of the hook joint. The center of the perforated sieve's rectangular envelope is attached to the top of the hook joint. At the four corners of the perforated sieve, four sets of positioning holes are symmetrically distributed, using the envelope's rectangular center as the origin. Four sets of positioning pins are employed to accurately position the four-fork frame bearing seats into the designated fixed holes.

The multi-degree-of-freedom sieving device is integrated into the cleaning shoe, as illustrated in Fig. 3. By combining the configurations shown in Fig. 1 and Fig. 2, a ball joint is mounted into the fork frame bearing seat of the multi-degree-of-freedom screening structure. A slider is affixed to the screw slide platform, and the central region of the slider incorporates a cylindrical structure designed to connect with the lower spherical joint. This design enables the lower spherical joint to move synchronously with the active end of the screw slide platform. The lower end of the damping rod is connected to a spherical joint on the damping rod support, while the upper end is linked to the fork frame bearing seat positioned behind the moving sieve. This configuration enables stable three-degree-of-freedom adjustment, even within the constraints of limited installation space.

Coupled simulation of threshed outputs in gas-solid two-phase flow

CFD and DEM coupled simulation model

To accurately reflect the cleaning process, it is necessary to analyze the combined effects of gas flow and vibrating sieves. In a gas-solid two-phase flow system, gas typically acts as the continuous phase, while the solid phase is dispersed as particles or clumps within the gas.

This study uses the computational fluid dynamics software Fluent (V15.0, CFD Inc., USA) to simulate the gas phase flow field, and discrete element method software EDEM (V2.7, DEM Solutions Ltd., UK) to analyze the motion and force states of solid phase particles. Through a coupling interface, CFD and DEM achieve real-time data exchange, including the transfer of mass, momentum, and energy, thus completing a bidirectional coupled numerical simulation of gas-solid two-phase flow. The advantage of this coupling technology is that it integrates the geometric characteristics of solid particles (such as shape and size) and physical properties (such as material properties and friction coefficients), providing a more accurate capture of the interactions and effects between the gas and solid phases (Tanneru et al, 2024).

The continuity equation and momentum equation for the gas phase can be represented as follows (Xu et al, 2020):

$$\frac{\partial \varepsilon \rho}{\partial t} + \nabla \cdot \rho \varepsilon u = 0 \quad (1)$$

$$\frac{\partial \varepsilon \rho}{\partial t} + \nabla \cdot \rho \varepsilon u \mu = -\nabla \rho + \nabla \cdot (\mu \varepsilon \nabla u) + \rho \varepsilon g - S \quad (2)$$

where:

ε represents the volume fraction term; ρ is the gas density, $\text{kg}\cdot\text{m}^{-3}$; u is the gas velocity, $\text{m}\cdot\text{s}^{-1}$; μ is the dynamic viscosity coefficient, $\text{Pa}\cdot\text{s}$, and S is the momentum sink, $\text{kg}\cdot\text{m}^2\cdot\text{s}^{-1}$.

The contact model forms the core basis of the Discrete Element Method (DEM). It essentially simulates the elastic-plastic mechanical behavior of particles under quasistatic conditions when in contact. Although the contact relationships between particles are nonlinear, approximate superposition principles are often used for analysis. In EDEM software, the default contact model is the Hertz-Mindlin model, also known as the "elastic-damping-friction contact mechanics model." This model takes into account the elastic deformation, damping effects, and frictional forces between particles during contact. Hertz-Mindlin model was employed to investigate the motion behavior of rapeseed particles in a multi-airflow cleaning device, the equations can be represented as follows (Ma et al, 2022).

$$F_{cni} = \frac{4}{3} E^* (R^*)^{1/2} \alpha^{3/2} \quad (3)$$

$$F_{dni} = -2 \sqrt{\frac{5}{6}} \beta \sqrt{S_n m^*} v_n^{rel} \quad (4)$$

$$F_{cti} = -S_t \delta \quad (5)$$

$$F_{dti} = -2 \sqrt{\frac{5}{6}} \beta \sqrt{S_t m^*} v_t^{rel} \quad (6)$$

where:

F_{cni} represents the normal contact force between particles, N; E^* is the equivalent elastic modulus, Pa; R^* is the equivalent particle radius, m; α is the normal overlap between the particles. F_{dni} represents the normal damping force between particles, N; β is the coefficient; S_n is the normal stiffness, $\text{N}\cdot\text{m}^{-1}$; m^* is the equivalent mass, kg; v_n^{rel} is the normal component of relative velocity, $\text{m}\cdot\text{s}^{-1}$. F_{cti} is the tangential contact force between particles, N; S_t is the tangential stiffness between the particles, $\text{N}\cdot\text{m}^{-1}$; δ is the tangential overlap between the particles. F_{dti} represents the tangential damping force between particles, N; v_t^{rel} is the tangential component of relative velocity, $\text{m}\cdot\text{s}^{-1}$.

Fluent - EDEM Gas-Solid Coupling Simulation

Establishment of flow channel model and boundary mesh division. After preliminary research and simulation of the airflow distribution on the sieve surface, it was found that a leaning forward and leaning right condition of the multidimensional cleaning sieve is most advantageous for the selection process in a combine harvester. Therefore, this configuration was selected as the basis for particle analysis and designated as the experimental group, while the condition with a horizontal sieve surface served as the control group. The Fluent-EDEM digital simulation method was employed to compare the movement of rapeseed threshed outputs under the influence of terrain and the movement of the threshing drum. The coupled flow path model of the experimental group is illustrated in Fig. 4.

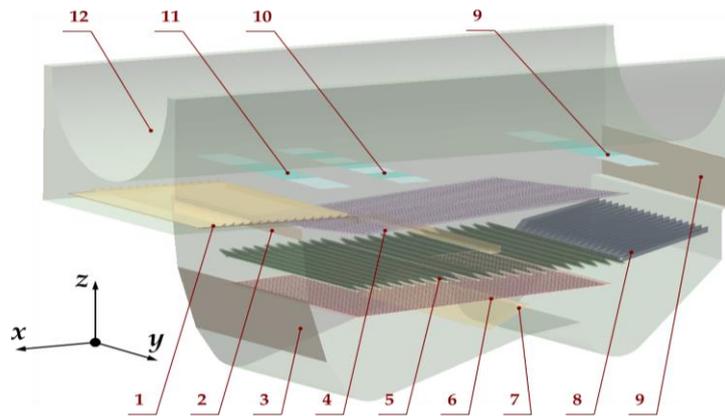

Fig. 4 - Coupled flow channel model of the cleaning shoe

- 1. Shaking plate; 2. Upper inlet; 3. Lower inlet; 4. Adjustable perforated sieve; 5. Fish scale sieve; 6. Woven sieve; 7. Guiding plate;
- 8. Tail sieve; 9. Outlet; 10. Threshing drum; 11. Concave sieve; 12. Particle factory ①-③;
- 13. Particle factory ④-⑩; 14. Particle Factory ⑪-⑬.

The flow path model was designed with an arcuate structure for the perforated plate sieve to facilitate observation of grain movement. The model includes upper and lower air inlets representing the fan's air outlets, with the airflow speed set to the average speed of the section. The meshing software was used to create a tetrahedral mesh for the cleaning shoe flow path model, resulting in a total of 6,021,268 mesh elements. The mesh file was saved as an MSH file and imported into both Fluent and EDEM software for simulation.

Establishment of EDEM environment and particle model. An experiment was conducted to observe the distribution pattern of the threshed outputs under the longitudinal axial threshing drum. This involved uniformly arranging 70 collection boxes, each with dimensions of 110×190×110 mm³, beneath the Longitudinal axial threshing drum, as illustrated in Fig. 5. In the EDEM software simulation, it is necessary to model the simulation objects. Therefore, the components of the output materials need to be categorized. The threshed output samples, collected from beneath the longitudinal axial-flow threshing device (as shown in Fig. 5), were manually sieved to identify four main types of threshed output components, as illustrated in Fig. 6.

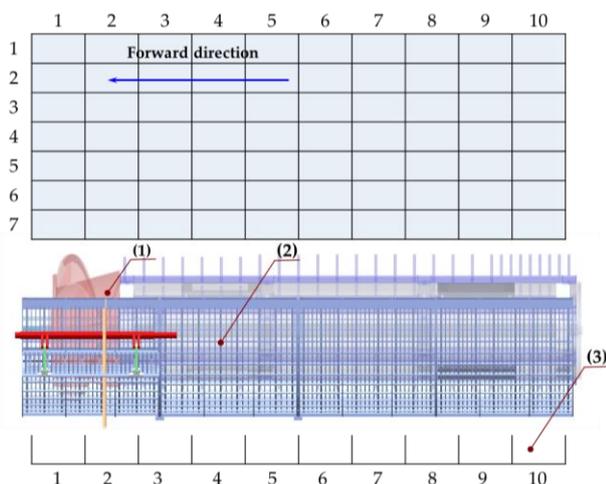

Fig. 5 - Longitudinal axial threshing drum and receiving box placement position

- (1) Longitudinal axial threshing drum; (2) Concave sieve;
- (3) Receiving box.

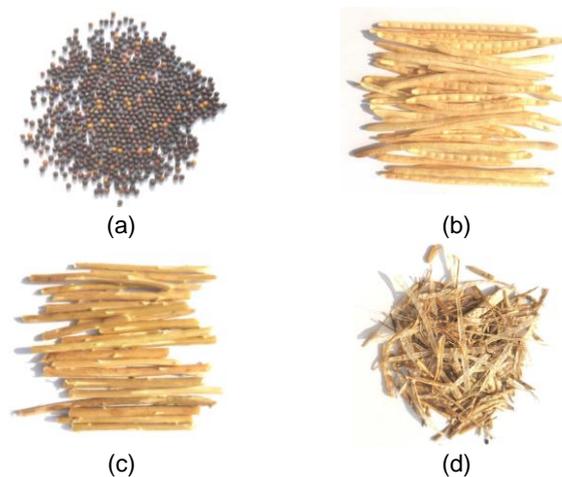

Fig. 6 - Main components of the rapeseed threshed outputs

- (a) Rapeseeds; (b) Pod shell; (c) Stem; (d) Light impurities.

In a gas-solid two-phase flow system, the dynamic behavior of different components under the influence of airflow within the cleaning shoe creates a complex multicomponent coupled simulation scenario. To conduct simulations in EDEM, these components must be modeled as particles. Due to limitations in EDEM's modeling capabilities, only spherical particles can be created. Therefore, a particle packing method is used to simulate the shape of the actual components by combining multiple spherical particles. The models of the four component types are shown in Fig. 7.

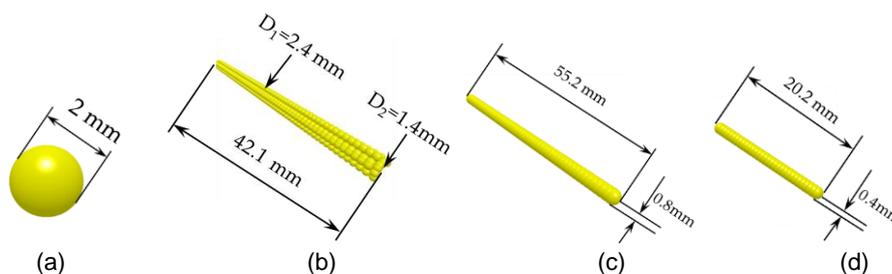

Fig. 7 - Particle filling model of the rapeseed threshed outputs
 (a) Rapeseed; (b) Pod shell; (c) Stem; (d) Light impurities

The shape of the rapeseeds is approximated as spherical, so a single spherical particle can satisfy the requirements. The pod shell can be approximated as a semi-cylindrical hollow structure, while the stems and light impurities can be approximated as cylindrical.

In EDEM software, it is necessary to input the mechanical properties of the threshed output particles, as well as their contact coefficients with other objects. According to relevant references, the contact coefficients and mechanical property parameters for the threshed outputs are set as shown in Tables 2 and 3.

Particle Factory Settings. In EDEM software simulations, it is essential to define the distribution state of the threshed outputs within the cleaning shoe. To achieve this, the mass of each threshed output component was measured. The mass of threshed outputs collected in each receiving box was recorded (Fig. 5), and the overall three-dimensional distribution trend of the threshed outputs in the cleaning shoe was analyzed, as shown in Fig. 8(a). The proportion of each component was determined, with the results depicted in Fig. 8(b).

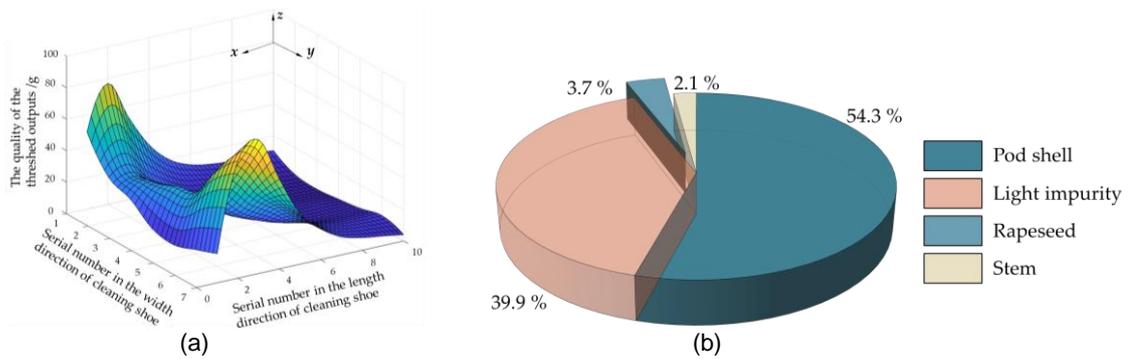

Fig. 8 - Distribution of rapeseed threshed outputs under the threshing drum
 (a) Distribution pattern of rapeseed threshing residue quality; (b) Proportion of threshed output components.

The cleaning efficiency and performance are directly related to the distribution of threshed outputs falling from the threshing device. To more accurately simulate real conditions, the generation and distribution of particles in the EDEM software are aligned with the actual distribution characteristics of the threshed outputs under the longitudinal axial flow threshing drum.

Based on the distribution patterns of the rape threshed outputs shown in Fig. 5 and Fig. 8 (b), three particle factory areas, slightly narrower than the width of the cleaning sieve and positioned 100 mm above the shaking plate, were established. These areas include a total of 13 particle factories, which are polygonal virtual regions in EDEM software used for particle generation. The total particle mass assigned to each particle factory corresponds to the mass distribution of threshed outputs shown in Fig. 8(a). The spatial distribution of the particle factory areas on the xy-plane is illustrated in Fig. 9.

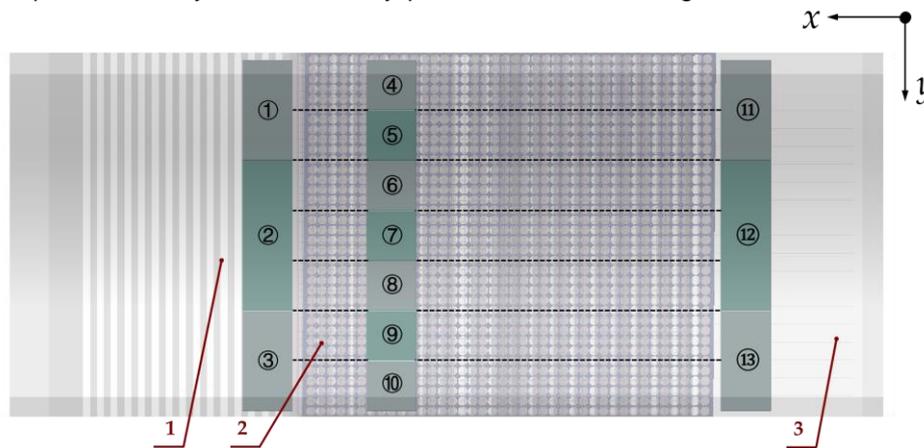

Fig. 9 - The particle factory distribution
 1. Vibrating plate; 2. Perforated sieve; 3. Tail sieve

The first particle factory area is located above the tail of the vibrating plate, its length in the x direction is 110 mm, and the length in the y direction is 770 mm, and the ratio of 2:3:2 in the y direction is divided into three particle factories ①~③, which are mainly used to simulate the effect of the shaking plate in front of the threshing drum. The second particle factory area is positioned above the middle part of the perforated sieve, with a length of 110 mm in the x direction and 770 mm in the y direction. It is divided into seven particle factories (④~⑩) along the y direction. This area is situated in the region where the threshed outputs from the vertical axis flow threshing drum falls most densely and is primarily used to simulate the effect of the perforated sieve on the threshed outputs. The third particle factory area is located above the front part of the tail sieve, its length in the x direction is 110 mm, the length in the y direction is 770 mm, and the ratio of 2:3:2 in the y direction is divided into 3 particle factories ⑪~⑬, which is mainly used to simulate the effect of the tail sieve on the threshed outputs.

Based on experimental measurements, the ratio of input to threshed outputs in the cleaning shoe of the combine harvester is 9:4. Considering the proportions of each component in the threshed outputs shown in Fig.8(b), along with the density and moisture content of each component, the required number of particles for each particle factory can be calculated.

With the input rate of the combine harvester set at 3 kg·s⁻¹, the differentiated settings of the particle factories allow for the creation of a distribution pattern in the cleaning shoe that is “more on the sides and less in the middle” along the y direction.

Coupling Simulation Settings. Import the MSH file format into Fluent to set up the numerical simulation parameters for the airflow phase. The standard κ - ϵ turbulence model was chosen to describe turbulent flow, and a pressure-based transient solver was employed. The environmental pressure was set to standard atmospheric pressure, and the direction of gravity acceleration was specified as the negative z-axis with a magnitude of 9.81 m·s⁻². Subsequently, the same MSH file was imported into EDEM for solid phase numerical simulation, with gravity acceleration also set as the negative z-axis, maintaining consistency. The boundary condition for the inlet was set as a velocity inlet, the airflow speed at inlet 1 was set to 17 m·s⁻¹, and at inlet 2, it was set to 14 m·s⁻¹. The model's outlet was set as a pressure outlet with a relative pressure of 0 Pa. The vibrating sieve includes a shaking plate, a fish-scale sieve, a tail sieve, and a woven screen. The opening of the fish-scale sieve was set to 45°, with an x direction displacement of 6 mm, and a z direction displacement of 17 mm. The vibration frequency was set to 6.5 Hz.

User-defined function (UDF) was used to establish coupling between Fluent and EDEM, utilizing the Eulerian-Eulerian model for numerical simulation of the gas-solid two-phase flow. During the coupling process, the time steps were synchronized, Fluent's time step was set to 5×10⁻⁵ s, and Rayleigh time step was set to 5×10⁻⁷ s. The total simulation duration was set to 1 s, with Fluent computational time being 100 times that of EDEM.

RESULTS AND DISCUSSION

Qualitative analysis of threshing outputs motion trends

The post-processing module in EDEM was used to export the movement trends of the particles. Distributions of the particles in the cleaning shoe at six representative time instances, 0.4 s, 0.6 s, 0.8 s, and 1 s, were selected to clearly observe the movement process of the particles, as shown in Fig. 10. Different colors were used to distinguish the components, black particles represent rapeseeds, green particles represent pod shells, yellow particles represent stems, and cyan particles represent light impurities.

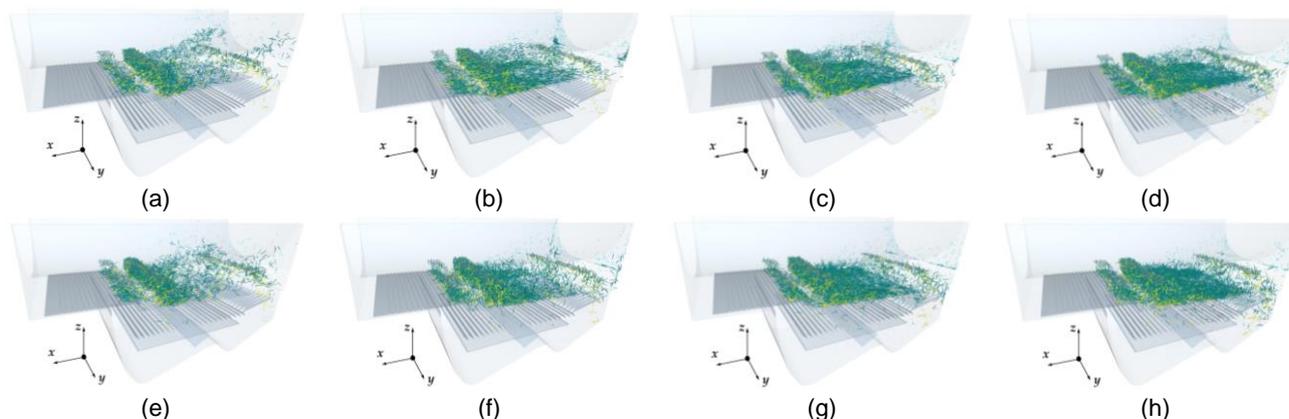

Fig. 10 - Distributions of the particles in the cleaning shoe

Figures (a), (b), (c) and (d) represent 0.4 s, 0.6 s, 0.8 s, and 1 s, respectively. The state of the cleaning sieve surface relative to the cleaning shoe is leaning forward and leaning right. Figures (e), (f), (g) and (h) represent 0.4 s, 0.6 s, 0.8 s, and 1 s, respectively. The state of the cleaning sieve surface relative to the cleaning shoe is horizontal.

In Fig. 10, these observations can be made, during the stage when the rapeseed threshed outputs fall from the particle factories to the perforated sieve (0–0.4 s), the particles of various components are influenced by the airflow from the fan's air duct, creating a waterfall-like descent. Rapeseed in both conditions begins to penetrate through the sieve, while threshed output components, excluding the rapeseeds, are driven by the airflow away from the sieve surface and towards the outside of the cleaning shoe. By this time, the threshed outputs passing through the perforated sieve is less than in the cleaning shoe horizontal condition.

In the period of 0.6–0.8 seconds, rapeseeds undergo further layering and sieving, with some rapeseeds having fallen onto the seed and impurities augers. In both conditions, along with rapeseeds falling through the perforated sieve, there are also impurities including pod shell, stem, light impurities.

By 0.8 seconds, the projectile motion trend of pod shells and light impurities gradually disappears. Pod shells that were suspended at relatively higher positions move to lower positions. At 1.0 second, the impurities particles above the perforated sieve move rapidly towards the outside of cleaning shoe in a flowing manner. The impurities exhibit a continuous outward movement trend. Additionally, there are more rapeseeds at the grain auger baffle in the cleaning sieve leaning forward and leaning right condition compared to the cleaning sieve horizontal condition.

Calculation of the rapeseed impurity rate and cleaning grain loss rate

After completing the numerical simulation, two key areas for counting the number of threshed output particles were defined in EDEM software, as shown in Fig. 11.

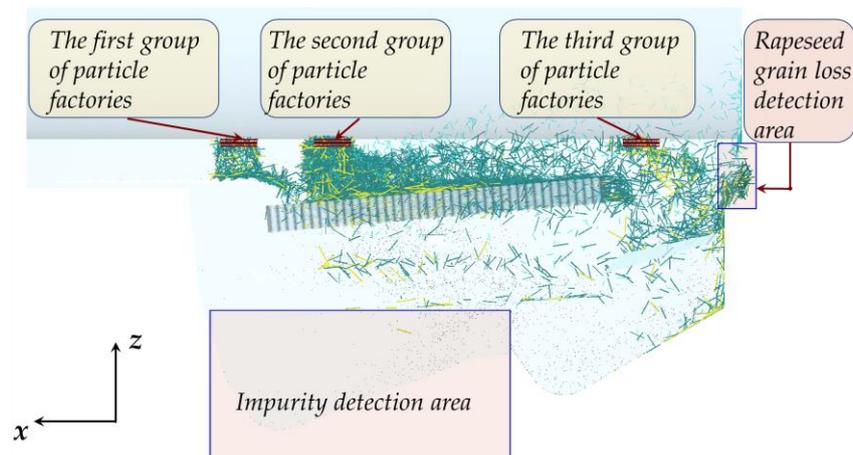

Fig. 11 - Schematic diagram of grain loss detection area and impurities detection area in the cleaning shoe

The first region is set near the grain auger and is used to count the number of rapeseeds, pod shells, stems and light impurities particles that pass through the cleaning sieve. This count is then used to calculate the impurity rate of the grains, which can be described by equation (7). The second statistical region is located at the outlet of the flow model and is intended to count the number of rapeseeds that are expelled from the cleaning shoe, thereby determining the cleaning loss rate. This rate can be calculated using equation (8).

$$P_1 = \frac{Q_1 M_1 + Q_2 M_2 + Q_3 M_3}{Q_1 M_1 + Q_2 M_2 + Q_3 M_3 + Q_4 M_4} \cdot 100\% \quad (7)$$

where:

P_1 represents the impurity rate of the grains, %; Q_1 represents the number of pod shells that pass through the perforated sieve and vibrating sieve, pieces; Q_2 represents the number of stems that pass through the perforated sieve and vibrating sieve, pieces; Q_3 represents the number of light impurities that pass through the perforated sieve and vibrating sieve, pieces; Q_4 represents the number of rapeseeds that pass through the perforated sieve and vibrating sieve, pieces; M_1 represents the mass of a single pod shell, g; M_2 represents the mass of a single stem, g; M_3 represents the mass of a single piece of light impurities, g; M_4 represents the mass of a single rapeseed, g.

$$P_2 = \frac{Q_5}{Q_4 + Q_5} \cdot 100\% \quad (8)$$

where:

P_2 represents the cleaning loss rate, %; Q_5 represents the number of grains that are expelled from the cleaning shoe, pieces.

Based on equations (7) and (8), the grain impurity rate and cleaning loss rate for both cleaning conditions can be calculated. The combined evaluation metric, defined as cleaning performance, is determined by weighted summation. Given the practical requirements, the cleaning loss rate is generally considered slightly more important than the grain impurity rate. Therefore, the weight for the cleaning loss rate is set at 0.6, and the weight for the grain impurity rate is set at 0.4. A lower combined evaluation value indicates better cleaning performance. The calculation results are shown in Fig. 12.

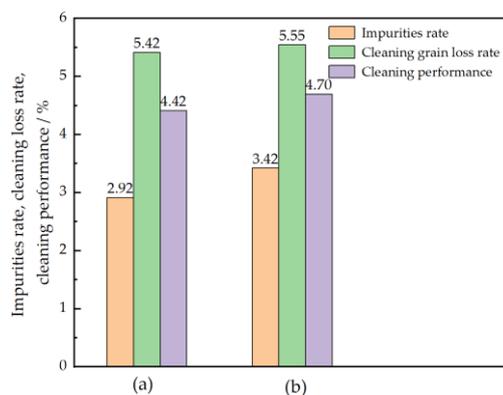

Fig. 12 - Comparison of cleaning performance

(a) The state of the cleaning sieve surface relative to the cleaning shoe is leaning forward and leaning right;
 (b) The state of the cleaning sieve surface relative to the cleaning shoe is horizontal

The grain impurity rate and cleaning loss rate for the control group are 3.42% and 5.5%, respectively. In contrast, in the experiment group, the grain impurity rate and cleaning loss rate are 2.92% and 5.42%, respectively. Both values are lower than those for the horizontal position. Specifically, the grain impurity rate decreases by 14.6%, the cleaning loss rate decreases by 2.30%, and the overall cleaning performance metric decreases by 5.9% in the experiment group. This indicates that the sieve in the leaning forward and leaning right condition is more favorable for the cleaning of the threshed outputs.

Field experiment

To evaluate the operational performance of the multi-dimensional cleaning sieve, a harvesting operation was conducted in a hilly area where rapeseed is grown. Field experiments were carried out at the Longxin Agricultural Machinery Cooperative in 2023, Jiangxi Province. The selected rapeseed variety was Ganyouza 8, with a yield of 186 kg, an average plant height of 1480 mm, a pod height of 720 mm, a pod layer diameter of 460 mm, a thousand-seed weight of 3.86 g, and a seed moisture content of 17.3%. The field experiment is shown in Fig. 13.

Fig. 13 - Combine harvester harvesting rapeseed in hilly and mountainous areas

Before the experiment, a 25 m test field was measured, and markers were placed at both ends. The cutting width of the combine harvester was 2.0 m, with a stubble height of 700 mm and a forward speed of $1.0 \text{ m}\cdot\text{s}^{-1}$. During the experiment, all material thrown out from the tail of the cleaning shoe was manually collected using mesh bag, rapeseed cleaning losses were manually separated from the tailings. The weight of the cleaning losses and the rapeseed grains in the grain tank was measured, and the impurity content in the grains was determined by sampling from the grain tank.

The rapeseed grain losses and impurity content under the conditions of the experimental group and the control group were compared, with each condition being repeated three times and the average value taken. The rapeseed grain loss and impurity content were calculated using the methods outlined in the Rapeseed Identification Guidelines. The cleaning loss rates for the experimental group and the control group were 1.41% and 2.03%, respectively, while the impurity contents were 2.18% and 2.64%, respectively. The experiment demonstrated that the rapeseed loss in the experimental group was reduced by 30.54% and 17.42%, proving that the designed multi-dimensional cleaning device effectively reduces field losses.

CONCLUSIONS

During the process of rapeseed harvesting in hilly and mountainous areas, terrain undulation and threshing device rotary operation lead to uneven threshed outputs distribution and on the sieve results in localized accumulation. This leads to poor airflow sieving efficiency and low cleaning efficiency in areas with higher threshed outputs concentration, while excessive airflow in areas with less threshed outputs causes grain-loss due to blowing rapeseeds out of the cleaning shoe. To address these issues, a multidimensional cleaning sieve design method is proposed. This method enables multi-degree adjustment within a limited space, enhancing both the uniformity of material distribution and the overall sieving efficiency.

The CFD-DEM gas-solid coupling approach was used to perform a detailed numerical simulation of a multi-degree-of-freedom cleaning device under specific feeding conditions. The grain impurity rate and grain loss rate were calculated for both the cleaning sieve leaning forward and leaning right condition (the experimental group) and the cleaning sieve horizontal condition (the control group). The comprehensive evaluation index of cleaning performance showed that, under the experimental group, the grain impurity rate decreased by 14.6% and the grain loss rate decreased by 2.3%.

This study not only deepens the understanding of the internal gas-solid two-phase flow characteristics within a multi-degree-of-freedom cleaning device but also provides important theoretical and technical support for improving the cleaning efficiency and operational performance of combine harvesters. By optimizing the sieve orientation, significant improvements in cleaning effectiveness can be achieved. Furthermore, this research provides a new measure to solve the problem of poor harvesting performance caused by the terrain of small harvesting machinery operating in hilly and mountainous areas.

Keywords: low head turbines, irrigation systems, PV panels, energy efficiency, energy autonomy

ABSTRACT

This paper presents an improved solution for solar powered irrigation systems by integrating low-head micro-hydro turbines for energy recovery when discharging the water from the storage tank. The proposed solution is justified by the potential energy available when storing water in a tank using pumps powered by PV panels. This energy can be used to provide additional electricity when discharging the water, by placing a low-head micro-hydro turbine at the bottom of the tank. The energy produced can be used for pumping back a fraction of the consumed volume of water, or to ensure the pressure for longer distance irrigation networks. The energy surplus provided by the turbine is necessary especially when irrigating during mornings and evenings, when PV system power production is reduced. A low head micro-hydro turbine suitable for a small scale solar powered irrigation systems was tested on a dedicated testing stand in order to demonstrate its efficiency. The turbine was designed to generate 1 kW of power operating at 2.4 m head and 360 m³/h flow. The tested model reached a maximum output of 526 W at 2 m head and 240 m³/h flow. The rotor is made from thermoplastic by 3D printing, thus the flow through the turbine was limited to avoid damaging the blades. The experimental data was compared to the specific data of a small-scale solar powered irrigation system to determine the total efficiency of a hybrid irrigation system. The calculation takes into account the medium flow rate needed for turbine operation during irrigation phase, correlated with the electricity requirements of the pump for obtaining specific flows. The additional power output can increase the global efficiency of a solar powered irrigation system by feeding the electricity back to the pumping unit. For a PV power system that provides 20 kWh/day, the turbine can ensure around 22.5% of the energy needed for irrigation.

REZUMAT

Această lucrare prezintă o soluție îmbunătățită pentru sistemele de irigare cu energie solară prin integrarea micro-hidroturbinelor de joasă cădere pentru recuperarea energiei la golirea apei din rezervorul de stocare. Soluția propusă este justificată de energia potențială disponibilă atunci când se stochează apă într-un rezervor de acumulare, folosind pompe alimentate de panouri fotovoltaice. Aceasta poate fi valorificată prin amplasarea unei micro-hidroturbine de joasă cădere în partea inferioară a rezervorului. Astfel, turbina poate furniza energie electrică suplimentară la descărcarea apei. Energia produsă poate fi utilizată pentru pomparea înapoi a unei fracțiuni din volumul de apă consumat sau pentru asigurarea presiunii pentru rețele de irigare pe distanțe mai lungi. Surplusul de energie produs de turbină este necesar mai ales la irigarea dimineața și seara, când producția de energie a sistemului fotovoltaic este redusă. O microturbină pretabilă pentru sistemele de irigare de mică putere care utilizează energia solară a fost testată pe un stand dedicat pentru demonstrarea eficienței acesteia. Turbina a fost proiectată să genereze o putere de 1 kW funcționând la o cădere de 2.4 metri și un debit de 360 m³/h. Modelul de turbină testat a furnizat o putere maximă de 526 W la o cădere de 2 metri și un debit de 240 m³/h. Rotorul este realizat din termoplastice prin printare 3D; prin urmare, debitul prin turbină a fost limitat pentru a evita deteriorarea palelor. Datele experimentale au fost comparate cu datele specifice ale unui sistem de irigare la scară mică, alimentat din panouri fotovoltaice, pentru a determina eficiența totală a sistemului hibrid de irigare. Calculul ține cont de debitul necesar pentru funcționarea turbinei în faza de irigare, corelat cu necesarul de energie electrică pentru obținerea debitelor specifice. Energia electrică adițională obținută poate crește randamentul global al sistemului de irigare cu energie solară prin alimentarea pompei instalației. Pentru un astfel de sistem care furnizează 20 kWh/zi, turbina poate asigura până la 22,5% din energia necesară pentru irigare.

INTRODUCTION

The development of efficient and affordable PV systems is at hand for implementation in agriculture within solar powered irrigation systems. Moreover, some agricultural activities can be combined with solar systems, including crops, livestock, greenhouses and other agriculture domains that require electricity. Integrating renewable energy systems in agricultural infrastructure can be a promising solution for sustainable development. Moreover, considering that 70% from the world freshwater is used in agriculture (UNESCO, 2019; Garcia-Espinal et al., 2024), designing efficient technologies and equipment to be used for watering crops is of significant importance. For irrigation purposes, Lorentz solar water pumps provide special designed DC pumps suitable for operation in remote PV irrigation system. They can be used along with increased efficiency PV panels in portable systems that can be deployed wherever needed.

The pump can have a timer switch that offers the advantage of a time-controlled water-saving system. Precise timing must be set in accordance with the dependence of the solar cells power generation on the intensity of the sun radiation. The plants have to receive irrigation at the exact moment when the soil beneath is dry and needs watering the most. Water savings compared to general irrigation are achieved by using drip irrigation, thus avoiding watering unused areas and consequently weed growth (Jandova et al., 2022). The problem that arises when implementing PV systems for irrigation is that the timing of maximum power generation and the period needed for irrigation does not overlap. The solution for this issue is to use storage systems that can ensure the use of electricity at the time needed, when access to the grid is not possible. The most accessible solution is to use batteries for storing the energy during most active sunlight hours. Irrigation systems require reservoirs or tanks to be filled to ensure the proper flowrate when needed. Since potential energy is available when storing water in a tank, then a low-head micro-hydro turbine placed at the bottom of the tank can be added into the system to provide additional electricity when discharging the water. Considering that irrigation is performed during mornings and evenings, when the PV system power production is reduced, the energy surplus provided by the turbine is not only necessary, but makes the irrigation system more reliable and versatile. Among all types of irrigation systems, micro-irrigation is the most efficient way of irrigating crops according to Evans et al., 2018. The mentioned study shows that micro-irrigation has 60% less water waste comparing to the flood irrigation method. In this irrigation type, a water pump supplies water with pressure into the pipes and drippers. Although renewable energy-powered irrigation systems can improve the productivity of crops, the storage method to be used is still a challenge for large land areas (Rejekiingrum et al., 2021). Some studies have raised concerns about the water tank costs. Soenen et al., 2021 conducted a techno-economic comparison between battery and tank-based water pumping systems, concluding that the lifecycle cost (LCC) of tank-based systems is 22% higher than that of battery-based systems in terms of using domestic water supply. An optimization study carried out by A. Mazloumi et al. (2023) on a water tank storage-based solar-powered system showed that the cost of water supplied in the case of tank-based systems was lower compared to battery or diesel-based systems, but the tank size was limited to 10 m³. Therefore, the sizing of the tank can pose a challenge and the optimum storage volume must be identified. For example, building a 200 m³ water tank to meet water needs cannot be feasible given the required cost of construction, materials, and labour (Jahanfar et al., 2022). In another study, the cost of the tank-based systems increases twice that of the battery-based systems when scaling up (Attia et al., 2022).

Given the aspects mentioned above, if the envisaged project requires water storage tanks, then the use of complementary low-head micro-hydro turbine can be a solution for increasing the global efficiency of the PV irrigation systems. The downside of using the turbine is the impact of the hydraulic parameters, resulting in a reduced flow rate downstream. The hydraulic head, as the main flow parameter, is strongly modified by the presence of the turbine which causes the main head loss of the entire installation and hence the reduced flow. This happens because the turbine transforms most of the water pressure into mechanical energy, which the generator then converts into electrical energy. This drawback is not significant where reduced flow is needed, as the case of drip irrigation. Likewise, some irrigation systems already have regulating valves for adjusting the flow, in order to have a longer irrigation time with a limited flow, to avoid the quick discharge of the storage tank. If needed, the local pressure loss can be overcome by an increased head or by reducing the friction loss in pipes. The different opinions regarding the selection of suitable storage for PV irrigation systems have determined the development of various optimization models. The total efficiency of the system can be increased by using an intelligent system based on SCADA or IoT, like the one depicted in Kun et al., (2021).

Obstacles in expanding solar power generation to other purposes such as irrigations, involve the cost of solar cells and the dependency on weather conditions. The efficiency and performance of photovoltaic panels are tied to environmental variables, including climate factors.

Bălăceanu *et al.*, (2024), highlighted the influence of the environmental factors on the PV panel performance and proposed the use of simulation software to ensure the best results in terms of efficiency when placing the panels. Recent developments in electronics allowed the implementation of a network acquisition system based on multiple sensors for automatic irrigation and fertilization, which can reduce water consumption by 74.92% (Karunanithy *et al.*, 2020). Matheswaran *et al.* (2021) carried out a performance evaluation of standalone solar powered water irrigation system using DC pump. The good results recommend the system as a suitable candidate for the replacement of the existing grid connected pumping system. Few articles have been published on optimizing renewable energy-powered irrigation with battery or tank storage. The identified literature mostly uses the life cycle cost and either loss of load or loss of power supply probability as optimization criteria (Khatib *et al.*, 2021; Irandoostshahrestani *et al.*, 2023). Another approach of storage suitable for irrigation systems is to use compressed air that enhances the environmentally friendly and efficient operation of drip irrigation systems. Conventional storage methods commonly used in photovoltaic-powered drip irrigation systems, such as elevated tanks and batteries, have notable technological, economic, and environmental limitations. Thus, a group of researchers presents a novel photovoltaic drip irrigation technology (CAES-PVDI) that uses solar energy as the exclusive source of power, enabling stable and cost-effective high-quality drip irrigation using compressed air (Junjie *et al.*, 2024). The appropriate solution for storage must be customized depending on the project and takes into account many aspects such as: irrigated area, daily solar irradiation, investment and life-cycle cost, environmentally friendly solutions, environmental protection conditions. Each solution has advantages and disadvantages as stated by Jahanfar *et al.*, (2022), who performed a comparative study of solar water pump storage systems. The authors concluded that battery storage provide a constant power to pump, which results in a higher life span of the pump but has a significant replacement and maintenance cost. On the other hand, water tank storage has high life span, but presents challenges in building and installation of high-capacity water tanks.

None of the previous articles approaches the use of other means of producing electricity such as hydro-turbines connected within the PV irrigation system for increasing their efficiency. Clearly, some benefits can arise, as the global efficiency of the pumping system can be increased. However, a more in-depth analysis is required and will be performed in this paper, emphasizing the power output of water turbines operating in solar powered irrigation systems.

MATERIALS AND METHODS

The micro-hydro turbine suitable to use in a small scale solar powered irrigation system was tested on a dedicated stand specially designed for performing tests on low head turbines. These turbines are an environmentally friendly way to generate electricity by using a certain flow and a relatively low head of at least 1 meter, allowing water to pass through and be discharged at a lower level. Kaplan turbines offer good efficiency when operating at low head and despite their complexity, can be a suitable option for producing electricity within storage tank-based irrigation systems. Compared to other propeller or crossflow turbines, the Kaplan reaction turbine can be a solution at hand with sufficient performance even with fixed rotor blades and guide vanes. The turbine was designed, built and optimized using the methodology for conventional Kaplan turbines, noting that the installed flow rate and reduced head determined the optimization and adaptation of the rotor and stator according to recent parameters identified in literature (Różowicz *et al.*, 2019). The overall dimensions were correlated with the water drainage section at the bottom of the upper tank of the test stand as recommended by Peczkis *et al.*, (2021). The microturbine is made up of 3 main elements:

1. The base plate - consists of a lower flange (5) which performs two functions: at the lower part it ensures the sealing of the flange (4) glued to the transparent plexiglass tube (2) by pressing it against the bottom of the tank (3) using six screws (15). At the upper part, this plate constitutes the support for the guide vanes system which are fixed between the upper and lower plates, thus strengthening the entire assembly.

2. The upper plate (8) - has attached the hydrodynamic profiled cone with a set of screws (13), which consists of a core (7) that directs the flow towards the turbine rotor and has a glass bearing (11) at the bottom, where the shaft goes through. The plate has 16 holes through which the screws (14) that fix the guide vanes (6) are screwed into the base plate. At the top, another bearing is provided for the shaft (9). A conical housing (10) is also centrally placed using a set of screws (12) for supporting the pipe that ensures the connection with the mechanical testing assembly and through which the turbine shaft (9) passes.

3. The turbine rotor (1) - is placed as a continuation of the hydrodynamic profiled cone and has 4 blades with a NACA 2412 profile, having a diameter of 228 mm. The rotor is supported by the hydrodynamic cone and rotates inside the transparent plexiglass tube with an inner diameter of 230 mm.

The plexiglass tube is 2 meters long and is immersed at the bottom in the lower tank. The rotor is fixed to the transmission shaft by a transverse screw and thus the rotational movement is transmitted to the mechanical testing assembly. The basic drawing of the turbine is shown in figure 1.

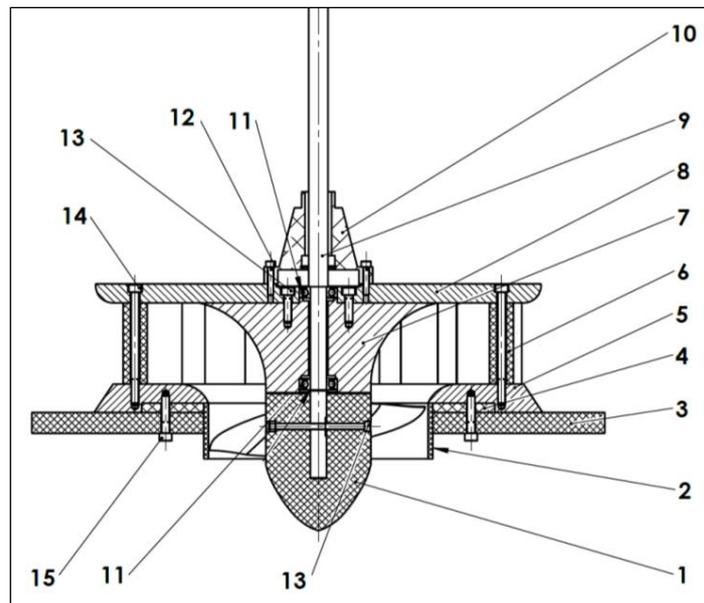

Fig. 1 – Low head micro-hydro turbine drawing

In order to calculate the rotor diameter, the statistical design method of Kaplan turbines can be used, based on the following relations according to *Anton, (1979)*:

$$D = a_D \frac{Q^{0.5}}{H^{0.25}} \quad a_D = 0,37 + \frac{270}{n_s} \quad n_s = 3,16n \frac{Q^{0.5}}{H^{0.75}} \quad (1)$$

where D – turbine diameter, a_D – coefficient expressed in relation with specific speed, Q – flow through the turbine, H – head of the turbine.

By applying the above formulas, resulted a rotor diameter of 228 mm and a specific speed n_s of 476. The hub diameter is recommended to respect a certain ratio between the total surface area exposed to the flow and the equivalent surface area where only the blades are exposed to flow. Therefore, according to *Anton, (1979)*, it is recommended that the ratio between the hub diameter and that of the rotor to be approximately 0.5 for a specific speed of approximately 500, resulting a hub diameter of 110 mm. Taking into account the distance of 1 mm between the tip of the blades and the wall of the draft tube, it results a 230 mm diameter of the plexiglass tube, around the rotor blades. The turbine draft tube is actually the transparent plexiglass tube that connects the two tanks of the testing stand. For the turbine model, a clear straight tube of plexiglass was chosen, although conical draft tubes with an opening angle of 10-12° contribute to a higher efficiency of the turbine (*Anton, 1979*). The straight clear tube was used in order to visualize the phenomena and considering that conical transparent tubes made from plexiglass were not available on the market. For the rotor blades design, the NACA 2412 hydrodynamic profile was chosen, which ensures good results in terms of lift coefficient. The rotor geometry was designed in 3D format and made of ABS on a 3D printer in the form of a compact part, with a transverse hole for the fixing screw. The overall drawing of the rotor in 3D view is shown in figure 2.

The guide vane system of the turbine is made of 16 blades that ensure de flow control and proper direction towards the rotor. In order to obtain maximum efficiency, the blade body must present minimal resistance to the current flow, resulting in a hydrodynamically optimized shape. The thickness of the profile must be large enough to withstand the water pressure in the completely closed position. The positioning angle α_D , between the tip of the trailing edge and the tangent to the circle drawn from centre and passing through its trailing edge must be precisely the angle α from the velocity triangle at the entrance of the rotor, in order not to cause sudden deviations of the current at the entrance. The dimensions of the guiding vanes system were chosen in such a way as to allow opening up to the maximum designed angle and closing to be done between the trailing edge of one blade and the inner surface of the next blade at a maximum of 0.25 of the chord length. For these blades, a symmetrical NACA 0018 profile was chosen that is slender enough to direct the water jet but with an adequate thickness to be securely in place with a M8 screw.

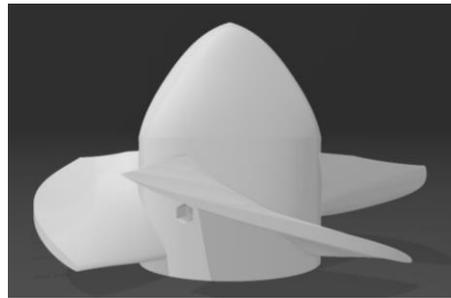

Fig. 2 – Rotor design for the low head micro-hydro turbine

The guide vanes are not adjustable during operation. Their position can be set at different angles before the turbine assembly. For the current testing, the placement angle was chosen to be 35° , according to the velocity triangle. The guide blade height is one of the parameters that, along with the angle α_b and the turbine speed, significantly influences the value of the flow rate Q and the circulation at the rotor entrance, respectively the energy conversion in the turbine (Anton, 1979).

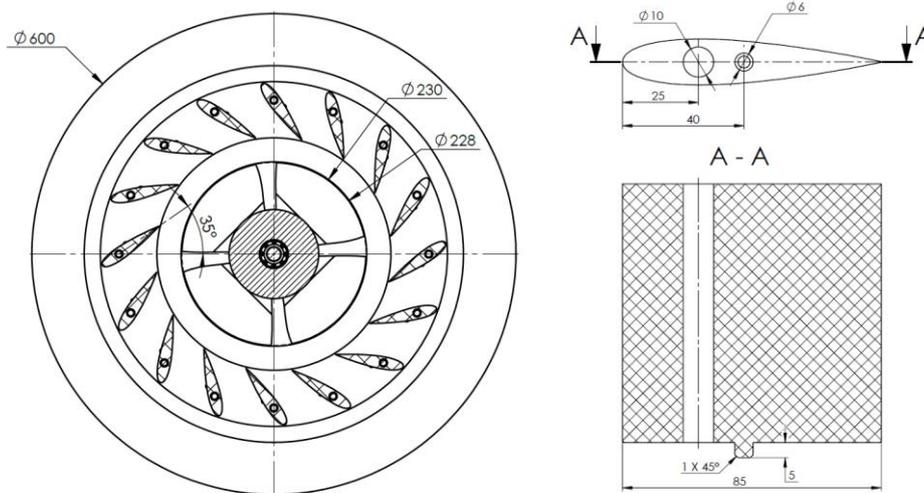

Fig. 3 – Guide vanes design of the turbine

The design of the guide vanes system is presented in figure 3. The base plate flange, the upper plate and the conical housing were made by CNC machining from aluminium. The rotor and the guide vanes were made from ABS using a 3D printer. Two glass bearings were used and the entire assembly was fitted using 16 screws (position 6 from figure 1). A rubber gasket was used to seal the bottom tank and was placed under the turbine assembly presented in figure 4.

Fig. 4 – Low head micro-hydro turbine assembly ready for testing

The turbine has a mechanical testing assembly attached to its upper part. It comprises of an assembly consisting of elastic couplings, a torque transducer and an electromagnetic brake and is capable of performing torque measurements up to 20 Nm and rotational speeds up to 4000 rpm. Figure 5 schematically shows the mechanical test assembly and the related components.

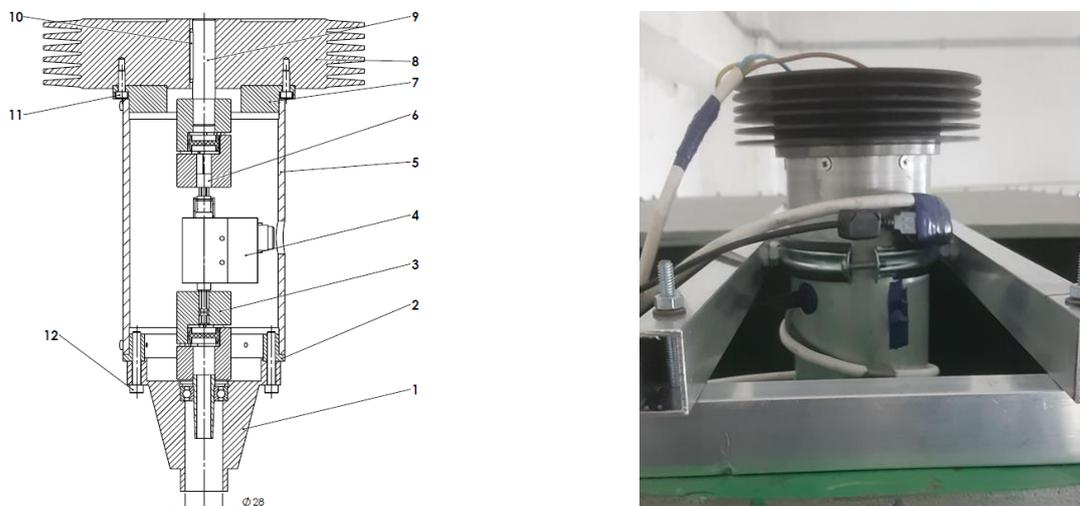

Fig. 5 – Mechanical testing assembly for the low head micro-hydro turbine

The assembly is mounted on the support rod using the conical part (1), which is connected to a plate (2) bolted into a cylindrical housing (5), on which an intermediate flange (7) is supported. This flange also represents the support for the electromagnetic particle brake (8). A shaft (9) transmits the movement from the turbine to this testing assembly through an elastic coupling (3) connected to the torque and speed transducer (4). At the top of the enclosure, the brake is also connected through an elastic coupling (6). The entire assembly is joined using a set of screws (11,12). The mechanical testing assembly is attached to the turbine and the entire assembly is lowered into the upper tank for integration into the hydraulic testing stand.

The turbine was designed to generate 1 kW of power operating at 2.4 m head and 360 m³/h flow. The tested model reached a maximum output of 526 W at 2 m head and 240 m³/h flow. The rotor is made from thermoplastic by 3D printing; thus, the flow through the turbine was limited to avoid damaging the blades. The turbine efficiency depends on the flow and head parameters. It can operate at partial load with reduced flow but the efficiency is highly affected where there is no adjustable blade system for the runner and the guiding vanes. Such a system is very complex, adds additional costs, is subject to more frequent wear and tear and requires periodic maintenance. Thus, it is not suitable for small scale microturbines due to the fact that the power increase is not significant in order to justify the additional cost of implementation and maintenance. The turbine can operate in water with sand or some small debris, but overtime, the turbine can be damaged. To avoid such issues, a screen can be fitted at the discharge pipe that supplies water to the reservoir; it can be cleaned or changed periodically, depending on the water quality.

TURBINE TESTING

The turbine was integrated into a specially designed testing facility. The testing stand comprises of a pumping unit with three pumps (7.5 kW, 120 m³/h) that circulates water between two overlapping tanks, the lower one with a volume of 3840 litres and the upper one with a volume of 2400 litres, located on a supporting metal structure (Popescu *et al.*, 2024). The pumping unit is connected using a hydraulic circuit made of pipes of 200 mm diameter, which has integrated an electromagnetic flow meter in order to permanently monitor the flow through the stand and turbine, respectively. The connection between the two tanks is ensured by a transparent plexiglass tube. The operation of the stand and data acquisition are performed using a programmable logic controller connected to a PC that can monitor the parameters and store them for further analysis. The low head micro-hydro turbine testing stand and its main components are presented in figure 6.

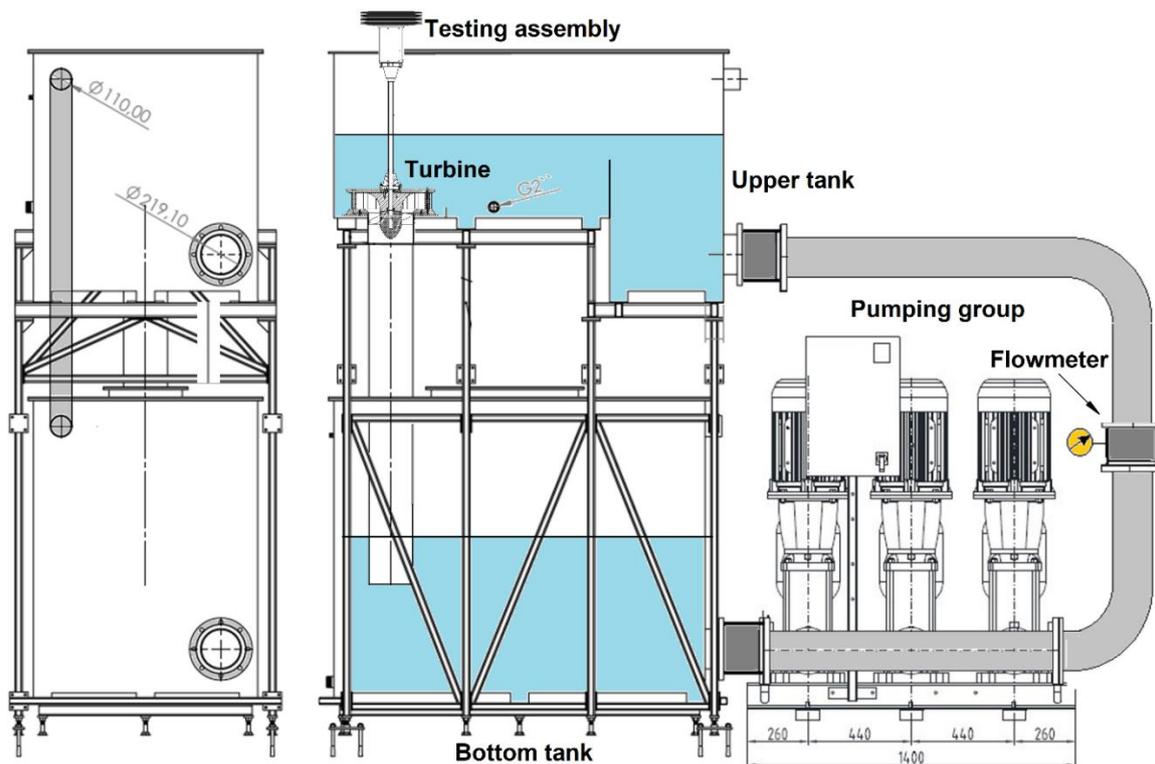

Fig. 6 – The testing stand of the low head micro-hydro turbine

The turbine was placed into position, according to figure 6, with the rotor aligned inside the transparent plexiglass tube. The testing procedure involved the following steps:

- Filling the lower tank to a maximum level, determined so that the volume of water ensures the filling of the entire installation (draft tube + pump + discharge pipe + buffer tank + vertical tube), providing a proper level in the upper tank of about 1 meter above the turbine;
- Setting the working flow rate and monitoring the rotational speed and torque of the turbine after stabilizing the flow regime; by slowly activating the brake, results a progressive increase in the useful torque at the rotor shaft;
- Progressively actuating the brake until the rotor stops and thus the maximum power of the turbine can be determined at a specific flow rate and head.

Figure 7 shows the turbine placed inside the tank, with the rotor protruding into the transparent tube, so that it can be observed during the experiments. In order to ensure a constant head for testing the turbine, the stand pumps are operated by an automatic flow rate adjustment system depending on the level set by the user, through a software application. To determine the energy parameters of the turbine, its shaft is coupled to an electronically adjustable electromagnetic brake and a torque/speed transducer. The recorded values are integrated into a data measurement and storage system in the form of a .csv database.

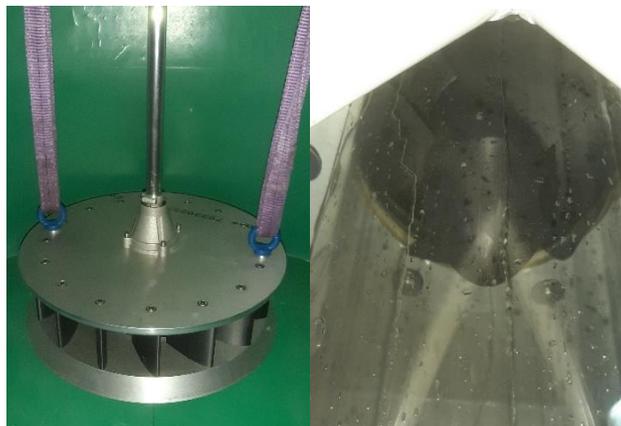

Fig. 7 – The low head micro-hydro turbine during mounting

Aspects from the turbine testing were captured in Figure 8 with details on the data acquisition system, the electromagnetic flow transducer and the transparent Plexiglas tube through which the wake caused by the rotor movement can be observed.

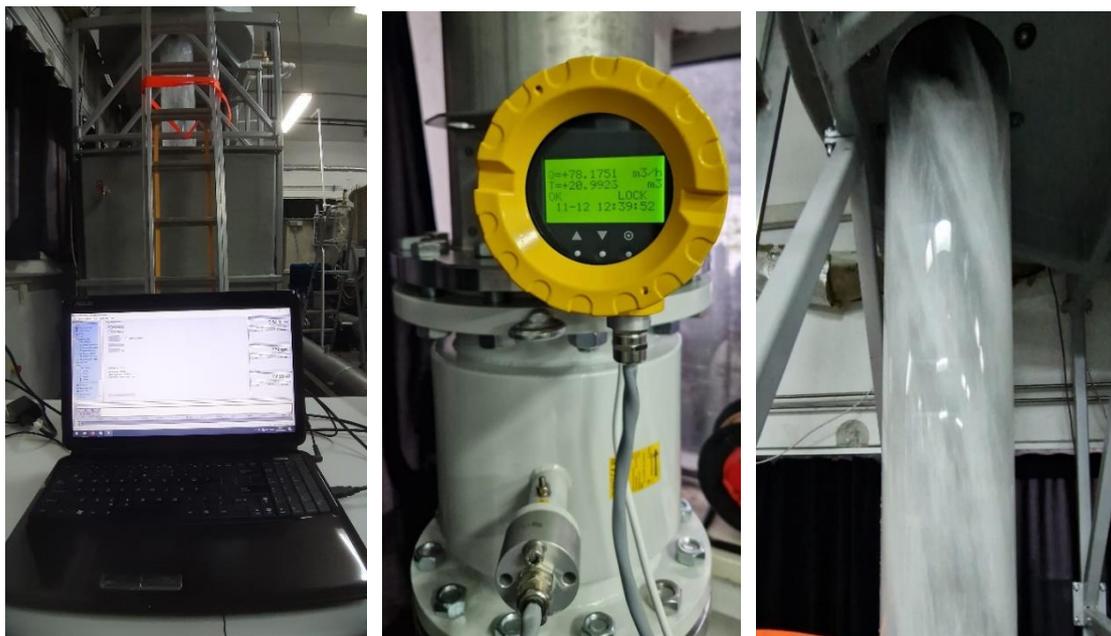

Fig. 8 – Testing of the integrated low head micro-hydro turbine

The rotor used for the experiments, made from ABS thermoplastic, withstood the tests without any damage. For evaluation purposes, this type of material can be used given the reduced operation time, but in real operating conditions, other materials must be considered, such as aluminium or stainless steel. Plastic rotors can be easily damaged by debris and are more prone to wear. The guide vanes and the draft tube should also be manufactured from strong, corrosion resistant materials. The draft tube of the testing stand was made from plexiglass in order to observe the flow around and after the rotor. This material is suitable only for laboratory conditions; for full-scale turbines, this tube must be replaced with a metal pipe.

RESULTS

The maximum flow considered when testing the turbine was of 240 m³/h, along with a head of 2 meters. The results demonstrated the importance of operating as close as possible to the design conditions, otherwise the efficiency can be greatly diminished. The objective of the tests was to study how the energy conversion occurs at the rotor level in order to improve its efficiency and determine how a low head micro-hydro turbine can be used for efficiency increase in solar powered irrigation systems. In addition to the hydraulic parameters that are critical for maximizing power, the resistant torque of the generator coupled to the turbine must be also taken into account.

The mechanical torque at the shaft resulting from the turbine-generator interaction determines a certain rotational speed and the optimal operating point must be identified through experimental tests. The high torque at the shaft breaks the rotor and a low rotational speed negatively influences the power output. On the other hand, the maximum speed is obtained at idle operating point and the generator load must be adapted to maintain a relatively high rotational speed, while maintaining a useful torque. Thus, such systems require a dedicated power converter unit based on a MPPT algorithm using perturb and observe method, integrating boost and buck converters for powering a considered load (*Chihai et al., 2020*). The robust power peak seeking control algorithm also presents a good option for attaining a high operating efficiency by achieving maximum power point tracking through a line search triggered by real-time measurements (*Naik et al., 2024*). These types of electronic controllers are also used for hydrokinetic turbines and have proven their functionality. The testing results of the turbine are synthesized in the diagram in figure 9, which shows the power output depending on the rotational speed of the rotor.

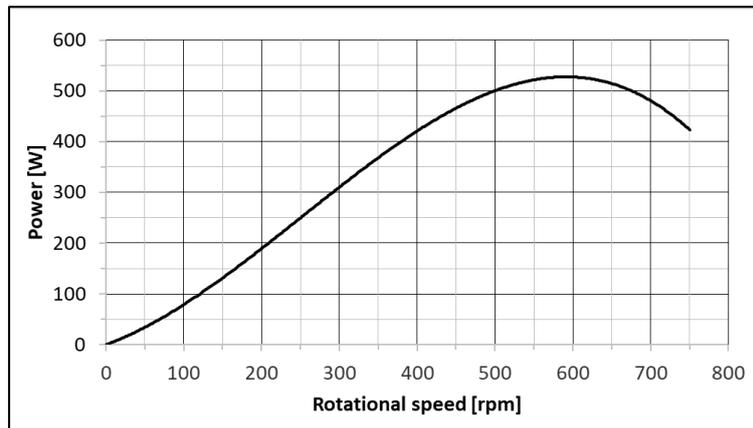

Fig. 9 – The power diagram of the micro-hydro turbine

The curve shows a peak of 526 W at around 600 rpm for the turbine tested at a 240 m³/h flow and 2 meters head. The efficiency varies depending on the available flow and head reaching up to 40% at the highest power value, as shown in figure 10.

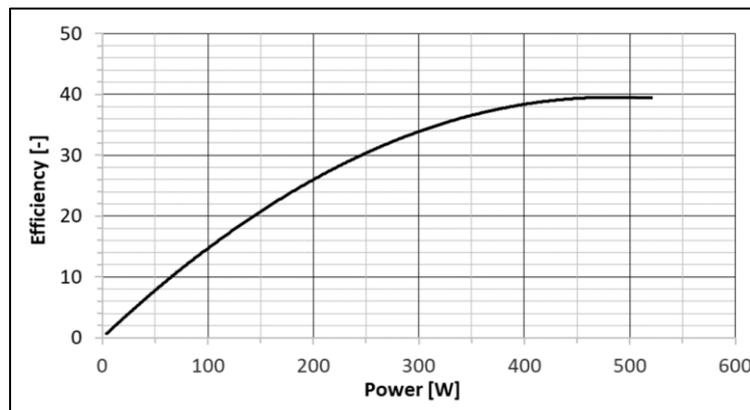

Fig. 10 – Efficiency curve of the micro-hydro turbine

The results demonstrate that a turbine can produce a power of around 500 W placed beneath a tank suspended at about 2 meters, where sufficient flow is ensured, as the case of irrigation systems using storage tanks. This power output can increase the global efficiency of a solar powered irrigation system feeding the electricity back to the pumping unit. In order to demonstrate the feasibility of the system, a reduced scale solar powered irrigation system with a turbine embedded can be designed and studied. The basic operating principle of such systems is presented in figure 11.

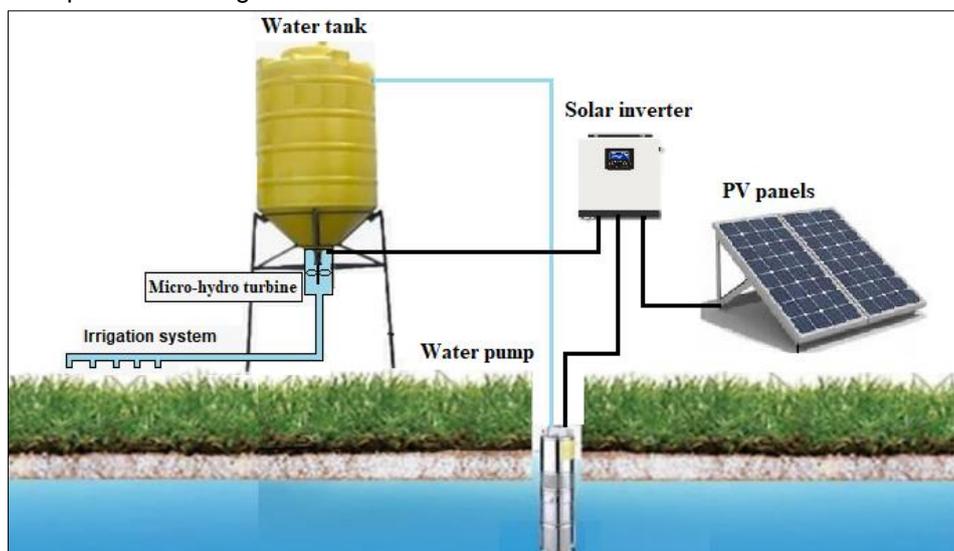

Fig. 11 – Reduced scale solar powered irrigation systems with embedded low head micro-hydro turbine

The water pump creates pressure that fills the tank when supplied with electricity from PV panels. The solar inverters manage the power received by the pump according to the power supplied by the panels, and the batteries state of charge (if the system is equipped with storage). The micro-hydro turbine is placed beneath the tank and supplies electricity when water flows for irrigation. It is also connected to the solar inverter and thus increases the overall efficiency of the system. In order to perform efficiency calculations for the proposed system, the parameters of the involved devices are presented below:

- **PV panels:** 5 x 500 W_{peak} , 2094 x 1134 x 35 mm, half-cut, monocrystalline cells, 21% efficiency;
- **Electric pump** CBM 303/A, 2.2 kW power, 42 m^3/h , head up to 22 meters, single-phase 230V. Another type of pump that can be used for DC application is Lorentz S1-700 model, with a maximum flowrate of 10 m^3/h and a power of 750 kW. In this case, 3 pumps can be deployed for ensuring 30 m^3/h at around 2.25 kW similar with the a.c. version.
- **Solar inverter/hybrid inverter:** 3200 W maximum power, off-grid type, single phase 230 Vac output, input from PV panels and hydro-turbine using a power controller and voltage stabiliser;
- **Micro-hydro turbine** of 1 kW maximum power, obtainable at 2.4 m head, with a flow rate of 360 m^3/h and a rotational speed of 850 rpm. The turbine will be connected to a permanent magnets synchronous electric generator with the rated power of 1 kW at 850 rpm, single phase output. Although the generator voltage will be around 230 Vac, due to the variation of the flow parameters, the turbine will have speed variations and thus the output voltage will be affected. To avoid any issues and to safely connect the solar inverter, a voltage stabilizer must be inserted in between in order to handle the voltage fluctuation in the range of 120 V-270 V ensuring a stable output of 230 Vac. If a DC system is considered, then the electric generator will have to comply with 24/48 Vdc voltage with a DC-DC buck-boost converter added to supply a constant voltage.

For an irrigation system, any type of PV panel is suitable as long as the string of panels are compatible in terms of voltage and current with the selected inverter. Lightweight PV panels are at hand because they are easy to handle and can be integrated into a mobile system. A renewable energy mobile containerized system can be deployed for off-grid application based on PV panels and micro-wind turbine in order to directly provide the energy via DC-DC power supply.

This type of application can be intended for irrigation and fertirrigation, in semi-dry and dry-sub-humid arid climates and was developed within a project that envisaged innovative technologies for crop irrigation, (Onose *et al.*, 2020).

In terms of energy balance, if a daily electricity production from PV panels of 20 kWh is considered, it results in approximately 9 hours operation time of the 2.2 kW pump. If the flow through the turbine is ensured in the range of 200 to 300 m^3/h flow and a minimum of 2 meters head, then the energy produced can be estimated to be around 4.5 kWh. Thus, across 24 hours, the turbine can ensure about 22.5% of the electricity needed for irrigation.

CONCLUSIONS

The work presented in this paper demonstrated the benefit of using low head micro-hydro turbines for increasing the efficiency of solar powered irrigation systems that use storage tanks. Testing performed with such a turbine in laboratory conditions using dedicated testing stand highlighted the fact that it can supply up to 526 W at 240 m^3/h and 2 meters head, making it a feasible solution for a small-scale irrigation system. The contribution of the turbine is useful because energy surplus is needed especially when irrigating during mornings and evenings, when the power production of the PV system is reduced. The additional power output can increase the global efficiency of a solar powered irrigation system, feeding the electricity back to the pumping unit. For a PV power system that provides 20 kWh/day, the turbine can ensure around 22.5% of the energy needed for irrigation. Given the aspects mentioned above, if the envisaged irrigation systems require water storage tanks, then the use of complementary low-head micro-hydro turbine can be a solution for increasing the global efficiency of the PV irrigation systems. The turbine converts the pressure energy of the stored water into mechanical energy and is suitable where reduced flow is needed, as the case for drip irrigation. Further research must be carried out in order to correlate a proper storage solution for a certain PV panel configuration used in an irrigation system. Renewable energy systems based on PV panels represent the best choice for powering a remote irrigation system without access to the grid. Improved solutions are being continuously developed worldwide and the work presented in this paper gives a new perspective on how to optimize the operation of solar powered irrigation systems in terms of energy efficiency.

Keywords: Corn grains, damage, CDDRS-SCK, threshing damage

ABSTRACT

This study addresses the issue of corn grain damage, which limits the efficiency of mechanized corn harvesting. The characteristics and distribution of corn grain surface damage resistance (CDDRS-SCK) were investigated. The "vulnerable" surface of the corn grain was selected for damage testing. The results revealed significant variations in damage resistance across different surfaces and locations of the corn grains. A regression model for damage resistance strength, based on surface position, was developed. Additionally, the impact of grain damage resistance on threshing damage was compared and analyzed for different threshing devices, in accordance with their working principles. This research provides theoretical insights and data support for the development of corn mechanized threshing technology and equipment.

摘要

针对玉米籽粒损伤制约玉米籽粒机械化收获的问题。本文开展了对玉米籽粒表面抗损伤强度(CDDRS-SCK)的特征及分布研究。选取“易伤”表面进行损伤试验,结果表明玉米籽粒不同表面、位置的抗损伤强度具有显著差异性,构建了基于表面位置的籽粒抗损伤强度回归模型。结合不同脱粒装置工作原理,对比分析了籽粒抗损伤特性对不同装置脱粒损伤的影响规律。为玉米机械化脱粒技术与装置开发提供了理论指导与数据支持。

INTRODUCTION

Threshing is a critical stage in the corn harvesting process. High-moisture corn kernels are particularly susceptible to damage during direct harvest due to the interaction and friction between the kernels and threshing teeth (Kruszelnicka *et al.*, 2024). This damage not only affects the quality of the harvested corn but also compromises the secure storage of the grain (Li *et al.*, 2022). Research has shown that the majority of physical damage to corn kernels occurs during threshing, primarily as a result of random collisions (Petkevichius *et al.*, 2008). Consequently, minimizing threshing-induced damage has become a fundamental objective in the mechanical harvesting of corn.

Extensive research has been conducted on the characteristics of corn kernel damage, highlighting the influence of various factors on threshing outcomes. Corn variety and grain moisture content are significant determinants of the degree of threshing damage (Sehgal *et al.*, 1965). Studies have shown that as the moisture content increases, the damage ratio of corn kernels also rises (Yi *et al.*, 2016). Experimental findings further reveal that when corn kernels are positioned flat, moisture content exerts the greatest influence on the force required for kernel damage (Yu *et al.*, 2019). To investigate the mechanisms of corn kernel damage, research has focused on the stresses experienced by kernels during damage. The internal structural properties of kernels are a primary cause of damage (Dorsey-Redding *et al.*, 1990). Using electron microscopy, it was observed that fractures in maize subjected to high-temperature drying initially appeared in the silty endosperm and then rapidly propagated along the starch granule boundaries (Gunasekaran *et al.*, 1985). Compression experiments on corn kernels have demonstrated that their damage-resistance strength varies significantly under different stress conditions (Gao *et al.*, 2011; Yuan *et al.*, 1996).

Zhao further established the maximum tensile stress that can be sustained by different kernel surfaces (Zhao., 2012). The effects of threshing structures and operational parameters on maize damage have also been extensively studied. Waelti identified drum speed, threshing gap, and rasp bar structure as the primary factors contributing to threshing damage (Waelti, 1967). Arnold demonstrated that reducing drum speed is the most effective method to decrease the rate of corn kernel damage (Arnold et al., 1964). Additionally, Wu showed that plate-tooth threshing offers advantages over traditional pin-tooth threshing, including a higher threshing rate, lower kernel breakage, and reduced power consumption (Wu et al., 2006). Geng explored the application of the flexible threshing concept and proposed a novel strategy to mitigate maize damage during the threshing process (Geng et al., 2020).

In conclusion, extensive research has characterized corn damage resulting from various mechanical components and forces, leading to the development of threshing devices with diverse mechanical structures and operating principles. However, the characteristics and spatial distribution of damage-resistance strength on the surface of corn kernels (CDDRS-SCK) have not been thoroughly investigated. This knowledge gap limits the understanding of the mechanisms underlying corn kernel damage and hinders the establishment of a robust foundation for parameter optimization in threshing device design. This study aims to analyze the CDDRS-SCK and its contributing factors, and to evaluate its potential influence on the structural and operational design of threshing machinery.

MATERIALS AND METHODS

Test equipment

The experimental data were obtained through a surface damage experiment conducted on corn kernels. The experimental setup consisted primarily of corn kernels, a custom-designed indenter, and a WDS-5 liquid crystal display electronic universal testing machine (accuracy: 0.2% F.S.), which included a lifting table, guide rails, a lift controller, a compression head, and a display screen. The corn kernels used in this study were from the widely cultivated "Zhengdan 958" variety, commonly grown in the Huanghuaihai region of China. The experimental apparatus for corn kernel surface damage is depicted in Fig. 1.

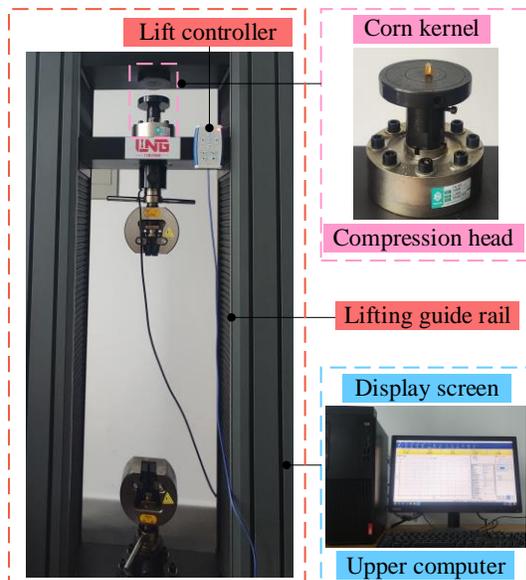

Fig. 1 - Corn kernel damage experiment device

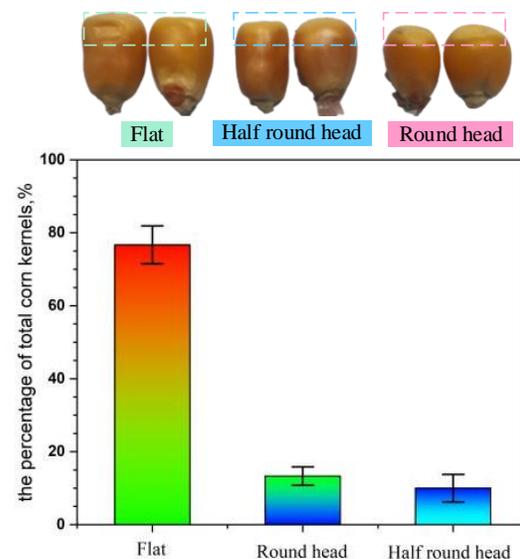

Fig. 2 - Corn kernel shape distribution map.

Selection of experimental corn kernels

Corn ears of the "Zhengdan 958" variety, with a moisture content of 24.5%, were harvested on September 26, 2024. Due to variations in component distribution and exposure to light, the head, middle, and tail sections of the corn ears exhibit distinct morphological characteristics. All corn kernels were manually peeled and categorized into three types based on their apex morphology: flat, round, and half-round. It was observed (Fig. 2) that approximately 80% of the kernels from the middle section of the corn ear are flat kernels.

Notably, flat kernels exhibit the lowest damage-resistance strength (DRS) among the three kernel types, as reported by (Vyn *et al.*, 1988). This implies that as long as the flat kernels remain intact during threshing, other kernel types are unlikely to be damaged. Consequently, flat kernels are representative of the DRS of corn kernels and were selected as the focus for investigating the characteristics and distribution of damage-resistance strength on the surface of corn kernels (CDDRS-SCK) in this study.

Test scheme

Definition of corn kernel test surface

The internal heterogeneity of corn kernels, as illustrated in Fig. 3, contributes to variations in the damage-resistance strength (DRS) across different kernel surfaces. This necessitates a comprehensive investigation of the DRS across all kernel surfaces. Preliminary damage testing of corn kernels revealed that the DRS of the left and right sides of the kernel is nearly identical, while the DRS of the main surface is significantly lower than that of the back surface. To accurately determine the characteristics and distribution of damage-resistance strength on the surface of corn kernels (CDDRS-SCK), it is critical to focus on surfaces most susceptible to damage, as these are the first to fail under repeated impacts from threshing elements. Therefore, the main surface, top surface, and left surface of corn kernels—referred to as "damage-susceptible" surfaces—were selected for this study.

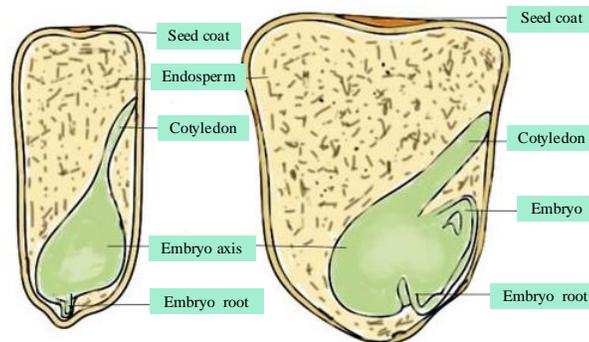

Fig. 3 - Corn kernel shape distribution map

Test procedure

A random sample of approximately 1000 hand-threshed corn kernels, with a moisture content of 24.3%, was selected for the study. To ensure uniform contact between the kernel surfaces and the indenter, the "damage-susceptible" surfaces of the experimental kernels were subjected to micro-grinding and marked using the point-marking method illustrated in Fig. 4. The marked points on each kernel surface were sequentially numbered from top to bottom and left to right. The indenter was carefully adjusted to align with a specific marked point on the corn kernel. Each marked point was then subjected to loading at a constant rate of 200 mm/min until the maximum damage-resistance force was recorded. To ensure reproducibility and statistical reliability, the average damage-resistance force F_i at each marked point was determined as the arithmetic mean of 20 repeated measurements, as expressed in equation (1):

$$F_i = \frac{1}{n} \sum_{j=1}^n F_{ij} \quad (1)$$

where F_i is the average force at point i ; F_{ij} is the j -th force measured at the same point, and $n=20$.

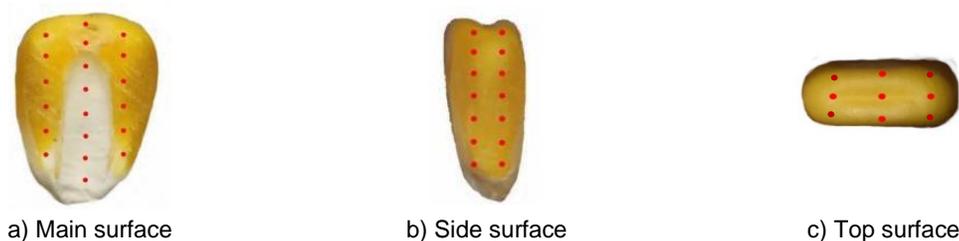

Fig. 4 - Different surface markers of corn kernels

Test evaluation index and calculation method

(1) Maximum damage-resistance force (F)

The maximum damage-resistance force (F) is defined as the highest force that can be applied to the surface of corn kernels before visible damage occurs. It corresponds to the maximum load sustained by the kernels under continuous application of pressure using a testing machine.

(2) Damage-resistance strength (DRS)

Damage-resistance strength (DRS) is defined as the maximum contact stress that corn kernels can endure without sustaining damage, serving as a critical parameter for evaluating their load-bearing capacity. To enhance the precision of DRS measurements across the surface of corn kernels, the concept of equivalent damage-resistance strength ($EDRS$) is introduced. The $EDRS$ is calculated as the mean DRS value derived from n experiments conducted at the same location on different corn kernels. The following formula is used to determine the $EDRS$:

$$\sigma_0 = \sigma_v = \frac{1}{n} \sum_{i=1}^n \frac{F_i}{A_0} \quad (2)$$

where, σ_0 represents the DRS at a specific location on the corn kernel, σ_v denotes the $EDRS$ at the same location, F_i is the maximum damage-resistance force recorded at the specific position across n repeated experiments on different kernels, A_0 is the contact area between the kernel and the custom-made indenter during the experiment, approximately 1 mm².

Test

The aforementioned testing protocol was applied to conduct loading tests at different locations on the same corn kernel until visible damage occurred. As illustrated in Fig. 5, the following tests were performed. For the main surface (a) of the corn kernel, two loading tests were conducted sequentially from left to right. For the side surface (b), a total of 14 loading tests were performed from left to right. For the side surface (c), nine loading tests were conducted, also from left to right. This systematic approach ensured comprehensive evaluation of the damage-resistance strength across multiple kernel surfaces.

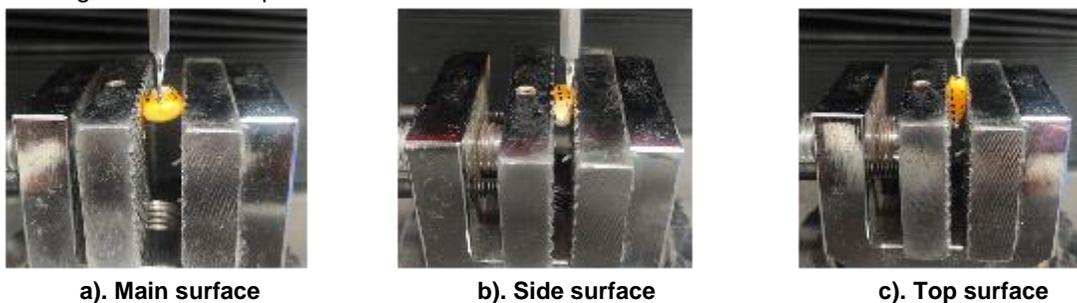

Fig. 5 - Surface loading test of different corn kernels

Based on the test sequence described above, a series of repeated experiments were conducted, as shown in Fig. 6. The resulting trends in the load-displacement curves were generally consistent. The average load-bearing capacity across different surfaces of the corn kernels exhibited a similar pattern: as the indenter displacement increased, the load on the kernel surface increased linearly until surface damage occurred, at which point the load-bearing capacity dropped abruptly. This behavior can be attributed to the elastic deformation of the kernels during the initial loading phase. Within this elastic deformation range, the stress on the kernel surface increases linearly with the indenter displacement. However, when the load exerted by the indenter exceeds the kernel surface's load-bearing capacity, the kernel surface fails, leading to a sudden decline in its carrying capacity. These findings highlight the importance of controlling the applied load during the mechanized harvesting of corn. Ensuring that the load remains below the kernel surface's carrying capacity is critical for maintaining harvest quality and minimizing kernel damage.

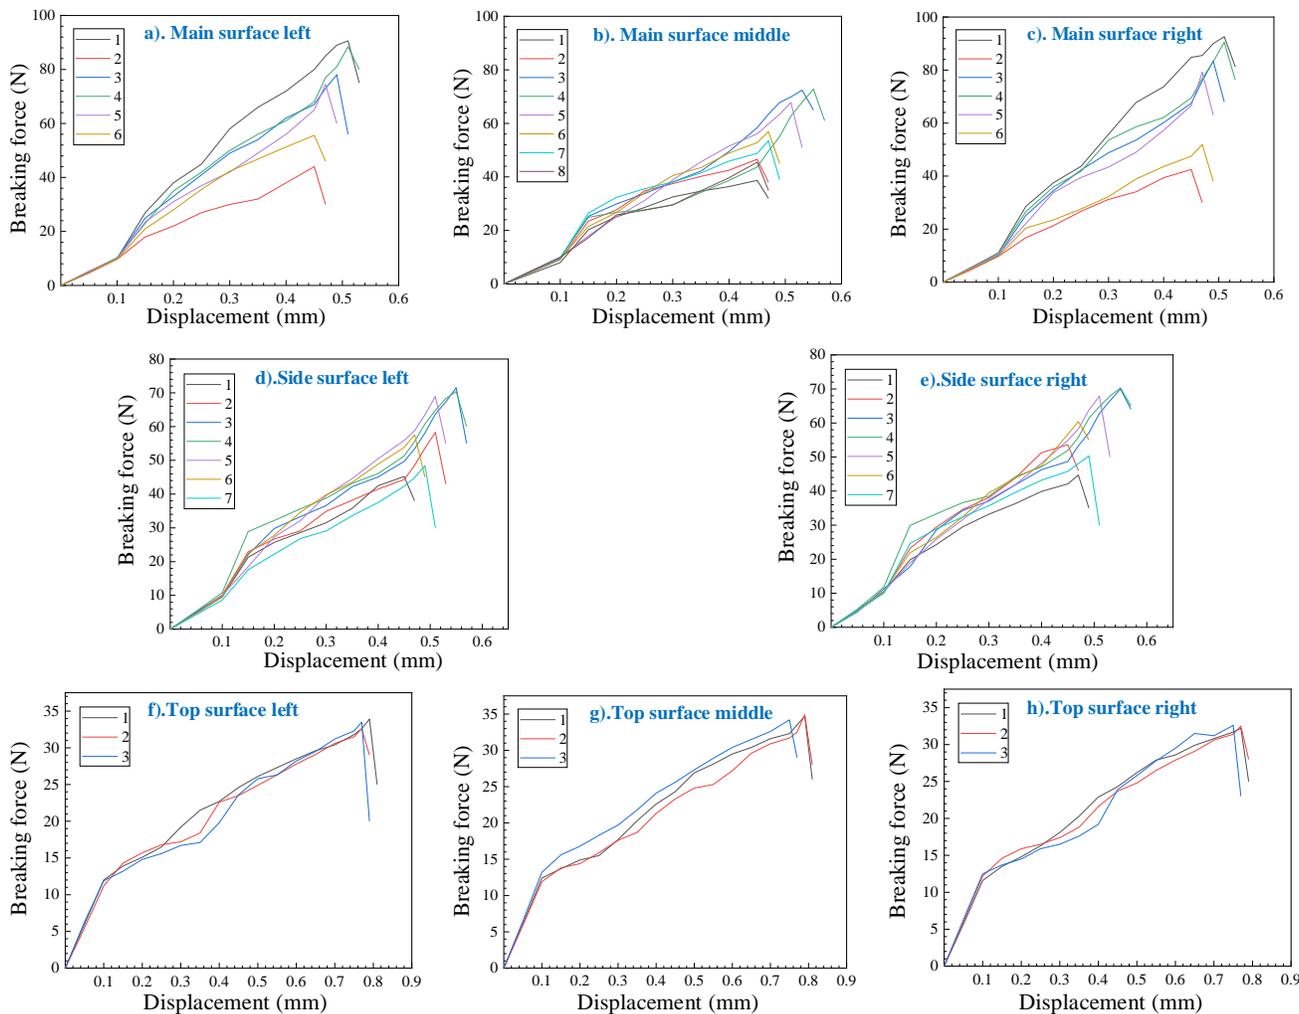

Fig. 6 - Grain surface stress curve

RESULTS AND DISCUSSIONS

Results

The results of the corn kernel damage experiment are summarized in Table 1, highlighting the maximum damage-resistance force for each surface. The data indicate that the main surface of the corn kernel exhibits the highest maximum damage-resistance force, while the top surface demonstrates the lowest. These findings suggest that during corn harvesting, kernel damage can be effectively minimized if the force applied by the threshing element remains below the maximum damage-resistance force of the top surface. This observation aligns with the conclusion that beak threshing results in reduced threshing damage, as reported by (Li et al., 2015).

[*] The numbering of marked points follows the instructions in Fig 4. 44.5 ± 9.0 ; [†] represents the damage resistance force of the first marked point on the left side of the main surface of the corn kernel is 44.5 N and the mean square is 9.05.

While the damage-resistance force provides a partial measure of the relationship between applied force and corn kernel damage, failure theory indicates that a large applied force does not necessarily cause damage. Damage to the corn kernel surface or interior tissue occurs only when the externally applied load exceeds the material's inherent resistance strength. To better quantify this phenomenon, the equivalent damage-resistance strength (EDRS) at each marked point was calculated in this study. To visually represent the characteristics and distribution of damage-resistance strength on the surface of corn kernels (CDDRS-SCK), all calculated results were processed using the Origin software. The resulting contour maps of damage-resistance strength distribution across the three kernel surfaces are shown in Fig. 7. The analysis revealed distinct differences in the characteristics and distribution of damage-resistance strength across the three surfaces, as well as variations within each individual surface. These findings highlight the need for further investigation into the distribution and characteristics of damage-resistance strength on each kernel surface, with a focus on identifying the locations with the highest resistance to damage.

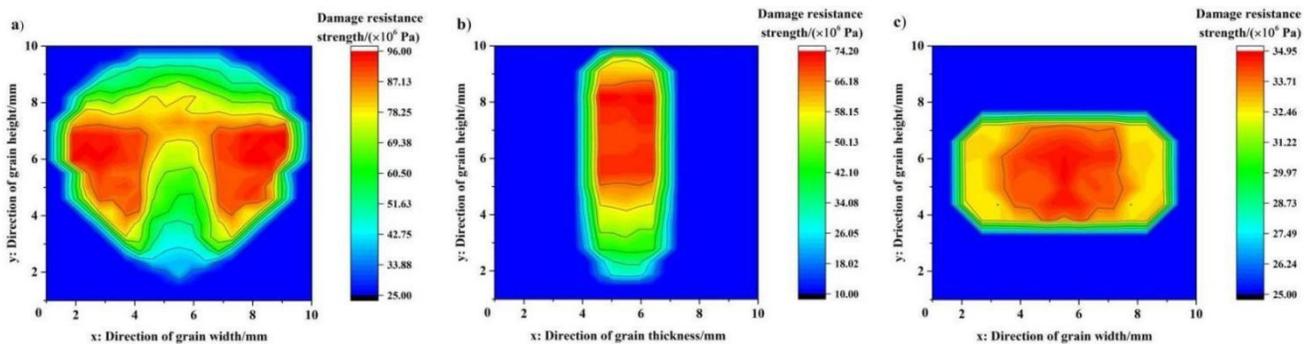

Fig. 7 - The distribution of damage-resistance on the a) main, b) side, and c) top surface of the corn kernel

Characteristics and distribution of damage resistance strength on the main surface of corn kernels

The characteristics and distribution of damage-resistance strength on the main surface of the corn kernel (CDDRS-MSCK) are shown in Fig. 8(a). The x-axis is defined along the lower boundary of the corn kernel, while the y-axis is defined along its left boundary. The CDDRS-MSCK is analyzed in both the width and height directions of the corn kernel. The distribution curve of damage-resistance strength in the horizontal direction at $y=6$ mm, which is symmetrically distributed along the width, is depicted at the top of Fig. 8(a). This curve represents the distribution and characteristics of damage-resistance strength along the width of the kernel's main surface. The results indicate that the damage-resistance strength in the middle of the kernel is approximately 74.5×10^6 Pa, while it symmetrically increases to about 97×10^6 Pa on both sides of the kernel. This pattern is attributed to the structural composition of the kernel in the width direction: the sides predominantly consist of endosperm deposits, whereas the central region mainly contains cotyledons, the germ, and the radicle, which are structurally weaker. Based on the CDDRS-MSCK findings, it is recommended that when the main surface is selected as the primary stress surface for threshing, the loading position should target the sides of the kernel while avoiding the central region. Additionally, to prevent the threshing load from concentrating on the kernel's center, the contact position between the threshing element and the kernel should span more than half the kernel's width.

The vertical directions $x = 3.5\text{mm}$, 5.5mm , and 7.5mm are chosen to evaluate the damage-resistance strength in the height direction at the right of Fig 6. The characteristics and distribution of damage-resistance strength at $x = 3.5\text{mm}$ and $x = 7.5\text{mm}$ are essentially identical in that the damage-resistance strength of the height direction range $y \in [4.2\text{mm}, 6.85\text{mm}]$ approaches $90 \times 10^6 \text{ Pa}$. While the damage-resistance strength decreases gradually in height direction between $y \in [0\text{mm}, 4.2\text{mm}]$ and $y \in [6.85\text{mm}, 10\text{mm}]$. This is because the region is predominantly endosperm and has a progressive maturation pattern. At a height of $x = 5.5\text{mm}$, the damage-resistance strength of the higher component is greater than that of the smaller lower portion. That's because, in the direction of height $x = 5.5\text{mm}$, the structures at the bottom are the radicle, germ, and hypocotyl, while the structures at the top are the endosperm structure. And during corn development, water is transferred from the radicle to the endosperm, and the kernel's aggregation leads the upper surface to lose more water than the lower section.

The vertical positions $x=3.5 \text{ mm}$, 5.5 mm , and 7.5 mm were selected to evaluate the damage-resistance strength in the height direction. The characteristics and distribution of damage-resistance strength at $x=3.5 \text{ mm}$ and $x=7.5 \text{ mm}$ are largely similar. In the height range $y \in [4.2 \text{ mm}, 6.85 \text{ mm}]$, the damage-resistance strength approaches approximately $90 \times 10^6 \text{ Pa}$. However, the damage-resistance strength decreases progressively in the height ranges $y \in [0 \text{ mm}, 4.2 \text{ mm}]$ and $y \in [6.85 \text{ mm}, 10 \text{ mm}]$. This reduction is attributed to the predominance of endosperm tissue in these regions, which exhibits a gradual maturation pattern. At $x=5.5 \text{ mm}$, the damage-resistance strength in the upper region is higher than in the lower region. This difference arises from the structural composition along this height direction: the lower portion predominantly contains the radicle, germ, and hypocotyl, whereas the upper portion consists mainly of endosperm tissue. During corn development, water transfer occurs from the radicle to the endosperm, leading to differential moisture loss. The upper region, composed primarily of endosperm, loses more water due to aggregation effects, resulting in greater resistance compared to the lower section.

When the main surface of the corn kernel is subjected to loading by the threshing element, it is recommended to select loading positions within the width range $x \in [2 \text{ mm}, 4.5 \text{ mm}] \cup [6.5 \text{ mm}, 9 \text{ mm}]$ and the height range $y \in [4.2 \text{ mm}, 6.85 \text{ mm}]$. This selection is expected to be more effective in reducing the corn kernel damage rate.

Characteristics and distribution of damage resistance on the side surface of corn kernels

As illustrated in Fig. 8(b), the characteristics and distribution of damage-resistance strength on the side surface of the corn kernel (CDDRS-SSCK) are presented. In the thickness direction, the damage-resistance strength exhibits a trapezoidal distribution. This pattern arises because the sides of the corn kernel predominantly consist of endosperm, which has a relatively homogeneous texture. Within a specific range, the damage-resistance strength remains largely uniform. However, as the edge of the kernel is approached, the resistance to damage decreases sharply due to stress concentration at the borders. Consequently, when the side of the kernel is subjected to loading by a threshing element, the loading position along the thickness direction has minimal impact on kernel damage. The damage-resistance strength along the vertical direction at $x=5.5 \text{ mm}$ follows an upward-sloping "bathtub" distribution. The maximum damage-resistance strength is observed in the height range $y \in [5.75 \text{ mm}, 8.1 \text{ mm}]$, while it decreases both above and below this range. The decline is more pronounced in the downward direction, as the middle and upper portions of the kernel are primarily composed of endosperm, with greater endosperm accumulation in the middle. In contrast, the lower portion consists mainly of radicle tissue, which exhibits lower resistance to damage.

Based on the analysis, selecting a threshing loading position within the height range $y \in [5.75 \text{ mm}, 8.1 \text{ mm}]$ along the side surface of the corn kernel is more effective in reducing the kernel damage rate during threshing.

Characteristics and distribution of damage resistance on the top surface of corn kernels

The characteristics and distribution of damage-resistance strength on the top surface of the corn kernel (CDDRS-TSCK) are analyzed along the width and thickness directions, as shown in Fig. 8(c). The damage-resistance distribution curve along the width direction at $y=5.5 \text{ mm}$ is illustrated in the upper curve of Fig. 8(c), which exhibits an "inverted bathtub" shape. This pattern arises because the top surface of the corn kernel primarily consists of endosperm, resulting in generally comparable damage-resistance strength. However, the longer endosperm precipitation time in the central region produces a smaller peak in the middle of the curve.

The curve further demonstrates that the damage-resistance strength on the top surface remains stable within the width range $x \in [2.1 \text{ mm}, 8.9 \text{ mm}]$ before rapidly decreasing. This decline is primarily attributed to the narrow upper and lower kernel structures and the stress concentration at the edges. In the thickness direction, the characteristics and distribution of damage-resistance strength, depicted on the right side of Fig. 10, resemble those observed in the thickness direction of the corn kernel's side surface. This similarity indicates that variations in loading positions along the thickness direction have minimal impact on threshing damage.

Therefore, to minimize the risk of corn kernel damage, the threshing element should target the width range $x \in [2.1 \text{ mm}, 8.9 \text{ mm}]$ on the top surface of the kernel.

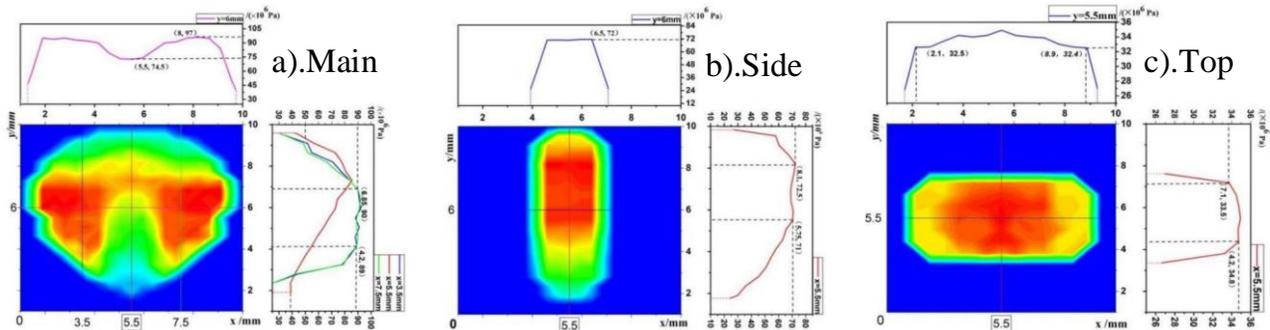

Fig. 8 - Distribution of Damage Resistance on the Surface of Corn Kernels

Discussions

Development of a damage resistance model for corn Kernels

Based on the test results and the distribution patterns of damage-resistance strength on the main, side, and top surfaces of the corn kernel, a spatial rectangular coordinate system was established. The origin was defined at the seed radicle. The Z-axis extends forward perpendicular to the top surface above the origin, the X-axis points leftward perpendicular to the side surface, and the Y-axis points outward perpendicular to the main surface. This coordinate system adheres to the right-hand rule. Using Design Expert software, response surface analysis was performed to construct a damage-resistance model for the typical surfaces of the corn kernel, as illustrated in Fig. 11. The nonlinear regression equation representing the damage-resistance strength of the corn kernel surface was established as follows:

$$\begin{cases} \sigma_z = -29.56x^2y^2 - 36y^3 - 0.85xy^2 + 22.39x^2y - 32.49y^2 + 13.4x^2 - 0.1xy + 39.77y + 0.27x + 74.6 & (z = \pm 2mm) \\ \sigma_x = 24.06y^2 - 0.12zy + 13.69y + 0.11z + 68.41 & (x = \pm 4mm) \\ \sigma_y = -0.42z^2 - 1.52x^2 + 0.098xz + 0.026z + 34.54 & (y = \pm 5mm) \end{cases} \quad (3)$$

In the established model, x denotes the width of the corn grain. y represents the height of the corn grain. z corresponds to the thickness of the corn grain. σ_z is the nonlinear regression equation representing the damage resistance strength of the principal plane of the maize kernel. σ_x is the nonlinear regression equation for the damage resistance strength of the side surface of the corn kernel. σ_y is the nonlinear regression equation for the damage resistance strength of the top surface of the corn kernel.

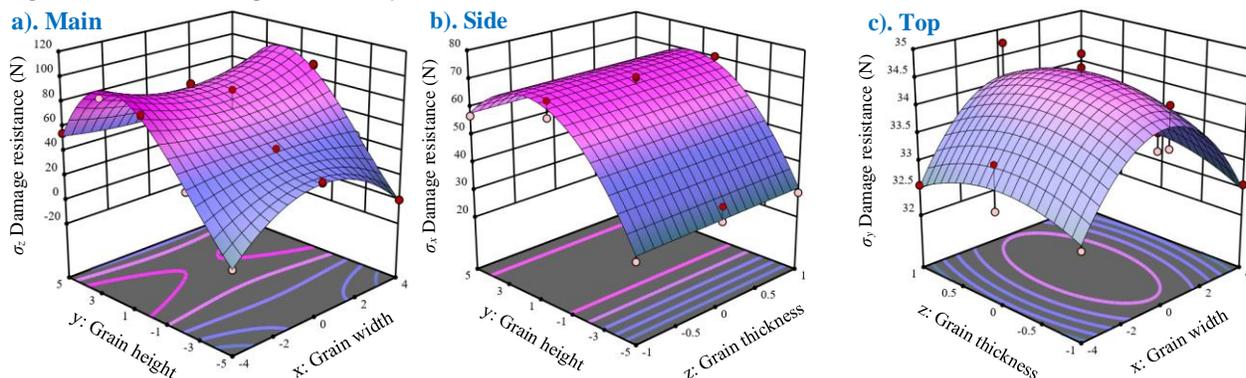

Fig. 11 - The damage resistance strength model of maize kernel typical surface

Among the models, the determination coefficients for the main plane and side surface damage strength were $R^2=0.9726$ and $R^2=0.9764$, respectively, with significance levels of the lack-of-fit terms $P>0.25$, indicating a strong fitting performance for these models. In contrast, the determination coefficient for the top surface damage strength model was $R^2=0.8170$, with a lack-of-fit significance level of $P>0.25$. This comparatively lower fitting accuracy is attributed to the stable distribution of damage strength on the top surface, which is less influenced by location variability. The models enable more accurate prediction of the damage strength of corn kernels across different surfaces and locations, providing valuable guidance for selecting optimal threshing loading positions and reducing threshing damage.

Effect of kernel damage resistance on mechanical threshing performance

Our findings reveal the characteristics and distribution of damage-resistance strength on the defined "damage-susceptible" surfaces of corn kernels. The distribution of damage-resistance strength varies across different kernel surfaces due to the influence of internal structural differences, yet follows specific patterns in certain directions. These distribution laws provide a basis for describing, analyzing, and optimizing the design, working principles, and application of corn harvesting equipment. Building on the analysis of the characteristics and distribution of damage-resistance strength on the surface of corn kernels (CDDRS-SCK), this section explores the influence of various threshing devices and threshing gaps on threshing-induced damage.

Corn kernel threshing primarily employs two methods: tangential flow and axial flow. The tangential flow threshing cylinder operates at rotation speeds ranging from 800 r/min to 1200 r/min (*Fu et al., 2018*), resulting in significant forces applied to the corn kernel surface. Previous analysis indicates that the surface of a corn kernel cannot withstand forces exceeding its maximum damage-resistance force. Under comparable conditions, the load exerted by tangential flow threshing is greater than that of axial flow threshing, leading to a higher rate of kernel damage. This observation aligns with practical experience and explains why most corn harvesters utilize the axial flow threshing technique. Axial flow threshing devices can be further categorized into two modes: transverse axial flow threshing and longitudinal axial flow threshing (*Tang et al., 2022; Wang, 2019*).

These methods differ significantly in the feeding mechanism and action process of the corn ears. In transverse axial flow threshing, the ears are fed radially and move along the axial direction of the drum, with the threshing element completing the process. During this procedure, the initial loading position of the corn kernels is on the top surface, which later transitions to the side surface as the direction of ear movement changes from radial to axial. According to the analysis in Table 1 and the section "The Characteristics and Distribution of Damage-Resistance Strength on the Top Surface of the Corn Kernel," the damage-resistance strength (DRS) of the top surface is the lowest, ranging between 33×10^6 Pa and 35×10^6 Pa. Consequently, this threshing method tends to cause more damage to kernels. In contrast, longitudinal axial flow threshing exerts force consistently on the side surface of the kernel, as the corn ears move entirely in the axial direction. The results from the section "The Characteristics and Distribution of Damage-Resistance Strength on the Side Surface of the Corn Kernel" reveal that the DRS of the side surface is significantly higher, ranging between 60×10^6 Pa and 70×10^6 Pa. This superior strength reduces the likelihood of kernel damage compared to transverse axial flow threshing. These findings align with practical threshing results, where longitudinal axial flow threshing is associated with a lower damage rate (*Wang et al., 2021*).

The influence of the threshing gap on mechanical threshing loss is analyzed theoretically based on the characteristics and distribution of damage-resistance strength on the surface of corn kernels (CDDRS-SCK). Proper regulation of the threshing gap is critical to minimizing threshing loss, as excessively small or large gaps can lead to undesirable outcomes (*Yang et al., 2021*). When the threshing gap is too small, the increased threshing load results in the threshing element acting on the top surface of the corn kernel, which has the lowest damage-resistance strength, or on the lower portions of the side and main surfaces, where the damage-resistance strength decreases gradually from approximately 55×10^6 Pa to 35×10^6 Pa. This inevitably exacerbates kernel damage. Conversely, when the threshing gap is too large, the threshing element primarily interacts with the top surface of the kernel, which also increases threshing loss. Therefore, an appropriate threshing gap is essential to reducing kernel damage, underscoring the need for adjustable threshing gaps in corn harvesters. According to previous studies, the threshing load is highest when processing the entire corn ear, and it decreases significantly as kernels are removed (*Li et al., 2017*).

Regardless of whether a tangential or axial flow threshing mechanism is used, a higher rotational speed of the threshing drum is required at the start of threshing to ensure the removal of kernels from the entire ear. During this initial phase, threshing damage is inevitable due to the mutually exclusive nature of effective threshing and damage prevention. However, as the structure of the threshing mechanism causes the corn ear to align parallel to the drum after partial threshing, the side surface of the corn kernel is subjected to greater stress. The findings in the section "The Characteristics and Distribution of Damage-Resistance Strength on the Side Surface of the Corn Kernel" indicate that the damage-resistance strength along the height direction of the side surface follows an upward-sloping "bathtub" distribution, whereas the strength along the thickness direction remains relatively uniform. Based on these results, it is recommended that the threshing gap be adjusted such that the threshing load is primarily exerted on the upper side of the corn kernel. For the "Zhengdan 958" corn variety studied here, it is advised that the action point of the threshing element be positioned approximately 2–4 mm from the kernel's top surface. While the proposed threshing position is specific to the "Zhengdan 958" variety, it is theoretically derived from experimental results and can serve as a valuable reference for analyzing and selecting optimal threshing positions for other corn varieties. Due to the variability among corn varieties, further adjustments may be necessary to adapt these recommendations to other cultivars.

CONCLUSIONS

This study addresses the issue of corn grain damage during the harvest of high-moisture corn using a combine harvester. A method for evaluating the surface damage load of corn grains is proposed. Multiple sets of loading tests were conducted, with the main, side, and top surfaces of the corn grains subjected to different loading conditions. The aim was to investigate the damage resistance of the various surfaces of the corn grains.

(1) Several groups of surface damage loading tests were conducted on different types of corn grains to investigate the distribution of damage resistance across the flat grain surface. The results revealed significant variations in the damage resistance of the "vulnerable" surface of the flat grain. Specifically, the surface exhibited the highest resistance, followed by the side surface, with the top surface showing the lowest resistance.

(2) By measuring the characteristics and distribution of damage resistance across different surfaces of corn grains, the variation in damage resistance on typical surfaces was determined. Based on the differences in the internal structure of corn grains, a distribution model of damage resistance for the typical surfaces was developed. The main factors influencing the variation in damage resistance were identified. This research provides a basis for selecting optimal threshing loads and positions in the mechanized threshing process of maize.

(3) Based on the characteristics and distribution of the surface damage resistance (CDDRS-SCK) of corn grains, the factors contributing to the lower damage rate observed in longitudinal axial flow threshing were analyzed. Theoretical analysis of the influence of the threshing gap on mechanical threshing was also conducted, and an optimal loading position for corn threshing was proposed. This study provides data support for the development of corn threshing technology and equipment, as well as for determining key operational parameters.

Keywords: industrial hemp, multifunctional crop, food and pharmaceutical products, hempcrete, biofuels and bioenergy, phytoremediation, sustainability

ABSTRACT

*This review explores the multiple directions of industrial hemp (*Cannabis sativa L.*) utilization at a global level, highlighting the importance of this crop as a renewable, sustainable, and environmentally friendly resource. While hemp has traditionally been employed for the production of fibers, seeds, and medicinal products, recent studies have expanded its applications into innovative fields such as eco-friendly construction materials (e.g., hempcrete and composite materials), automotive and aerospace industries, cosmetics, biofuels, and others. The remarkable properties of hemp, including low density, superior mechanical strength, carbon sequestration capability, and moisture regulation, helps reduce energy consumption and enhances the performance of construction materials, thereby providing competitive advantages in sustainability-oriented sectors. Moreover, hemp extracts and oils, rich in bioactive compounds (essential fatty acids, vitamins, antioxidants, and cannabinoids), have demonstrated therapeutic potential, reinforcing the role of hemp in the development of food, cosmetic, and pharmaceutical products. Additionally, hemp significantly contributes to phytoremediation by absorbing heavy metals and contaminants from the soil, and hemp fibers stand out for their durability and resistance, being valued in the textile industry for their ecological characteristics and superior performance. Industrial hemp stands out for its high versatility, and its valuable properties along with its favorable environmental impact support its integration into a wide range of sectors, opening promising perspectives for a more sustainable and environmentally responsible future.*

REZUMAT

*Această lucrare de sinteză explorează direcțiile multiple de utilizare ale cânepii industriale (*Cannabis sativa L.*) la nivel global, evidențiind importanța acestei culturi ca resursă regenerabilă, sustenabilă și cu impact ecologic redus. În timp ce cânepa a fost folosită tradițional pentru producția de fibre, semințe și medicamente, studiile recente au demonstrat extinderea aplicațiilor sale în domenii inovatoare precum construcțiile ecologice (de exemplu, betonul de cânepă și materialele compozite), industria auto și aeronautică, cosmeticele, biocombustibilii și altele. Proprietățile remarcabile ale cânepii, de la densitatea redusă și rezistența mecanică superioară la capacitatea de sechestrare a carbonului și de reglare a umidității, contribuie la reducerea consumului de energie și la îmbunătățirea performanțelor materialelor de construcție, oferind astfel avantaje competitive în sectoare ce pun accent pe sustenabilitate. Mai mult, extractele și uleiurile din cânepă, bogate în compuși bioactivi (acizi grași esențiali, vitamine, antioxidanți și cannabinoidi), au demonstrat potențial terapeutic, consolidând rolul acestei culturi în dezvoltarea produselor alimentare, cosmetice și farmaceutice. În plus, cânepa contribuie semnificativ la fitoremediere, absorbind metale grele și contaminanți din sol, iar fibrele textile de cânepă se remarcă prin durabilitate și rezistență, fiind apreciate în industria textilă pentru caracteristicile lor ecologice și performanțele superioare. Cânepa industrială se remarcă prin versatilitatea sa ridicată, iar proprietățile valoroase și impactul ecologic favorabil pe care îl are susțin integrarea acesteia într-o gamă largă de sectoare, deschizând perspective promițătoare pentru un viitor mai sustenabil și mai responsabil din punct de vedere ecologic.*

INTRODUCTION

Industrial hemp (*Cannabis sativa* L.) is a remarkably versatile plant, with significant social and economic value, being grown for a wide range of purposes, from the production of textile fibers, hurds, and seeds to the extraction of oils, with applications that include medicinal and recreational uses (Adesina et al., 2020; Cerino et al., 2021; EIHA Conference 2016–2023). Considered the ideal crop for the circular bioeconomy of the future, hemp is one of the oldest plants cultivated by humanity, with documented use dating back to around 8000 BCE, having played an essential role in the evolution of human agriculture (Cherney and Small, 2016; Promhuad et al., 2022). Central Asia is considered the birthplace of domesticated hemp, with the oldest evidence of hemp fiber use discovered in Taiwan (Manian et al., 2021). Starting around 2700 BCE, hemp began to be cultivated in China, becoming an important agricultural practice used to obtain various products (Mariz et al., 2024).

Industrial hemp can be harvested and valorized in multiple fields, being used in the production of food, feed, pharmaceutical and cosmetic products, construction materials, biodegradable plastics, textiles, paper, biofuels, and as energy source (Adesina et al., 2020; Cerino et al., 2021; Popa et al., 2021; EIHA Conference 2016–2023; Mariz et al., 2024). It is estimated that there are approximately 25,000 hemp-derived products, distributed across various industrial and commercial subsectors (Kraenzel et al., 1998). Its unique properties, especially its ecological benefits and high yield of natural technical fibers, make hemp a valuable crop for the development of a sustainable, biomass-based economy (Carus et al., 2013).

Hemp cultivation areas have shown an upward trend in recent years, both in Europe and globally. In fact, since the late 20th century, hemp cultivation has been revitalized and has emerged as one of the fastest-growing agricultural and industrial markets in recent decades (EIHA Conference 2016–2023).

Hemp is a multifunctional crop (Adesina et al., 2020), potentially addressing many existing climate and environmental issues. Its versatile nature could transform into billion-dollar markets, especially in the segments focused on reusable, recyclable, and compostable biomaterials. According to statistical evaluations (EIHA Conference 2023), the industrial hemp market has a potentially higher value (USD 350 billion) than the cannabis market (USD 233 billion).

Hemp has become a global billion-dollar business, and its market share in the industrial sector has reached new dimensions, with a growing number of publicly listed companies. According to a consumer behavior survey, the wholesale market value of hemp in the United States was estimated at over USD 700 million (Valizadehderakhshan et al., 2021; Malabadi et al., 2023). Globally, the industrial hemp market was valued at USD 4.13 billion in 2021, with forecasts indicating an annual growth rate of 16.8% for the period 2022–2030 (Malabadi et al., 2023). This expansion is supported by increasing demand from various industries using it, as well as by consumer interest in natural fibers, sustainable products, and hemp seed extracts/products (oil, press cakes, seeds, etc.) recognized for their nutritional and functional properties (EIHA Conference 2019; Malabadi et al., 2023).

In the United States, the market for hemp seeds and fiber is expected to grow at an annual rate of 17.1% between 2023 and 2030, reaching a value of approximately USD 16.75 billion (Khanal and Shah, 2024). In 2022, Canada was the world's largest producer of hemp seeds, with a total output of 32,988 tons (Čolić et al., 2024). Turkey, also considered a major global hemp producer, has recently increased its investments and support measures for this crop. The country's current strategy aims to expand production to meet the growing needs of various economic sectors (Aslan, 2024).

According to data from FAOSTAT, USDA, and TURKSTAT, the global production of hemp for fiber was estimated at 302,000 tons, cultivated on 79,000 hectares. This upward trend reflects not only the increasing demand for hemp-based products but also the ecological and economic advantages of this sustainable crop (Textile Exchange, 2023).

The aim of this paper is to analyze the multiple directions of industrial hemp (*Cannabis sativa* L.) utilization, in the context of its agricultural, economic, and ecological potential, highlighting both traditional uses, such as fiber, seed, and oil production, as well as innovative applications in biocomposites, bioenergy, and phytoremediation.

1. Use in human and veterinary medicine/pharmacy

Hemp (*Cannabis sativa* L.) represents a valuable source for medical and pharmaceutical applications due to its rich content of cannabinoids, the main active chemical compounds with unique pharmacological properties, as well as terpenes and flavonoids. This species contains over 100 cannabinoids, among the most important being THC (delta-9-tetrahydrocannabinol) and CBD (cannabidiol), each with distinct therapeutic

applications (Van Bakel et al., 2011; Andre et al., 2016; Aizpurua-Olaizola et al., 2016; Adesina et al., 2020; Seltzer et al., 2020; Malabadi et al., 2023).

THC, the main psychoactive cannabinoid, is approved in many European countries for medicinal uses, including the treatment of chronic pain, glaucoma, and disorders associated with multiple sclerosis (EIHA Conference, 2022). For example, the market dedicated to medicinal THC in Germany is showing an upward trend in both sales and the number of prescriptions issued. However, several challenges remain to be addressed, including an inconsistent and incoherent legal framework, ambiguous regulations, and regional disparities (EIHA Conference 2022), all of which limit the consistent use of this compound in medicine (Van Bakel et al., 2011).

CBD, the main non-psychoactive cannabinoid, is recognized for its anti-inflammatory, neuroprotective, and antioxidant effects (Sharma et al., 2014; Piomelli and Russo, 2016; Malabadi et al., 2023). Clinical studies have demonstrated its potential in treating inflammatory conditions, arthritis, diabetes, neurodegenerative diseases, cancer, drug-resistant epilepsy, and pain (Schultes, 1970; Izzo et al., 2009; Seltzer et al., 2020; Valizadehderakhshan et al., 2021; Malabadi et al., 2023). In addition, preclinical research suggests that CBD exerts a wide range of biological effects, including anticonvulsant, anxiolytic, anti-inflammatory, immunomodulatory, and antineoplastic activities (Cerino et al., 2021), potentially reducing inflammation and oxidative stress, with applications in the treatment of neurodegenerative diseases such as Alzheimer's and Parkinson's (Cassano et al., 2020; Bhunia et al., 2022).

Epidiolex, a drug approved by the European Medicines Agency (EMA) and the U.S. Food and Drug Administration (FDA), uses CBD to treat epileptic seizures associated with Lennox-Gastaut and Dravet syndromes (FDA, 2018). To date, the U.S. FDA has approved THC-based drugs such as nabilone and dronabinol for the treatment of chemotherapy-induced nausea and vomiting, sleep disorders, and weight loss regulation in HIV-AIDS patients. In Australia, Canada, and several European countries, nabiximol, a combined THC-CBD formulation, has been approved for the treatment of spasticity associated with multiple sclerosis, with positive results confirmed by recent studies (Mashabela and Kappo, 2024).

Recent studies explore the application of cannabinoids in oncology therapies, highlighting the potential of delta-9-tetrahydrocannabinol (THC) and cannabidiol (CBD) to inhibit tumor growth, alleviate the side effects of chemotherapy, and induce cellular processes such as autophagy and apoptosis, alongside significant anti-inflammatory effects (Mashabela and Kappo, 2024). Various preclinical studies have demonstrated potential anticancer properties of CBD and THC, which are experimentally used in the treatment of cancers such as prostate and breast cancer (EIHA Conference, 2022; Guggisberg et al., 2022). Researchers and medical professionals support the use of cannabis extracts in medical prescriptions, especially following the legalization of cannabis in numerous countries (Mashabela and Kappo, 2024).

Protein hydrolysates from hemp seeds have been studied for their antihypertensive and antioxidant properties, with promising results in both in vitro and in vivo studies on rats (Girgih et al., 2011). In addition, hemp is used in medicinal and therapeutic products, including pharmaceuticals for conditions such as prostate cancer, breast cancer, coronary heart disease, constipation, blood cholesterol reduction, and, experimentally, in the treatment of glaucoma, epilepsy, multiple sclerosis, dystonia, asthma, psychosis, Niemann–Pick disease, and topical infections (Găucă and Berea, 1997; Hazekamp and Fishedick, 2012).

McPartland and Russo (2001) emphasize the therapeutic potential of terpenes, describing their role in modulating cannabinoid receptors and regulating neurotransmitters such as serotonin, dopamine, and GABA. This synergistic interaction between terpenoids and cannabinoids opens new perspectives for the treatment of pain and mood disorders.

Essential oils extracted from hemp flowers are valued in the pharmaceutical industry due to their content of β -myrcene and limonene, recognized for their anti-inflammatory and sedative effects (Gurgel do Vale et al., 2002; Hazekamp and Fishedick, 2012). Additionally, hemp oils have demonstrated antimicrobial properties and the ability to accelerate wound healing following topical application (Callaway, 2004; Wylie et al., 2020). Other terpenes, such as β -caryophyllene, exert anti-inflammatory, analgesic, and anxiolytic effects, being beneficial in the management of conditions such as osteoarthritis, bronchial asthma, and colitis. Their efficacy is closely related to the interaction with inflammation-related receptor channels and the reduction of oxidative stress (Cerino et al., 2021).

Hemp is also gaining ground in veterinary medicine due to the therapeutic properties of cannabinoids, especially CBD. Hemp-based products are used to alleviate symptoms in animals, including anxiety, chronic pain, and inflammation (Wylie et al., 2020). Recent studies confirm the positive effects of CBD supplements on animals, focusing on reducing inflammation and improving quality of life, particularly for musculoskeletal,

neurological, or epileptic conditions (Gamble et al., 2018; McGrath et al., 2019; Garcia et al., 2022; Kosukwatthana et al., 2024).

A wide range of commercial cannabidiol (CBD)-based products are available for dogs and cats, used to manage conditions such as anxiety, depression, and chronic pain (Solcan et al., 2023). Studies conducted by Solcan (2017) and Solcan et al. (2002) recommend these products for the treatment of psychogenic dermatitis and chronic atopic dermatitis, as well as for managing anxiety and depression in companion animals (Falcă et al., 2011). Additionally, CBD can be used as palliative treatment in certain tumor diseases (Solcan et al., 2023).

2. Uses in human and animal nutrition

Applications in human nutrition

Industrial hemp represents a valuable resource for the food industry due to the exceptional nutritional profile of products derived from this crop. In Europe in particular, hemp has been considered for centuries a traditional source of nutritious food (Aladic et al., 2015), being used for the production of oils, flour, protein, dietary fibers, and other functional products such as hemp milk (Aladic et al., 2015; Lančaričová et al., 2021; Yano and Fu, 2023; Rizzo et al., 2023).

Various parts of the hemp plant, such as seeds and inflorescences, are valuable sources of food and ingredients for nutritional supplements. While hemp inflorescences are rich in terpenes, polyphenols, and non-psychoactive but biologically active cannabinoids such as cannabidiol (CBD), which exerts anxiolytic, spasmolytic, and anticonvulsant effects (Mechoulam et al., 2002), hemp seeds, with their high nutritional value and pleasant nutty flavor, are a valuable source of essential amino acids, fatty acids, minerals, vitamins, fiber, and high-quality protein essential for a balanced diet (Callaway, 2004; Carus and Sarmiento, 2016; Lančaričová et al., 2021; Montero et al., 2023). Additionally, hemp seed oil is a source of healthy polyunsaturated fatty acids, and hemp sprouts are rich in antioxidants (Cerino et al., 2021).

Hemp seeds are rich in high-quality, balanced, easily digestible, and sustainable proteins, containing between 20% and 30% protein, depending on variety and cultivation conditions. They provide all essential amino acids, including arginine, and present a unique protein profile consisting mainly of edestin and albumin (Callaway, 2004; Kolodziejczyk et al., 2012; Mihoc et al., 2012; Carus and Sarmiento, 2016; Montero et al., 2023; Yano and Fu, 2023). This protein profile makes hemp seeds suitable for use in energy bars, protein flour, and nutritional shakes. Studies show that these proteins may help lower blood pressure, cholesterol, and oxidative stress, having a positive effect on the cardiovascular system and supporting overall immune health (Callaway, 2004; Girgih et al., 2011a; Girgih et al., 2011b; Montero et al., 2023; Rizzo et al., 2023).

The benefits of using hemp seeds in food also derive from their valuable lipid composition, containing more than 80% polyunsaturated fatty acids, such as linoleic acid (ω -6) and alpha-linolenic acid (ω -3), in a 3:1 ratio, considered optimal for human health (Simopoulos, 2002; Oomah et al., 2002; Simopoulos, 2008; Pop et al., 2012; Rezapour-Firouzi et al., 2013; Lančaričová et al., 2021; Montero et al., 2023; Rizzo et al., 2023; Tura et al., 2023). In addition, hemp seeds are a valuable source of dietary fiber, vitamins, minerals, and contain 20–36% carbohydrates, along with other essential phytonutrients (Oomah et al., 2002; Callaway, 2004; Sirițanu and Sirițanu, 2007; Rezapour-Firouzi et al., 2013; Aladic et al., 2015; Popa et al., 2021; Yano and Fu, 2023).

Hemp seeds are also an important source of fat-soluble vitamins, especially vitamin E and vitamin A. Among the present tocopherol isomers (α -, β -, γ -, and δ -), γ -tocopherol is predominant and contributes to the oxidative stability of the oil, while α -tocopherol, though present in lower amounts, is the most biologically active. Moreover, hemp provides a wide range of essential macro- and microelements such as phosphorus, potassium, magnesium, calcium, iron, zinc, and copper, nutrients important for maintaining metabolic and physiological functions (Montero et al., 2023).

Due to the absence of gluten, lactose, and genetically modified organisms (GMOs), hemp products are suitable for special diets, including vegetarian, vegan, and paleo (EIHA Conference, 2016–2023; Wylie et al., 2020). Recognized for their nutritional value, hemp seeds have become an important source of nutrients, now integrated into current dietary trends and available in most European supermarkets in muesli, chocolate, and other products. These seeds can also be processed into beverages and yogurts similar to soy products (EIHA Conference, 2016–2023). In the form of protein flour, cold-pressed oil, dehulled and consumed raw or roasted, hemp seeds are a beneficial food, also having therapeutic applications for various ailments (Sirițanu and Sirițanu, 2007). Thanks to their nutty flavor, hemp seed flour is used to enrich bakery products (Adesina et al., 2020), helping to increase their protein and fiber content. Some studies suggest that the inclusion of hemp in products such as functional bread or nutritional bars may support digestive and metabolic health (Popa et al.,

2021; *EIHA Conference, 2016–2023*). Innovative food products developed from hemp highlight its role in a healthy and sustainable diet.

In recent years, public-private partnerships in Europe have focused on processing hemp protein into various food forms and textures and developing innovative products, with analyses revealing a very good and complete amino acid profile containing all essential amino acids (*EIHA Conference, 2023*).

High-quality hemp oil is obtained mainly by pressing industrial hemp seeds. This vegetable oil is 100% natural, with a greenish color and fine texture, and is commonly used unheated as a nutritional supplement or olive oil substitute, having a pronounced nutty aroma. Hemp seed oil is not recommended for cooking or frying at high temperatures due to its low smoke point (*Cherney and Small, 2016*). Cold-pressed, this oil stands out for its nutritional value thanks to its content of polyunsaturated fatty acids, phenols, flavonoids, and vitamin E, which give it significant antioxidant and anti-inflammatory properties by neutralizing free radicals (*Simopoulos, 2002; Cherney and Small, 2016; Cerino et al., 2021; Popa et al., 2021; Kaur and Kander, 2023*). Thanks to its distinctive flavor, hemp oil is frequently used in salads, canned goods, pastries, and confectionery, as well as a dietary supplement with benefits for skin and hair health (*Şandru et al., 1996; Cherney and Small, 2016; Gherasim, 2017; Popa et al., 2021; Kaur and Kander, 2023*).

Research conducted by IBA Bucharest highlighted that hemp seed cakes obtained by cold pressing are a valuable source of bioactive proteins, minerals, and total fiber, making them an ideal ingredient for the bakery industry (*Popa et al., 2021*). Thus, the use of these cakes allows for the creation of functional food products capable of supporting and improving health and positively impacting quality of life.

With proper quality management and marketing, the use of hemp seeds and oil in healthy human nutrition will continue to grow (*Carus and Sarmento, 2016*).

The use of hemp leaves provides a significant intake of calcium, magnesium, iron, vitamin E, flavonoids, phenols, chlorophyll, and other beneficial compounds, making them an exceptional natural and regional ingredient for teas, infusions, smoothies, or dietary supplements. They are an ideal source of minerals and nutrients in their natural form, especially recommended for vegans, without inducing psychotropic effects (*Simopoulos, 2002; Popa et al., 2021; Teleszko et al., 2022; EIHA Conference 2023*).

Besides its use in medicines, hemp is also used in the production of nutritional supplements such as CBD capsules and tinctures, which represent approximately one-third of the global \$1.34 billion CBD market (*Cerino et al., 2021*). These products are marketed for their benefits in reducing anxiety, improving sleep, and supporting the immune system (*EIHA Conference, 2023*). However, regulations regarding hemp-based supplements vary globally, limiting uniform access to these products (*Kaur and Kander, 2023*). In Europe, as a dietary supplement, CBD concentrate was classified as a novel food in January 2019 and therefore must undergo the approval process, which is cumbersome and expensive.

Hemp sprouts/microgreens can also be consumed as food. They are characterized by a high content of organic acids, amino acids, total polyphenols, flavonoids, etc., compounds known for their positive effects on cardiovascular and metabolic health (*Cerino et al., 2021; Montero et al., 2023; Popa et al., 2024*).

Applications in animal nutrition

Hemp plays an increasingly important role in animal nutrition, particularly through seeds and the oil obtained from pressing them. Hemp-based feed is becoming increasingly popular, being a sustainable and healthy alternative to conventional feed. It provides a natural source of protein and also offers essential fatty acids and fiber, contributing to a balanced diet with beneficial effects on animal health (*EIHA Conference, 2023*).

The main market for hemp seeds in animal nutrition is feed for birds and fish, which require high intakes of omega-3 and omega-6 for optimal development (*Carus and Sarmento, 2016*). Unhulled seeds and cakes resulting from oil extraction provide both valuable proteins and essential fatty acids with important nutritional benefits (*Oomah et al., 2002; Constantinescu, 2011; EIHA Conference, 2022*). Some studies also show that including these in laying hens' diets improves the omega fatty acid profile in eggs, thereby increasing the nutritional value of the final product (*Callaway, 2004*).

In the context of rising feed prices and supply challenges, hemp-based products represent a sustainable alternative, offering both economic and nutritional benefits (*EIHA Conference, 2022*).

Recent studies highlight that the inclusion of hemp-derived products in animal feed, including raw hemp oil as a valuable source of polyunsaturated fatty acids, may contribute to supporting overall health by improving cognitive function and reducing inflammation (*EIHA Conference, 2022; Haake et al., 2023; Puttharaksa et al., 2025*).

Against the backdrop of growing global demand for healthy and sustainable food, hemp emerges as a valuable nutritional resource suitable for both human and animal consumption. As the market for hemp-based food products expands, cereal bars, hemp seed butter, and plant-based beverages are gaining popularity in Europe and North America, reflecting the growing interest in natural and ecological diets (*Kaur and Kander, 2023*).

The economic potential of hemp in the food industry is estimated at billions of dollars, and the development of innovative products supports the transition to a more sustainable global food industry. In this context, the turnover in the hemp food segment and related raw materials is growing significantly. The increasing demand for natural food products has stimulated trade in hulled and unhulled seeds, hemp oil, protein powder, and leaves, visible both in retail and the industrial sector. Furthermore, collaboration among farmers, associations, and processors, focused on seed quality as a raw material, contributes to the sustainable consolidation of the hemp food market (*EIHA Conference 2016–2023*).

3. Use in the cosmetic industry

Industrial hemp has become increasingly used in the cosmetic industry due to its active compounds with multiple benefits for skin health, such as essential fatty acids, vitamins, and antioxidants.

Hemp-based cosmetic products, especially those made from cold-pressed seed oil, are appreciated for their ability to hydrate and soothe dry, irritated, or sensitive skin (*Cherney and Small, 2016*). The value of the oil is particularly due to its linoleic, α -linolenic, and γ -linolenic acid content, which have a significant impact on cellular membrane functions (*Vogl et al., 2004*). In addition to its role in restoring the skin's lipid barrier, hemp oil also helps prevent transepidermal water loss, maintaining optimal hydration (*Kaur and Kander, 2023*); it also contributes to the healing of skin inflammations and balancing acne conditions (*Vogl et al., 2004; Sapino et al., 2005*). Furthermore, hemp oil is used in personal care products such as soaps, lotions, and bath gels (*Şandru et al., 1996; Gherasim, 2017; Popa et al., 2021; Malabadi et al., 2023*), as well as in hair care products like shampoos and conditioners (*Adesina et al., 2020*), due to its ability to strengthen hair strands and moisturize the scalp. Vitamin E and essential fatty acids contribute to reducing hair loss and improving hair elasticity (*Popa et al., 2021*).

Cannabidiol (CBD), the main non-psychoactive compound in hemp, is increasingly used in the cosmetic industry due to its antioxidant, anti-inflammatory, anti-wrinkle, and brightening effects (*Karache and Singh, 2019; Chen et al., 2023*). The growing demand for natural and sustainable cosmetics has led to the integration of hemp into innovative formulations such as anti-aging creams, serums, deodorants, and facial masks (*Karache and Singh, 2019; Kaur and Kander, 2023*). Hemp extracts are appreciated for their antioxidant properties, helping to protect the skin against free radicals and reduce signs of premature aging (*Kaur and Kander, 2023*).

4. Use in the construction industry

Industrial hemp stands out as an ecological and sustainable solution in the construction industry due to its remarkable properties, such as thermal and acoustic insulation, durability (<https://www.carmeuse.com/ro-ro/aplicatii/materiale-de-constructii/hempcrete>; https://dumbrava47.ro/constructii_verzi/despre-proprietatile-ignifuge-ale-betonului-de-canepa-hempcrete/; *Kaboré et al., 2024*) and mechanical strength. Hemp-based construction materials include hempcrete, insulating panels, plasters, and composites for lightweight structures.

An interesting segment of the green materials market is the use of hemp shives (hurds) combined with lime for construction, a segment that holds approximately 16% market share (*Carus and Sarmiento, 2016*). Hempcrete, obtained by mixing hemp shives with hydrated lime, is an ecological material (<https://www.casadecanepa.org/betonul-de-canepa>), lightweight yet strong, used in wall, roof, and floor construction (*Asli et al., 2021; Kaboré et al., 2024*). Studies show that this material has a significantly lower environmental impact than conventional building materials (*Pretot et al., 2014*), due to its ability to absorb and store CO₂ and its low embodied energy (*Pretot et al., 2014; Adam, 2024; Kaboré et al., 2024*).

The favorable thermal properties of hempcrete (*Limam et al., 2016*) are due in part to its low thermal conductivity and good moisture regulation capacity, contributing to improved hygrothermal comfort and reduced energy demand (*Collet and Pretot, 2012; Palumbo et al., 2016*). Moreover, hempcrete is used in passive house construction thanks to its performance characteristics, being a recyclable, biodegradable, non-flammable, and mold- and pest-resistant material, making it ideal for green building projects (*Vogl et al., 2004; Asli et al., 2021; EIHA Conference, 2018*).

In the same vein, Romania has also successfully combined traditional raw materials, hemp and hydrated lime, with modern technologies for “green” construction and renovation. The resulting material, 100% sustainable and biodegradable, is naturally fire- and pest-resistant, allows water vapor permeability, and “breathes”; in this way, it regulates humidity by absorbing excess moisture and releasing it when levels drop below optimal (*EIHA Conference, 2018*). It is a carbon-negative material that continuously absorbs CO₂, making it ideal for those seeking to minimize environmental impact (<https://app.materlibrary.ro/ro/materiale/SHEMP-0001>).

The hemp shives resulting as a by-product of primary hemp processing can be used as a building material or as sound insulation between drywall panels (*Şandru et al., 1996*), while hemp fibers are used in the production of ecological insulation materials, which provide efficient thermal and acoustic insulation (*Kymäläinen and Sjöberg, 2008*). In 2015, hemp fiber insulation accounted for about 26% of total applications, being the second most important use (*Carus and Sarmento, 2016*). These materials are valued for their ecological properties, being biodegradable, non-toxic, offer high thermal performance, and have a long lifespan, thus contributing to reducing the carbon footprint of the final products (*Carus et al., 2013; Călăţan, 2018; Adam, 2024*). Romania, France, and Germany are among the pioneering countries in implementing eco-friendly materials, such as hemp fiber, in building insulation (*Călăţan, 2018*).

Beyond construction, other applications include the production of composite panels made from hemp fibers and natural resins for interior components, which are distinguished by their low weight, mechanical strength, and superior durability, being more resistant to rot, fire, fungi, and pests than wood (*Kymäläinen et al., 2005; Kymäläinen and Sjöberg, 2008; Călăţan, 2018; Popa et al., 2021*).

Using hemp in construction significantly contributes to reducing the carbon footprint of buildings, optimizing thermo-mechanical performance with minimal resources, and the fully recyclable nature of hemp-based materials supports the transition toward a circular economy (*Adam, 2024*).

5. Use in the automotive and aerospace industries

Industrial hemp is increasingly used in the automotive and aerospace industries due to its distinctive features such as low weight, mechanical strength, sustainability, and low production costs. These properties allow hemp to contribute to reducing the reliance on non-renewable resources and synthetic or petroleum-based materials, thus promoting a more environmentally friendly production model (*Faruk et al., 2012; Balakrishnan et al., 2016; Wellbrock et al., 2020; Balo and Sua, 2024*).

Significant advances in hemp research, supported by the European Commission and member states since the 1990s, have led to the identification of new applications for hemp fibers, such as biocomposites (*Carus and Sarmento, 2016*). In recent decades, the use of hemp fibers in composites as reinforcement material has increased considerably, meeting the demands for the development of biodegradable, sustainable, and recyclable materials (*Shahzad, 2012*).

Use of hemp fibers in the automotive industry

Natural fiber-reinforced biocomposites and/or biopolymers have seen significant development due to multiple advantages - processing efficiency, biodegradability, low cost, low density, high specific strength, and renewable nature (*Faruk et al., 2012; Wellbrock et al., 2020*).

Hemp, recognized as one of the most ecological and traditional natural fibers (*Shahzad, 2012*), has been integrated into the production of vehicle interior components, from door panels and dashboards to headrests, trunk linings, and spare wheel covers, due to its competitive mechanical properties and potential for carbon footprint reduction (*Carus et al., 2013; Carus and Sarmento, 2016; Wellbrock et al., 2020*), especially in mid- and high-class vehicles (*Karus et al., 2006*).

These biocomposite materials are durable and lightweight, have superior mechanical properties (*Karus et al., 2006; Faruk et al., 2012; Carus et al., 2013*), low density, and excellent energy absorption characteristics (*Carus et al., 2013*), thus contributing to energy savings (*Shahzad, 2012*) and improving fuel efficiency through vehicle weight reduction (*Sahib et al., 2023; https://www.energy.gov/eere/vehicles/lightweight-materials-cars-and-trucks*). They also offer favorable crash performance, a high proportion of biomass-based content, and competitive prices for high-quality interior designs (*Carus et al., 2013*). Life cycle assessments show that using hemp fibers as reinforcement can significantly reduce greenhouse gas emissions and increase the recyclability of vehicles (*Faruk et al., 2012; Shahzad, 2012*).

The European automotive industry, especially luxury manufacturers, have already adopted hemp fiber use in visible components like door panels, highlighting the potential of these materials to improve both technical performance and the sustainability of final products (*Shahzad, 2012; Wellbrock et al., 2020*).

Research shows that using hemp fibers as reinforcement in composites significantly improves the ecological characteristics of vehicles due to their low carbon footprint and high recyclability (*Faruk et al., 2012; Shahzad, 2012*).

Use of hemp in the aerospace industry

In the aerospace sector, adopting composites based on natural fibers, such as those derived from hemp, represents a promising strategy for reducing aircraft weight and enhancing sustainability. These materials are characterized by low density, excellent strength-to-weight ratios, and ecological properties (renewable, biodegradable, and recyclable), contributing to reduced fuel consumption and lower greenhouse gas emissions (*Mansor et al., 2019; Singh et al., 2023*).

A study by Balo and Sua (2024) highlights that using natural fibers, such as hemp, in combination with polymers, can significantly reduce the ecological impact of aircraft manufacturing, emphasizing the importance of optimal fiber and polymer matrix selection to enhance both mechanical performance and material sustainability. Moreover, Balakrishnan et al. (2016) demonstrated that fiber-based composite materials are increasingly used in the construction of aircraft and spacecraft due to their benefits, including weight reduction, increased specific strength, extended service life, and decreased corrosion problems.

The findings of these studies underline the significant potential of natural fiber composites in the aerospace industry, providing green solutions that, alongside improved mechanical performance, can support the development of future technologies in the field.

6. Use in agriculture

Industrial hemp is a versatile and environmentally friendly crop with numerous benefits for agriculture. It contributes to improving soil quality, reducing pesticide use, and increasing biodiversity, thus supporting the transition to sustainable agricultural practices. In Europe, hemp is among the few crops that can be cultivated conventionally without agrochemical inputs (*Carus and Sarmiento, 2016*). Compared to cotton, hemp requires less water and is less dependent on phytosanitary treatments, helping to reduce environmental impact (*Malabadi et al., 2023*).

Phytoremediation capacity

Hemp is known for its ability to regenerate depleted soils due to its deep root system, which improves aeration and reduces compaction, thereby optimizing soil structure and fertility (*Struik et al., 2000*).

Hemp also provides significant environmental benefits, being considered a hyperaccumulator, a plant capable of accumulating metals or other compounds (aromatic hydrocarbons, radioactive contaminants, etc.) in its tissues hundreds or thousands of times more than other species. Due to this characteristic, hemp can be used in phytoremediation processes (*Citterio et al., 2003; Reeves et al., 2017; Rhey et al., 2020; Malabadi et al., 2023; Sunoj Valiarambil et al., 2023*).

This plant can remediate contaminated soils by accumulating heavy metals such as lead (Pb), zinc (Zn), nickel (Ni), and cadmium (Cd) in its roots (*Linger et al., 2002; Ivanova et al., 2003; Adesina et al., 2020; Rhey et al., 2020; Sunoj Valiarambil et al., 2023; Visković et al., 2023; Guo et al., 2024*), allowing the plant to be harvested together with hazardous compounds (*Adesina et al., 2020*). A notable example is the use of hemp in 1986 for decontaminating soil in the area affected by the Chernobyl nuclear disaster (*Citterio et al., 2003*), demonstrating hemp's efficiency in phytoextraction. In this context, hemp has been repeatedly used to remediate polluted sites, particularly through phytoremediation targeting the accumulation of heavy metals such as copper (Cu), cadmium (Cd), chromium (Cr), cobalt (Co), zinc (Zn), iron (Fe), nickel (Ni), mercury (Hg), lead (Pb), arsenic (As), silver (Ag), and platinum (Pt), commonly found in contaminated areas (*Moscariello et al., 2021*).

Although hemp can accumulate heavy metals in roots and shoots, studies show that the stems and seeds used for fiber and biomass production contain low concentrations of inorganic contaminants, especially heavy metals, without reaching phytotoxic thresholds. Thus, these parts remain suitable for valorization, even when grown on contaminated soils (*Kurczyński and Wcisło, 2024*).

Carbon sequestration and CO₂ capture

A particularly important feature of hemp is its capacity to capture and store carbon. When used as an alternative to carbon-based raw materials, hemp enables the sequestration of substantial amounts of CO₂ in both the stem and the roots, through biosequestration (*Adesina et al., 2020; Popa et al., 2021*). Due to its rapid growth and development, hemp is one of the fastest carbon-to-biomass converters, one hectare of hemp can absorb up to 22 tons of CO₂ (*Adesina et al., 2020; Kurczyński and Wcisło, 2024*). Most of the carbon is stored in the harvested stem, and less in the roots and leaves (*Adesina et al., 2020*). On the other hand, in their study,

Finnan and Styles (2013) show that hemp has one of the highest CO₂ absorption rates among agricultural crops, with about 1.5–2.0 tons of CO₂ absorbed per hectare annually.

One potential application of hemp biomass is its conversion into biochar. According to Günther (2019), hemp cultivation can produce at least 13 tons of biochar per hectare per year. This biochar has the potential to increase soil carbon sequestration and reduce greenhouse gas emissions, thus contributing to climate change mitigation (Lehmann *et al.*, 2006).

The resulting biomass contributes to long-term carbon storage, especially when used in construction materials such as hempcrete (Arehart *et al.*, 2002; Jami *et al.*, 2016; Jami and Kumar, 2017; Kumar *et al.*, 2021; Sunoj Valiaparambil *et al.*, 2023).

Cover crop role

Hemp is frequently used as a cover crop due to its rapid growth and weed-suppressing capacity. This practice helps protect soil from erosion, retain moisture, and reduce the need for herbicides. Furthermore, after harvest, hemp biomass can be incorporated into the soil, enriching it with organic matter and essential nutrients (Linger *et al.*, 2002; Malabadi *et al.*, 2023).

Role in crop rotation

Including hemp in crop rotations helps reduce the incidence of pests and diseases specific to other crops. Studies show that this plant can reduce the need for pesticides (Adesina *et al.*, 2020) due to its natural weed-suppressing ability and disease resistance (Adesina *et al.*, 2020; Struik *et al.*, 2000). Vigorous hemp crops, with their fast growth rate, suppress weeds without chemical interventions, and the plant is not significantly affected by pests or diseases requiring pesticide use. Moreover, hemp adapts well to organic farming systems (Carus and Sarmento, 2016).

Mulch and compost production

Hemp stalks and leaves can be used for producing mulch and compost, providing an organic source of natural fertilizer. These materials improve soil water retention and add essential nutrients, reducing the need for chemical fertilizers (Struik *et al.*, 2000; Linger *et al.*, 2002; Carus *et al.*, 2013).

Animal bedding

Hemp stalks and hurds are frequently used as animal bedding due to their excellent absorbency. This natural material reduces moisture and odors in shelters, providing a healthier environment for animals. Moreover, hemp bedding is biodegradable and can later be composted, contributing to a sustainable agricultural cycle (Linger *et al.*, 2002).

Use for biofertilizers

Recent research highlights hemp's potential to be utilized in biofertilizer development, through microbial degradation of plant residues that support the growth of beneficial soil microorganisms (Donati *et al.*, 2025).

Use of residues in plant protection

Some residues from hemp processing can be valorized as botanical insecticides, miticides, or repellents, being integrated into ecological pest management programs (Adesina *et al.*, 2020; Benelli *et al.*, 2018). Hemp oil and plant residues can be used as natural insecticides and pesticides in organic agriculture (Hall *et al.*, 2014; Benelli *et al.*, 2018). Hemp also produces essential oils with insect-repellent properties and antifungal effects (Kurczyński and Wcisło, 2024).

Valorization in circular agricultural systems

Integrating hemp into circular agricultural systems is promoted through the reuse of residual biomass to produce natural fibers and other value-added products, thus reducing resource waste and supporting the transition toward a sustainable bioeconomy (Jayaprakash *et al.*, 2022).

7. Use in the textile industry

Industrial hemp is one of the oldest plants cultivated for textile fiber production, having been traditionally used in the textile industry. Due to its high mechanical strength, durability, and reduced environmental impact, hemp represents a sustainable alternative to synthetic fibers and cotton. Life Cycle Assessment (LCA) evaluations indicate that, compared to cotton and other natural fibers, hemp requires significantly less water and pesticides and has a lower environmental impact across most analyzed categories, especially when processing stages are optimized (Van der Werf and Turunen, 2008; Mariz *et al.*, 2024). Moreover, thanks to its high yield and low agricultural input requirements, hemp is also an economically viable option, with agricultural costs estimated to be more than 75% lower compared to cotton (Schumacher *et al.*, 2020).

Hemp fiber is recognized as one of the strongest and most durable natural fibers (Adesina *et al.*, 2020), exhibiting higher tensile strength than cotton, with values between 550–1110 MPa, compared to 287–800 MPa

for cotton (Mariz *et al.*, 2024). These properties make hemp suitable for a wide range of applications, from technical and coarse textiles to fine fabrics (Bălțeanu, 2001). Due to its high cellulose content (68–75%) and favorable mechanical properties such as tensile strength (310–900 MPa) and stiffness (Young's modulus of 30–80 GPa), hemp fiber is considered a viable option for durable textile applications (Elfaleh *et al.*, 2023). In addition, hemp exhibits natural antimicrobial properties, making it suitable for functional textiles such as sportswear or underwear (Mariz *et al.*, 2024).

To be effectively utilized in industry, fiber quality is assessed based on factors such as biochemical composition, mechanical properties, degree of processing and retting, performance under various stresses, morphological characteristics, and industrial spinnability (EIHA Conference, 2016–2023).

Modern technologies, such as enzymatic retting, allow for the production of finer and more flexible fibers capable of competing with cotton and other natural fibers. These advances have facilitated the integration of hemp into the fashion industry, including sustainable collections launched by well-known designers and brands (Carus *et al.*, 2013).

The combination of hemp fibers with other natural fibers, such as wool or silk, has opened new opportunities for producing premium textiles that blend the durability of hemp with the finesse and aesthetics of other materials (Shahzad, 2012).

The growing demand for sustainable textile products has stimulated the development of the hemp industry, particularly in Europe and Asia. Countries such as China, France, and Canada are leading in hemp fiber production and processing, while emerging markets are exploring innovative applications for this versatile resource (Faruk *et al.*, 2012).

8. Use in the energy industry

Climate change and the depletion of fossil resources make the identification of sustainable energy solutions a global priority. The increased energy demand in recent decades, along with the extraction and processing of conventional fuels, has caused significant negative environmental effects, including biodiversity loss and the acceleration of climate change (UNEP, 2020). In this context, innovative technologies and advances in green energy have opened new pathways for addressing these global challenges (Chang *et al.*, 2024). At the core of this energy transition lies the need to replace fossil fuels with renewable sources, with biomass energy emerging as a promising and versatile alternative (Liu and Huang, 2024).

One of the major global issues is represented by greenhouse gas emissions, especially carbon dioxide (CO₂) and nitrogen oxides (NO_x). CO₂ is primarily released during fossil fuel combustion, while NO_x is generated during high-temperature combustion processes (Zuo *et al.*, 2024). In this regard, the European Union has set the goal of achieving climate neutrality by 2050, with an intermediate objective of reducing emissions by at least 55% by 2030 compared to 1990 levels (European Commission, 2021).

According to the Production Gap Report, although most governments have committed to climate neutrality, projections indicate that by 2030, fossil fuel production will double the amount compatible with the 1.5°C threshold set by the Paris Agreement. Estimates suggest that by 2030, fossil fuel production could exceed the 1.5°C-compatible level by over 110% and the 2°C-compatible level by 69% (Achakulwisut *et al.*, 2023). In this context, lignocellulosic materials such as hemp are gaining recognition as low-carbon renewable resources, used not only for energy generation but also for the production of bioproducts and biofuels (Forfora *et al.*, 2024).

Hemp biomass as an energy resource

Hemp is a promising resource for energy production due to its high biomass yield and its capacity to generate biodiesel, biogas, bioethanol, and solid fuels (Kraszkievicz *et al.*, 2019; Rheay *et al.*, 2020). Currently, hemp biomass can be used to generate heat and electricity, produce vehicle fuel, and be compressed into briquettes or pellets (Prade *et al.*, 2012).

With a lignocellulosic composition rich in cellulose and lignin, hemp proves to be an excellent material for biochar (BC) and biofuel production, supporting the development of renewable energy applications (Minhas *et al.*, 2025). Its high cellulose content (50 - 70%) is comparable or even superior to that of other agricultural residues, such as wheat straw (35 - 45%) or *Miscanthus* (40 - 60%) (Roman, 2025).

Biogas from hemp waste

The plant residues resulting from hemp processing can be valorized through anaerobic digestion, a process that produces biogas while reducing methane emissions, thus having a positive environmental impact (Finnan and Styles, 2013). According to studies by Adamovics *et al.* (2014), hemp leaves have proven to be

the most efficient part of the plant for biogas production. In experiments on hemp biomass, hydrothermal pretreatment significantly increased methane yields compared to untreated material, as the process breaks down rigid cell structures, allowing anaerobic microbes better substrate access, stimulating enzymatic activity, and accelerating digestion (Mamimin *et al.*, 2024). The resulting methane-rich biogas (CH₄) can be used for producing electricity and heat or upgraded to biomethane suitable for gas grids or as an alternative fuel. The nutrient-rich digestate can be applied as natural fertilizer, supporting sustainable agricultural practices (Chang *et al.*, 2024).

Hemp harvested in autumn provides a higher biomass yield, and enzymatic treatment of the residues has been shown to enhance methane production (Prade *et al.*, 2012b; Asquer *et al.*, 2019). Although biogas/methane yields from hemp are lower than those from corn silage, the lower cost of hemp straw and its favorable behavior during anaerobic digestion make it an economically viable option (Asquer *et al.*, 2019).

Biofuels

Industrial hemp is a versatile source for producing various types of biofuels. These can be classified by physical state into solid (compressed biomass and biochar), liquid (bioethanol, biodiesel, bio-oil), and gaseous (biogas, biohydrogen, bio-syngas) fuels, all obtained from renewable feedstocks (Suhara *et al.*, 2024; Addison *et al.*, 2024). First-generation biofuels remain the most viable option in today's industry, ideal for large-scale production and commercialization due to the constant availability of raw materials (Suhara *et al.*, 2024).

Hemp bioethanol

Bioethanol is obtained by fermenting renewable biomass, followed by distillation and dehydration. While in the past the main raw materials were predominantly crops such as corn or sugarcane, nowadays agricultural waste and by-products, including those derived from hemp, are increasingly being used (<https://www.sterlingsihi.com/cms/ro/Romania/home/piete/sectorul-industrial/produse-alimentare/productia-de-biodiesel-si-bioetanol/produceria-bioetanolului.html>).

Hemp biomass has a high content of cellulose and glucans, which facilitates the production of fermentable sugars and, consequently, a higher bioethanol yield (Zhao *et al.*, 2020). Thus, hemp is considered one of the most valuable fiber sources, appreciated for its applications in the production of biochemicals, biogas, bioethanol, and biohydrogen (Brar *et al.*, 2024). Studies show that efficient pretreatment of the biomass and the use of conventional yeasts, such as *Saccharomyces cerevisiae*, can lead to good ethanol yields, which can subsequently be recovered through fractional distillation. The remaining solid fraction after fermentation can be used in thermochemical processes such as pyrolysis (Zhao *et al.*, 2020).

Bioethanol is produced by fermenting sugars extracted from biomass sources such as corn, sugarcane, agricultural residues, and wood. Yeasts or bacteria convert these sugars into ethanol, which can be used either on its own or blended with gasoline (Sartaj *et al.*, 2023). Biomass sources can be converted in various ways to serve as energy sources, thus contributing to reducing greenhouse gas emissions and replacing fossil fuels in sustainable energy generation (Chang *et al.*, 2024). In this regard, second-generation bioethanol, obtained from lignocellulosic materials, has become a promising alternative due to the availability and lower cost of raw materials (Viswanathan *et al.*, 2020).

Biodiesel production

Biodiesel can be obtained through several methods, including blending, micro-emulsification, thermal cracking and, most commonly, transesterification (Bhonsle *et al.*, 2025). This process involves the reaction of triglycerides (from vegetable oils, waste oils, or animal fats) with an alcohol, usually methanol, in the presence of a catalyst, resulting in biodiesel and glycerol (https://www.hielscher.com/ro/biodiesel_transesterification_01.htm). The feedstocks may come from first-generation sources (edible vegetable oils) or second-generation sources (waste oils, non-edible animal fats) (Sartaj *et al.*, 2023).

In this context, hemp seeds represent a promising resource for biodiesel production due to their oil content, which can be transformed through transesterification into a renewable, biodegradable, and non-toxic biofuel (Osman A. *et al.*, 2024). Hemp biodiesel is a viable alternative to conventional diesel, being non-flammable, low in emissions, and having excellent combustion properties, in compliance with international standards ASTM D6751 and EN 14214 (Prade *et al.*, 2011; Patel *et al.*, 2016; Sunoj Valiaparambil *et al.*, 2023).

According to recent literature, industrial hemp can produce up to 789 liters/ha of biodiesel, with a conversion rate of 75.9% (Parvez *et al.*, 2021; Abreu *et al.*, 2022), and increasing the lipid content to 10% could potentially double the output (Viswanathan *et al.*, 2020). It is also estimated that this crop could yield up to 3.95 million gallons of biodiesel annually (Visković *et al.*, 2024). Among the technical challenges is the high

viscosity of hemp oil, which can be effectively reduced through physicochemical pretreatments or ultrasonic processing (*Moscariello et al., 2021*).

A major advantage of biodiesel is that it can be used in existing diesel engines without significant modifications, making it a practical and sustainable solution for reducing fossil fuel dependence (*Singh et al., 2024*). Blends such as B5 (5% biodiesel, 95% diesel) and B20 (20% biodiesel, 80% diesel) are already widely used, helping to reduce carbon emissions and enhance energy sustainability (*Osman W. et al., 2024*). Tests conducted on hemp biodiesel revealed thermal efficiencies between 15.98% and 24.97%, lower carbon monoxide and hydrocarbon emissions, and performance comparable to commercial diesel (*Addison et al., 2024*).

Compared to bioethanol, biodiesel offers superior environmental benefits and greater energy efficiency (*Suhara et al., 2024*). In the study conducted by Ahmad et al. (2011), non-edible hemp oil was transesterified using a base catalyst, and the final product was analyzed using GC-MS, FT-IR, and NMR methods, revealing characteristics that comply with international standards and indicate good fuel quality.

Solid biofuels

The densification of hemp biomass plays a key role in the development of sustainable solid biofuels (*Roman and Grzegorzewska, 2024*). Dried hemp biomass can be compressed into briquettes or pellets without the need for chemical additives, as the lignin naturally present in the plant acts as a binder (*Kolodziej et al., 2012; Popa et al., 2021*). The energy properties of hemp are comparable or even superior to other solid biofuel sources such as cereal straw or wood (*Prade et al., 2012a*). Hemp briquettes have a calorific value of approximately 18,000 kJ/kg, higher than that of wood, and are characterized by rapid combustion and low sulfur emissions (*Kolodziej et al., 2012*).

Studies show that factors such as moisture content and particle size significantly influence processing efficiency and the quality of the final product. For example, briquettes exhibit higher vertical strength, while pellets are more durable during handling and transport. To obtain high-quality solid biofuels, it is essential to control moisture levels, analyze density, and conduct resistance tests (*Roman and Grzegorzewska, 2024*).

The compactness and durability of briquettes are influenced by different factors, especially lignin content. Thus, dioecious hemp, with its higher lignin content, is better suited for briquetting, particularly in northern regions (*Kraszkievicz et al., 2019*). Additionally, in the case of these biofuels, the presence of heavy metals does not pose a major risk, as long as the resulting ash is not used as fertilizer (*Alaru et al., 2013*).

Beyond its direct energetic benefits, the use of hemp in the bioenergy sector contributes to reducing greenhouse gas emissions, capturing carbon dioxide (CO₂) during the growth period, and improving soil quality, thus reinforcing the ecological value of this crop in the transition towards a sustainable energy system (*Citterio et al., 2003; Iványi and Izsáki, 2007; Adesina et al., 2020; Amaducci et al., 2015*).

9. Other uses

Hemp is a sustainable alternative to wood for paper production. Its long fibers provide high strength to the resulting paper, which can be used for documents, packaging, and industrial products. Hemp processing requires fewer chemicals and less water than wood-based paper production, thus reducing environmental impact (*Enarevba and Haapala, 2024*).

Hemp is also used in the production of industrial filters, carpets (*Tutek and Masek, 2022*), braids, fine fabrics, twine, sacks, mats, insulating materials, and other products (*Şandru et al., 1996; Gherasim, 2017; Leonte et al., 2022*).

CONCLUSIONS

Industrial hemp (*Cannabis sativa* L.) is increasingly emerging as a strategic crop in the context of the global transition toward sustainability, due to its remarkable versatility, economic value, and low environmental impact. The analysis of its various applications reveals significant potential that transcend traditional uses and extends into emerging fields such as green construction, renewable energy, the pharmaceutical industry, as well as environmental protection, through its phytoremediation capacity and contribution to carbon sequestration.

Through its ability to provide durable textile fibers, composite materials, biofuels, therapeutic products, and by contributing to soil regeneration and the reduction of greenhouse gas emissions, hemp offers coherent and sustainable solutions to today's economic, ecological, and social challenges. Its integration into sustainable agricultural systems and diversified value chains strengthens its strategic role in current policies aimed at combating climate change and advancing the transition toward a circular bioeconomy.

Future prospects include the development of a dedicated market for high-quality hemp-based products, with focus on health, innovation, and sustainability, as well as raising awareness among the public and decision-makers about the multifunctional nature of hemp and its role in delivering innovative solutions to current economic, social, and environmental challenges.

Keywords: tomato leaf disease; improved MobileNetV3; attention mechanism; dilated convolution

ABSTRACT

Aiming to address the issues of low accuracy and slow response in tomato leaf disease recognition models, an enhanced lightweight model for tomato leaf disease recognition was proposed. The SE attention module in the MobileNetV3-Large model was substituted with a CA attention module, and dilated convolution was incorporated to improve the model's recognition accuracy and response speed. The CA attention module enhances the perception and feature extraction capabilities of spatial coordinate information in images. Dilated convolution was introduced into the deep network architecture to expand the model's receptive field. The model was trained using a transfer learning approach that partially froze specific convolutional layers. Experimental results on a dataset comprising 10 common tomato leaf disease images and healthy leaf images demonstrated that the unimproved model achieved a recognition accuracy of 90.11% and an F1 score of 89.98%. After replacing the SE attention module with the CA attention module, the model's accuracy increased to 91.15%, with the F1 score rising to 91.08%. Furthermore, introducing the dilated convolution model improved the accuracy to 94.33% and the F1 score to 94.22%, while maintaining a parameter count of 2.79×10^6 and a validation set operation time of 11.76 seconds. Compared to other traditional lightweight models, this model exhibits significant advantages. The field test results show that the detection accuracy rate is 88.79% and the omission rate is 8.44%, which has practical application value. The DC-CA-MobileNetV3 tomato leaf disease recognition model proposed in this study can accurately and efficiently identify tomato leaf diseases, featuring a small number of parameters and ease of deployment in embedded systems.

摘要

针对番茄叶片病害识别模型的准确度低、响应速度慢的问题，提出了一种改进的轻量级番茄叶片病害识别模型，将 MobileNetV3-Large 模型中的 SE 注意力模块替换为 CA 注意力模块，并引入空洞卷积，以提高模型识别准确度与响应速度。利用 CA 注意力模块提高对图像空间坐标信息的感知能力和特征提取能力。在深层网络中引入空洞卷积模型，扩大模型感受野。使用只冻结部分卷积层的迁移学习方法对模型进行训练。在常见的 10 种番茄叶片病害图像与健康叶片图像构成的数据集上的实验结果表明，未改进的模型识别精准率为 90.11%，F1 值为 89.98%；改为 CA 注意力模块后，模型的精准率提高至 91.15%，F1 值提高至 91.08%；在此基础上引入空洞卷积模型后，精准率提高至 94.33%，F1 值提高至 94.22%，其模型参数量为 2.79×10^6 ，验证集运行耗时 11.76s，与其他传统轻量化模型相对比具有明显优势。在实际温室场地进行实地试验验证，检测准确率达 88.79%，漏检率为 8.44%，具有实际应用价值。本文提出的 DC-CA-MobileNetV3 番茄叶片病害识别模型可精准、高效地识别番茄叶片病害，同时具有参数量小、易搭载至嵌入式系统的优点。

INTRODUCTION

China ranks among the leading countries in global tomato production, and modern cultivation techniques such as greenhouse planting have significantly enhanced both the yield and quality of tomatoes. Nevertheless, during their growth cycle, tomatoes are susceptible to various diseases, including leaf mildew, yellow leaf curl virus, and powdery mildew. The absence of timely detection and intervention can severely compromise tomato yield and quality (Zhang et al., 2020).

Cheng Chi, M.S. Stud. Eng.; LiFeng Qin, Associate professor, Ph.D. Eng.

However, prompt identification of diseases and implementation of preventive and control measures can effectively mitigate disease propagation, which holds substantial significance for enhancing tomato yield and quality while minimizing economic losses (Tian *et al.*, 2021).

Vision-based technology for the detection and diagnosis of vegetable diseases has garnered significant attention. Xu developed an intelligent tomato disease diagnosis model using Bayesian optimization with LightGBM, preprocessed raw prescription data, and further extracted features from crop disease prescription data through a Wrapper-based recursive feature elimination method, achieving a comprehensive diagnostic accuracy of 89.11% (Xu *et al.*, 2022). Sladojevic employed a deep CNN model along with the Stanford background dataset to classify plant diseases, identifying 13 distinct types of plant diseases from healthy leaves and distinguishing plant leaves from their surrounding environment. The model's accuracy ranged between 91% and 98%, with an average accuracy of 96.3% for individual class tests (Sladojevic *et al.*, 2016). Brahim integrated AlexNet and GoogleNet models within a CNN framework, leveraging transfer learning and fine-tuning mechanisms to classify tomato leaf diseases, achieving accuracies of 98.66% and 99.18%, respectively (Brahimi *et al.*, 2017). Jiang utilized ResNet-50 to identify several tomato leaf diseases - primarily late blight, leaf mold, and yellow leaf curl virus - achieving a detection accuracy of 98% after multiple training iterations (Jiang *et al.*, 2020). Han employed infrared thermal imaging in conjunction with an improved version of YOLOv5 for the early detection of crop diseases. Their model achieved a mean Average Precision (mAP) exceeding 90% across various temperature gradients, enabling more precise and rapid identification of early-stage diseases (Han *et al.*, 2023). Ullah proposed the integration of EfficientNetB3 and MobileNet to detect tomato leaf diseases, achieving a detection success rate of 99.92% (Ullah *et al.*, 2023). Yang optimized the YOLOv5s-based crop yellowing and leaf bending detection model by applying trunk replacement, model pruning, and knowledge distillation techniques. Their approach reduced memory usage by 90% while maintaining an average accuracy reduction of less than 3% (Yang *et al.*, 2023).

The research on tomato leaf disease detection using deep learning models addresses the limitations of traditional manual inspection methods, significantly enhancing both the efficiency and accuracy of detection. However, several challenges remain. First, most deep learning models are characterized by their large size and complex architecture, requiring a substantial number of parameters to achieve high recognition accuracy. This results in heavy computational demands, poor real-time performance, and difficulties in deploying these models on embedded devices for practical applications. Second, given the diverse range of tomato leaf diseases and the similarity of symptoms among some conditions, there is still potential for improvement in the accuracy of existing recognition models.

To address the aforementioned issues, this paper proposes an enhanced algorithm based on the MobileNetV3 model, which is specifically designed for the detection of leaf diseases in tomato greenhouses. By leveraging transfer learning, the model is further optimized to extract both feature representations and their corresponding location information. This not only provides valuable data resources for subsequent inspection tasks but also effectively addresses the challenges of limited deployment on embedded devices.

MATERIALS AND METHODS

Data set construction

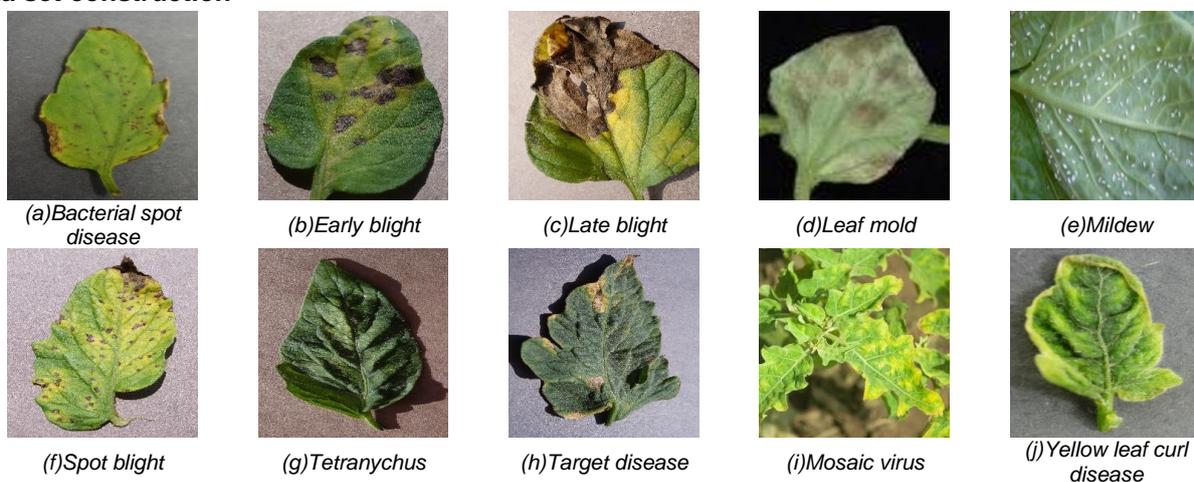

Fig.1 - Sample images of different tomato leaf diseases

In this study, tomato leaves were selected as the research subject, with healthy leaves and 10 common tomato leaf diseases chosen to construct a dataset. All images were sourced from a dataset published on Kaggle's official website. This dataset has been classified by domain experts, ensuring high reliability, which facilitates deep learning models in performing classification tasks effectively. Additionally, the original images underwent augmentation through rotation and mirroring techniques to expand the dataset size and enhance model generalization. Our dataset primarily comprises 10 types of tomato diseases, including bacterial spot, early blight, late blight, leaf mold, mildew, spot blight, spider mite damage, target spot, mosaic virus, yellow leaf curl virus, and healthy leaf images. A total of 32,534 images were split into training and validation sets at an 8:2 ratio. Disease names, corresponding labels, and sample counts are presented in Table 1, while partial image samples are illustrated in Figure 1.

Table 1

Label	Name of tomato leaf diseases	Number of sample images/piece
0	Healthy leaf	3856
1	Bacterial spot disease	3558
2	Early blight	3098
3	Late blight	3905
4	Leaf mold	3493
5	Mildew	1256
6	Spot blight	3628
7	Tetranychus	2182
8	Target disease	2284
9	Mosaic virus	2737
10	Yellow leaf curl disease	2537

Tomato leaf disease recognition model

(1) Lightweight network MobileNetV3 model

MobileNetV3 is a lightweight deep learning model introduced by the Google research team in 2019, and characterized by a reduced number of parameters, lower computational requirements, and shorter inference times (Shi *et al.*, 2024), which makes it particularly suitable for deployment on mobile and embedded devices. Building upon the MobileNetV2 architecture (Sandler *et al.*, 2018), MobileNetV3 incorporates the Squeeze-and-Excitation (SE) attention mechanism to enhance feature representation capabilities. Additionally, it introduces the h-swish activation function, which offers computational efficiency while maintaining high performance. The tail network structure has also been further optimized to improve overall accuracy (Howard *et al.*, 2020). MobileNetV3 provides two variants—MobileNetV3-Large and MobileNetV3-Small—to accommodate diverse hardware configurations and performance needs (Wu 2024). This study focuses on the MobileNetV3-Large model, with its structural parameters detailed in Table 2.

Table 2

Input	Operations	SE	Activation function	Stride
224 ² ×3	Conv2d	—	HS	2
112 ² ×16	Bneck,3×3	—	RE	1
112 ² ×16	Bneck,3×3	—	RE	2

(2) Improved MobileNetV3 model

Since the existing MobileNetV3 network model exhibits limited sensitivity to location information and insufficient feature learning capability for similar diseases, this paper proposes an enhanced approach for this network model. The improved network architecture is illustrated in Figure 2. First, the SE (Squeeze-and-Excitation) attention module in the bottleneck layer of the network is substituted with the CA attention module, enabling the network to better capture image location information, which facilitates further processing of such information. Second, dilated convolution is incorporated into the last two bottleneck layers, effectively expanding the receptive field without increasing computational complexity, thereby enhancing feature extraction.

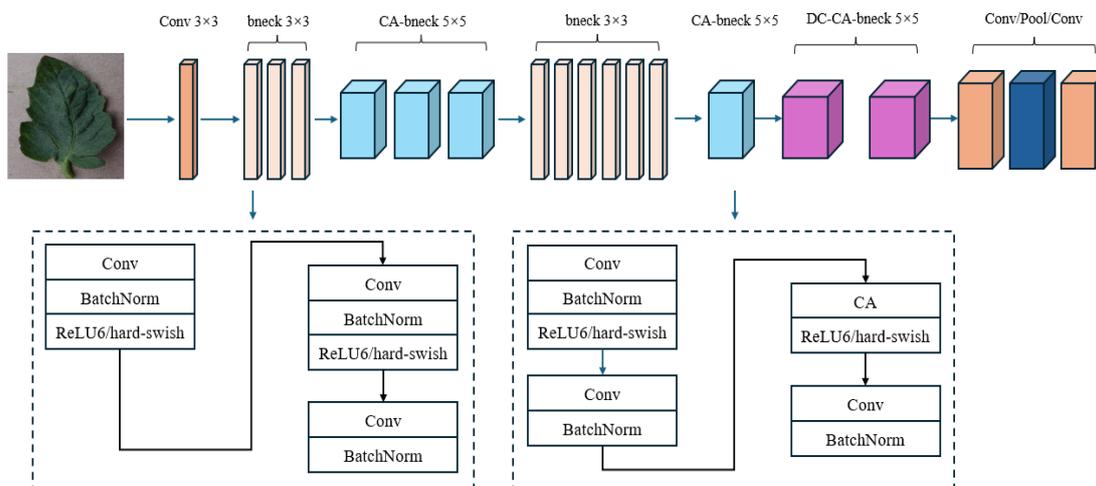

Fig. 2 - Structure diagram of improved MobileNetV3

Since the SE module primarily emphasizes the relationship between channels (*Li et al., 2020*) without accounting for spatial position information, its capability to acquire image information of tomato disease leaves is constrained. The CA attention module integrates decomposed coordinate coding to embed the diseased area's coordinate information into the feature map, thereby enhancing the model's spatial perception of the diseased region. Consequently, the CA attention module, which captures positional information, was employed to replace the SE attention module. This substitution only marginally increased the computing resources required and facilitated seamless integration into mobile inspection devices.

The CA attention mechanism effectively captures image features by modeling inter-channel relationships and long-range spatial dependencies (*Hou et al., 2021*). Specifically, channel attention is decomposed into two one-dimensional feature encoding processes. Global average pooling of input feature maps is performed along both the vertical and horizontal directions to generate perception maps in each direction. Subsequently, these perception maps are combined, and a series of convolutional layers along with nonlinear activation functions are employed to produce a pair of direction-aware and position-sensitive

attention maps. Ultimately, the generated attention maps are applied to the input feature maps via element-wise multiplication, thereby enhancing the representation of the object of interest while preserving accurate positional information (Zheng et al., 2024).

The calculation process of the CA attention mechanism primarily consists of three stages (Gu et al., 2025). Given an input feature map of size $C \times H \times W$, where C denotes the number of channels, H represents the height, and W indicates the width of the feature map, the CA module initially applies two pooling kernels, $(H,1)$ and $(1,W)$, to perform global average pooling along the horizontal and vertical directions, respectively. This operation yields two feature maps of dimensions $C \times H \times 1$ and $C \times 1 \times W$, which are subsequently concatenated to produce a feature map of size $C \times (H+W)$. The concatenated feature map is then transformed via 1×1 convolution, followed by batch normalization and a nonlinear activation function. Subsequently, the transformed feature map is split into horizontally and vertically independent feature maps, which undergo another 1×1 convolution operation. The resulting feature maps have the same number of channels as the input feature map. Finally, the Sigmoid activation function is applied to generate the attention map, which is used to emphasize feature regions through element-wise multiplication, thereby producing the final output feature map. Figure 3 illustrates the detailed calculation process of the CA attention module.

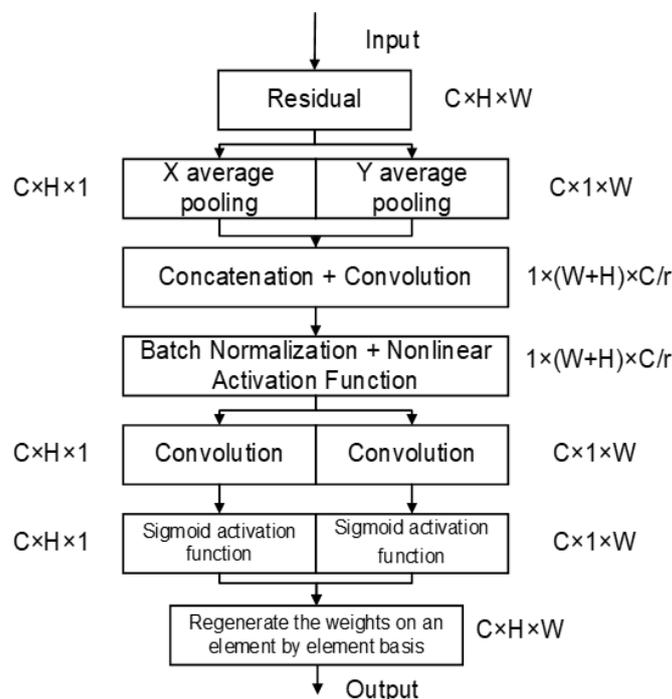

Fig. 3 - Flowchart of calculation of coordinate attention

Dilated Convolution is a technique that incorporates intervals into the convolution kernel, thereby expanding the receptive field of the kernel without increasing computational complexity or introducing additional parameters (Kumar et al., 2022). This facilitates more effective extraction of image features and enhances model learning and training. Given the diversity of tomato leaf diseases and the similarity among different diseases, it is crucial to preserve detailed texture information of disease spots. By leveraging its sparse sampling and resolution-preserving mechanism, dilated convolution effectively addresses detail loss issues caused by traditional down-sampling operations. Furthermore, it establishes correlations between the pathology of lesions and the entire leaf through a large receptive field, achieving a balance between detail enhancement and global perception in multi-scale feature fusion.

Figure 4 illustrates the cavity convolution expansion process. The critical aspect of this process involves the expansion coefficient r , which determines the number of intervals between elements within the convolution kernel. This mechanism enables the establishment of convolution kernels of varying sizes across different bottleneck layers, facilitating the extraction of image features at a deeper level and enhancing their alignment with the target object. In this study, cavity convolution is incorporated into the last two bottleneck modules of the MobileNetV3 network, with expansion coefficients r set to 2 and 4, respectively. The corresponding convolution kernels are also depicted in Figure 4.

Initially, cavities are inserted into the convolution kernel based on the specified expansion coefficient, followed by the computation of feature graph convolution. Finally, the resulting feature graph is output. The size of the feature map can be determined using the following formula:

$$o = \left\lceil \frac{i + 2p - (k - 1)r + 1}{s} \right\rceil + 1 \quad (1)$$

- o - Output the dimension (width or height) of the feature map.
- i -- Input the dimension (width or height) of the feature map.
- p --The extent of edge padding
- k --The size of the convolution kernel
- r --Coefficient of expansion
- s -- Stride. In a hollow convolution, the value is consistently set to 1.

The initial convolution kernel size is set to 3×3. When the expansion coefficient $r=2$, the convolution kernel expands to 5×5; when $r=4$, it further expands to 9×9. It is evident that as the expansion coefficient r increases, both the size of the convolution kernel and its receptive field grow significantly, without introducing any additional operational parameters.

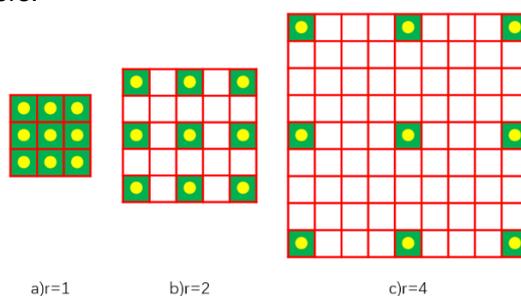

Fig. 4 - Schematic diagram of dilated convolution expansion

(3) Transfer Learning

Transfer learning (Jain *et al.*, 2021; Li *et al.*, 2023) is a machine learning technique that enables the adaptation of a pre-trained model to a new yet related problem, thereby enhancing the model's performance. By leveraging transfer learning, the amount of annotated data required for new tasks can be significantly reduced. In scenarios where existing data resources are limited, transfer learning can significantly boost model accuracy and generalization. This approach enables the model to leverage knowledge from related tasks, thereby learning more robust and transferable features. Consequently, this paper employs transfer learning to optimize the model for deployment and usage. Specifically, MobileNetV3 pre-trained on the ImageNet dataset serves as the source domain model, while the target domain is the tomato leaf disease dataset constructed in this study. To fine-tune the model, a transfer learning optimization strategy involving the freezing of selected convolutional layers is adopted.

The architecture of MobileNetV3 was optimized through techniques such as cavity convolution, coordinate attention module embedding, and other methods. Subsequently, the features of the ImageNet pre-trained model were transferred. The model was trained using a feature transfer approach based on freezing shallow common features and a model transfer approach involving fine-tuning of deep parameters. As a result, the tomato disease recognition model DC-CA-MobileNetV3 was developed.

RESULTS AND ANALYSIS

Experimental platform

The cloud platform provided by Featurize was utilized in this study. The hardware configuration comprised a 6-core Intel E5-2680 v4 processor, an NVIDIA RTX 3060 graphics card with 12GB of memory, and 32GB of system RAM. The software environment included Python 3.7 and the deep learning framework Tensorflow 2.7.

Performance index

Precision (P), Recall (R), mean Average Precision (mAP), and F1 Score (F1) (Sun *et al.*, 2025; Chen *et al.*, 2024) were employed as evaluation metrics to assess the performance of the DC-CA-MobileNetV3 model proposed in this study.

The formulae for precision (P) and recall (R) are:

$$P = \frac{TP}{TP + FP} \times 100\% \quad (2)$$

$$R = \frac{TP}{TP + FN} \times 100\% \quad (3)$$

In the context of mean Average Precision (mAP), P represents the accuracy rate, AP denotes the Average Precision for a single label (the average of the maximum precision values at each recall level), and mAP signifies the mean of the Average Precision across all labels.

The formula is as follows:

$$AP = \frac{\sum P}{N(\text{TotalImages})} \quad (4)$$

$$mAP = \frac{\sum AP}{N(\text{Classes})} \quad (5)$$

Taking bacterial spot disease as an example, TP denotes the count of samples that correctly identify bacterial spot disease among all samples; FP indicates the count of samples that erroneously classify another category or background as bacterial spot disease; FN refers to the count of bacterial spot disease samples misclassified as other categories or unidentified. AP represents the average of the highest precision values achieved for a single disease species across varying recall rates, while mAP signifies the mean value of AP across all disease categories.

The F1 score is a metric employed to comprehensively assess the performance of a classification model. It integrates the precision rate (P) and the recall rate (R), serving as their harmonic mean. This metric allows for the evaluation of model performance while maintaining equilibrium between precision and recall, and its calculation formula is as follows:

$$F1 = \frac{2PR}{P + R} \quad (6)$$

A Comparative Experiment on Transfer Learning Methods

Transfer learning can be categorized into three approaches, namely: Full Migration, which involves freezing all convolutional layers and training only the fully connected layer; Reuse Model, which employs only the model architecture without utilizing pre-trained parameters; and Fine-Tuning, which freezes only a portion of the convolutional layers (Cui et al., 2023). In this study, the Fine-Tuning method was adopted. To evaluate the effectiveness of the transfer learning approach used in this study, the improved MobileNetV3 model was employed as a benchmark, and the same experimental dataset was utilized. The three models were trained using the aforementioned transfer learning methods, respectively, and a tomato disease classification experiment was conducted. The results are presented in Table 3, while the training and validation accuracy curves for the three transfer learning methods are illustrated in Figure 5.

Table 3

Experimental results of test-set of the three migration methods			
Transfer Methodology	Precision/%	Recall/%	F1 Score/%
Fine tuning	94.33	94.12	94.22
Full migration	93.59	92.94	93.28
Reuse model	93.88	93.69	93.78

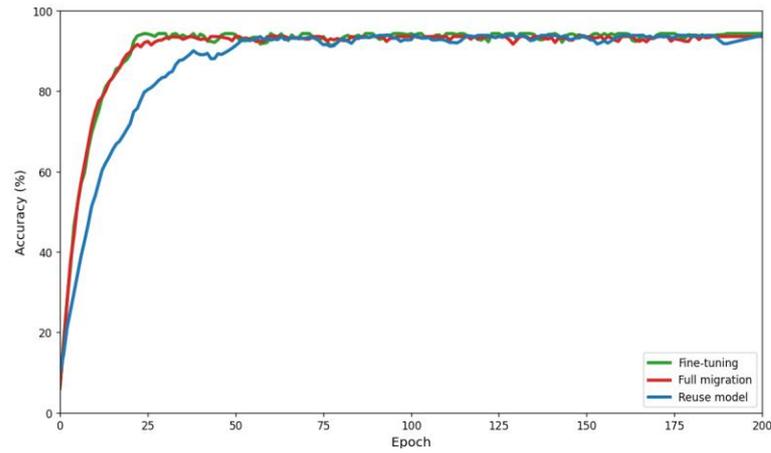

Fig. 5 - Comparison of accuracy of three migration methods

Ablation Study

To validate the effectiveness of the improvement measures, an ablation study was designed. Specifically, the CA attention module and cavity convolution techniques were integrated into the original model to enhance its performance. A classification experiment was subsequently conducted to compare the results, as detailed in Table 4.

Table 4

MobileNetV3-based ablation experiments

Serial Number	CA	DC	Precision (%)	Recall (%)	mAP (%)	F1 Score (%)
1			90.11	89.86	90.02	89.98
2	√		91.15	91.02	91.34	91.08
3		√	92.36	92.30	91.91	92.33
4	√	√	94.33	94.12	93.64	94.22

As shown in Table 4, the introduction of the CA attention module and the cavity convolution module individually led to a certain degree of improvement in model performance. When both methods were combined, the overall effect was optimal. The accuracy of tomato leaf disease identification reached 94.33%, and the F1 score reached 94.22%, surpassing the results obtained by either method alone as well as those of the unimproved model. Simultaneously, the improved model contains 2.79×10^6 parameters, enabling deployment on mobile devices. The increase in required training time is minimal, satisfying the demands for immediate application. In conclusion, the enhanced DC-CA-MobileNetV3 model demonstrates superior comprehensive performance compared to the original model.

A Comparative Study on Various Attention Mechanisms

In this study, the original SE module in MobileNetV3 was replaced with the CA module, which is capable of recognizing spatial positions. To compare and validate the performance of the CA module, MobileNetV3 models incorporating SE, ECA, and CA modules were evaluated under identical experimental data, model architecture, and training conditions. Under these consistent conditions, a fine-tuned transfer learning approach was employed for training over 200 epochs. Figure 6 presents the confusion matrix of classification results under different attention mechanisms, where the values on the main diagonal indicate the number of correctly classified samples. Detailed experimental data are provided in Table 5.

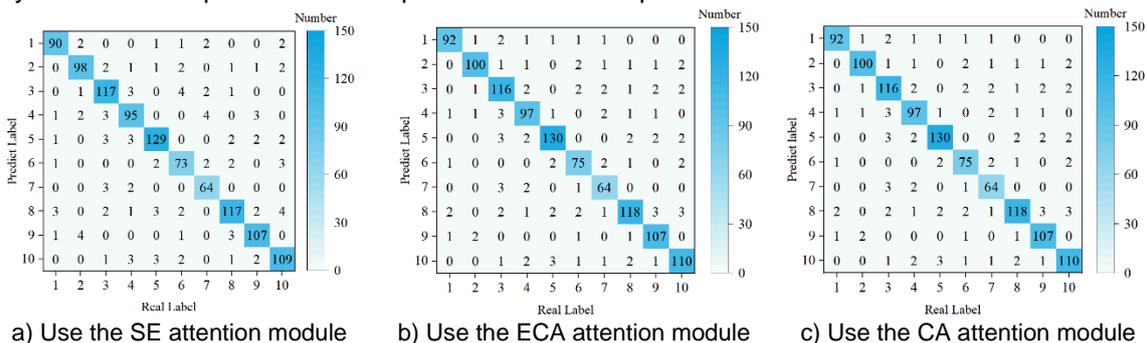

Fig. 6 - The confusion matrix of the MobileNetV3 model using different attention modules

Table 5

Comparison experiments of different attention mechanisms based on MobileNetV3

Methodology	P [%]	R [%]	mAP [%]	F1 Score [%]
SE	90.20	89.97	90.27	90.08
CA	91.15	91.02	91.34	91.08

Comparative experiment of different models

To validate the effectiveness and practicality of the model proposed in this study, comparative experiments were conducted with ShuffleNetV2 (Ma et al., 2018), AlexNet (Krizhevsky et al., 2012), VGG-16 (Simonyan et al., 2015), and ResNet-50 (He et al., 2014), respectively.

Among these models, ShuffleNetV2 is a classic lightweight convolutional neural network that shares similar applications with MobileNetV3. Additionally, AlexNet, VGG-16, and ResNet-50 have gained widespread recognition for their performance in visual classification tasks and thus provide valuable references for comparison. Under identical experimental datasets and model parameter configurations, the proposed model was evaluated against the four aforementioned models with the number of epochs set to 200. The results are presented in Table 6.

Table 6

Experiments of five models on test set

Name	Parameter number/number	Time / s	P / %	R / %	mAP / %	F1 Score / %
AlexNet	6×10^7	18.72	91.62	91.42	90.03	92.52
ShuffleNetV2	1.31×10^6	19.5	92.92	92.19	92.33	92.55
VGG-16	1.39×10^8	35.34	92.52	92.25	92.16	92.38
ResNet-50	2.21×10^7	24.12	93.56	93.28	93.27	93.42
Textual method	2.79×10^6	11.76	94.33	94.12	93.64	94.22

As shown in Table 6, the accuracy P of the enhanced MobileNetV3 network model proposed in this paper reaches 94.33%, which is respectively 2.71%, 1.41%, 1.81%, and 0.77% higher than that of the other four networks. This improvement can be attributed to the incorporation of CA (Coordinate Attention) and void convolution mechanisms, which enable the model to learn image features more effectively. The number of parameters in the model is only marginally higher than that of the lightweight ShuffleNetV2 model, while its recognition time is significantly shorter at 11.76 seconds, representing a reduction of 7.74 seconds compared to ShuffleNetV2. This performance ensures the real-time and high-efficiency requirements necessary for mobile devices and enables the processing of video stream image information. Additionally, the F1 score of the model's recognition capability reaches 94.22%, which is the highest among the compared models, indicating an excellent balance between precision and recall. In conclusion, the improved model presented in this study not only enhances recognition accuracy, but also maintains the characteristics of a lightweight architecture and fast response speed, thereby demonstrating its strong application potential.

Mobile Deployment and Experimentation of the Model

To verify the performance of the improved tomato leaf disease recognition model in practical scenarios, it was applied to the ROS framework and mounted on a patrol device to conduct a patrol experiment for tomato leaf diseases.

The ROS system selected the ROS2 Foxy version, where a workspace and module package were created, and a detection node was designed. The camera image topic /camera/image_raw was subscribed as the model input, and the labeled image /detection_results was used as the model output. The package.xml and setup.py and other dependency files were modified, and the module package was compiled using the colcon command.

Fig. 7 - Inspection device for field experiment drawing

In the experimental glass greenhouse in Wuquan Town, Yangling District, Xianyang City, Shaanxi Province, China, an Ackermann intelligent car equipped with a Raspberry Pi 4B development board was used as the patrol device, as shown in Figure 7.

A total of 121 tomato leaf images were collected to form the target detection validation set. The improved DC-CA-MobileNetV3 model combined with the SSD algorithm module was used to detect tomato leaf disease targets, and the results are shown in Figure 8, where only the rectangular boxes with a confidence level greater than 0.8 are retained. The comparison of the average detection accuracy and missed detection rate of the improved model and the original model on 121 images is shown in Table 7.

Table 7

Comparison of model detection results before and after improvement

Detection method	Precision / (%)	Omission Rate / (%)
Before improvement	84.55%	10.29%
After improvement	88.79%	8.44%

Fig. 8 - Model testing results in the actual scenario

CONCLUSIONS

In this study, we proposed an enhanced MobileNetV3-based model for tomato leaf disease recognition. Specifically, the CA attention module is integrated to replace the SE attention module in the original architecture, enabling more effective extraction of image target feature location information and facilitating subsequent localization tasks on mobile recognition devices. Additionally, dilated convolution is incorporated to expand the model's receptive field and improve its feature recognition capabilities. Experimental results demonstrate that the proposed DC-CA-MobileNetV3 model achieves a recognition accuracy of 94.33%, a recall rate of 94.12%, an average accuracy of 93.64%, and an F1 score of 94.22%, with a parameter count of 2.79×10^6 and an operation time of 11.76 seconds. These performance metrics indicate that the model satisfies the requirements for stability, rapidity, and accuracy, providing robust technical support for the development of intelligent monitoring and inspection systems for tomato leaf disease information. The model was deployed to mobile devices in a greenhouse environment. In actual environmental scenarios, the accuracy rate reached 88.75%, and the missed detection rate was 8.44%, demonstrating practical application value.

In practical application scenarios, factors such as illumination and occlusion can interfere with the performance of the tomato leaf disease recognition model. In future work, we will further optimize the model architecture by incorporating training with images captured under diverse complex conditions, thereby improving accuracy in real-world scenarios and enhancing network robustness.

ACKNOWLEDGEMENT

ABSTRACT

To improve the utilization rate of fertilizers by peanut seeds, this study presents the synchronous hole fertilization and directly-above seeding of peanuts and designs a pneumatic horizontal disc hole fertilization device. A theoretical analysis of the ditching process of the fertilization furrow opener was carried out, and the height of the hole fertilization device from the ground was determined to be 40 mm. Through the analysis of the hole fertilization and directly-above seeding operation process, the time difference between seed metering and fertilizer metering was determined. Combining with theoretical analysis, EDEM-FLUENT coupling simulation tests and field tests were carried out on the device. The field test results showed that the error of the fertilization hole spacing ranges between 2.3-4.5%, the error of the hole fertilization depth is 3.2-5.1%, the seed - fertilizer distance is 64.8-67.2 mm, and the fertilizer distribution length is 99.3-107.5 mm. The test results meet the requirements specified in the sowing and fertilization standards.

摘要

为了提高花生种子对肥料的利用率, 本文以花生穴施肥同步正位播种为研究目标, 设计了这一种气吹式水平圆盘穴施肥装置。对施肥开沟器开沟过程进行了理论分析, 确定了穴施肥装置距离地面的高度为 40mm。通过对穴施肥及正位播种作业过程的分析, 确定了排种与排肥的时间差。结合理论分析对该装置进行了 EDEM-FLUENT 耦合仿真试验及田间试验, 田间试验结果表明施肥穴距误差为 2.3%-4.5%, 穴施肥深度误差为 3.2%-5.1%, 种肥间距为 64.8 mm-67.2 mm, 肥料分布长度为 99.3 mm-107.5 mm。试验结果满足播种施肥标准中规定的要求。

INTRODUCTION

Peanuts, an important oil crop and economic crop in China, play a crucial role in ensuring food security and supporting the agricultural economy (Tang et al., 2019; Shi et al., 2016). With the improvement of agricultural mechanization, peanut seeding technology is gradually evolving toward high efficiency and precision (Timilsena et al., 2015; Shang et al., 2016). Currently, traditional seeding operations still rely primarily on strip fertilization, which faces challenges such as low efficiency and poor fertilizer utilization (Liu., 2017;). Excessive use of chemical fertilizers is likely to lead to problems such as soil compaction, degradation, and environmental pollution (Parent et al., 2020). However, precision fertilization serves as an effective means of supporting the goals of sustainable agricultural development (Gyami et al., 2019). The peanut hole fertilization technique involves applying a fixed quantity of fertilizer in a hole-like pattern at a specific distance beside or directly beneath peanut seeds or plants. Studies have shown that this method enables quantitative and precise fertilization, thereby enhancing fertilizer use efficiency (Luo et al., 2016; Wang et al., 2016).

Da Silva et al. designed a perforating and injecting device for liquid fertilizer, which combines soil perforation with liquid fertilizer injection to reduce disturbance to roots, crop residues, and soil, thereby improving plant fertilizer utilization (Da Silva et al., 2019); Martins et al. proposed a method for variable rate nitrogen fertilization in corn using optical sensors, providing data reference for variable rate fertilization decisions through a portable chlorophyll detector (Martins et al., 2020). Du Xin et al. designed an inclined trapezoidal hole-type hole fertilization distributor (Wang et al., 2018; Du et al., 2021) which achieves precision fertilizer filling through inclined trapezoidal holes with fixed volume and uses airflow assistance at the fertilizer discharge port to rapidly discharge fertilizers into holes. However, the distributor has a complex structure and requires replacing the fertilizer discharge adjustment plug to regulate the fertilization amount. Liu et al. designed an automatic seed-aligned fertilization system for corn based on a planetary gear system, which uses a rotary cavity disc hole fertilization device, which can detect in real-time the falling information of seeds and fertilizers, calculate their relative positions, and make real-time adjustments via a control motor (Liu et al., 2023).

To enhance fertilizer utilization rate and the yield per unit area of peanuts, this study focuses on the designed pneumatic horizontal disc hole fertilization device. By analysing the motion trajectories of seeds and clustered fertilizers, the phase difference between the seed metering disc and the fertilizer metering disc was determined. Moreover, field tests were carried out to evaluate the performance of hole fertilization and directly - above seeding performance of the synchronous hole fertilization and directly - above seeding device. The results are expected to provide both theoretical insights and practical references on the equipment for the advancement of precision fertilization technology in peanut cultivation.

MATERIALS AND METHODS

Overall structure and working principle of the synchronous hole fertilization and directly-above seeding device for peanuts

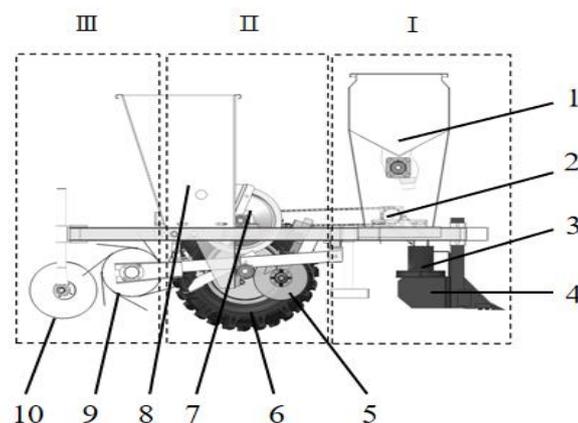

Fig. 1 - Overall structure of the synchronous hole fertilization and directly-above seeding device for peanuts

I - Fertilization unit; II - Seeding unit; III - Soil covering unit; 1 - Main fertilizer tank; 2 - Transmission device; 3 - Hole fertilization device; 4 - Fertilization furrow opener; 5 - Seeding opener; 6 - Ground wheel; 7 - Seed metering device; 8 - Seed box; 9 - Press wheel; 10 - Soil covering wheel.

The synchronous hole fertilization and directly-above seeding device for peanut planters is mainly composed of a seeding unit, a hole fertilization unit, and a motor control unit. The hole fertilization unit mainly includes a fertilization furrow opener, a hole fertilization device, a commutator, etc. During seeding operations, the hole fertilization device extracts fertilizer particles from the fertilizer box and forms clusters in the fertilizer cavity. These particles are transported by the fertilizer metering disc to the fertilizer discharge port, where they are discharged into the fertilization furrow in holes under the action of air flow. The seeding unit consists of a seed metering device, a disc-type furrow opener, a press wheel, a soil covering disc, etc., and uses a spoon-wheel precision seed metering device to achieve precise peanut seeding. The motor control unit is mainly composed of a microprocessor, a speed measurement device, a stepper motor, and a transmission system.

A speed sensor is installed on the ground wheel axle to detect in real-time and to calculate the travel speed, and regulate the motor rotation speed, ensuring that fertilizer particles are applied in holes along the fertilization furrow according to the peanut hole spacing. Meanwhile, the fertilizer metering disc shaft and the seed metering disc shaft maintain a fixed transmission ratio.

By analysing the motion relationship between seeds and hole-applied fertilizers, the phase difference between the seed metering disc and the fertilizer metering disc is determined to ensure that seeds are accurately placed directly above the fertilizers.

Design of hole fertilization device

The horizontal disc hole fertilization device is mainly composed of a fixed plate, housing, fertilizer metering disc, fertilizer quantity adjustment disc, fertilizer tank, motor, coupling, air inlet pipe, etc. According to the fertilizer metering workflow, the fertilizer metering disc can be divided into a fertilizer filling zone I, fertilizer transport zone II, fertilizer discharge zone III, transition zone IV, as shown in Figure 2.

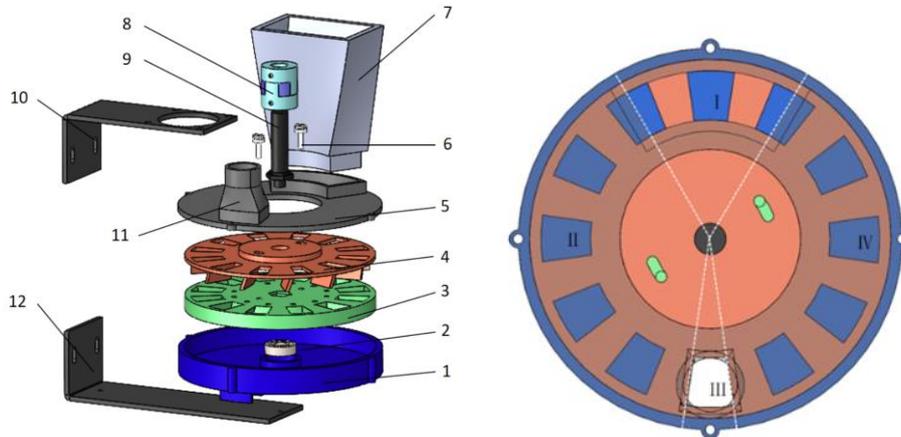

Fig. 2 - Structure of hole fertilization device and fertilizer metering disc zoning

1-Lower housing; 2-Bearing; 3-Fertilizer metering disc; 4-Fertilizer quantity adjustment disc; 5-Upper housing; 6- Fertilizer quantity adjustment bolt; 7-Fertilizer distributor tank; 8-Coupling; 9-Shaft; 10-Upper mounting plate; 11-Air inlet pipe; 12-Lower mounting plate; I -Fertilizer filling zone; II -Fertilizer transport zone; III-Fertilizer discharge zone; IV-Transition zone.

During fertilization, fertilizer particles fall from the planter's fertilizer box into the fertilizer distributor tank through the fertilizer discharge pipe, forming a fertilizer layer of a certain thickness. The fertilizer metering disc and the fertilizer quantity adjustment disc are fixed by fertilizer quantity adjustment bolts. By loosening these bolts and rotating the adjustment disc, the volume of the fertilizer cavities can be changed to regulate the filling amount. The fertilizer metering disc has multiple fertilizer cavities evenly distributed along its central axis. Driven by the shaft, the fertilizer metering disc and adjustment disc rotate counterclockwise in synchronization. As they pass through the fertilizer filling zone at a certain speed, fertilizer particles fill the cavities under gravity and the disturbance of the metering disc. Protected by the upper and lower housings and pushed by the metering disc, the clustered fertilizers travel through the fertilizer transport zone to the fertilizer discharge zone. An air inlet pipe is installed directly above the fertilizer discharge port, connected to a fan above. Under the action of positive pressure airflow and gravity, the fertilizer particles are rapidly discharged, forming holes in the field for application.

Analysis of the installation position of the hole fertilization device

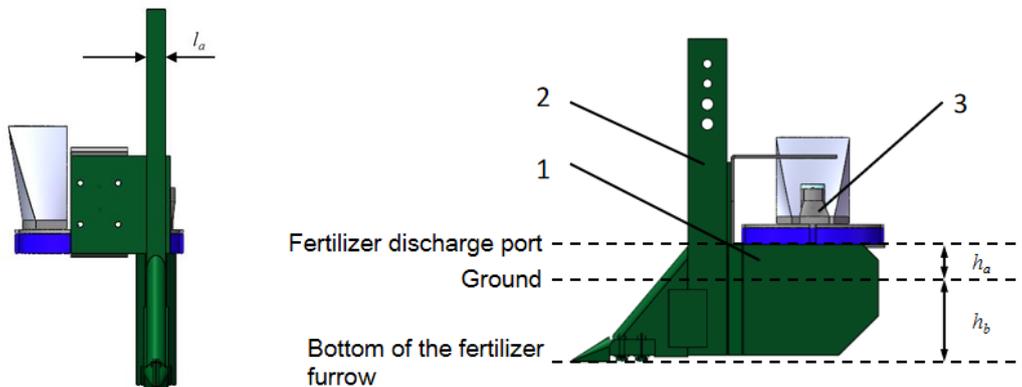

Fig. 3 - Schematic diagram of hole fertilization device installation position

1-Furrow opener wing; 2-Shovel column; 3-Hole fertilization device.

The hole fertilization device is fixed above the furrow opener wings, with the fertilizer discharge port located between the two wings, as shown in Figure 3. During fertilization operations, the furrow opener creates a fertilizer furrow in the soil. Hole-applied fertilizers are discharged from the fertilizer discharge port, fall into the furrow through the wings, and the extended wings on both sides prevent soil from collapsing on the sides of the furrow, maintaining a complete furrow shape.

To reduce the falling time of hole-applied fertilizers and to minimize bouncing and scattering caused by collisions with soil, the installation height of the fertilizer metering disc should be minimized to ensure low-position fertilization. The relative positions of the fertilizer distributor of the hole fertilization device with respect to the ground and the bottom of the fertilizer furrow are shown in Figure 3. During fertilization, the furrow opener lifts and throws part of the soil in the furrow to both sides, forming soil mounds on the edges of the furrow. To prevent excessive soil mounds from squeezing the fertilizer distributor, the installation height of the fertilizer discharge port must be analyzed and calculated. Assuming no soil compaction during furrowing and conservation of soil volume, the height h between the fertilizer discharge port and the ground satisfies the following condition:

$$l_a \cdot h_b \leq \frac{1}{2} h_a \frac{2h_a}{\tan \theta_t} \tag{1}$$

where: l_a is the width of the furrow opener shovel column, [m]; h_b is the height from the ground to the bottom of the fertilizer furrow, [m]; h_a is the height from the fertilizer discharge port of the fertilization device to the ground, [m]; θ_t is the soil angle of repose, [°].

The relational expression for the height from the fertilizer discharge port to the ground can be derived as:

$$h_a \geq \sqrt{l_a \cdot h_b \cdot \tan \theta_t} \tag{2}$$

The width of the furrow opener shovel column used in this study is 30 mm. According to relevant literature, the distance from the ground to the bottom of the fertilizer furrow is generally 90–110 mm, and the soil angle of repose is 31°. Calculations using Equation (2) show that the minimum height from the fertilizer discharge port of the fertilization device to the ground is 40 mm.

Motion analysis of clustered fertilizers

The synchronous direct-position seeding device for peanut hole fertilization first applies fertilizer particles in clustered form into the fertilizer furrow at the hole spacing required by peanut seeding agronomy, then places seeds directly above the fertilizers while maintaining a certain distance. The relative position between seeds and fertilizers directly affects peanut yield and fertilizer utilization efficiency. Here, h_j represents the vertical distance between seeds and fertilizers after seeding and fertilization, and the distribution of seeds and fertilizers is shown in Figure 4.

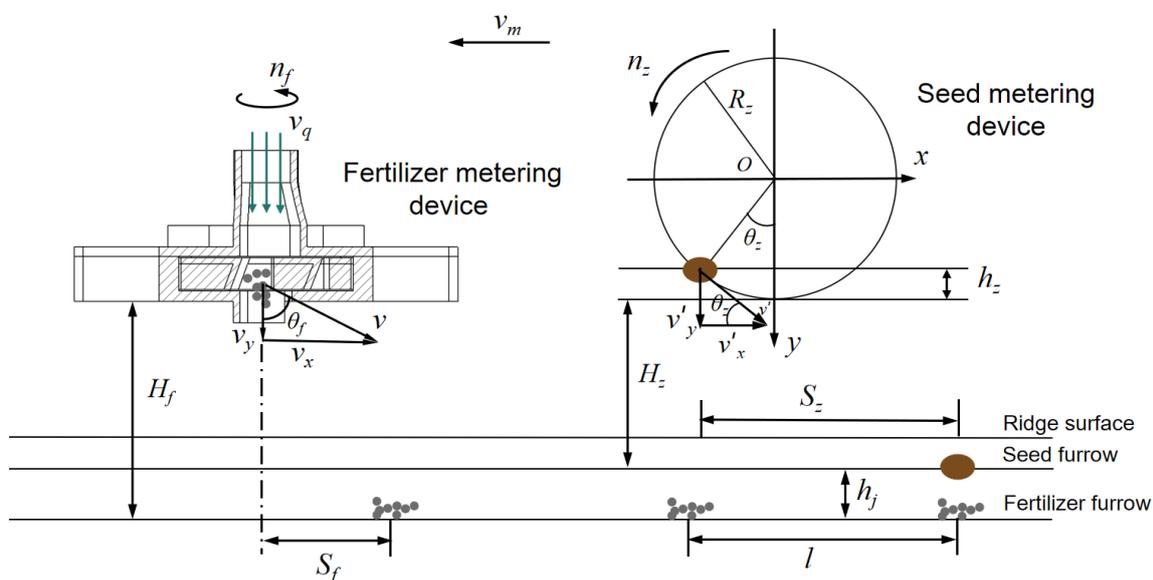

Fig. 4 - Analysis of motion trajectories of seeds and fertilizers

During fertilization, the fertilizer metering disc transports clustered fertilizer particles to the fertilizer discharge port. The fertilizers are discharged backward under the combined action of wind force and gravity, where v_m is the machine travel speed in the direction of machine movement. When the fertilizer distributor starts discharging at the fertilizer discharge port, the horizontal and vertical velocities of the clustered fertilizers when they leave the fertilizer cavities are:

$$\begin{cases} v_x = -v_m + v \cdot \sin \theta_f \\ v_y = v \cdot \cos \theta_f \end{cases} \quad (3)$$

where: v_x is the horizontal component velocity of hole-applied fertilizers when leaving the fertilizer cavity, [m/s]; v_y is the vertical component velocity of hole-applied fertilizers when leaving the fertilizer cavity, [m/s]; v_m is the machine travel speed, [m/s]; v is the resultant velocity of hole-applied fertilizers when leaving the fertilizer cavity, [m/s]; θ_f is the angle between the resultant velocity of hole-applied fertilizers and the vertical direction, [°].

When the hole-applied fertilizers leave the fertilizer cavity and fall into the fertilizer furrow, the distance they move in the vertical direction is:

$$H_f = v_y \cdot t_1 + \frac{1}{2} g t_1^2 \quad (4)$$

where: H_f is the distance from the fertilizer discharge port to the bottom of the fertilizer furrow, [m]; t_1 is the time for hole-applied fertilizers to fall from the fertilizer cavity to the furrow bottom, [s]; g is the gravitational acceleration, [m/s²].

From Equations (3) and (4), it results:

$$t_1 = \frac{-v \cdot \cos \theta_f + \sqrt{v^2 \cdot \cos^2 \theta_f - 2gH_f}}{g} \quad (5)$$

The horizontal displacement of hole-applied fertilizers when leaving the fertilizer cavity and falling into the fertilizer furrow is:

$$S_f = v_x \cdot t_1 \quad (6)$$

where: S_f is the horizontal moving distance of the fertilizer when it falls from the fertilizer cavity to the fertilizer trench during hole - application fertilization, [m].

Seed motion analysis

Peanut seeds start to detach from the seed metering disc at the position shown in [Figure 4](#) and fall into the seed furrow under the action of gravity. The horizontal and vertical velocities of peanut seeds when detaching from the seed metering disc are:

$$\begin{cases} v'_x = -v_m + v' \cdot \cos \theta_z \\ v'_y = v' \cdot \sin \theta_z \end{cases} \quad (7)$$

where: v'_x is the horizontal component velocity of seeds when detaching from the seed metering disc, [m/s]; v'_y is the vertical component velocity of seeds when detaching from the seed metering disc, [m/s]; v_m is the machine travel speed, [m/s]; v' is the resultant velocity of the peanut seed when it detaches from the seed - discharging disc, [m/s]; θ_z is the seed dropping angle, [°].

The distance travelled by peanut seeds in the vertical direction after detaching from the seed metering disc is:

$$H_z + h_z = v'_y t_2 + \frac{1}{2} g t_2^2 \quad (8)$$

where: H_z is the vertical distance from the bottom of the seed metering disc to the bottom of the seed furrow, [m]; h_z is the distance from the seed detachment position on the seed metering disc to the bottom of the seed metering disc, [m]; t_2 is the time for peanut seeds to detach from the seed metering disc and reach the seed furrow, [s].

Among these distances, distance h_z from the position where peanut seeds detach from the seed metering disc to the bottom of the seed metering disc is:

$$h_z = R_z (1 - \cos \theta_z) \tag{9}$$

where: R_z is the radius of the seed metering disc, [m].

From Equations (7), (8), and (9), it results:

$$t_2 = \frac{-v' \cdot \sin \theta_z + \sqrt{(v' \cdot \cos \theta_z)^2 + 2g[H_z + R_z(1 - \cos \theta_z)]}}{g} \tag{10}$$

The horizontal displacement of seeds, S_z , [m], when detaching from the seed metering disc and falling into the seed furrow is:

$$S_z = v'_x \cdot t_2 \tag{11}$$

The time difference between the falling of peanut seeds and fertilizers, Δt [s] is:

$$\Delta t = t_1 - t_2 \tag{12}$$

On the premise of ensuring the normal operation of the fertilizer metering device, its installation position should be as low as possible to reduce the scattering of hole-applied fertilizers and improve the hole-forming performance of the fertilizer metering device. According to the previous design, the installation height h_1 of the fertilizer metering device is 130 mm, which is lower than that of the seed metering device. Therefore, the falling time of seeds is longer than that of fertilizers, and the time difference between their descent must be considered to ensure that the seeds land directly above the hole-applied fertilizers.

Simulation model construction

The device model was established using SolidWorks software. To improve simulation efficiency and reduce simulation time, components without direct contact with fertilizer particles were simplified. A conveyor belt was added 130 mm below the fertilizer metering device to simulate the bottom of the fertilizer furrow for intuitive and quantitative analysis of the hole-fertilizing performance of the fertilizer metering device. The completed 3D model was saved in .STP format and imported into EDEM simulation software. A plane was added 40 mm below the seed discharge port to simulate the bottom of the seed furrow. Fertilizer particles were spherical with an equivalent diameter of 3.3 mm. Since there is no adhesive force between particles or between particles and the fertilizer metering device, the Hertz-Mindlin no-slip contact model was selected (Zhu *et al.*, 2020). The simulation models of the fertilizer metering device and fertilizer particles are shown in Figure 5, with model parameters listed in Table 1 and Table 2 (Ding *et al.*, 2019; Liu *et al.*, 2018; Ding *et al.*, 2018).

Table 1

EDEM simulation parameters for fertilizer metering process

Item	Fertilizer particles	Fertilizer metering device	Soil	Peanut	Seed metering device
Poisson's ratio	0.25	0.41	0.31	0.30	0.35
Shear modulus/Pa	1.13×10^8	1.71×10^8	7.27×10^8	5.72×10^7	1.22×10^8
Density/kg·m ⁻³	1625	1150	2210	1300	1455

Table 2

Item	Contact parameters between materials				
	Fertilizer-fertilizer	Fertilizer-fertilizer metering device	Fertilizer-soil	Peanut-seed metering device	Peanut-soil
Coefficient of restitution	0.31	0.35	0.05	0.6	0.11
Static friction coefficient	0.33	0.26	1.27	0.34	1.17
Kinetic friction coefficient	0.13	0.21	1.21	0.04	0.92

The 3D model of the fertilizer metering device was imported into the Fluent module of Workbench in .STP format. The fluid domain model was extracted using the DesignModeler tool, and adjusted into three regions—air inlet pipe, fertilizer chamber, and fertilizer outlet—in SpaceClaim software. The adjusted fluid model was then imported into the Meshing module of Fluent for mesh generation (Sun et al., 2024). Polyhedral meshes were selected as the grid type, with interfaces set between the air inlet pipe and fertilizer chamber, as well as between the fertilizer chamber and fertilizer outlet. The air inlet and fertilizer outlet were set as pressure inlet and pressure outlet, respectively, as shown in Figure 6. In EDEM software, the time step was set to 3×10^{-6} s, while in Fluent software, the time step was 3×10^{-4} s. The total simulation duration was the time required for fertilizing 15 holes.

Simulation of experimental design

The magnitude of airflow speed affects the fertilizer metering performance of the hole fertilization device. To obtain optimal airflow speed parameters and reduce the number of subsequent test combinations, a preliminary pre-experiment was first conducted. Specifically, when the machine's traveling speed was 4 km/h, the airflow speed was set from 0 to 16 m/s, and a single-factor test was carried out using the test indicators of fertilizer distribution length and accuracy of hole fertilization amount.

In the EDEM post-processing interface, Grid Bin Groups were added at the fertilizer metering disc and conveyor belt respectively (Liu et al., 2022), as shown in Figure 7.

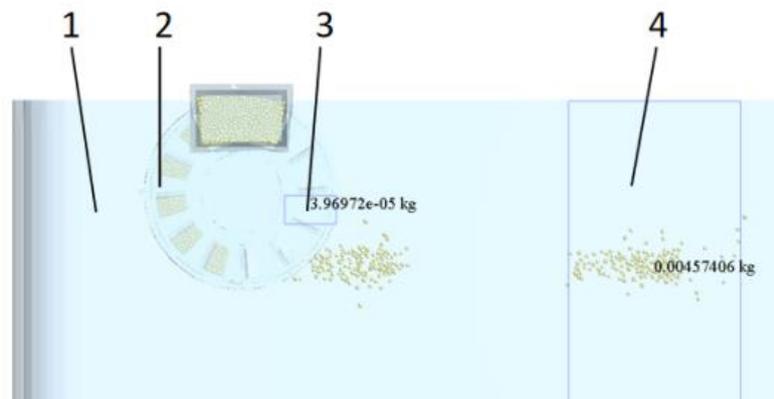

Fig. 7 - Grid cell group position
 1-Conveyor belt; 2- Hole fertilization device; 3- Grid cell group 1; 4- Grid cell group 2

The grid cell group on the fertilizer metering disc is located at two fertilizer chambers behind the fertilizer outlet, with a height of 30 mm and the same length and width as a single fertilizer chamber, used to count the mass of residual fertilizer in the chamber after metering. The grid cell group on the conveyor belt has its bottom on the same plane as the conveyor belt bottom, with a height of 40 mm and a width of 300 mm, used to count the mass of discharged fertilizer and the fertilizer distribution length. By adjusting the length of the grid cell group to match the fertilizer's distribution length, the desired fertilizer distribution length can be obtained.

Data for 15 fertilized holes were collected each time, and their average value was calculated to analyze the accuracy of hole fertilization amount and fertilizer distribution length. The calculation formula for the accuracy of hole fertilization amount is:

$$Y_1 = \frac{\sum_{i=1}^j \frac{m_i}{m}}{j} \times 100\% \quad (13)$$

where: Y_1 is the accuracy of hole fertilization amount, [%]; m is the standard fertilization mass per hole, [g]; m_i is the actual fertilization mass per hole, [g]; j is the number of fertilizer holes passing through the grid cell group.

The influence of airflow speed on the accuracy of hole fertilization amount and fertilizer distribution length is shown in Figure 8.

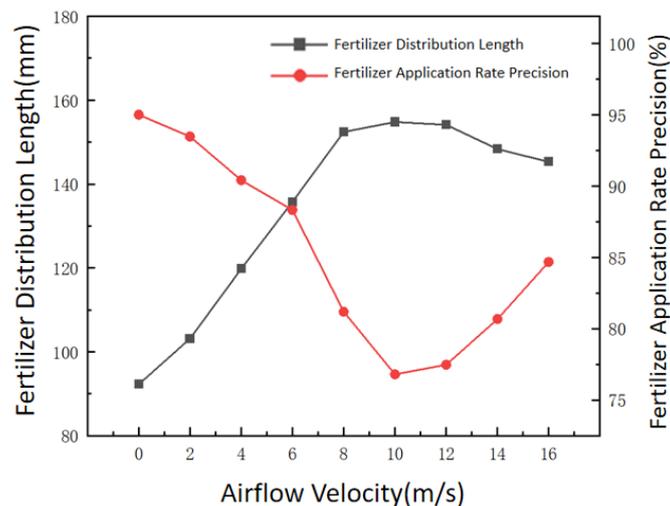

Fig. 8 - Effects of airflow speed on test indicators

When the airflow speed ranges from 0 m/s to 16 m/s, the accuracy of hole fertilization amount first increases and then decreases with the increase of airflow speed, though the decreasing trend is relatively slow. The fertilizer distribution length initially decreases and then increases, with both test indicators—fertilization amount accuracy and distribution length—reaching their optimal values at an airflow speed of 10 m/s. Under the conditions of a machine traveling speed of 4 km/h and a wall inclination angle of 70°, the hole fertilization performance of the fertilizer metering device is relatively stable when the airflow speed is approximately 10 m/s. The test results indicate that when the airflow speed is too low, the fertilizer metering device cannot discharge fertilizer from the chamber in time, reducing the accuracy of hole fertilization amount. When the speed is too high, although the fertilizer clearing rate of the metering device increases, the excessive velocity of fertilizer particles leaving the chamber causes splashing when they contact the conveyor belt, increasing the fertilizer distribution length. Therefore, the inlet airflow speed should be controlled between 8 m/s and 12 m/s.

RESULTS

Hole fertilization synchronous positioning seeding simulation test

Combining the results of single-factor tests, the airflow speed was designed to range from 8 m/s to 12 m/s, the machine traveling speed from 2 km/h to 6 km/h, and the hole spacing was set at 200 mm. Simulation tests were conducted with the longitudinal spacing between seeds and fertilizer, fertilizer distribution length, and hole spacing error in fertilization as test indicators.

The longitudinal spacing between seeds and fertilizer is defined as the distance between peanut seeds and the fertilizer distribution center in the machine's forward direction. The hole spacing in fertilization is taken as the distance between the centers of two adjacent fertilizer accumulations after fertilization, and the calculation formula for the hole spacing error is:

$$W = \frac{\sum_{i=1}^j |S - S_i|}{j S} \times 100\% \tag{14}$$

where: W is the hole spacing error in fertilization, [%]; S is the designed hole spacing for fertilization, [m]; S_i is the actual hole spacing at the i -th position during operation, [m]; j is the number of fertilizer holes passing through the grid cell group.

The results of the simulation test are shown in Figure 9, and the test results are presented in Table 3.

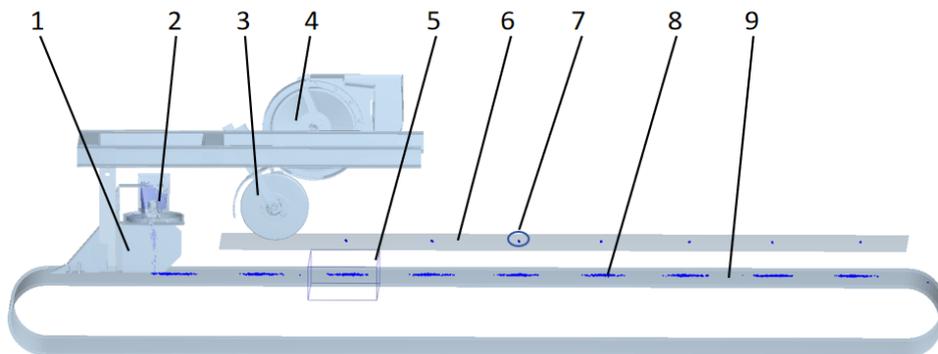

Fig. 9 - Synchronous positioning seeding simulation test for hole fertilization

Table 3

Test results of synchronous positioning seeding for hole fertilization

Machine traveling speed [km·h ⁻¹]	Airflow speed [m·s ⁻¹]	Longitudinal spacing between seed and fertilizer [mm]	Fertilizer distribution length [mm]	Hole spacing error in fertilization [%]
2	8	6.8	93.3	3.6
	10	6.1	91.2	3.3
	12	7.7	92.9	3.9
4	8	7.3	91.7	4.9
	10	8.1	84.2	4.8
	12	8.7	85.6	5.1
6	8	10.2	98.5	5.2
	10	10.9	94.2	5.7
	12	11.7	95.7	6.0
Mean		8.6	91.9	4.7
Standard deviation		1.82	12.87	2.64

Data in Table 3 show that when the airflow speed is constant, the longitudinal spacing between seeds and fertilizer and the hole spacing error in fertilization show an increasing trend with the increase in machine traveling speed, with a mean longitudinal spacing between seeds and fertilizer of 8.6 mm and a mean hole spacing error of 4.7%. When the machine traveling speed is constant, the fertilizer distribution length shows a trend of first increasing and then decreasing, with a mean distribution length of 91.9 mm, and the minimum distribution length occurs at an airflow speed of 10 m/s. Considering the test data comprehensively, the airflow speed is determined to be 10 m/s.

Field experiment

The field experiment was conducted in Guangrao County, Dongying City, Shandong Province. The peanut variety used was Yuhua 18 and Luhua 10, and the fertilizer was granular slow-release compound fertilizer produced by Liuguo Chemical Industry Co., Ltd. Before the experiment, the soil was rototilled, leveled, and loosened to ensure that it meets the sowing conditions for peanuts.

Fig. 10 - Hole fertilization device and field experiment

Based on the widely used peanut fertilization amount in the region, we evaluated the hole fertilization performance and positioning seed metering performance of the device with reference to the *Technical Specifications for Quality Evaluation of Fertilizer Machinery* (NY/T 1003-2006) and *Operation Quality of Mulching Hole Seeding Machines* (NY/T 987-2006) (Hu et al., 2016; Geng et al., 2018). A 10 m operation length was selected as a test area, and field test data were analyzed using hole spacing error in fertilization, fertilization depth error, seed-fertilizer spacing, and fertilizer distribution length as test indicators. The test results are shown in Figure 11.

Fig. 11 - Field experiment data collection

Table 4 presents the field trial results for Yuhua 18 peanut seeds. When the machine travel speed ranges from 2 km/h to 6 km/h, the hole spacing accuracy rate can reach over 94.5%. The vertical distance between seeds and fertilizer is between 64.8 mm and 67.2 mm, and the fertilizer distribution length ranges from 95.7 mm to 107.5 mm.

Table 4

Field trial results of Yuhua 18 peanut seeds				
Machine traveling speed [km·h ⁻¹]	Hole spacing error [%]	Vertical spacing between seed and fertilizer [mm]	Fertilizer distribution length [mm]	Longitudinal spacing between seed and fertilizer [mm]
2	3.3	67.2	99.3	5.4
4	4.9	66.4	95.7	6.2
6	5.5	64.8	107.5	7.1

Table 5 presents the field trial results for Luhua 10 peanut seeds. The hole spacing accuracy rate can reach over 94.1%, the vertical distance between seeds and fertilizer ranges from 65.4 mm to 71.1 mm, and the fertilizer distribution length is between 91.1 mm and 105.8 mm.

Table 5

Field trial results of Luhua 10 peanut seeds				
Machine traveling speed [km·h ⁻¹]	Hole spacing error [%]	Vertical spacing between seed and fertilizer [mm]	Fertilizer distribution length [mm]	Longitudinal spacing between seed and fertilizer [mm]
2	3.7	71.1	101.3	6.2
4	4.6	68.7	91.1	7.7
6	5.9	65.4	105.8	10.1

Both sets of trials meet the requirements for simultaneous and correctly positioned hole fertilization and sowing.

CONCLUSIONS

(1) A hole fertilization device was designed, and its installation position was analysed to determine that the minimum distance between the fertilizer discharge port and the ground is 40 mm. The movement trajectories of seeds and fertilizer during the sowing and fertilization process were analysed to obtain the time difference between seed metering and fertilizer metering. Based on theoretical analysis, simulation tests were designed. The results of single-factor tests showed that the optimal hole fertilization performance occurs when the airflow speed is 8 m/s to 12 m/s. The two-factor test results indicated that the average values of the test indicators for the designed synchronous positioning seeding device with hole fertilization are as follows: longitudinal spacing between seeds and fertilizer of 8.6 mm, fertilizer distribution length of 91.9 mm, and hole spacing error in fertilization of 4.7%.

(2) A field experiment of the synchronous positioning seeding device with hole fertilization was carried out. The hole fertilization device was installed on a peanut seeding and fertilizing machine for two rows per ridge, and the transmission mode was changed simultaneously. The theoretical fertilization depth was set at 100 mm, the seeding depth at 30 mm, the theoretical hole spacing at 200 mm, and the machine traveling speed at 2 km/h to 6 km/h. The field trial results for Yuhua 18 peanuts showed a hole spacing error of 3.3% to 5.5%, a seed-fertilizer spacing of 64.8 mm to 67.2 mm, and a fertilizer distribution length of 99.3 mm to 107.5 mm. For Luhua 10 peanuts, the corresponding results were: 3.7% to 5.9% (hole spacing error), 65.4 mm to 71.1 mm (seed-fertilizer spacing), and 91.1 mm to 105.8 mm (fertilizer distribution length). The experimental results meet the requirements specified in the seeding and fertilization standards.

(3) Compared to the traditional strip fertilization, where the minimum fertilizer application rate is 450 kg/ha, the hole fertilization device used in this study achieves a minimum fertilizer application rate of 375 kg/ha, saving approximately 16.7% of fertilizer/ha and improving fertilizer utilization efficiency.

ABSTRACT

To solve the problems of slow system response speed and poor uniformity of seeding and fertilizer application, this paper designs a control system for synchronized corn seeding and precision hole fertilization. A sliding mode control method with integral variable structure and disturbance observer composite (ISMDO-SMC) is proposed. Furthermore, a three-factor, five-level quadratic orthogonal rotation combination experiment was conducted to develop a mathematical model for parameter optimization using a multi-objective variable optimization method. Simulation results from four algorithms were compared, revealing a regulation time of 0.42 seconds, a recovery time to steady state of 0.13 seconds, and a descending rotational speed of 2.5 r/min, which demonstrates the strongest dynamic response and stability. Moreover, the optimal parameter combination was determined to be the forward speed of 2.8 km/h, the fertilizer discharge shaft speed of 42 r/min, and the fertilizer discharger opening of 5.5 mm, resulting in the fertilizer application error of 1.7 g and the seed-fertilizer spacing error of 2.2 mm. The results of this study provide a theoretical basis for achieving efficient and stable seeding and fertilization operations.

摘要

为了解决系统响应速度慢和播种施肥均匀性差的问题, 本文设计了一种同步玉米播种与穴施肥的控制系统。提出了一种基于积分变量结构和扰动观测器复合的滑模控制方法。此外, 采用三因素五水平的二次正交旋转组合实验, 通过多目标变量优化方法建立了参数优化的数学模型。通过比较四种算法的仿真结果, 得出该系统的调节时间为 0.42 秒, 恢复稳态时间为 0.13 秒, 下降转速为 2.5 r/min, 表明其具有最强的动态响应和稳定性。进一步, 优化的参数组合为前进速度 2.8 km/h, 施肥轴转速 42 r/min, 施肥器开度 5.5 mm, 在此条件下, 施肥误差为 1.7 g, 种肥间距误差为 2.2 mm。该研究结果为实现高效稳定的播种施肥作业提供了理论依据。

INTRODUCTION

Corn is an important food and income crop that holds a significant position in global agriculture. In corn production, fertilizer application plays a crucial role in ensuring both high yield and high quality (Yu *et al.*, 2021). Traditional fertilizer application methods typically involve manual application or the use of fertilizer spreaders to distribute fertilizer across the ground surface (Vieira-Megda *et al.*, 2015). However, these methods increase production costs and result in low fertilizer utilization, preventing the achievement of spatially differentiated fertility replenishment (Zhang *et al.*, 2012). Irrational fertilizer application not only leads to environmental pollution but also negatively affects crop yield and quality (Qi *et al.*, 2024). Control systems that synchronize corn seeding with precision hole fertilization are an integral component of sustainable precision agriculture systems. These systems enhance fertilizer use and yield while reducing application rates and mitigating the environmental pressures caused by over-fertilization.

In recent years, variable fertilization techniques have gained increasing attention in several countries (Cheng *et al.*, 2022). Japan's Iseki Agricultural Machinery Co., Ltd. has developed a series of self-propelled variable spray fertilizer applicators for paddy fields. These machines are equipped with a variable fertilizer application system that collects real-time information on soil nutrients and crop characteristics through various sensors. The amount of fertilizer applied is adjusted by the controller to meet the specific requirements for crop growth (Shi *et al.*, 2019; Yu *et al.*, 2019; Chen *et al.*, 2019).

¹ Ziyu Wang, master degree; Hongchao Wang, Ph.D.; Chunying Liang, Prof. Ph.D.; Naichen Zhao, Ph.D.

To achieve refined operations, some researchers have extensively explored aspects such as fertilizer prescription decisions and variable control algorithms. Tola developed a fertilizer control system based on real-time fertilizer discharge sensors, which has reduced fertilizer application errors (Tola *et al.*, 2008). Bu proposed an optimization model for the fertilization control sequence based on a differential evolutionary algorithm, enabling online regulation of fertilizer application and improving fertilization performance (Bu *et al.*, 2022). The control system is the core of variable fertilizer application technology and plays a decisive role in the effectiveness of fertilizer application. A significant number of scholars have widely adopted the external grooved wheel fertilizer application method for variable fertilizer application, with fertilizer volume adjustment achieved by altering the rotational speed of the fertilizer discharge shaft. Sugirbay investigated the effect of groove wheel parameters on the stability of high-speed fertilizer discharging in external groove wheel fertilizer dischargers. They designed 25 groove wheel configurations and conducted bench tests to identify the optimal parameters and speed range (Sugirbay *et al.*, 2020). Alameen developed a variable-speed granular fertilizer application control system that uses cylinders to regulate the openings of all fertilizer dischargers. This system was able to accurately control the rate of granular fertilizer application, with an overall system error of less than 2.6% (Alameen, Al-Gaadi, & Tola, 2019). In summary, numerous scholars have conducted in-depth research on fertilizer application devices and control systems (Pramod *et al.*, 2023; Wang *et al.*, 2023). However, issues such as slow system response time and poor uniformity in seeding and fertilizer application during corn seeding and hole fertilization still require further investigation. Addressing these challenges is crucial for improving the overall performance and adaptability of fertilizer application devices, and for providing stronger technical support for the realization of precision agriculture.

The main objective of this study is to design a control system for synchronizing corn seeding and variable hole fertilization. An integral sliding mode variable structure controller was designed, and a novel convergence rate was introduced to significantly improve both the steady-state and dynamic performance of the control system. Additionally, the system incorporates an extended state observer to monitor perturbations caused by changes in motor parameters and load torque. The observed perturbation values are then fed into the sliding mode controller as feed-forward compensation, enhancing the system's ability to resist interference. Furthermore, the performance of the control system for synchronized variable hole fertilization during corn seeding was validated through a bench experiment.

MATERIALS AND METHODS

Machine Structure and Working Principle

The experimental bench primarily consists of a conveyor platform, a box, a corn hole application device, a seed discharger, a control system, and a photoelectric detection device, as shown in figure 1. The fertilizer and seed boxes are filled with fertilizer and seeds, respectively, and the conveyor belt moves at a constant speed once the power is turned on, simulating the relative motion between the locomotive and the field. Upon activating the system, the fertilizer discharge motor is first controlled to rotate, ensuring the preparation of fertilizer for the first hole application. The photoelectric sensor probe installed at the outlet of the seed discharger detects the seed, transmits the signal to the microcontroller, and controls the rotation of the fertilizer discharge tube stopper to a set angle, aligning the fertilizer discharge opening with the circular notch on the stopper to synchronize seeding and fertilizer application.

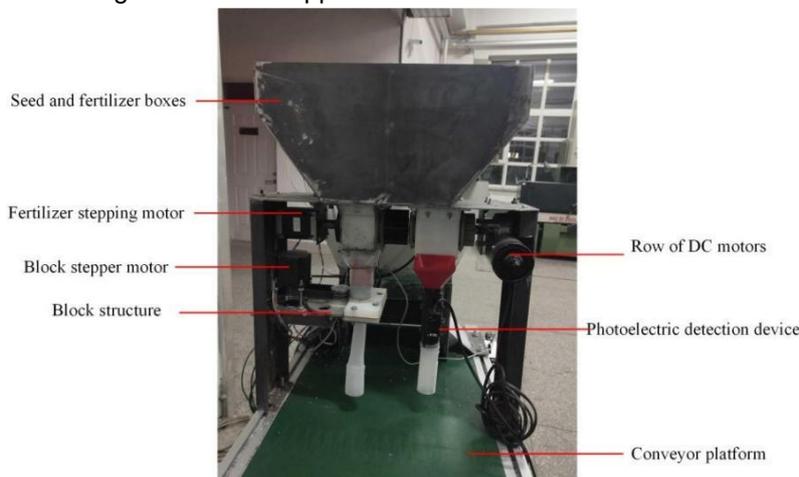

Fig. 1 - Experimental bench for synchronized corn seeding and precision hole fertilization

A disc stopper was designed to control the intermittency of the fertilizer discharge at the fertilizer discharge opening, using a non-corrosive plastic material. The stopper has three holes that are 120° apart from the center of the circle, the same size as the fertilizer pipe. The position of the baffle round hole coincides with the position of the mouth of the fertilizer discharge tube, allowing the fertilizer to fall through the round hole. The stopper is closed when the stopper round hole is turned 60°. The fertilizer builds up above the stopper, providing enough fertilizer for the next time the stopper switch is turned on. During this time the fertilizer discharged from the discharger is stored in the tube. The physical drawing of the stopper structure of the fertilizer discharge port is shown in figure 2.

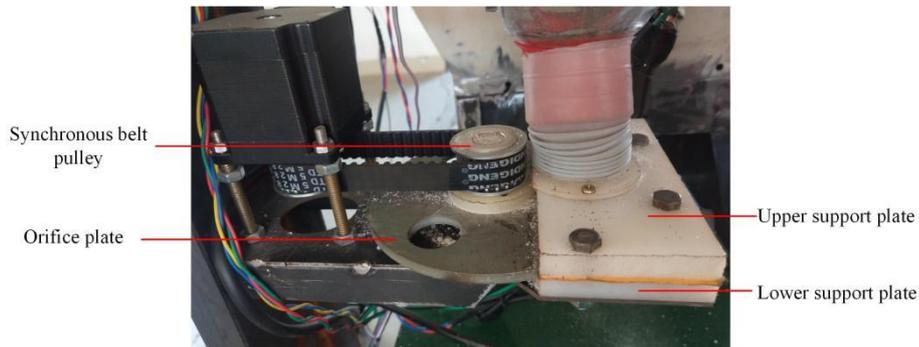

Fig. 2 - Physical drawing of the stopper structure of the fertilizer discharge port

Control System Design for Synchronization of Corn Seeding and Variable Hole Application of Fertilizer

The control system is an important part of the whole experimental bench, which is mainly composed of a data acquisition module, microcontroller control module, human-machine interface module, and actuator module, as shown in Fig. 3. The control system controls the fertilizer discharger by changing the motor speed for precise fertilizer discharge. The microcontroller chosen is the more commonly used STC15F2K60S2, which is simple to program, has a stable system, and lower cost. The single clock machine cycle of the microcontroller, the internal integration of high-precision R/C clock, and the highly reliable reset circuit make it a good option. The overall circuit diagram of the control system is shown in figure 4.

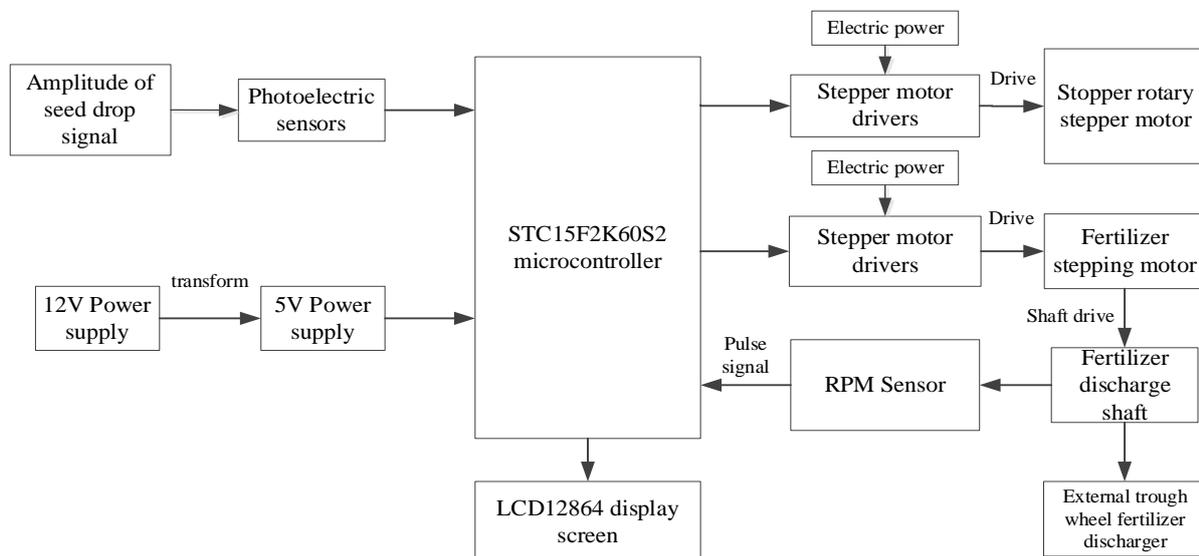

Fig. 3 - Hardware block diagram of the control system

After system initialization, the control system operates as in the flowchart is shown in figure 5. Initially, the motor controls the fertilizer spreader to rotate the corresponding number of slots, completing one fertilization cycle and waiting for the first seed to drop. Starting from the second fertilization cycle, when the photoelectric sensor detects a seed drop, it is necessary to determine whether the time interval since the previous drop is shorter than a predefined threshold. If the interval is shorter, it indicates a repeat drop, and the system returns to the waiting state.

Otherwise, it is considered a normal sowing cycle, and the corresponding pulse is immediately sent. The control flaps open and close at the corresponding angles to allow the prepared fertilizer to fall into the soil. After a delay, the flaps are closed at the specified angle, completing one cycle of hole fertilization, which repeats continuously. When no seed drop is detected, a missed sowing check is performed. If a missed sowing is detected, all interrupts are disabled, the fault code is displayed, and the system waits for a reset. Otherwise, it returns to continue waiting for the next seed drop.

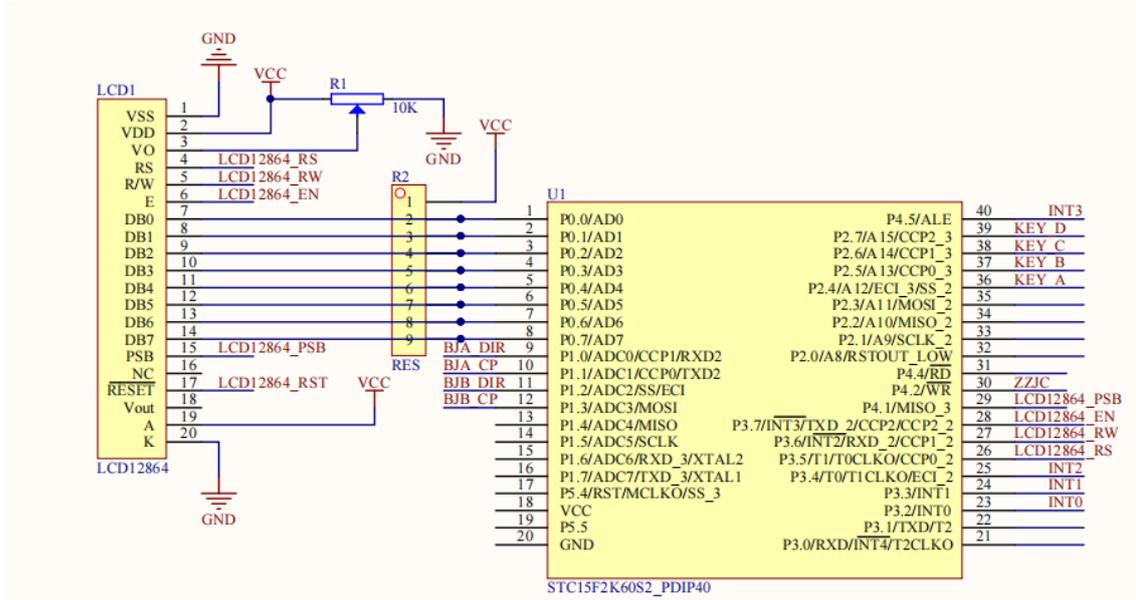

Fig. 4 - Overall circuit diagram of the control system

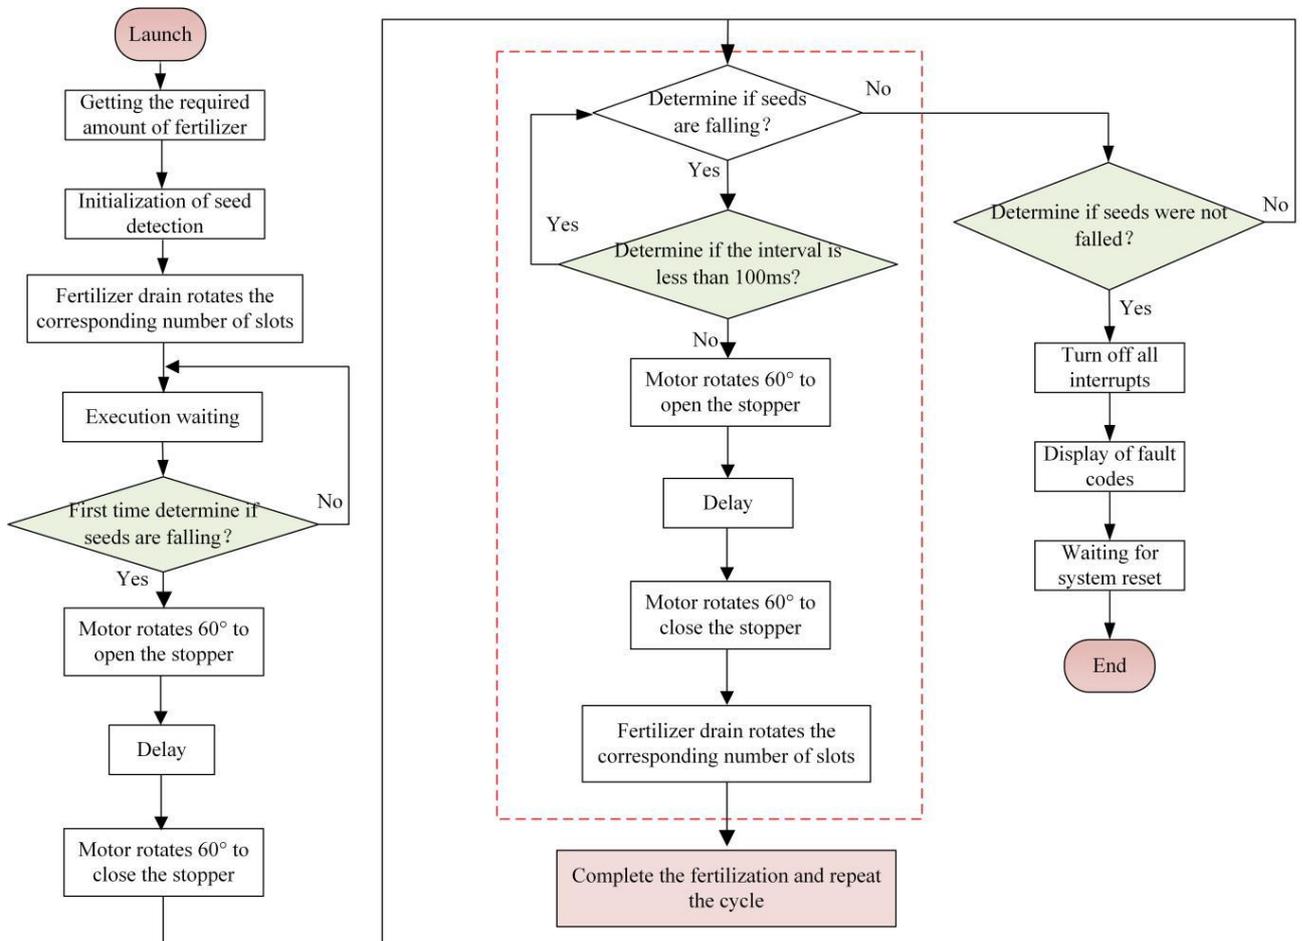

Fig. 5 - Control system flowchart

System Control Strategy

Mathematical Modeling of The Motor

Under the assumption of neglecting motor parameter variations and external disturbances, the mathematical model of the motor can be established, and the voltage equation is given by Equation (1).

$$\begin{cases} u_d = Ri_d + L_d \frac{di_d}{dt} - p\omega_m L_q i_q \\ u_q = Ri_q + L_q \frac{di_q}{dt} + p\omega_m L_d i_d + p\omega_m \psi_f \end{cases} \quad (1)$$

where:

u_d, i_d, L_d represent the voltage, current, and inductance on the d-axis, respectively;

u_q, i_q, L_q represent the voltage, current, and inductance on the q-axis, respectively;

R is the stator winding resistance; ω_m is the motor output speed; ψ_f is the magnetic chain;

p is the number of pole pairs.

Additionally, since the permanent magnet synchronous motor has $L_d = L_q$, the torque equation is given by equation (2), where T_e is the target torque.

$$T_e = \frac{3}{2} p \psi_f i_q \quad (2)$$

The equations of motion for the motor are given in Equation (3).

$$\frac{d\omega_m}{dt} = \frac{3p\psi_f}{2J} i_q - \frac{T_L}{J} - \frac{B}{J} \omega_m \quad (3)$$

where: B is the coefficient of viscous friction; J is the rotational inertia; T_L is the load torque.

Equation (4) is derived by considering the variation in system parameters and torque.

$$\frac{d\omega_m}{dt} = \left(\frac{3p\psi_f}{2J} + \Delta\alpha_1 \right) i_q - \left(\frac{T_L}{J} + \Delta\alpha_2 \right) - \left(\frac{B}{J} + \Delta\alpha_3 \right) \omega_m = \frac{3p\psi_f}{2J} i_q - \frac{B}{J} \omega_m + \beta \quad (4)$$

$$\beta = \frac{3p\psi_f}{2J} \Delta\alpha_1 i_q - \Delta\alpha_2 - \frac{B}{J} \Delta\alpha_3 \omega_m - \frac{T_L}{J} \quad (5)$$

where: $\Delta\alpha_1, \Delta\alpha_2, \Delta\alpha_3$ denote the values of parameter changes of the motor; β denotes the value of perturbation brought by the load torque and parameters.

Design Of Sliding Mode Controller

The motor state variable is given by Equation (6).

$$\begin{cases} x_1 = \omega_{ref} - \omega_m \\ x_2 = \dot{x}_1 \end{cases} \quad (6)$$

where ω_{ref} is the target speed; The derivation of Equation (6) leads to Equation (7).

$$\begin{cases} \dot{x}_1 = - \left(\frac{3p\psi_f}{2J} i_q - \frac{B}{J} \omega_m + \beta \right) \\ \dot{x}_2 = - \left(\frac{3p\psi_f}{2J} \dot{i}_q - \frac{B}{J} \dot{\omega}_m + \dot{\beta} \right) \end{cases} \quad (7)$$

The system sliding mode surface function is defined by Equation (8).

$$s = cx_1 + x_2 \quad (8)$$

Substituting Equation (6) into Equation (8) yields the following:

$$\dot{s} = c \dot{x}_1 - \frac{3p\psi_f}{2J} i_q + \frac{B}{J} \dot{\omega}_m - \dot{\beta} \tag{9}$$

In the actual motor control, the sliding mode control method suffers from high-frequency jitter. Therefore, it is necessary to select a suitable exponential convergence rate that can effectively attenuate the sliding mode jitter. To improve the system's performance, a novel, improved convergence rate will be introduced, as shown in Equation (10).

$$\begin{cases} \dot{s} = -\varepsilon|x_1| \operatorname{sgn}(s) - ks \\ \lim_{t \rightarrow \infty} |x_1| \end{cases} \tag{10}$$

where $\varepsilon > 0, k > 0$; $-\varepsilon|x_1| \operatorname{sgn}(s)$ is the isochronous convergence term; ks is the exponential convergence term.

As the error increases, the isochronous convergence term drives the system state variable toward the sliding mode surface, while the exponential convergence term reduces the system state variable to zero.

By combining Equations (9) and (10), the output equation of the controller is given by:

$$i_q^* = \frac{2J}{3p\psi_f} \int c \dot{x}_1 + \frac{B}{J} \dot{\omega}_m + \varepsilon|x_1| \operatorname{sgn}(s) + ks - \dot{\beta} dt \tag{11}$$

The Lyapunov function is chosen as shown in Equation (12):

$$V = \frac{1}{2} s^2 \tag{12}$$

According to the Lyapunov stability theorem, it is sufficient to prove that $V < 0$, in which case the system is asymptotically stable. Equation (13) can be derived from Equations (10) and (12).

$$\dot{V} = -\varepsilon|x_1| \operatorname{sgn}(s)s - ks^2 \tag{13}$$

where $\varepsilon > 0, k > 0$, and $\operatorname{sgn}(s)s > 0$: It follows that $V < 0$. Therefore, the system error can converge to 0 in a finite time, making the system stable. Meanwhile, the saturation function $\operatorname{sat}(s, \delta)$ is used instead of $\operatorname{sgn}(s)$, which can effectively suppress the jitter and further improve the robustness of the system. The saturation function $\operatorname{sat}(s, \delta)$ is selected as shown in Equation (14).

$$\operatorname{sat}(s, \delta) = \begin{cases} 1 & s > \delta \\ \frac{s}{\delta} & |s| < \delta \\ -1 & s < -\delta \end{cases} \tag{14}$$

Design of the Expansion Observer

The control law designed using the sliding mode surface accounts for motor parameter variations and load torque perturbations. Since the perturbation value cannot be measured, this paper designs a perturbation observer for estimation. In the actual motor speed control system, the system parameter perturbations change slowly, and the first-order derivative of the perturbation can be approximated as zero.

The system state-space equation is given by Equation (15).

$$\begin{cases} \dot{\omega}_m = \frac{3p\psi_f}{2J} i_q - \frac{B}{J} \omega_m + \beta \\ \dot{\beta} = 0 \\ y = \omega_m \end{cases} \tag{15}$$

Taking ω_m and β as the observation objects to establish the gain feedback for the speed estimation error e_1 , the extended disturbance observer is designed based on Equation (15), as shown in Equation (16).

$$\begin{cases} \dot{\hat{\omega}}_m = \frac{3p\psi_f}{2J} i_q - \frac{B}{J} \hat{\omega}_m + \hat{\beta} + \frac{\lambda_1}{\eta} e_1 \\ \dot{\hat{\beta}} = \frac{\lambda_2}{\eta^2} e_1 \\ e_1 = \omega_m - \hat{\omega}_m \end{cases} \quad (16)$$

where: $\hat{\omega}_m$ and $\hat{\beta}$ are the electrical angular velocity estimation, and load parameter uptake estimation, respectively; λ_1 , λ_2 , and η are positive real numbers. To achieve high gain, η is set to a small value. Using this observer allows not only the estimation of the disturbance terms $\hat{\beta}$ related to motor parameter variations and load torque, which can be used for feedforward compensation in the sliding mode control, but also ensures that $\hat{\beta}$ converges to β and $\hat{\omega}_m$ converges to ω_m .

From Equations (15) and (16), the error equation of the extended observer is given by Equation (17).

$$\begin{cases} \dot{e}_1 = \left(\frac{\lambda_1}{\eta} - \frac{B}{J} \right) e_1 + e_2 \\ \dot{e}_2 = \frac{\lambda_2}{\eta^2} e_1 \end{cases} \quad (17)$$

where e_1 denotes the speed estimation error; e_2 denotes the system parameters, and load torque estimation error.

The error equation of the state for the extended observer is shown in Equation (18).

$$\dot{e} = Ae + B\beta \quad (18)$$

$$\text{where } A = \begin{bmatrix} \frac{\lambda_1}{\eta} - \frac{B}{J} & 1 \\ \frac{\lambda_2}{\eta} & 0 \end{bmatrix}; B = \begin{bmatrix} 0 \\ 1 \end{bmatrix}; e = \begin{bmatrix} e_1 \\ e_2 \end{bmatrix}.$$

Substituting the observed perturbations and load torque uptake values into Equation (11), Equation (19) is obtained.

$$i_q^* = \frac{1}{D} \int c\dot{x}_1 + \frac{B}{J} \dot{\omega}_m + \varepsilon|x_1|sat(s) + ks - \dot{\beta} dt \quad (19)$$

From equation (19), it can be seen that parameter variations and load perturbations are used for feed-forward compensation. When both the load and motor parameters change, the controller can mitigate the effects of these perturbations on the system, thereby effectively improving system stability.

Experimental Methods

Simulation Experiments of the Control System

The simulation environment for the control system consists of 256GB of RAM, a 64-bit Windows 10 operating system, and MATLAB 2021b/Simulink as the simulation software. To verify the feasibility of the ISMDO-SMC algorithm proposed in this paper, simulation experiments were conducted on the control system. The control test groups include the Proportional-Integral-Derivative (PID) algorithm, the classical Sliding Mode Control (SMC) algorithm, and the Optimized Sliding Mode Control (OSMC) algorithm. The simulation setup of the control system is shown in figure 6.

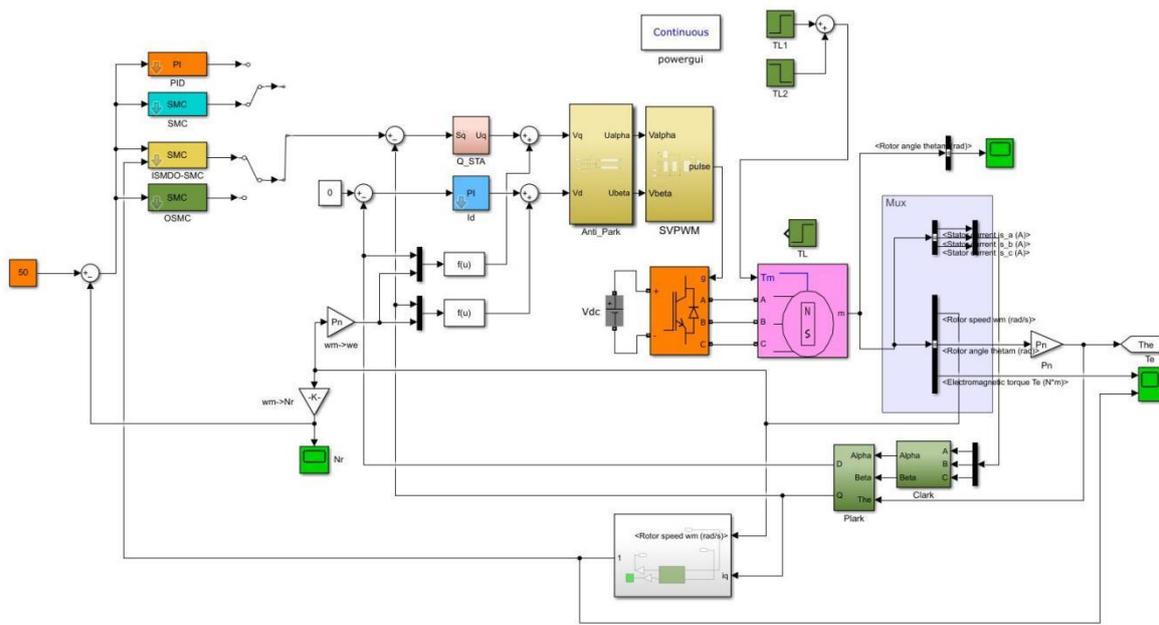

Fig. 6 - Simulation experiment of the control system

Bench Experiment

To investigate the fertilization precision of the control system, an experiment was conducted using a self-designed experimental setup, as shown in figure 7. The experimental material was “Siyu 335” corn seed, which was manually screened to ensure the purity of the seeds reached 100%. The moisture content of the corn seeds was $(11.4 \pm 0.2) \%$, and the mass of 1,000 kernels was $(323.0 \pm 0.3) \text{ g}$. The fertilizer used in this experiment was sulfur-containing, potassium-controlled slow-release urea. The experimental setup is based on the principle of relative motion, using the relative movement of the seed bed belt in relation to the device, thereby simulating the forward operation of the machine. Parameters such as the amount of fertilizer dispensed, the speed of the fertilizer discharge motor, and the hole spacing are controlled through the system. The fertilizer discharger opening was set to 10 mm, with rotational speeds of the fertilizer discharger at 30, 40, and 50 r/min. Four control strategies were tested in the experiment. The amount of fertilizer applied and the coefficient of variation of the grooved wheel’s rotation over one week were used as performance indexes to assess the impact of fertilizer application and variation on the stability of the control system.

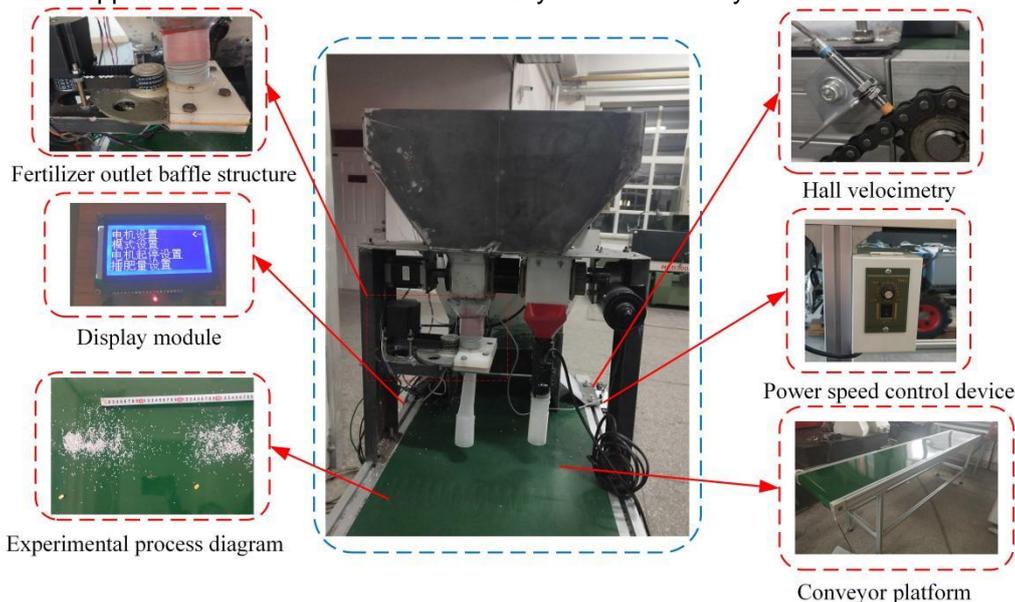

Fig. 7 - Self-designed experimental bench

The fertilizer discharger opening, fertilizer discharge shaft speed, and forward speed are key factors affecting the effectiveness of fertilizer application. These parameters interact with and constrain each other.

The difference between the sum of the actual fertilizer application rates and the theoretical fertilizer application rate in the stationary state for each group represents the fertilizer application error. A multifactor experiment was conducted, with the fertilizer application error and seed-fertilizer spacing error as performance indexes, to investigate their effects on the stability of the system under different operating parameters. The factor codes are shown in Table 1.

Table 1

Coded value	Factor		
	Forward speed x_1 (km/h)	Fertilizer discharge shaft speed x_2 (r/min)	Fertilizer discharger opening x_3 (mm)
1.682	3.6	50	25
1	3.28	45.9	20.9
0	2.8	40	15
-1	2.32	34.1	9.1
-1.682	2.0	30	5

RESULTS AND DISCUSSIONS

Stepper Motor Simulation Results Analysis

The target speed was set to 50 r/min, the DC side voltage to 311 V, and the initial load to 1 Nm. Figure 8 shows the speed response curves of the ISMDO-SMC, OSMC, PID, and SMC algorithms when a load of 10 Nm is abruptly applied at 0.75 s.

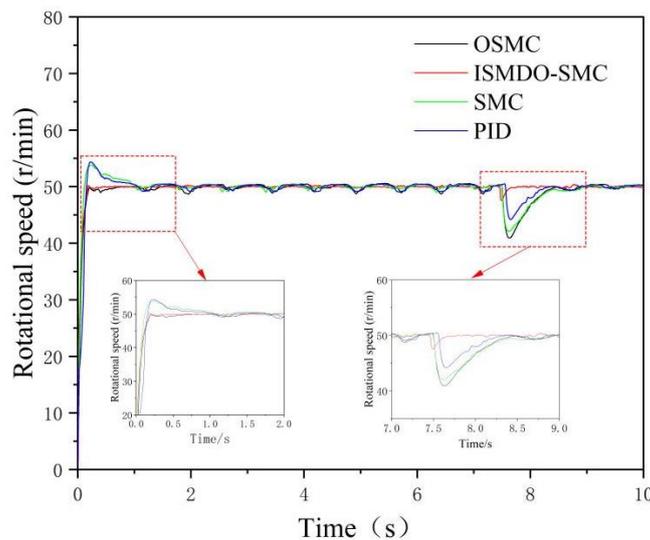

Fig. 8 - Speed response curves of the PID, SMC, ISMDO-SMC, and OSMC algorithms

From Figure 8, it can be observed that, during the starting phase, there are significant differences in the response time and the ability to follow the setpoint quickly across the four algorithms. The fast response and initial stability of the algorithms during startup affect the time required to reach the target speed. Large overshoot and oscillations typically occurred during the PID control startup phase, indicating that PID control produced significant fluctuations initially, which may cause the system to take a longer time to stabilize. The SMC algorithm performed slightly better than PID control, though some overshoot still occurred. The OSMC exhibited smoother performance at startup and was able to approach the target speed quickly with fewer fluctuations. The ISMDO-SMC showed almost no overshoot at the beginning and reached the set speed rapidly, demonstrating excellent control. After the sudden load addition, the PID, SMC, and OSMC all showed significant fluctuations and took a long time to return to a steady state. Among them, OSMC had the largest fluctuations and took the longest time to recover. In contrast, the ISMDO-SMC performed the best under sudden load changes, quickly suppressing the disturbances. In summary, the ISMDO-SMC reached the target speed faster and more smoothly during startup and exhibited superior resistance to disturbances with fast recovery after a sudden load change. In this study, the dynamic and anti-interference performance of four control algorithms (PID, SMC, ISMDO-SMC, and OSMC) were quantitatively analyzed and compared, as shown in Table 2.

The PID and SMC algorithms exhibited varying degrees of overshoot, 9% and 7.4%, respectively, and longer regulation times, 1.12 s and 1.03 s, respectively. The OSMC required 0.35 s more to regulate than the ISMDO-SMC algorithm, although it showed no overshoot. In terms of anti-jamming performance, the ISMDO-SMC algorithm demonstrated the best capability, with a descending speed of only 2.5 r/min and the shortest recovery time to steady state of 0.13 s. The OSMC algorithm had the longest recovery time of 0.85 s, with a descending speed of 9 r/min. In comparison, the PID and SMC algorithms had steady-state restoration times of 0.73 s and 0.75 s, respectively. The OSMC's performance was weaker, with a longer recovery time and higher descending speed. Overall, the ISMDO-SMC algorithm showed significant advantages in both dynamic and anti-interference performance. It achieved zero overshoot, with a peak time of 0.18 s and a regulation time of 0.42 s, both of which were significantly better than those of the other algorithms.

Table 2

Comparison of dynamic performance and anti-interference performance of PID, SMC, ISMDO-SMC, and OSMC algorithms

Algorithm	Overshoot	Peak time (t/s)	Regulation time (t/s)	Down speed (r/min)	Recovery of steady state time (t/s)
PID	9%	0.22	1.12	6	0.73
SMC	7.4%	0.25	1.03	8	0.75
ISMDO-SMC	0	0.18	0.42	2.5	0.13
OSMC	0	0.2	0.77	9	0.85

To verify that the designed expanding sliding mode observer exhibited good robustness to the system, the ISMDO-SMC algorithm was used to apply a torque of 10 Nm abruptly at 7.5 s and to unload the torque at 10.5 s. Figure 9 shows the comparison between the estimated and actual torque during sudden load addition and removal by the expanding observer. The actual torque curve in the steady-state phase showed jitter between 0 and 7.5 s, and between 10.5 s and 15 s, with an average magnitude of approximately ± 0.2 Nm. This jitter may have been caused by sensor noise or mechanical disturbances inside the motor. The estimated torque exhibited a significant step change near 7.5 s and 10.5 s, followed by a rise in the actual torque response, though with noticeable delays and overshoots. The peak value of the actual torque reached 1.1 times the set value at 7.5 s, corresponding to an overshoot of about 10%. This overshoot suggests that the control gain may have been set too high, leading to an over-response to the target torque. To reduce this overshoot, it may be necessary to lower the gain or mitigate the overshoot by introducing a derivative term. During sudden torque changes, the ISMDO-SMC algorithm provided a smoother torque estimation than the actual measured torque. Therefore, the perturbed values of estimated motor parameter variations and load torque, recorded by the expanding observer, can be effectively used in the sliding mode controller.

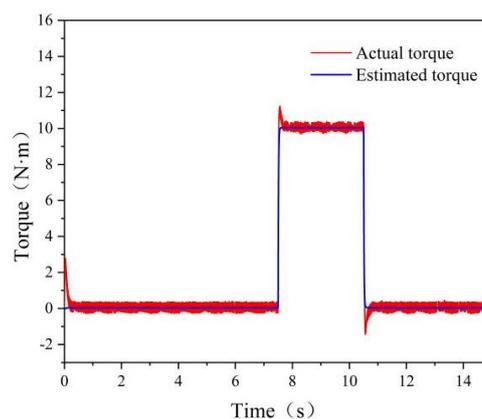

Fig. 9 - Comparison between the estimated and actual torque during sudden load addition and removal by the expanding observer

Fertilizer precision experiment

Figure 10 shows the distribution of fertilizer application amounts for the control algorithms (PID, SMC, ISMDO-SMC, and OSMC) at rotational speeds of 30, 40, and 50 r/min.

From the dynamic characteristics of the fertilizer application distribution, significant differences in stability performance were observed across the four control algorithms at different rotational speeds. The PID

algorithm exhibited large fluctuations in the amount of fertilizer applied, particularly at high rotational speeds (50 r/min), where both the fluctuation amplitude and extreme values increased significantly, indicating poor stability. The SMC algorithm improved the fluctuation amplitude compared to PID, resulting in a smoother distribution of the fertilizer application amount. However, it was still unable to completely eliminate the impact of large disturbances under complex working conditions. The OSMC algorithm significantly reduced the fluctuation amplitude by optimizing the sliding mode control, especially at high rotational speeds, where the distribution became more concentrated, demonstrating strong anti-disturbance capabilities. The ISMDO-SMC algorithm exhibited the smallest fluctuation amplitude and the smoothest distribution of fertilizer application at all rotational speeds. Even at the high speed of 50 r/min, the amount of fertilizer applied remained stable. Overall, the fertilization stability of the four control algorithms is ranked as follows: ISMDO-SMC > OSMC > SMC > PID. The ISMDO-SMC control algorithm significantly outperforms the others and is well-suited for scenarios that require high fertilization stability under complex working conditions.

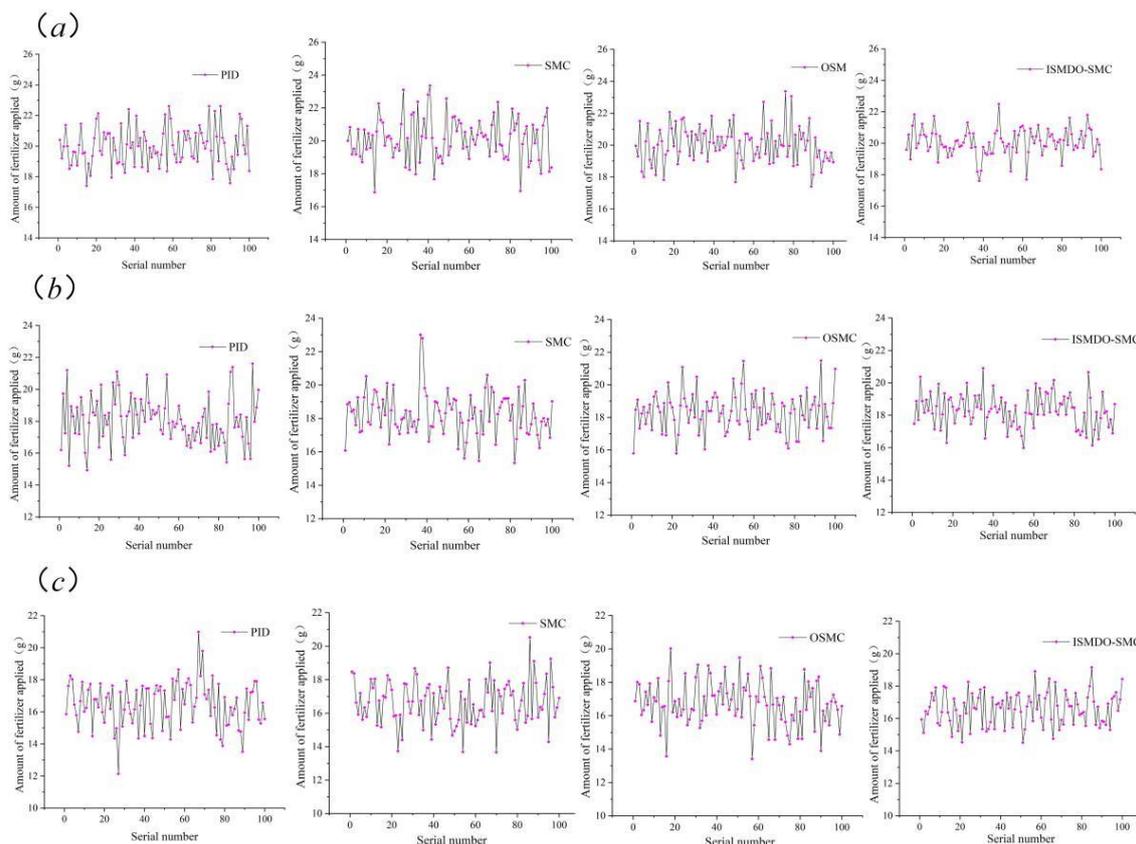

Fig. 10 - Distribution of fertilizer application amounts for the control algorithms (PID, SMC, ISMDO-SMC, and OSMC). (a) 30 r/min; (b) 40 r/min; (c) 50 r/min

Figure 11 shows the distribution of the coefficient of variation for the four control algorithms (PID, SMC, ISMDO-SMC, and OSMC) at rotational speeds of 30, 40, and 50 r/min. The coefficient of variation for the PID algorithm increased progressively with speed, from 6.50% at 30 r/min to 8.60% at 50 r/min, indicating poor performance in handling dynamic disturbances at high rotational speeds and a significant decrease in the stability of the fertilizer application system. The SMC algorithm partially compensated for the perturbations using sliding mode control, with coefficients of variation of 6.10%, 7.20%, and 8.20% at 30, 40, and 50 r/min, respectively. While this showed improvement over PID control, it did not completely resolve the issue of large fluctuations at high speeds. The OSMC algorithm further optimized sliding mode control, achieving coefficients of variation of 5.70%, 6.30%, and 7.60%, which were significantly lower than those of PID and SMC, demonstrating better robustness and anti-disturbance capability. The ISMDO-SMC algorithm exhibited the lowest coefficients of variation, at 4.90%, 5.70%, and 6.50%, respectively, and demonstrated the best stability across all rotational speeds. The dynamic disturbance suppression capability of the system was further enhanced by the intelligent optimization algorithm, effectively controlling fluctuations in the fertilizer application system. Therefore, based on the coefficient of variation, the stability of the four control algorithms is ranked as follows: ISMDO-SMC > OSMC > SMC > PID. The ISMDO-SMC algorithm significantly reduced the variability in fertilizer application, making it particularly suitable for scenarios that require high accuracy and stability in fertilizer application.

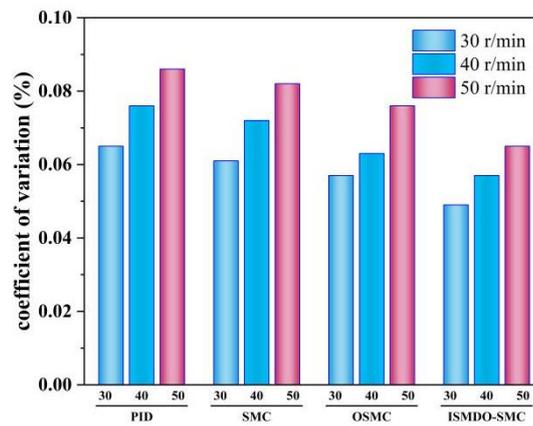

Fig. 11. Distribution of the coefficient of variation for the four control algorithms (PID, SMC, ISMDO-SMC, and OSMC)

Multi-factor Parameter Optimization Analysis

The experimental scheme and results are shown in Table 3. The regression equations for the factors influencing fertilizer application error and seed-fertilizer spacing error were obtained through multiple regression fitting using Design-Expert 8.0.6 software. The results of the analysis of variance (ANOVA) for the regression equations are shown in Table 4. The regression equations for both groups were highly significant ($P < 0.01$). The misfit P-value was not significant, indicating a good fit for the equation. The ANOVA results for fertilizer application error showed a P-value of 0.55 for the misfit term, indicating that no other factors affected the fertilizer application error. The ANOVA results for seed-fertilizer spacing error showed a misfit P-value of 0.06, indicating that no other factors influenced seed-fertilizer spacing error. After confirming that the models were significant and the misfit terms were not significant, the insignificant factors were removed, and the factor-coded regression equations (20-21) were developed.

$$y_1 = 140.92 - 4.03x_2 + 4.71x_3 + 15.23x_1^2 + 0.02x_2^2 \tag{20}$$

$$y_2 = 41.04 - 16.55x_1 - 0.69x_3 + 0.21x_1x_2 \tag{21}$$

where y_1 is the fertilizer application error, g; y_2 is the seed-fertilizer spacing error, mm; x_1 is the forward speed, km/h; x_2 is the fertilizer discharge shaft speed, r/min; and x_3 is the fertilizer discharger opening, mm.

Table 3

Experimental scheme and results

Experiment number	Forward speed x_1 (km/h)	Fertilizer discharge shaft speed x_2 (r/min)	Fertilizer discharger opening x_3 (mm)	Fertilizer application error y_1 (g)	Seed-fertilizer spacing error y_2 (mm)

23	0	0	0	2.11	3.24

The experiment on the coefficients of the regression equations showed that the effects of the forward speed, fertilizer discharger opening, and fertilizer discharge shaft speed on fertilizer application error increased gradually. Fertilizer application error is an important indicator for assessing the performance of the fertilization system. Therefore, this paper focuses on analyzing the effects of interactions among various factors on fertilizer application error. To intuitively analyze the relationship between the test factors and fertilizer application error, Design-Expert 6.0.8 software was used to generate the response surface diagrams of the forward speed, fertilizer discharger opening, and fertilizer discharge shaft speed on the fertilizer application error indexes, as shown in figures 12-14.

Table 4

Results of the analysis of variance for the regression equations

Source of variance	Fertilizer application error (g)				Seed-fertilizer spacing error (mm)			
	Square sum	Degrees of freedom	F	P	Square sum	Degrees of freedom	F	P

Errors	95.85	8			0.95	8		
Sum of all	732.41	22			10.88	22		

Note: * indicates significant ($P < 0.05$) and ** indicates highly significant ($P < 0.01$).

Figure 12 shows the effect of the interaction between x_1 and x_2 on the fertilizer application error when x_3 is 15 cm. When x_1 is certain, with the increase of x_2 , the error in the amount of fertilizer applied firstly decreases and then increases by a small margin. When x_2 is certain, the error in the amount of fertilizer applied decreases first and then increases with the increase of x_1 . However, in terms of magnitude, the magnitude of the fertilizer application error size influenced by the rotational speed exceeds the influence of the forward speed, so the appropriate speed of the fertilizer discharger can reduce the error.

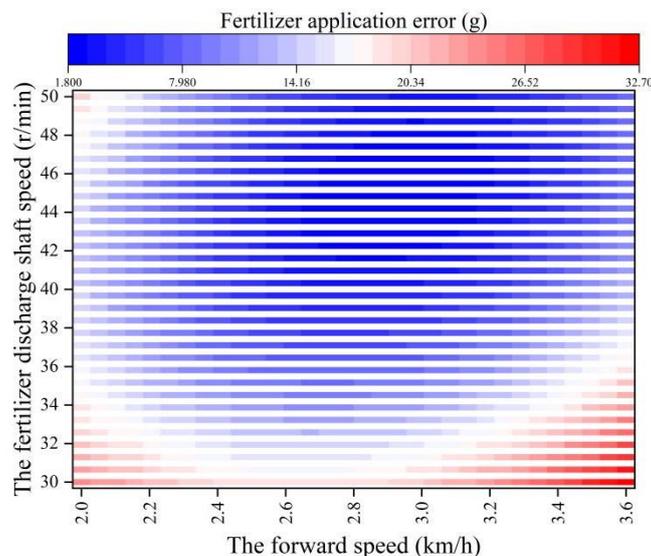

Fig. 12 - Interaction between forward speed and fertilizer discharge shaft speed on the fertilizer application error

Figure13 shows the effect of the interaction between x_1 and x_3 on fertilizer application error when x_2 is 40 r/min. At a fixed forward speed, the fertilizer application error gradually increases with the increase of x_3 . When x_3 is fixed, the fertilizer application error first decreases and then increases as forward speed increases. Therefore, selecting a smaller fertilizer discharger opening and driving at a moderate speed can effectively reduce the fertilizer application error.

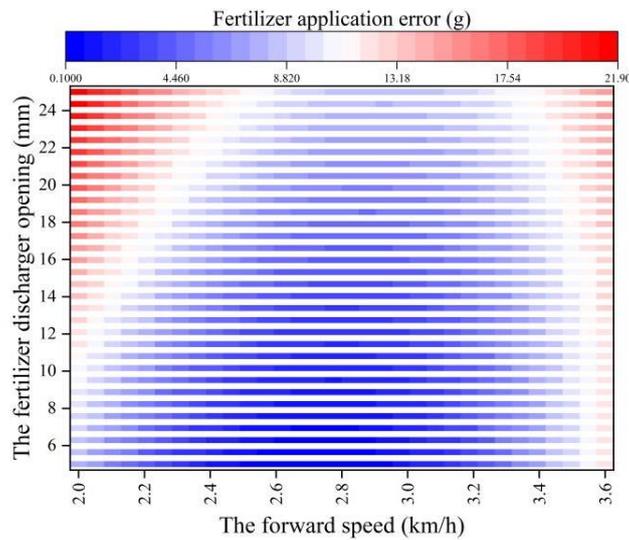

Fig. 13 - Interaction between forward speed and fertilizer discharger opening on the fertilizer application error

Figure 14 shows the effect of the interaction between x_2 and x_3 on fertilizer application error when x_1 is 2.8 km/h. When x_3 is larger, the fertilizer application error with x_2 gradually decreases, with a noticeable amplitude. When x_3 is smaller, the fertilizer application error first decreases and then increases with x_2 , with a smaller and less noticeable magnitude. When x_2 is fixed, the overall fertilizer application error increases gradually as x_3 increases.

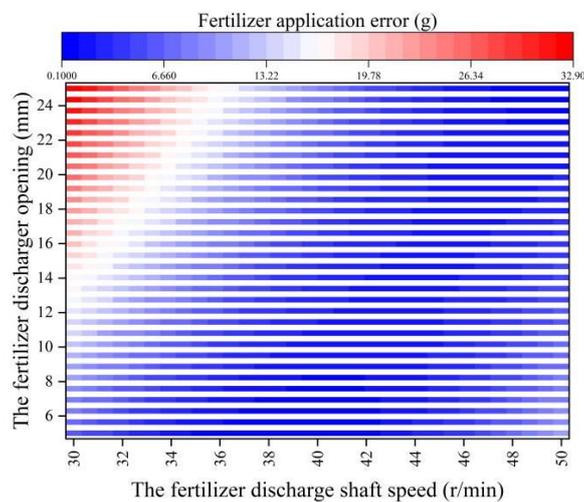

Fig. 14 - Interaction of fertilizer discharge shaft speed and fertilizer discharger opening on the fertilizer application error

Optimizing the best combination of parameters using the software requires setting the boundary conditions, and the mathematical model was developed as shown in equation (22).

$$\begin{cases} \min y_1 \\ \min y_2 \\ \text{s. t. } \begin{cases} 2 \text{ km/h} \leq x_1 \leq 3.6 \text{ km/h} \\ 30 \text{ r/min} \leq x_2 \leq 50 \text{ r/min} \\ 5 \text{ mm} \leq x_3 \leq 25 \text{ mm} \end{cases} \end{cases} \quad (22)$$

The optimization module in Design-Expert 8.0.6 software completed the parameter optimization. When the forward speed was 2.8 km/h, the fertilizer discharge shaft speed was 42 r/min, and the fertilizer discharger opening was 5.5 mm, the fertilizer application error and seed-fertilizer spacing error were minimized. Three sets of repetitive tests were conducted based on the optimized parameters, and the results showed that the error between the actual and optimized fertilizer application amounts was about 0.32, while the seed-fertilizer spacing error was 0.21. These results indicate that the optimized parameters effectively completed the fertilizer application operation. Under the condition of the optimal parameter combination, the fertilizer application error and seed-fertilizer spacing error in actual operation were 1.7 g and 2.2 mm, respectively.

CONCLUSIONS

(1) A control system for synchronizing corn seeding and precision hole fertilization was designed. The sliding mode controller with integral variable structure utilizes observed changes in motor parameters as feed-forward compensation, enabling the speed control system to respond quickly without overshoot. The jitter is minimal, and the regulation time is short under sudden load addition or removal, effectively suppressing the oscillations typically associated with sliding mode control.

(2) The mathematical model of the motor was established, and the controller was designed and simulated. The simulation results showed that the ISMDO-SMC algorithm had 0% overshoot, a peak time of 0.012 seconds, a regulation time of only 0.02 seconds, a steady-state recovery time of 0.02 seconds, and a descending rotational speed of 4 r/min, indicating the strongest dynamic response and stability. Additionally, the ISMDO-SMC algorithm demonstrated the lowest coefficient of variation for fertilizer application compared to the PID, SMC, and OSMC algorithms, with coefficients of variation of 4.90%, 5.70%, and 6.50% for rotational speeds of 30, 40, and 50 r/min, respectively.

(3) The regression equations of each factor on fertilizer application error and seed-fertilizer spacing error were obtained by fitting the experimental data with multiple regression. The mathematical model for parameter optimization was established through multi-objective variable optimization, yielding the optimal parameter combination. The optimal parameters were determined to be 1.7 g for fertilizer application error and 2.2 mm for seed-fertilizer spacing error, with the forward speed of 2.8 km/h, the fertilizer discharge shaft speed of 42 r/min, and the fertilizer discharger opening of 5.5 mm. These results demonstrate that the control system can significantly improve the stability and precision of fertilizer application and seeding, providing valuable insights for the development of fertilizer application control systems.

Keywords: Grape leaves; variety recognition; Swin Transformer; Focal Loss.

ABSTRACT

Aiming at the problem of differentiated cultivation strategies for different grape varieties, the AF-Swin Transformer model is proposed in this study. Firstly, Focal Loss is used to effectively tackle data imbalance in grape leaves. Secondly, the AdamW optimizer is selected to better control model complexity and improve generalization. The results show that the training accuracy of AF-Swin Transformer model is 7.87 percentage points higher than that of the original Swin Transformer model. Precision and recall improved by 4.4 and 4.3 percentage points, respectively. This study enables accurate automated variety monitoring within vineyard cultivation systems, assisting growers in implementing targeted cultivation strategies.

摘要

针对不同葡萄品种栽培策略存在差异化问题, 本研究提出了 AF-Swin Transformer 模型。首先, 引入 Focal Loss, 有效应对葡萄叶片数据不平衡, 其次, 选用 AdamW 优化器, 更好地控制模型复杂度并提高泛化能力。结果表明, AF-Swin Transformer 模型的训练集准确比原始 Swin Transformer 模型提高了 7.87 个百分点; 精准率和召回率分别提高了 4.4 和 4.3 个百分点。本研究能够在葡萄园中种植系统中实现准确的自动化品种监测, 帮助种植者实施有针对性的种植策略。

INTRODUCTION

Effective recognition of grape leaf varieties can assist grape growers in managing their crops more conveniently and making precise decisions (Cecotti *et al.*, 2020). During the development and maturation of grapes, they are susceptible to various diseases. Understanding the susceptibility of specific leaf varieties to certain diseases and their effective identification will enhance targeted prevention and treatment of grape diseases (Pereira *et al.*, 2019). Traditional methods for identifying grape varieties primarily depend on manual observation. While this method is straightforward, it is often affected by subjective factors and environmental changes, resulting in insufficient accuracy and stability in identification. Therefore, achieving automated identification of grape varieties through leaf image analysis will provide growers with more convenient management tools, helping them make more precise decisions and ultimately enhance the efficiency and competitiveness of the entire grape industry.

In recent years, the rapid development of deep learning technologies and computer vision has brought new solutions for plant leaf recognition (Patricio *et al.*, 2018). Convolutional Neural Networks (CNNs) such as AlexNet (Ni *et al.*, 2021), MobileNet (Zou *et al.*, 2024), and ResNet (Yang *et al.*, 2023) can automatically extract image features (Pushpanathan *et al.*, 2021) and have demonstrated superior performance in the classification tasks of different leaf varieties from the same plant. Deep learning has particularly become an effective tool for leaf feature extraction and variety recognition.

Yin et al. employed the GoogLeNet model to recognize leaf images of 11 camellia plant varieties, achieving an overall accuracy of 94.1% (Yin et al., 2023). Lin et al. used ResNet50 for variety recognition of 9 types of Wuyishan Fujian tea leaves, with an accuracy rate reaching 96.04% (Lin et al., 2021). Sun et al. conducted research on the recognition of southern medicinal leaf varieties in complex backgrounds using an improved EfficientNetv2 model, achieving an accuracy rate of 99.12% (Sun et al., 2023). Chen et al. utilized a Multi-Attention Fusion Convolutional Neural Network (MAFNet) for recognizing apple leaf images, with the model achieving an accuracy rate of 98.14% (Chen et al., 2022). Tavakoli et al. applied Convolutional Neural Networks (CNNs) for the variety recognition of 12 types of legumes, where the model showed good recognition performance on a dataset of legume leaf back images, achieving an accuracy rate of 95.86% (Tavakoli et al., 2021). Dong et al. used an improved RegNet model to recognize varieties of 118 mature camellia leaves that grew under natural light conditions and achieved an overall accuracy of 93.7% (Dong et al., 2024). Su et al. used an improved ResNet50 to recognize datasets of 12 types of wine grape leaf images collected at different growth stages, achieving an accuracy of 88.75% (Su et al., 2021). Zhang et al. improved the YOLO-D1 model by integrating the YOLO object detection mechanism and proposed the YOLO-VOLO-LS method, which significantly enhanced the variety identification accuracy of lettuce at the early SP growth stage, achieving a test accuracy of 93.452% (Zhang et al., 2022). Islam et al. applied transfer learning based on the YOLO model to successfully recognize and localize Bangladeshi plant leaves, attaining a classification accuracy of 96% (Islam et al., 2019). Das et al. employed the YOLOv7 model to improve the identification and localization of medicinal plant leaves in complex environments, providing technical support for automated recognition in the herbal medicine industry (Das et al., 2024). Sennan et al. proposed a convolutional neural network (CNN) for spinach classification, achieving a classification accuracy of 97.5% on a dataset comprising four leaf categories (Sennan et al., 2022). Kaur et al. enhanced DenseNet-121 for grapevine variety identification, reaching 96% classification accuracy on high-resolution images of five grape leaf types (Kaur et al., 2024). Maulana et al. conducted a comparative analysis of various CNN models for grapevine leaf classification, with DenseNet and MobileNetV2 both achieving 99% accuracy, thereby improving classification precision and model robustness (Maulana et al., 2024).

Although the deep learning models mentioned above have achieved certain results in crop leaf variety recognition, research on grape leaf variety identification remains limited due to imbalanced sample sizes arising from varying rarity and collection difficulties, and the widely used YOLO model exacerbates this by requiring labor-intensive data annotation. This study focuses on mature grape leaves that have newly sprouted for 30 to 60 days in spring and addresses this issue by proposing the AF-Swin Transformer model. We utilize the AdamW optimizer, which incorporates weight decay. AdamW applies the weight decay term independently during parameter updates, separating it from the learning rate adjustments, which allows for a more precise implementation of weight decay. This approach effectively manages model complexity, reduces overfitting risk, and enhances stability. Moreover, the Focal Loss function is introduced to tackle the sample imbalance problem. Focal Loss mitigates the loss gradients of easily recognizable samples by introducing a modulation factor, encouraging the model to focus more on difficult-to-recognize samples. This enhances the model's ability to recognize rare varieties and improves its learning capacity for hard-to-identify samples, enabling the model to better recognize subtle differences and ultimately increase overall accuracy.

Therefore, the AF-Swin Transformer model proposed in this paper exhibits greater robustness and accuracy in recognizing grape leaf varieties, providing a scientific foundation for their identification.

MATERIALS AND METHODS

Sample dataset

All the leaf samples in this study were collected at the Fruit Tree Research Institute in Taigu District, Jinzhong City, Shanxi Province. A total of 5,516 images were collected using a Huawei Mate 40 smartphone, taken from various angles and time periods in a natural environment. The distribution of the number of samples for each variety is shown in Figure 1.

The leaves were collected from the upper-middle part of the grapevine branches, and they were healthy, mature leaves that had newly sprouted for 30 to 60 days in spring. At this stage, the leaves exhibit standard morphology, with clear leaf lobes, leaf shape, and visible venation structures. The image resolution is 3024x4032, the image format is JPEG, and the color mode is RGB.

Figure 2 displays sample images of 26 different grape varieties.

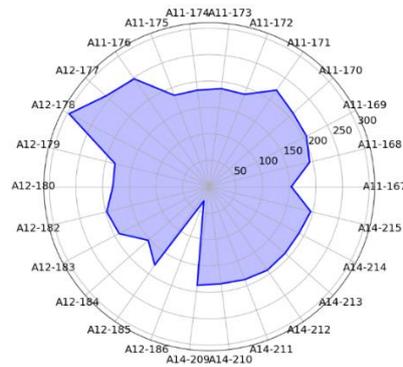

Fig. 1 - Distribution of the number of grape leaf varieties

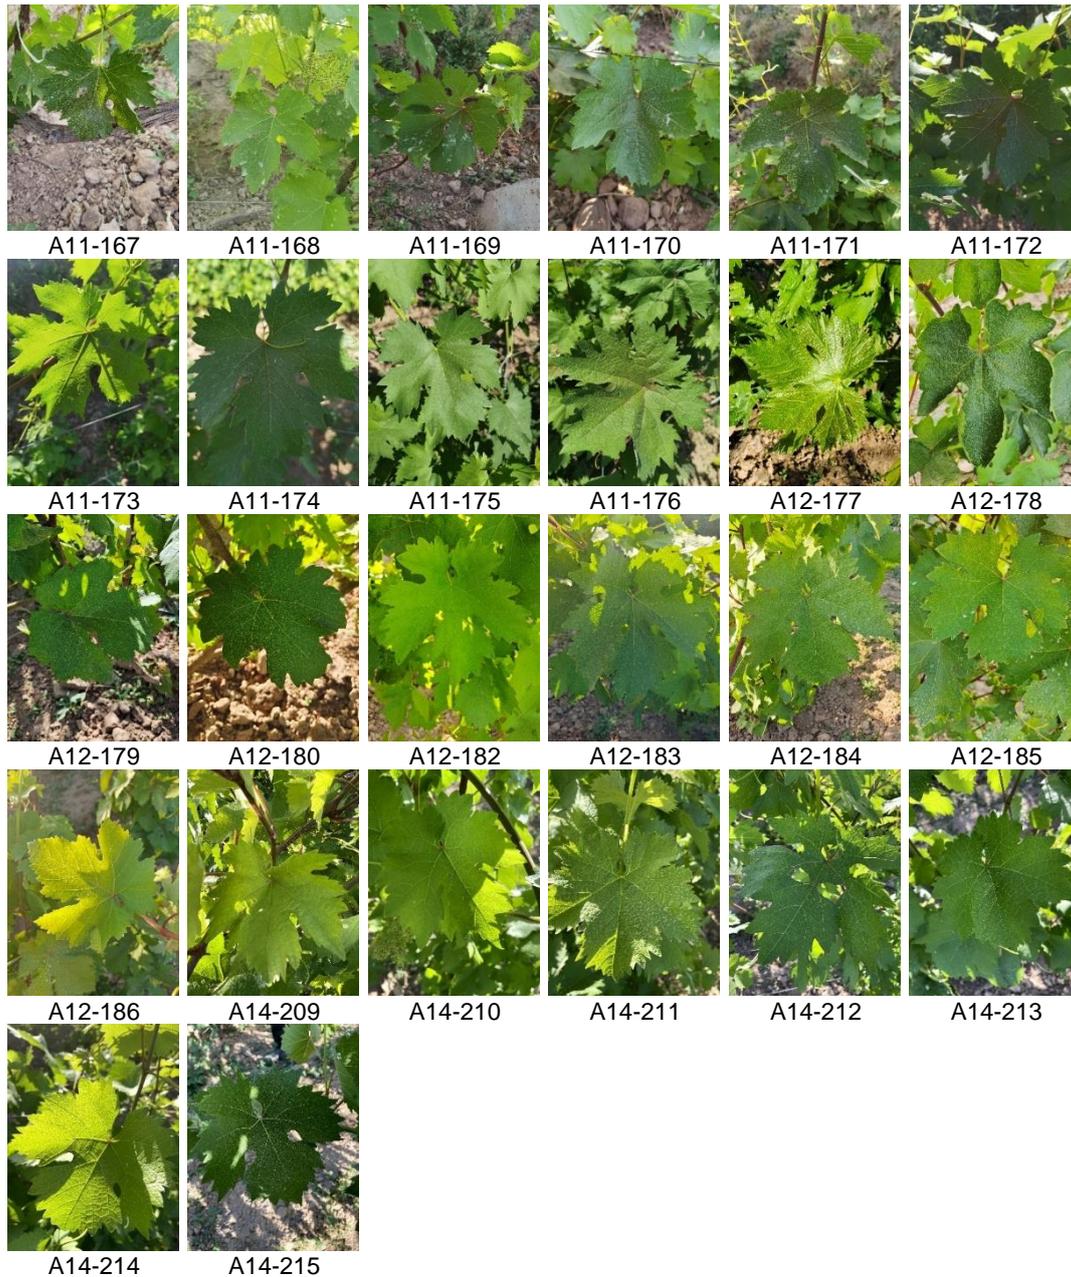

Fig. 2 - Examples of grape leaf samples from different varieties

Data augmentation

To enhance the recognition capability of the network model, four data augmentation methods—random rotation, flipping, brightness adjustment, and adding Gaussian noise—were randomly combined and artificially expanded during training to create a training dataset. The number of images for each variety after data augmentation is shown in Table 1.

This image augmentation technique is versatile and computationally efficient, effectively training deep learning models. The dataset was divided into training, validation, and testing sets in an 8:1:1 ratio. A schematic diagram of the grape leaf data augmentation (Lacate) is illustrated in figure 3. Figure 3(a) shows the original image, (b) displays the flipped image, (c) demonstrates the addition of Gaussian blur, (d) depicts an increase in brightness, (e) shows the rotated image, and (f) illustrates a decrease in brightness.

Improved swin transformer model

The Swin Transformer model addresses image tasks through a hierarchical design by dividing the input image into multiple windows, treating the elements within each window as independent tokens, and performing linear embedding to create initial feature representations. This mechanism not only enhances the model's capacity to process large images but also effectively avoids the computational and memory limitations that traditional Transformers face when dealing with high-dimensional inputs.

In several stages, the Swin Transformer blocks progressively extract features and adjust spatial resolution, with each stage further integrating information through a "Patch Merging" operation, which reduces computational load and increases the number of channels. The key aspect of the Swin Transformer is the combination of a sliding window multi-head self-attention mechanism (SW-MSA) and a multi-layer perceptron (MLP), which enhances the model's ability to learn local and global features. Additionally, layer normalization (LN) operations ensure the model's stability and training effectiveness.

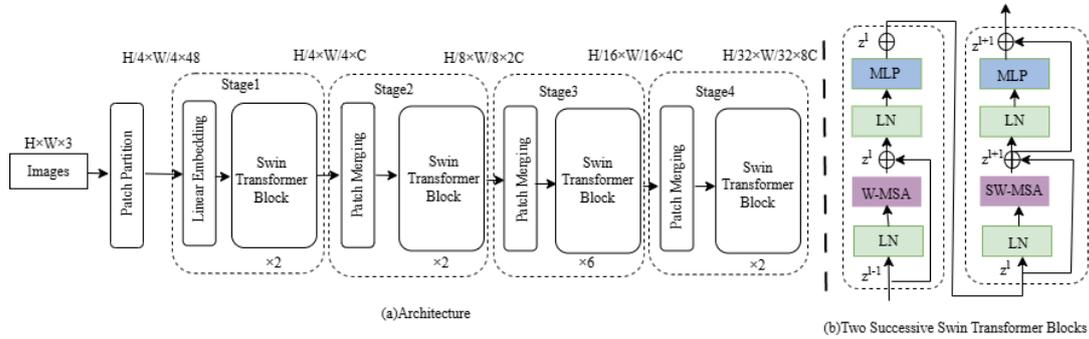

Fig. 4 - Structure diagram of the Swin Transformer model

Due to the imbalance of sample sizes among different grape leaf varieties, this study introduces the Focal Loss function. Focal Loss assesses the difficulty of each sample based on the model's predicted probabilities. It dynamically adjusts the model's focus by reducing attention to easily distinguishable samples during training, allowing the model to concentrate more on harder-to-distinguish samples. Unlike the cross-entropy loss function, Focal Loss introduces a tunable parameter that adjusts the model's focus between easily recognizable and difficult-to-recognize samples. When the value of γ is low, the model pays more attention to easily recognizable samples; when γ is high, the model focuses more on difficult-to-recognize samples. The formula for Focal Loss is as follows:

$$FocalLoss = -a_t (1 - p_t)^\gamma \log(p_t)$$

In the equation, the difficulty of recognition is reflected by p_t . When p_t is larger, it indicates a higher confidence level in identification, suggesting that the sample is easier to distinguish. Conversely, when p_t is smaller, it indicates a lower confidence level in identification, suggesting that the sample is more difficult to distinguish.

Experimental environment

The operating system was 64-bit Windows 10, using an Intel(R) Core(TM) i7-14650HX CPU@2.20 GHz processor with 32 GB of memory. The graphics card model was the NVIDIA GeForce RTX 4060. All CNN models are developed based on the PyTorch framework, with Python 3.8 used as the programming language for implementing network model training and testing. The training parameters included an initial learning rate of 0.00001, a stochastic gradient descent (SGD) optimizer, a weight decay coefficient of 0.05, and a batch size of 4. A cosine learning rate scheduler was utilized for a total of 50 epochs, ensuring a smooth adjustment of the learning rate to avoid sudden changes during training. After each iteration, the trained model was saved in a folder, and the training logs were recorded.

Model evaluation metric

To comprehensively evaluate model performance, several commonly used classification metrics were introduced, including Confusion Matrix, Accuracy, Precision, Recall, F1-score, ROC Curve, and AUC. The ROC Curve, plotted with the False Positive Rate (FPR) on the x-axis and the True Positive Rate (TPR) on the y-axis, represents each point corresponding to a potential classification threshold. The optimal classification threshold can be determined by selecting the point on the ROC Curve that is closest to the top left corner. Furthermore, the model's performance can be assessed using the Area Under the Curve (AUC), where a larger AUC indicates better performance. The formulas for each metric are as follows:

$$ConfusionMatrix = \begin{pmatrix} TP & FP \\ FN & TN \end{pmatrix} \quad (1)$$

$$Precision = \frac{TP}{TP + FP} \tag{2}$$

$$Recall = \frac{TP}{TP + FN} \tag{3}$$

$$Accuracy = \frac{TP + TN}{TP + FP + TN + FN} \tag{4}$$

$$F1 - score = \frac{2 \cdot Precision \cdot Recall}{Precision + Recall} \tag{5}$$

In the equation, *TP* represents the number of samples predicted as positive that are actually positive; *FP* represents the number of samples predicted as positive, but are actually negative; *FN* represents the number of samples predicted as negative, but are actually positive; *TN* represents the number of samples predicted as negative that are actually negative.

RESULTS AND ANALYSIS

Model training

This study evaluated the performance of four convolutional neural network models: Swin Transformer, MobileNetV2, MobileNetV3, and ViT for grape leaf recognition. The model training accuracy curves and loss change curves are shown in figures 5 and 6; the testing accuracy results are presented in Table 2.

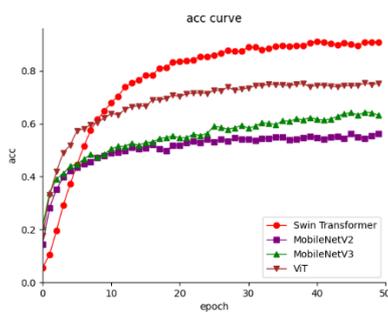

Fig. 5 - Training accuracy change curve

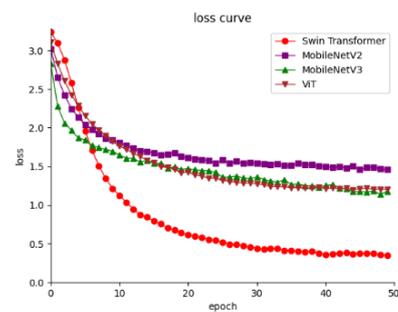

Fig. 6 - Training loss change curve

From the accuracy change curves, it can be observed that the Swin Transformer model achieves a faster improvement in accuracy, ultimately reaching approximately 90.85%. In comparison, MobileNetV2 and MobileNetV3 show relatively small changes in overall accuracy, with final accuracies of only 56.39% and 63.20%, respectively. Additionally, the Swin Transformer converges more quickly and stably than ViT. The loss change curve shows that the Swin Transformer model experiences a rapid decrease in loss during the first 30 training epochs and eventually stabilizes. In contrast, MobileNetV2, MobileNetV3, and ViT exhibit minimal loss reduction throughout the training process. Therefore, the Swin Transformer outperforms the other models in both training accuracy and loss, demonstrating strong robustness and performance advantages.

After model training, performance evaluation was conducted using a test dataset collected from real orchard environments, which included various natural conditions such as strong front lighting, backlighting, and different levels of occlusion.

Table 2

Recognition model testing accuracy

Class	Model1	Model2	Model3	Model4	Class	Model1	Model2	Model3	Model4
A11-167	0.967	0.867	0.967	0.5	A12-180	0.806	0.806	0.75	0.556
A11-168	0.947	0.842	0.868	0.711	A12-182	0.923	0.872	0.897	0.795
A11-169	0.927	0.878	0.878	0.488	A12-183	0.947	0.895	0.895	0.395
A11-170	0.929	0.786	0.976	0.667	A12-184	0.867	0.867	0.833	0.667
A11-171	0.932	0.614	0.932	0.227	A12-185	0.972	0.778	0.917	0.333
A11-172	0.946	0.919	0.838	0.432	A12-186	1.0	1.0	0.8	0.0
A11-173	0.919	0.622	0.973	0.162	A14-209	1.0	0.784	0.919	0.514
A11-174	0.972	0.75	0.917	0.306	A14-210	0.919	0.541	0.811	0.243

Class	Model1	Model2	Model3	Model4	Class	Model1	Model2	Model3	Model4
A11-175	1.0	0.865	0.973	0.324	A14-211	0.838	0.865	0.919	0.568
A11-176	0.837	0.857	0.878	0.571	A14-212	0.921	0.947	0.895	0.868
A12-177	1.0	0.922	1.0	0.627	A14-213	0.789	0.474	0.947	0.289
A12-178	0.966	0.864	0.966	0.847	A14-214	1.0	0.921	0.974	0.263
A12-179	1.0	0.833	0.861	0.194	A14-215	1.0	1.0	0.974	0.769

Note: In this paper, Model1 represents Swin Transformer, Model2 represents MobileNetV2, Model3 represents MobileNetV3, and Model4 represents Vision Transformer (ViT).

The experimental results show that the accuracy of the ViT and MobileNetV2 models is only 50.05% and 82.19%, respectively. The accuracy of the MobileNetV3 model is 90.61%, while the Swin Transformer model achieved 93.55%, the highest among the four models. It exceeds the accuracies of MobileNetV2, MobileNetV3, and ViT by 11.3, 2.94, and 43.50 percentage points, respectively.

Model parameter selection

Choose the Swin Transformer as the recognition model to test the impact of different training parameters on recognition performance. Keeping other parameters constant, four experimental sets (T1-T4) are established, with a batch size fixed at 4. The selected optimizers are SGD and AdamW, with initial learning rates of 0.0001 and 0.00001, respectively. The results of the experiments using different parameter selections are presented in Table 3.

Table 3

Test	Optimizer	Initial Learning Rate	Bach Size	Accuracy
T1	SGD	0.0001	4	90.85%
T2	SGD	0.00001	4	42.42%
T3	AdamW	0.0001	4	94.21%
T4	AdamW	0.00001	4	95.46%

The results indicate that, with the batch size held constant, the AdamW optimizer demonstrated better performance compared to SGD, particularly at the lower learning rate (0.00001), where model T4 achieved the highest accuracy of 95.46%. For models using the SGD optimizer, a higher learning rate (0.0001) contributed to improved model performance, as seen in model T1 with an accuracy of 90.85%, whereas the accuracy of model T2 with a lower learning rate significantly dropped to 42.42%. This suggests that for SGD, an appropriate increase in the learning rate may help enhance the model's training effectiveness. Overall, AdamW demonstrates greater robustness at low learning rates, likely due to its internal mechanisms, including momentum and adaptive learning rate characteristics. Therefore, it is recommended to prioritize the AdamW optimizer for similar tasks and adjust the learning rate appropriately to find the optimal configuration.

Based on this analysis, the Swin Transformer model demonstrates the best recognition performance with the AdamW optimizer, a batch size of 4, and an initial learning rate of 0.00001.

Improvement Of Loss Function

In this study, the loss function of the Swin Transformer model was improved by replacing the original standard loss function with the Focal Loss function. To validate the effectiveness of Focal Loss, comparative experiments were conducted with Cross-Entropy Loss and Label Smoothing Loss. Focal Loss increases the loss gradient for hard-to-classify samples, enhancing the model's learning ability for these challenging samples and effectively addressing class imbalance.

Table 4

Test	Loss	Accuracy	Precision	Recall
T5	Cross-Entropy Loss	93.55%	93.70%	93.60%
T6	Label Smoothing Loss	95.87%	95.87%	95.80%
T7	Focal Loss	98.64%	98.64%	97.90%

From Table 4, it can be observed that Focal Loss demonstrates the best performance in grape leaf variety recognition. In terms of accuracy, the model using Focal Loss achieved an accuracy of 98.72%, which is an improvement of 3.26 percentage points over the accuracy using Cross-Entropy Loss and 2.85 percentage points over Label Smoothing Loss.

In terms of precision, Focal Loss improved by 2.19 percentage points compared to Label Smoothing Loss and by 4.40 percentage points compared to Cross-Entropy Loss. Regarding recall, Focal Loss enhanced performance by 2.10 percentage points over Label Smoothing Loss and by 4.30 percentage points over Cross-Entropy Loss. This improvement can be attributed to Focal Loss's ability to dynamically adjust the loss gradient based on sample difficulty, enabling the model to focus more on samples prone to errors or from rare categories during training. In contrast, Label Smoothing Loss primarily enhances generalization by reducing the model's overconfidence in certain categories, but it does not address class imbalance directly like Focal Loss. Label Smoothing Loss may result in insufficient learning of easier categories, potentially impacting overall performance. In contrast, Focal Loss ensures balanced learning across all categories by focusing on hard-to-classify samples. This attention mechanism enhances the model's learning for difficult samples, thereby improving overall accuracy.

Confusion Matrix

To evaluate the performance of the improved AF-Swin Transformer network model, a test set that was not used in the training or validation phases was employed. The confusion matrix generated is shown in figure 7, where the shading indicates the magnitude of the values; lighter colors represent smaller values, while darker colors represent larger values. The horizontal axis represents the true labels, while the vertical axis represents the predicted labels. The diagonal elements indicate the number of correctly identified samples.

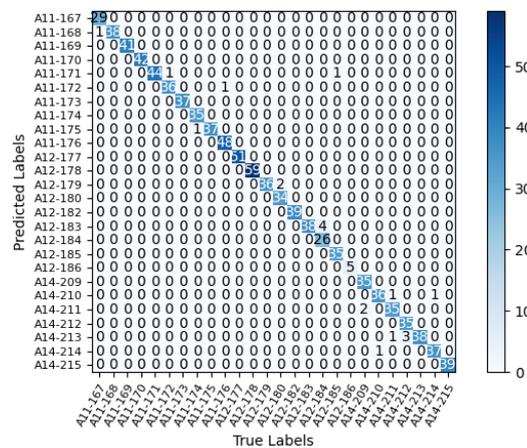

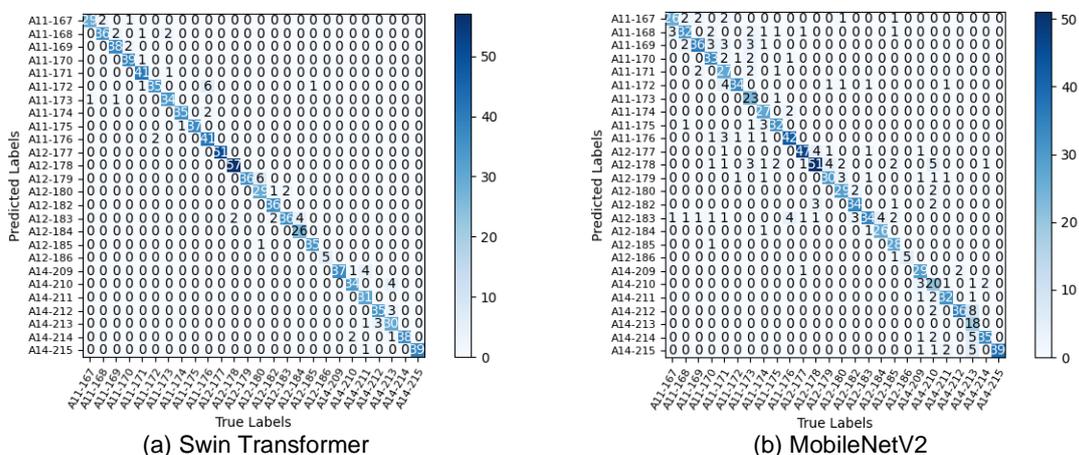

Fig. 7 - Confusion Matrix of AF-Swin Transformer Model

From figure 7, it can be observed that varieties A11-170, A11-171, and A11-172 exhibited no misidentification, indicating that their features are distinct. However, varieties A11-172 and A12-185 were misidentified as A11-171. This suggests that the recognition features for varieties A11-172 and A12-185 do not differ significantly from those of other varieties, making them susceptible to interference. This may also be influenced by shooting angles and lighting conditions.

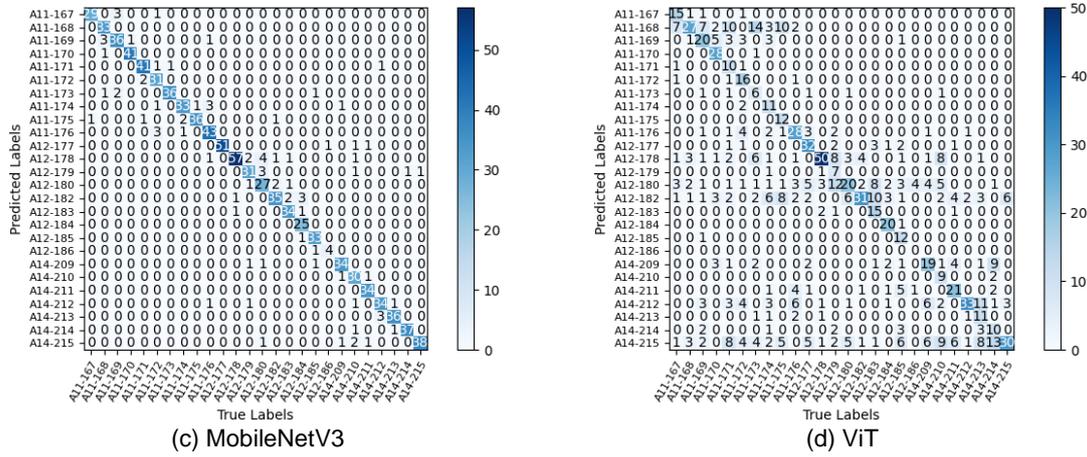

Fig. 8 - Confusion Matrix of Different Models

By comparing figures 7 and 8, which show the confusion matrices of the AF-Swin Transformer, Swin Transformer, MobileNetV2, MobileNetV3, and ViT models, it can be observed that the AF-Swin Transformer model correctly identifies varieties A11-169, A11-173, and A11-178, while the other models exhibit misidentifications for these varieties. This is primarily because Focal Loss enhances the model's ability to learn from hard-to-identify samples, addressing the issue of class imbalance, while the weight decay characteristics of the AdamW optimizer help improve the model's generalization capability, making it more precise when dealing with varieties that have subtle differences. These improvements provide the AF-Swin Transformer with a significant advantage in processing varieties with closely similar features. The above analysis demonstrates that the proposed improved model, AF-Swin Transformer, has strong robustness in recognizing grape leaf varieties.

Grad-CAM Visual Analysis

To understand the feature learning of grapevine leaf sample, this study used the Grad-CAM algorithm to output the gradient heatmap of the weights in the final convolutional layer and visualize the network model. As shown in figure 9, areas that are redder indicate that these features play a more critical role in class orientation.

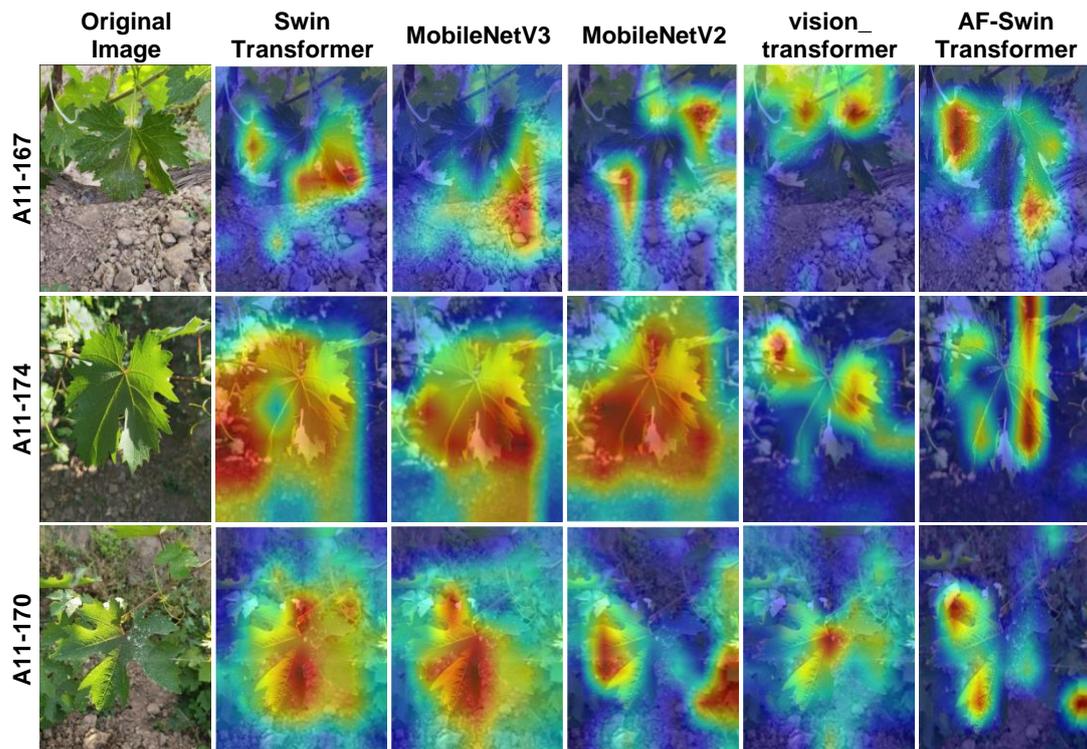

Fig. 9 - Grad-CAM Visualization of Recognition Results for Different Convolutional Neural Network Algorithms

Figure 9 compares the heatmaps of the Swin Transformer, MobileNetV2, MobileNetV3, ViT, and AF-Swin Transformer. The heatmap of the AF-Swin Transformer focuses on both the leaf veins and edges, with a broad distribution that covers a significant portion of the leaf area. In contrast, the heatmaps of MobileNetV2 and MobileNetV3 show higher activity only at the leaf edges, while the Swin Transformer and ViT heatmaps primarily focus on regions where leaf veins are located. Therefore, compared to the other four models, AF-Swin Transformer has a broader and more accurate recognition capability for grapevine leaves.

ROC Curve

To evaluate the recognition performance of the models comprehensively, ROC curves were analyzed. By comparing the area under the curve (AUC), we can intuitively assess the strengths and weaknesses of different models. The ROC curve for the AF-Swin Transformer is shown in Figure 10, while Figure 11 displays the ROC curves for the various models.

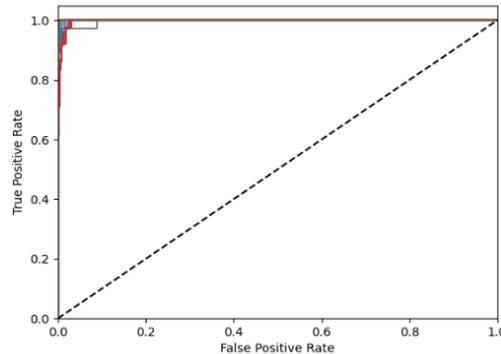

Fig. 10 - ROC Curve of AF-Swin Transformer

From figure 10, it can be seen that the AF-Swin Transformer model exhibits good distinguishing performance among different varieties.

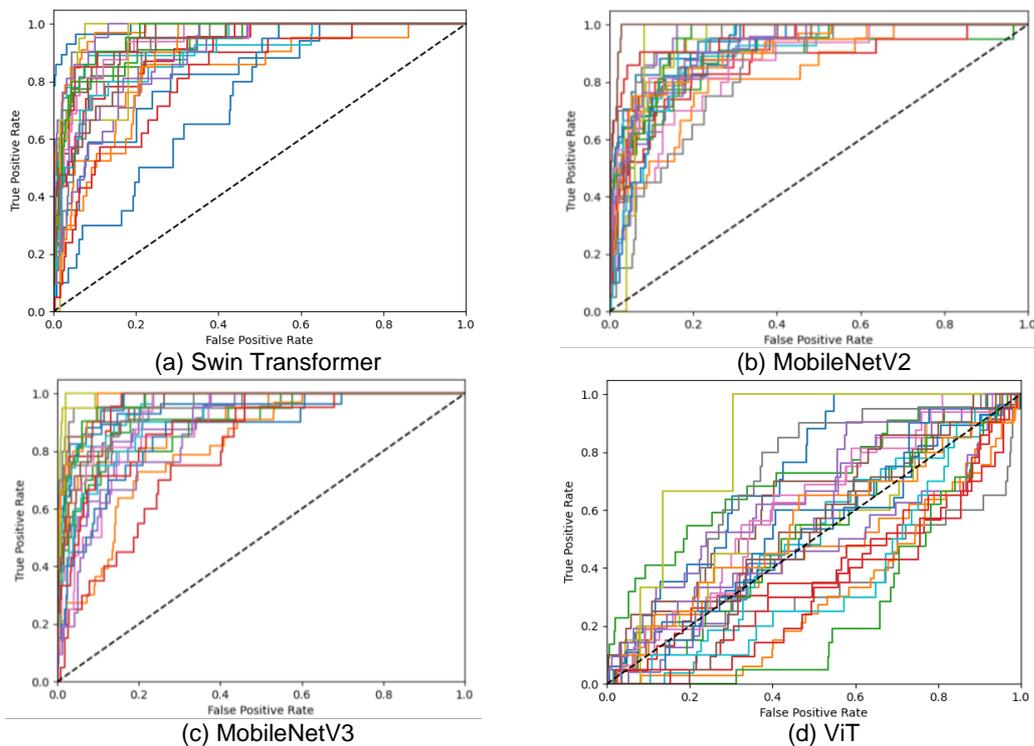

Fig. 11 - ROC Curves of Different Models

- Note: ■ A11-167 ■ A11-168 ■ A11-169 ■ A11-170 ■ A11-171 ■ A11-172 ■ A11-173 ■ A11-174 ■ A11-175
 ■ A11-176 ■ A12-177 ■ A12-178 ■ A12-179 ■ A12-180 ■ A12-182 ■ A12-183 ■ A12-184 ■ A12-185
 ■ A12-186 ■ A14-209 ■ A14-210 ■ A14-211 ■ A14-212 ■ A14-213 ■ A14-214 ■ A14-215

To further comprehensively evaluate the performance of the AF-Swin Transformer model, a comparative assessment was conducted using evaluation metrics such as precision, recall, F1-score, and AUC value for all the models used. As shown in Table 5:

Table 5

Evaluation Metrics of Different Models				
Models	Precision	Recall	F1 Score	AUC
Swin Transformer	0.937	0.936	0.934	0.910
MobileNetV2	0.811	0.798	0.795	0.918
MobileNetV3	0.859	0.863	0.856	0.932
ViT	0.626	0.474	0.478	0.520
AF-Swin Transformer	0.981	0.979	0.980	0.999

The table 5 shows that the AF-Swin Transformer achieves an overall precision of 0.981 in grapevine leaf variety identification, which is higher than that of the Swin Transformer, MobileNetV2, MobileNetV3, and ViT by 4.4, 17, 12.2, and 35.5 percentage points, respectively. The Recall value for the AF-Swin Transformer is 0.979, exceeding that of the Swin Transformer, MobileNetV2, MobileNetV3, and ViT by 4.3, 18.1, 11.6, and 50.5 percentage points, respectively. Additionally, the AF-Swin Transformer has the highest area under the ROC curve (AUC) among the models. The Focal Loss function reduces overfitting on simple samples compared to the cross-entropy loss function, enabling the model to concentrate on misclassified samples and effectively capture complex features and patterns. The AdamW optimizer maintains model stability during training and mitigates overfitting, particularly when handling complex datasets with subtle varietal differences. Therefore, the AF-Swin Transformer proposed in this study significantly outperforms other models in identifying grape leaf varieties and demonstrates clear advantages across various evaluation metrics.

CONCLUSIONS

This study focuses on recognizing grapevine leaf varieties and proposed the AF-Swin Transformer model, which efficiently identifies different grapevine leaf varieties despite sample imbalance conditions. The main conclusions are as follows:

(1) Compared to four other deep learning models, the AF-Swin Transformer model demonstrates better performance in grapevine leaf variety identification.

(2) To address the issue of sample imbalance among different grape leaf varieties, the Swin Transformer model's loss function was replaced with the Focal Loss function. Additionally, the AdamW optimizer was introduced to improve the model's generalization capability. The results show that the AF-Swin Transformer model demonstrates good stability in identifying grape leaf varieties.

This study identified only 26 grape leaf varieties, and future research will expand to include more varieties and further optimize the model. Additionally, exploration of data augmentation techniques and transfer learning methods will be undertaken to achieve efficient recognition of various plant leaves.

ACKNOWLEDGEMENTS

The data utilized in this study was provided by the National Grape Germplasm Resource Center (Pomology Institute, Shanxi Academy of Agricultural Sciences) and funded through Shanxi Agricultural University's Technology Innovation Improvement Project (CXGC2023046) and Youth Science & Technology Innovation Project (No.2019024).

Keywords: high ground clearance weeding robot; inter-row chassis design; stability analysis; field test

ABSTRACT

This study addresses the inefficiency, high crop damage, and poor adaptability of traditional cornfield weeding machinery. A High-Clearance Inter-Row Weeding Robot Chassis was developed and tested through simulations and experiments. With a refined suspension and floating wheels, it achieves 800 mm ground clearance for dual-row weeding. Simulations show maximum chassis stresses of 124.7 MPa and 134.88 MPa under sharp turns and braking. Stability assessments indicate theoretical climb angles of 26.5° longitudinally and 35° transversely, with experimental test results of 22° and 32°, respectively. The robot operates at speeds exceeding 0.8 m/s, overcomes obstacles of up to 370 mm, and traverses trenches narrower than 350 mm or wider than 600 mm. Results confirm its stability, obstacle-crossing ability, and precision, offering a viable solution for intelligent weeding in complex fields.

摘要

本研究针对传统玉米田除草机械存在的低效率、高作物损伤率和适应性差等问题，研制并测试了一种高离地间隙的行间除草机器人底盘。通过设计浮动轮悬架结构，该底盘实现了 800 mm 的离地间隙，可用于双行除草。仿真结果表明，在急转弯和制动工况下，底盘的最大应力分别为 124.7 MPa 和 134.88 MPa。稳定性评估显示，理论纵向爬坡角为 26.5°，横向爬坡角为 35°，实际测试结果分别为 22° 和 32°。机器人运行速度大于 0.8 m/s，可跨越 370 mm 高的障碍物，并可通过宽度小于 350 mm 或大于 600 mm 的沟渠。结果表明，该机器人具备较高的稳定性、优异的越障能力和精确的作业性能，为复杂农田环境下的智能除草提供了一种可行方案。

INTRODUCTION

Weed infestation significantly impacts crop production by competing for resources such as water, nutrients, light, and space, especially during the seedling stage. Weeds hinder crop growth, reducing yields and potentially causing crop failure. While chemical weeding is effective, it poses risks to food security, and manual weeding is labor-intensive and inefficient. Intelligent weeding robots could provide a viable solution (Upadhyay et al., 2024; Yang, L. et al., 2023; Zhang, Z. et al., 2024).

Research on domestic weeding robots is mainly conducted by academic institutions. For example, Xin Li from Northeast Agricultural University designed a tracked weeding robot for paddy fields. Wei Li's team at China Agricultural University developed a tractor-drawn robot with crescent-shaped hoes and machine vision for efficient weeding. Liang'an Zhang from Anhui University of Technology created a four-legged laser weeding robot, offering better mobility and adaptability. Additionally, researchers at Nanjing Forestry University designed a robot for targeted pesticide application. However, most of these robots are limited to inter-row operation and have small payloads and short battery life (Bručienė et al., 2022; Guo, 2022; Hussain et al., 2023; Mao, 2020; Zhang L. et al., 2020).

To address labor intensity, plant damage, soil compaction, and the limitations of traditional methods, developing a high-clearance inter-row intelligent weeding robot is essential for improving precision in field operations.

MATERIALS AND METHODS

Suspension System Design

To enhance the robot's adaptability to complex operating environments and improve its off-road performance, the chassis suspension incorporates a front-and-rear cross-floating design. The two side wheels are mounted on a cross axle, and each wheel is equipped with an independent shock-absorbing damper, enabling vertical movement and rotational flexibility within a defined range around the cross axle. Furthermore, to prevent forward or backward tilting of the robot's body, the left and right cross arms are interconnected via linkages and a balance bar (Băzăvan and Ionita, 2024; Yao et al., 2023; Zhao et al., 2024). The installation configuration of the entire suspension system is presented in figure 1.

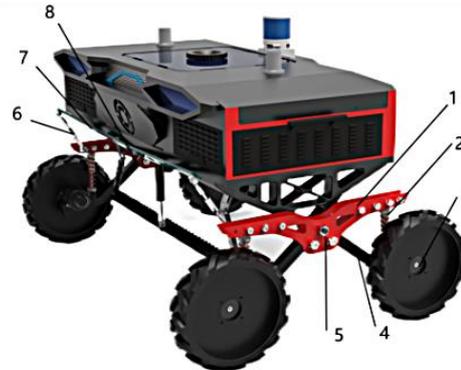

Fig. 1 – Installation position of the weeding robot suspension system

Robot Chassis Stability Analysis

In SolidWorks, appropriate materials are assigned to each component of the robot, and their mass properties are analyzed to determine the robot's overall center of mass and center of gravity (Tao, 2024). Figure 2 illustrates the robot platform in a fully loaded state. The height of the center of gravity from the ground is approximately 730 mm. As shown in figure 3, the distance from the center of gravity to the front wheel axle is 370mm, while the distance to the rear wheel axle is 443mm.

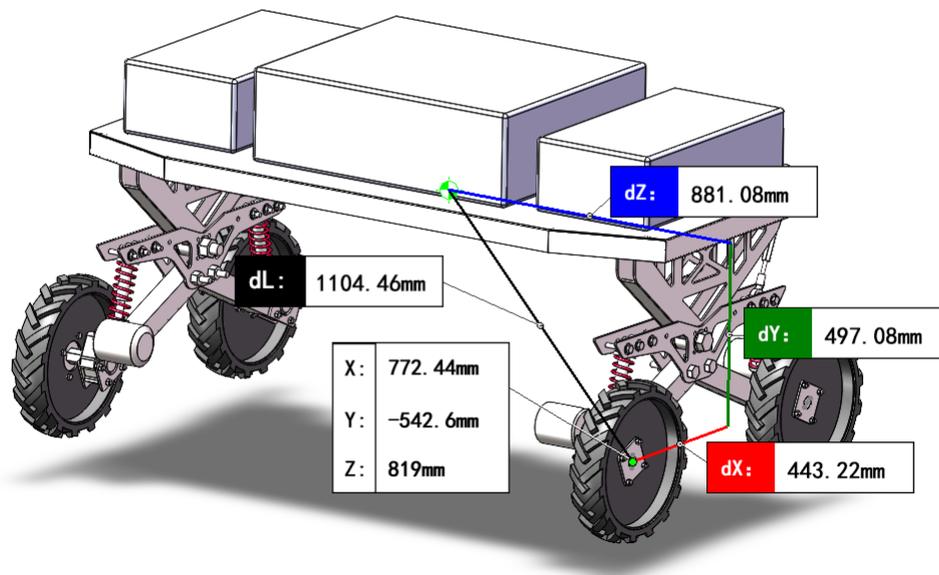

Fig. 2 – Relative position of the center of gravity and front axle under full-load conditions

Longitudinal stability analysis

When the robot operates on a field or roadway slope (moving along the slope), excessive slope angles may lead to longitudinal slip or overturning.

During actual operation, the robot's slow speed allows the effects of inertia, air resistance, and sliding resistance on its motion to be neglected (Mou et al., 2023; Zhou et al., 2024).

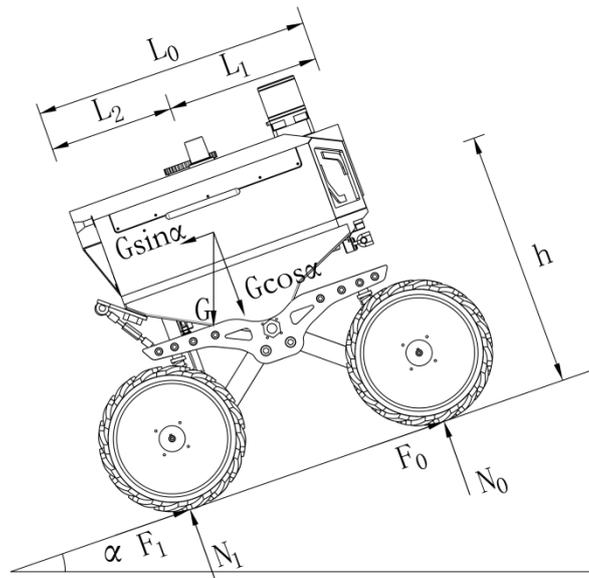

Fig. 3 – Schematic diagram of force distribution during longitudinal movement

As illustrated in figure 3, L_0 denotes the distance between the front and rear wheel axles of the high ground clearance, inter-row weeding robot; L_1 represents the distance from the robot's center of gravity to the front wheel axle center; L_2 is the distance from the center of gravity to the rear wheel axle center; G signifies the robot's weight; θ is the longitudinal slope angle; h is the height of the center of gravity; F_1 and F_2 are the tangential reaction forces at the contact points of the front and rear wheels, respectively; and N_0 and N_1 are the normal reaction forces at the contact points of the front and rear wheels, respectively.

(1) Conditions for Longitudinal Overturning

When the robot operates on a slope, the standard and tangential reaction forces acting on the front wheel are influenced by the terrain and slope angle. Longitudinal overturning occurs when these reaction forces reduce to zero ($N_0=0, F_0=0$), causing the robot to pivot around the rear wheel's contact point with the ground. The critical condition for longitudinal overturning is defined by the limit equilibrium equation at this point:

$$G \cos \alpha_1 \cdot L_2 - G \sin \alpha_1 \cdot h = 0 \tag{1}$$

Simplified, it becomes (2):

$$i_1 = \tan \alpha_1 = \frac{L_2}{h} \tag{2}$$

where:

G - Gravity acting on the robot; i_1 - longitudinal rollover stability; α_1 - slope angle, [°]; h - height of the center of gravity, [mm]; L_2 - distance from the robot's center of gravity to the rear axle along the direction of travel, [mm].

From the equation, both the height of the center of gravity and its distance from the wheel axles influence overturning stability. A greater distance between the center of gravity and the rear wheel axle increases the maximum climbing overturning angle, while a greater distance from the front wheel axle enhances the maximum descending overturning angle. When the longitudinal slope angle remains below the robot's overturning limit, the high ground clearance weeding robot maintains stability without overturning.

(2) Conditions for Longitudinal Sliding

During operation on a longitudinal slope, the robot may also experience wheel slip. The critical balance condition for longitudinal sliding is expressed as:

$$G \sin \alpha_2 - P_k \mu = 0 \tag{3}$$

where:

P_K - driving load on the robot's wheels, [N]; μ - road adhesion coefficient.

$$P_K = G \cos \alpha_2 \quad (4)$$

Substituting the values, it will result:

$$i_2 = \tan \alpha_2 = \mu \quad (5)$$

where:

i_2 - longitudinal slip stability; α_2 - critical angle for longitudinal slip, [°]; μ - adhesion coefficient.

According to the formula, longitudinal sliding stability depends on the coefficient of friction between the ground and the tires. When the slope angle is below the critical sliding angle, the robot operates normally. However, if the slope angle exceeds this critical value, the robot loses traction, leading to longitudinal sliding and reduced stability.

Transverse stability analysis

When the high ground clearance inter-row weeding robot operates transversely on a slope, a height difference may arise between its left and right sides, potentially resulting in transverse overturning or sliding. Neglecting the influences of air resistance, inertial resistance, and rolling resistance during the robot's motion, the force analysis of the robot moving transversely on a slope is illustrated in figure 4.

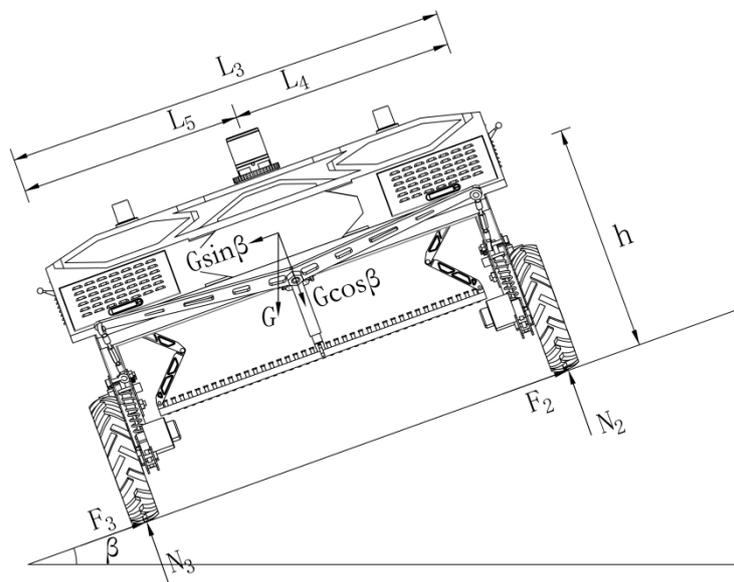

Fig. 4 - Schematic of transverse forces during travel

(1) Conditions for Transverse Overturning of the high ground clearance Inter-Row Weeding Robot

When the robot undergoes transverse overturning while traversing a slope, the standard and tangential reaction forces on the upper wheels reduce to zero. The robot will then rotate around the contact point between the lower wheel and the ground, leading to overturning. The critical balance equation for transverse overturning is as follows:

$$G \sin \beta_1 \cdot h - G \cos \beta_1 \cdot L_5 = 0 \quad (6)$$

Simplified, it becomes:

$$i_3 = \tan \beta_1 = \frac{L_5}{h} \quad (7)$$

where:

i_3 - denotes the transverse overturning stability; L_5 - represents the horizontal distance from the center of gravity to the lower wheel, [mm]; β_1 - indicates the slope angle, [°]; h - corresponds to the vertical distance from the center of gravity to the ground, [mm].

From the above equation, it is evident that both the height of the center of gravity and the horizontal distance from the center of gravity to the lower wheel significantly influence transverse overturning stability.

For a fixed track width, a lower center of gravity and a greater horizontal distance between the center of gravity and the lower wheel result in a larger critical angle for transverse overturning. Consequently, the risk of transverse overturning is reduced, thereby enhancing the robot's transverse stability.

(2) Conditions for Transverse Sliding of the high ground clearance Inter-Row Weeding Robot

In addition to the risk of overturning, transverse movement of the robot on slopes may also result in sliding. When the robot approaches the critical sliding condition, the limit equilibrium equation can be expressed as:

$$i_3 = \tan \beta_2 = \frac{L_5}{h} \tag{8}$$

Simplified, it becomes:

$$i_4 = \tan \beta_2 = \mu' \tag{9}$$

where:

i_4 - denotes transverse sliding stability; β_2 - represents the slope angle in degrees, [°]; μ' - transverse adhesion coefficient.

From this equation, it is evident that the robot can maintain normal transverse operation without slipping when the slope angle is smaller than the sliding angle.

Chassis Structural Strength Analysis

Analysis of Emergency Turning Conditions and Result Interpretation

During emergency turning maneuvers, transverse forces are exerted on the chassis frame components, generating transverse loads (Dharma et al., 2024; Dudescu et al., 2023; Kiran, 2024; Deulgaonkar et al., 2022). Given the robot's relatively low maximum speed, the centrifugal acceleration was set to 0.2g, based on its minimum turning radius and maximum operating speed. This results in transverse inertial forces acting on the chassis frame and its components. The load and constraints under steady-state driving conditions remain unchanged, with the inertial force applied in the direction of centrifugal force. The force magnitude is calculated as $F=0.2g$, where M represents the combined mass of the battery and water tank.

The analysis results for the emergency turning condition are shown in figure 5. The maximum stress of 124.7 MPa occurs at the contact point between the main beam of the platform's upper plate frame and the vertical side plate. The deformation contour map indicates a maximum deformation of 1.71 mm, which satisfies the strength requirements.

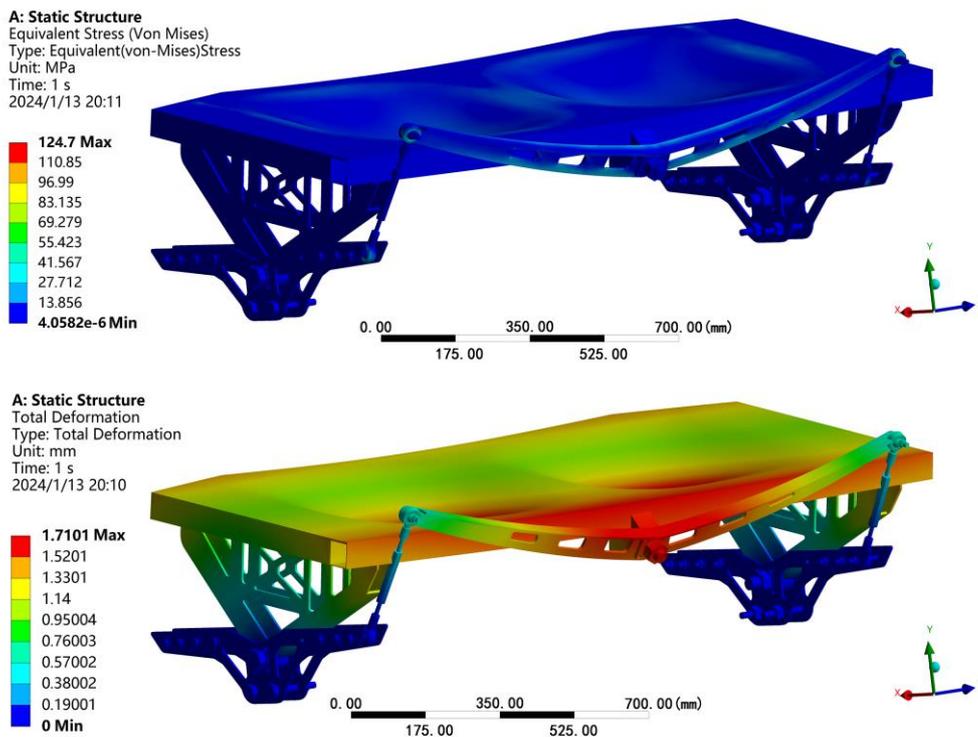

Fig. 5 - Analysis results of emergency turning conditions

Analysis of Emergency Braking Conditions and Result Interpretation

During field operations, the high ground clearance Inter-Row Weeding Robot may undergo emergency braking or reverse operation. In such scenarios, the chassis frame experiences significant inertial loads, acting in the direction opposite to the motion. The braking acceleration was estimated based on the robot's maximum speed, with the load and constraints under steady-state driving conditions remaining unchanged. The inertial force, applied to the upper components, acts opposite to the direction of motion. The braking acceleration was set to $0.4g$, and the inertial force magnitude was calculated as $F=0.4g$, where M represents the combined mass of the battery and water tank.

The analysis results for the emergency braking condition are shown in figure 6. The maximum stress of 134.88 MPa occurs at the connection between the tie rod and the middle balance connecting rod. The deformation contour map shows a maximum deformation of 4.52 mm on the upper plate of the chassis, primarily attributed to the large 125 l pesticide tank mounted on the upper side.

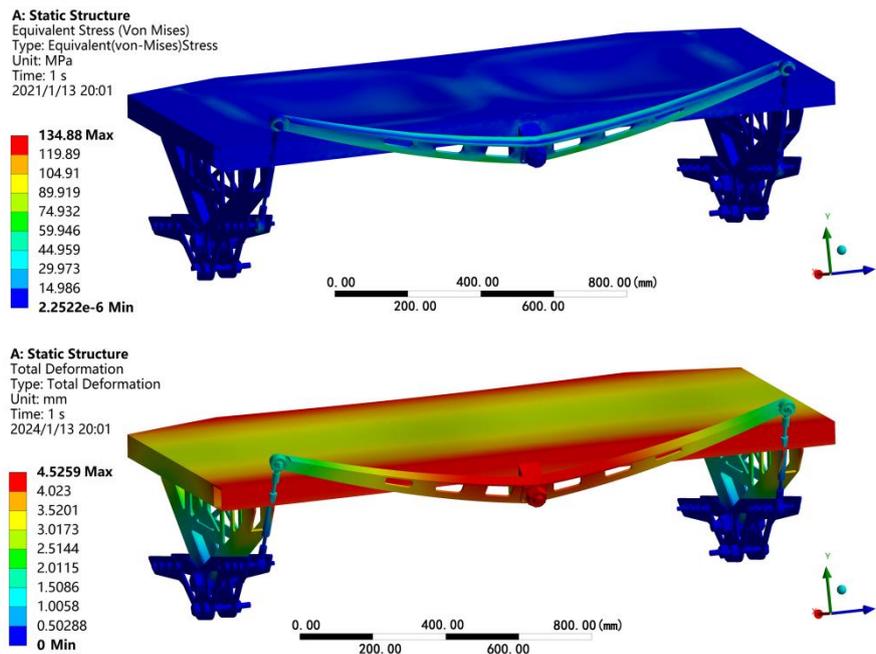

Fig. 6 - Analysis results of braking conditions

RESULTS

Weeding Robot Speed Test

Based on the theoretical design specifications, the high ground clearance Inter-row Weeding Robot achieves a speed exceeding 0.8 m/s on flat terrain. To validate whether the robot meets the theoretical speed requirements, a 50-meter test section on a flat farm road was selected. The robot's forward and reverse speeds were measured at both 50% and 100% throttle settings. The detailed testing procedure is illustrated in figure 7 (Cen, 2023; Jiang et al., 2023; Yang Z., 2023).

Fig. 7 - Test diagram of the weeding robot's deviation rate

Table 1

Test Results of the Weeding Robot's Speed on Field Terrain								
Test number	Forward				Reverse			
	50% Throttle		100% Throttle		50% Throttle		100% Throttle	
	Time of the experiment (s)	Speed (m/s)	Time of the experiment (s)	Speed (m/s)	Time of the experiment (s)	Speed (m/s)	Time of the experiment (s)	Speed (m/s)
1	84.3	0.593	56.8	0.880	85.2	0.587	55.4	0.923
2	83.5	0.600	57.4	0.871	84.8	0.590	56.8	0.880
3	83.8	0.597	55.1	0.907	86.9	0.575	56.4	0.887
Average	83.87	0.596	56.4	0.887	85.63	0.584	56.2	0.890

As presented in Table 1, the average forward speed at 50% throttle is 0.596 m/s, while the reverse speed is 0.584 m/s. At full throttle (100%), the average forward and reverse speeds increase to 0.887 m/s and 0.890 m/s, respectively. These results indicate that the weeding robot's operational speed on field roads complies with the design specifications.

Weeding Robot Obstacle-Crossing Performance Test

The high ground clearance Inter-Row Weeding Robot may encounter obstacles such as potholes or uneven terrain during field operations. To address these challenges, the robot is equipped with a specialized suspension system featuring independent suspension on all four wheels and cross arms on both sides. The four-wheel drive configuration ensures continuous ground contact for all wheels during obstacle traversal. To validate the effectiveness of this mechanism, the robot's obstacle-crossing performance must be experimentally evaluated to determine its maximum obstacle-crossing capacity.

(1) Single Wheel Vertical Obstacle Test

This test simulates scenarios where the robot encounters sudden obstacles, such as rocks or raised surfaces, as well as more considerable obstacles during regular operation. A brick is utilized to replicate these obstacles, with each brick having a thickness of approximately 50 mm. By stacking multiple bricks, obstacles of varying heights are simulated. The robot is gradually driven toward the vertical obstacle and attempts to traverse it. The height of the obstacle is incrementally increased until the chassis is no longer capable of crossing. The results are documented in Table 2.

Table 2

Single Wheel Vertical Obstacle Test		
Test number	Obstacle height [mm]	Crossing Result
1	53	Passed
2	106	Passed
3	159	Passed
4	212	Passed
5	265	Passed
6	318	Passed
7	371	Passed
8	424	Failed

Fig. 8 - Aspects from the experiment of crossing vertical obstacles with a single wheel of the weeding robot

(2) Single Wheel Trench Crossing Test

This experiment simulates scenarios in which the weeding robot encounters depressions or trenches in the field. The study evaluates the robot's trench-crossing capability by testing its performance on artificially dug trenches of varying widths. The trench width is incrementally increased until the robot fails to cross, and the corresponding data are recorded in Table 3.

Table 3

Single-Wheel Trench Crossing Experiment		
Test number	Trench width [mm]	Through the effect
1	200	Passed
2	250	Passed
3	300	Passed
4	350	Passed
5	400	Failed
6	450	Failed
7	500	Failed
8	550	Failed
9	600	Passed
10	650	Passed

Fig. 9 - Aspects from the experiment of the Weeding Robot's single-wheel trench crossing

The robot is capable of surmounting vertical obstacles with a maximum height of 371 mm. However, its trench-crossing performance varies depending on trench width: it can effectively traverse trenches narrower than 350 mm or wider than 600 mm. When the trench width is between 400 mm and 550 mm, the ditch width is close to the wheel diameter. When the wheels come into contact with the ditch walls, they are prone to slipping, resulting in temporary entrapment.

Experimental results demonstrate that the suspension system significantly improves the robot's obstacle-crossing capabilities by ensuring continuous ground contact for all four wheels during the traversal process.

Stability Test of the Chassis Platform of the Weeding Robot

During field operations, the high-ground clearance weeding robot encounters sloped terrain, an evaluation of its stability to determine the maximum operational angles and suitable working environments being necessary. To replicate real-world conditions, the robot was positioned on a slope board at various incline angles. The water tank was filled, and additional weights were applied to the battery compartment to simulate the actual load distribution during operation. The robot's tipping and slipping thresholds were recorded under these conditions, as illustrated in figure 10.

Fig. 10 - Stability test of the Weeding Robot

For the high-clearance Inter-Row Weeding Robot, the position of the center of gravity is shown in figure 2. After calculation, $i_1=0.602$, and the friction coefficient $\mu=0.5$. Thus, it is determined that $i_1 \geq i_2$. This indicates that when the robot travels on a slope, sliding occurs before overturning. The critical climbing angle is 26.5° . By calculation, $i_3=1.14$, and the typical dynamic friction coefficient is 0.71 . Thus, it is determined that $i_3 \geq i_4$. This indicates that sliding occurs first when the robot moves laterally on a slope, and the maximum operating angle is 35° .

The stability test results, summarized in Table 4, reveal that the maximum slope climb angle for longitudinal movement is 22° , while the robot can achieve up to 32° for transverse (horizontal) movement. A discrepancy exists between the measured values and theoretical calculations, primarily attributed to differences between the slope board surface and actual field conditions. Furthermore, theoretical analyses assume ideal conditions, such as rigid robot components and constant friction coefficients, which are seldom encountered in practical scenarios. As indicated in Table 4, the robot demonstrates a higher maximum climb angle during transverse (horizontal) movement compared to vertical (uphill) movement, highlighting its enhanced stability and reduced likelihood of slipping during field operations.

Table 4

Test Item	Stability Test Results		Instability Type
	Theoretical Value ($^\circ$)	Actual Value ($^\circ$)	
Longitudinal Climb Angle	26.5	22	Slipping
Transverse Climb Angle	35	32	Slipping

CONCLUSIONS

1. A high-clearance, floating-wheel weeding robot was developed for weed control in maize seedling stages under complex field conditions. The robot features a floating suspension, electric drive, and differential steering, with a wheelbase of 1,800 mm. It can cover two rows of crops in a single pass. Static analysis using Ansys revealed maximum stress values of 124.7 MPa during braking and 134.88 MPa during turning, with corresponding deformations of 1.71 mm and 4.52 mm. These results confirm that the chassis meets the required specifications.

2. A stability analysis was conducted on the high-ground-clearance cross-row floating wheel weeding robot chassis system. The theoretical maximum climb angles for longitudinal and transverse movement on slopes were determined to be 26.5° and 35° , respectively.

3. Field experiments were conducted to evaluate the chassis of the weeding robot. The results demonstrated an average field travel speed exceeding 0.8 m/s. The robot could overcome vertical obstacles up to 371 mm in height on a single wheel. Additionally, it successfully traversed ditches with widths below 350 mm and above 600 mm. Stability tests revealed maximum climb angles of 22° for longitudinal movement and 32° for transverse movement.

Keywords: SWT (small wind turbine), renewable energy, residential small wind turbine, Darrieus vs Savonius

ABSTRACT

This paper provides an overview of the recent developments on small wind turbines in terms of their distinguishing characteristics, experimental research and structural and operational development of small vertical axis wind turbines. Emphasizing their decentralized generation capability, cost savings, and sustainability, the first part discusses the characteristics of small wind turbines. Then the review paper goes through a synthesis process of experimental research work on small wind turbines to evaluate their performance, technological advancements evolved in line with actual world problems encountered. The paper also describes what was achieved by way of small vertical-axis wind turbine design, material problems, and aerodynamic theories that control their operation. Finally, the study provides a review of experimental research studies that were conducted on the performance of small vertical axis wind turbines. The study also shows the functioning methods of small vertical axis wind turbines examined by means of experimental research, which investigate their efficiency under different environmental circumstances and where they may be optimized. Emphasizing the interdependence between theory and practice, this paper examines answers wind turbine researchers have already looked at. A small part of international research data seeking to improve the efficiency and design of small wind turbines is collated here.

REZUMAT

Această lucrare oferă o imagine de ansamblu asupra dezvoltărilor recente ale turbinelor eoliene mici în ceea ce privește caracteristicile lor distinctive, cercetarea experimentală și dezvoltarea structurală și operațională a turbinelor eoliene mici cu ax vertical. Subliniind capacitatea lor de generare descentralizată, costuri și durabilitatea, în prima parte a lucrării sunt prezentate caracteristicile turbinelor eoliene mici. Analiza trece printr-un proces de sinteză a lucrărilor de cercetare experimentală asupra turbinelor eoliene mici pentru a evalua performanța acestora, progresele tehnologice evoluând în concordanță cu problemele reale întâlnite în timpul funcționării turbinelor. Lucrarea descrie, de asemenea, ceea ce s-a realizat prin proiectarea unei turbine eoliene mică cu ax vertical, problemele legate de selecția materialelor și teoriile aerodinamice care controlează funcționarea acestora. În cele din urmă, studiul oferă o trecere în revistă a studiilor experimentale de cercetare care au fost efectuate asupra performanței turbinelor eoliene cu ax vertical. Studiul arată, de asemenea, metodele de funcționare ale turbinelor eoliene cu ax vertical examinate prin cercetări experimentale, care investighează eficiența acestora în diferite circumstanțe de mediu și unde pot fi optimizate. Subliniind interdependența dintre teorie și practică, această lucrare examinează soluțiile existente la care cercetătorii de turbine eoliene au ajuns deja. O mică parte din datele cercetării internaționale care încearcă să îmbunătățească eficiența și proiectarea turbinelor eoliene mici este inclusă în lucrare.

INTRODUCTION

Wind power is currently among the most promising and sustainable sources of energy today. Wind turbines are essential in tapping into the use of natural resources to generate energy with the growing need for renewable energy sources. The technology in the devices is able to convert wind energy into electrical energy and present a clean source compared to fossil fuels, according to Brown et al. (Brown et al., 2015). Apart from reducing the use of non-renewable energy sources and greenhouse gas generation, wind power stands for environmental sustainability.

The main function of a wind turbine is to harness the energy of the wind and transfer it into the form of motion and afterwards into mechanical form and finally into electrical form. The principle on which it works is simple: the turbine's blades are pushed by the wind and rotated to create motion, as Ning et al. explained in their paper (Ning et al., 2014). Figure 1 shows the key components of a horizontal-axis wind turbine. The main components are the tower, nacelle, rotor, generator, and the blades. In the rotor's core is fitted the generator, which functions because the turbine's blades are spinning around it. The generated electrical power from the generator can be utilized on-site or transmitted through the power network.

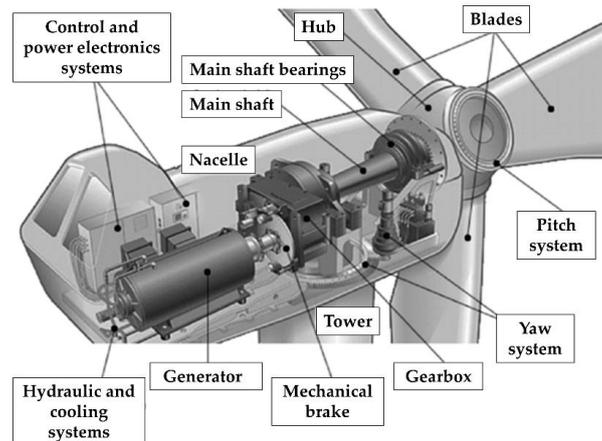

Fig. 1 - Diagram of key components of a wind turbine (Civera et al., 2022)

Designed to resemble the wings of an airplane in most instances, the blades capture the energy in the air (wind). The blades, along with the hub they are attached to, make up the rotor. The nacelle, the housing atop the tower, contains the generator and gearbox among the main components. The tower positions the turbine to elevated levels where the speed of the air is stronger and safer. The mechanical energy has to be transferred to electrical energy by the generator, as Enevoldsen et al. stated in their paper regarding the study of an extensive dataset consisting of 35 years of multi-megawatt wind turbine inventions (Enevoldsen et al., 2019). The wind delivers mechanical rotation energy in the form of spinning the blades around the rotor. A gear alters the speed in rotation after the mechanical energy is transferred to it via a shaft. The rotation is amplified to a functional speed with the aim of producing power. The mechanical energy is transferred from the gear to the generator, where electromagnetic induction is utilized to transform it into electrical energy. An interesting study belongs to Xiaohui et al., who presented in their paper an algorithm for calculating the magnetic transient effects in a wind turbine tower struck by lightning (Xiaohui et al., 2010).

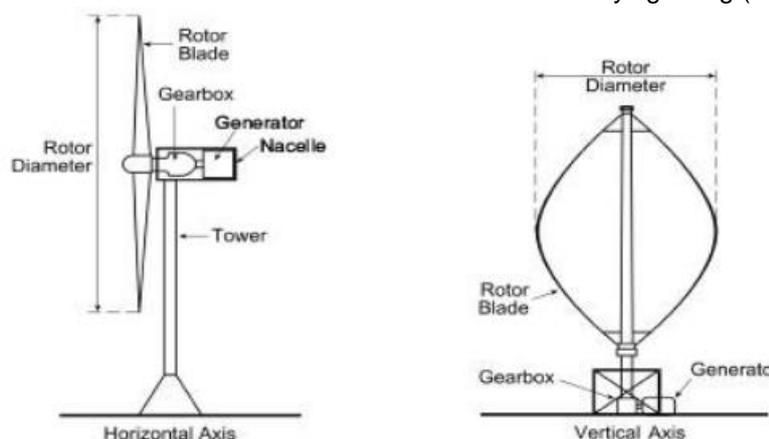

Fig. 2 - Horizontal axis wind turbine vs. vertical axis wind turbine (Salem et al., 2016)

HAWT (horizontal axis wind turbines) and VAWT (vertical axis wind turbines) are the two major types of wind turbines. In figure 2 are presented the resemblances between these two types. Although both are utilized to generate electricity from wind energy, they have different design, efficiencies, and applications. Eriksson et al. presented in their paper a comparative study of three wind turbines: a horizontal axis wind turbine and two vertical axis wind turbines; the Darrieus turbine and the H-rotor. Their study includes aspects like structural dynamics, control systems, maintenance, manufacturing and electrical equipment (Eriksson et al., 2008).

Just like propeller blades, the blades in the most prevalent type of turbine are mounted on a horizontal axis. Such turbines are mounted on tall towers in order to avail themselves of the stronger winds higher up in the air. They are suitable for onshore and offshore use due to high efficiency in high winds. However, they require a mechanism to alter the direction of the turbine so the blades may face the direction in which the wind blows, as also Elkodama et al. stated in their paper (Elkodama et al., 2023). The blades on vertical-axis wind turbines, on the other hand, rotate on a vertical axis. Such turbines are suitable for regions where the wind flows are turbulent or irregular because they neither require turning and can harvest the wind from any direction as Khammas et al. suggest in their paper (Khammas et al., 2015). Due to the fact that VAWTs are smaller and compact in nature, they may be utilized where there is limited space in urban areas or even within residential areas. Although they provide improved quietness and flexibility compared to HAWTs, they typically exhibit lower efficiency. They are utilized in ordinary-scale energy use; however, in the best conditions in terms of winds, they are less efficient in comparison to ordinary-scale large-size HAWTs.

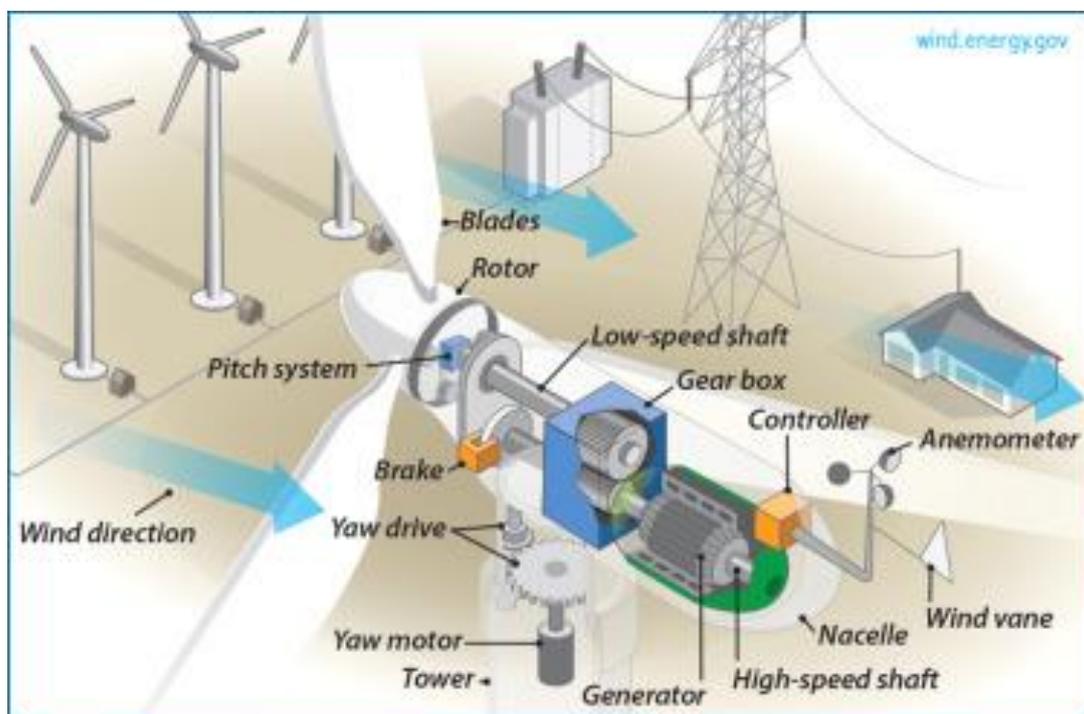

Fig. 3 - The process of generating energy through wind turbines
(Junginger et al., 2020)

There are several similarities and dissimilarities between the two categories, but the energy generation process is basically the same (as Figure 3 shows). HAWTs are efficient in energy conversion in regions with consistent and powerful winds. They are the turbines preferred for use in large-scale wind farms due to their long blades, which enable them to capture more energy (Adams et al., 2011). They would be difficult to service but are prone to wear and tear in extreme weather conditions. A very interesting study on the structural health monitoring of a HAWT was conducted by Adams et al., focusing on a Micon 65/13 horizontal-axis wind turbine.

Although VAWTs are less efficient in regions with powerful winds, they are suitable for use in residential or urban regions because they are compact and better suited to handle changes in the direction of the wind.

Having major components closer to the ground, they are easier to service. Kragten A. in his report presents the main advantages and disadvantages of a Darrieus wind turbine rotor and concludes that because of many disadvantages and only a few advantages, Darrieus is less efficient than a HAWT (Kragten A., 2004), and because of that, this type of wind turbine is not suitable for use in large-scale power production because they have low efficiency in energy conversion.

The graphic below depicts a categorization of the primary types of wind turbines based on their power coefficient at various tip speeds. Currently, the horizontal-axis wind turbine and vertical-axis wind turbine Darrieus type are more typical and widely employed on a large scale.

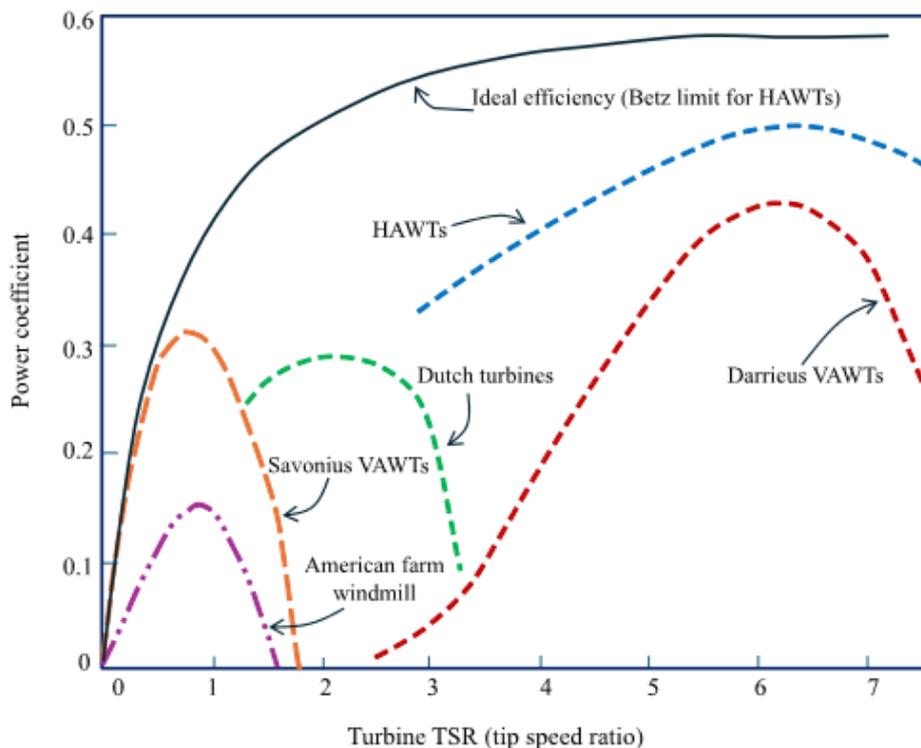

Fig. 4 - Comparison of HAWT and VAWT efficiency
(Abdolahifar et al., 2024)

Wind turbine technology in the last decades has seen tremendous improvement with advances in efficiency, design, and material technology. Wind turbine blades today are longer than 100 meters and much larger in size relative to the last generation (Winters et al., 2018). Low-speed winds are not a problem for such large-scale machines; now even at low wind speeds they produce a great amount of power. Apart from improving the durability of the turbine, advances in material technology in the form of light but strong composite material have reduced production costs. It is well known that the driving force behind the renewable energy revolution is represented by the wind farms. Figure 5 shows a wind farm where the horizontal-axis wind turbines are installed to replace fossil fuels with emissions-free electricity.

Advances in technology in offshore in the form of floating turbines allow it to be installed in the deep seas where the traditional fixed-based ones are no longer installable. Wu et al. present in their paper the state-of-the-art geotechnical and structural issues that affect offshore wind turbine foundations (Wu et al., 2019). The floating turbine expands the ability to produce power in areas previously inaccessible. Further, with the addition of smart grid technology, the wind turbine operates in the larger power network at optimal performance and enhances distribution and overall reliability in the network, aspects seen by Johnson et al. even from 1976 (Johnson et al., 1976). In Figure 6 three type of offshore floating wind turbine foundations are presented.

Fig. 5 - Wind farm (<https://drawdown.org/solutions/onshore-wind-turbines>)

Although they are promising, wind turbines are also detrimental. Possibly one of the greatest detriments is the fact that the wind is not always available. Wind speed is inconsistent, and there could be some locations where there are stretches of little or no wind at all, which generates intermittent energy generation. *Szlivka et al., (2017)*, presents the advantages and disadvantages of different types of wind turbines and their use in urban environments, with an emphasis on small wind energy systems that generate under 100 kW.

Storage facilities for the surplus energy generated during windy days, such as batteries or pumped hydro storage, are on the agenda as solutions. Environmental impact brought about by wind turbines is the other issue. They are thought to be cleaner than fossil fuels but can also impact wildlife in the immediate area, particularly birds and bats that may become entangled in the spinning blades. *Krijgsveld et al.* evaluated the collision rate of birds with contemporary, big 1.65 MW wind turbines for three months in fall and winter. They concluded that the collision rate was 0.08 birds per turbine per day on average (range 0.05-0.19) (*Krijgsveld et al., 2009*). The construction and upkeep of wind farms themselves also impact the immediate environments.

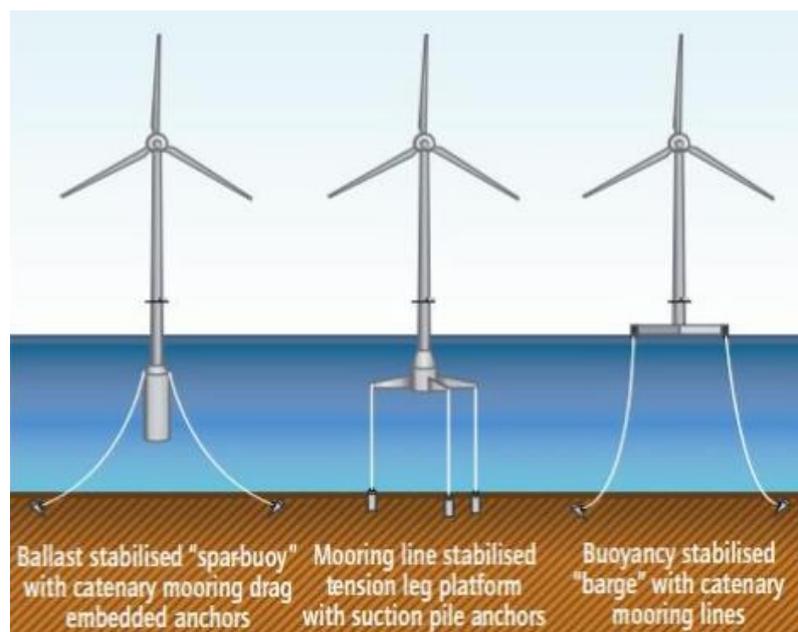

Fig. 6 - Offshore floating wind turbine
(*Wiser et al., 2011*)

The sound generated by the big wind turbines and their aesthetic effect are other issues. In his paper, Liu, (2017), reviews the aerodynamic and mechanical noise mechanisms of wind turbines, as well as de-noising methods used in health condition monitoring. The study concludes that new time-frequency analysis techniques in signal processing are still needed to effectively de-noise signals based on the unique characteristics of wind turbines. There has been opposition to the sight of wind farms in some areas, and the sound generated by the turbine blades can be bothersome to residents in the vicinity. While such concerns are contentious, technological advancements have made the noise levels less.

The installation of wind turbines can also involve high upfront costs, especially for large commercial farms. Wind turbines generally have low maintenance and operational costs; however, high initial costs in certain locations may pose a barrier to deployment. Sieros et al. investigated the cost-effectiveness of wind turbines with rotor diameters up to 250 m and hub heights over 150 m. Their conclusion was that the total optimization issue, including all additional expenses, had optimal solutions on a bigger scale (Sieros et al., 2012). Figure 7 depicts the cost history over 12 years and clearly shows a decline in cost per kW.

However, the future of wind turbines is promising. As research and development continue, wind turbines are increasingly economical, efficient, and environmental. Wind energy, along with other renewable sources such as solar energy, is expected to be a core component in global efforts to reduce dependence on fossil fuels and mitigate the effects of global warming. Badwawi et al., (2015), published a comprehensive review paper that summarizes major research on optimal sizing design, power electronics topologies, and control strategies. The paper also presents the state of the art for both grid-connected and stand-alone hybrid solar and wind energy systems.

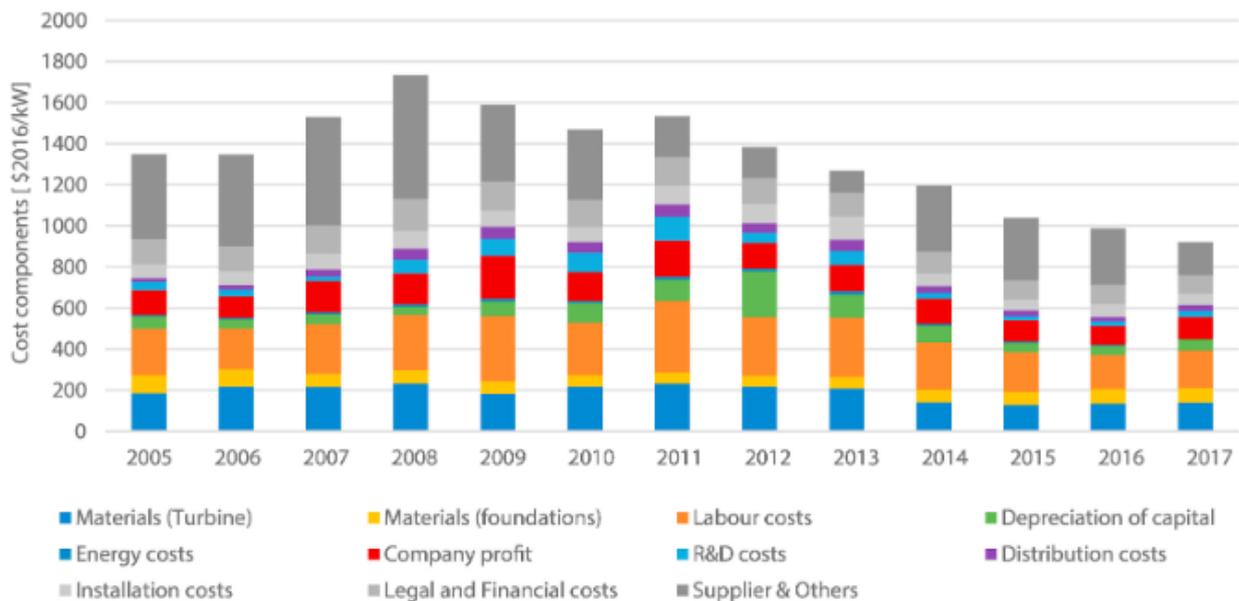

Fig. 7 - Cost comparison (initial investment vs. operating cost) (Elia et al., 2020)

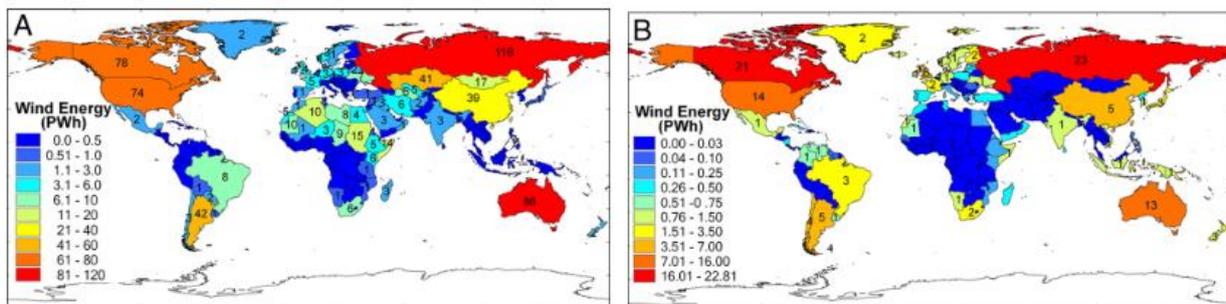

Fig. 8 - Global wind energy potential (A - Onshore. B - Offshore.) (Lu et al., 2023)

Wind turbines are among the most significant technologies supporting the transition from non-renewable to sustainable energy. As the ability to harness wind energy is a cornerstone of the renewable energy portfolio, both horizontal-axis and vertical-axis wind turbines are utilized, each offering distinct advantages. With ongoing technological advancements, wind turbines are expected to become more efficient and serve as a critical foundation in global efforts to mitigate climate change. Despite persistent challenges, such as the intermittency of wind power and its environmental impacts, the continued development of wind energy technology is projected to secure wind turbines a dominant role in clean energy production for the foreseeable future. However, location remains a crucial factor for the effective operation of wind energy systems. Figure 8 illustrates the global zones suitable for wind energy development, including both onshore and offshore applications.

Small wind turbines are increasingly being installed on farms as an inexpensive, clean source of energy. Farmers can reduce their consumption of grid electricity and decrease their energy bill by powering homes with electricity produced from a clean source. Small wind turbines have the capability of offering a stand-alone power source to drive farm lighting, irrigation (Figure 9), and machinery in rural or off-grid settings.

By harnessing wind power, an environmentally friendly and zero-hazardous pollutant-emitting source of power, small wind turbines conserve running expenses while promoting environmental efficiency. This serves to reduce the carbon footprint of farming activities. Small wind turbines can also be coupled with other renewable power systems, such as solar power, to make hybrid systems that can offer a round-the-clock power supply.

Small wind turbines are inexpensive since farmers themselves also get subsidized or encouraged by the government for using renewable technology. Apart from fulfilling the sector's energy requirement, farm wind power is helping to promote larger efforts to green the agricultural sector and mitigate the effects of climate change.

INTRODUCTION ON THE SPECIFICITY OF SMALL WIND TURBINES

Medium and small wind generators have attracted much excitement for application as an alternative energy source for small-scale off-grid scenarios. Small wind turbines convert wind into electricity as one step in achieving a more sustainable way of living: providing cleaner alternatives for traditional energy. An overview of challenges, solutions, and future needs in the wind energy domain is presented by Wallenius et al. in their paper (*Wallenius et al., 2016*). Small wind energy generation also offers numerous pros and few cons, in spite of becoming even more useful as concerns about climate change and energy security grow.

They all have that common principle: converting wind energy into mechanical energy, even at very small sizes. According to Bashir, the wind turbine is a promising technology because of its enormous energy potential, environmental friendliness, and minimal maintenance operation when compared to traditional energy generation, and future study on wind turbines should focus on the wind turbines' recycling capacity (Bashir, 2022).

As it is shown in figure 10, the wind turbines consist of three main parts: generator, rotor blades, and supporting structure (tower). The speed of the rotation of the blades is caught by the generator shaft. Then, through electromagnetic induction, it gets transformed into usable energy for homes or companies.

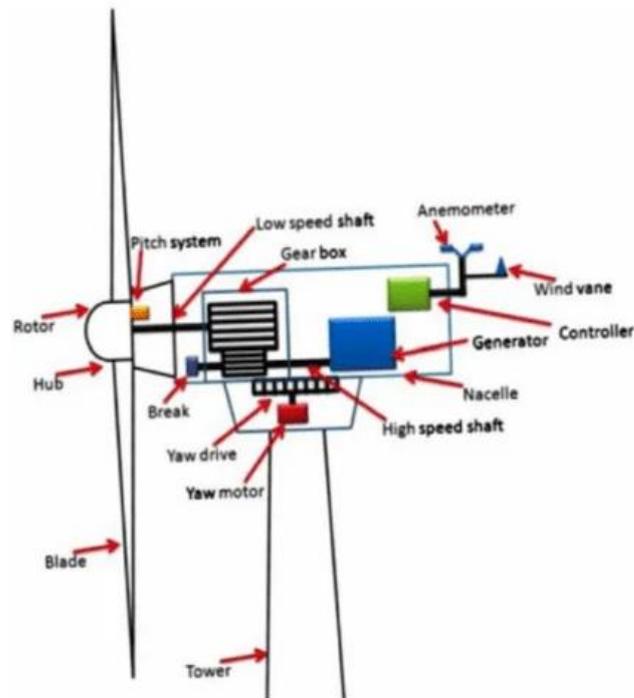

Fig. 10 - Basic components of a wind turbine

(<https://electricalsphere.com/wind-energy-basic-component-and-site-selection>)

Small-scale wind turbines are primarily classified, like all types of wind turbines, according to their axis of rotation, i.e., vertical-axis wind turbines (VAWTs) or horizontal-axis wind turbines (HAWTs). Typically, large installations as well as small ones most often go in for horizontal-axis wind turbines (HAWTs). Rotor blades of these wind turbines rotate in the horizontal plane, much like a normal aircraft propeller. The horizontal-axis wind turbines are specifically more effective in areas where the direction of the wind is relatively constant and predictable, such as open rural areas with ample space and high-speed wind, largely from farmland or coastal locations, as Kabak et al. specified in their paper, where an algorithm in order to determine the suitable regions where the wind turbines would be located was used (Kabak et al., 2022).

Vertical-axis wind turbines (VAWTs) can be more effective at collecting wind because they rotate their blades around a vertical axis and can thus take winds from any direction. Due to buildings and obstacles on the ground level, wind directions can be random at times in an urban setting, which is why such applications are suitable for VAWTs. Alqahtani, (2024), published an intriguing article in which the primary goal was to close the gap in process parameter optimization required to transform wind energy wake from highway traffic into electrical energy using vertical-axis wind turbines. VAWTs are not known to be as popular as HAWTs. However, they tend to be a lot more silent, smaller, and thus preferred for residential endeavors.

Both types of turbines have varied benefits based on the region and application, although they function on the same principle. Small wind turbines have a wide availability of application areas due to their adaptation and can be used to offer renewable energy in remote rural areas where small businesses and private homes can depend on it as a reliable alternative to normal energy sources. To back up this claim, Battisti et al. produced research in which they evaluated the effectiveness of small wind turbines in urban settings (Battisti et al., 2018). As a consequence, a new constraint for estimating the quantity of energy that a wind turbine will create in a certain location was proposed.

In a good wind resource area, a small wind turbine can provide a sufficient amount of electricity for the energy needs of a typical home. Normally, these systems are combined with solar panels to create a hybrid energy solution that optimizes energy production during both day and night. Hence, even if the sun or the wind doesn't provide the required power, homes can still be powered because of high power output resulting from both sources being harnessed. Small wind turbines will support the sustainable energy supply for remote or rural sites where grid connection is impossible or very expensive. The results of using a small wind turbine system to build environment lamps to comply with the green building approach can be found in Ozgener, (2006).

Besides, it can be proved beneficial for small businesses, particularly when they are stably and remotely located. For example, wind turbines can be installed at farms and small manufacturing sites to share the burden of energy expenses. It will help them reduce their dependency upon fossil fuels, which is particularly central since energy is costly and unreliable in certain areas. A review paper summarizing the different studies that have been carried out on the application of SWT technology in the built environment to study the inflowing wind characteristics, their performance, and to detect the knowledge gap, and also exploring the degree to which the international design standard of SWTs, IEC 41400-2, was written by Anup et al. (Anup et al., 2019).

Small wind turbines are the perfect choice for remote places where it is extremely expensive to have electricity lines installed. In places that are not part of the national power grid, a small wind turbine can be a power lifeline (Singh et al., 2013). Consider isolated villages, research facilities, homes, and even rescue missions after natural disasters—these all can use wind power to create electricity. For example, wind power can provide the energy required for daily living in coastal towns or mountain resorts or even remote research stations in distant corners of the Globe. By integrating energy storage devices with wind energy, isolated systems can be developed to ensure energy security in areas that would otherwise rely on costly and unreliable fuel supplies (Simic et al., 2013). A few examples of small wind turbines that are easily incorporated into urban settings because of their distinctive shapes and low noise pollution are shown in Figure 11.

Fig. 11 - Example of a residential small wind turbine installation

(<https://www.linkedin.com/pulse/does-small-wind-turbine-your-home-increase-thomas-vogel>)

A small vertical-axis wind turbine captures the wind energy naturally and can hence decrease reliance on fossil fuels. These types are essential for the reduction in carbon footprint and stopping climate change. The production of wind turbines as well as their installation is very low in carbon when compared to those emissions that have been produced in the very long term in coal, oil, or gas power plants. However, as Lenzen et al. stated in their paper, despite the fact that the construction and technology of most current wind turbines are rather consistent throughout a wide range of power ratings, existing life-cycle assessments of their energy and CO₂ intensity indicate significant variances (Lenzen et al., 2002).

Ultimately, reducing energy costs is one of the most attractive benefits of small wind turbines, although these wind turbine types, after being installed, require less maintenance and operation. The construction of residential systems can be quite costly; however, in the long run, the costs will be offset with savings on energy bills. For example, initial investment can be supported by subsidies, tax credits, and government incentives, thus making wind energy more affordable for consumers. The Global Framework for Climate Services (GFCS) is leading global initiatives to enhance the quality, availability, and application of climate data and forecasts to support renewable energy producers in decision-making processes (Terrado et al., 2017). Many households and companies will hence generate more of their own power, thereby decreasing their dependence on the utility system, and therefore saving up a considerable amount of money. Small wind turbines are expected to last for decades with very little maintenance, usually sporadic maintenance required by most systems, and an expected operating time of 20 to 30 years. Based on the power loss criterion of wind turbines, Hu et al., (2025), proposed a yaw system control strategy aimed at improving power output and extending turbine lifespan. When calculating the wind power loss threshold and delay time threshold, the proposed control strategy in their research uses historical data from the wind turbine. From this, they can directly control wind power loss and enhance wind turbine output.

Unlike solar panels, which might need some component repairs or routine cleaning, wind turbines rarely require frequent maintenance. Basic maintenance includes ensuring that the turbine remains aligned with the wind, noting the inspection of the electrical part of the system, as well as ensuring that the blades are clear of defects. Many small turbines tend to be built to withstand tormenting weather conditions, e.g., high winds, rain, and snow; hence, such turbines are strong and very suitable for many settings (Gonçalves et al., 2021). As Gonçalves et al. reported in their study, the highest values of wind energy output occurred on stormy days, implying that these high-impact storms had a favorable influence on wind energy production.

Small wind turbines indeed have their share of challenges, but they also come with their benefits. While they can prove to be cost-effective over time, a small wind turbine can be costly to construct at present, such as in the case of using a wind turbine system that also includes all mounting poles and electrical connections. Such systems are often financially out of reach for most businesses and homes. The most significant challenges are believed to be linked with social acceptance, transportation and installation logistics, and medium-term sustainability of the economic and political backing of wind energy as per McKenna et al. study (McKenna et al., 2016). In certain locations, however, these costs can be reduced through various incentives, tax credits, and rebates that make wind energy much more cost-effective.

The power output of small wind turbines has further dependence on wind speed at the site. Wind speed and direction are also the most important and of prime importance in determining the productivity of a turbine. In locations where there are very limited wind resources, the turbine will not generate enough power to make the project worthwhile. For this reason, the local wind conditions must be assessed prior to making a decision to install a turbine, as Mangos specifies in his doctoral dissertation (Mangos, 2024).

Despite all the advantages, the noise pollution is still created when it operates, especially in larger systems, though new wind turbines are typically quieter than their predecessors. People or businesses within residential areas may be disturbed by this. There are also visual issues, as some people may not prefer a wind turbine on their property because they do not want the appearance of it. Extensive research on the issues of noise pollution linked to the use of wind turbines was undertaken by Ruggiero et al. The paper concerns a predictive software program and experimental frequency spectrum and time history acoustic noise generated by wind turbines (Ruggiero et al., 2015).

A promising alternative for renewable energy production, small wind turbines are energy independent, cost-effective, and eco-friendly. With the improving technology, these systems are quieter, more efficient, and faster to install. The ability of small wind turbines to provide renewable power over a wide range of uses, from household use at home to rural regions, cannot be overstressed, even in the presence of issues such as installation costs and site location, aspects that are presented in Fingersh et al.'s report (Fingersh et al., 2006). Small wind turbines play a significant role in the global energy transformation as the world seeks cleaner alternatives to fossil fuels in creating a more sustainable and robust energy future.

SYNTHESIS OF EXPERIMENTAL RESEARCH ON SMALL WIND TURBINES

Small wind turbines (SWT) are very important units for producing decentralized renewable energy sources and are sustainable opportunities for rural and away-from-the-grid communities. Unlike the large turbine designs, these small wind turbines are designed to service small businesses and applications that are domestic and agricultural in nature, where the critical factors are reliability and efficiency (Glasberg et al.,

2024). Experimental testing is crucial to render these machines safe, long-lasting, and operationally efficient so as to fill the gap between theoretical designs and real-world performance. A typical example of the corresponding wind turbine class for each application can be seen in Figure 12. As Bianchini et al. suggested in the paper, a house requires a small wind turbine of around 1.5 kW, and one up to 15 kW can be used in a farm.

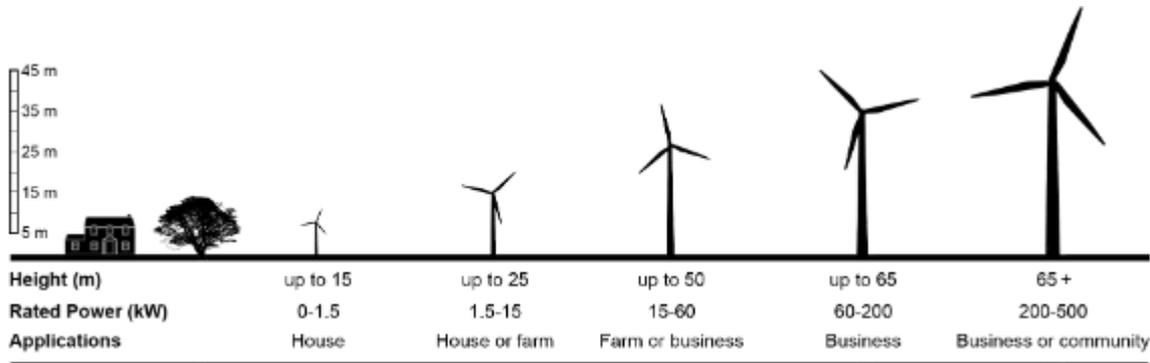

Fig. 12 - Small wind turbines vs large wind turbines (Bianchini et al., 2022)

In addition to maximizing turbine performance and compliance with regulation, experimental testing also ensures the validation of computer models. Environmental conditions commonly simplify computational fluid dynamics (CFD) and other theoretical models, and thus, a difference between predicted and actual performance exists (Dumitrescu et al., 2015). Experimental testing rectifies the gaps by providing empirical data in simulated and actual environments. In addition, such tests ensure turbines withstand turbulence, dynamic wind loads, and weather conditions for more extended periods, making them safer and more reliable. Representative research in the field belongs to Syawitri et al., who have conducted a flow field analysis to gain insight into the inherent flow physics, such as dynamic stall behavior, using hybrid RANS-LES turbulence models (Syawitri et al., 2021).

Field testing, hybrid approaches, and wind tunnel testing are the three broad categories into which small wind turbine test procedures are grouped. Torque, tip speed ratio (TSR), power coefficient (C_p), etc., are tested methodically. The models tend to be on a small scale, and sophisticated measuring devices such as particle image velocimetry (PIV) provide information about the air patterns surrounding the blades of the turbine. In their scientific paper, Edwards et al. used experimental PIV visualization in a wind tunnel on a three-bladed small vertical axis wind turbine experimental model to experimentally validate the CFD numerical simulation results (Edwards et al., 2015). An interesting experimental test was conducted by Nietiedt et al., which consists of using two optical measurement systems to simultaneously record fluid (PIV system) and deformation (photogrammetry system) information in one global coordinate system. Their setup can be seen in Figure 13.

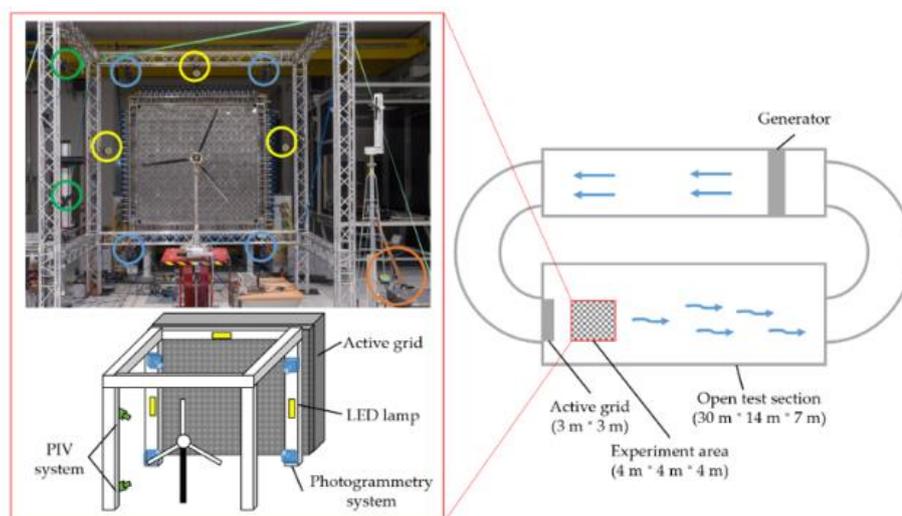

Fig. 13 - Wind tunnel with scale turbine models, airflow visualization (Nietiedt et al., 2022)

By placing turbines in their proper operating environments, field testing enhances wind tunnel research. This method takes into account variables such as wind direction, temperature changes, and environmental barriers such as trees or buildings. To evaluate material fatigue, erosion, and noise production under real-world operating conditions, long-term field experiments are crucial. The figure below depicts a stand-alone solution for this sort of study, which may be used practically anywhere on the globe. These solutions include a small wind turbine and a compact housing unit that contains all electronics, energy storage, data collection, and remote-control systems.

Fig.14 - Field test site with small wind turbines installed

(<https://nachhaltigwirtschaften.at/en/iea/technologyprogrammes/wind/iea-wind-task-27-workingperiod-2018-2019.php>.)

To offset individual limitations, hybrid test procedures—blending field testing with wind tunnel testing—are increasingly employed. Such procedures, economical and time-efficient, are accurate by utilizing wind tunnels for first-order parameter optimization and field testing for field validation without compromising on precision. In their paper, LeBlanc et al. report the procedures utilized in the development of a model of an H-type vertical axis wind turbine, which include physical measurement of the as-built form, experimental test updates to the models, and lastly, tests to model correlation on a component-by-component basis, as well as a completely assembled system, bringing in the ideas of "machine learning" and "digital twins" (LeBlanc et al., 2020). Emerging technologies, such as machine learning-based data analysis and digital twins, have further increased the strength of hybrid testing systems.

Yilmaz's work compares CFD simulation and experimental data to gain better knowledge of basic rotor aerodynamics principles for designing an aerodynamically efficient small wind turbine rotor by establishing the optimum design tip speed ratio (TSR) and number of blades. Figure 15 depicts part of his results.

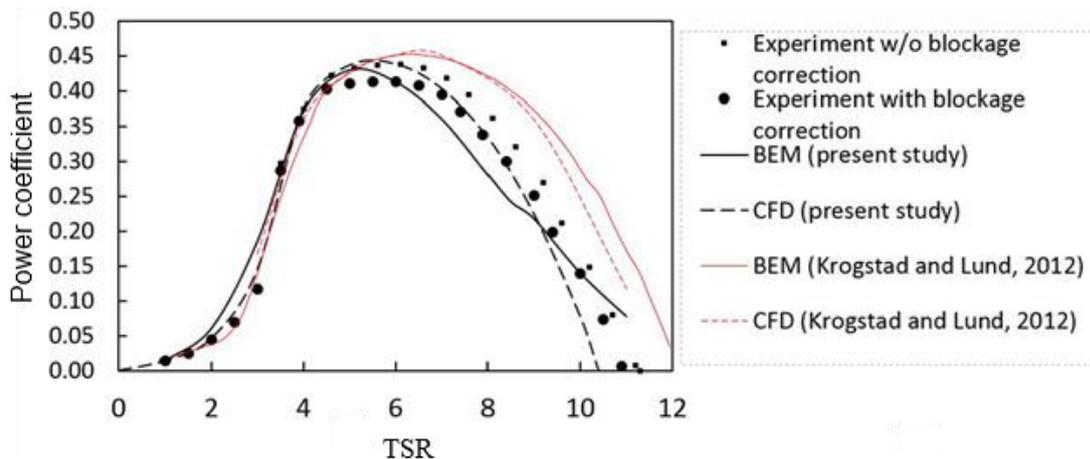

Fig. 15 - Power coefficient as a function of TSR (Yilmaz., 2022)

While it has its benefits, experimental testing has its disadvantages, such as very high costs, uncertain climatic conditions, and scaling issues. It requires a high cost to set up wind tunnels or test facilities in the field, and the cost is further increased through the use of high-accuracy sensors and data acquisition systems. The inhomogeneity in the field test condition makes it difficult to process data, and scaling issues in wind tunnel tests could lead to incorrect conclusions when applying the results to full-scale turbines.

High-definition sensors augment precise data, allowing real-time monitoring of important factors while the machine learning software detects patterns and anomalies from complex data sets, improving predictive modelling. Hybrid platforms, which combine virtual simulation and actual-world testing, such as digital twins, offer a cost-effective, scalable substitute for conventional practices (Pimenta et al., 2020).

A paper that examines the state-of-the-art of predictive digital twin platforms for wind energy systems based on a five-year review of literature, challenges, and limitations, and debates future research directions belongs to the Kandemir et al. They organize their review based on popular approaches like physics-based modeling, data-driven approaches, and hybrid modeling. Figure 16 is their depiction of a wind turbine development process that entails the digital twin technology.

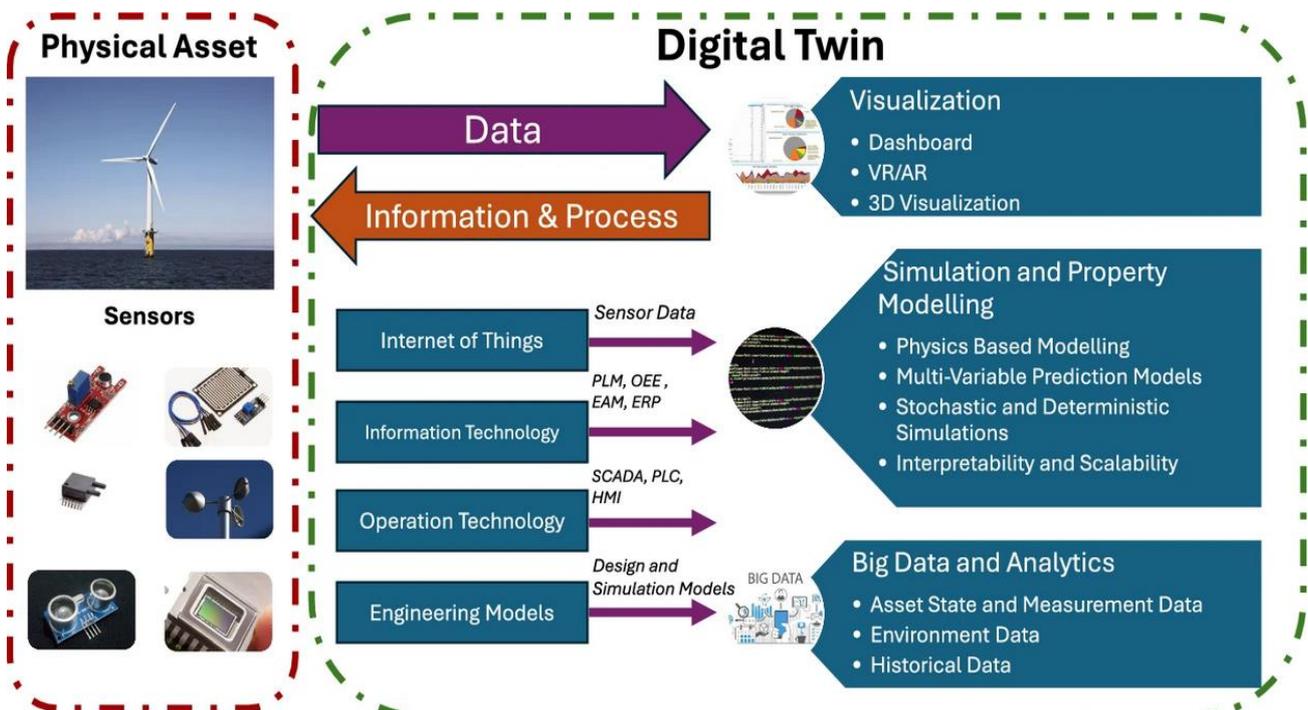

Fig. 16 - Wind turbine testing with digital twin technology (Kandemir et al., 2024)

The experimental testing of efficient and effective SWTs and their interaction with theory provides useful verification of theoretical expectations, guiding design improvements and performance limits consistent with safety and efficiency requirements across development stages. New technologies such as sensors, data analytics, and hybrid tests are changing the domain. These technologies could potentially be turning points for the sustainable future of human beings as they considerably increase the affordability and scalability of small wind turbines.

RESEARCH SYNTHESIS ON THE STRUCTURE OF SMALL VERTICAL AXIS WIND TURBINES

A couple of decades ago, wind power increased its popularity as an alternative and renewable energy compared to other energy resources. One of the most promising types of wind turbines is the vertical axis wind turbines (VAWTs), which are recommended for small-scale applications (Mălăeș et al., 2015). These turbines are the simplest to operate, require lower maintenance, and are the most environmentally friendly. Vertical-axis wind turbines can be located in residential and urban settings where wind and space conditions are less uniform due to their vertical axis.

The basic working principle of vertical-axis wind turbines is the same as that of horizontal-axis wind turbines, which is transforming wind energy into mechanical energy, which will then be used to generate electricity.

The major difference is noticed in the rotor direction. The VAWT turbine blades rotate around a vertical axis of rotation. There exist different VAWT designs, such as the Savonius and Darrieus (*Garmana et al., 2021*). For efficiency, the curved blades of the Darrieus turbine are comparable to the aerodynamic surfaces of an airplane wing. However, due to its simplicity and strength, the Savonius turbine—a semicircular blade with a simpler thrust design—is frequently used in low-wind conditions where other wind turbines struggle even to start. Figure 17 illustrates the principal types of vertical-axis wind turbines. They can gather wind from any direction and thus operate very efficiently with changing winds. Each type has its own advantages and applications, depending on the siting and intended energy output.

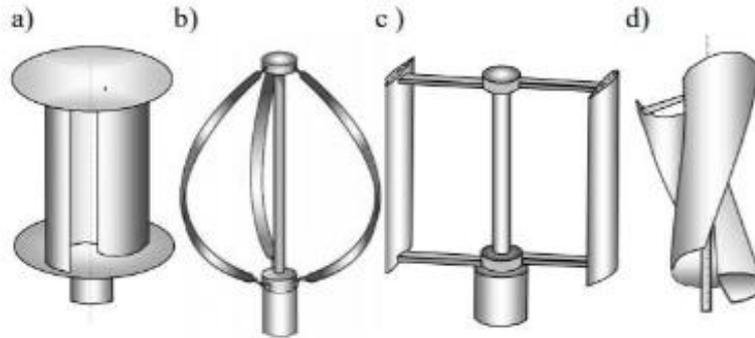

Fig. 17 - VAWT models: a) Savonius type, b) Darrieus type, c) H type, d) spiral type
(*Polak et al., 2006*)

Power rating, typically a few watts to a few kilowatts, defines small VAWTs. The turbines are utilized in domestic, rural, or off-grid applications. Small VAWTs can be inefficient, unreliable, and prone to structural issues - challenges highlighted in several recent studies (*Wood et al., 2011*) - particularly when their design does not align with the characteristics of the installation site. The efficiency and longevity of small VAWTs depend largely on their structural design. These turbines involve close attention to numerous parameters, ranging from material and blade shapes to aerodynamics. Of the most needed is the ability of the turbine to harness energy in low-speed wind, a condition that also comes in abundance for wind systems of small scales (*Clausen et al., 2023*).

The material and form of the blade on the turbine will have a direct impact on the mode of operation of the turbine. Darrieus turbine blades (Figure 18), for example, possess an airfoil cross-section and thus are more aerodynamically efficient and can provide more energy. Manufacturing such blades can be more expensive and complicated, though.

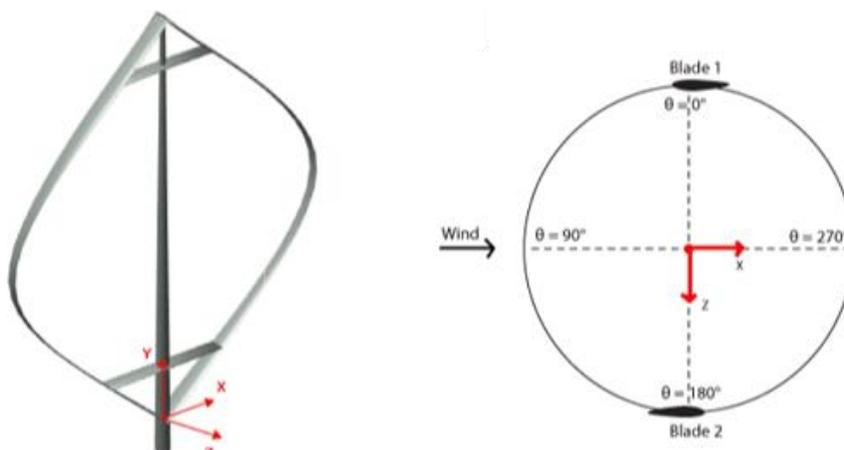

Fig. 18 - Cross-section of the aerodynamic profile of a Darrieus turbine blade
(*Sakib et al., 2021*)

The blade shape, rotor size, and blade number can affect the aerodynamics in small VAWTs. Three-bladed Darrieus turbines have been found to be a good balance between stability and efficiency. Due to its simplicity and ability to start rotating from low wind speeds, the Savonius type, despite its lower efficiency, is still predominantly used for small applications. The choice of material for the support frame of the turbine is also an important aspect in small VAWT design.

In addition to providing strength to withstand wind forces as well as other weather conditions, the blades, rotor, and support frame must also be light enough to allow for easy start-up and smooth running of the system. Fiberglass, composite, steel, and aluminum are the popular materials for manufacturing small VAWTs. Material science and aerodynamics research, as *Condruz et al. (2019)* have shown, and aerodynamics development have improved the vertical axis wind turbine efficiency. A comparison of materials for turbine blades is presented in Figure 19. Though the materials that can be used in the wind turbine blade manufacturing are composites, metals, wood, foams, and even polymers.

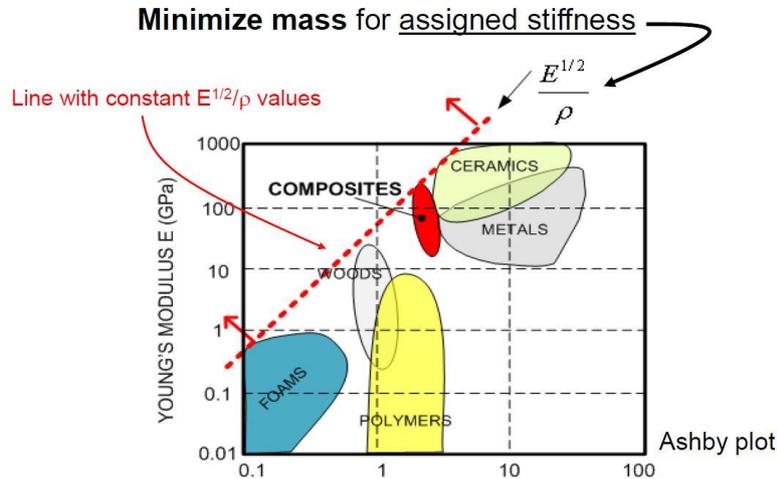

Fig. 19 - Comparison of materials for turbine blades: metal and composite materials
(<https://www.windfarmbop.com/why-wind-turbine-blades-are-made-of-composite-materials/>)

With its lightweight and corrosion-resistant properties, aluminum is very applicable for use on an urban scale on a small scale. On the other hand, steel is primarily used in large-scale developments due to its high strength, but it can also be employed in small VAWTs to meet stability requirements, provided that weight distribution is carefully managed. Their strength-to-weight ratios and resistance to environmental degradation also make fiberglass and composites increasingly sought after. Stability of turbine construction is vital, particularly as wind force changes fairly regularly in VAWTs. Computer-aided and advanced structural analysis techniques like finite element modelling (FEM) have been researched for their ability to optimize structural design. Such simulation makes it possible to accurately predict stress levels, vibration, and likely points of failure within the turbine structure. *Marzec et al., (2023)*, wrote a paper on structural topology optimization of the H-Rotor wind turbine coupled with the one-way Fluid Structure Interaction (FSI) approach. They aim to minimize the volume of the maximum stressed and deformed blades. The results consist of comprehensive information about unstable flow fields around the operating wind turbine coupled with the optimized topology of the interior of the blade without changing the external aerodynamic profile. Part of their results, blade deformations, are presented in Figure 20.

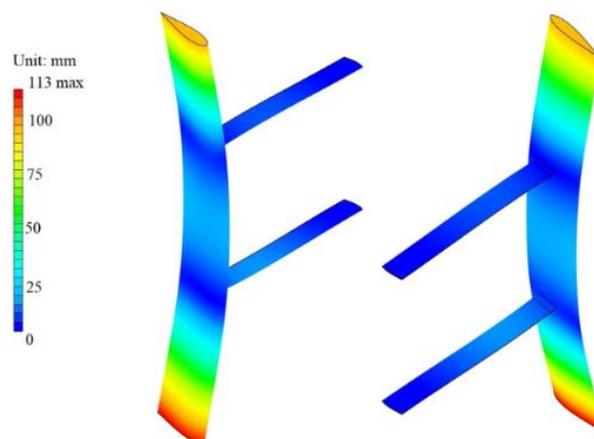

Fig. 20 - Finite element analysis of the VAWT rotor
(*Marzec et al., 2023*)

Small VAWTs' capacity to withstand the stresses of bending and torsion without malfunction is a major worry for engineers. One way to address that is by looking at hybrid turbine designs and multiple blades. The performance of a small vertical axis wind turbine depends on a few key factors: the wind conditions, the design of the turbine itself, and the control systems. To get the most out of small VAWTs, researchers have concentrated on boosting that power coefficient—the measure of how efficiently a turbine can turn wind energy into mechanical power. And that's because wind speeds in domestic and urban areas are notoriously unpredictable; there is a lot of turbulence and wind change in direction. That's why small VAWTs are designed to respond quickly. Savonius turbines, for example, may not produce as much power as Darrieus turbines, but they do operate efficiently at lower wind speeds—and that's a real advantage (Figure 21). A research study that aims to reveal the effect of the rotor radius ratio on the performance of the hybrid vertical axis wind turbine Savonius-Darrieus, using the Computational Fluid Dynamics methods, belongs to Irawan et al. Their results consist of the increase in the rotor radius ratio value causing an increase in the initial torque coefficient but a decrease in the maximum power coefficient value.

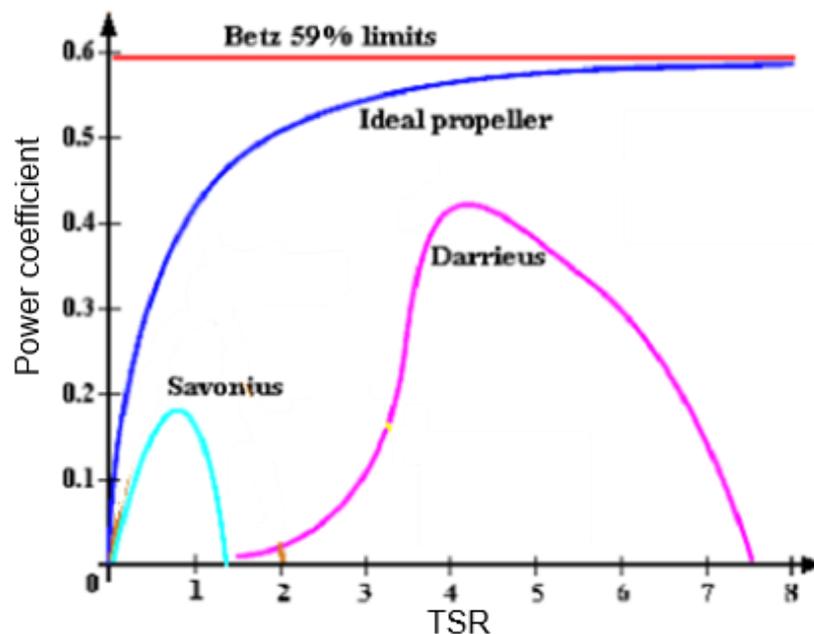

Fig. 21 - Darrieus vs Savonius efficiency

(Irawan et al., 2023)

Major design specifications of small vertical-axis wind turbines (VAWTs) include wind speed cut — the lowest speed at which the turbine starts to produce electricity. At this point, technologies like variable speed systems and pitch control come into play because these control systems maximize small VAWTs for a broader range of wind conditions. Small VAWTs generally aren't as efficient as large horizontal-axis wind turbines (HAWTs) because of the inherent aerodynamic losses of the vertical axis. Drag forces that build up as the blades rotate in the wind — especially when the wind speed isn't ideal — can reduce efficiency even further.

Researchers have been trying to drive efficiency up by pitching the blades, using hybrid designs (Malael et al., 2018), and implementing control strategies to cut down on drag resistance. Smart grid tech can be used to optimize turbine performance in real-time, based on the latest wind data. But one of the biggest challenges in designing a small VAWT is making sure the structure lasts a long time. That's because small turbines are most susceptible to the kind of mechanical fatigue that comes from variable loads and stresses—turbulence, wind gusts, and other environmental conditions. Blades, bearings, and other mechanical parts can break down and degrade over time. That's why ensuring durability is one of the biggest challenges in the development of small VAWTs. Ali et al. investigated structural optimization of sea-capable VAWTs designed for long-term reliable operation. Based on their analysis, the maintenance cost would be minimized with considerable savings without compromising structural integrity in the marine environment if their optimized combination is utilized. The outcomes of their structural fatigue analysis are demonstrated in the figure below.

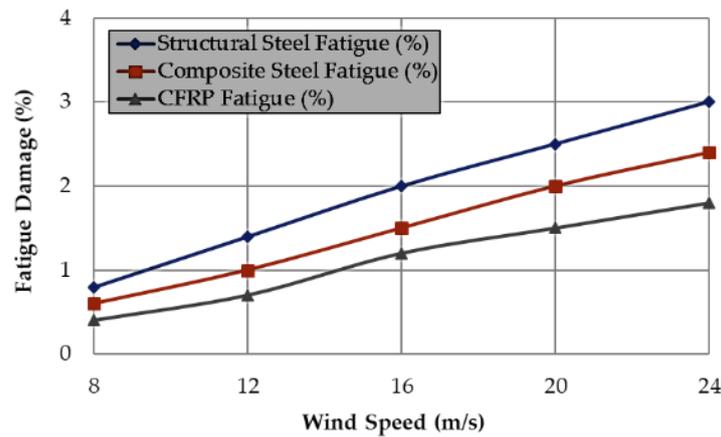

Fig. 22 - Structural fatigue analysis
(Ali et al., 2024)

Compact VAWTs depend on some pretty sophisticated bearing systems, vibration-damping technologies, and materials that can withstand fatigue much better. That's not the only thing driving adoption of these turbines in urban areas, though; aesthetics and noise pollution are just as much a factor. A major design challenge for urban wind turbines is the noise generated during operation. A study examining the power produced and noise generated by two small wind turbines that were tested inside a wind tunnel is one of Hays et al. Their suggested configuration showed a 9% increase in power generation and noise reduction of up to 7 dB(A) (Hays et al., 2019). Another paper that deals with the vertical axis wind turbine noise generation is Yue, (2023), in which URANS equations were used to numerically investigate the noise level for VAWT at three different wind speeds (Figure 23).

In residential areas, some of those compact designs — especially the ones with fewer blades — can be pretty loud. Engineers are refining those designs to reduce noise generation and adding features that do just that. And because in many places, people care deeply about how wind turbines look, aesthetics often ends up being a major factor in adopting small-scale wind turbines—especially in residential situations. Researchers are developing turbine designs that integrate seamlessly with their surroundings while maintaining high efficiency.

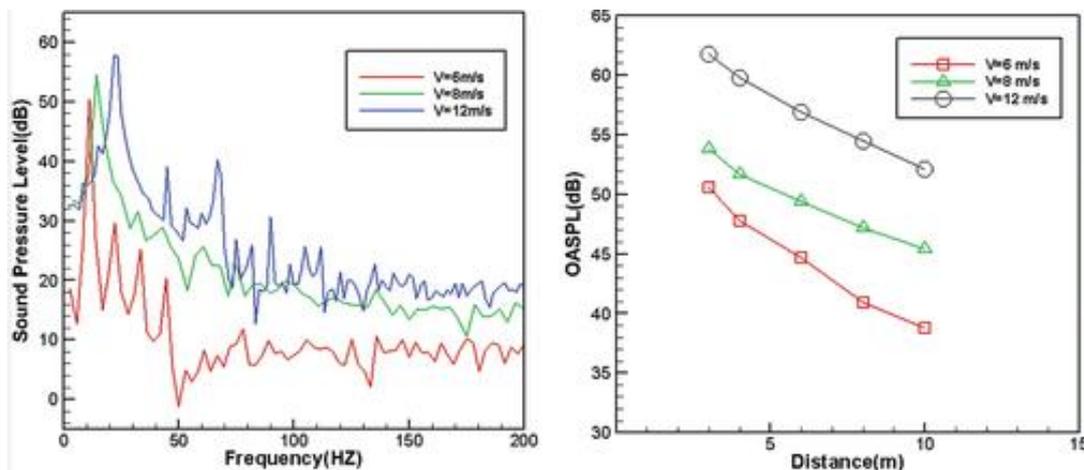

Fig. 23 - Noise levels for VAWT
(Yue., 2023)

Solving the problem of an increasing need for residential and off-grid energy, which can be renewable, is possible with the help of a small vertical-axis wind turbine. These turbines are still not the ultimate solution to generation without sporadic interference from the weather but are a step in the right direction that is reliable and can be efficient as well. Nevertheless, a whole lot of questions remain not only about the feasibility of their long-term use but also about whether they are a danger to the environment or not.

Currently, the possibilities of materials, aerodynamics, and control systems are being investigated as a means of overcoming these limitations and ensuring that the overall performance of small VAWTs gets better. The potential of small VAWTs in the renewable energy era, alongside innovation and consequent efficiency, especially in urban environments, which are normally characterized by inadequate wind speeds and little space, helps the situation to bounce back and take advantage of these possibilities. An interesting solution that can be integrated into the urban environment is presented in Figure 24. Three small wind turbine configurations can be easily mounted on a roof building.

Fig. 24 - Small vertical axis wind turbines installed in an urban area
(<https://www.cbc.ca/news/science/what-on-earth-wind-turbines-cities-1.6710512>)

SYNTHESIS OF EXPERIMENTAL RESEARCH ON THE WORKING PROCESS OF SMALL VERTICAL WIND TURBINES

The exponential growth of clean power generation has led to the widespread use of small wind turbines. These systems are present especially in places where the energy and space are limited, such as rural and urban areas. The vertical-axis wind turbine is among the most common wind turbine designs due to its straightforward construction, safety, low maintenance requirements, and ability to capture wind from all directions. The configuration also has several other advantages, particularly in urban areas where the wind can change its direction very often. In order to draw wind energy from any direction without a yaw system, VAWTs (*Mirecki et al., 2007*) represent a simplified solution due to their structural and mechanical structure. Energy conversion in VAWT is realized by using both drag and lift aerodynamic forces. The wind blows directly on the turbine blade's surface and causes the pressure reaction. The motion of the blades is resisted by drag, while lift is the force generated perpendicular to the wind direction, producing torque. An optimal turbine minimizes drag and maximizes lift, thereby achieving high efficiency. The balance between these two forces significantly impacts the energy capture efficiency of the turbine.

A famous example of most elementary turbines is the design of Savonius (Figure 25) turbines, which have the shape of cups, and the number of blades can be two or more (*Zemamou et al., 2017*). The most fitting use of these designs is the collection of energy from low wind rates. However, with the increase of wind velocities, its efficiency goes down as it highly depends on drag only.

Fig. 25 - A basic Savonius design (*Aboufares et al., 2015*)

Fig. 26 - Darrieus WT
(<https://en.wind-turbine-models.com>)

Fig. 27 - Helical wind turbine design (*Kumar et al., 2019*)

Similar to an airplane wing, the Darrieus turbine uses curved blades in a form like "egg beater" to create power. The more efficient this type of design is when there are stronger winds, the more advanced mechanical parts it requires to work effectively. The conventional structure of this type of turbine is seen in Figure 26. The benefits of Darrieus and Savonius forms are combined into a helical turbine (Figure 27) to demonstrate a balanced performance. Its helix-shaped blade structure makes the system go through minimal mechanical stress while maximizing efficiency over a wide range of wind speeds.

Because there is no need for complex components to direct the turbine towards the wind, VAWTs can collect wind energy from any direction. When the wind is irregular and turbulent, this is beneficial for the power production of these devices. The gearbox and generator, and other components, tend to be placed at the base of the turbine, so it is easier to perform maintenance and reduce downtime. For urban applications where space is limited, VAWTs are preferable since they are generally smaller and can be accommodated in small areas. Anup et al. in their paper elaborate on the diversified studies that have been conducted on the application of SWT technology in the built environment for the purposes of finding out about the inflowing wind characteristics, their performance, and establishing the knowledge gaps (Anup et al., 2019). Their paper also delves into the validity of the international design standard for SWTs, IEC 41400-2, for urban installations.

A test rig must mimic different wind conditions to be able to test the performance of a small vertical axis wind turbine. Tests may be done outdoors or in a controlled condition wind tunnel based on the resources available and the level of precision required. Both the direction and speed of the wind can be kept under controlled laboratory conditions at the wind tunnel. Even if a controlled environment like this would be expensive, it is very convenient for reproducible research. When the turbine is outside, natural wind is applied to the turbine. Performance is less predictable and less controllable even if results are more realistic. The detailed outdoor small wind turbine configuration test facility is illustrated by Figure 28. Such a facility has been used in the research work conducted by Mostafavi et al. Outdoor experimental testing under real conditions and without the use of a control environment presented difficult effects such as variability of rotor speed, generation of noise, overloads, and any external environmental influence.

An interesting research work paper that documents comprehensive wind tunnel test results data collected on six airfoils of applicability to small wind turbines is Selig et al., (2004). The authors used airfoils like E387, FX 63-137, S822, S834, SD2030, and SH3055. They used the NASA Langley Low Turbulence Pressure Tunnel as their experimental facility.

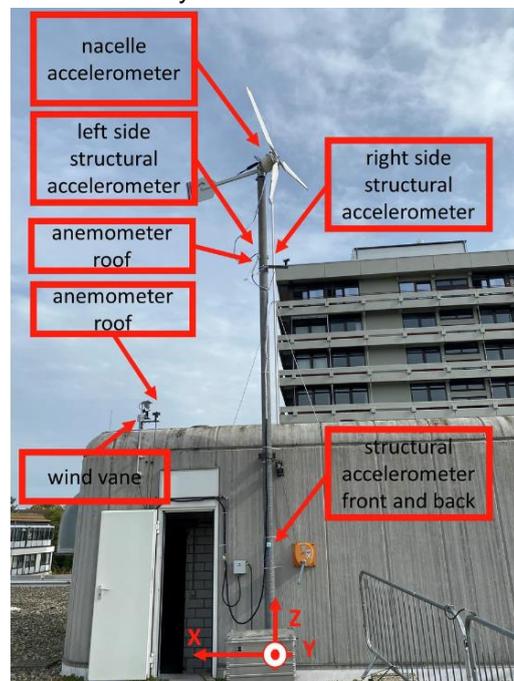

Fig. 28 - Small wind turbine - experimental setup (Mostafavi et al., 2024)

An anemometer is a very important measuring instrument used for assessing the turbine's efficiency under various conditions since it estimates the wind speed. Whereas an electrical output produced by the turbine is measured by a power meter, rotational torque transferred on the turbine shaft is measured by a

torque meter. Experiments are conducted in the laboratory with the help of a data acquisition system that stores and records data from an anemometer, a torque meter, and a power meter for post-processing afterwards. Torque, rotational speed, and power output are taken when the turbine is tested with changing wind conditions. The primary goal of experimental testing is to measure how effectively the turbine converts wind energy into electrical energy under different operating conditions (Migliore *et al.*, 2004).

Low (2 m/s) to high (15 m/s) wind speeds are employed to test the turbine. Test wind speed ranges are employed to determine the optimal wind speed to attain maximum turbine efficiency. Wind speed measurements are made progressively higher for torque and power output. Different blade configurations are employed to test to observe the impact on performance. Savonius, Darrieus, and helical blades are compared (Wakui *et al.*, 2005) under the same wind conditions to determine which of them is most appropriate for small-scale turbines. A comparison of Savonius, Darrieus, and the new configuration is done by Siddiqui *et al.* The results can be observed in the following graph in which the electrical power with respect to wind speed for each configuration is depicted.

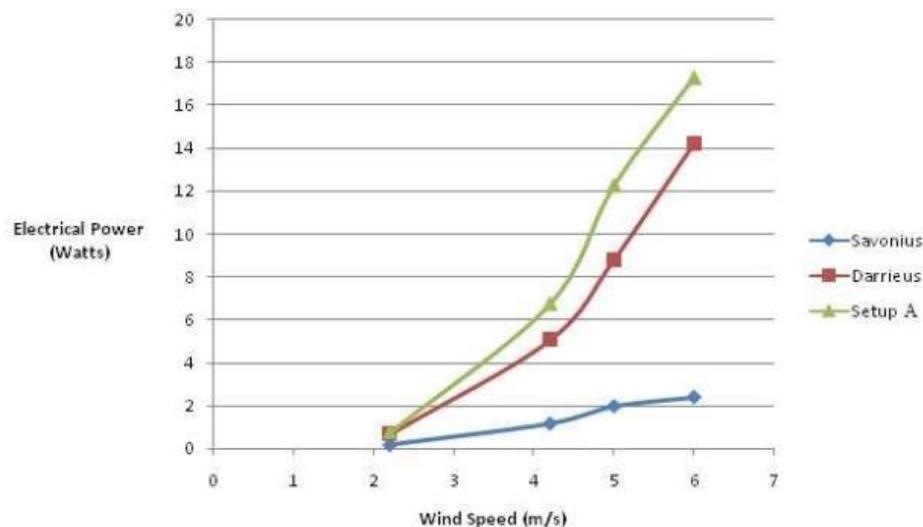

Fig. 29 - Performance comparison (Siddiqui *et al.*, 2016)

Performance curves are obtained from the analysis of experimental data and depict the relationship between wind speed and power generation. Efficiency is quantified by the power coefficient (C_p), or the ratio of actual power generated to the theoretical maximum power available from the wind. Conclusions about small vertical axis wind turbine performance can be drawn from experimental test data (Scungio *et al.*, 2016). Power output increases rapidly with rising wind speed to an optimum, a quite nonlinear relation between energy produced and wind speed. Performance is normalized after this because of aerodynamic and mechanical constraints.

At a moderate wind speed of about 8 to 12 m/s, the turbine is operating at its most efficient rate. The turbine can overspeed outside this range, decreasing its efficiency and possibly causing the system to be subjected to mechanical stress (Wood *et al.*, 2001). With higher wind speed, there is greater rotational speed and torque. The rotational speed of the turbine stabilizes as it approaches its mechanical limits, but at extremely high wind speeds. This implies that at higher speeds, the rotational speed is stable, but torque increases with the wind speed.

The mechanism of the drag-based Savonius turbine was connected to less efficiency at higher wind speeds, while that of the helical blade of the Darrieus turbine led to maximum efficiency for a wide range of wind speeds. The shape of the blade and the angle of attack contributed significantly towards the optimization of the maximum lift increment and the minimum decrement in drag, thereby maximizing the overall efficiency of the turbine. A typical power versus speed curve of a wind turbine is shown in Figure 30. It is the representation of Mittal *et al.*'s research and it shows how the power mechanically taken from wind is dependent on rotor speed. Small turbines have been observed to have lower energy conversion efficiency than large commercial turbines (Ozgener *et al.*, 2006), measured in terms of electrical power output to available wind energy. Small-scale systems are restricted, there are mechanical losses, and aerodynamic efficiency is poor. Notwithstanding this, small VAWTs are still very useful in decentralized power generation.

Experimental direct testing can provide vital information on the aerodynamic performance, performance parameters, and field applications of small vertical axis wind turbines. Since VAWTs with helical blades (Han et al., 2018), among others, feature a simple configuration, are easy to service, and can capture winds from any direction, they are an ideal choice for low to moderate wind speeds. Although they have lower energy conversion efficiency compared to large turbines, small VAWTs offer compact size and simple installation, making them well-suited for domestic applications and small-scale power generation in areas with fluctuating wind conditions.

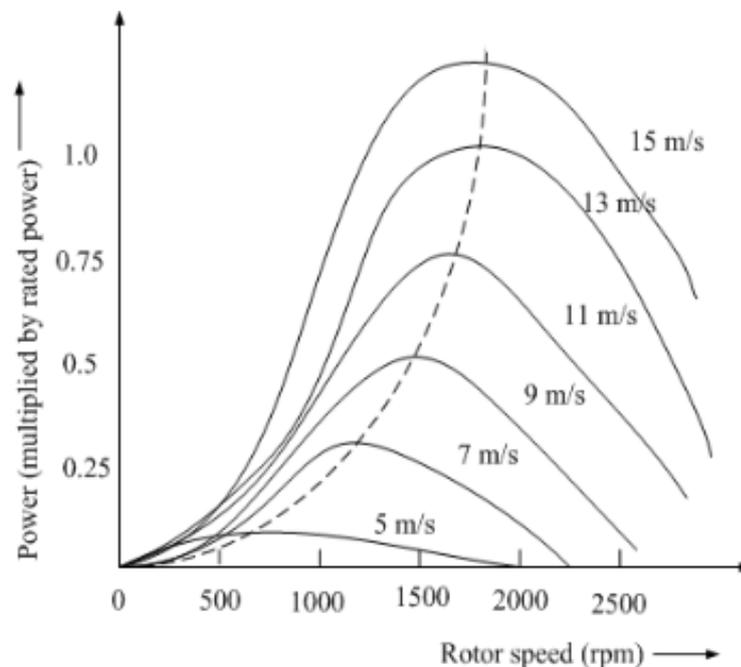

Fig. 30 - A typical power versus speed characteristic of a wind turbine (Mittal et al., 2011)

Research and development in small wind turbine technology will have to focus on improved blade design, reduction of mechanical losses, and use of optimized control systems in order to deliver optimum efficiency. On application of the advances, small vertical axis wind turbines can be an important part of the renewable energy industry that delivers sustainable energy solutions to urban and rural communities.

CONCLUSIONS

The paper is part of the documentation done for the PhD thesis, which has as the topic the research of a new wind turbine system integrated into the urban architecture. This review has highlighted the small wind turbine characteristics, including cost-effectiveness, environmental benefits, and suitability for various installation sites. The work is structured in four chapters that reveal the research done by the researchers in the field of small wind turbines. The first section belongs to the introduction on the specificity of small wind turbines with an accent on the advantages and disadvantages along with the challenges despite their benefits.

The synthesis of experimental research presented here highlights both the evolution and the barriers faced by small wind turbines in real-world applications. Issues such as energy conversion efficiency, reliability under various environmental conditions, and durability remain essential for optimizing small wind turbine systems. However, innovations in aerodynamic modelling, structural materials, and hybrid systems pave the way for improved performance in practical conditions.

Vertical-axis wind turbines offer clear advantages in urban areas and low-wind environments and are particularly well-positioned to play a leading role in these settings. With increasingly sophisticated design principles, new materials, and optimized work processes with ongoing research, small VAWTs can be more efficient and versatile in most areas of application. In the long term, ongoing improvement in small wind turbine technology is a giant opportunity for developing sustainable energy. The knowledge resulting from this review undoubtedly portrays areas to be investigated in the future, thereby giving ways for development and exploration in small wind energy systems.

RESEARCH ON ROOT PRUNING METHODS APPLIED TO ORCHARD TREES

CERCETARI PRIVIND METODE DE TAIERE A RADACILOR POMILOR FRUCTIFERI

Keywords: tree, roots characteristics, cutting resistance, cutting indices

ABSTRACT

Root pruning is a widely adopted practice in modern orchard management, with the primary goal of stimulating regeneration and optimizing annual fruit production. There are numerous researches on the architecture of the root system of trees, the volume and depth of root development, as well as the importance of cutting them in fruit growing. Also, the specialized literature presents different types of equipment intended for cutting roots, but there are few studies that address aspects related to the resistance forces encountered during this work. This paper presents research conducted using a specialized root-cutting implement equipped with a chisel-type blade. The study outlines the technical characteristics and performance indicators of the equipment, which was tested on various soil types to evaluate its working parameters. As a result of the experiments, the following were determined: the root cutting resistance at different working depths and across three soil categories - sandy, clayey, and loamy - as well as the corresponding working speeds required to maintain efficient operation under maximum tractor power conditions. Using the experimentally determined values, the variation diagrams of these indices were plotted, such as: the stress distribution diagram and the speed variation depending on the cutting resistance, the maximum total cutting resistances were identified, at the maximum depth of 50 cm, at the most unfavorable blade inclination angle of 45°. The maximum values determined for these were 768.5 daN for sandy soil, 1185.5 daN for clay soil and 1602.5 daN for loamy soil. These results highlight the influence of soil type and working parameters on the mechanical stresses of the blade during root pruning work in fruit plantations.

REZUMAT

Lucrarea de tăierea rădăcinilor pomilor este o lucrare des folosită în pomicultură, scopul acesteia fiind acela de a determina stimularea și regenerarea plantației în vederea gestionării producției anuale de fructe. Există numeroase cercetări privind arhitectura sistemului radicular al pomilor, volumul și adâncimea de dezvoltare a rădăcinilor, precum și importanța efectuării lucrării de tăiere a acestora în pomicultură. De asemenea, literatura de specialitate prezintă diferite tipuri de echipamente destinate tăierii rădăcinilor, însă sunt puține studii care abordează aspectele legate de forțele de rezistență întâmpinate în timpul acestei lucrări. Articolul prezintă cercetările efectuate cu un echipament de tăiat rădăcini prevăzut cu cuțit de tip daltă, pentru care sunt prezentate caracteristicile și indicii de performanță aferenți, testat pe diferite categorii de sol, în vederea determinării indicilor de lucru ai acestuia. În urma realizării experimentărilor s-au determinat: rezistența de tăiere a rădăcinilor, la diferite adâncimi de lucru, pe diferite tipuri de sol (nisipos, argilos și argilos), precum și vitezele de lucru în funcție de rezistența totală la tăiere, pentru utilizarea puterii maxime a tractorului. Utilizând valorile determinate experimental s-au trasat diagramele de variație ale acestor indici, precum: diagrama de distribuție a tensiunilor și variația vitezei în funcție de rezistența la tăiere, s-au identificat rezistențele totale maxime de tăiere, la adâncimea maximă de 50 cm, la cel mai nefavorabil unghi de înclinare a cuțitului de 45°. Valorile maxime determinate pentru acestea au fost de 768,5 daN pentru sol nisipos, 1185,5 daN pentru sol argilos și 1602,5 daN pentru sol lutos. Aceste rezultate evidențiază influența tipului de sol și a parametrilor de lucru asupra solicitărilor mecanice ale cuțitului în timpul lucrărilor de tăiere a rădăcinilor în plantațiile pomicole.

INTRODUCTION

The process stimulating and regenerating a tree involves removing some of the tree's surface roots to encourage the growth of deeper, stronger roots. Pruning shallow roots reduces the tree's need for water and nutrients and encourages the growth of deeper roots. These deeper roots are better able to absorb water and nutrients, which helps the tree grow and produce more fruit.

Pruning is usually done during the tree's dormant season, which is in the fall or spring, before active growth begins. It is important to do this carefully and avoid cutting too many roots to avoid damaging the tree's health too much (*Wade et al., 2020*).

The consequences of root cutting include root degradation, root structural depth, root location, root regeneration, drying of fine roots, formation of rounded roots, scorched roots, and root grafts (*Watson et al., 2014*). The root system architecture and a possible root orientation can be adapted for mechanical reinforcement (*Beier et al., 2020*).

The sizes and shapes of root systems for different plant growth forms vary depending on above-ground plant size, climate, and soil texture. With the exception of trees, root systems tend to be shallower and wider in dry, warm climates, and deeper and narrower in cold, wet climates. Shrubs are more shallowly rooted in regions with summer rainfall compared to those with winter rainfall (*Schenk and Jackson, 2002*).

A study on cherry trees aimed to examine the influence of root pruning on tree vigor, with the goal of managing the harvest through more compact canopies (*Perry, 2015*).

Tree roots play a crucial role in various aspects such as soil penetration, degradation, root architecture, root defects, available rooting space, regeneration, deep root structure, and root extension (*Watson et al., 2014*).

In other research, issues related to rooting depth, lateral root spread, and aboveground/belowground allometries of plants have been explored (*Schenk et al., 2002*). Additionally, studies have examined the effects of root pruning on leaf nutrient content, photosynthesis, and tree growth in a poplar plantation. These studies aimed to investigate the impact of root pruning on tree growth and physiology by quantifying the extent of root pruning through allometric analysis, taking initial steps toward developing a practical tool for arborists to support root management and care decisions (*Da-wei Jing et al., 2018; Jing DW et al., 2017*).

To stimulate growth, some researchers performed root pruning twice a year, 60 cm away from the trunk and 30 cm deep, as follows: the first pruning was done on one side of the row before autumn leaf fall, and the second in spring during flowering (*Mitre et al., 2012*).

Various methods of classifying individual roots have been documented. Based on their distribution, roots are categorized as either vertical or horizontal, while in terms of length and thickness, they are classified as either skeletal or fibrous. Horizontal roots grow more or less parallel to the soil surface, typically at a depth of about 30 to 100 cm, whereas vertical roots extend downward into the soil. Skeletal roots are characterized by their considerable length and thickness - ranging from a few centimeters to several meters long - and can reach several centimeters in diameter. In the management of mature trees, it is critical to assess the diameter at breast height (DBH) prior to any root pruning activity. Current guidelines recommend avoiding the cutting of roots located within a radial distance of less than five times the DBH from the trunk. For example, in a tree with a DBH of 12 inches, root pruning should be limited to areas beyond a 60-inch radius from the trunk. Younger trees exhibit greater resilience and may tolerate root cuts at a closer distance - approximately three times the DBH. Nevertheless, in all cases, root pruning should be conducted as far from the trunk as practicable to minimize physiological stress. When performed with care, root pruning can be compatible with tree health; however, imprecise or overly aggressive interventions may compromise structural integrity, disrupt water and nutrient uptake, and ultimately result in tree decline or mortality. The severity of damage caused by root pruning increases significantly with proximity to the trunk. It is generally recommended not to remove more than 25% of a tree's root system, as exceeding this threshold may result in tree decline, structural failure, or mortality. A recovery period of at least two years should be allowed between successive root pruning interventions. Additionally, root pruning should be avoided during the spring period following bud break (*Coffie, 2001*). Roots are commonly classified based on diameter into six main categories: very fine (< 0.5 mm), fine (0.5–2 mm), small (2–5 mm), medium (5–10 mm), large (10–20 mm), and very large (> 20 mm) (*Gliński and Lipiec, 1990*).

Most fine roots are concentrated within the surface layer of approximately 1 m² of medium-textured soil, with the majority of fine, non-woody roots located at a depth of about 15 cm. This distribution is largely influenced by genetic factors under favorable growth conditions in the topsoil (*Craul, 1993*).

Approximately 70% of roots are located within the humus layer of the soil profile (*Wasterlund, 1989*). Key morphological characteristics of individual roots include surface texture, color, and diameter (*Fitter et al., 1991*).

Several studies have sought to establish correlations between root parameters - such as number, diameter, and spatial orientation - and aboveground plant dimensions, including stem and crown diameter. Notably, highly significant positive correlations have been identified between stem diameter measured at 1.3 m above ground level and total root biomass (*Kuiper and Courts, 1992*).

Roots may be classified based on several criteria:

A - According to their growth orientation within the soil profile, roots are categorized as follows:

- horizontal roots - those that grow nearly parallel to the soil surface or form an angle between 60° and 90° with the vertical axis;
- oblique roots - those that form an angle between 30° and 60° with the vertical axis;
- vertical roots - those that grow at an angle of up to 30° relative to the vertical axis.

B - According to size, roots can be classified into the following categories:

- skeletal roots, these are roots longer than 30 cm and thicker than 3 mm, with diameters that can exceed 10–15 cm. The primary skeletal root is the taproot (or embryonic root);
- filling roots (also referred to as fibrous or transitional roots) - these roots occupy the spaces between skeletal roots and measure between 0.5 and 30 cm in length and 1–5 mm in diameter;
- absorptive roots characterized by their small size - 0.1 to 0.4 cm in length and 0.1 - 1 mm in thickness - these roots are typically white and have a short lifespan of 15 to 25 days. They are covered with numerous root hairs or, in certain species such as walnut, hazelnut, and currant, replaced by mycorrhizae, which fulfill the absorptive function (Cichi, 2011).

Two descriptive models are commonly used to characterize root system parameters: root density as a function of soil depth and root density as a function of horizontal distance from the plant (Van Noordwijk et al., 1996).

Modeling the mechanical reinforcement of soil by root networks is inherently complex and requires the application of advanced computational methods. One such method involves finite element analysis, which incorporates appropriate constitutive equations to simulate soil–root interactions. The finite element software PLAXIS - short for Plasticity Axisymmetric - is widely used for such analyses (Brinkgreve and Vermeer, 1998).

Trenches excavated closer to the trunk than the recommended tree protection zones did not compromise the stability of two commonly occurring tree species. Although *Tilia cordata* exhibited lower overall stability compared to *Acer platanoides*, neither species showed significant adverse effects even under the most severe trenching treatments (Pallafray et al., 2024).

Additionally, studies have quantified both the average and maximum vertical forces required to uproot stumps in a single piece. These investigations also considered the influence of soil type and uprooting techniques. It was hypothesized that increasing soil moisture content and employing preparatory treatments - such as the application of initial mechanical forces - would decrease the subsequent force needed for stump extraction (Lindroos, et al., 2010).

Various types of equipment for tree root cutting have been developed globally by renowned manufacturers. An Italian company has produced the *Root-cutting tool SHARK*, which features a lamellar blade with hydraulically adjustable working depth and operates without a pendulum mechanism. This equipment is designed to perform effectively in light soils free of stony inclusions (AGROFER). Additionally, a Dutch company has developed the *Root Pruner*, which incorporates a stability system based on a wheel train to enhance operational control (BORECO). However, neither manufacturer provides detailed information regarding the mechanical stresses acting on the cutting blades during operation, nor do they present comprehensive research on the equipment's performance across different soil types or under varying working conditions. This study presents the results of experimental research on the root pruning of fruit trees, carried out using a prototype device specifically designed for this purpose and tested under varying soil conditions.

MATERIALS AND METHODS

Based on the considerations outlined above, INMA Bucharest, developed an experimental root-cutting device for trees. This equipment was employed in the present study, and its main components are illustrated in Figure 1.

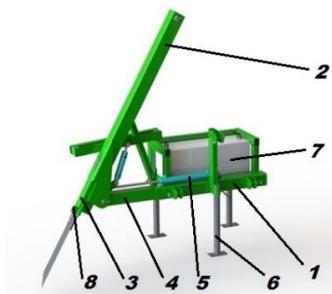

Fig. 1 - Schematic diagram of the experimental equipment for tree root cutting.

1. framework; 2. blade holder arm; 3. sliding pipe; 4. traverse; 5. hydraulic system;
6. foot support; 7. ballast block; 8. cutting force monitoring system.

During operation, the equipment should be positioned so that the cutting blade is aligned at the predetermined distance from the tree row, taking into account the age and size of the trees. The blade, actuated by a hydraulic system, is inserted into the soil to the specified depth, following the cutting protocol established by the operator. Once positioned, the tractor, coupled to the implement, is started, and the root-cutting operation is carried out.

Main technical characteristics:

- maximum working depth, 500 mm;
- maximum horizontal telescopic extension of the blade, 500 mm;
- adjustable blade inclination (working angle), 45°...70°;
- total equipment weight (including ballast), approximately 600 kg.

The equipment and measuring devices used for the experimental procedures consisted of the following components: a force transducer, a micro PLC 13, a force amplifier, and an operator terminal. An agricultural tractor with a rated power of 100 HP was employed as the energy source for operating the root-cutting implement.

Determination of root cutting resistance

The root-cutting operation, illustrated in Fig. 2, involves a sequence of mechanical actions performed by the cutting blade:

- Vertical soil penetration: the blade is inserted vertically into the soil to a predetermined depth, initiating the cutting process
- Horizontal soil displacement: As the blade moves forward, it deforms and displaces the surrounding soil laterally. The volume of displaced soil is defined by the difference between the physical volume of the blade and the volume of the deformed soil.
- Root severance: As the blade progresses, it encounters and severs tree roots located within its path.

This process is influenced by several factors, including soil type, moisture content, and root density. A clear understanding of these interactions is essential for optimizing the design and operation of root-cutting equipment.

The total resistance to root cutting R_t is calculated using relation (1):

$$R_t = R_c + R_d + R_f + R_{rc} \quad [\text{daN}] \quad (1)$$

in which:

R_c - resistance to soil cutting, [daN];

R_d - resistance to soil deformation, [daN];

R_f - frictional resistance between the coulter and the soil, [daN];

R_{rc} - resistance to root cutting, [daN];

To further explain the components of relation (1), the following expressions (2), (3), (4) and (5) were used, adapted from *Scripnic and Babiciu, (1979)*:

$$R_c = k_c \cdot l_c = k_c \cdot \frac{d_c}{\sin \beta} \quad (2)$$

$$R_d = k_d \cdot l_d \cdot l_c = k_0 \cdot \frac{t_c}{2} \cdot \frac{t_c}{\sin \alpha} \cdot \frac{d_c}{\sin \beta} \quad (3)$$

$$R_f = \mu_f \cdot G_c \quad (4)$$

$$R_{rc} = k_{rc} \cdot S_r \quad (5)$$

where:

k_c - specific resistance to soil cutting, [daN/cm];

k_d - specific resistance to soil deformation, [daN/cm²];

k_0 - volume coefficient of deformation, [daN/cm³];

d_c - working depth of the cutting blade, [cm];

l_c - contact length of the blade with the soil, [cm];

t_c - thickness of the cutting blade, [cm];

l_d - contact width of the blade with the soil in the cutting area, [cm];

α - sharpening angle of the cutting blade, [degrees];

β - penetration angle of the blade into the soil, [degrees];
 μ_f - coefficient of friction between the blade and the soil;
 G_c - portion of the equipment weight acting on the blade, [daN];
 k_{rc} – specific resistance to root cutting, [daN/cm²];
 S_r - total cross-sectional area of roots cut simultaneously, [cm²] (*Scripcic and Babiciu, 1979*).

Substituting (2), (3), (4), (5) into (1), the relation (6) results:

$$R_t = k_c \cdot \frac{d_c}{\sin \beta} + k_0 \cdot \frac{t_c}{2} \cdot \frac{t_c}{\sin \alpha} \cdot \frac{d_c}{\sin \beta} + \mu_f \cdot G_c + k_{rc} \cdot S_r, \text{ daN} \quad (6)$$

The resistances acting on the blade during operation are schematically illustrated in Fig. 2.

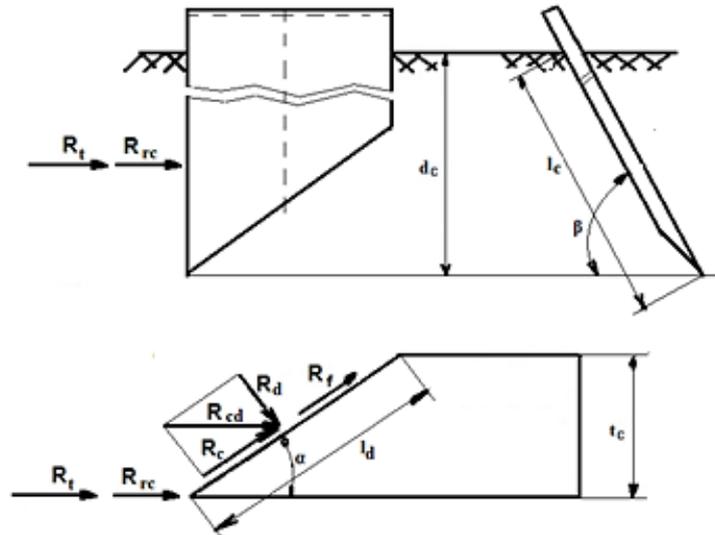

Fig. 2 - Schematic representation of the resistances acting on the cutting blade during operation

In the design of technical equipment for tree root pruning, two primary factors must be considered. First, the resistance encountered by the main cutting component, as defined in Equation (1), plays a critical role in determining the mechanical requirements of the system. Second, the type, condition, and characteristics of the soil, along with the tree species, must be taken into account, as these are governed by specific physical and chemical properties that influence root structure and resistance.

The working speed of the equipment, under specific operating conditions, is limited by factors such as the power of the tractor within the aggregate, the total resistance to root cutting, and the penetration angle of the blade into the soil. The relationship governing this limitation is expressed by Equation (7):

$$v = \frac{P}{R_t} \quad (7)$$

Where:

v - working speed of the equipment, [m/s];
 P - available working power, [W];
 R_t - total resistance to root cutting, [daN], (*Kepner et al., 1987*)

According to the fundamental principles of agricultural mechanics (*Kepner et al., 1987*), the working speed of an implement is directly proportional to the power developed and inversely proportional to the resistance exerted by the soil and biological material - in this case, tree roots.

RESULTS

The total resistance to cutting tree roots is influenced by several key factors, including:

- the type and condition of the soil;
- the distribution and development of roots within the soil profile;
- the working depth of the cutting blade and the penetration angle into the soil.

To evaluate the energy efficiency of the tractor-equipment aggregate during the root-pruning operation, it is necessary to calculate the total resistance encountered by the cutting mechanism. This resistance is determined using Equation (6).

The parameters and coefficients used in the calculation are as follows: $k_c = 5 \dots 10$ daN/cm; $k_0 = 1 \dots 2.5$ daN/cm³; $d_c = 50$ cm; $t_c = 1.5$ cm; $\alpha = 15^\circ$; $\beta = 45 \dots 70^\circ$; $\mu_f = 0.4 \dots 0.6$ soil/metal (Scripnic and Babiciu, 1979); $G_c = 100$ daN, measured by weighing; $R_{rc} = 60 \dots 75$ daN, resistance to cutting an apple tree root with $S_r = 1$ cm², the average value adopted in calculations was 67.5 daN.

The cutting resistance of the root R_{rc} was determined experimentally using a custom-designed cutting device equipped with a force transducer. This device was developed by the authors and manufactured within the institution where the research was conducted. By substituting both the known values and those determined experimentally into equations (2) through (5), the resulting resistances acting on the cutting blade were calculated for different soil types. These results, presented in Table 1, correspond to a maximum cutting depth of 50 cm and a blade inclination angle of 45°.

Table 1

Resistances on the root cutting blade, $d_c = 50$ cm, $S_r = 1$ cm², $\beta = 45^\circ$

Soil type	R_c [daN]	R_d [daN]	R_r [daN]	R_{rc} [daN]
Sandy soil $k_c = 5$ daN/cm; $k_0 = 1$ daN/cm ³ ; $\mu_f = 0.4$	354	307	40	67.5
Loamy soil $k_c = 7.5$ daN/cm; $k_0 = 1.25$ daN/cm ³ ; $\mu_f = 0.5$	530	538	50	67.5
Clay soil $k_c = 10$ daN/cm; $k_0 = 2.5$ daN/cm ³ ; $\mu_f = 0.6$	707	768	60	67.5

Since the experimental equipment for cutting tree roots allows for the adjustment of both cutting depth and blade penetration angle, and is designed to operate across various soil types with differing characteristics, it is equipped with a monitoring system that records real-time values of total cutting forces. This feature enables the selection of optimal working parameters while ensuring that the resistance does not exceed the mechanical strength limit of the blade.

The diagram presented in Figure 3 illustrates the variation in total root cutting resistance as a function of cutting depth for three different soil types. This graphical representation supports the selection of an appropriate tractor for the implement, ensuring that the machine provides sufficient traction force to achieve the required working depth.

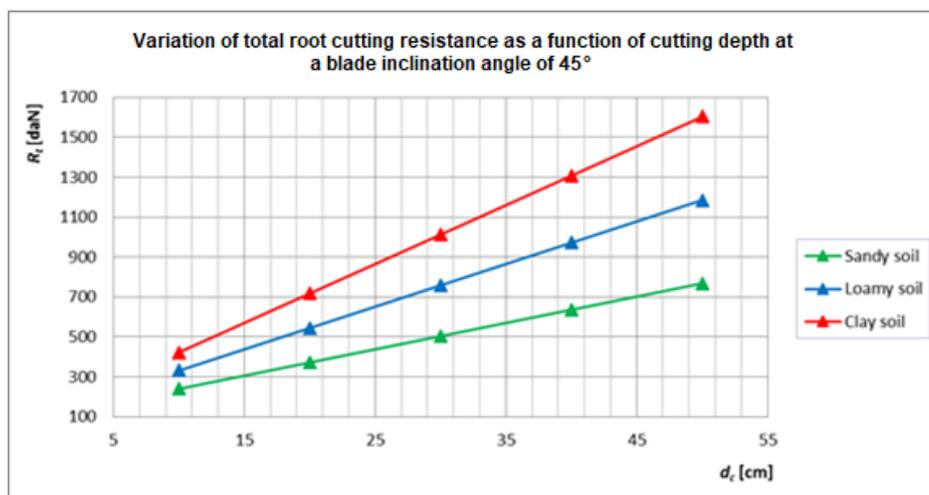

Fig. 3 - Variation of total root cutting resistance as a function of the working depth

Figure 4 illustrates the variation of total root cutting resistance as a function of the inclination angle of the cutting blade during operation, for the three soil types evaluated. The values obtained from this analysis can be used to adjust the cutting process according to the age and structural characteristics of the trees, ensuring that the operation aligns with the parameters defined by the established root pruning technology.

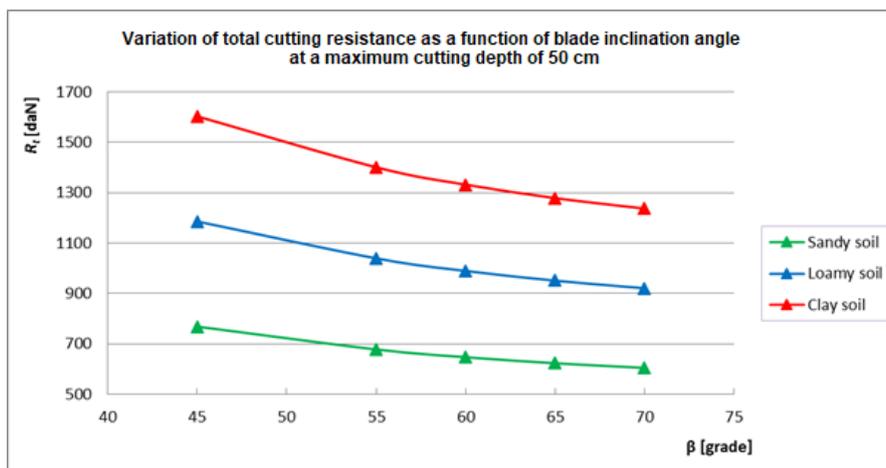

Fig. 4 - Variation of total cutting resistance as a function of blade inclination angle

The variation of working speed as a function of root cutting resistance, at different blade inclination angles, is presented in Figure 5.

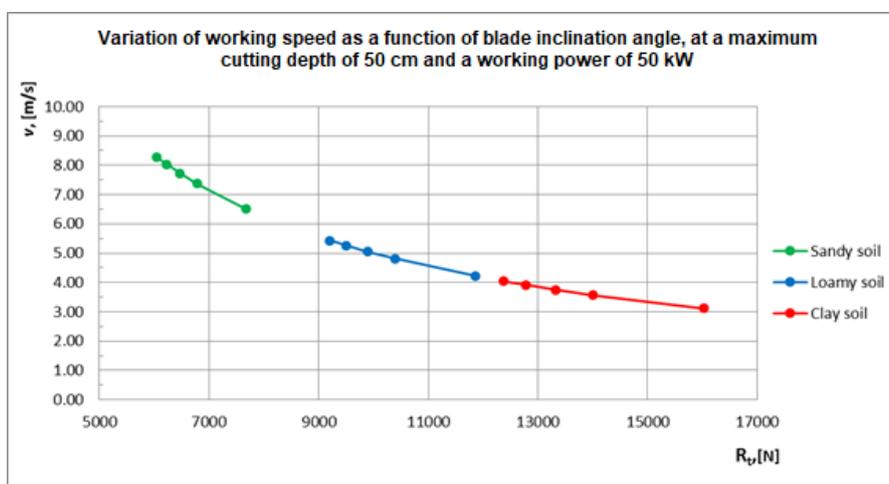

Fig. 5 - Variation of working speed as a function of total resistance to root cutting

This diagram provides practical guidance for operators who, based on the available tractor power and the resistance values presented in Figures 3 and 4, can determine the optimal working speeds for root cutting operations.

CONCLUSIONS

Root pruning is a valuable technique in pomology, aimed at improving tree health and enhancing annual fruit production.

The performance indicators of the experimental equipment were evaluated. The total resistance to root cutting varied with working depths from 10 to 50 cm, with values ranging as follows: 235...768 daN for sandy soil; 310...1185.5 daN for loamy soil; 405...1602.5 daN for clayey soil. The maximum achievable working speed, at a blade inclination angle of 50° and tractor power of 50 kW, ranged between: 6.5...8.5 m/s for sandy soil; 3...4 m/s for loamy soil; 4...5.5 m/s for clayey soil.

Equipping the device with a cutting resistance monitoring system allows for real-time adjustment of working parameters, ensuring the operation remains within mechanical safety limits. The findings of this study are significant both for the design of efficient root pruning equipment for fruit trees and for advancing research toward the development of intelligent, adaptive pruning technologies.

ABSTRACT

To address the challenges of low automation, insufficient precision in seed-powder-liquid ratio control, and suboptimal coating quality in current domestic small-sized forage grass seed pelletization coating equipment, this study designed and developed a fully automated pelletization coating system. The system employs a Microcontroller Unit as the core controller, integrates an ATFC101 serial touchscreen for human-machine interaction, and combines programming and electronic control technologies to achieve precise regulation of material and liquid supply, enabling fully automated and quantized coating operations. The hardware of the feeding system adopts a bidirectional thyristor circuit, while the software implements a hierarchical switching control strategy to ensure high precision and stable material delivery. Experimental trials using Caragana seeds and pelletization powder demonstrated that the integrated electro-control system achieved full automation, with seed dispensing deviation controlled within 1.2 g and powder deviation within 0.32 g, significantly improving dosing accuracy. This research provides critical theoretical and technical insights for optimizing automated pelletization coating equipment for small-sized forage grass seeds.

摘要

针对当前国内小粒牧草种子丸化包衣设备存在的自动化程度低、种粉液比例控制精度不足及包衣质量欠佳等问题,本研究设计并开发了一种小粒牧草种子全自动丸化包衣设备,系统以单片机为核心控制器,采用ATFC101串口屏作为人机交互界面,结合编程与电控技术,实现了供料与供液量的精确调控,进而达成全自动精量化包衣操作。供料系统硬件部分采用双向晶闸管电路,软件采用分层切换控制策略,确保了供料的高精度与稳定性。以柠条种子及丸粒化粉料为试验对象,研究结果表明,该电控系统与丸化包衣设备的集成实现了全自动操作,其中落种偏差控制在1.2g以内,落粉偏差控制在0.32g以内,显著提升了精确落料性能。本研究为小粒牧草种子全自动丸化包衣设备的设计与优化提供了重要的理论依据与技术参考。

INTRODUCTION

Seed pelletization coating technology is a processing method that uniformly encapsulates seeds with powdered agents, liquid binders, and other nutritional or protective materials to form small, spherical pellets with consistent size and shape. This technology not only significantly improves seed precision in mechanical precision seeding but also enhances seed resilience against biotic and abiotic stresses (Jarrar *et al.*, 2023; Paravar *et al.*, 2023; Yi, 2020). This technique has been widely applied in grassland ecological restoration projects to rehabilitate degraded and desertified grasslands through aerial seeding. By increasing seed size and mass, pelletization effectively mitigates the impact of wind speed and direction on seed dispersal, improves landing stability, and ensures better soil surface embedding, thereby substantially enhancing aerial seeding quality (Pedrini *et al.*, 2023; Zheng *et al.*, 2024). These benefits are particularly pronounced for small-sized forage grass seeds, which exhibit markedly improved germination rates and ecological adaptability post-treatment (Javed *et al.*, 2022).

Pelletization coating technology originated internationally in the 1940s. Over nearly 80 years of advancement, equipment development has evolved from rudimentary mechanical operations to intelligent and precision-driven modern systems. For instance, Denmark's HEID Corporation produces the CC-type rotary seed coater, which utilizes automated control systems to precisely coordinate the metering of materials and coating agents, effectively minimizing human error and enhancing coating uniformity and pelletization quality. Canada's Ohara Technologies developed the HVCC3015 continuous coater, featuring a zone-controlled, multi-angle spray nozzle design that optimizes spray angles and chemical dosage, significantly reducing coating dead zones and improving uniformity, efficiency, and final product quality. With dynamic metering and modular design, Niklas Germany has developed W.N.14 continuous coating machine, which realizes precise proportioning and automated operation through metering roller linkage and PLC control to enhance coating uniformity, reduce pharmaceutical waste and improve production efficiency (Ma *et al.*, 2023). In contrast, domestic research on pelletization in China began relatively late, transitioning from manual operations in the 1990s to fully automated systems. Chinese scholars have designed and tested pelletizers for diverse seed types while continuously optimizing their electro-control systems. Examples include the 5BY-5.0V Seed Coater by Jiuquan Okay Seed Co., which ensures precise chemical-to-seed ratios and thorough mixing. Yang *et al.* (2014) developed an intelligent control system to enhance coating quality and synchronize seed-chemical delivery. Sang *et al.* (2015) integrated advanced detection and control systems into the BY-150 coater, significantly improving dosing accuracy for both seeds and liquid agents. The 5BYR-100 Seed Coater, designed by the Guangdong Provincial Agricultural Machinery Research Institute, was optimized for batch coating of vegetable seeds. Despite these advancements, existing equipment predominantly targets vegetable and crop seeds, with limited options for small-sized forage grass seeds, and automation levels remain suboptimal. While researchers have improved pelletization quality through mechanical refinements, critical factors such as seed-powder-liquid ratios - key determinants of coating efficacy - are often inadequately addressed in current studies.

To address the aforementioned challenges, this study designed a fully automated pelletization coating system for small-sized forage grass seeds, achieving precise control over seed, powder, and liquid supply, alongside fully automated coating operations. Centered around a microcontroller unit and integrated with a closed-loop control strategy, the system enables intelligent regulation and stable operation throughout the entire process. This innovation aims to enhance the quality and efficiency of seed pelletization coating, providing robust technical support for forage cultivation and ecological restoration projects.

MATERIALS AND METHODS

Overall Structure and Operational Principle

System Architecture

The grass seed pelletization coating equipment consists of a powder feeding device, seed feeding device, liquid feeding device, pelletization coating device, and control system. Its structure is shown in Fig.1.

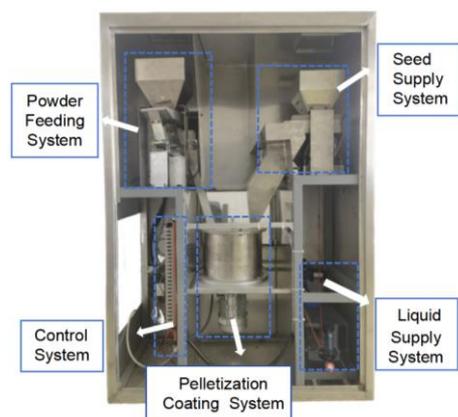

Fig. 1 – Schematic diagram of the overall system structure

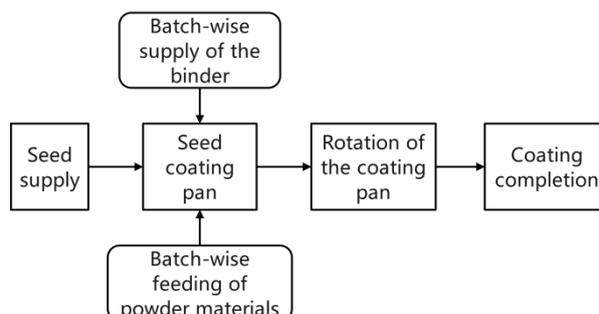

Fig. 2 – Flow chart of the pelletization process

The operational workflow of the pelletization coating equipment is as follows: First, the seed feeding device delivers seeds into the pelletization coating drum. After initiating drum rotation, the seeds are evenly distributed within the drum.

The liquid supply system then activates, injecting the coating solution into the drum. The drum continues rotating in an idle state to ensure thorough wetting of the seed surfaces. Subsequently, the powder feeding device supplies powdered material into the drum, followed by another idling phase to achieve uniform powder coating. Throughout the process, the liquid coating agent is supplied in quantitatively controlled batches, with powder dosing always synchronized after the liquid application. The batch-wise liquid and powder supply sequence is illustrated in Figure 2, operating in a cyclic "liquid supply-idling-powder supply-idling" mode until the preset pelletization criteria are met (Pasha et al., 2017). Finally, the drum idles for an extended period to enhance the compressive strength and surface smoothness of the coated pellets, completing one full coating cycle.

Control Workflow Overview

Based on the operational workflow of the pelletization coating equipment, the overall control flowchart of the system was designed, as illustrated in Figure 3. After system startup, initialization is completed first. Subsequently, operational parameters are configured via the touchscreen, and the equipment is activated. The system initiates seed feeding and enters an idle operation state once the seed quantity reaches the preset value. After the idle operation time meets the set duration, the liquid supply process is triggered. When the liquid supply volume reaches the single-cycle target, the system halts the liquid supply and re-enters idle operation. Following this, the powder supply process is activated, succeeded by another idle phase. The system operates cyclically in the "liquid supply-idle operation-powder supply-idle operation" sequence until the predetermined number of cycles is achieved, after which it transitions to the pelletization phase. During pelletization, the system runs for the set duration, concluding the process. The equipment then stops, marking the completion of a full coating cycle.

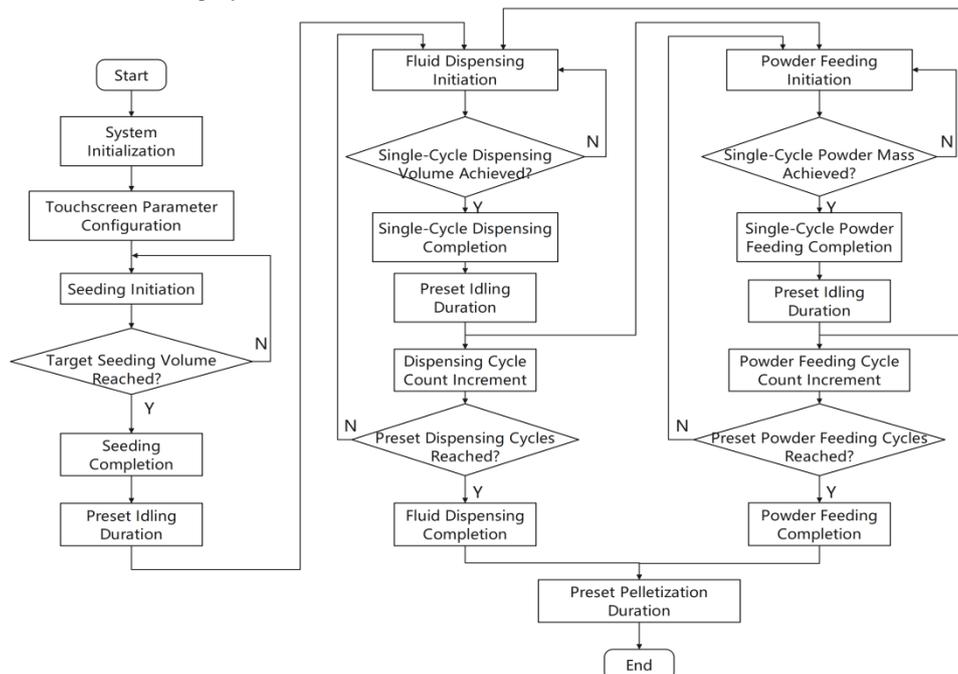

Fig. 3 – Control system flow diagram

Design of the Seed Supply Device Structure and Working Process

A seed metering device was ultimately designed by integrating a load cell, servo motor, and weighing hopper into the electromagnetic vibratory feeder. The structure of the feeder, as shown in Figure 4, comprises a material trough, leaf springs, an electromagnetic vibratory exciter, a base frame, and vibration isolation springs (Afzal et al., 2020). The electromagnetic exciter consists of critical components such as an electromagnet (coil with iron core) and an armature. In the alternating current (AC)-driven electromagnetic vibratory feeder, the operational principle relies on the coupling of electromagnetic forces and mechanical vibrations. When AC flows through the electromagnet coil, an alternating magnetic field is generated, producing periodic electromagnetic forces. During the positive half-cycle of the AC, current energizes the coil, creating an electromagnetic force that attracts the armature to the iron core. This action drives the trough backward while deforming the leaf springs to store elastic potential energy. During the negative half-cycle, the current direction reverses, weakening or eliminating the electromagnetic attraction.

The leaf springs then release stored energy, propelling the armature and iron core in the opposite direction, thereby moving the trough forward. With a standard AC frequency of 50 Hz, the feeder completes 50 reciprocating vibrations per second, equivalent to 3,000 cycles per minute (Mucchi *et al.*, 2013). This process converts electrical energy into mechanical energy through electromagnetic forces, enabling periodic vibrations of the trough to achieve material conveyance.

The feeding capacity of an electromagnetic vibratory feeder is influenced by multiple critical factors, including the mechanical index, trough inclination angle, and material properties (particle size, density, and moisture content). Among these, the mechanical index (K), defined as the ratio of the trough's maximum acceleration to gravitational acceleration, serves as a core parameter that directly governs material conveying speed and uniformity (Despotović *et al.*, 2017; Chandravanshi *et al.*, 2017).

$$K = 4\pi^2 f^2 a/g \quad (1)$$

In the formula: f - vibration frequency, [Hz];

a - amplitude, [m];

g - gravitational acceleration, [m/s²].

In this study, the vibration frequency was set to 3,000 cycles per minute (50 Hz). By adjusting the vibration amplitude (a), the feeding capacity was optimized to accommodate the conveying requirements of diverse materials, thereby improving operational efficiency and precision. Building on this foundation, the electromagnetic vibratory feeder was enhanced and an intelligent seed feeding device was designed. This device enables two operational modes-high-speed and low-speed-by modulating the exciter's amplitude: high-speed mode prioritizes feeding rate for rapid material delivery, while low-speed mode minimizes feeding error to ensure precise quantitative dosing.

During system operation, the seed supply system drives the trough vibration via the electromagnetic vibratory exciter in high-speed mode, conveying seeds to the weighing hopper. The Microcontroller Unit monitors the real-time seed weight in the hopper through feedback from the load cell. When the feeding rate reaches the switching point (expressed as a percentage of the total seed quantity), the Microcontroller Unit switches the exciter to low-speed mode to enhance dosing precision (Zhang *et al.*, 2021; Campos *et al.*, 2012). Upon achieving the preset seed quantity, the Microcontroller Unit halts the exciter's vibration and controls the servo motor to rotate at a specified angle, thereby opening the discharge gate to deposit the quantified seeds into the pelletization coating drum. The process flowchart is illustrated in Figure 5.

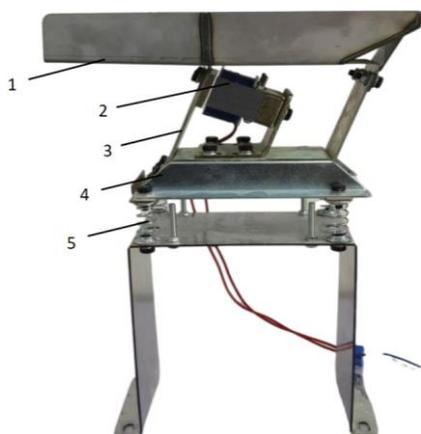

Fig. 4 – Structural diagram of the electromagnetic vibration feeder

3. leaf spring; 4. base frame; 5. vibration isolation spring

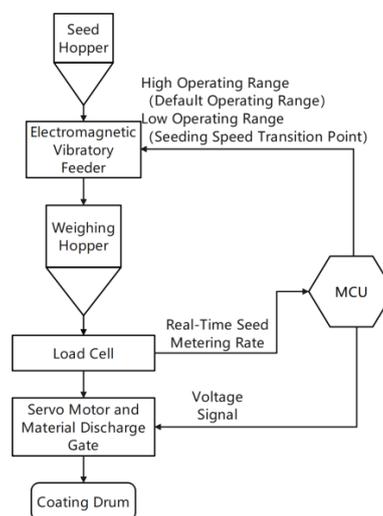

Fig. 5 – Process flow chart of the seed supply system

Hardware Design

The hardware components of the seed-feeding device primarily consist of a load cell, electromagnetic vibrator, and servo motor. To ensure precise seed delivery, the system employs a high-precision parallel cantilever load cell with a 0-2 kg range and 0.02 g accuracy. This load cell features a composite error of <0.02% F.S., an operational temperature range of -20 to +75°C, sensitivity of 1±0.03 mV/V, a power supply voltage of 5-12 V, and an overload capacity of 150% F.S., offering high accuracy, user-friendly operation, and strong anti-interference capability. Since the load cell's output signal is weak and susceptible to interference, the system incorporates an HX711 module to amplify and convert the analog signals.

This module integrates a high-precision 24-bit A/D converter with a 2.6-5.5 V operating voltage range, delivering low-noise, high-resolution performance for stable digital output, making it ideal for high-accuracy weighing applications.

The amplitude regulation of the electromagnetic vibrator is achieved through a TRIAC-based voltage control circuit (shown in Figure 6). This circuit connects the mains power to the signal input terminal, with the output terminal linked to the electromagnetic vibrator. The circuit configuration includes: Q1 as the bidirectional thyristor (TRIAC), D1 as the bidirectional trigger diode (DIAC), RX/R2/C2 forming the phase-shift network, and C1/R1 composing the snubber circuit to suppress voltage transients during switching operations and protect circuit components. By adjusting the resistance value (RX) in the phase-shift network, the circuit controls the charging time of capacitor C2 until it reaches the DIAC's trigger voltage (32 V), thereby modulating the TRIAC's conduction phase angle. This directly varies the output RMS voltage, enabling the electromagnetic vibrator to operate at two distinct speed settings (high/low) for seed feeding applications.

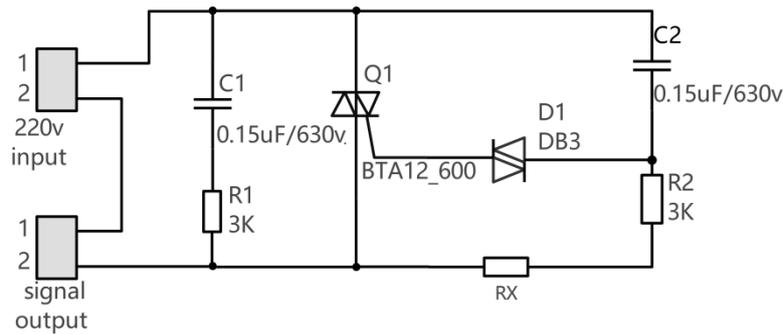

Fig. 6 –TRIAC voltage regulating circuit

The system employs a metal-gear micro servo with a 0.4413 N·m torque and a 180° controllable rotation range, featuring a no-load speed of 0.14s/60° at a 6V operating voltage. This servo provides precise angular positioning while maintaining excellent wear resistance and operational stability, ensuring consistent performance during prolonged high-frequency operation for rapid and accurate gate control in the feeding process. The servo is controlled through PWM signals with pulse widths ranging from 500 μs to 2500 μs (0.5-2.5 ms), where smaller pulse widths correspond to smaller rotation angles and larger pulses produce proportionally greater angles. This enables smooth 0-180° rotation for fine-tuned gate positioning, meeting the precise angular control requirements of the feeding system.

Design of the Powder Feeding Device

Although the material hoppers and specifications of the weighing system (hopper dimensions and weighing hopper capacity) differ between the powder feeding device and the seed feeding device, their mechanical structures, operational workflows, and hardware designs remain highly consistent. The process flowchart of the powder feeding system is illustrated in Figure 7.

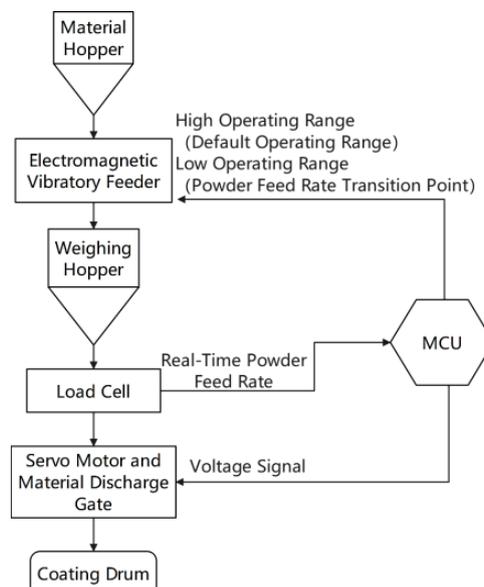

Fig. 7 – Process flow chart of the powder supply system

Design of the Liquid Delivery Device

Structure and Working Process

The liquid feeding system comprises a medicinal solution tank, a liquid supply pump, a flow meter, and an electromagnetic valve. The flow meter monitors the liquid flow rate in real-time and transmits the data to the Microcontroller Unit, enabling precise measurement and control of the liquid supply volume. The operational workflow is as follows: the liquid supply pump delivers the medicinal solution through a pipeline to the pellet coating pot, while the flow sensor continuously collects flow rate data and sends it back to the Microcontroller Unit. When the detected value reaches the preset threshold, the Microcontroller Unit immediately triggers a shutdown command to the electromagnetic valve, terminating the current liquid supply cycle. The process flow diagram of the liquid feeding system is illustrated in Figure 8.

Hardware Design

The hardware components of the liquid feeding system primarily consist of a liquid supply pump, flow meter, and solenoid valve. To ensure accurate flow measurement, the system employs a Digma flow meter with a measurement range of 0.05-0.82 L/min and an accuracy of $\pm 0.5\%$ F.S. This flow meter has a total error of less than 0.5% F.S., an operating temperature range of -10 to +60°C, output signals of 4-20mA or pulse, a power supply voltage of 12-24V DC, and an overload capacity of 120% F.S. With advantages such as high measurement accuracy, fast response speed, and strong resistance to medium contamination, it is particularly suitable for fluid control applications requiring low flow rates and high precision.

In the liquid feeding system, a normally closed DC 12V solenoid valve is installed at the outlet of the liquid supply pump to prevent backflow. Coupled with its dedicated driver circuit (shown in Figure 9), this solenoid valve allows for real-time, precise control of liquid flow. The driver circuit utilizes a high-response configuration consisting of a transistor-relay combination for accurate flow regulation. The control mechanism operates via the Microcontroller Unit's I/O port, which is connected to the solenoid valve driver circuit. When the I/O port outputs a high-level signal, the transistor enters saturation, energizing the relay to open the solenoid valve and initiate liquid flow. Conversely, a low-level signal from the I/O port drives the transistor into cutoff, de-energizing the relay to close the solenoid valve and stop the liquid flow. This switching mechanism provides reliable on/off control, with response times under 15ms, as confirmed through experimental testing.

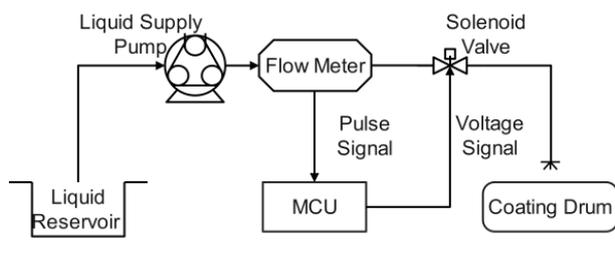

Fig. 8 – Process flow chart of the liquid supply system

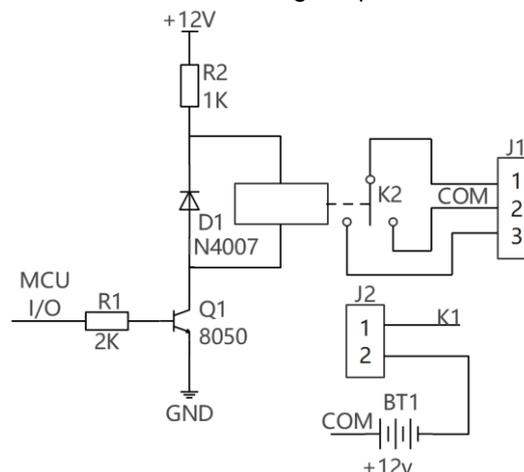

Fig. 9 – Driving circuit of the solenoid valve

Overall Control System Design

The small grass seed pelleting and coating equipment consists of a feeding device and a pelleting-coating unit. The pelleting-coating unit includes a speed sensor, frequency converter, AC motor, and coating drum. Based on closed-loop control principles, this study designed both the feeding device and pelleting-coating unit, with the closed-loop control system structure shown in Figure 10 (Upasan et al., 2013; Gai et al., 2013). In this system, sensors continuously collect controlled variables (such as flow rate, rotational speed, weight, etc.) from the controlled object and send the detected signals back to the controller. The controller compares the feedback values with setpoints to calculate deviation errors, then generates corresponding control signals based on preset control algorithms. Upon receiving the control signals, actuators adjust control variables (such as valve opening, motor speed, vibration frequency, etc.) to affect the controlled object, dynamically driving the controlled variables toward their setpoints. This process achieves automatic system regulation and precise control (Fowler et al., 2013).

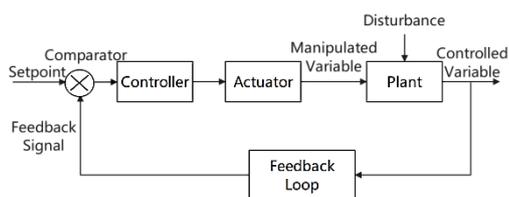

Fig. 10 – Block diagram of the closed-loop control system

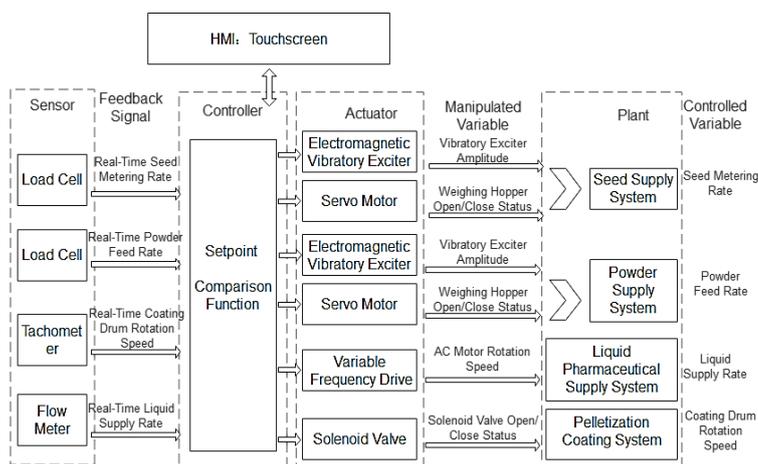

Fig. 11 – Schematic diagram of the control system

Based on the structural characteristics and operational workflow of the feeding device and pelleting-coating unit, the overall control system architecture was developed, as shown in Figure 11. This architecture includes a human-machine interface (touch screen), a controller (Microcontroller Unit), sensors (load cell, flow meter, speed sensor), actuators (electromagnetic vibrator, servo motor, solenoid valve, frequency converter), and controlled objects (seed feeding system, powder feeding system, liquid feeding system, and pelleting-coating system). The system achieves coordinated multi-subsystem control and integrated operation (Du et al., 2025).

RESULTS AND DISCUSSION

Experimental Study on the Seed Supply Device

In this study, using Caragana seeds as test specimens, the focus was on analyzing the seeding speed and accuracy of the testing equipment. The experiment required the determination of two key parameters: resistance values corresponding to high/low seeding speeds and the optimal speed switching point (expressed as a percentage of the total seed quantity). The high-speed mode primarily enhances throughput, while the low-speed mode improves dosing accuracy. The speed switching point represents a critical control parameter for error reduction: excessively high values may cause airborne seeds to exceed the remaining quantity before switching, compromising accuracy; excessively low values prolong the process duration due to slower low-speed discharge of substantial residual seeds.

To analyze the seed feeding rate and error, the resistance (R_X) in Figure 6 was adjusted from 0 to 1000 k Ω , with resistance values partitioned at 40 k Ω intervals. At each resistance setting, five replicate speed measurements were performed, and the mean value was calculated to generate the seed feeding rate variation curve corresponding to different resistance values, as illustrated in Figure 12.

As demonstrated by the test results in Figure 12, the seed feeding rate exhibited a downward trend with increasing resistance values. Within the resistance range of 0 to 440 k Ω , the feeding rate remained relatively stable above 50 g/s. Considering the maximum uniform coating capacity of the pelletization coating drum (200 g of seeds), the resistance value corresponding to the high-speed mode was selected as 480 k Ω , yielding a feeding rate of 42.61 g/s. This configuration balances rapid seed delivery and operational stability, effectively meeting the demands of high-throughput pelletization processes.

To mitigate seed feeding error by selecting resistance values in the low-speed mode, a focused investigation into error characteristics at high resistance values was conducted. A resistance range of 920 k Ω to 1000 k Ω (corresponding to seed feeding rates of 1.18 g/s to 4.33 g/s) was tested. The resistance values were partitioned at 10 k Ω intervals, with five replicate measurements performed at each interval. The mean value of these measurements was adopted as the error result for the respective resistance value. This methodology yielded the error variation curve corresponding to different resistance values, as shown in Figure 13.

As demonstrated by the experimental results in Figure 13, the error exhibited a decreasing trend with increasing resistance values. Combined with the seed feeding rate data from Figure 12, at a resistance value of 1000 k Ω , the corresponding seed feeding rate was 1.18 g/s with an error of 1.32 g. Both the feeding rate and error at this resistance value met the design requirements. Therefore, 1000 k Ω was selected as the optimal resistance value for the low-speed mode.

To investigate the influence of different seed feeding rate switching points on dosing accuracy, resistance values of 480 k Ω (high-speed mode) and 1000 k Ω (low-speed mode) were selected for a 200 g seed dosing error test. The switching points were set at 75%, 80%, 85%, 90%, and 95% of the target seed quantity. At each switching point, five replicate measurements were conducted. The mean error and standard deviation for each switching point were calculated, yielding the error variation curve corresponding to different switching points, as shown in Figure 14.

According to the experimental results shown in Figure 14, the seeding error reaches its minimum value with the smallest standard deviation when the seed feeding speed switching point is set at 90% of the total seed feeding amount, indicating optimal seeding stability under this condition. Therefore, 90% of the seed feeding amount is selected as the optimal switching point for seed feeding speed adjustment.

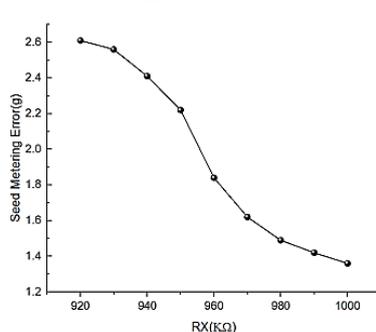

Fig. 13 – Variation curves of seed feeding error under different resistance values

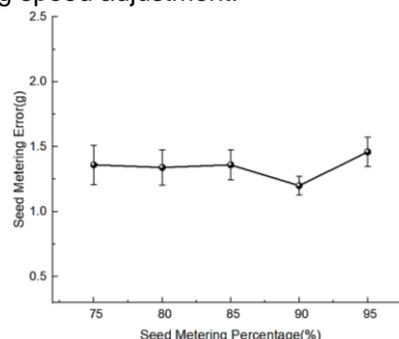

Fig. 14 – Variation curves of seed feeding error at different speed switching points

Experimental Study on the Powder Supply Device

Given the identical hardware design between the powder feeding device and the seed feeding device, the parameters requiring determination in the experiments are the same: the resistance value (RX) of the phase-shifting network and the powder feeding speed switching point (percentage of powder feed amount). To analyze the relationship between feeding speed and error, RX was set within the range of 260-680 k Ω , with resistance values partitioned at 20 k Ω intervals. For each resistance value, five speed measurements were conducted, and the average values were calculated to derive the powder feeding speed variation curve corresponding to different RX values, as shown in Figure 15.

As evidenced by the experimental results in Figure 15, the powder feeding speed exhibits a declining trend with increasing resistance values. When the resistance exceeds 520 k Ω , the rate of speed reduction accelerates markedly. Considering the total powder supply amount of 30 g in this study, the resistance value corresponding to the high-speed setting was selected as 260 k Ω , where the feeding speed reaches 2.41 g/s, thereby fulfilling the requirement for rapid powder delivery.

To reduce powder feeding errors by selecting resistance values under the low-speed setting, a focused investigation into error characteristics at high resistance values was conducted. Resistance values ranging from 920 k Ω to 1000 k Ω (corresponding to feeding speeds of 0.17 g/s to 0.46 g/s) were systematically tested. The resistance values were partitioned at 10 k Ω intervals, and five repeated measurements were conducted at each resistance value, with the average value adopted as the representative error result. This methodological framework yielded the powder feeding error variation curve corresponding to different resistance values, as illustrated in Figure 16.

As demonstrated by the experimental results in Figure 16, the powder feeding error exhibits a declining trend with increasing resistance values. Combined with the seed feeding speed data from Figure 15, at a resistance value of 600 k Ω , the corresponding powder feeding speed is 0.28 g/s, with a feeding error of 0.29 g. Both the feeding speed and error at this resistance value meet the design requirements. Therefore, 600 k Ω is selected as the optimal resistance value under the low-speed setting.

To investigate the influence of different powder feeding speed switching points on feeding accuracy, resistance values of 260 k Ω (high-speed setting) and 600 k Ω (low-speed setting) were selected for 30 g powder feeding accuracy tests. The switching points were set at 75%, 80%, 85%, 90%, and 95% of the total powder feeding amount. Five repeated measurements were conducted at each switching point. The average error values and standard deviations were calculated for each switching point, yielding the powder feeding error variation curve corresponding to different switching points, as shown in Figure 17.

As evidenced by the test results presented in Figure 17, the powder feeding error reaches its minimum value when the speed switching point is set at 85% of the total powder feeding amount. Notably, this configuration also yields the smallest standard deviation, demonstrating optimal feeding stability under these conditions. Based on these findings, 85% of the total powder feeding amount was determined to be the optimal speed switching point for the system.

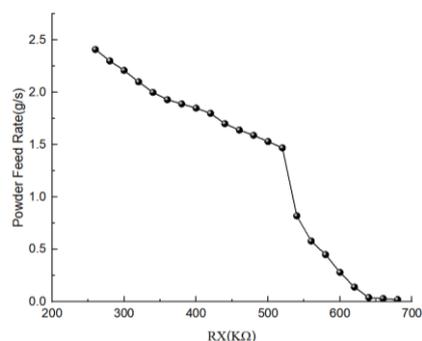

Fig. 15 – Variation curves of powder feeding speed under different resistance values

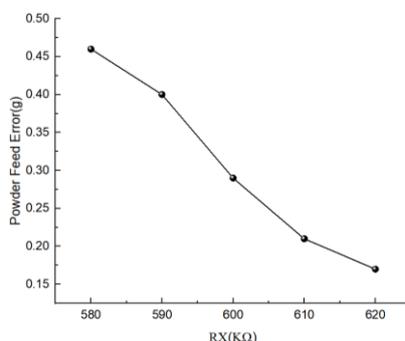

Fig. 16 – Variation curves of powder feeding error under different resistance values

Error Test Testing

To verify whether the designs of the seed-feeding and powder-feeding devices meet the error requirements for coating operations, error analysis tests were conducted for both systems. The results of the seed-feeding error test are presented in Table 1, while the results of the powder-feeding error test are shown in Table 2.

Table 1

Seed Metering Error Test Value			
SEED METERING QUANTITY [G]	NUMBER OF TRIALS	AVERAGE SEED DISPENSED [G]	ABSOLUTE ERROR [G]
100	5	101.2	1.2
150	5	151.16	1.16
200	5	201.16	1.16
250	5	251.1	1.1
300	5	301.18	1.18

Table 2

Powder Feeding Error Test Value			
POWDER FEEDING QUANTITY [G]	NUMBER OF TRIALS	AVERAGE POWDER DISPENSED [G]	ABSOLUTE ERROR [G]
20	5	20.32	0.32
25	5	25.31	0.31
30	5	30.29	0.29
35	5	35.3	0.3
40	5	40.3	0.3

Based on the statistical calculations of the experimental data (n=5 trials), the systematic errors showed a gradual decrease with the increase of material quality. Specifically, the seed supply error gradually decreased from 1.2% to 0.39% (100-300 g interval), and the flour supply error decreased from 1.6% to 0.75% (20-40 g interval). Compared to the existing state-of-the-art systems, the maximum seed supply error in this study was reduced by 32% (from 1.8% to 1.2%) and the powder supply error was reduced by 53% (from 2.0% to 0.75%) compared to the benchmark study by Zhang et al. (2022). The team reported seed supply/powder supply errors of 1.25-1.8% vs. 1.6-2.0%, respectively, under the same working conditions. The above performance improvement is due to the optimized layered switching control strategy, which effectively suppresses the inertial drop of the airborne residual material after the load cell triggers the closing of the drop plate.

CONCLUSIONS

This study developed a fully automated intelligent control system that integrates seed feeding, powder feeding, liquid supply, and coating functions to meet the specific process requirements of small grass seed pelleting and coating. The modular design of the system enables real-time monitoring and segmented adjustment of coating parameters through multi-sensor data fusion and hierarchical switching control, significantly enhancing the consistency of quality and the controllability of the pelleting and coating process for small seeds.

1) The study designed the seed-feeding and powder-feeding devices using a dual-mode control strategy, while employing a closed-loop control approach for the liquid-feeding device. The design was optimized to enhance the feeding accuracy of both the seed and powder delivery systems.

2) This study successfully integrated the control system with the pellet coating equipment and performed systematic performance validation tests. The experimental results show that the system achieves a seed feeding accuracy error of ≤ 1.2 g and a powder feeding accuracy error of ≤ 0.32 g, both of which meet the design specifications.

In order to further expand the application value of the system, the subsequent research can focus on the following directions:

1) optimization of multi-species adaptability: verify the system's adaptability to the coating of quinoa, sesame and other seeds with ultra-small particle sizes ($\Phi < 1$ mm), and develop parameter self-matching algorithms.

2) industrialization expansion research: design modular expansion interface, support multi-machine cooperative operation and flexible capacity configuration (50-500 kg/h), to adapt to the needs of large-scale production lines.

This technology can also be extended and applied in the field of precision powder engineering, such as pharmaceutical micro-pill coating, functional fertilizer preparation, etc., to provide technical support for the upgrading of agricultural intelligent manufacturing equipment.

Keywords: YOLOv8s, apple leaf lesions, target detection, attention mechanism, complex environments

ABSTRACT

The detection of apple leaf lesions in complex environments is hindered by several factors, such as the small size of lesion areas, variability in lighting conditions, and occlusions caused by overlapping leaves. These issues significantly limit the performance of existing detection models. Therefore, an enhanced detection algorithm for apple leaf lesions, termed PAME-YOLO, is proposed in this study, building upon the YOLOv8s framework. First, the main convolutional module is reconstructed using the Parallelized Patch-Aware Attention Module (PPA) while fusing Efficient Multi-Scale Attention (EMA). This effectively strengthens the model's capacity to localize small target lesions in complicated environments. Second, an Attention-based Intra-scale Feature Interaction (AIFI) is introduced into the feature extraction network to replace the Spatial Pyramid Pooling-Fast (SPPF) module, which better captures the subtle features of apple leaf lesions. Next, the downsampling enhancement module is designed to mitigate information loss during the original downsampling process, which contributes to a significant improvement in detection precision. Finally, the Efficient Head is designed, a lightweight and efficient detection head that lowers parameter count and computational intricacy without sacrificing accuracy. Compared with YOLOv8s, the proposed model delivered a notable enhancement in performance, with precision (P) increasing by 0.8 points and recall (R) by 1.5 points. The mAP@0.5 achieved 91.4%, which is 1.5 percentage points higher than that of YOLOv8s. Meanwhile, the mAP@0.5:0.95 rose to 56.4%, reflecting an increase of 1.4 percentage points. The improved model realizes the accurate detection of apple leaves lesions in complicated surroundings, offering reliable technical assistance for disease prevention and contributing to the development of the apple industry.

摘要

在复杂环境中，苹果叶片病斑的检测受到诸多因素的影响，如病斑区域尺寸较小、光照条件变化以及叶片重叠造成的遮挡等问题。这些因素严重限制了现有检测模型的性能。为此，本文在 YOLOv8s 算法的基础上提出了一种称为 PAME-YOLO 的苹果叶片病斑检测算法。首先，本文使用并行补丁感知注意力模块同时结合高效多尺度注意力机制对主干卷积模块进行重构，这有效增强了模型在复杂环境中对小目标病斑的定位能力。其次，本文在特征提取网络中引入基于注意力的尺度内特征交互模块，来替换原有的快速空间金字塔池化模块，以更好地捕捉苹果叶片病斑的细微特征。随后，本文设计了新的下采样增强模块，以弥补原有下采样过程中的信息丢失，从而显著提高检测精度。最后，我们设计了一种轻量高效的检测头 Efficient Head，该检测头能够在保持精度的同时降低模型参数和计算复杂度。与 YOLOv8s 相比，所提出的模型在性能上取得了显著提升，精确率 (P) 提高了 0.8 个百分点，召回率 (R) 提高了 1.5 个百分点，mAP@0.5 达到了 91.4%，比 YOLOv8s 高出了 1.5 个百分点，同时 mAP@0.5:0.95 达到了 56.4%，提高了 1.4 个百分点。综上所述，改进后的模型实现了在复杂环境下对苹果叶片病斑的精准检测，为病害防控提供了可靠的技术支持，助力了苹果产业的可持续发展。

INTRODUCTION

Apple is a major cash crop that is widely consumed across the globe (Bai *et al.*, 2021). However, it is susceptible to diseases, particularly those affecting the leaves. Leaf infections can significantly disrupt physiological metabolism and photosynthesis, directly impairing apple growth and harvest. Consequently, prompt and precise identification of apple leaf diseases is essential for effective orchard management. This not only enables growers to prevent the spread of diseases and improve fruit quality and yield but also contributes to substantial economic and environmental benefits.

In earlier years, manual observation was the primary method for identifying apple diseases in most orchards and farms. However, this approach is time-consuming, prone to misdiagnosis, and increasingly inadequate for meeting the demand for fast and accurate disease identification. As artificial intelligence continues to evolve, object detection techniques powered by deep learning (Yann *et al.*, 2015) have found increasing application in the agricultural situations. According to the processing pipeline, models for object detection are typically categorized into two distinct groups: two-stage and one-stage detectors. The most representative example of a two-stage detection method is R-CNN (GIRSHICK *et al.*, 2014). Gong *et al.*, (2023) suggested an improved Faster R-CNN algorithm. This algorithm has an average accuracy of 63.1% on an annotated apple leaf disease dataset, which surpasses other target detecting techniques. Zhang *et al.*, (2021) presented a soybean leaf disease detection model named MF3R-CNN, which employs skip connections between multiple layers in the feature extraction network to facilitate multi-feature fusion, thereby effectively fulfilling the necessities of object detection tasks. Despite the great detection accuracy provided by two-stage algorithms, their training and inference processes are time-consuming, which limits their suitability for deployment in intelligent agricultural equipment.

Compared to two-stage detectors, one-stage detection methods are more appropriate for practical applications due to their better scalability and faster inference speed. Among the most well-known one-stage detection methods is the YOLO series, which has gained widespread deployment in the agriculture industry. Abulizi *et al.*, (2024) integrated lightweight dynamic Sampling (DySample) to enhance small lesion feature extraction and employed Margin Penalty Distance Intersection over Union (MPDIoU) for precise localization of overlapping lesion boundaries. These enhancements achieved higher accuracy in tomato leaf disease recognition. To identify apple leaf diseases, Li *et al.*, (2023) proposed an improved YOLOv5s model by introducing a Bi-Directional Feature Pyramid Network (BiFPN), a Transformer module, and the Convolutional Block Attention Module (CBAM) to reduce background interference. The model achieved an average detection accuracy of 84.3% in natural environments. Gao *et al.*, (2024) replaced the traditional convolution and C2f structure with GhostConv and C3Ghost, respectively. They also incorporated the Global Attention Mechanism (GAM) and a BiFPN to enhance the detection of small apple leaf lesions in complicated environments.

Although the studies described above have made some progress, several problems in detecting apple leaf diseases remain unresolved. First, some disease spots are small, and different diseases may exhibit similar features, resulting in the model struggling to detect the lesions accurately. Additionally, in real-world cultivation environments, factors such as leaf occlusion and uneven lighting can reduce the model's capability to concentrate on diseased areas, limiting detection performance. Moreover, some studies have placed excessive emphasis on improving precision, while overlooking the increased model intricacy and computing expenses.

To overcome these issues, PAME-YOLO was developed, an enhanced YOLOv8s-based model for detecting apple leaf disease spots. The following contributions were made by this paper:

1. The C2f-PE module is designed by incorporating the PPA (Xu *et al.*, 2024) module and the EMA (Ouyang *et al.*, 2023) attention mechanism to further enhance the capability of identifying small lesions and differentiating similar features.
2. The SPPF module is substituted with the scale interaction module AIFI (Zhao *et al.*, 2024), which strengthens the high-level feature extraction, improves detection performance, and reduces redundant computation.
3. The downsampling enhancement module MPC is designed to improve the model's attention to small lesions in complex backgrounds, enabling it to better preserve key contextual information and enhance detection accuracy.
4. Aiming at the problem of high computational and large parametric quantities of the original detection head, the Partial Convolution (PConv) (Chen *et al.*, 2023) was employed to design the Efficient Head detection head, which increases detection efficiency while lowering computing costs and model complexity.

MATERIALS AND METHODS

Dataset

The raw images of the apple leaf disease in this research are acquired by the publicly available dataset AppleLeaf9 (Yang et al., 2022). Approximately 94% of the images in this dataset were taken in field settings, which ensures that the collected image data meet the requirements for complex backgrounds. From the dataset, 1,607 images of three common apple leaf spot diseases—Alternaria leaf spot, rust, and grey spot—were selected as the original image data. To address the limited original dataset, the data augmentation was applied to increase the images to 8952. After that, the augmented images were separated into training, validation, and test sets at a proportion of 8:1:1, with disease locations and categories annotated using the Labeling annotation tool.

YOLOv8

YOLOv8 is a strong visual recognition framework made to handle a range of computer vision tasks, including object detection, image classification, and instance segmentation (Wang et al., 2025). Compared to its predecessors YOLOv5 and YOLOv7, YOLOv8 delivers improved recognition precision along with accelerated inference performance. Its architecture comprises three primary components: the backbone, the neck, and the detection head (Tian et al., 2024). In feature extraction and fusion stages, YOLOv8 substitutes the C2f structure for the C3 module that was utilized in YOLOv5, facilitating richer gradient flow and improving feature representation. The classification and detection tasks are separated in the head by YOLOv8's decoupled structure, enhancing detection performance. Furthermore, it replaces the anchor-based mechanism of YOLOv5 with an anchor-free approach, giving the model greater flexibility and efficiency in identifying objects of different sizes and forms.

Improved YOLOv8 Algorithm

To address challenges such as the small size of disease spot features, high similarity among different lesions, reduced detection accuracy in complicated cultivation environments, and the extensive parameters, this study suggests an improved model based on YOLOv8s, named PAME-YOLO, as illustrated in Fig. 1.

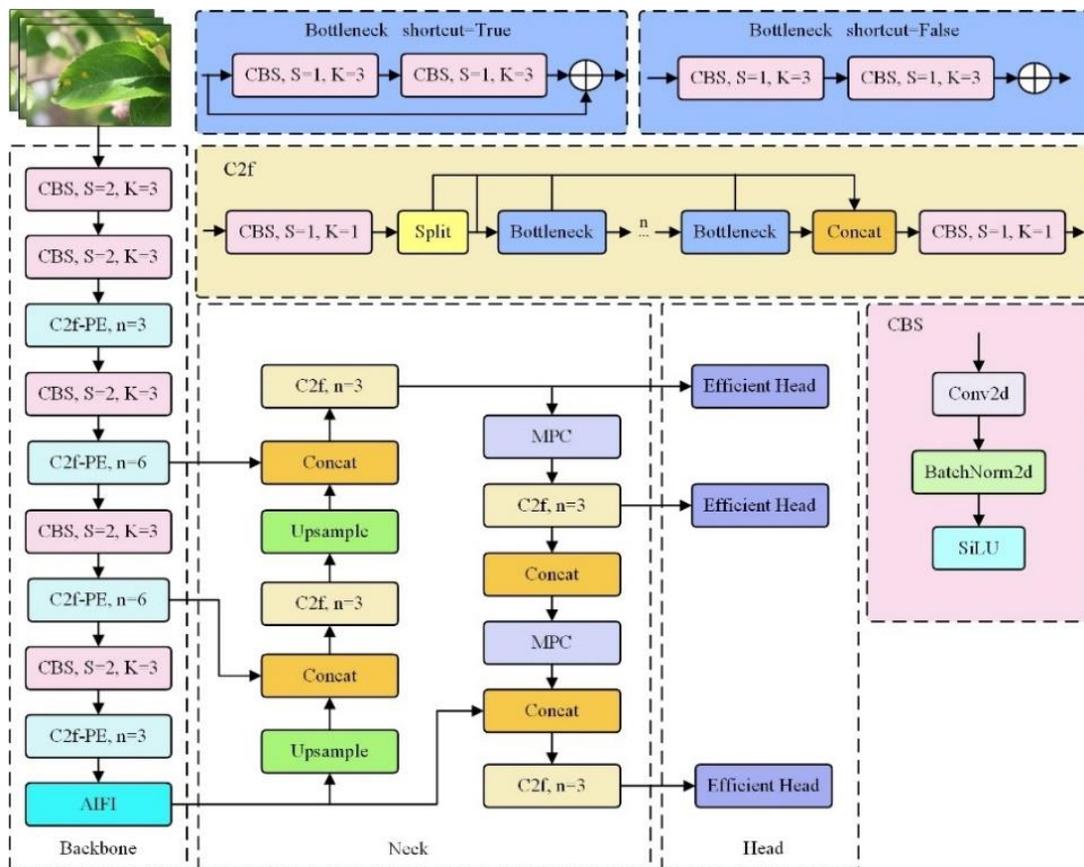

Fig. 1 - Overall architecture of the PAME-YOLO

C2f-PE

The C2f module can enable multi-scale feature extraction and fusion. Its multi-branch design strategy enhances the network's adaptability and representation capability. However, its ability to detect small targets and distinguish similar features remains limited. Therefore, this study redesigns and enhances the C2f module by integrating the PPA module and the EMA attention mechanism. The enhanced C2f-PE module is displayed in Fig. 2.

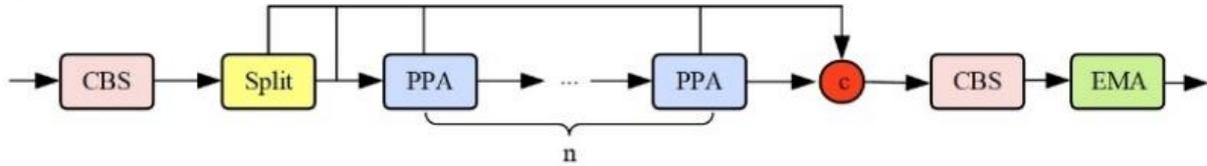

Fig. 2 - Structure of C2f-PE Module

Multiple downsampling operations can lead to the loss of details about small targets and missed detections. To make the model better at locating small disease spots, this paper incorporates the PPA module from the context fusion network HCF-Net into the C2f module. As illustrated in Fig. 3, the PPA module is made up of two essential parts: a multi-branch feature extraction architecture and an attention mechanism. The main benefit of PPA is its multi-branch feature extraction strategy. This method effectively increases the accuracy of detecting tiny disease spots on apple leaves by employing parallel branches, which extract features at different sizes and levels. The initial step in the feature extraction procedure is to convert the input tensor $F \in \mathbb{R}^{H \times W \times C}$ into $F' \in \mathbb{R}^{H \times W \times C'}$ using point-wise convolution. Then, F' is handled through three distinct parallel paths, which respectively generate the local feature tensor $F_{local} \in \mathbb{R}^{H \times W \times C'}$, the global feature tensor $F_{glocal} \in \mathbb{R}^{H \times W \times C'}$, and the linear feature tensor $F_{conv} \in \mathbb{R}^{H \times W \times C'}$. Lastly, the fused feature map $\tilde{F} \in \mathbb{R}^{H \times W \times C'}$ is obtained by adding the three tensors. After multi-branch feature extraction, an attention module is applied to produce the final output. The attention module is constituted by a sequence of channel attention (Wang et al., 2020) and spatial attention mechanisms (Woo et al., 2018). This design is particularly effective for detecting small disease spots on apple leaves and suppressing background noise, leading to improved accuracy and robustness of the model. The parameter p, which defines the patch size, serves to differentiate local and global branches, thereby promoting spatial feature fusion and displacement encoding (Bi et al., 2025).

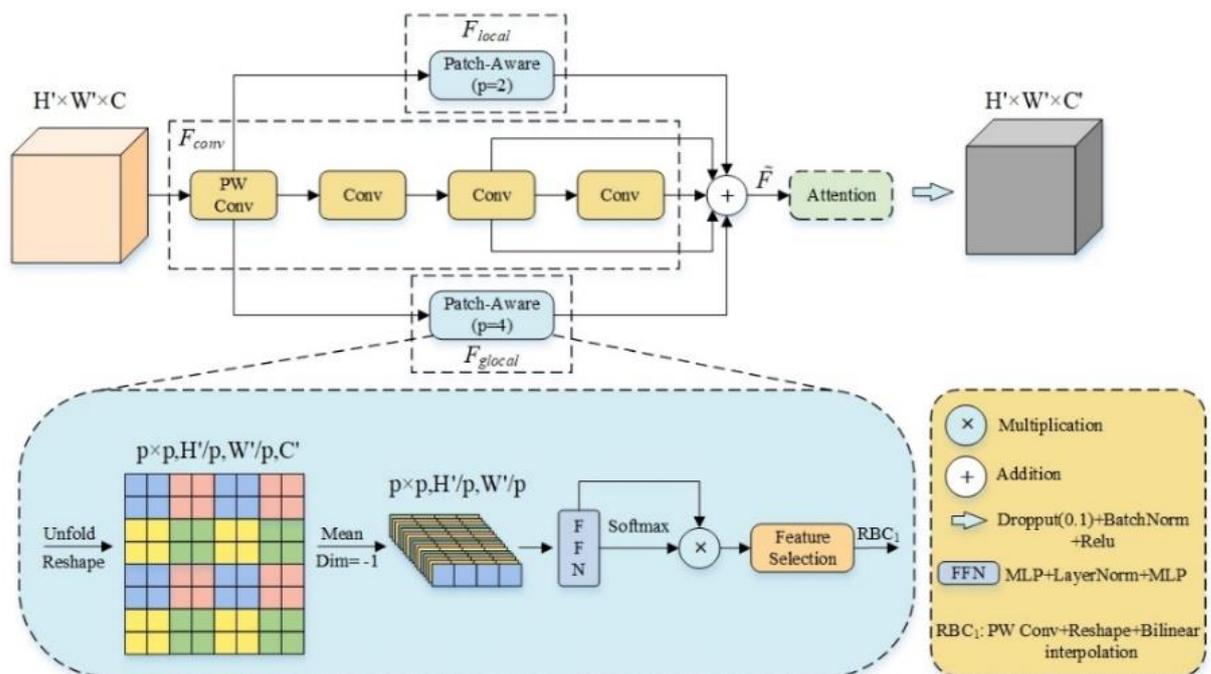

Fig. 3 - Parallelized Patch-Aware Attention Module

A certain degree of feature similarity exists both among different types of disease spots and between disease spots and surrounding objects, which can result in false detections. This issue is related to the limitation in the model feature extraction capability or the insufficient ability to select extracted feature information. To strengthen the model's feature extraction capacity, this paper also incorporates the EMA attention mechanism after the C2f module.

Fig. 4 presents the EMA module, which adopts cross-spatial learning to achieve efficient scale-aware attention. It reshapes part of the channels into the batch dimension and applies grouping in the channel dimension without requiring dimensionality reduction. This successfully stops channel feature information from being lost while reducing computational cost, and it features high accuracy and a low parameter count.

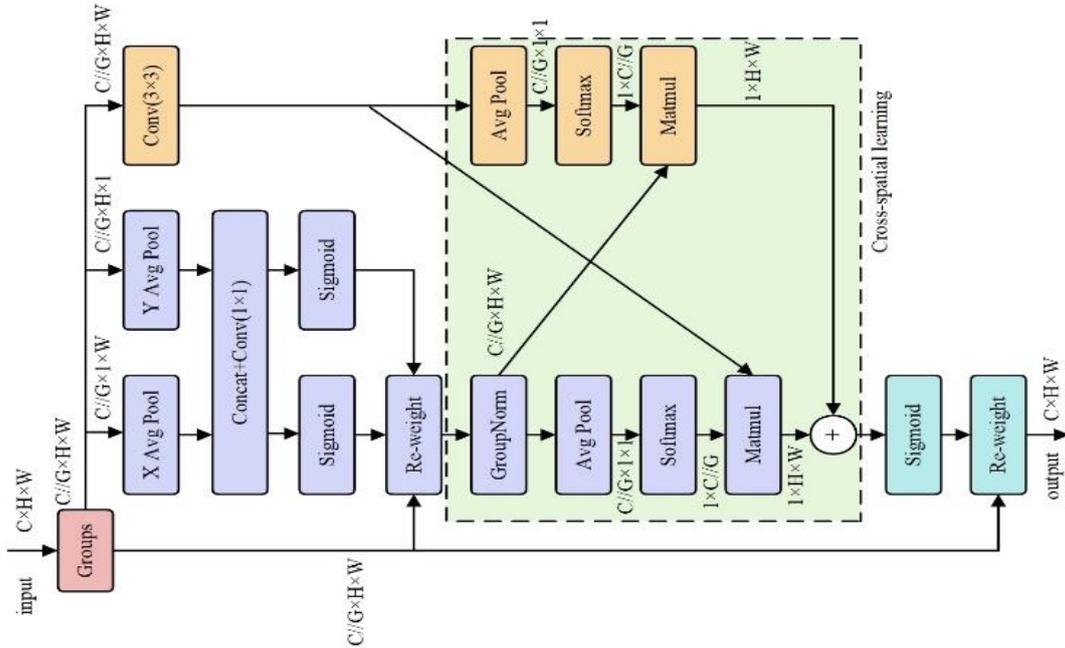

Fig. 4 - EMA attention mechanism framework diagram

AIFI

The SPPF module is an essential component of YOLOv8, enabling multi-scale feature fusion to enhance contextual information capture. However, it incurs a high cost of calculation. To mitigate this problem, the SPPF module is substituted with the AIFI module, which focuses on processing advanced image features. This contributes to enhanced detection accuracy while lowering computational cost. Compared to traditional multi-scale feature fusion methods, AIFI employs a single-scale Transformer encoder to focus feature fusion within the same scale. This helps capture finer-grained information and reduces the computational cost. Advanced features contain richer semantic content compared to low-level features, which have limited contribution due to insufficient semantic representation. As a result, the intra-scale interactions of lower-level features are redundant.

As seen in Fig. 5, the AIFI firstly linearizes the input 2D picture S_5 , converting it into a one-dimensional vector by arranging the rows sequentially. Then, a multi-head attention mechanism is employed, enabling the model to gather information from different spatial locations in the sequence, which strengthens its capacity to model long-range dependencies in the feature representation. The processed sequence is then combined with the original input for layer normalization. Afterward, the output undergoes a feed-forward network (FFN) for non-linear transformation and feature extraction. Finally, the FFN output is added to the previously normalized result and undergoes an additional layer of normalization. The one-dimensional vector is then reshaped back into its 2D form, F_5 , for further processing in the subsequent network. The specific process can be described by Equations (1) and (2).

$$Q = K = V = Flatten(Input) \tag{1}$$

$$Output = Reshape(FNN(MultiHead(Q, K, V))) \tag{2}$$

Here, Flatten refers to the flattening operation, Q , K , and V are the results of applying the flattening operation on the 2D image, MultiHead denotes the multi-head attention mechanism, Reshape stands for the reshaping operation, and FFN represents the feed-forward network operation.

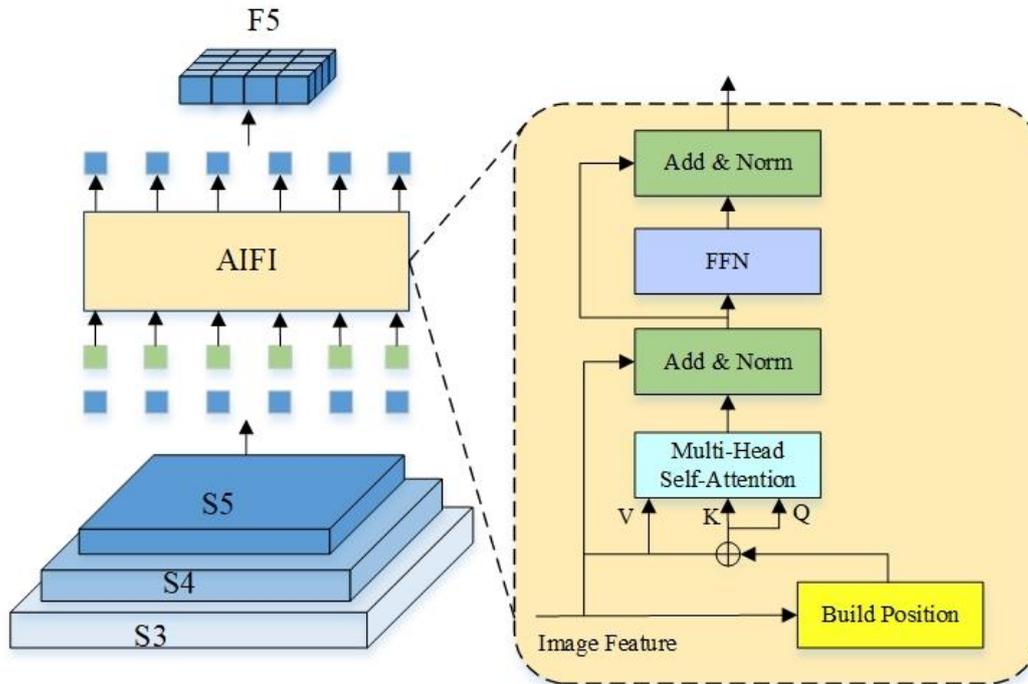

Fig. 5 - Structure of AIFI module, S3, S4, S5 represent different scale feature maps

Thanks to the Multi-Head Self-Attention and the FFN network, AIFI realize a scale-level interactions between advanced features, which helps the network better represent the connections of conceptual entities in the picture. This leads to improved extraction of subtle features of apple leaf spots, enhancing the detection performance and reducing false detections. Meanwhile, due to the feature fusion within the scale in AIFI, the computational cost of the detection model is reduced.

MPC Downsampling Enhancement Module

Downsampling techniques facilitate the processing of feature maps at different scales and objects by reducing the spatial size of feature maps. However, they also lead to information loss and a reduction in resolution. To address the partial loss of leaf spot information during downsampling, this study designs an improved downsampling module called MPC, as visualized in Fig. 6. The MPC downsampling is designed to strengthen the model's concentration on small lesion details in complex backgrounds, effectively preserving crucial contextual information and improving detection accuracy. The main components of the MPC are a 1x1 convolution, a Maxpool2d operation, a PConv, and a 3x3 convolution.

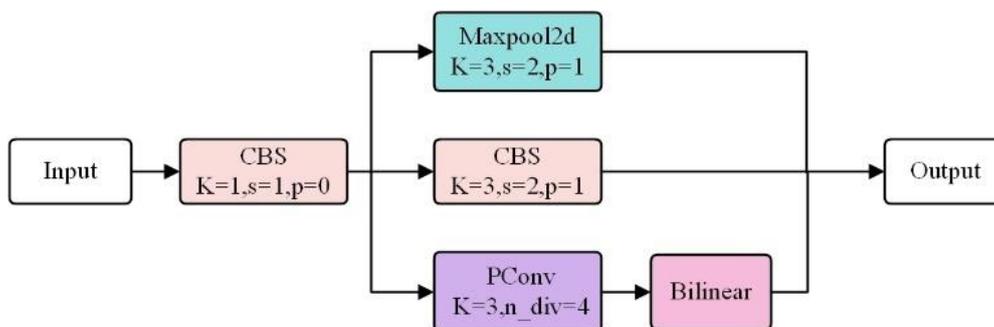

Fig. 6 - Structure of MPC module

Traditional downsampling in YOLOv8 uses a standalone 3x3 convolution module. While this module captures key features from the input data through filtering operations on the feature map, it also reduces the resolution of the feature map, impairing the capability to capture subtle patterns. To overcome this difficulty and improve the model's effectiveness and lightweight design, this study integrates PConv into the downsampling process. A comparison of the convolution operations between partial convolution and standard convolution is shown in Fig. 7.

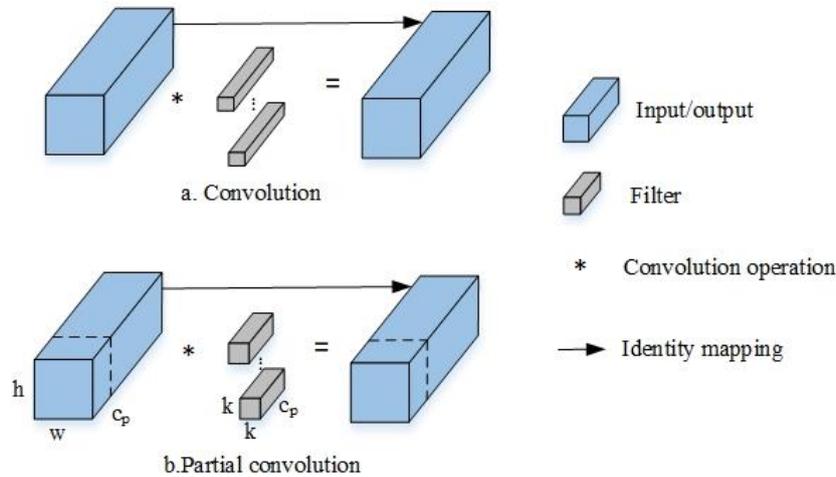

Fig. 7 - Convolutional operation comparison diagram

PConv leverages the inherent redundancy of feature representations by selectively performing standard convolution on a portion of the input channels without influencing the transformations of the remaining channels (Fu et al., 2024). Here, h , w represent the input height and width dimensions, respectively; c is input channels count; c_p refers to used convolution channels count; k denotes the kernel size used for the partial convolution; and r indicates the ratio of used convolution channels. The Floating Point Operations (FLOPs) after using partial convolution can be represented by Equation (3).

$$F_{PConv} = h \times w \times k^2 \times c_p^2 \tag{3}$$

$$r = \frac{c_p}{c} \tag{4}$$

Given the default participation ratio r set to 1/4, PConv achieves only 1/16 of the computational complexity compared to standard convolution, significantly reducing the time and memory required for convolution operations.

During the downsampling enhancement process, MPC integrates PConv with Maxpool2d to better balance computational efficiency and information integrity. Partial convolution extracts spatial features by applying convolution operations to only a portion of channels, keeping the other channels unaltered during feature processing. This strategy enables the model to efficiently process complex input images while demonstrating excellent capability in extracting disease spot features in complex backgrounds. Furthermore, it keeps the model from obsessively concentrating on irrelevant information, such as the background, thus reducing unnecessary computational overhead. As a result, both detection precision and computing efficiency in leaf spot detection are improved.

Efficient Head

Compared to the coupled structure of the detection head in the YOLOv5 model, the YOLOv8 head design employs a decoupled structure, in which classification and regression operation are processed separately, as presented in Fig. 8. Specifically, each branch comprises a 3x3 convolutional and a 1x1 convolutional, with each branch designed to focus on its respective task.

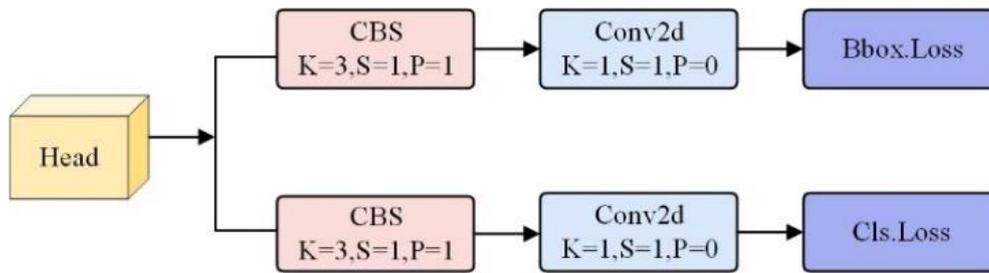

Fig. 8 - Structure of YOLOv8 Detection Head

To lessen the computational overhead and the parameter quantity while improving both detection speed and accuracy, this paper redesigns the Efficient Head based on the concept of parameter sharing, as shown in Fig. 9. The idea of merging first and then splitting is adopted, replacing the original two 3×3 convolutional blocks with a combination of the fast and efficient PConv and a 1×1 convolution. This improvement lowers parameter quantity and computing load while enabling more efficient feature extraction.

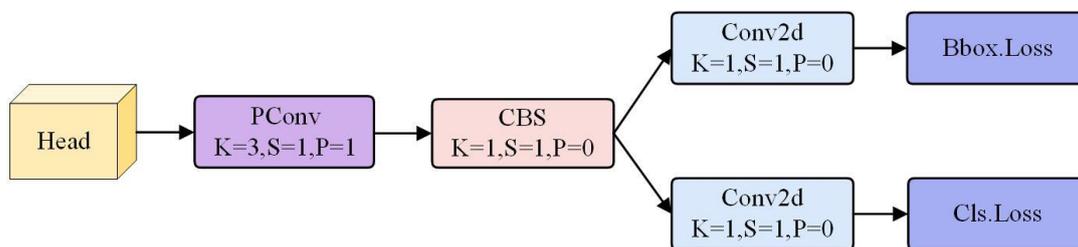

Fig. 9 - Structure of Efficient Head

RESULTS

Experimental Environment

The experimental environment comprised CUDA 11.7 on Ubuntu 18.04, using PyCharm as the development platform, PyTorch 2.0. as the deep learning framework, Python 3.8.10. An NVIDIA RTX 3060 GPU (12 GB) provided hardware acceleration. The training process spanned 150 epochs, adopting the Stochastic Gradient Descent (SGD) optimizer, an initial learning rate of 0.01, a batch size of 16, an initial learning rate of 0.01, with a patience parameter of 50.

Evaluation Metrics

To evaluate the model's performance impartially, frequent object detection metrics are employed, including Precision (P), Recall (R), mean Average Precision (mAP), and FLOPs. The formula is used for calculating P and R can be expressed by Equations (5) and (6).

$$P = \frac{TP}{TP + FP} \tag{5}$$

$$R = \frac{TP}{TP + FN} \tag{6}$$

Here, TP represents the quantity of diseases that the algorithm successfully recognized; FP represents the quantity of diseases that the algorithm incorrectly identified; FN represents the quantity of diseases not identified.

Although precision and recall are commonly used performance metrics, there is an inherent trade-off between them—optimizing one metric often comes at the expense of the other. Therefore, relying solely on either precision or recall fails to present a thorough and intuitive assessment of overall performance of a model. In contrast, mAP integrates characteristics of both metrics by calculating the average precision across varying recall levels, offering a more holistic evaluation. Furthermore, mAP more accurately reflects a model's performance under different detection difficulty levels, making it a more representative metric. The expression used to compute mAP is provided below:

$$AP = \int_0^1 P(R)dR \tag{7}$$

$$mAP = \frac{1}{c} \sum_{i=1}^c AP_i \quad (8)$$

Here c represents the count of classes in the dataset, i stands for the class index, and AP represents the area under the P-R curve for a single class.

Ablation Experiment

To evaluate the effectiveness of the suggested improvements in apple leaf lesion detection, ablation experiments were conducted on each improved method, as illustrated Table 1. All experiments were conducted without the use of transfer learning to ensure a fair and accurate evaluation of the proposed model's performance. A "√" marks that the improved method was applied in the experimental group.

Table 1

Results of ablation experiments										
No.	C2f-PE	AIFI	MPC	Efficient Head	P/%	R/%	mAP@0.5/%	mAP@0.5:0.95/%	FLOPs/G	
1	x	x	x	x	90.5	80.8	89.9	55.0	28.4	
2	√	x	x	x	90.1	81.1	90.9	55.7	33.3	
3	x	√	x	x	91.5	81.3	90.9	56.1	28.3	
4	x	x	√	x	90.1	81.2	90.3	55.3	29.4	
5	x	x	x	√	89.8	81.7	90.5	55.2	21.5	
6	√	√	x	x	89.6	82.4	91.1	56.2	33.2	
7	√	√	√	x	91.6	82.0	91.2	56.1	34.1	
8	√	√	√	√	91.3	82.3	91.4	56.4	27.2	

In Experiment 2, the C2f-PE module was substituted for the C2f module, which leads to a 1.0% improvement in mAP@0.5 relative to the Experiment 1. This result confirms that the C2f-PE module can strengthen the model's capacity for localizing small disease spots, but it also increases the model's computational cost by 14.7%. Experiment 3 replaced the SPPF layer with the AIFI module, resulting in improvements of 0.5% in recall, 1.0% in mAP@0.5, and 1.1% in mAP@0.5:0.95. This demonstrates that the model benefits from intra-scale feature interaction, which enables better extraction of fine-grained features of apple leaf spots and enhances overall detection accuracy. In Experiment 4, the downsampling enhancement module MPC was added, resulting in a 0.4% improvement in mAP@0.5. This confirms that incorporating the MPC module can help the feature extraction process better preserve contextual information and make up for the information lost due to downsampling. After the Efficient Head was introduced in Experiment 5, the model's average precision improved by 0.6%, while its floating-point operations were reduced by 24.3%. This verifies the efficiency and lightweight characteristics of the Efficient Head. In Experiment 7, the ablation results demonstrated a 1.3% improvement in mAP@0.5 and 1.1% and 1.2% increases in precision and recall, respectively, compared with the baseline model. This improved detection performance but also increased the computational cost by 16.7%. Finally, the PAME-YOLO algorithm, which integrates four improvement methods, was compared to the baseline model. The improved PAME-YOLO demonstrated performance gains of 0.8%, 1.5%, 1.5%, and 1.4% in Precision, Recall, mAP@0.5, and mAP@0.5:0.95, respectively, while achieving a 4.2% reduction in computational load. Through a succession of experiments and comparative analysis, the improvements suggested in this paper has been effectively validated.

Detection Head Comparison

This study designs a novel lightweight detection head to enhance the detection efficiency and precision. In comparison experiments, several schemes were tested: (a) sharing two 3×3 convolutions; (b) sharing two 3×3 grouped convolutions; (c) sharing one 1×1 convolution and one 3×3 convolution; (d) sharing one PConv and one 1×1 convolution. Table 2 illustrates the comparison results of four schemes.

Table 2

Comparison experiment of different detection heads					
Plan	P/%	R/%	mAP@0.5/%	FLOPs/G	Parameters/M
(a)	91.5	81.9	91.0	37.5	18246403
(b)	89.9	82.9	91.0	27.0	12311299
(c)	91.2	82.2	91.2	32.5	15493891
(d)	91.3	82.3	91.4	27.2	12589955

From the Table, it can be seen that although schemes (a) and (c) achieve higher mAP values, their computational cost and parameter count are too large, resulting in lower detection efficiency. Scheme (b), while exhibiting lower computational costs and fewer parameters, achieves the lowest precision among all schemes. Scheme (d) effectively balances detection precision with model complexity, delivering a high mAP value alongside a reduction in model parameters. Therefore, scheme (d) is selected as the detection head for the improved model to enhance detection efficiency.

Comparison with Current Advanced Algorithms

A comparison between the PAME-YOLO and other mainstream methods is conducted under the same condition and the same dataset. As presented in Table 3, the PAME-YOLO outperforms other mainstream object detection algorithms in terms of recall, mAP@0.5, and mAP@0.5:0.95. Specifically, the recall is higher than RT-DETR-L, YOLOv5s, YOLOv5m, YOLOv7-tiny, YOLOv8n, YOLOv8s, and YOLOv10s by 6.2%, 3.6%, 2.6%, 2.1%, 4.3%, 1.5%, and 0.4%, respectively, while the mAP@0.5 is higher by 5.2%, 3.0%, 2.0%, 3.4%, 2.8%, 1.5%, and 0.7%, respectively. The YOLOv5m model achieves the highest detection precision, but its parameter and computational requirements are too large. This means it requires higher computational resources and larger storage space to operate, making it unsuitable for real-time tasks. Considering all metrics, PAME-YOLO demonstrates higher detection precision, recall, and stability than other algorithms, with a reasonable model size and computational complexity, allowing it more appropriate for agricultural applications.

Table 3

Model	P/%	R/%	mAP@0.5/%	mAP@0.5:0.95/%	Parameters/M	FLOPs/G
RT-DETR-L	87.1	76.1	86.2	51.9	31989905	103.4
YOLOv5s	91.5	78.7	88.4	54.0	7018216	15.8
YOLOv5m	92.3	79.7	89.4	54.5	20861016	47.9
YOLOv7-tiny	87.2	80.2	88.0	51.6	6020400	13.2
YOLOv8n	89.9	78.0	88.6	54.2	3006233	8.1
YOLOv8s	90.5	80.8	89.9	55.0	11126745	28.4
YOLOv10s	90.6	81.9	90.7	54.5	8037282	24.5
PAME-YOLO	91.3	82.3	91.4	56.4	12589955	27.2

Comparison of different diseases under YOLOv8s and PAME-YOLO

A comprehensive comparative analysis of precision, recall, and mAP@0.5 was conducted for each type of leaf disease using the YOLOv8s and PAME-YOLO models. In Table 4, PAME-YOLO achieves notable improvements in all three metrics relative to the original YOLOv8s. This implies that the model possesses a stronger ability to recognize diseases and can effectively reduce the occurrence of missed detections and false positives, particularly for small target lesions.

Table 4

Class	YOLOv8s			PAME-YOLO		
	P/%	R/%	mAP@0.5/%	P/%	R/%	mAP@0.5/%
Alternaria leaf spot	91.6	69.7	85.8	92.4	71.2	86.7
Grey spot	89.1	82.4	88.4	89.5	85.1	91.6
Rust	90.8	90.4	95.5	92.0	90.5	95.9

Heatmap Visualization

In the apple leaf disease detection task, the Grad-CAM (Selvaraju et al., 2017) method was used to visually highlight the regions of interest and the areas where the model concentrates its attention during object detection, further enhancing the comprehension of the decision-making process. In the heatmap, darker pixels indicate a greater contribution to the prediction result, while lighter pixels indicate a smaller contribution. The heatmaps before and after model improvement are displayed in Fig. 10. It is evident that the PAME-YOLO model pays less attention to irrelevant information such as the background, and focuses more on the disease spots, making it better suited for complex orchard environments.

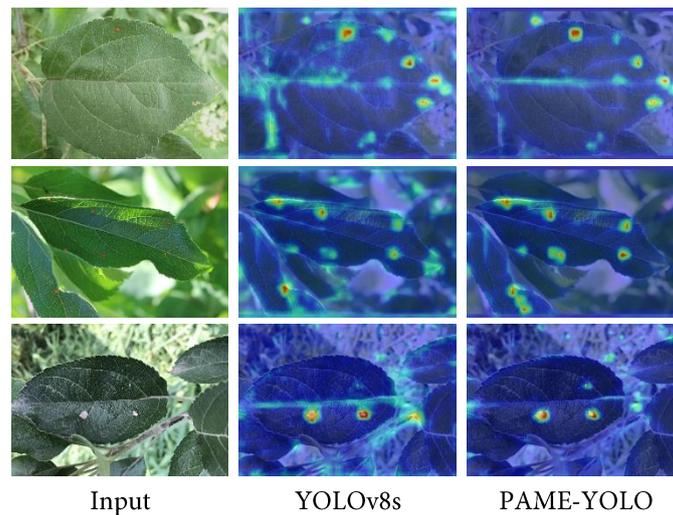

Fig. 10 - Visualization results of a heatmap

Visualization of Detection Results

Several images of leaves affected by Alternaria leaf spot, grey spot, and rust diseases were randomly selected to present detection results. As illustrated in Fig. 11, YOLOv8s shows suboptimal performance in detecting small spots on leaves in complex backgrounds. Specifically, it fails to detect some instances of Alternaria leaf spot and rust disease when the targets are small. In contrast, PAME-YOLO enhances the localization capability for small lesions by introducing the C2f-PE module, enabling accurate detection of spots without missed cases. Additionally, when detecting grey spot disease, the baseline model mistook the photographer's finger at the bottom left of the image for a lesion, resulting in a false detection. In contrast, PAME-YOLO correctly distinguished the actual spots from irrelevant objects, avoiding false detections and demonstrating higher robustness. In the figure, the yellow box represents a missed target, the blue box represents an error detection target.

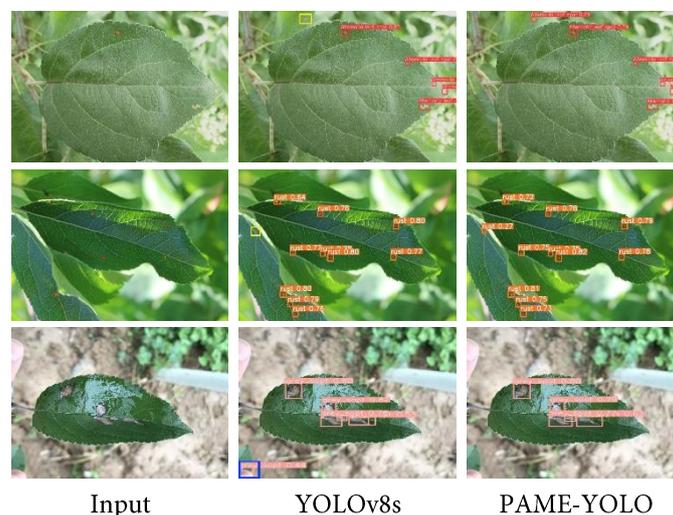

Fig. 11 - Detection effect comparison diagram

Model Deployment and Application Implementation

As illustrated in Fig. 12, the trained model for apple leaf disease spot detection was quantized using the NCNN inference framework and it was deployed to a mobile platform, based on which an application named Apple Leaf Disease Detector was subsequently developed. To ensure cross-platform compatibility, the user interface was developed using uni-app. The application was then compiled into an APK file via Android Studio and subsequently installed and tested on a smartphone running Android 13. The main interface of the application includes an image preview panel, a button for uploading images from the gallery, a camera button for real-time capture, and a detection button.

Users are provided with the option to either import apple leaf images from the device gallery or acquire them in real time via the built-in camera. After the image is uploaded or captured, the user can click the "Detection" button to initiate model inference. The detection results are displayed on the image in the form of bounding boxes, along with disease category labels and confidence scores. As can be observed from Fig. 13, this app can accurately detect apple leaf lesion across different categories even in challenging orchard environments.

The deployed application is lightweight and responsive, supporting accelerated inference via NCCN. This enables efficient, low-latency identification of apple leaf diseases in the field, offering strong practical value for fruit growers.

CONCLUSIONS

This study proposed an enhanced object detection algorithm called PAME-YOLO that focused on the issues of low detection accuracy and the susceptibility to overlooking small lesion targets in apple leaf disease diagnosis under complicated backgrounds. Specifically, the C2f-PE feature extraction module was designed to improve the model's detection accuracy for small lesion targets. In addition, an intra-scale feature interaction mechanism was introduced to capture more fine-grained lesion information and reduce false detections. The downsampling enhancement module, MPC, was designed to ensure that critical contextual information was comprehensively preserved at the feature extraction stage. Lastly, a lightweight and efficient detection head was employed to reduce model parameters and computational cost, thereby enhancing both detection efficiency and accuracy. The outcomes of the experiment demonstrate that, compared with the YOLOv8s baseline, the improved algorithm yields an increase of 1.5% in recall, 1.5% in mAP@0.5, and 1.4% in mAP@0.5:0.95. Relative to other mainstream algorithms, the proposed algorithm shows exceptional detection performance under complicated conditions, highlighting its advantages for practical applications. This provides important technical assistance for the early control and management of apple leaf diseases, helping to reduce crop loss and improve orchard health. In subsequent research, the dataset will be further expanded by incorporating a greater diversity of apple leaf disease images, aiming to strengthen the model's generalization capability and practical usefulness.

Keywords: Individual identification; 3D point cloud; PointNet++; local context fusion; bilinear regularization

ABSTRACT

Individual pig identification is a key technology to realize fine farming management, which is of great value in the fields of animal behavior tracking and health monitoring. Aiming at the limitations of traditional 2D vision methods in stereo feature extraction, this study uses pig back point cloud to effectively capture deep 3D features such as back contour and skin texture and proposes an improved PointNet++ model for pig individual identification, which explicitly captures the local geometric and feature differences through two-stream differential coding, refines the feature distribution by using low-rank bilinear decomposition and residual sharpening strategies, and then establish the two-way dependency between channel and space to generate the global perceptual map, and finally combine with Mish activation function to enhance the nonlinear feature extraction. The experiment takes the hybrid long white pig as the research object and uses the Intel D435i depth camera to collect data and construct the segmentation and identification model. The results show that the improved model PointNet++LR3D achieves an overall accuracy of 97.11% in the individual identification task, which is an improvement of 1.9% compared to the base PointNet++MSG model. In addition, extended tests on the ModelNet40 dataset show an improvement in classification accuracy to 93.1%, validating the generalization ability of the architectural improvements. This study provides an efficient solution for non-contact pig identification based on point cloud, demonstrating the potential for application in fine-tuned farming.

摘要

猪只个体识别是实现精细化养殖管理的关键技术，在动物行为追踪、健康监测等领域具有重要价值。针对传统二维视觉方法在立体特征提取上的局限性，本研究使用猪背点云有效捕捉背部轮廓和皮肤纹理等深度三维特征，提出了一种改进的 PointNet++ 模型用于猪只个体识别，通过双流差分编码显式捕捉局部几何与特征差异，利用低秩双线性分解和残差锐化策略细化特征分布，进而建立通道与空间的双向依赖关系生成全局感知图，最后结合 Mish 激活函数增强非线性特征提取。实验以杂交长白猪为研究对象，使用 Intel D435i 深度相机采集数据，构建分割与识别模型。结果表明，改进模型 PointNet++LR3D 在个体识别任务中整体准确率达 97.11%，相比基础 PointNet++MSG 模型提升 1.9%。此外，在 ModelNet40 数据集上的扩展测试显示分类准确率提升至 93.1%，验证了架构改进的泛化能力。本研究为基于点云的非接触式猪只识别提供了高效解决方案，展现了在精细化养殖中的应用潜力。

INTRODUCTION

In modern agriculture and animal management, individualized management and fine monitoring have become the key factors in improving breeding efficiency and animal welfare (Neethirajan *et al.*, 2024). Individual identification is the key technology to realize individual tracking of health data (Vidal *et al.*, 2021), which provides the necessary support for various aspects of precision management, health monitoring, fine feeding, behavioral monitoring and analysis, breeding selection, and automated management (Su *et al.*, 2024; Krampe *et al.*, 2024).

The traditional animal individual identification technology mainly has two major categories: physical tag identification and radio frequency identification (Ruiz *et al.*, 2011); currently applied in the breeding industry is still the most used in the physical tag using ear tags or collars to distinguish each body, however, the physical tags are prone to wear and tear, loss and damage, but also requires manual operation close contact with the animal, which increases the human cost as well as the risk of animal stress (Martínez *et al.*, 2016).

With the rapid development of computer vision and deep learning technologies (Wang *et al.*, 2022), vision-based individual identification methods have gradually become a research hotspot, which significantly improves the flexibility and robustness of identification mainly by capturing the external features of pigs, such as their faces, body sizes, or back contours (Saleem *et al.*, 2021; García *et al.*, 2020). However, 2D images are still unresolved due to factors such as light, angle and occlusion, which make it difficult to fully capture the three-dimensional morphological features of pigs, especially in dynamic scenes, and the stability of the identification effect still needs to be improved. In contrast, 3D point cloud technology (Guo *et al.*, 2020) obtains three-dimensional information about pigs through depth sensors (Yu *et al.*, 2024), which can more comprehensively describe the dorsal contour, curvature, and spatial structural features of pigs (Shuai *et al.*, 2020), and has become a hot spot of research by its advantage of being able to obtain three-dimensional depth information of pigs.

In recent years, significant progress has been made in applying point cloud technology in livestock individual identification. Zhou and others first proposed an individual identification method based on the pig back point cloud, utilizing PointNet++ for back point cloud segmentation and constructing a pig individual identification model based on the improved PointNet++LGG algorithm by increasing the adaptive global sampling radius, deepening the network structure, and increasing the number of features, with accuracy reaching 95% (Zhou *et al.*, 2023). Similarly, Kyaw *et al.* used the PointNet++ algorithm to detect and segment the dorsal surface region of a cow from a point cloud image, providing applications for individual cow identification, lameness detection, and body condition scoring (Kyaw *et al.*, 2024). These studies achieved non-contact and high-precision individual identification through 3D point cloud technology, overcoming traditional methods' limitations and providing technical support for fine farming.

Inspired by the above studies, this study notes that the application of point cloud technology in livestock individual identification is still in its infancy and that most of the current improvements of PointNet++ focus on the feature extraction stage, especially on enhancing the expression of local features by optimizing the grouping of points such as multi-scale grouping or dynamic grouping (Luo *et al.*, 2024; Nong *et al.*, 2023). However, fewer studies have systematically improved the characterization ability of point cloud features by starting from the fusion mechanism of local and global features. Therefore, this study proposes a new improvement strategy based on this, constructing an innovative module of local context fusion and global bilinear regularization, integrating it into the network architecture of PointNet++, explicitly modeling geometric and feature differences within the framework of PointNet++, and refining the feature distributions through global sensing, and utilizing low-rank bilinear decomposition and residual sharpening strategies to refine the feature distributions. Feature distributions to establish the bidirectional dependence between channel and space. This approach not only enhances the model's sensitivity to the local details of the pig back point cloud, such as curvature and edges, but also improves the feature differentiation through global regularization, thus achieving higher accuracy and robustness in the task of livestock individual identification in dynamic scenes.

MATERIALS AND METHODS

Introduction of experimental pig data

The data on the pigs used in this experiment were collected from Huifeng Breeding Professional Cooperative in Guangling County, Datong City, Shanxi Province, and the experimental pigs were labeled and approved by the pig farm. The pig farm features a semi-enclosed structure, and the experimental data were collected under two natural conditions: with sunlight and without sunlight. In order to increase the robustness of the experiment, no external lights were used throughout the collection, and point cloud data were collected from the backs of ten pigs, all of which were crossbred long white pigs and pigs with similar age, weight, and body hair color were selected as the collection objects.

Data Acquisition

In this study, the following acquisition plan was developed during the acquisition process, as shown in Fig.1. The depth camera Intel D435i was used to collect the depth information of the pig's back, the D435i adopts a dual-camera design and calculates the depth information based on binocular stereo vision (Servi *et al.*, 2024; Zhang *et al.*, 2022), which generates high-resolution depth data by capturing the parallax images from both cameras. In order to capture individual pigs in multiple postures, the recorded video was used to capture depth information and RGB color images simultaneously from the upper part of the pig's back.

To verify whether different camera heights and angles affect identification accuracy, the camera positions were intentionally varied. The cameras were mounted on the top of a telescopic pole, which was handheld to capture approximately one minute of video from each angle of the pig's back. The videos were recorded at a resolution of 468 × 828 pixels and a frame rate of 30 Hz. In total, 10 video recordings in the BAG format were collected.

Fig. 1 - (a) Environment of the pig house and Acquisition of pig back point cloud data

Data pre-processing

(1) Depth image to point cloud image conversion

Each BAG file stores the depth and RGB color information of the ten pigs. Additionally, the camera's intrinsic parameters (focal lengths f_x , f_y and principal point coordinates C_x , C_y) are recorded within each file. These parameters are extracted by parsing the BAG files.

First, the BAG files are parsed frame by frame using Intel RealSense to extract depth and color frames. Depth images are manually filtered with the assistance of corresponding color images; only those with poor-quality back data are removed to ensure the reliability of the experimental dataset. Since the objective of this experiment is to assess whether individual pigs can be accurately identified based on body features - such as the contours and curvature of the back - rather than color features, only the depth images are retained after filtering. These retained depth images are subsequently converted into point cloud representations.

The depth value of each pixel in the depth image is converted to the actual 3D coordinates by combining the camera's internal reference, assuming that the pixel coordinates are U and V , and the actual depth is Z . The 3D coordinates (X, Y, Z) of the point can be expressed as:

$$X = \frac{(U - C_x) \cdot Z}{f_x}, \quad Y = \frac{(V - C_y) \cdot Z}{f_y}, \quad Z = \text{depth_image}(U, V) \quad (1)$$

where: $(U - C_x)$ and $(V - C_y)$ denote the horizontal and vertical distances of the pixel point relative to the center of light, and the X Y coordinates of the pixel point in the actual 3D space can be obtained by multiplying the distance by the depth value of the point, Z , and dividing by the focal length, f_x or f_y .

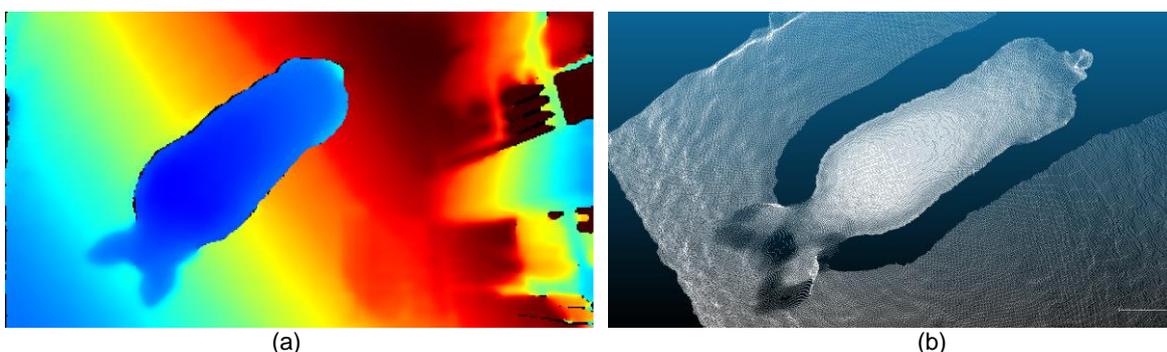

Fig. 2 - Depth images converted to point cloud images

(a) Pig depth image (b) Pig point cloud image

(2) Pig back point cloud labeling

The generated dorsal point cloud data not only has the pig body point cloud but also includes a large number of background point clouds, using CloudCompare software to label the point clouds as pig dorsal point clouds and background point clouds because the pig is in a low head posture most of the time and the head bobbing is more obvious, most of the captured head point cloud images are incomplete and badly adhered to the ground and walls, in order to avoid the interference of the head point cloud, the head is labeled as the background point when labeling the point clouds, only the dorsal point cloud is retained as the segmentation target. As shown in Fig. 3, the pig has two main postures, standard standing and twisted body, and the two points with the most considerable curvature changes between the neck and the back of the pig are segregated for labeling.

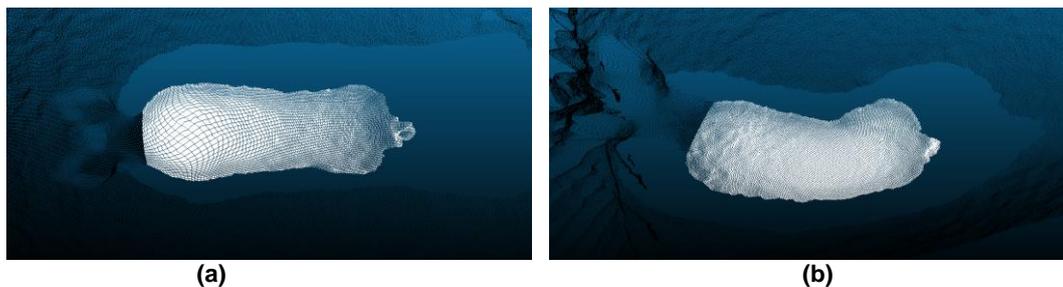

Fig. 3 - Pig back point cloud labelling in two poses
 (a) Splitting of a pig in standard standing position (b) Segmentation of a pig with twisted body

Segmentation and identification Modelling

The process of pig individual identification based on pig back point cloud is mainly composed of two parts: segmentation model construction and identification model construction. First, the collected raw data are converted into point cloud images, then the background and head are removed by the segmentation model. Finally, the segmented pig back point cloud is input into the individual identification model, and the specific number of the pig is output.

Back - background point cloud segmentation

(1) Segmentation method

The PointNet family of networks are neural networks specialized in point cloud data processing that directly manipulate irregular point cloud data without the need to convert the point cloud data into regular grids or voxels (Qi *et al.*, 2017). The segmentation problem in this study is relatively simple, with only two parts, the back and the background, but the data used in this study is a dynamic moving image of a pig, and the posture of the pig at the neck is severely deformed when it is moving. Compared with PointNet, PointNet++ extracts local features layer by layer through the process of 'sampling-grouping-feature extraction-feature propagation,' which is more delicate processing of local features, so the PointNet++ network is chosen to build the segmentation model in this study.

(2) Segmentation model based on PointNet++MSG

As shown in Fig. 4, the segmentation network chooses the PointNet++ Multiscale Grouping Feature Learning (PointNet++MSG) framework, which includes four parts: two-layer sampling, multiscale grouping, feature extraction downsampling and feature propagation upsampling (Qi *et al.*, 2017).

Due to the vast number of points in the original point cloud, random sampling of the original point cloud is required, and the network receives the randomly sampled globally uniformly sampled points containing xyz coordinates and normal vectors. Feature extraction is performed by three Set Abstraction (SA) layers downsampling step by step: SA1 receives the 6-dimensional point cloud input, extracts 64-, 128-, and 128-dimensional features and splices them in [0.1,0.2,0.4] triple radius on 512 sampling points; SA2 generates 256-dimensional features in [0.4,0.8] double radius on 128 sampling points; SA3 generates 256-dimensional features by global pooling to generate 1024-dimensional global features. Feature propagation is performed by Feature Propagation (FP) with layer-by-layer upsampling: FP3 fuses global and SA2 features, FP2 reconstructs the mid-level geometry, and FP1 splices the original point coordinates with labels to recover fine-grained features. The classification head uses a two-layer convolutional network to output semantic category probability distributions for pig back and background.

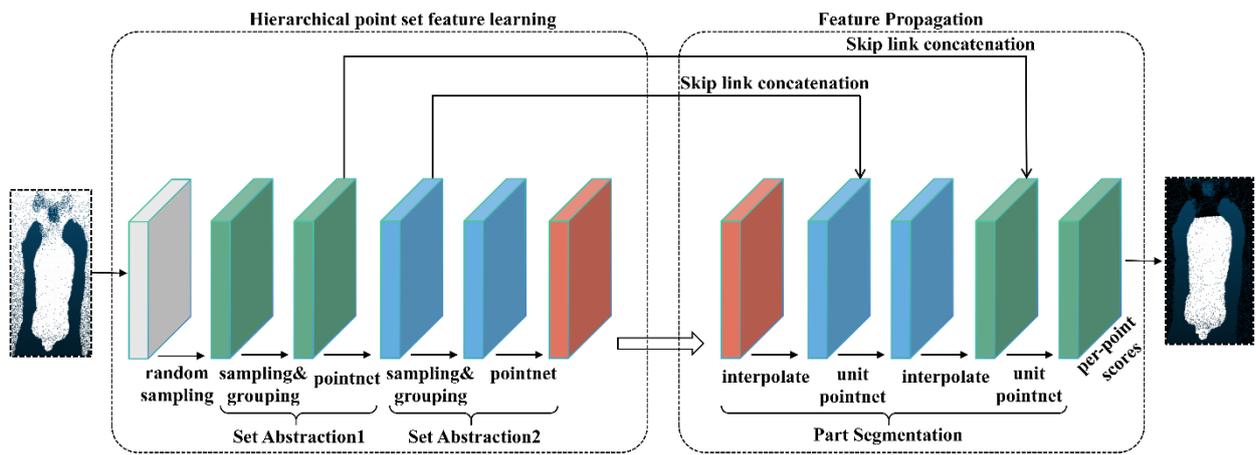

Fig. 4 - Segmentation model for pig back based on PointNet++MSG

Individual identification of pigs

(1) Individual identification method

Compared with segmentation, the identification task needs to focus on local and global feature extraction. In this study, individual identification models for pigs are developed based on the single-scale (SSG) and multi-scale (MSG) grouping strategy algorithms of PointNet and PointNet++, respectively, as the baseline model for individual identification. An improved model PointNet++LR3D with local context fusion as well as global bilinear regularization is proposed, which significantly improves the characterization of high-dimensional features of pig dorsal point clouds by means of dual-stream differential coding of geometries and features, low-rank bilinear decomposition and residual sharpening strategies.

(2) Individual pig identification model based on PointNet++MSG

As shown in Figure 5, the individual pig identification model and segmentation model are similar in principle, except that compared to the segmentation task, the individual identification only has 'sampling-grouping-feature extraction' without the process of feature propagation, and the 1024-dimensional global features obtained after three-layer SA feature extraction are directly input into the classification layer, and the classification layer outputs the category of each pig through a three-layer full connection. The classification layer outputs the class distribution probability of each pig.

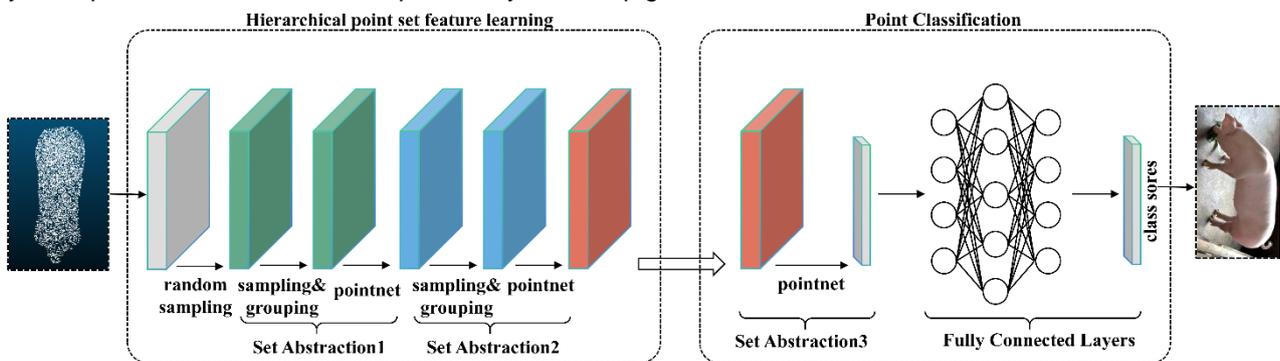

Fig. 5 - Individual identification model for pigs based on PointNet++MSG

Local Context Fusion with Bilinear Regularization Strategies for LR3D Modules

In traditional point cloud data processing networks, PointNet++ only aggregates MLP-encoded features in local coordinates, ignoring differences in features between neighboring points, and PointNet++'s Set Abstraction aggregates local features through farthest-point sampling and grouping and extracts features only through MLP stacking, does not explicitly model point-neighborhood relationships, and lacks the sensitive capture of geometric differences such as curvature and regular vector changes. EdgeConv, on the other hand, mainly performs dynamic graph convolution based on neighborhood point feature differences without directly modeling 3D geometric coordinate relationships. As shown in Figure. 6, this study uses a CNN-based model to learn feature maps, proposes dual-stream differential coding to model both geometric and feature differences to capture local structural changes explicitly, and enables geometric and feature contexts to be encoded separately through shared MLP and asymmetric pooling using split aggregation to avoid confusion between coordinate and feature information and enhance interpretability.

(1) Local context fusion strategy for two-stream feature splicing

To construct the local context for each point, the k-nearest neighbor (KNN) algorithm is employed to identify its neighborhood, which is a widely used neighborhood finding method in point cloud processing. The KNN algorithm calculates the 3D Euclidean distances from all points in the point cloud to a target point p_i and selects the k closest points as its neighbors: $\mathcal{N}(p_i) = \{p_{i1}, p_{i2}, \dots, p_{ik}\} \in \mathcal{N}(p_i)$, by combining the edge $\forall p_{ik} \in \mathcal{N}(p_i)$ between p_i itself and its k neighbors, the local geometric map in 3D space is: $\tilde{p} = [p_i; p_{ik} - p_i] \in \mathbb{R}^{k \times 6}$, where p_i is the current point, and $p_{ik} - p_i$ is the coordinate difference reflecting the local geometric structure. Thus, the local geometric map of all points P is denoted as $\tilde{P} = [p_1, p_2, \dots, p_i, \dots, p_N] \in \mathbb{R}^{N \times k \times 6}$. Finally, the local geometric map is encoded by shared MLP, and the local geometric context encoding is aggregated by applying the Max Pooling function to k neighbors:

$$P = \max_k \left(MLP_{\theta}(\tilde{P}) \right), P \in \mathbb{R}^{N \times \frac{C}{2}} \quad (2)$$

Meanwhile, the local feature map of f_i in C-dimensional space can be formed: $\tilde{f} = [f_i; f_{ik} - f_i] \in \mathbb{R}^{k \times 2C}$, where f_{ik} is the corresponding feature of $p_{ik} \in \mathcal{N}(p_i)$, and $f_{ik} - f_i$ is the feature difference, which reflects the semantic difference. Therefore, the local feature map of a feature map F is represented as $\tilde{F} = [f_1, f_2, \dots, f_i, \dots, f_N] \in \mathbb{R}^{N \times k \times 2C}$. The local feature context encoding is obtained by following a similar operation in Equation (2):

$$F = \max_k \left(MLP_{2\theta}(\tilde{F}) \right), F \in \mathbb{R}^{N \times \frac{C}{2}} \quad (3)$$

Where $MLP_{2\theta}$ is another shared MLP encoding the local feature map, finally the local geometric context and the local feature context() are concatenated as the output of the final local context fusion block:

$$\mathcal{F}_L = \text{concat}(P, F), \mathcal{F}_L \in \mathbb{R}^{N \times C} \quad (4)$$

Compared with EdgeConv operations, the method proposed in this study defines and constrains both local geometric context and feature context and has inherent 3D geometric relationships that can directly reflect local surface geometric changes and semantic differences. In addition, local context fusion blocks can be flexibly deployed at different point cloud resolutions and CNN layers, which benefits most existing point cloud networks.

(2) Global bilinear regularization

In addition to collecting more local details for the feature representation of each point, the global bilinear regularized blocks proposed in this study aim to refine the feature maps by considering the global perception of the entire point cloud. In conventional self-attention mechanisms, global perception is estimated as long-range dependencies between point features, i.e., cosine similarity, which consumes significant memory. In contrast, the global perception in this study is computed as element-wise dependencies between feature maps based on global channels and point descriptors, and through a low-rank decomposition strategy, the memory consumption is significantly reduced.

In order to encode the global channel descriptor, firstly, the input features are linearly transformed by applying the weight matrix $W_C \in \mathbb{R}^{C \times \frac{C}{r}}$, where r is the reduction factor to reduce the dimension of the fused output $\mathcal{F}_L \in \mathbb{R}^{N \times C}$; then, the ReLU function is utilized to not only provide the nonlinearity after linearly mapping with W_C but also to satisfy the requirement of non-negativity in Equation (7); lastly, through the average pooling operation on the N elements along the spatial axis, the spatial information can be compressed into the global channel descriptor g_c . The above operation is as follows:

$$g_c = \text{avg}_N \left(ReLU(\mathcal{F}_L W_C) \right), g_c \in \mathbb{R}^{\frac{C}{r}} \quad (5)$$

Where ' $\mathcal{F}_L W_C$ ' is the matrix product between \mathcal{F}_L and W_C , and 'avg' denotes the average pooling along the spatial dimension N with a reduction factor satisfying $r \geq 2$. Furthermore, $g_c = [\mu_1, \mu_2, \dots, \mu_j, \dots, \mu_{\frac{C}{r}}]$, where μ_j represents the global response of the j -th channel in the whole point cloud feature map.

The global point-by-point descriptor g_p can also be generated using a similar approach in the context of another weight matrix $W_p \in \mathbb{R}^{C \times \frac{C}{r}}$, the ReLU function, and an average pooling operation on the $\frac{C}{r}$ elements along the channel axis:

$$g_p = \text{avg}_{\frac{C}{r}} \left(ReLU(\mathcal{F}_L W_p) \right), g_p \in \mathbb{R}^N \quad (6)$$

In addition, $g_p = [\lambda_1, \lambda_2, \dots, \lambda_i, \dots, \lambda_N]$, where λ_j is the global response of the i -th point in the whole point cloud feature map.

Unlike the use of Hadamard product between vectors, the geometric mean $\sqrt{\lambda_i \mu_j}$ captures the higher-order interactions of the channel with the space, providing a more robust global response than arithmetic averaging, and captures the low-rank global bilinear response by taking the square root of the outer product of g_p and g_c :

$$G = \text{sqrt}(g_p \otimes g_c), G \in \mathbb{R}^{N \times \frac{C}{r}} \tag{7}$$

where the element η_{ij} located in the i th row and j th column of G is mathematically computed as:

$$\eta_{ij} = \sqrt{\lambda_i \mu_j}, \eta_{ij} \in \mathbb{R} \tag{8}$$

The synthesis of the global bilinear response of all elements according to the corresponding point-by-point and channel descriptions in Equation 6 can be interpreted as an effective and efficient method in the following way. For each element, λ_i and μ_j are the arithmetic mean of the i th point and j th channel, respectively, and η_{ij} is the geometric mean of λ_i and μ_j . Firstly, taking the square root enhances the numerical stability, and secondly, it captures the bi-directional dependence of the channel on the space and provides a higher-order averaged response based on the spatial and channel-related information.

(3) Residual Sharpening Feature Recovery

After restoring the channel dimensions using a shared MLP, a residual connection is employed to preserve local features. Finally, the channel dimensions are fully recovered, and a full-size global perceptual map is generated:

$$\mathcal{F}_G = \text{MLP}(G + \mathcal{F}_L W_C + \mathcal{F}_L W_p), \mathcal{F}_G \in \mathbb{R}^{N \times C} \tag{9}$$

The average pooling operations in Equations 4 and 5 are used to compress global information from the point cloud and channel space, respectively; however, average pooling, as a conventional method for feature map compression, tends to generate smooth global representations that may weaken the uniqueness and representativeness of the features. To this end, this study proposes a more effective global-aware feature exploitation strategy to enhance feature differentiation in point cloud analysis. Specifically, to sharpen the learned features, the uniqueness of local features is emphasized by subtracting the global perceptual feature \mathcal{F}_G from the local context fusion output \mathcal{F}_L . This subtraction effectively filters out redundant patterns originating from the global average vectors g_p and g_c , thereby reinforcing the distinctiveness of local features. The use of the Mish activation function further enriches the final output feature map by introducing additional nonlinear transformations.

$$\mathcal{F}_{out} = \text{Mish}(\mathcal{F}_L - \mathcal{F}_G), \mathcal{F}_{out} \in \mathbb{R}^{N \times C} \tag{10}$$

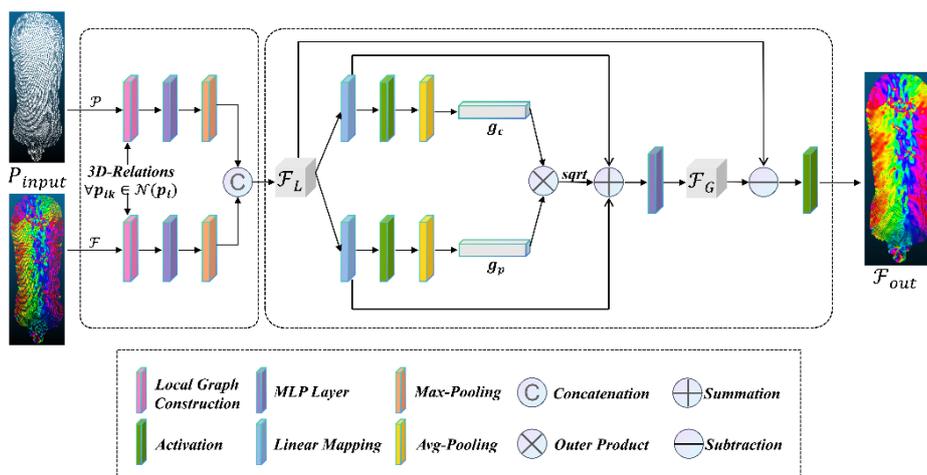

Fig. 6 - LR3D module introducing local context fusion and bilinear regularization

Integration of LR3D module in PointNet++MSG network

The LR3D (Local-Regional 3D) module proposed in this study is a novel point cloud feature extraction mechanism that enhances point cloud feature representation through two key components: local context fusion and global bilinear regularization. The LR3D module is integrated into the PointNet++(MSG) network architecture, and feature enhancement is mainly performed at two key layers, as shown in Figure 7, in the Set

Abstraction (SA) layer of PointNet++(MSG), by inserting the LR3D module after the SA1 and SA2 layers, respectively, with the following improvement strategies:

The LR3D module is introduced after the SA1 layer to explicitly capture local geometric and feature differences through a two-stream differential coding strategy for local context fusion. Local context encoding \mathcal{F}_L is generated using a shared MLP with asymmetric pooling, while the global perceptual map \mathcal{F}_G is produced via a global bilinear regularization block applied to the dual feature streams. This process refines the feature distribution using low-rank bilinear decomposition and a residual sharpening strategy, establishing a bidirectional dependency between channel and spatial dimensions. As a result, the network gains a stronger understanding of the relationship between global structures and local details in the pig back point cloud. The final output feature map \mathcal{F}_{OUT} undergoes nonlinear transformation through the Mish activation function, further enhancing the model's robustness and generalization capability in complex point cloud scenarios, such as distortions caused by pig movement and variations in height. This approach strengthens the SA1 layer's ability to capture low-level local structures (e.g., back edges and body contours), addressing the limitation of traditional PointNet++ architectures that rely solely on stacked MLPs, and improves both global consistency and individual differentiation. The LR3D module is subsequently applied after the SA2 layer to further integrate the high-dimensional features extracted by SA1. Finally, the feature stream enhanced by the two LR3D modules is passed through a third Set Abstraction (SA3) layer for global feature aggregation, followed by classification via a multilayer perceptron (MLP).

This staged integration approach makes full use of the multi-scale grouping properties of the SA1 and SA2 layers, enabling the LR3D module to optimize the local and global representation capabilities in the feature extraction stages at different resolutions, respectively. The experimental results show that after adding the LR3D module after the SA1 and SA2 layers, the model's accuracy in the individual pig identification task is significantly improved while maintaining the balance of computational efficiency, which fully verifies the effectiveness of this improvement strategy.

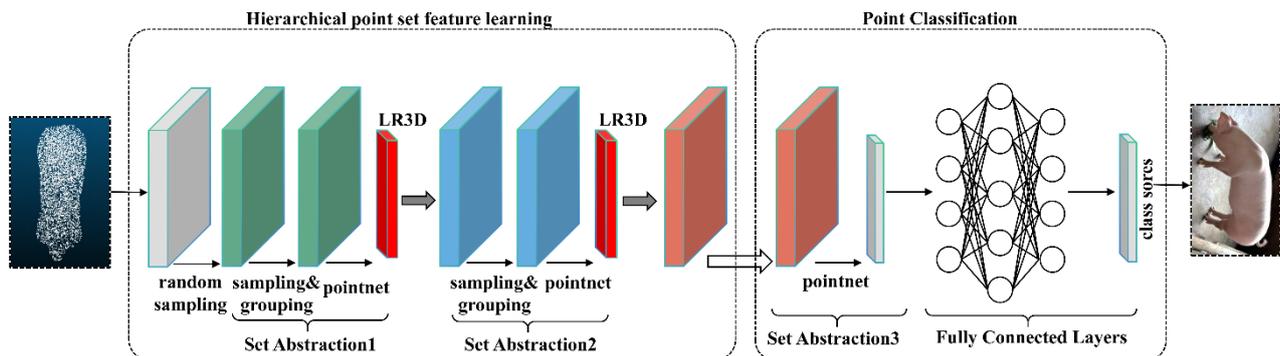

Fig. 7 - PointNet++ MSG classification model incorporating LR3D module

Experimental Sample Setting

This experiment collected 8,300 point cloud images from 10 pigs and processed them to obtain the experimental dataset for 10 pigs. The dataset was divided into training, validation, and test sets in a ratio of 7:1.5:1.5. The training set was used for model learning, the validation set was used for parameter adjustment and performance evaluation, and the test set was used to verify the model's generalization ability.

Experimental parameter settings

The operating system used in this experiment is Ubuntu 20.04, the CPU is Intel Xeon Platinum 8270 2.70GHz, the memory is 64GB, the GPU is NVIDIA GeForce RTX 4090 D, the video memory is 24GB, and the deep learning frameworks are PyTorch 2.4.1 and Python 3.8.

Considering the impact of segmentation and identification speed, the initial sampling and target point numbers for the segmentation model are set to 1024 and 5000, respectively, while the sampling point number for the identification model is set to 2048. The batch size (Batch Size) is set to 8 for both models. The total number of training iterations (Epochs) for the segmentation and identification models is set to 100 and 200 cycles, respectively. The initial learning rate is set to 0.001, using the Adam optimizer with a weight decay rate of $1e-4$. The learning rate is adjusted via a StepLR scheduler, decreasing to 0.7 of the original value every 20 cycles. The loss function employs negative log-likelihood loss (NLL Loss). The experiment is run on a single GPU, with data loading using 10 worker threads to enhance efficiency.

RESULTS

Experimental evaluation indexes

In the segmentation test, six metrics, namely, overall accuracy (OA), mean intersection and merger ratio (mIoU), precision, recall, F1 score, and average segmentation time (AvgTime) for pig back categories, were used to evaluate the segmentation performance of the model for pig back and background. In the identification (classification) test, the six metrics of OA, Precision, Recall, F1, Top-3 Accuracy, and Average identification Time (AvgTime) were used to evaluate the model's identification performance for individual pigs.

In the segmentation test calculation process, four key metrics are primarily used: true positive (TP), false positive (FP), true negative (TN), and false negative (FN). True positive (TP) represents the number of points predicted as pig back that are actually pig back. False positive (FP) represents the number of points predicted as pig back that are actually background. True negative (TN) represents the number of points predicted as background that are actually pig back. False Negative (FN) represents the number of points predicted as background but actually being pig back. In the identification test, TP represents the number of pigs correctly identified as belonging to a specific pig category, FP represents the number of pigs incorrectly identified as belonging to that category, TN represents the number of pigs correctly identified as belonging to the category but not actually belonging to it, and FN represents the number of completely incorrect identifications.

$$\begin{aligned}
 \text{Over Accuracy} &= \frac{TP + TN}{TP + FP + TN + FN} \\
 \text{IOU} &= \frac{TP}{TP + FP + FN} \\
 \text{Precision} &= \frac{TP}{TP + FP} \\
 \text{Recall} &= \frac{TP}{TP + FN} \\
 \text{F1 - score} &= \frac{2(\text{Precision} * \text{Recall})}{\text{Precision} + \text{Recall}}
 \end{aligned} \tag{11}$$

Pig back-Background Segmentation Model training results

In the pig back-background segmentation experiment, this study trained three models on the training and validation sets. Each model's validation accuracy and loss changed during training, as shown in Figure 8. All models' accuracy and loss values steadily increased and decreased with the increase in training iterations and gradually stabilized and converged after approximately 40 iterations. Among them, the PointNet++ MSG and PointNet++ SSG models performed well, with validation accuracy reaching approximately 99.8% and loss values tending towards 0, while the PointNet model performed slightly worse. Therefore, no significant overfitting was observed during training in the models. Overall, PointNet++ MSG achieves the best segmentation performance under the multi-scale grouping strategy, effectively capturing the local geometric features of pig back point clouds, thereby demonstrating stronger robustness and stability in segmentation tasks.

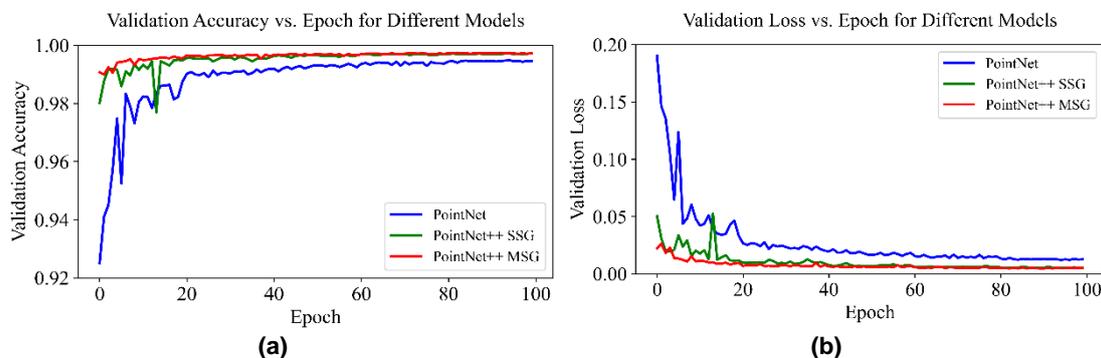

Fig. 8 - Segmentation model validation results

(a) Validation accuracy curves (b) Validation loss curve

Pig back-Background Segmentation model test results

To further explore the segmentation performance of the models on unfamiliar datasets, the segmentation performance of the three models was evaluated using a test set, and the results are shown in Table 1.

PointNet++ MSG achieved 99.83% in Overall Accuracy (OA), which is an improvement of 0.03% to 0.30% compared to the other models. In terms of mean intersection and merger ratio (mIoU), PointNet++ MSG achieved 99.35%, which is 0.10% to 1.05% higher than other models, showing stronger segmentation consistency. In terms of Precision, Recall, and F1 scores, PointNet++ MSG achieved 99.38%, 99.53%, and 99.46%, respectively, which were 0.15% to 1.25%, 0.03% to 0.55% and 0.10% to 0.90% higher than the other models, indicating that it has a significant advantage in reducing misclassification and missed classification with significant advantages. Considering the real-time task requirements of individual identification, in terms of segmentation time (AvgTime), PointNet has the fastest inference speed of 0.004 s/sample but performs relatively poorly regarding segmentation accuracy. Although the inference time of PointNet++ MSG is slightly higher than the other two models at 0.071 s/sample, it still meets the real-time requirements.

In summary, PointNet++ MSG shows excellent performance in the pig back-background segmentation task. This task effectively deals with the complex geometric changes in the dynamic point cloud data and provides a high-quality segmentation basis for the subsequent individual identification task.

Table 1

Segmentation model test results						
Model	OA	mIoU	Precision	Recall	F1	AvgTime
	[%]	[%]	[%]	[%]	[%]	[s/pig]
PointNet	99.53	98.30	98.13	98.98	98.56	0.004
PointNet++SSG	99.80	99.25	99.23	99.50	99.36	0.064
PointNet++MSG	99.83	99.35	99.38	99.53	99.46	0.071

Individual Pig Identification Model training results

In order to evaluate the performance of different models in the pig back point cloud individual identification task, the validation loss and accuracy of the base models (PointNet, PointNet++SSG, PointNet++MSG) and the improved PointNet++LR3D model were compared during the training process. The trend of the validation accuracy and loss of each model is shown in Figure 9. The experimental results show that the loss of all models decreases rapidly at the beginning of training and then levels off. At the same time, the accuracy increases rapidly and stabilizes at the end of training. The base PointNet model has the worst performance with higher test loss and lower accuracy; PointNet++SSG and PointNet++MSG have reduced loss and improved accuracy through hierarchical feature extraction. The improved PointNet++LR3D model performs best with the lowest test loss and highest accuracy. This excellent performance is attributed to the LR3D module's significant improvement in feature extraction through bilinear regularization of geometry and features, which better captures the complex geometric properties of pig dorsal point cloud data and provides a more efficient solution for individual identification tasks.

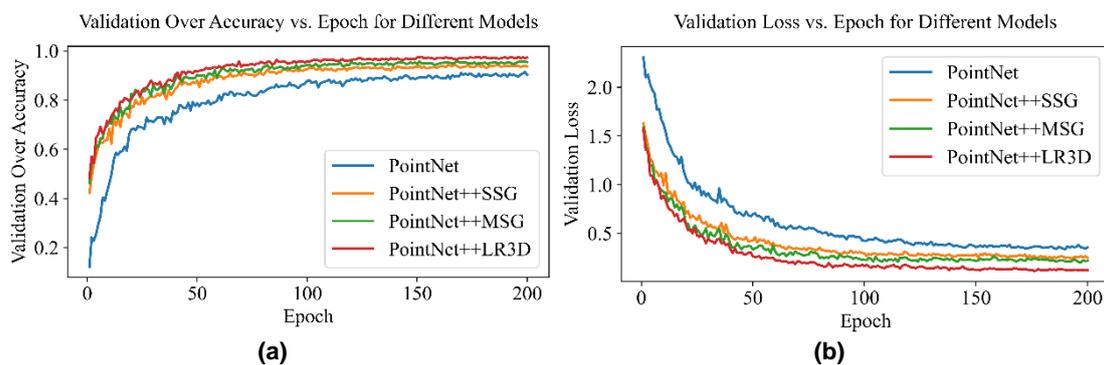

Fig. 9 - Individual Identification model validation results

(a) Validation accuracy curve (b) Validation loss curve

Individual Pig Identification model testing results

In order to further verify the performance of different models in the pig dorsal point cloud individual identification task, the optimal training models were selected to test the PointNet, PointNet++SSG, PointNet++MSG, and the improved PointNet++LR3D models.

The overall performance indexes of each model in the individual identification task and the accuracy of individual identification for 10 pigs are shown in Tables 2 and 3.

The experimental results show that the basic PointNet model has an overall accuracy of 88.92% and an average identification time of 0.0015 s, which exhibits very high computational efficiency. However, its accuracy ranges from 75.89% to 95.24% from Pig1 to Pig10, with large fluctuations, and some individuals are poorly identified, especially Pig7 (75.89%), reflecting PointNet's limited ability to extract pig dorsal point cloud features. PointNet++SSG and PointNet++MSG through hierarchical feature extraction significantly improved the performance, where the overall accuracy of PointNet++SSG was 92.93% and that of PointNet++MSG was further improved to 95.42%, and the individual identification accuracies of the two were more balanced, ranging from 88.46% to 96.67% and 92.73% to 99.17%, respectively, and the individual identification accuracies of both were more balanced, ranging from 88.46% to 96.67% and 92.73% to 99.17%, respectively, due to the hierarchical feature extraction layer is introduced, the identification time grows to 0.0529 s and 0.0540 s. The improved PointNet++LR3D model proposed in this study performs the best, with the highest overall accuracy of 97.11%, a precision rate of 97.04%, a recall rate of 97.09%, an F1 score of 97.06%, and a Top-3 accuracy rate of 99.44%, the best performance in all indicators, and its accuracy on 10 pigs ranges from 95.38% to 99.21%, with the slightest fluctuation and the most stable identification effect. Due to the inclusion of the two-layer LR3D module, although the average inference time is slightly elevated to 0.0576 seconds, it still meets the real-time time requirement of the individual identification task. The LR3D module proposed in this study significantly enhances the model's ability to fine-grain feature extraction from point cloud data through geometric and feature bilinear regularization. Although the inference time of PointNet++LR3D is slightly higher than that of the other models, it strikes a good balance between performance enhancement and computational efficiency. It provides a better solution for the individual identification task in pigs.

Table 2

Overall test results of the different models under the individual identification task

Model	OA	Precision	Recall	F1	Top-3	AvgTime
	[%]	[%]	[%]	[%]	[%]	[s/pig]
Pointnet	88.92	89.04	88.82	88.74	97.51	0.0015
PointNet++SSG	92.93	92.97	92.96	92.88	98.31	0.0529
PointNet++MSG	95.42	95.49	95.42	95.42	98.47	0.0540
PointNet++LR3D	97.11	97.04	97.09	97.06	99.44	0.0576

Table 3

Individual identification accuracy of each pig under different models

Model	Accuracy									
	[%]	[%]	[%]	[%]	[%]	[%]	[%]	[%]	[%]	[%]
pig	Pig1	Pig2	Pig3	Pig4	Pig5	Pig6	Pig7	Pig8	Pig9	Pig10
Pointnet	95.24	86.81	87.69	90.15	94.12	93.20	75.89	87.30	83.64	94.17
PointNet++SSG	93.33	93.06	88.46	91.67	92.44	94.56	90.18	92.86	96.36	96.67
PointNet++MSG	95.24	94.44	94.62	94.70	95.80	95.92	95.54	96.03	92.73	99.17
PointNet++LR3D	97.14	95.83	95.38	97.73	98.32	97.96	95.54	99.21	95.45	98.33

Confusion Matrix

In order to more intuitively assess the performance of the different models in the pig dorsal point cloud individual identification task, a classification confusion matrix was constructed for the four models, as shown in Figure 10. The horizontal axis of the confusion matrix represents the predicted labels, the vertical axis represents the actual labels, and the values on the diagonal indicate the number of correctly predicted samples. In contrast, the off-diagonal values indicate the number of misclassified samples. The results show that all models have high identification performance on most individuals, with correctly predicted samples mainly concentrated on the diagonal and fewer misclassified samples, verifying the effectiveness of the pig dorsal point cloud in the individual identification task.

By comparing the confusion matrices of the four models, it can be found that the base model has significant confusion in some categories. Among them, PointNet performed relatively poorly, with multiple misclassifications to other classes for pig2, 8, 9, and 6 misclassifications to pig4 for the predictions of pig3, pig7, and pig8, and bidirectional confusion between pig5 and pig9, with the error numbers of 7 and 4, respectively.

PointNet++SSG was significantly optimized by a single-scale grouping of the categorical purity of pig3, pig7, and pig8 and eliminated the one-way confusion of misclassification of pig9 to pig5. However, there were still four misclassifications of pig5 to pig9. PointNet++MSG further reduced the confusion of some categories by introducing multiscale grouping, significantly reduced the occurrence of misclassification of pig2, and further eliminated the two-way confusion between pig5 and pig9 bi-directional confusions.

In contrast, the improved model PointNet++LR3D shows significant advantages, with an average improvement of 10.7% in the number of correct diagonal predictions and a reduction in the maximum single-class error from 9 to 3 in PointNet. In particular, the bi-directional confusion between the confusing pig5 and pig9 is almost eliminated. Experiments show that the introduced local context and bilinear regularization strategy effectively enhances the ability to distinguish fine-grained feature differences and significantly reduces the misclassification rate between similar individuals.

Discussion

Since the classification performed in this experiment and that performed in the ModelNet40 dataset are fundamentally different, the classification task in ModelNet40 is to classify different objects with significant differences in shape features, while the pig individual identification task performed in this experiment is to classify similar individuals within the same species, which inherently increases the classification difficulty.

To further validate the feasibility of the innovative LR3D bilinear regularization module introduced in this study for individual pig back point cloud identification, extended tests were conducted on the ModelNet40 public point cloud dataset, a classic benchmark for point cloud multi-classification tasks. Testing on this public dataset aims to evaluate the generality and robustness of the proposed method and verify its performance across different point cloud data scenarios.

The test results show that the improved PointNet++ model proposed in this study, by incorporating two LR3D modules, achieves an overall accuracy (OA) and average accuracy (macc) of 93.1% and 91.0% on the ModelNet40 dataset, representing improvements of 2.4% over the original PointNet++ model's 90.7% and 87.6%, respectively. This demonstrates that the proposed improved model enhances classification performance across diverse point cloud data scenarios.

CONCLUSIONS

This study proposes an individual identification method for pig back point cloud data based on the improved PointNet++ model. By introducing local context fusion and a global bilinear regularized LR3D module, the model's ability to extract and classify dynamic pig point cloud features is significantly enhanced. Experimental results demonstrate that the improved model achieves an identification accuracy of 97.11% in the individual identification task, performing the best among all methods. Furthermore, extended testing on the ModelNet40 public dataset further demonstrates the generality and effectiveness of the proposed method.

The LR3D module proposed in this paper significantly enhances the geometric sensitivity and semantic expressiveness of point cloud feature extraction through the local context fusion strategy of dual-stream differential coding and the global bilinear regularization mechanism, providing an efficient solution for analyzing complex 3D scenes. Its modular design gives LR3D excellent flexibility, enabling it to adapt easily to various point cloud processing network architectures, including PointNet++, DGCNN, and other mainstream models. It is seamlessly deployed at different feature extraction stages and CNN layer resolutions. LR3D effectively captures rough geometric structures in the low-resolution layer, such as edges and curvature changes; in the high-resolution layer, its ability to refine local features further enhances semantic differentiation. Experiments show that LR3D significantly improves the model accuracy in the classification task of similar individual identification while maintaining the balance of computational efficiency, demonstrating strong robustness and versatility. Looking ahead, the LR3D module can be widely applied to tasks such as point cloud segmentation and detection, providing a solid feature enhancement framework for 3D vision research.

Compared with traditional physical tags and RFID identification, this study achieves non-contact and high-precision pig individual identification using 3D point cloud technology, which overcomes the problems of fragile tags, the high cost of manual operation, and environmental interference. It provides an efficient solution for individual tracking, health monitoring, and behavioral analysis in fine-tuned farming. However, there are still some limitations in this study: the experimental sample size is small, with only 10 pigs and a single pig breed, and the model can be extended to a larger and multi-breed pig population to verify the generalization ability in the future. In addition, the dynamic point cloud data acquisition is limited by the camera view and the moving speed of the pigs, and the data acquisition process needs to be further optimized. This study provides innovative ideas and technical support for animal individual identification based on point cloud, which has high theoretical value and application prospects.

Keywords: Grain depot scenario, Hybrid A* algorithm, Dynamic node extension, KD-Tree, Path planning

ABSTRACT

To address the problems of low search efficiency, long time-consuming planning and poor adaptability to narrow passages of the original Hybrid A* algorithm in path planning for intelligent grain transfer vehicles in grain depot scenarios, a Hybrid A* algorithm with variable resolution and variable step size is proposed. First, the dual-heuristic function and the cost function with steering and reversing penalties are reasonably designed to ensure that the algorithm can search for a derivable path. Second, the distance cost based on the KD-Tree algorithm is combined into the node extension, and the node extension is performed using variable resolution and variable step size according to the change of the distance cost to improve the node search efficiency. Then, Reeds-Shepp curve search fitting is used to pinpoint the target point pose. The simulation validation results show that the improved Hybrid A* algorithm reduces the number of search nodes by 83% and the planning time by 37% in simple maps, while the number of search nodes and the planning time are reduced by 80.6% and 56.6%, respectively, in complex maps, which improves the path search efficiency. After the real-vehicle test, the improved Hybrid A* algorithm reduces by 52.9% and 61.4% in terms of the number of search nodes and planning time consumed, respectively, and there is a significant improvement in the planning efficiency, which enhances the operational efficiency of the grain transfer vehicle.

摘要

针对粮库场景中智能粮食转运车辆在路径规划时原始 Hybrid A*算法存在搜索效率低、规划耗时长及狭窄通道适应性差等问题,提出一种变分辨率和变步长的 Hybrid A*算法。首先,合理设计双启发函数与含有转向和倒车惩罚的代价函数,保证算法能够搜索到一条可行驶的路径。其次,将基于 KD-Tree 算法的距离代价结合到节点扩展中,根据距离代价的变化使用变分辨率和变步长进行节点扩展,提高节点搜索效率。然后,采用 Reeds-Shepp 曲线搜索拟合精确定位目标点位姿。仿真验证结果表明,在简单地图中,改进 Hybrid A*算法的搜索节点数量缩短了 83%,规划耗时缩短了 37%;在复杂地图中,搜索节点数量和规划耗时分别缩短了 80.6%, 56.6%,提高了路径搜索效率。经过实车试验,改进 Hybrid A*算法在搜索节点数量和规划耗时方面分别缩短了 52.9%、61.4%,规划效率有明显提升,从而提升了粮食转运车辆的运行效率。

INTRODUCTION

Granaries are a critical component of food storage (Nayak et al., 2020). However, traditional grain depots face several challenges in the processing and transfer of residual grain. These include narrow passages, complex environments with numerous grain piles, and reliance on manually operated vehicles for transportation, which results in low efficiency and high operational costs. In order to overcome this problem, intelligent grain transfer vehicle has gradually become a research hotspot (Teng et al., 2023). By integrating advanced sensors, high-precision positioning system and intelligent decision-making module (Peng et al., 2021), the intelligent grain transfer vehicle can quickly and accurately sense the obstacles in the known surrounding environment and make obstacle avoidance decisions.

The movement of the intelligent grain transporter is inseparable from the path planning, and a good path planning algorithm can improve the efficiency of the transporter and reduce the waste of grain. At the same time, the application of automatic driving technology to the residual grain transfer in grain depot scenarios is of great significance in guaranteeing the quality of grain and the construction of smart grain depots (Tang et al., 2024).

Path planning, as one of the key technologies in autonomous driving technology, is to generate optimal paths that satisfy collision avoidance constraints, kinematic constraints (e.g., minimum turning radius and speed constraints), and dynamic constraints such as acceleration constraints, deceleration constraints in structured roads (e.g., urban roads) or unstructured road scenes (e.g., harbors, grain warehouses, etc.) (Xiong et al., 2020), which is of great significance to improve vehicle driving safety and the efficiency of residual grain transfer in grain warehouses. At present, the commonly used path planning algorithms include three major categories: ant colony algorithm (Wu et al., 2023) based on machine learning method, PRM algorithm (Huang et al., 2024) and RRT algorithm (Yin et al., 2023) based on sampling method, and Dijkstra algorithm (Dijkstra, 2022) and A* algorithm (He et al., 2022) based on graph search method. However, none of these path planning algorithms consider vehicle kinematic characteristics when planning paths, resulting in limitations of the planned paths in grain depot scenarios. For this reason, Dolgov et al. proposed the Hybrid A* algorithm that considers satisfying the vehicle kinematic characteristics, which is able to plan a driving path close to the global optimum due to its novel node extension, but its planned paths will suffer from the problems of curvature not being able to maintain continuity, poor quality of the paths, and inefficient searching, which is still difficult to satisfy the practical needs (Dolgov et al., 2010). Therefore, some scholars are attracted to study the Hybrid A* algorithm. Aiming at the problems that the curvature of the paths planned by Hybrid A* algorithm cannot be kept continuous, the path quality is poor and the search efficiency is low, scholars carry out the improvement research from the aspects of path quality and search efficiency.

In the realm of path quality enhancement, diversified methodologies have been proposed to address trajectory optimization. Deng et al. (Deng et al., 2022) implemented a segmented spline curve optimization framework based on quadratic programming, while Zhang (Zhang, 2024) investigated the motion trajectory of warehouse robots by deriving spatial kinematic equations and introducing an enhanced Ant Colony Optimization-Dynamic Window Approach (ACO-DWA) algorithm. Ren et al. (Ren et al., 2022) innovatively designed a variable-radius Reeds-Shepp curve, integrating it with segmented Bessel curves and gradient descent techniques to ensure path smoothness. Concurrently, Tang et al. (Tang et al., 2021) synergized the artificial potential field method with the Hybrid A* algorithm, collectively mitigating discontinuities in curvature and improving navigational safety. Regarding search efficiency optimization, Tian et al. (Tian et al., 2023) augmented the heuristic function through distance field mapping, whereas Cao et al. (Cao et al., 2023) refined heuristic value acquisition by incorporating bidirectional path search strategies. Qin et al. (Qin et al., 2024) introduced collision risk cost into node extension mechanisms, and Li (Li, 2024) proposed an obstacle feature extraction method via raster map preprocessing to optimize ant colony algorithms. Furthermore, Sedighi et al. (Sedighi et al., 2019) enhanced path exploration efficiency by integrating Voronoi diagrams with the Hybrid A* framework. Although the Hybrid A* algorithm has made significant progress in both path quality and search efficiency, the existing methods still face challenges in grain depot scenarios. Especially in the complex environment of narrow aisles and many obstacles in the grain depot, the existing methods are still deficient in dynamically adjusting the resolution and the linkage between the step size and the distance to the obstacles.

The original Hybrid A* algorithm has the problems of low node search efficiency, long time consumption and poor adaptability to narrow channels when planning paths in the grain depot scenario. In this paper, a Hybrid A* algorithm with variable node resolution and variable step size is proposed, which mainly makes reasonable design of the heuristic function, the actual cost function and reasonable improvement of the node extension method. Among them, the dynamic node extension method is evaluated with the distance cost based on the KD-Tree algorithm, which changes the static extension into the dynamic extension with variable resolution and variable step size, and improves the path search efficiency.

MATERIALS AND METHODS

Hybrid A* algorithm

The Hybrid A* algorithm is a graph search algorithm improved from the A* algorithm, and its planned path takes into account the kinematic constraints of the vehicle, so that a path close to the global optimum can be planned.

The idea of Hybrid A* algorithm is the same as that of A* algorithm, both are heuristic search. The cost function of Hybrid A* algorithm is as follows:

$$f(n) = g(n) + h(n) \tag{1}$$

In equation (1), the defining domains of the cost function $f(n)$, the actual cost $g(n)$, and the heuristic function $h(n)$ are all the nodes N in the search space, and the value domain R is a non-negative real number; where n is the current node, $g(n)$ is the actual generation value from the starting node to the current node, and $h(n)$ is the heuristic generation value from the current node to the goal point, and $f(n)$ integrates the actual cost from the starting point to the current point and the estimated cost to the goal point.

The Hybrid A* algorithm searches as described below:

First, the Hybrid A* algorithm (Cao, 2023) receives the start position, end position, and a 2D raster map containing vehicle position coordinates and heading angle information. It performs path planning within this static 2D raster map (Elfes, 1989), which includes obstacle data and passable areas. The algorithm initializes an empty Open list and Closed list to manage the search nodes and inserts the start node into the Open list. Next, the algorithm selects the current node for expansion based on the heuristic cost to the target point, choosing the node with the lowest cost function value $f(n)$ from the Open list. It then checks whether this node can be connected to the goal using an obstacle-free Reeds-Shepp curve (Reeds & Shepp, 1990). If a valid connection is found, the curve is accepted as the final path, and the algorithm terminates. If no direct connection is possible, the current node is moved to the Closed list and treated as a parent node. Child nodes are generated based on vehicle kinematic constraints, and the cost function $f(n)$ is calculated for each. These child nodes are then added to the Open list. The process repeats, expanding nodes, checking for connections, and updating the Open and Closed lists, until either a valid path is found or the Open list is empty. The overall workflow of the algorithm is illustrated in Fig. 1.

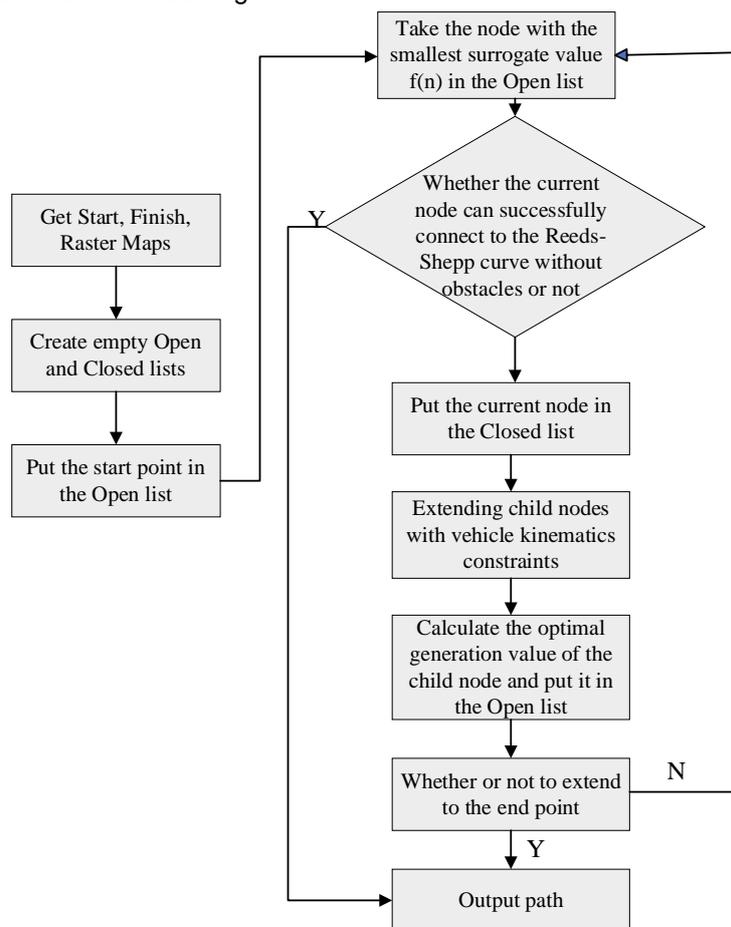

Fig. 1 - Flowchart of Hybrid A* algorithm

Improvements to the Hybrid A* algorithm

In order to solve the problems of low search efficiency and high time consumption in the original Hybrid A* algorithm when applied to complex grain depot scenarios with narrow aisles and numerous obstacles, an improved Hybrid A* algorithm is proposed.

Firstly, a more effective design of the heuristic function and the actual cost function is implemented to enhance the accuracy and relevance of the path planning. Secondly, the KD-Tree algorithm (Ram & Sinha, 2019) is used for nearest neighbor and distance range search to compute the distance to the nearest obstacle. When multiple points have the same calculated distance and surrogate value, to ensure the smoothness and safety of the driving path, priority is given, based on the calculation results, to the point with a smaller angle relative to the current driving direction, or to the point that is farther away from the obstacle. At the same time, the calculated obstacle distance cost is fused into the node expansion process. Based on this distance, dynamic expansion with variable resolution and variable step size is applied, improving the efficiency of path searching. Finally, the Reeds-Shepp curve (Reeds & Shepp, 1990) is used to generate the final path, ensuring it meets vehicle motion constraints and is optimal for driving. Combined with the vehicle schematic shown in Fig. 2, the Hybrid A* algorithm is specifically improved in the following ways:

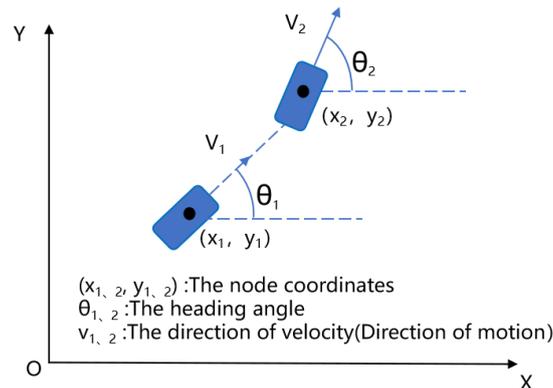

Fig. 2 - Schematic diagram of the vehicle

Heuristic function design

In Hybrid A* algorithm, the heuristic function plays a key role to estimate the heuristic generation value from the current node to the goal point to help the path search. To satisfy the vehicle kinematics and environmental constraints, two heuristic functions are used in parallel and the larger value of the two is selected as the heuristic search value as shown in equation (2).

$$h(n) = \max\{h_1(n), h_2(n)\} \quad (2)$$

In equation (2), the domain of definition of $h_1(n)$ and $h_2(n)$ is the set N of all nodes in the search space, where each node $n \in N$ contains the position coordinates (x, y) and the heading angle θ , and the value domain R is a nonnegative real number; where $h_1(n)$ is the first heuristic function that considers the kinematic constraints of the vehicle while ignoring the environmental obstacle constraints. When considering the kinematic constraints of the vehicle, it is necessary to incorporate factors such as minimum turning radius and speed into the heuristic function. This ensures that the planned path aligns with the vehicle's actual motion capabilities and avoids generating infeasible trajectories. Typically, this is achieved by using Reeds-Shepp curves to compute the shortest feasible path from the current node (x_n, y_n, θ_n) to the goal point (x_g, y_g, θ_g) . The length of this path serves as the first heuristic function, denoted as $h_1(n)$. The second heuristic function, $h_2(n)$, takes into account environmental obstacle constraints while ignoring the vehicle's kinematic limitations. To enable obstacle avoidance, an obstacle distance field is introduced into the heuristic. The A* algorithm is used to evaluate the distance between the path and surrounding obstacles, where greater distances yield higher heuristic values. This steers the path away from obstacles, generating a safer route from the current node (x_n, y_n, θ_n) to the goal point (x_g, y_g, θ_g) . The length of this path defines the value of the second heuristic function, $h_2(n)$. Here, n represents the current node, g is the goal point, (x, y) are the node coordinates, and θ is the heading angle.

$h_1(n)$ incorporates the feasible steering range of the Reeds-Shepp curve, helping to avoid dead ends where the vehicle cannot turn around. In contrast, $h_2(n)$ performs a search on the raster map using the A* algorithm, enforcing obstacle avoidance by utilizing obstacle grid markers. The combination of these two heuristics ensures that the planned path remains clear of hazardous areas. As a result, the final driving path not only complies with the vehicle's kinematic constraints but also effectively navigates around environmental obstacles.

Cost function design

In order to avoid unnecessary steering and reversing of the vehicle, it is necessary to ensure the continuity of the search path. In this paper, a penalty term is added for steering and reversing in the cost function to make the planned path more continuous.

The actual cost of each child node $n_i(x_i, y_i, \theta_i)$ in the search path of the Hybrid A* algorithm is shown in equation 3; where the child node n_i is a new node generated by expanding from the current node through vehicle kinematics constraints.

$$\begin{cases} g_i(n) = g_p(n) + g_{turn}(n) \times \omega_1 + g_{reverse}(n) \times \omega_2 \\ g_{turn}(n) = |\theta_i - \theta_p| \\ g_{reverse}(n) = L \end{cases} \quad (3)$$

In equation (3), $g_i(n)$ is the generation value of child node n_i , $g_p(n)$ is the generation value of parent node n_p , $g_{turn}(n)$ is the vehicle steering penalty coefficient, $g_{reverse}(n)$ is the vehicle reversing penalty coefficient, L is the length of the variable step length, θ is the heading angle, and ω_1, ω_2 are the weighting coefficients. Through several experiments, the parameters are adjusted according to the needs of vehicle driving in different scenarios, usually $\omega_1 > 1$ and $\omega_2 > 1$ (Wilt & Ruml, 2012).

In the designed cost function, $g_{turn}(n)$ represents the penalty associated with changes in the heading angle at a path point - that is, the angle between the vehicle's direction of movement and the X-axis of the global coordinate system. This change reflects a shift in the vehicle's actual trajectory. By applying a penalty for turning, the number of steering actions is reduced, thereby improving the smoothness of the planned path. The corresponding weight ω_1 can be flexibly adjusted based on the specific application scenario; for instance, if frequent steering is undesirable, a higher value of ω_1 can be used. Similarly, $g_{reverse}(n)$ represents the penalty for reverse driving. This is combined with the variable step length L to reduce the number of backward steps in the path, thereby encouraging forward motion. The weight ω_2 can also be flexibly adjusted; for example, if reversing is permitted but should be minimized, a higher value of ω_2 can be applied. By designing the cost function in this way, the planned path can be adapted to meet different driving requirements, balancing between path smoothness, forward motion preference, and scenario-specific constraints.

Node Extension Method Design

Although the original Hybrid A* algorithm satisfies vehicle kinematics and can generate extended trajectories based on these constraints, it expands nodes using a fixed resolution and fixed step size. This approach limits the diversity of path options, making it difficult to approximate optimal paths, reduces the flexibility of the search process, and results in high computational cost. Consequently, the node expansion process - where the current node generates a series of potential new nodes based on vehicle kinematics and the algorithm's search strategy - becomes time-consuming and inefficient. To address these issues, the node expansion method is improved by incorporating the distance $d_{nearest}(n)$ from the current node to the nearest obstacle, calculated using the KD-Tree algorithm. A dynamic node expansion strategy is proposed, which adjusts both the resolution and step size according to $d_{nearest}(n)$. This enhancement increases the flexibility of node expansion in the Hybrid A* algorithm and reduces extension time.

KD-Tree is a tree-based data structure designed for storing and efficiently retrieving points in k-dimensional space, enabling fast nearest neighbor searches (Bi et al., 2022). When using conventional methods to calculate the nearest distance (i.e., the minimum distance from the current node to an obstacle), it is necessary to compute the distance to each obstacle and compare the results, which is inefficient and yields poor performance. To address this, obstacles in the map are structured into a 2D KD-Tree, allowing both nearest neighbor and range searches between the current node and surrounding obstacles. By applying the KD-Tree algorithm within the 2D raster map, the nearest distance from an expanding node to nearby obstacles can be quickly determined, significantly improving the efficiency and safety of the path search.

In this context, obstacles refer to static objects that obstruct vehicle movement, and their positions in the 2D raster map are represented as coordinate points (i.e., obstacle coordinates).

The nearest distance between a node and an obstacle is calculated using the Euclidean distance formula: $\sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}$ which represents the straight-line distance between two points. The implementation process is illustrated in the flowchart shown in Fig. 3.

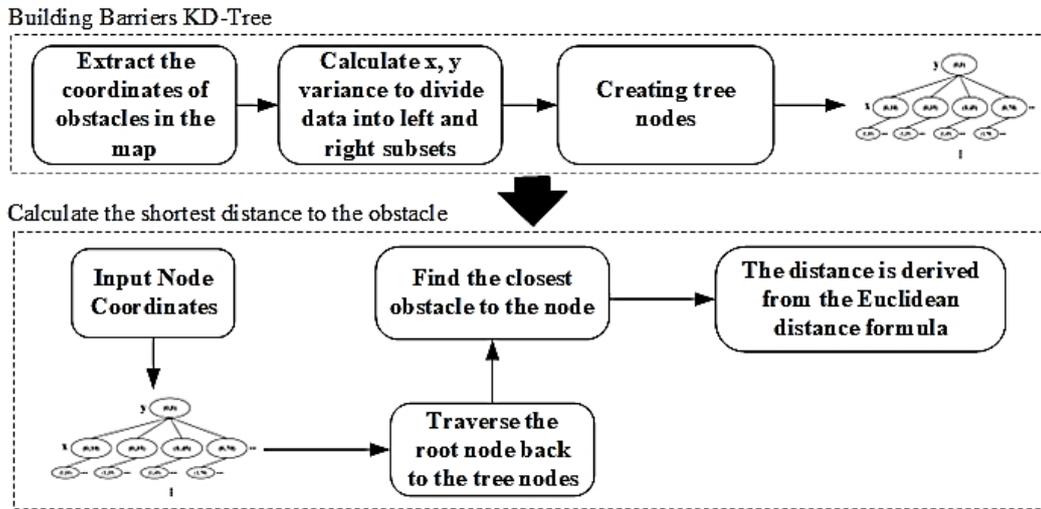

Fig. 3 - Flowchart of KD-Tree algorithm implementation

Based on the nearest distance $d_{nearest}(n)$ between the current vehicle node and the nearest obstacle, calculated using the previously constructed 2D KD-Tree of the obstacle data, the raster map can be globally partitioned into different regions according to d_{max} and d_{min} . Specifically, when $0 < d_{nearest}(n) < d_{min}$, the node is considered to be within a collision region, as illustrated in Fig. 4.

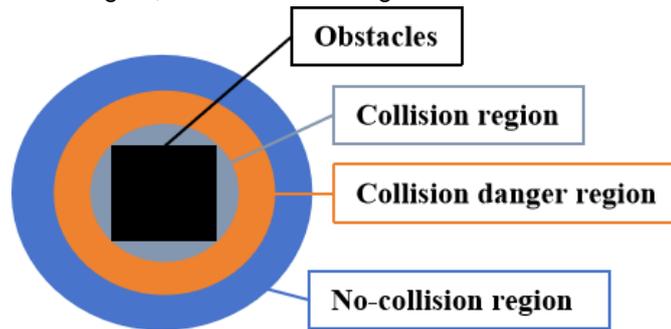

Fig. 4 – Schematic diagram of the region

The value of $d_{nearest}(n)$ is used to determine which region the vehicle occupies along the planned path. Simultaneously, the variable resolution K and variable step length L are linked to the nearest obstacle distance $d_{nearest}(n)$, enabling a dynamic adjustment of the node expansion strategy. As $d_{nearest}(n)$ changes, the search mode for node expansion is dynamically modified. Upper and lower bounds are defined for both the resolution and step length, and their values are adjusted in real time using Equations (4), (5), and (6). This adaptive approach allows the algorithm to select the most suitable node expansion mode based on the surrounding environment, significantly enhancing the efficiency of the path search.

$$K = \begin{cases} K_{min} & , \quad d_{max} \leq d_{nearest}(n) \\ K_{min} + a_1 \times b_1 & , \quad d_{min} \leq d_{nearest}(n) \leq d_{max} \\ K_{max} & , \quad 0 \leq d_{nearest}(n) \leq d_{min} \end{cases} \quad (4)$$

$$L = \begin{cases} L_{max} & , \quad d_{max} \leq d_{nearest}(n) \\ L_{min} + a_2 \times b_2 & , \quad d_{min} \leq d_{nearest}(n) \leq d_{max} \\ L_{min} & , \quad 0 \leq d_{nearest}(n) \leq d_{min} \end{cases} \quad (5)$$

where the values of a_1 , a_2 , b_1 , b_2 are shown in equation (6):

$$\begin{cases} a_1 = K_{max} - K_{min} \\ a_2 = L_{max} - L_{min} \\ b_1 = \frac{d_{max} - d_{nearest}(n)}{d_{max} - d_{min}} \\ b_2 = \frac{d_{nearest}(n) - d_{min}}{d_{max} - d_{min}} \end{cases} \quad (6)$$

In the above, d_{min} is the minimum safe distance from the obstacle and d_{max} is the maximum safe distance from the obstacle. In equation (5), K_{max} is the maximum discretization level of the variable resolution during node expansion and K_{min} is the minimum discretization level. Similarly, in Equation (6), L_{max} and L_{min} represent the maximum and minimum values, respectively, of the variable step length used during node expansion.

Therefore, after obtaining the vehicle position in the path, the algorithm determines whether the vehicle collides with the obstacle through $d_{nearest}(n)$. If in the collision-free region, the algorithm uses the resolution of the minimum discretization and the step size of the maximum length for node extension, and the resolution and step size of the node extension process if the obstacle is encountered in the search path will be changed with the change of the nearest distance $d_{nearest}(n)$. Fig. 5 shows the schematic diagram of dynamic extension, in which black squares are obstacles, green circles are collision-free regions, and red circles are dangerous collision regions. Fig. 6 shows the comparison diagram before and after the improved node extension, in which the blue box is the starting point of the vehicle, the red box is the end point of the path, the black square is the obstacle, the white grid part is the passable area, and the red track is the node trajectory. This improved node extension method can reduce the collision probability and improve the path accuracy by increasing the resolution discretization of the search path and decreasing the step length in the narrow channel and complex environment of the granary; in the normal environment of the granary, it can reduce the number of nodes to be searched and accelerate the search speed by decreasing the resolution discretization of the search path and increasing the step length. This not only improves the search efficiency of the Hybrid A* algorithm, but also ensures that the vehicles search over long distances and narrow aisles, further guaranteeing the safety of the path.

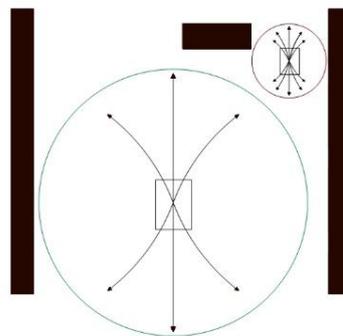

Fig. 5 - Schematic diagram of dynamic node extension

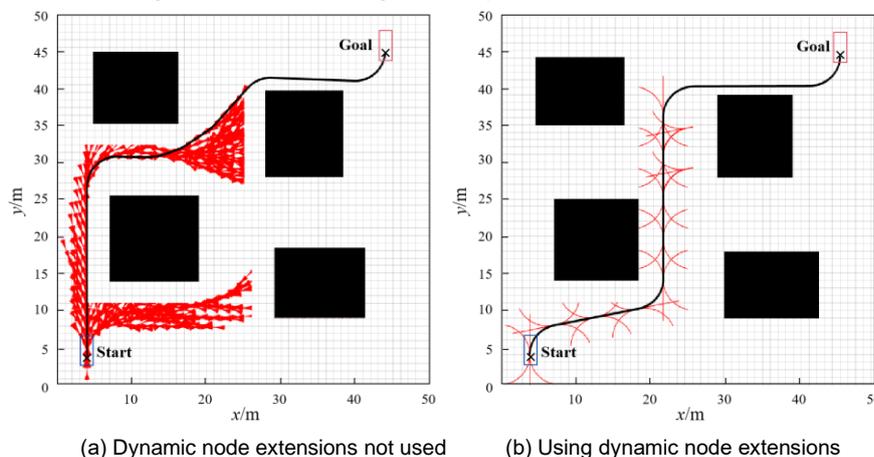

Fig. 6 - Comparison of planning before and after improving the way of extension nodes

Table 1

Comparison of dynamic node extension data

Title	Dynamic node extensions not used	Using dynamic node extensions
Number of nodes/piece	843	49
Search time/s	1.95	0.62

From the comparison data in Table 1, it can be concluded that the use of dynamic extension nodes reduces the number of search nodes by 94% and the search time by 68% compared to not using dynamic extension. The path search efficiency of the improved Hybrid A* algorithm can be improved by using dynamic extension nodes.

Search Path Fitting

It may not be possible to search the exact target point pose by the improved node extension approach, and in this paper, the Reeds-Shepp curve, which takes into account the vehicle kinematics constraints, is used for the final path search fitting. As shown in Fig.7, the blue box is the starting point, the red box is the end point, the black square is the obstacle, and the red dashed line is the Reeds-Shepp search curve. When the Hybrid A* algorithm is extended to the current node and the target point, it will use the Reeds-Shepp curve for path search; if there is no collision with obstacles during the path fitting process, the fitted path is a valid path to stop searching; otherwise, it continues to use the Hybrid A* algorithm to conduct path searching until a drivable path is obtained.

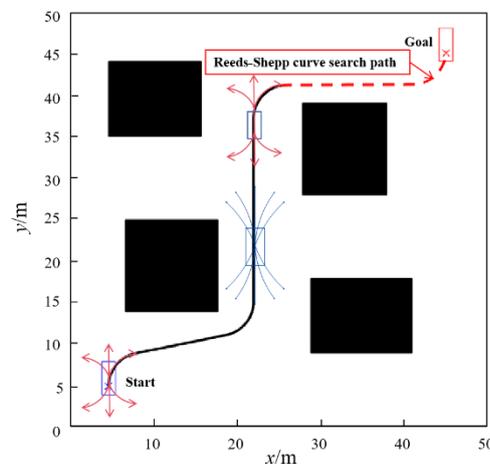

Fig. 7 - Schematic diagram of Reeds-Shepp curve path search fitting

RESULTS

Algorithm Testing

To verify the effectiveness and feasibility of the proposed algorithmic improvements, two types of obstacle distribution maps, simple and complex, were carefully designed within environment maps featuring diverse topologies. These maps included narrow passages and multi-obstacle layouts typical of grain depot scenarios. Based on these two simulated grain depot environments, the performance of the original Hybrid A* algorithm and the improved version proposed in this study was evaluated. The comparison focused on two key indicators: search time and number of search nodes, allowing for a comprehensive analysis of algorithmic performance. The experiment was conducted using MATLAB R2020a. The simulated vehicle parameters are as follows: a length of 4.0 m, a width of 1.6 m, a wheelbase of 2.75 m, and front and rear overhangs of 1.0 m each. The maximum turning angle of the front wheels is 0.6 rad. The simulation environment is a 50 m × 50 m raster map. The vehicle's starting position and orientation, as well as the distribution of obstacles, are illustrated in Fig. 8 and Fig. 9. In the figures, the blue box indicates the vehicle's starting position, the red box marks the target position, black squares represent obstacles, white grids denote traversable areas, and the red line shows the trajectory through the path nodes. According to the obstacle layout, Fig. 8 represents a simple map with a sparse and regular distribution of obstacles, while Fig. 9 depicts a complex map characterized by a high density and irregular distribution of obstacles. The simulations were performed on a Windows 10 platform with an Intel i5-1135G7 processor and 16 GB of RAM. MATLAB R2020a was used to simulate the proposed algorithm in the context of two grain depot environments. In both scenarios, the starting and target positions remained fixed, and the obstacle configuration was unchanged. Under these conditions, the generated path trajectories were largely consistent across multiple runs. Performance metrics such as the number of nodes, search time, and path length were evaluated based on the average results from more than ten simulation trials.

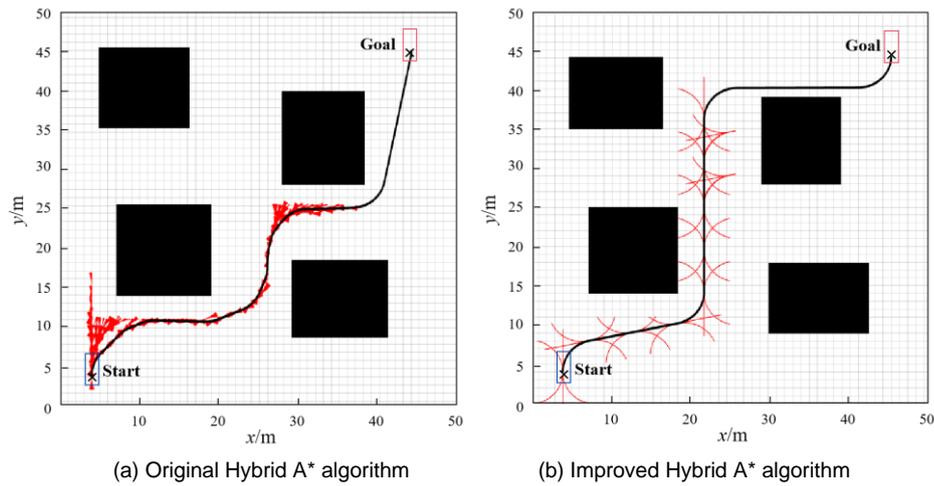

Fig. 8 - Comparison of simple map path planning

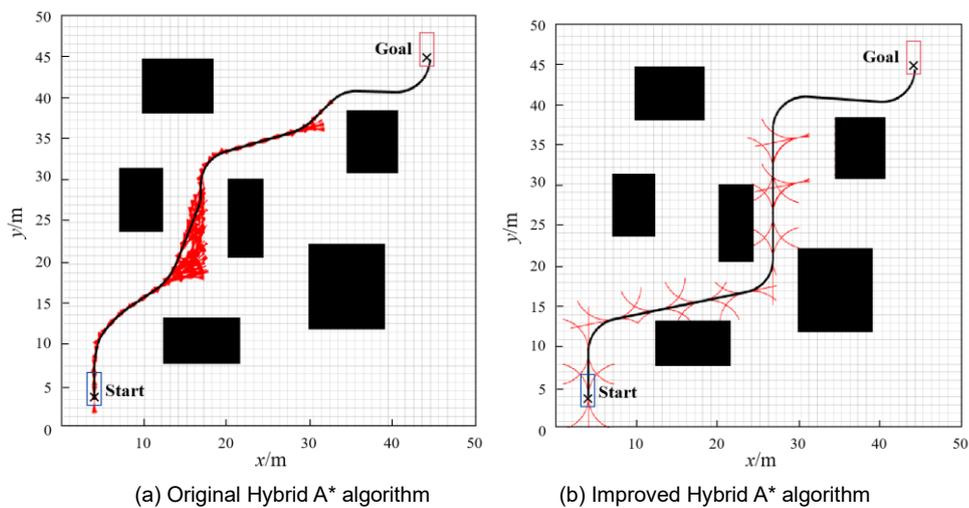

Fig. 9 - Comparison of complex map path planning

Table 2

Simple map simulation test data comparison

Algorithm	Number of nodes/piece	Search time/s	Path length/m
Original Hybrid A*	301	0.99	66.2
Improved Hybrid A*	49	0.62	71.4

Table 3

Complex map simulation test data comparison

Algorithm	Number of nodes/piece	Search time/s	Path length/m
Original Hybrid A*	191	1.66	64.1
Improved Hybrid A*	37	0.72	71.5

As shown in Table 2 and Fig. 8, in the setup of simple grain depot map, the improved Hybrid A* algorithm reduces by 83% and 37% in the number of search nodes and path search time, respectively, compared to the original Hybrid A* algorithm. As shown in Table 3 and Fig. 9, the improved Hybrid A* algorithm reduces the number of search nodes and path search time by 80.6% and 56.6%, respectively, compared with the original Hybrid A* algorithm in the setup of complex grain depot maps. The simulation results show that the improved Hybrid A* algorithm has a significant improvement in the number of search nodes and the search path time compared to the original Hybrid A* algorithm in the setup of two kinds of maps of grain depot environments, but in terms of path length, the improved algorithm takes vehicle kinematics constraints and collision avoidance into consideration when planning paths and chooses paths more in line with the driving requirements, so there is no substantial enhancement. The efficiency order of the original and improved algorithms may be different under different grain depot obstacle topologies.

When the distribution of obstacles is sparse and the shape is regular, the performance of the two algorithms may be similar; however, when the distribution of obstacles is dense and the shape is complex, the improved algorithm may show higher efficiency.

Real-vehicle Verification

In order to further verify the effectiveness and feasibility of the improved Hybrid A* algorithm, the test vehicle used in this paper is an intelligent grain transfer vehicle conforming to the Ackermann steering model (Ren et al., 2009), with a vehicle length of 4.0 m, width of 1.6 m, height of 2.2 m, wheelbase of 2.75 m, a minimum turning radius of 5.5 m, and a maximum turning angle of 0.54 rad at the front wheels, and is equipped with 16-wire LIDAR. RTK inertial guidance, millimeter wave radar and other sensors are shown in Fig.10 (a). Tested using the ROS operating system under Ubuntu 18.04, the original planning algorithm in the ROS system was replaced with the improved Hybrid A* algorithm and the original Hybrid A* in the form of the ROS plugin, and then experimental testing was carried out. The map used for navigation is constructed by RTK inertial guidance acquisition of road boundary points, and is processed into the raster map needed in the ROS system through image processing. The experimental results are shown in Fig. 10, the blue line area in (b) is a selected part of the grain depot scene, the black part in (c) and (d) is the obstacle, the green square is the starting point, the blue square is the end point, and the yellow line is the planned trajectory. As can be seen in Fig. 9, both Hybrid A* algorithms can plan a drivable path. In terms of search time, the original Hybrid A* algorithm takes 25.34s and the improved Hybrid A* algorithm takes 9.76s, and the improved algorithm improves 61.4% compared to the original one. In terms of the number of search nodes, the original algorithm searches for 34 nodes and the improved algorithm searches for 16 nodes, which is 52.9% higher compared to the original algorithm. In terms of the path length, the original algorithm and the improved algorithm plan a length of 80.85m and 80.73m, respectively, with no significant improvement. The results show that the improved Hybrid A* algorithm proposed in this paper is effective in improving the path search efficiency and safety in the presence of narrow aisles and the complex environment of the grain depot scenario.

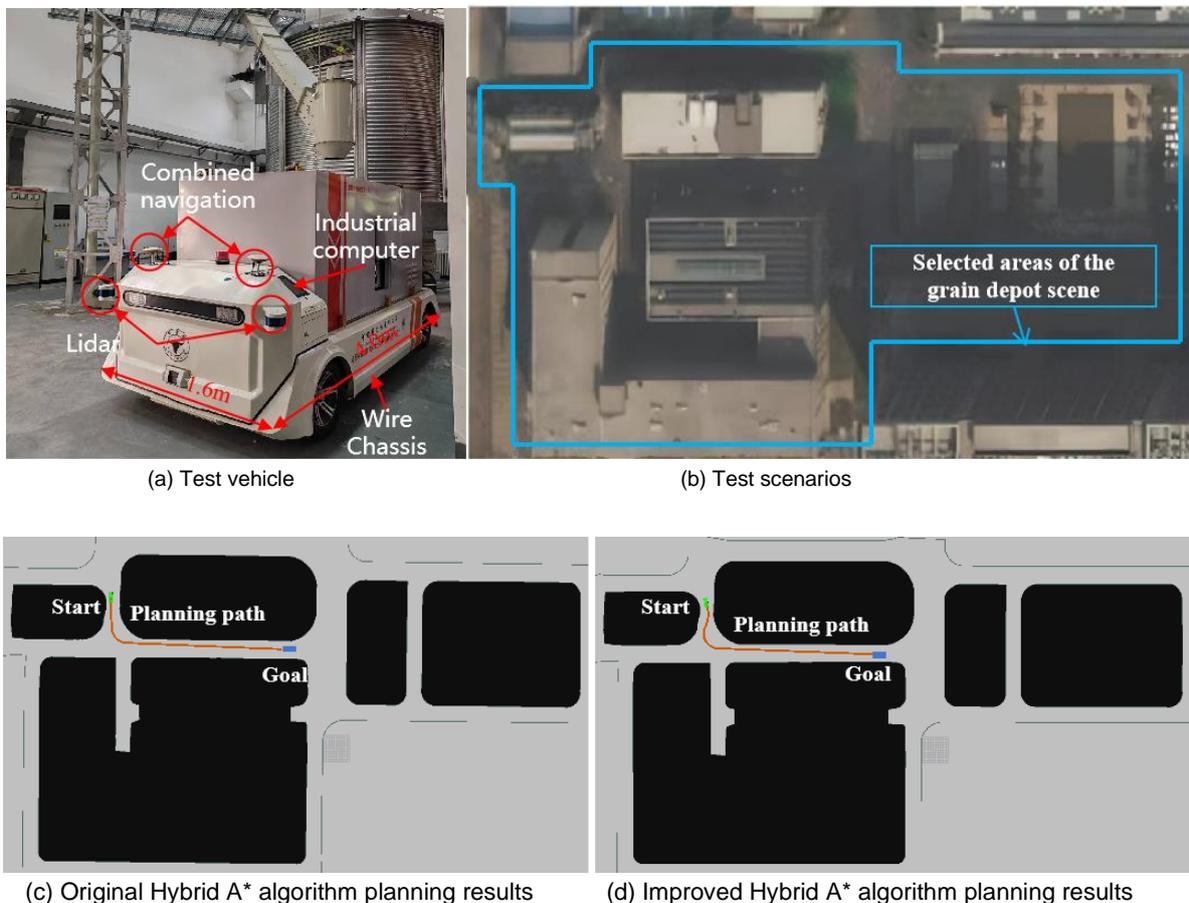

Fig. 10 - Real vehicle validation results

CONCLUSIONS

In this paper, a Hybrid A* algorithm based on variable resolution and variable step size is proposed for the deficiencies of the original Hybrid A* algorithm in the grain depot scenario. Firstly, by introducing weight coefficients and penalty terms, the heuristic function and cost function are reasonably designed to reduce the number of times that the vehicle turns and reverses in path planning. Secondly, combining KD-Tree to calculate the distance cost between nodes and obstacles, the resolution and step size are dynamically adjusted to realize the flexibility of node extension. Finally, in order to accurately locate to the target position, Reeds-Shepp curves are used for path search fitting to ensure the accuracy of the planned path. Simulation results show that the improved Hybrid A* algorithm reduces 83% and 37% in simple maps compared to the original Hybrid A* algorithm in terms of the number of search nodes and planning elapsed time, respectively. In complex maps, the reduction is 80.6% and 56.6%, respectively. The results of the real-vehicle experiments show that the improved Hybrid A* algorithm reduces the number of search nodes and planning time by 52.9% and 61.4%, respectively, compared with the original Hybrid A* algorithm. In summary, the improved Hybrid A* algorithm proposed in this paper significantly improves the path search efficiency of the intelligent grain transporter in the grain depot scenario by dynamically adjusting the resolution and step size, combining the KD-Tree distance cost with the Reeds-Shepp curve search fitting, which further validates the feasibility of the improved algorithm. Future research topics may include improving the adaptability of the algorithm for real-time planning in dynamic obstacle environments as well as conducting experiments in obstacles with different topologies to expand the scale and diversity of the experiments, while considering vehicle travel time and energy consumption to enhance the effectiveness of the improved algorithm. At present, although the improved algorithm has been experimentally validated, its in-vehicle validation needs further improvement. At this stage, the research focuses on being able to improve the search efficiency when planning paths in grain depot scenarios, and subsequent research will be further expanded on this basis.

Keywords: internet of things, fuzzy PID control, adaptive particle swarm optimization algorithm, smart agriculture, greenhouse control

ABSTRACT

Traditional greenhouse management often suffers from slow responsiveness and limited adaptability due to its reliance on manual operations. This study proposes a greenhouse environment monitoring and control system that integrates Internet of Things (IoT) technologies with a fuzzy PID controller optimized through an Adaptive Particle Swarm Optimization (APSO) algorithm. A real-time monitoring platform was developed based on a WebSocket-enabled front-end/back-end separation architecture. Environmental parameters, such as temperature and humidity, were collected by sensors and transmitted in real time to the platform via the MQTT protocol, enabling data visualization and anomaly detection. The APSO algorithm was employed offline to optimize the fuzzy PID parameters, and the resulting controller was implemented on a microcontroller to achieve real-time control. Compared with conventional PID control, the APSO-optimized controller reduced overshoot by 72.1% and shortened the settling time by 20%. Experimental results demonstrated that the system was less susceptible to external environmental disturbances, maintaining temperature fluctuations within 0.3°C. This study provides a robust and effective solution for smart greenhouse management.

摘要

由于依赖人工操作，传统的温室管理往往存在响应速度慢、适应性有限等问题。本研究提出了一种温室环境监测和控制系统，该系统将物联网（Internet of Things, IoT）技术与通过自适应粒子群优化（Adaptive Particle Swarm Optimization, APSO）算法优化的模糊 PID 控制器相结合。提出基于 WebSocket 的前端/后端分离架构，开发了一个实时监控平台。温度和湿度环境参数由传感器收集，并通过 MQTT 协议实时传输到平台，从而实现数据可视化和异常检测。采用 APSO 算法离线优化模糊 PID 参数，并在微控制器上实现控制器的实时控制。与传统的 PID 控制相比，APSO 优化控制器将过冲降低了 72.1%，并将稳定时间缩短了 20%。实验结果表明，该系统不易受外部环境干扰的影响，能将温度波动保持在 0.3°C 以内。本研究为智能温室管理提供了一个稳健有效的解决方案。

INTRODUCTION

In recent years, advancements in agricultural production technologies have become increasingly critical due to the continuous growth of the global population and the rising demand for food. Predictions indicate that by 2050, the global population will reach approximately 8.52 billion, reflecting a 10.6% increase from 7.7 billion in 2020 (Akaev, 2022). Correspondingly, global food demand is expected to rise by nearly 60% (van Dijk et al., 2021). However, the agricultural sector faces escalating challenges, including limited arable land, water scarcity, and environmental concerns.

A significant portion the world's freshwater resources is used for agricultural irrigation, while a large proportion of greenhouse gas emissions can be attributed to the global food production system (*Hemathilake and Gunathilake, 2022, Khondoker et al., 2023*). In addition, climate change has led to an increased frequency of extreme weather events, further complicating agricultural production and heightening its unpredictability (*Kumar et al., 2022*). Therefore, improving agricultural efficiency and sustainability has become imperative.

Smart agriculture, which integrates information technology, automated control, and agricultural science, has emerged as a promising solution to these challenges (*Goli et al., 2024*). Among its various applications, greenhouse cultivation plays a pivotal role in enhancing crop yield and quality by providing controlled environmental conditions (*Atia and El-madany, 2017*). Globally, over 470,000 hectares of land worldwide are dedicated to greenhouse cultivation, yielding approximately ten times more per unit area compared to open-field cultivation (*Zhou et al., 2021*). Many crops grown in greenhouses (e.g. tomatoes, strawberries, etc.) require stable temperature and humidity levels to promote optimal flowering, fruit set and ripening. Temperature deviations can adversely affect fruit quality and yield, while high humidity may increase the risk of fungal diseases. Therefore, precise microclimate control is essential for successful crop cultivation. However, traditional greenhouse control systems often struggle to maintain precise environmental regulation due to fluctuating external conditions and complex parameter interactions. Many conventional approaches lack the responsiveness and precision required for modern agricultural standards (*Katzin et al., 2022*). In particular, traditional control methods face challenges such as response delays and insufficient adjustment precision in regulating key environmental parameters like temperature and humidity concentration, making it difficult to meet the high standards of modern agriculture.

The concept of the Internet of Things (IoT) can be traced back to the 1990s (*Chin et al., 2019, Schoder, 2018*). With advancements in technology and the expansion of its applications, IoT holds the potential to revolutionize various fields, including supply chain management, logistics tracking, intelligent transportation, and environmental monitoring (*Fadhel et al., 2024*). In agriculture, IoT has emerged as a key emerging technology driving agricultural development, with widespread applications in cultivation, livestock farming, and agricultural product traceability, playing a crucial role in promoting agricultural advancement (*Gatkal et al., 2024, Mohamed et al., 2022, Omasa et al., 2022*). Wang *et al.* (2018) developed an IoT-based intelligent greenhouse control system that can effectively monitor the greenhouse environment. However, the cloud platform lacks analysis and algorithm control and cannot achieve accurate environmental control.

Fuzzy logic control, with its advantages in handling nonlinear and uncertain systems, has become an effective method for greenhouse environment control. Unlike traditional control methods, fuzzy logic control does not require precise mathematical models and can achieve flexible control of complex systems through fuzzy rules and fuzzy inference, making it particularly suitable for the multi-variable and highly coupled environment of greenhouses (*Cheng, 2020, Wang and Zhang, 2018, Thomopoulos et al., 2024*). Marco A. Márquez-Vera *et al.* (2016) developed an internal temperature control system for greenhouses based on an inverse fuzzy model. The fuzzy partitions for each climate variable used two membership functions, which enhanced the model's accuracy and response speed. The model was tuned using batch least squares and updated with recursive least squares to optimize control performance. Adaptive Particle Swarm Optimization (APSO) is an improved algorithm that introduces an adaptive mechanism to the traditional Particle Swarm Optimization (PSO) algorithm (*Zhang et al., 2014*). Different from the standard PSO algorithm, APSO dynamically adjusts the key parameters of the algorithm and automatically optimizes them based on feedback information during the search process. This improves the global search capability and helps avoid convergence to local optima. Through this adaptive mechanism, APSO can better balance global exploration and local exploitation, and enhance the convergence and search efficiency of the algorithm, which is especially suitable for complex, multi-peaked, nonlinear, and high-dimensional optimization problems (*Zheng et al., 2023*).

Based on the aforementioned background, this paper develops and tests a small greenhouse control system that integrates fuzzy PID control optimized by an APSO algorithm and an intelligent monitoring platform. The system design includes data collection from a network of sensors, parameter adjustment via a fuzzy controller, and seamless integration with the intelligent monitoring platform. The overall cost of the system is lower compared to traditional greenhouse methods, which not only improves the accuracy of environmental regulation, but also provides significant economic benefits. It can accurately control greenhouse temperature, reducing energy consumption, and the use of sensors and low-maintenance communication equipment helps to lower design costs. Furthermore, the intelligent monitoring platform minimizes manual intervention, improving management efficiency and reducing labour costs.

MATERIALS AND METHODS

Hardware equipment

In a small-scale greenhouse control system for smart agriculture, sensors are critical components for achieving real-time monitoring and control of environmental parameters (Lee *et al.*, 2019). The system described in this paper utilizes a variety of devices to monitor key environmental data in the greenhouse, as shown in Table 1. The soil sensor (Model: VMS-3001-TR-*) and air sensor (Model: VMS-3002-WS) were sourced from VEMSEE flagship store (Address: Hangzhou, Zhejiang Province, China). The 8-channel RS485 hub supports multi-channel input and can connect up to 8 RS485 signal inputs, thereby enabling centralized management of data from multiple sensor devices. The system gateway was obtained from the PUSER flagship store. Its main function is to receive RS485 signals from the hub, convert them into JSON format, and then transmit the converted JSON data to the control system using the MQTT protocol.

In terms of actuators, the system is equipped with PTC heaters and semiconductor coolers to adjust the temperature. To optimize the circulation of cold and warm air, the heater is installed in the lower part of the greenhouse, while the cooler is installed in the upper part. In addition, ventilation fans are included to provide effective air circulation. To control the air humidity in the greenhouse, the system is equipped with an ultrasonic humidifier, supplemented by fans to enhance the humidification effect. The fan installed next to the humidifier helps to evenly distribute the misted moisture throughout the greenhouse, ensuring uniform humidity.

Table 1

Hardware Equipment		
Equipment	Models	Producers
soil sensor	VMS-3001-TR-*	VEMSEE Flagship Store
air sensor	VMS-3002-WS	VEMSEE Flagship Store
hub	HM-RS485-16-JX	eMybos
gateway	USR-M100	PUSER Flagship Store
heater	DJR	Kunli Electric
cooler	12V Semiconductor Chiller	ZeJie
humidifier	SHILU-12568	ShiLu
fan	15050-17251	SanXie

Greenhouse structure

The greenhouse frame is shown in Figure 1. It is constructed from 3-mm thick acrylic panels, providing good light transmission for plant growth. The greenhouse was designed in a square shape with a length of 800 mm, a width of 600 mm and a height of 700 mm. Ventilation openings with a diameter of 150 mm are provided on both sides to facilitate air circulation. The top of the greenhouse is provided with three square holes 47 mm long to hold the cooler and the bottom is provided with mounting holes 5 mm in diameter for the heater. To further ensure temperature stability, an insulating film was added to the exterior of the greenhouse to improve thermal efficiency and minimize heat loss.

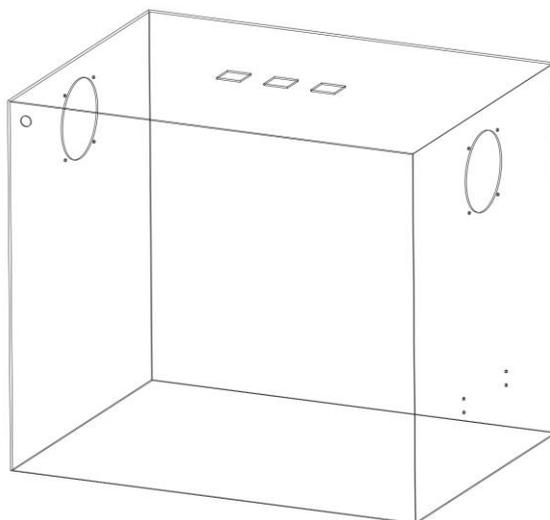

Fig. 1 - Greenhouse frame

System architecture

The overall conceptual diagram of the proposed system is shown in Figure 2. The system architecture consists of three main components: an environmental monitoring system, a control system and a data visualization platform. The primary function of the environmental monitoring system is to collect, transmit and initially process environmental data. The system comprises six RS485 sensor nodes and one edge gateway.

Each sensor is connected to the hub via an RS485 interface and communicates with the edge gateway through a serial port. The edge gateway is responsible for receiving environmental data from the hub performing initial processing and converting the data format. First, it receives sensor data such as temperature and humidity from the hub via a pre-configured interface, encapsulates the data into JSON format, and sends the JSON data to the specified MQTT topic via the MQTT protocol. The system utilizes the ESP8266 Wi-Fi module to connect to the MQTT server and subscribe to the topic to receive the environmental data. The received JSON data is transferred through serial communication to STM32F103ZET6 microcontroller, which is responsible for processing and analysing the received data. It compares the real-time data with the pre-set parameters to determine if the environmental conditions are within the expected range. Based on the comparison results, the control system adjusts the duty cycle of the PWM (pulse width modulation) signal to fine-tune the system's response. By modulating the PWM signal, the switching state of the electromagnetic relay is controlled, which in turn regulates actuators such as fans, heaters, coolers, etc., ensuring real-time monitoring and fine-tuning of environmental parameters.

The data visualization platform adopts MVVM (Model- View - ViewModel) separation framework for the front-end and back-end, which ensures the modularity and efficiency of the system. The back-end is implemented using the Django Channels framework, which is mainly responsible for processing the data received from the edge gateway and facilitating real-time communication with the front-end via WebSocket (*Fuentes et al., 2024*). The front-end is implemented using a JavaScript framework, which receives the data pushed from the back-end via WebSocket and updates the display interface in real time. The data is finally stored in a MySQL database for post-processing and analysis. The whole system is designed to be efficient and reliable, ensuring that users can monitor environmental data in real time and respond in a timely manner.

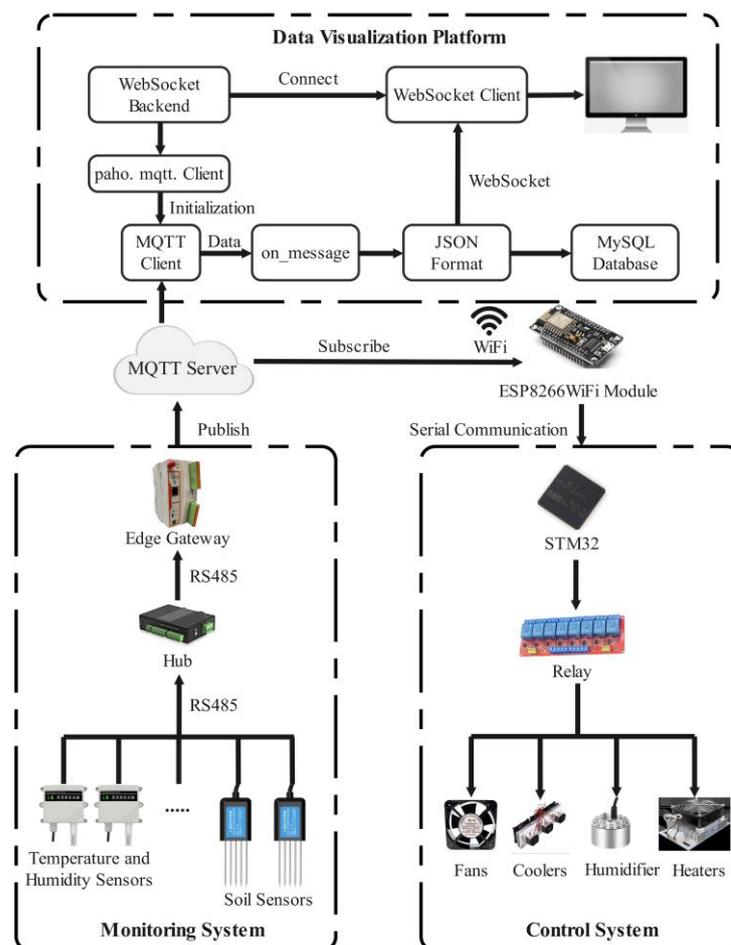

Fig. 2 - System framework

Optimization of fuzzy PID control parameters based on APSO

PSO is a global optimization algorithm that simulates the foraging behaviour of a flock of birds and searches for an optimal solution by updating the positions and velocities of each particle in the population. PSO relies on fixed parameter settings (e.g., inertia weights and learning factors), which are adjusted by the guidance of the individual optimums and global optimums during the search process (Chen and Chi, 2010). In a traditional PSO, the formula for updating the velocity and position of each particle is:

$$v_i(t+1) = w \cdot v_i(t) + c_1 \cdot r_1 \cdot (pdest_i - x_i) + c_2 \cdot r_2 \cdot (gbest - x_i) \quad (1)$$

$$x_i(t+1) = x_i(t) + v_i(t+1) \quad (2)$$

where:

v_i is the velocity of particle i ; x_i is the position of particle i ; w is the inertia weight, which is used to control the velocity of the particle; c_1, c_2 is the learning factor; r_1, r_2 is a random number in the range of [0,1]; $pdest_i$ is the historical optimal position of particle i ; and $gbest$ is the historical optimal position of the whole particle.

However, traditional PSO is prone to fall into local optimal solutions and is sensitive to parameter settings (Pan et al., 2020). The APSO algorithm introduces a dynamic adjustment mechanism on this basis, which automatically adjusts the inertia weights, learning factors and other parameters according to the current search stage, making the algorithm more flexible in balancing the global and local searches, improving the search efficiency and robustness of the algorithm, and reducing the probability of falling into a local optimum (Weng et al., 2024). In optimizing the parameters of the fuzzy PID controller, APSO can accurately adjust the proportional (KP), integral (KI), and differential (KD) coefficients, which makes the controller more adaptable and robust in the face of complex, nonlinear, and time-varying systems (Liu, 2016).

First, the position and velocity of the particle swarm are initialized. The initial position of each particle represents a set of PID control parameters. The velocity of the particle determines the step size and direction of its search, and the initial velocity is typically set to a random value. The position and velocity of the particle are respectively:

The position and velocity of the particle are given by:

$$x_i = (KP, KI, KD) \quad (3)$$

$$v_i = (v_{KP}, v_{KI}, v_{KD}) \quad (4)$$

where: i denotes the number of the particle.

APSO primarily enhances the search ability of particle swarms and optimizes the convergence speed by dynamically adjusting inertial weights and learning factors, thereby improving the search efficiency of the global optimal solution and reduces the likelihood of falling into the local optimal solution.

The inertia weight controls the relationship between the particle's current speed and its previous speed, and determines the particle's "inertia". The inertia weight is generally reduced during the iteration process so that particles can conduct extensive searches in the early iterations and then focus their searches in the later iterations to converge to the global optimal solution.

The calculation formula is as follows:

$$W = w_{max} - \frac{(w_{max} - w_{min})}{T_{max}} T \quad (5)$$

where:

w_{max} is the initial inertia weight; w_{min} - minimum inertia weight; T_{max} - maximum number of iterations; T - current number of iterations.

The learning factor controls the speed at which particles approach their personal optimal solution and the global optimal solution, determining the dependency of particle search. Usually, the PSO algorithm uses two learning factors: one is the individual learning factor and the other is the group learning factor. The individual learning factor controls how the particle depends on its own historical experience, that is, how the particle adjusts its current speed according to the optimal position it has reached.

The group learning factor controls how the particle depends on the global experience of the group, that is, how the particle adjusts its current speed according to the optimal solution in the group.

The specific adjustment formula is:

$$c_1(t) = c_{1,\max} - \frac{(c_{1,\max} - c_{1,\min})}{T} \cdot t \quad (6)$$

$$c_2(t) = c_{2,\max} - \frac{(c_{2,\max} - c_{2,\min})}{T} \cdot T \quad (7)$$

where:

$c_{1,\max}$, $c_{2,\max}$ - maximum value of the learning factor; $c_{1,\min}$, $c_{2,\min}$ - minimum value of the learning factor; t - current number of iterations; T - maximum number of iterations.

The standard random number in PSO can lead to search restrictions in the particle update process, increasing the likelihood of falling into local optimal solution, especially when the solution space is complex and the dimension is high. After the introduction of Levy flight, a random term with heavy-tail distribution is usually used to replace the original random numbers r_1 and r_2 , so that the particle position update is no longer determined only by uniform random numbers, but a "heavy-tail jump" mechanism is introduced. The update formula is as follows:

$$v_i(t+1) = w \cdot v_i(t) + c_1 \cdot L_1 \cdot (pdest_i - x_i) + c_2 \cdot L_2 \cdot (gbest - x_i) \quad (8)$$

where:

L_1 and L_2 are random numbers generated based on Levy distribution, following a heavy-tailed distribution. These random numbers are usually generated through the distribution formula of Levy flight, which is characterized by occasional large jumps to help particles perform global search.

RESULTS

Model identification

A PTC heater was installed at the base of the small-scale greenhouse, complemented by fans mounted symmetrically at the top. Temperature and humidity sensors were positioned at different locations within the greenhouse, and different target temperatures are set to simulate the operational process of the greenhouse and infer its transfer function model. In the closed greenhouse model, the ambient temperature is approximately 25.4°C, and the target temperature is set to 30.0°C. When the ambient temperature has not reached the target value, the heater will continue to operate; if the temperature exceeds the target value, the ventilation fan will be activated to cool the environment. Temperature data is recorded once per second over a period of 750 seconds.

To identify the system model, the recorded sample data was imported into the MATLAB/Simulink environment to determine the system's transfer function. The System Identification Toolbox in MATLAB, employing the nonlinear least squares method, is used for this process. The best fit value is calculated using the following formula: after importing the collected temperature data into MATLAB, the System Identification Toolbox in Simulink applies the least squares method to analyse and identify the system's transfer function.

The model's best fit R^2 is calculated using the following equation:

$$R^2 = 1 - \frac{\sum (y - y_m)^2}{\sum (y - \bar{y})^2} \quad (9)$$

where:

R^2 represents the model's best fit, y is the actual recorded temperature data, y_m is the predicted temperature data based on the identified transfer function model, and \bar{y} is the mean of the actual temperature data.

This equation evaluates the model's accuracy by calculating the ratio between the sum of the squared errors between the predicted values and the actual measurements (numerator) and the total variance of the actual measurements from their mean (denominator). If the R^2 value approaches 100%, it indicates that the identified transfer function model fits the actual data well; conversely, a lower R^2 value suggests a poorer fit. As shown in Figure 3, the output temperature of the greenhouse system and the fitted curve are presented.

The resulting fitted curve is as follows:

$$G(s) = \frac{4.87}{151s + 1} e^{-30s} \tag{10}$$

the fit of the curve is: 94.54%

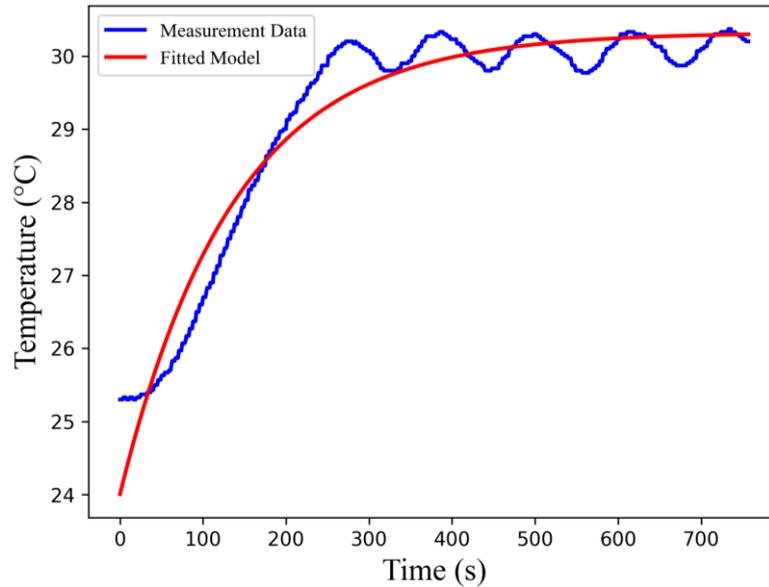

Fig. 3 - Real-time temperature parameters and fitted curves

Fuzzy control strategy and rules

In accordance with the principles of the fuzzy PID control algorithm, the inputs to the fuzzy PID controller are the error and the rate of E and the rate of error Ec . These inputs are crucial for the controller to assess the system's deviation from the desired setpoint. The outputs of the fuzzy PID controller correspond to the adjustments of the proportional, integral, and derivative gains, represented as ΔKP , ΔKI , and ΔKD . As shown in Table 2, the fuzzy domains for E , Ec , KP , KI , KD are $[-6, 6]$, $[-6, 6]$, $[-3, 3]$, $[-0.3, 0.3]$, and $[-0.3, 0.3]$, respectively. The fuzzy subsets are PB, PM, PS, ZO, NS, NM, and NB. The membership functions for the inputs E and Ec are shown in Figures 4 (a) and (b), while the membership functions for the outputs ΔKP , ΔKI , and ΔKD are depicted in Figure 4(c), (d), and (e), respectively.

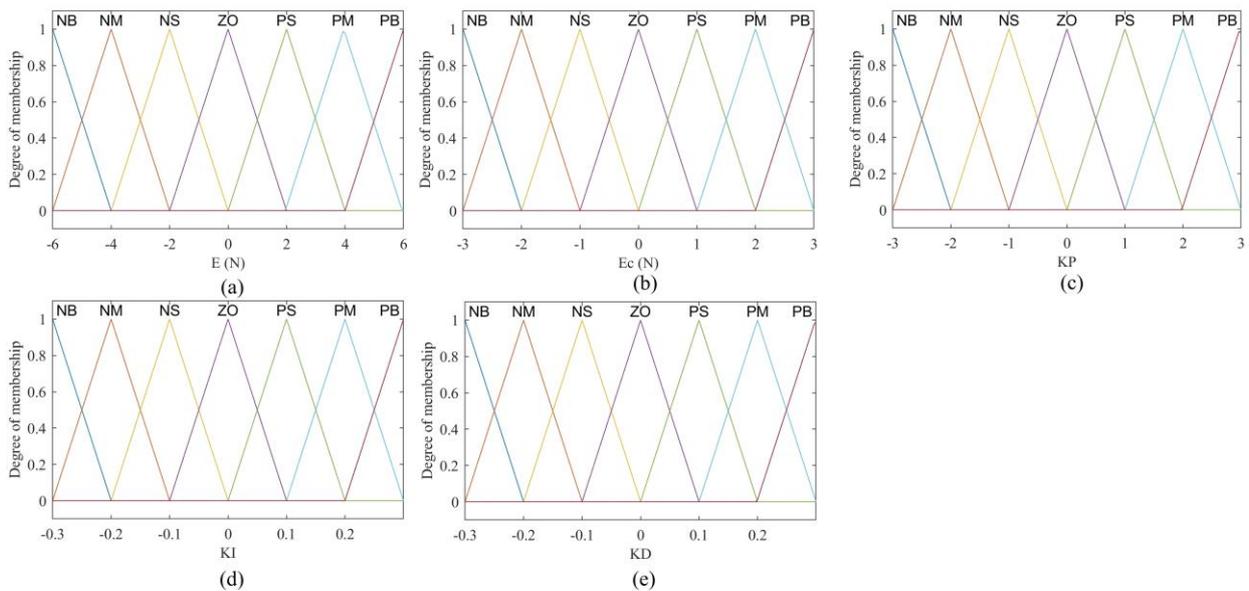

Fig. 4 - Domain and membership function of (a) E , (b) Ec , (c) ΔKP , (d) ΔKI and (e) ΔKD

Table 2

Fuzzy quantization parameters for input and output quantities

Variable	E	Ec	KP	KI	KD
Fuzzy discourse domain	[-6,6]	[-6,6]	[-3,3]	[-0.3,0.3]	[-0.3,0.3]
Fuzzy subset	PB, PM, PS, ZO, NS, NM, NB				
Membership function	Trimf				

The fuzzy rule base is composed of several "if-then" rules, where each rule is designed for specific input conditions and corresponding outputs. The input variables— E and Ec —are fuzzified into different linguistic variables, while the output variables represent adjustments to the PID controller parameters. Based on different combinations of error E and error rate Ec , 49 strategies and rules have been developed for adjusting ΔKP , ΔKI , and ΔKD in the fuzzy PID control system, as shown in Table 3. The input-output characteristic surfaces are presented in Figure 5 (a), (b), and (c).

Simulation and experimental results

The structure of the APSO fuzzy PID controller is shown in Figure 6. The APSO algorithm is executed to optimize the three parameters of the fuzzy PID controller, and the resulting optimization curve is presented in Figure 8 (a) - (e).

The optimization process illustrates the trend of each parameter across multiple iterations. As the number of iterations increases, the parameters gradually stabilize, indicating that the APSO algorithm effectively adjusts the particle swarm's search strategy and quickly finds the optimal control parameters. The fitness variation curve is shown in Figure 8 (f). From the curve, it can be observed that the APSO algorithm performs a global search in the initial stage, identifies a better solution within a short time, and then gradually converges to the optimal solution.

During the system simulation, the initial temperature of the greenhouse was set to 30°C, and the simulation time was set to 750 seconds. The performance of APSO fuzzy PID control, fuzzy PID control, and traditional PID control were compared. As shown in Figure 7, during the dynamic response phase, the APSO-optimized fuzzy PID control method significantly reduces the oscillation amplitude and frequency compared to the PID and fuzzy PID methods. This effectively improves the dynamic characteristics of the system and ensures that the response curve meets the control requirements.

By analysing the fluctuation curves of the simulation experiments using a MATLAB oscilloscope, the time domain performance metrics can be derived and the results are shown in Table 4. Compared to fuzzy PID and PID, APSO fuzzy PID reduces overshoot by 22.8% and 72.1%, respectively; the adjustment time is reduced by 9% and 20%, respectively; and the system's stability is significantly improved. By observing the oscilloscope waveform, it is evident that the optimized controller can quickly identify and effectively suppress the influence of disturbances, allowing the system output to return to a stable state in a short time. This demonstrates that the fuzzy PID controller optimized by APSO has strong anti-disturbance capability, enabling the system to maintain high control accuracy and robustness under interference.

Analysis of simulation results

Performances	Methodologies		
	APSO Fuzzy PID	Fuzzy PID	PID
Rising time t_r/s	23.8	27.7	20.6
Overshoot $\sigma/\%$	3.65%	4.73%	13.07%
Adjustment time t_s/s	110.1	121	137.5

The structural layout of the greenhouse is depicted in Figure 9. Three air temperature and humidity sensors were placed around the greenhouse to monitor the overall temperature, while a soil parameter sensor was embedded in the soil to monitor soil conditions. Two fans were symmetrically installed to facilitate air circulation, and the heater and cooler were installed in the upper and lower parts of the greenhouse, respectively, to control the temperature.

Fig. 9 - Greenhouse structure

In this experiment, the effectiveness of the greenhouse control system was tested at set temperatures of 24°C, 28°C, and 30°C, as shown in Figure 10 (a), (b), and (c). Throughout the experiment, the internal temperature of the greenhouse was continuously adjusted and monitored in real time using a precise environmental control system. The results showed that the temperature control system in the greenhouse responded quickly and remained near the set point, with fluctuations within 0.3°C. This demonstrates the system's strong temperature regulation capability, effectively maintaining the required temperature range and ensuring the stability of the greenhouse environment. In terms of humidity control, the greenhouse humidity was regulated using direct control methods, as ambient humidity decreases slowly. The experimental results are shown in Figure 10 (d).

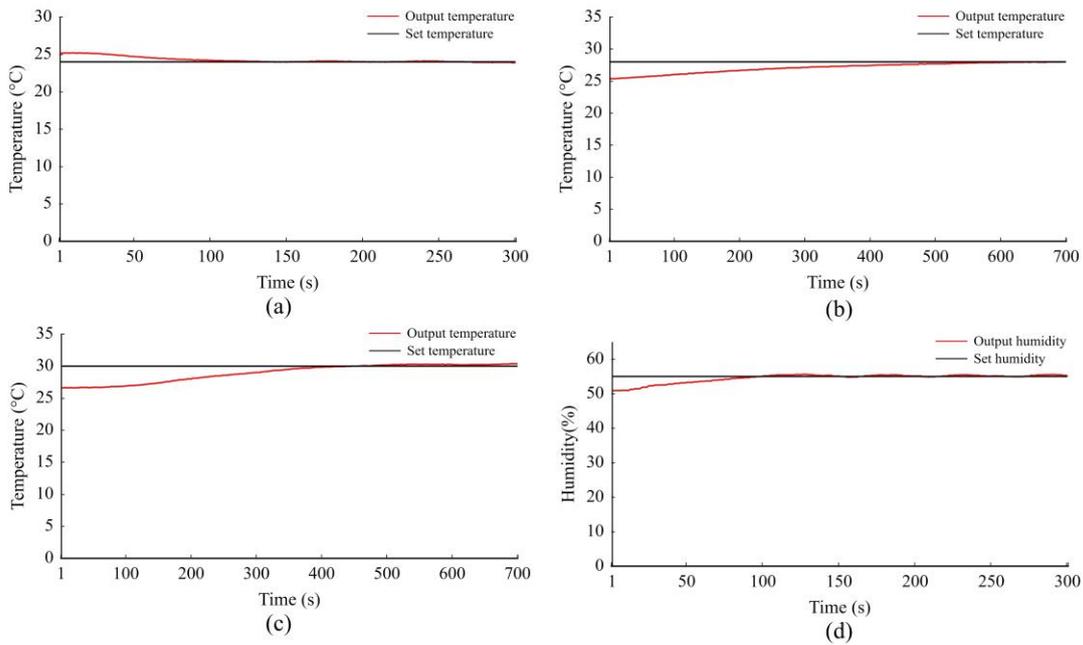

Fig. 10 - Temperature control curves at (a) 24°C, (b) 28°C, (c) 30°C, (d) 55% Humidity

The performance tests of the system at outside temperatures of 22°C and 17°C are shown in Figure 11 (a) and (b), respectively. The test results revealed that as the ambient temperature decreased, the system's response time extended accordingly; however, this did not affect the overall control effectiveness. To evaluate the system's performance under varying humidity conditions, tests were conducted at greenhouse humidity levels of 30%, 40%, 50%, and 60%, with the results displayed in Figure 11 (c), (d), (e), and (f). The results showed that the different humidity levels had almost no effect on the system's responsiveness or its stabilizing effect.

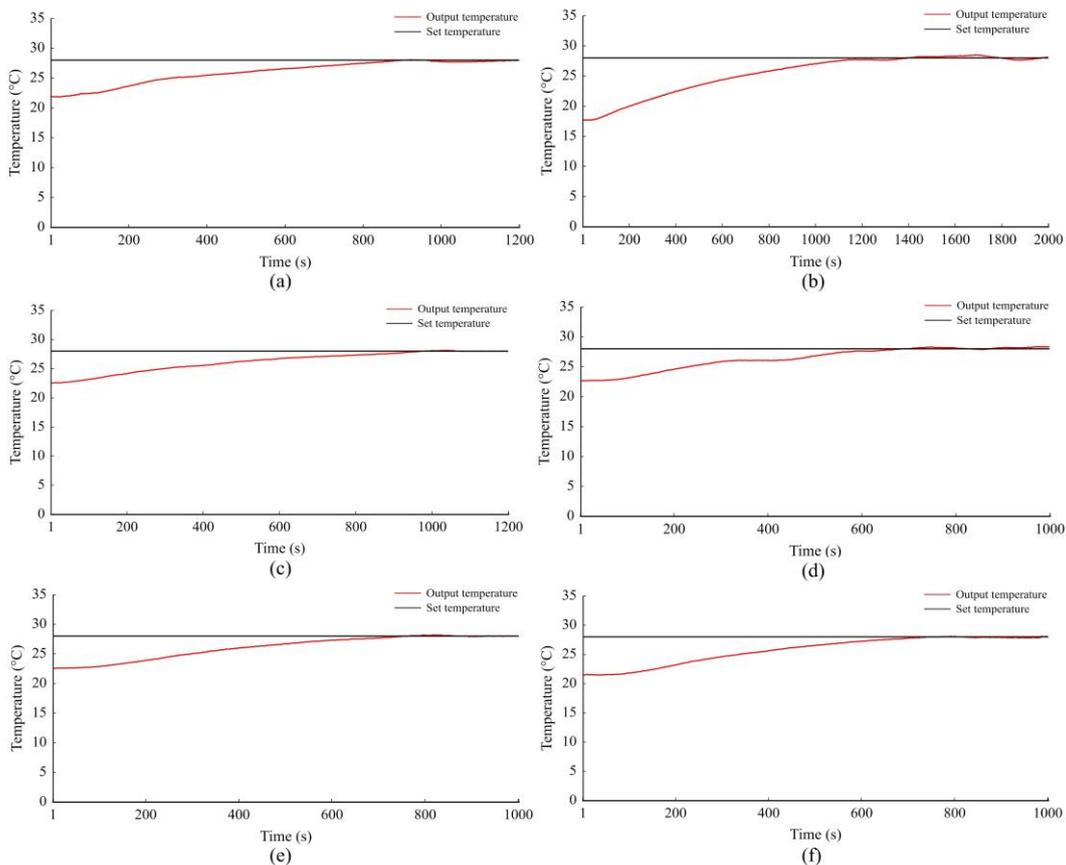

Fig. 11- Control effect at different ambient temperatures: (a) 22°C, (b) 17°C; control effect at different humidity: (c) 30%, (d) 40%, (e) 50%, (f) 60%

The configured data visualization platform, shown in Figure 12, clearly displays various environmental parameters within the greenhouse, including temperature, humidity, soil salinity, and pH. The platform is also equipped with an anomaly alert function, which automatically triggers an alarm when any environmental parameter exceeds the preset safety range, prompting the user to take timely action. Figure 13 shows the developed MySQL database, which allows different data to be stored for later analysis and processing.

CONCLUSIONS

This study focused on the design and implementation of a greenhouse environmental control system, with an in-depth investigation of a fuzzy control-based temperature regulation strategy and the integration of an intelligent display platform for environmental monitoring. Through experimental validation, the greenhouse environment achieved stable and precise control under different temperature settings, confirming the effectiveness of the fuzzy control method in managing complex nonlinear systems. In addition, the constructed big data display platform successfully collected and visualized greenhouse parameters such as temperature and humidity in real time, providing managers with intuitive and detailed environmental information. Moreover, the platform included an anomaly alert feature that could promptly identify and notify users of potential environmental risks, thereby enhancing the safety and automation of greenhouse management.

Future work will focus on optimizing the control algorithms for broader deployment, integrating more diverse environmental sensors, and enhancing the robustness of the platform under varying network conditions. This study not only validated the efficacy of fuzzy control in greenhouse environmental management but also demonstrated the broad application potential of intelligent display platforms in agricultural management.

The system ensures the stability of the crop growth environment while simplifying management processes and reducing the need for manual intervention, providing strong support for the intelligent and precise development of modern agriculture.

INSTRUCTIONS FOR AUTHORS

Article Types

Three types of manuscripts may be submitted:

1. **Regular articles:** should describe new and carefully confirmed findings, and experimental procedures should be given in sufficient detail for others to verify the work. The length of a full paper should be the minimum required to describe and interpret the work clearly (max.10 pages). *Additional pages will be supplementary charged.*
2. **Review articles:** must contain at least three basic elements: an introduction or background information section; the body of the review containing the discussion of sources; and, finally, a conclusion and/or recommendations section to end the paper. The length of a full paper should be the max. 20 pages (if the number of references is 80-100) and max. 45 pages (if the number of references is over 300). *Additional pages will be supplementary charged.*

Manuscripts should be written in English (American or British usage is accepted, but not a mixture of these) and submitted directly on the journal website. The 2nd, 3rd and the next versions can be sent by e-mail, at the following address: inmatehjournal@gmail.com, mentioning the registration number (N...).

Please be sure to include your full affiliation and e-mail address (see Sample manuscript)

The authors are responsible for the accuracy of the whole paper and references.

There are allowed 2 papers by each first author.

The text layout should be in single-column format. To avoid unnecessary errors, it is strongly advised to use the "spell-check" and "grammar check" functions of your word processor.

Review Process

All manuscripts are reviewed by 2 members of the Scientifically Review Office.

Decisions will be made as quickly as possible, and the journal strives to return reviewer comments to authors within 3 weeks to 4 months, depending on the reviewers' responses. The editorial board will re-evaluate manuscripts that are accepted pending review.

NOTE:

Submission of a manuscript implies: that the work described has not been published before (excepting as an abstract or as part of a published lecture or thesis) that it is not under consideration for publication elsewhere.

1. REGULAR ARTICLES

- Manuscripts should be concise, in **1.15 line spacing**, and should have 2 cm all over margins. The font should be **Arial 10 pt.** Ensure that each new paragraph is clearly indicated, using TAB at 1 cm.
- Title will be **Arial 12 pt.** and explicit figures will be **Arial 9 pt.**
- Text will be written in English.
- Chapters' titles are written by **Arial 10 pt, Bold, Uppercase** (e.g INTRODUCTION, MATERIAL AND METHODS), between chapters is left a space for 10 pt. At the beginning of each paragraph, leave a tab of 1 cm.
- The paper body will be written in **Arial 10 pt., Justify alignment.**

TITLE **Arial 12 pt., Uppercase, Bold, Center** (in English language) and **Bold Italic** (in native language).

Should be a brief phrase describing the contents of the paper. Avoid long titles; a running title of no more than 100 characters is encouraged (without spaces).

AUTHORS: **ARIAL 9, Bold, Centre alignment (Max. 6 authors)**

Under the paper's title, after a space (enter) 9 pt., write **authors' name and surname** and **affiliations** (**Arial 8 pt.-Regular**)

When the paper has more than one author, their name will be followed by a mark (Arabic numeral) as superscript if their affiliation is different.

Corresponding author's name (next row), (**Arial 8 pt.**). Should be added also: phone, fax and e-mail information, for the paper corresponding author (**font: 8 pt., Italic**).

If the authors wish, academic positions can be added in the Footnote, by Times New Roman, Italic, 9pt.

KEYWORDS (*In English*) about 4 to 7 keywords that will provide indexing references should be listed (*title: Arial 10pt, bold italic, text Arial 10 pt., italic*).

A list of non-standard *Abbreviations* should be added. In general, non-standard abbreviations should be used only when the full term is very long and used often. Each abbreviation should be spelled out and introduced in parentheses the first time it is used in the text. Standard abbreviations (such as ATP and DNA) need not to be defined.

ABSTRACT (*in English and Native language, Arial 10 pt.*), the title *bold*; the text of abstract: *italic*) should be informative and completely self-explanatory, briefly present the topic, state the scope of the experiments, indicate significant data, and point out major findings and conclusions. The Abstract should be max.250 words. Complete sentences, active verbs, and the third person should be used, and the abstract should be written in the past tense. Standard nomenclature should be used and abbreviations should be avoided. No literature should be cited.

INTRODUCTION (*Arial 10 pt.*) should provide a clear statement of the problem, the relevant literature on the subject, and the proposed approach or solution. It should be understandable to colleagues from a broad range of scientific subjects. We should refer to the current stage of researches performed in the field of the paper to be published, by quoting up-to-date specialty studies, preferably published **in the last 10 years**, excepting certain referential specialty books/studies, especially papers issued in magazines/journals/conferences/ISI quoted symposia or in other international data bases, which are well known and available.

It is imperative to incorporate references from a diverse range of countries globally, rather than limiting sources to those from the native country.

MATERIALS AND METHODS (*Arial 10 pt.*) should be complete enough to allow experiments to be reproduced. However, only truly new procedures should be described in detail; previously published procedures should be cited, and important modifications of published procedures should be mentioned briefly. Methods in general use need not be described in detail.

RESULTS (*Arial 10 pt.*) should be clarity presented. The results should be written in the past tense when describing findings in the authors' experiments. Results should be explained, but largely, without referring to the literature. Discussion, speculation and detailed interpretation of data should not be included in the Results, but should be put into the CONCLUSIONS section.

CONCLUSIONS (*Arial 10 pt.*) The main conclusions drawn from results should be presented in a short Conclusions section. Do not include citations in this section.

Formulae, symbols and abbreviations: Formulae will be typeset in Italics (preferable with the Equation Editor of Microsoft Office or MathType) and should be written or marked as such in the manuscript, unless they require a different styling. They should be referred to in the text as Equation (4) or e.g. (4). The formulae should be numbered on the right side, between brackets (*Arial 10 pt.*):

$$P = F \cdot v \quad (1)$$

Terms of the equation and the unit measure should be explained, e.g.

P is the power, [W];

F – force, [N];

v – speed, [m/s]

SI units must be used throughout.

Equation terms in text, must be written using the same style as in Equation.

Tables should be self-explanatory without reference to the text. The details of the methods used in the experiments should preferably be described in the legend instead of in the text. The same data should not be presented both in table and graph form or repeated in the text.

Table's title will be typed *Arial 9 pt, Bold, Centered*.

In the table, each row will be written *Arial 9 pt*, single-spaced throughout, including headings and footnotes.

The table should be numbered on the right side, between brackets (*Arial 10 pt*):

Figure (*Arial 9 pt., Bold, Center*) should be typed in numerical order (Arabic numerals). Graphics should be high resolution (e.g.JPEG). Figure number is followed by what represent the figure or graph e.g.:

Fig. 1 - Test stand

Legend: (*Arial 8 pt., Italic, Center*), e.g.

1 - plansifter compartments; 2- break rolls; 3 – semolina machines; 4 – reduction rolls; 5 – flour

ACKNOWLEDGMENTS (*Arial 10 pt.*) of people, grants, funds etc should be brief (*if necessarily*).

REFERENCES (*Arial 10 pt.*)

(*In alphabetical order, in English and in the original publication language.*)

Minimum 20 references, from which minimum 3 references from the last 3 years

It is imperative to incorporate references from a diverse range of countries globally, rather than limiting sources to those from the native country.

The number of self-cited papers should not exceed 10% of the total references !

It can be used "References" tool from the *Word Editor*.

References should be cited in the text in brackets as in the following examples:

(*Babiciu P., Scripcnic V., 2000*)

All references must be provided in English with a specification of original language in round brackets.

Authors are fully responsible for the accuracy of the references.

References should be alphabetically, **automatically numbered or without numbering**, with complete details, as follows:

Examples:

Books: Names and initials of authors, year (between brackets), title of the book (Italic), volume number, publisher, place, pages number or chapter, ISSN/ISBN:

[1] Vlăduț V., (2009), *Study of threshing process in axial flow apparatus (Studiul procesului de treier la aparatele cu flux axial)*, vol.1,"Terra Nostra", Publishing House, ISSN/ISBN, Iași/Romania;

Journal Article: Names and initials of authors, year (between brackets), full title of the paper, full name of the journal (Italic), volume number, publisher, place, page numbers, DOI or URL:

[1] Li Q., Feng J., (2024). Design and experimental analysis of rotary spoon soybean precision seeder (转勺式大豆精密排种器设计与试验分析), *INMATEH Agricultural Engineering*, vol.74, no.3, pp.13-24, Bucharest/Romania. DOI: <https://doi.org/10.35633/inmateh-74-01>

Conference or Symposium: Names and initials of authors, year (between brackets), full title of the paper (Regular), full name of the conference/symposium (Italic), volume number, publisher, place, ISSN, page numbers

[2] Bungescu S., Stahl W., Biriș S., Vlăduț V., Imbrea F., Petroman C., (2009), Cosmos program used for the strength calculus of the nozzles from the sprayers (Program Cosmos folosit pentru calculul de rezistență la zgomet al aparatelor de distribuție), *Proceedings of the 35 International Symposium on Agricultural Engineering "Actual Tasks on Agricultural Engineering"*, pp.177-184, Opatija / Croatia;

Dissertation / Thesis: Names and initials of authors, year (between brackets), full name of the thesis (Italic), specification (PhD Thesis, MSc Thesis), institution, place;

[3] Matache M.G., (2016). *Researches regarding testing in simulated and accelerated regime of agricultural machinery resistance structures (Cercetări privind încercarea în regim simulat și accelerat a structurilor de rezistență ale mașinilor agricole)*, PhD dissertation, POLITEHNICA University, Bucharest/Romania.

Patents: Names and initials of authors, year (between brackets), patent title (Italic), patent number, country:

[4] Grant P., (1989), *Device for Elementary Analyses*. Patent, No.123456, USA.

Legal regulations and laws, organizations: Abbreviated name, year (between brackets), full name of the referred text, document title/type (Italic), author, place:

[5] *** EC Directive, (2000), Directive 2000/76/EC of the European Parliament and of the Council of 4 December 2000, on the incineration of waste, Annex V, *Official Journal of the European Communities*, L332/91, 28.12.2000, Brussels.

Web references: The full URL should be given in text as a citation, if no other data are known. If the authors, year, and title of the documents are known and the reference is taken from a website, the URL address has to be mentioned after these data:

The title of the book, journal and conference must be written in Italic.

The title of the article must be written Regular.

Citation in text

Please ensure that every reference cited in the text is also present in the reference list (and vice versa). Do not cite references in the abstract and conclusions. Unpublished results, personal communications as well as URL addresses are not recommended in the references list.

Making personal quotations (one, at most) should not be allowed, unless the paper proposed to be published is a sequel of the cited paper. Articles in preparation or articles submitted for publication, unpublished, personal communications etc. should not be included in the references list.

Citations style

Text: All citations in the text may be made directly (or parenthetically) and should refer to:

- **single author:** the author's name (without initials, unless there is ambiguity) and the year of publication: "as previously demonstrated (*Brown, 2010*)".

- **two authors:** both authors' names and the year of publication: (*Adam and Brown, 2008; Smith and Hansel, 2006; Stern and Lars, 2009*)

- **three or more authors:** first author's name followed by "et al." and the year of publication: "As has recently been shown (*Werner et al., 2005; Kramer et al., 2000*) have recently shown"

Citations of groups of references should be listed first alphabetically, then chronologically.

Units, Abbreviations, Acronyms

- Units should be metric, generally SI, and expressed in standard abbreviated form.
- Acronyms may be acceptable but must be defined at first usage.

2. REVIEWS

Reviews and perspectives covering topics of current interest in the field, are encouraged and accepted for publication. A review must have **at least 80 references**.

It might give a new interpretation of old material or combine new with old interpretations. Or it might trace the intellectual progression of the field, including major debates. And depending on the situation, the literature review may evaluate the sources and advise the reader on the most pertinent or relevant.

Literature reviews must contain at least three basic elements: an introduction or background information section; the body of the review containing the discussion of sources; and, finally, a conclusion and/or recommendations section to end the paper.

The following provides a brief description of the content of each: Introduction: Gives a quick idea of the topic of the literature review, such as the central theme or organizational pattern. Body: Contains your discussion of sources and is organized either chronologically, thematically, or methodologically. Conclusions / Recommendations: Discuss what you have drawn from reviewing literature so far.
