ABSTRACT

In order to improve the seed supply performance of high-speed dense planting maize seeder, an air-assisted spiral seed-supply device was designed and optimized. The kinetic model of maize seeds in the migration zone was established. Based on computational fluid dynamics (CFD) simulation, the pressure and velocity distribution in the axial plane were explored when the blower pressure was 4.0, 4.5, 5.0, 5.5, 6.0 kPa, respectively. A two-factor, five-level central composite design (CCD) experiment was conducted using blower pressure and spiral shaft rotational speed as test factors while seed supply rate, coefficient of variation of seed supply rate stability and seed breakage rate were selected as seed supply performance indicators. The influence trends of the interaction terms on these performance indicators were explored. Based on the multi-objective variable optimization method, the optimal working parameter combination of the air-assisted spiral seed-supply device was determined and verified by bench experiments. The results showed that the optimal combination of working parameters was a blower pressure of 6.0 kPa and a spiral shaft rotational speed of 80 r/min. Under the verification test, the seed supply rate, the coefficient of variation of seed supply rate stability and the seed breakage rate were 2933.21 g/min, 1.87 % and 1.69 %, respectively, with a relative error of less than 5.5% compared to the optimized results. This study can provide a reference for the optimized design of seed-supply devices for high-speed dense planting seeders.

摘要

为提高玉米高速密植播种机供种环节的供种性能, 设计并优化了一种气送式螺旋供种装置。建立了玉米种子在迁移区的动力学模型。基于 CFD 仿真探究了气流送种区在风机压力分别为 4.0、4.5、5.0、5.5、6.0 kPa 时中轴面的压强与流速分布。以风机压力、螺旋轴转速为试验因素, 以供种速率、供种速率稳定性变异系数、种子破损率为供种性能指标进行了二因素五水平的中心组合设计试验, 探究了因素的交互项对供种速率、供种速率稳定性变异系数、种子破损率的影响趋势。基于多目标变量优化的方法确定了气送式螺旋供种装置的最佳工作参数组合并进行了试验验证。结果表明: 装置的最佳工作参数组合为风机压力 6.0 kPa、螺旋轴转速 80 r/min, 验证试验下该参数组合的供种速率、供种速率稳定性变异系数、种子破损率分别为 2933.21 g/min、1.87 %、1.69 %, 与参数优化结果相对误差在 5.5 % 以内。本研究可为高速密植播种机供种装置的优化设计提供参考。

INTRODUCTION

Maize is one of the most widely planted and productive food crops in the world (Tang et al., 2024; Fanigliulo et al., 2022). With the increasing demand for feed raw materials and the rapid development of deep-processing industry, the demand for maize in China has expanded rapidly (Huai et al., 2024). To improve maize yield, the dense planting pattern has gained widespread attention among agricultural workers. Maize densification planting mode (Sun et al., 2024) is based on the precision sowing technology, which can reasonably reduce the seed spacing of maize. That not only ensures the space for plant growth, but also improves the planting density and increase production and efficiency. But in the dense planting mode, the

sowing quantity per unit area of soil will increase, the seed spacing will decrease, and the sowing frequency of the seeder will also be higher during high-speed operation. In addition, maize seeds are often coated before sowing, and damage to the seed coating skin should be avoided during the sowing process.

At present, the seed box of the seeder used for conventional operation is generally not provided with a seed supply control unit, and the seed is quantitatively supplied according to the outlet structure size of the seed box (Ding *et al.*, 2021). The seed supply device of the centralized pneumatic dense planting seeder is mainly controlled by machinery, and the sowing speed is generally below 10 km/h. When the seed supply device operates at a high speed (above 10 km/h), it is easy to appear the phenomenon of "lack of power" of seed supply (Wang *et al.*, 2021; Wang *et al.*, 2020). Gao Xiaojun *et al.*, (2022), explored a quantitative feeding device with a staggered symmetrical spiral groove wheel based on the discrete element method (DEM), and analyzed the effects of different inclination angles and lengths of the grooved wheels on the uniformity of maize particles flow. Yuan Hao *et al.*, (2020), designed a piezoelectric vibration seed supply device to improve the seeding performance of low seeding capacity seed-metering device for plug seedling of super hybrid rice, and explored the influence law of seed tank depth and amplitude on seed supply performance based on DEM. Lei Xiaolong *et al.*, (2017), explored the effects of dimple depth, dimple pitch and length of pressurized tube on the seed distribution and seeding uniformity during the seed supply stage of the air-assisted centralized planter, and optimized the structural parameters of the pressurized tube. Gao Xiaojun *et al.* (2018) investigated the changing rules of fluid field, coupling field, and particle field of venturi feeding tube under different nozzle mouth shrinkage angles, and optimized the constriction angle. However, there is little research on the seed-supply link of maize dense planting seeder under high-speed operation.

In order to improve the seed supply performance of seed-supplying link of high-speed dense planting seeder of maize, an air-assisted spiral seed-supply device with spiral seed relocation and airflow seed delivery was designed and optimized. The theoretical model of maize seeds in the migration zone of the device was established, and the airflow distribution of the airflow seed delivery zone under different blower pressures was explored by computational fluid dynamics (CFD) simulation. The optimal working parameter combination of the device was obtained through the central composite design (CCD) test of two factors and five levels. The seed supply performance of the device was further improved.

MATERIALS AND METHODS

Overall structure and working principle

The high-speed dense planting seeder of maize can complete the continuous operation links such as stubble cleaning, ditching, sowing, pressing and soil-covering at one time. As the seed-supply unit of the sowing link (Sun *et al.*, 2024), the air-assisted spiral seed-supply device is mainly composed of a blower, an inlet pipe, an outlet pipe, a pipe, a seed box, a spiral shaft, a sleeve, a motor, a seed-supply nozzle and other parts. The seeds in the seed box have to undergo three processes of migration, mixing and conveying in the device, which can be divided into two parts of the migration zone and the airflow seed delivery zone according to the working process. As the medium connecting the seed box and the airflow seed delivery zone, the migration zone is the core unit of the device. The spiral shaft and the sleeve are the main components of the migration zone, and the hollow part between the spiral shaft and the sleeve accommodates the migration movement of the maize seeds. The spiral shaft parameters include spiral shaft outer diameter D_1 of 56 mm, inner diameter d_1 of 19 mm, guide P_t of 56 mm, etc. The sleeve parameters include opening angle φ of 180° , sleeve length L_1 of 145 mm, sleeve axial opening L_2 of 45 mm, sleeve outer diameter D_2 of 63 mm, etc.

As shown in Fig.1, the maize seeds in the seed box fall from the seed inlet to the migration zone by gravity, and orderly migrate towards the airflow seed delivery zone under the push of the spiral blades. Following the principle of "first come, first out", they fall from the seed outlet of the migration zone to the airflow seed delivery zone. The motor drives the spiral shaft to rotate clockwise at an angular velocity of ω , and the spiral blades are left-handed. The edge of the spiral blades rises along the left arm. The migration amount of the seeds in the migration zone in unit time is adjusted by changing the rotational speed of the motor. The airflow generated by the blower flows in from the inlet pipe. The migrated seed cluster are mixed with the airflow in the seed-supply nozzle to form a gas-solid two-phase flow, and then flows into the seed-metering device through the outlet pipe and the pipe. The conveying velocity of the seeds in the airflow seed delivery zone is changed by adjusting the blower pressure. By adjusting the rotational speed of spiral shaft and the blower pressure, the aim of precisely adjustable and efficient seed-supply of the device is achieved, and the seed supply operation requirement on the device when the maize dense planting seeder operates at a high speed is met.

Analysis of the seed-supply process in the migration zone

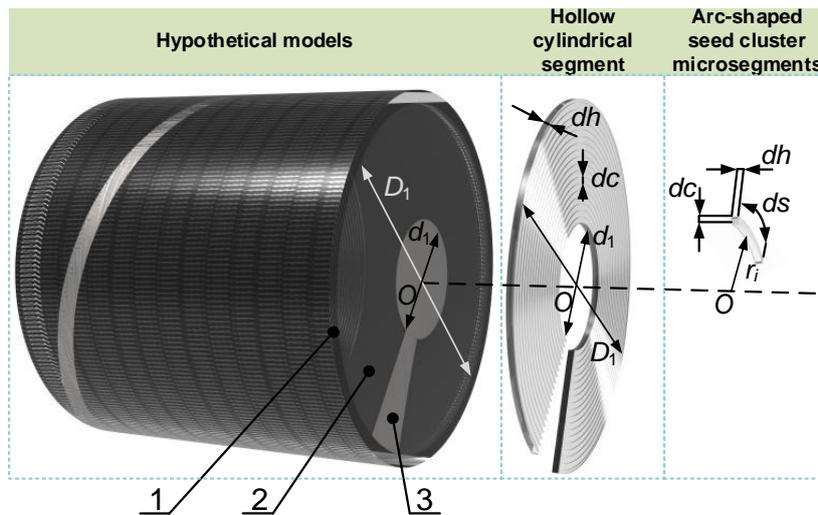

Fig. 2 - Theoretical assumptions of the seed supply process

1. sleeve; 2. seed cluster; 3. spiral shaft.

After the seeds flow into the migration zone from the seed box, they will complete the migration process in the form of bulk particles under various forces such as gravity, inertia, friction and so on. Due to the great difference in the shape and size of maize seeds, in order to facilitate the theoretical analysis of the seed cluster in the migration zone, the following motion assumptions are established for the stable seed supply process of maize seeds in the migration zone based on the infinitesimal method (Yao *et al.*, 2022):

(1) Seed cluster in the migration zone are filled completely in the hollow between the spiral shaft and the sleeve, the phenomena of separation, jumping and other like cannot occur, and the seed cluster are tightly attached to the spiral blade;

(2) Seed cluster are axially divided among the spiral blades into uniform and complete seed cluster segments, where in each segment is a hollow cylindrical segment which take the center O of a spiral shaft as a circle center, has the same inner diameter as the inner diameter of the spiral shaft, has the same outer diameter as the outer diameter of the spiral shaft and has the thickness of dh , and radially dividing each hollow cylindrical segment into arc-shaped seed cluster microsegments with the length of dc ;

(3) The arc-shaped seed cluster microsegment ds at any radius r_i on the radial section of any spiral shaft is taken as the research object, and the microsegment section is a rectangle of $dc \times dh$, as shown in Fig.2. The rotational speed of the adjacent annular seed cluster microsegments diffusely distributed in any radial direction will change.

The spiral shaft of the device is a standard single-head screw with equal guide and equal diameter. The spiral blade exerts a force on the seed cluster, which makes the seed cluster produce a migration motion, in which the rotation of the spiral shaft is induced motion, and the motion of the seed cluster relative to the spiral blade is relative motion. The seed cluster forms a complex composite motion under these two motions. A dynamic analysis is performed on the migration process of the seed cluster microsegments clinging to any radius r_i of the middle segment of the spiral blade, and a spatial rectangular coordinate system is established with the center of mass of the seed cluster microsegments as the coordinate origin, the axial direction of the spiral shaft as the z axis, the radial direction as the x axis, and the tangential direction as the y axis, as shown in Fig.3.

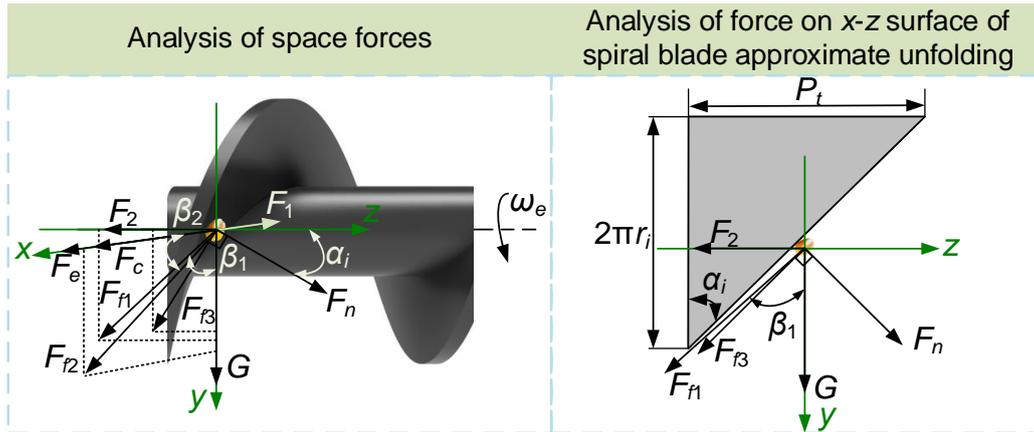

Fig. 3 - Dynamic analysis of seed cluster microsegments

The force acting on the seed cluster microsegments during the rotation of the spiral shaft can be divided into a supporting force F_n perpendicular to the spiral blade and a friction force F_{f3} between the seed and the spiral blade. In the process of seed movement, the microsegments will have the trend of moving axially to the seed outlet and radially outward. According to Newton's third law of motion-force and acceleration, the microsegments will be subjected to the interaction forces F_1 and F_2 of the adjacent seed cluster microsegments in the radial and axial directions, and at the same time, the moving microsegments will generate additional friction forces F_{f1} and F_{f2} due to the forces F_1 and F_2 . In addition, because the motion of the microsegment is a composite motion composed of relative motion and induced motion, and the induced motion is rotation, the inertial centrifugal force F_e and the Coriolis force F_c should be considered when analyzing the force model of the microsegment. According to the basic equation of particle relative motion dynamics, the microsegment dynamics equation is established as follows:

$$\left\{ \begin{array}{l} ma_r = F_e + F_c + F \\ F_e = mr_i\omega_e^2 \\ F_c = 2mr_i\omega_e\omega_r \\ \omega_a = \omega_e - \omega_r \\ F_{f1} = \mu_2F_1 \\ F_{f2} = \mu_2F_2 \\ F_{f3} = \mu_1F_n \\ G = mg \\ \tan \alpha_i = \frac{P_t}{2\pi r_i} \end{array} \right. \quad (1)$$

where: m is the mass of the microsegment, (kg); α_r is the relative acceleration of the microsegment, ($m \cdot s^{-2}$); ω_a is the absolute angular velocity of the microsegment, (rad/s); ω_e is the angular velocity of the spiral shaft, (rad/s); ω_r is the angular velocity of the microsegment relative to the spiral shaft, (rad/s); μ_1 is the friction coefficient between spiral blade and seed; μ_2 is the friction coefficient between the seeds; G is the gravity exerted on the microsegment, (N); g is the acceleration of gravity, ($m \cdot s^{-2}$); α_i is the helix angle at the position of the spiral shaft where the microsegment are located, ($^\circ$).

Projecting the relative acceleration α_r to the x-axis, y-axis and z-axis, the rectangular coordinate form of the seed relative motion differential equation is

$$\begin{cases} m \frac{d^2 r_x}{dt^2} = m \frac{dv_x}{dt} = ma_{r-x} = F_c + F_e + F_{f2} \cos \beta_2 - F_1 \\ m \frac{d^2 r_y}{dt^2} = m \frac{dv_y}{dt} = ma_{r-y} = G + F_{f1} \cos \beta_1 + F_{f3} \cos \alpha_i + F_n \sin \alpha_i + F_{f2} \sin \beta_2 \\ m \frac{d^2 r_z}{dt^2} = m \frac{dv_z}{dt} = ma_{r-z} = F_n \cos \alpha_i - F_{f3} \sin \alpha_i - F_{f1} \sin \beta_1 - F_2 \end{cases} \quad (2)$$

where:

α_{r-x} is the projection of the relative acceleration of the microsegment on the x-axis, ($m \cdot s^{-2}$); α_{r-y} is the projection of the relative acceleration of the microsegment on the y-axis, ($m \cdot s^{-2}$); α_{r-z} is the projection of the relative acceleration of the microsegment on the z-axis, ($m \cdot s^{-2}$); β_1 is the angle between the friction force F_{f1} and the gravity G , ($^\circ$); β_2 is the angle between the friction force F_{f2} and the positive x-axis, ($^\circ$).

The relative accelerations of the microsegment in the x-, y-, and z-axes are

$$\begin{cases} a_{r-x} = r_i \omega_r^2 \\ a_{r-y} = 0 \\ a_{r-z} = 0 \end{cases} \quad (3)$$

Simultaneous (1-3), available:

$$\frac{mr_i[(2\omega_e - \omega_a)^2 - 2(\omega_e - \omega_a)^2]}{F_1[1 - T\mu_2 \sin \beta_2 - \mu_2 \cos \beta_2 (T\mu_2 \cos \beta_1 - \mu_2 \sin \beta_1)] - T\mu_2 mg \cos \beta_2} = \frac{1 - T\mu_2 \sin \beta_2}{1 - T\mu_2 \sin \beta_2} \quad (4)$$

which:

$$\begin{cases} T = \frac{\mu_1 \sin \alpha_i - \cos \alpha_i}{\mu_1 \cos \alpha_i + \sin \alpha_i} \\ \sin \alpha_i = \frac{P_t}{\sqrt{P_t^2 + (2\pi r_i)^2}} \\ \cos \alpha_i = \frac{2\pi r_i}{\sqrt{P_t^2 + (2\pi r_i)^2}} \end{cases} \quad (5)$$

It can be seen from the formula (4) that the absolute angular velocity ω_a is related to the angular velocity ω_e , the radius r_i , and the guide P_t . When the angular velocity ω_e is constant, the absolute angular velocity ω_a will change with the radius r_i of the microsegment location, which is consistent with the motion assumption in the previous content. Studies have shown (Chen *et al.*, 2015; Yang *et al.*, 2020) that when the rotational speed of the spiral shaft is too fast, the seed cluster near the inner diameter of the spiral shaft will produce an additional seed-cluster-flow, which will jump and roll in the radial direction and affect the axial motion of the seed cluster. In addition, if the rotational speed is too fast, the seeds just leaving the migration zone will splash around due to the excessive inertial force. The maximum inertial centrifugal force of the seeds should be less than the gravity of the seeds to ensure a smooth transition from the migration zone to the airflow seed delivery zone:

$$m\omega_{max}^2 \frac{D_1}{2} \leq K_1 mg \Rightarrow n_{max} \leq \frac{30K_1}{\pi} \sqrt{\frac{2g}{D_1}} \quad (6)$$

where:

ω_{max} is the limiting angular velocity of the spiral shaft, (rad/s); n_{max} is the limiting rotational speed of the spiral shaft, (r/min); K_1 is the reliability coefficient.

Simulation based on CFD

The UG NX 12.0 software is used to draw the fluid domain model and import it into Space Claim software for correction. The corrected model is imported into Fluent Meshing module for meshing. The minimum and maximum values of the surface grid are set to 0.5 mm and 5 mm, respectively. After the surface grid is generated, the fluid domain is calculated using polyhedral grid to fill the body grid. The fluid domain model is shown in Fig. 4.

According to the characteristics of the gas flow in the device, the standard K-epsilon model is used as the turbulence model, the second-order upwind equation is used as the momentum equation, the first-order upwind equation is used for the turbulent kinetic energy and the turbulent dissipation rate, the turbulent intensity is set to be 5 %, the turbulent viscosity ratio is set to be 10. The Fluent time-step is 1×10^{-3} s, and the total simulation time is 2 s. The inlet pressure was set as 4.0, 4.5, 5.0, 5.5, 6.0 kPa, respectively, and the outlet pressure was set as 0 Pa to explore the airflow distribution in the airflow seed delivery zone under different blower pressures.

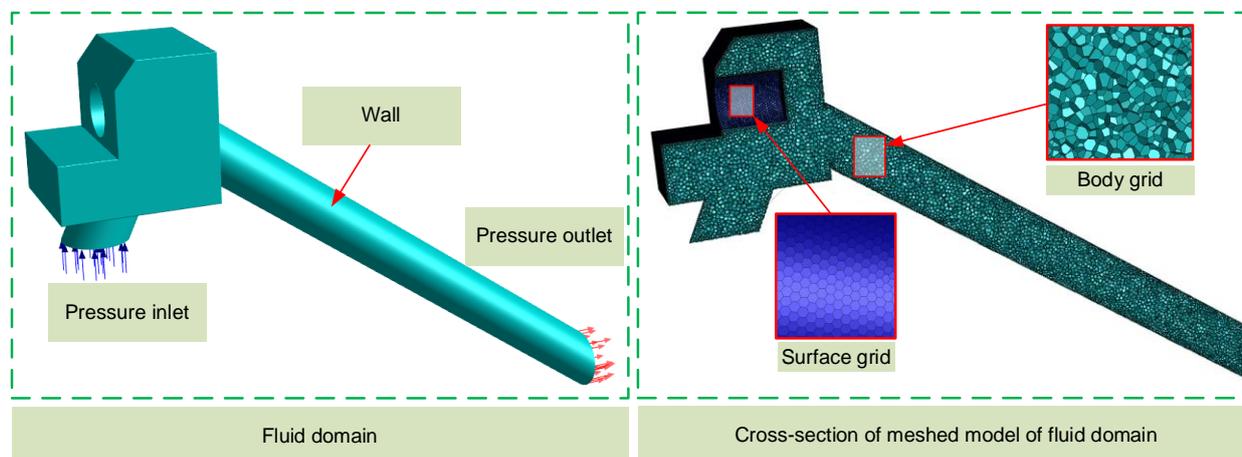

Fig. 4 - Establishment of CFD simulations

Bench test

In June 2024, the bench test of the air-assisted spiral seed-supply device was carried out in the high-speed precision seeding laboratory of the College of Engineering, Heilongjiang Bayi Agricultural University, Daqing City, Heilongjiang Province, China. The test conditions and results are shown in Fig. 5.

Fig. 5 - Bench test

1. electronic balance; 2. measuring cylinder; 3. DP2000 intelligent pressure and wind velocity air volume meter; 4. frequency converter;
5. HTB-multi-stage blower; 6. air tube; 7. switch power supply; 8. infinite speed control knob; 9. display screen; 10. motor;
11. inlet pipe; 12. seed box; 13. outlet pipe; 14. pipe; 15. seed net.

The main test equipment includes HTB-multi-stage blower, frequency converter, DP2000 intelligent pressure and wind velocity air volume meter, seed net, motor, infinite speed control knob, switch power supply, electronic balance, etc. The typical maize variety "Farley 1439" (small rounded) planted in Heilongjiang Province of China were selected as the test seeds, and the basic material characteristic parameters were shown in Table 1. The selected seeds were all coated and sorted, and the results were the average values after multiple measurements.

Table 1

Basic material characteristics of maize seed								
Variety name	Seed picture	Moisture content /%	Thousand grain weigh/g	Density /g·cm ⁻³	Pile angle/(°)	Length mm	Width mm	Thickness mm
Farley 1439 (small rounded)		12.6	296.4	1.122	20.23	8.03±0.41	7.12±0.46	6.34±0.43

In order to determine the optimal working parameters of the device and explore the interaction between the blower pressure and the rotational speed of spiral shaft on the seed-supply performance, a multi-factor experiment with two factors and five levels was carried out based on the CCD method. According to the actual test conditions, the blower pressure at 4.0 ~ 6.0 kPa and the rotational speed of spiral shaft at 50.0 ~ 80.0 r/min was set. The test factor codes are shown in Table 2, where X_1 and X_2 are the factor code values of the pressure and the rotational speed respectively.

Table 2

Experimental factors and level codes in multi-factor experiments			
Coded values	Experimental factors		
	X_1 / kPa	X_2 / r·min ⁻¹	
-1.414	4.0	50.0	
-1	4.29	54.4	
0	5.0	65.0	
1	5.71	75.6	
1.414	6.0	80.0	

Referring to GB/T 9478-2005 "Testing methods of sowing in lines", the test indexes were seed supply rate ϑ_i , coefficient of variation of the seed supply rate stability CV and seed breakage rate K_1 . Wherein, the seed supply rate is defined as the mass of the seeds flowing out of the device in unit time. The coefficient of variation of seed supply rate stability is defined as the percentage of the standard deviation of the seed supply rate to the average value of it at the same level of device parameter, measured many times to evaluate the uniformity of seed supply in the device. The seed breakage rate is defined as the percentage of the broken seed mass Z_1 out of the total seed mass Z_n flowing out of the device in given time. The evaluation index expression of seed supply performance is as follows:

$$\left\{ \begin{array}{l} \vartheta_i = \frac{\sum_{i=1}^{N_1} G_i}{N_1} \\ CV = \sqrt{\frac{\sum_{i=1}^{N_1} (G_i - \vartheta_i)^2}{N_1 - 1}} \times 100\% \\ K_1 = \frac{Z_1}{Z_n} \times 100\% \end{array} \right. \quad (7)$$

where: G_i is the seed quality of the i -th test, (g); N_1 is the number of experiments.

In the experiment, the seeds discharged from the device were collected using the seed net for 1 minute. The net weight was measured, and then the broken seeds were picked up and weighed. Each group of experiments was repeated 5 times, and the seed supply rate, the coefficient of variation of the seed supply rate stability and the seed breakage rate were calculated under different treatments.

RESULTS AND DISCUSSIONS

Simulation analysis of flow field in the airflow seed delivery zone

In order to explore the pressure distribution in the airflow seed delivery zone under different inlet pressures, the pressure nephogram in the axial plane of the fluid domain at 2 s was intercepted, as shown in Fig. 6 a ~ e. In the figure, the pressure distribution in the axial plane is similar for different inlet pressures, the pressure is higher in the area from the inlet of the inlet pipe to the inlet of the outlet pipe, the pressure in the outlet pipe and the pipe is lower, and negative pressure appears near the outlet pipe and the pipe inlet.

With the increase of the inlet pressure, the pressure range of the airflow seed delivery zone is gradually increased. The pressure ranges at 4.0, 4.5, 5.0, 5.5 and 6.0 kPa were -1271.52 ~ 3993.05, -1426.41 ~ 4558.55, -1693.46 ~ 4994.76, -1957.58 ~ 5525.13, -1950.10~5961.19 Pa, respectively.

Dividing the segment of the flow field of the axial plane in the fluid domain from the pressure inlet to the pressure outlet into Q_1Q_2 , Q_2Q_3 and Q_3Q_4 , and randomly and continuously selecting 20, 120 and 550 sample points from each segment in turn according to the arrow direction respectively. The pressure of the sample points on the line segments of 4.0, 4.5, 5.0, 5.5, and 6.0 kPa were recorded as shown in Fig. 6 f. In the process of airflow from Q_1 to Q_2 , the vertical section area of the line segment is basically unchanged. The pressure shows a downward trend, but the downward speed gradually slows down. The inlet pressure of 4.0, 4.5, 5.0, 5.5, 6.0 kPa decreased by 292.83,310.76,359.53,406.06 and 437.51 Pa, respectively, and the higher the inlet pressure, the more the pressure decreased. In the process of the airflow from Q_2 to Q_3 , the vertical sectional area of the line segment of the sample points before and after Q_2 suddenly changes from small to large. The vertical sectional area of the line segment of the sample points before and after Q_3 suddenly changes from large to small. The pressure first increases slowly, then fluctuates slowly, and finally decreases rapidly. The pressure inlet of 4.0, 4.5, 5.0, 5.5 and 6.0 kPa reached the maximum pressure of this segment at the 42nd, 48th, 54th, 54th and 48th sample points respectively, which are 2974.79, 3405.17, 3783.44, 4227.45 and 4446.06 Pa. During the process of airflow from Q_3 to Q_4 , the vertical cross-sectional area of the line segment remains basically unchanged, and the pressure first rapidly decreases to the lowest point of the entire flow field sample point. The inlet pressure of 4.0, 4.5, 5.0, 5.5, and 6.0 kPa reaches the minimum value at sample points 189, 189, 189, 184, and 185, respectively, which are -679.32, -828.05, -820.72, -1053.8, and -1153.51 Pa, and then shows an upward trend but the upward speed gradually slows down, reaching a local maximum before slowly decreasing again. Each inlet pressure at the 690th sample point is 0 Pa.

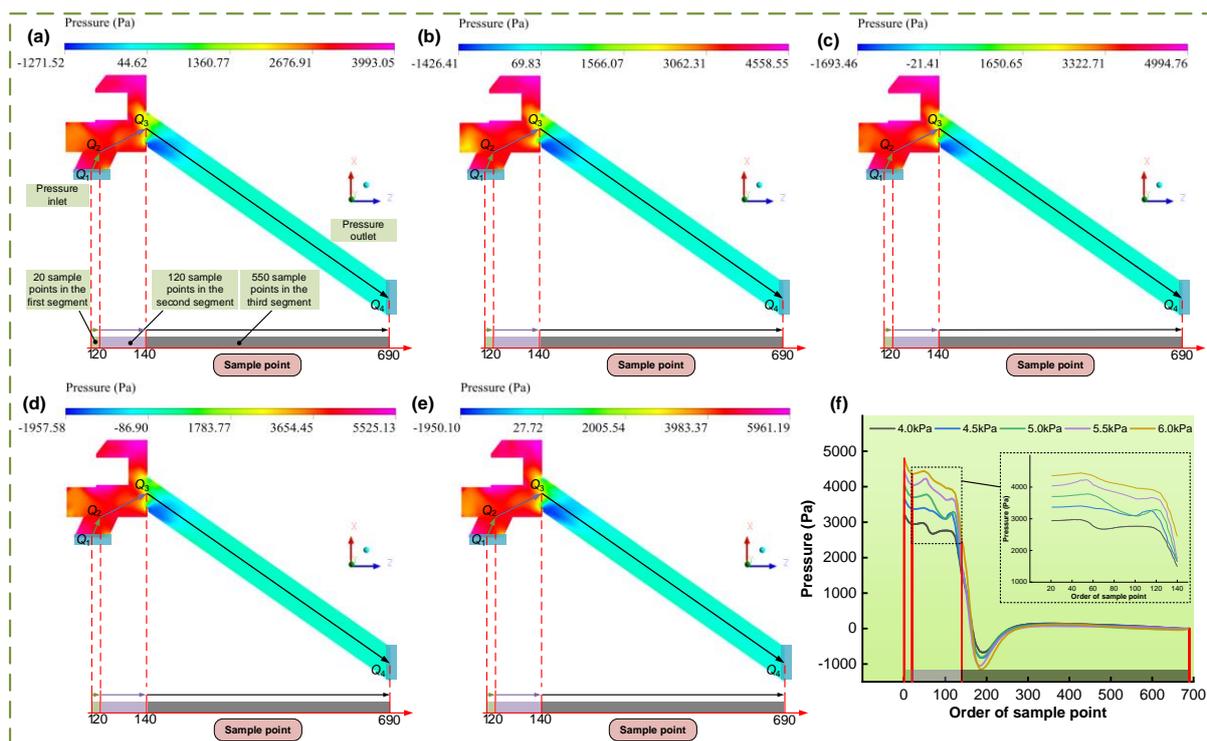

Fig. 6 - Pressure situation of the airflow seed delivery zone under different inlet pressures

a. pressure inlet=4.0 kPa; b. pressure inlet=4.5 kPa; c. pressure inlet=5.0 kPa; d. pressure inlet=5.5 kPa; e. pressure inlet=6.0 kPa; f. sample point pressure curve of different inlet pressures.

In order to explore the velocity distribution under different inlet pressures in the airflow seed delivery zone, the axial plane velocity nephogram of the fluid domain at 2 s was intercepted, as shown in Fig. 7 a ~ e. In the figure, with the increase of inlet pressure, the maximum velocity of the whole flow field shows a gradual upward trend, and the maximum velocity reaches 88.61 m/s when the inlet pressure is 6.0 kPa. There was little difference in the velocity distribution of the axial plane under different inlet pressures, and the highest velocity appeared at the outlet pipe, which was caused by the sudden decrease of the cross-sectional area of the airflow from the seed-supply nozzle to the outlet pipe.

The velocity at the sample points on Q_1Q_2 , Q_2Q_3 and Q_3Q_4 with inlet pressures of 4.0, 4.5, 5.0, 5.5, 6.0 kPa were recorded as shown in Fig. 7 f. In the process of the airflow from Q_1 to Q_2 , the vertical sectional area of the line segment is basically unchanged, and the velocity shows an upward trend, but the rising speed gradually slows down, which is completely opposite to the pressure change trend in the segment, and conforms to the relationship between the velocity and the pressure in Bernoulli's principle. The Q_1Q_2 segment reaches a maximum velocity of 51.7 m/s at the inlet pressure of 6.0 kPa. In the process of airflow from Q_2 to Q_3 , the velocity of each inlet pressure sample does not change much from the 21st to about the 50th sample points, and then it decreases rapidly. The inlet pressures of 4.0, 4.5, 5.0, 5.5, and 6.0 kPa reach the local minimal of the velocity of this segment at the 68th, 61st, 66th, 58th, and 65th sample points, respectively, which are 23.23, 19.52, 28.32, and 22.94, 29.1 m/s. After which the velocity roughly shows a trend of first rising, then falling and then rising. The inlet pressures of 4.0, 4.5, 5.0, 6.0 kPa reach the minimum velocity in this segment at the 111th, 113th, 118th, 115th sample points, respectively, which are 13.62, 16.7, 17.39, and 23.75 m/s. In the process of the airflow from Q_3 to Q_4 , the velocity first rises rapidly to the maximum of the whole flow field sample points. The inlet pressures of 4.0, 4.5, 5.0, 5.5, and 6.0 kPa reach the maximum velocity at the 168th, 164th, 168th, 168th and 168th sample points, respectively, which are 65.66, 64.71, 72.9, 78.88 and 79.4 m/s, and then decreased rapidly. Among them, the inlet pressure of 4.0 kPa and 5.0 kPa decreased relatively slowly, and the inlet pressure of 4.5 kPa was the lowest value of 16.74 m/s at the 229th sample point. The velocity of the sample points before and after the lowest value fluctuated greatly. Finally, the velocity showed an upward trend, but the rising speed gradually slowed down. The velocities at the 690th sample point were 47.68, 52.64, 60.21, 56.8 and 64.82 m/s at the inlet pressures of 4.0, 4.5, 5.0, 5.5, 6.0 kPa, respectively.

Results of the multi-factor experiments

According to the range of factors in Table 2, a multi-factor test was conducted, and the test results are shown in Table 3. In the table, X_1 , X_2 , and X_3 are coded values of seed supply rate, coefficient of variation of seed supply rate stability, and seed breakage rate, respectively. The test results were processed and analyzed by Design-Expert 12 software, and the quadratic equation variance analysis was obtained as shown in Table 4.

Note: * indicates a significant impact; ** indicates a highly significant impact.

In Table 4, the p values of the regression models of seed supply rate $Y1$, Coefficient of variation of seed supply rate stability $Y2$, and seed breakage rate $Y3$ were all less than 0.01, indicating that the regression models were extremely significant. The p -values of the lack of fit test were all more than 0.05, indicating that the regression models had good fit. In the variance analysis of the $Y1$, $Y2$ and $Y3$, the blower pressure $X1$ and rotational speed of spiral shaft $X2$ showed extremely significant effects, and the interaction $X1 X2$ showed significant effects. The influence order of each factor on the $Y1$, $Y2$ and $Y3$ was: $X1$, $X2$. The quadratic regression equation of $Y1$, $Y2$ and $Y3$ is as follows:

$$\begin{cases} Y1 = -1584.37 + 567.44X1 + 0.44X2 + 2.69X1X2 - 18.21X1^2 + 0.075X2^2 \\ Y2 = 2.33 - 0.35X1 + 0.011X2 + 0.017X1X2 - 0.11X1^2 - 0.00062X2^2 \\ Y3 = -0.97 + 0.37X1 + 0.027X2 - 0.0057X1X2 + 0.015X1^2 + 0.000067X2^2 \end{cases} \quad (8)$$

In order to explore the influence trend of interaction terms of factors on the $Y1$, $Y2$ and $Y3$, the contour map is drawn as shown in Fig. 8.

In Fig. 8a, when the rotational speed is constant, the $Y1$ is positively correlated with the blower pressure. The greater the pressure, the faster the conveying velocity of maize seeds entrained by airflow, the shorter the conveying time, and the higher the seed supply rate. When the pressure is constant, the $Y1$ is positively correlated with the rotational speed. The increase of the rotational speed can improve the migration velocity of the seeds in the migration zone, thereby improving the seed supply rate of the device. When the

pressure is 5.75~6.0 kPa and the rotational speed is 75~80 r/min, the $Y1$ is relatively high, ranging from 2712.86 to 2975 g/min. In Fig. 8b, when the rotational speed is constant, the $Y2$ is negatively correlated with the pressure at the rotational speed of 50 ~ 75 r/min, and it increases slowly at first and then decreases with the increase of the pressure at the rotational speed of 75 ~ 80 r/min. When the pressure was constant, the $Y2$ increased first and then decreased with the increase of the rotational speed at the pressure of 4.0~4.6 kPa, and it was roughly positively correlated with the rotational speed at the pressure of 4.6~6.0 kPa. When the pressure is 5.75~6.0 kPa and the rotational speed is 50~52.5 r/min, the $Y2$ is relatively low, ranging from 0.53 % to 0.83 %. In Fig. 8c, when the rotational speed is constant, the $Y3$ is positively correlated with the pressure. The higher the pressure, the faster the airflow entraps the seeds in the airflow seed delivery zone, and the easier it is to cause damage to the seeds coating when the seed collides with the seed and the seed collides with the inner wall of the device. When the pressure was constant, the $Y3$ was positively correlated with the rotational speed. With the increase of the rotational speed, the disturbance effect of the spiral shaft on the seed cluster in the migration zone is more obvious. The frequency of friction between seeds and seeds, seeds and components in the migration zone is increased. At the same time, with the increase of the rotational speed, the inertia force when the seeds flow out from the migration zone also increases, and the collision between the seeds and the seed-supply nozzle is intensified under the action of airflow. When the pressure is 4.0~4.25 kPa and the rotational speed is 50~55 r/min, the $Y3$ is relatively low, ranging from 1.12 % to 1.25 %.

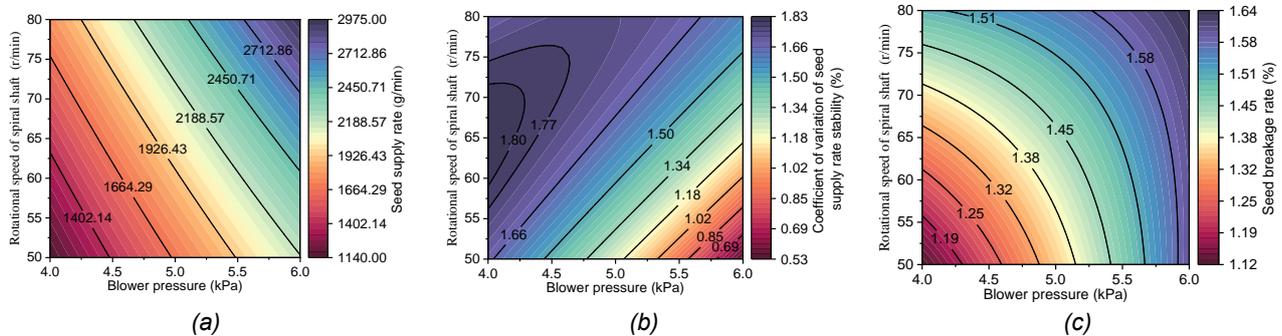

Fig. 8 - Effect of interactivity on test index

According to the results of multi-factor experiments, the optimal working parameter combination of the device was determined based on the multi-objective variable optimization method. With the highest $Y1$, the lowest $Y2$ and $Y3$ as the optimization objectives, the optimization equation is established within the range of factors and solved by Design-Expert 12 software.

The optimization equation is as follows:

$$\left\{ \begin{array}{l} \max Y1 \\ \min Y2 \\ \min Y3 \\ s. t. \left\{ \begin{array}{l} 4\text{kPa} \geq X1 \geq 6\text{kPa} \\ 50\text{r/min} \geq X2 \geq 80\text{r/min} \\ 1 \geq Y2(X1, X2) \geq 0 \\ 1 \geq Y3(X1, X2) \geq 0 \end{array} \right. \end{array} \right. \quad (9)$$

After calculation, the optimal working parameter combination for the device is: the pressure and the rotational speed are 6.0kPa and 80r/min, respectively. Under this parameter combination, the $Y1$, $Y2$, and $Y3$ are 2971.515 g/min, 1.774 %, and 1.616 %, respectively. The results were verified by bench test, and the $Y1$, $Y2$, and $Y3$ were 2933.21 g/min, 1.87 %, and 1.69 %, respectively, with the relative error of less than 5.5 % compared to the parameter optimization results. The optimized combination of working parameters makes the device achieve better test results in the bench test, and the error is small, which shows that the parameter optimization is effective.

CONCLUSIONS

In this study, according to the working process, the air-assisted spiral seed-supply device was divided into the migration zone and the airflow seed delivery zone. By establishing the kinetic model of maize seeds in the migration zone, the theoretical relationship between the absolute angular velocity ω_a of the seed cluster microsegment and the angular velocity ω_s of the spiral shaft was obtained. Based on the CFD simulation, when the inlet pressure of the airflow seed delivery zone at 2 s was 4.0, 4.5, 5.0, 5.5 and 6 kPa, the pressure range

was -1271.52 ~ 3993.05, -1426.41 ~ 4558.55, -1693.46 ~ 4994.76, -1957.58 ~ 5525.13, -1950.10 ~ 5961.19 Pa, and the maximum velocity of the airflow was 88.61 m/s. Based on the CCD, the multi-factor experiment was carried out, and the influence order of blower pressure X_1 and rotational speed of spiral shaft X_2 on seed supply rate, coefficient of variation of seed supply rate stability and seed breakage rate was: X_1 , X_2 . Based on the multi-objective variable optimization method, the optimal working parameter combination of the device was determined as the blower pressure of 6.0 kPa and the rotational speed of spiral shaft of 80 r/min. Under the verification test, the seed supply rate, the coefficient of variation of seed supply rate stability and the seed breakage rate were 2933.21 g/min, 1.87% and 1.69%, respectively. The relative error is within 5.5% compared with the result of parameter optimization. The device obtains higher seed supply performance under the optimized working parameter combination.

Keywords: air suction type, directional metering device, guide cam, garlic, garlic clove direction

ABSTRACT

To enhance the upright orientation rate of garlic clove bud tips, an air-suction garlic clove directional metering device with a guiding cam was developed. Key parameters influencing garlic clove discharge performance were determined through mechanical analysis. After optimization, the guiding cam's thickness (D) was set at 4 mm, with the lead-in and the seeding section tilt angles (α, β) of 5° and 15° , respectively. Comparative tests were conducted using optimal parameters, focusing on seed discharge disc rotational speed (n) and negative pressure (P) as main variables, with the upright rate of seeds in the receiving hopper serving as the evaluation index. Under conditions of -11.5 kPa negative pressure and 7 rad/s rotational speed, the upright rate reached 97.2%. Results demonstrated that the addition of guiding cams significantly improved the upright rate, increasing it by over 10% compared to directional metering devices without guiding cams.

摘要

为了提高排种后蒜种芽尖向上直立率低的问题。设计了一种带有导向凸轮的气吸式定向排种器，通过完成蒜种接触导向凸轮过程的力学分析，明确了影响导向排种性能的关键参数。得出导向凸轮厚度为 4mm、导入段倾斜角度为 5° 、投种段倾斜角度为 15° 。并且接料斗最优参数组合下进行对比验证试验，排种盘转速 (n) 以及负压大小 (P) 为试验因素，落入接料斗直立率为评价指标。增设导向凸轮排种器 p 为 -11.5kPa、 n 为 7rad/s 时，落入接料斗直立率达到 97.8%。稳定吸附时，排种器直立率之差 $\Delta > 10\%$ 。因此，增设导向凸轮的直立率显著高于不安装导向凸轮。

INTRODUCTION

The metering device in sowing machinery typically performs four functions: seed filling, cleaning, guarding, and casting, with a guide mechanism ensuring uniform plant spacing. In garlic planting, maintaining an upright bud orientation is crucial (Wu et al., 2024; Liu et al., 2022; Xu et al., 2021). The garlic clove discharger must ensure uniform seed feeding in both timing and speed while discharging cloves with the bud tip upward to facilitate smooth entry into the hopper and improve seed uprightness (Babatunde et al., 2020; Chen et al., 2016).

Recent studies by both domestic and international scholars have led to advancements in seed guiding devices (Kang et al., 2022; Zhao et al., 2018; Liao et al., 2020; Liu et al., 2015). A belt-type, high-speed corn seed guiding device using a rotating clamping method to improve seed entry accuracy and stability was developed (Ma et al., 2023). A soybean precision seeding device was designed to ensure consistent grain spacing (Chen et al., 2022). A corn posture-controlled seeding device that optimizes the seed guiding trajectory to maintain constant seed placement and speed was introduced (Dong et al., 2023). A finger-driven, synchronous belt seed guiding system was developed (Liu et al., 2017). John Deere of the United States created a brush belt seed guiding device to ensure stable seed guidance at high speeds (Ji et al., 2021). The seeds discharged from the seed meter are thrown onto the partition of the conveyor belt by turning the fingers. The seeds move to the seeding port along the conveyor belt and are delivered to the seed furrow at a consistent speed (Liu et al., 2020).

The primary goal of seed guidance design is stable, accurate seeding. While prior research focuses on non-directional crops, this study introduces a fixed guide cam for air-suction garlic seeders, ensuring cloves discharge with the bud tip upward for smooth hopper entry.

MATERIALS AND METHODS

Principle and composition of the guided cam working profile

The air-suction garlic seeding device rotates at speed n , guiding suction holes through seed suction (I), directional (II), and discharge (III) areas, as shown in Figure 1. In the suction area, cloves are captured; in the directional area, they align tangentially with the suction hole's center circle, maintaining an attitude angle of -15° to 15° . In the discharge area, cloves are released with the bud tip upward. Positioning the discharge point at S (horizontal) causes instability due to height, while lowering it to P resolves this. The guide cam adjusts the deflection angle for proper orientation, making its contour and position critical.

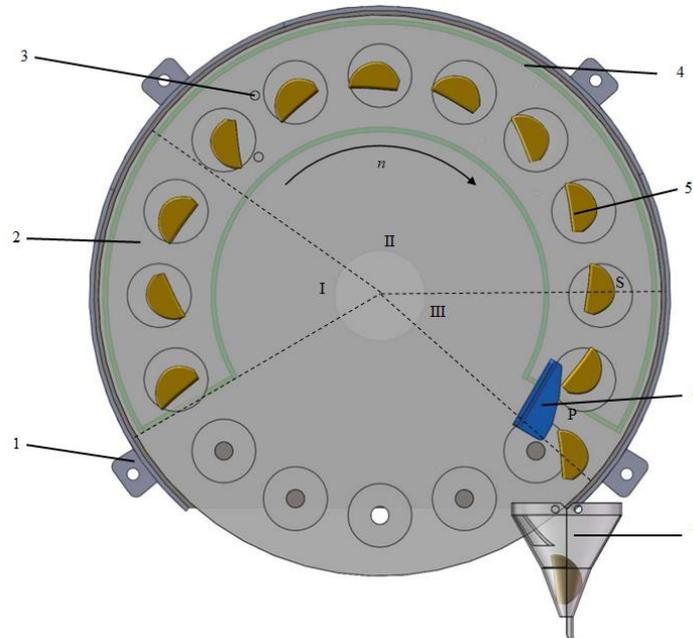

Fig. 1 - Working principle diagram of a seed tray

1 - Shell; 2 - Seed plate; 3 - Directional needles; 4 - Negative pressure chamber; 5 - Garlic clove; 6 - Guide cam; 7 - Hopper.

The guide cam's working profile comprises two curved sections, ab and bc , connected smoothly by rounded corners. In-plane projection, these sections appear as straight lines. When garlic cloves contact the ab and bc sections, their posture and deflection angles are adjusted, correcting the 30° deflection at point P observed without a guide cam. This ensures the cloves fall smoothly into the receiving bucket with the bud tip facing upward, completing the guiding and seeding process.

Guided Process Analysis

The guiding process of garlic cloves was analyzed using a plane analytical method to examine the contact torque between cloves and the guide cam. Contact types include side edge and arc surface contact. For side edge contact, the cloves' posture angle at point S ranges from -15° to 15° , with contact occurring along varying straight-line segments. A coordinate system X and Y with point b as the origin was established to analyze the garlic clove contact, as shown in Fig.2.

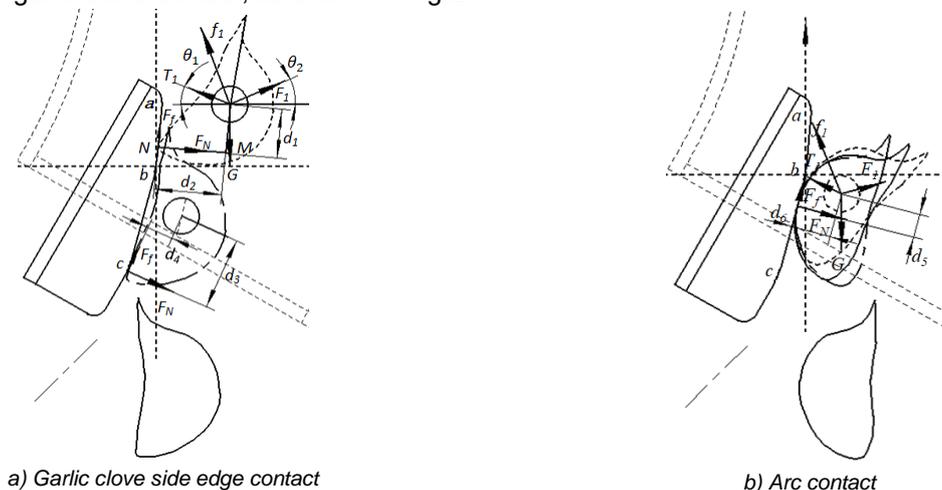

Fig. 2 - Analysis of garlic clove contact guide cam process

When the garlic clove first contacts the ab segment, as shown in Fig.2 (a), the counterclockwise torque (M_1) must exceed the clockwise torque (M_2) to meet the guidance requirements, as shown in formula (1).

$$\begin{cases} M_1 > M_2 \\ M_1 = F_N \cdot d_1 \\ M_2 = F_f \cdot d_2 \end{cases} \quad (1)$$

where: M - rotational torque of garlic clove, N·mm;

d - rotational force arm of garlic clove, mm;

F_N, F_f - the force of the guide cam relative to the garlic clove, N;

The force arm (d) is defined as the distance from the center of the suction hole to the straight line (l). The expression for the force arm is determined by solving the equations of the two straight lines.

$$\begin{cases} y_1 = \frac{1}{\tan a_t} \cdot x_1 \\ y_2 = -\tan a_t x_2 + \frac{\sqrt{x_a^2 + y_a^2}}{\cos a_t} \end{cases} \quad (2)$$

Garlic clove rotation arm(d) is obtained, as shown in formula (3):

$$d_1 = \frac{\left| \tan a_t x_b + y_b - \frac{\sqrt{x_a^2 + y_a^2}}{\cos a_t} \right|}{\sqrt{1 + \tan^2 a_t}}, \quad d_2 = \frac{\left| -\frac{1}{\tan a_t} x_b + y_b \right|}{\sqrt{-\frac{1}{\tan^2 a_t} + 1}} \quad (3)$$

where: y_1, y_2 - expression for straight line segment l_{MN}, l_{ab} ;

a_t - the lead-in section (ab) tilt angle, °;

Taking the suction hole as the origin, F_N and F_f are obtained by analyzing the force on the garlic clove.

$$\begin{cases} T_1 \cos \theta_1 = F_1 \cos \theta_2 \\ F_f = \mu F_N \\ F = \sqrt{F_N^2 + F_f^2 + 2F_N F_f \cos \theta_3} \end{cases} \quad (4)$$

where: θ_1 - angle between centripetal force (T) and horizontal direction, °;

θ_2 - angle between resultant force (F_1) and horizontal direction, °;

θ_3 - the angle between the force (F_N) and the friction force (F_f), °;

T - centripetal force on a garlic clove, N;

Substituting Formula (4), and Formula (3) into Formula (1), Formula (5) can be obtained by simplifying it:

$$\left(\sin a_t + y_b \cos a_t - \frac{\sqrt{x_a^2 + y_a^2}}{\cos a_t} \right) \cdot F_N > x_b \cos a_t + y_b \sin a_t \cdot F_f \quad (5)$$

The analysis of formula (5) reveals that counterclockwise rotation requires a relationship between a_t and contact point positions (x_a, y_a). When the garlic clove first contacts the bc segment (Figure 2b), and the adjustment angle β aligns with the clove's deflection angle, the force arm $d_3 > d_4$, making β crucial for guiding. Therefore, the parameters a_t, β , and the contour require precise design.

Determination of guide cam profile

The guide cam's position and contour were optimized using Jinshan garlic as the study object. Most cloves, measuring 27-34 mm in length and 16-23 mm in width, account for 96% of the total sample, with larger cloves contacting the guide cam earlier. For analysis, a clove length of 34 mm and width of 20 mm were selected. Initial contact scenarios were evaluated to determine the guide cam's position parameters.

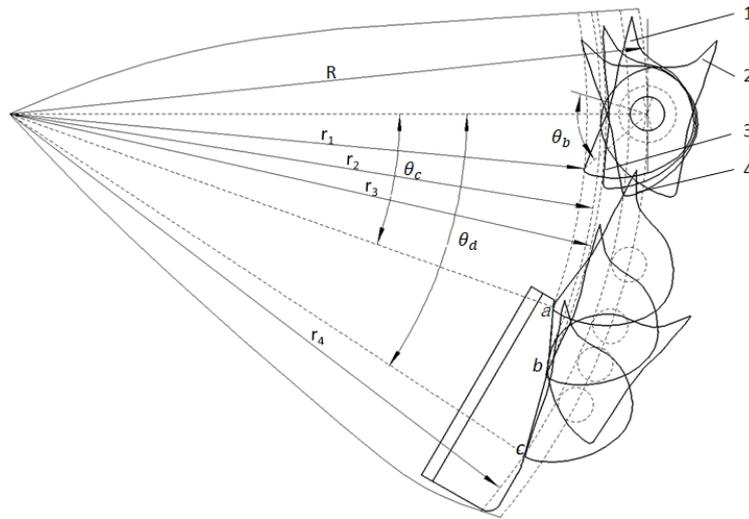

Fig. 3 - Schematic diagram of the position where the garlic clove first contacts the guide cam
 1 - Side edge contact $\theta_z = 15^\circ$; 2 - Arc contact $\theta_z = 15^\circ$; 3 - Side edge contact $\theta_z = 0^\circ$; 4 - Side edge contact $\theta_z = -15^\circ$.

The design conditions for guide cam points *a*, *b*, and *c* are as follows: First, when θ_z is 15° , the side edge contacts point *a* at a distance r_1 from the center, ensuring that cloves of various sizes make contact with the *ab* segment. Second, when θ_z is 15° , the arc surface contacts point *b* at a distance r_2 from the center, positioning the force below the suction hole. At θ_z , the side edge passes smoothly through point *b*, and at θ_z is -15° , it contacts point *c* at a distance r_4 from the center, as shown in figure 3. This design ensures garlic cloves maintain contact with the guide cam before separating from negative pressure, optimizing the guidance effect.

$$\left\{ \begin{array}{l} \tan \theta_b = \frac{L/2}{D/2} \\ r_1 = R - \frac{D}{2 \cos \theta_b} \cdot \cos 90^\circ - \theta_b \\ r_2 = R - \frac{D}{2 \cos \theta_b} \\ r_3 = R - \frac{D}{2} \\ r_4 = R - \frac{D}{2 \cos \theta_b} \cos \theta_b + 15^\circ \end{array} \right. \quad (6)$$

where: *R* - Radius from the center of the suction hole to the center of the seed plate, mm;
 θ_b - The angle between the length *L* and width *B* of the garlic clove, $^\circ$.

The dimension parameters of the guide cam *ab* segment meet the following requirements:

$$129.47\text{mm} \approx r_1 < 134.2\text{mm} \approx r_2 < r_3 < r_4 \approx 141.35\text{mm} \quad (7)$$

From formula (7), point *a* is positioned at $r_1 = 130\text{mm}$, point *b* at $r_2 = 135\text{mm}$, and point *c* at $r_4 = 140\text{mm}$.

Determination of guide cam thickness and installation position

The precise guiding of garlic cloves depends on the thickness of the guide cam and its distance from the seed plate. An improper distance can lead to ineffective contact or tipping of the garlic clove. Measurements of Jinxiang garlic cloves indicate side edge contact points (l_1) ranging from 2.6mm - 4.8mm and arc surface contact points (l_2) from 5.1mm - 7.2mm. Consequently, the distance between the guide cam's center line and the seed plate (*T*) was set at $T=5\text{mm}$. The final thickness was established at $D=4\text{mm}$, ensuring effective guidance for 98% of the cloves.

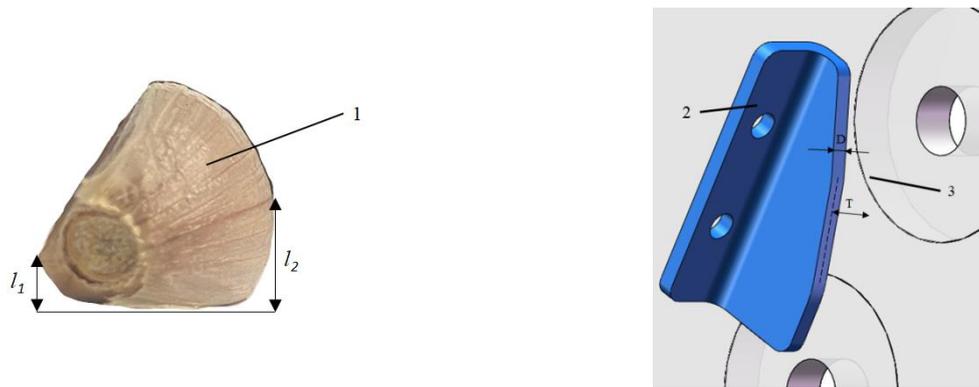

Fig. 4 - Garlic clove contact surface height
 1 - Garlic clove; 2 - Guide cam; 3 - Seed plate.

Determination of tilt angle parameters

The determination of the inclination angle of the lead-in section (α_t) and the seeding section are crucial, as it directly influences the direction of the resultant force (F). If F points toward the center, it can cause the garlic clove to move radially, resulting in jamming and reduced sowing accuracy. To prevent this, the contact between the garlic clove and point a is analyzed. Ensuring point a does not cause jamming guarantees that as the clove contacts the ab section, the angle between the force and the suction hole center increases, thus avoiding jamming. By appropriately setting the α_t angle, $\lambda_l > 0$ is maintained, ensuring smooth guidance of the garlic clove, as shown in Figure 5(a).

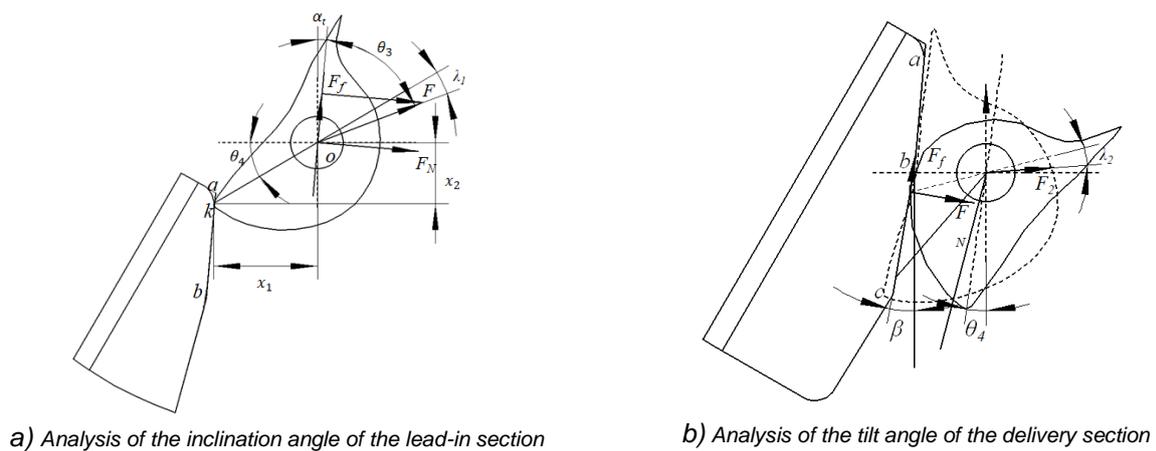

Fig. 5 - Garlic clove contact profile analysis

Geometric analysis of garlic clove contacting point a in the lead-in section:

$$\begin{cases} \tan \theta_4 = \frac{x_1}{x_2} \\ \theta_3 = \arccos \frac{F_f}{F_1} \\ \lambda_1 = \beta + \theta_4 + \theta_3 - 90^\circ \end{cases} \quad (8)$$

where: θ_4 - the angle between ok and the horizontal direction, °; λ_1 - the angle between ok and F , °; x_1, x_2 - horizontal distance and vertical distance between k and O , mm.

Experimental measurements showed that for varying size ranges x_1 and x_2 , $\theta_2 \approx 60^\circ$, and θ_3 ranged from $20.5^\circ - 25.6^\circ$. Substituting θ_2 and θ_3 into formula(13), when $\lambda_1 > 0$, the value range of α_t is $2.3^\circ - 8.6^\circ$.

If $\beta < \alpha_t$, misguidance occurs ; if $\beta > \alpha_t$, root engagement fails, altering torque. β must position the force below the suction hole while ensuring root contact, as shown in Figure 5(b). For $\lambda_2 > 0$, β ranges from 10° to 30.3° . To avoid misdirection, $\beta < 18.5^\circ$, setting the bc section's inclination between 13° and 19.5° .

Experimental materials and equipment

The JPS-12 sowing bench test, with a modified air control system, positioned the negative pressure zone and seeding point 30° below the horizontal plane, as shown in Figure 7. Garlic cloves, categorized by thickness—A (12–15 mm, 30%), B (15–18 mm, 41%), and C (18–21 mm, 25%)—covered 96% of Jinxiang samples (Li et al., 2022). The guide cam and hopper are 3D printed using resin.

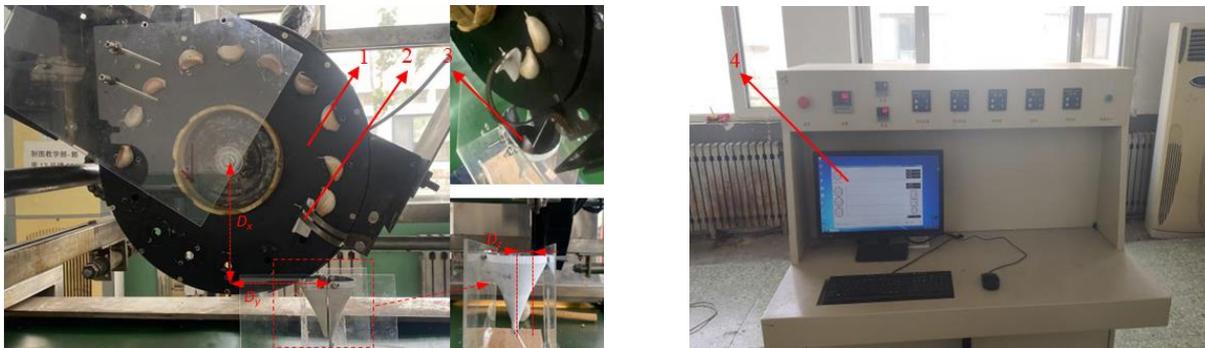

Fig. 7 – Bench testing of metering devices

Test methods

(1) A five-factor, three-level design experiment was conducted in a stable environment with initial trials to determine α_t , β , D_x , D_y and D_z ranges. The optimal parameter combination was determined using the upright orientation rate (Y_1) as the evaluation index. The experimental structure code is shown in Table 1.

Table 1

Table of factors and levels

Level	Factors				
	Angle of the lead in section, $\alpha_t / ^\circ$	Angle of the seeding section, $\beta / ^\circ$	Lateral distance, D_x / mm	Longitudinal distance, D_y / mm	Vertical distance, D_z / mm
-1	3	13	140	125	9
0	5	15	145	130	11
1	7	17	150	135	13

(2) Based on the experiment (1), a bench high-speed operation performance comparison test was conducted on the seed meter with and without additional guides. A two-factor experiment tested negative pressure across 10 gradients (-8.5 to -13 kPa) and rotational speed at 4 levels(6–9 rad/s).

The upright orientation rate(Y_1) evaluated the guide cam's effectiveness:

$$Y_1 = \frac{m_1}{Q} \times 100\% \tag{9}$$

where: m_1 - the number of buds falling into the receiving hopper with the buds pointing upwards;

Q - total number of garlic cloves.

RESULTS

Analysis of test results

The results of the orthogonal test are shown in Table 2, where A, B, C, D, and E are structural coding values. Each group of tests was performed 4 times to obtain the average value.

The test results were analyzed using Design-Expert software to establish a quadratic regression model for the upright orientation rate (Y₁). The model's significance was verified through Anova and regression coefficient tests, the results showed that the most significant factors were A, D, and E, Results are presented in Table 3. The responses between the important factors and their effects on Y₁ were analyzed by completing the response surface, as shown in Figure 8.

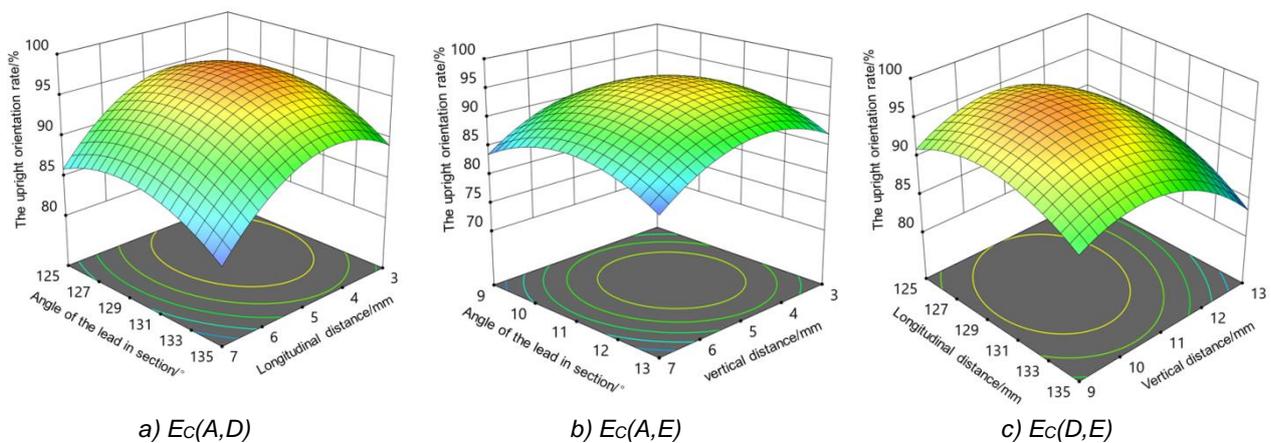

Fig. 8 – Bench testing of metering devices

Optimization of the model by parameter combination with Y₁ taking the maximum value of $\alpha_i=5^\circ$, $\beta=15^\circ$, $D_x=140\text{mm}$, $D_y=128\text{mm}$, $D_z=9\text{mm}$. Verification tests with these parameters resulted in an average uprightness of 96.8%, which was determined to be the optimal parameter.

Comparative test

Table 4 compares the performance of devices *K* and *T* under varying pressures and speeds. Device *T*'s upright rate rose and then fell with increasing pressure; low pressure caused unstable C-size clove adsorption, while high pressure impeded posture adjustment. Optimal rates (>92%) were achieved at -10 to -12 kPa. Device *K*'s upright rate stabilized at -10 kPa after an initial rise.

Table 4

Comparison of the qualified index of *K* and *T* seeding devices (Short version)

Working speed (n) / (rad/s)	-8.5 kPa			-9 kPa			-9.5 kPa			-10 kPa			-10.5 kPa		
	K	T	Δ	K	T	Δ	K	T	Δ	K	T	Δ	K	T	Δ
6	66.3	67.2	-0.9	71.2	70.2	1.0	72.2	76.4	-4.2	78.5	82.6	-4.1	82.4	88.4	-6.0
7	63.2	61.2	-2	68.8	70.6	-1.8	75.8	78.0	-2.2	79.0	83.8	-4.8	84.2	90.2	-6.0
8	54.2	58.0	-3.8	63.4	60.4	3.0	60.2	61.8	-1.6	68.3	73.0	-4.7	76.3	84.6	-8.3
9	50.3	48.6	1.7	50.2	49.4	0.8	55.2	56.4	-1.2	68.0	70.4	-2.4	70.2	78.4	-8.2
Working speed (n) / (rad/s)	-11 kPa			-11.5 kPa			-12 kPa			-12.5 kPa			-13 kPa		
	K	T	Δ	K	T	Δ	K	T	Δ	K	T	Δ	K	T	Δ
6	82.6	93.4	-10.8	86.2	95.6	-9.4	82.0	94.6	-12.6	86.5	92.8	-6.3	82.0	89.6	-7.6
7	83.5	93.5	-10.0	87.6	98.8	-11.2	88.5	97.9	-9.4	87.6	94.4	-6.8	86.2	95.2	-9.0
8	83.5	90.8	-7.3	86.4	96.6	-10.2	83.4	94.2	-10.8	84.4	91.4	-7.0	81.3	90.6	-9.3
9	82.4	91.4	-9.0	85.6	95.8	-10.2	85.4	94.0	-9.6	84.6	92.6	-8.0	83.4	92.5	-9.1

Note: *K* represents the upright rate of the bud tip without a guide cam (%), *T* represents the upright rate with a guide cam (%), and Δ is the difference between the two rates (%)

As shown in Table 4, the difference in the vertical rate (Δ) highlights the guide cam's impact on seeders *T* and *K*. Δ increases and then decreases with pressure changes. At -8.5 to -10 kPa, $|\Delta| < 5\%$, showing minimal impact. Between -10 and -12 kPa, Δ reaches up to 10%, significantly improving the vertical rate. At -11.5 kPa and 7 rad/s, the *T* seeder achieves a vertical rate of 98.8%, with Δ at -11.2%, confirming the guide cam's superior performance.

CONCLUSIONS

The traditional air-absorbing garlic clove metering device has been improved by adding a guiding cam to control the orientation of the garlic cloves so that the bud tips are discharged in an upward direction, which improves the stability of the sowing and meets the agronomic requirements. The analysis of garlic clove size and attitude determined the key parameters: introduction angle $\alpha_t = 5^\circ$, thickness $D = 4$ mm, and seeding section inclination $\beta = 15^\circ$, $D_x=140$ mm, $D_y=128$ mm, $D_z=9$ mm, enabling effective posture adjustment. Validation experiments showed the guide cam significantly improved upright rates. At -10.5kPa, the upright rate difference (Δ) exceeded 5%, reaching (Δ) to 10% at -11 to -12kPa. At -11.5kPa and 7 rad/s, the upright rate peaked at 97.2%, 11.2% higher than without the guide cam, confirming its design effectiveness.

Keywords: Clutch, Engagement trajectories, Pseudo-spectroscopy, Optimization

ABSTRACT

To address the issue of reduced comfort and operational accuracy in tractors caused by the clutch engagement process in combination with automatic transmissions, dual-clutch transmissions, and hybrid power tractors, a new method is proposed that considers both the slipping process and synchronous instantaneous control at the moment of engagement. In this method, the optimal engagement process model of the clutch considering the clutch sliding process and synchronous instantaneous control was established, and the optimal trajectory of the clutch engagement process was solved based on the pseudo-spectral method. Then, the optimization results were compared with those obtained without considering the synchronous instantaneous. The results show that the proposed method considering the sliding process and synchronous instantaneous constraint can reduce the frictional loss of the clutch by 9%, and suppress the impact to below 10 m/s³. Finally, this method was applied to the control of tractor starting up, gear shifting and hybrid power mode switching processes. Simulation results demonstrate that this method can be effectively applied to these three operating conditions.

摘要

为解决搭配自动变速器、双离合变速器 and 混合动力拖拉机离合器接合过程导致的拖拉机舒适性和作业精度降低问题，提出了一种考虑滑摩过程和同步瞬间控制的新方法。在该方法中，建立了考虑离合器滑摩过程和同步瞬间控制的离合器最优接合过程模型，并基于伪谱法求解了离合器接合过程的最优轨迹。结果表明，考虑滑动过程和同步瞬间约束优化方法可使离合器的摩擦损耗降低 9%，并可抑制冲击降低到 10 m/s³ 以下。最后，将该方法应用于拖拉机起步、换挡和混合动力模式切换过程的控制，仿真结果表明，该方法能较好地应用于上述三种工况。

INTRODUCTION

As a key component in the tractors' driveline, the clutch has important impact on the comfort of the vehicle during start-up, shifting and mode switching of hybrid vehicles (Fig.1) (Park et al, 2021; Van Berkel et al, 2014; Lu, 2012; Li et al, 2020; Minh et al, 2012). To ensure smooth driving and prolong the service life of components, the clutch is supposed to be engaged quickly and smoothly during the start-up, shift and mode switch process of tractors equipped with automatic transmission and hybrid-driven driveline (Gavvani et al, 2016; Zhao et al. 2016; Fu et al., 2016). Researches have shown that the fast and smooth engagement can be obtained by controlling the drive and driven disc of the clutch to engage in a certain trajectory (Zhao. et al., 2016). Therefore, it is necessary to optimize the engagement trajectory of the clutch.

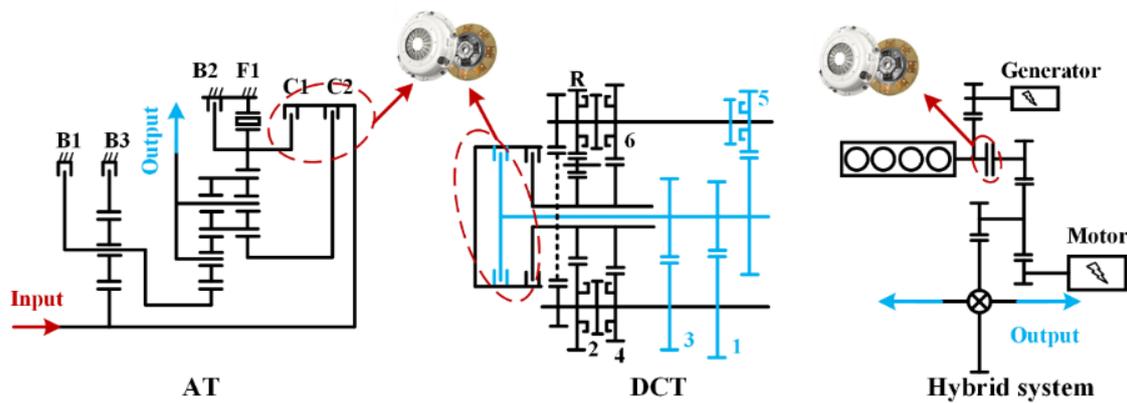

Fig. 1 - Typical driveline in the tractors

For the optimization of clutch engagement trajectory, many experts and scholars have carried out extensive and in-depth research. *Peng et al., (2009)*, proposed a clutch engagement curve correction algorithm based on optimization theory, which corrects the original curve by judging the Hamilton function on the basis of the basic structure of the original curve. However, this method only analyzed the situation of the initial speed of the driven disc as 0, they did not analyze the gear shift process and the mode switch process of hybrid vehicles. To solve the problem of the variability of clutch engagement trajectory under uncertain factors such as system parameter perturbation and external load disturbance, *Li et al., (2018)*, proposed an optimization method which take the frictional loss and jerk as the optimization goal, and solve the optimization problem by using the Pontryagin theory. The result showed that, this method can reduce the frictional loss of the clutch during its engagement process, but the method did not solve the jerk of the synchronous instantaneous of the clutch. *Li et al., (2018)*, optimized the shifting process with optimal control theory, and designed a linear quadratic optimal controller for the torque phase and the inertial phase. The results show that this method can reduce the jerk of torque phase and inertia phase during gear shifting process. To reduce the vibration during the inertial phase of the clutch engagement of shifting process, *Lu et al., (2014)*, proposed to use the model predictive control method to control the inertial phase in the shifting process, and the results show that the method reduces the inertial phase vibration in the vehicle shifting process while ensuring the minimum change of the control amount in the shifting process. *Mesmer et al. (2017, 2018)*, optimized the shifting process with the goal of minimizing the shifting time and frictional loss, and designed the optimal trajectory tracking controller for the shifting process by using the method of embedded nonlinear model predictive control, the simulation and experimental results show that the method can obtain better shifting quality, but the instantaneous synchronization of the clutch was not controlled in this study, resulting in residual oscillation on the drive shaft after clutch engagement. *Guo, (2017)*, analyzed the clutch engagement process of hybrid vehicles from pure electric mode to hybrid drive state, he divided the clutch engagement process into two stages, slipping friction phased and synchronization phase. He proposed to use the method of Laguerre function set to optimize the control process of clutch engagement in hybrid vehicles, the results show that this method can reduce the torsional vibration of the transmission system during the engine starting process of hybrid vehicles.

Making the clutch engage fast and smoothly is an important measure to improve the vehicle start-up, shifting and hybrid vehicle mode switching process (*Wurm et al., 2016, Kim et al, 2017*), in view of the problems of synchronous instantaneous jerk existing in the current research, a method combining process control and terminal constraints was proposed.

The frictional loss and jerk during the clutch engagement process were chosen as the optimization goals during the slipping phase. In addition, the same acceleration of the drive and driven clutch was set as the terminal constraint. The pseudo-spectral method was used to solve this optimization problem, and the proposed method was applied to the start-up, shifting, and mode-switching processes of the hybrid vehicle.

MATERIALS AND METHODS

Modeling the clutch engagement process

In practice, the working state of the clutch is divided into two types, engagement and disengagement. During the engagement process, the actuator pushes the clutch driven disc move to the drive disc, and the disc rubs against each other to transmit the torque, which can be illustrated in Figure 2.

Assuming that the input torque is T_{in} , the torque transmitted during slipping phase is T_c , and the resistance clutch is T_r , according to Newton's second law, the clutch engagement process can be modeled (Li, J., 2016).

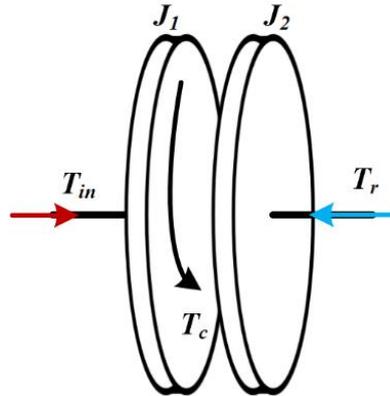

Fig. 2 - Model of clutch engagement process

$$\begin{cases} J_1 \dot{\omega}_1 = T_{in} - T_c \\ J_2 \dot{\omega}_2 = T_c - T_r \end{cases} \quad (1)$$

Take $x = [\omega_1, \omega_2, \omega_1 - \omega_2, T_{in}, T_c]^T$ as the state variable, $u = [T_{in}, T_c]^T$ as the control variable, the model of the clutch engagement process can be transferred into state space equation.

$$\begin{cases} \dot{x}_1 = \frac{1}{J_1} (x_4 - x_5) \\ \dot{x}_2 = \frac{1}{J_2} (x_5 - T_r) \\ \dot{x}_3 = x_1 - x_2 \\ \dot{x}_4 = u_1 \\ \dot{x}_5 = u_2 \end{cases} \quad (2)$$

where, J_1 is the inertia of drive disc of clutch, J_2 is the inertia of driven disc of clutch, ω_1 is the rotation speed of clutch drum and ω_2 is the rotation speed of clutch hub.

Indicators for clutch engagement process

1. Jerk. In the longitudinal dynamics of the tractor, the jerk (the change rate of longitudinal acceleration) is generally used to reflect the comfort of the tractor during acceleration. Moreover, the jerk can be represented by equation (3). When the value of the jerk is less than 10 m/s³ during clutch engagement process, the tractor can get good comfort during acceleration (Fu et al., 2016).

$$j = \frac{da}{dt} = \frac{1}{J_e} \frac{d(T_c - T_r)}{dt} \quad (3)$$

To prevent the clutch from generating a large jerk during the engagement process, it is generally necessary to control change rate of the transmitted torque T_c when the clutch engages.

2. Frictional loss. The frictional loss of the clutch during the engagement process can be measured by the slipping work, it reflects the degree of the wear of the clutch during the engagement process. Therefore, it is necessary to control its slipping work during the clutch engagement process, and the clutch slipping work can be measured with equation (4).

$$W = \int_{t_s}^{t_e} T_c |\omega_1 - \omega_2| dt \quad (4)$$

Wherein, W is the clutch slipping work, t_s is the time when the clutch starts to slip with each other, and t_e is the time when the clutch engaged totally.

During clutch slipping phase, it is generally required that the frictional loss and jerk to be as small as possible. Meanwhile, it is important to control the jerk caused by the synchronous instantaneous. According to the above requirements, the optimization goal of the clutch engagement process can be established.

$$l = \int_{t_s}^{t_e} \lambda_1 u_1^2 dt + \lambda_2 \int_{t_s}^{t_e} T_c |\omega_1 - \omega_2| dt \quad (5)$$

where, λ_1, λ_2 is the weight coefficient, u_1 is the control variable. The objective function consists of two parts. The first part is the sum of squares of the torque change rate, which represents the limit of the torque change rate during the clutch engagement process; it also represents jerk control. The second part is expressed as the frictional loss during the clutch engagement process. In addition, keeping the acceleration of the two discs at the moment of synchronous can reduce the jerk generated by the clutch engagement synchronous instantaneous.

Based on the above objective function of the clutch engagement process, the clutch engagement process can be converted into an optimization problem, which can be expressed as equation (6).

$$\begin{aligned} \min J(x(t), u(t), t) &= \int_{t_s}^{t_e} \lambda_1 u_1^2 dt + \int_{t_s}^{t_e} T_c |\omega_1 - \omega_2| dt \\ \text{st } &\begin{cases} \dot{x} = f(x, u, t) \\ x_1(t_e) - x_2(t_e) = 0 \\ \dot{x}_1(t_e) - \dot{x}_2(t_e) = 0 \\ T_{in_min} \leq T_{in} \leq T_{in_max} \\ T_{c_min} \leq T_c \leq T_{c_max} \\ x_{1_min} \leq x_1 \leq x_{1_max} \\ x_{2_min} \leq x_2 \leq x_{2_max} \end{cases} \end{aligned} \quad (6)$$

wherein, T_{in_min} is the minimum of the input torque, the T_{in_max} is the maximum of the input torque, the T_{c_min} is the minimum torque transmitted during the clutch slipping process, the T_{c_max} is the maximum torque transmitted during the clutch slipping process, the x_{1_min} is the minimum speed of the clutch drum, the x_{1_max} is the maximum speed of the clutch drum, the x_{2_min} is the minimum speed of the clutch hub, and the x_{2_max} is the maximum speed of clutch hub.

It can be seen from the above optimization problem that this problem is an optimization problem with terminal constraints, especially for the clutch synchronous moment, the constraint problem of the acceleration of the main and slave disks. For optimization problems with terminal constraints, the general analytical method is difficult to solve, therefore, this paper uses the numerical solution method to solve.

When solving optimization problems with terminal constraints, pseudo-spectral method uses global interpolation polynomials to approximate state variables and control variables on a series of discrete points, and converts differential equation constraints into algebraic constraints by introducing pseudo-spectral difference matrices similar to finite difference matrices, and then solves nonlinear optimization problems with complex constraints. According to different distribution methods, pseudo-spectral methods can be divided into Legendre pseudo-spectroscopy, Radau pseudo-spectroscopy, Gauss pseudo-spectroscopy and Chebyshe pseudo-spectroscopy (Feng et al, 2023).

Radau pseudo-spectroscopy (RPM) is a numerical solution algorithm for solving nonlinear optimization problems. The basic idea is to discretize first and then optimize. Firstly, the unknown state quantity and control quantity to be solved are discretized at a series of Legendre-Gauss-Radau (LGR) points, and then the state variables and control variables are approximated by constructing global interpolation polynomials, and the original kinetic differential equation is replaced by derivation of the state variables, the optimization problem of continuous system is discretized into a series of algebraically constrained nonlinear optimization problems, and the nonlinear optimization problem of algebraic constraint is solved by numerical solving algorithm.

Radau pseudo-spectral optimization problems can be divided into the following steps (Feng et al, 2022).

1) Time domain transformation:

To satisfy the time domain of the Legendre orthogonal polynomial, it is necessary to convert the time domain in the optimization problem to the standard time domain [-1,1], and the variable τ represents the transformed time variable.

$$\tau = \frac{2t - (t_f + t_0)}{t_f - t_0} \tag{7}$$

2) Polynomial approximation of state variables and control variables

Based on the normalized time variable, the Lagrange interpolation polynomial is used to approximate the state and control variable.

$$\begin{cases} \mathbf{x}(\tau) \approx \mathbf{X}(\tau) = \sum_{j=1}^{N+1} X_j L_j(\tau) \\ \mathbf{u}(\tau) \approx \mathbf{U}(\tau) = \sum_{j=1}^{N+1} U_j L_j(\tau) \end{cases} \tag{8}$$

wherein, $L_j(\tau)$ is the Lagrange interpolated polynomial.

$$L_j(\tau) = \prod_{\substack{i=1 \\ i \neq j}}^{N+1} \frac{\tau - \tau_i}{\tau_j - \tau_i}, \quad j = 1, \dots, N+1 \tag{9}$$

wherein, τ_1, \dots, τ_N is the root of the Legendre polynomial, and τ_{N+1} is the unconfigured node, which represents the end time.

3) Polynomial approximation of differential equations

Based on the approximation of the state quantity, the approximate state variable can be derived.

$$\frac{dX}{dt} = \frac{t_f - t_0}{2} f(\mathbf{X}(\tau), \mathbf{U}(\tau), \tau) \tag{10}$$

$$\frac{dX}{d\tau} \equiv \dot{\mathbf{X}}(\tau) = \sum_{j=1}^{N+1} X_j \dot{L}_j(\tau) \tag{11}$$

Substituting Equation 11 into 10 and discretizing at the LGR point, equation (12) is obtained.

$$\sum_{j=1}^{N+1} X_j D_{ij} - \frac{t_f - t_0}{2} f(\mathbf{X}(\tau), \mathbf{U}(\tau), \tau) = 0 \tag{12}$$

where D_{ij} is the differential matrix of the Radau pseudo-spectral method, and it can be expressed by equation (13).

$$D_{ij} = \begin{cases} \frac{\dot{h}(\tau_i)}{(\tau_i - \tau_j) \dot{h}(\tau_i)} & i \neq j \\ \frac{\ddot{h}(\tau_i)}{2\dot{h}(\tau_i)} & i = j \end{cases} \tag{13}$$

After the conversion of the above steps, the optimization problem of the clutch engagement process can be expressed by equation (14).

$$\begin{aligned} \min J &= \int_{-1}^1 l(x(\tau), u(\tau)) d\tau \\ &\begin{cases} \sum_{j=1}^{N+1} X_j D_{ij} - \frac{t_f - t_0}{2} f(\mathbf{X}(\tau), \mathbf{U}(\tau), \tau) = 0 \\ C_{eq}(x(\tau), u(\tau)) = 0 \\ C_{ieq}(x(\tau), u(\tau)) < 0 \\ \phi(x(\tau_0), u(\tau_0), x(\tau_f), u(\tau_f), \tau_0, \tau_f) = 0 \end{cases} \end{aligned} \tag{14}$$

where, $l(x(\tau), u(\tau))$ is the stage value function in the clutch engagement process. C_{eq} is the equality constraint, C_{ieq} is the inequality constraint, and ϕ is the terminal constraint.

Thus, the optimization problem of continuous system is transformed into a series of nonlinear programming problems with algebraic constraints, and the discretized algebraic optimization problem is solved by using the sequence quadratic programming (SQP).

RESULTS

To test the effectiveness of the algorithm. The Optimization results were compared with the results obtained without considering the terminal constraint case.

Case 1. With terminal constraints

In this case, the engagement of the clutch for start-up was optimized. The initial speed of the clutch hub was set to be 0 r/min, the speed of clutch drum was set to be 764 r/min. The optimization problem was solved with *GPOPS*. The optimized engagement trajectory is shown in the Figure 3 illustrating the rotation speed of the clutch drum and hub. It can be seen from this figure that the rotation speed of the clutch hub increases gradually. The rotation speed of the clutch drum is kept as low as possible to keep the speed difference between clutch drum and hub at a small value because the objective function requires the frictional loss as small as possible. The clutch drum has small fluctuation at the synchronization stage to make the acceleration of the drive and driven disc tend to be consistent. When synchronized, the acceleration of the drive and driven disc is the same, as shown in the enlarged section in Figure 3a.

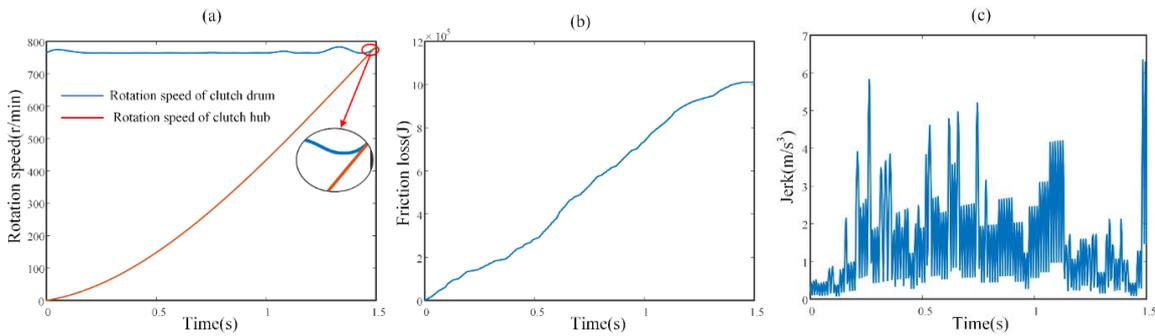

Fig. 3 - Clutch engagement trajectory optimized by pseudo-spectroscopy

Figure 3b shows the frictional loss during the engagement process. It can be seen from Figure 3b that the frictional loss is 10.12×10^5 J. Figure 3c shows the value of the jerk during the engagement process, and it can be seen from Figure 3c that the value of the jerk is less than 10 m/s^3 during the entire engagement process of the clutch, and at the moment of clutch synchronization, although the value of the jerk is larger, it is still less than 10 m/s^3 .

2. Case 2. Without terminal constraints

To check the effectiveness of the optimal problem that considers the process constraints and terminal constraints, the optimal problem without terminal constraints, which is mostly used in the optimal problem for clutch engagement process was also solved.

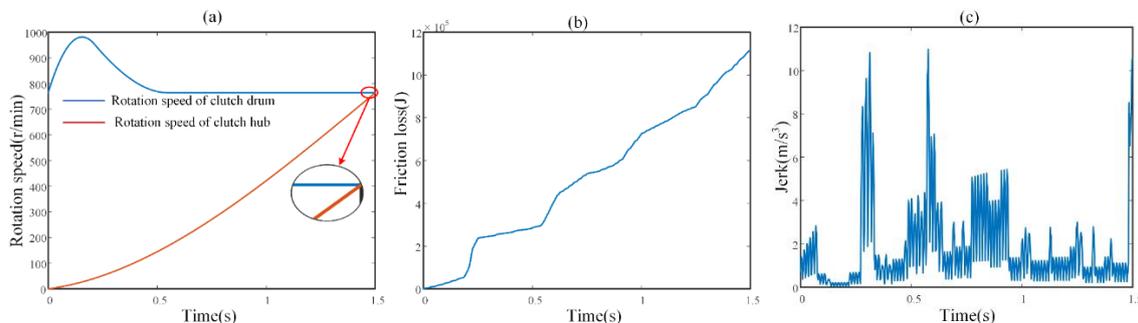

Fig.4 - Optimization results of clutch engagement process without considering terminal acceleration constraints

Figure 4 shows the results without considering the terminal constraint, Figure 4a is the rotation speed of the clutch drum and hub. It can be seen from the figure that the rotation speed of the clutch drum increases at first and then quickly decreases to the lowest value of the engine to make difference of the clutch drum and hub to be smallest during the whole engagement process. The rotation speed of the clutch drum was not adjusted at the synchronization stage, so the acceleration of the clutch drum and hub

was inconsistent, as shown in the enlarged section of the figure. Figure 4b shows the frictional loss during clutch engagement, and it can be seen from the figure that the frictional work is $11.1 \times 10^5 \text{ J}$, which is higher than the values produced by the pseudo-spectroscopy. Figure 4c shows the value of the jerk during the engagement process. It can be seen from the figure that the maximum values of jerk exceed 10 m/s^3 at 0.25 s, 0.6 s and synchronization moment. Compared with the optimization without considering terminal constraints, the frictional loss is reduced by 9%, and the jerk is less than 10 m/s^3 .

From the result of optimization with terminal constraints and without terminal constraints, it can be seen that the rotation speed of the clutch hub gradually increases, and the rotation speed of the clutch drum has been running at a lower value to keep the difference between the clutch drum and hub at a smaller value, so as to minimize the slip loss. Wherever, the rotation speed of the clutch drum was adjusted, and during the adjustment period, it resulted in two large jerks (0.25 s, 0.6 s) during the engagement process.

Meanwhile, the rate of change of the torque transmitted by the clutch is constrained in the value function, resulting in a smaller value of the jerk throughout the clutch engagement process. When the terminal constraint is considered, the process constraint and the terminal constraint are both applied, resulting in a smaller jerk during the clutch engagement process, while if only the process constraint is applied without the terminal constraint, the clutch not only experiences a larger jerk at the slip phase, but also at the moment of synchronization.

Clutch engagement trajectory optimization under different operating conditions

(1) Start-up process

In vehicles equipped with automatic transmissions, the clutch driven disc starts at zero and the rotation speed of drive disc is limited by the minimum engine speed. Therefore, the clutch engagement process during the start-up process is optimized with the condition that the initial speed of the driven disc is zero.

Figure 5 shows the optimization curve of the clutch engagement process in the vehicle start-up process. To validate different start-up situations that are often present, three different start-up times was set to be 1.5 s, 2.0 s and 2.5 s, respectively. The optimization result is shown in Figure 5. It can be seen from the figure that the rotation speed curve of the driven disc is a smooth curve, and when the clutch is about to synchronize, the acceleration of the drive and driven disc is consistent, thus ensuring that the clutch has a small jerk during the slipping process and the synchronization moment.

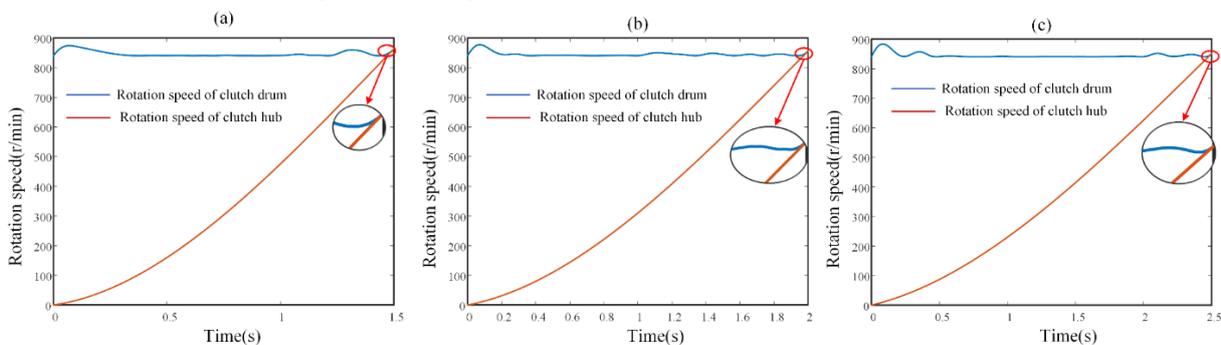

Fig. 5 - Start-up process, clutch engagement process optimized

Shift process

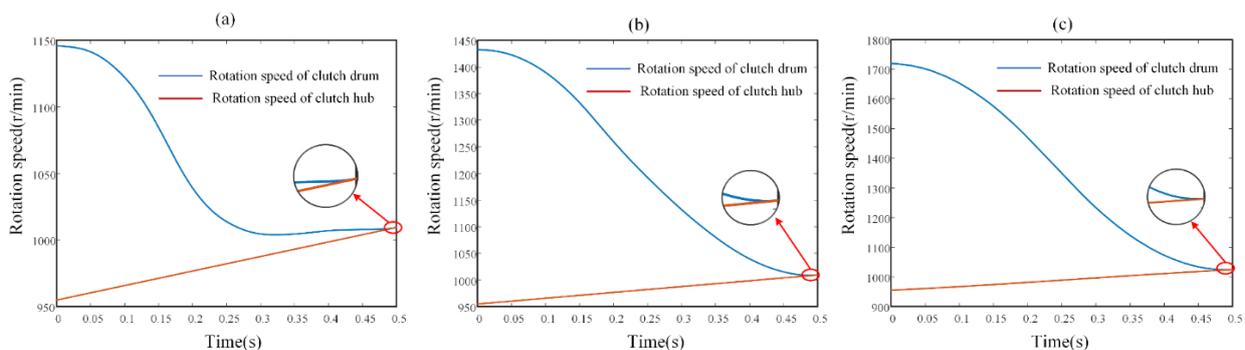

Fig. 6 - Optimal engagement curve of the clutch during the upshift process

Unlike in the vehicle starting process, the initial speed value of the clutch driven disc is not zero during the shifting process. In this study, the upshift process was taken as an example. During the upshift process, the initial speed value of the driven disc is not zero, and the speed of drive disc is higher than the speed of driven disc of the target gear.

To simulate the upshift process of different gears, the shift process time is set to 0.5 s, and three different gear values are set, the corresponding gear ratios are 1.2, 1.5, 1.8, respectively and the clutch driven disc speed value is set to 955 r/min. The optimization process of the optimal engagement path of the clutch in the upshift process under different transmission ratios is shown in Figure 6. From the figure, it can be seen that the drive disc speed decreases actively, the driven disc speed rises gradually, and at the end of the shift, the rotation speed of the drive and driven disc were consistent, and the angular acceleration value is the same at the same time.

Mode switching situation in the hybrid tractor

In parallel hybrid tractors, at high speeds, the engine is usually used to drive the vehicle directly to reduce the overall energy consumption. Parallel hybrid vehicles require clutch control when the engine intervenes to prevent sudden engine intervention and vibrations in the driveline. For the parallel hybrid vehicle, a small generator is used to drive the engine to start when the parallel hybrid vehicle engine is involved, and the speed of the engine is adjusted to be slightly higher than the speed of the clutch driven disc, meanwhile, the difference between the speed of drive and driven disc is small so that the clutch can be engaged smoothly and quickly when engaged. To verify the applicability of the method in the clutch engagement process of mode switch process, three different small speed differences were set to be 48 r/min (5 rad/s), 95 r/min (10 rad/s) and 144 r/min (15 rad/s), respectively, and the engagement time of the clutch was set to be 0.5 s, the optimization results are shown in Figure 7. It can be seen from Figure 7 (a) (b) that the rotation speed of driven disc increases gradually, the speed of the drive disc decreases gradually, and there are some fluctuations when the speed of the drive disc decreases, the reason for this fluctuation that the difference between the drive and driven disc is small, is that the engine needed to be adjusted to make the acceleration of the drive and driven disc be consistent. For the large value of the difference between the drive and driven disc, the engine speed can be smoothly reduced, which can be seen in Figure 7c, and the acceleration of drive and driven disc can still be consistent at the synchronization moment.

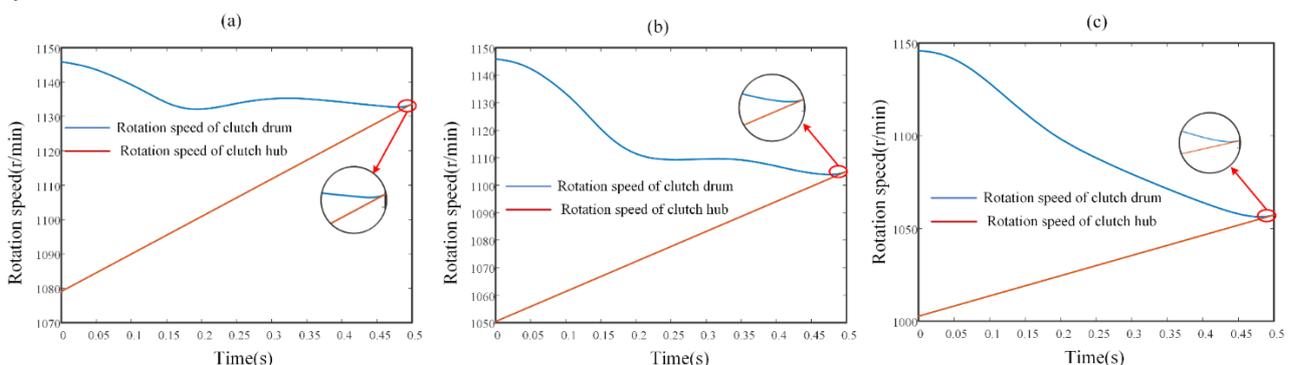

Fig. 7 - In hybrid systems, the clutch engages the optimal curve when the engine is involved

CONCLUSIONS

In this study, an optimization method that considers the slipping phase and synchronization moment of the clutch engagement was proposed. The frictional loss and jerk during the slipping phase were considered and the jerk at the moment of clutch synchronization was also considered as well, and the clutch engagement process was transformed into an optimization problem with terminal constraints. To solve this problem, the pseudo-spectral method was used and the optimization result was compared with the optimization method without considering the terminal constraints, and the results show that the frictional loss can be reduced by 9% and the jerk is lower than 10 m/s^3 by using the pseudo-spectral method considering the terminal constraint method, and this method was applied to the start-up, shift and mode switch process of the hybrid driveline. The results show that the method can ensure that the acceleration value of the clutch drum and hub tends to be consistent when the clutch is synchronized, which will reduce the residual oscillation on the drive shaft after clutch engagement (Petrescu et al, 2018).

This study optimizes the engagement trajectory of the clutch engagement process in terms of jerk and frictional loss, and solves the problem of jerk at the moment of clutch synchronization. However, the efficiency and energy consumption of the engine/motor connected to the clutch drum during its adjustment in the clutch engagement process have not been considered. In future work, the overall energy consumption of the process will be thoroughly analyzed. Additionally, a test rig will be developed to validate this method, and a novel control approach for tracking the optimal trajectory will also be explored.

DOI: <https://doi.org/10.35633/inmateh-75-04>**Keywords:** mechanical weeding, inter-row weeding, weeding device, weeding shovel, ridge planting**ABSTRACT**

Aiming at the complexity and insufficient adaptability of current weeding devices for ridge tillage, this paper presents the design of a clamping-shear weeding device that mimics the hand-grabbing motion. Through the force analysis of the weed root system, the optimal shovel surface inclination angle is determined to be $10^{\circ}\sim 40^{\circ}$. To ensure the sliding cutting condition, the shovel blade angle is calculated and determined as 30° . Based on the Mohr-Coulomb shear theory, the shovel width is set at 50 mm. A single-factor test was conducted with the soil penetration depth of 40 mm and the clamping-shear speed of 4 cm/s, the results showed that the weed removal rate was over 85% and the crop injury rate was less than 6%. The optimal performance was observed with the shovel inclination angle of 30° .

摘要

针对现有垄作田间株间除草装置结构复杂、适应性差等问题，本文设计了一种模仿人手抓取操作的夹持剪切式除草装置。通过对杂草根系的受力分析，确定最佳铲面倾角为 $10^{\circ}\sim 40^{\circ}$ 。以满足滑切条件为原则，对铲刃倾角进行分析计算，确定铲刃角为 30° 。基于摩尔-库仑剪切理论，确定除草铲宽度为 50mm。设定入土深度 40mm、夹持剪切速度 4cm/s，进行了铲面倾角单因素试验，结果表明：除草率在 85% 以上，伤苗率在 6% 以下，当铲面倾角为 30° 时，除草性能为最优值。

INTRODUCTION

Ridge tillage is one of the important farming methods in China, cultivating numerous food crops and supporting significant benefits to society, ecology, and economy (Liang et al., 2022). However, weeds grow disorderly on the ridges and compete with crops for sunlight, water, and nutrients, resulting in a decrease in crop yield and quality, causing huge losses to the agricultural economy (Li et al., 2022; Ahmad et al., 2020). To reduce labor costs and minimize environmental pollution, mechanical weeding is considered an ideal method (Fang et al., 2022; Dilipkumar et al., 2020). According to different weed operating areas in the field, mechanical weeding can be divided into intra-row weeding and inter-row weeding (Bing et al., 2021). Since intra-row weeds are closer to crops, there is a higher risk of damaging crops when removing weeds. Therefore, intra-row weeds are more difficult to control than inter-row weeds (Longzhe et al., 2021). At present, the optimization and innovation of intra-row weeding devices have become the research and focus of many scholars.

From the perspective of function, intra-row weeding devices can be divided into those that cut weed roots, those that separate weeds from soil, and those that combine both functions. Devices that cut weed roots mainly include rotary discs (Pérez-Ruiz et al., 2011) and swing hoes (Huang et al., 2012). The rotary discs were used earlier, and the weeding blades reciprocated rotating between crops to achieve the two actions of avoiding crops and weeding. They have a simple structure, but they cannot separate weed roots from the soil, therefore, weed control is not effective. The swing hoes mainly use the reciprocating swing of the weeding blades to achieve the actions of avoiding crop and weeding. The structure of this device is relatively compact and the crop injury rate is low, but current models use the pneumatic system to drive the swing weeding shovel, and the supporting power system is complex and heavy, making it unsuitable for lightweight operations. Devices that cut weed roots offer good crop-avoidance performance and minimize the risk of crop damage. However, the roots remain in the soil, leading to incomplete weeding. Devices that separate weeds mainly include finger weeder (Riemens et al., 2007), brush weeder (Ziwen et al., 2015), torsion weeder (Cirujeda et al., 2013) and cycloid hoe (Hu et al., 2012). The first three are relatively common weeding devices, but they can only remove weeds with shallow root systems and have a high risk of damaging crops; the cycloid hoe is

also a commonly used weeding device. Research on the cycloid hoe intra-row weeding device conducted by Hu Lian et al (*Hu et al., 2012*) shows that the weeding effect is remarkable and the damage to crops is less than 8%. However, the cycloid hoe structure is complex, the maintenance cost is high, and the control is difficult. Weeding devices that separate weeds can completely remove weeds from the soil, but there is a certain risk of damaging the crops. The main hybrid weeding devices include the rotary hoe (*Qinsong et al., 2022*). This device uses the rotation of the rotary hoe, and the needle teeth penetrate the soil to cut the weed roots and take them away from the soil. The hybrid type has a better weeding effect. However, the mechanism is generally complex and the production cost is high.

In summary, most existing intra-row weeding devices suffer from complex structures, poor adaptability, high crop injury rates, and suboptimal weeding performance. To address these challenges, this paper designs a clamping and shearing intra-row weeding device tailored for corn ridge fields, particularly for operations during the 3-4 leaf stage. The design mimics the hand-grasping motion, with a parallelogram mechanism used in the finger component to reduce drive elements and simplify the device's structure. The weeding device is mounted on a six-axis robotic arm, leveraging the arm's multi-degree-of-freedom and flexibility to perform crop-avoidance and weeding tasks. This enhances the device's field adaptability and minimizes crop damage. Key parameters are designed, and the device's effectiveness is validated through tests using crop injury and weed removal rates as evaluation indexes.

MATERIALS AND METHODS

Weeding device design

Weeding field environment

Ridge tillage is the most common farming method in China, with ridge parameters varying by region. In plain areas, ridge heights (H) range from 160~350 mm, ridge spacing (D_1) from 500~1000 mm, ridge top width (W_1) about 300 mm, and ridge bottom width (W_2) about 600 mm. Taking 3~5 leaf stage corn field as an example, the intra-row ridge spacing (D_2) is about 240~300 mm, with the planting ridge parameters shown in Fig. 1. Weeds grow unorderedly on the ridges. While tillage can effectively remove weeds between rows, intra-row weeds must be removed precisely to avoid accidentally damaging crops. According to field surveys and relevant literature (*Fujun et al., 2018*), weed roots typically extend about 20 mm below the surface, while corn roots at the same depth have a radial spread of about 50 mm. To protect crop roots, the diameter of the crop protected area is set to 60 mm.

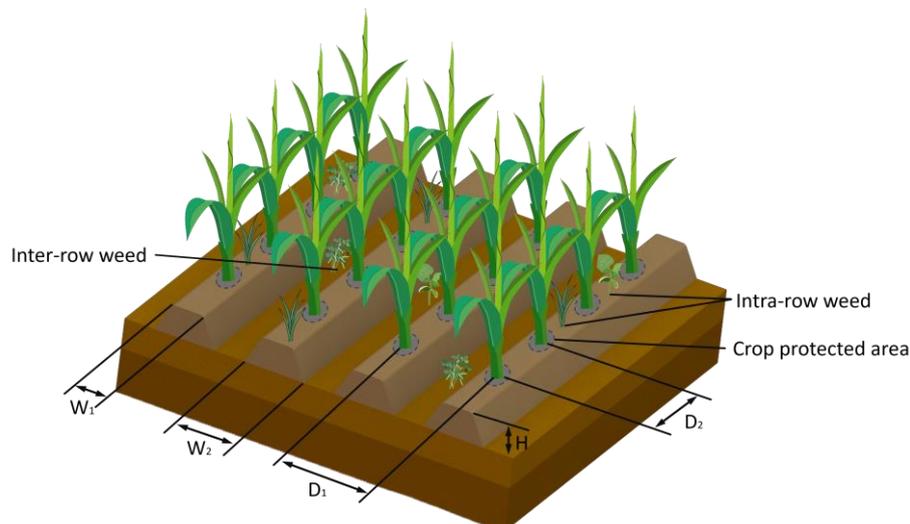

Fig. 1 - Ridge parameters

Weeding device configuration design

A human-like mechanical gripper is highly effective at grasping various objects due to its flexibility and adaptability (*Bircher et al., 2021*). Inspired by this, the weeding device in this paper is designed using the human hand as a bionic prototype. The human hand's structure primarily consists of an open kinematic chain with a series of moving and rotating joints. The configuration of the weeding device is divided into two main parts: the fingers and the palm. The fingers consist mainly of rotating joints, while the palm features moving joints. Key considerations in designing the fingers include the number and structure of the bionic fingers.

Having too many bionic fingers can complicate the structure and make control more difficult. Therefore, the number of bionic fingers should be minimized, provided the weeding function is maintained. For the palm, important factors include the connection between the palm and fingers, as well as the layout of the bionic fingers on the palm.

The configuration of the bionic weeding device designed in this paper is shown in Fig. 2. The device features four fingers, each with two degrees of freedom, comprising two joints and two connecting rods. The joints control the rotation angles of the connecting rods, allowing the fingers to bend by adjusting these angles. The fingers are symmetrically distributed on either side of the palm, which has one degree of freedom. The connection between the fingers and the palm is achieved through a slider pair, enabling the fingers to open and close.

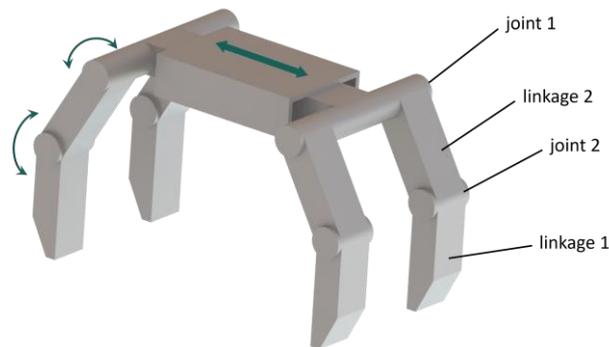

Fig. 2 - Weeding device configuration diagram

Weeding device structure design

Based on the configuration design described in the section 2.2, each finger has two degrees of freedom. To achieve full constraint, two drive elements are necessary. However, directly adding a drive element to the second joint would result in a bulky finger structure and require a large driving torque. To address this, a multi-link mechanism is employed for the single-finger design. By utilizing the characteristics of a parallelogram mechanism, a revolute pair is added to introduce a constraint, allowing the avoidance of placing drive elements at the second joint. This design makes the mechanism compact and lightweight. To further simplify the structure, the two fingers on the same side are driven synchronously by a double-head servo. The distal end of the finger, designed for weeding, is shaped like a cross-finger to closely mimic a human hand. The design model of the finger mechanism is shown in Fig. 3.

Fig. 3 - Finger design model

The design model of the palm is shown in Fig. 4. A single-head servo serves as the power source, driving the fingers at both ends of the palm. The inward and outward opening and closing movements of the fingers are achieved through a gear rack transmission mechanism.

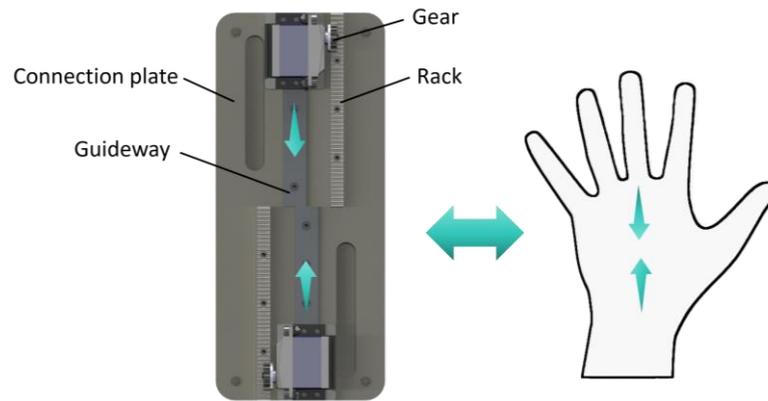

Fig. 4 - Palm design model

The overall structure of the weeding device is shown in Fig. 5. A double-head servo is connected to the second connecting rod of the two fingers on the same side, providing the necessary driving torque. This second connecting rod acts as a power arm, transmitting force to the weeding shovel via a parallelogram mechanism, allowing the shovels on both sides to mesh inward. The fingers on the same side are mounted on a shared slider, with a single-head servo driving their opening and closing along a guide rail through a gear rack transmission, thereby enabling the claw's movement.

The principle of avoiding crop and weeding of the weeding device

The weeding device is mounted on a six-axis robotic arm, and the operation process is divided into the avoiding crop process and the weeding process. The weeding operation is shown in Fig. 6.

(a) When the operation begins, the visual system first detects crops and weeds. If no weeds are detected, the robotic arm positions the weeding components in the neutral position between the rows. When the visual system detects weeds, a crop protection and a weeding areas are constructed.

(b) After identifying and locating the weeds, the robotic arm, receiving signals from the control system, maneuvers the weeding device to bypass the crops and position itself over the weeding area at an appropriate height, avoiding the crops.

(c) The weeding device's two double-head servos rotate the second connecting rod, causing the weeding shovels to move toward the center. The tips of the shovels penetrate and break the soil surface, initiating the weeding process.

(d) Once the soil-breaking is completed, the double-head servos cease rotation. Then, the single-head servos engage, rotating gears on a rack that slides the two clamping claws toward the center along the guide rail. The weeding shovels advance into the field ridge at a fixed angle, continuing to break the soil. The root-soil complex is then sheared under the combined effects of gravity and soil friction, gradually lifting along the shovel surface as the shovels mesh, initially separating the weed roots from the soil. Once the shovels completely mesh and shear the weed roots, the single-head servos stop.

(e) Finally, the robotic arm lifts the weeding device, completely separating the weeds from the soil. After the weeds are clamped and removed from the soil, all servos reverse direction, returning the weeding device to its initial state, simultaneously releasing the weeds, thereby completing the weeding operation.

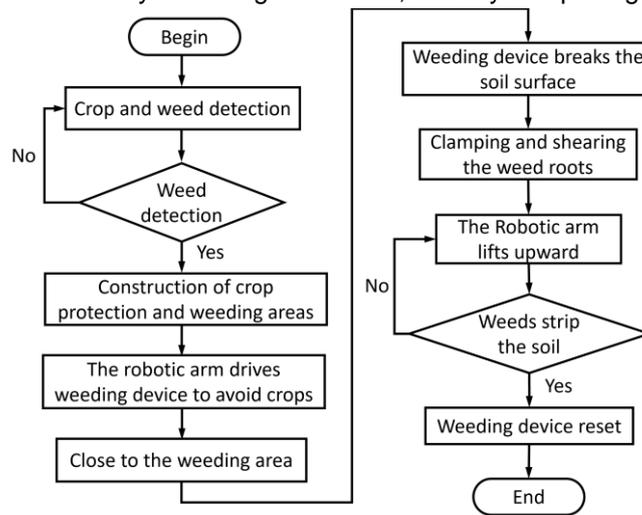

Fig. 6 - Flow chart for the weeding operation

Design of key parameters of weeding device

In order to meet the operation requirements of the weeding device, its key parameters are designed in this paper. These requirements include minimizing soil excavation during weed removal, possessing the ability to crush clay, incorporating a self-cleaning function in the weeding shovel to prevent grass and soil buildup, and ensuring excellent wear resistance.

Shovel surface inclination angle

The integrity of weeds is closely linked to the stability of their roots. Therefore, to ensure the complete removal of weeds from the soil, it is essential to disrupt the stability of the weed roots. The force analysis during the clamping and shearing process is shown in Fig. 7.

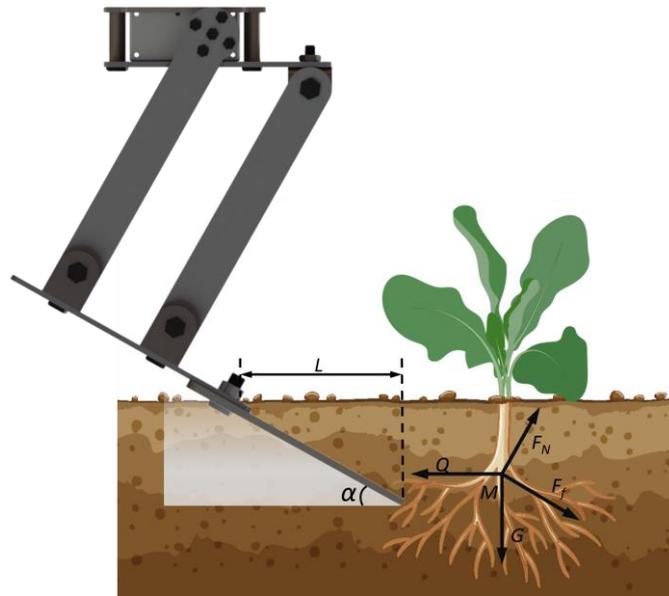

Fig. 7 - Force analysis diagram of weed root

Note: F_N is the support of weeding shovel to weed roots; F_f is the friction between root-soil complex and weeding shovel; G is the gravity of weed roots; Q is the force required to move the weed; α is shovel surface inclination angle; point M is the center of the weed roots; L is the projection length of weeding shovel in the horizontal direction

From the force analysis in Fig. 7, the force on the weed root in the X and Y directions is:

$$F_f \cos \alpha + F_N \cos(\pi / 2 - \alpha) = m_0 a_x \tag{1}$$

$$F_N \sin(\pi / 2 - \alpha) - F_f \sin \alpha - G = m_0 a_y \tag{2}$$

This is obtained from the momentum theorem:

$$\left[F_f \cos \alpha + F_N \cos(\pi/2 - \alpha) \right] \Delta t = m_0 v \quad (3)$$

where:

m_0 is the quality of weeds, kg; Δt is the time of weeding shovel acting on weeds, s; v is inward clamping-speed of weeding shovel, cm/s; a_x is acceleration of weed root moving in horizontal direction, cm/s²; a_y is acceleration of weed root moving in vertical direction, cm/s².

From Eq. (1) and (2), it is evident that a_x increases with an increase in the shovel surface inclination angle, while a_y decreases as the angle rises. Eq. (3) shows that when the clamping speed v of the weeding shovel is constant, an increase in the shovel surface inclination angle leads to a decrease in the L . This results in a shorter horizontal contact time between the weeds and the weeding shovel, increasing the impulse. Consequently, as the shovel surface inclination angle rises, the stability of the weed root system diminishes, making it easier to disrupt the roots. However, if the angle is excessively large, the resistance encountered during the clamping shear of the weeding shovel will also increase. Combined with the analysis of the operation process of the weeding shovel and the root-soil complex, the mechanical relationship between the two is obtained:

$$F_f + G \sin \alpha = Q \cos \alpha \quad (4)$$

$$G \sin \alpha + Q \sin \alpha = F_N \quad (5)$$

$$F_f = \mu_1 F_N \quad (6)$$

$$\alpha \leq \arctg \frac{Q - \mu_1 G}{\mu_1 Q + G} \quad (7)$$

where: μ_1 is the friction factor between soil and weeding shovel.

Through preliminary field tests, it was found that the force required to move the weeds was 10 N, the weight of the weed roots was 0.05 N, and the friction factor between the soil and the weeding shovel was 0.7. Applying these values to Eq. (7), it was determined that $\alpha \leq 54^\circ$. However, when $\alpha \leq 10^\circ$, the depth of the weeding shovel's penetration into the soil is insufficient, preventing complete weed removal. Based on this analysis and referencing relevant literature (Jinchuan *et al.*, 2017), the optimal range for the weeding shovel inclination angle is $10^\circ \leq \alpha \leq 40^\circ$ to ensure effective weeding while minimizing working resistance.

Shovel blade angle

During the weeding process, the weeding shovel must demonstrate effective soil penetration and a self-cleaning function for its surface. To achieve this, it is essential to ensure that the sliding cutting force of the soil on the blade exceeds the friction force between the soil and the blade. The force of the weeding shovel blade designed in this paper is shown in Fig. 8.

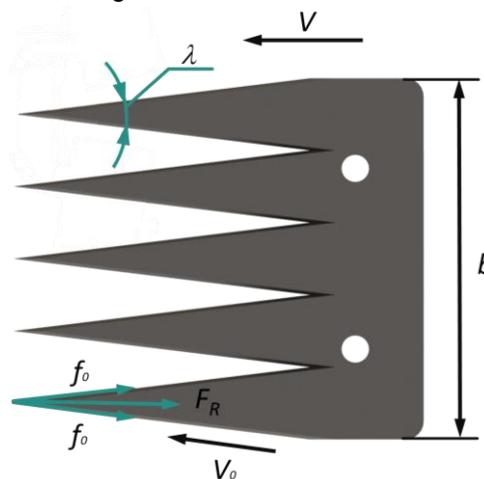

Fig. 8 - Force analysis diagram of weeding shovel blade

Note: F_R is the sliding cutting force on the blade, N; f_0 is the friction between soil and shovel blade, N; v_0 is the sliding cutting speed, cm/s.

Sliding cutting conditions should meet:

$$F_R \sin(90^\circ - \frac{\lambda}{2}) \geq f_0 \quad (8)$$

$$f_0 = \tan \varphi F_R \cos(90^\circ - \frac{\lambda}{2}) \quad (9)$$

where:

λ is shovel blade angle, ($^\circ$); φ is the friction angle between soil and weeding shovel surface, ($^\circ$).

From Eq. (8) and Eq. (9), shovel blade angle λ should be satisfied:

$$90^\circ - \frac{\lambda}{2} \geq \varphi \quad (10)$$

$$\mu_2 = \tan \varphi \quad (11)$$

where:

μ_2 is the friction factor between weed root and weeding shovel.

It can also be seen from Fig. 8 that the relationship between v and v_0 is :

$$v_0 = v \cos \frac{\lambda}{2} \quad (12)$$

Through the actual field measurements and reference to relevant literature (Jinchuan *et al.*, 2017), the friction factor between the soil and the weeding shovel is 0.569~0.718, and the friction factor between the weed root and the weeding shovel is 0.89~0.97, so it is enough to meet the friction factor between the weed root and the weeding shovel, and it can be brought into the Eqs. (10) and (11) to calculate that $\lambda \leq 120^\circ$ can meet the requirements. It can be seen from Eq. (12), that the smaller the λ , the smaller the v_0 , so the weeding shovel weeding process is more stable, however, when $\lambda < 30^\circ$, the weeding shovel strength is greatly reduced, resulting in weeding shovel wear and tear aggravated, and easy to cause the shovel surface bending, so the weeding shovel blade angle is designed for 30° .

Weeding shovel width

In order to further improve the performance of the weeding device, reduce the resistance in the weeding process, and ensure the smooth shear removal of the weed root-soil complex, the weeding shovel width is designed. In order to completely remove the weed root, the weeding shovel width should be greater than the radiation diameter of the weed root. The weeding shovel width is calculated as:

$$w \geq d + \varepsilon + n \quad (13)$$

where:

w is the weeding shovel width, mm; d is the radiation diameter of weed roots, mm; n is the weeding shovel operation deviation; ε is the standard deviation of weed root diameter.

Through relevant literatures and field research (Longzhe *et al.*, 2021), the depth of weed roots under the surface is about 20 mm, the radiation diameter is about 40 mm, the weeding shovel operation deviation is 7 mm, and the standard deviation of weed root diameter is 3 mm. Therefore, the width of weeding shovel should be $w \geq 50$ mm.

According to the shovel structure resistance model of Mohr-Coulomb soil shear theory proposed by Wheeler *et al.*, (1996), the resistance during the inward clamping process of the weeding shovel is also related to the weeding shovel width. The resistance model is shown in Fig. 9. When the weeding shovel is clamped and sheared inward at speed v , the soil in the triangular ABC area in front of the weeding shovel produces resistance P to the shovel surface, which can be divided into horizontal force F_x and vertical force F_y . In the absence of other external forces applied to the soil:

$$F_x = (\gamma h^2 N_\gamma + chN_{ca}) [w + h(m - (m-1)/3) + \gamma v^2 N_a h(w + 0.6h)] \sin(\alpha + \varphi) \quad (14)$$

$$F_y = (\gamma h^2 N_\gamma + chN_{ca}) [w + h(m - (m-1)/3) + \gamma v^2 N_a h(w + 0.6h)] \cos(\alpha + \varphi) \quad (15)$$

where:

γ is the soil volume weight, $\text{kg}\cdot\text{m}^{-3}$; c is the soil cohesion, $\text{kN}\cdot\text{m}^{-2}$; h is the depth of weeding shovel into soil, mm; m is the soil fracture width-depth ratio; N_γ is the soil gravity coefficient; N_{ca} is the soil bonding coefficient; N_a is the soil inertia coefficient.

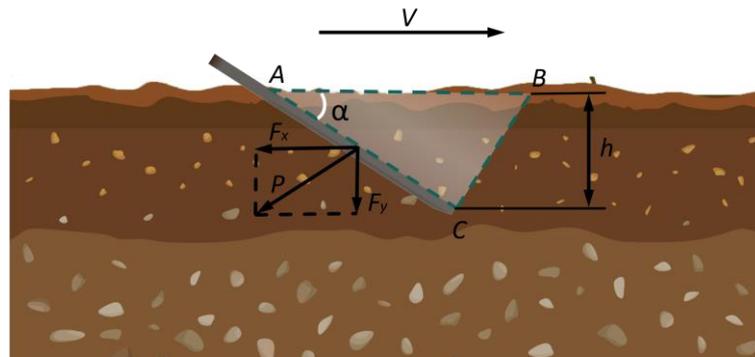

Fig. 9 - Resistance model diagram

Therefore, the resistance P is:

$$P = (\gamma h^2 N_\gamma + ch N_{ca} + \gamma v^2 h N_a) w \quad (16)$$

It can be seen from Eq. (16) that under the condition of a certain clamping speed, the resistance of the weeding shovel is linearly related to the width of the shovel surface, and the larger the width of the shovel surface, the greater the resistance of the weeding shovel. Therefore, in the case of smooth shearing and removing weeds, the weeding shovel width should be as small as possible. Combined with Eq. (13), the weeding shovel width is designed to be 50 mm, which can ensure that the weeding shovel can completely remove the weeds under the condition of small resistance.

Test and result analysis

Test condition

This test simulated the corn ridge field environment and was conducted in the Robotics Laboratory of the School of Mechanical and Electrical Engineering, Northeast Forestry University. The main test equipment includes a weeding device, AUBO-E5 robotic arm, LegionY7000P computer, mobile power supply, etc., as shown in Fig. 10. The weeding device is installed on the AUBO-E5 robotic arm test platform, and the speed of the robotic arm is adjustable.

The constructed ridge length is 3 m, the ridge distance is 600 mm, the average ridge height is 200 mm, and the soil water content is 17%~18%. The focus of this study is to verify the weeding effect of the weeding device. Therefore, in this test, the 3-4 leaf stage corps with similar sizes were used to replace the real corns and the weeds were transplanted to the weeds growing in the natural environment of the field. In order to reduce the test error, the distribution of crops and weeds in each group was as consistent as possible. The sample crop distance is 240~300 mm, and the weed density is 0.01~0.02 plants/ cm^2 .

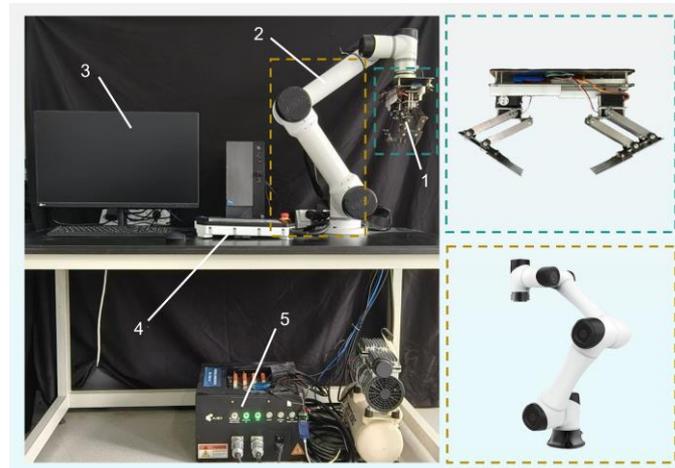

Fig. 10 - Test environment

1. weeding device; 2. robotic arm; 3. desktop computer; 4. control panel; 5. mobile power supply

Test method

Based on the determination of key parameters for the weeding components, insights from relevant literature, and field testing experience, it is evident that a small shovel surface inclination angle negatively impacts the weeding effect, while a large inclination angle increases weeding resistance. Therefore, the selected inclination angle is set to 10°~40°, and a single-factor test is conducted. The weeding operation process is illustrated in Fig. 11.

The weeding device remains in an initial state, ready for operation. The visual system identifies and locates the weeds, after which the robotic arm drives the weeding device to avoid the crops and position itself in the designated weeding area. The weeding device, powered by two sets of steering engines, performs the actions of breaking the soil and clamping and shearing the weeds roots. Once complete, the mechanical arm lifts the weeding device to separate the weeds from the soil. After the weeding operation, the mechanical arm resets the device in preparation for the next task.

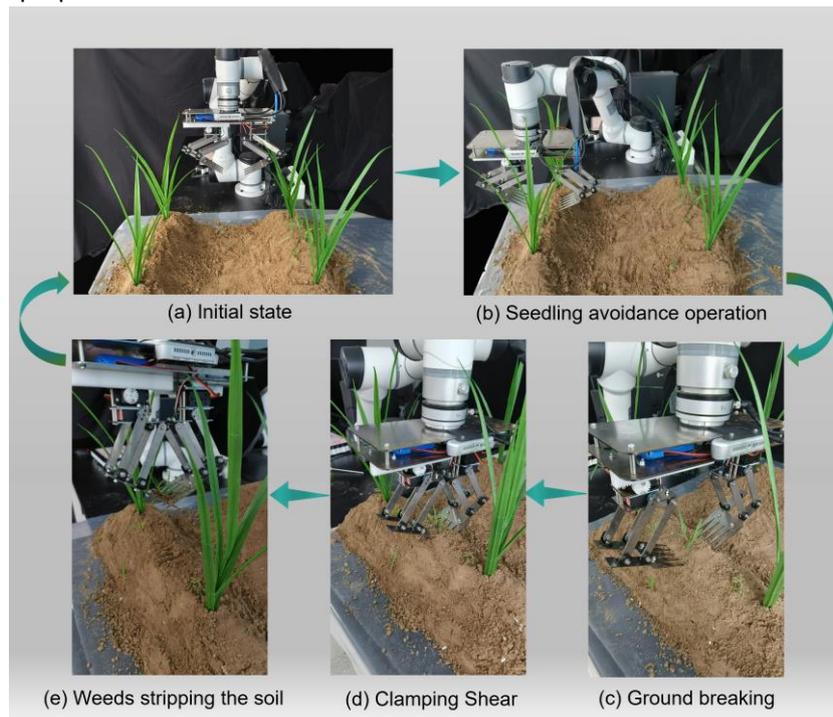

Fig. 11 - Weeding operation process

Weeding operation process

In this test, the crop injury rate and weed removal rate were used as test indexes. Successful weeding was defined by the cutting and destruction of the weeding area and the removal of soil. Due to test limitations, the corns used were at the 3-5 leaf stage. During the test, any sample crops that were uprooted or significantly displaced were considered injured. The number of injuries was counted manually. The calculation formula for the test metrics is as follows (Bao et al., 2020):

$$k = \frac{Q_z - H_z}{Q_z} \times 100\% \quad (17)$$

$$s = \frac{M_s}{M_z} \times 100\% \quad (18)$$

where:

k is weed removal rate, %; Q_z is the number of weeds before weeding in the test area; H_z is the number of weed plants after weeding in the test area; s is crop injury rate, %; M_s is the number of injured crops after weeding in test area; M_z is the number of injured crops before weeding in test area.

RESULTS

According to the previous test research, the deepest penetration depth $p=40$ mm and the clamping shear speed $v=4$ cm/s were set. According to the shovel surface inclination angle ranging from 10° to 40°, the

test was set to 7 levels of 10°, 15°, 20°, 25°, 30°, 35° and 40°. The test results are shown in Table 1, and the relationship between each performance evaluation index and the shovel surface inclination angle is shown in Figure 12.

As shown in Table 1, the weed removal rate exceeds 85%, while the crop injury rate remains below 6%. These results indicate that the weeding device has a reasonable structure and effectively meets the current needs for intra-row weeding in the field.

Table 1

Results of weeding test					
Test number	Shovel surface inclination angle (°)	Penetration depth (mm)	Clamping-shear speed (cm/s)	Weed removal rate (%)	Crop injury rate (%)
1	10	40	4	85	3
2	15	40	4	85.5	3.3
3	20	40	4	86.3	3.5
4	25	40	4	87.2	3.7
5	30	40	4	88.8	4.2
6	35	40	4	89.6	4.7
7	40	40	4	90	5.5

As shown in Fig. 13, with the increase of the shovel surface inclination angle, the weed removal rate first increased slowly, and then tended to be stable, and the crop injury rate first increased slowly and then increased sharply. When $\geq 30^\circ$, the weed removal rate tends to be stable, but the crop injury rate rises sharply. Therefore, the suitable range of the inclination angle is 10°~30°. Considering the weeding shovel penetration ability, weeding resistance and intra-row soiling effect in the process of intra-row weeding device, $\approx 30^\circ$ is the better value.

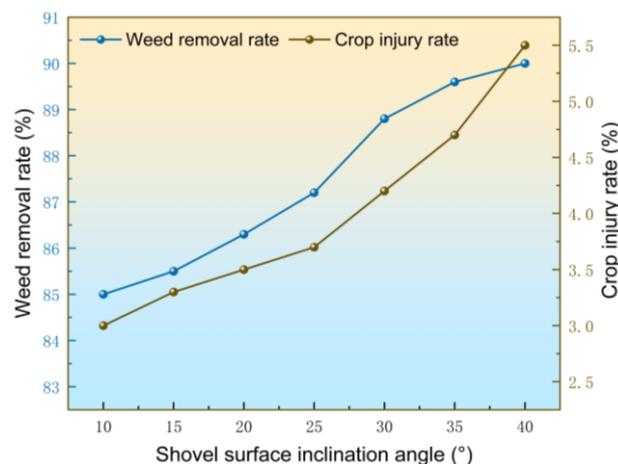

Fig. 12 - The relationship between evaluation index and the shovel surface inclination angle

CONCLUSIONS

(1) For intra-row weeding in ridge fields, a clamping-shear intra-row weeding device was designed by imitating the clamping operation of human hands. The weeding shovel part of the device adopts a parallelogram mechanism, which makes the finger mechanism compact and lightweight, effectively reduces the driving torque, and prolongs the life of the steering gear. The weeding part is mounted on the six-axis manipulator. When the visual system does not recognize the weed, the manipulator drives the weeding part to be in the neutral position between the rows. When the visual system recognizes the weed, the manipulator drives the weeding part to bypass the crop, and the weeding device is accurately moved to the weeding area for weeding.

(2) Through the analysis of the forces acting on the weeding shovel during the clamping and shearing of weeds, it was concluded that the stability of the weed root system decreases as the digging angle of the shovel increases. Consequently, the optimal inclination angle for the weeding shovel was determined to be between 10° and 40°. By analyzing and calculating the shovel blade angle, it is determined that when the blade angle is 30°, there will be no winding grass and soil in the weeding operation. Additionally, a resistance model was established based on the Mohr-Coulomb soil shear theory, leading to the determination of the weeding shovel width, which was set at 50 mm to ensure minimal resistance while completely removing weeds.

(3) On the test platform built in the laboratory, the designed weeding device was tested with the shovel inclination angle as a single factor. The test results showed that the weed removal rate of the weeding device was above 85 %, and the crop injury rate was below 6 %. Meet the requirements of intra-row weeding in the ridge field, and when the shovel inclination angle is 30°, the weeding performance of the device is optimal. The research in this paper can provide a reference for the design and improvement of intra-row weeding devices in ridge fields.

DETECTION OF ADULT PEACH FRUIT MOTH BASED ON IMPROVED YOLOv8m

/ 基于改进 YOLOV8M 的桃小食心虫成虫检测方法

Lijun CHENG^{*1)}, Yihe ZHANG¹⁾, Jianglin YAN¹⁾, Zhengkun ZHAI¹⁾, Zhiguo ZHAO^{*2)}, LinQiang DENG¹⁾¹⁾ College of Software, Shanxi Agricultural University, Taigu, Shanxi / China;²⁾ College of Software, Shanxi Agricultural University, Taigu, Shanxi / ChinaCorresponding authors: Lijun Cheng; Tel: +86-13835441585; E-mail: cljzyb@sxau.edu.cnZhiguo Zhao; Tel: +86-15034664518; E-mail: nice2me@126.comDOI: <https://doi.org/10.35633/inmateh-75-05>**Keywords:** YOLOv8m; pest detection; down sampling; CPCA attention mechanism; Inner-WIoU**ABSTRACT**

The peach fruit moth was a fruit-eating pest and one of the major pests of fruit trees in China, Korea, Japan, and Australia. Due to long-term problems such as improper control methods, low technical quality, and untimely treatment, the yield and efficiency of fruit products were greatly affected, which constrained the development of the fruit industry. This paper developed a method for detecting adult peach fruit moths based on an improved YOLOv8m to address the challenging problem of manually detecting peach fruit moths. To increase the Receptive Field of the model, v7Down Sampling was introduced in its backbone network. Then, the channel-prioritized Convolutional Attention Mechanism Module (CPCA), which dynamically allocated the spatial attention weights on each channel, reducing the noise and the algorithm's complexity, was incorporated. Finally, the inner-WIoU loss function was introduced to enhance the convergence and generalization of the bounding box. The precision (P) of the improved model increased by 3.4 percentage points compared to YOLOv8m. The recall (R) improved by 2.1 percentage points, and the mAP improved by 1.2 percentage points. The single-category precision (AP) for peach fruit moth detection improved by 2.4 percentage points. Moreover, the weight size, number of model parameters, and computational volume were reduced by 3.6MB, 1.8M, and 1.7G, respectively. This achieved an improvement in the model's effectiveness in detecting adult peach fruit moths without increasing the model's complexity. The results provided strong technical support for the subsequent real-time monitoring of the peach fruit moth.

摘要

桃小食心虫是一种食果害虫，也是中国、韩国、日本、澳大利亚等果树的主要害虫之一。因为长期的防治方法不当、技术素质低、处理不及时等问题，使果品的产量和效益都受到很大影响，制约果业的发展。本文针对人工检测桃小食心虫困难问题，开发了一种基于改进 YOLOv8m 的桃小食心虫成虫检测方法。我们在其主干网络引入 v7Down Sampling，增加模型的感受野。然后引入通道优先卷积注意力机制模块（CPCA），动态分配各个通道上的空间注意力权重，减少了噪声及算法的复杂度。最后引入 Inner-WIoU 损失函数，增强了边界框的收敛和泛化能力。改进后模型的精确度 P 相较 YOLOv8m 提高了 3.4 个百分点。召回率 R 提高了 2.1 个百分点。mAP 提高了 1.2 个百分点。桃小食心虫单类别精度 AP 上提高了 2.4 个百分点。并且权重大小、模型参数量和计算量分别减少了 3.6MB、1.8M、1.7G。实现了在不增加模型复杂度的同时提高模型对桃小食心虫成虫的检测效果，其结果可为后续桃小食心虫的实时监测提供有力的技术支撑。

INTRODUCTION

The peach fruit moth (*Carposina sasakii* Matsumura), is a fruit-eating pest of the genus Peach Fruit Moth in the family Lepidoptera. It is widely distributed and has a serious infestation in China, Japan, Korea, Russia, Australia, and other countries (Kim et al., 2000). The peach fruit moth had a wide range of host plants, with the Rosaceae, Rhamnaceae, and Pomegranateaceae being the primary ones. When the damage was severe, it caused worm droppings and rotten fruits, which directly affected the yield and quality of fruits and resulted in significant economic losses (Fang et al., 2022). Prediction could prevent the occurrence of the pest in advance based on the dynamic patterns of its emergence. At present, the detection and counting of adult peach fruit moths relied on visual discrimination. From 2021 to 2022, Zhang Xiaowei monitored the population size of adult pear fruit moths and peach fruit moths in pear orchards in Shanxi Province. This study was conducted manually for two consecutive years, using pear orchards in Shanxi Province as monitoring sites. It provided a theoretical basis for the prediction and integrated management of these two types of pear fruit moths (Zhang et al., 2024).

This manual method of detecting and counting peach fruit moths was time-consuming and inefficient. Moreover, the number of adult peach fruit moths was high during the peak incidence period, and accurate counting was challenging due to the wide range of infested fruit species (Zhang *et al.*, 2023). These difficulties seriously hindered the accurate control of peach fruit moths.

In recent years, the level of agricultural intelligence gradually increased, and deep learning detection algorithms were applied to the field of agricultural pest detection (Yue *et al.*, 2024). Min Dai *et al.*, (2023), proposed an improved plant pest detection method based on YOLOv5m. Experimental results showed that the improved YOLOv5m achieved 95.7% accuracy, a 93.1% recall rate, a 94.38% F1 score, and a 96.4% mean average precision (mAP). Li Bin proposed an improved YOLOv5 rice pest detection method, and the mAP value of the improved model was 1.49 percentage points higher than that of YOLOv7 and 12.89 percentage points higher than that of Faster R-CNN (Li *et al.*, 2024). Ma Pan *et al.*, (2023), proposed a cotton aphid image detection algorithm based on the YOLO neural network and integrated it into software. The average time for cotton aphid image detection was 4.1 seconds, and the counting accuracy for both live and dead cotton aphids exceeded 93%. The use of deep learning algorithms could enable the rapid detection of peach fruit moths, significantly improving detection efficiency. Therefore, this study aimed to use a YOLO series of algorithms to address the problems of difficult target recognition and low detection accuracy caused by background clutter and overly dense samples in the peach fruit moth dataset. The base model was optimized and improved to provide a model basis for the detection of peach fruit moths.

MATERIALS AND METHODS

Data set establishment

The adult peach fruit moth dataset used in this study was obtained from the Institute of Fruit Tree Research, Shanxi Agricultural University, Taigu District, Jinzhong City, Shanxi Province, China. In this study, triangular traps were hung on fruit trees 1.2-1.5 m above the ground in pear and apple orchards from May to October 2023 -2024. The traps consisted of a triangular trap frame, white sticky boards, and peach fruit moth traps (Zhao *et al.*, 2023). 2-3 days later, the white sticky boards were removed and images of the dataset were captured with a Nikon D7000 camera from different angles. A total of 1781 images in JPG format were taken in this study, as shown in Fig. 1.

The 1781 original data were randomly divided into a training set (1068), a validation set (356), and a test set (357) in the ratio of 6:2:2 to ensure that the training set and validation set were completely independent and not duplicated. To improve the generalization ability and robustness of the model during the training process, this study first uses Open Computer Vision Library (OpenCV) and randomly selects Gaussian fuzzy, adding noise, rotation, brightness change, flipping panning, and other methods for data enhancement of the divided training set. A dataset containing 4982 images was finally obtained, of which 4269 were for the training set, 356 for the validation set, and 357 for the test set. In the process of data collection, it was found that in addition to peach small heartworms, many pear small heartworms and Chinese pear louse also appeared on the white sticky board. Therefore, in this experiment, adult pear small heartworm and Chinese pear louse were added to the data categories, and the data set was labelled with the software Labellmg. The labelling was divided into “*Carposina lipogenesis*”, “*Psylla chinensis*” and “Oriental Fruit Moth”.

Improved YOLOv8m target detection algorithm

The improved YOLOv8m model structure in this paper is shown in Fig. 2. Firstly, the v7Down Sampling (v7DS) from YOLOv7 was added to the backbone network of YOLOv8. Then, the Channel-Prior Convolutional Attention Mechanism Module (CPCABlock) was incorporated into the backbone section. Finally, the Inner-WIoU loss function was introduced.

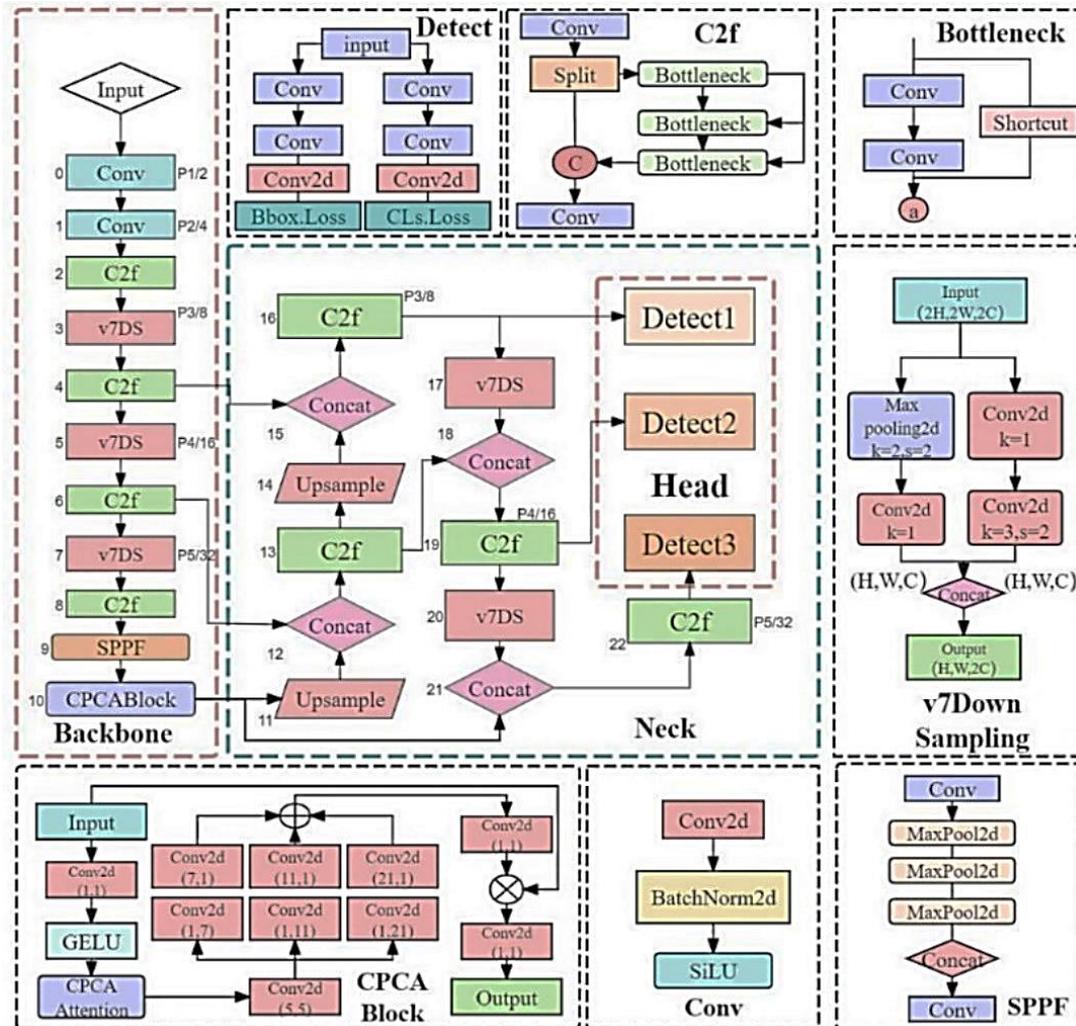

Fig. 2 - Improved YOLOv8m model structure diagram

Conv is convolution, V7DownSampling is the YOLOv7 downsampling module, SPPF is the spatial pyramid pooling module, CPCABlock is the channel-first convolutional attention mechanism module, Contact is the feature connection module, Upsample is upsampling module, Detect is detection head, Bbox. Loss and Cls. Loss is bounding box loss and classification loss, Split is the slice operation, Bottleneck is the bottleneck layer, SiLU is the activation function, MaxPooling is the maximum pooling operation, Maxpool2d is the maximum pooling, Conv is the convolution, Contact is the feature connection module and Bbox. Loss and Cls. The Losses are bounding box losses and classification losses, respectively.

Downsampling Module v7DS

Downsampling is a commonly used image processing method in image detection. It can shrink the image without altering its effective content, reduce the image resolution, decrease the amount of data computation, and generate a downsampling map corresponding to the image. This helps extract high-level semantic features from the image and increases the model's Receptive Field, thereby enhancing the model's ability to detect targets (Lin et al., 2023).

The downsampling v7DS of YOLOv7 utilizes the Spatial Pyramid Pooling (SPP) structure. It produces a feature map with the number of output channels equal to the number of input channels and reduces the spatial resolution by a factor of two. The structure is shown in Figure 3 below. By reducing the size and resolution of the input image and the computational load of the model, the network can better capture features in the image, process detailed information of the input image, and handle large image data more efficiently (Wang et al., 2022).

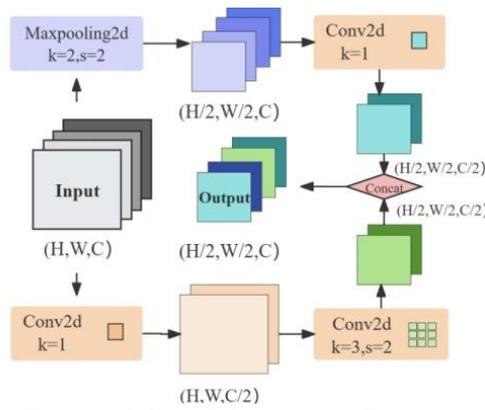

Fig. 3 -v7DS model structure diagram

Channel Prioritized Convolutional Attention Mechanism Module

The peach fruit moth dataset was collected in an open-air environment and was characterized by a cluttered background and fuzzy samples, which required the model to have the ability to judge target objects more accurately. The attention mechanism can suppress the expressive ability of non-essential features on the feature map and enhance the expressive ability of main features, effectively weakening the influence of the cluttered background on the detection results during the detection process.

The Channel-Prior Convolutional Attention Mechanism (CPCA), proposed by Hejun Huang et al. (Huang et al., 2024), combines channel attention and spatial attention. It reduces noise and algorithm complexity while achieving dynamic allocation of spatial attention weights on each channel. CPCA is a lightweight yet high-performance attention mechanism that can alleviate computational burden. The model structure is shown in Figure 4 below.

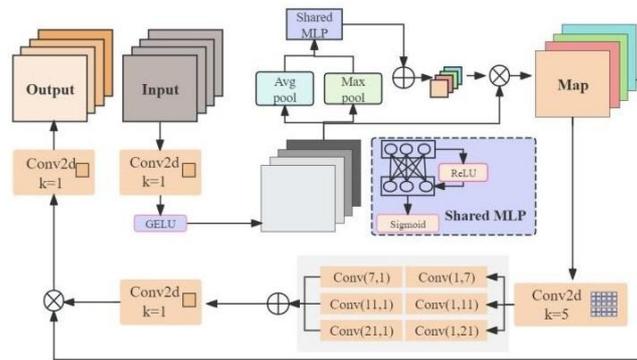

Fig. 4 -CPCABlock module structure diagram

Channel Attention Module of CPCA: The input feature maps are subjected to global average pooling and global maximum pooling respectively to obtain new feature maps, then the weight coefficients are obtained through the σ function, and the weight coefficients are multiplied with the new feature maps to finally obtain the output feature maps, which is calculated as in equation (1).

$$CA(F)=\sigma\left(MLP(AvgPool(F_m))+MLP(MaxPool(F_m))\right) \tag{1}$$

where: σ is the Sigmoid function, *AvgPool* is the global average pooling, and *MaxPool* is the global maximum pooling (Wang et al., 2024).

Spatial Attention Module for CPCA: Utilizing depth-separable convolution to capture spatial relationships between features, a multi-scale structure is used to enhance the ability of the convolution operation to capture spatial relationships, which is calculated as in equation (2).

$$SA(F)=Conv_{1\times 1}\left(\sum_{i=0}^3 Branch_i(DwConv(F))\right) \tag{2}$$

where: *DwConv* denotes the depth convolution. *Branch_i*, $i\in\{0,1,2,3\}$ denotes the *i*-th branch. *Branch₀* is the identity connection.

Inner-WIoU loss function

The peach fruit moth dataset has problems such as high sample density and different target scales, *Inner-WIoU* implements the similarity calculation by considering the scale difference between the auxiliary

border and the actual border, which is suitable for the situation that needs to adjust the loss of focus dynamically and meets the needs of this experiment. As shown in Fig. 5.

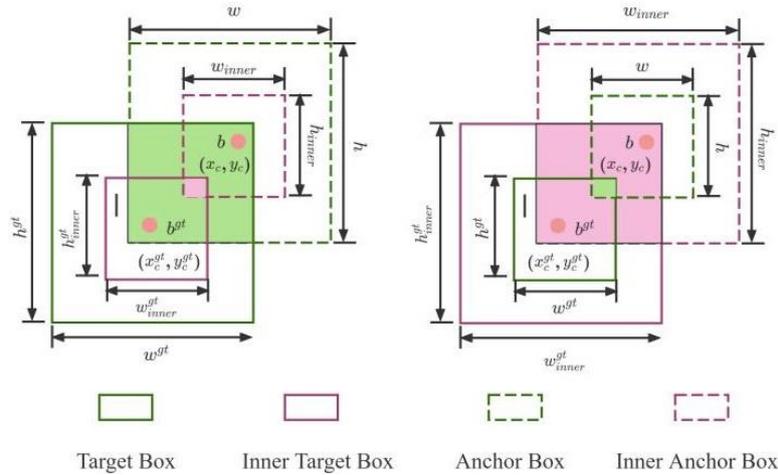

Fig. 5 -Description of Inner-WIoU

Inner-IoU is a combination of loss functions such as *EIoU* and *WIoU* using the idea of Inner. It controls the scale size of the auxiliary bounding box for calculating the loss by introducing the scale factor ratio, which can simultaneously take into account the convergence of the high *IoU* samples and the regression of the low *IoU*, and overcomes the limitations of the existing methods in terms of generalization ability (Zhang et al., 2023). *WIoU* is a kind of bounding box loss based on the dynamic non-monotonous focusing mechanism, whose loss function is shown in Eq. (3):

$$L_{WIoU} = r \times R_{WIoU} \times L_{WIoU}, R_{WIoU} \in [0, 1] \quad (3)$$

where: the distance focusing mechanism is used to amplify the ordinary moderate anchor frame L_{IoU} , and the non-monotonic focusing coefficient r is used to focus the ordinary quality anchor frame, which provides better target frame regression loss to improve the performance of the target detector. *WIoU* removes the aspect ratio penalty term in *CIoU*, and also balances the effects of high and low-quality anchor frames on the regression of the model, which enhances the model's generalization ability, and improves the model's overall performance (Tong et al., 2023).

The *Inner-IoU* is applied to the existing *WIoU*-based marginal regression loss function defined as in equation (4):

$$L_{Inner-WIoU} = L_{WIoU} + IoU - IoU^{inner} \quad (4)$$

Experimental Platform

The main parameters of the AutoDL server platform used in this experiment are as follows: 12 vCPU Intel(R) Xeon(R) Silver 4214R CPU with 2.40 GHz, 90 GB of RAM, and an RTX 3080 Ti (12 GB) GPU. The experiments were conducted on the Linux operating system, and the PyTorch deep learning framework was used for model building, training, and evaluation. The model was built, trained, and evaluated using PyTorch version 1.13.1, Python version 3.8.6 (Ubuntu 20.04), and CUDA version 11.7.

Training Parameter Settings

The image input size was set to 640×640, the batch size was set to 16, and multithreading was configured to 8. The Stochastic Gradient Descent (SGD) optimizer was selected, and the training rounds were set to 200 with YOLOv8m's early stopping mechanism applied. The initial learning rate was 0.01, and the final learning rate was 0.001. The momentum parameter was set to 0.937, and the weight decay parameter was set to 0.0005. The random seed was fixed at 0.

Evaluation Metrics

To evaluate the performance of the model's detection results on the peach fruit moth dataset, the following evaluation criteria were chosen: precision (P), recall (R), mean average precision (mAP@0.5), mAP@0.5:0.95, single-category precision for peach fruit moth (**Carposina sasakii** AP%), number of parameters (Params), model weights (Weight), and computational volume (FLOPs). These metrics were used to assess the model's effectiveness in detecting peach fruit moths and to compare its performance with other models.

RESULTS

Ablation Experiments

Ablation experiments were conducted for different improvement points, and the results are shown in Table 1. YOLOv8m-A introduced v7DS for downsampling in the backbone network, which improved the single-category accuracy of the peach fruit moth by 3.1 percentage points. YOLOv8m-B introduced the CPCA attention mechanism in the backbone network, which significantly reduced model weights and computational load. It reduced the weights by 45.52 MB and the computational volume by 70.3 G, respectively, compared to YOLOv8m. YOLOv8m-C introduced the Inner-WIoU loss function in the backbone network, which improved the all-category precision (P) by 1.6 percentage points over the original model. Both YOLOv8m-D and YOLOv8m-E showed improved performance compared to YOLOv8m. However, the YOLOv8m-VCI model, which incorporated all three improvement points, demonstrated even more significant enhancements. It achieved a 3.4 percentage point improvement in precision (P) compared to YOLOv8m. The recall (R) improved by 2.1 percentage points, and the mAP improved by 1.2 percentage points. The single-category precision (AP) for peach fruit moth detection improved by 2.4 percentage points. Additionally, the weight size, the number of model parameters, and the computational volume were reduced by 3.6 MB, 1.8 M, and 1.7 G, respectively. These improvements enhanced the model's detection effectiveness for adult peach fruit moths without increasing the model's complexity.

Table 1

Ablation test results for different improvement points.

Model	v7DS	CPCA	Inner-WIoU	P	R	mAP@0.5	AP	Weight	Params	FLOPs
				[%]	[%]	[%]	[%]	[MB]	[M]	[G]
YOLOv8m	—	—	—	84.8	84.4	85.6	92.2	52	25.8	78.7
YOLOv8m-A	√	—	—	85.6	84.5	86.3	95.3	47.2	23.4	76.2
YOLOv8m-B	—	√	—	85.0	84.1	85.6	94.4	6.5	31.	8.4
YOLOv8m-C	—	—	√	86.4	84.0	86.4	94.1	52	25.8	78.7
YOLOv8m-D	√	√	—	85.7	85.3	86.0	93.6	48.4	24.0	77.0
YOLOv8m-E	√	—	√	88.0	83.2	87.0	93.6	47.2	23.4	76.2
YOLOv8m-VCI	√	√	√	88.2	86.5	86.8	94.6	48.	24.0	77.0

Note: √ indicates that the module is used; — indicates that the module is not used

Detection results of YOLOv8m-VCI

(1) The improved YOLOv8m-VCI achieved 88.2% precision, 86.5% recall, and 86.8% mAP. The single-class precision (AP) for peach fruit moth detection reached 94.6%. The detection results of YOLOv8m-VCI are visualized in Fig. 6. YOLOv8m incorporates an early-stopping mechanism to prevent model overfitting. The experiment was automatically halted when the optimal performance was achieved at 100 training epochs. The training curve of YOLOv8m-VCI stabilized in the later stages of the training process, exhibiting minimal fluctuations.

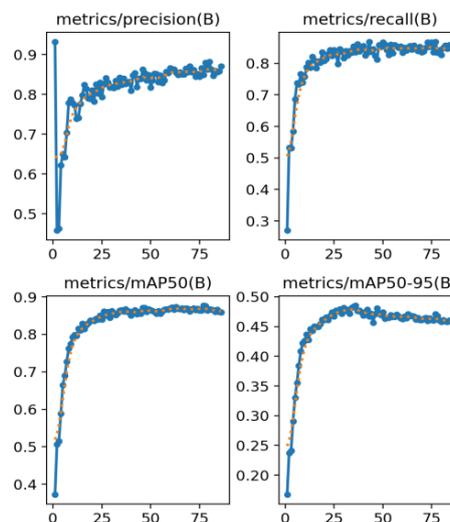

Fig. 6 -YOLOv8m-VCI curves during the training period

(2) In order to examine the improved model more closely, the P-R curves and F1-Confidence Curve for different categories are observed, as shown in Fig.7. The P-R curve, also known as the precision-recall curve, is a comprehensive representation of the model's performance. The more convex the P-R curve is, and the closer it is to the upper-right corner of the coordinate system, the better the model's performance. The more convex the P-R curve is and the closer it is to the right corner of the coordinate system, the better the model performance. Analysing the P-R curve, it can be seen that YOLOv8m-VCI is 98.5% effective in detecting the adult peach small heartworm. The mAP for the whole category reached 86.7%. The F1-Confidence Curve demonstrates the relationship between the F1 scores and different confidence thresholds. The F1 score is the harmonic mean of Precision and Recall, ranging from 0 to 1, with larger values indicating better model performance. Analysing the F1-Confidence Curve shows that YOLOv8m-VCI is the best for detecting the adult peach small heartworm. The F1 score for the whole category reaches 84% when the confidence threshold is 0.304.

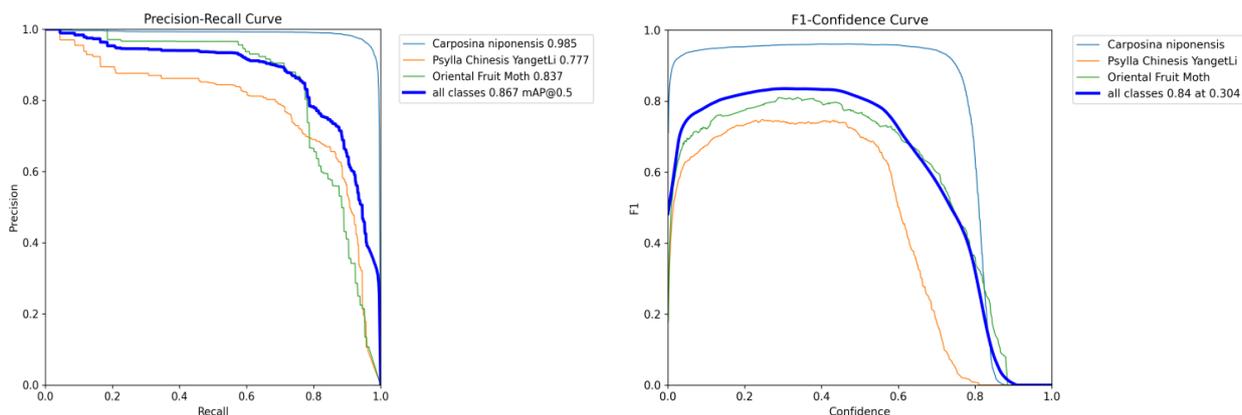

Fig. 7 - P-R curves and F1-Confidence Curve for YOLOvm-VCI during training

Performance Comparison of Different Target Detection Models

(1) In this experiment, seven mainstream target detection models—YOLOv5s, YOLOv5n, YOLOv7, YOLOv7-tiny, YOLOv8m, YOLOv8l, and YOLOv9c—were compared. The improved model, YOLOv8m-VCI, was also introduced for comparison. The results are presented in Table 2.

Table 2

Comparison of detection effects of different models

Model	P	R	mAP@0.5	mAP@.5 .95	Weight	Params	FLOPs
	[%]	[%]	[%]	[%]	[MB]	[M]	[G]
YOLOv5s	83.6	86.5	83.8	43.8	14.4	7.02	15.8
YOLOv5n	83.	85.7	84.8	44.7	3.8	1.76	4.1
YOLOv7	83.3	85.4	84.3	41.9	71.3	37.2	105.1
YOLOv7-tiny	81.7	87.0	85.1	44.5	11.7	6.02	13.2
YOLOv8m	84.8	84.4	85.6	45.7	52.0	25.8	78.7
YOLOv8l	85.6	83.0	85.7	45.9	87.6	43.6	164.8
YOLOv9c	85.5	83.1	85.1	44.9	102.8	51.0	237.7
YOLOv8m-VCI	88.2	86.5	86.8	45.2	48.4	24.0	77.0

As can be seen from Table 2, YOLOv8m-VCI is optimal in terms of precision, which is also 2.7 percentage points better than YOLOv9c. It is only 0.5 percentage points lower than YOLOv7-tiny in recall, which is better than other models. It improves by 3 percentage points over YOLOv5s in mAP and is optimal. mAP50-95 reaches 45.2%. In addition, the model is lower than YOLOv8m in terms of weight, number of parameters, and computational effort. YOLOv8m-VCI meets the requirements for real-time detection of peach fruit moths in real environments.

(2) The detection effects of the improved YOLOv8m-VCI model and the YOLOv8m model are shown in Fig. 8. In (1a), the peach fruit moth was wrongly detected as peach fruit moth, and in (1b), it was detected correctly and with an accuracy P of 66%; in (2a), the YOLOv8m model in the lower-right corner of the figure omitted the detection of the peach fruit moth, and in (2b) the improved YOLOv8m-VCI model detected it correctly. The accuracy P of the improved YOLOv8m-VCI model for detecting peach fruit moth in (3b) is higher

than the accuracy of the YOLOv8m model in (3a). It can be seen that compared with the original model, the improved YOLOv8m-VCI model has improved the misdetection and omission of peach fruit moth, and the accuracy P has been significantly improved.

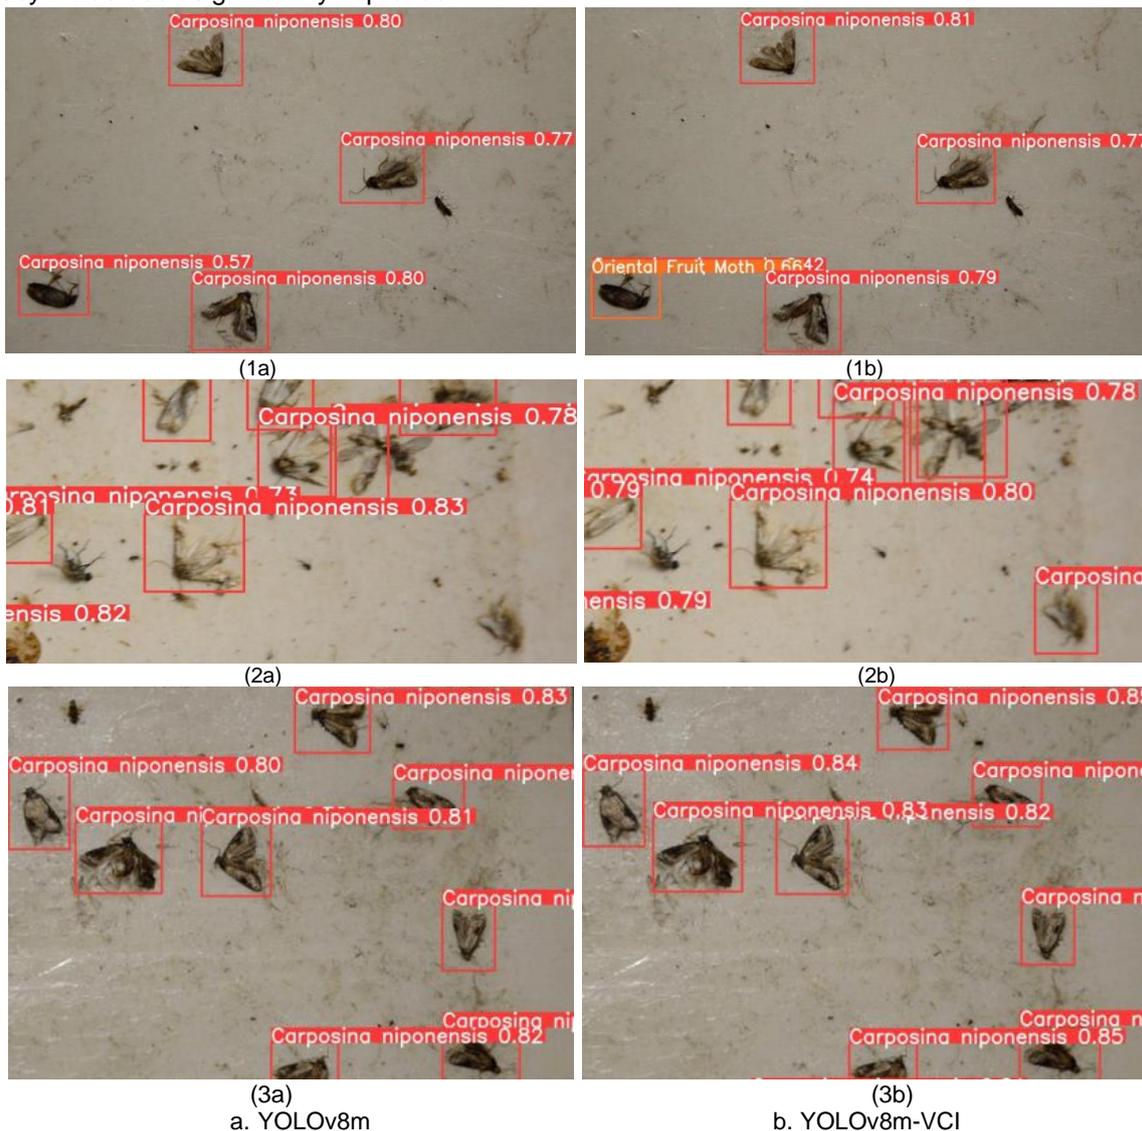

Fig. 8 - Comparison of detection effect of YOLOv8m-VCI model and YOLOv8m model

The Peach Fruit Moth Detection System

The Peach Fruit moth identification application utilized the PyQt framework of Python for front-end interface development. PyQt combined the concise syntax of Python with the powerful functionalities of Qt. It offered a rich library of controls, facilitating users in constructing interfaces, and also achieved cross-platform compatibility, ensuring the consistency and stability of the user interface across different operating systems. The QtDesigner tool of PyQt allowed for a more intuitive and rapid design of the program interface, enhancing the development speed of the program, and separating the program interface from its logic, which made it easier to maintain in the later stages. As shown in Figure 9.

The application primarily implemented the following four functions:

1) Pest image file import function. This section provided four methods for importing image files: importing a single image, an entire file, a video file, and real-time detection via a camera.

2) Detection results display function. This section was responsible for displaying the detection data to the user, including the time taken for detection, the number of targets detected, the type of targets, confidence levels, and the location of targets. Additionally, it offered a target selection feature to meet the user's need to view the detection results of a single target.

3) Detection results and target location information display function. This section generated a list after the detection was completed. The list included the target serial number, file path, category, confidence level, and coordinate location.

4) Operation function. This section provided two operations that users could perform on the system. These were the save and exit functions.

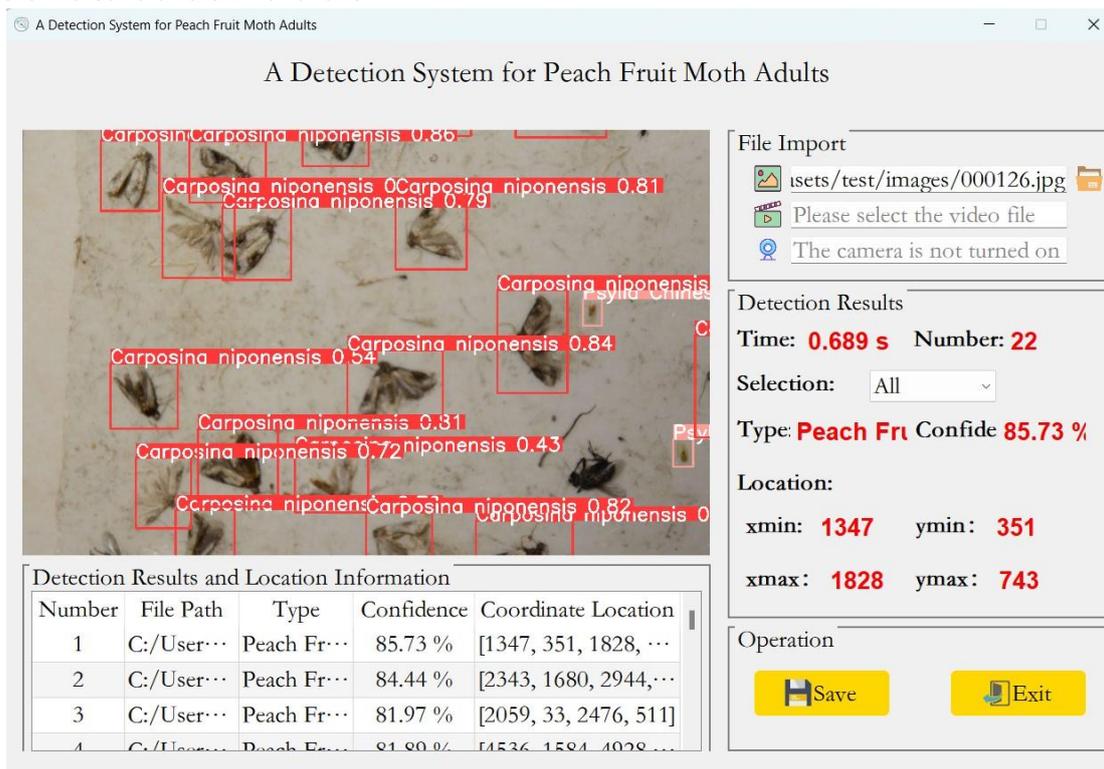

Fig. 9 - The Peach Fruit Moth Detection System

CONCLUSIONS

By introducing v7Down Sampling, CPCA Attention Mechanism, and Inner-WIoU Loss Function in the backbone network of YOLOv8m, the precision P is improved by 3.4 percentage points compared to YOLOv8m. Recall R improved by 2.1 percentage points. mAP improved by 1.2 percentage points. Peach fruit moth single-category precision AP improved by 2.4 percentage points. The size of weights, the number of model parameters, and the computational volume were reduced by 3.6MB, 1.8x106M, and 1.7G, respectively, which realized the improvement of the model's detection effect on adult peach fruit moth without increasing the model's complexity. The detection effect was better than the other seven YOLO series models compared.

The datasets of this study were collected outdoors, taking into account the real application scenarios of the model, and the real background was retained in the image processing, which is conducive to the model's ability to accurately detect small peach fruit moths even when the background is cluttered.

Follow-up research can expand the collection area of the dataset to broaden the scope of application of the model.

In the process of data collection, it was found that there was still a lot of Pear small heartworm and Chinese pear louse on the sticky boards with the addition of small peach fruit moth cores, so the two were added to the study together. However, the proportion of peach fruit moth, pear small heartworm, and Chinese pear louse samples in the actual dataset differed greatly, and there was the problem of sample imbalance. The detection accuracy of the single category of peach fruit moth with more sample data was high, while the detection accuracy of Pear small heartworm and Chinese pear louse with less sample data was low, thus affecting the detection effect of the whole category. In future research, the peach fruit moth and Chinese pear woodlouse can also be taken as research objects to increase the number of samples of the two, which can nearly improve the detection accuracy of the model for these three pests and enhance the detection efficiency.

Follow-up research can deploy the model on mobile terminals, deploy cameras in triangular traps in orchards, and utilize Internet of Things (IoT) technology to connect cameras and mobile terminals to realize real-time monitoring of peach fruit moth and improve the detection efficiency of peach fruit moth.

ACKNOWLEDGEMENT

This research was supported by the Teaching Reform Innovation Project of Higher Education Institutions in Shanxi Province (J20220247) and the Youth Scientific Research Project of the Basic Research Program of Shanxi Province (NO.202303021222039).

ABSTRACT

Silk is a biomaterial with remarkable properties, used in various fields: the textile industry, aeronautics, medicine, etc. Sericulture is the practice of raising silkworms to obtain silk threads. This activity provides an opportunity to improve economic and social status, especially for rural populations. The high demand for labor, along with technical progress, has led to the necessity to implement technical solutions and modern activities in sericulture farms. This paper presents a brief analysis of the current state of research on some innovative technical solutions applied in sericulture sectors and activities, aimed at increasing silk thread production.

REZUMAT

Mătasea este un biomaterial cu proprietăți deosebite, utilizat în diverse domenii: industria textilă, aeronautică, în medicina, etc. Sericicultura se ocupa cu creșterea viermilor de mătase pentru obținerea firelor. Aceasta activitate oferă posibilitatea de creștere a statutului economic și social, mai ales pentru populația rurală. Consumul ridicat de forță de muncă, precum și progresul tehnic au impus implementarea unor soluții tehnice și activități moderne în fermele sericicole. Aceasta lucrare prezintă o scurtă analiză a stadiului actual al cercetărilor privind unele soluții tehnice inovative aplicate în sectoarele și activitățile din sericicultură, în vederea sporirii producției de fire de mătase.

INTRODUCTION

Sericulture is a science (a branch of zootechnics) that focuses on the breeding and multiplication of silkworms for the purpose of obtaining cocoons intended for processing. In 2022, UNESCO inscribed "Sericulture and traditional production of silk for weaving" (17.COM) on the Representative List of the Intangible Cultural Heritage of Humanity (<https://ich.unesco.org/en/RL/sericulture-and-traditional-production-of-silk-for-weaving-01890#video>).

According to the ISC (*International Sericultural Commission*) statistics for 2022, the total silk production was 91,319 metric tons, produced by 22 countries, with 8 of them being the main producers, accounting for 99.9% of the total production. China, which holds the lead, contributed over half of the world's production (approximately 55%), followed by India, which provided 40%. 90% of the silk was obtained from the mulberry silkworm, while the remaining 10% was non-mulberry silk, produced by silkworm species that feed on plants other than mulberry (<https://inserco.org/en/statistics>). These species include: *Antheraea mylitta*, *Antheraea assamensis*, and *Samia ricini*, producing types of silk such as Tasar, Eri, and Muga. Only India produces all these commercial types of silk, which are also classified based on the number of generations of silkworms in a year: univoltine, bivoltine, and multivoltine (*Taufique and Hoque, 2021; Gautam et al., 2022; Kaviraj et al., 2021*). The mulberry silkworm (*Bombyx mori* L.), a moth in the order Lepidoptera, is monophagous and survives only on mulberry leaves. It is the only domesticated insect since ancient times, in China between 2600 and 2700 BC, for silk fiber production. The finest silk, known as "The Queen of Textiles," is obtained from it, characterized by its glossy shine, softness, elegance, and durability (*El-Shewy and Elgizawy, 2017; Hailu, 2016*). Silk threads are known for their extraordinary biocompatibility with the human body, along with a range of exceptional properties: elasticity, high strength, and hardness. Additionally, these animal-origin threads are eco-friendly and biodegradable compared to synthetic fibers, which are polluting (*Popescu et al., 2024; Baci et al., 2021*). They are produced by the silk glands of mature larvae in the fifth stage. They are a natural polymer of silk proteins, consisting of fibroin and sericin, produced in PSG (posterior silk gland) and, respectively, MSG (middle silk gland). Fibroins are the basic fibrous proteins and are hydrophobic, while sericins surround the fibroins and are hydrophilic. The anterior silk gland (ASG) is the third division of the silk gland in silkworms, where the liquid silk protein is assembled into silk fibers (*Saikia and Saikia, 2022; Zhu et al., 2022*).

Sericulture has the advantage of being practiced profitably both on a small, artisanal scale and on an industrial scale, capable of scalable production (Altman and Farrell, 2022). This rural and ecological industry comprises three interconnected sectors: sericulture, which deals with the cultivation of mulberry (*Morus sp.*) to provide food for the silkworms (*Bombyx mori*), which form the protective cocoon, from which raw silk threads are obtained through various processes in the post-cocoon sector (Chanotra and Bali, 2019). The goal is to produce high-quality cocoons with the highest silk content, with current efforts focusing on the most efficient use of this precious material. Beyond traditional uses related to fashion (clothing, shoes, bags, wallpapers, etc.), technological progress has made silk indispensable for medicine, nanotechnology, biotechnology, optical industry, etc. The entire activity of producing primary products represented by natural fibers generates various by-products and waste, which are aimed to be utilized as efficiently as possible (Reizabal et al., 2023; Hăbeanu et al., 2023; Lujerdean et al., 2022; Jaiswa et al., 2021; Pop et al., 2018). The use of by-products (such as silkworm pupae) for animal feed, food, cosmetics, vermiculture, biogas production, artisanal products, etc., by promoting circular economy supply chains, represents new trends in sericulture. Additionally, all these applications and activities reduce environmental impact, increase employment in certain rural areas, and raise their socio-economic level (Seo et al., 2023; Ekka and Bais, 2023; Tassoni et al., 2022; Sharma et al., 2022; Barcelos et al., 2021).

Since sericulture involves multiple sectors and activities, mechanization in sericulture refers to: agricultural tools, machines, and equipment for mulberry cultivation (land preparation, crop maintenance), harvesting mulberry leaves and proper storage, systems for silkworm rearing, and machinery for the post-cocoon sector. Machinery is important for increasing land and labor productivity, helping manage activities that must be performed within specific time frames. It is also indispensable for the actual production of silk fabrics, with the quantity and quality of the silk depending on it (Karthick Mani Bharathi et al., 2024; da Silva et al., 2018).

Silkworms are very sensitive to their diet, specifically the quantity and quality of the food, as well as to environmental factors such as temperature, humidity, light, and air. Silkworm rearing is strongly influenced by the rearing techniques adopted, including feeding, cleaning, spacing, etc. An unsuitable environment negatively impacts the growth of silkworms, and consequently, the quantity and quality of the cocoons (Gupta and Dubey, 2021; Andadari et al., 2021). Immediately after collection, silkworm cocoons undergo several operations. They are steamed/dried (to destroy the butterfly pupa) after being pre-sorted, with undeveloped or double cocoons removed. The goal is to preserve their quality for long-term storage. Properly conditioned cocoons can undergo further operations to obtain silk threads: final sorting, cleaning of impurities, scalding, reeling, etc. A wide range of machinery has been studied and optimized for these operations (Safarov et al., 2019; Angel et al., 2018; Alim et al., 2016).

It is important for improved silkworm rearing technologies to be known and adopted by farmers in the field. Enhancing competence in sericulture depends on investment, promotion of technologies, and advancements in professional training. Modern agricultural technologies and production systems have the potential to increase efficiency and open new opportunities for various agricultural methods (Vlăduț and Ungureanu, 2024; Hajam et al., 2021; Singh et al., 2021).

The paper provides a brief overview of the current state of research on innovative technical solutions applied to mulberry shoot cutting, monitoring/control of silkworm growth factors, and the post-cocoon sector, aiming to reduce labor and energy consumption, thereby improving the efficiency of operations and the final quality of silk.

MATERIALS AND METHODS

The quality and nutritional composition of mulberry leaves influence the growth performance of silkworms (Gheorghe et al., 2023). In sericulture, obtaining these leaves is a major issue. Mulberry branches are cut individually, which requires significant time and labor. Cutting can be done with a hydraulic shear or other cutting tools/machines. Therefore, research has been conducted to reduce the physical effort exerted by the operator. A device was developed for this operation, featuring a mobile arm and a rotating saw (fig. 1). The cut branches are collected in a tray specifically designed for this purpose. Figure 2 shows the block diagram of the device's operation (Kumar et al., 2021).

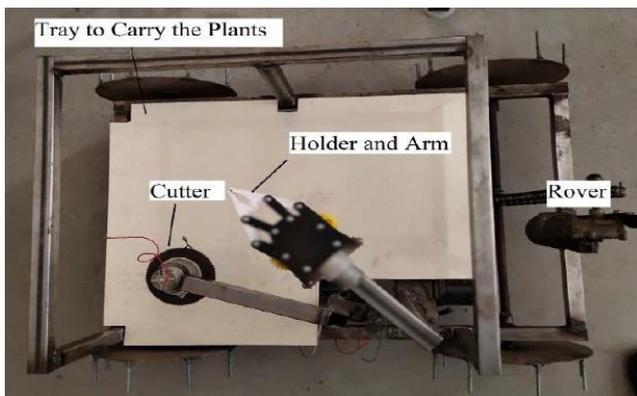

Fig.1 - Mulberry Branch Cutting Device
(Kumar et al., 2021)

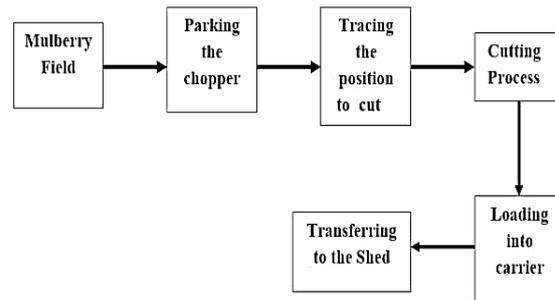

Fig.2 - Block diagram
(Kumar et al., 2021)

The arm is attached to a rod driven by a DC motor (like those used in windshield wipers), allowing the arm to move in the desired direction, meaning its opening and closing are controlled. The circular saw is also powered by a DC motor, but with high torque for effective cutting. The cutting device is manually moved to the position of the branch that needs to be cut. The automatic module is activated, and the control system manages and monitors the sequence of operations:

- The support holding the arm opens so that the arm can extend outward to grasp the branch, then it closes.
- The open-source Arduino Uno platform immediately activates the cutting system, and the arm extends to cut the branch.
- After cutting, the arm holding the mulberry branch retracts, loosening its grip. This sequence is controlled by the controller and relay.
- Finally, the branch is discharged into the storage tray, and the cycle repeats (Kumar et al., 2021).

In China, several research efforts have focused on developing mulberry leaf harvesting equipment, including piston-type, spiral-type, semi-automatic, and multi-degree-of-freedom devices. However, these innovations have not eliminated manual labor, although they have reduced the physical effort required by operators and improved the efficiency of the picking operation. As a result, research has been initiated to develop intelligent mulberry leaf harvesting techniques. The first stage involves locating the picking points. Using appropriate infrastructure, researchers began by identifying and segmenting the harvesting nodes area through the development of a Mask R-CNN model, which classifies nodes based on their shape ("Y" or "rectangle"). This model was then optimized to enhance recognition accuracy. Finally, a method was devised to obtain the picking points of the mulberry leaf nodes, along with visual information for intelligent harvesting (Zeng et al., 2023). Mask R-CNN is a Convolutional Neural Network (CNN) and represents the state-of-the-art in image segmentation. This Deep Neural Network variant detects objects in an image and generates high-quality segmentation masks for each instance. Researchers developed Mask R-CNN based on the original Faster R-CNN, a Region-Based Convolutional Neural Network, by extending it with an additional branch and using existing detection to predict the target in parallel (Hassan et al., 2022).

Other researchers have used neural networks to develop early detection models for mulberry leaf diseases, aiming to combat these diseases and prevent the use of affected leaves as feed for silkworms, as they negatively impact their health and development (Nahiduzzaman et al., 2023).

In agriculture, robots are often mobile platforms, which have seen remarkable development over the past decade (Shamshiri et al., 2018). Research has been conducted to expand their use in sericulture, particularly for handling large frames used in the rearing process of silkworms. For a stacking device, a model of a mobile transport platform was designed (fig. 3), focusing on making it: compact, capable of movement along two axes, with reduced construction and functional complexity, thus resulting in a low production cost while still achieving high efficiency in handling and placing the frames. The mobile platform (fig. 3) includes: (1) electric drive motors, (2) rack-and-pinion transmission for movement along the X axis (horizontal), (3) rack-and-pinion transmission for movement along the Z axis (vertical), (4) frame gripping system for silkworm frames (not described in this work). Additionally, (5) the main frame of the device supports the mobile transport platform. For movement along the X axis, the pinion of the rack-and-pinion transmission receives motion from the electric motor via a straight-toothed gear mounted on its shaft, forming a cylindrical gear system.

The pinion shaft is supported by two sliding bearings located on either side. The bearings are mounted on the mobile platform, which slides. Thus, Figure 4 shows: (1) the mobile platform, (2) the cylindrical gear system, (3) the rack, (4) the guide, (5) the pinion shaft for the rack-and-pinion transmission, (6) the roller bearings. For movement along the Z axis, the pinion of the rack-and-pinion transmission receives motion from the electric motor via a bevel gear system (fig. 5). On the shaft of the electric motor (5), a bevel pinion engages with the bevel gears (4) which transmit motion to the pinion (2) through a common shaft supported by bearings (3) mounted on the mobile platform (1). The pinion (2) moves along the rack (6) (Jiang et al. 2024).

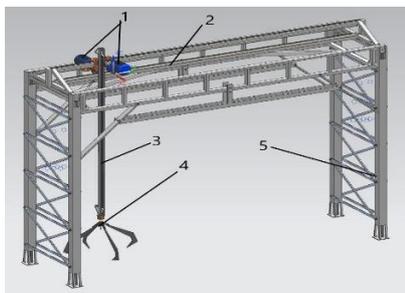

Fig.3 - Mobile Transport Platform
(Jiang et al., 2024)

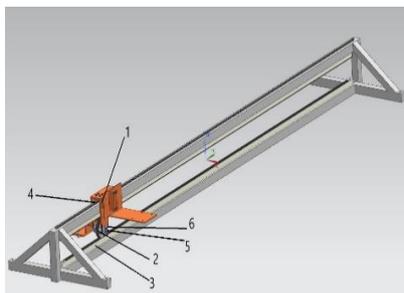

Fig.4 - Movement Transmission of the Mobile Platform along the X Axis (Jiang et al., 2024)

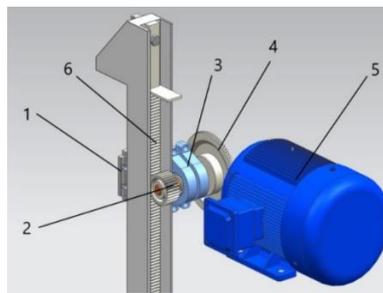

Fig.5 - Movement Transmission of the Mobile Platform along the Z Axis (Jiang et al. 2024)

Considering the dimensions of the frames (1000mm x 1500mm), the stacking height of these frames in a group (2000 mm), the distance between the platform and the frame gripping system (500 mm), as well as the horizontal distances that need to be maneuvered, the height of the main frame was established as 3000 mm, and the length of the transverse beam as 4000 mm. For the pinion shafts of the rack-and-pinion transmissions, made of quality carbon steel (with 0.45% C content), a strength check was conducted using simulated modal analysis (Jiang et al., 2024).

To avoid losses in sericulture, in addition to diet, monitoring environmental factors and the health status of silkworms is critically important (Bekkamov and Samatova, 2023; Chopade et al., 2021). Numerous research efforts have been undertaken, resulting in various automated systems or methods (experimental or prototypes) designed to be as efficient, cost-effective, and interactive for farmers as possible. Although these systems aim for the same goal, they differ in their components and technologies used.

Thus, a system was developed that utilizes a microcontroller combined with a GSM module to offer tracking and automatic control features. The automated system, with the architecture shown in Figure 6, detects temperature, light intensity, humidity, and gases (LPG, carbon dioxide) in the sericulture farm environment. These represent the inputs, and when threshold values are exceeded, information is transmitted to the user via a wireless network, with the microcontroller taking necessary actions (e.g., correcting temperature, humidity, air quality, light intensity, etc.) to avoid losses due to silkworm deaths. The system communicates with the user via the GSM module to perform tasks such as feeding the silkworms. The system can be divided into: a detection part and an action part (Gunasheela et al., 2018).

In another study, a similar embedded system was developed (fig.7) for close monitoring and regular control of environmental parameters in the silkworm rearing chamber/enclosure. The system maintains temperature, humidity, light intensity, and CO₂ concentration. It is equipped with a fire alarm, and also ensures the distribution of food and medicine for the silkworms.

The system consists of sensors, an Arduino controller, and actuators (cooling fan, food dispenser, medication sprayer). The sensors circuit comprises four analog sensors: temperature, humidity, light, and CO₂ sensors, and a digital fire sensor. The Arduino is programmed with threshold values and the capacity to monitor and control the system. The system comprises both software and hardware components (Manjunatha and Neelagar, 2018).

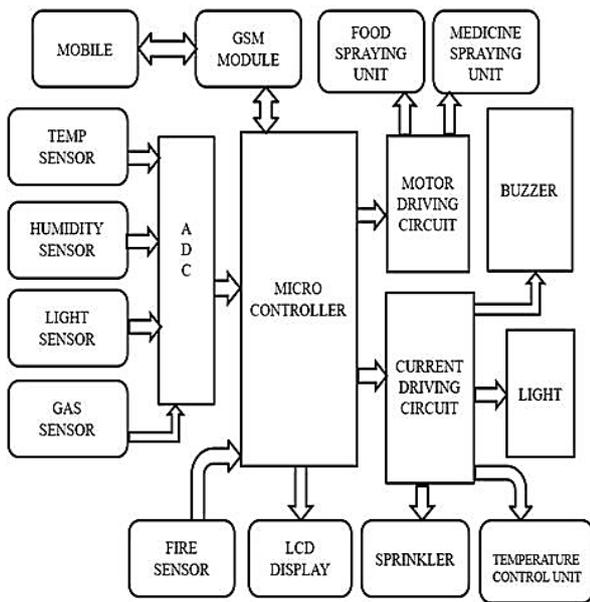

Fig.6 - Architecture of the Automated System
(Gunasheela et al., 2018)

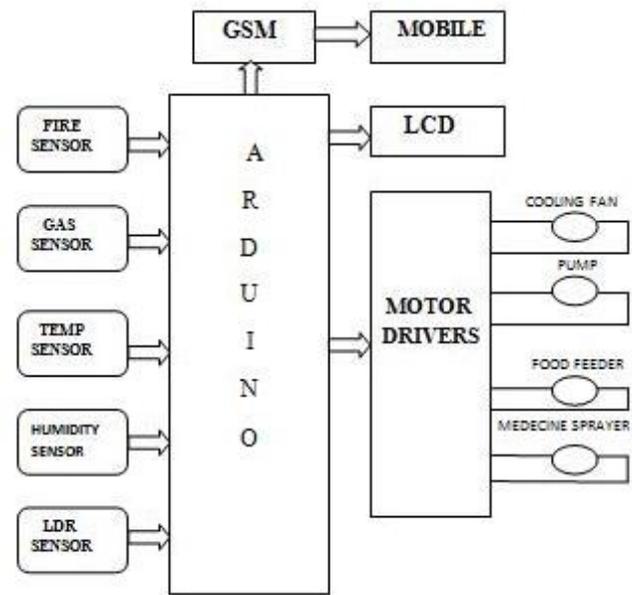

Fig.7 - Embedded System Diagram
(Manjunatha and Neelagar, 2018)

For a silkworm incubator (fig.8), a monitoring system was used that employs an open-source, low-cost data acquisition and transmission system. This system utilized an embedded platform with cloud remote monitoring through the Google Drive file hosting service and the Internet of Things. The proposed conceptual model (fig.9) includes: sensor readings, communication channel, and data storage in the cloud. Several sensors record environmental parameters (humidity, temperature, and light) in a silkworm incubator. The information is uploaded to the Google Drive cloud via Wi-Fi. With a username and password, information can be accessed from any device that can access Google Drive. The system is highly flexible, with possibilities for expansion or adaptation. The monitoring system was used in the silkworm incubator (*Incubapremium Columbia type*) equipped with 9 trays with metal mesh (food-grade aluminum) to allow air circulation, for 200 silkworms, continuously for 25 days. The trays for silkworms (1x0.6m) are arranged on shelves, spaced 15 cm apart. (Duque-Torres et al., 2018).

Fig.8 - Silkworm incubator
(Duque-Torres et al., 2018)

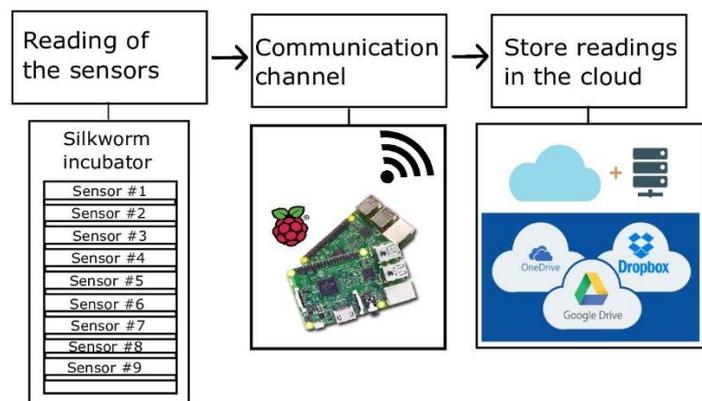

Fig.9 - Silkworm incubator monitoring system conceptual model
(Duque-Torres et al., 2018)

The temperature in the chamber is controlled by a heating system based on an electric heater, and a humidifier placed in the lower part of the incubator controls the humidity. For monitoring, DTH22 sensors were used. Silkworms are photosensitive and do not like light that is too strong or too weak. For light measurement, the APDS-9301 sensor was used due to its high accuracy and low energy consumption. For the prototype of the monitoring system, a Raspberry Pi version 3 (RPi3) controller was used due to its technical and economic advantages (Duque-Torres et al., 2018).

In another study, an advanced monitoring and control system for ecological conditions in a silkworm incubator was proposed (fig.10), based on the use of an Arduino Uno microcontroller due to its numerous capabilities. To ensure favorable conditions for silkworm development in the incubator, temperature and humidity are the primary factors to be controlled. Their estimation is done continuously. The threshold levels for temperature and humidity can be easily set and modified remotely from a portable device. When the temperature falls below the set value, the microcontroller is programmed to activate the heater loop. When the humidity falls below the threshold value, the humidifier is activated. Temperature and humidity can be checked remotely (Kokila et al., 2021).

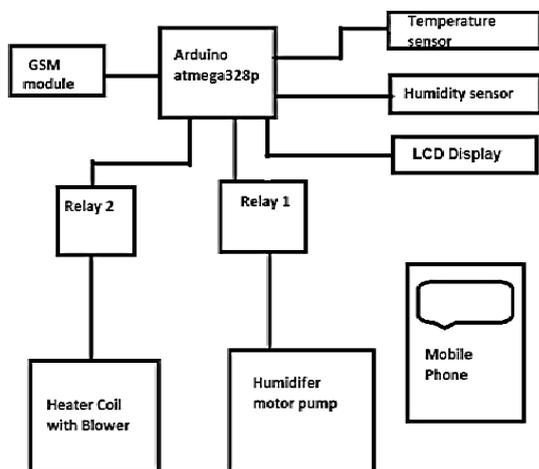

Fig.10 - Block diagram of advance silkworm incubator with environment control
(Kokila et al. 2021)

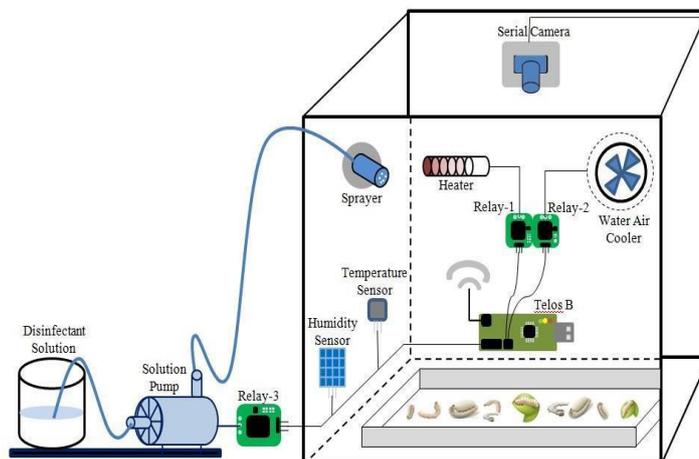

Fig.11 - IoT based Block Representation of the Sericulture Monitoring and Actuation System
(Arun et al., 2019)

To prevent unfavorable conditions and actions affecting the development of silkworms (such as temperature variation, humidity, lack of food, disease occurrence, etc.), an Automated Smart Sericulture System has been developed. Figure 11 shows the proposed system architecture for a silkworm rearing chamber, based on IoT, consisting of temperature and humidity sensors, a camera, actuating devices (electric heater, cooler, digital image processing, sprayer) connected to smart nodes, with wireless communication. Based on real-time data provided by the sensors, the smart nodes will make decisions and perform actions. Raw images from the camera are digitally processed to extract improved versions and additional information. For visualization, application development (using various built-in signal processing algorithms), and numerical calculations, MATLAB will be used (Arun et al., 2019).

In another study, for classifying silkworms as healthy or unhealthy, CNN neural network archives were used due to their proven high accuracy for less complex elements. The proposed system consists of two parts: Hardware and Software. For these, widely available component parts, open-source software such as Arduino IDE and Rest API, and commercial software MATLAB for image processing techniques were utilized (Yogeshraj et al., 2022).

Regarding post-cocoon operations, two methods (infrared drying and combined drying) were investigated and compared for their effectiveness in killing and drying silkworm cocoons. Fresh cocoons stored in the refrigerator were maintained at room temperature for 15 minutes before drying. The cocoons were spread out in a single layer on stainless steel trays of the drying equipment used. The entire sample was weighed every 30 minutes to trace the drying curves. An infrared laboratory dryer of type "ASIA," with a power of 750 W, incorporating three 250 W infrared emitters, and an experimental dryer with a 50 Hz ultrasonic frequency and 1000 W IR radiation power were used. Drying temperatures for both experiments were set at 60°C, 65°C, and 70°C, with an ultrasonic exposure time of 10 seconds. Initial material moisture, instantaneous moisture, and drying rate for a specific time interval Δt were calculated. Experimental data were processed using statistical analysis programs (Samandarov et al., 2023).

During the life cycle of silkworms, gender classification of cocoons is important for ensuring the perpetuation and preservation of genetic material through egg production, as well as for post-cocoon operations. A non-destructive multi-sensor system for gender classification and separation of silkworm cocoons was developed, with the schematic and prototype shown in Figures 12 and 13.

The machine consists of the vertical conveyor module (VCM) that individually picks up cocoons from the hopper at a constant speed without causing physical damage, and then transfers them to the feature extraction module (FEM). Here, each cocoon is analyzed, extracting data related to its shape and weight. Using dedicated software running on an autonomous workstation, a digital image is obtained. The image characteristics and weight information are combined into an input feature vector, analyzed by a pre-trained pattern recognition classifier for making decisions regarding gender classification/sorting. The final module is a horizontal conveyor (HCM) that directs individual cocoons to be physically sorted and blown into designated baskets (male or female) (Raj et al., 2019).

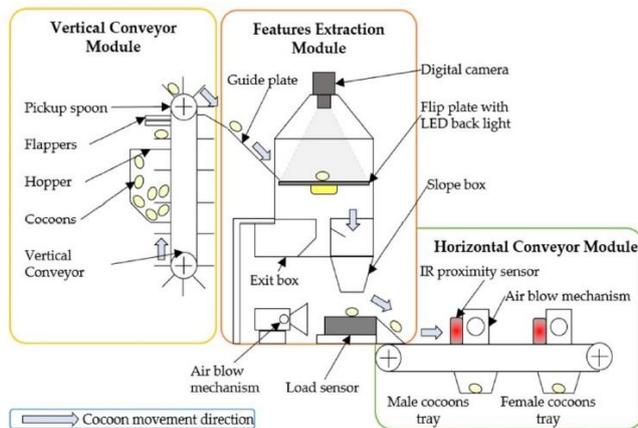

Fig. 12 - The scheme of the machine for separating cocoons by gender (Raj et al. 2019)

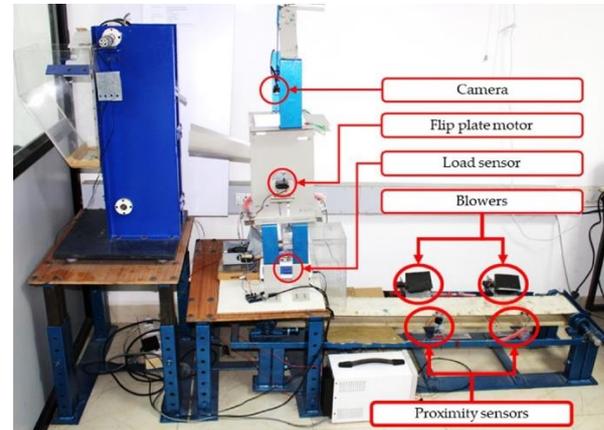

Fig.13 - The prototype of the machine for separating cocoons by gender (Raj et al., 2019)

VCM is a vertical belt conveyor driven by an electric motor (12V, 10 rpm). On the belt, which has a speed of 6.3 cm/s, 16 special, concave pockets shaped like spoons are mounted equidistantly by riveting. Two rows of flaps help remove excesses, so each pocket only holds one cocoon. FEM consists of a support frame with a mount for a 5-megapixel digital camera, an inclined feed chute, an output chute, a detachable load sensor, and a blowing system. Image processing and cocoon weight measurement provide information sent to a binary classifier to determine gender. Under the camera, there is a tilting acrylic plate that, through a shaft driven by a servomotor, can be positioned in three directions (horizontal 0°, 90° clockwise, -90° counterclockwise). The tilting plate receives cocoons from the VCM in the horizontal position. A square LED panel light (18 W), directed from back to front, is used to capture the hard shell silhouette of the cocoon, allowing precise area calculation through image threshold techniques. The cocoon is transferred to the load sensor after the image is acquired. The falling speed of the cocoon is dampened by moving across multiple inclined planes. Cocoon weight data is acquired with an error of 0.01 g and transferred to the workstation after reaching the load sensor surface. The cocoon is transferred to the HCM using a blowing system, which consists of a blower and a pivoting "U" shaped cover that stops the air flow. One side of the cover is coupled to a servomotor, while the other rotates freely relative to the wall via a cylindrical pin joint. Normally, the cover is closed, and no airflow is directed towards the cocoon. Once weight data is acquired, the system sends a command to the servomotor, and the pivoting arm opens for 2 seconds to allow cocoon transfer. The power requirement for FEM is 25 W. HCM consists of a horizontal belt conveyor, 2 infrared proximity sensors (IR) paired with 2 blowing units, all placed along the conveyor. The positions were empirically determined to ensure the workstation has the necessary time for classification index calculation and provision. Based on this, the blowers in each pair are activated/deactivated to transfer the cocoon to the appropriate tray (Raj et al., 2019).

The quality and lighting of the image were aimed to be optimized to obtain the best experimental conditions, so the Otsu Method was used for processing. Thus, this algorithm performs thresholding for image binarization on the acquired image. In the FEM module, an image is obtained and sent to the workstation, where shape characteristics (area, perimeter, major axis length, minor axis length, etc.) are calculated. The area of the cocoon from the binarized image is compared with an empirical threshold value. If the threshold is exceeded, excess cocoons are ejected by rotating the tilting plate counterclockwise, moving them out of the module through the output box to return to the feed hopper. If only one cocoon is on the tilting plate, the binarized image area does not exceed the threshold.

The microcontroller is signaled to rotate the tilting plate clockwise, and the cocoon reaches the load sensor, where its weight is acquired and transmitted to the workstation.

Shape and weight characteristics are combined and sent to a pre-trained SVM (Support Vector Machine), assigning an index and gender label stored in the workstation. The air blowing system moves the cocoon from the sensor to the HCM. As it moves, the cocoon reaches the first proximity sensor (IR), which sends a signal to another microcontroller. This retrieves the classification label of the current cocoon to control the blowers. If the designated label is “male,” the first blower is activated, pushing the cocoon onto the “male cocoon tray.” Conversely, if the cocoon's label is “female,” the second blower is activated, pushing the cocoon onto the “female cocoon tray.” The prototype of the machine for separating cocoons by gender was tested on two silkworm races, CSR2 and Pure Mysore, provided by an industry partner (*Raj et al., 2019*).

Additionally, to further optimize the sorting operation, which can be done before drying cocoons and before spinning, a prototype was developed based on a patent No. IT201900016208A1. Unlike the previously mentioned equipment that uses one camera and several sensors, this one relies on three cameras and image algorithms that identify the shape, size, and external spots of cocoons, along with a custom light sensor and an AI model to remove dead cocoons. The equipment (Fig. 14), which practically embodies a patented invention, is an opto-electrical machine, with cocoon selection occurring through three zones, each with different functions (*Vasta et al., 2023, Assirelli et al., 2019*).

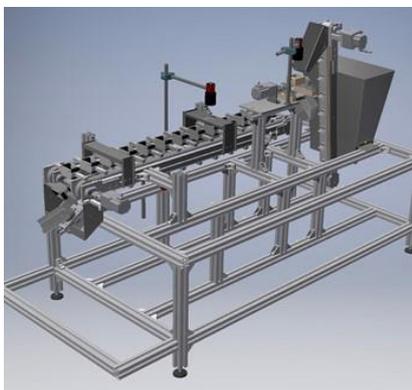

Fig. 14 - 3D CAD render of the prototype (*Vasta et al., 2023*)

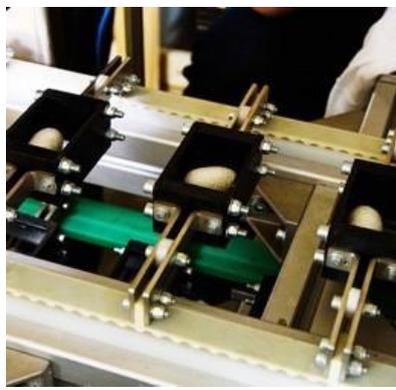

Fig. 15 - Custom-made conveyor belt (*Vasta et al., 2023*)

Fig.16 - Screenshot of GUI written in Java (*Vasta et al., 2023*)

The equipment was built around a conveyor belt (Fig. 15) driven by a stepper motor, with all mechanical movement systems controlled by a programmable PLC. It also controls the solenoid valves that activate the pneumatic actuators for initial and final selection (Fig. 16). The frame of the equipment was made from aluminum profiles, and the horizontal conveyor, having a special construction, was custom-made. The feeding is done with a vertical feeding system that directs the cocoons to an inclined feeding chute at 45° (Fig. 14). The first camera was placed at the end of this chute, and the two pneumatic actuators, mounted perpendicular to its direction, serve to remove cocoons that are unsuitable in shape. Those approved in shape fall into small capsules placed on the horizontal conveyor. Due to the horizontal movement of the belt, each capsule with a cocoon inside reaches the next two specialized cameras for spot selection, one providing an image from bottom to top and the other from top to bottom. This way, both faces of the same sample are captured to reduce any possible reading error. The last selection zone was dedicated to distinguishing between live and dead pupae inside the cocoons. For this, a complex sensor based on photodiodes was used, for which a PCB (Printed Circuit Board) and dedicated software were designed. At the end of sorting, based on different quality grades, the cocoons were directed into different containers with the help of a pneumatic device placed at the end of the belt (*Vasta et al., 2023*).

The three cameras installed on the prototype were connected to a main personal computer (PC) via an Ethernet cable, each receiving trigger signals to take pictures at a specific moment. The preliminary operations performed before the acquisition process were managed with a GUI (Graphical User Interface) designed and managed in the Java programming language. Using the GUI, various parameters were monitored: the number of photos taken, the status of the cameras, the status of the analog-to-digital converter (ADC), etc., as well as starting or stopping data acquisition. Multi-threading programming techniques were used for the main PC to perform all tasks while simultaneously storing all synchronized images from the cameras and raw data received from the sensor.

Synchronization between the PC, the custom light sensor, and the PLC was achieved using the Modbus Ethernet communication protocol, which was implemented on the Arduino Portenta H7 using the corresponding software library. Based on this protocol, the hierarchy can be summarized as a client (PC) and two servers (Arduino and PLC). To coordinate the movement of all mechanical parts, a Boolean data exchange between the PC and PLC was designed. The correlation between the light sensor and the computer allowed Boolean data to manage the timing of acquisition. To transmit raw data to the Modbus registers of the computer, the same bus was subsequently used (Vasta et al., 2023).

RESULTS

The performance of the intelligent mulberry branch cutting device was analyzed in comparison with existing methods, which involve manual cutting using a cutter-type tool. Thus, the operation durations and associated costs are presented comparatively in Figures 17 and 18 (Kumar et al., 2021).

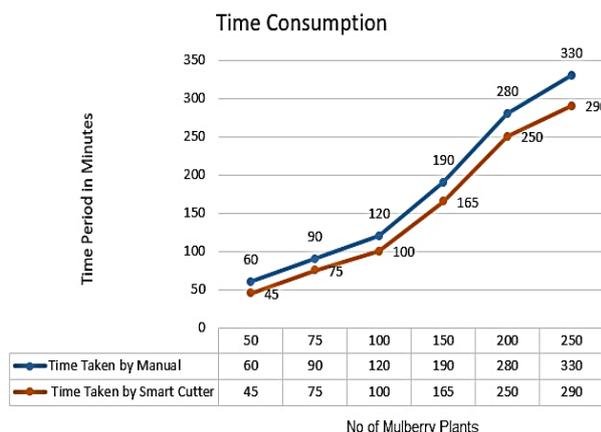

Fig. 17 - The time consumed for performing the cutting operation for a number of mulberry plants (shoots) (adapted from Kumar et al., 2021)

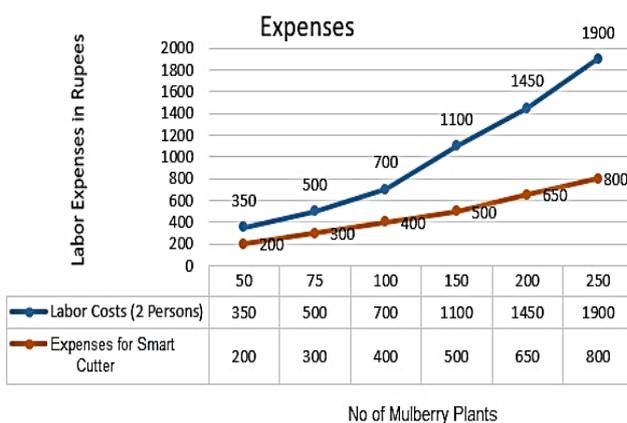

Fig. 18 - The expenses for the cutting operation for a number of mulberry plants (shoots) (adapted from Kumar et al., 2021)

The intelligent cutting device is operated by a single person, and the results obtained constitute an important premise for increasing productivity and reducing the labor required for feeding silkworms.

For the development of intelligent harvesting, Zeng et al. (2023) improved the detection capability of the mulberry leaf node area by replacing the ResNet network with an enhanced ResNeXt network, adding a bottom-up fusion path, as well as a multi-scale regional suggestion network. The optimization efficiency was evaluated through: precision rate (P), recall rate (R), average precision (AP), and F1 score (Table 1). The final detection precision improved by 2.8%, and the F1 score increased by 3.5% compared to the non-enhanced model. The method used in this study can accurately locate the harvesting point, with the leaf nodes obtained through segmentation (Zeng et al., 2023).

Table 1

Evaluation results of the model before and after improvement (Zeng et al. 2023)

	Precision rate (P)	Recall rate (R)	Average precision (AP)	Scor (F1)
	[%]	[%]	[%]	[%]
Model Mask R-CNN	84,2	63,2	86,3	72,2
Improved Model Mask R-CNN	86,7	67,1	89,1	75,5

In the study by Nahiduzzaman et al. (2023), a PDS CNN model based on XAI (Explainable Artificial Intelligence) was proposed to classify mulberry leaves into categories of healthy, rust-affected, and spotty leaves using a newly created database containing 764 original images, selected by experts. These images were preprocessed into 6000 synthetic images, with an additional 218 and 109 images for testing and validation, respectively. The PDS-CNN model is a unique, parallel, depth-separable CNN (Conventional Neural Network) developed by applying depth-separable convolutional layers to reduce parameters, layers, and size, while enhancing classification performance. The model achieved an accuracy of $95.05 \pm 2.86\%$ for three-class classifications and $96.06 \pm 3.01\%$ for binary classifications with 0.53M parameters, 8 layers, and 6.3 MB in size. Thus, promising classification performance was achieved, with model interpretability induced by SHAP (Shapley Additive Explanations) and confirmed by sericulture experts.

Due to its specific features, the developed model can be accessible to a wide range of users in sericulture (both professionals and ordinary farmers). Early identification of mulberry leaf diseases leads to significant production savings and benefits for farmers.

In the study by *Jiang et al. (2024)*, considering all the necessary elements for using modal analysis in a simulated regime to verify the durability of pinion transmission trees with rack, it was found that they meet the durability requirements. The development of a cheap mobile transport platform that helps handle the frames/trays used in sericulture would substantially reduce labor consumption, improving work efficiency in this field.

The system designed in the study by *Gunasheela et al. (2018)* has a configuration that responds to any climatic changes occurring inside the silkworm rearing enclosure, efficiently responding to stimuli. If the user closes the phone or if the signal strength is low, causing disruptions in the GSM network, the system does not respond adequately. Solutions applied to eliminate these disadvantages include automating the farm so that operations are performed in a timely manner and enabling call redirection. Thus, the system can send messages to a specified alternative number by placing the GSM module in an area where full signal strength is available for communication.

Manjunatha and Neelagar (2018) developed an embedded system model for monitoring and controlling environmental parameters in the silkworm rearing unit, which was tested. The preliminary test demonstrated that the model can work progressively to monitor conditions within the enclosure. Its actuators operate only when necessary, reducing the need for human intervention. The system was implemented smartly, using cost-effective and energy-efficient components. As the system can be relatively easily realized, it is expected to be optimized by using broadband/Wi-Fi and Internet of Things (IoT) for matching processes and securing information.

The system monitoring environmental conditions during the process conducted in a silkworm incubator, as described in the study by *Duque-Torres et al., (2018)*, was tested in real time. Data were exported from RPi3 into a simple .txt file (in a Google Drive account). This provided the date, time, temperature measurements from sensor one to sensor nine, humidity measurements from sensor one to sensor nine, and light intensity measurements. Uniformity of environmental conditions inside the incubator is essential. However, the analysis of automatically recorded data revealed the generation of microclimates between the levels of the incubator, highlighted by temperature variation (Fig. 19) and humidity variation (Fig. 20). Besides its low cost, the developed system also features portability, and data visualization and analysis can be performed remotely. Additionally, it is directly programmable, based on open-source codes, which enhances its flexibility compared to commercial tools that only offer predetermined functions.

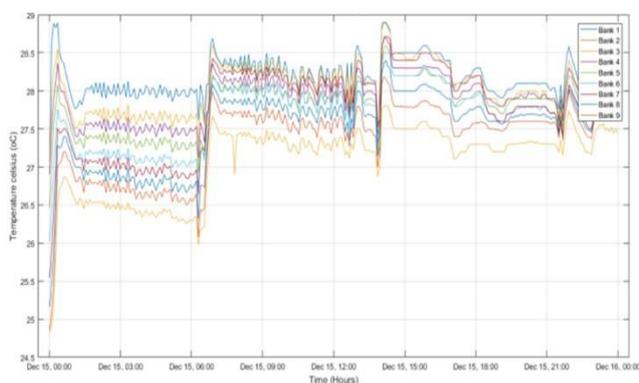

Fig. 19 - Temperature variance graphic
(*Duque-Torres et al., 2018*)

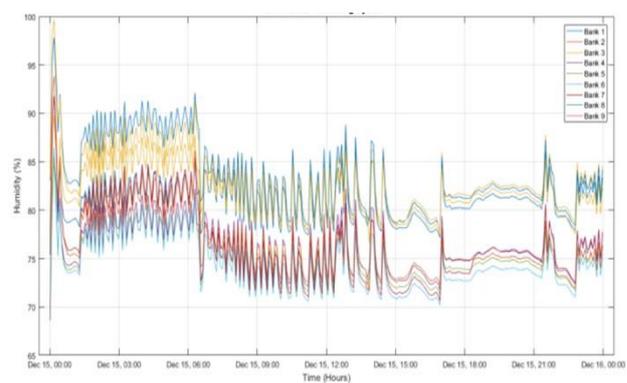

Fig. 20 - Humidity variance graphic
(*Duque-Torres et al., 2018*)

Using the advanced ecological monitoring and control system in a silkworm rearing incubator proposed by *Kokila et al., (2021)*, the egg hatching to larvae occurred between 10-11 days, and the production of silkworm cocoons from larvae lasted 25-30 days. Additionally, productivity was high due to the low mortality rate. Thus, by using this system, farmers have the opportunity to achieve 12-15 iterations of silk production in a year, with reduced labor consumption. Being easy to use and maintaining temperature and humidity with ease, its application scope is expected to expand in the future.

The preliminary test for the Automated Smart Sericulture System from the study by *Arun et al., (2019)*, showed that it is capable of successfully monitoring and controlling established state parameters in real time.

These parameters can be monitored remotely, with automation handling the creation of suitable conditions inside. In addition to temperature and humidity sensors, many other sensors for different parameters can be interfaced with this system. Furthermore, image capture can be performed wirelessly, making it more compatible and intelligent. The system's optimization prospects involve deploying the sensor network for sericulture based on CoAP and connecting it to the IPv6 framework for real-time internet monitoring.

The system developed by *Yogeshraj et al. (2022)* can monitor environmental factors (temperature and humidity) and control them using heating systems and fans. Image processing algorithms were used to successfully resize images by detecting edges and performing maximum grouping (Fig. 21). The processed images (Fig.22) allowed differentiation between healthy and unhealthy silkworms, with sick ones being detected. The convolutional neural network-based classification introduced in the proposed scheme improved accuracy and reduced computation time.

Fig. 21 - Worm resized images
(*Yogeshraj et al., 2022*)

Fig. 22 - Output the healthy and unhealthy silkworms are detected
(*Yogeshraj et al., 2022*)

The effects of drying mulberry silkworm cocoons in an infrared (IR) device at temperatures of 60, 65, and 70°C, and durations of 15, 12, and 10 minutes, are presented in the figures below (Fig. 23, 24, 25) (*Samandarov et al., 2023*).

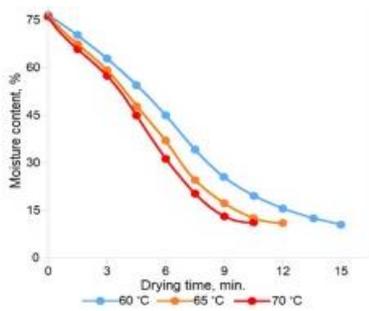

Fig. 23 - Variation in humidity (IR)
(*Samandarov et al., 2023*)

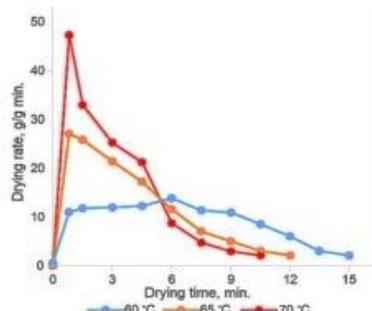

Fig. 24 - Variation in drying speed (IR)
(*Samandarov et al., 2023*)

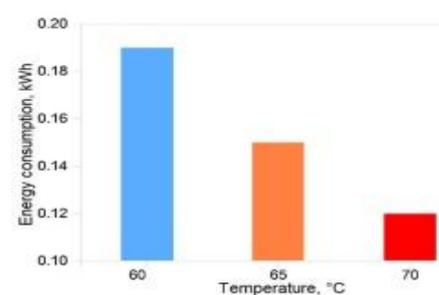

Fig.25 - Variation in energy consumption (IR)
(*Samandarov et al., 2023*)

For the drying of mulberry silkworm cocoons under the same conditions (IR), with the addition of exposure to ultrasonic (US) waves, the effects are presented in Figures 26, 27, 28 (*Samandarov et al., 2023*).

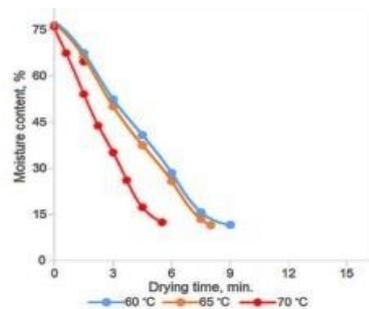

Fig. 26 - Variation in humidity (IR+US)
(*Samandarov et al., 2023*)

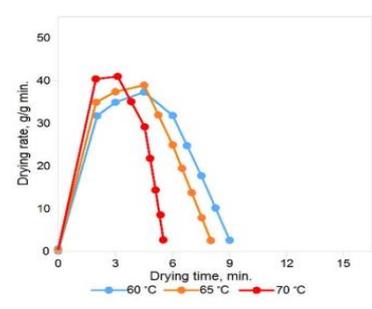

Fig. 27 - Variation in drying speed (IR+US)
(*Samandarov et al., 2023*)

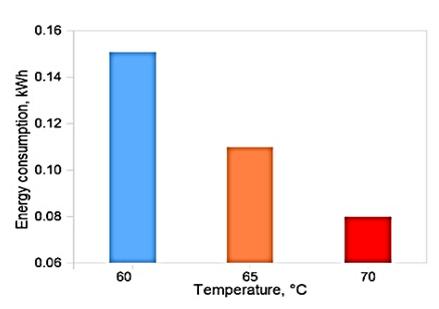

Fig. 28 - Variation in energy consumption (IR+US)
(*Samandarov et al., 2023*)

Combining the two methods (Infrared IR and Ultrasound US) results in faster and more efficient drying, reducing energy consumption, as ultrasound can affect the microstructure of mulberry cocoons. Thus, the optimal drying conditions were determined to be: temperature 70 °C, ultrasound frequency 50 Hz, and exposure time of approximately 5 minutes (Samandarov *et al.*, 2023).

The performance of the prototype machine for separating cocoons by gender is evaluated based on accuracy, robustness, and speed. Table 2 shows the performance metrics calculated, namely: Accuracy, True Male Rate (TMR), True Female Rate (TFR), Male Predictive Rate (MPR), and Female Predictive Rate (FPR), with reference to both training and test phases for CSR2 and Pure Mysore cocoons (Raj *et al.*, 2019).

Table 2

Performance metrics (PM) obtained for CSR2 and pure Mysore cocoons from SVM

(Raj *et al.* 2019)

Performance metrics (PM)	Training		Testing	
	CSR2	Pure Mysore	CSR2	Pure Mysore
Accuracy	0.9259	0.9778	0.8649	0.9355
True Male Rate (TMR)	0.9642	1.000	0.8947	0.9286
True Female Rate (TFR)	0.8846	0.9583	0.8333	0.9412
Male Predictive Rate (MPR)	0.9000	0.9545	0.85	0.9286
Female Predictive Rate (FPR)	0.9583	1.000	0.8824	0.9412

During the gender separation operation, a cocoon moves from the VCM module of the machine to the FEM module in an average time of approximately 4.6 seconds. It remains there for about 2.2 seconds, consuming 1 second to acquire shape characteristics and 1.2 seconds for weight characteristics. It then reaches the collection tray through the HCM in approximately 3.6 to 4.1 seconds. Thus, a cocoon moves from the hopper to the collection tray in approximately 10.9 seconds. The machine can classify about 5.5 cocoons per minute, which translates to about 330 cocoons per hour, or approximately 2640 cocoons per shift (8 hours). With an average cocoon weight of 1.3 grams, the machine can classify about 3.4 kg of cocoons per shift, with an accuracy of approximately 86.48% to 93.54% and a repeatability of 88%. The results demonstrate the machine's potential to enhance the productivity of gender classification of cocoons in silk farming centers, as well as in the industry. The cocoon gender sorting machine, which does not damage the casing, represents a significant step forward in reducing human intervention and automating operations in sericulture (Raj *et al.*, 2019).

The performance of the automated prototype for *Bombyx Mori* cocoon sorting varied depending on the selection parameters considered. Following the tests and improvements in both software and hardware, the equipment achieved a maximum sorting frequency of 80 cocoons per minute. The equipment also achieved optimal performance for oversized cocoons, but performance for undersized cocoons was lower due to their tendency to be positioned vertically in the capsule (Fig. 29), which affected the accurate image capture for identification (Vasta *et al.*, 2023).

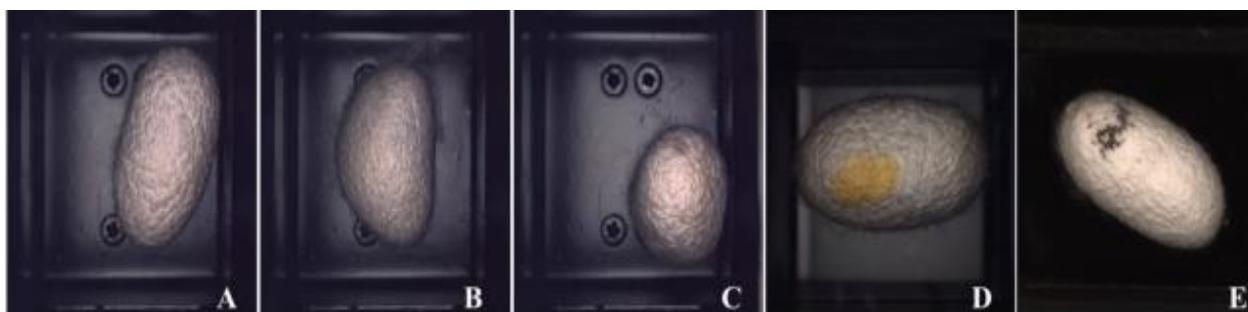

Fig. 29 - The position of cocoons inside their housing (Vasta *et al.*, 2023).

A - regular cocoon; B - defective shape; C - incorrect size due to positioning; D - stained at the top (large orange spot); E - stained at the bottom (black spot)

The performance regarding the dimensional selection of cocoons is presented in Table 3 (Vasta *et al.*, 2023).

Table 3

The equipment performances (defective cocoons marked as such) (Vasta et al. 2023)

Parameters	True Positive Percentage [%]
Oversized cocoons (larger than 450 mm ²)	87.8
Undersized cocoons (smaller than 300 mm ²)	29.6
Undersized cocoons with no vertically positioned ones	90.0

The performance metrics of the prototype in dead-cocoon selection based on the logistic regression model from the photodiode matrix were: classification ratio and cross-validation accuracy. The correct classification ratio achieved for dead-cocoon selection was 81.5% on the training set and 78.4% on the test set. Cross-validation with 100 steps was also performed, yielding an average accuracy of 80.7% for training and 81.6% for testing. The development and testing of the equipment allowed for a detailed study of the patented idea. Additionally, its encouraging performance contributed to identifying various aspects, especially practical ones, that should be optimized and could be the subject of further research (Vasta et al. 2023).

CONCLUSIONS

This paper provides a synthesis of recent research on innovative technical solutions across various sectors related to sericulture. Generally, in agriculture, the use of modern machinery, equipment, and production systems ensures sustainability and enhances both production and quality. Technological innovations play a crucial role in the employment opportunities offered by sericulture.

Despite a global decline in cocoon and silk production, current trends make natural silk fibers highly favored in the fashion and textile industries, as well as in numerous other fields, due to their unique characteristics.

The technical solutions presented are highly accessible to users, aiming to minimize human intervention in silk production or increase the productivity of operations that cannot maintain consistent performance levels when done manually. They also focus on implementing innovative ideas or smart applications to enhance the added value of sericulture products. These innovative solutions provide a significant basis for future research aimed at developing and modernizing specific technologies and revitalizing or resuming sericulture activities in geographic areas where they were once intensively practiced in the past century.

ABSTRACT

Conventional simultaneous localization and mapping (SLAM) systems for agricultural robots rely heavily on static rigidity assumptions, which makes it susceptible to the influence of dynamic target feature points in the environment thus leading to poor localization accuracy and robustness of the system. To address the above issues, this paper proposes a method that utilizes a target detection algorithm to identify and eliminate dynamic target feature points in a farm depot. The method initially employs the YOLOv5 target detection algorithm to recognize dynamic targets in the captured warehouse environment images. The detected targets are then integrated into the feature extraction process at the front end of the visual SLAM. Next, dynamic feature points belonging to the dynamic target part are eliminated from the extracted image feature points using the LK optical flow method. Finally, the remaining feature points are used for location matching, map construction and localization. The final test on the TUM dataset shows that the enhanced vision SLAM system improves the localization accuracy by 91.47% compared to ORB-SLAM2 in highly dynamic scenes. This improvement increases the accuracy and robustness of the system and outperforms some of the best SLAM algorithms while maintaining high real-time performance. These features make it more valuable for mobile devices.

摘要

农业机械人的传统同步定位和地图构建 (SLAM) 系统在很大程度上依赖于静态刚性假设, 这使得它很容易受到环境中动态目标特征点的影响从而导致系统的定位精度和鲁棒性变差。针对上述问题, 本文提出了一种利用目标检测算法来识别和消除农场库房中动态目标特征点的方法。该方法最初采用 YOLOv5 目标检测算法来识别采集库房环境图像中的动态目标。然后将检测到的目标整合到视觉 SLAM 前端的特征提取过程中。接着, 使用 LK 光流方法从提取的图像特征点中剔除属于动态目标部分的动态特征点。最后, 剩余的特征点用于位置匹配、地图构建和定位。在 TUM 数据集上的最终测试表明, 在高动态场景中, 增强型视觉 SLAM 系统与 ORB-SLAM2 相比, 定位精度提高了 91.47%。这一改进提高了系统的准确性和鲁棒性, 并在保持高实时性的同时超越了一些优秀的 SLAM 算法。这些特点使其对移动设备更有价值。

INTRODUCTION

With the development of autonomous mobile robot platforms, agricultural robots have been widely used in agricultural production and warehousing services, such as farm management, orchard inspection, fruit picking, and automation of warehousing tasks. In these scenarios, robots need to understand the entire area and the precise location of the target objects in the map to accomplish autonomous navigation. In order to realize autonomous navigation, mobile robots need to accomplish two tasks: attitude estimation and map construction. Simultaneous localization and mapping (SLAM) refers to the robot in an unknown environment, which through its own matching sensors estimates its own position and build the environment map (He et al., 2020). SLAM according to the different sensors are mainly divided into two categories. One is SLAM equipped with LiDAR, which is a mature system with small computation and accurate ranging, but the cost of LiDAR is high and not easy to maintain, so it is not commonly used in indoor robots. The other category is the camera-equipped vision SLAM, which is characterized by low cost, high cost-effectiveness, and the ability to obtain rich environmental information, so it has become a hot spot of attention in the field of robotics research.

Currently, visual SLAM can be classified into two kinds according to the methods used: the feature point method with FAST corner points as feature extraction and BRIEF descriptors as identity information matching, which can be used for sparse point cloud building; and the direct method with the information of the image gray value to directly judge the camera motion, which can be used for dense point cloud building, but with certain assumptions on the gray invariance. ORB-SLAM2 is considered to be one of the most complete one of the visual SLAM frameworks and also represents the feature point method (*Mur et al., 2017*), but its results are not satisfactory in highly dynamic working environments, which leads to the low applicability of SLAM systems in real-world scenarios. The implementation of the direct method is based on the assumption of constant gray scale, but the light in the environment changes from time to time, and the assumption is difficult to be completely valid, so the SLAM system based on the direct method has poor robustness. In indoor dynamic environments, the feature points extracted from irregularly changing moving objects will seriously affect the accuracy of the camera position evaluation. *Engel et al., (2014)*, proposed LSD-SLAM, which utilizes gray values to achieve localization and construct semi-dense point cloud stacks. *Wang et al., (2017)*, contributed DSO-SLAM based on the sparse direct method is superior to LSD-SLAM in terms of robustness, accuracy, and speed, but it does not include the loopback detection function, which is an incomplete SLAM algorithm.

Among the approaches relying on deep learning, *Bescos et al., (2018)*, proposed the DynaSLAM algorithm, which utilizes a priori information for segmenting dynamic targets by means of a deep learning neural network, Mask R-CNN, which was first proposed by *He et al., (2017)*, and *Liu et al., (2018)*, utilized semantic segmentation to identify the a priori dynamic regions of an image, and tracking and mapping using static feature points. *Yu et al., (2018)*, proposed a DS-SLAM algorithm that combines a SegNet real-time semantic segmentation network with motion consistency detection to reduce the impact of dynamic targets on the system and reduce the localization accuracy in dynamic scenes compared to ORB-SLAM2. Compared with ORB-SLAM2, the localization accuracy in dynamic scenes is improved by one order of magnitude, but the semantic segmentation is time-consuming and fails to meet the real-time requirements. RDS-SLAM proposed by *Liu et al., (2021)*, adds semantic tracking threads and optimization threads on the basis of the ORB-SLAM3 system and eliminates the outliers of the tracking threads by using the data correlation algorithm. The RTD-SLAM proposed by *Wang et al., (2023)*, adds YOLOV5-based parallel semantic threads and optical flow modules to the tracking threads to eliminate dynamic feature points, which improves the system's localization accuracy and real-time performance. Based on the ORB-SLAM3 system, the semantic segmentation thread is added to improve the camera localization accuracy in dynamic scenes, but the dynamic feature points of potential dynamic targets (e.g., books held by people) are detected as static feature points, which are used in the tracking thread for feature matching and camera pose computation, resulting in a decrease in the system localization accuracy (*Law et al., 2018*).

In summary, the SLAM system's positioning accuracy may be affected by dynamic objects in the complex environment, leading to poor real-time performance. To tackle these issues, this paper selects YOLOv5 as the target detection network. Then, it combines the optical flow method in the tracking thread of the SLAM system to eliminate feature points that do not meet the requirements. Finally, only the processed feature points are utilized for estimating the camera position. Experiments were conducted on the TUM dataset and compared with ORB-SLAM2 and other dynamic SLAM algorithms. The results showed that the localization accuracy of the improved visual SLAM system was 91.47% higher than that of ORB-SLAM2. Compared to ORB-SLAM2, the improved visual SLAM system demonstrated a 91.47% increase in localization accuracy in highly dynamic scenes. This enhancement effectively improves the system's robustness and localization accuracy, while also providing higher real-time performance on mobile devices. As a result, the system has greater application value.

MATERIALS AND METHODS

ORB-SLAM2 system

ORB-SLAM2 is a feature-point based SLAM system that enables simultaneous localization and map construction using camera-captured image data. It is highly stable, operates quickly, and is easy to implement. Currently, it is the most widely used system in the field of vision SLAM. The system contains three main threads: tracking, local map construction, and closed-loop detection. Figure 1 shows the system framework.

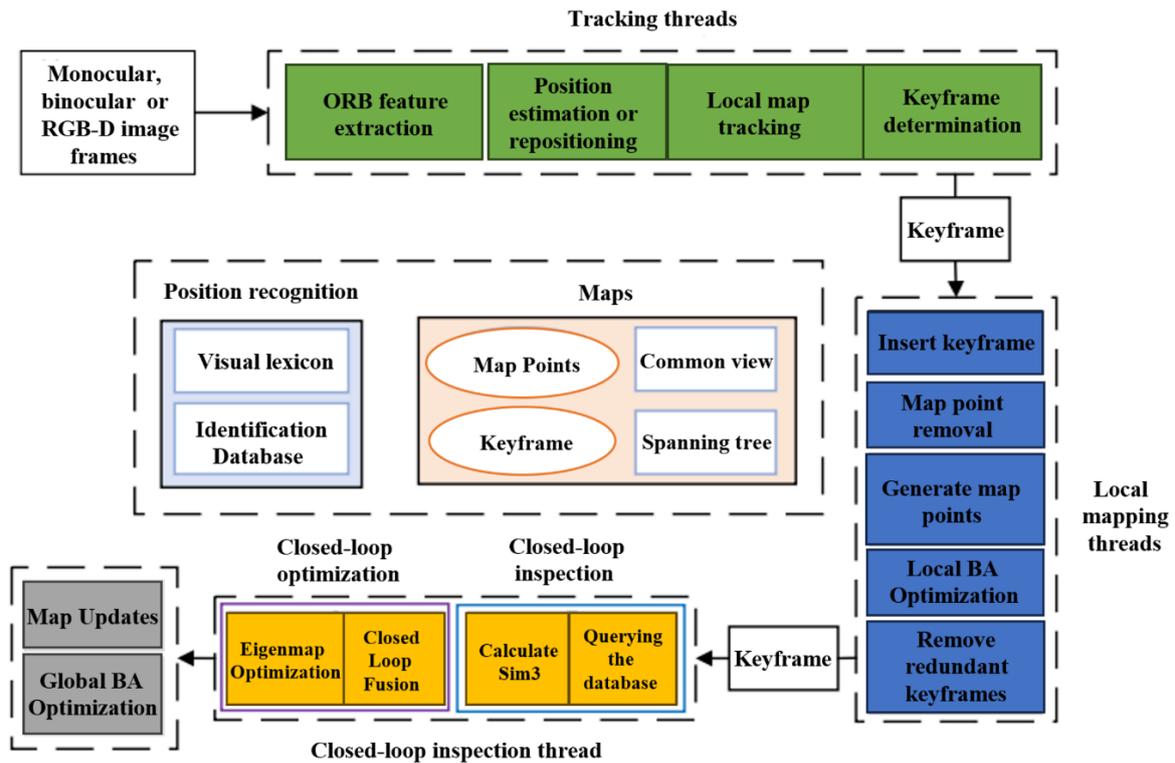

Fig. 1 – ORB-SLAM2 algorithm system framework

Improved SLAM system

The ORB feature points extracted from dynamic objects in the traditional tracking thread can accumulate errors when matching positions, resulting in reduced position evaluation accuracy or even localization failure (Liang et al., 2022). To minimize the impact of dynamic objects on the system and improve positioning accuracy, this paper proposes a method that combines target detection and optical flow algorithms to reject dynamic feature points in the scene (Liang et al., 2022). A target detection module and a dynamic feature point rejection module have been added to the tracking thread of the ORB-SLAM2 framework, as shown in Figure 2. A new detection thread has been included in the front-end, and the tracking and detection threads share information (Placed et al., 2022). When the system receives the image frames, they are processed by the tracking and detection thread. The process involves two threads: tracking and detection. The tracking thread extracts ORB feature points from the image and uses the optical flow method to track and match the remaining feature points. The detection thread recognizes the object based on a priori information, such as the screen, chair, and human, and calculates the frame position of each category. The tracking thread then divides the frames into dynamic and static categories based on the returned frame information and categories, and calculates the basis matrix. The system's robustness and positioning accuracy are improved by matching the remaining static points with features to estimate their position, which reduces the influence of dynamic objects in the environment (Khan et al., 2022; Wang et al., 2022; Tian et al., 2023; Engel et al., 2017).

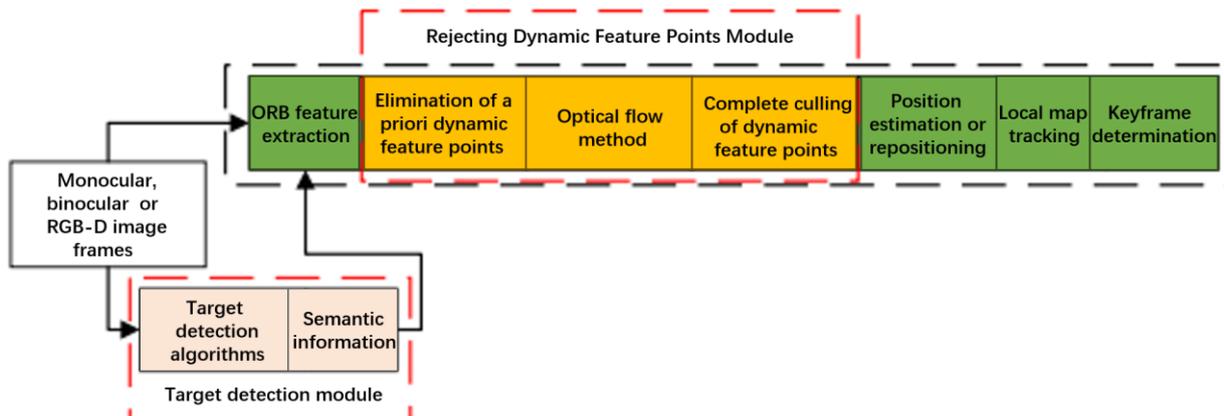

Fig. 2 – Improved trace threads

Feature tracking and matching based on the LK optical flow method

The optical flow method can be used for computer vision tasks by comparing the change in brightness values of corresponding pixels in two images to infer the direction and magnitude of the pixel's motion in the image. This method can track the motion process of a stationary pixel and a dynamic target's same pixel in the image (Xu et al., 2021). The two types of optical flow are sparse optical flow, which describes the motion state of some pixels in the image, and dense optical flow, which describes the motion state of all pixels (Shen et al., 2023). The Hom-Schunck optical flow represents the dense optical flow, while the Lucas-Kanade optical flow, also known as LK optical flow, dominates the sparse optical flow (Zou et al., 2022).

In this paper, the purpose is to reduce computation by computing only the optical flow field of the ORB feature points extracted by the visual odometry of the SLAM system. Therefore, the LK optical flow is used (Fang et al., 2009).

The LK optical flow is founded on 3 assumptions:

1. For a moving target in a grayscale image, the luminance (gray scale) of its pixel points does not change between adjacent frames.
2. Time continuity or motion is small enough that there is no drastic change in the target position due to time change in each computation, and the change in the corresponding position of pixel points of a moving target between adjacent frames is relatively small.
3. Spatial consistency, the vicinity of feature points All neighboring pixel points move similarly.

As shown in Fig. 3, the gray scale of an image can be regarded as a function of time: at moment t , the gray scale of an ORB feature point located at (x, y) in the image can be written as $I(x, y, t)$. According to the gray scale invariance assumption of the optical flow method, the gray scale value of the same feature point is fixed in each image. For a feature point located at (x, y) at time t , it will move to $(x+dx, y+dy)$ at time $(t+dt)$ (Zhang et al., 2020).

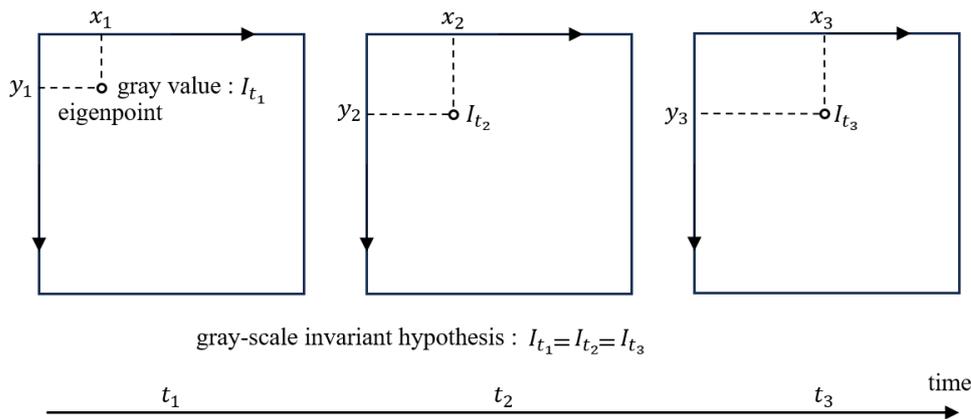

Fig. 3 – Schematic diagram of LK optical flow method

The following mathematical formula is obtained based on the assumption of gray scale invariance:

$$I(x+dx, y+dy, t+dt) = I(x, y, t) \tag{1}$$

A Taylor expansion of the left-hand side of the equal sign of Eq. (1), retaining the first-order terms yields Eq. (2):

$$I(x+dx, y+dy, t+dt) \approx I(x, y, t) + \frac{\partial I}{\partial x} dx + \frac{\partial I}{\partial y} dy + \frac{\partial I}{\partial t} dt \tag{2}$$

According to the gray scale invariance assumption, the gray scale values of the feature points at moments t and $t+dt$ are equal, which can be obtained:

$$\frac{\partial I}{\partial x} dx + \frac{\partial I}{\partial y} dy + \frac{\partial I}{\partial t} dt = 0 \tag{3}$$

Both sides are obtained by dividing by dt at the same time:

$$\frac{\partial I}{\partial x} \frac{\partial x}{\partial t} + \frac{\partial I}{\partial y} \frac{\partial y}{\partial t} = - \frac{\partial I}{\partial t} \tag{4}$$

In Eq. (4) dx/dt is the motion velocity of the feature point on the X -axis and dy/dt is the velocity on the Y -axis, which are denoted as u and v , respectively (Kundu et al., 2009).

$\partial I/\partial x$ is the gradient of the image in the X -axis direction at the point, and $\partial I/\partial y$ is the gradient in the Y -axis direction, which are denoted as I_x and I_y , respectively (Migliore et al., 2009). The amount of change in the grayscale of the feature point with respect to the time is denoted as it. It is written in the form of a matrix, as shown in Eq. (5) as follows (Lin et al., 2010):

$$\begin{bmatrix} I_x & I_y \end{bmatrix} \begin{bmatrix} u \\ v \end{bmatrix} = -I_t \quad (5)$$

According to Eq. (5), additional constraints need to be introduced to find the velocity vector of a pixel (Zou et al., 2012). In the LK optical flow, a 6×6 window is assumed with the feature point as the center, and according to Assumption 3, the 36 pixels inside have the same motion, and the equation is transformed into a super-definite linear equation about u , v . The equation is transformed into a hyper-definite linear equation about, and solved by the least squares method (Du et al., 2020). Since in the actual application scenario, the static part of the image generates optical flow vectors due to the movement of the camera, the average optical flow vectors of the static part of the image are calculated according to Equation (6) (You et al., 2023).

$$\begin{bmatrix} U \\ V \end{bmatrix} = \frac{1}{N} \sum_{k=1}^N \begin{bmatrix} u_k \\ v_k \end{bmatrix} \quad (6)$$

The feature points are filtered using equation (6) to determine whether the feature points are dynamic or not (Xiao et al., 2019).

$$\sqrt{(u-U)^2 + (v-V)^2} > z \quad (7)$$

where z is the threshold value for determining whether the feature point is a dynamic feature point, which is generally twice the static mean optical flow vector. If it is greater than this value, it is judged to be a dynamic feature point, and vice versa for a static feature point (Zhong et al., 2018).

Dynamic property setting for indoor targets

The YOLO algorithm is a neural network-based object recognition and localization tool that is fast and can be used in real-time systems. It is currently one of the most widely used single-stage target detection algorithms. The YOLOv5 version contains five models: YOLOv5n, YOLOv5s, YOLOv5m, YOLOv5l, and YOLO5x. The detection accuracy of the YOLOv5 model gradually increases from YOLOv5n to YOLO5x, while the detection speed gradually decreases. YOLOv5 employs mosaic data enhancement technology to enhance the generalization of the model by synthesizing multiple images into one large image. Secondly, it performs adaptive optimization in anchor point and image scaling processing to improve the performance of the model. For the backbone layer, YOLOv5 combines Focus and CSP structures to extract more representative features. The neck network introduces FPN and PAN structures to realize multi-scale feature fusion and improve detection accuracy. Finally, in the head output layer, the loss function GIOU_Loss and the predictive frame filtering GIOU_nms are improved to increase the accuracy and recall of the model. (Wu et al., 2021; Redmon et al., 2016; Redmon et al., 2017; Redmon et al., 2018).

This paper selects the widely used YOLOv5s network for dynamic target detection due to its better balance between accuracy and speed. YOLOv5s is only 27MiB in size and has a fast inference speed, meeting the real-time detection requirements of the visual system when compared to YOLOv4 (Liu et al., 2016; Lin et al., 2017; Bochkovskiy et al., 2020).

The data structure of the YOLOv5 detection frame is output in the format (X , Y , W , H , class, confidence), where X and Y represent the X and Y coordinates of the center point of the detection frame, respectively, W and H represent the width and height of the frame, class represents the category, and confidence represents the confidence level. In order to facilitate reading in the SLAM system, it is necessary to transform the first 4 position information into the coordinates under the original image. The conversion formula is as follows:

$$\begin{cases} X_1 = \left(X - \frac{W}{2} \right) \times L \\ X_2 = \left(X + \frac{W}{2} \right) \times L \\ Y_1 = \left(Y + \frac{H}{2} \right) \times D \\ Y_2 = \left(Y - \frac{H}{2} \right) \times D \end{cases} \quad (8)$$

The current approach defines dynamic and static boxes based on given coordinates and image dimensions. Where (X_1, Y_1) and (X_2, Y_2) denote the upper left and lower right coordinates of the detection frame, and L and D denote the width and height of the image respectively. The detection frame for the human body is defined as dynamic, while the detection frames for other objects are tentatively defined as static. Once the ORB feature points are extracted, the tracking thread receives the detection data from YOLOv5 and traverses the feature points in the detection frame. The feature points are categorized according to the definition of different frames. Figure 4 depicts the schematic diagram of feature points. To determine whether a feature point is dynamic or static when two boxes overlap, check if it is located inside the dynamic box and outside the static box. If the condition is met, the feature point is considered dynamic. If not, it is considered static (Girshick et al., 2014; Borrego et al., 2018; Ren et al, 2015).

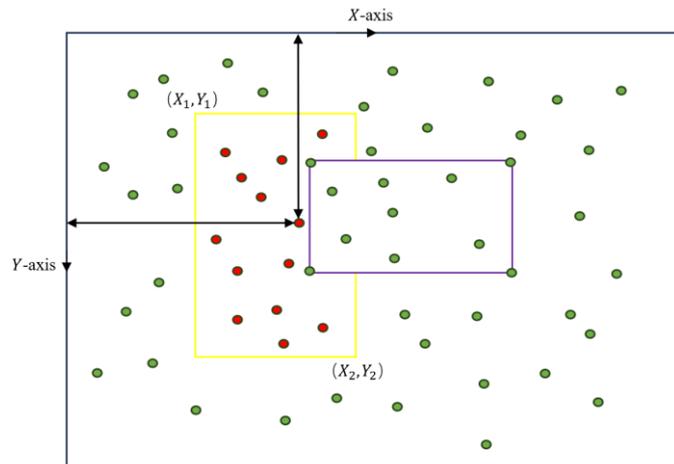

Fig. 4 – Schematic diagram of feature points

The current strategy for rejecting dynamic feature points necessitates the dynamic detection of all feature points within the target detection anchor frame. While this approach can improve localization accuracy in low dynamic sequences, it negatively impacts the system's real-time performance. To address this issue, this paper proposes a new dynamic feature point rejection strategy. This strategy employs a priori knowledge to classify targets. For instance, frequently moving targets like people, animals, and sweeping robots are classified as dynamic targets, while targets like tables and chairs that may move due to human movement are classified as potential dynamic targets.

Table 1

Dynamic property setting for indoor targets

Target objects	Target category	Target objects	Target category
Human	a	Desk	b
Dog	a	Chair	b
Cat	a	Water cup	b
Bird	a	Book	b
Pig	a	Laptop	b

Table 1 displays the categorization of common indoor targets, where 'a' denotes a dynamic target and 'b' denotes a potential dynamic target. Based on these classifications, feature points located in the anchor frame of dynamic targets are classified as dynamic feature points, feature points located in the anchor frame of potentially dynamic targets are classified as potentially dynamic feature points, and the remaining feature points are classified as static feature points. Assuming that the set of dynamic feature points in an image frame is Z , the set of potential dynamic feature points is Q , and the set of static feature points is P , the number of feature points that need to be dynamically detected can be reduced. This improves the real-time performance of the system.

Using Fig. 5 as an example, the tracking thread of the SLAM system extracts feature points while employing the YOLOv5s target detection network for target detection. Feature points in the anchor frames of dynamic targets (e.g. people in the two figures) are placed in set Z . Feature points in the anchor frames of potentially dynamic targets (e.g. the computer screen and chair in the figure) are placed in set Q , and the remaining feature points are placed in set P .

Calculate the optical flow vectors of the feature points in sets Q and P using the Lucas-Kanade optical flow method. The optical flow vectors of the feature points in set P are used as the optical flow vectors of the static region and are substituted into Equation (6) to calculate the average optical flow vectors. The optical flow vectors of the feature points in set Q are substituted into Equation (7) to make a judgment. If they are less than the threshold value, it means that the feature point is a static feature point and is then moved into set P of the static feature points. Finally, the feature points in set P are retained for feature matching and camera pose estimation, and the remaining feature points are rejected.

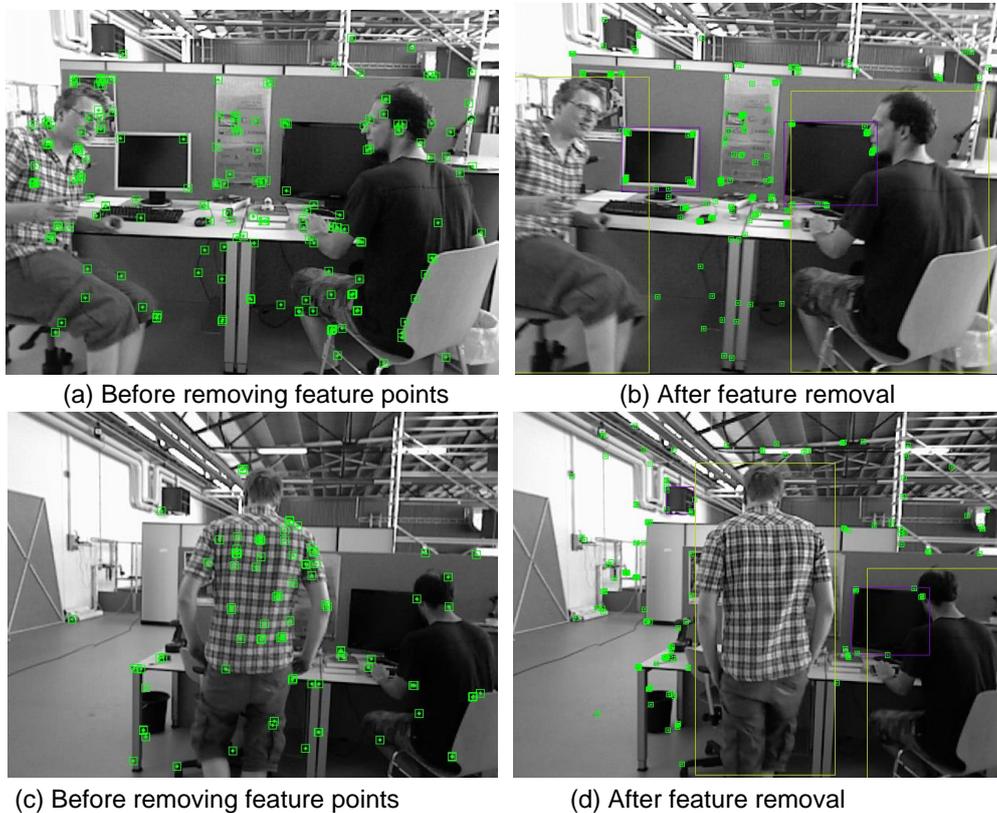

Fig. 5 – Dynamic feature point rejection effect comparison

Our strategy utilizes the LK optical flow method to determine whether a feature point is affected by a dynamic target, rather than simply removing all feature points in the target detection frame. An optical flow vector threshold is set; if the optical flow vector is less than this threshold, it indicates that the feature point is not affected by the dynamic target and can be added to the set P. Increasing the number of feature point matches can further improve the localization accuracy and robustness of the system. The effect of dynamic feature point rejection is demonstrated in Fig. 5. The algorithm rejects feature points on the person as dynamic and retains feature points on the computer anchor frame that overlap with the person's anchor frame, provided that the optical flow vector is less than the threshold. Feature points on the chair's anchor frame portion are also rejected as dynamic due to the person's movement. This strategy enables more accurate rejection of dynamic feature points, resulting in improved system stability and accuracy.

RESULTS

Experiment details

To evaluate the effectiveness of the improved ORB-SLAM2 algorithm, experiments and tests using the TUM dataset were conducted. This dataset consisted of synchronized RGB images and depth images of an indoor warehouse scene captured by a robot equipped with a Kinect sensor. It became one of the most widely used evaluation datasets in the field of SLAM for comparing the performance of different algorithms. This paper tested six sequences from the TUM dataset, including sitting_xyz, sitting_static, walking_halfsphere, walking_rpy, walking_static, and walking_xyz. The sitting_xx sequence was a low-dynamic scenario, while the walking_xx sequence was a high-dynamic scenario. Generally, SLAM algorithm evaluation considered aspects such as time consumption, complexity, and accuracy.

Accuracy evaluation was often the most important, and it involved metrics such as absolute and relative trajectory errors. This paper used root mean square error (RMSE) and standard deviation (STD) to evaluate these metrics. To reduce the impact of tracking failures in dynamic sequences during experiments, each sequence was run fifty times and the average value was recorded as the experimental data.

The experimental equipment used for the experiment was a Shenzhou laptop, its CPU model was I7-12650H, memory was 16G, the graphics chip was NVIDIA Geforce GTX4060, the system environment was Ubuntu20.04, and the deep learning framework PyTorch 1.9.0 was loaded in the virtual environment of Anaconda. The target detection experiment running software was Visual Studio Code. The target detection network was written in Python3.6, and the SLAM part was written in C++.

Analysis of experimental results

Since the system in this paper is an improvement on the ORB-SLAM2 system, the improved system with the ORB-SLAM2 system is compared and the evo tool is used to compare the bitwise trajectories estimated by the algorithm in this paper and the ORB-SLAM2 algorithm with the real trajectory map groundtruth.txt given by the dataset to quantify the effect of the algorithm in this paper on the improvement effect of the SLAM algorithm.

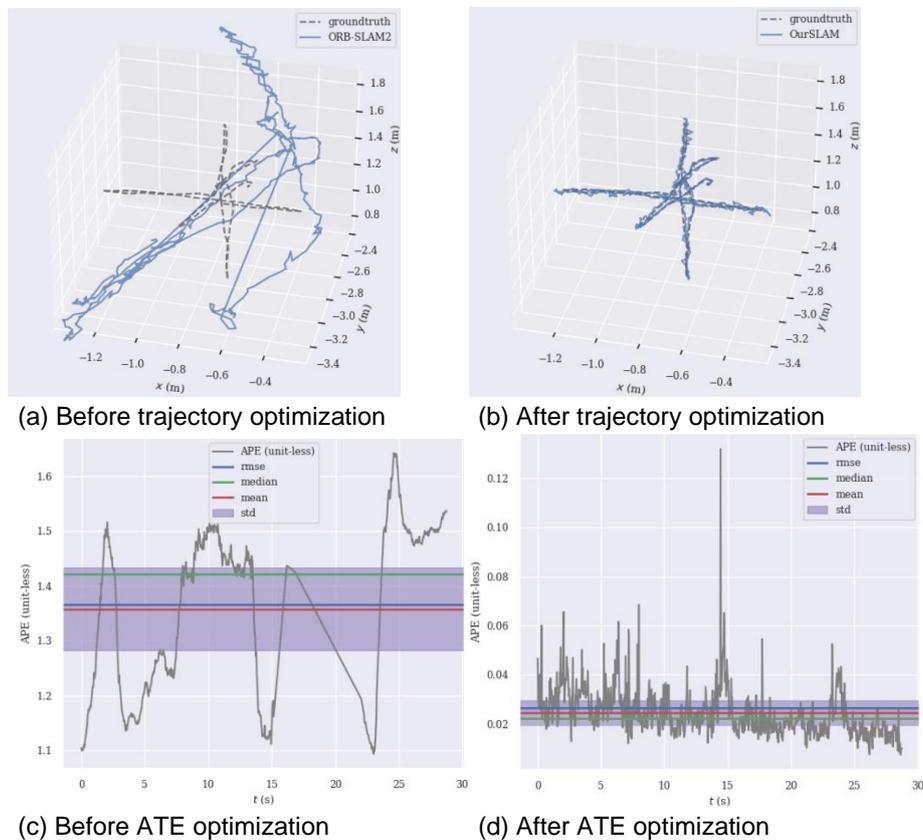

Fig. 6 – Comparison of trajectories and errors of datasets on walking_xyz

Figures 6 and 7 compare and analyze the camera trajectories evaluated by ORB-SLAM2 and this algorithm on the walking_xyz and walking_halfsphere datasets, respectively. The dotted line represents the real trajectory, while the solid line represents the camera trajectory evaluated by ORB-SLAM2 and this algorithm. The absolute trajectory error is denoted as (ATE). Figures 6 and 7 demonstrate the algorithm's accuracy by showing the similarity between its trajectories and the real trajectories. Additionally, the improved algorithm (Figures 6(d) and 7(d)) significantly reduces various types of error values compared to the unimproved algorithm.

To verify the effectiveness of the experimental design, ablation experiments were conducted on the TUM dataset. ORB-SLAM2 served as the base group, and the base group + YOLOv5s (ORB+YOLO) and the base group + LK optical flow method (ORB+LK), as well as the improved algorithm proposed in this paper, were tested.

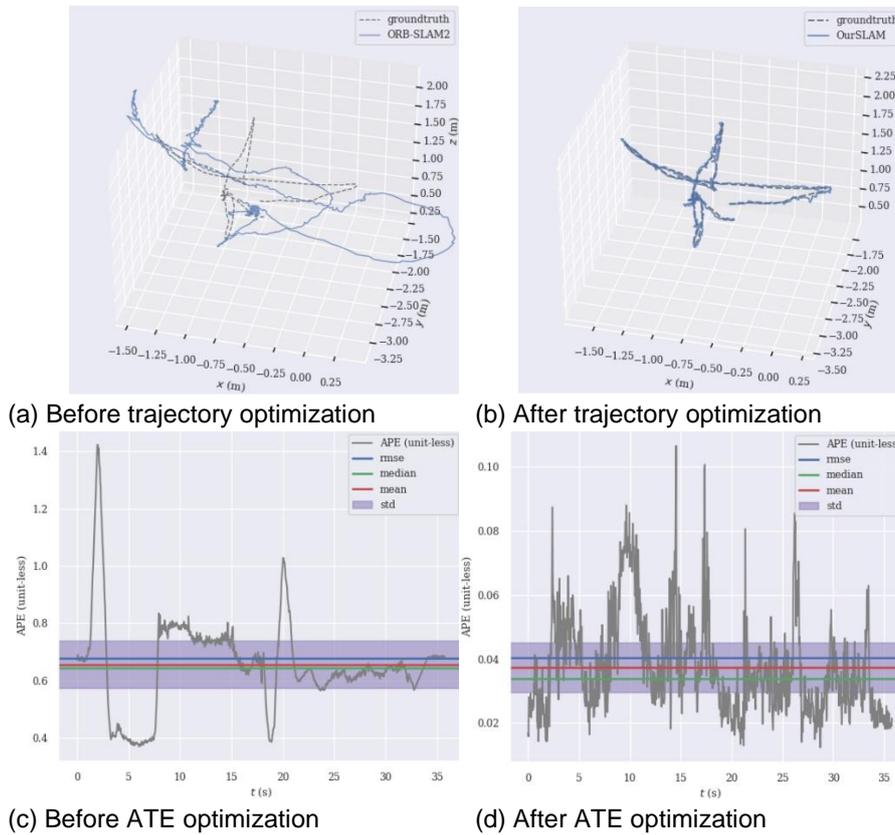

Fig. 7 – Comparison of trajectories and errors of datasets on walking_halfsphere

The comparison results are presented in Table 2, which demonstrate the superior effectiveness of the improved algorithm.

Table 2

Comparison results of ablation experiments

Data set	ORB-SLAM2		ORB + YOLO		ORB + LK		Ours	
	Rmse	STD	Rmse	STD	Rmse	STD	Rmse	STD
walking_xyz	0.2991	0.1186	0.0197	0.0116	0.1894	0.0752	0.0185	0.0092
walking_halfsphere	0.4754	0.1676	0.0411	0.0327	0.0752	0.0436	0.0381	0.0161
walking_static	0.0925	0.0714	0.0098	0.0087	0.0168	0.0114	0.0094	0.0082
walking_rpy	0.3575	0.2364	0.0468	0.0359	0.0748	0.0367	0.0349	0.0249
sitting_xyz	0.0153	0.0068	0.0161	0.0052	0.0151	0.0067	0.0134	0.0052
sitting_static	0.0122	0.0043	0.0124	0.0051	0.0097	0.0048	0.0082	0.0030

In this paper, the algorithm is simulated on six datasets in high and low dynamic environments, and the improvement degree of the improved algorithm over ORB-SLAM2 is calculated as shown in Eq. (9), which visually expresses the optimization effect.

$$\rho = \frac{\mu - \gamma}{\mu} \times 100\% \tag{9}$$

In the formula: ρ is the degree of improvement; μ is the result data of ORB-SLAM2 algorithm; γ is the result data of this paper's algorithm.

Table 3 and Table 4 show that the improved algorithm has an average improvement rate of RMSE and STD of less than 25% for the two sitting datasets in low dynamic scenarios, which is suboptimal. In datasets with dynamic objects, the removal of portrait feature points has little effect on the system's normal operation in low dynamic scenarios. However, in high dynamic scenarios, the algorithm presented in this paper shows an average improvement of 91.47% in the RMSE of four dynamic datasets compared to the ORB-SLAM2 algorithm. This indicates that the algorithm in this paper provides better localization accuracy in high dynamic scenarios.

Table 3

Comparison of absolute trajectory errors between ORB-SLAM2 and our algorithm

In recent years, scholars have presented numerous cases using the fusion of deep learning and optical flow methods. This paper compares the reliability of the algorithm with recent domestic and international dynamic vision SLAM algorithms, as shown in Table 5. The compared algorithms include DynaSLAM, DS-SLAM, and RDS-SLAM, with the root-mean-square error of the absolute trajectory path as the comparative data. The comparison data is the root mean square error of the absolute trajectory path. To eliminate the influence of other factors, such as hardware equipment, this paper calculates the relative improvement rate. This directly illustrates the improvement rate of the enhanced algorithm compared to the original SLAM algorithm under the same experimental conditions. The DynaSLAM algorithm and the algorithm proposed in this paper have shown the best results. However, the DynaSLAM algorithm's use of a semantic segmentation algorithm for dynamic feature point rejection consumes a lot of time, making it unsuitable for real-time requirements. In contrast, this paper's algorithm has demonstrated relatively impressive localization accuracy in highly dynamic scenes, confirming its reliability.

Table 4

Comparison of relative trajectory errors between ORB-SLAM2 and our algorithm

Data set	ORB-SLAM2		Ours		Relative uplift rate/%	
	Rmse	STD	Rmse	STD	Rmse	STD

CONCLUSIONS

This paper proposes a method that uses a target detection algorithm to identify and exclude feature points of dynamic targets in a farm depot. The method first utilizes the YOLOv5 target detection algorithm to identify dynamic targets in the acquired environment images. The recognized targets are then integrated into the visual SLAM front-end for feature extraction. Next, an LK optical flow method is used to eliminate dynamic feature points that belong to the dynamic target portion of the extracted image feature points. The remaining feature points are then utilized for bit matching and map construction to determine the location of the feature points. Tests were also conducted on the TUM dataset to evaluate the performance of the proposed method. The experimental results show that the enhanced visual SLAM system improves the localization accuracy by 91%. In highly dynamic scenes, the system effectively improves the localization accuracy and robustness by 47% over ORB-SLAM2. In addition, compared with other excellent SLAM algorithms, the system has significantly improved localization accuracy and higher real-time performance, so it is more suitable for the application of mobile devices on agricultural robots, which will promote the development of smart agriculture.

ABSTRACT

The lack of effective visualization research methods for the crushing process of grass kneading has restricted the development of grass kneading machine to a certain extent. In this paper, the hay kneading process was numerically simulated by using the discrete element method, the stem movement rule, the mechanical characteristics of the stem particle group and the power consumption of the kneading were analyzed, and the motion and breaking mechanism of the grass in the hay kneading machine were defined. The effects of motor output speed and feed rate on the spinning rate and power consumption were studied. The regression equation between test factors and evaluation indexes was established. With the goal of maximizing the silk rates and minimizing the power consumption, the motor output speed and feeding amount are optimized and solved. The optimal parameter combination is determined as follows: when the output speed of the motor is 282.88 r/min and the feeding amount is 1.86 kg/s, the knead verification test shows that the silk rates is 92.88% and the power consumption is 3.68 kJ. The research results provide a reference for realizing high efficiency and low power consumption of grass kneading and parameter optimization of kneading device.

摘要

针对牧草揉丝破碎过程缺乏有效可视化研究方法，在一定程度上制约了牧草揉丝机发展进程的问题。本文以铡切揉碎协同式牧草揉丝机为研究对象，采用离散元方法对牧草揉丝过程进行数值模拟，对牧草茎秆运动规律、茎秆颗粒群力学特性、揉丝功耗进行分析，明确了牧草在揉丝机内运动和破碎机理。进行了台架多因素性能试验，研究了电机输出转速和喂入量对丝化率和功耗的影响，构建了试验因素和评价指标之间的回归方程。以丝化率最大化和功耗最小化为目标，对电机输出转速和喂入量进行优化求解，确定最优参数组合为：电机输出转速为282.88r/min、喂入量为1.86kg/s时，揉丝验证试验表明，丝化率为92.88%、功耗为3.68kJ。研究结果为实现牧草高效、低功耗揉丝和揉丝装置参数优化提供参考。

INTRODUCTION

The kneading machine is a machine for processing and crushing forage grass (Wu et al., 2022; Wang et al., 2017; Fan et al., 2021). After kneading, the forage grass is filamentous with exposed internal nutrients (Kang et al., 2021; Tang, 2023), which can not only improve palatability, but also increase the contact area with the gastric juices of livestock, shorten the time of rumination and chewing, reduce the energy required for chewing of livestock, and have a better taste, which is convenient for the feeding and digestion of ruminant livestock (Li et al., 2023; Wang et al., 2017; Pei et al., 2023).

The contact between agricultural machinery and various agricultural materials and its impact on the design of agricultural machinery are important contents and difficulties in the digital design of modern agricultural equipment (Shi et al., 2022). As a computer numerical simulation method based on the discontinuity hypothesis, discrete element method can be used to simulate and analyze the interaction between agricultural materials and mechanical equipment, shorten the research and development cycle, and provide a means for the digital design of modern agricultural equipment, which has been widely used in the field of agricultural engineering (Zeng et al., 2021).

Aiming at the problem of the lack of effective numerical simulation methods for the kneading and crushing process of corn stem, *Zhang Fengwei et al. (2019)* established a corn stem simulation model based on the discrete element method, and checked the parameters of the corn stem bonding contact model through the combination of physical and virtual tests, and finally conducted the crushing simulation and test verification for the corn stem discrete element model. *Geng Duanyang et al. (2021)* established a silage corn straw bonding model based on discrete element method, and carried out a silk kneading simulation test using EDEM to explore the effects of the number of teeth, two-roll differential ratio, the number of gap spiral turns and the driving roll speed on the silk ratio of straw. The relative error between the simulation test and the bench test results was 3.03%. *Zhang Tao et al. (2018)* used EDEM software to simulate the influence of the rotor speed of the hammer straw crusher on the straw conveying performance and the impact force of the straw, as well as the movement process of straw particle groups in the kneading chamber under different rotor speeds, providing a basis for the rotor speed optimization of the crusher. At present, the numerical simulation of forage crushing is mainly focused on crop straw, and rarely involves the research of forage. Therefore, it is necessary to further expand the research methods of forage crushing, and realize the visualization of forage crushing process by using convenient and economical research methods, so as to facilitate parameter optimization and control.

In this paper, the cooperative forage kneading machine for cutting and kneading was taken as the research object (*Chen et al., 2024*). The flexible alfalfa stem was established through the Hertz-Mindlin with Bonding contact model in EDEM software, the working process of the kneading machine was numerically simulated, and the movement rule of alfalfa stem in the kneading machine was observed. The mechanical properties of stem particle groups and the power consumption of kneading were studied under different working parameters. The research results can provide a reference for expanding the research methods of grass crushing, and solve the problem that the traditional physical method is difficult to visualize the material movement in the kneading machine.

MATERIALS AND METHODS

Structure and working principle

Cutting and kneading cooperative grass kneading machine is mainly composed of feeding conveyor belt, conveyor chain plate, feeding mechanism, screening mechanism, kneading mechanism, cutting mechanism and other parts. The structure is shown in Fig.1.

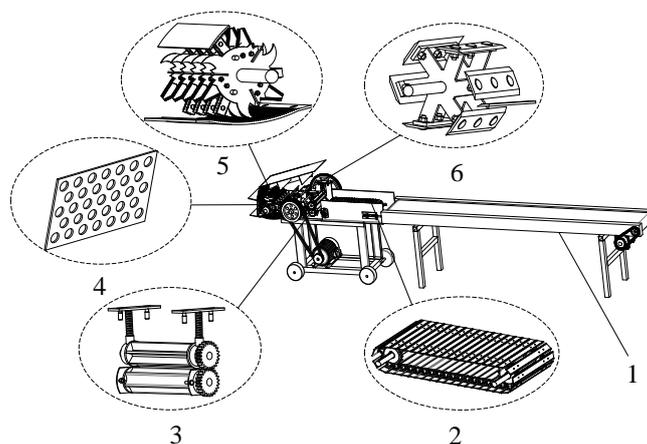

Fig. 1 – Structural diagram of cutting and crushing cooperative forage kneader

1. Feeding conveyor belt; 2. Conveyor chain plate; 3. Feeding mechanism;
4. Screening mechanism; 5. Kneading mechanism; 6. Cutting mechanism

The kneading operation is mainly divided into the following stages: feeding stage, the whole grass is transported to the conveyor chain plate through the feeding conveyor belt, and the grass enters the cutting chamber by rotation of the feed roller. In the cutting stage, the grass is cut into a certain length under the shearing action of the rotating motion of the grass knife and the fixed knife, and the cut grass is pushed to the kneading chamber under the rotation of the grass knife. In the kneading stage, the grass section is broken into filaments under the synergistic action of the hammer and serrated knife, the kneading and tearing between the hammer and serrated knife and the kneading tooth plate, the impact and friction between the sieve plate, etc.

In the screening and sending stage, the broken grass that meets the kneading length is thrown to the outside of the kneading machine through the screen plate under the combined action of the air flow generated by the rotation of the kneading rotor and the centrifugal force. The broken grass that is larger than the kneading length needs is kneaded in the kneading chamber for the next time, and further broken through the same crushing method as the last kneading until the length meets the kneading demand.

Determination of alfalfa stem intrinsic parameters and establishment of discrete element model
Determination of intrinsic parameters

The alfalfa used in the experiment was taken from the grass planting base in Duerbert County, Daqing City, Heilongjiang Province. The collected alfalfa was free from pests and diseases and there was no obvious mechanical damage. The average moisture content of alfalfa was determined by random sampling to be 78.4%. The stems were divided into root, middle and neck, and 100 mm stems were randomly intercepted as test materials. The diameter and length of the sample were measured using a digital display vernier caliper with an accuracy of 0.01 mm, and the distribution of stem samples and diameters was shown in Fig. 2.

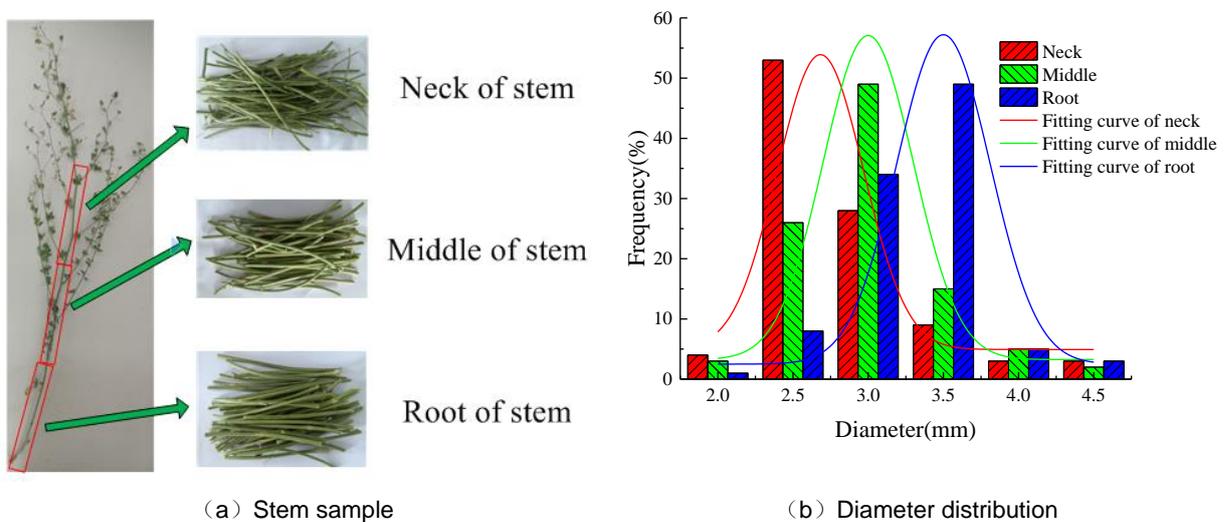

Fig. 2 - The sample and diameter distribution of alfalfa stem

The average diameter and length of alfalfa stem root were 3.24 mm and 128.47 mm respectively. The average diameter in the middle is 3.13 mm and the length is 142.73 mm. The average diameter of the neck is 2.87 mm and the length is 151.12 mm.

Contact model

In this study, the discrete element simulation model of alfalfa stem adopts the Hertz-Mindlin with bonding contact model. In this model, two adjacent particles are connected by Bonding bond, and both ends of the bond are fixed on the connected spherical particles. The end of the bond can be deformed with the movement of the spherical particle, such as elongation, bending and torsion (Wang et al., 2020; Zhang et al., 2023; Xie et al., 2023; Liu et al., 2022). In the simulation, the fracture of bond was used to simulate the breaking process of alfalfa stem. The established alfalfa stem discrete element flexible model is shown in Fig. 3.

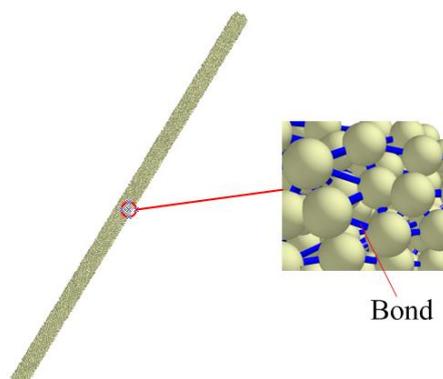

Fig. 3 - Alfalfa stem discrete element flexible model

Simulation parameter

According to the team's previous research results (*Chen et al., 2023*), the discrete element simulation parameters of alfalfa stem are shown in Table 1.

Table 1

Simulation parameters of alfalfa stem

Parameter class	Name	Numerical value
Intrinsic parameters	Poisson ratio of alfalfa stem	0.45
	Poisson's ratio of steel plates	0.30
	Clover stem shear modulus / MPa	17.5
	Shear modulus of steel plate / Pa	7.94×10^{10}
	Alfalfa stem density / ($\text{kg} \cdot \text{m}^{-3}$)	996
	Steel plate density / ($\text{kg} \cdot \text{m}^{-3}$)	7850
Contact parameter	Alfalfa stem - alfalfa stem collision recovery coefficient	0.44
	Alfalfa stem - alfalfa stem static friction factor	0.39
	Alfalfa stem - alfalfa stem rolling friction factor	0.13
	Collision recovery coefficient of alfalfa stem and steel plate	0.5
	Static friction factor of alfalfa stem and steel plate	0.5
	Alfalfa stem and steel plate rolling friction factor	0.2
Bonding parameter	Normal contact stiffness / ($\text{N} \cdot \text{m}^{-1}$)	3.57×10^9
	Tangential contact stiffness / ($\text{N} \cdot \text{m}^{-1}$)	4.01×10^8
	Critical normal stress / Pa	3.5×10^6
	Critical tangential stress / Pa	2.95×10^6
	Bonding radius / mm	0.5

Numerical simulation of kneading and crushing process

Simulation model

The 3D model of the kneading device was established in SolidWorks software. In order to improve the simulation efficiency, the simplified kneading device mainly includes feeding conveyor belt, conveying chain plate, feeding roller, cutting mechanism, kneading mechanism, screen plate, etc., which was saved as igs format and imported into EDEM 2020 software. The simulation model is shown in Fig. 4.

Fig. 4 - Simulation model of guillotine cutting and crushing cooperative forage kneading machine

RESULTS AND DISCUSSIONS

Analysis of movement state of alfalfa stem

The motion state of alfalfa stem during the kneading process in the simulation model was analyzed. At 0.3 s, the stems begin to be transported to the conveyor chain plate of the kneading machine, as shown in Fig. 5 (a). At 0.5 s, the stems begin to be transferred to the feed roller, as shown in Fig. 5 (b). At 0.8 s, the stem begins to be transported to the cutting chamber, as shown in Fig. 5(c). At 1.4 s, the cut alfalfa segment begins to be pushed to the kneading chamber, as shown in Fig. 5 (d). At 2 s, stems that meet the kneading length are thrown out of the body through the sieve plate, as shown in Fig. 5(e). At 2.6 s, the stems are all fed into the kneading machine, as shown in Fig. 5 (f).

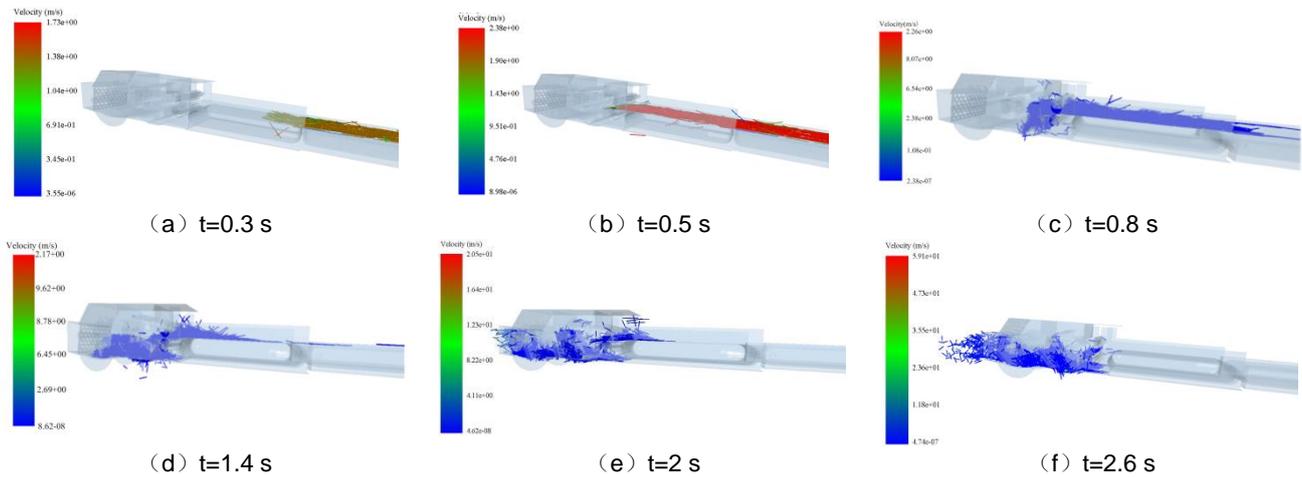

Fig. 5 - Alfalfa stem movement at different time

Change analysis of bond quantity

When the alfalfa stem model is broken, the bond between particles will be damaged and disconnected (Liu et al., 2019; Leblicq T. et al., 2016; Liu et al., 2020). At present, it is difficult to make quantitative statistics on the length of the material and the number of bonds contained after kneading. Therefore, this paper evaluated the effect of kneading machine crushing alfalfa stem by calculating the change of the number of all bonds in the domain.

In order to study the influence of rotor speed on the kneading effect, simulation was carried out under the motor output speed of 100 r/min, 200 r/min, 300 r/min, 400 r/min and 500 r/min respectively. According to the transmission ratio designed by the machine, the corresponding cutting shaft speed is 47 r/min, 94 r/min, 141 r/min, 188 r/min, 235 r/min; kneading shaft speed is 130 r/min, 260 r/min, 390 r/min, 520 r/min, 650 r/min; The effect of rotor speed on the number of bonds is shown in Fig. 6.

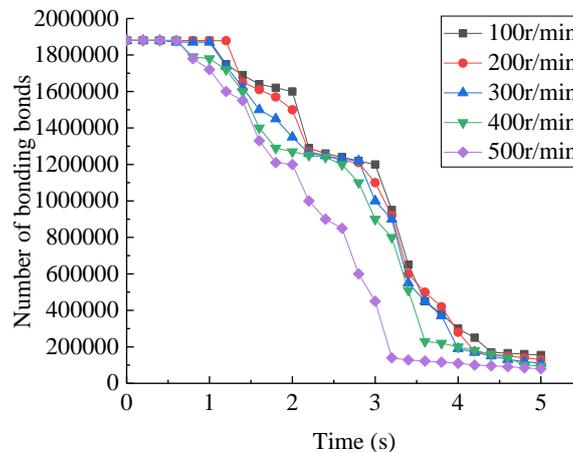

Fig. 6 - The number of bonds varies under different motor output speed

It can be seen from the Figure 6, that when $t=0\sim 0.5$ s, the stem is in the transport process, and the number of bonds remains unchanged. When $t=0.5\sim 1.5$ s, the stem is in the stage of cutting, and the bond gradually decreases at each speed, and the number of bonds decreases faster the higher the speed. From $t=1.5\sim 4$ s, the number of bonds began to decrease sharply at each speed, indicating that the stem entered the kneading chamber and began to be kneaded. At this stage, the speed has a great influence on the change of the bond, and the obvious difference can be seen. The material in the kneading chamber is stable for $4\sim 5$ s, and the number of bonds basically remains unchanged. Through the analysis of the change of the number of bonds at different rotational speeds, it can be seen that with the increase of rotational speed, the kneading efficiency will also accelerate.

Material quantity analysis in kneading machine

In the EDEM software, three monitoring areas (I , II , III) were established, as shown in Fig. 7, and the total number of alfalfa stems flowing through each interval was recorded, so as to calculate the change of the amount of materials at the cutting chamber, the kneading chamber and the discharge port with time at different rotating speeds.

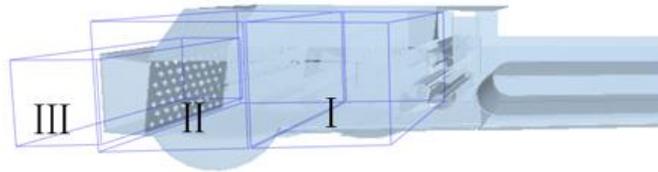

Fig. 7 - Material quantity monitoring area

Guillotine cutting chamber

The change of stem quantity in the cutting chamber under different rotation speed of the cutting shaft is shown in Fig. 8.

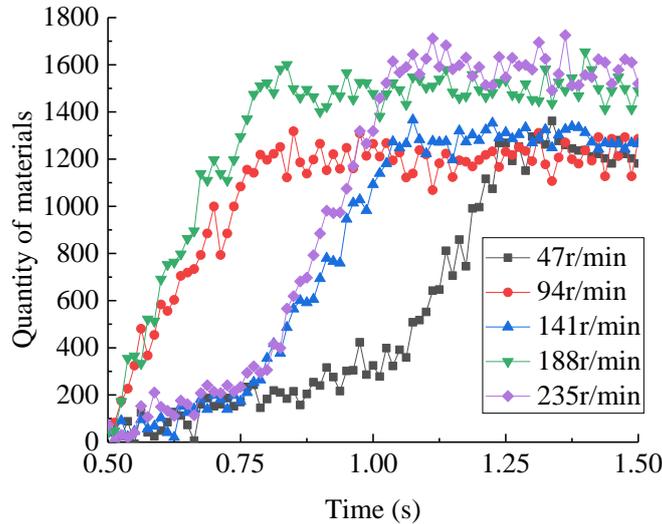

Fig. 8 – The number of stem in the cutting chamber with time

It can be seen from the figure that the number of stem in the cutting chamber under different cutting shaft speeds increases rapidly and shows a stable trend. After the number of stems was stabilized, the average number of stems in the knead chamber with the rotating speed of 47 r/min, 94 r/min, 141 r/min, 188 r/min and 235 r/min was 1085, 1170, 1224, 1532 and 1621, respectively, and then began to fluctuate around this number. The results showed that with the increase of the rotation speed of the cutting shaft, the number of stem cut in the cutting chamber in unit time also increased.

Kneading chamber

The changes in the amount of materials in the kneading chamber under different kneading shaft speeds are shown in Fig. 9.

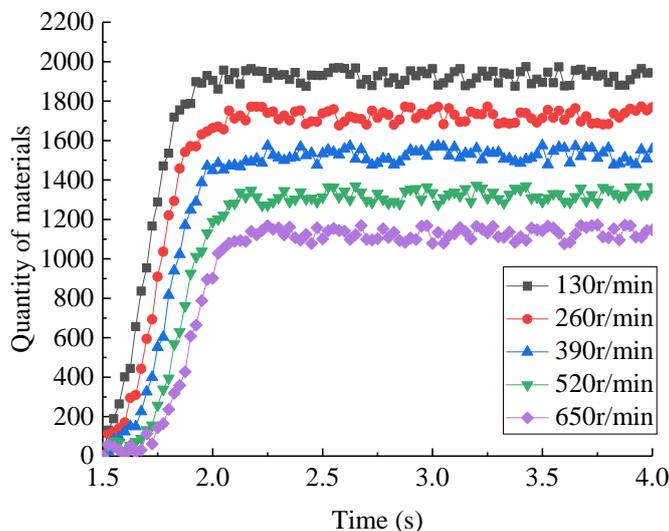

Fig. 9 - The number of stems in the kneading chamber changes with time

It can be seen from Fig. 9 that the number of stems in the kneading chamber increases rapidly and then shows a stable trend under different kneading shaft rotation speeds. After the number of stems was stabilized, the average number of stems in the knead chamber at 130 r/min, 260 r/min, 390 r/min, 520 r/min and 650 r/min were 1168, 1252, 1435, 1652 and 1836, respectively, and then began to fluctuate around this number. The results show that the amount of kneading machine per unit time increases with the increase of the rotational speed of the kneading shaft. The movement trajectory of the stem in the kneading chamber is shown in Fig. 10.

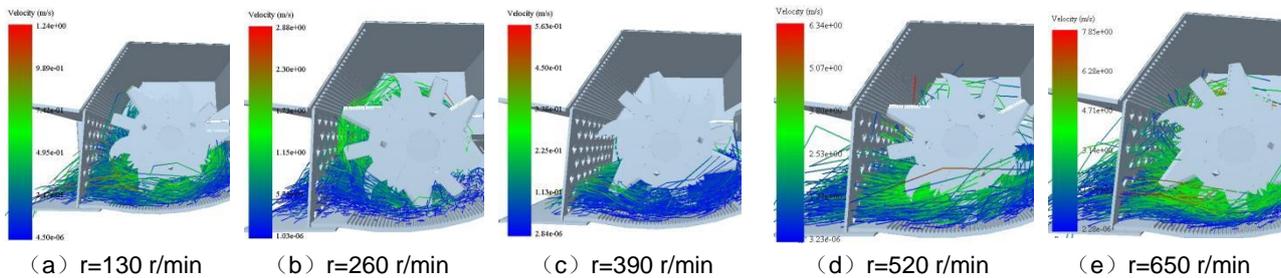

Fig. 10 - Stem movement trajectory in the kneading chamber

Discharge gate

The change of the number of broken stems at the discharge port over time is shown in Fig. 11.

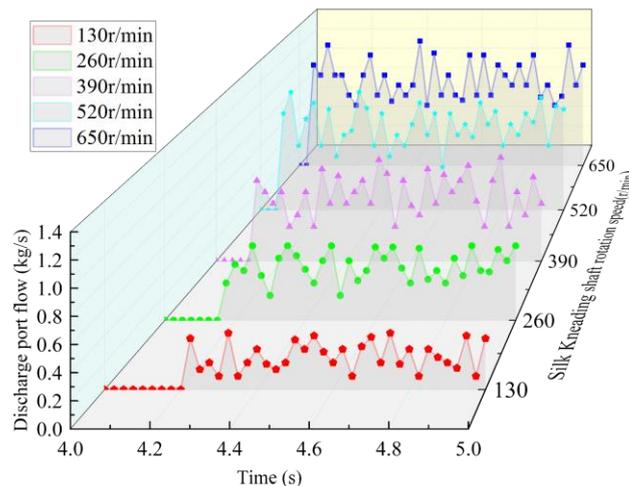

Fig. 11 - Changes in the quantity of materials at the discharge port over time

As can be seen from the figure, as the rotational speed of the kneading shaft increases, the number of broken stems at the discharge port also increases. When the rotational speed is lower than 260 r/min, due to the low interaction frequency between the stems and the kneading parts in unit time, the number of stems entering the kneading chamber in unit time is less, and the stems cannot be fully kneaded in a short time and cannot be timely screened, so the number of broken stems at the discharge port is less.

At 390 r/min, the stems can be broken in time, and there is almost no secondary kneading and circulation phenomenon. The silked stems can be stable and pass through the sieve, so the number of broken stems at the discharge port increases. When the rotational speed is higher than 520 r/min, due to the large centrifugal force on the stem, some of the longer stems that have not been fully kneaded are also directly discharged at the discharge port, so the amount of material at the discharge port increases significantly.

Mechanical analysis of stem particle group

Because there is only shear breakage for the alfalfa stem in the cutting chamber, the stress of the stem is relatively simple. However, in the kneading chamber, the stems are broken in various forms such as hitting, rubbing and impact, and the stress situation of the stems is more complicated (Hu et al., 2020; Zhu et al., 2022). Therefore, it is necessary to analyze the stress situation of the stem particle groups in the kneading chamber.

Analysis of stem energy change

The stem energy includes stem kinetic energy and potential energy. The influence of rotating speed of kneading axis on average stem energy is shown in Fig. 12.

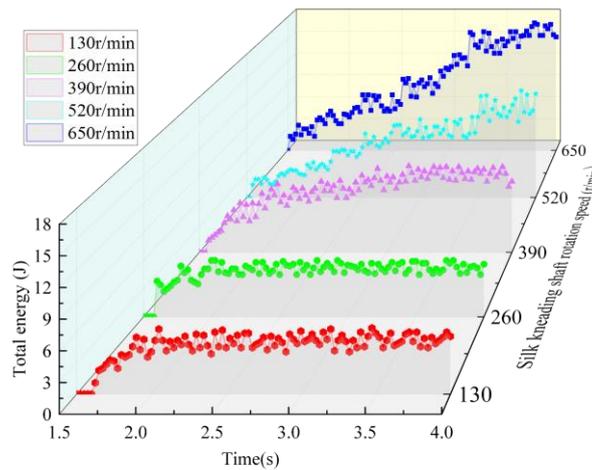

Fig. 12 - Effect of rotating speed of kneading shaft on average energy of stem

As can be seen from the figure, the average stem energy in the kneading chamber showed a trend of fluctuation and increase with the increase of the rotational speed of the kneading shaft. The average stem energy did not change significantly when the spindle speed increased from 130 r/min to 260 r/min. The average stem energy increased significantly when the spindle speed increased from 260 r/min to 650 r/min. The difference between the mean energy of stems at 390 r/min and that at 520 and 650 r/min increased with time.

Mean stem to stem interaction force

The influence of rotating speed of the kneading shaft on the average force between stems is shown in Fig.13.

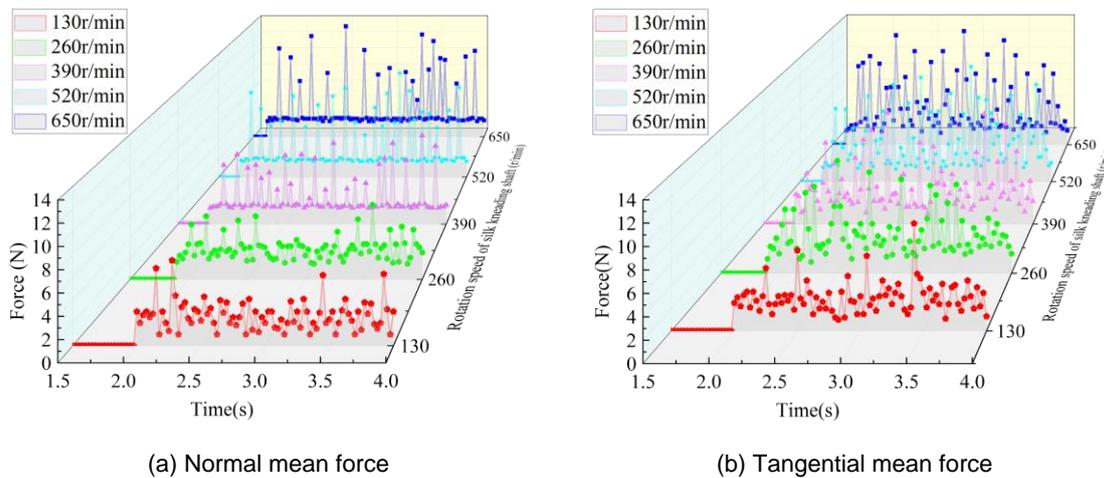

Fig. 13 - Effect of rotating speed of kneading shaft on average stem to stem force

As can be seen from the figure, the average stem to stem interaction force fluctuated sharply, and the fluctuation amplitude increased with the increase of the rotational speed of the kneading shaft. When the rotating speed of the kneading shaft was 130 r/min, 260 r/min, 390 r/min, 520 r/min and 650 r/min, the maximum normal forces of stem to stem could reach 7.2 N, 7.5 N, 9.3 N, 11.8 N and 13.5 N respectively. The maximum tangential mean force can reach 9.6 N, 10.9 N, 11.6 N, 12.9 N and 13.6 N respectively. The fluctuation of the average stem to stem interaction force is related to the random movement of a large number of stems in the kneading chamber, and the collision between the stems has a great influence on the movement of the stems in the kneading chamber. On the other hand, the increase of the rotational speed of the kneading shaft increases the energy of the stem, leading to the intensification of the collision between the stem, thus accelerating the energy loss of the stem itself, which is not conducive to the smooth screening of the stem.

Mean stem to sieve plate interaction

The influence of the rotating speed of the kneading shaft on the average force of the stem to sieve plate is shown in Fig. 14.

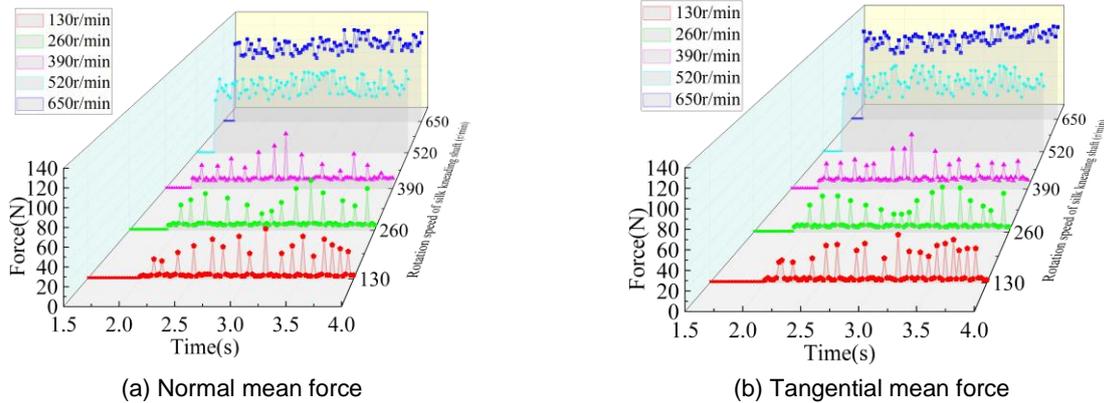

Fig. 14 - Effect of the rotational speed of the wire kneading shaft on the average force between the crushing rod and sieve plate

As can be seen from the figure, the average force of stem to sieve plate at different kneading shaft speeds all showed a fluctuating state after increasing from zero to a certain range. At 130 r/min, 260 r/min, 390 r/min, the mean interaction force of stem and sieve plate fluctuated sharply, and the maximum normal interaction force reached 53, 57, 68 N, and the maximum tangential interaction force reached 49, 50, 65 N, respectively. The fluctuation intensity of the average interaction force at 520 and 650 r/min is smaller than that at 130~390 r/min, and the maximum normal average interaction force can reach 110 and 130 N, and the maximum tangential average interaction force can reach 110 and 129 N, respectively. The increase of the rotational speed of the kneading shaft intensifies the collision between the stem and the sieve plate, resulting in a large amount of loss of the stem energy in the collision. Therefore, the rotational speed of the kneading shaft is not easy to be too fast under the premise of satisfying the quality of the kneading wire. The high-speed rotating hammer collides with the alfalfa section, thus providing the power for the alfalfa section to move. However, the collision between the alfalfa segment and the kneading chamber shell will consume the kinetic energy of the alfalfa segment. Therefore, in this paper, a serrated knife is installed on the kneading rotor of the cooperative grass kneading machine, which forms a staggered arrangement with the hammer in the axis to improve the distribution density of the kneading parts, so that it covers more kneading space in the work, and increases the frequency of interaction between the stem and the kneading parts per unit time. In order to increase the collision between the alfalfa segment and the kneading parts, and reduce the collision between the alfalfa segment and the kneading chamber shell, it is more beneficial to the movement of the alfalfa segment.

Influence of different parameters on power consumption

Effect of rotational speed on power consumption

The influence of rotation speed on power consumption is shown in Fig. 15.

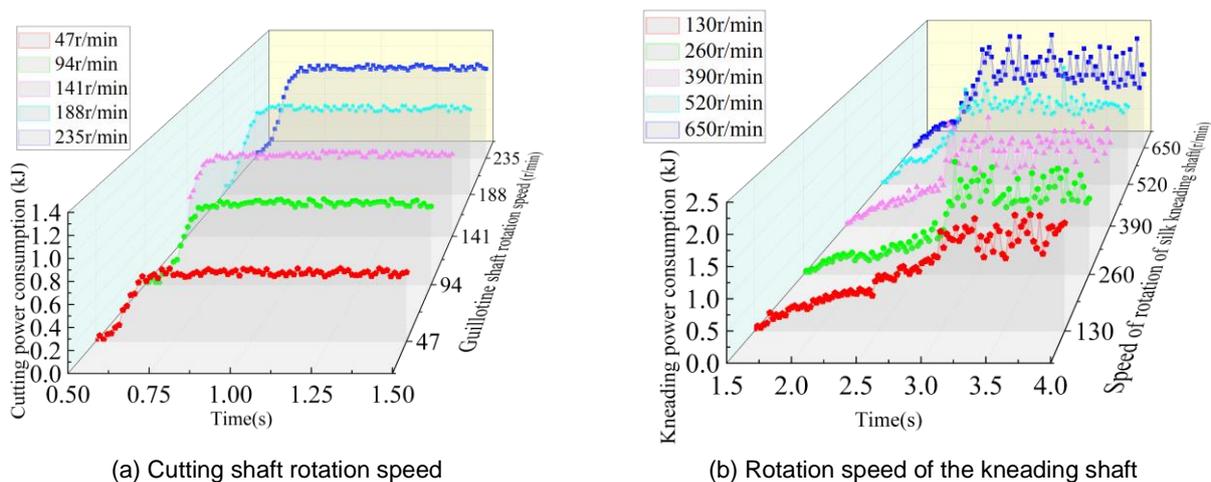

Fig. 15 - Influence of rotational speed on power consumption

As can be seen from the figure, the fluctuation of the kneading power consumption is more severe than the cutting power consumption. Cutting power consumption and kneading power consumption are increased with the increase of rotor speed, the reason is that the speed increases, the number of interactions between the mechanical parts and the stem per unit time increases, and the power consumption increases. When the speed of the kneading shaft is lower than 260 r/min, the power consumption increases slowly, and when the speed reaches 390 r/min, the power consumption increases sharply, because the stem and the rotor rotate at the same speed, forming a material circulation layer, and the torque required for high speed is also greater. When the cutting shaft speed is 47, 94, 143, 188, 235 r/min, the average power consumption is 0.56, 0.71, 0.84, 0.94, 1.08 kJ, and the maximum is 0.66, 0.84, 0.91, 1.02, 1.14 kJ, respectively. When the rotating speed of the kneading shaft is 130, 260, 390, 520 and 650 r/min, the average power consumption of the kneading shaft is 1.39, 1.54, 1.76, 1.89 and 2.05 kJ, respectively, and the maximum power consumption is 1.89, 1.98, 2.06, 2.38 and 2.46 kJ, respectively.

Influence of feeding amount on power consumption

The influence of feeding amount on power consumption is shown in Fig. 16.

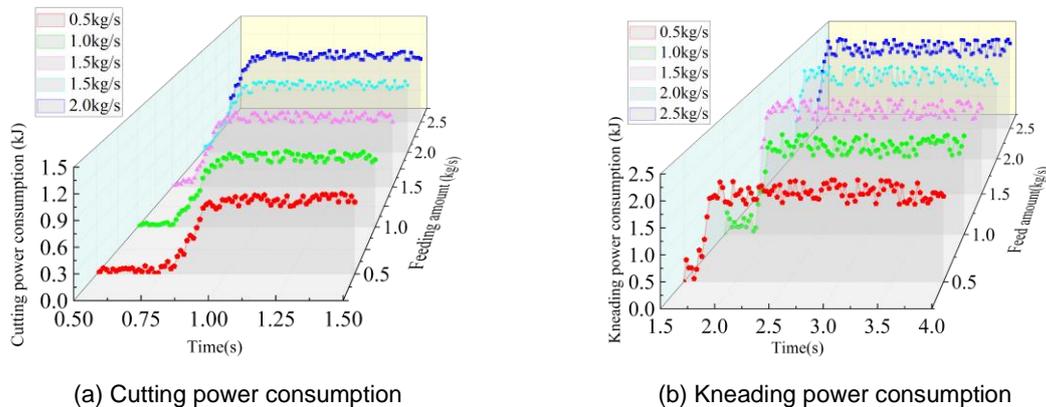

Fig. 16 - Influence of feeding amount on power consumption

It can be seen from the figure that with the increase in the amount of feeding, the cutting power consumption and kneading power consumption are increased, the reason is that with the increase in the amount of feeding, the number of stems in the cutting chamber increases, the density of the stems in the cutting chamber and the kneading chamber increases, the impact force increases, the impact resistance of the cutting knife and the hammer increases, the friction between the stems leads to an increase in resistance, the number of collisions increases, resulting in an increase in power consumption. When the feeding amount is the same, the fluctuation of the kneading power consumption is more severe than that of the guillotine power consumption. When the feeding amount is 0.5, 1.0, 1.5, 2.0, 2.5 kg/s, the average power consumption of cutting is 0.57, 0.68, 0.81, 0.88, 0.99 kJ, and the maximum power consumption is 0.94, 0.97, 1.03, 1.06, 1.12 kJ, respectively. The average power consumption of kneading is 1.60, 1.61, 1.87, 1.98, 2.09 kJ, and the maximum power consumption is 1.97, 2.10, 2.13, 2.25, 2.32 kJ, respectively.

Bench test

The bench performance test was carried out on the self-developed kneading test bench, and the test was carried out in the crop harvest Laboratory of Heilongjiang Bayi Agricultural University, as shown in Fig. 17.

Fig. 17 - Test site

1. Power consumption test device 2. Kneading machine 3. Feeding conveyor belt

Experimental design

The evaluation indicators are calculated as follows:

Silk rates

Samples were collected at the outlet, at the same time interval for 3 times, each time no less than 200 g. All samples were mixed and weighed. Qualified alfalfa silk was screened and weighed, and its silk rate was calculated as:

$$W_h = \frac{m_1}{m_0} \times 100\% \quad (1)$$

where: m_1 is quality of alfalfa silk in the sample, g; m_0 is alfalfa sample quality, g.

Power consumption

The power consumption is determined by the DYN-200 torque power sensor installed on the motor spindle. After each group of tests, the instantaneous torque, power and required time measured by the sensor are derived through the torque measurement system, and the instantaneous power of the effective working period is calculated to obtain the kneading power consumption. The calculation formula is as follows:

$$W_z = \int P(t) dt_z \quad (2)$$

where: W_z is kneading power consumption, kJ; $P(t)$ is instantaneous power, kW; t_z is kneading time, s.

Test results and analysis

In the range of output speed 100~500 r/min and feed rate 0.5~2.5 kg/s, two-factor and five-level quadratic rotation orthogonal combination tests were carried out. The regression equation and optimization model between test factors and evaluation indexes are established by using Design-Expert 12.0 software. Factor coding is shown in Table 2. x_1 and x_2 are factor coding values, and the values in brackets in the table are rounded results according to actual operation requirements.

Table 2

Coding	Factor	
	Motor output speed x_1 (r/min)	Feeding quantity x_2 (kg/s)
1.414	500	2.5
1	441.44 (440)	2.21 (2.2)
0	300	1.5
-1	158.56 (160)	0.79 (0.8)
-1.414	100	0.5

The test scheme and results are shown in Table 3.

Table 3

Test scheme and results				
Number	Motor output speed x_1 (r/min)	Feeding quantity x_2 (kg/s)	Silk rate W_h (%)	Power consumption W_z (kJ)
1	-1	-1	90.49	3.31
2	1	-1	90.31	2.99
3	-1	1	97.27	4.26
4	1	1	91.97	3.88
5	-1.414	0	91.36	3.92
6	1.414	0	90.96	3.16
7	0	-1.414	89.67	3.37
8	0	1.414	96.37	4.21
9	0	0	92.26	3.38
10	0	0	92.18	3.35
11	0	0	91.07	3.36
12	0	0	91.28	3.26
13	0	0	91.41	3.48

The results of variance analysis of silk rate and power consumption are shown in Table 4 and Table 5 respectively.

Table 4

Analysis of variance of silk rate

Source of variance	Sum of squares	Degree of freedom	Mean sum of squares	F	P
Model	56.04	5	11.21	16.73	0.0009**
x_1	4.57	1	4.57	6.82	0.0348*
x_2	40.12	1	40.12	59.89	0.0001**
x_1x_2	6.55	1	6.55	9.78	0.0167*
x_1^2	0.13	1	0.13	0.19	0.6766
x_2^2	4.4	1	4.4	6.56	0.0374*
Residual error	4.69	7	0.67		
Lack of fit	3.51	3	1.17	3.95	0.1089
Error	1.18	4	0.3		
Sum total	60.73	12			

As can be seen from the table, the silk rate regression model ($P=0.0009$) is significant, while the loss of fit term ($P=0.1089$) is not, indicating that the model has a good degree of fitting and no loss of fit phenomenon occurs. The determination coefficient $R^2=0.9228$, the correction determination coefficient $R_{adj}=0.8676$, which is very close to 1, and the coefficient of variation is 0.89%, indicating that the test data is reliable. There is a significant relationship between the predicted value of the regression equation and the actual value obtained through the analysis of the test results. The regression equation of each factor and evaluation index obtained is shown as follows:

$$W_h = 91.64 - 0.76x_1 + 2.24x_2 - 1.28x_1x_2 - 0.14x_1^2 + 0.8x_2^2 \tag{3}$$

Table 5

Analysis of power consumption variance

Source of variance	Sum of squares	Degree of freedom	Mean sum of squares	F	P
Model	1.83	5	0.37	25.25	0.0002**
x_1	0.39	1	0.39	27.16	0.0012**
x_2	1.15	1	1.15	79.06	< 0.0001**
x_1x_2	0.0009	1	0.0009	0.062	0.8104
x_1^2	0.037	1	0.037	2.57	0.1526
x_2^2	0.27	1	0.27	18.86	0.0034**
Residual error	0.1	7	0.014		
Lack of fit	0.077	3	0.026	4.14	0.1018
Error	0.025	4	0.006		
Sum total	1.93	12			

As can be seen from the table, the power regression model ($P=0.0002$) is significant, while the loss of fit term ($P=0.1018$) is not, indicating that the model has a good degree of fitting and no loss of fit phenomenon occurs. The determination coefficient $R^2=0.9475$, the correction determination coefficient $R_{adj}=0.9099$, which is very close to 1, and the coefficient of variation is 2.99%, indicating that the test data is reliable. There is a significant relationship between the predicted value of the regression equation and the actual value obtained through the analysis of the test results. The regression equation of each factor and evaluation index obtained is shown as follows:

$$W_z = 3.87 - 0.22x_1 + 0.38x_2 - 0.02x_1x_2 - 0.07x_1^2 + 0.2x_2^2 \tag{4}$$

Parameter optimization and test verification

Design-Expert 12.0 software Optimization module was used to optimize the model with the goal of maximizing the silk rate and minimizing the power consumption, and the optimization mathematical model was established through the analysis.

$$\begin{cases} \max W_h(x_1, x_2) \\ \min W_z(x_1, x_2) \\ s.t. \begin{cases} -1.414 \leq x_1 \leq 1.414 \\ -1.414 \leq x_2 \leq 1.414 \end{cases} \end{cases} \quad (5)$$

The optimal parameter combination of the kneading machine is obtained as follows: when the output speed of the motor is 282.88 r/min and the feeding amount is 1.86 kg/s, the spinning rate is 93.13% and the power consumption is 3.63 kJ. At this time, the maximum value of the comprehensive evaluation index is 0.474, which is the optimal parameter combination, and the comprehensive evaluation response surface is shown in Fig. 18.

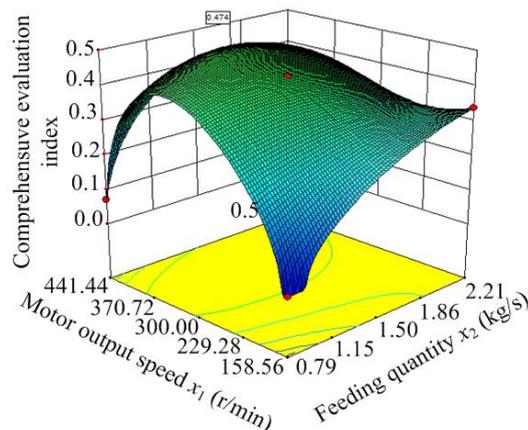

Fig. 18 - Comprehensive evaluation response surface

The bench verification test was carried out according to the optimal parameter combination obtained from the response surface analysis. In order to reduce the error, the test was repeated five times to take the average value, and the test results were as follows: the silk ratio was 92.88%, the power consumption was 3.68 kJ, and the difference between the actual test value and the software analysis value was 0.27% and 1.38%, respectively. The experimental results are close to the optimized values, which proves that the optimized results are accurate and reliable.

CONCLUSIONS

(1) EDEM discrete element simulation software was used to simulate the working process of the kneading machine in different working parameters, and the law of stem movement, mechanical characteristics of stem particle groups and power consumption were analyzed, and the motion and crushing mechanism of the forage in the kneading machine were defined.

(2) The multi-factor test of bench performance was carried out, and the regression model of the spinning rate and power consumption was established. The variance analysis showed that the main and secondary factors affecting the spinning rate and power consumption were the feeding amount and the output speed of the motor.

(3) With the goal of maximizing the silk rate and minimizing the power consumption, the output speed and feeding amount of the motor were optimized by multi-objective solution, and the optimal parameter combination was obtained as follows: when the output speed of the motor was 282.88 r/min and the feeding amount was 1.86 kg/s. The verification test shows that the silk rate is 92.88% and the power consumption is 3.68 kJ, which meets the requirement of high moisture content alfalfa silk kneading.

ABSTRACT

To address the challenge of parameter accuracy in discrete element method (DEM) simulations of buckwheat seeds within a seed metering device, this study characterized the physical properties of buckwheat seeds and subsequently calibrated the simulation model parameters. Initially, physical experiments were conducted to determine the triaxial dimensions, angle of repose, and static friction coefficients of buckwheat seeds against stainless steel surfaces. A three-dimensional model of the buckwheat seeds was then generated using Inventor and it was imported into EDEM to simulate the seed stacking process, with the angle of repose quantified via image processing techniques. Employing a Plackett-Burman design, initial parameters were screened, identifying the static friction coefficient between buckwheat seeds, the rolling friction coefficient between buckwheat seeds, and the static friction coefficient between buckwheat seeds and stainless steel as significant factors influencing the angle of repose. The optimal range for these significant parameters was determined through a steepest ascent experiment, and a second-order regression model was developed using Box-Behnken experimental results to optimize the angle of repose and the identified parameters. The optimized parameter set comprised a static friction coefficient between buckwheat seeds and stainless steel of 0.448, a rolling friction coefficient between buckwheat seeds of 0.038, and a static friction coefficient between buckwheat seeds of 0.372. Validation through both simulations and physical experiments revealed a relative error of 1.08%, confirming the reliability of the calibrated parameters for simulating buckwheat seed sowing machinery.

摘要

针对荞麦种子在排种器中进行离散元排种仿真模拟试验缺乏准确参数的问题,本研究对荞麦种子进行物性参数测定及仿真模型参数标定。首先,通过物理试验测定荞麦种子的三轴尺寸,休止角以及荞麦种子与不锈钢板间静摩擦系数。其次,运用 Inventor 绘制荞麦种子的三维模型,并导入到 EDEM 中建立荞麦离散元模型,来模拟荞麦种子的堆积过程,通过图像处理技术,获得准确的休止角。通过 Plackett-Burman 试验对初始参数进行筛选,得出荞麦间静摩擦系数、荞麦间滚动摩擦系数、荞麦-不锈钢之间的静摩擦系数对颗粒堆休止角影响显著。最后在最陡爬坡试验确定显著性参数最优值区间的基础上,根据 Box-Behnken 试验结果建立了休止角与显著性参数的二阶回归模型并对其进行优化,得到显著性参数的最佳组合。通过试验得出荞麦-不锈钢静摩擦系数为 0.448、荞麦间滚动摩擦系数为 0.038、荞麦间静摩擦系数为 0.372。通过仿真与物理试验对比验证,得到二者相对误差为 1.08%,标定参数可为荞麦播种机械仿真提供数据依据。

INTRODUCTORY

Buckwheat is one of the small grains native to China, planted area of about 850,000 hm², accounting for approximately one-third of the world's planted area. The average annual production is about 980,000 tons, ranking second globally (Wu L.G. et al., 2018). Buckwheat is valued for its unique functional components and high nutritional value, attracting increasing global attention. However, the level of mechanization in buckwheat sowing remains relatively low worldwide. In China's alpine and hilly regions, where buckwheat planting is extensive, mechanized harvesting is limited. Available models are scarce, and harvest quality is poor. Even in northern regions with higher mechanization levels, temporary modifications of other crop sowing machines are commonly used. These adaptations complicate interactions between seeds, seed dischargers, and machine components. Analysis using the discrete element method (DEM) allows for a detailed understanding of these interactions and facilitates the design and optimization of related equipment and process parameters (Zeng Z.W. et al., 2021).

Previous studies have calibrated DEM parameters for materials such as coal dust, cereal seeds, corn, potatoes, and garlic. *Zhang Rui et al., (2017)*, calibrated the contact parameters of sand and soil using standard and non-standard ball methods, and investigated whether different quality of sand and soil with different calibration methods would affect the results of stacking angle as well as the contact parameters. *Li Yong Xiang and others, (2019)*, simplified irregularly shaped wheat flour particles into soft spherical ones and scaled them, selected the “Hertz - Mindlin with JKR” contact model, and used the angle of repose to calibrate the contact parameters. *Wang Chengjun et al., (2012)*, determined the elastic properties of wheat and investigated the effects of collision material, material thickness, drop height and wheat moisture content on the coefficient of recovery of wheat, and determined the significance ranking of the effects of each factor on the coefficient of recovery of wheat for Q235 collision material. *Wu Jia Sheng et al., (2019)*, used the cylinder stacking method with EDEM simulation and combined with image processing technology to determine the stacking angle of forenut seeds, and calibrated the physical parameters of forenut seeds based on the response surface optimization method, *Liu Wen Zheng et al., (2018)*, optimized and calibrated potato parameters by combining physical and simulation tests. *González-Montellano et al., (2012)* studied maize and olive and obtained large CV (coefficient of variation) values for seeds at different collision velocities by means of a collision recovery test, which showed that in most cases the CV values were determined by the nature of the seeds themselves. In summary, it can be seen that most of the discrete element simulation calibration are powder, corn, seeds and large objects, and there is little content on the determination and calibration of discrete element simulation parameters of buckwheat grains.

This study combines physical and simulation tests to calibrate nine parameters for buckwheat grains. Physical test values were used as input ranges for Plackett-Burman, steepest climb, and Box-Behnken experiments. The results provide data support for future DEM simulations of buckwheat sowing machinery, enhancing simulation accuracy.

MATERIALS AND METHODS

Static friction angle measurement test

The static friction coefficient of buckwheat seeds represents the maximum static friction force divided by the normal force during contact. Seed surface roughness primarily determines this coefficient—greater roughness increases the coefficient and reduces seed movement tendency. The test apparatus is shown in Fig. 1. The oblique plane method was used to measure the static friction coefficient. The angle θ was gradually increased until the seeds began to slide, at which point θ was recorded.

The static friction coefficient μ was calculated using Eq. 1 (*Li et al., 2023*).

$$\mu = \frac{f}{N} = \frac{mg\sin\theta}{mg\cos\theta} = \tan\theta \quad (1)$$

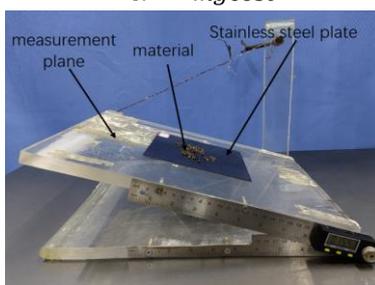

Fig. 1 - Static friction measurement

Based on the measured data, the angle of static friction between the buckwheat seeds and the stainless steel plate can be derived, and the static friction factor was calculated as 0.275.

Stacking Experiment

The methods of angle of repose measurement include gravitational equilibrium method and internal collapse method. Based on the experimental conditions of our institute, the funnel method was adopted to measure the angle of repose. The funnel apparatus is illustrated in Fig.2, with a large diameter (a_1) of 140 mm, a small diameter (a_2) of 25 mm, and a height (h_1) of 170 mm. The height of the funnel above the platform (h_2) is 100 mm, and the diameter of the frustum (a_3) is 100 mm. During the experiment, the distance between the bottom of the funnel and the frustum below (h_3) was adjusted and buckwheat seeds were uniformly added

into the funnel at a constant rate. The seeds gradually formed a conical pile, with the angle between the slope of the conical pile and the plane of the frustum representing the angle of repose (θ), as shown in Fig.3.

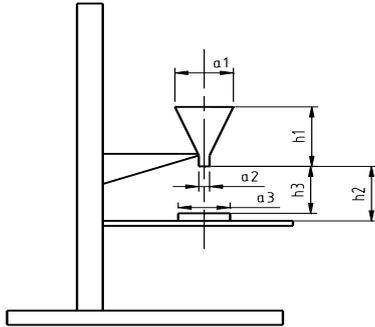

Fig. 2 - Schematic diagram of the funnel device

Fig. 3 - Buckwheat seed pile

In order to reduce human error in measurement, the computer image processing method Matlab is used here for image processing of buckwheat rest angle. As shown in Fig.4. First use the camera perpendicular to the side of the buckwheat pile to take a picture, to obtain the original image, as shown in Fig.4 (a).

The image is converted into a gray-scale image by Matlab processing as shown in Fig.4 (b), and then the image is binarized to obtain the binarized image, followed by extracting the curve data in the picture to obtain the boundary as shown in Fig.4 (c).

Subsequently the calibration between the picture and the curve is performed to obtain the unprocessed scatter plot. The scatter points are converted into useful curves and the scanned curves are shown in Fig.4 (d). Finally, the extracted data were fitted and the fitted curve was obtained as shown in Fig.4 (e). For each experiment, the repose angle of the buckwheat pile was measured in four directions: front, back, left, and right. The experiment was repeated twice to obtain an average value. The calculated repose angle α for the buckwheat in the actual experiment was found to be 27.65° .

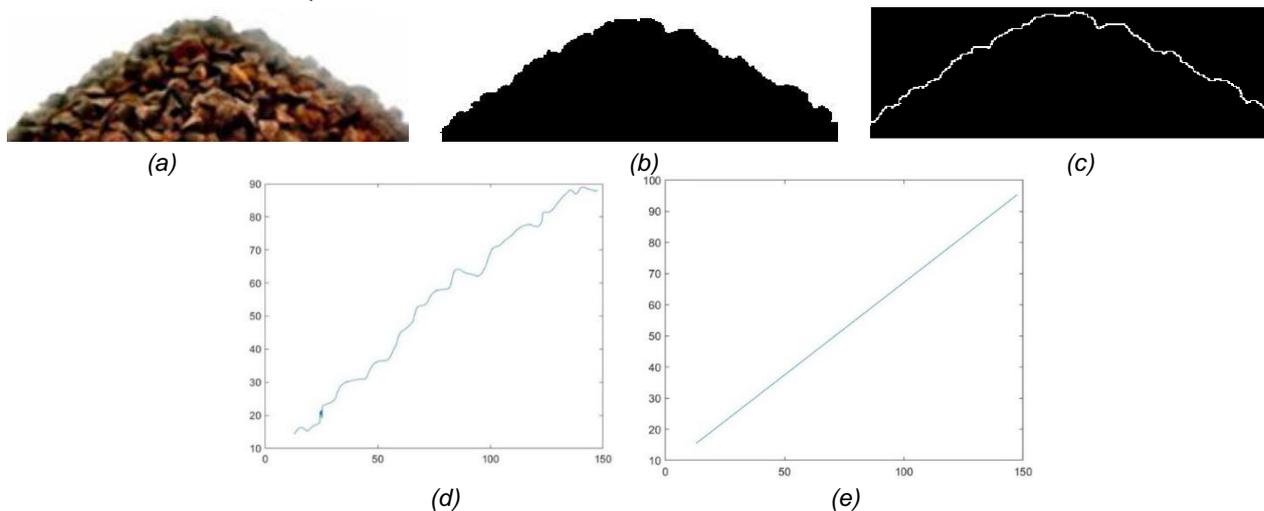

Fig. 4 - Angle of repose image processing

Establishment of discrete elemental model and parameter calibration of buckwheat

The discrete element model needs to roughly match the appearance of the actual object. In the discrete element simulation parameter settings, different input values give different results. Therefore, the physical test values are used as a target for the optimization of individual contact parameters (Xu B et al., 2021).

Model building

The three-axis dimensions of buckwheat were determined using a calliper, with the measurement results being presented in Table 1. This experiment focused on laboratory-cultivated bitter buckwheat and measurements were taken ten times to calculate the average value. Then, Inventor was used to draw the three-dimensional model of buckwheat, which was saved in STL format and imported into EDEM. Relevant literature shows that for the simulation modeling, smaller shape errors have less impact on the simulation results, and smaller errors between the size and shape of the actual particles and the discrete element model can be allowed. Therefore, the measured and statistical buckwheat shape dimensions were filled as shown in Fig. 5.

Table 1

Buckwheat triaxial size

	Length	Width	Height
maximum values /mm	6.15	4.92	4.58
average value /mm	6.01	4.13	4.09
minimum value /mm	5.84	4.02	3.96

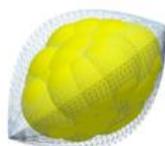

Fig. 5 - Discrete metamodel of buckwheat

Modeling of the funnel

The material chosen for the funnel is Q235 to model the discrete element of the funnel, where the diameter of the large end of the funnel is 140 mm, the diameter of the small end is 25 mm, and the height of the funnel is 170 mm. There is also a circular table with a diameter of 100 mm and a height of 7 mm (Chen G et al., 2024).

Formation of particle stacks

After the funnel model was established, it was imported into EDEM, and the dynamic particle generation method was used to establish a particle plane at the upper end of the funnel, the buckwheat seeds were discharged from the buckwheat grain container at a consistent rate, and eventually the grains would form a stable conical particle pile on the circular table. The whole process of seed grain formation is shown in Fig.6 (Lei et al., 2023).

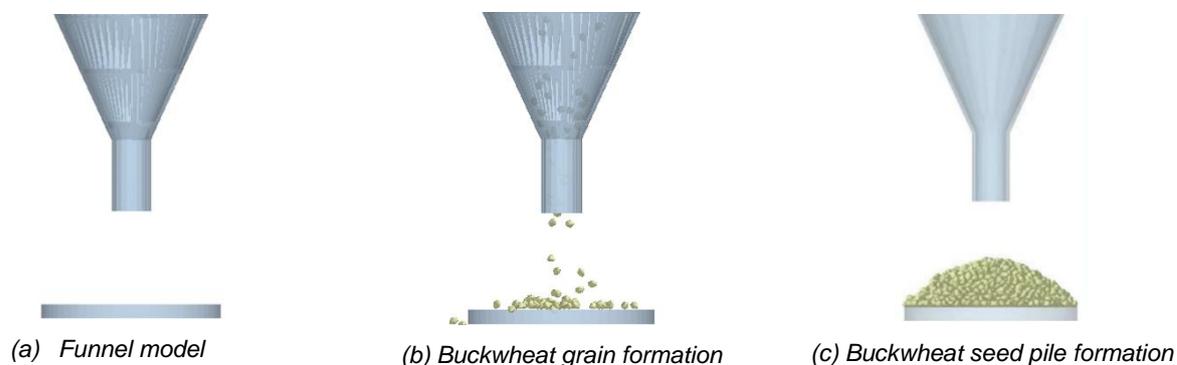

Fig. 6 - Simulated formation process of buckwheat kernels

Simulation model parameter calibration test

● **Plackett-Burman test**

Design-Expert software was applied to design the Plackett-Burman test, using the angle of repose of buckwheat seed drop test as the response value, and the simulation parameters with significant influence on the response value were screened out. It was combined with the previous physical tests and related literature to determine the individual simulation parameters in this study. The collision recovery coefficient for buckwheat ranges from 0.2 to 0.5, while the static friction coefficient is between 0.3 and 0.61. The rolling friction coefficient for buckwheat falls within 0.01 to 0.1. In interactions between buckwheat and stainless steel, the collision recovery coefficient is observed to be between 0.1 and 0.508, the static friction coefficient ranges from 0.2 to 0.7, and the dynamic friction coefficient is between 0.043 and 0.1. Simulation experiments were conducted to optimize nine parameters labelled A-I, selecting the upper and lower limits of two values to establish high and low levels, resulting in a total of 12 test groups, as detailed in Table 2 (Rittisak et al., 2023; Xu et al., 2023).

Table 2

Buckwheat simulation parameters

Symbol	Parameters	Levels	
		-1	+1
A	Buckwheat Intercollision Recovery Coefficient	0.2	0.5
B	Coefficient of static friction between buckwheat seeds	0.3	0.61
C	Coefficient of rolling friction between buckwheat seeds	0.01	0.1
D	Buckwheat seeds-stainless steel dynamic collision recovery coefficient	0.1	0.508
E	Buckwheat seeds-stainless steel coefficient of static and dynamic friction	0.2	0.7
F	Buckwheat seeds-stainless steel coefficient of kinetic friction	0.043	0.1
G	Buckwheat Poisson's ratio	0.3	0.5
H	Buckwheat density	1034	1250
J	Buckwheat shear modulus	1E+06	3.43E+06

- **Plackett-Burman experimental design**

Utilizing the Plackett-Burman design, the fundamental contact parameters influencing the buckwheat seed drop test as a variable factor were assessed, with each test yielding an average angle of repose of approximately 2. The experimental findings are presented in Table 3.

Table 3

Plackett-Burman experimental design

Test No.	A	B	C	D	E	F	G	H	J	Angle of repose / (°)
1	0.2	0.61	0.1	0.508	0.2	0.043	0.3	1250	1E+06	21.67
2	0.2	0.61	0.1	0.1	0.7	0.1	0.5	1034	1E+06	38.62
3	0.2	0.3	0.01	0.508	0.2	0.1	0.5	1034	3.43E+06	12.94
4	0.5	0.61	0.01	0.508	0.7	0.1	0.3	1034	1E+06	26.42
5	0.2	0.61	0.01	0.508	0.7	0.043	0.5	1250	3.43E+06	28.02
6	0.2	0.3	0.01	0.1	0.2	0.043	0.3	1034	1E+06	11.63
7	0.5	0.3	0.01	0.1	0.7	0.043	0.5	1250	1E+06	20.36
8	0.2	0.3	0.1	0.1	0.7	0.1	0.3	1250	3.43E+06	29.99
9	0.5	0.61	0.01	0.1	0.2	0.1	0.3	1250	3.43E+06	14.90
10	0.5	0.3	0.1	0.508	0.2	0.1	0.5	1250	1E+06	15.88
11	0.5	0.3	0.1	0.508	0.7	0.043	0.3	1034	3.43E+06	31.80
12	0.5	0.61	0.1	0.1	0.2	0.043	0.5	1034	3.43E+06	24.11

Analysis of variance was performed on the test data and the results of the Plackett-Burman test were used to identify significant effects using the Lenth method, which yielded a half-normal probability effects plot for the standardized effects of the factors as shown in Fig.7 (a) as well as a Pareto chart for the standardized effects of the factors as shown in Fig.7 (b). As can be seen from Fig.7 (a), the standardized effect points of factors B, C and E are farther away from the fitted line, so they are significant factors ($P < 0.05$), that is, the significant factors affecting the angle of repose are the coefficient of static friction between buckwheat seeds, the coefficient of rolling friction between buckwheat seeds, the coefficient of static friction between buckwheat seeds - stainless steel, and the standardized effect points of the other factors are smaller. The Pareto chart of standardized effects, shown in Fig.7 (b), further determines the magnitude and significance of the effect, factors B, C, and E exceeded the t-value as a significant factor.

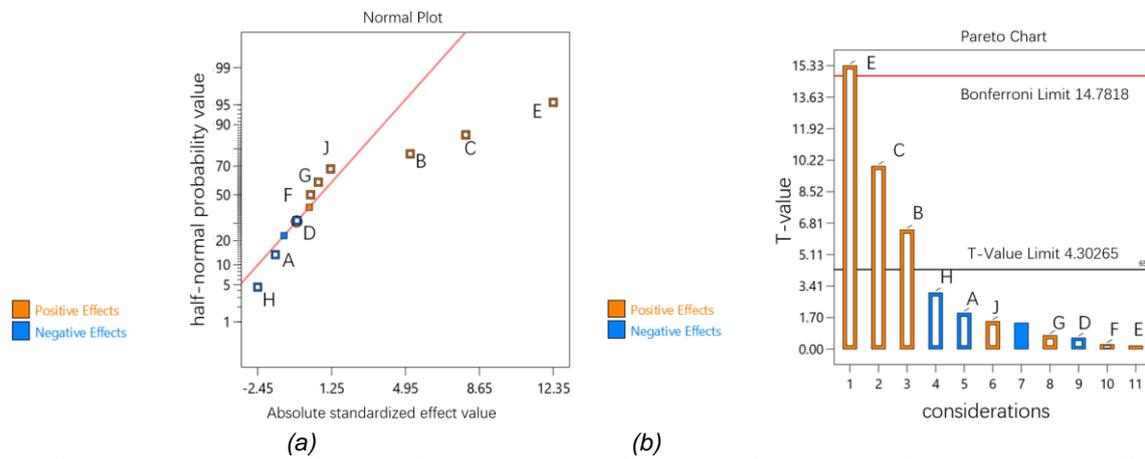

Fig. 7 - Half-normal probability effect plot for standardized effects and Pareto chart of standardization effects

A: Buckwheat Intercollision Recovery Coefficient; B: Coefficient of static friction between buckwheat seeds; C: coefficient of rolling friction between buckwheat seeds; D: Buckwheat seeds-stainless steel crash recovery coefficient; E: Buckwheat seeds-stainless steel static friction coefficient; F: Buckwheat seeds-stainless steel coefficient of kinetic friction; G: Buckwheat Poisson's ratio; H: Buckwheat density; J: Buckwheat Shear Modulus

As can be seen in Table 4, the p-value of the model is $0.0018 < 0.05$, which indicates significance, so the design is reliable and well fitted over the entire regression area of the study; the complex correlation coefficient $R^2=0.9644$, which indicates good correlation; and the corrected coefficient of determination $R^2_{adj}=0.9216$, which indicates that 92.16% of the variability of the experimental data can be accounted for by this regression model (Dun G et al., 2024).

Table 4

Plackett-Burman test factors, levels and significant analysis

Source	Square sum	Degrees of freedom	Mean square	F-value	P-value	
mould	760.04	9	84.45	43.38	0.0227	statistically significant
A	7.36	1	7.36	3.78	0.1914	
B	80.78	1	80.78	41.50	0.0233	
C	190.36	1	190.36	97.79	0.0101	
D	0.6984	1	0.69	0.36	0.6100	
E	457.38	1	457.38	234.96	0.0042	
F	0.1151	1	0.11	0.06	0.8306	
G	1.03	1	1.03	0.53	0.5427	
H	18.00	1	18.00	9.24	0.0933	
J	4.31	1	4.31	2.22	0.2750	
Residual	3.89	2	1.95			
Aggregate	763.93	11				

Typically, a lower coefficient of variation (CV) indicates greater reliability and accuracy of the test. In this case, a CV of 10.13% suggests that the Plackett-Burman test has acceptable reliability and accuracy. Additionally, precision, defined as the ratio of effective signal to noise, is considered reasonable when it exceeds 4.0. The precision of this test is 14.5784, confirming its reliability.

● **Steepest Climb Test**

By fitting a multiple regression equation to the data, the regression equation was obtained: $Y = 23.03 - 0.7829A + 2.59B + 3.98C - 0.2412D + 6.17E + 0.0979F + 0.2929G - 1.22H + 0.5996J$ (2)

From the formula, it can be seen that the partial regression coefficient of factor B is 2.59, indicating that factor B has a positive effect on the angle of repose; as factor B increases, the angle of repose will also increase. Factors C and E also exhibit positive effects.

As can be seen from Figure 7(a), the standardized effect points of factors B, C, and E are far from the fitting line, indicating that they are significant influencing factors. Furthermore, Figure 7(b) further determines the magnitude and importance of these effects, and factors B, C, and E all exceed the critical t-values as significant factors. Therefore, only these three factors are considered.

Since the most significant factor is E, E is used as the unit of climb.

Step E

$$\frac{0.7 - 0.2}{2} = 0.25 \tag{3}$$

Step C

$$\frac{3.98}{6.17} * \frac{0.1 - 0.01}{2} = 0.029 \tag{4}$$

Based on the experimental results, a value of 0.03 was utilized.

Step B

$$\frac{2.59}{6.17} * \frac{0.61 - 0.3}{2} = 0.065 \tag{5}$$

Based on the experimental results, a value of 0.07 was utilized.

The rest of the test parameters were buckwheat seeds collision recovery coefficient of 0.3, buckwheat seeds - stainless steel collision recovery coefficient of 0.5, buckwheat seeds - stainless steel coefficient of kinetic friction of 0.1, buckwheat Poisson's ratio of 0.3, buckwheat density of 1250, buckwheat shear modulus of 3.43E + 06. The results of the experimental design are shown in Table 5.

Table 5

Results of the steepest climb test design

0.3	0.65	0.16	0.5	0.45	0.1	0.3	1250	3.43E+06	43.05	43.69	43.37

The steepest climb test was performed to calculate the relative error between the steepest climb test rest angle β and the physical test rest angle α using the formula Y. Y=(|β-α|)/α*100%. From the relative error, it can be seen that test 2 can be used as the centre point of the response surface test.

● Response surface methodology tests

According to the steepest climb test, the Box-Behnken test was implemented with test 2 as the centre point, and three factors of static friction coefficient between buckwheat seeds, rolling friction coefficient between buckwheat seeds and static friction coefficient between buckwheat seeds and buckwheat seeds-stainless steel were selected as the independent variables, and a three-factor, three-level test was established according to the Box-Behnken design with the angle of repose as the response value. The experimental design is shown in Table 6 (Jyoti et al., 2019; Zhang et al., 2015).

Table 6

Level	Considerations	Coefficient of static friction between buckwheat seeds	Coefficient of rolling friction between buckwheat seeds	Buckwheat seeds-stainless steel static friction coefficient
1		0.36	0.03	0.44
2		0.37	0.04	0.45
3		0.38	0.05	0.46

RESULTS

● **Box-Behnken test data processing**

The experimental results of the Box-Behnken test are shown in Table 7.

Table 7

Box-Behnken experimental design and its results

Test number	Coefficient of static friction between buckwheat seeds	Coefficient of rolling friction between buckwheat seeds	Buckwheat seeds-stainless steel static friction coefficient	Angle of repose / (°)
1	0.37	0.04	0.45	27.87
2	0.36	0.03	0.45	27.19
3	0.38	0.04	0.46	32.53
4	0.37	0.03	0.46	29.27
5	0.36	0.05	0.45	30.03
6	0.38	0.05	0.45	31.73
7	0.37	0.03	0.44	28.68
8	0.38	0.03	0.45	30.16
9	0.38	0.04	0.44	31.22
10	0.37	0.04	0.45	27.67
11	0.37	0.05	0.46	32.1
12	0.37	0.04	0.45	27.72
13	0.37	0.04	0.45	27.56
14	0.37	0.04	0.45	27.28
15	0.37	0.05	0.44	30.38
16	0.36	0.04	0.44	29.53
17	0.36	0.04	0.46	30.16

A quadratic polynomial equation was obtained by fitting a quadratic multiple regression to the data:

$$Y = 27.62 + 1.09A + 1.12B + 0.5313C - 0.3175AB + 0.1700AC + 0.2825BC + 1.45A^2 + 0.7025B^2 + 1.79C^2 \quad (6)$$

The multivariate correlation coefficient of the equation is R2=0.9948, which indicates that the model fits well to the actual situation, and the experimental results can be analysed by the equation, and the results of the ANOVA of the response surface test are shown in Table 8.

Table 8

Box-Behnken experimental design quadratic model ANOVA

Source	Square sum	Degrees of freedom	Mean square	F-value	P-value	
Mould	49.46	9	5.50	148.16	< 0.0001	significant
A-buckwheat static friction	9.53	1	9.53	256.86	< 0.0001	significant
B-roll friction between buckwheat	9.99	1	9.99	269.36	< 0.0001	significant
C-buckwheat-stainless steel static friction	2.26	1	2.26	60.88	0.0001	significant
AB	0.4032	1	0.4032	10.87	0.0132	significant
AC	0.1156	1	0.1156	3.12	0.1208	
BC	0.3192	1	0.3192	8.61	0.0219	significant

Source	Square sum	Degrees of freedom	Mean square	F-value	P-value	
A ²	8.91	1	8.91	240.33	< 0.0001	significant
B ²	2.08	1	2.08	56.02	0.0001	significant
C ²	13.42	1	13.42	361.71	< 0.0001	significant
residual	0.2596	7	0.0371			
incoherent	0.0654	3	0.0218	0.4492	0.7316	insignificant
inaccuracies	0.1942	4	0.0485			
CV (%)	0.6534					
			R2	0.9948	R2adj	0.9881

As can be seen from Table 8, the model is highly significant ($P < 0.05$) while the out-of-fit term is not significant ($P > 0.05$), the model correlation coefficient $R^2 = 0.9948$ and the correction coefficient $R^2_{adj} = 0.9881$, which indicates that the model fit is better, and the model can explain 98.81% of the variation of the response value, and the angle of repose can be analysed and predicted using this model. From the results in Table 8, it can be seen that the factors primary terms A, B and C have significant effect on the angle of repose; the interaction terms AB, BC have significant effect on the angle of repose and AC has insignificant effect; the secondary terms A², B², C² have significant effect on the angle of repose. This indicates that the relationship between the factors and the response value is not a simple linear relationship, the degree of influence of the factors is: $B > A > C$, i.e., rolling friction between buckwheat seeds > static friction between buckwheat seeds > buckwheat seeds - stainless steel static friction.

The angle of repose was predicted using the regression model, and in order to facilitate the observation of the model prediction results, the correlation graph between the model predicted values and the experimental values was plotted. From Fig. 8, it can be found that the sample points are all in the vicinity of the 45° diagonal, indicating that the model's prediction of the angle of repose under each factor is highly correlated with the experimental values, and the difference between the two is relatively small. Figure 9 illustrates the distribution of the model's prediction error. A reliable model typically requires that the prediction error for most samples remains within the $\pm 2SD$ range.

As shown in Figure 9, all sample points lie within this range, with no anomalies observed. This indicates that the model has high prediction accuracy and is suitable for analysing the angle of repose.

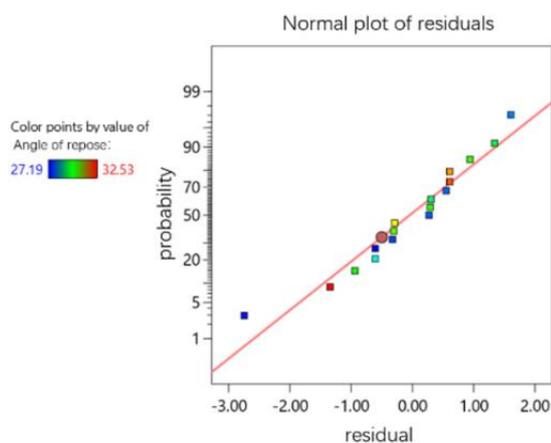

Fig. 8 - Correlation of model predicted values with experimental values

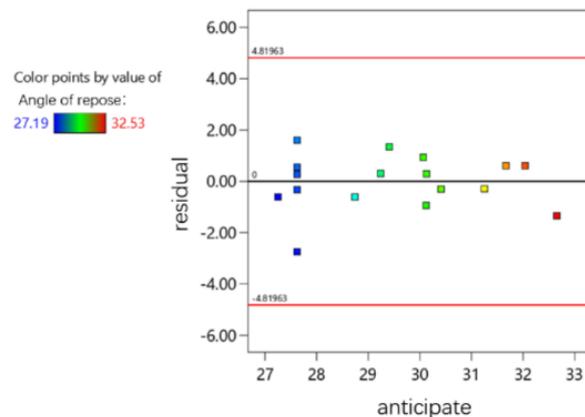

Fig. 9 - Plot of residuals on model predicted walks

Based on the regression equation, the response surface analysis was plotted using Design-expert and the results are shown in Figure 10. The three-dimensional plot of the response surface can be clearly seen through the range of tests performed including the area where the minimum value is located.

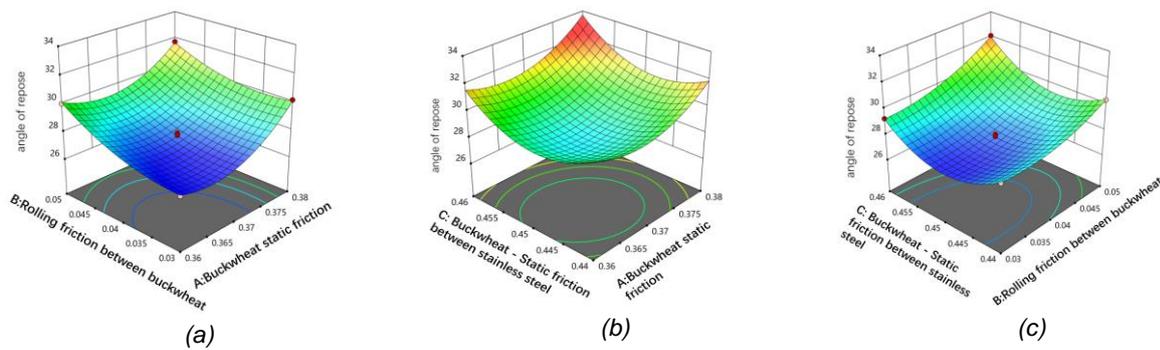

Fig. 10 - Response surface analysis plot

Response surface analysis plotted using Design-expert shows that static friction between buckwheat seeds and rolling friction interaction between buckwheat seeds-stainless steel have a significant effect on the angle of repose.

● Determination of optimal combination parameters and validation results

Based on the optimization module in the Design-Expert software, the regression model was optimized and solved with the target value of 27.65° of the physical test, and parameters similar to those of the physical test were obtained: the coefficient of static friction between buckwheat seeds was 0.372, the coefficient of rolling friction between buckwheat seeds was 0.038, and the coefficient of static friction between buckwheat seeds-stainless steel was: 0.448.

CONCLUSIONS

(1) A simulation model for the stacking angle of repose of buckwheat seeds was developed using EDEM software. MATLAB image processing technology was employed to linearly fit the edge contour of the angle of repose, providing an accurate response value. The results of the Plackett-Burman test indicate that the static friction coefficient between buckwheat seeds, the rolling friction coefficient between buckwheat seeds, and the static friction coefficient between buckwheat seeds and stainless steel significantly influence the angle of repose;

(2) Based on the results of the Box-Behnken response surface test, a quadratic regression model was developed to describe the relationship between significant parameters and the angle of repose. The analysis of variance revealed that the primary terms (static friction coefficient between buckwheat seeds, rolling friction coefficient between buckwheat seeds, and static friction coefficient between buckwheat seeds and stainless steel), the interaction terms (static friction coefficient and rolling friction coefficient between buckwheat seeds, as well as rolling friction coefficient and static friction coefficient between buckwheat seeds and stainless steel), and the quadratic terms of these coefficients significantly affect the angle of repose.

(3) By optimizing the regression equation to find the optimal solution, the following values were obtained: a static friction coefficient of 0.372 for buckwheat, a rolling friction coefficient of 0.038 for buckwheat, and a static friction coefficient of 0.448 for the buckwheat-stainless steel interaction. The remaining parameters were set to their intermediate levels. The relative error between the physical test results and the simulation outcomes was 1.08%, indicating that the contact parameters and the contact model parameters are both accurate and reliable.

Addressing the issues of water resource wastage, low fertilizer utilization efficiency, and uneven water-fertilizer mixing in current irrigation and fertilization practices, a new type of coaxial counter-rotating agitator was designed. Based on computer numerical simulation technology, this paper simulated and analysed the agitator's modes and flow field distribution, establishing the law that governed the variation of velocity distribution within the agitator's internal flow field with changes in rotational speed. An orthogonal experimental design was employed, utilizing stirring speed, stirring duration, and submerged depth as the experimental variables, and the outcomes were subsequently analysed utilizing Design-Expert software. The findings indicated that optimal fertilizer solubility was achieved when the stirring speed was 400 r/min, the stirring time was 5 minutes, and the stirring depth was 660 mm. This study provided a theoretical basis for the design and application of the coaxial counter-rotating agitator and aided in guiding parameter selection and optimization for practical applications.

摘要

针对目前灌溉施肥中存在的水资源浪费、肥料利用率较低以及水肥混合不均匀的问题,设计了一种新型同轴异转搅拌器。本文基于计算机数值模拟仿真技术,对搅拌器的模态、流场分布进行模拟分析,确定了搅拌器内部流场的速度分布随转速变化的规律;以搅拌转速、搅拌时间和潜液深度为试验因素设计正交试验,使用 Design-Expert 软件对结果进行分析,结果表明:当搅拌速度 400 r/min、搅拌时间 5 min、搅拌深度 660 mm 时,肥料溶解度最优。本研究为新型同轴异转搅拌器的设计和运用提供了理论依据,并有助于指导实际应用中的参数选择和优化。

INTRODUCTION

Currently, agriculture accounts for more than 60% of the country's total water consumption (Dali Fang et al., 2024), and traditional irrigation techniques such as flood irrigation and manual fertilization led to inefficient water and fertilizer use, with an average fertilizer utilization rate of only 33%, which not only increased the production cost, but also exacerbated the environmental pollution problem (Yuan Hongbo et al., 2016; He Weiyuan et al., 2020). Water-fertilizer integration technology could significantly improve the simultaneous efficiency of irrigation and fertilization by delivering nutrient solution directly to plant roots through drip irrigation system (Ma Martínez Gimeno et al., 2020), and the water-fertilizer mixing efficiency was directly correlated with the utilization rate of water-soluble fertilizers (Jin Zhou et al., 2020). Inadequate dissolution of fertiliser could easily lead to clogging of irrigation pipes, and such clogging was not only difficult to remove, but also time-consuming and labour-intensive to replace the pipes, as well as significantly increasing the cost of irrigation. Therefore, it was crucial to improve the efficiency of fertiliser dissolution and to ensure that the water and fertiliser were evenly mixed.

The application of large quantities of chemical fertilizers in agricultural production raised the risk of environmental pollution, Liu Shufeng et al., (2022), investigated the effects of different solid-liquid mixing ratios, agitator forms and mixing speeds on the mixing effect, and optimized the operating parameters of the agitator and fertilizer pumps to improve the homogeneity of fertilizer mixing. Mechanical agitation was an important method to promote the homogeneity of solid-liquid mixtures. Li Tianhua et al., (2023), analysed the

¹ Longlong Ren Lecturer Ph.D. Eng.; Yuqiang Li, M.Sc. Stud. Eng.; Zhenxiang Jing, M.Sc. Stud. Eng.; Yuepeng Song, Prof. Ph.D. Eng.; Jing Guo, Prof. Ph.D. Eng.; Siwen Shen, Lecturer M.Sc. Eng.;

hydrodynamic characteristics of different fertilizer mixing modes through numerical simulation of the mixing operation of different types of fertilizers, and designed a fertilizer mixing device combining unloading reflux and mechanical agitation to realize the mixing operation of different types of fertilizers. Different forms of agitators could produce different flow fields and agitation energies, thus realizing diversified mixing effects. *Tian Yongjian, (2024)*, designed a portable air agitator, which could agitate the sediment and fix impurities at the bottom of the storage tank while blowing them to improve the homogeneity of solid-liquid mixing. *Liu Wenliang et al., (2022)*, focused on improving the uniformity of fertilizer mixing, optimized and improved the fertilizer mixing components, and made use of the mixer's own structure to make the water and fertilizer fully mixed. *Zhang Shuai et al., (2018)*, designed a high-efficiency fertilizer mixer to analyse the flow field distribution diagram of different mixing speeds, and the fertilizer mixer produced more disturbed and turbulent flow inside the fertilizer mixer when the mixing speed was greater than the critical mixing speed, which could effectively improve the effect of fertilizer mixing. *Li Lei., (2024)*, designed an energy-saving axial flow mixer by setting the paddles in a circular arc shape and the arc side set diagonally downward, which enhanced the degree of turbulence in the axial and radial directions, so as to make the mixing effect better. When designing a mixing and blending device for fertilizers, it was crucial to ensure dissolution efficiency and mixing homogeneity of the fertilizers, and rational design of the mixing device was the key to achieving this goal (*Dang Lingui et al., 2013*).

This paper evaluated a newly designed mixer with a novel shape, explored the velocity distribution of the flow field inside the agitator with the change of rotational speed through computer simulation, compared with the coaxial co-rotating agitator, verified the superiority of the design of the fertilizer mixer, and obtained the optimal operating parameters of the agitator through design experiments and parameter optimization.

MATERIALS AND METHODS

Structural design of the fertilizer mixing unit

Selection of fertilizer mixing drum with an inner diameter of 600 mm and a height of 1,000 mm. According to the relevant literature and the requirements of the mechanical design of mixing equipment, combined with the relevant design specifications and empirical formulas, through the calculation of the overall size of the agitator, the relevant values were obtained:

$$d = (0.2 \sim 0.5)D \quad (1)$$

$$h = 0.02 d \quad (2)$$

$$S = 0.66 D \quad (3)$$

where: D - inner diameter of fertilizer mixing drum, mm; d - diameter of mixing paddle, mm; h - thickness of mixing paddle, mm; S - agitator submergence depth; mm;

By calculating the dimensional parameters of the agitator through the above formula, the diameter of the stirring paddle was set to 200 mm, the thickness of the stirring paddle was 4 mm, and the submerged depth of the agitator was 660 mm. Common agitators on the market are single-steering single-paddle axial-flow agitators, which have mediocre mixing effect and cannot form a turbulent field to dissolve fertilizers very well. Therefore, based on the shortcomings of the existing agitator, a new type of coaxial counter-rotating agitator was designed by making the stirring direction bidirectional and incorporating double paddles. A three-bladed propeller agitator paddle was used, providing improved mixing efficiency and enhanced hydrodynamic characteristics. The three-blade paddle could produce uniform radial and axial flow, improved mixing efficiency and reduced dead zone, while balancing the mechanical vibration in the mixing process and enhancing the stability of the system. The inclination angle of the agitator designed for 30° could be adapted to most of the equipment structure requirements of the water and fertilizer integration machine, under the condition of the same power consumption, small diameter, high speed agitator, the power was mainly consumed in the turbulent pulsation, which was conducive to the microscopic mixing.

The upper mixing paddle of the coaxial counter-rotating agitator was connected to the outer sleeve, and the lower mixing paddle was connected to the centre shaft, which was designed to be easy to install and prevent relative sliding in the working process. The upper and lower mixing paddles were connected by C-type coupling. When the mixer was working, the upper bevel gear and the lower bevel gear were synchronized to rotate in the reverse direction, which made the upper and lower mixing paddles rotate in the reverse direction coaxially. Realizing the effect of a composite cyclonic flow field in a single device could create a larger turbulence distribution during mixing and improve the homogeneity of mixing and blending (*Hua Jian et al., 2023*), the final design is shown in Fig. 1. Fig. 2 shows the overall structural diagram of the fertilizer mixer, and Fig. 3 shows the structure of the mixing paddle.

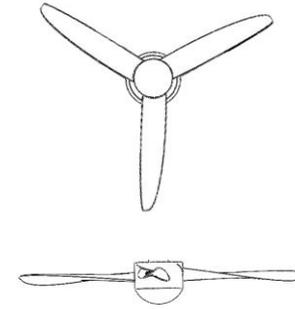

Fig. 3 - Mixing paddle

Calculation of critical stirring speed of the agitator

Agitation had a limited effect on the mass transfer coefficient, mainly by promoting the suspension of solid particles to increase the solid-liquid interface, and thus improved the mass transfer efficiency. When the complete suspension of particles was achieved, it was no longer obvious to increase the stirring intensity to improve the mass transfer efficiency. For the process of dissolving solids, the bottom of the particles can be suspended, without the need to achieve a complete uniform distribution of the liquid phase. In view of this, it was crucial to determine the critical stirring speed of the mixing equipment, which depended on the density difference between the solid and liquid phases, the liquid density, the solids concentration, the liquid viscosity, the physical properties such as particle size, and the geometrical relationship between the mixing vessel and the agitation device. Based on the formula for calculating the critical stirring speed published by Zwietering, it was possible to determine the appropriate stirring speed, avoiding unnecessary energy consumption:

$$N_c = Kd^{-0.85} \nu^{0.1} d_p^{0.2} \left| g \frac{\rho_p - \rho}{\rho} \right|^{0.45} \left| 100 \times \frac{\rho_p \phi_v}{\rho(1 - \phi_v)} \right|^{0.13} \quad (4)$$

where: N_c - critical RPM; K - equation constant, the propeller impeller is approximately $2.57 \sim 3.19(D/d)0.80 \sim 0.86$; D - inner diameter of fertilizer mixing drum, m; d_p - solid particle diameter, m; ϕ_v - solid volume fraction; ρ - density of liquids, kg/m^3 ; ρ_p - density of solid particles, kg/m^3 ; ν - kinematic viscosity of liquids, m^2/s ; d - diameter of mixing paddle, m; g - gravitational acceleration, m/s^2 ;

The majority of the parameters in the above equation were determined by the calculation of the specific dimensions of the mixer in the paper, and according to the study of *Yang Xiaozhen et al., (2014)*, it was known that the density of the water-fertiliser mixing liquid was 1150 kg/m^3 and its kinematic viscosity was $0.0016 \text{ m}^2/\text{s}$. The data provided by *Guo Shanming et al., (2017)*, pointed out that the particle diameter of the general-purpose water-soluble fertilisers was 2 mm , and its density was 1335 kg/m^3 . Based on these parameters, the critical stirring speed (N_c) was calculated to be approximately 398.28 r/min . The critical stirring speed (N_c) of the fertiliser mixer was calculated to be approximately 398.28 r/min , and this result was informative for subsequent comparative class studies.

Simulation modelling and meshing of agitator

In computer simulation analysis, meshing was crucial because proper meshing could improve simulation accuracy and reduce the time required for computation (*Zhang Yubin et al., 2018*).

Through COMSOL Multiphysics software, the simulation model used a tetrahedral mesh and the rotating part of the agitator was refined to ensure higher simulation accuracy (*An Bo et al., 2023*). The histogram of the mesh quality showed a normal distribution, ensuring uniformity and proper size distribution of the mesh. Figure 4 shows the grid details of the flow field analysis of the agitator and fertilizer mixing tank.

After the meshing was completed, the quality of the grid was viewed through the statistical information under the grid (mesh) component, where the agitator grid diagram in Figure 3 had a cell count of $187,122$, and the fertilizer mixing tank grid diagram had a cell count of $850,624$ for the statistical information of the domain cells.

Fig. 4 -Agitator grid figure; flow field analysis grid diagram of fertilizer mixing tank

Modal analysis of coaxial counter-rotating agitator

The high speed of rotation during agitator operation led to vibration. To ensure the stability of the equipment, modal analysis was essential to reveal the vibration characteristics. Modal analysis was designed to identify the inherent vibration modes of an object based on a fixed structural shape and constraints. Based on the established model and constraints imposed (Liu Shuangxi et al., 2020), modal analysis could be performed to obtain the first six modal frequencies of the agitator, the first six orders of modal diagrams were shown in Fig. 5.

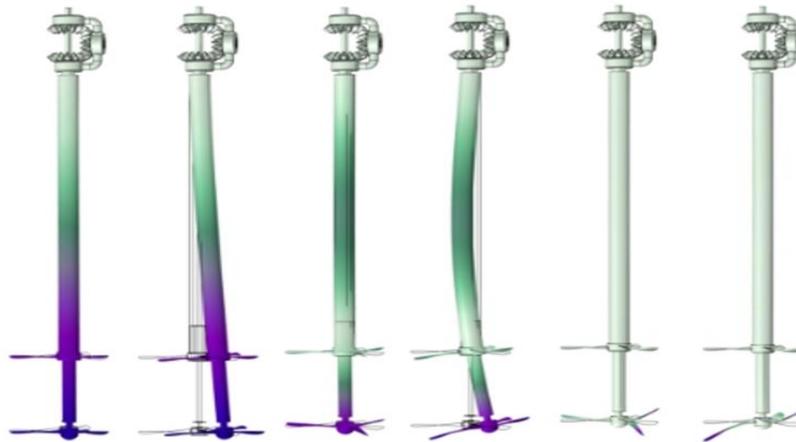

Fig. 5 - First six modes

Simulation analysis of the flow field of a coaxial counter-rotating agitator

In the study of fluid dynamics, velocity vector diagram was an important tool to reveal the dynamic trend, state and change of flow direction of the fluid in the flow field (Jin Yu et al., 2023). In this study, numerical simulation was used to simulate the flow at different rotational speeds, specifically analysing the velocity field distribution in the central profile of the fertilizer mixer at rotational speeds of 200, 300, 400 and 500 r/min, respectively.

The spatial distribution characteristics of the flow velocity could be observed visually through the generated velocity clouds. Comprehensive comparison of these velocity cloud maps enabled this study to explore in depth the law of the velocity distribution of the flow field inside the agitator as a function of the rotational speed, and to determine the optimal operating rotational speed accordingly.

Prototyping and design of experiments

In this paper, through mechanical design as well as simulation analysis, the coaxial counter-rotating agitator was designed and the prototype object was machined, as shown in Fig. 6. The main components of the agitator, such as the active teeth, motor, coupler, outer sleeve, lower stirring paddle, upper stirring paddle, lower follower teeth, centre shaft, upper follower teeth, etc., are indicated in the figure. The overall size and length of the agitator was consistent with the previous design model, while the structure was compact and the components had good working stability. In the actual production process, in order to save production costs, a fixed-speed motor with defined parameters could be chosen, which could effectively meet the production requirements and would not require frequent adjustment of the agitator's stirring speed.

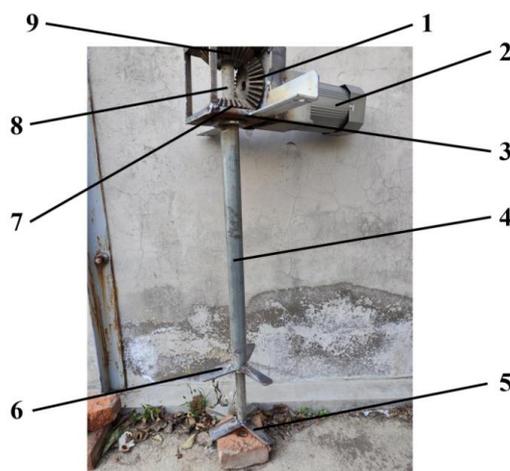

Fig. 6 -New coaxial counter-rotating agitator

1. Driving teeth, 2. Motor, 3. Coupler, 4. Outer sleeve, 5 down stirring paddle, 6. Upper stirring paddle, 7. Lower driven teeth, 8. Centre shaft, 9. Upper driven teeth

In this study, in order to determine the optimal agitation conditions, the Box-Behnken design method was used with stirring speed, stirring time and submergence depth as independent variables and electrical conductivity (EC) as the response variable. By implementing a three-factor, three-level orthogonal experimental design, it was aimed to find the optimal combination of stirring speed (A, a), stirring time (B, b) and agitator submergence depth (C, c). The experimental conditions were designed as follows: the N, P, and K ratio of the mixed fertilizer was 20% ~ 20% ~ 20%. For the test, 1000 g of fertilizer was selected and mixed with 100 L of aqueous solution under different test conditions. After the mixing was completed, 200 ml of the fertilizer aqueous solution was taken out and its concentration was determined using a portable PH/EC tester. In this case, electrical conductivity (EC value) was used as a measure of the solubility of the fertilizer. Fig.7 shows the physical picture of the composite fertilizer and Fig. 8 shows the test site.

Fig. 7 - Physical Map of Fertilizer

Fig. 8- Pilot test site

The experimental range of stirring speed was set at 300 to 500 r/min, based on the results of previous hydrodynamic simulations. The stirring time was selected from 3 to 7 minutes to ensure adequate dissolution of the fertilizer and reasonable energy consumption. The submerged depth of the agitator was set between 610 and 690 mm based on previous calculations. Table 1 demonstrated the experimental factors with their corresponding coded values. This experimental design and parameter selection was devoted to evaluate the effectiveness of the new coaxial counter-rotating agitator in the fertilizer mixing process, so as to provide theoretical and experimental support for the optimization of the fertilizer mixing process.

Table 1

Correspondence between Test Factor Level and Coded Value in Stirring Process

Coded value	Stirring speed A / (r/min)	Stirring time B / min	Agitator submergence depth C / mm
-1	300	3	610
0	400	5	650
1	500	7	690

RESULTS

Analysis of agitator simulation results

According to the results of the modal analysis in Table 2, the fundamental frequency of the agitator was 38.57 Hz, which was the lowest among all modes. Considering that the operating frequency interval of the speed-regulated motor was 0-500 r/min, this corresponded to a vibration frequency of 0-8.34 Hz. Since this frequency was much lower than the first order modal frequency of the agitator, the effect of other external excitation frequencies on the fertilizer mixing tank could be neglected. Literature indicates that the lower order modes had a more significant effect on the vibration of the equipment, while the effect of the higher order modes gradually decreases (Liu Shuangxi et al., 2020). In summary, the highest frequency of external excitation was significantly lower than the lowest mode of the mixer, which means that the agitator had good anti-vibration performance and would not enter into resonance due to external excitation, meeting the design specification requirements.

Table 2

Sixth-order mode of blender						
ORDER	1	2	3	4	5	6
FREQUENCY / Hz	38.57	41.11	250.42	256.28	449.16	449.41

Fig. 5 showed that the vibration pattern of the agitator was mainly divided into the vibration of the stirring rod and the vibration of the stirring paddle, in which the vibration pattern corresponding to the first, second, third and fourth order modes was mainly the left and right oscillation of the stirring rod. The vibration mode corresponding to the fifth and sixth order modes was mainly the up and down swinging of the agitator paddle, while the agitator was mainly operated by the central shaft and outer sleeve rotating around the centre with the same direction and speed. The vibration characteristics of the agitator were mainly expressed as torsional vibration in the direction of the central axis, which was different from the transverse and vertical vibration modes.

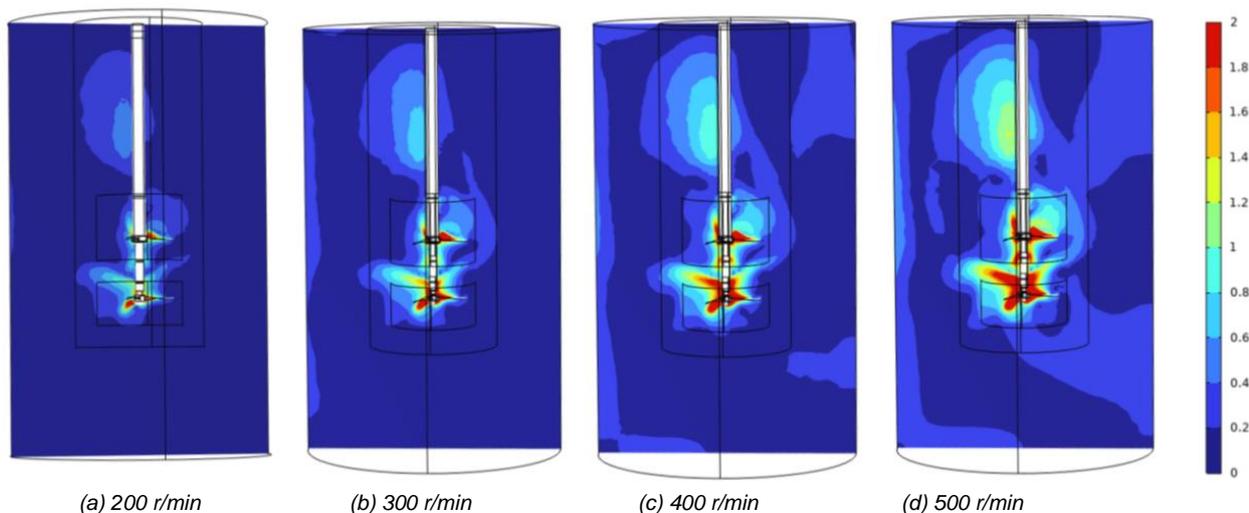

Fig. 9 - Speed cloud picture of agitator at different speeds

From Fig. 9, it could be observed that at critical speeds lower than 400 r/min, the velocity was higher near the rotating paddle and lower at the periphery away from the rotor. The velocity distribution in this region was more uniform and lacked a significant velocity gradient, resulting in a weakening of the interlayer flow, which was not conducive to the development of turbulence, thus affecting the dissolution and mixing efficiency of the fertilizer.

When the rotational speed was higher than the critical rotational speed of 400 r/min, it was observed that the overall velocity cloud map showed a similar pattern, with a larger value of velocity in the rotating region of the agitator's stirring paddles, and the overall velocity in the fertilizer mixing drum showed the distribution characteristics of the middle being the highest, the edge the second highest, and the mezzanine being the lowest, which formed an obvious middle-low-high velocity distribution. This velocity distribution effectively enhanced the relative motion between the liquid layers, and this frequently changing medium-low-high velocity distribution formed a complex flow field distribution, which promoted turbulence and was conducive to the dissolution of the fertilizer.

Analysing the velocity clouds under different speed conditions, it could be seen that: under the condition of lower than critical agitation speed, the flow field of the agitator showed a single flow pattern, and the turbulence distribution was restricted, which limited the dissolution efficiency of the fertilizer.

In contrast, when the speed was higher than the critical agitation speed, the distribution of the flow field became more complex, the value of the velocity in the rotating area of the agitator's mixing paddles was larger, and the overall velocity in the fertiliser mixing drum showed the distribution characteristics of the highest in the middle, the second on the edge, and the lowest in the mezzanine layer, which phenomenon improved the shear action and circulation characteristics inside the fluid and thus accelerated the dissolution mechanism of the fertilisers. With the increase of velocity, the velocity vector field and velocity isosurface map mainly reflect the growth of velocity amplitude, while the overall distribution pattern of velocity was kept relatively consistent with the trend of vector change.

Therefore, after the speed exceeded the critical stirring speed, increasing the rotational speed had less effect on the distribution of the flow field, but the velocity value would increase. After comparison and analysis, both 400 r/min and 500 r/min speed could meet the requirements. Considering the overall power consumption, the rotational speed should be reduced as much as possible to improve the energy efficiency while generating a good flow field distribution. Therefore, 400 r/min is finally selected as the optimum speed for the new coaxial counter-rotating agitator.

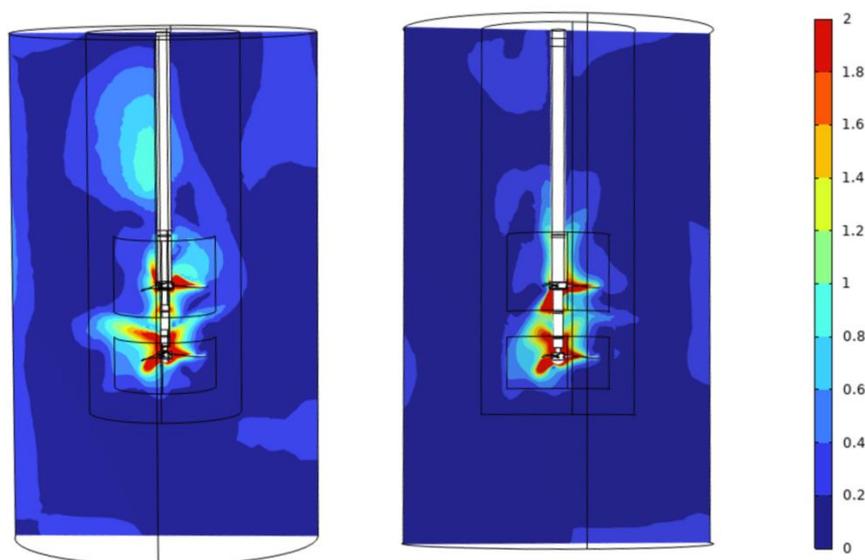

Fig. 10 - Velocity distribution at 400 r/min under coaxial differential rotation and coaxial simultaneous rotation

The simulation results in Fig. 10 showed that the overall flow velocity distribution of the coaxial counter-rotating agitator was significantly better than that of the coaxial co-rotating agitator when the rotational speed was 400 r/min. Due to the fact that the stirring blades of the coaxial co-rotating stirrer rotated in the same direction, it resulted that the flow velocity in the flow field was concentrated in the rotating region of the stirring blade, and the mobility was insufficient. Therefore, this situation was not conducive to the dissolution of fertiliser and other processes. The coaxial counter-rotating agitator produced stronger vortex and turbulence effects due to the opposite direction of rotation of the agitator paddles. Such flow characteristics were conducive to diffusion and mixing, making the process of dissolving fertiliser more complete and rapid.

Through numerical simulation analysis, the multi-dimensional flow field structure produced by the coaxial counter-rotating agitator could promote the effective contact between the fertiliser particles and the solvent, which increased the surface area of dissolution, and was conducive to improving the dissolution rate and efficiency

Regression modelling and analysis of variance

An important indicator for assessing the results of the working parameters was the electrical conductivity (EC value) of the fertilizer solution, which was obtained by removing 200 ml of aqueous fertilizer solution from the fertilizer mixing drum after mixing and measuring its concentration using a portable PH/EC tester. In accordance with the principles of Box-Behnken experimental design, 17 sets of experiments on fertilizers were executed in this study and the corresponding data were collected. The experimental program and its results were summarized in Table 3.

Table 3

Fertilizer Mixing Test Scheme and Result				
No	Stirring speed A/(r/min)	Stirring time B/min	Agitator submergence depth C/mm	Fertiliser EC M/(us/cm)
1	0	1	1	10840
2	0	0	0	11430
3	0	-1	-1	10380
4	0	0	0	11480
5	0	-1	1	10240
6	1	-1	0	10620
7	-1	0	1	10110
8	0	0	0	11450
9	-1	-1	0	9780
10	1	0	-1	10940
11	0	0	0	11460
12	0	0	0	11430
13	-1	1	0	10480
14	1	1	0	11090
15	0	1	-1	10920
16	1	0	1	10710
17	-1	0	-1	10060

Note: m_1 , m_2 and m_3 are the corresponding coded values of M_1 , M_2 and M_3 , the same as below.

A quadratic regression model was obtained as a result of analysing and processing the experimental data shown in Table 3 by entering them into the Design Expert software. The model describes the relationship between the electrical conductivity (EC value) of the water-soluble fertilizer obtained after dissolving the fertilizer and the coded values of the three variables: agitation speed, agitation time, and agitator submergence depth. The quadratic regression equations obtained from the EC value of the water fertilizer solution and the coded values of the three influencing factors, stirring speed, stirring time and agitator submergence depth, respectively, were:

$$M = 11450 + 366.25a + 288.875b - 49.875c - 57.5ab - 70ac + 15.25bc - 548.875a^2 - 408.625b^2 - 446.125c^2 \quad (5)$$

The results obtained from the analysis of variance (ANOVA) of the regression equation for fertilizer solubility using Design Expert software showed that the P-values of all the factors in the model were significantly below the 0.05 threshold. And the P-values of three variables, namely, agitation speed, agitation time and submerged depth of agitator were well below 0.01, which characterizes the regression model as being extremely statistically significant. The magnitude of the F-statistic further indicated the importance of these variables in the model, manifesting their impact on the amount of fertilizer dissolved. A larger F value implies a stronger influence. Accordingly, among the factors examined, agitation speed had the most significant effect on fertilizer solubility, followed by agitation time, and then submerged depth of the agitator.

Two-factor interaction effect analysis and parameter optimization

Based on the results obtained from the analysis of the above regression equation, the effect of the remaining factors on the solubility of the fertilizer will be further investigated by arbitrarily selecting the level of one of the factors to be zero. By applying Design Expert software, the response surface for the interaction effects was derived as shown in Fig. 11.

(a) stirring speed versus stirring time response surface (b) stirring speed versus submerged liquid depth response surface (c) stirring time versus submerged liquid depth response surface

Fig. 11- Corresponding surfaces for the effect of interacting factors on test metrics

When observing the images, it was found that the two-factor response surface morphology of different fertilizers showed remarkable consistency, and there was also an essential similarity in the influence pattern of each factor. First of all, through Figure 11a it was noticed that the solubility of fertilizers tended to increase with the increase of time under the condition that the stirring speed was kept constant. However, the effect on the solubility gradually decreased with the continuous increase of time. In the case where the stirring time was kept constant, the solubility of the fertilizer tended to increase as the stirring speed increased. The effect on solubility gradually decreased as the speed was increased to a certain level. Observation of Fig. 11c reveals a similar pattern, which also showed a tendency of decreasing and then increasing as the depth of the submerged liquid increased.

Finally, observation of Figure 11b reveals that the solubility of the fertilizer tended to increase as the stirring speed increased while the depth of the submerged liquid was kept constant, but once the speed was increased to a certain level, its effect on the solubility gradually diminished. The effect of stirring time also showed a similar pattern. Therefore, the above analysis showed that the effects of stirring time, stirring speed and submerged liquid depth on the solubility of fertilizers had similar regular trends. Under well-mixed conditions, continuing to increase the stirring speed made a decreasing contribution to the dissolution of the fertilizer, consistent with the simulation data. Therefore, optimizing the stirring speed can reduce energy consumption while ensuring mixing efficiency. Similarly, the increase in dissolution rate by extending the agitation time had a marginal effect and was limited by the inherent solubility of the fertilizer.

Selecting the appropriate stirring time was a key factor in reducing energy consumption and improving operational efficiency.

The depth of submerged liquid had a significant effect on the solubility of fertilizer, showing a non-linear relationship. The undissolved amount of fertilizer decreased and then increased as the submerged depth increased. This phenomenon would be due to the fact that too deep a submerged depth would result in the flow field generated by agitation at the bottom of the container, although it was ideal, but its effect could not be effectively extended to the upper layer of the liquid; and when the submerged depth was insufficient, the flow field could not reach the bottom of the container adequately.

Therefore, optimizing the submerged liquid depth was a key factor to improve the efficiency of fertilizer dissolution.

Combining the above factors, global multi-objective optimization was carried out, and the fertilizer solubility was taken as the objective function, and the stirring speed, stirring time and submerged liquid depth were optimally designed. The best combination of each parameter was available through the optimization mathematical model equation, according to the optimization mathematical equation :

$$\begin{cases} \max M = f_1 & A, B, C \\ s.t. \begin{cases} A \in 300, 500 \\ B \in 3, 7 \\ C \in 610, 690 \end{cases} \end{cases} \quad (6)$$

where: A, B, and C were the actual values corresponding to stirring speed, stirring time, and agitator submergence depth, respectively.

In order to obtain the optimal parameter combinations, Design expert software would be applied to solve the optimization. Finally, Table 5 would present the optimal operating parameter combinations of the agitator.

Table 5

Type	Optimum stirring speed / (r/min)	Optimum stirring time /min	Optimum Submersible Depth /mm
Theoretical	394.3	5.31	651.64
Actual value	400	5	660

To ensure the feasibility of the theoretically optimized values in practical applications, rounding was performed and experimentally verified. The results showed that the optimal agitation parameters were 400 r/min, 5 min stirring time, and 660 mm agitator submerged liquid depth.

CONCLUSIONS

(1) A new type of coaxial counter-rotating agitator was designed and the results of modal analysis showed that the agitator had good vibration performance and did not cause equipment resonance, which was in line with the design expectations.

(2) The field simulation analysis showed that when the stirring speed exceeded the critical agitation speed threshold, the fluid flow was complicated, the speed in the agitation zone was higher, and the velocity distribution in the fertilizer mixing drum was characterized as the highest in the middle, the second highest at the edge, and the lowest in the mezzanine. In order to improve energy efficiency, 400 r/min was finally determined as the optimal speed.

(3) The Box-Behnken design method was used to optimize the working parameters, and quadratic regression analysis was used to investigate the effects of stirring speed, time and agitator submerged depth on the solubility of fertilizers, and it was found that the solubility of fertilizers increased with the increase of stirring speed and time, but the positive effect was weakened beyond the specific threshold, and the relationship between the submerged depth of the agitator and the solubility showed a nonlinear correlation. The optimal working parameters were stirring speed of 400 r/min, stirring time of 5 min, and submerged depth of 660 mm.

DOI: <https://doi.org/10.35633/inmateh-75-11>**Keywords:** Garlic seeding unit, Air-suction, Garlic seed sowing, the bud reversing device.**ABSTRACT**

Based on the requirements for hybrid garlic seed sowing, the overall structure of an air-suction garlic seeding unit was designed, and its working principle was described. The adsorption pressure required for the seed metering device was determined to be -5 kPa. One hopper was selected for the bud reversing device, with an angle of 24.5°, and the perimeter of the insertion device measured 600 mm. The optimal combination of parameters for sowing involved a negative pressure of -5 kPa and a forward speed of 1 km/h at the third level. Under these conditions, the qualified rate of individual sowing reached 84.26%, while the missed sowing rate was 7.12%, meeting the agronomic requirements for garlic seed sowing. Field experiments validated the theoretical analysis and bench tests, providing a solid foundation for the future production and promotion of garlic sowing units.

摘要

根据杂交大蒜种子的播种要求, 设计了吸气式大蒜播种单体的整体结构, 并描述了其工作原理。确定种子计量装置所需的吸附压力为-5 KPa。为磷芽交换装置选择了一个料斗, 角度为24.5°, 插入装置的周长为600 mm。播种的最佳参数组合为负压-5 KPa, 前进速度为1 km/h, 设定在三级档位。在此条件下, 单粒播种的合格率达到了84.26%, 漏播率为7.12%, 满足了大蒜种子播种的农艺要求。田间试验验证了理论分析和台架试验的准确性, 为大蒜播种单体的未来生产和推广奠定了基础。

INTRODUCTION

Garlic can be consumed as both garlic head and garlic sprouts and can also be used as a seasoning. Garlic has the effects of disinfection, swelling relieving, insecticidal, and dysentery stopping (Jia-feng et al., 2021). Garlic polysaccharides extracted from garlic have a specific lipid-lowering effect, which can improve human intestinal microbiota, reduce liver burden, and may reduce the risk of metabolic syndrome (Chan-yuan et al., 2020). In 2020, the global garlic planting area was 1.68 million hectares, with a garlic production of 32 million tons. Its planting area, production, and foreign trade export volume ranked first globally (Xiang-yuan et al., 2017; Bin-bin et al., 2019). At present, the cultivation of garlic in China is still mainly artificial (Jia-lin et al., 2018). However, due to the high planting cost and long planting cycle, the mechanization of garlic planting should be strengthened. At present, Minghao Lu from Anhui Agricultural University, one of the article's author, has designed an anti-seed tooth assisted air suction garlic seeder. Chun-ling Zhang et al., (2021), designed an electric hydraulic mixed regulation garlic seeder. Xiang et al., (2023), from Nanjing Vocational and Technical University of Technology have designed a self-propelled garlic sowing and fertilization integrated machine. Internationally, Türkiye DEMSAN Company has designed a traction garlic planter (Zhao-guo et al., 2021). Italian company SPAPPERI has also designed a mechanical garlic seeder that can sow a single seed, avoiding situations where there is multiple or no garlic seeds at once (Shuang-xi et al., 2015). French company ERME has designed three different series of garlic seeders (Dong et al., 2020).

Garlic seeders on the market still mainly use mechanical seed picking and metering. People used metering components similar to the spoon chain type (Ai-jun et al., 2018), which cannot adapt well to different garlic sizes and may cause congestion. At the same time, there will be significant vibration when sowing in the field, making the efficiency of the mechanical seeder low (Yu-xiang et al., 2022). The pneumatic type relies on the negative pressure provided by the fan to tightly adsorb garlic onto the seed tray, meeting the requirements of garlic seeds of different sizes and ensuring the stability of single seed picking (Xin-peng et al., 2022; Han et al., 2023).

Zaidi *et al.*, (2019), invented a pneumatic planter for peas planting. However, current research is still limited to seeders, and it is necessary to study a garlic seeding unit to solve the seeding problem (Yu-dao and Xue-zhen, 2020).

To increase the single seed rate of garlic seeding, a kind of air-suction garlic seeding unit was designed in this paper. It mainly includes an air-suction garlic seeder, an upright planting mechanism, a pneumatic system, and a profiling mechanism. It can achieve the functions of single seed picking and upright planting of garlic seeds, meeting the agronomic requirements of garlic planting.

MATERIALS AND METHODS

The air-suction garlic sowing unit mainly consists of components such as an air-suction garlic seeder, a bracket, a profiling rod, a ground wheel, a seed guide device, a bud reversing device, and an upright insertion device, as shown in Figure 1. The unit body adopts a traction type and is connected to the tractor through a three-point suspension. The bracket mainly consists of square, tubular, and fixed brackets. The front end of the tubular support is fixedly connected with a three-point suspension hanger, the upper part of the tubular support is fixedly connected with a negative pressure fan, and the tubular support is fixedly connected with fixed support. The two sides of the fixed support are connected with four profiling rods through shaft hinges, and the other end of the four profiling rods is hinged with the square frame through another pair of shafts. The rear end of the negative pressure fan is fixedly connected to the belt pulley on the PTO (Power Take-Off) device through a belt, forming a mechanical structure with belt transmission. The belt pulley serves as the driving wheel, and the shaft at the rear end of the fan serves as the driven shaft. Through a hose, the fan is connected to the negative pressure pipe of the suction garlic seeder to form a closed channel, and the fan provides stable negative pressure for the air chamber of the seeder.

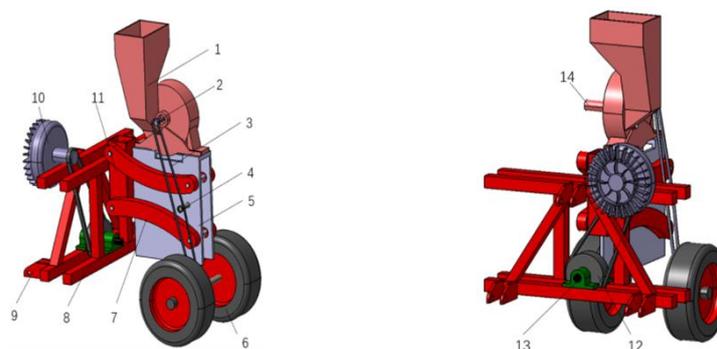

Fig. 1 - Schematic Diagram of the Air-Suction Garlic Sowing Unit Structure

(1) Air suction garlic seeder; (2) Seeding shaft; (3) Chain; (4) Tensioning wheel; (5) Square bracket; (6) Ground wheel; (7) Profiling rod; (8) Pipe bracket; (9) Three-point suspension hanger; (10) Negative pressure fan; (11) Fixed bracket; (12) Belt pulley; (13) PTO device; (14) Negative pressure pipe

Inside the square bracket, a seed guide device is fixedly connected below the seed discharge port of the air-suction garlic seed metering device. A bud reversing device is fixedly connected below the seed guide device. A vertical insertion device is fixedly connected below the bulb-reversing device. A tensioning wheel is fixedly connected to the outer surface of the square bracket and meshes with the chain to help adjust its tension. A ground wheel is fixedly connected to the rear of the vertical insertion device below the square bracket.

The suction-type garlic sowing unit provides negative pressure adsorption of garlic seeds on the seeding tray through a negative pressure fan and rotates regularly with the seeding tray. Subsequently, the hybrid garlic seeds are discharged from the seed discharge port of the seeder and then enter the bulb-reversing device. Finally, they enter the vertical insertion device in an upright posture. With the insertion device standing upright, they are planted in the soil, and the air-suction garlic sowing unit achieves a single seed sowing operation.

Structure of the bud-reversing device

Below the seed guide device is a bud reversing device, mainly composed of a conical hopper, connecting rod, gear, and other components, as shown in Figure 2. The apex of the conical hopper faces downwards. When the garlic seed falls into the conical hopper, it leans against the side wall. After the garlic seed stabilizes in the hopper, the hopper opens from the top of the cone, it leans against the side wall.

After the garlic seed stabilizes in the hopper, the hopper opens from the height of the cone, and the garlic seed that tends to be upright at this time falls out in this posture. The movement process of the hopper is shown in Figure 3. In this upright state, the hybrid garlic seeds enter the insertion device to achieve the goal of upright sowing.

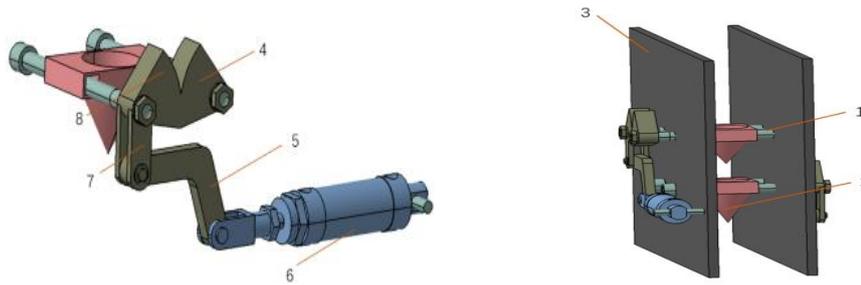

Fig. 2 - Schematic diagram of the structure of the bud-reversing device:

(1) Rotary shaft; (2) Conical hopper; (3) Square frame; (4) Right gear; (5) Obtuse angle connecting rod; (6) Cylinder; (7) Straight connecting rod (8) Left gear

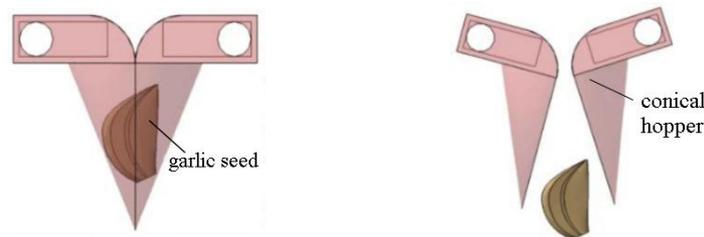

Fig. 3 - Working process of conical hopper

For the opening and closing of the conical hopper, the principle is controlled by the motion of the connecting rod mechanism. A pair of rotating shafts with gears connected to the surface are symmetrically fixed near the conical top surface of the hopper. The two gears mesh together, and a straight connecting rod is fixedly connected below the left gear. Its lower hinge is hinged with an obtuse angle connecting rod, and a small cylinder is hinged with it below this obtuse angle connecting rod. The small cylinder relies on an electromagnetic valve to control the extension of the piston, which causes the left gear to rotate clockwise, driving the right gear and its corresponding rotating shaft to rotate, making the hopper open and close. After some time, the piston rod retracts, and similarly, the hopper becomes tightly closed.

For the design of a conical hopper size, the following conditions must be met, as shown in the formula (1) (Rong-jiang et al., 2022).

$$\begin{cases} D_Z > h_{\max} \\ D_1 > t_{\max} \\ D_1 > w_{\max} \\ H_Z > h_{\text{avg}} \end{cases} \quad (1)$$

$$k = \frac{D_1}{2H_Z} \quad (2)$$

where:

D_Z is the top diameter of the seed dropping and D_1 is the stabilizing zones of the conical hopper, [mm]; H_Z is the height of the stabilizing zone, [mm]; h_{\max} is the maximum length of the hybrid garlic seed, 34.1 mm; t_{\max} is its maximum thickness, 19.8 mm; w_{\max} is the maximum width of the hybrid garlic seed, 21.8 mm; h_{avg} is the average length of the hybrid garlic seed, 29.6 mm. k is the slope of the generatrix of the conical hopper.

Therefore, the seed falling area of the conical hopper is designed to be 40 mm, the diameter of the stable area is not less than 21.8 mm, and the height of the stable area is not less than 29.6 mm. According to formula (2), the slope of the hopper generatrix can be obtained.

Support and profiling mechanism

In the design of the air suction garlic sowing unit, a square bracket is set up with a U-shaped side view. Above, it is used to place an air-suction garlic seeder, and a groove is opened for the seeder to drop seeds at the seed discharge port. Two profiling rods are hinged on the square frame's outer side. During the movement of the air suction seeding unit, the relative position of the fixed bracket remains unchanged and is only affected by the traction of the tractor. The components behind the fixed bracket will fluctuate with the fluctuation of the ground.

For the contour line of the profiling rod, a certain degree of curvature is used to ensure that the rod can withstand internal and external pressure during stationary and moving processes. One side of the four rods is hinged on a fixed bracket, and the other is hinged on a square bracket (Safari et al., 2019; Patel and Prajapati, 2018).

In order to carry the garlic seeder with a bottom length of 405 mm and a width of 88.5 mm, accommodate the bud reversing device, and reduce weight, volume, and cost; its length is designed as 410 mm, and its width is designed as 120 mm. For the design of the profiling rod, the parallelogram profiling mechanism, known for its parallelogram movement characteristics, is widely used in corn seeders to ensure consistent sowing depth during operation and enhance the overall stability of the machine (Patel and Prajapati, 2018).

The profiling rod is in contact with the square bracket, so the lateral width of the profiling rod is designed to be 120 mm, the length is designed to be 250 mm, and the profiling rod is designed to be parallel to the profiling rod, as shown in Figure 4.

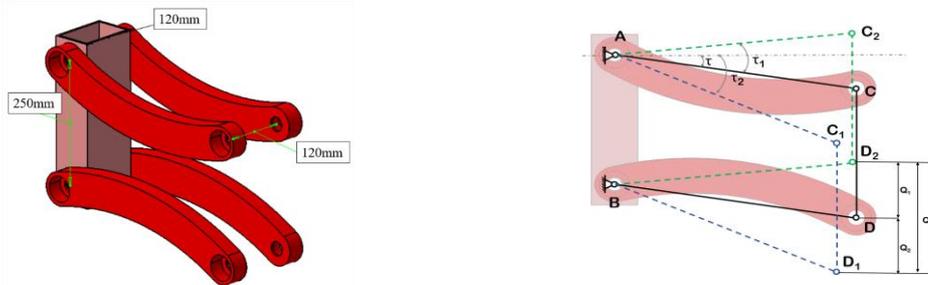

Fig. 4 - Schematic Diagram and Dimensional Drawing of the Profiling Rod

The calculation formula for the upper and lower profiling quantities (Shu-hong et al., 2013) is shown below.

$$Q = L[\sin(\tau + \tau_2) + \sin(\tau_2 - \tau)] \tag{3}$$

$$L = \frac{Q_2}{\sin \tau + \sin(\tau_2 - \tau)} \tag{4}$$

$$Q_1 = L[(\tau + \tau_1) - \sin \tau] \tag{5}$$

where:

Q is the total profiling displacement, [mm]; Q_1 is the upper profiling displacement, [mm]; Q_2 is the lower profiling displacement, [mm]; L is the length of the line connecting the hinge points on both sides of the profiling rod, [mm]; τ is the traction angle, [°]; τ_1 is the upper profiling angle, [°]; and τ_2 is the lower profiling angle, [°].

According to the formula, when the upper and lower profiling quantities are the same, the shorter the profiling rod L , the greater the variation of τ . Therefore, it is necessary to reduce the variation range of τ appropriately while ensuring that the machine's overall size and center of gravity are reasonable. Referring to the work Ji-guo et al., (2022), substituting formula (6) yields $L_{AC} = 413.4$ mm, taken as $L_{AC} = 410$ mm, and substituting formula (5) yields $Q_2=99.2$ mm, satisfying the condition.

Performance analysis of air-suction garlic sowing unit operation

The angle of the conical hopper is set to the intermediate value of 24.5° , and simulation experiments are conducted on 1, 2, and 3 hoppers, as shown in Figure 5. The statistical test results show the effect of the number of conical hoppers on the rate of bulb erection. Set each hopper's opening and closing times to 10 times, and each particle factory drops seeds ten times. After repeating the experiment at three levels five times, statistically analyze the number of garlic seeds with upright scales and record the upright rate of scales, as shown in Table 1. The maximum upright rate of scale buds is 92.09%, the minimum is 90.83%, and the difference is 1.26%. Therefore, the number of conical hoppers has little effect on whether the scale buds of hybrid garlic seeds can stand upright. Therefore, one is selected as a component of the bud-reversing device in selecting the number of conical hoppers.

Fig. 5 - Simulation process diagram of the effect of the number of hoppers on the upright scale of hybrid garlic seeds

(a) 2-stage conical hopper (b) 3-stage conical hopper

Analysis of the influence of conical hopper angle

When the number of conical hoppers is 1, a single-factor experiment is conducted on the angle of the conical hopper to analyze the influence of its angle on the vertical rate of the scales.

Seven levels, 18.5° , 20.5° , 22.5° , 24.5° , 26.5° , 28.5° , and 30° , were set as hopper angles. Each hopper's opening and closing times were set to 10 times, and each particle factory dropped ten times. After repeating the experiment five times at the three levels, the vertical rate of the experimental evaluation index was statistically analyzed. The specific experimental plan and results are shown in Table 2.

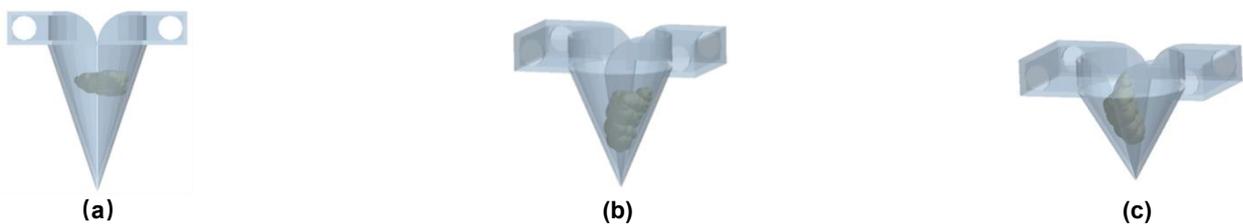

Fig. 6 - Simulation process diagram of the effect of hopper angle on the upright scale of hybrid garlic seeds

(a) 18.5° conical hopper (b) 24.5° conical hopper (c) 30° conical hopper

Analysis of Vertical Insertion Performance

As the final step in the sowing process of hybrid garlic seeds, the performance of the vertical sowing device directly affects the sowing results. In the previous section, the angle of the conical hopper was determined to be 24.5° . In order to make the seeding depth meet the requirements, a cone with the same top diameter and a height of 50 mm is designed on the external surface of the inserter, as shown in Figure 7(a).

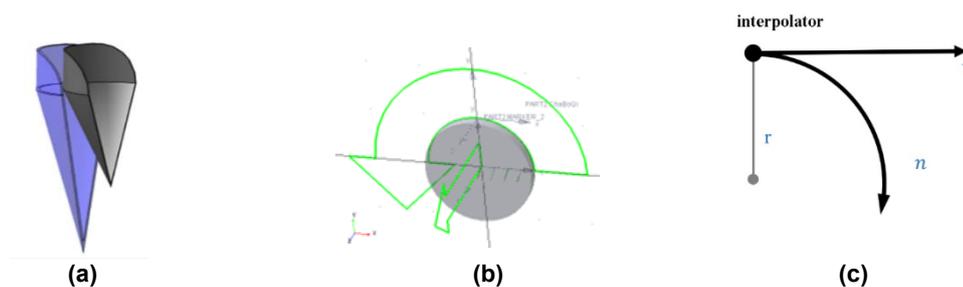

Fig. 7 - Schematic diagram of the structure and motion principle of the insertion device

The movement of the planting mechanism is composed of the horizontal movement of the air-suction garlic planting unit and the planting motion of the planting device. Using the Adams virtual prototype analysis software, a dynamic simulation analysis of the planting mechanism was conducted. The planting device model was simplified to a circular cam, and the planting mechanism was simplified to a marked point on the edge of the cam. In the simulation software, it was assumed that there is no gravity, as shown in Figure 7 (b).

Conduct dynamic analysis on the insertion device, where the insertion device is located at the highest position relative to the ground, the initial position of movement, and moves in a circular direction while also moving horizontally with the tractor, as shown in Figure 7 (c).

Set the distance between the marked point and the axis of the circular convex block as r , and as time passes, the coordinates (x, y) of the marked point will continuously change, as shown in the following equation.

$$x = vt + r \cos 2\pi nt \quad (6)$$

$$y = 2r - \sin 2\pi nt \quad (7)$$

where: x is the horizontal displacement component of the seeding unit, [m]; y is the vertical displacement component of the seeding unit, [m]; v is the forward speed of the machine unit, [m/s]; n is the rotational speed of the seeding unit, [r/s]; r is the radius of the seeding unit, [m].

In general, during actual sowing operations, the forward speed of the unit is 0.5~1.5 km/h, and the spacing of garlic seeds is 10 cm. Therefore, when the insertion device rotates around the axis to the next insertion device and comes into contact with the ground, the arc length is 10 cm. The relationship between the perimeter of the insertion device, the number of insertion devices installed on the insertion mechanism, and the rotation speed of the insertion device is shown below.

$$C = 0.1u \quad (8)$$

$$C = 2\pi r \quad (9)$$

$$n = \frac{v}{C} \quad (10)$$

where: C is the circumference of the seeding unit, [m]; u is the number of seeding unit; v is the forward speed of the machine unit, [m/s].

From the above equation, it can be concluded that the circumference of the insertion device is only related to the number of insertion devices. Once the circumference is determined, the size of the rotational speed can be determined.

Field trials

This article tests the sowing performance of air-suction garlic seeders by GB/T 6973-2005 “Test Methods for Single Grain (Precision) Planters”. A field experiment was conducted in the Agricultural Cuiyuan of Anhui Agricultural University in April 2023, with a temperature of 15-22°C. Before sowing, rotary tillage was performed on the soil.

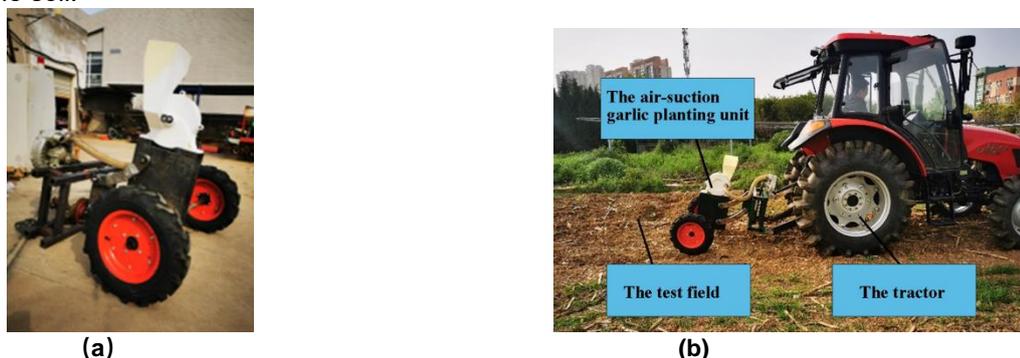

Fig. 9 - Field Experiment

As shown in Figures 9(a) and 9(b), the sowing unit includes a frame, profiling rod, seed guide, scale bud reversing device, vertical planting device, pneumatic system, and transmission system. The tractor powers the fan to supply negative pressure for the air-suction metering device, allowing stable discharge of garlic seeds. Hybrid garlic seeds, separated from low-quality seeds, served as the experimental material, with an average length, width, thickness, and sphericity of 29.6 mm, 16.9 mm, 15.1 mm, and 66.3%, respectively.

The seeds were spot-sown at 100 mm intervals, with a 30-40 mm depth and 45-52 plants/hm² density. The air-suction seeder operated under a -5 kPa pressure and at forward speeds of 0.5, 1, and 1.5 km/h.

After each sowing, record the number of holes without garlic seeds as the missed seeding count, and record the number of holes with a single garlic seed as the qualified seeding count. The formulas for calculating the missed seeding rate and qualified seeding rate are as follows:

$$A = \frac{a}{S} \times 100\% \quad (11)$$

$$B = \frac{b}{S} \times 100\% \quad (12)$$

where: A is the missed seeding rate, [%]; a is the number of holes without garlic seeds; S is the total number of hybrid garlic seeds counted; B is the qualified seeding rate, [%]; b is the number of holes with a single garlic seed.

RESULTS

The effect of the number of conical hoppers on the rate of bulb erection

After repeating the experiment at three levels five times, statistically analyze the number of garlic seeds with upright scales and record the upright rate of scales, as shown in Table 1. The maximum upright rate of scale buds is 92.09%, the minimum is 90.83%, and the difference is 1.26%. Therefore, the number of conical hoppers has little effect on whether the scale buds of hybrid garlic seeds can stand upright. Therefore, one is selected as a component of the bud-reversing device in selecting the number of conical hoppers.

Table 1

The effect of the number of hoppers (1, 2, 3) on the uprightness rate of garlic seeds, including the standard deviation and coefficient of variation of the experimental results

Number of conical hoppers X_1 (piece)	Scale bud upright rate (%)	Average (%)	Standard deviation (%)	Coefficient of variation (%)
1	91.62	91.54	0.39	0.43
	92.09			
	91.76			
	91.31			
	90.94			
2	90.98	91.26	0.37	0.40
	90.83			
	91.37			
	91.21			
	91.89			
3	91.38	91.60	0.28	0.31
	91.95			
	91.53			
	91.21			
	91.88			

The influence of single-factor hopper angles on the upright scale of hybrid garlic seeds

After repeating the experiment five times at the three levels, the vertical rate of the experimental evaluation index was statistically analyzed. The specific experimental plan and results are shown in Table 2.

The simulation process diagram shows the influence of single-factor hopper angles on the upright scale of hybrid garlic seeds. Seven angle levels were set in the experiment, and the diagram only displays three different conical hopper designs.

Table 2

Results of single factor test on the effect of hopper angle on hybrid garlic seed upright rate

Hopper angle (°)	Upright rate of hybrid garlic seeds (%)				
	1	2	3	4	5
18.5	84.31	84.87	85.09	85.01	84.62
20.5	87.56	86.57	87.43	86.96	87.02
22.5	90.03	90.14	89.94	91.24	90.53
24.5	91.98	92.65	91.44	91.88	91.32
26.5	90.26	89.42	89.57	88.79	89.36
28.5	86.01	85.71	86.47	85.71	86.39
30.0	84.12	85.21	84.01	84.98	85.62

Note: In the single-factor experiment, the number of hoppers was set to 1.

By analyzing the trend of changes in the upright rate of the bulb, it can be concluded that when the number of conical hoppers is 1, the upright performance of the bulb reversing device first increases and then decreases with the increase of hopper angle. When the angle of the conical hopper is 24.5°, the upright effect of the bulb is the best. The upright rate of hybrid garlic seeds is 91.85%, which can meet the requirements for the upright rate of garlic seeds.

The influence of the insertion device perimeter on the trajectory of the inserter

Draw a trajectory map of the inserter with a 400-900 mm circumference, as shown in Figure 8. Observe the trend of changes in the trajectories of each graph. The point corresponding to the end of the vertical axis is the lowest point of the inserter. Moving 50 mm above the vertical axis is the trajectory of the inserter entering and exiting the soil.

As the inserter's perimeter increases, the inserter's trajectory entering the soil tends towards a vertical line. However, considering the position relationship of the insertion device and the size of the individual machine, 600 mm is selected as the perimeter of the insertion device, which means there are six insertion devices, and the rotation speed of the insertion device is 0.463 rad/s.

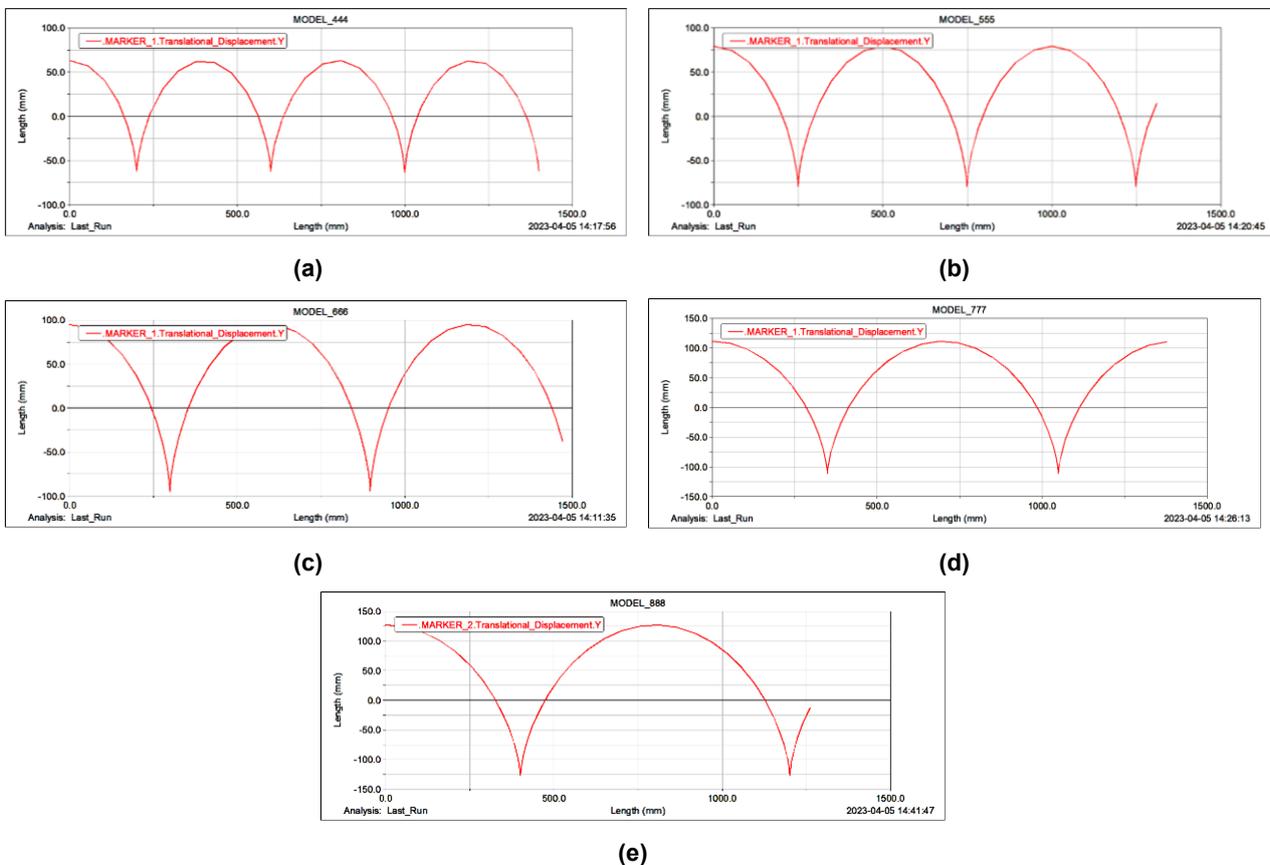

Fig. 8 - Spooler trajectory diagram

(a) 400 mm perimeter trajectory; (b) 500 mm perimeter trajectory; (c) 600 mm perimeter trajectory; (d) 700 mm perimeter trajectory; (e) 800 mm perimeter trajectory

Field trials results

The experiments were conducted under the specified conditions, and the following results were obtained. Statistical analysis revealed the effect of the unit's forward speed on the seeding qualification rate and missed seeding rate. Each experiment was repeated three times, with the average values calculated and presented in Table 3.

Table 3

Impact of three-level unit forward speed on garlic seeding qualification and missed seeding rates

Level	Forward speed of the unit (km/h)	Seeding qualification rate (%)	Missed seeding rate (%)
1	0.5	81.12	11.33
2	1	84.26	7.12
3	1.5	79.29	9.54

Table 3 shows that when the negative pressure remains constant, and the unit advances at a speed of 1 km/h, it is the level with the highest qualified seeding rate and the lowest missed seeding rate among the three levels.

The forward speed of the unit is set to 1 km/h, and three levels of negative pressure (-4, -5, and -6 kPa) were applied to regulate the metering devices in the seeding unit. Each experiment is repeated three times. Calculate the average of the test results and record the results as shown in Table 4.

Table 4

Impact of three-level negative pressure on garlic seeding qualification and missed seeding rates

Level	Negative pressure (kPa)	Seeding qualification rate (%)	Missed seeding rate (%)
1	-4	80.39	9.33
2	-5	84.26	7.12
3	-6	82.86	7.83

When the negative pressure is -5kPa, the qualified rate of sowing reaches the highest among the three levels, and the missed rate reaches the lowest among the three levels.

CONCLUSIONS

This study proposes an air-suction garlic seeding unit. This unit allows the garlic to be stably planted upright in the soil. The unit adsorbs garlic seeds onto the seeding tray through negative pressure and delivers the seeds to the seed guide device at zero speed. Finally, it enters the vertical planting device upright and is planted in the soil. Therefore, it meets the agronomic requirements of garlic seeds to achieve single-seed sowing and erect scales during the mechanical sowing process.

According to the requirements of hybrid garlic seed sowing, the overall structure of the air-suction garlic sowing unit is designed, and its working principle is explained. For the principle analysis and theoretical calculation of the critical components of the seeding unit, the adsorption pressure required for the seed metering device is -5kPa, the number of hoppers used for the bulb seed changing device is selected as 1, the angle is selected as 24.5 °, and the perimeter of the insertion device is selected as 600 mm. These data provide support for subsequent field experiments.

When conducting a three-level field experiment, the optimal parameter combination for sowing results is negative pressure of -5kPa and a forward speed of 1 km/h at the three-level. The qualified rate of individual sowing can reach 84.26%, and the missed sowing rate is 7.12%, which meets the agronomic requirements for garlic seed sowing. Field experiments have verified the accuracy of theoretical analysis and bench tests, laying the foundation for the future production and promotion of garlic sowing units.

ABSTRACT

The feed rate is an important index for evaluating the performance of a combine harvester. Determining how to accurately reflect the feed rate during harvesting and establishing a reliable detection model is a major focus of current research and an important basis for the next step of feed rate stable control. This paper provides an overview of feed rate detection methods and stable control techniques for combine harvesters. It reviews methods that estimate the feed rate based on the inclined conveyor extrusion pressure, header power, and threshing unit energy consumption. Additionally, it introduces machine learning-based methods that incorporate multiple influencing factors to predict the feed rate. A comparison of different noise reduction techniques used in feed rate detection is also presented, analyzing their effectiveness. Furthermore, this study examines feed rate control methods in combine harvesters, discussing various control approaches with an emphasis on methods that stabilize the feed rate by adjusting header height and harvester forward speed. In response to the current issues of inadequate detection accuracy in feed rate monitoring, limited adaptability, and instability in control systems, it is pointed out that future research needs to innovate in developing advanced sensor technology, optimizing automatic control algorithms as well as data fusion and analytical methodologies.

摘要

喂入量是衡量联合收割机性能的重要指标，通过何种方式将收获时机的喂入量反应出来并建立可靠的检测模型是当前研究的重点，也是下一步稳定控制喂入量的重要依据。该文概述了联合收割机喂入量检测方法以及喂入量稳定控制方法的研究现状，综述了基于过桥挤压力、割台功率、脱粒元件功耗等反应收割机喂入量的方法，介绍了利用机器学习结合多种影响喂入量的因素预测喂入量的方法，并对比了喂入量检测中不同降噪方法的降噪效果的优劣，接着对联合收割机喂入量控制方法进行了梳理，探讨了不同控制策略，着重分析了通过调节喂入量高度、收割机前进速度使喂入量保持稳定的方法。结果表明现阶段喂入量检测方法均能在一定程度上反映出喂入量变化情况，但普遍存在稳定性差、检测精度不高等问题。通过控制喂入量有效减少了收获损失率，但控制误差易受田间环境影响、波动大。针对上述问题，指出今后研究需要在发展先进传感器技术、优化自动控制算法、数据融合与分析等方面开拓创新。

INTRODUCTION

A combine harvester is a field operation machinery that integrates cutting, threshing, separation, and cleaning functions. Its introduction has significantly reduced the labor intensity of farmers and enhanced production efficiency in agricultural settings (Pingali, 2007). As the crucial mechanical equipment in the grain harvesting process, the harvesting quality and efficiency of the combine harvester have always been the indicators of user's concern, and also the focus of research by scholars. Crop feeding process is the front-end operation of combine harvester, affecting the machine threshing, cleaning and other subsequent operations. The feed rate has always been an important indicator for evaluating the performance of the harvester. Both excessive or insufficient feed rate can lead to a decrease in the efficiency of the harvester (Fan et al., 2022). Therefore, it is beneficial for the harvester to keep the best working condition by monitoring the real-time data of the feed rate and stabilizing feed rate during field harvesting (Chen et al., 2011).

At present, scholars at home and abroad have conducted a series of studies on the feed rate and its stable control methods, and have made some progress. Overseas research focuses on the height and density of feeding crops, estimating the feed rate indirectly by calculating the crop density in front of the harvester. Domestic research on feed rate detection methods mainly focuses on the following three aspects: estimating the feed rate by detecting grain flow rate; predicting the feed rate by measuring the squeezing force on inclined conveyor during crop feeding; establishing a feed rate detection model through analyzing the power consumption of major threshing components (*Tang et al., 2023; Zhang, 2019; Wang et al., 2019; Abdeen et al., 2022*).

In terms of feed rate control, mature feed rate control systems have been widely applied on large combine harvesters abroad, while most domestic research in China remains at the experimental stage, with a certain gap between research and practical application.

This review aims to present the research status of feed rate detection and stability control methods in combine harvesters. It summarizes common feed rate detection methods, feed rate signal denoising methods, feed rate stability control methods, highlights the problems and limitations of existing approaches, and proposes future research directions for improving feed rate detection and control methods.

RESEARCH PROGRESS ON FEED RATE DETECTION METHODS IN COMBINE HARVESTERS

The feed rate of the combine harvester refers to the total mass of all materials fed into the thresher body within a unit of time. It is closely related to header cutting width, operation speed, yield per mu, grain-straw ration, etc. Real-time monitoring and controlling the feed rate is crucial for the combine harvester to achieve optimal working efficiency (*Jie, 2009*).

Since the 1970s, many experts have conducted research on feed rate detection and have achieved certain results. In *Cao Chongwen, (1975)*, many parameters that were considered as the basic for adjusting the feed rate were summarized, including the torque of several important transmission shafts such as cutter drive shaft and screw conveyor shaft, the speed of threshing cylinder and the pressure of concave plate, etc. (*Cao, 1975*).

Jie Zhan et al. (1990) began researching quantitative measuring techniques for feed rate, using two methods of measuring pressure and displacement, and conducting a rice bench simulation experiment. By utilizing the principle that the sensor can convert the feed rate into electrical signals, the study explored the correlation between feed rate and electrical signals, and respectively summarized the fitting equations between pressure sensor voltage and feed rate, and displacement sensor voltage and feed rate. The error calculation results showed that the test accuracy of the pressure sensor is better than that of the displacement sensor. In order to improve the detection accuracy, the pressure sensor was calibrated. Firstly, the sensor was statically calibrated through weight loading, and after obtaining the static calibration regression equation, dynamic calibration was conducted through bench testing (*Jie et al., 1990*).

In 2009, a mathematical model for feed rate testing was established (*Jie et al., 2009*). The force-electric sensor was installed on the bottom plate of the inclined conveyor to conduct real-time analysis and processing of feed rate signals. The regression curves were established for the preset feed rate data group and the signal mean, as well as the signal change value. Due to random errors caused by factors such as the state of the feed-in material, placement factors and conveying factors, the repeatability of the feed rate data was poor. Although the stability and reliability of this system have been greatly improved, it still did not meet the technical requirements for telemetry of feed rate in field experiments.

Tang Zhong et al. (2012) analyzed the power consumption of the longitudinal flow threshing-separation process, and deduced the relationship between the feeding rate and the net threshing power consumption of the longitudinal-flow threshing cylinder in wheat harvesting. The field test results showed that the net threshing power consumption of the longitudinal-flow threshing cylinder could accurately predict the feed rate (*Tang et al., 2012*).

Lu Wentao et al. (2011) designed a hydraulic infinitely variable speed system for threshing cylinder of grain combine harvester and installed a pressure sensor in hydraulic to measure oil pressure. This oil pressure was used to represent the feed rate. By analyzing the data of oil pressure, threshing cylinder and engine speed under different feed rate, the fitting equation of oil pressure and feed rate was established. However, the feed rate model established by this method can be valid only when the combine harvester is operating stably, the physical properties of the crop are consistent and the feeding is uniform, which is an ideal condition (*Lu et al., 2011*).

Liang Xuexiu et al. (2013) analyzed the flow rate of grains, the torque and the speed of the threshing cylinder, corrected and calculated the formula for the feed rate, and designed a set of field online monitoring system for the feed rate (Liang et al., 2013).

Liu Yuanyuan et al. (2017) analyzed the power and dynamic model of the header auger conveyor, and designed a power consumption monitoring system for the auger conveyor. The location of the sensor is shown in Figure 1. This monitoring system was installed on the Guwang TB60 combine harvester for field experiments. Through linear fitting of the power of the header screw conveyor and the feed rate data, it was found that there is a linear relationship between the two, with a correlation coefficient $R^2=0.9099$, indicating that the method of predicting the feed rate based on monitoring the power of the auger conveyor is feasible (Liu et al., 2017).

Yin Yanxin et al. (2018) designed a chain wheel torque speed sensor based on the feeding auger structure characteristics, and constructed a multi-information acquisition system for combine harvester based on the distributed data collection, transmission and processing system of CAN bus (Fig 2). This system can synchronously obtain online parameter information such as the power output of the header lifting, auger conveyor, inclined conveyor, and threshing cylinder of the combine harvester, providing reliable data for predicting the feed rate and operation quality of the grain combine harvester (Yin et al., 2018).

Zhang Zhenqian et al. (2019a) designed a feed rate monitoring system, which obtains the header drive shaft torque signal through a wireless torque sensor, and measures the header drive shaft speed signal with a Hall sensor to predict the feed rate (Zhang et al., 2019).

Sun Yifan et al. (2020) selected the feed rate detection method based on the power of the header active shaft and the power of the inclined conveyor to design the text system, and compared the detection accuracy of the two methods. After processing and analyzing the field text data, the linear regression equations between the torque voltage signal of the header's driving shaft, the inclined conveyor's power shaft torque voltage signal and actual feed rate were respectively established by the least square method. Although this method simplifies the calculation process for the feed rate model, it cannot reflect the relationship between feed rate and power at different shaft speeds (Sun et al., 2020).

At present, the related research results of feed rate detection method based on traditional mathematical model are shown in Table 1.

Table 1

Research on the detection method of combine harvester feed rate				
Detection method	Sensor type	Installation position	Grain type	Error
Inclined conveyor extrusion pressure	Force-electric sensor	Inclined conveyor bottom plate	Rice	Bench test error $\leq 8\%$.
Power consumption of threshing element	Torque sensor	Threshing cylinder active shaft	Wheat	Bench test error $\leq 0.89\%$
	Oil pressure sensor	Threshing cylinder hydraulic stepless variable speed system oil circuit	Rice	
Header power	Torque sensor	Header auger conveyor active shaft	Wheat	$R^2=0.9099$
	Torque sensor	Header active shaft	Wheat	$R^2=0.8520$
	Torque sensor	Header drive shaft	Wheat	$R^2=0.8325$
Combined type	Torque sensor; Pressure sensor	Between the threshing cylinder power source and the load; Between the grain elevator and the grain outlet	Rice	Error $\leq 5\%$
	Chain wheel torque speed sensor	Header auger active shaft; Inclined conveyor drive shaft; Threshing cylinder active shaft	Rice	Error $\leq 2\%$

With the development of computer science, more and more scholars use machine learning models such as fuzzy neural networks and convolutional neural networks to predict the feed rate (Dorokhov et al., 2019). Lu Wentao (2014) considered that when the physical characteristics of the grain changed, the one-to-one correspondence between the feed rate and the oil pressure was not established. In this condition, it was difficult to obtain the accurate feed rate by using the theoretical equation, so they used a neural network to establish the model for the feed rate. Through the orthogonal test, it was concluded that the feed rate, material humidity and grain-straw ration had significant effects on the oil pressure, so the oil pressure, material humidity and grain-straw ration were taken as the three neurons of the input layer, and the feed rate was taken as the neuron of the output layer. A feed rate neural network model was established by processing and analyzing the experimental data. Comparing the training results of the network model with the multiple linear regression function, it was concluded that the network model is superior to the regression equation. This method can reduce the impact of the changes in physical characteristics of the feed material on the accuracy of the feed rate detection (Lu et al., 2014).

Sun Yifan (2022) used rice as the harvest object and designed a feeding monitoring system that could simultaneously monitor the header height, rice moisture content and the torque changes of the header's power shaft. In order to accurately calculate the feed rate, he established a three-layer BP neural network with 12 neurons in the hidden layer, with header height, grain moisture content and header's power shaft torque as input layers, and the feed rate as the output layer. The structure of the neural network is shown in Fig. 3. To prevent the neural network from getting stuck in local minima during the fitting process, the particle swarm optimization algorithm was introduced to optimize the initial value and threshold of BP network. The average absolute percentage error of the optimized feed rate model decreased from 8.42% to 7.62% (Sun et al., 2022). The neural network prediction method of feed rate is summarized as shown in table 2.

Table 2

Neural network prediction method of feed rate		
Model	Input layer signal	Effect
Fuzzy neural network	Crop density deviation, Crop density deviation change rate	
BP neural network	Oil pressure, material humidity, grain-straw ration	SSE=0.769
	Header height, grain moisture content, header's power shaft torque	MAE=7.69%
Convolutional neural network		Accuracy=86.7%

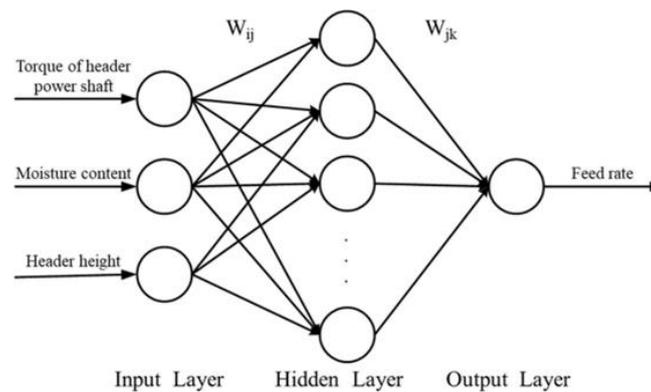

Fig. 3 - Structure of the BP neural network
(Sun et al., 2022)

In response to the issue of insufficient interpretability of processing results in machine learning prediction models, some scholars have begun to predict the feed rate model through grey relational analysis and association rule analysis. Grey relational analysis is an analytical method based on grey system theory, mainly used to deal with incomplete information or uncertainty. Compared to traditional machine learning methods, grey relational analysis places more emphasis on evaluating the degree of correlation and establishing correlation models. Zhang Yawei et al (2018) studied the factors affecting the feed rate of combine harvester based on the grey correlation analysis. The feed rate, crop attributes and harvesting conditions were regarded as a grey system with some information being clear and some unclear. Combined with the data of crop attributes and the feed rate, the grey relational analysis was used to find out the correlation between factors such as operating speed, crop density, torque and speed of the feeding auger and the inclined conveyor, torque and speed of threshing cylinder and the feed rate. It was concluded that in the actual field harvesting, the correlation degrees of operation speed and the feed rate were the highest, followed by the torque of the threshing cylinder. Based on this, a prediction model of feed rate detection error based on grey prediction was proposed, using the product of operating speed and crop density, feeding auger torque, inclined conveyor and threshing cylinder torque as inputs to establish the feed rate detection model (Zhang et al., 2018). Liu Yehong et al (2023) incorporated the torque and speed of the threshing cylinder, grain, grain augers and tailing augers into the feed rate monitoring. He proposed using association rules to explore the relationship between each parameter and the feed rate (Liu et al., 2023).

In addition to detecting the feed rate by measuring the power, pressure and other key components of the combine harvester during operation, many scholars have studied the crop growth status at the front end of the harvester, proving reference basis for subsequent feed rate detection and control. Ji Binbin (2005) designed a combine harvester feed rate prediction system based on fuzzy neural network. According to the crop density deviation and the change rate of crop density deviation measured by the combine harvester grain feeding amount sensor at time t , the actual crop density deviation of $t + \Delta t$ was predicted. Fuzzy neural networks combine the advantage of fuzzy logic and neural networks and can overcome the shortcomings of traditional neural networks in handling fuzzy and uncertain information. This combination can help in dealing with fuzzy inputs, outputs and rules, making the network more adaptable to problems involving fuzzy concepts (Ji, 2005).

Saeyns et al. (2009) used two types of light detection and ranging sensor and different online processing methods to estimate the crop density in front of the combine harvester. They proposed a new method for estimating crop volume by fitting thin plate splines to ground and ear points to calculate the volume between ground profiles and crop profiles (Saeyns et al., 2009; Blanquart et al., 2020).

Pan Jing et al (2010) used computer image processing technology to fit the 2R+G color feature value extracted by image processing with the actual measured feed density image, and established relevant model coefficients. The feed density of the combine harvester was obtained in real time to predict the feed rate of the harvester (Pan et al., 2010). Zhang Shuqi (2021) used machine vision to measure the height of rapeseed in the field, and built a convolutional neural network model to predict the density of rapeseed in the field, which was used as the basis for detecting the feed rate. Based on obtaining accurate feed rate detection results, an adaptive control strategy was used to achieve a scientific match between the forward speed and the rotation speed of the reel wheel (Zhang, 2021).

SIGNAL NOISE REDUCTION PROCESSING METHODS IN FEED RATE DETECTION

The working environment of the combine harvester is special. The terrain fluctuates in the field making it impossible to maintain a consistent flatness. The density and height of the harvested crops also vary. Moreover, the combine harvester itself has a complex system and harsh operation conditions. During operation, noise caused by the machine's vibrations and bumps inevitably interferes with sensor signals. In order to improve the accuracy of feed rate prediction, it is necessary to denoise the signal collected by the sensors.

Zhang Zhenqian (2019b) performed double threshold filtering on the torque signal of the header drive shaft collected by the sensor for edge detection and segmentation, and then used piecewise linear interpolation to obtain more detailed information to remove singular values. He made a comparison on the noise reduction effects of Butterworth low-pass filtering, FIR low-pass filtering, moving average filtering and adaptive filtering on the torque signal. After error analysis, it was found that the adaptive filtering had the best noise reduction effect (Zhang et al., 2019).

Sun Yifan et al. (2020) performed Fourier transform on the collected data, converting the data from the time domain to the frequency domain, providing clearer frequency domain information for filtering processing, and then using Butterworth band-pass filter to filter the torque signal (Sun et al., 2020). The denoising framework is shown in Figure 4.

In order to solve the signal noise issue in the feed rate monitoring system, Tao Jiang et al. (2022) first performed Fast Fourier Transform on the torque of the auger conveyor drive shaft during the no-load rotation of the harvester to obtain the noise frequency domain information. Since the signal during the harvester's loaded operation is a non-stationary process, Fourier transform has limitations in that it can only determine the frequency components contained in a segment of the signal overall, without knowledge of when each component appears. Therefore, it cannot determine the changes in signal frequency during feeding, nor can it filter out noise in the signal. In response to this situation, wavelet transform was applied to the torque signal obtained during the harvester loaded operation, followed by denoising using a fixed threshold estimation method to reduce errors in the relationship between torque and the feed rate (Jiang et al., 2022). The denoising framework is shown in Figure 5.

Fengzhu Wang et al. (2023) studied a feed rate detection method based on multi-component power monitoring, effective data automatic screening and multivariate data fusion regression. The Mann-Kendall algorithm was used to detect the boundary points of field harvest data. The Grubbs standard was used to validate the data, and outliers were rejected one by one at a confidence level of 0.05. The correlation of the established regression model was verified by Pearson algorithm, and multi-parameter calibration and fusion feeding amount detection were realized (Wang et al., 2023).

RESEARCH PROGRESS ON THE FEED RATE CONTROL METHOD IN COMBINE HARVESTERS

The application of automatic control technology in agricultural machinery has a breakthrough impact on modern agricultural production, which is conducive to the intelligent and sustainable development of agricultural equipment in production operations. Currently, research on the automatic control of combine harvesters mainly focuses on controlling the rotational speed of the threshing drum, the concave screen clearance, the height of the header, the forward speed etc. (Ivan et al., 2015).

Alabushev et al. (2020) explored the factors influencing the binding force of winter wheat grains and ears and established a regression model to provide a basis for intelligent control of threshing process (Alabushev et al., 2010). Xu Baoyan et al. (2020) conducted experiments by setting different concave plate clearances and drum speeds, and derived the relationships among concave plate clearance, drum speed, and

threshing quality. Based on a type - 2 fuzzy logic controller, they designed a threshing controller with a low loss rate (Xu et al., 2020). Fan Chenglong et al. (2022) designed a guide vane inclination adjustment mechanism with a hydraulic cylinder as the driving source under the monitoring of the feed rate (Fan et al., 2022). Li Ying et al. (2021) designed a frequency subsection regulation system for the combine harvester header cutter. By constructing the cutter trajectory equation, they analyzed the relationship between the forward speed of the harvester and the cutting frequency, as well as the impact on the cutting area, and determined the optimal cutting frequency range at different operating speeds (Li et al., 2021). In view of the shortcomings of current combine harvester research, such as the focus on single-device control, inaccurate feedback information, and poor adaptability of control models, Li Yang et al. (2024) regarded the threshing cylinder device as an integrated control object. They designed an electric adjustment mechanism for the main operating parameters of the threshing and cleaning devices. Based on the fusion method of particle swarm optimization and wavelet neural network, they conducted system identification on the state - space model and the NARMAX model to explore their applicability and obtain the optimal model. They adopted the model predictive control method to adjust the threshing and cleaning parameters and carried out the control process simulation in Simulink, achieving good results (Li et al., 2022; Li et al., 2024). Yang Yu et al. (2024) designed an electric control adjustment device for threshing clearance based on a crank - rocker mechanism, proposed a control method for threshing clearance based on a fuzzy neural network PID, and established relevant models and determined parameters (Yang et al., 2024).

Controlling the feed rate within a stable range during the operation of a combine harvester is beneficial for the machine to achieve optimal performance and reduce grain loss. The feed rate cannot be directly controlled. Zhang Yawei et al. (2018) found through grey relation analysis that the forward speed during harvesting has the highest correlation with the feed rate, followed by the correlation between the threshing cylinder torque and the feed rate (Zhang et al., 2018). At present, there are two main methods for controlling the feed rate: one is to control the forward speed of the harvester to control the feed rate, and the other is to achieve stable control of the feed rate by adjusting the height of the header (Maertens and Baerdemaeker, 2004).

The CR90.90 combine harvesters developed by Case New Holland Company use two ultrasonic sensor to detect the feed rate of threshing cylinder. When an excessive feed rate is detected, the machine's overload anti-spitting device can automatically adjust. The machine is equipped with the AFS advanced precision agriculture system, which effectively combines and analyzes data from several key stages of cultivation, providing users with personalized agricultural solutions (Cheng et al., 2018; Wang, 2021).

Huang Zhigen (2010) designed a multi-signal acquisition system for combine harvester, which can detect the rotation speed, feeding rate and grain loss signal during the operation. In order to obtain a stable feeding rate, he designed an automatic speed control mechanism for the combine harvester. The main control unit based on ARM was used to control the stepper motor and then control the angle of the hydraulic stepless transmission joystick to control the forward speed of the combine harvester. In addition, a load feedback automatic control system of the combine harvester was established, utilizing fuzzy control technology to create a multi-information fuzzy control model (Huang, 2010).

Fuzzy control system is a control method based on fuzzy logic theory, which simulates human thinking and decision-making process, and can deal with the problems of uncertainty and fuzziness.

Mahmoud Omid et al. (2010) designed a fuzzy logic control system combined with human expert knowledge, which integrates human expert knowledge into the learning process, and finds the best technical parameters of the harvester through continuous trial and error based on expert knowledge and relevant experience. It provided a reference for the design of combine harvester control system in the future (Omid et al., 2010). You Huiyuan et al. (2015) used PLC to establish a fuzzy control system for feed rate, and controlled the working speed of the combine harvester to keep the feed rate within a stable range. The actuator adopts an electronically controlled hydrostatic system, which changed the speed of the hydraulic motor by altering the current signal and the swashplate angle of the variable pump to adjust the travel speed (You et al., 2015).

Wang Li et al. (2021) designed an intelligent control test bench for combine harvesters. The designed double - closed - loop PD controller can effectively and dynamically adjust the control parameters according to the changes in the driving speed of the harvester. The motor module was utilized to simulate the rotational speeds of rotating components such as the combine drum, conveyor through, and header screw conveyor of the combine harvester, while the simulation module was used to simulate the feeding and loss processes. The intelligent control algorithm for the forward speed of the test bench was tested, achieving good results (Wang et al., 2021).

He Yongqiang *et al.* (2024) proposed a control algorithm that combines the Pose Vector Method (PVM) and the Support Vector Regression (SVR) model. They designed a research platform for traveling control adapted to different Paddy Ground Conditions (PGCs), and used the Real - Time Kinematic Global Navigation Satellite System (RTK - GNSS) to measure information such as the pose of the combine harvester. The PVM was proposed to determine the steering radius online, and the SVR model was used to predict the error - correction factor for the steering trajectory radius. A feedforward compensation control method was designed based on the steering control model. This study provided new ideas for enhancing the online perception of the motion state of crawler combine harvesters and improving the adaptive control performance (He *et al.*, 2024).

Because the combine harvester is a complex system with nonlinear time-varying and time delay and has numerous and complex working components and changeable working environment, the traditional control theory was difficult to be applied to the harvester control system (Pan *et al.* 1999).

Fuzzy control considers fuzzy and imprecise input and output, making the system more adaptable to fuzzy, uncertain, or difficult to model situations. In the past two decades, it has been widely used in the design of combine harvester control system. However, fuzzy control has low interpretability, complex calculation, and lack of global optimization. Many scholars have begun to try to combine fuzzy control with some algorithms such as adaptive control to make the system more adaptable to complex environments and changes (Wang *et al.*, 2014.; Randal *et al.*, 2005).

Chen Jin *et al.* (2014) designed a fuzzy adaptive control system of forward speed for combine harvester based on model reference, as shown in Figure 6. Compared with the traditional fuzzy control, the adaptive fuzzy control system introduces self-adaptability. The system can dynamically adjust the reference fuzzy rules and member functions according to real-time feedback to adapt the changes of the system. The control system received input and loss signals collected by sensors, and then calculated the change of the forward speed of the combine harvester through the model reference fuzzy adaptive control algorithm, and outputted the control signal to drive the actuator to adjust the forward speed (Chen *et al.*, 2014).

Ning Xiaobo *et al.* (2015) conducted a comprehensive dynamic analysis of the motion mechanism of the combine harvester, and designed a fuzzy logic controller, with the speed deviation of the threshing cylinder and the rate of change of the speed deviation as input variable, and the rotation angle of the stepping motor as the output variable. If the input variable exceeded the range of change, the controller would adjust the forward speed of the harvester by controlling the hydraulic infinite transmission based on the output variable (Ning *et al.*, 2015).

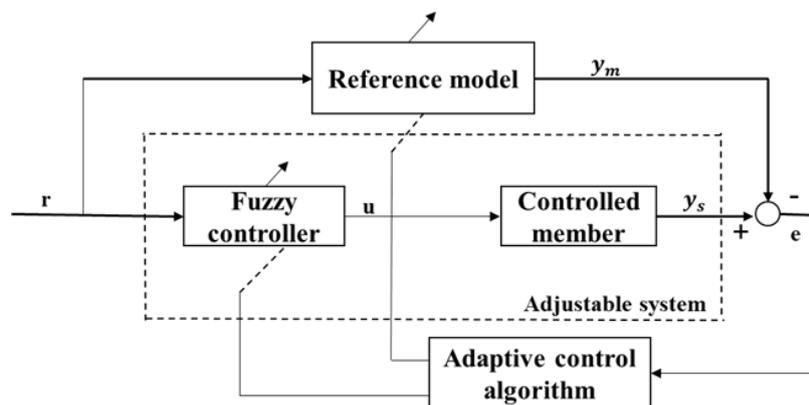

Fig. 6 - Structure diagram of model reference fuzzy adaptive control system (Chen *et al.*, 2014)

Because fuzzy control requires more professional knowledge to model the system, and the design process is more complex and subjective, some scholars began to use optimization algorithms to help adjust the parameters of fuzzy controllers to improve system performance.

Ning Xiaobo (2015) further used a multi-objective genetic algorithm to optimize the influence factors of each parameter in the constructed multi-parameter fuzzy control system, such as the speed of the tangential cylinder. By comparing the simulation test with the model before optimization, it can be seen that the overall performance of the harvester is improved (Ning, 2015). In addition, Ning Xiaobo, Chen Jin *et al.* (2016) used association rule knowledge to evaluate the weight factor of association rules between each operating parameter of the harvester and the feed rate and loss rate, studied the principle of adaptive fuzzy control, constructed the adaptive control model of the whole domain operating speed of combine harvester and designed the adjustable factor fuzzy controller (Ning *et al.*, 2016).

In 2017, *Chen Jin (2017)* proposed a multi-parameter fuzzy control strategy for the forward speed of the combine harvester based on Knowledge Discovery in Databases (KDD). She found the optimal trade-off point between the auger conveyor, the inclined conveyor and the threshing cylinder, and used MATLAB to establish a multi-parameter control model based on KDD (*Chen et al., 2017*).

Hou Ankang (2021) designed the control system of header module, threshing module, grain tank and travel module of combine harvester, and established the speed control model of each component of the combine harvester. The core idea was to control the feed rate to be constant, and this was achieved by controlling the flow rate of the hydraulic valve (*Hou, 2021*). *Li Xiaoyu et al. (2023)* designed the automatic control algorithm of corn grain harvester, with a travel system using closed-loop hydrostatic drive. They proposed an improved particle swarm optimization that combines the cuckoo search algorithm's local wandering strategy, and built a PSO-CS-Fuzzy PID control model based on MATLAB Simulink. This algorithm was beneficial for addressing the issue of traditional particle swarm algorithms easily getting stuck in local minima, and achieved good control effects in subsequent simulation experiments (*Li et al., 2023*).

Sun Yifan et al. (2023) established a model for detecting the change of feed rate during the operation of the combine harvester. The harvester operation speed was taken as the control object, and the stable control of feed rate was taken as the control target. The model prediction method was used to simulate and control the feed rate. The grey wolf optimization algorithm was used to optimize the weight matrix to reduce the control error of the output feed rate (*Sun et al., 2023*). Table 3 summarized the research on the stable control strategy of feed rate with the control target of controlling the forward speed of harvester.

Table 3

Research on the stable control strategy of feed rate		
Control strategy	Optimistic algorithm	Advantage
Fuzzy control		The rules are intuitive in form, adaptable and flexible.
MSIFC		Control precision and robustness are improved.
AFC	Association rules analysis	The extraction of fuzzy rules is more accurate, and the control system is more interpretable.
FRAMFC		The system response speed and modeling accuracy are improved.
MPFC	MOGA	The global optimization ability is improved, and the multi-parameter coordinated optimization is improved.
	KDD	Parameter optimization is more targeted.
PID control	PSO-CS	Avoid falling into local optimal value
MPC	GWO	The convergence speed is faster and adapts to the multivariable complex system.

In addition to controlling the forward speed of the combine harvester, another effective way is to adjust the height of the header to control the feed rate. By raising or lowering the header, the cutting position of the crop can be changed, and this flexible control method can more finely adjust the feed rate (*Cheng et al., 2018; Tai et al., 2020; Wang et al., 2024*).

Chen Jin et al. (2018) designed a key electric controlled adjustment device for header parameters with PLC as main controller, which can realize the key electric controlled of header height, reel height and reel speed. The actuator of the header was controlled by hydraulic pressure, and the components were three-position four-way solenoid directional valve and proportional solenoid valve. The speed control model of the reel was established, and the fuzzy control and PID control were combined to realize the real-time control of the system. Effective header height control is helpful to improve the stability of feed rate and reduce the load fluctuation of each link of the whole machine (*Chen et al. 2018*).

Zhuang Xiaobo and Li Yaoming (2020) analyzed the dynamics of the header and established the model. According to the hydraulic motion equation, the state space model of the header height hydraulic system was established. They proposed a height control strategy of combine harvester header based on robust feedback linearization, which could make the header height follow the ground fluctuation. They designed a controller and compared it with the PID controller in experiments. The results showed that under the same simulation conditions, the error under the control of this method was smaller than that under the PID control (*Zhuang et al., 2020*).

Ni Youliang *et al.* (2021) developed a height adjustment system for soybean harvester header. They designed a profiling mechanism and a hydraulic drive system based on existing soybean harvesters, and designed a header height self-adaptive adjustment system, and established an evaluation index for the height adjustment system of the soybean harvester header (Ni *et al.*, 2021; Liu *et al.*, 2023).

Ji Kuizhou *et al.* (2022) proposed a multi-sensor data fusion technique based on a backpropagation (BP) neural network. This method integrates ultrasonic sensors for ground height detection, infrared sensors for monitoring crop lodging status, and pressure sensors for real-time measurement of header load. By adaptively adjusting the weighting of data from various sensors through the neural network, the system optimizes the self-adaptive regulation of header height in combine harvesters (Ji *et al.*, 2022).

Ruan Mingjian *et al.* (2019) designed an automatic control system for the header height of a combine harvester. They established a relational model between the header height of the combine harvester and the sensor signals, and adopted the grey prediction PID algorithm to reduce the hysteresis of the header height control model. Good results were achieved in the field experiments (Ruan *et al.*, 2022).

CONCLUSIONS AND RECOMMENDATIONS

In summary, at present, researchers have made a lot of achievement in the research of combine harvester feed rate detection and stability control methods. However, the existing methods still have certain limitations, and there is still a considerable gap in the application of combine harvester design. The main problems are as follows:

(1) The current feed rate detection method is difficult to adapt to the complex environmental changes during the operation of the harvester, and the detection accuracy is not high. The mainstream detection method is to establish the relationship between the feed rate and the power consumption of the main working components such as the header and the threshing cylinder during the harvester operation. However, it is difficult to avoid the fluctuation of land and the change of crop density when the harvester is working, which can lead to insufficient stability of sensors, and noise interference from driveline torsional vibration, bending moment, and engine vibration can affect the signals collected by the sensors. The filtering method is difficult to completely eliminate noise and can only reduce noise to a certain extent.

(2) The stability of the control system is low, and research on the speed control algorithms remains limited. Currently, widely used fuzzy rules mainly depend on expert experience. Some improved methods are also based on fuzzy rule control, making it difficult to dynamically adjust weight factors and other relevant parameters for different situations. Additionally, combine harvesters exhibit significant time delays during operation, yet current research rarely considers factors such as actuator delays, resulting in control effects that fail to meet expected performance levels.

In response to the current issues, the future research on the feed rate detection and stability control of combine harvester is supposed to focus on the following aspects:

(1) Advanced sensing technology. In view of the limitations of current sensors, research is being conducted on more advanced and stable sensor technology to improve detection accuracy in complex environments and adapt to changes in land topography and crop density.

(2) Data fusion and analysis. Introducing big data technology to conduct more comprehensive and real-time analysis on data collected by sensors. Utilizing data fusion technology, combined with machine learning algorithms, to establish more accurate feed rate models.

(3) Advanced control algorithms. By studying more advanced speed control algorithms, including model predictive control, adaptive control etc., it is possible to better cope with complex environments and time-delay characteristics and improve the stability of the control system.

(4) Delay compensation technology. The control algorithm considering the delay of the harvester actuator is studied to adapt to the time delay of the harvester.

The future development of combine harvesters will move towards the application of intelligent technology, modular design, and autonomous driving technology. By utilizing advanced sensors, machine learning, and artificial intelligence technology, the harvester will be able to better adapt to different field condition, and modular design will enhance the flexibility of machine applications. It is necessary to accelerate research and innovation in the detection and stable control of the feed rate of combine harvesters to align with the development trend.

Keywords: pH Prediction, Water Quality Management, Water Monitoring System, Shrimp Farming

ABSTRACT

Water quality is a critical factor in shrimp farming, directly influencing the growth, reproduction, and survival of shrimp. pH is one of the key parameters that affect water quality, with deviations from the optimal range (5.5–8.5) leading to stress, weakened immune responses, and potential infections in shrimp. This research presents the development of an automated pH monitoring and forecasting system aimed at improving water quality management in shrimp farms. The system uses a moving average algorithm to predict future pH levels based on real-time data collected by a pH sensor. The predicted and real-time values are transmitted to a cloud database, and farmers receive alerts via the Line application if pH levels deviate from the acceptable range. The system's performance was evaluated through six experiments, using different data collection intervals and durations. The most accurate forecasting results were achieved with 10-minute data collection intervals over a 2-hour period, yielding a mean squared error (MSE) of 0.003050 and a root mean square error (RMSE) of 0.038628. The system also demonstrated its ability to send real-time alerts to the farmer, ensuring prompt corrective action in the event of critical pH values.

บทคัดย่อ

คุณภาพน้ำเป็นปัจจัยสำคัญในอุตสาหกรรมการเลี้ยงกุ้ง ซึ่งส่งผลโดยตรงต่อการเจริญเติบโต การสืบพันธุ์ และอัตราการรอดชีวิตของกุ้ง โดยค่า pH เป็นหนึ่งในตัวแปรสำคัญที่มีผลต่อคุณภาพน้ำ หากค่า pH เบี่ยงเบนจากช่วงที่เหมาะสม (5.5–8.5) จะทำให้กุ้งเกิดความเครียด ภูมิคุ้มกันอ่อนแอลง และเสี่ยงต่อการติดเชื้อ งานวิจัยนี้นำเสนอการพัฒนาระบบตรวจสอบและพยากรณ์ค่าความเป็นกรด-ด่าง (pH) แบบอัตโนมัติที่มีวัตถุประสงค์เพื่อปรับปรุงการจัดการคุณภาพน้ำในฟาร์มกุ้ง ระบบนี้ใช้เทคนิคการพยากรณ์แบบค่าเฉลี่ยเคลื่อนที่ (Moving Average Algorithm) เพื่อทำนายค่าความเป็นกรด-ด่างในอนาคต โดยอิงจากข้อมูลแบบเรียลไทม์ที่เก็บรวบรวมจากเซ็นเซอร์ตรวจวัดค่า pH ข้อมูลค่าที่ทำนายและค่าที่วัดได้ในปัจจุบันจะถูกส่งไปยังฐานข้อมูลบนคลาวด์ และเกษตรกรจะได้รับการแจ้งเตือนผ่านแอปพลิเคชัน Line หากค่าความเป็นกรด-ด่างเบี่ยงเบนออกจากช่วงที่เหมาะสม ประสิทธิภาพของระบบได้รับการประเมินผ่านการทดลอง 6 ครั้ง โดยใช้ช่วงเวลาและระยะเวลาการเก็บข้อมูลที่แตกต่างกัน ผลการพยากรณ์ที่แม่นยำที่สุดได้รับการเก็บข้อมูลทุก ๆ 10 นาทีเป็นระยะเวลา 2 ชั่วโมง ซึ่งให้ค่า MSE (Mean Squared Error) เท่ากับ 0.003050 และค่า RMSE (Root Mean Square Error) เท่ากับ 0.038628 นอกจากนี้ระบบยังแสดงความสามารถในการส่งการแจ้งเตือนแบบเรียลไทม์ไปยังเกษตรกร ทำให้สามารถดำเนินการแก้ไขได้อย่างทันท่วงทีเมื่อเกิดค่าความเป็นกรด-ด่างที่ผิดปกติ

INTRODUCTION

Shrimp farming is an important sector of Thailand's economy, providing significant income to cultivators. However, the success of shrimp farming is highly dependent on various environmental factors that affect shrimp growth, reproduction, and survival rates. Among these factors, water quality plays a critical role. Factors such as pH levels, oxygen concentration, and salinity directly influence the health and productivity of shrimp (Komarudin et al., 2021; Hsieh et al., 2021; Kim et al., 2024). Maintaining optimal water quality is essential to ensure the long-term sustainability of shrimp farming operations (Ariadi et al., 2020; de los Santos et al., 2020; Tarunamulia et al., 2024).

One of the most important indicators of water quality is the potential of hydrogen ions (pH), which measures the acidity or alkalinity of the water. The pH scale ranges from 0 to 14, with a value of 7 considered neutral. Water with pH levels below 7 is acidic, while levels above 7 indicate alkalinity (Gambin *et al.*, 2021). In shrimp farming, maintaining pH levels between 5.5 and 8.5 is essential to minimize stress, promote healthy growth, and prevent infections in shrimp (Yu *et al.*, 2020; Ariadi *et al.*, 2023). Extreme fluctuations in pH can lead to stress, poor growth, and susceptibility to diseases, impacting the overall productivity of shrimp farms (Supriatna *et al.*, 2023).

Fluctuations in water pH are primarily caused by natural processes such as photosynthesis and respiration in aquatic environments. During the day, photosynthesis by phytoplankton reduces carbon dioxide (CO₂) levels in the water, causing a decrease in acidity and a rise in pH. At night, the respiration of aquatic organisms increases CO₂ levels, resulting in higher acidity and a drop in pH (Qiao *et al.*, 2020). Such fluctuations can disrupt the balance of microorganisms and chemical parameters in the water, making pH monitoring essential for effective water management in shrimp farming (Durai *et al.*, 2021; Shirly-Lim *et al.*, 2024).

Given the importance of pH stability, predictive systems that can forecast pH levels in advance are valuable tools for shrimp farmers. By anticipating changes in pH, cultivators can implement timely interventions to maintain water quality and optimize shrimp production. Previous studies have successfully applied predictive models to monitor and forecast water quality parameters in aquaculture. For example, Mirsanjari and Mohammadyari (2018) used time series models to predict groundwater quality, while Monteiro and Costa (2018) evaluated statistical models to forecast dissolved oxygen concentrations in river water. Similarly, Thai-Nghe *et al.* (2020) developed an IoT-based system for real-time water quality monitoring and prediction using deep learning techniques.

Building upon this body of knowledge, the present study introduces a predictive model aimed at forecasting pH levels in shrimp farming systems. By utilizing historical pH data, this model seeks to anticipate fluctuations and alert shrimp farmers to potential deviations from optimal water quality conditions. The development of such a model is expected to contribute significantly to improving water management strategies in shrimp farming, ultimately enhancing shrimp health, growth rates, and overall farm productivity.

MATERIALS AND METHODS

This research was conducted in shrimp farm of Mr. Prasopchoke Somsua, a shrimp cultivator from Donka district, Bangpae province, Rachaburi city, Thailand. The experiments were performed during January to March 2024. The experimented farm consisted of 4,000 square meters with 120 population of shrimps per square meter. The method used in this research were as followed.

System Infrastructure Design

The system developed for this study consists of four key components that are an automatic water quality measurement system, a processing and reporting system, a cloud-based database, and an automatic notification system. Figure 1 illustrates the overall infrastructure of the pH forecasting system.

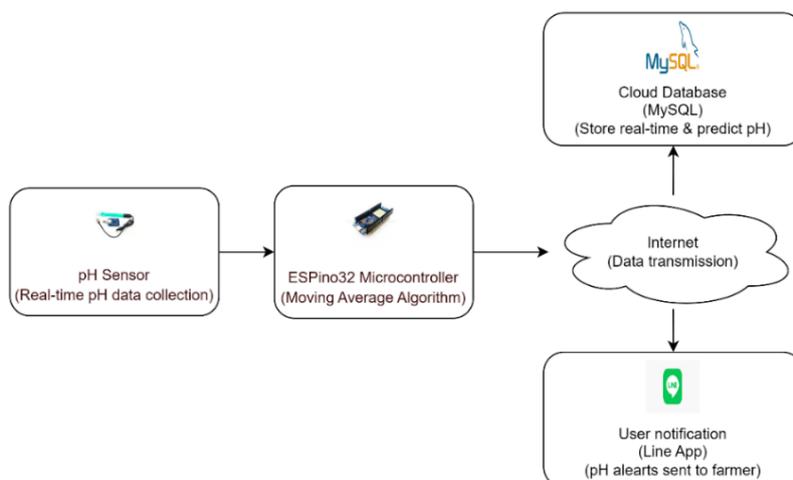

Fig. 1 - Infrastructure of the pH forecasting system for shrimp farms

- Automatic Water Quality Measurement System, a pH sensor was used to continuously monitor the water's pH level. This sensor was connected to an ESPino32 microcontroller, which collected real-time pH data.

- Processing and Reporting System, the collected pH values were processed using a moving average model to predict future pH levels. The predictions were then reported to the cloud database and the user's mobile device via the Line application.

- Cloud-Based Database, all collected and predicted pH data were stored in a MySQL cloud database for easy access and management. This cloud-based system allowed the data to be accessed remotely by the shrimp farmer at any time.

- Automatic Notification System, the system was configured to automatically notify the user via the Line application if the pH level deviated from the acceptable range (5.5–8.5). Both real-time pH values and predicted future pH values were sent to the farmer's device, allowing for immediate corrective actions if necessary.

pH Monitoring and Forecasting System

The pH monitoring and forecasting system operates in a sequential manner to ensure real-time data collection, analysis, and predictive capabilities. The process begins with the collection of pH values from the shrimp pond and continues through data processing, forecasting, and notification to the farmer. The system's workflow is outlined as follows.

1. Data Collection

The system initiates by collecting real-time pH values from the shrimp pond using a pH sensor. This data serves as the basis for both immediate evaluation and predictive modelling.

2. Data Processing

Once the pH value is collected, the system processes the data to assess its validity and determine whether further action is required. The collected pH data is first evaluated against a predefined range of acceptable values (5.5–8.5), which represents the optimal water conditions for shrimp growth and health.

3. Critical Value Detection, the system then checks if the collected pH value exceeds the acceptable thresholds.

3.1 If the pH value is either higher than 8.5 or lower than 5.5, the system identifies this as a critical value. In this case, an alert is triggered to notify the shrimp farmer via a mobile application (Line notification). This notification prompts immediate corrective action to prevent potential harm to the shrimp population.

3.2 If the pH value is within the acceptable range, the system proceeds to the next step, bypassing the alert stage.

4. pH Forecasting

For pH values that fall within the acceptable range, the system uses a moving average algorithm to predict future pH values. This forecasting process is essential for identifying potential trends that could lead to unfavorable water conditions if left unaddressed. The forecasting model uses historical pH data collected over time to generate accurate predictions of future pH fluctuations.

5. Current and Future pH Reporting: The system outputs both the current pH value and the forecasted future pH value. These values are then stored in a cloud-based database (MySQL) for further analysis and record-keeping. The availability of historical and predicted data allows for long-term monitoring and provides insights into water quality trends.

6. Database Integration

The pH data, both real-time and forecasted, is stored in the system's cloud database. This storage provides a centralized platform for accessing and analyzing pH data, enabling the farmer to review historical water quality data and respond proactively to changes in water conditions.

7. System Termination

The system completes the workflow after storing the pH data and either alerting the farmer or completing the forecasting process. The system continuously loops, allowing for ongoing real-time monitoring of water quality.

Experimental Setup

During the first quarter of 2024, the experiments were conducted in the shrimp farm at Donka district, Bangpae province, Rachaburi city, Thailand. The experiment was conducted under six different data collection configurations to evaluate the performance of the pH prediction model. The configurations were as follows:

1. pH data collection every 10 minutes for 2 hours
2. pH data collection every 10 minutes for 4 hours
3. pH data collection every 10 minutes for 6 hours
4. pH data collection every 30 minutes for 2 hours
5. pH data collection every 30 minutes for 4 hours
6. pH data collection every 30 minutes for 6 hours

For each configuration, the collected pH data was used to generate predictions using the moving average model. The accuracy of the predictions was evaluated using the mean squared error (MSE) and root mean square error (RMSE) metrics. These metrics provided an objective measure of the model's predictive performance, with lower MSE and RMSE values indicating higher accuracy.

Accuracy Evaluation

Time series forecasting is a technique which solely depends on past collected data to predict future value of the collected data. It is based on the assumption that the future data can be predicted through the existing data. This research is conducted relied on moving average (MA) which is one of the three average value forecasting techniques, including, Naïve approach, constant model, and moving average. The MA equation is as shown in equation (1) (Ivanovski *et al.*, 2018; Amali *et al.*, 2022; Huriati *et al.*, 2022).

$$MA = \frac{\sum(actual)}{n} \quad (1)$$

In this research, the accuracy of the predicted result is measured through mean squared error (MSE) and root mean square error (RMSE). The best result is selected from the predicted value with the lowest MSE and RMSE out of six calculation schemes. The selected result is considered the most accurate prediction since it has the least different value from the real data. The equations of MSE and RMSE are as shown in equations (2) and (3), respectively (Hu *et al.*, 2019; Eze *et al.*, 2021; Ardiansah *et al.*, 2021; Ensafi *et al.*, 2022).

$$MSE = \frac{\sum(actual-forecast)^2}{n} \quad (2)$$

$$RMSE = \sqrt{\frac{\sum(actual-forecast)^2}{n}} \quad (3)$$

RESULTS

The developed pH monitoring and forecasting system was tested in a shrimp farm to evaluate its performance in predicting water quality and ensuring real-time alerts in cases of critical pH values. The system collected pH data at regular intervals, processed the data, and generated both real-time and forecasted pH values, which were subsequently compared to the observed values.

Hardware Design

The hardware component, as shown in Figure 2, including the pH sensor (number 2) combined with a probe head (number 3) and the ESPino32 microcontroller (number 1), functioned reliably throughout the experimental period. Data collection was performed at 10-minute intervals over a 2-hour period, and the sensor demonstrated consistent accuracy in capturing real-time pH levels. The data was transmitted to the cloud database without notable communication delays or data loss, ensuring smooth operation across all components.

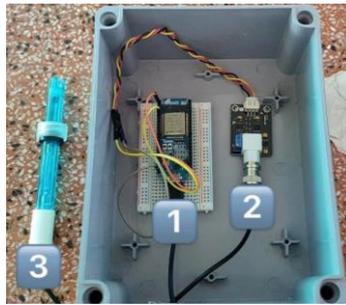

Fig. 2 - Hardware design of the pH forecasting

Prediction Accuracy

To assess the accuracy of the pH forecasting model, six experiments were conducted with varying data collection intervals and durations, ranging from 10-minute to 30-minute intervals, and covering periods of 2, 4, and 6 hours. For each experiment, the system generated both current and forecasted pH values. The accuracy of the forecasts was evaluated based on the mean squared error (MSE) and root mean square error (RMSE) metrics.

The experiment that collected pH data every 10 minutes over a 2-hour period produced the most accurate predictions, with an MSE of 0.003050 and an RMSE of 0.038628 (Figure 3a). In contrast, the experiment with 30-minute intervals over a 6-hour period yielded higher error values, with an MSE of 0.003307 and an RMSE of 0.042485 (Figure 3f). Table 1 presents the results of the forecasting accuracy for each experimental setup.

Fig. 3 - The results of six experiments for the pH forecasting

Real-Time pH Monitoring

During the experiment, the system continuously monitored the real-time pH values in the shrimp pond. Whenever the pH value deviated from the acceptable range (5.5–8.5), the system immediately triggered an alert. As shown in Figure 4, the system successfully notified the farmer via the Line application whenever the pH level fell below or exceeded the threshold, allowing the farmer to take prompt corrective actions. This immediate response helped maintain optimal water quality and minimized potential stress on the shrimp.

Fig. 4 - The result of system notification whenever the pH level fell below or exceeded the threshold

Predictive pH Analysis

The predictive analysis component of the system proved effective in forecasting pH values during the first quarter of 2024. The experiment as shown in Figure 5 was conducted, the shrimp pond was 4,000 square meters with 120 density of shrimps per square meter. The pH values were collected every 10 minutes within 2 hours for further prediction calculation. The monthly average collected pH, predicted pH, MSE and RMSE are as shown in Table 1.

The average deviation between the forecasted and actual pH values remained low across all months, with the lowest MSE (0.000225) observed in March 2024, demonstrating the robustness of the moving average algorithm in predicting pH fluctuations.

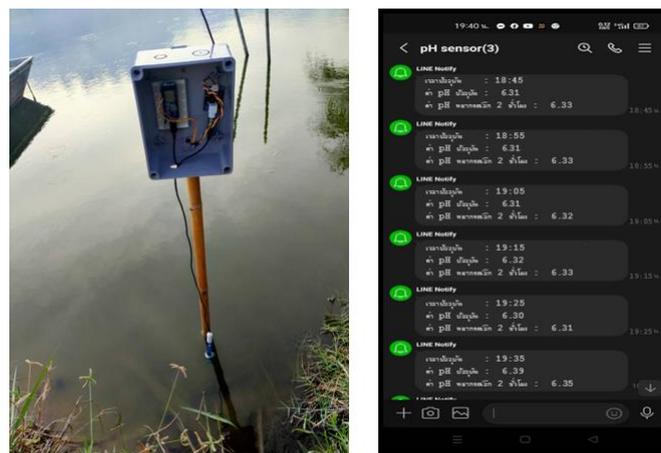

Fig. 5 - The experiment and the notification of current pH and predicted pH

Table 1

Results in actual pH, forecast pH, MSE and RMSE during the first quarter of 2024

Month	Actual average pH value	Forecast average pH value	MSE	RMSE
January 2024	7.85	7.83	0.000434	0.020833
February 2024	7.83	7.83	0.000711	0.026667
March 2024	7.83	7.83	0.000225	0.015000

Notifications and Data Storage

The system's notification functionality performed as expected, sending timely alerts to the farmer when critical pH levels were detected. Both real-time and forecasted pH values were successfully stored in the cloud-based MySQL database, ensuring that the data could be accessed at any time for further analysis or reporting purposes. The database provided a comprehensive record of water quality data, including historical trends and predictive insights, facilitating long-term water quality management.

Overall, the pH monitoring and forecasting system demonstrated a high level of accuracy and reliability in both real-time monitoring and predictive analysis. The system effectively maintained water quality within the acceptable range, reduced the risk of pH-related stress on the shrimp population, and provided the farmer with timely notifications of potential issues. These results suggest that the system is a valuable tool for improving the management of water quality in shrimp farming environments.

CONCLUSIONS

This research presents the development and evaluation of an automated pH monitoring and forecasting system for shrimp farming, designed to enhance water quality management. The system integrates real-time pH data collection, predictive analysis using a moving average algorithm, and automated notifications to alert shrimp farmers when critical pH values are detected.

The experimental results demonstrate that the system performs reliably in both monitoring and forecasting pH levels. The hardware components, including the pH sensor and ESPino32 microcontroller, consistently captured and transmitted pH data, ensuring stable system operation. Moreover, the cloud-based storage of real-time and forecasted data facilitates easy access to historical and predictive water quality data for future reference. The pH forecasting model, evaluated through multiple experiments, exhibited high accuracy in predicting future pH values. The experiment utilizing 10-minute intervals over a 2-hour period produced the lowest MSE and RMSE, indicating the effectiveness of the model in short-term pH forecasting. These predictions provided shrimp farmers with valuable insights into potential future fluctuations in water quality, allowing for timely interventions to prevent adverse conditions.

In addition, the system's automated notification feature performed as expected, sending immediate alerts to the farmer via the Line application whenever the pH values fell outside the acceptable range (5.5–8.5). This real-time feedback ensured that the farmer could promptly respond to changes in water quality, reducing the risk of pH-related stress on the shrimp population and improving overall farm productivity.

While the system has demonstrated effectiveness in monitoring and predicting pH levels, future enhancements could include the integration of additional water quality parameters, such as dissolved oxygen (DO) and salinity. This would provide a more comprehensive tool for managing water conditions in shrimp farming. Moreover, the use of advanced predictive algorithms, including machine learning techniques, may further improve the accuracy of the forecasts, particularly over longer time periods.

ACKNOWLEDGEMENT

This research was made possible with the research budget support from the Research and Development Institute of Nakhon Pathom Rajabhat University, and Creating Innovation for Sustainable Development Research Center, Nakhon Pathom Rajabhat University, Nakhon Pathom, Thailand, which supported laboratories, equipment and tools used for research. Finally, we would like to express our deepest appreciation to Mr. Prasopchoke Somsua, a shrimp cultivator from Donka district, Bangpae province, Rachaburi city, Thailand, for providing experimenting location for this research.

Keywords: vibration characteristics; chassis; static analysis; vibration velocity

ABSTRACT

To investigate the vibration characteristics of the Thinker Agricultural Machinery 4LZ-2.0 crawler-type combine harvester under operational conditions, vibration tests were conducted on the chassis frame at three different engine speeds: 2700 r/min, 1500 r/min, and 800 r/min. A static analysis was initially performed to identify regions of significant stress and deformation on the chassis frame, which guided the placement of measurement points for collecting vibration acceleration data. Subsequent processing of the acceleration data in the frequency domain revealed the variation in vibration velocity at each measurement point on the chassis frame. It was found that as the engine speed increased, the excitation frequencies from the vibrating screen and cutting platform appeared as dominant resonance frequencies at nine out of twelve measurement points on the chassis frame. By referencing the international standard ISO 20816, it was determined that most of these measurement points fell into Class D, indicating a high level of vibration severity. To mitigate the vibration of the chassis frame, two measures were implemented: enhancing the structural rigidity of the frame and reducing the area of the center of mass trajectory of the vibrating screen. Following these modifications, re-testing showed that the average vibration intensity at the three maximum vibration measurement points of the chassis in the high engine speed condition successfully decreased by 34.57% compared to the original structure.

摘要

为了解收割机运行状态下底盘机架振动特性，以星光农机 4LZ-2.0 型履带式联合收割机为研究对象，在发动机处于 2700r/min, 1500r/min, 850r/min 三种不同转速下对其底盘机架进行振动测试。首先通过静力分析找到底盘机架应力与变形较大的区域，并以此在其表面布置测点，采集振动加速度数据。通过在频域内对加速度数据进行处理得到底盘机架各测点振动速度变化情况。发现随发动机转速提升，振动筛与割台的激励频率在收割机底盘机架 12 个测点中 9 个测点作为主振频率出现。结合国际标准 ISO 20816，发现这些测点大多处于振动等级最大的 D 级，振动强度过大。为减小收割机底盘机架振动，采取增强机架结构、减小振动筛质心运动轨迹面积两种措施。经重新测试，发动机高转速状态下底盘 3 个振动最大测点各方向平均振动强度较原结构成功降低 34.57%。

INTRODUCTION

The chassis is the primary load-bearing component of a tracked combine harvester, subject to complex external excitations. Variations in the working environment and the machine's operational state can significantly affect its vibration characteristics, leading to considerable discrepancies in vibrational responses. Excessive vibrations not only impact the comfort of the operator (Biriş et al., 2022; Viăduț et al., 2023; Dimitriadis et al., 2023; Marin et al., 2024) but also increase the risk of fatigue failure at structurally weak points, thereby posing a serious threat to the overall reliability of the machine (Zhou et al., 2023; Noh et al., 2024). Consequently, it is crucial to investigate the vibrational characteristics of the combine harvester chassis.

Currently, research on the vibrations of harvesters, both domestically and internationally, primarily focuses on the cutting platform, chassis, and operator comfort (Ma et al., 2020; Jiang et al., 2017; Sun et al., 2014; Xie et al., 2019). Various methodologies, including dynamic simulation and analysis, experimental modal analysis, and test rig design, have been employed to obtain the vibrational characteristics of these

components. Wang *et al.* (2021) designed an intelligent control test bench for combine harvesters, which is capable of regulating the forward speed of the combine harvester based on data processing results. Additionally, the system can classify and handle faults, as well as transmit and print stored data via serial communication. This design not only enhances the intelligence level of combine harvesters but also provides reliable technical support for fault diagnosis and performance optimization. By integrating data processing and automatic control functions, the test bench serves as a significant experimental platform and research foundation for the intelligent development of agricultural machinery. Comparing the results of the different methods for vibration and sound datasets, Karagiovanidis *et al.* (2023) found that classification accuracy showed that in the case of vibration, the detection of cavitation in real conditions is possible. Rabbani *et al.* (2011) constructed a dynamic three-dimensional model for a half-track tractor, incorporating its bounce, pitch, and roll motions, to elucidate the tractor's vibration characteristics. Driving experiments were conducted to validate the effectiveness of the motion equations derived from the proposed dynamic model. Pang *et al.* (2019) measured and analyzed the time-domain and frequency-domain characteristics of the cutting platform's vibrational response, designing a rubber-sleeved nut that successfully reduced the vibrations transmitted to the operator's seat. Chen *et al.* (2020) assembled the combine harvester's chassis and threshing frame into a complete structure, deriving its vibrational response under multi-source excitations to provide a reference for further improvements to the chassis. Tang *et al.* (2021) conducted finite element modal analysis and vibration testing on the threshing cylinder and frame, designing support beams based on test results to mitigate vibrations generated during the threshing process.

In summary, the vibration characteristics of agricultural machinery systems have garnered considerable attention from numerous scholars (Yao *et al.*, 2017; Li *et al.*, 2023; Ding *et al.*, 2022; Zhang *et al.*, 2023). However, analyses regarding the impact of the engine, vibrating screen, and cutting mechanism on the chassis of tracked combine harvesters during operational conditions remain limited. This study primarily employs digital signal processing, complemented by finite element analysis and multi-body dynamic simulation, to explore this issue further.

MATERIAL AND METHODS

SOURCES OF CHASSIS FRAME VIBRATION AND INTRODUCTION TO CHASSIS STRUCTURE

The study focuses on the 4LZ-2.0 tracked combine harvester produced by Xingguang Agricultural Machinery, with its chassis frame primarily subjected to excitations from the engine, cutting platform, threshing drum, vibrating screen, and screw conveyor (Zhang *et al.*, 2021; Gao *et al.*, 2017; Zhang *et al.*, 2001). The spatial distribution of these components is illustrated in Figure 1.

Research on the excitatory conditions affecting the chassis is based on its structural design, as depicted in Figure 2. The chassis measures 2.75 m in length, 1.87 m in width, and 0.6 m in height. Constructed from carbon structural steel, the components are connected via welding. The orange section represents the chassis frame, with a steel pipe cross-section parameter of 40 x 60 x 3 mm. This frame directly connects to the engine, elevator, threshing drum, vibrating screen assembly, cutting platform, and the hydraulic support rods for the conveyor trough, while being anchored to two longitudinal beams (blue structure) that play a major load-bearing role.

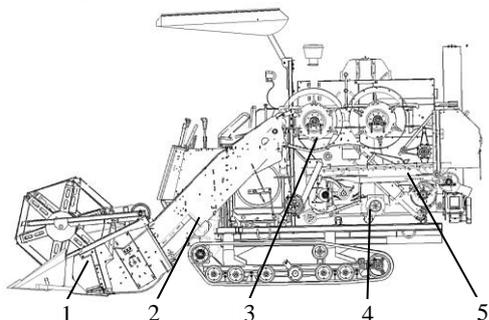

Fig. 1 - Sources of excitation for the chassis frame
1. Cutter bar; 2. Conveying trough; 3. Threshing drum;
4. Auger; 5. Vibrating screen

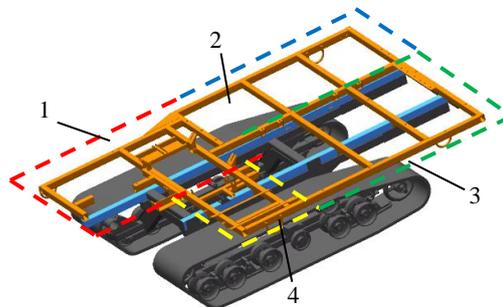

Fig. 2 - The chassis structure of the 4LZ-2.0 crawler-type combine harvester
1. Engine and cab area; 2. Grain bin area; 3. Threshing drum and vibrating screen area; 4. Cutter bar and conveying trough area

The longitudinal beams utilize steel pipes with a cross-section parameter of 50 × 70 × 3 mm, welded and fixed in place by two transverse beams with a cross-section parameter of 70 × 70 × 3 mm. These transverse beams are strategically located beneath the chassis frame at the front and middle sections, with each transverse beam linked to a truss structure. The loads borne by the chassis frame are transmitted through the truss to the track bearing wheel assembly, ultimately transferring the forces to the ground.

The structural simplification of the chassis model for the 4LZ-2.0 tracked combine harvester involves removing through-holes with diameters less than 10 mm and fillets with radii less than 5 mm, which have minimal impact on structural strength. Small flat surfaces are merged before importing the model into the finite element analysis software Ansys for static analysis. To enhance computational efficiency, the track components are excluded, and the track bearing wheel assembly is fixed as a boundary condition.

The connection methods between structures utilize the software's default settings, with structural steel selected as the material. The element size is set to 10 mm, resulting in a total of 1111691 nodes and 387396 elements. Based on manufacturer-provided parameters, the total mass of the machine is 2870 kg, with the chassis mass being 1318 kg. A vertical load of 15520 N is applied downward on the chassis frame's upper plane to simulate its stress condition in a static state, allowing for the calculation of total deformation and equivalent stress, as shown in Figure 3.

The static analysis results indicate that the chassis frame experiences the maximum deformation in the regions of the vibrating screen and threshing drum, which are farthest from the truss support. The grain tank area exhibits the next highest deformation. Stress and strain concentrations are most significant near the support points, highlighting these areas as relatively weak points in the overall frame that warrant close attention.

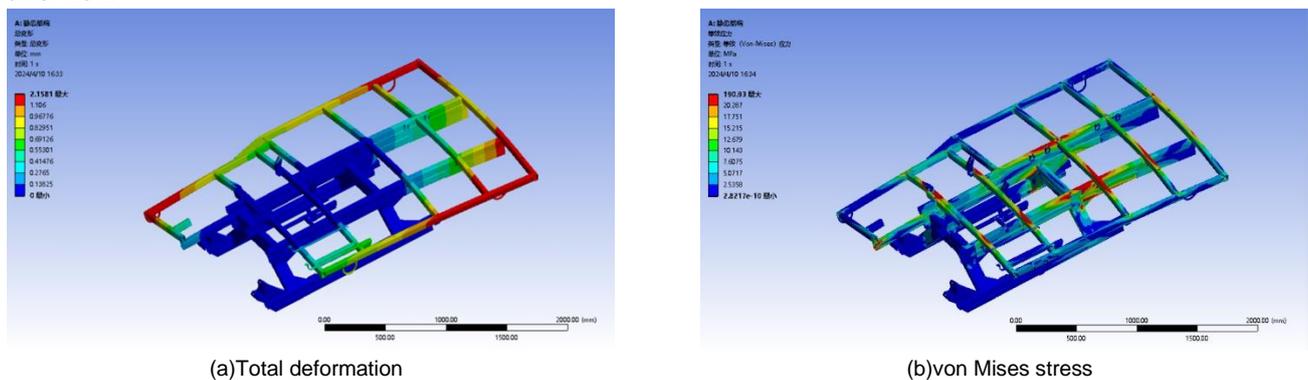

Fig. 3 - The static analysis results of the chassis

TESTING OF CHASSIS VIBRATION CHARACTERISTICS

The current international standard ISO 20816 provides guidelines for evaluating mechanical vibrations on non-rotating components based on the root mean square (RMS) vibration velocity. Vibrational intensity is categorized into four levels—A, B, C, and D—ranging from low to high. Given the differing operational characteristics of various types of machinery, the boundaries for each level are presented as fuzzy intervals, allowing users to make determinations based on their specific contexts. The boundary intervals are detailed in Table 1. In this study, each vibration level is defined by its maximum value as the boundary. Due to the large size of vibration velocity sensors, which makes them impractical for installation on the harvester chassis, vibration data is collected using acceleration sensors. This data is subsequently integrated to obtain the vibration velocity.

Vibration testing of the entire machine and the chassis frame was conducted using the Donghua Testing DH5902 data acquisition and analysis system, along with a portable computer and 12 tri-axial piezoelectric accelerometers (1A314E). This accelerometer captures acceleration amplitudes in the mutually orthogonal x, y, and z directions, with a measurement range of 500 m·s⁻² and a frequency acquisition range of 0.5 to 7000 Hz, set at a sampling frequency of 1000 Hz.

In conjunction with the static analysis results, 12 measurement points were selected on the chassis frame, evenly distributed across areas of significant deformation or stress, as shown in Figure 4. Measurement points 1, 2, 8, and 10 are located in the regions of the vibrating screen and threshing drum, points 3, 4, 5, and 11 in the grain tank area, points 6 and 12 near the engine, and points 7 and 9 in the cutting platform and conveyor trough areas.

Table 1

Boundary Intervals of Vibration Levels		
AB Boundary / mm•s ⁻¹	BC Boundary / mm•s ⁻¹	CD Boundary / mm•s ⁻¹
0.71-4.5	1.8-9.3	4.5-14.7

Table 2
The Vibration Frequencies of the Main Excitation Sources of the Harvester at Different Engine Speeds

Excitation source	Main excitation frequency /Hz		
	Low speed	Medium speed	High speed
Engine	28.33	50.00	90.00
Cutter drive shaft	2.83	5.00	9.00
Vibrating screen	2.37	4.17	7.50
Threshing drum	7.08	12.50	22.50
Screw conveyor	1.01	1.79	3.21

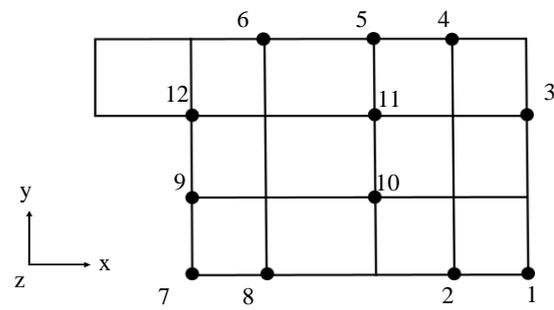

Fig. 4 - Distribution of measurement points

The vibration acceleration information in the x, y, and z directions was collected at various engine speeds: low (850 r/min), medium (1500 r/min), and high (2700 r/min). The time-domain information was analyzed, and the primary excitation frequencies associated with each source at different engine speeds are summarized in Table 2. The main excitation frequency of the engine is primarily determined by its second-order ignition frequency (Wu, et al., 2020; Hu, et al., 2015), The main vibration frequency f is calculated using the formula:

$$f = \frac{n}{60} \times \frac{c}{2} \tag{1}$$

where: n is the engine speed in revolutions per minute (r/min),

- c is the number of cylinders in the engine.

This formula provides the primary excitation frequency related to the engine's operational characteristics.

RESULTS

Calculation of Vibration Velocity at Each Measurement Point

To obtain the vibration velocity at each measurement point on the combine harvester chassis, the collected vibration acceleration data must be integrated. However, the velocity data obtained from direct time-domain integration is significantly affected by factors such as zero drift of the accelerometer and disturbances from other low-frequency signals, leading to noticeable trends in the results, as illustrated in Figure 6.

To eliminate these influences, it is necessary to fit the integration results and remove the trend components. However, fitting each group of signal data during large-scale signal processing can consume significant computational resources. Additionally, filtering out low-frequency components from the signal can also achieve a similar effect to detrending after integration (Wei, et al., 2018) Therefore, this study processes the data in the frequency domain to obtain velocity information while analyzing the primary sources of vibration at each measurement point.

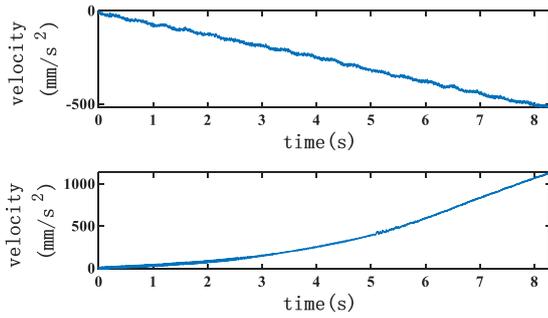

Fig. 6 - Velocity variation chart obtained by integrating untreated time-domain data from some measurement points

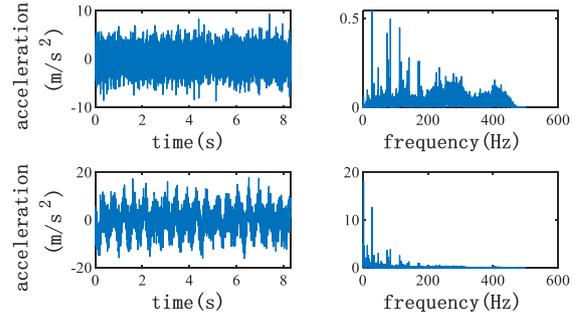

Fig. 7 - Time-domain and frequency-domain feature plot for measurement point 1

The Fast Fourier Transform (FFT) is used to convert the time-domain discrete signals collected by the accelerometers into the frequency domain. FFT is a computationally efficient method that simplifies the Discrete Fourier Transform (DFT) for faster calculations. While they are fundamentally equivalent, both methods perform the transformation of the time-domain signal as described in the following equation:

$$X(k) = \sum_{n=0}^{N-1} x(n)e^{-j\frac{2\pi}{N}kn} \quad (k=0,1,2\dots N-1) \quad (2)$$

In the context of FFT or DFT transformation, the symbols can be defined as follows:

- $X(k)$: Represents the frequency-domain signal in its complex form after FFT or DFT transformation.
- $x(n)$: Represents the discrete time-domain signal.
- $e^{-j\frac{2\pi}{N}kn}$: Describes the unit circle in the frequency domain, as defined by Euler's formula.
- k : Represents the frequency-domain signal sequence.
- N : Represents the total number of data points in the time-domain signal.
- j : Represents the imaginary unit.

The relationship between the time-domain integral of a digital signal and its corresponding representation in the frequency domain can be expressed by the following equation:

$$\mathcal{F} \left[\int_{-\infty}^t f(\tau) d\tau \right] = \frac{F(\omega)}{j\omega} + \pi F(0)\delta(\omega) \quad (3)$$

In the equation provided, the following symbols represent specific concepts:

- \mathcal{F} : Represents the Fourier transform.
- $\int_{-\infty}^t f(\tau) d\tau$: Indicates the time-domain integration of the digital signal.
- $F(\omega)$: Represents the frequency-domain value of the digital signal.
- $F(0)$: Represents the DC component.
- $\delta(\omega)$: Denotes the unit impulse function, an idealized narrow pulse with an area equal to 1.
- t : Represents the maximum time point of the selected time interval.
- ω : Represents the frequency-domain variable.

For the discrete data collected during the experiment, $F(\omega) = X(k)$ and $j\omega = jk$.

In general, the DC component is the primary factor causing trends in integration results; therefore, $F(0)$ is set to 0. To obtain the time-domain integral of the digital signal, it is sufficient to divide its frequency-domain data by $j\omega$ and then perform the inverse Fourier transform (IFT).

The process involves using the Fast Fourier Transform (FFT) to convert the acceleration signals from each measurement point into frequency-domain form. After processing the data in the frequency domain, the velocity is obtained through the inverse Fourier transform.

For example, the time-frequency characteristics of the acceleration and velocity at measurement point 1 are illustrated in Figure 7, demonstrating how the transformation and processing effectively capture the vibrational behavior of the chassis.

Analysis of Vibration Velocity at Measurement Points

After performing frequency domain integration on the vibration acceleration data collected from various measurement points of the engine under low-speed conditions, it was found that the vibration velocity does not exhibit a periodic variation exceeding 2 seconds in the time domain. To improve computational efficiency while ensuring the completeness of frequency domain information, acceleration data collected over 2 seconds at mid to high engine speeds, characterized by shorter periods, were selected for processing. It is assumed that this data contains velocity and acceleration information encompassing more than one cycle, thereby excluding frequency domain data below 0.5 Hz. The frequency characteristics of the first three modes of vibration velocity in different directions at various engine speeds (high, medium, and low) for all measurement points are presented in Table 3.

Due to the resolution limitations of frequency domain data and the fact that the engine speed remains at a specific value near the preset rotation speed, the experimentally measured vibration frequencies of excitation sources exhibit minor deviations from their theoretical values. As indicated in Tables 1 and 3, under low-speed conditions, the vibrations at measurement points on the chassis frame are influenced comparably by excitations from engine cylinder ignition, cutter drive shaft, and vibrating sieve, with their respective frequencies contributing comparably to the observed vibration spectra. However, at medium and high rotation speeds, except for measurement points 5 and 6 near the engine - which predominantly exhibit a dominant vibration frequency of 91.8 Hz in the z-direction (closely matching the engine excitation frequency) - other measurement points primarily demonstrate vibration frequencies adjacent to those generated by the vibrating sieve and cutter drive shaft. This characteristic is particularly pronounced in the x- and y-directions. These findings suggest that the reciprocating motions of the header and vibrating sieve progressively surpass engine-induced excitations as rotation speed increases, ultimately emerging as the predominant excitation sources affecting the chassis frame. This phenomenon highlights the speed-dependent evolution of excitation dominance in harvester dynamic responses.

Table 3

Frequencies of the First Three Orders of Vibration Velocity									
Measurement Points	Fundamental Frequency/Hz (Velocity /m•s ⁻¹)								
	Low Speed			Medium Speed			High Speed		
	x	y	z	x	y	z	x	y	z
Measurement Points 1	28.32 (18.1)	28.81 (3.7)	28.32 (18.2)	4.88 (77.9)	4.88 (41.2)	3.91 (63.8)	7.32 (150.0)	8.79 (75.5)	7.32 (80.5)

Measurement Points 12	2.44 (13.6)	28.32 (2.6)	1.46 (7.8)	4.88 (20.9)	4.88 (21.9)	3.91 (19.7)	8.30 (97.7)	7.32 (46.3)	7.32 (42.3)

At medium and high speeds, the reciprocating motion of the cutting platform and vibrating screen increasingly affects the chassis frame as the speed rises. Only measurement points 5 and 6, close to the engine, exhibit a principal vibration frequency of 91.8 Hz in the z-direction at high speeds, closely aligning with the engine excitation frequency. Consequently, in 30 out of the 36 data sets from the 12 measurement points, the primary vibration frequencies align more closely with the excitation frequencies from the vibrating screen and cutting platform, indicating a shift in the primary excitation source from the engine to these components. Since the cutting platform and vibrating screen are located on the left side between the chassis frames, their reciprocating motions generate inertial forces that also apply torsional moments to the chassis frame. This could explain why measurement points in the x and y directions are significantly influenced by the cutting platform and vibrating screen.

The root mean square (RMS) values of the vibration velocities for each measurement point were calculated and are presented in Figure 8. Overall, at low engine speeds, the vibration velocities in the x, y, and z directions at most measurement points are close to the boundaries of vibration levels A and B. At medium speeds, the vibration intensities at most points do not significantly change from low speeds; however, measurement points 1, 2, and 3—located at the rear of the chassis frame and far from the support structure—exhibit significantly higher vibration intensities across all three testing directions, reaching vibration levels C and D.

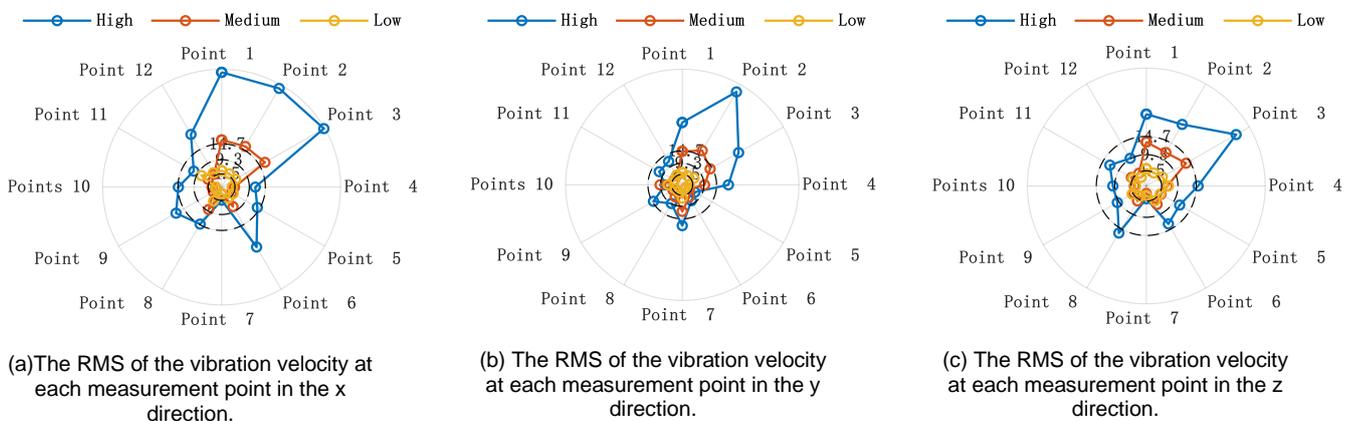

Fig. 8 - The vibration status of each measurement point

At high speeds, the vibration levels at all measurement points increase noticeably. Points that already displayed higher vibrations at medium engine speeds exhibit even greater intensities at high speeds. This suggests that, at medium engine speeds, the structural strength of the chassis frame, particularly away from the support locations, is beginning to fail under the demands of excitation from the vibrating screen and cutting platform, and this phenomenon becomes more pronounced at high engine speeds.

STRUCTURAL OPTIMIZATION OF THE COMBINE HARVESTER

To reduce the vibrations in the chassis frame of the combine harvester, improvements are made from two aspects: enhancing the structural strength of the frame and reducing excitation. First, structural reinforcements are applied to the regions at the rear of the chassis frame, specifically near measurement points 1, 2, and 3, which are far from the support points, as illustrated in Figure 9.

To decrease the excitation experienced by the chassis frame, vibration-damping pads are added at the connections between the cutting platform's hydraulic cylinders and the vibrating screen's drive shaft bearings. Additionally, given the inherent characteristics of the vibrating screen, achieving complete balance while ensuring the proper operation of other components is unrealistic. Instead, measures can be taken to reduce the area of the overall center of mass movement trajectory of the vibrating screen, thereby lowering its excitation on the chassis frame (Wang *et al.*, 2012; Zhang *et al.*, 2012; Li *et al.*, 2016).

Considering the principles of dynamic balance and the structural features of the vibrating screen and its nearby components, the decision was made to modify the center of mass of the vibrating screen's drive pulley and add eight cast iron counterweights, as depicted in Figure 10. A three-dimensional model of the vibrating screen was created, and simulations of its motion characteristics were conducted using Adams software to calculate the trajectory of the vibrating screen system's center of mass. The changes in the center of mass before and after implementing the dynamic balance design are shown in Figure 11.

After adding the counterweights, the area of the center of mass movement trajectory for the vibrating screen system was reduced, and it also moved closer to the coordinates of the drive shaft center (-1000, 0). Theoretically, this adjustment successfully weakens the inertial forces caused by the movement of the vibrating screen's center of mass.

Following these structural modifications, the vibration testing of the chassis frame was conducted again using the previously described methods. The results indicated that the vibration intensities at various measurement points were reduced to varying degrees. For example, at the more vibrationally intense measurement points 1, 2, and 3, the changes in vibration intensity at different engine speeds are summarized in Table 4.

At low engine speeds, the excitation experienced by the chassis frame is relatively low, resulting in minimal changes in vibration intensity compared to the mid and high-speed conditions. As the engine speed increases, the excitation on the chassis frame rises continuously, highlighting the advantages of the optimized structure. At high engine speeds, the average vibration intensity at the three measurement points decreased by 34.57% in different directions. Notably, the vibration velocity at measurement point 3 in the x-direction decreased from 42.67 mm·s⁻² to 11.51 mm·s⁻², shifting the vibration level from D to C, indicating a significant reduction in vibration intensity.

(a) Enhancement of horizontal structural integrity.

(b) Enhancement of vertical structural integrity.

	after modification	3.15	5.09	5.03	5.15	6.36	11.90	11.51	13.49	18.77

CONCLUSIONS

Static Analysis: Finite element analysis of the combine harvester's chassis frame revealed that the areas farthest from the support structure, particularly around the vibrating screen and threshing cylinder, experienced the greatest deformation. The maximum stress and strain were located near the support points, indicating these are relatively weak regions of the frame.

Vibration Velocity Measurement: Frequency-domain processing of the measured vibration acceleration data successfully provided the vibration velocities at various measurement points. According to the international standard ISO 20816, the original vibration levels of all points in the chassis frame were classified as the highest D level under high engine speeds.

Influence of Components: An analysis of the principal vibration frequencies at different engine speeds revealed that the impact of the vibrating screen and cutting platform on the chassis frame increased with engine speed. At high speeds, 30 out of 36 sets of data showed principal frequencies closely aligned with the excitation frequencies of the vibrating screen and cutting platform drive shafts.

Mitigation Measures: To reduce vibration intensity at various measurement points, enhancements to the chassis structure were implemented, vibration-damping pads were added at the connections between the excitation sources and the chassis, and the area of the vibrating screen's center of mass movement trajectory was minimized. Testing indicated an average vibration intensity reduction of 34.57% at the three previously most affected measurement points under high engine speeds.

Although the structural enhancements have successfully diminished the vibration intensity, the levels remain relatively high. Further research is necessary to analyze the effects of other factors, such as the center of mass of the combine harvester and support points on the chassis frame vibrations.

ABSTRACT

Despite the abundance of agricultural straw as a renewable resource, its low utilization efficiency remains a significant challenge due to inadequate mechanical processing methods. To solve the problem, the ANSYS finite element simulation software was employed to simulate and analyze two screw configurations (parallel and staggered arrangement) and four compression zone designs. The optimal coupling breaking method was determined to be the parallel type with a 2-2-2 compression zone combination for the twin-screw system. Based on the simulation results, a twin-screw straw pulping machine was constructed. The test factors included screw speed, thread pitch, and straw moisture content, with straw breaking rate as the test index. Simulation test was conducted to optimize the structural parameters of the twin-screw straw pulping machine, followed by a verification test. The results indicated that at a screw speed of 120 r/min, a thread pitch of 203 mm, and a straw moisture content of 60%, the straw breaking rate was the highest at 79.9%. The verification test results were consistent with the simulation results, with less than 5% deviation, confirming the reliability of the simulation model and optimization outcomes. This paper provides a basis for the design and optimization of twin-screw pulping machines and offers theoretical support for the high-value utilization of agricultural waste through enhanced mechanical processing technologies.

摘要

尽管农业秸秆作为一种可再生资源非常丰富，但由于机械加工方法不足，其利用效率低下仍然是一个重大挑战。为了解决这个问题，采用 ANSYS 有限元仿真软件，对并列型与错列型 2 种螺杆配置和 4 种压缩区设计进行模拟分析，确定最佳耦合碾压破碎方式为并列型 2-2-2 压缩区组合的双螺杆，根据仿真结果试制稻秆双螺杆制浆机。以螺杆转速、螺纹间距和稻秆含水率为试验因素，以秸秆破碎率为试验指标，通过仿真试验对稻秆双螺杆制浆机进行结构参数优化，并进行验证试验。试验表明：螺杆转速为 120r/min，螺纹间距为 203mm，秸秆含水率为 60%时，秸秆破碎率最高为 79.9%；验证试验结果与仿真结果具有一致性，误差小于 5%，仿真模型和优化结果具有可靠性。本文为双螺杆制浆机的设计和优化提供了依据，为通过强化机械加工技术实现农业废弃物的高值化利用提供了理论支持。

INTRODUCTION

China has an abundant production of straw, and the raw materialization of straw is an important direction for its high-value utilization. However, the utilization rate of raw materialization is only 2.1%, which is one of the main factors constraining the improvement of the comprehensive utilization rate of straw (Hirani et al., 2018). Currently, straw pulping is one of the emerging methods for straw raw material utilization (Subramaniyan et al., 2022). The annual production of rice straw exceeds 200 million tons, accounting for about 22.74% of the total agricultural straw production, and the production is only less than that of corn straw (Gong et al., 2019). Therefore, the study of rice straw pulping is of great significance for improving the comprehensive utilization rate of straw, promoting sustainable agricultural development, alleviating the current shortage of pulp, and reducing the dependence on foreign trade in pulp.

Cheng Huiting, Ph.D. Stud. Eng.; Zhao Nan, MS. Stud. Eng.; REN Dezhi, Lec. Ph.D. Eng.; Wang Wei, Prof. Ph.D. Eng.; Gong Yuanjuan, Prof. Ph.D. Eng.; Huang Wanyuan, Lec. Ph.D. Eng.

Chemical pulping, mechanical pulping, and two-stage pulping are the principal pulping methods currently (Li *et al.*, 2023). The traditional chemical pulping method is technologically mature but poses significant environmental challenges.

The mechanical pulping method is mainly applicable to wood pulping, when used in agricultural straw and other non-wood raw materials pulping, the obtained pulp often exhibits inferior quality and cannot meet industry standards. The two-stage pulping method combines chemical or biological pre-treatment with mechanical refining post-treatment in the pulping process. Pulp obtained from non-wood raw materials using this method is of better quality than that produced by mechanical pulping, making the two-stage pulping method suitable for pulping agricultural straw and other non-wood raw materials. The two-stage pulping method is mainly divided into chemical mechanical pulping (CMP) and biological mechanical pulping (BMP). The BMP method is more environmentally friendly in terms of reduced chemical usage and lower wastewater generation.

With the emergence of BMP technology, scholars have conducted extensive research on the biological pre-treatment processes of non-wood raw materials such as rice straw (Guan *et al.*, 2018), corn straw (Qing *et al.*, 2017), and wheat straw (Kang *et al.*, 2021). However, significant challenges remain in the preparation stage of non-wood bio-mechanical pulp, highlighting the need for specialized equipment development to advance BMP technology. Twin-screw pulping machines have emerged as the primary choice for pulping equipment due to their high breaking efficiency and fibrillating capacity (Arthur and Rahmanian, 2024), yet research in this area in China is still in its infancy. Kowalski *et al.* used MDT software to design and analyze co-rotating twin-screw extruders for food applications (Kowalski *et al.*, 2018); Düphans applied CAD/CAE technology for the design and simulation of twin-screw pulping machinery (Düphans *et al.*, 2024). These studies are limited to the design of twin-screw components and have not yet addressed the complete machine design and optimization of twin-screw pulping machines. Fleur utilized Ludovic simulation software to optimize the twin-screw pulping machine, improving the production efficiency of cellulose nanofibrils and reducing energy consumption through the simulation and optimization of screw profiles (Rol *et al.* 2020). The physical and chemical properties and the matched twin-screw pulping machine are different from the BMP method for the pretreatment of wooden raw materials and the pulping raw materials produced by the chemical method. Therefore, it is of great significance to design and optimize a twin-screw pulping machine with BMP pulping technology for rice straw as raw material to promote the comprehensive utilization of straw. Rol optimized the twin-screw extrusion process through simulation software, achieving efficient production of high-quality cellulose nanofibrils (CNF), demonstrating the feasibility of simulation design in the field of pulping machinery design and optimization (Rol *et al.*, 2019).

In this paper, ANSYS finite element simulation software is used to determine the flow channel structure and the combination of compression zones of the twin-screw device, designing and constructing a twin-screw pulping machine. Based on the previously calibrated Ab-T10 breaking model, the Rocky discrete element simulation software is employed to simulate the breaking process of straw particles. Through a three-factor quadratic orthogonal rotational combination simulation test, the effects of screw speed, thread pitch, and straw moisture content on the breaking rate of rice straw were investigated to optimize the working and structural parameters of the twin-screw pulping machine, thereby increasing the breaking rate of rice straw. The accuracy and reliability of the model are verified by comparing the results of the simulation with those of the validation tests.

MATERIALS AND METHODS

Twin screw pulping machine design

Structure and Working Principle

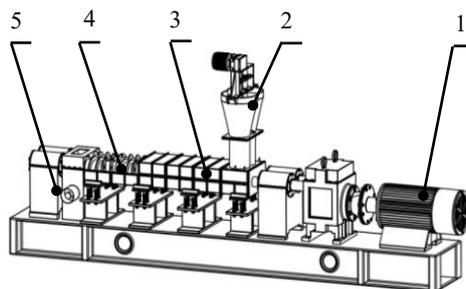

Fig. 1 - Three-dimensional model of the twin-screw pulping machine of rice straw

1 - Motor; 2 - Material feeding device; 3 - Grinding device; 4 - Grinding twin screw; 5 - Discharging device

The structure of the twin-screw pulping machine is shown in Figure 1, which mainly consists of a grinding device, an electric motor, a material feeding device, and a discharge device. During operation, rice straw is placed into the feed opening of the material feeding device at a uniform speed and in appropriate amounts to avoid blockages. The straw first enters the pulping machine through the feeding device, and after being crushed, sheared, and broken by the twin-screw grinding device, it is sent to the discharge device, where the broken pulp is collected.

Selection and design of threaded elements

The cross-section of screw elements is typically rectangular or serrated. The asymmetry of serrated screw elements enhances the mixing of materials, promotes the dispersion of fibers, and refines the pulp, thereby improving the pulping quality. Compared to the traditional rectangular cross-section, serrated screw elements are more suitable for the compression and homogenization stages of the pulping process. The shearing action can effectively improve the flowability of the material, reduce retention phenomena, and enhance uniformity and efficiency. Therefore, screw elements with a serrated cross-section were used, as shown in Figure 2.

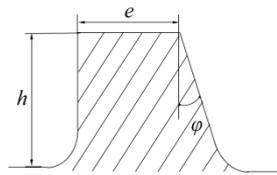

Fig. 2 - Thread cross-section shape

The screw diameter directly affects the material processing capacity and the power consumption of the device, while the screw length is related to the residence time of the material within the screw, which in turn affects the pulping efficiency (Lyashuk *et al.*, 2022). Screw elements are commonly selected in sizes of 180 mm, 240 mm, 300 mm, 350 mm, etc. Based on the laboratory equipment conditions, screw elements with an outer diameter of 180mm were chosen. The optimal diameter range of 60-200 mm ensures efficient material conveying, mixing and processing capabilities while maintaining compatibility with existing equipment (Delvar *et al.*, 2025).

$$h = (0.02 \sim 0.2)D_e \quad (1)$$

$$e = (0.08 \sim 0.12)D_e \quad (2)$$

where: h is the groove depth, mm; e is the width of normal screw prong, mm; D_e is the outer diameter of the screw, mm.

Design of thread pitch

The pitch of the screw thread affects the fill rate of the material in the screw and its flow characteristics. A smaller pitch can increase the fill rate of the material, but may lead to hindered material flow and increased screw wear, affecting the shearing action of the screw on the material. A larger pitch can provide stronger shearing forces, which is beneficial for material mixing and the disruption of the cellulose structure, but it also increases the wear on the screw. According to the transport rate of solid materials and the theory of pulp flow, the thread lift angle φ should be designed between 17° and 30° to ensure effective transport and mixing of the material within the screw. Based on equations (3) and (4), the range of pitch values can be calculated to be 172~326 mm.

$$S = \pi \cdot D_e \tan \varphi \quad (3)$$

where: S is the lead, mm; φ is the thread rising angle, $^\circ$.

$$S = pz \quad (4)$$

where: p is the thread pitch, mm; z is the number of threads, $z=1$.

Design of structural clearance

During pulping, the pulping raw materials exhibit the characteristics of soft solids, hence the clearances can be selected to be on the larger side.

$$\delta_a = (0.01 \sim 0.03)D_e \quad (5)$$

According to equation (5), the range of values for the gap σ_a between the top of the screw prong and the shaft were calculated as 1.8~5.4 mm. The smaller the σ_a , the less the leakage flow and the higher the conveying efficiency, but the mixing effect is reduced. Therefore, σ_a was chosen to be 3 mm.

At this clearance value, the equipment can maintain a certain conveying efficiency while keeping pressure fluctuations and friction between the screw and barrel moderate, thus avoiding excessive energy consumption.

$$\delta_b = (0.01 \sim 0.02)D_e \quad (6)$$

According to equation (6), the range of the gap between the twin screws δ_b was calculated as 1.8~3.6 mm. The smaller the δ_b , the higher the manufacturing precision required for the twin screws. Therefore, δ_b was chosen to be 3 mm. With this clearance, material flows stably between the twin screws, allowing sufficient time for mixing and shearing without over-pressurization or excessive residence time, which could cause overheating or degradation, thus enhancing pulp quality consistency.

$$C_L = D_e + \delta_b \quad (7)$$

Therefore, according to equation (7), the center distance C_L between the twin screws was calculated to be 180.3 mm, which ensures a moderate gap between the screws, avoiding material residue and ensuring efficient shearing and mixing effects.

$$D_s = D_e + 2\delta_a \quad (8)$$

From equation (8), the internal diameter D_s of the shaft was calculated to be 180.6 mm.

TWIN-SCREW COUPLING SIMULATION DESIGN

By integrating numerical computation and finite element simulation methods (Zhang *et al.* 2023), the two established flow channel models were simulated under various conditions by ANSYS 2022 R1. By comparing the pressure field distribution of the two flow channels, the coupling method for the twin-screw straw pulping machine was selected. Using the finite element simulation method and the selected twin-screw coupling method, the four established compression zone models were simulated under various conditions. By comparing the flow of material between the screws, the compression zone combination method for the twin-screw straw pulping machine was selected.

Model Establishment

(1) Flow Channel Model Establishment

The screws of twin-screw pulping machines are often designed in a modular fashion, allowing the installation of thread elements on the core shaft as needed, with single-start threads commonly used (Gu *et al.*, 2019). The coupling forms between thread elements are divided into parallel and staggered types, as shown in Figure 3(a). Based on the uniform continuous mixing and transportation mechanism (Düphans *et al.*, 2024), the parallel thread element coupling model used single-start thread screws; based on the shear dispersion uniformization mechanism (Kolomiets and Jirout, 2021), the staggered thread element coupling model used a 180° staggered configuration of single-start thread elements. With the Boolean operation modeling capabilities of SolidWorks software, the flow channel structure models corresponding to the two types of twin-screw coupling models were constructed, as shown in Figure 3(b).

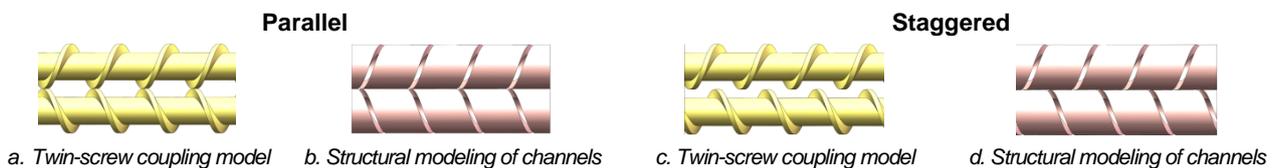

Fig. 3 - The model of twin-screw and flow channel

(2) Compression Zone Model Establishment

Positive threads have the function of conveying and compressing material, while reverse threads have the function of blocking material and increasing pressure. When the material was pushed from the positive thread to the reverse thread to the next thread area, the material was compressed and sheared under the extrusion of the positive and reverse threads. The flow channel area formed by the positive and reverse threads is a compression zone. A twin-screw device generally have three compression zones, and each segment of thread elements forming the compression zone should have 2-3 threads.

The compression zones are combined with two types, positive threaded element-reverse threaded element (referred to as 1) and reverse threaded element-positive threaded element (referred to as 2). Using SolidWorks software, four types of compression zone combination models were established as shown in Figure 4.

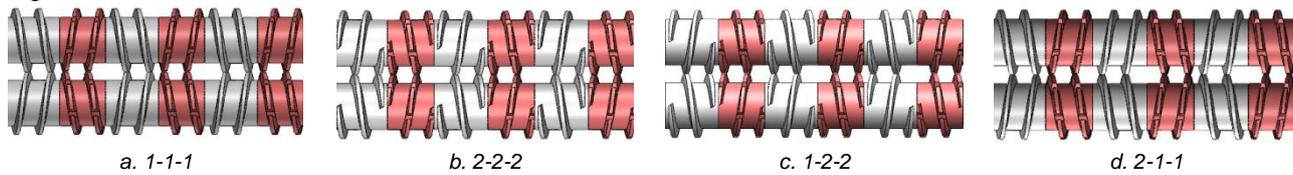

Fig. 4 - Compression zone combination model

Meshing and Simulation Parameter Settings

The model was imported into Ansys software (Xiao *et al.* 2024), and hexahedral meshing was used to optimize computational efficiency and accuracy. Local mesh refinement was performed on complex areas of the screws and flow channels to analyze the flow characteristics of the material within the channels. The rheological model of the straw pulp was set to the power-law fluid model to describe its non-Newtonian characteristics (Liu *et al.* 2019). The material properties of the rice straw pulp were shown in Table 1, Twin-screw material parameters were shown in Table 2.

Table 1

Physical parameters of straw pulp

Parameter	Value	Parameter	Value
Straw pulp consistency	682	density	232.3 kg/m ³
Power law index	0.49	specific heat capacity	6.585 J/(kg·K)
Temperature coefficient	0.042 K ⁻¹	heat transfer coefficient	0.2 W/(m·K)
Reference temperature	373.15 K		

Table 2

Twin-screw material parameters

Part	Material	Density/kg·m ⁻³	Elastic modulus/MPa	Poisson's ratio
Shaft core	42CrMo	7850	2.06×10 ⁵	0.28
Threaded element	A ₂ tool steel	7860	2.06×10 ⁵	0.28

The twin-screw rotation speed was set to 120 r/min, the entrance velocity of the rice straw pulp was set to 1 m/s, and a pressure outlet boundary condition was used. The inner wall was set to a no-slip boundary condition, using the no-slip option in Ansys-Fluent to ensure no relative sliding between the pulp and the device walls. The initial temperature was set to 25° C, the initial pressure was set to 101325 Pa, the time step was set to 0.01 seconds, the number of iterations was set to 500, and the relaxation factor was set to 0.7 to accelerate convergence. The Euler multiphase flow model was used to simulate the motion of the mixed phase of the straw pulp, capturing the flow characteristics of the straw pulp in the twin-screw device.

Dynamic Solution of Straw Pulp

To accurately analyze the dynamic characteristics of straw pulp within the crushing flow channel, the following assumptions were made: the effects of gravity and inertia forces in the flow field were neglected; the straw pulp was assumed to move in a laminar flow within the crushing device, completely filling the device and behaving as an incompressible fluid; the straw pulp was assumed to move without slippage within the cavity of the crushing device. Based on the constitutive equations of fluid dynamics and the rheological properties of the fluid, numerical simulation and analysis of the flow of straw pulp under isothermal and non-isothermal conditions were performed.

To describe the changes in the volumetric flow rate of straw pulp and the dynamic relationship between fluid density and velocity field, the conservation of straw pulp phase material during the crushing process was captured according to the continuity equation, as shown in equation (9). This equation demonstrates the conservation of mass of the straw pulp and its flow behavior within the channel during the crushing process by considering the vector velocity and density.

$$\nabla \cdot (\rho \vec{v}) + \frac{\partial \rho}{\partial t} = 0 \quad (9)$$

where: \vec{v} is the vector velocity of straw pulp, m/s; ρ is the straw pulp density, kg/m³.

The internal momentum transfer mechanism of straw pulp during the crushing process was described by the Navier-Stokes equation, as shown in equation (10). The equation reveals the mechanism of internal momentum transfer and transformation within the straw pulp during the crushing phase and enables the prediction of the flow patterns of the pulp based on relevant parameters.

$$\rho\left(\frac{\partial \vec{v}}{\partial t} + (\vec{v} \cdot \nabla) \vec{v}\right) = -\nabla p + \nabla \cdot \vec{\tau} + \vec{f}_v \quad (10)$$

where: p is the static pressure on straw pulp, Pa; $\vec{\tau}$ is the stress tensor of straw pulp, Pa; \vec{f}_v is the Volumetric force of straw pulp, N/m³.

Energy conservation equation expresses the thermodynamic behavior of straw pulp through changes in internal energy, heat exchange with the environment, and energy loss due to fluid flow, as shown in equation (11). This equation quantifies the change in internal energy of the straw pulp during crushing, taking into account the energy alterations caused by molecular thermal motion and interactions, thereby analyzing the energy trajectory of the straw pulp throughout the crushing process.

$$\rho C_p \left(\frac{\partial T}{\partial t} + \vec{v} \cdot \nabla T \right) = \nabla \cdot (k \nabla T) + \frac{\vec{\tau}}{\nabla \vec{v}} \quad (11)$$

where: C_p is the specific heat capacity, J/(kg·K); T is the temperature, K. ∇T is the temperature gradient, K/m; $\nabla \vec{v}$ is the velocity gradient tensor, s⁻¹; k is the heat transfer coefficient, W/(m·K).

Straw pulp conform to the characteristics of pseudoplastic fluids (Terashima et al., 2022). Under isothermal conditions, power-law model is used to describe rheological behavior as shown in equation (12). This equation illustrates the variation in the flow characteristics of straw pulp under different shear rates in an isothermal environment.

$$\eta = m \dot{\gamma}^{(n-1)} \quad (12)$$

where: η is the straw pulp viscosity, Pa·s; m is the straw pulp consistency, Pa·sⁿ; n is the power law index of straw pulp; $\dot{\gamma}$ is the shear rate tensor of straw pulp, s⁻¹.

Under non-isothermal conditions, the rheological behavior of straw pulp is significantly affected by temperature, and is represented by a temperature-dependent rheological model (Gienau et al., 2018). Equation (13) describes the relationship between the apparent viscosity (η) of straw pulp and the shear rate ($\dot{\gamma}$) as well as temperature. The function $H(T)$ is temperature-dependent, serving to adjust the viscosity to reflect the effects of temperature variations.

$$\eta = m \dot{\gamma}^{(n-1)} \cdot H(T) \quad (13)$$

$$H(T) = \exp[-\beta(T - T_\alpha)] \quad (14)$$

where: T is the temperature, K; β is the temperature coefficient of straw pulp, K⁻¹; T_α is the reference temperature for straw pulp, K.

SIMULATION ANALYSIS AND OPTIMIZATION OF RICE STRAW PARTICLE BREAKING

Test factors and indicators

Rice straw pre-treated by biological method was selected as the test material. In accordance with the requirements of the "HJ/T 340-2007 Clean Production Standard for the Papermaking Industry" standard, pretreated rice straw was made into oven dried pulp with a moisture content of 10%, followed by the testing samples with different moisture contents prepared using biofungal liquid and drying method.

To optimize the working performance of the rice straw twin-screw pulping machine, based on preliminary design and pretesting, the thread pitch, screw speed, and rice straw moisture content were taken as the test factors. Based on the previous section on design, the range of thread pitch was 172~326 mm; the range of screw speed was 100~140 r/min (Jiang et al., 2024); considering the characteristics of rice straw material, the moisture content range for rice straw was taken as 50~70% (Cheng et al., 2022). Based on the function of the rice straw twin-screw pulping machine, the rice straw breaking rate was chosen as the evaluation index of its working performance, and the calculation formula is as follows:

$$P = \frac{m_b}{m_t} \times 100\% \quad (15)$$

where: m_b is the mass of broken particles, g; m_t is the total mass of particle sample, g.

Test Design

The discrete element model of rice straw particles established by Jiang and others, along with the parameter calibration results of the Ab-T10 crushing model (Jiang et al., 2024), and the mechanical model constructed in this paper were imported into the Rocky DEM 4.5 to simulate the crushing process of rice straw particles and conduct a three-factor quadratic orthogonal central composite simulation test, and the factor level coding table is shown in the table 3. The screen aperture diameter x_1 , pitch x_2 , and blade and shell clearance x_3 are the actual values of the factors.

Table 3

Coding table			
Code	Screw speed (x_1)/r/min	Thread pitch (x_2)/mm	Moisture content (x_3)/%
-1.682	100	172	50
-1	108	203	54
0	120	249	60
+1	132	295	66
+1.682	140	326	70

RESULTS

Simulation results and analysis

Simulation results and analysis of twin-screw channel characteristics

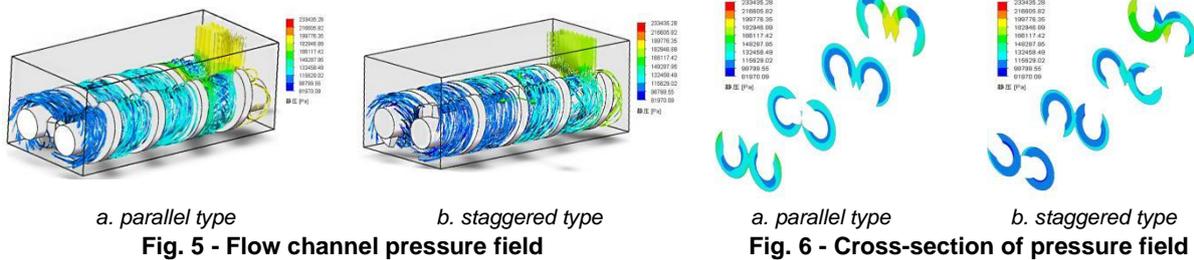

Figure 5(a) showed a mirror symmetry in the pressure gradients of the left and right flow channels, with the maximum pressure difference being less than 0.5 MPa. This symmetry was particularly evident in the screw engagement area, where symmetrical High-Pressure Ridges formed, and peak pressures were concentrated at the thread top clearance. The symmetric pressure field suppressed the lateral exchange of materials through the force equilibrium, indicating a lateral flow velocity of less than 0.1 m/s, which aligned with the flow characteristics dominated by laminar flow, where the Reynolds Number is approximately 120 (Saldana et al., 2024). The symmetric high-pressure area created a uniform shear stress field of about 450 kPa, which continuously acted on the straw particles through viscous dissipation, promoting the uniform delamination of cellulose microfibrils.

Figure 5(b) showed a significantly higher pressure peak in the left flow channel compared to the right. Local pressure discontinuities greater than 3 MPa/mm occurred at the thread top clearance and engagement area, leading to a substantial lateral pressure difference. This asymmetry triggered secondary flows, increasing the lateral flow velocity to 0.6 m/s and inducing vortices, with the flow state exhibiting transitional turbulence characteristics, where the Reynolds Number is about 450. The high pressure difference drove fibers to undergo bending-shear coupled damage in the engagement area. However, the local peak shear stress exceeded the yield strength of the straw fibers, and the uneven stress distribution resulted in a mixture of over-pulverized particles and unbroken coarse grains.

Figure 6(a) showed a cross-sectional pressure distribution that decreased in a concentric circular pattern, aligning with the predicted trend of the Generalized Herschel-Bulkley Model. Near the wall, the shear rate was synchronized with the compression-relaxation cycle of the thread clearance, forming periodic stress loading that facilitated the progressive disintegration of fibers.

Figure 6(b) showed a cross-sectional pressure field with a left-high and right-low gradient, generating a normal pressure component that compelled fibers to migrate along an inclined path, increasing the likelihood of collisions with the flight flanks. A low-pressure vortex area appeared at the bottom of the right flow channel, increasing the average residence time for some fibers and intensifying the risk of thermal degradation.

The simulation results showed that the pressure distribution of the left and right channels of the parallel type is almost symmetric in the twin-screw, keeping the material transfer and pressure state in the channel uniform. Such symmetric pressure distribution reduced the cross exchange of straw particles in the engaging area, which made the material flow more stable and continuous.

It is more favorable to destroy the structure of cellulose, hence the parallel type has more uniform effect on the grinding and shearing action of the material. The pressure distribution in the left and right flow channels with staggered thread element coupling exhibited asymmetry, especially at the screw crests and in the meshing zone. The asymmetric pressure distribution created a transverse pressure difference across the grooves, causing the shearing force experienced by straw fibers in the meshing zone to be uneven, leading to an uneven crushing and breaking effect on the straw particles.

Consequently, to ensure the pulping effect and quality of the twin-screw pulping machine, the twin-screw with parallel thread element was selected as the core breaking element of the breaking device in the twin-screw pulping machine.

Compression zone simulation results and analysis

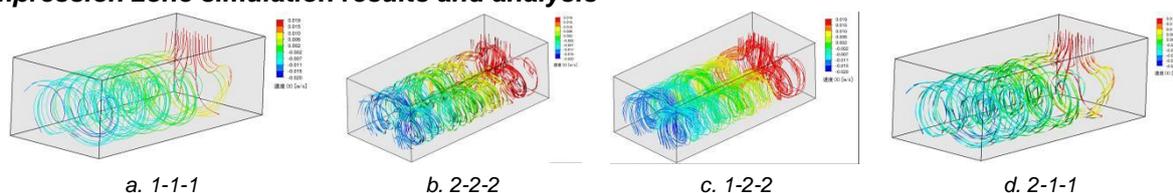

Fig. 7 - Compression zone combination velocity field

The simulation results of the four compression zones were shown in Figure 7. From Figure (a), the flow field of the 1-1-1 configuration exhibited a low-gradient uniform distribution. No significant velocity shear layer was formed between the twin screws, leading to a lower shear rate. The analysis of the flow lines indicated that the material primarily moved axially in the engagement area, with a low rate of lateral migration. Due to insufficient shear strength, the straw fibers underwent only limited disintegration, resulting in a higher retention of fiber length and a lower proportion of hydrogen bonds being broken, which caused uneven dispersion of the fiber bundles.

From Figure (b), it was observed that in the engagement area of the 2-2-2 twin screw configuration, symmetrical "V" shaped high-speed shear zones were formed. Within this region, uniform velocity gradients led to the generation of uniform shear layers, with the flow field symmetry index reaching as high as 0.92. The velocity components of the material in the axial and radial directions approached a ratio of 1:1, promoting three-dimensional mixing. The preliminary shearing action in the "V" shaped area, in conjunction with the reverse shearing action in the inverted "V" shaped area, created a cyclic loading mechanism. This mechanism significantly enhanced the efficiency of hydrogen bond breaking, effectively increased the fiber surface area, and resulted in a concentrated particle size distribution, achieving efficient crushing and dispersion. Additionally, this velocity field had good stability, which could effectively reduce the material residence time, making it the optimal configuration.

From Figure (c), the 1-2-2 configuration exhibited an asymmetric velocity distribution, with the peak velocity in the left flow channel being higher than that in the right, creating an inclined shear zone. The generation of localized vortices enhanced mixing, but the distribution of shear rates was uneven. The reverse shearing in the inverted "V" region led to a coupling of fiber bending and tearing, which reduced the proportion of coarse fibers but resulted in over-pulverization.

From Figure (d), the 2-1-1 configuration resulted in velocity dead zones between the screws, with the primary shear area being confined near the thread clearance. The streamlines indicated that the material circulated and lingered within these dead zones, leading to localized temperature increases and thermal degradation. The efficiency of fiber disintegration was relatively low, and the particle size distribution exhibited a bimodal pattern, indicating a coexistence of insufficient fragmentation and over-pulverization.

As shown in Figure 7, the 2-2-2 and 1-2-2 compression zone combinations created strong shear zones, enhancing the shearing and mixing of straw particles between the twin screws and improving their breaking efficiency. Under the action of the twin screws, straw particles entered the "V" shaped area and underwent pre-shearing, where fibers begin to separate. After entering the inverted "V" shaped area, straw particles were subjected to reverse shear forces, further breaking the hydrogen bonds between fibers, increasing the surface area of the fibers, and promoting the effective dispersion of fiber bundles. The 2-2-2 configuration demonstrated superior symmetry in the velocity distribution field compared to the 1-2-2 combination, ensuring more uniform transport of rice straw material through the flow channel and reducing flow instability caused by uneven pressure distribution.

The movement of rice straw in the 2-2-2 flow channel was more stable, and the shearing action was more uniform, which is conducive to the destruction of the cellulose structure and the dispersion of fiber bundles. Therefore, the twin-screw with the in-line 2-2-2 compression zone combination was used as the core breaking element of the breaking device in the twin-screw pulping machine.

Simulation Results and Analysis of the Crushing Process

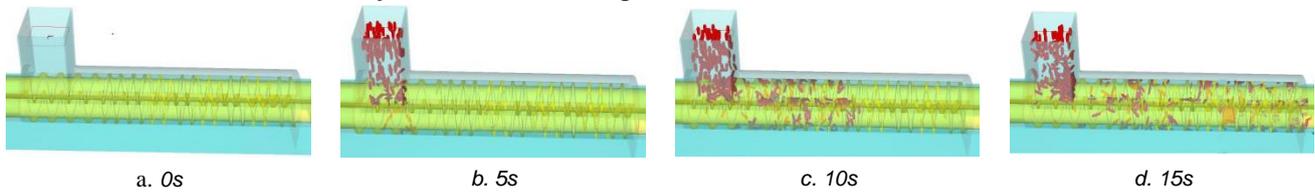

Fig. 8 - Simulation of straw particles crushing process in pulping machine

The Rocky simulation software was utilized to simulate and analyze the breaking process of straw particles from the feeding side to the crushing side, as shown in Figure 8.

Test results and analysis

The simulation results of the breaking process for rice straw particles are shown in Table 4, where A, B, and C were the factor encoding values. The experimental data were analyzed using Analysis of Variance (ANOVA) to determine the significance of the factors affecting the rice straw breaking rate. The ANOVA was conducted using the Design-Expert software, which provided a comprehensive analysis of the variance components and their corresponding F-values and P-values. The regression equation for the rice straw breaking rate (P_c) was derived from the ANOVA results, and the significance of each term in the equation was assessed. The optimization of the process parameters was performed using the Response Surface Methodology (RSM) in Design-Expert software, which allowed for the determination of the optimal screw speed, thread spacing, and straw moisture content to maximize the breaking rate. The results of the ANOVA was presented in Table 5.

Table 4

Test design and results

No.	Screw speed (A)/r/min	Thread Pitch (B)/mm	Moisture content (C)/%	Breaking rate (P_c)/%
1	1	1	1	48

Residual	66.54	13	6.58		
Lack of fit	71.79	5	9.36	12.51	0.1013
Error	34.75	8	4.34		
Total value	1799.30	22			0.0010

From Table 5, it is known that the regression equation model has a P-value less than 0.01, indicating a highly significant result. The lack of fit item has a P-value of 0.1013, which suggests a good fit of the equation. The thread pitch, screw speed, rice straw moisture content, interaction terms AB, and the quadratic terms A²,

B^2 , C^2 have a highly significant effect on the rice straw crushing rate ($P < 0.01$). The interaction terms AC and BC have a significant effect on the rice straw breaking rate ($P < 0.05$). Under the interaction effects, the order of influence of each factor on the rice straw breaking rate is moisture content > thread pitch > screw speed. After eliminating the non-significant terms, the regression model for the encoded values of the rice straw breaking rate (P_c) is:

$$P_c = 71.41 - 1.63A + 0.5012B - 2.46C - 0.3000AB - 2.15AC - 2.35BC - 5.83A^2 - 5.39B^2 - 4.37C^2 \quad (16)$$

The optimal working parameters were obtained using the Optimization Numerical module of Design-Expert 8.0.6 software and based on Equation 16. When the screw speed was 120 r/min, the thread pitch was 203 mm, and the rice straw moisture content was 60%, the rice straw breaking rate reached its highest value of 79.9%.

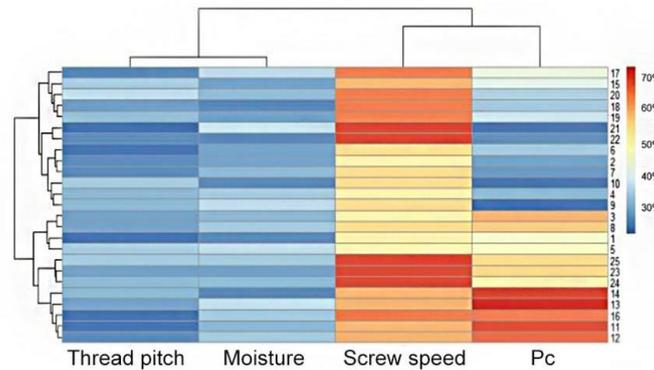

Fig. 9 - The influence of screw speed, thread pitch and straw moisture content on straw pulp rate

As shown in Figure 9, the screw speed has a significant impact on the rice straw breaking rate. When the screw speed is less than 120 r/min, the rice straw breaking rate tends to increase, and it begins to decrease after exceeding 120 r/min. This phenomenon can be attributed to the enhancement of mixing and shearing of the material by the screw as the speed increases (Fan et al., 2023). When the speed exceeds 120 r/min, the residence time of the material in the screw is shortened, reducing the breaking of the material, leading to a decrease in the breaking rate. The effect of rice straw moisture content on the rice straw breaking rate is relatively smaller. The rice straw breaking rate increases with the increase of moisture content until it reaches 60% and then begins to decrease. The expansion degree of the rice straw material increases with the increase of moisture content, leading to an increase in hardness and viscosity, a decrease in the filling density of the material in the screw, and a reduction in contact and shearing between the materials, which reduces the breaking effect. The effect of screw thread pitch on the rice straw crushing rate is the least significant. When the thread pitch is less than 203 mm, the rice straw breaking rate tends to increase, which is attributed to the increased contact frequency between the rice straw and the screw, thereby enhancing the shearing and breaking effects. When the thread pitch reaches 203 mm, the rice straw breaking rate decreases, which may be due to the overly wide pitch reducing the effective contact and shearing of the material. The effective contact and shearing of rice straw between the screws are reduced, lowering the local pressure and shearing force.

Test bench test verification

a. Rice straw twin-screw pulping machine

b. Rice straw particle grinding and breaking process

Fig. 10 - Verification test of rice straw particle breakage

Rice straw was prepared into test samples with a moisture content of 60% according to the methods previously described. Based on the simulation optimization results, the twin-screw rotation speed was set to 120 r/min, and the thread pitch was set to 203 mm. Under the optimal parameter combination, a validation test on the breaking of rice straw particles was conducted using the rice straw twin-screw pulping machine, as shown in Figure 10. To reduce random error, five replicate tests were performed.

The test values of the rice straw breaking rate were 82.7%, 78.6%, 83.4%, 81.3%, and 84.1%, with an average of 82.02% and an error value of 2.6%. The error between the simulation test results and the actual test results was less than 5%, indicating that the results of the simulation optimization are accurate. Furthermore, the proposed model demonstrates significant potential for broader applicability across diverse straw material systems (e.g., wheat, corn, and barley straws), while also providing a method to explore the intricate chemical reactions during pulping, thereby revealing the pulping mechanism.

CONCLUSIONS

(1) The ANSYS analysis software was used to conduct simulation analysis on two flow channel structures and four compression zone combinations. ANSYS analysis software was used to simulate two flow channel structures and four compression zone combinations. Results showed that the parallel 2-2-2 compression zone combination in the twin-screw design offered significant advantages in mixing and extruding rice straw material, providing a more uniform force environment compared to the staggered coupling, which performed poorly in the same speed range. This finding provides a practical basis for optimizing pulping equipment design, enabling the selection of efficient structural configurations for industrial-scale straw processing, thereby enhancing production efficiency and reducing energy consumption.

(2) Based on the simulation analysis results and the characteristics of rice straw material, a rice straw twin-screw pulping machine was designed with a screw outer diameter of 180 mm, a thread pitch range of 172–326 mm, a clearance of 3 mm between the top of the screw thread and the shaft, a clearance of 3 mm between the twin-screws, and a barrel inner diameter of 180.6 mm. This design enables industrial-scale rice straw pulping, supporting sustainable development in straw-based industries.

(3) The calibrated Ab-T₁₀ breaking model and Rocky simulation software were used to perform a three-factor quadratic orthogonal central composite simulation experiment, and a validation test was conducted using the rice straw twin-screw pulping machine. The simulation results showed that the order of influence on the straw breaking rate was: moisture content > thread pitch > screw speed. When the screw speed was 120 r/min, the thread pitch was 203 mm, and the straw moisture content was 60%, the maximum rice straw breaking rate was 79.9%. The validation test results indicated that the error between the simulation and actual test results was 2.6%, and the simulation results basically matched the actual situation, confirming the reliability of the optimization results for the rice straw twin-screw pulping machine. These findings provide a practical foundation for the design and optimization of industrial-scale pulping equipment, promoting the high-value utilization of agricultural waste.

ABSTRACT

Aiming at the problems such as low seeding qualification rate of vegetable precision seeder, this paper designs a kind of air-absorbing precision seeder. The device is mainly composed of chassis part, seed discharge device, power unit, fan, gearbox and transmission device. ADAMS software is used to simulate the kinematics and dynamics of the air-absorbent seed discharger, and the simulation results show the movement and falling process of the seeds inside the seed discharger, and at the same time analyze the movement and force of the whole machine. By building a test bench, the seeding qualified rate under different factors is obtained to meet the requirements, which verifies the rationality of the machine design.

摘要

针对蔬菜精量播种机播种合格率低等问题, 本文设计了一种气吸式精量播种机。该装置主要由底盘部分、排种装置、动力装置、风机、变速箱以及传动装置等组成。利用 ADAMS 软件对气吸式排种器进行运动学和动力学仿真, 仿真结果显示了种子在排种器内部运动及下落过程, 同时对整机的运动及受力情况进行分析。通过搭建试验台, 得到不同因素下的播种合格率均满足要求, 验证了整机设计的合理性。

INTRODUCTION

With the gradual increase in the demand for vegetables in China, which caused the increase in the area of vegetable planting, under this trend, the research on vegetable seeding device to improve the performance of the seeding device has an important value (Tian et al., 2023; Zhao et al., 2020; Yang et al., 2018). In mechanized seeding, the seed discharger is the core component in the mechanical seeder. The seed discharging performance of the seed discharger will directly affect the seeding quality and seeding efficiency (Biocca et al., 2023). Currently, the domestic seeder is mainly used for sowing corn, wheat, grains, soybeans and other common large grain size crops. Seeding devices for small-sized vegetables such as carrots are rarely developed and studied, and are still in the initial stage of development (Zhang et al. 2021; Huang et al., 2022).

Common mechanical seed dischargers are prone to scratching and damaging vegetable seeds in the seed discharge process, making the efficiency and quality of seed sowing unsatisfactory. In contrast, pneumatic seed dischargers can well prevent the phenomenon of damage to the outer skin of vegetable seeds in the seed discharge process (Li et al., 2023). Pneumatic precision seed dischargers began to appear in some foreign countries with advanced science and technology in the 1950's (Zhang et al., 2022). Arzu Yazgi et al., (2007) in order to solve the problem of poor uniformity of seed discharge in pneumatic precision seed dischargers, applied the response surface methodology to optimize the parameters of pneumatic precision seed dischargers, and came up with the optimal parameters of the working combination of the dischargers. Karayl et al., (2004), optimized the structure and parameters of the pneumatic seed expeller on the basis of the physical properties of seeds, and at the same time established a vacuum model to improve the seed discharge performance of the discharger.

Onal *et al.*, (2012), developed the Noetherian model to explain the mechanism of the seeds relying on the principles of fluid and aerodynamics, in response to the phenomenon of the instability of the seed suction generated in the airflow field of the pneumatic seed discharger.

Li Qichao., (2020), of Northeast Agricultural University established a stable critical transport model for non-regular small-grained vegetable seeds through a technical study on the adaptation of a variety of small-grained vegetable seeds, and clearly resolved the mechanism of seed population separation and transport.

This study aims to design and analyze an innovative air absorbing precision seeder, using ADAMS software for kinematic and dynamic simulations and conducting experimental evaluations of its performance to provide a reference basis for the research and development of vegetable precision seeder.

MATERIALS AND METHODS

Overall design of the seeder

Composition of the whole machine

The seeder is mainly composed of two parts, the first part is the chassis movement part, the second part is the seeder sowing part, the specific structure is shown in Figure 1. The machine consists of a frame platform carried by four wheels as well as an engine drive module, the motor output power is transmitted to the gearbox, after the gearbox speed change, a part of the power is transmitted to the gears of the rear wheels of the chassis in order to drive the total device forward, which can be adjusted by adjusting the transmission ratio to control the forward speed of the machine. The seeding device adopts air-absorbing seed discharge disk, which is powered by another part of the gearbox. The suction holes on the vertical disk in the seed discharge disk use the negative pressure formed on both sides of the disk to suck the seeds. As the seed discharge disk rotates, it reaches a certain angle where the differential pressure no longer exists, causing the suction to disappear. At this moment, the seeds previously held on the seed discharge disk fall.

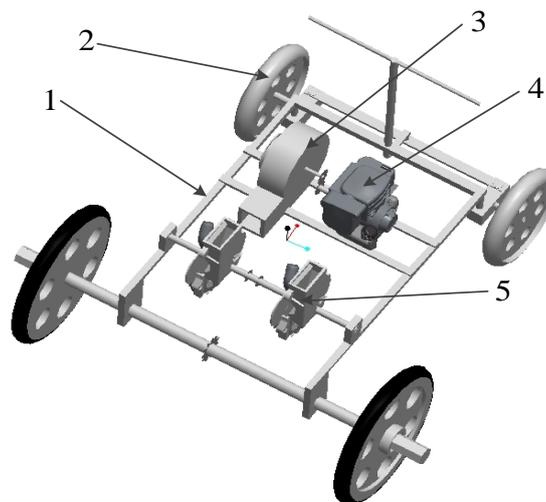

Fig. 1 - Overall structure of seeder

1.chassis; 2.tire; 3.fan; 4.gear box; 5.precision seed-metering device

Working principle

At working, the fan starts and gets a certain angular rotation speed. At the same time, the air inside the seed discharge disk sucked out. Thus, there is a certain pressure difference between the inside and outside of the two sides of the formation of suction on the seeds. The seeds in seed box fall because of gravity. At the same time, the seeds are sucked by suction onto the holes in the seed discharging disk and rotate with the disk. And in a certain range of angles, the negative pressure has always existed. This process is called seed taking and seed carrying process. When the seed discharge disk rotates at a certain angle, the negative pressure disappears, and the seeds fall back to the seed chamber or are discharged under the action of self-weight, vibration and friction. This process is called seed clearing and seed discharge process (Li *et al.*, 2024). The seed discharger keeps doing circular motion, and this process is continuously circulated to complete the seeding operation, and different specifications of seed discharging disk can be selected according to the different vegetable crops sown.

Adams virtual experiment

The kinematics and dynamics simulation is mainly carried out for the seeder in the model to analyze the influence of the rotational speed of the seed discharge disk on the trajectory of the seed drop, as well as the changes of the seed velocity, angular velocity and the force situation, to validate the stability of the rotation of the seed discharge disk (Yu *et al.*, 2024; Li *et al.*, 2021).

The model of air-aspirated vegetable precision seeder created in SolidWorks was imported into ADAMS. According to the size of the model, adjust the size and density of the grid. According to past experience, in order to get more accurate simulation results, set the range of grid activity in the X, Y direction at 6000 mm and 5000 mm, respectively. The grid size in the X, Y direction is 50 mm. The units were chosen according to the standard MMKS. The Cartesian coordinate system is selected as the ground coordinate system. After the model is imported into ADAMS, the attributes of each component should be defined, including the component name, material properties, etc. (Shi *et al.*, 2019). ADAMS can automatically calculate the mass and center of gravity position of each component, and the frame is 87 kg, and the seed discharger is 20.8 kg.

According to the connection between the components of the seeder, the corresponding fixed joint, moving joint, cylindrical joint, etc. were created in turn. Mainly create the motion joint of the internal structure of the seed discharger. The seed discharger and the frame are the fixed joint, the rotary disk inside the seed discharger and the seed discharger shell are the rotary joint; the seed inside the seed discharger and the shell are the contact joint. The specific constraints are shown in Fig. 2.

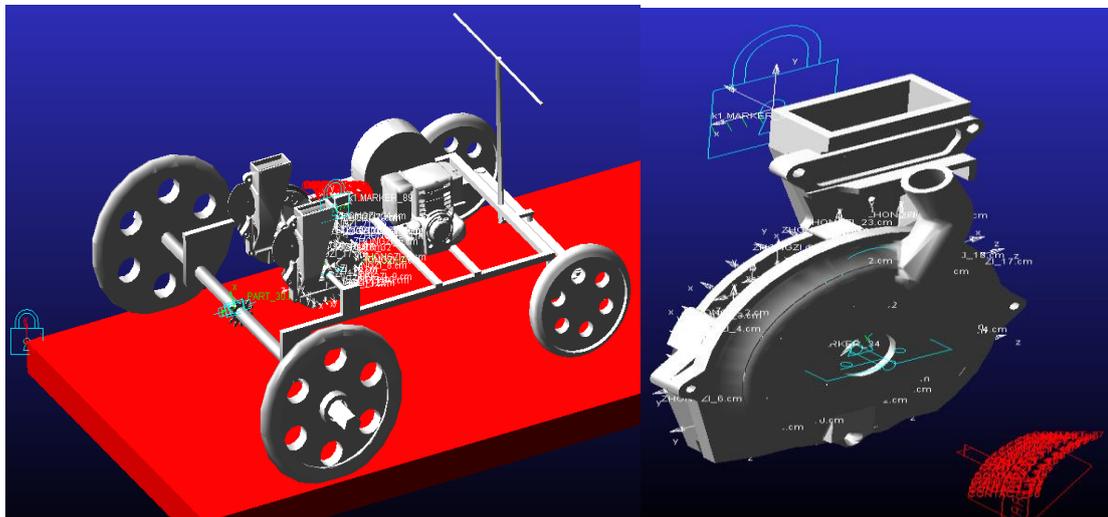

Fig. 2 - The constraints of hoisting system

Applied load and drive: This study primarily examines the relationship between the seed discharger and the speed of the seeding machine, considering two key factors: the speed of the seeder and the seed discharge rate at a given rotational speed of the seed discharger. The relationship between these factors is analyzed through simulation. The drive is applied to the mobile joint of the planter, while the rotary drive is applied to the rotational joint of the seed discharger. The traveling speed of the machine relative to the seeding speed is considered uniform. The main calculations for several operational groups are shown in Table 1.

Table 1

Working conditions of each group		
operation	rotational speed of the seed discharger	speed of the seeder
1	30 d/s	0.3 m/s
2	30 d/s	0.2 m/s
3	30 d/s	0.1 m/s
4	60 d/s	0.1 m/s

Verification test of carrot seeder

Yellow Sword No. 1 pelletized carrot seeds of Shouhe Company with less than 8% moisture content were used as the test material in the experiment (Wang *et al.*, 2015).

The whole test bench is shown in Fig. 3, which is mainly powered by a 190F gasoline engine with a continuous output of 7.0 kw. Other test supporting pieces of equipment are a rotational speed tester (3402, TACHO Hi Tester, Japan), wind pressure tester, camera, stopwatch, and meter scale.

Fig. 3 -Test bench of air-suction carrot seeder

1.chassis; 2.precision seed-metering device; 3.gear box; 4.fan; 5.petrol engine; 6.tire

Test indexes and test methods

Precision seeder adopts the national standard GB/T 6973-2005. The adoption of this standard can make the test results of different types of single grain (precision) seeders comparable. In in this standard, the three major performance indexes of precision seeders are the qualified rate of seeding, the miss-seeding rate, and the reseeding rate.

Test design

The key components of the air-absorbent seeder lie in the structure and installation position of the seeder, etc. However, there are various factors affecting the seeding of the seeder, among which the key influencing factors are the vacuum degree of the air chamber produced by the fan, the rotational speed of the seeding disk driven by the engine, the seeding height, the thickness of the seeder and the angle of the seeder when it is installed, and the number, size, layout and so on of each suction hole of the seeding disk when it is designed (Abdolazare *et al.*, 2018). Since the minimum size of the triaxial dimensions of the carrot seeds for sowing is greater than 2 mm, the diameter of the suction holes in the clock discs designed during the test was 2 mm. Using the control variable method, the pitching height was adjusted separately while keeping all other conditions unchanged. Several groups of different test results were recorded, and the obtained data were processed to determine the average value for the air-absorbent carrot planter. The study examined the effects of three factors—the vacuum degree of the air chamber, the rotational speed, and the pitching height—on the performance of seed placement. The test factor levels are shown in Table 2.

Table 2

Factors and level of orthogonal test

Level	Factors		
	A. Vacuum degree pa	B. Rotational speed of the seeding disk r/min	C. seeding height mm
1	2000	36	20
2	3000	60	30
3	4000	96	40

Through the simulation test, the trajectory and speed of the seed can be obtained, while the bench test provides data on the seed discharge performance of the seeder. Combining both methods allows for a comprehensive analysis of the seeder's operational performance.

RESULTS AND DISCUSSION

Simulation results analysis

Seed movement trajectory analysis

When the seeder is in operation, the seeds make a circumferential motion in the seed discharger and are finally discharged in a certain form of motion. The trajectory of the seed i.e. the actual curve of the seed falling on the ground. The dynamics of the seed movement is simulated using the ADAMS/ view module with a simulation time of 10 s and a simulation step count of 200 steps. The trajectory curves of the seeds under different working conditions are shown in Figure 4-7.

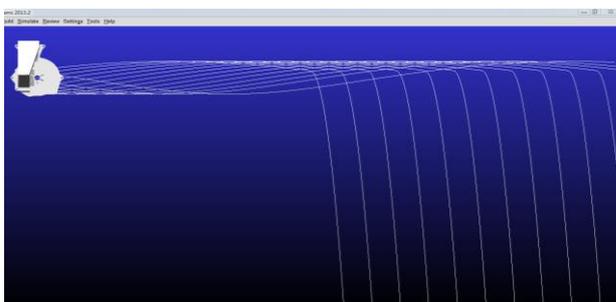

Fig. 4 - The trajectories of seeds in operation 1

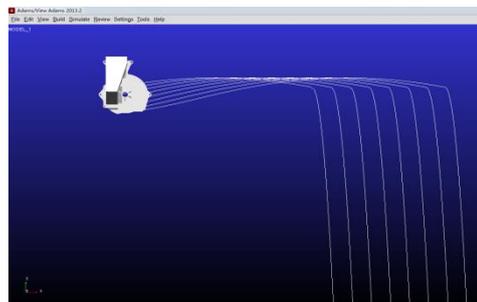

Fig. 5 - Trajectory of seeds in operation 2

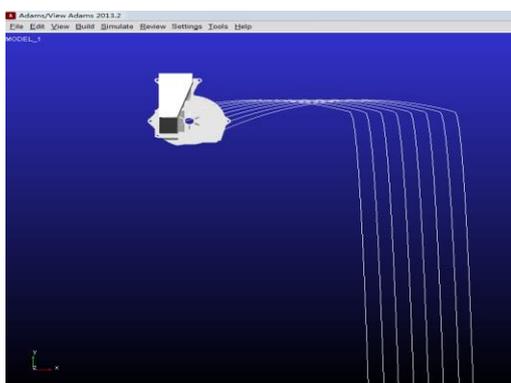

Fig. 6 - Trajectory of seeds in operation 3

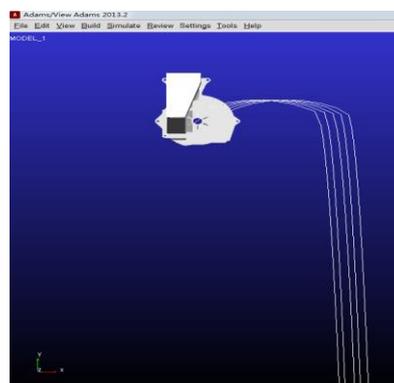

Fig. 7 - Trajectory of seeds in operation 4

In case of operation 1, the landing distance of the seeds is 100 mm, in case of operation 2, the landing distance of the seeds is 150 mm, in case of operation 3, the landing distance of the seeds is 200 mm, in case of operation 4, the landing distance of the seeds is 250 mm, and the results of the statistical calculations are shown in Table 3.

Table 3

Calculations			
Operation	Rotational speed of the seed discharger	Seeder speed	Sowing spacing
1	30 d/s	0.3 m/s	100 mm
2	30 d/s	0.2 m/s	150 mm
3	30 d/s	0.1 m/s	200 mm
4	60 d/s	0.1 m/s	250 mm

By simulating the situation of seeding spacing under different operating conditions, the ideal seeding distance can be determined. The desired seeding spacing can be obtained by adjusting the self-propelled speed of the whole machine and the speed of the upper shaft of the seed discharger.

Simulation result curve of seed under virtual prototype

In the case of the seed discharger under working operation 1, i.e., the speed of the seeder is 0.3 m/s and the rotational speed of the seed discharger is 30 d/s, the curves of the seed velocity changes during sowing are shown in Fig. 8, and the angular velocity changes of different seeds are shown in Fig. 9.

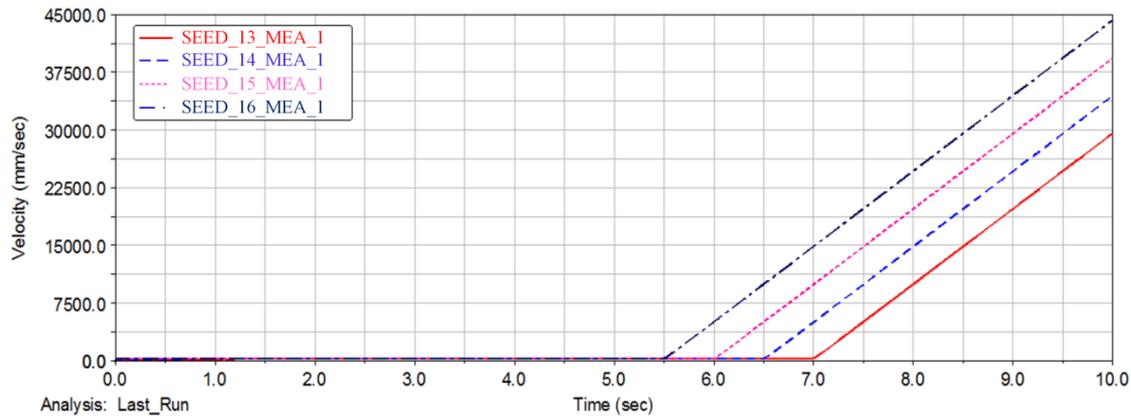

Fig. 8 - Velocity map of four seeds

As can be seen from the seed velocity change curve in Fig. 8, the seeder sequentially releases seeds from the seed discharge tray, after which they accelerate downward with constant acceleration during sowing. The time interval between the fall of every two seeds was approximately 0.5 s. The time interval between the fall of each seed is roughly the same, which shows that the seed discharger is installed more firmly. There is a small vibration which has a negligible effect on it. The simulation was carried out under ideal conditions, without the influence of external wind speed, etc. In addition, there is friction to be taken into account, but compared to the traditional coated seed, this seed is adsorbed on the seed discharging disk, and friction also has a small effect on it. Therefore, based on the time interval between seed falls, it can be concluded that the seeds are sown at relatively uniform spacing, and the emergence of the seedling is neat and tidy.

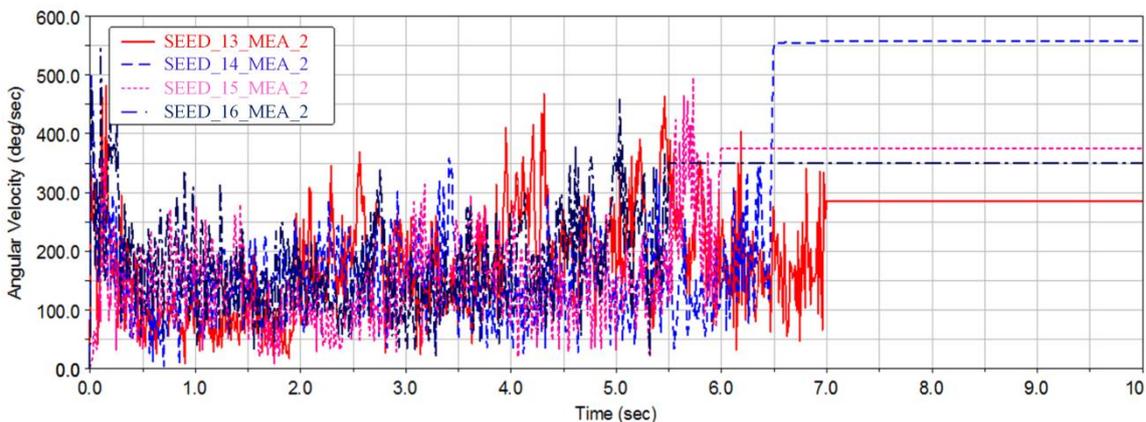

Fig. 9 - Angular velocity diagram of four seeds

Through the angular velocity of different seeds in Fig. 9, it can be seen that the seeds inside the seed discharger are rotating together with the seed discharger, and finally detach from the seed discharger from the seed casting mouth due to their own gravity and the seed scraping device. There is a certain fluctuation of the seeds inside the seed discharger, which is caused by the vibration of the whole machine and its own movement due to the seed discharger being installed on the rear axle of the frame. The angular velocity of all the seeds is basically the same as the angular velocity of the seed discharging disk, and when the seeds are discharged from the seed discharger, they will complete the later work with constant angular velocity.

Analysis of bench test results

Effect of air chamber vacuum on seeding performance

For different vegetable crop seeds, the required vacuum pressure is different, in general, the larger the vacuum degree of the air chamber, the stronger the seeds are adsorbed, and it is not easy to cause missing sowing phenomenon, but the large pressure difference inside the air chamber causes the seed discharge tray to adsorb more than one seed in one type of hole, and the phenomenon of reseeding is obvious, which makes it difficult to realize the precision sowing. Therefore, this experiment was conducted to study the effect of different vacuum degrees on the performance, to find the optimal vacuum degree and range. The wind pressure generated by the fan at work was 2000 Pa, 3000 Pa, 4000 Pa, and the grain spacing under different vacuum degrees was measured and calculated when the traveling speed of the seeder was stable. The results are shown in Table 4.

Table 4

Effect of vacuum degree in air chamber on seeding performance					
Test No.	Vacuum degree of air chamber (pa)	Qualification rate (%)	Reseeding rate (%)	Miss-seeding rate (%)	Average seed spacing (mm)
1	2000	61.25	12.71	27.62	8.4
2	3000	80.71	8.01	12.34	10.1
3	4000	71.44	14.27	15.71	22.6

From Table 4, it can be concluded that as the vacuum degree inside the seed chamber increases, the qualified seed rate rises, the reseeding rate increases, and the miss-seeding rate decreases. In this test, increasing the vacuum degree of the air chamber led to a higher qualified rate; however, it also inevitably resulted in a higher reseeding rate. Considering these three performance indexes comprehensively, the air pressure in the seed chamber should be controlled within the range of 3000–4000 Pa. When the vacuum degree in the seed chamber is at the minimum setting of 2000 Pa, the seed discharge performance is the worst—the qualified rate is relatively low, and the occurrence of empty holes is severe. However, as the air pressure increases, various performance indexes gradually improve. Once the vacuum in the seed chamber reaches a certain level, further increasing the air pressure no longer enhances the qualified rate, while the reseeding phenomenon becomes more pronounced.

Effect of seeding disk's rotational speed on seeding performance

The rotational speed of the seeding disk is another important factor affecting seeding performance. If the rotational speed is too high or too low, it may result in inefficient seeding. Therefore, when selecting the seeding disk's rotational speed, it is essential to ensure that the three key seeding performance indexes remain optimal. This test quantitatively examines the impact of the seeding disk's rotational speed on these three major performance indexes. The rotational speeds were set at 36 r/min, 60 r/min, and 96 r/min, respectively. The seed spacing at different rotational speeds was measured under stabilized conditions, and the results are presented in Table 5.

Table 5

Effect of seeding disk's rotational speed on seeding performance					
Test No.	Seeding disk's rotational speed (r/min)	Qualification rate (%)	Reseeding rate (%)	Miss-seeding rate (%)	Average seed spacing (mm)
1	36	65.20	17.49	5.52	7.8
2	60	77.02	9.14	3.48	15.3
3	96	88.74	7.48	2.73	40.3

From Table 5, it can be seen that the rotational speed and the qualified rate have a non-linear relationship. When the rotational speed is constantly increasing, the qualified rate of the seed discharger first increases and then decreases, and when it increases to a certain peak, the re-seeding rate decreases, but the miss-seeding rate increases. This occurs because when the rotational speed increases, the linear velocity of the seed discharging disk increases continuously, and the time for the seeds to be adsorbed in the seed chamber becomes shorter, resulting in the phenomenon of empty cavities, which leads to the increase of the leakage rate. When the rotational speed is 60-96 r/min, the three major performance indexes of the seed discharger are higher.

Effect of seeding height on seeding performance

Seeding height (the distance between the falling position of the seed and the furrow) is also an important parameter that has a great influence on the seeding performance, and it is an important factor in achieving precision seeding. Due to the light weight of carrot seeds, air resistance during the falling process cannot be ignored. Additionally, friction and collisions within the seed guide tube cause deviations in the falling trajectory, preventing the seeds from following the expected path precisely. Therefore, when selecting the seeding height, the optimal working height should be determined while ensuring that the three major seed discharge performance indexes remain within a reasonable range. This study quantitatively examines the effect of seeding height on these performance indexes. The selected seeding heights were 20 mm, 30 mm, and 40 mm. Once the seed falling process stabilized, grain spacing was measured, and the performance indexes within the grain spacing were calculated. The results are presented in Table 6.

Table 6

Effect of seeding height on seeding performance					
Test No.	Seeding height (mm)	Qualification rate (%)	Reseeding rate (%)	Miss-seeding rate (%)	Average seed spacing (mm)
1	20	87.35	16.49	2.75	69.7
2	30	78.62	10.62	3.47	90.3
3	40	70.28	9.13	5.53	105.4

From Table 6, it can be observed that seeding height and the qualified rate exhibit a generally linear relationship. As seeding height increases, both the qualified rate and reseeding rate of the seed discharger gradually decrease, while the miss-seeding rate increases. When the seeding height is 20 mm, the three major performance indexes show the best results. The reason is that a lower seeding height results in a shorter seed drop distance, reducing the impact of wind on the seeds. Thus, the following conclusion can be drawn: the higher the seeding height, the greater the seed drop distance, leading to increased influence from wind, inter-seed friction, collisions, and other external factors, ultimately reducing seeding accuracy. To ensure optimal seed discharge, the seeding height should be minimized as much as possible to reduce the falling distance of the seeds.

In summary, as the vacuum inside the chamber increases, the seed spacing gradually decreases, indicating a reduction in the miss-seeding rate. This occurs because an increase in vacuum pressure leads to more carrot seeds being adsorbed onto the disk, thereby increasing the number of discharged seeds and reducing seed spacing. However, if the vacuum pressure becomes too high, multiple seeds may be discharged simultaneously, leading to an increased reseeding rate. When the rotational speed of the seed discharge disk increases, the seed spacing increases. However, at very low rotational speeds, the increase in seed spacing is slower, whereas at higher rotational speeds, seed spacing increases more significantly. The reason for this phenomenon is that at higher speeds, the seed discharge disk has less time to properly adsorb enough seeds, resulting in larger seed spacing and a higher miss-seeding rate. When the seeding height is increased, seed spacing also increases, leading to a higher miss-seeding rate. This occurs because carrot seeds are very lightweight, and as the seed discharge height increases, seeds fall a greater distance and are more affected by wind, causing uneven seed distribution. Therefore, when determining the installation height of the seed discharger, it should be kept as low as possible while ensuring it does not come into contact with uneven ground.

CONCLUSIONS

(1) An air-absorbing precision seeder was designed, and its overall structure was developed. The device mainly consists of a chassis, seed discharging device, power unit, fan, gearbox, and transmission system. The working principle of the entire machine and the four seed discharge processes of the seed discharger were introduced, providing a theoretical basis for subsequent simulations to analyze the trajectory and movement process of seeds.

(2) Using ADAMS software, kinematic and dynamic simulations of the air-absorbing seed discharger were conducted. The seeding process was simulated, and the seeding speed curve was generated. The simulation results illustrate the movement and falling process of seeds within the seed discharger, while also analyzing the motion and forces acting on the entire machine.

(3) The influence of three factors—vacuum degree of the air chamber, rotational speed, and seeding height—on seed discharge performance was investigated through a test bench. The reasons for variations in test results were explained by analyzing the data. The effects of different factor levels on seed discharge performance were determined, verifying the validity and reliability of the test results.

Keywords: Self-propelled sprayer, spray boom, levelling control system, adjustment threshold, ultrasonic distance sensor, performance experiment

ABSTRACT

To address the issues of poor boom stability and inconsistent spray quality due to harsh field conditions and varying boom height relative to the target, a five-section planar truss boom capable of height adjustment, overall tilt adjustment, and unilateral tilt adjustment was designed. A contour levelling control system for the boom was developed based on the STM32F103 platform. The levelling system uses ultrasonic distance sensors to detect the distance between the boom's ends and the target in real-time. The limit average filtering method is employed to eliminate sudden signal interference and process feedback data. The control system then drives electric actuators to adjust the boom's posture in real-time. Field and spray tests were conducted using a small electric self-propelled sprayer as the test platform. The results indicate that the best levelling performance was achieved with overall height adjustment, overall tilt adjustment, and unilateral tilt adjustment thresholds set to 30 mm, 30 mm, and 40 mm, respectively. The field spray tests showed minimal relative errors in droplet deposition coverage and density on both sides. The coefficient of variation CV of deposition along the boom direction was less than 15%, ensuring good spray distribution uniformity. These findings provide valuable references for the design and optimization of sprayer booms.

摘要

本文设计了一种可实现高度调节、整体倾斜调节、单侧倾斜调节功能的平面五段式桁架喷杆。基于STM32F103平台设计了喷杆仿形调平控制系统，调平系统采用超声波测距传感器实时检测喷杆两侧末端与目标物之间距离，利用限幅平均滤波法以排除突变信号的干扰并对反馈数据进行计算处理，控制系统驱动各机构电动推杆伸缩对喷杆姿态进行实时调整。以小型电动自走式喷雾机为试验平台，分别进行了场地试验及田间喷雾试验，场地试验结果表明当设定整体高度调节阈值为30mm、整体倾斜调节阈值为30mm、单侧倾斜调节阈值为40mm时调平效果最佳，田间喷雾试验结果表明两侧雾滴沉积覆盖率及沉积密度相对误差较小，沿喷杆向上的沉积量变异系数CV小于15%，可以保证较好的喷雾分布均匀性，研究成果为喷雾机喷杆的设计与优化提供了参考。

INTRODUCTION

Self-propelled boom sprayers are widely used in field pest and disease control due to their high operational efficiency and excellent spray quality (Dou et al., 2021; Baltazar et al., 2021; Lin et al., 2022). However, harsh field conditions often cause the sprayer to pitch, roll, and yaw, leading to boom imbalance relative to the ground, and in severe cases, the boom ends may even touch the ground (Ali et al., 2023; Li et al., 2023; Lipiński et al., 2022). Furthermore, to ensure spray quality, the boom should maintain an optimal and nearly parallel distance to the crop canopy. Therefore, the boom height must automatically adjust in real-time according to changes in crop canopy height and terrain to ensure uniform spray distribution and operational safety (Dou et al., 2021; Dou et al., 2021; Bayat et al., 2018). To this end, researchers both domestically and internationally have conducted studies on boom levelling control. Llica et al. (2018) studied boom height measurement methods and developed an automatic height adjustment control algorithm to maintain a constant

¹ Yu CHEN, Prof. Ph.D. Eng; Zhenyu ZhANG, M.R. Stud. Eng; Jiayu CAO, M.R. Stud. Eng; Peijie GUO, M.R. Stud. Eng;

distance between the nozzle tip and the target area (soil or canopy), enhancing the sprayer's application efficiency. Okamoto et al. integrated multiple sensors to detect the boom's posture, providing precise detection methods for the boom adjustment system (Okamoto et al., 2015). An Jiahao et al., (2022), designed a boom levelling mechanism based on the pendulum suspension principle, allowing the boom to swing left and right between -20° and 20° relative to the vehicle body. Based on this principle, they developed a boom levelling control system. Sun Xing et al., (2020), used a weighted average algorithm to integrate data from inclination sensors and ultrasonic sensors, and based on this, designed an expert-controlled boom height adjustment system. Zhang Meng et al., (2019), designed an automatic boom levelling control system using inclination sensors based on MEMS inertial navigation technology to achieve real-time boom posture adjustments.

This study focuses on the boom of a small electric sprayer, aiming to enhance boom operational stability and spray uniformity by designing a boom structure capable of ground contour following. Based on its working principle, ultrasonic sensors are used to detect the distance between the boom and the spraying target. The limit average filtering method is employed to eliminate sudden signal changes, and the boom contour levelling control is achieved by controlling the forward and reverse rotation and extension of electric actuators in each mechanism.

MATERIALS AND METHODS

Overall structure of the boom

The boom contour levelling system is designed based on our team's independently developed small self-propelled electric sprayer, with the overall boom structure shown in Fig. 1. The boom uses a five-section planar truss structure (left small boom, left large boom, middle boom, right small boom, right large boom), the small booms are connected to the large booms via small boom folding mechanisms, and the large booms are connected to the middle boom via unilateral tilt mechanisms and large boom folding mechanisms, the middle boom is connected to the boom mounting frame through an overall tilt mechanism, while the boom mounting frame is connected to a parallelogram lifting mechanism for height adjustment. The parallelogram lifting mechanism is connected to the chassis to secure the entire boom.

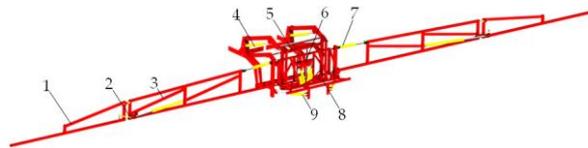

Fig. 1 - High clearance self-propelled sprayer test platform

1 – Small boom; 2 – Small boom folding mechanism; 3 – Large boom; 4 – Parallelogram lifting mechanism; 5 – Boom mounting frame; 6 – Overall tilt mechanism; 7 – Unilateral tilt mechanism; 8 – Middle boom; 9 – Large boom folding mechanism

Design of key mechanisms

(1) Design of the parallelogram lifting mechanism

The parallelogram lifting mechanism primarily consists of a boom mounting frame, upper link, lower link, boom bracket, and height-adjusting push rod, as shown in Fig. 2. The boom bracket is bolted to the sprayer chassis through pre-set bolt holes, securing the entire parallelogram lifting mechanism to the sprayer frame. The boom bracket and boom mounting frame are connected via the upper and lower links, which are of equal length and remain parallel during height adjustment. This forms a double parallelogram linkage. The double link structure enhances structural strength and prevents deformation during height adjustment.

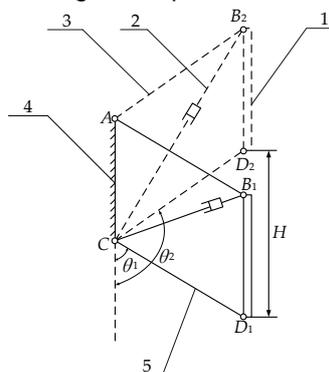

Fig. 2 - Operating principle of the parallelogram lifting mechanism

1 – Boom mounting frame; 2 – Height-adjusting push rod; 3 – Upper link; 4 – Boom bracket; 5 – Lower link

In Fig. 2, quadrilateral AB1CD1 represents the lowest position of the parallelogram lifting mechanism, and AB2CD2 represents the highest position. l_{AB} is the length of the upper link, l_{CD} is the length of the lower link, l_{AC} is the length of the fixed end of the boom bracket, θ_1 and θ_2 are the angles between the lower link and the vertical direction at the extreme positions of the boom. H denotes the maximum height adjustment distance of the boom.

As shown in Fig. 2, the maximum range of boom height adjustment is:

$$H = |l_{CD} (\cos \theta_2 - \cos \theta_1)| \tag{1}$$

The minimum length of the height-adjusting electric push rod is:

$$L_{\min} = \sqrt{l_{AB}^2 + l_{AC}^2 - 2l_{AB}l_{AC} \cos \theta_1} \tag{2}$$

The maximum length of the height-adjusting electric push rod is:

$$L_{\max} = \sqrt{l_{AB}^2 + l_{AC}^2 - 2l_{AB}l_{AC} \cos \theta_2} \tag{3}$$

If h_1 is the minimum distance from the fixed end of the boom bracket to the ground, and h_2 is the distance from the lower link hinge point of the parallelogram lifting mechanism to the bottom of the boom, then the minimum adjustable height of the boom is,

$$h = h_1 - l_{AB} \cos \theta_1 - h_2 \tag{4}$$

(2) Design of the overall inclination mechanism

The working principle of the overall inclination mechanism is shown in Fig. 3. Figures 3(a), (b), and (c) represent the left limit, horizontal, and right limit states of the spray boom. When the overall tilt angle range is set to -5° to 5° , the angles between the tilt link and the overall tilt push boom at their left and right limit positions are:

$$\theta_L = \arcsin \frac{l_a}{l_b \sin \delta} + 5^\circ, \theta_R = \arcsin \frac{l_a}{l_b \sin \delta} - 5^\circ \tag{5}$$

The length of the overall tilt push boom is:

$$l_a^2 + (l - l_L)^2 - 2l_a(l - l_L) \cos \theta_L = l_b^2, l_a^2 + (l + l_R)^2 - 2l_a(l + l_R) \cos \theta_R = l_b^2 \tag{6}$$

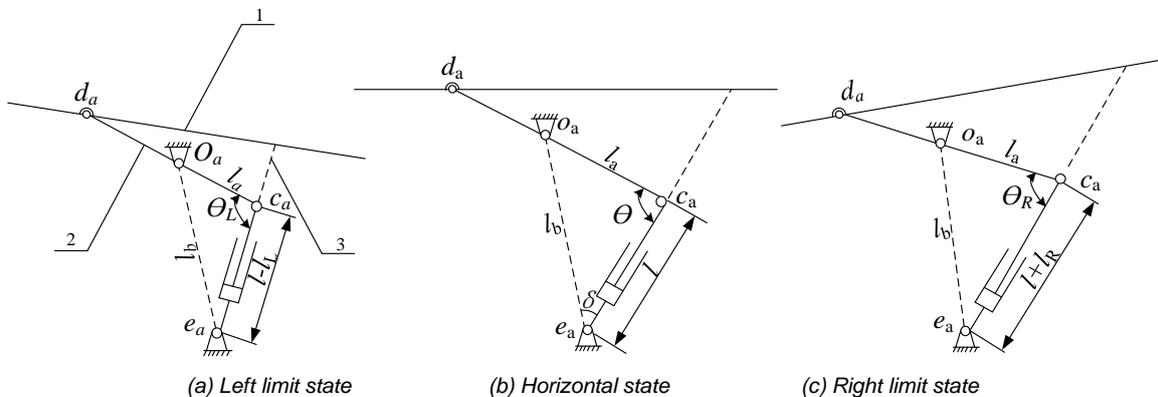

Fig. 3 - Working principle of the overall inclination mechanism
 1 – Central spray boom; 2 – Inclined link rod; 3 – Integrated inclined push rod

As shown in Fig. 4, the three-dimensional model of the integrated tilting mechanism allows relative rotation among the inclined link rod, the welded inclined plate, and the central spray boom. Additionally, the relative rotation is possible between the inclined link rod and the fixed column. By controlling the extension and retraction of the electric push rod, the overall inclination of the spray boom can be achieved. When the small-range height adjustment push rod remains stationary, shortening the integrated inclined push rod causes the right end of the inclined link rod to rotate around its center, transferring thrust to the fixed column at the left end. Since the fixed column is welded to the central spray boom, this results in a clockwise rotation and inclination of the spray boom. Conversely, when the integrated inclined push rod extends, the spray boom rotates counterclockwise. When both the small-range height adjustment push rod and the integrated inclined push rod extend or retract simultaneously at the same speed, the welded inclined plate, inclined link rod, central spray boom, and guide plate move together along the guide tube, achieving small-range height adjustment of the spray boom.

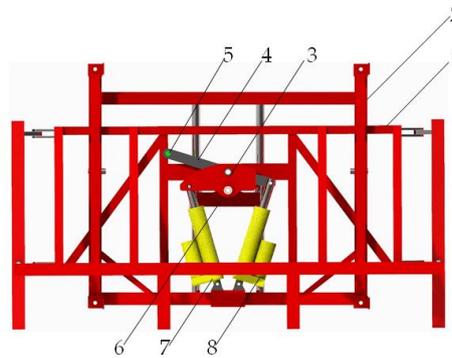

Fig. 4 - Overall inclination mechanism

1 – Central spray boom; 2 – Spray boom mounting bracket; 3 – Welded inclined plate; 4 – Inclined link rod; 5 – Fixed column; 6 – Guide plate; 7 – Small-range height adjustment push rod; 8 – Integrated inclined push rod

(3) Design of the unilateral tilting mechanism

Taking the right spray boom as an example, the working principle of the unilateral tilting mechanism is shown in Fig.5. One end of the unilateral tilting push rod is hinged to the fixed rod of the large arm spray boom, while the other end is hinged to the large arm spray boom itself. The unilateral tilting rotating block is connected to the pin shaft below the fixed rod of the large arm spray boom, the large arm spray boom can rotate at a certain angle around the fixed rod through the rotating block. When the unilateral tilting push rod contracts, it drives the large arm spray boom to rotate clockwise, when the unilateral tilting push rod extends, it drives the large arm spray boom to rotate counter clockwise, thereby achieving the tilting adjustment of the unilateral spray boom.

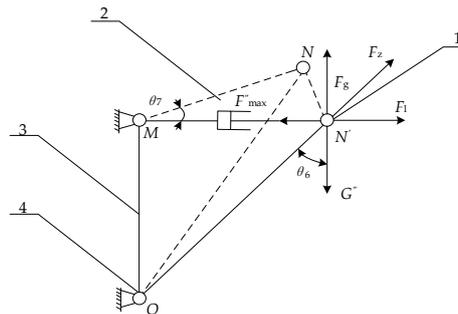

Fig. 5 - Working principle of the unilateral inclination mechanism

1 – Large arm spray boom; 2 – Unilateral inclination push rod; 3 – Large arm spray boom fixing rod; 4 – Unilateral inclination rotating block

The length of the unilateral inclination push rod at the extreme rotation position of the spray boom is,

$$l_{MN'} = l_{MN} \cos \theta_7 \tag{7}$$

The support force provided by the pin to the main arm spray boom is,

$$F_z = F_g / \cos \theta_6 \tag{8}$$

$$F_g = G'' \tag{9}$$

The maximum thrust required by the single-sided inclined push rod is,

$$F_{max}^* = F_1 = F_z \cos(90^\circ - \theta_6) \tag{10}$$

Design of the boom profiling and levelling system

(1) Working principle of the system

Currently, boom levelling systems primarily use distance sensors to detect boom height or tilt sensors to measure boom inclination (Li et al., 2020; Wang et al., 2019; Fu et al., 2020; Zürey et al., 2020; Burgers et al., 2021). Tilt sensors can measure the entire boom's tilt angle in dynamic environments and are widely used in small drones, intelligent agricultural equipment, and automobiles (Li et al., 2023; Shi et al., 2020; Yan et al., 2021). However, the boom designed in this paper is divided into five sections during profiling and levelling, allowing for separate control of the overall boom and the two sides. The use of tilt sensors alone cannot meet control requirements, so ultrasonic distance sensors are selected for real-time boom height detection.

The working principle of the boom contour levelling system is shown in Fig. 6. An ultrasonic distance sensor is installed at the end of each small arm on both sides of the boom, measuring the height of the side

booms and the overall boom above the ground. The controller processes the sensor feedback data to drive height adjustment, overall tilt, and single-side tilt electric push rods to adjust the height of each boom section, ensuring precise levelling for various terrains. To avoid repetitive adjustments near the target height during levelling, a height adjustment threshold is set. When the real-time collected boom height falls within the threshold range, the system automatically stops the levelling action.

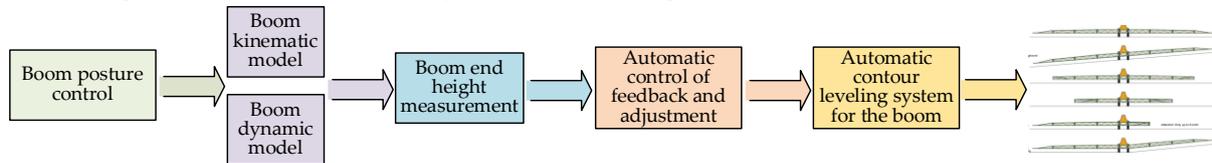

Fig. 6 - The working principle of the boom contour levelling system

The boom contour levelling control system is designed with an STM32 micro-controller as its core, with its hardware structure shown in Fig. 7. The system uses two ultrasonic distance sensors to accurately measure the ground clearance on both sides of the boom, and the detected data is input into the microprocessor for filtering and evaluation. Based on the levelling requirements, the microprocessor generates corresponding control signals to operate the H-bridge module, driving the appropriate electric actuators to adjust the boom's height or angle, thus providing real-time posture adjustments. The distance sensors are HY200P4C ultrasonic sensors with built-in temperature compensation, having a detection range of 100-2000 mm. The communication protocol used is RS485, which supports high-speed and long-distance data transmission, making it suitable for wide boom sprayers. The response time is 40 ms, with a repeat accuracy of 0.3%. The data conversion module is the GN-15 RS485-TTL module, which supports a wide voltage range (3.0-33V) and baud rates of 110-460800 BPS. The motor drive module uses the GZ-PMDC-120A7T H-bridge L298 logic speed controller, with an input voltage of 12-27V and a rated output current of 7A. Fast recovery diodes are used to prevent the control section from being damaged by large counter-electromotive forces during motor startup. The microprocessor selected is the STM32F103ZET6 based on the Cortex-M3 core, featuring 112 I/O ports, 5 UART communication ports, and 1 CAN communication port.

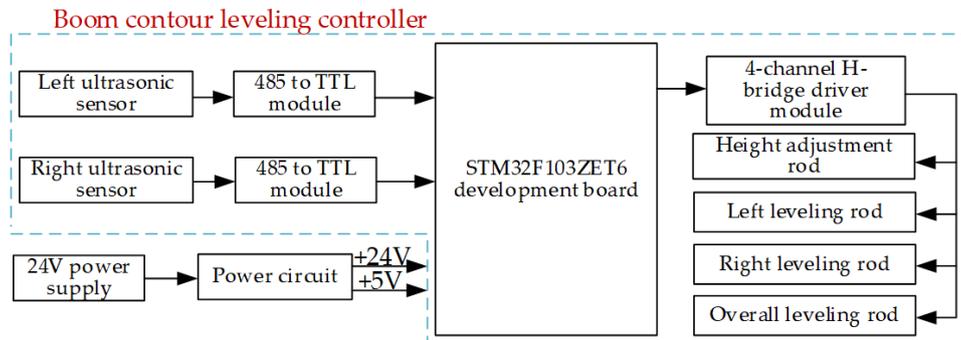

Fig. 7 - The hardware structure for boom contour levelling

(2) Information acquisition and processing of ultrasonic distance sensors

When the sprayer operates in the field, ultrasonic distance sensors are used to send measurement signals to the crop canopy. However, the spacing between crops may cause the signals to pass through gaps and reach the ground, resulting in abrupt changes in measurement values and leading to erroneous judgments by the control system. To ensure the accuracy of height information, it is necessary to apply filtering to exclude interference from sudden signal changes during data collection. After comparing various filtering techniques, the amplitude-limited averaging filter method was selected for processing the sensor signals. This method effectively eliminates deviations caused by occasional pulse interference and provides good signal smoothing (Li et al., 2022). The filtering principle is as follows: based on the plant height at different application stages, the maximum allowable deviation value A between two successive samples is determined. If the difference between the current sample value and the previous one is less than or equal to A , the current sample value is accepted; otherwise, it is discarded, and the previous value is used instead.

The filtering algorithm, shown in Equation (11), averages 20 samples that meet the criteria. If the deviation exceeds the pressed height range, the output signal drives the electric actuator to adjust the boom position.

$$y'(k) = \begin{cases} y(k), & |y(k) - y(k-1)| \leq A \\ y(k-1), & |y(k) - y(k-1)| > A \end{cases} \quad (11)$$

In the equation, $y(k)$ represents the k -th sample value, $y(k-1)$ represents the $k-1$ -th sample value, A is the maximum allowable deviation between two successive sample values, and $y'(k)$ denotes the signal value after the k -th filtering process.

(3) Control logic of the contour levelling system

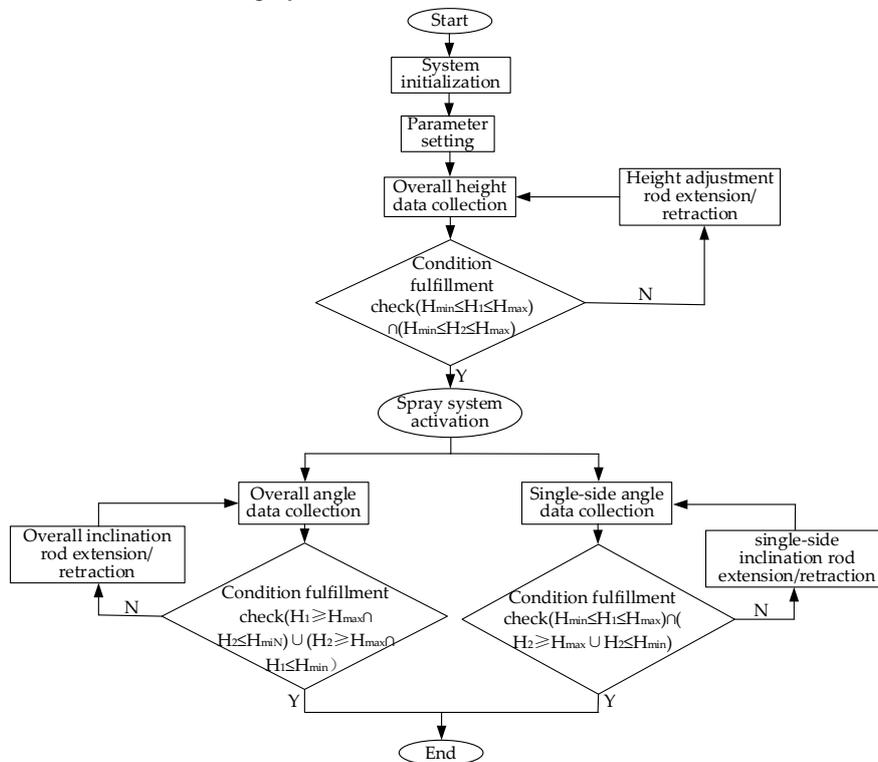

Fig. 8 - The terrain following levelling process

When the sprayer enters the field, the boom is fully extended, operator activates the ground contour levelling control system, upon entering the main program, the overall height of the crop canopy is first adjusted. If the heights on both sides do not fall within the preset range, the height adjustment rod drives the parallelogram lift mechanism to adjust the overall height of the boom. When both sides meet the preset height requirements, the spraying system is activated, and the sprayer enters the boom angle adjustment program. Angle adjustment includes both overall and single-side adjustments. If one side is below the minimum preset height and the other side is above the maximum preset height, an overall angle adjustment is performed, with the inclination rod adjusting the overall boom angle. If one side meets the preset height range while the other does not, a single-side angle adjustment is performed, with the inclination rod adjusting the angle of the single side. After adjustment, the system returns to the angle adjustment program for continuous monitoring. After spraying is completed, the ground contour levelling control system is turned off, the booms are adjusted to their initial extended state, and the booms are folded for transport.

(4) Experimental methods and procedures

The terrain in the field during the operation of the sprayer is complex and variable. To simulate the imbalance of the spray boom caused by field undulations, a stepped test site and a single-sided inclined surface were designed. To simulate the wheat plant height at different growth stages, the optimal preset distance between the spray boom and the crop canopy was adjusted. These three sets of experiments were used to verify the effectiveness of the spray boom ground contour levelling control system. After comparing the data from each experiment, the optimal threshold parameters for the control system were selected. To verify the designed spray boom's performance, spray tests were conducted in a wheat field. The spray boom ground contour levelling test methods and procedures are shown in Fig. 9.

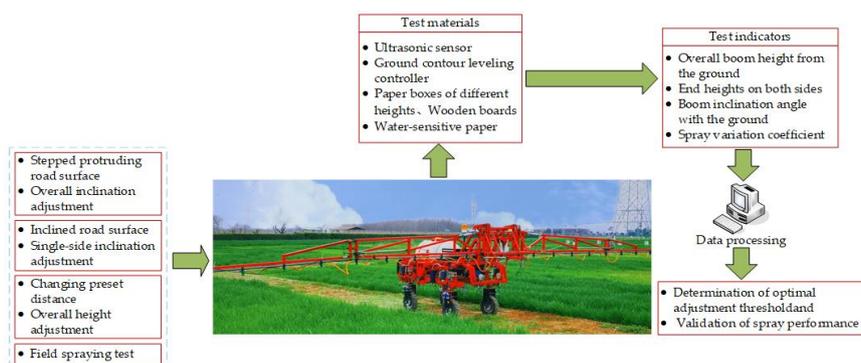

Fig. 9 - Spray boom ground contour levelling test methods and procedures

Experimental methods and condition settings

(1) Spray boom overall height adjustment experiment

During the wheat growth cycle, plant height changes continuously. If the spray boom height is not adjusted, excessive spray overlap can lead to over-spraying or missed areas. The overall ground clearance of the spray boom can be adjusted using a parallel four-bar lifting mechanism. However, due to the difficulty of altering wheat plant height, the performance of spray boom height adjustment was validated by changing the preset height of the spray boom relative to the wheat canopy. Before the test, the spray boom was fully extended and its initial ground clearance was adjusted. Controller parameters were modified to set the target height of the spray boom above the crop canopy at 400, 500, and 600 mm, with height adjustment thresholds set at 20, 30, 40, and 50 mm. After setting these parameters, the sprayer was driven at a constant speed in a straight line, and the ground contouring control system was activated. Once the spray boom height stabilized, the control system was turned off and the overall height of the spray boom was recorded.

(2) Stepwise field experiment

During field operations, undulations in the ground surface prevent the boom from maintaining a nearly parallel state relative to the application target. To simulate the inclination of the boom relative to the target during sprayer operation, a stepwise test surface was designed, as shown in Fig. 10.

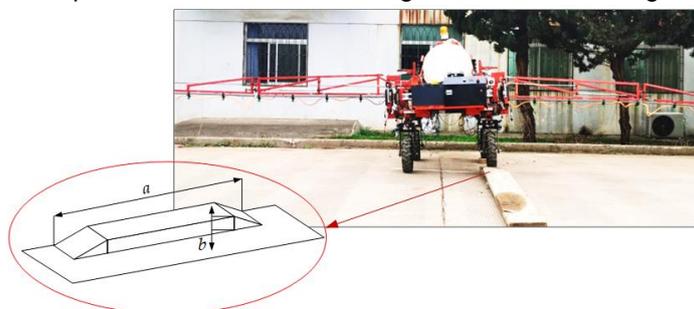

Fig. 10 - Stepwise field experiment

The designed boom has a maximum spray width of 9000 mm, and the sprayer's wheel track is 1200 mm. If the height b of the stepwise surface is set to 50 and 100 mm, and the length a is set to 5000 mm, the maximum tilt angle of the boom relative to the ground can reach 4.8° , causing a maximum displacement of 400 mm at the boom's end. To prevent collisions between the boom and the ground, the boom height was set to 700 mm, and adjustment thresholds were set to 20, 30, 40, and 50 mm. After stabilizing the boom height using the ground contour levelling system, the sprayer was driven over the stepwise surface at a constant speed of 8 km/h for four adjustment thresholds. After the front and rear right-side tires completely entered the highest point and the boom height stabilized, the control system was turned off. The heights of the boom ends on both sides and the tilt angle of the boom relative to the ground were recorded.

(3) Single-side inclination adjustment experiment

During field operations, the sprayer boom may encounter asymmetrical terrain within its coverage area. As shown in Figure 11(a), after overall tilt levelling, one side of the boom meets the spraying requirements, but the other side still fails to remain parallel to the application target. However, single-side tilt levelling can independently control the boom's posture on each side, as illustrated in Figure 11(b), enabling the boom to follow asymmetric terrain changes and maintain the optimal spraying height.

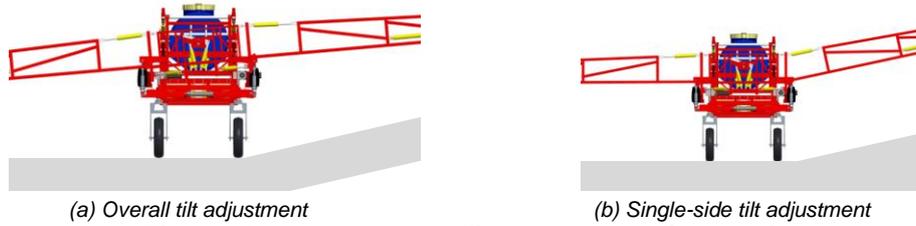

Fig. 11 - Boom contour levelling on asymmetrical terrain

The single-sided tilt adjustment test setup is shown in Fig.12, where a 10° tilted road surface was constructed beneath the right spray bar using wooden boards and cloth.

Fig. 12 - Single-sided inclination adjustment test

To prevent the spray bar from scraping against the tilted road surface, the height of the spray bar was set to 900 mm before the experiment. The adjustment thresholds were set to 20, 30, 40, and 50 mm, respectively. After stabilizing the height of the spray bar using the ground simulation levelling system, the sprayer was driven at a constant speed of 8 km/h over the tilted road surface at each of the four adjustment thresholds. Forward movement was stopped when the ultrasonic sensor detected the tilted road surface. After the spray bar height stabilized, the control system was shut down, and the angle of the right spray bar was recorded.

(4) Field spraying experiment

Water-sensitive papers were fixed to wheat plants at 25 cm intervals along the transverse direction of the spray bar to collect droplets (excluding the central 2 m of the road where the sprayer passes without wheat crops, totaling 24 water-sensitive papers). The spraying system was activated in advance to ensure that each nozzle reached the rated pressure when passing over the water-sensitive paper strip. The sprayer moved through the wheat field at a constant speed of 8 km/h. The power was turned off after the rear spray bar completely passed the water-sensitive paper strip. Once the water-sensitive papers dried naturally, they were collected into sealed bags (Liu et al., 2022). The droplet information was analyzed using the software ImagePy-master on the scanned water-sensitive papers. The experimental process is shown in Fig. 13.

Fig. 13 - Field spray test

RESULTS

The results of spray boom overall height adjustment experiment

The test results of spray boom overall height adjustment experiment are shown in Table 1.

Table 1

Results of the spray boom overall height adjustment test /mm

Target height	Adjustment threshold	Final stable height	Target height	Adjustment threshold	Final stable height	Target height	Adjustment threshold	Final stable height
/400	50	438	/500	50	531	/600	50	640
	40	420		40	517		40	626
	30	404		30	509		30	614
	20	instability		20	instability		20	instability

As shown in Table 1, when the height adjustment threshold is set between 30-50 mm, the boom profiling levelling control system stabilizes the boom height near the target value. As the adjustment threshold decreases, the overall boom height gradually approaches the target spraying height. However, when the adjustment threshold is set to 20 mm, overshoot occurs, causing the height adjustment rod to extend and retract repeatedly, failing to maintain a stable height. This instability is primarily due to the delay in the control system's input and output. The height adjustment rod maintains its previous action until it receives the next adjustment signal, leading to overshoot. Therefore, the adjustment threshold should be set to 30 mm for overall boom height adjustment.

The results of stepwise field experiment

The results of stepwise field experiment are shown in Table 2.

Table 2

Results of the stepwise field experiment

Step height/mm	Adjustment threshold/mm	Left end height/mm	Right end height/mm	Boom inclination angle/°
50	50	742	664	0.5
	40	729	675	0.35
	30	710	688	0.15
	20	/	/	/
100	50	746	670	0.5
	40	721	683	0.25
	30	714	684	0.2
	20	/	/	/

As shown in Table 2, the boom ground contour levelling control system effectively reduces the boom inclination caused by step surfaces. With different adjustment thresholds, the boom's inclination angle relative to the ground decreases as the threshold decreases. When passing over a 100 mm step surface, the boom inclination angle can be reduced to approximately 0.2°. However, with an adjustment threshold of 20 mm, an overshoot phenomenon occurs, causing the overall tilt push rod to repeatedly extend and retract, making it difficult for the boom to stabilize. The primary factor is the latency in the control system's input-output response, causing the overall tilt adjustment rod to maintain the previous adjustment action until the next signal is received, leading to overshoot. Therefore, the adjustment threshold should be set to 30 mm for the overall tilt adjustment of the boom.

The results of single-side inclination adjustment experiment

The results of Single-side inclination adjustment experiment are shown in Table 3.

Table 3

Results of the single-sided spray boom inclination adjustment test

Pavement inclination Angle /°	Adjustment threshold /mm	Right spray boom inclination angle /°	Relative error /%
10	50	9.2	8
	40	9.4	6
	30	9.6	4
	20	/	/

As shown in Table 3, the ground-following levelling control system for the spray bar effectively reduces single-sided spray bar inclination caused by uneven pavement. At different adjustment thresholds, the spray bar's inclination angle relative to the ground decreases as the adjustment threshold is reduced. When traversing a pavement with a 10° inclination angle, the single-sided spray bar can adjust to approximately 9.6°. However, when the adjustment threshold is set to 20 mm, the system experiences an overshoot phenomenon, causing repeated extensions and retractions of the single-sided tilt rod, making it difficult for the single-sided spray bar to achieve a stable state. To prevent instability caused by single-sided tilt adjustments after overall tilt adjustments, the single-sided tilt adjustment threshold is set to 40 mm.

The results of field spraying experiment

The results of the treatment of 24 water-sensitive papers were statistically analyzed. The papers on the left and right sides near the center of the road were labelled as Left 1 and Right 1, respectively. The results of the field spray test are shown in Tables 4 and 5.

Table 4

The results of the field spray test on the left side

Label	Droplet deposition coverage rate / %	Droplet deposition density / (Grain /cm ²)	Deposition amount / (μL/cm ²)
Left 1	33.44	179.33	1.26
Left 2	31.59	164.13	1.23
Left 3	35.63	172.64	1.21
Left 4	37.42	180.69	1.30
Left 5	38.71	175.38	1.25
Left 6	33.87	167.74	1.29
Left 7	39.64	181.42	1.35
Left 8	31.37	174.26	1.34
Left 9	35.79	183.97	1.27
Left 10	36.54	167.69	1.31
Left 11	34.46	171.56	1.26
Left 12	32.00	180.53	1.30

Table 5

The results of the field spray test on the right side

Label	Droplet deposition coverage rate / %	Droplet deposition density / (Grain /cm ²)	Deposition amount / (μL/cm ²)
Right 1	36.15	180.23	1.20
Right 2	34.20	168.19	1.26
Right 3	31.29	176.75	1.25
Right 4	35.49	184.46	1.31
Right 5	34.13	172.91	1.27
Right 6	34.85	183.10	1.29
Right 7	33.48	174.66	1.30
Right 8	35.69	178.43	1.29
Right 9	32.28	167.52	1.24
Right 10	37.51	171.67	1.32
Right 11	31.28	175.41	1.25
Right 12	30.66	180.42	1.34

Statistical processing was conducted on the spray test data from both sides of the nozzle to calculate the average fog droplet deposition coverage rate, the average fog droplet deposition density along the direction of the nozzle, and the coefficient of variation (CV) of deposition quantity. The results are shown in Table 6.

Table 6

Field spray test results			
Area	Average deposition coverage rate / %	Average deposition density / (Grain /cm ²)	Deposition variation coefficient (CV) / %
Left side	35.04%	174.90	3.1
Right side	33.92%	176.51	

As shown in Table 6, the average droplet deposition coverage rates on the left and right sides of the boom were 35.04% and 33.92%, respectively, and the average droplet deposition densities were 174.9 and 176.51 particles/cm², respectively. The relative errors in droplet deposition coverage and density between the two sides were minimal. The coefficient of variation (CV) of deposition along the boom direction was 3.1%, indicating that the sprayer exhibited good stability during field operations. The overall oscillation of the boom was minimal, ensuring uniform spray distribution.

CONCLUSIONS

(1) To ensure the optimal spraying height between the boom and the crop canopy, thereby improving spray quality, a five-section boom capable of ground contour following was designed. It includes a parallelogram lift mechanism, an overall tilt mechanism, and a single-side tilt mechanism. The boom height adjustment range is 360-1160 mm, the overall boom tilt angle range is -5° to 5°, and the single-side boom tilt angle range is 0° to 11°.

(2) A boom ground-following levelling control system was designed with the STM32F103ZET6 microprocessor at its core. This system employs ultrasonic distance sensors to detect the distance between the boom ends and the target objects in real-time. The microprocessor utilizes a limited amplitude averaging filter method to eliminate sudden signal interference and processes the feedback data to drive the electric actuators of each mechanism, thus adjusting the boom's position in real-time.

(3) A small electric self-propelled sprayer was used as the test platform to evaluate the performance of the boom ground-following levelling control system through various field tests. The results showed that the system performed best when the overall height adjustment threshold was set to 30 mm, the overall tilt adjustment threshold to 30 mm, and the single-side tilt adjustment threshold to 40 mm. The spray uniformity was assessed through field spray tests, which indicated that the relative error in droplet deposition coverage and density on both sides of the boom was minimal, and the coefficient of variation (CV) for deposition along the boom direction was less than 15%, ensuring good spray distribution uniformity.

ACKNOWLEDGEMENT

The research was funded by the Key R&D projects in Shaanxi Province (2024NC-YBXM-202, 2024NC-YBXM-244, 2023-YBNY-241).

Keywords: Greenhouse transplantation, Seedling planter, Contact stress distribution, Peak resistance

ABSTRACT

To explore the change law of contact stress distribution in the process of planting seedlings, the greenhouse transplanting equipment was developed to reduce labor intensity and improve the mechanization level of facility horticulture. This paper takes the direct insertion seedling planter as the research object, adopts the pressure distribution measurement system to study the soil stress distribution rule of different cross-section, digging depth and types of seedling planter. Both horizontal and longitudinal sections were obtained to show an increasing and then decreasing trend. The stress distribution is basically consistent at different digging depths, and the peak contact stress is roughly located at the center position. With the increasing of digging depths, the soil disturbance increases by the seedling planter and the hole tray seedlings, and the peak contact stress also shows a gradually increasing trend, leading to a gradual increase in the peak resistance of the seedling planter. The peak contact stress of the four opening seedling plant was higher than that of the three opening seedling plant. The main reason was that the soil disturbance of the four opening seedling plant increased, the peak contact stress distribution increased, and the peak resistance also increased. This study provides a basis for designing the greenhouse transplanters.

摘要

为探明栽苗过程中接触应力分布变化规律, 研制温室移栽机具, 降低劳动强度, 提高设施园艺机械化水平。本文以直插式栽苗器为研究对象, 采用压力分布测量系统研究了不同截面、不同入土深度和不同类型栽苗器的接触界面土壤应力分布变化规律。通过分析不同截面土壤应力的变化规律, 得出横向截面和纵向截面均是呈现先增加后减小的趋势。不同入土深度下接触应力分布基本一致, 接触应力峰值大致位于中心位置。随着入土深度的逐渐增加, 栽苗器、穴盘苗对接触界面土壤的扰动增加, 高应力区域占比逐渐增大, 接触应力峰值也呈现逐渐增加的趋势, 导致栽苗器的峰值阻力也呈现逐渐增大的趋势。四开口栽苗器的峰值接触应力大于三开口的栽苗器, 主要原因是由于栽苗过程中四开口栽苗器的土壤扰动量增加, 峰值接触应力分布增大, 导致峰值阻力也增大。该研究为温室移栽机具的设计提供参考。

INTRODUCTION

Seedling transplantation technology is beneficial for mitigating the impact of seasons on crops, making full use of light and heat resources, improving land use efficiency, and increasing the index of multiple cropping. With the development of seedling transplanting technology, the demand for automated greenhouse transplanting equipment is also increasing (Khadatkar et al., 2018; Jiang, 2017; Zhao et al., 2009).

At present, the change law of contact stress distribution during seedling planting is not clear, and the shape, size and operation parameters of seedling planter directly affect the contact stress distribution, and ultimately affect the planting quality. The research of greenhouse plant-transplanter has been reported abroad, mainly focusing on the effects of different seedling claws on transplantation efficiency and adaptability. These studies provide guidance for the development of greenhouse transplantation equipment (Kutz et al., 1987; Kutz, 1985; Paradkar et al., 2021; Ting et al., 1990).

Developed countries such as Japan, the United States, and Australia have developed greenhouse transplanting equipment, but its cost is high, the structure is complex, and the maintenance cost is high. It is not compatible with China's seedling cultivation technology and transplanting auxiliary operations, making it difficult to adapt to the Chinese market (Brewer *et al.*, 1994; Choi *et al.*, 2002; Simonton *et al.*, 1991; Rahul *et al.*, 2019).

In recent years, domestic scholars have also strengthened their research on greenhouse transplanting equipment. For example, Zhou *et al.*, (2009), designed an oblique wedge lever end effector, with a transplanting success rate of 76.11%. It designed a light and simple automatic transplanting machine, using two fingers and four pins to take seedlings, and transplanting experiments on 72 and 128 hole trays, respectively. The transplanting efficiency reached 1025 and 1221 plants/h, respectively, and the average transplanting success rate was 90.7% (Han *et al.*, 2016; Han *et al.*, 2015).

Cui *et al.*, (2022), designed an adjustable seedling end effector based on cylindrical cam, which can adapt to various transplanting operations with different spacing between hole trays. The success rate of transplanting is 93.33%, and the transplanting efficiency is 22 plants/min.

Tian *et al.*, (2010), designed a transplanting machine with four rows of seedling claws. The transplanting efficiency is 1800-2400 plants/h, and the transplanting success rate is 81.2%.

Yu *et al.*, (2023), designed an 8-row synchronous seedling picking mechanism with a success rate of 95% for transplantation.

Meng, 2021, developed a small space secondary clamping claw for taking seedlings, the average efficiency of transplanting was 4320 plants/h, and the success rate of transplanting could reach 97.22%.

Zhang *et al.*, (2023), designed a seedling end effector based on the principle of top clamp seedling picking, and achieved a success rate of 93.25% in seedling feeding. The pot has good integrity and meets the requirements for automatic transplanting and seedling retrieval of leafy vegetables in dry land.

In order to improve the mechanization level of facility horticulture, it is also urgent to study the change law of seedling planter, hole tray seedling and soil during the seedling planting process. Therefore, it is of great significance to study the change law of contact stress distribution in planting process to reduce planting resistance and improve planting efficiency.

The direct insertion seedling planter can quickly complete the planting of the hole tray seedlings and reduce the labor intensity. During the seedling planting process, there is an impact load between the seedling planter, hole tray seedlings, and the soil. Different soil physical properties, the structural parameters of the seedling planter, and specifications of the hole tray seedlings can affect the distribution of contact stress. It is difficult for the contact stress of soil in the theoretical state to accurately describe the stress in the complex field environment. The pressure distribution measurement system developed by the Tekscan in the United States is widely used to detect contact points and areas, contact interface shapes, and contact stresses (Komarnicki *et al.*, 2017; Stopa *et al.*, 2018). In this paper, the pressure distribution measuring system was used to carry out transplanting experiment with the direct insertion seedling plant, and the change law of soil stress distribution at the contact interface was studied under different factors. This study provides a basis for designing a greenhouse transplanter, reducing labor intensity, and improving the mechanization level of facility horticulture.

MATERIALS AND METHODS

Basic structure and motion analysis of the direct insertion seedling planter

The direct insertion seedling planter primarily consists of a tension spring, planting cylinder, pulling hook, and planting claw, as shown in Figure 1.

The planter has a height of 900 mm, a diameter of 76 mm. The planting claw opening is 140 mm in length. Its working principle involves the planting claw impacting the soil, while the puller drives the pulling hook to move the connecting ring upward. This motion causes the lower pulling hook to drive the planting claw, thereby facilitating the breakthrough of the soil. Once the seedling tray sinks to the bottom, the planting claw opens to release the seedling. The planter is then withdrawn, and the soil automatically backfills, completing the transplanting process.

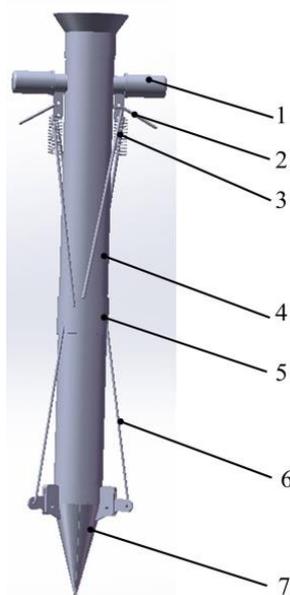

Fig. 1 – The 3D model of the direct insertion seedling planter.

Sensor deployment

The pressure distribution measurement system primarily consists of the 3150 flexible thin-film network tactile pressure sensor, along with handles, computers, and other components. The core of the system is the 3150 flexible thin-film grid sensors, as shown in Figure 2. This sensor is based on a matrix that incorporates a large number of horizontal and longitudinal conductors, intersecting to form an array of stress-sensing points (Hunston. 2002; Yang *et al.*, 2018; Li. 2020). The sensing area is 435.9 mm × 368.8 mm in length × width and 0.1 mm in thickness, with a thickness of 0.1 mm. The sampling frequency of the sensor is 0~100 Hz.

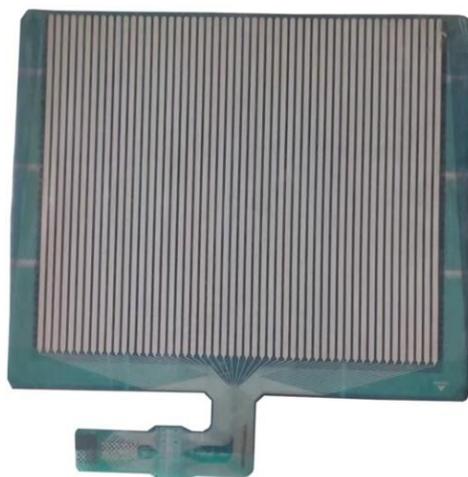

Fig. 2 - 3150 Flexible thin-film network tactile pressure sensor

To ensure the testing system records accurate data, the sensor is first calibrated. As shown in Figure 3, the sensor was placed in the middle of the black rubber pad and the transparent plastic sheet (L×W×H of 470 mm × 450 mm × 1 mm) before the test started. An acrylic frame is then placed on top. Soil is added to the acrylic frame (L × W × H of 470 mm × 450 mm × 170 mm) above the measurement system and compacted. The sensors are zeroed in preparation for the planting test.

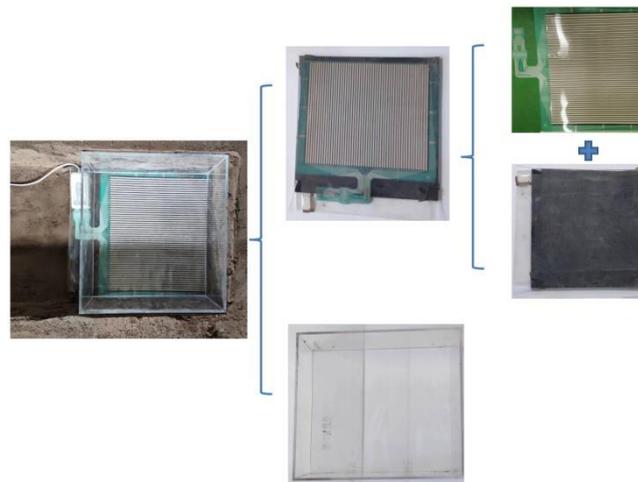

Fig. 3 - Installation of sensor

Test materials and equipment

The experiment was conducted in collaboration with Inner Mongolia Heyuan Agricultural Technology Co., Ltd., which cultivated 72 hole tray seedlings. The seedling substrate consisted of grass charcoal, vermiculite and perlite with a mass ratio of 3:1:1. The age of the seedlings was 30 d. The moisture content of the seedlings was measured between 58.78% and 62.47% using the DHG-9245A blower dryer. To study the soil stress distribution during the planting process of the direct insertion seedling planter, a contact stress distribution test bench was developed, as shown in Figure 4. The test stand mainly consists of a seedling planter, a pressure distribution measurement system, a computer and an acrylic frame. The test soil was a sandy loam and the measured soil moisture content ranged from 6.42% to 8.15%. The sensor needs to be calibrated before the test was started. The sensors were laid out in a fixed area, sieved for foreign matter such as clods and stones, and the completed sieved soil was filled into an acrylic frame and levelled off. Before testing, the sensor was calibrated, and sensors were laid out in a fixed area. The soil was sieved to remove foreign matter such as clods and stones, then filled into the acrylic frame and leveled. The sensor was zeroed before starting the test. At the end of the experiment, soil stress and pressure distribution data were retrieved from the I-Scan system. By analyzing the data at various moments and positions, the pressure distribution changes during the seedling planting process were examined. The soil compactness inside the acrylic frame was measured before each test, yielding values of 0-10 N/cm² at a depth of 100 mm.

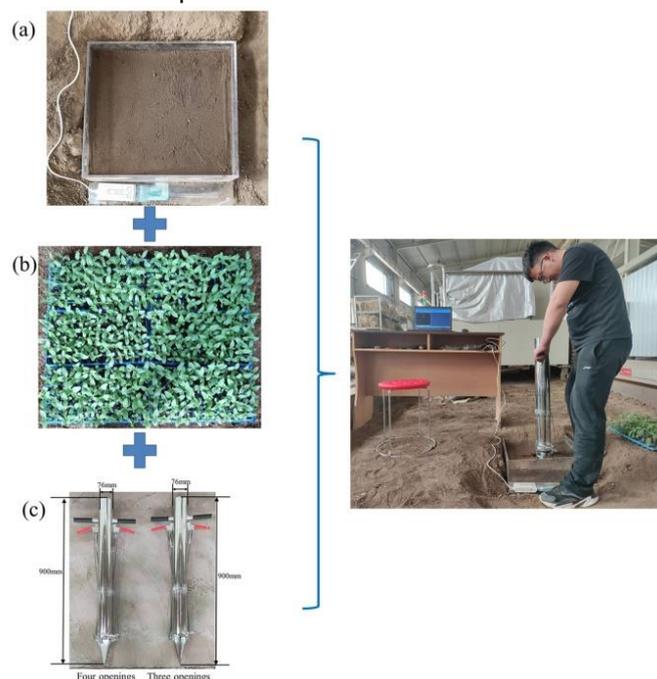

Fig. 4 - Soil stress distribution test at the contact interface during seedling planting process. (a) Sensor deployment; (b) Hole tray seedlings; (c) Different types of seedling planters

Test methods

This study investigates soil stress distribution during the seedling planting process by varying the soil depth within the acrylic frame and changing the type of seedling planter (three openings, four openings). Using a pressure distribution measurement system, peak contact stress and peak resistance pressure data were collected to analyze how soil stress distribution changes with different soil depths and planter types. The test factors and levels are shown in Table 1.

Table 1

Factors	Three axis dimensions of peanut seeds		
	Level		
	1	2	3
Digging depth[mm]	60	80	100
Type of seedling planter	Three openings		Four openings

RESULTS

Changing law of soil stress distribution in different cross sections during seedling planting process

The direct insertion seedling planter, configured with three openings and a 100 mm planting depth, was lowered at a constant speed during the planting test. A pressure distribution measurement system was used to monitor changes in soil stress at the contact interface. Low-stress areas are indicated by dark blue, high-stress areas by red, and areas with zero contact stress are colorless. Peak contact stress (Pmax) was obtained through the I-Scan system, with test results shown in Figure 5. When the soil depth of the seedling planter is 100 mm, its peak contact stress Pmax = 68 kPa. Due to the presence of a large number of horizontal and longitudinal conductors inside the sensor, it is necessary to analyze the changes in soil stress distribution during the seedling planting process in order to thoroughly study the changes in soil stress distribution at the horizontal and longitudinal sections. Both horizontal and longitudinal sections were obtained to show an increasing and then decreasing trend.

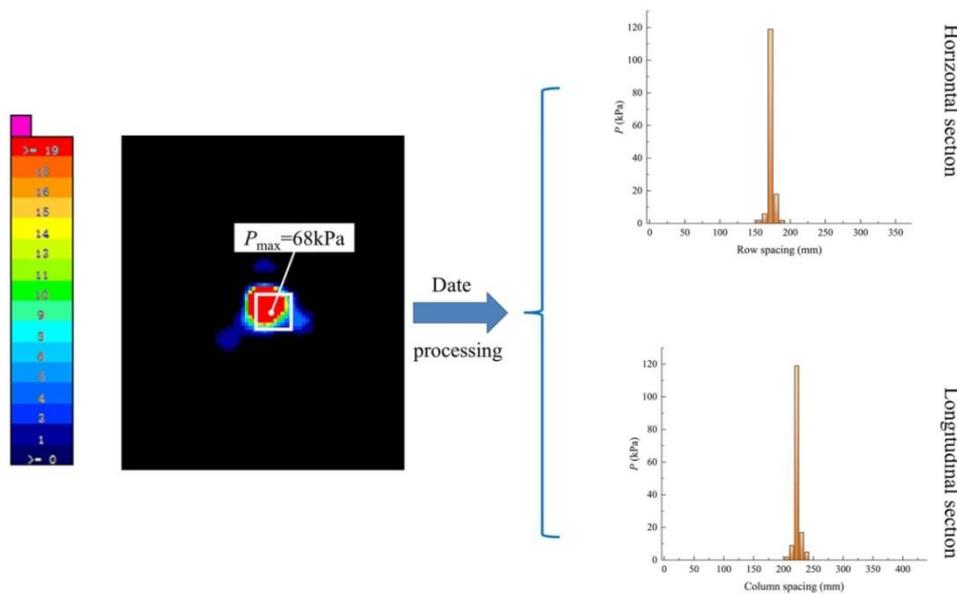

Fig. 5 - Variation of soil stress distribution in different cross sections

Effect of the contact stress distribution at different digging depths

The direct insertion seedling planter used in the experiment had three openings, with digging depths set to 60 mm, 80 mm, and 100 mm. The planter was lowered at a fixed rate during the planting tests. After the experiment, the data were processed using the I-Scan system, and the results are shown in Figure 6. The contact stress distribution remained largely consistent across different digging depths, with the peak contact stress (Pmax) generally occurring at the center.

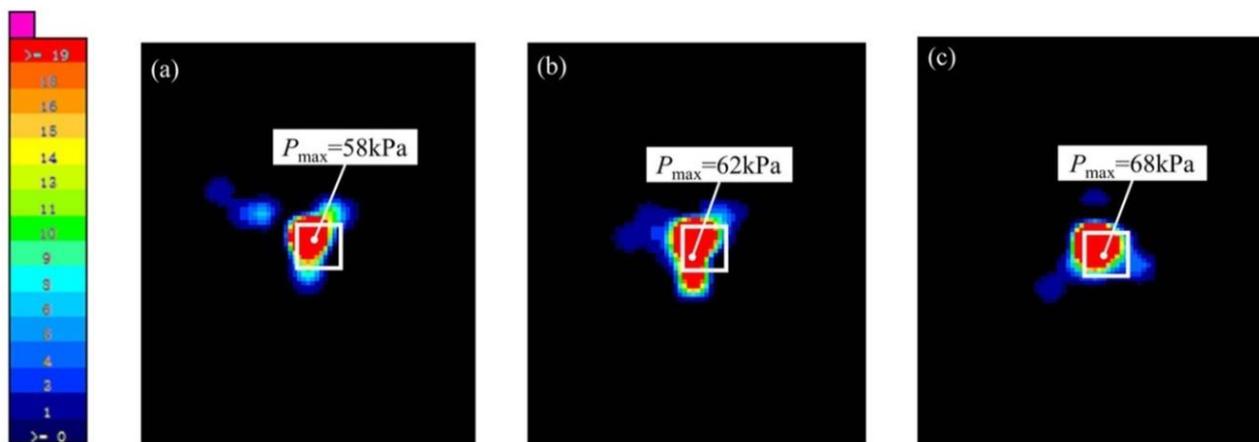

Fig. 6 - Variation of soil stress distribution at the digging depth. (a) Digging depth 60 mm; (b) Digging depth 80 mm; (c) Digging depth 100 mm

The direct insertion seedling planter compresses and shears the soil, causing soil particles to shift. At the same time, the planter experiences a reaction force from the soil, which represents the resistance encountered during planting. To further investigate the contact stress distribution, the variation in peak resistance at different digging depths was examined, as shown in Figure 7. As the digging depth of soil increases, the soil disturbance and the seedlings increases, the contact area gradually increases, and the peak resistance also shows a gradually increasing trend.

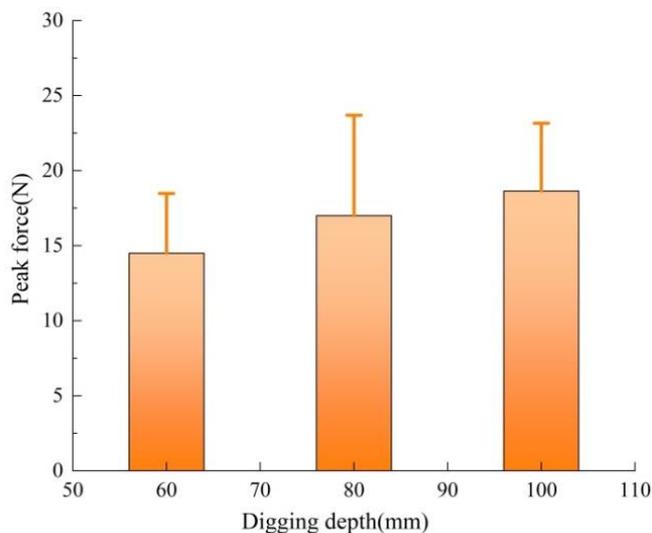

Fig. 7 - Variation changes of peak resistance at the digging depth.

Influence of contact stress distribution in different types of seedling planters

The digging depth of the direct insertion seedling planter is 80 mm, and the types of seedling planters are three or four openings. The planter is lowered at a fixed speed for seedling planting experiments. A pressure distribution measurement system was used to track changes in soil stress distribution. The experimental results are shown in Figure 8. The contact stress distribution in different types of seedling planters is basically consistent, and the peak contact stress (P_{max}) is roughly located at the center, with high stress areas occupying the main area. The peak contact stress of the four opening seedling planter is greater than that of the three opening seedling planter. The main reason is that the four opening seedling planter has more planting claws than the three opening seedling planter, which increases the soil disturbance, leading to an increase in the distribution of peak contact stress.

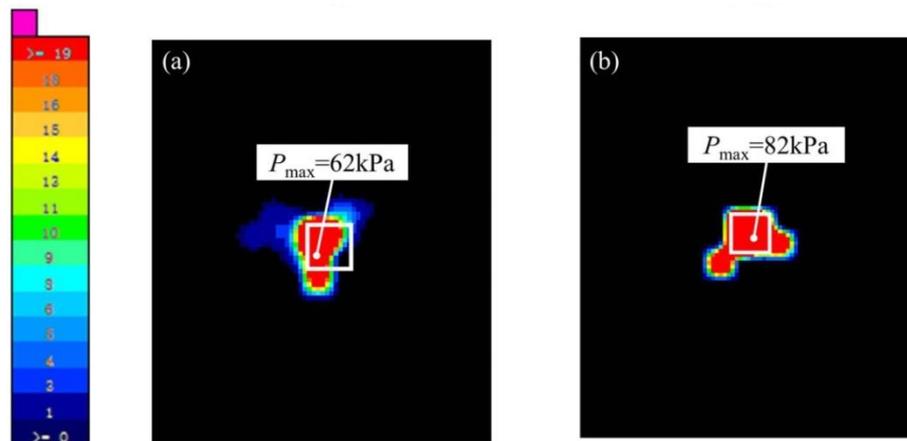

Fig. 8 - Variation of soil stress distribution in different types of seedling planters. (a) Seedling planter with three openings; (b) Seedling planter with four openings

To further study the contact stress distribution, it is necessary to study the variation of peak resistance of different types of seedling planters, as shown in Figure 9. The peak resistance of the four opening seedling planter is greater than that of the three opening seedling planter, mainly due to the increased soil disturbance caused by the four opening seedling planter during the seedling planting process, which increases the distribution of peak stress and leads to an increase in peak resistance.

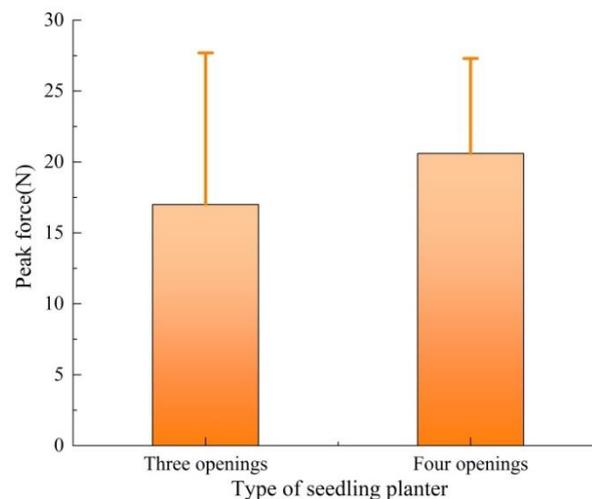

Fig. 9 - Variation changes of the peak resistance in different types of seedling planters

Discussion

This paper takes the direct insertion seedling planter as the research object, adopts the pressure distribution measurement system to study the soil stress distribution rule of different cross-section, digging depth and types of seedling planter. Both horizontal and longitudinal sections were obtained to show an increasing and then decreasing trend. The stress distribution is basically consistent at different digging depths, and the peak contact stress is roughly located at the center position. With the increasing of soil depth, the soil disturbance increases by the seedling planter and the hole tray seedlings, and the peak contact stress also shows a gradually increasing trend, leading to a gradual increase in the peak resistance of the seedling planter. The peak contact stress of the four opening seedling planter was higher than that of the three opening seedling planter. The main reason was that the soil disturbance of the four opening seedling planter increased, the peak contact stress distribution increased, and the peak resistance also increased. However, the labor intensity of the direct insertion seedling planter is still relatively high, and there are problems such as uneven depth during the actual seedling planting process, resulting in significant changes in the experimental data of soil stress distribution. Therefore, it is reasonable to choose the type of seedling planter and design the greenhouse direct insertion transplanter to reduce labor intensity and improve the mechanization level of facility horticulture.

CONCLUSIONS

This paper takes the direct insertion seedling planter as the research object, adopts the pressure distribution measurement system to study the soil stress distribution rule of different cross-section, digging depth and types of seedling planter. The main conclusions are as follows:

1) Both horizontal and longitudinal sections were obtained to show an increasing and then decreasing trend. The stress distribution is basically consistent at different digging depths, and the peak contact stress is roughly located at the center position. With the increasing of digging depth, the soil disturbance increases by the seedling planter and the hole tray seedlings, and the peak contact stress also shows a gradually increasing trend, leading to a gradual increase in the peak resistance of the seedling planter.

2) The peak contact stress of the four opening seedling planter was higher than that of the three opening seedling planter. The main reason was that the soil disturbance of the four opening seedling planter increased, the peak contact stress distribution increased, and the peak resistance also increased.

Keywords: Walnut shell-cracking, Radio frequency heat treatment, Mechanical properties, Moisture content, Compression tests

ABSTRACT

The mechanical properties of walnuts play an influential role in the process of walnut shell-cracking. To determine the optimal mechanical properties of walnuts, the effect of moisture content (MC) on the mechanical properties of walnuts was investigated. The results showed that Rupture force (F), Rupture displacement (D), and Rupture energy (E) of walnuts decreased proportionally with a reduction in the MC. To select an optimal pre-treatment for enhancing the mechanical properties of walnuts prior to shell-cracking, the effects of radio frequency (RF) and hot air (HA) heating treatment to change the mechanical properties of the walnuts were examined. The results indicated that the heating treatments of walnuts could lead to a brittle and easily breakable shell, with the F decreasing from 231.99 ± 34.31 N to 174.73 ± 24.89 N, the D decreasing from 1.68 ± 0.18 mm to 1.36 ± 0.13 mm, and the E decreasing from 207.31 ± 44.29 mJ to 119.47 ± 25.99 mJ. The mechanical properties of walnut shells are optimized to the best condition with the application of either a 2-minute RF treatment, a 3-minute RF treatment, or an 8-minute HA treatment. Notably, RF heating is significantly more time-efficient compared to the HA treatment. Quality evaluation indicated that there were no significant ($p > 0.05$) changes in color values, hardness, and brittleness between the heat-treated walnut kernels and the untreated walnut kernels. Overall, the results obtained from this study demonstrate that RF heating treatment is an effective method for optimizing the mechanical properties of walnuts prior to shell-cracking, and the results may provide guidance for the design and improvement of walnuts shell-cracking processes.

摘要

核桃的力学性能是影响核桃破壳效果的重要因素。为了获取最优的力学性能，研究了含水率对核桃力学性能的影响。结果表明，核桃的破壳力、破壳位移和破壳能均随着含水率的降低而降低。为了确定核桃破壳之前最佳的预处理方法，研究了射频(RF)加热处理和热风(HA)加热处理对核桃力学性能的影响。结果表明，加热处理使核桃壳变脆易碎， F 从 231.99 ± 34.31 N 降至 174.73 ± 24.89 N， D 从 1.68 ± 0.18 mm 降至 1.36 ± 0.13 mm， E 从 207.31 ± 44.29 mJ 降至 119.47 ± 25.99 mJ；其中，在 RF 2min、RF 3min、HA 8min 三种加热处理方法下，核桃的力学性能达到最优；并且与 HA 加热处理相比，RF 加热处理大大缩短了加热时间。品质分析结果表明，加热处理后的核桃和未处理的核桃仁的颜色值、硬度和脆性没有显著变化 ($p > 0.05$)。本研究的结果表明，RF 加热处理是优化核桃力学性能的有效方法，此研究结果可为核桃破壳工艺的设计和改进行提供指导。

INTRODUCTION

Walnuts (*Juglans regia* L.) are cultivated worldwide, with the global production of in-shell walnuts reaching approximately 3.87 million metric tons in 2022 (FAOSTAT, 2022). Walnut kernels, renowned for their significant medicinal value, are rich in a variety of unsaturated fatty acids, which have been shown to effectively reduce serum cholesterol, blood pressure, and the risk of heart disease (Guasch-Ferré, et al., 2017; Turek & Wszolek, 2021). The process of walnut shell-cracking is a pivotal step in the primary processing of walnuts, directly influencing the quality of the end product (Liu et al., 2021). There is a substantial price disparity among walnut kernels, with whole walnuts significantly outpricing their fragmented counterparts. This price gap is primarily attributed to the integrity of the walnut kernels; intact kernels fetch a higher market price due to their

superior quality and strong consumer demand. However, the task of cracking walnut shells presents a challenge, as they are predominantly composed of lignin and hemicellulose, which make them hard and resistant to breakage (Antreich *et al.*, 2019; Shi *et al.*, 2023). Moreover, the minimal gap between the shells and kernels complicates the separation process, hindering the achievement of a high whole kernel yield (Zhang *et al.*, 2022; Wang *et al.*, 2023).

Current studies on walnut shell-cracking methods primarily include multi-point extrusion (Zhang *et al.*, 2022), impact (Cao *et al.*, 2017), combined force (Wang *et al.*, 2024), and flexible-belt shearing extrusion (Liu *et al.*, 2016), among others. It is also possible to adjust parameters such as speed, angle and spacing to optimize the adaptability of the machine to different types and sizes of walnuts (Liu, *et al.*, 2021). However, the current technology for obtaining whole walnut kernels is not satisfactory and people continue to rely on manual labor to extract whole walnut kernels. Manual walnut shell-cracking methods are fraught with issues, including low processing efficiency, high costs, and concerns over food hygiene. Therefore, there is an urgent need for the development of equipment and methods that can achieve a high whole kernel yield.

Moisture content (MC) is a critical parameter in nut production, with studies demonstrating its significant impact on the rupture force, rupture energy, specific deformation, and elastic modulus of nut shells (Altuntas & Erkol, 2011; Maghsoudi *et al.*, 2012). In conventional engineering, heat treatment is a convenient, economical, and swift method to modify MC. Common heat treatment methods for agricultural products include hot air (HA) heating (Chen *et al.*, 2020), radio frequency (RF) heating (Mao *et al.*, 2021), microwave heating (Wang *et al.*, 2022), and other thermal processes.

RF energy, a non-ionizing form of electromagnetic waves ranging from 3 kHz to 300 GHz, generates heat through the frictional interaction of polarized molecules and charged ions within a product in response to RF fields (Ling *et al.*, 2023). As an emerging technology based on electromagnetic waves, RF heating possesses advantages such as high heating rates, volumetric heating, selective heating, and energy efficiency (Kou *et al.*, 2019; Zuo *et al.*, 2022). For tree nuts, such as hazelnuts and walnuts, RF heating has been applied for various purposes, including pasteurization (Zhang Ma, & Wang, 2021), disinfestation (Wang *et al.*, 2007), and drying (Wang, Tang, & Zhao, 2021). Concurrently, heat treatment can alter the mechanical properties of materials (Gao, Li, & Chen, 2023; Hao, *et al.*, 2021; Wang, *et al.*, 2020). Therefore, the effect of RF heating on the mechanical properties of walnuts warrants investigation and comparison with conventional HA heating.

Therefore, the objectives of this study were to (1) compare the effects of different MC on the mechanical properties of walnuts, (2) compare the changing in mechanical properties of walnuts under different heating treatments, and (3) evaluate walnut kernel quality under different heating treatments.

MATERIALS AND METHODS

Pre-Experiments Investigating the Impact of MC on Walnut Mechanical Properties

Walnut samples were procured from the Xinjiang Production and Construction Corps, with the cultivar selected being Wen 185. To mitigate moisture loss and damage to the walnuts, the green walnuts underwent drying and compression tests following the removal of the green husk and washing. The initial MC of the walnut shells was $31.30 \pm 2.14\%$ following the AOAC Official Method 925.40 (AOAC, 2002). A drying treatment was processed for the walnuts to obtain samples at different MC, then followed by compression tests to study the effect of MC on mechanical properties of walnuts.

For each HA drying experiment, the preset temperature was set at 60°C to ensure kernel quality (Man, *et al.*, 2024). Based on the experiments conducted on the relationship between MC and HA drying time, walnuts with HA drying times of 0, 4, and 10 hours were selected for compression experiments. After each HA drying session of the walnuts was completed, they were cooled to room temperature and compression tests were carried out immediately, with each test group repeated five times. The walnuts were dried to approximately 8% MC, placed in ziplock bags, and stored in a dry room for use in the subsequent part of the study.

Compression test and mechanical parameters

An electronic universal testing machine (DDL10, Changchun, China) was used for the compression test with an effective force range of 0–10 KN and a loading speed range of 0.01–1000 mm/min (Fig 1). The compression system mainly consists of a computer, a compression structure, and sensors. Upon commencement of the actual compression process, the deformation of the specimen induces varying forces. The sensors are capable of detecting these force and displacement changes, subsequently conveying this data to the computer for analysis.

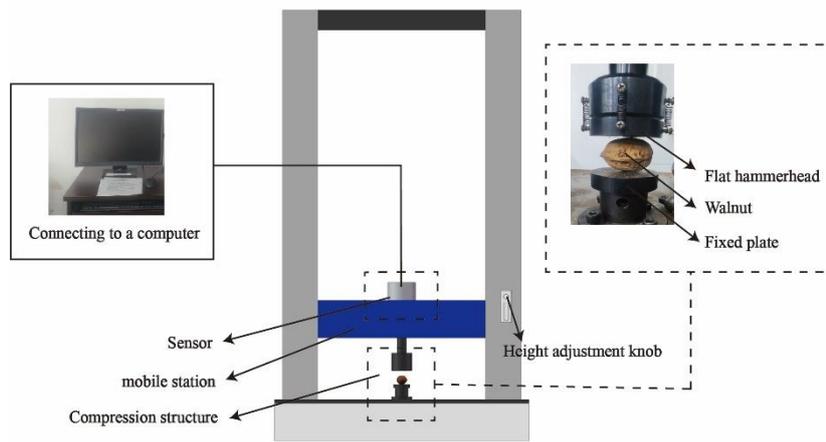

Fig. 1 – Schematic diagram of Mechanical Compression System

As depicted in Fig. 1, the compression experiment was conducted along the thickness direction of the walnuts. A flat hammer head was chosen for the compression, and the compression speed was set at 10 mm/min. Fig. 2 shows a typical force-displacement curve for compressed walnuts. It is evident from Fig. 2 that the compressive deformation process of the walnuts can be bifurcated into two distinct stages: an initial elastic deformation stage, prior to rupture, followed by a crack expansion stage post-rupture. The mechanical properties of walnut kernels are predominantly characterized by three parameters: rupture force (F), rupture displacement (D), and rupture energy (E). F (N) and D (mm) represent the force and displacement at the point of fracture, respectively, obtained from the data points exported from the electronic universal testing machine. The E (mJ) was determined from the chart by measuring the area under the force-deformation curves (Koyuncu, Ekinci, & Savran, 2004). By numerically integrating the force and displacement data points in the 0-D compression range derived from the electronic universal testing machine using the compound trapezoidal formula, the value of E can be derived as follows (Sauer, 2011):

$$E = \int_0^D f(x) dx \approx \frac{h}{2} \left(y_0 + y_m + 2 \sum_{i=1}^{m-1} y_i \right) \tag{1}$$

where:

D (mm) is the transverse coordinate of the rupture point, the value of m is the number of data points minus 1 in the 0-D interval for each set of compression tests, $h = D/m$, y_i (N) are the values of the longitudinal coordinates of each data point.

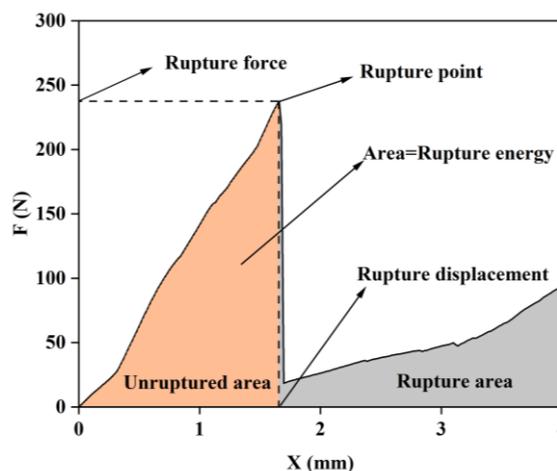

Fig. 2 – The classic force-displacement diagram of a walnut, showing the definitions of Rupture force (N), Rupture displacement (mm), and Rupture energy (mJ)

RF heating treatment

A 6 kW, 27.12 MHz free-running oscillator RF system (SO6B, Strayfield International, Wokingham, UK) associated with a HA system supplied by a 6 kW electric heater (Fig. 3) was used to heat walnuts (Wang *et al.*, 2010).

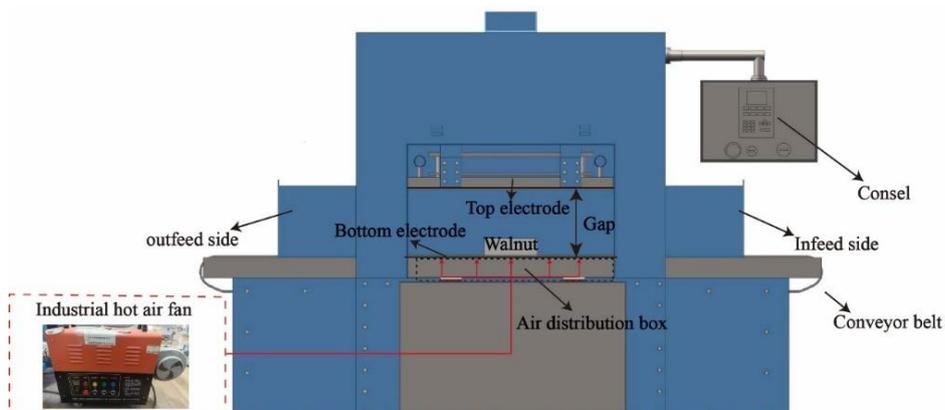

Fig. 3 – Schematic diagram of RF system

Approximately 750 g of the walnut samples were placed in a plastic container (300 mm × 250 mm × 80 mm) made of PP (Fig. 4a), which had a perforated bottom wall to allow HA to pass through the sample from the bottom, effectively expelling water vapor during the process. Before each heat treatment, the walnuts underwent a brief surface wetting procedure to clean and maintain them in the same initial conditions. According to the method proposed by Jiao *et al.* (2012), the electrode gap of 100 mm was selected for improve the evaporation of the water on the walnut surface. To obtain the optimum heating effect, the RF treatment time was carried out for 1, 2, and 3 min, respectively. To evaluate the effect of RF heating on the mechanical properties of walnuts, 15 walnuts were used in the compression test and labelled to occupy one quarter of the plastic container (Fig. 4b).

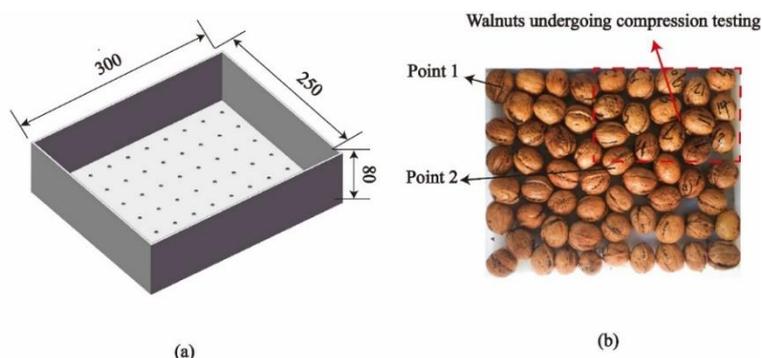

Fig. 4 – Arrangement of heat-treated walnut and fiber optic insertion point (a), shape and size of box (b) (mm)

Two methods were used to record the temperature during the heating process. Two probes of a six-channel fiber-optic temperature sensor system (HQ-FTS-D120, Heqi Technologies Inc., Xian, China) were inserted into two walnuts in the center of the vessel through pre-drilled holes in the walnut shells (Fig. 4b). The samples were photographed with an infrared thermographic camera (A300, FLIR System, NH, U.S.) to obtain the temperature distribution on the walnuts surface. After the walnuts had completed the RF heating, the samples were quickly removed from the RF chamber. The heated 15 labelled walnuts were then quickly transferred to an electronic universal testing machine for compression testing (approximately 15 minutes).

HA heating treatment

To evaluate the effect of HA heating on the mechanical properties of walnuts and compare it with RF heating treatment, an electrically heated blast heater (DGG-AGG-9030A, Shanghai, China) was used to heat the walnuts (Fig. 5). The temperature of 60°C was selected in the HA heating test same as the HARF heating (Zhang *et al.*, 2016). The walnuts were placed in plastic containers and the containers were placed in an electric radiation drying oven (Fig 5a).

The temperatures of the kernel and shell of walnuts were measured separately using a six-channel fiber-optic temperature sensor system and an infrared camera. Based on the thermal characteristics of HA heating, 8 minutes (the average temperature of walnut shells was not significantly different from that of RF heating for 2 minutes) was selected as the experimental temperature for comparison with the optimal treatment of RF heating. Similar to the RF heating treatment, 15 walnuts used for the compression experiment were placed in a quarter of the plastic container (Fig. 4b). When the HA heating of the walnuts was completed, the walnuts were quickly transferred to the electronic universal testing machine to complete the compression test (approximately 15 min).

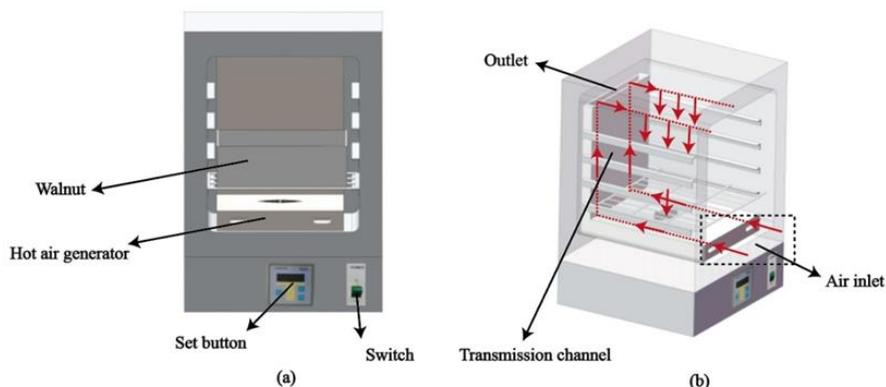

Fig. 5 – Schematic diagram of HA heating system

Evaluation of walnut kernels quality

The color of walnut kernel samples was measured with a computer vision system (CVS) reported before (Tang *et al.*, 2008). Photographs of the samples taken by the camera were utilized to capture the values of L^* , a^* , and b^* of samples as follows (Hou, Ling, & Wang, 2015; Kong *et al.*, 2007):

$$L^* = \frac{L}{2.5} \quad (2)$$

$$a^* = \frac{240}{250} a - 120 \quad (3)$$

$$b^* = \frac{240}{250} b - 120 \quad (4)$$

where:

L^* denote the brightness values of walnut kernels, a^* stand for the red-green values of walnut kernels, and b^* indicate the blue-yellow values of walnut kernels. The color values of walnut kernels from untreated, RF 1min, RF 2min, RF 3min, and HA 8min walnuts were measured using the aforementioned method on five separate occasions.

Hardness and brittleness of walnut kernels were determined using a texture analyzer (TA.XTC-18, Baosheng Industrial Development Co., Ltd., Shanghai, China) fitted with a TA/2 cylindrical probe (Jiao *et al.*, 2022). A quarter of the walnut kernels were placed on a flat surface, a compression test was applied using a cylinder probe, and a test speed of 1.0 mm/s. Texture properties were measured and calculated by the given software.

RESULTS AND DISCUSSION

Effect of water content

The changes in MC of walnut shells after HA drying are shown in Fig 6. The MC of walnut shells decreased as the drying time increased, with the drying rate gradually decreasing, which was in accordance with the typical drying curves of food and agricultural materials (Chen *et al.*, 2020). Walnuts were selected for compression tests with the MC of $31.30 \pm 2.14\%$, $14.27 \pm 1.99\%$, and $6.49 \pm 0.46\%$, corresponding to the drying time of 0, 4, and 10 hours, respectively. The results showed that the values of F, E, and D decreased significantly as the MC decreased (Fig. 7). This observation indicates that when the MC is high, the shell has a greater resistance to cracking. The lower MC tends to result in walnut shells with reduced mechanical properties, making them more susceptible to breakage. However, there was no significant changes between

the D and E values when the MC was below $14.27 \pm 1.99\%$. It can be concluded that the mechanical properties of walnuts do not change significantly at a certain level of MC and that further reduction of the MC of walnuts will only increase the cost.

Evaluation of RF heating treatment

Fig. 8 illustrates the heating profiles of walnuts at both the edge and center positions. The heating rate of the walnut at the edge is higher than at the center due to the edge effect of RF heating, which is consistent with the findings of other researchers (Dong *et al.*, 2023; Hou, Zhang, & Wang, 2021). After three minutes of heating, the highest temperature inside the walnut only reached $57.95^{\circ}\text{C} \pm 2.33^{\circ}\text{C}$, which helps to preserve the quality of the walnut kernels. From Fig. 9, it is evident that the *F* value significantly declined, whereas the alterations in *D* and *E* are less discernible, when the heating time is 1 min. This observation can be explained by the minimal water evaporation (approximately 46.77%) and the low surface temperature (approximately 44.06°C) of the walnut shells during the heating process. Consequently, the mechanical properties of the walnut shell remain largely unaltered. As shown in Fig. 9 (b) and Fig. 9 (c), the *D* value of walnuts were 1.66 ± 0.16 mm, 1.36 ± 0.13 mm and 1.39 ± 0.14 mm, and the *E* value of walnuts were 152.51 ± 40.81 mJ, 119.47 ± 25.99 mJ and 120.45 ± 29.28 mJ, subjected to the heating time of 1, 2, and 3 min, respectively. The mechanical properties of walnuts show no significant changes after more than 2 minutes of RF treatment. This may be due to the fact that the water on the surface of the walnuts was almost evaporated after 2 minutes (approximately 82.25%, no significant from the time of 3 min), and longer heating time did not significantly affect the mechanical properties of the walnuts. As shown in Figure 10, after 1 minute of RF treatment, the walnut surfaces displayed multiple low-temperature zones, indicating residual unevaporated water. As the treatment duration extended to 2 minutes, these low-temperature areas became inconspicuous, suggesting that the water on the walnut surfaces had substantially evaporated. This observation underscores the effectiveness of RF treatment in accelerating the evaporation process, efficiently removing water from the walnut surfaces.

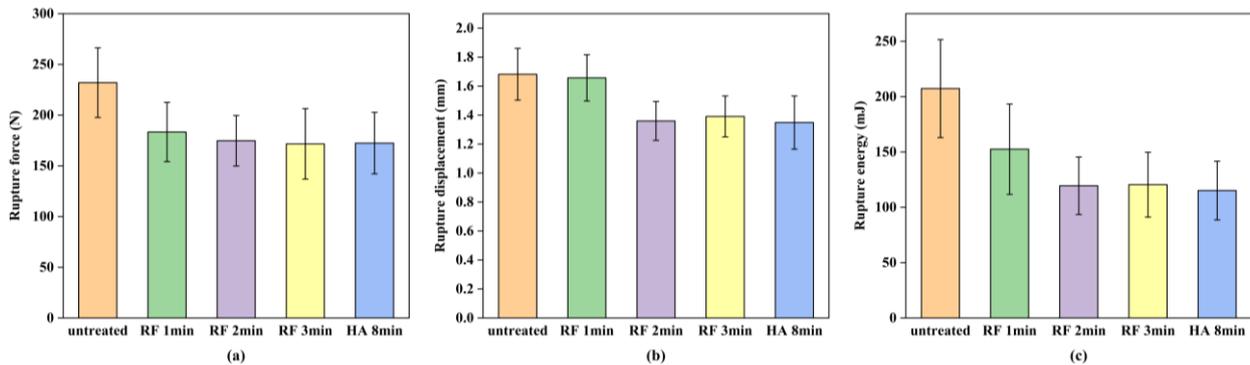

Fig. 9 – Changes in rupture force (a), rupture displacement (b) and rupture energy (c) after heating treatment (mean ± SD of fifteen replicates)

Comprehensive evaluation of HA heating and RF heating

In Fig. 8 and Fig. 11 it is demonstrated that RF heating achieves a higher heating rate compared to HA heating. The HA heating process requires 8 minutes to raise the average temperature of the walnut shell to about 50°C, whereas RF treatment accomplishes this in just 2 minutes. Table 1 shows the effect of different heating times for RF and HA on the mechanical properties of walnuts. According to the different mechanical properties of the walnuts, the walnuts were classified into three grades: A, B and C. Grade A (RF 2min, RF 3min, HA 8min): The mechanical properties of the walnut shells have been optimized to the greatest extent possible, resulting in a brittle and easily breakable shell. Grade B (RF 1min): An initial improvement in the mechanical properties of the walnut shells is observed, indicated by a significant reduction in F; however, there is no significant reduction in D, which is the factor most associated with kernel damage. Grade C (untreated): The walnuts remain untreated, resulting in tough shells that are difficult to break open to extract the kernels. Consequently, utilizing RF heating for 2 min represents the optimal pre-treatment strategy prior to the process of walnut shell-cracking.

Grade	C	B	A	A	A

(#Different lower-case letters within a row indicate that means are significantly different at $P < 0.05$ among different treatments.)

Quality evaluation

The quality of walnut kernels was analyzed. As demonstrated in Table 2, there was no significant effect on the hardness, brittleness, and color values of the walnuts ($p > 0.05$), when RF treatment was applied for 1, 2, and 3 minutes, or HA treatment for 8 minutes. This is because the heating time is short (less than 8 min) and the heating temperature is low (not exceed 60°C). RF heat treatment, which changes the mechanical properties of the shell, does not affect the quality of the kernel while changing the mechanical properties of the shell. This process is suitable for industrial applications.

CONCLUSIONS

The objective of this paper was to propose a method for optimizing the mechanical properties of walnut shells by a heating treatment. The results of the heating treatment experiments demonstrated that 2-minute RF, 3-minute RF, and 8-minute HA heating treatments were effective in reducing the *F*, *D*, and *E* values of walnuts. Among them, under 2-minute RF treatment, *F* decreased from 231.99±34.31 N to 174.73±24.89 N, *D* decreased from 1.68±0.18 mm to 1.36±0.13 mm, and *E* decreased from 207.31±44.29 mJ to 119.47±25.99 mJ, which will help to crack the walnut shells. Moreover, 2-minute RF can significantly reduce time costs compared to other methods, making it the optimal treatment process for walnut shell-cracking. The results of the quality analysis demonstrated that the 2-minute RF process had no significant ($p > 0.05$) effects on the hardness, brittleness and color values of walnut kernels, making it suitable for industrial application. Future research may be conducted to investigate the impact of RF heating on the performance of walnut shell-cracking machinery.

Keywords: Soybean Seeds, Moisture Content, Mechanical Properties, Breakage Rate, Mechanized Harvesting

ABSTRACT

This study addresses the issue of grain crushing during the mechanical harvesting of soybeans, systematically analyzing the effect of moisture content on its mechanical crushing characteristics. Single-factor and multi-factor orthogonal experimental methods were employed to record the grain crushing process through compression tests combined with high-speed camera technology, enabling a quantitative analysis of moisture content, loading speed, compression direction, and their interactions. Field experiments were conducted in five different planting areas. The results confirmed that when the moisture content was controlled within the range of 13% to 17%, the grain crushing force could be maintained at a stable level between 137 N and 182 N. Simultaneously, the crushing rate was reduced to a minimum value of $2.15\% \pm 0.43\%$, generally remaining within a favorable range of 1.09% to 3.34%. The research findings provide a necessary theoretical basis for improving the design of key components of harvesting machinery.

摘要

本研究针对大豆机械收获过程中的籽粒破碎问题，系统分析含水率对其力学破碎特性的影响，采用单因素试验和多因素正交试验方法，通过压缩试验并结合高速摄像技术记录籽粒破碎过程，对含水率、加载速度、压缩方向及其交互作用进行定量分析。在五个不同种植区域开展田间试验，结果验证当含水率控制在 13%-17% 范围内时，籽粒压破力能够保持在 137N~182N 之间的稳定水平，此时破碎率降至最低值 $2.15\% \pm 0.43\%$ ，总体维持在 1.09%~3.34% 的良好范围内。研究结果为改进收获机械关键部件的设计提供了重要的理论依据。

INTRODUCTION

Soybeans are a vital global source of oil and protein, holding an indispensable role in modern agriculture and the food industry (Anderson et al., 2019; Mariashibu et al., 2013). In 2023, the area dedicated to soybean cultivation in China reached 10.47 million hectares, yielding a total of 20.84 million tons. However, this production is insufficient to meet domestic demand, leading to substantial annual imports of 99.409 million tons (National Bureau of Statistics, 2024; Wang, 2024; National Agricultural and Rural Economic Operation, 2024). As global demand continues to increase, large-scale mechanized harvesting has become essential for enhancing efficiency and reducing costs.

Nevertheless, high seed breakage rates during mechanical harvesting significantly impact both harvest efficiency and product quality (Gao et al., 2010; Liu et al., 2017; Fernando et al., 2004). Research has demonstrated that seed moisture content is a critical factor influencing breakage, as it affects the mechanical properties of seeds and, consequently, their integrity during harvest (Chen et al., 2010; Krishnan et al., 2014). Therefore, improving soybean harvest quality, reducing seed breakage rates, and minimizing harvest losses to decrease import dependency have become particularly crucial objectives. Theoretically, lowering seed breakage rates is an effective strategy to enhance harvest quality, with current domestic mechanized harvesting exhibiting an approximate 5% breakage rate, highlighting an urgent need for optimization.

Domestic and international scholars have conducted extensive research that has yielded significant findings regarding the relationship between seed moisture content and mechanical properties. Waelti et al. (1969) pioneered the quantification of moisture content's impact on breakage rates through mathematical relationships, establishing a foundation for subsequent research. Chowdhury et al. (1975), in corn kernel studies, demonstrated that seed breakage rates increase significantly with rising moisture content, indicating

¹ Panpan Li, MS. Stud. Eng; Zheng Liu, Ph.D. Eng; Jin Wang, MS. Stud. Eng; Lulu Lv, MS. Stud. Eng; Anqi Jiang, MS. Stud. Eng; Han Yan, Stud. Eng; Chengqian Jin, Prof

that variations in moisture directly influence seed mechanical behavior. *Zhang et al. (2017)* further revealed that the chemical composition and moisture content of soybeans significantly affect their hardness, with moisture levels playing a crucial role in mechanical properties and breakage characteristics. Additionally, *Resende et al. (2013)* investigated the mechanical properties of brown rice and paddy under varying moisture contents, finding enhanced compression resistance at higher moisture levels, which highlights the key role of moisture content in determining the compression resistance of different crops. *Kang et al. (2021)* conducted compression tests to analyze the influence of moisture content on breakage rates across various soybean varieties, further expanding the application of moisture content in soybean harvesting processes. In other crop studies, *Dong et al. (2009)* discovered a negative correlation between moisture and mechanical properties within specific moisture ranges during mechanical tests on rice, providing valuable insights into understanding seed breakage behavior at different moisture contents. *Yang et al. (2015)* studied the friction characteristics of millet seeds, while *Qiu et al. (2019)* explored the effects of millet variety and moisture content on mechanical properties. *Teng et al. (2020)* investigated the influence of external factors on the mechanical characteristics of different soybean varieties. These research outcomes have enriched theories and provided a solid theoretical foundation.

Building on these research foundations, this study employs soybean seed moisture content as the primary experimental variable. Through systematic compression experiments, high-speed imaging technology is innovatively utilized to record seed breakage processes in real time, comprehensively analyzing the effects and interactions of moisture content, loading speed, and force direction on seed breakage rates. Furthermore, by combining field trial data from multiple cultivation regions, the practical impact of moisture content on seed breakage rates is verified, key mechanical properties are identified as evaluation indicators, and ultimately the optimal moisture content range is determined for minimizing breakage rates. Results indicate that controlling moisture content between 13% to 17% can reduce seed breakage rates to $2.15\% \pm 0.43\%$, which is significantly better than the current mechanized harvesting level of approximately 5%. This research provides a scientific basis for optimizing soybean mechanical harvesting parameters and improving harvest quality, while also offering important theoretical support and engineering references for enhancements in harvesting machinery component design. Ultimately, it achieves the goals of reducing seed breakage rates, minimizing harvest losses, and enhancing soybean harvest quality, contributing to a decreased dependency on soybean imports.

MATERIALS AND METHODS

Experimental Protocol

This study systematically investigates the effects of moisture content, loading speed, and force direction on the breakage characteristics of soybean seeds. Six distinct moisture content levels (8%, 10%, 14%, 19%, 23%, and 27%) were precisely prepared using drying and spray humidification methods. In the compression tests, moisture content, loading speed, and direction were established as experimental variables to comprehensively analyze seed breakage characteristics, with compression failure force serving as the evaluation index. Notably, high-speed imaging technology was employed to capture and record real-time dynamic changes during seed breakage, providing direct evidence for an in-depth analysis of seed breakage characteristics under varying conditions.

To ensure the scientific validity and reliability of experimental data, moisture content adjustments and measurements strictly adhered to the national standard "Grain and Oilseed Inspection - Moisture Determination Method" (GB/T 5497-1985) (*State Administration of Grain and Reserve, 1985*). Additionally, mechanical testing procedures followed to the American Society for Testing and Materials (ASTM) "Standard Practices for Force Calibration and Verification of Testing Machines" (ASTM E4-24) (*ASTM International, 2024*). During the moisture adjustment process, the amount of water to be added or removed was precisely calculated using the equation (1) (*Faryal Fatima et al., 2025*).

$$W = m \times \frac{M_t - M_i}{1 - M_t} \quad (1)$$

where: W represents the target water quantity to be added or removed; m represents the initial sample mass; M_t represents the target moisture content; M_i represents the initial moisture content.

Experimental Equipment

In this experiment, the PM-8188-A moisture meter, manufactured by KETT Corporation, USA (as shown in Figure 1(a)), was utilized to measure the moisture content of the samples. This device maintains a measurement error within $\pm 0.3\%$, ensuring precise moisture content measurements. To further enhance the reliability and representativeness of the data, each sample was measured five times, and the average value was recorded as the final result.

The mechanical testing system utilizes the Instron 3340 Series single-column tabletop universal testing machine, manufactured by Instron Corporation, USA, as illustrated in Figure 1(b). This equipment provides load and strain measurement accuracy within $\pm 0.5\%$, ensuring reliable support for the precise acquisition of mechanical data. The testing machine system primarily consists of the following core components: a Force Sensing System that measures the force applied to the sample, equipped with a built-in Force Sensor for accurate force data collection; a Controller that precisely adjusts the loading rate and monitors the entire testing process; and the Computer-Aided Data Acquisition and Display Unit, located on the left side of Figure 1(b), which facilitates real-time data acquisition, display, and storage, thereby making the experimental process and results more intuitive and manageable.

To achieve high-precision recording of the dynamic fracture behavior of soybean grains under applied force, the testing system incorporates a Phantom series high-speed camera manufactured by Vision Research Inc. (VRI), USA, as illustrated on the right side of Figure 1(b). This camera offers a high resolution of 1280×800 pixels and a maximum frame rate of up to 76,000 frames per second, ensuring comprehensive capture of the grain's transient fracture process. Furthermore, the system is equipped with specialized power source and control components to ensure stable operation of the entire setup and facilitate reliable data acquisition.

Experimental Methods and Procedures

In the soybean grain compression test, the stable loading and precise stopping of the upper indenter and fixed platform must be carefully controlled to ensure the reliability of the test data. As illustrated in Figure 2, soybean grains are positioned horizontally at the center of the fixed platform. Through precise manual adjustment, the upper indenter is gradually lowered until the gap between the indenter and the soybean grain is less than 5 mm. This predetermined gap helps form a stable contact surface at the beginning of loading, effectively reducing stress fluctuations caused by rapid loading. During compression, the high-speed camera's angle and position are adjusted to clearly capture the complete fracture process of the soybean grain under compression. This image capture technique not only records the progressive deformation characteristics of the soybean grain but also provides reliable, visual data support for subsequent force analysis and fracture mechanism studies. When irreversible morphological changes in the soybean grain (such as cracking or fracturing) are observed, the downward movement of the upper indenter is immediately stopped to prevent excessive fracturing from interfering with experimental data.

Figure 2 illustrates the force application on soybean grains from different directions, covering three typical modes of compression force application: (a) Vertical Compression, where the upper indenter applies force vertically onto the grain; (b) Lateral Compression, which simulates horizontal lateral compression acting on the grain; and (c) Symmetrical Horizontal Compression, achieving symmetric loading on the grain in the horizontal direction. For each compression mode, the deformation process of the soybean grain between the upper indenter and the fixed platform is visually presented using corresponding mechanical schematic diagrams. The design of these three different loading modes facilitates a comprehensive analysis of the fracturing behavior of soybean grains under various force conditions encountered during actual harvesting. This approach provides systematic experimental support for a multi-perspective analysis of the mechanical properties of soybean grains.

RESULTS

Analysis of the Single-Factor Effect on Crushing Force

In this experiment, the moisture content of soybean grains, machine loading speed, and compression orientation were selected as the primary test factors, with the crushing force of the grains serving as the evaluation metric. A systematic analysis was conducted to observe the variation patterns of crushing force under different conditions. A single-factor analysis approach was adopted, meaning that while keeping two other test factors constant, the working parameters of the factor under study were adjusted to perform compression tests. This approach enabled an investigation into each test factor's influence on the soybean grains' crushing force.

Based on the Compression Force-Displacement curve in Figure 3 and the staged images of a compression fracture in Figure 4, this study systematically analyzes soybean grains' force variation and fracturing behavior during the Symmetrical Horizontal compression process. High-speed imaging technology was used to fully capture the entire process from initial loading to final fracture, providing an intuitive basis for an in-depth exploration of the compression fracture mechanism of soybean grains. Figure 3 quantitatively displays the changes in crushing force with displacement across different stages. In contrast, Figure 4 presents the morphological evolution and internal structural changes of the grains at five critical moments, making the physical process of compression fracture more visually accessible.

The compression fracture process of soybean grains can be distinctly divided into five characteristic stages. In the initial non-contact stage (0–0.2 mm, Stage 1), as shown in Figure 4(a), the upper platen has not yet made contact with the grain, and the crushing force remains zero. Upon entering the initial contact stage (0.2–0.6 mm, Stage 2), as shown in Figure 4(b), the force-displacement curve exhibits slight fluctuations, and preliminary indentations appear on the grain surface. In the subsequent linear deformation stage (0.6–1.4 mm, Stage 3), as depicted in Figure 4(c), the force continues to increase, minor cracks form within the grain, and the force-displacement relationship shows a significant linear trend, indicating that the grain retains substantial structural rigidity. Upon reaching the unloading stage (1.4–1.6 mm, Stage 4), as illustrated in Figure 4(d), the applied force reaches a critical value (approximately 130–140 N), with prominent internal cracks developing, and localized collapse and separation occur. The crushing force begins to decrease, indicating a gradual loss of the grain's load-bearing capacity. In the final irreversible stage (1.6–1.8 mm, Stage 5), as shown in Figure 4(e), continuous pressure causes internal cracks to expand further, ultimately leading to complete structural failure. The force-displacement curve stabilizes, indicating that the grain has fully entered an irrecoverable fractured state. This process vividly illustrates the complete mechanical behavior of soybean grains, transitioning from elastic deformation to final fracture.

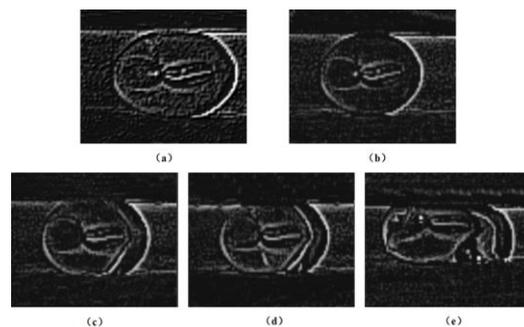

Fig. 4 - Staged images of Soybean Grain Compression Fracture Process

Effect of Moisture Content on Crushing Force

This experiment systematically investigated the impact of six different moisture content levels (8%, 10%, 14%, 19%, 23%, and 27%) on the crushing force of soybean grains, with the loading direction set to Symmetrical Horizontal compression and the loading speed maintained at a constant 30 mm/min. The Moisture Content-Crushing Force curve, is shown in Figure 5, visually depicting the trend in crushing force as moisture content varies. The curve reveals that, under low moisture content (8%), the crushing force reaches approximately 160 N, indicating a denser and harder internal structure with strong brittleness. Consequently, cracks propagate rapidly during compression, requiring a higher crushing force. As the moisture content rises to around 13%, the crushing force peaks at roughly 190 N, before dropping significantly to around 80 N as the moisture content continues to increase to 28%, exhibiting an initial increase followed by a decrease.

This trend is primarily due to changes in the internal structure of the grains caused by increasing moisture content. At lower moisture levels (8%-13%), moderate moisture increases the bonding force between cell walls, enhancing the overall strength of the grain. However, when moisture content rises beyond 13%, excessive water increases the grain's flexibility, leading to more plastic deformation under compression and thus a notable reduction in crushing force. This observation highlights the critical regulatory role of moisture content on the physical properties and compressive strength of soybean grains, offering a theoretical basis for determining optimal moisture levels for harvesting and processing.

Effect of Compression Orientation on Crushing Force

In this experiment, with the moisture content of soybean grains maintained at 14% and a loading speed of 30 mm/min, the influence of three different compression directions—Lateral Compression, Symmetrical Horizontal Compression, and Vertical Compression—on the crushing force was systematically studied. The Compression Direction-Crushing Force curve, plotted shown in Figure 6, clearly illustrates the trend in crushing force according to the compression orientation. From the curve, it can be observed that the crushing force is highest under Symmetrical Horizontal compression (approximately 186 N), followed by Lateral compression (approximately 175 N), and lowest under vertical compression (approximately 162 N). This demonstrates that variations in compression direction significantly impact the compressive strength and mechanical behavior of soybean grains.

The observed differences in crushing force are primarily due to the unique force characteristics and structural properties of soybean grains under each compression orientation. Under Symmetrical Horizontal compression, the platen applies force perpendicular to the cotyledon surfaces, with the direction of force aligned with the cotyledon's bonding interface. The large contact area and even distribution of force require a higher crushing force to induce fracture. In the Lateral compression state, the compression force directly acts on the cotyledon bond, causing cracks to initiate in the middle area of the cotyledons, leading to localized damage between the seed coat and cotyledons and thus requiring a relatively lower crushing force. In vertical compression, the force is concentrated at the top of the cotyledon bond, leading to a highly localized stress point that results in stress concentration near the embryo, making fracture easier and thus yielding the lowest crushing force.

Effect of Loading Speed on Crushing Force

In this experiment, with the moisture content of soybean grains fixed at 14% and the compression direction set to horizontal, the effect of three different loading speeds (10 mm/min, 30 mm/min, and 45 mm/min) on the crushing force was systematically studied. The Loading Rate-Crushing Force curve, shown in Figure 7, clearly illustrates the trend in crushing force with changes in loading speed. From the curve, it can be observed that at a loading speed of 10 mm/min, the crushing force is the lowest (approximately 140 N), indicating that at slower loading speeds, internal stress propagation within the grain is slower, making the structure more susceptible to damage under sustained pressure, thereby showing lower compressive strength.

As the loading speed increases to 30 mm/min, the crushing force significantly rises to around 185 N, an increase of 32.1%. This indicates that a higher loading rate accelerates stress transmission within the grain, requiring the grain to withstand greater pressure before fracturing. However, when the loading speed is further increased to 45 mm/min, the crushing force slightly decreases (to about 182 N), suggesting that at very high loading speeds, the grain's load-bearing stress reaches a stable limit, and further increases in loading speed do not significantly enhance crushing force. This finding reveals an optimal range of loading speed for maximizing crushing force: excessively low loading speeds reduce the grain's compressive performance, while excessively high speeds fail to further increase crushing force.

Interaction Analysis of Multiple Factors Affecting Crushing Force

To investigate the interactive effects of moisture content, compression orientation, and loading speed on the crushing force of soybean grains, a three-factor, three-level regression orthogonal experimental design was adopted in this study, with crushing force Y_1 as the evaluation index. As shown in Table 1, the experiment selected moisture content (A), loading speed (B), and compression orientation (C) as the main influencing factors, each set at three levels: -1, 0, and 1. Specifically, moisture contents were set at 8%, 14%, and 23%; loading speeds at 10 mm/min, 30 mm/min, and 45 mm/min; and compression orientations included vertical compression (2), symmetrical horizontal compression (3), and lateral compression (4). Each experiment was repeated five times, and the average value was used as the final result to ensure data reliability.

Table 2 provides the specific orthogonal experimental scheme and results, comprising 17 test combinations. From the results, it is evident that crushing force Y_1 varies significantly across different combinations of factor levels: the minimum value recorded was 43 N (Test No. 6, with high moisture content, medium loading speed, and vertical compression), while the maximum reached 198 N (Test No. 14, with all factors at the medium level). A comparison of the center point replicates (Test Nos. 13-17) shows that when all three factors are at the 0 level, the crushing force is relatively stable, fluctuating between 176 N and 198 N, with an average of 185.6 N. This suggests that under moderate parameter conditions, soybean grains exhibit good mechanical stability. Furthermore, the results reveal an important pattern: moisture content has the most significant effect on crushing force, followed by loading speed, with compression orientation having a comparatively minor impact. Under low moisture content conditions (-1 level), the crushing force remains generally high regardless of changes in loading speed and compression orientation. As moisture content increases to the 1 level, the crushing force significantly decreases, consistent with the results from the single-factor experiments.

Table 1

Experimental Factor Levels			
Level	Factor		
	Moisture Content [%]	Loading Speed [mm/min]	Compression Orientation
-1	8	10	2
0	14	30	3
1	23	45	4

Note: The numbers 2, 3, and 4 represent Vertical compression, Symmetrical Horizontal compression, and Lateral compression, respectively.

Table 2

Orthogonal Experimental Design and Results				
Experimental Number	A	B	C	Y_1
1	-1	-1	0	152
2	1	1	0	195
3	-1	0	-1	64
4	1	0	-1	43
5	-1	0	1	89
6	0	1	-1	184
7	0	-1	1	132

Experimental Number	A	B	C	Y_1
8	0	1	1	196
9	0	0	0	186
10	0	0	0	198
11	0	0	0	180

Note: A represents moisture content (%), B represents loading speed (mm/min), C represents compression orientation, and Y_1 represents crushing force (N).

Based on the experimental results in Table 2, variance analysis of crushing force was conducted using Design-Expert 10.0 software. The analysis results indicate that moisture content (A), loading speed (B), compression orientation (C), and their interactions significantly influence the crushing force of soybean grains ($P < 0.0001$), demonstrating that the established model has strong statistical significance. The second-order polynomial model obtained through regression analysis is shown in Equation (2):

$$Y_1 = 185.6 + 31.00 * A - 7.75 * B + 11.00 * C + 26.00 * AB + 1.50 * AC - 2.00 * BC - 63.30 * A^2 + 25.20 * B^2 - 54.80 * C^2 \quad (2)$$

where: A^2 , B^2 and C^2 are the quadratic terms of each factor; and AB , AC , and BC are the interaction terms between factors.

From the analysis of the regression coefficients, it can be observed that, in terms of linear effects, the coefficient of moisture content (A) is the largest (31.00) and positive, indicating that moisture content has the strongest positive influence on crushing force. The loading speed (B) coefficient is -7.75, showing a negative correlation with crushing force, while the compression orientation (C) coefficient is 11.00, suggesting a moderate positive impact on crushing force. In terms of interaction effects, the interaction coefficient between moisture content and loading speed ($AB = 26.00$) is the largest, showing a significant synergistic effect between the two. The interaction between moisture content and compression orientation ($AC = 1.50$) is weaker, while the interaction effect between loading speed and compression orientation ($BC = -2.00$) shows a slight antagonistic effect. For the quadratic terms, the absolute value of the moisture content's quadratic coefficient ($A^2 = -63.30$) is the largest, followed by compression orientation ($C^2 = -54.80$), with loading speed ($B^2 = 25.20$) being relatively smaller. This suggests the existence of optimal value points for moisture content and compression orientation concerning their effect on crushing force. This conclusion is corroborated by the specific experimental data.

Table 3

Analysis of Variance (ANOVA) for the Regression Model					
Crushing Force (N)					
Variance Source	Sum of squares	degree of freedom	mean square	F value	P value
Model	44476.06	9	4941.78	78.67	< 0.0001***
A	7688.00	1	7688.00	122.39	< 0.0001***
B	480.50	1	480.50	7.65	0.0279*
C	968.00	1	968.00	15.41	0.0057**
AB	2704.00	1	2704.00	43.05	0.0003***
AC	9	1	9.00	0.14	0.7163
BC	16.00	1	16.00	0.25	0.6293
A ²	16871.12	1	16871.12	268.59	< 0.0001***
B ²	2673.85	1	2673.85	42.57	0.0003***
C ²	12644.38	1	12644.38	201.30	< 0.0001***
Lack of Fit	156.50	3	52.17	0.74	0.5825

Note: *** indicates $P < 0.001$ (extremely significant), ** indicates $P < 0.01$ (highly significant), and * indicates $P < 0.05$ (significant).

The ANOVA results in Table 3 show that the factors of moisture content (A), compression orientation (C), and loading speed (B) all have a significant effect on the crushing force of soybean grains. From the F-values in the ANOVA, the overall F-value for the model is 78.67 ($P < 0.0001$), which is far above the critical value required for significance, indicating that the model has a high degree of reliability.

The F-values for the main effects are as follows: moisture content (A) is 122.39 ($P < 0.0001$), compression orientation (C) is 15.41 ($P = 0.0057$), and loading speed (B) is 7.65 ($P = 0.0279$), aligning with their influence on crushing force in the order of moisture content $>$ compression orientation $>$ loading speed. Among the interaction effects, the interaction between moisture content and loading speed (AB) is the most significant, with an F-value of 43.05 ($P = 0.0003$, extremely significant). In contrast, the interactions between moisture content and compression orientation (AC) and between loading speed and compression orientation (BC) are weaker, with F-values of 0.14 ($P = 0.7163$) and 0.25 ($P = 0.6293$), respectively, neither reaching significance ($P > 0.05$).

Examining the sum of squares from the variance sources, the total sum of squares for the model is 44,476.06 with 9 degrees of freedom, and a mean square of 4,941.78, indicating that the model effectively explains the major portion of the variability in crushing force. F-value analysis of the quadratic terms shows that A^2 has the highest F-value (268.59, $P < 0.0001$), followed by C^2 (201.30, $P < 0.0001$) and B^2 (42.57, $P = 0.0003$), all reaching extreme significance levels ($P < 0.001$), demonstrating the strong nonlinear effects of these three factors on crushing force. Specifically, the sum of squares for moisture content (A) is 7,688.00, and the sum of squares for A^2 is 16,871.12, further confirming the significant impact of moisture content on crushing force. The lack of fit sum of squares is 156.50 with 3 degrees of freedom, a mean square of 52.17, and an F-value of 0.74 ($P = 0.5825 > 0.05$), indicating that the lack of fit is not significant, which further validates the reliability of this regression model.

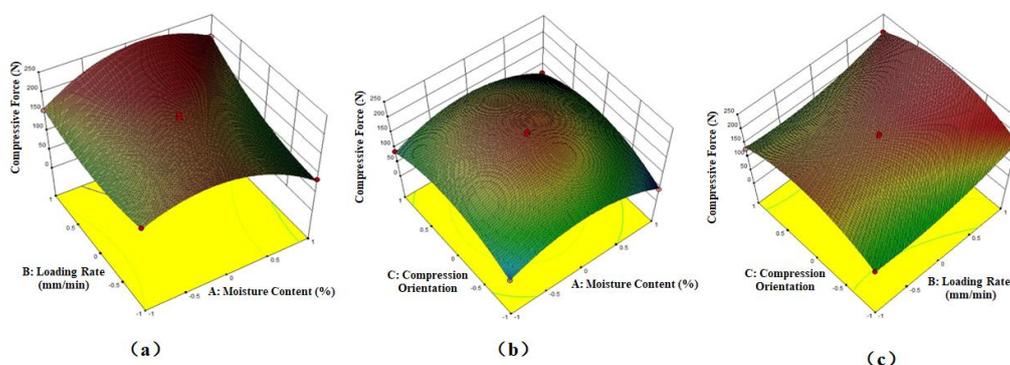

Fig. 8 - Interaction Response Surface of Soybean Seed Crushing Force

(a) Interaction between moisture content and loading speed; (b) Interaction between moisture content and compression orientation; (c) Interaction between compression orientation and loading speed.

Figure 8(a) illustrates the interaction effect between moisture content (A) and loading speed (B) on the crushing force of soybean seeds. When moisture content is fixed, the crushing force of seeds increases gradually with the rise in loading speed (B). This phenomenon can be reasonably explained by the increase in kinetic energy as the loading speed enhances, which in turn raises the crushing force. With a constant loading speed, an increase in moisture content alters the internal structure of the seed, making it softer, which leads to a trend where crushing force first increases and then decreases. As loading speed shifts from high to low levels while moisture content rises, the crushing force initially increases and then decreases noticeably. The response surface plot clearly shows that the maximum crushing force occurs at around 14% moisture content, indicating that a moderate moisture level helps preserve the structural integrity of the seeds. This significant interaction reflects the combined effect of moisture content and loading speed on crushing force.

Figure 8(b) demonstrates the interaction between moisture content (A) and compression orientation (C) on seed crushing force. At a low compression orientation level, an increase in moisture content leads to a decrease in crushing force, which is more pronounced than the effect of loading speed. As compression orientation shifts from a low to a high level, crushing force exhibits a trend of initially increasing and then decreasing. The undulations in the response surface indicate a nonlinear interaction between moisture content and compression orientation, with the interaction effect most evident at a medium compression orientation level. However, variance analysis reveals that this interaction has an F-value of only 0.14 ($P = 0.7163 > 0.05$), suggesting that although a trend is observable on the response surface, its impact is not statistically significant.

Figure 8(c) illustrates the interaction between compression orientation (C) and loading speed (B) on seed crushing force. When the compression orientation is at the 0 level, an increase in loading speed enhances the impact force, thereby increasing the crushing force. When both loading speed and compression orientation

reach high and low levels, respectively, the crushing force reaches its peak, as the machine's kinetic energy is maximized under high loading speed, with compression force primarily applied to the cotyledon surface, significantly increasing the crushing force. The response surface's overall shape suggests that compression orientation's effect becomes more prominent in high-loading-speed regions, highlighting a more significant interaction between the two factors under high-speed conditions. However, variance analysis shows that this interaction's F-value is only 0.25 ($P = 0.6293 > 0.05$), indicating that while observable on the response surface, it lacks statistical significance.

FIELD EXPERIMENT

Field Experiment Design and Preparation

The field experiment was conducted in strict accordance with national standards GB8097-2008 "Test Methods for Harvest Machinery Combine Harvesters" and GB/T 35488-2017 "Monitoring System for Combine Harvesters," ensuring compliance with regulatory requirements. The experiment site was selected at the high-standard soybean farmland testing base in Suixi County, Anhui Province (Figure 9 (b)). This site features fertile soil, well-developed irrigation facilities, and organized field plots, providing ideal conditions for the experiment. As shown in the images, the test plots are well-leveled, with uniform soybean growth and well-supported infrastructure, all contributing to the reliability of the experimental data.

For this experiment, the Lovol Gushen GM80 (4LZ-8M5) grain combine harvester was selected (Figure 9(a)). This model demonstrates strong adaptability and reliable operational performance. As shown in the image, the harvester is well-maintained, with a clean appearance and fully functional operation components.

Fig. 9 - Field Experiment Images

(a) GM80 combine harvester used in the experiment; (b) High-standard soybean farmland test base

Field Experiment Procedure

In this field experiment, the experimental area was first divided into five sections, each 10 meters long. On the first day of the experiment, soybean samples were collected from these sections at 8:00, 10:00, 12:00, 14:00, and 16:00, and the moisture content of each sample was manually measured. After that, a harvester was used to harvest the soybeans in each section at a speed of 4.4 km/h. Three groups of samples were randomly taken from the harvested soybeans and placed in sealed bags to prevent moisture changes, as shown in Figure 10, where (a) shows the experimental samples placed in sealed bags, ensuring the representativeness and sealing of the samples. Subsequently, the total mass of the soybean samples in each sealed bag was weighed one by one, and the corresponding weight data was recorded. The breakage rate analysis was conducted for each group of samples, manually selecting the broken soybean seeds from each group (as shown in Figure (b)), and weighing the mass of the broken parts. Figure (c) shows the weighing process of the broken seeds, ensuring the accuracy and reliability of the data. Finally, to determine the crushing condition for each sample group, the crushing rate was calculated using Equation (3) (Liu *et al.*, 2021) based on the actual data for each sample:

$$n = \frac{N}{M} \quad (3)$$

where: n represents the crushing rate of the seeds, N denotes the weight of the damaged seeds in the sample, and M is the total weight of the seeds in the sample. By analyzing the crushing rate of samples collected from various sections and time points, along with the sample total weight measurement process shown in Figure 10(d), a large amount of empirical data was obtained. This provides reliable foundational data to support the optimization of soybean harvesting processes and equipment, which is of significant practical importance in reducing seed damage during the harvesting process.

Field Experiment Data Analysis and Results

Table 4

Partial Field Experiment Data				
NO	Calibrated Moisture Content [%]	Damaged Soybean Mass [g]	Sample Mass [g]	Crushing Rate [%]
1	15.52	3.87	356.61	1.09
2	14.45	6.23	406.54	1.53
3	16.02	9.62	412.65	2.33
4	17.58	8.43	252.36	3.34
5	18.61	16.23	414.62	3.91
6	22.51	17.13	335.24	5.11
7	20.63	17.77	380	4.68
8	16.53	8.84	361.64	2.44
9	20.49	8.19	382.19	2.14
10	19.64	9.03	330.24	2.73
11	16.31	9.97	397.41	2.51
12	15.58	8.05	351.33	2.29

Analysis of the experimental data in Table 4 reveals that moisture content significantly affects seed breakage during mechanized harvesting. When the moisture content exceeds 17%, the breakage rate increases notably. For example, samples numbered 5, 6, and 7 have moisture contents of 18.61%, 22.51%, and 20.63%, with corresponding breakage rates of 3.91%, 5.11%, and 4.68%. In contrast, when moisture content is in the range of 13%-17%, the breakage rate remains low. For instance, samples numbered 1, 2, and 3 have moisture contents of 15.52%, 14.45%, and 16.02%, with breakage rates of only 1.09%, 1.53%, and 2.33%. Furthermore, the total mass of samples ranged from 252.36g to 414.62g, ensuring the reliability and representativeness of the experimental results, providing valuable data support for moisture content control in soybean mechanized harvesting.

In summary, to effectively reduce seed breakage during mechanical harvesting and minimize soybean harvest losses, it is recommended to enhance field environment monitoring before harvest. Harvest timing should be carefully managed, especially during humid weather or when rain is forecasted. Regular monitoring of seed maturity and weather conditions is advised to maintain the moisture content of harvested seeds within the 13%-17% range. Coupled with appropriate harvester settings and precise operating methods, this will significantly reduce the breakage rate, thereby improving harvest quality and reducing post-harvest processing losses.

CONCLUSIONS

Field trials confirm that the optimal moisture content range for harvest is 13%-17%, resulting in the lowest seed breakage rate (2.15% ± 0.43%). To ensure high harvest quality, it is recommended to operate in the afternoon on sunny days, maintain a harvesting speed of 3-5 km/h, keep the drum speed at 400-450 r/min, and regulate the feed rate at 4-6 kg/s. Considering regional differences, the recommended moisture content for southern regions is 14%-16%, while northern regions can maintain a range of 15%-17%. Field trials further

verify the significant impact of moisture content on seed breakage rates during mechanical harvesting. Tests conducted across different regions show that seeds with moisture content between 13%-17% exhibit lower breakage rates (1.09%-3.34%). These optimized parameter recommendations provide practical guidance for improving mechanized harvest quality, enhancing efficiency, and reducing harvest losses.

ACKNOWLEDGEMENT

This research was funded by the National Key Research and Development Plan project (2021YFD2000503), the National Natural Science Foundation of China (No. 32171911), the National Soybean Industry Technology System (CARS-04), and the CAAS Center for Science in Smart Agriculture and Equipment (CAAS-SAE-202301), the authors thank relevant scholars for their assistance in the literature.

Keywords: Fuel Rolls, Agricultural Crop Stem Biomass, flax, density, compaction pressure, Variable-volume Pressing Chamber

ABSTRACT

The paper develops a regression model to predict the density of Fuel Rolls produced from Agricultural Crop Stem Biomass. The study evaluates the influence of Variable-volume Pressing Chamber pressure (P , MPa), biomass volume per linear meter (V , m^3), and flax stem content (m , %) on Fuel Roll density (ρ). The goal is to optimize these parameters to ensure the desired density of Fuel Roll. A regression analysis combined with response surface methodology was employed. The optimal parameters for Fuel Rolls production include Variable-volume Pressing Chamber pressure of 0.45–0.55 MPa, biomass volumes of 0.65–0.75 m^3/m and flax stem content 75%. These technological parameters enable the production of fuel rolls with required density of 110–130 kg/m^3 . The results show that increasing pressure in the Variable-volume Pressing Chamber enhances Fuel Roll density, while larger biomass volumes lead to lower densities. Additionally, higher flax stem content improves cohesion and compaction, resulting in higher densities. These findings emphasize the importance of fine-tuning technological parameters to optimize Fuel Roll production. Utilizing agricultural crop stems for biofuel production offers significant environmental benefits, including reduced agricultural waste and lower combustion emissions.

РЕЗЮМЕ

У статті розроблено регресійну модель для прогнозування щільності паливних рулонів, вироблених із біомаси стебла сільськогосподарських культур. Дослідження оцінює вплив тиску камери пресування змінного об'єму (P , МПа), об'єму біомаси на погонний метр (V , m^3) і вмісту стебла льону (m , %) на щільність рулону палива (ρ). Мета полягає в тому, щоб оптимізувати ці параметри для забезпечення бажаної щільності паливного рулону. Було використано регресійний аналіз у поєднанні з методологією поверхні відгуку. Оптимальними параметрами для виробництва паливних рулонів є тиск у камері пресування змінного об'єму 0,45–0,55 МПа, об'єм біомаси 0,65–0,75 m^3/m і вміст стебла льону 75%. Ці технологічні параметри дозволяють виготовляти паливні рулони необхідної щільності 110–130 kg/m^3 . Результати показують, що збільшення тиску в камері пресування зі змінним об'ємом збільшує щільність паливного ролика, тоді як більші об'єми біомаси призводять до зниження щільності. Крім того, більш високий вміст стебла льону покращує когезію та ущільнення, що призводить до більшої щільності. Ці висновки підкреслюють важливість точного налаштування технологічних параметрів для оптимізації виробництва паливних роликів. Використання стебел сільськогосподарських культур для виробництва біопалива забезпечує значні переваги для навколишнього середовища, включаючи зменшення сільськогосподарських відходів і менші викиди в результаті згоряння.

INTRODUCTION

According to data (FAOSTAT, n.d.), approximately 400 million tons of agricultural plant stems are burned annually worldwide.

This practice leads to the emission of harmful substances such as solid particles (soot), nitrogen oxides, various carcinogens, and carbon monoxide, which contribute significantly to air pollution and degradation of the surface ozone layer. These pollutants exacerbate global climate change. That has been examined in depth by international researchers (Lan et al, 2022; Amann M., 2017, Milton Halder et al., 2023). To mitigate these negative effects, many scholars propose efficient methods for utilizing agricultural residues (Gatkal, N.R. et al, 2024; Kashytskyi V.P. et al, 2023). However, among the most effective solutions is the conversion of plant biomass into biofuels (Marian Gregory, 2016, Gageanu I. et al, 2022). Fossil fuels represent a limited energy resource that will eventually be exhausted. Over the past several years, the significance of environmentally sustainable biofuels has become increasingly apparent. Crop Stem Biomass is a potential renewable energy source, offers notable energy content per unit mass, albeit lower than that of fossil fuels (C.F.N, n.d.). Its utilization as a sustainable energy alternative is a growing focus of interest among researchers. (Mehmood Ali, et al., 2019, Jiang Y., et al, 2019). Although significant research has been conducted on the use of agricultural biomass for energy, there is still a lack of comprehensive studies addressing the specific technical challenges associated with compacting agricultural residues into small, high-density fuel rolls (FRs).

Solid biofuels not only address the disposal problem of agricultural residues but also serve as an eco-friendly energy source. A particularly economical and straightforward approach is the production of small-sized Fuel Rolls (FRs), designed for use in modern solid-fuel heating boilers (Yaheliuk et al., 2020). The biomass of various crops, including flax, corn, sunflower, and grain stems, can be effectively utilized for this purpose (Yaheliuk et al., 2021).

The property of crop stem biomass plays a critical role in its efficient conversion into biofuels. Key characteristics to consider include Elasticity, Strength, Viscosity, Moisture Content, Density, etc. (Hajlis G. 2004, Ibrahim Ayman, 2008, Goudenhoft C., 2018). Analyzing and accounting for these properties allow for the optimization of equipment settings, improving processing efficiency and the quality of the biofuel produced. Reducing the elastic properties of agricultural stems is an important step in improving the efficiency of biomass processing for biofuel production. High elasticity in stems can hinder effective compaction during the production of FRs or briquettes, as the material resists deformation and may spring back after compression. Didukh, V. suggested strategy to solve this issue (Didukh V. et al., 2022). This research continues this work by focusing on optimizing the pressing chamber design to minimize elasticity-related losses and ensure consistent compaction of small-sized FRs.

Despite significant achievements, there remains a clear research gap in the development of efficient technologies for converting Agricultural Crop Stem Biomass into high-quality solid biofuels. Existing research has mainly focused on large-scale pellet or briquette production, with limited attention to the specific challenges of producing small-sized FRs for decentralized energy systems. There is a lack of research on designing pressing chambers that can sustainably produce small-sized, high-density FRs and determining rational parameters for processing different types of stem biomass.

The determining quality indicators for small-sized FR are the twisting density of stem biomass and the dimensions of the roll. It is advisable to use a specially designed variable volume chamber for the production of small-sized FRs. In this case, the twisting density of the stem biomass depends on the pressure created by the rollers and the volume of a linear meter of the stem biomass tape that is fed into the Variable-volume Pressing Chamber.

The aim of this study is to investigate the effect of pressing parameters on the density of small-sized FRs and determine the optimal operating conditions for a variable volume pressing chamber to ensure high fuel efficiency.

The production of small-sized Fuel Rolls represents a promising direction for sustainable biomass utilization. By addressing existing technological gaps, this research seeks to improve the viability of biofuel production, contributing to cleaner energy solutions and reducing the environmental impact of agricultural plant residues.

MATERIALS AND METHODS

Experimental equipment was designed for research. It is a Variable-volume Pressing Chamber (VPC). The formation of small-sized FRs from the Agricultural Crop Stem Biomass (ACSB) and the determination of rational technological modes for obtaining small-sized FRs of the required density was studied with its help. The scheme of the Variable-volume Pressing Chamber for studying the impact of the compression force on the density of the obtained small-sized FRs is presented in Fig.1, a, the general view in Fig.1, b.

The ACSB (1) enters the VPC between the press rollers (2), which compress the material into a denser form. The tension springs (3) ensure that the rollers apply consistent pressure while the drive belt (5), powered by the engine (7), rotates the rollers. With each rotation of the compacting rollers (8), the action of the spring (3) increases. This allows obtaining a roll of a required density. The tension roller (6) ensures the drive belt stays taut, minimizing slippage and maximizing efficiency.

The result is compacted biomass in the form of FRs, suitable for use as biofuel. This design efficiently solves issues such as reducing elasticity in plant stems, achieving consistent compaction, and producing high-density FR. The density of the formed small-sized FR is determined by the force exerted on the biomass. Two tension springs are positioned to control compaction force (Fig. 1). The lower roller axis is mounted on the frame (4), ensuring stability and alignment during operation.

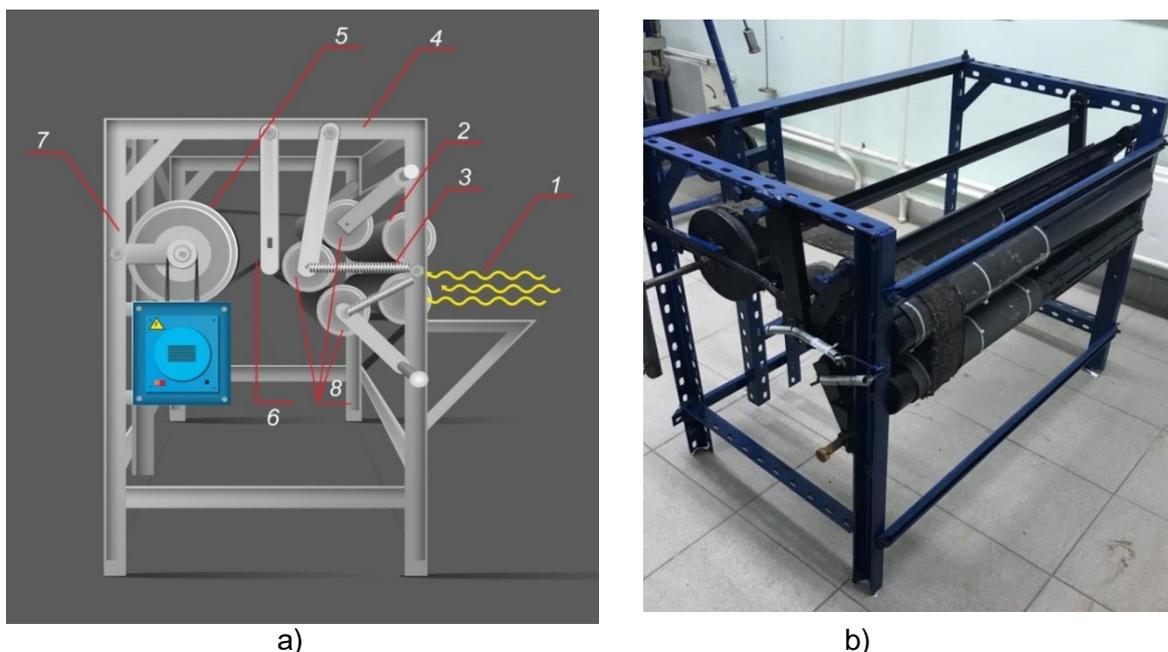

Fig. 1 – The Variable-volume Pressing Chamber (VPC) for the formation of small-sized Fuel Roll (FR) from the Agricultural Crop Stem Biomass (ACSB)

a – scheme, b – natural appearance:

1 – biomass of agricultural crop stems; 2 – press rollers; 3 – tension springs; 4 – frame; 5 – drive belt; 6 – tension roller; 7 – engine; 8 – compacting rollers.

The advantages of the VPC are:

1. Efficient Biomass Compaction. The system effectively addresses the challenge of reducing elasticity in plant stems, creating compact, dense small-sized FRs.
2. Adjustable Density. The tension springs provide flexibility to control the compaction force, allowing the production of rolls with required density.
3. Early Roll Formation. The minimum free space between the rollers at the beginning of twisting allows to form a roll from the first turns of rollers.

It was investigated (Yaheliuk *et al.*, 2019) that the operation of forming FR from the ACSB has such phases (Fig. 2):

- Initial Phase. The pressing rollers (2) compact the stem biomass (1) to form the base or "seed" of the FR. This phase has the shortest duration, as its purpose is simply to establish a FR starting point.
- Intermediate Phase (Roll Formation). The FR grows as layers of biomass are continuously wound and compacted in the pressing chamber. During this phase, the biomass is pressed further to achieve an intermediate level of density.
- Final Phase (Maximum Density). The tension springs (3) enable the compacting rollers (4) to adjust their position as the FR grows in size and density. The biomass is wound tightly to ensure maximum density, with the rollers continuously applying pressure. The springs allow the compacting rollers to move outward as the radius of the FR increases, maintaining consistent pressure throughout the process.

The rollers are designed to move outward to accommodate the increasing size of the FR, thanks to the flexibility provided by the tension springs (3).

For the production of FR, the biomass of wheat, rye, flax stems (ACSB) were used in different proportions as a raw material (Table 1). The stems were destroyed before twisting (*Didukh V. et al, 2022*). The initial relative humidity of the crop stem biomass material was 8.5-15%.

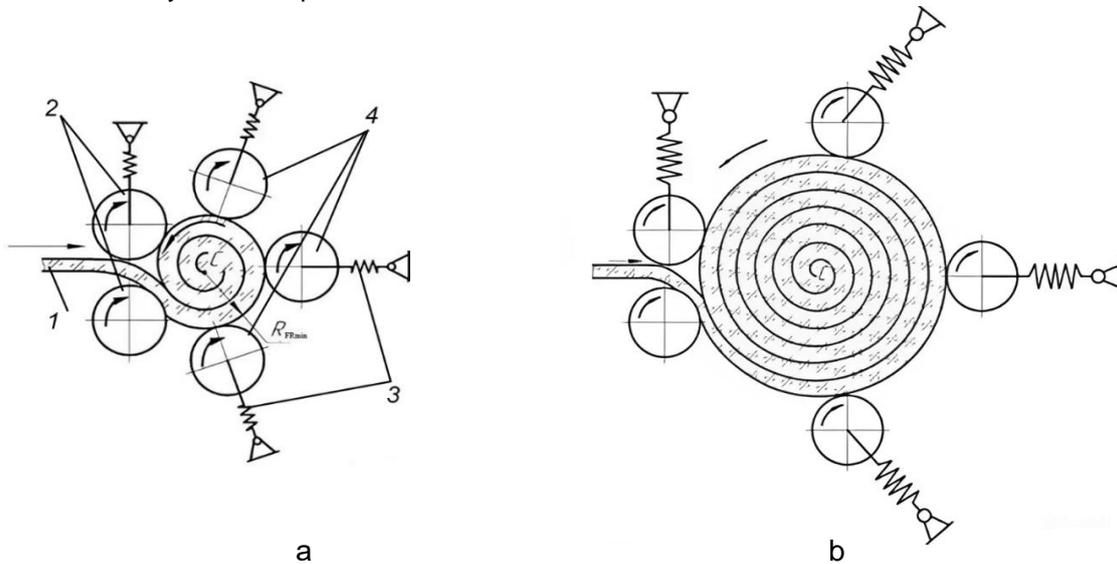

Fig. 2 – The scheme of the formation of FR from the ACSB in the VPC
a - the Initial Phase of the formation of the FR, b - the Final Phase of the formation of the FR:
 1 – biomass of agricultural crop stems; 2 – press rollers; 3 – tension springs; 4 –compacting rollers

The complexity of forming rolls from ACSB is associated with the elastic properties of plants. The stem mass obtained after the separation of seeds is not destroyed much under the action of the threshing machine. Therefore, its elastic properties are high. To preserve the shape of the roll, it is necessary to use binding agent (rope). But this is not permissible for small-sized FRs. Therefore, it is necessary, besides other, to use fiber stem materials, as flax stems, for the production of FRs.

Table 1

Content of flax stems in the Agricultural Crop Stem Biomass (ACSB)

ACSB	FR75/25	FR50/50	FR25/75
Flax stems, %	75	50	25
Wheat, rye, %	25	50	75

Fig. 3 – The FRs from biomass of agricultural plants stem:
 1 – FR25/75; 2 –FR75/25; 3– FR50/50

Density is a determining indicator of quality for FR. It affects the calorific value of FR, their transportation and storage.

The following technological parameters were determined to influence the density of FR: the pressure created by the rollers in the Variable-volume Pressing Chamber (P , MPa), the volume of a linear meter of ACSB fed into the VPC (v , m³), the content of flax stems in the ACSB fed into the VPC on the density of the obtained FR (m , %).

The study of the influence of the pressure in the pressing chamber of variable volume and the volume of a linear meter of the stem biomass of agricultural plants entering the pressing chamber on the density of the FR was carried out by the method of mathematical planning of the experiment. (Box G.E.P., Behnken D.W., 1960; Aziz R.A., Aziz S.A., 2018).

The purpose of the experiment was to determine the density of the formed FR while varying the technological parameters: the pressure created by the rollers in the VPC (P , MPa), the volume of a linear meter of the Agricultural Crop Stem Biomass, which is fed into the VPC (v , m³) and the content of flax stems in the ACSB fed into the VPC on the density of the obtained FR (m , %) (Table 2).

Table 2

Variables and Their Levels in Box-Behnken Design

Levels of variation	X, pressure P (MPa)	X2, volume of a linear meter ACSB V, (m ³)	X3, content of flax stems m, (%)
Upper (+1)	0.60	0.8	75
Main (0)	0.55	0.7	50
Lower (-1)	0.50	0.6	25
Range of variation	0.05	0.1	25

Table 3 shows the planning matrix of the three-factor experiment according to the Box-Behnken design (Box G.E.P., Behnken D. W., 1960). Matrix is presented in a coded format. The order of experiments was determined using a table of random numbers.

Table 3

Design of experiment

Run	Pressure P (MPa)	Volume of a linear meter ACSB V (m ³)	Content of flax stems m, (%)
1	1	1	0
2	-1	1	0
3	1	-1	0
4	-1	-1	0
5	1	0	1
6	-1	0	1
7	1	0	-1
8	-1	0	-1
9	0	1	1
10	0	-1	1
11	0	1	-1
12	0	-1	-1
13	0	0	0
14	0	0	0
15	0	0	0

The response function, representing the density of the FR, is expressed in the factor space as a nonlinear regression equation (1):

$$Y = b_0 + b_1 X_1 + b_2 X_2 + b_3 X_3 + b_{12} X_1 X_2 + b_{13} X_1 X_3 + b_{23} X_2 X_3 + b_{11} X_1^2 + b_{22} X_2^2 + b_{33} X_3^2 \quad (1)$$

where:

Y is the response (density of the FR, ρ), and X_1, X_2, X_3 are the coded variables for P, V , and m .

RESULTS AND DISCUSSION

As a result of the research (Table 4) data have been obtained on the density of the Fuel Roll (FR), ρ , kg/m^3 , that depends on the pressure created by the rollers in the Variable-volume Pressing Chamber (VPC), (P , MPa), the volume of a linear meter of the Agricultural Crop Stem Biomass (ACSB), which is fed into the VPC (v , m^3) and the flax stem content in the ACSB (m , %).

Table 4

Box-Behnken design scheme and the density of the FR response values

Run	P (MPa)	V (m^3)	m (%)	ρ (kg/m^3)
1	0.60	0.8	50	119.067
2	0.50	0.8	50	107.167
3	0.60	0.6	50	124.933
4	0.50	0.6	50	113.233
5	0.60	0.7	75	128.167
6	0.50	0.7	75	115.133
7	0.60	0.7	25	112.533
8	0.50	0.7	25	103.100
9	0.55	0.8	75	122.300
10	0.55	0.6	75	127.233
11	0.55	0.8	25	106.100
12	0.55	0.6	25	112.067
13	0,55	0.7	50	119.400
14	0,55	0.7	50	119.200
15	0.55	0.7	50	118.900

The experiment conducted according to the Box-Behnken design enabled the development of a mathematical model describing the dependence of FR density on technological parameters in the form of a regression equation. The results of three-factor experiments were processed according to a second-order, three-level design using a program developed in the Mathcad environment. The Box-Behnken experimental design allowed for an efficient investigation of the influence of three independent variables (technological parameters) on the response variable (density of the formed FR) (Montgomery C. Douglas, 2013). The regression model in coded factors is presented as follows (2):

$$\rho = 119.2 + 5.8X_1 - 2.8X_2 + 7.4X_3 + 0.9X_1X_3 - 2.6X_1^2 - 1.8X_3^2 \quad (2)$$

The homogeneity of the variance series was evaluated using the Cochran criterion. The calculated value $G_{res} = 0.19$ was compared to the tabular value $G_{tab} = 0.335$ (for $\alpha = 0.05$, $f_1 = 10$, $f_2 = 3$) and an alternative tabular value of 0.373. Since $G_{res} < G_{tab}$ it can be concluded that the experimental process is reproducible. The adequacy of the regression equation (2) was verified using Fisher's F -test. The calculated F -statistic value was $F_{res} = 16.196$, based on the variance of inadequacy $S_{nead}^2 = 1.026$ and the variance of reproducibility $S_y^2 = 0.063$. The tabular value of the Fisher statistic at a 5% significance level ($\alpha = 0.05$) with degrees of freedom $f_1 = 2$, $f_2 = 7$ was $F_{table} = 19.4$. Since $F_{res} < F_{tab}$ the regression model was confirmed to be adequate.

Using the given central levels ($P_0=0.55$ MPa, $V_0=0.7$ m^3 , $m_0=50$ %) and the corresponding ranges of variation ($\Delta P=0.05$, $\Delta V=0.1$, $\Delta m=25$), the regression equation in coded factors was converted into natural variables. The resulting equation, expressed in natural factors P (pressure, MPa), V (volume of a linear meter ACSB, m^3), and m (content of flax stems, %), is as follows (3):

$$\rho = -224.4 + 1240P - 28.5V + 0.19m + 0.72P * m - 1038.2P^2 - 0.003m^2 \quad (3)$$

This equation accounts for the scaling and centering of the factors, ensuring the model is directly applicable to the original experimental conditions. The regression coefficients reflect the influence of the natural variables on the response (density of the FR, ρ), making the equation suitable for practical interpretation and optimization. The response surfaces (Fig.4, a and Fig.5, a) and their contour plots (Fig.4, b and Fig.5, b) are constructed using the regression equation (3).

The response surface (Fig.4a) and contour plot (Fig.4b) illustrate the relationship between the density of FR and two variables: the pressure applied by rollers in the (P , MPa) and the volume of a linear meter of ACSB (V , m³) fed into the chamber. The response surface shows a clear trend where increasing the pressure in the pressing chamber (P) leads to a significant increase in the density of the FR.

This is evident from the upward slope of the surface as pressure values increase. Conversely, increasing the volume of biomass (V) tends to decrease the density, as represented by the downward slope of the surface in the direction of larger biomass volumes. This interplay indicates that higher pressure compresses the material more effectively, while larger volumes of biomass tend to resist compression, leading to lower densities.

The contour plot (Fig.4b) provides a detailed view of how combinations of pressure and biomass volume influence density. The interaction between pressure and biomass volume indicates that maintaining a moderate biomass volume (around 0.6–0.7 m³) while increasing pressure to values near 0.58–0.6 MPa yields the highest density. This is important for achieving FR with structural integrity, as density directly correlates with combustion efficiency and energy potential.

*a – response surface; b - contour plot of the response surface:
 1 – $V=0.6$ m³; 2 – $V=0.7$ m³; 3 – $V=0.8$ m³*

The images (Fig. 5 a, b) showcase visualization of a study analyzing the dependence of FR density (ρ) on the pressure (P , MPa) exerted by rollers in a VPC and the flax stem content in FR (m , %) for three different material compositions: FR75/25, FR50/50, and FR25/75. For all material compositions, the density increases with higher rollers pressure (P). The FR75/25 composition, which has a higher proportion of flax stems, results in higher densities compared to FR50/50 and FR25/75 under similar conditions. This is due to the fibrous nature of flax, which enhances material cohesion during compression.

The contour plot (Fig.5 b) provides a top-down view of the response surface, showing density lines as a function of P and V . These contours clearly illustrate how the density changes within the defined parameter space. The spacing of the contour lines suggests that the effect of increasing P on ρ becomes less pronounced at higher pressures, indicating at a potential saturation point in compaction efficiency.

The studied (*C.F.N, n.d.*) data show (Table 5) that flax stems are a good source of biomass energy with an energy potential of 18 MJ/kg. Compared to traditional fossil fuels such as coal (22 MJ/kg) or fuel oil (37 MJ/kg), this is less. However, such an energy potential of flax stems makes it possible to compare flax-based FR with wood fuels (16-20.5 MJ/kg).

Flax and wheat straw are structurally similar and possess the same energy value, making them compatible for mixing. This compatibility ensures uniform energy production, which is critical for efficient combustion. Additionally, their fibrous nature enhances mechanical properties such as cohesion and density when compressed into fuel rolls. The abundant availability of these materials as by-products of agricultural processes provides economic and environmental benefits, as their use for energy production reduces waste while offering a sustainable energy source.

Table 5

The energy potential of various types of sources (*C.F.N, n.d.*)

Sources	Traditional sources of energy		Agriculture biomass							Wood biomass			
	Hard coal	Fuel oil	Corn	Flax stem	Wheat straw	Sunflower stem	Rape pomace	Sunflower husks	Cotton stems	Basket willow	Poplar	Beech	Fir
Energy potential, MJ/kg	22	42	15	18	15	15	19	18	17,5	18,5	16	18	20,5

The study presents a regression model for predicting the density of fuel rolls (FRs) produced from agricultural crop stem biomass (ACSB). To ensure efficient production of FRs from ACSB, the following technological parameters are recommended:

1. Compaction Pressure in the Variable-Volume Pressing Chamber (VPC). Recommended pressure ranges for different blends are:

- FR75/25 (75% flax stems, 25% other materials): 0.50–0.55 MPa;
- FR50/50 (50% flax stems, 50% other materials): 0.45–0.55 MPa;
- FR25/75 (25% flax stems, 75% other materials): 0.40–0.50 MPa.

Higher flax stem content requires slightly higher pressures to achieve uniform density due to its fibrous structure. Within these pressure ranges, densities of 110–130 kg/m³ can be achieved, meeting mechanical stability and energy performance requirements.

2. The volume of a linear meter of the Agricultural Crop Stem Biomass. Optimal biomass volumes for achieving the required density without compromising material cohesion or creating excessive porosity are:

- FR75/25: 0.7–0.75 m³;
- FR50/50: 0.65–0.7 m³;
- FR25/75: 0.65–0.7 m³.

By maintaining compaction pressures of 0.45–0.55 MPa, biomass volumes of 0.65–0.75 m³ of a linear meter of the ACSB, and rational blending ratios of flax stems with complementary biomass, fuel rolls can achieve densities of 110–130 kg/m³ and energy potentials of 16–18 MJ/kg. These optimized parameters ensure a balance of mechanical strength, energy efficiency, and resource sustainability, positioning flax-based FR as a competitive and eco-friendly option for bioenergy production.

CONCLUSIONS

The study highlights the significant potential of agricultural crop stem biomass (ACSB) as a sustainable and environmentally friendly resource for biofuel production. By optimizing technological parameters, it is possible to produce small-sized Fuel Rolls (FRs) with high density and substantial energy potential. Regression analysis indicates that achieving densities between 110 and 130 kg/m³ requires compaction pressures of 0.40–0.55 MPa and feed volume of 0.65–0.75 m³ of a linear meter of the Agricultural Crop Stem Biomass depending on the blending ratio of flax stems with other biomass materials. Higher flax stem content, due to its fibrous properties, demands increased pressure to ensure uniform density and material cohesion.

Flax-based FRs have energy potentials of 16–18 MJ/kg, comparable to wood fuels and sufficient for modern solid-fuel heating systems. The introduction of the Variable-Volume Pressing Chamber (VPC) successfully addressed challenges such as stem elasticity, allowing for efficient compaction and consistent density throughout production. These findings underscore the importance of integrating rational compaction pressures, biomass volumes, and blending ratios to achieve a balance between energy efficiency, mechanical strength, and sustainability.

By converting agricultural residues into biofuels, the study provides a practical solution to mitigate environmental pollution from residue burning, reduce waste, and promote renewable energy. Fuel rolls represent a competitive and sustainable alternative to traditional fossil fuels, contributing to cleaner energy solutions and advancing the global transition towards more sustainable energy practices.

Keywords: chassis for hilly and mountainous areas; leveling strategy; control system; chassis.

ABSTRACT

The cultivated land in hilly and mountainous areas of China accounts for a high proportion. However, the complex terrain makes it extremely difficult for traditional agricultural machinery to operate. There is a high risk of rollover, and the operation effect is not satisfactory. Achieving agricultural mechanization in these areas faces huge challenges. This study is dedicated to designing a four-wheel adaptive chassis suitable for hilly and mountainous areas to solve the stability problem of agricultural machinery during operation. The research adopts the leveling strategy of tracking the lowest fixed point plane in the four-point leveling method. By constructing the chassis coordinate system and analyzing the coordinate transformation matrix, the motion relationships of each support point are determined, and precise leveling is achieved based on this. In the system design, the hydraulic system is crucial. According to the preset vehicle parameters, various parameters of the hydraulic cylinder are accurately calculated, and a suitable gear pump is selected to ensure stable operation under different working conditions. The control system calculates the height errors of each point based on the body tilt angle data collected by the biaxial sensor, and then controls the action of the hydraulic valve to achieve automatic leveling of the chassis. The MATLAB/Simulink platform is used to simulate different tilt angle conditions, verifying the effectiveness of the control system. The experimental results show that the chassis can achieve rapid leveling within the range of -12° to 12° in the transverse direction and -8° to 8° in the longitudinal direction, and the leveling time is within two seconds. The leveling process is stable, without shaking and insufficient stroke problems. This indicates that the leveling strategy and system design of the chassis are reasonable and effective, which can significantly improve the stability and safety of agricultural machinery during operation in hilly and mountainous areas, providing important technical support for promoting agricultural mechanization in hilly and mountainous areas.

摘要

中国丘陵山区耕地占比高，但地形复杂致使传统农机作业困难重重，翻车风险大且作业效果不佳，实现农业机械化面临巨大挑战。本研究致力于设计一种适用于丘陵山区的四轮自适应底盘，以解决农机作业的稳定性问题。研究采用四点调平中的最低点不动面追逐调平策略，通过构建底盘坐标系和分析坐标变换矩阵，确定各支撑点的运动关系，以此为基础实现精准调平。在系统设计上，液压系统是关键，根据预设的车辆参数，精确计算液压缸的各项参数，选用合适的齿轮泵，确保在不同作业工况下都能稳定运行。控制系统依据双轴传感器采集的车身倾斜角度数据，计算各点高度误差，进而控制液压阀动作，实现底盘自动调平。利用 MATLAB/Simulink 平台对不同倾斜角度工况进行仿真，验证了控制系统的有效性。实验结果显示，该底盘在横向 -12° 至 12° 、纵向 -8° 至 8° 范围内可实现快速调平，且调平时间在两秒以内，调平过程平稳，无晃动和行程不足问题。这表明底盘的调平策略和系统设计合理有效，能显著提升农机在丘陵山区作业的稳定性和安全性，为推动丘陵山区农业机械化发展提供了重要技术支持¹。

INTRODUCTION

China has a vast territorial area and complex and diverse terrains. Among them, the cultivated land area in hilly and mountainous areas with a slope exceeding 2 degrees accounts for 38% of the country's total cultivated land area.

YuQian Zhao, M.S. Stud. Eng.; Wei Liu, M.S. Stud. Eng.; ShiJun Song, M.S. Stud. Eng.; Peng Liu, M.S. Stud. Eng.; YiHu Wang, M.S. Stud. Eng.; Guohai Zhang Prof. Ph.D. Eng.

The southwestern region is a typical representative of hilly and mountainous areas in China, and the area of hilly and mountainous areas in its major provinces generally exceeds 70% of the total area. Specifically, the area of hilly and mountainous areas in Sichuan Province accounts for 94.1% of the total area, 92.5% in Guizhou Province, 88.8% in Yunnan Province, 85.3% in Chongqing City, and the proportion of the area of hilly and mountainous areas in the Guangxi Zhuang Autonomous Region also reaches 76.1% (Luo, 2019). Due to the undulating terrain, fragmented plots and relatively large slopes in hilly and mountainous areas, conventional agricultural machinery is faced with the predicament of "difficulty in accessing and poor stability". If this problem is not properly solved, rollover accidents are highly likely to occur during the operation of agricultural machinery, resulting in irreparable losses. In addition, as the terrain is sloping, the chassis of agricultural machinery often fails to remain level during operation. Coupled with the rugged and uneven terrain, the operation effect of agricultural machinery, especially that of harvesting operations, is significantly affected. Therefore, achieving the full mechanization in hilly and mountainous areas has always been a difficult problem that urgently needs to be solved (Wang *et al.*, 2024; Sun *et al.*, 2023; Mou *et al.*, 2024; Li *et al.*, 2019).

In recent years, the international and domestic academic communities have conducted extensive research on the adaptive performance of agricultural machinery chassis. For example, the Tri-star II robot developed by the National Space Development Agency of Japan (NASDA), as a typical representative of three-wheeled all-terrain mobile robots, adopts a suspension structure design with three components arranged at equal angles (Liu *et al.*, 2005). This design significantly improves the robot's performance in obstacle crossing and adaptation to diverse terrain environments. The SHRIMP robot, developed by the Swiss Automation and Systems Laboratory (SASL), is a representative six-wheeled all-terrain mobile robot (Hussain *et al.*, 2005). This robot adopts six-wheel drive technology and has the ability to overcome obstacles with a height up to twice the diameter of its wheels. The bipedal robot Atlas, developed by Boston Dynamics, needs to be controlled by algorithms to simulate human walking movements and has the working ability in complex environments (Kuindersma *et al.*, 2016). In China, remarkable progress has also been made in relevant fields in recent years. For example, Wu *et al.*, (2021), designed an electromechanical automatic leveling system based on STM32, which achieves multi-point leveling by controlling the speed of different leg servo motors, avoiding mutual coupling caused by step-by-step adjustment of legs, and combining sensor technology to solve the problem of virtual legs. Finally, an experimental platform was built according to the design scheme to prove the feasibility of the leveling method and control system. Jian *et al.*, (2023), aimed to solve the problems of easy tipping and poor trafficability of tractors in hilly and mountainous areas. In this study, the virtual prototype technology was applied. A three-dimensional simplified model of the chassis was established by SolidWorks. The roll stability and obstacle-crossing performance were analyzed under simulated working conditions in ADAMS/View, and the finite element analysis was carried out on key components using ANSYS Workbench. The results show that the maximum roll stability angle of the tractor chassis meets the standard, the obstacle-crossing performance is good, the stress and deformation displacements of key components all meet the requirements, and the whole machine is within the safe range of use and can meet the operation requirements in hilly and mountainous areas. Yin Xiang *et al.*, (2021), and the research team developed an automatic leveling system for the spray boom of high-clearance pesticide applicators. This system utilizes the incremental PID algorithm. By calculating and outputting control signals to the solenoid valve, it further controls the movement of the leveling cylinder to achieve real-time adjustment of the spray boom's posture.

This research aims to design an adaptive wheeled chassis suitable for the terrain characteristics and working environment of hilly and mountainous areas. This chassis can achieve precise stability adjustment to solve the problems of excessive adjustment amplitude and insufficient stability that occur during the adjustment process of existing adaptive chassis. Through the chassis design proposed in this study, it is expected to significantly improve the overall operational stability of agricultural machinery and the safety during its movement.

MATERIALS AND METHODS

Construction of the Motion Model for the Leveling Strategy

Under the classification of support structures, leveling systems can mainly be divided into three types: three-point leveling, four-point leveling, and six-point leveling. The advantages of three-point leveling are its simple structure, absence of virtual legs, and simple control. However, due to the small number of support points, it has poor stability and cannot bear heavy loads, and is suitable for occasions with small slopes and light loads. Four-point leveling, as the most widely used method in practical applications, can maintain balance

both longitudinally and transversely compared with three-point leveling, ensuring stability during the operation process. Six-point leveling, due to the large number of support points and complex control process, is usually applied in large machinery (Skrickij *et al.*, 2024). Based on this, this research chooses to adopt the four-point leveling method.

According to the differences in leveling methods, they can mainly be classified into two major categories: position leveling and angle leveling. The position error leveling method mainly adopts the "tracking" leveling strategy, which can be further subdivided into four ways: the highest point remaining fixed, the lowest point remaining fixed, the center point remaining fixed, and the specified point remaining fixed. The core of the tracking leveling method lies in using the highest point, the lowest point, the center point or the specified point as the reference and achieving precise leveling through continuous adjustment (Peng *et al.*, 2018). This method performs well in terms of leveling speed and accuracy, but its control algorithm is relatively complex. In this design, the tracking leveling strategy with the lowest point remaining fixed was adopted. Given that harvesting machinery has a relatively large mass when fully loaded, using other leveling methods may lead to mechanical tilting or shaking. Therefore, choosing the tracking leveling strategy based on the lowest point is aimed at improving the stability of agricultural machinery during operation and ensuring the high efficiency of agricultural machinery operations. The angle leveling method detects the tilt angle through an angle sensor and adjusts the length of each support leg accordingly to reach the preset minimum angle threshold and complete the calibration process. This calibration technique is often applied in two-point calibration scenarios. Its algorithm structure is simple and avoids complex coupling calculations. However, this method has certain limitations in calibration time.

In practical application scenarios, the lowest point adjustment method within the position adjustment methods can be further subdivided into the conventional lowest point fixed leveling method, the lowest point fixed line tracking leveling method, and the lowest point fixed plane tracking leveling method. During the four-point leveling process, the conventional lowest point tracking leveling method may lead to chassis tilting or large movement amplitudes, thus having a negative impact on the operation effect. Comparatively, the lowest point edge tracking leveling method, that is, leveling by connecting two points and taking the lowest point as the target, is more suitable for the application of three-point leveling. Given that this research adopts the four-point leveling technique, this research has adopted the plane tracking leveling mode within the lowest point fixed leveling method (Che *et al.*, 2023). This mode constructs three adjustment points into a plane and conducts posture adjustment based on the lowest point to achieve the adjustment goal.

Fig.1 illustrates the schematic diagram of the rotation of the chassis coordinate system. A biaxial sensor is installed at the center of the chassis to measure the tilt angles of the chassis relative to the X - axis and Y - axis. Taking the plane ABCD as the coordinate plane of the chassis, OXYZ represents the chassis coordinate system. In this coordinate system, the center point of the chassis remains fixed, while the XY - axis will tilt at specific angles according to different terrains, forming the plane $OX_1Y_1Z_1$. Nevertheless, the position of the center point O remains unchanged. The tilt angles θ and δ of the X - axis and Y - axis can be measured by the sensor located at the center of the chassis.

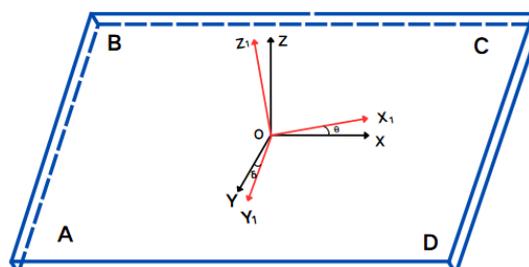

Fig. 1 – Schematic Diagram of the Rotation of the Chassis Coordinate System

Based on the rotation angles θ and δ detected by the sensor, and in combination with the transformation scenarios in different sequences, the following situations can be distinguished:

1. The moving coordinate system rotates by an angle θ around the X-axis of the reference coordinate system, and then rotates by an angle δ around the Y-axis. Since the operations in the back are performed first when multiplying, the transformation matrix is obtained as follows:

$$\begin{aligned}
 F_1 &= \text{Robot}(Y, \delta)\text{Robot}(X, \theta) \\
 &= \begin{bmatrix} \cos\delta & 0 & \sin\delta \\ 0 & 1 & 0 \\ -\sin\delta & 0 & \cos\delta \end{bmatrix} \cdot \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\theta & -\sin\theta \\ 0 & \sin\theta & \cos\theta \end{bmatrix} \\
 &= \begin{bmatrix} \cos\delta & \sin\theta\sin\delta & \sin\delta\cos\theta \\ 0 & \cos\theta & -\sin\theta \\ -\sin\delta & \sin\theta\cos\delta & \cos\theta\cos\delta \end{bmatrix}
 \end{aligned} \tag{1}$$

2. The moving coordinate system rotates by an angle δ around the Y-axis of the reference coordinate system first, and then rotates by an angle θ around the X-axis, and the transformation matrix is obtained as follows:

$$\begin{aligned}
 F_2 &= \text{Robot}(X, \theta)\text{Robot}(Y, \delta) \\
 &= \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\theta & -\sin\theta \\ 0 & \sin\theta & \cos\theta \end{bmatrix} \cdot \begin{bmatrix} \cos\delta & 0 & \sin\delta \\ 0 & 1 & 0 \\ -\sin\delta & 0 & \cos\delta \end{bmatrix} \\
 &= \begin{bmatrix} \cos\delta & 0 & \sin\delta \\ \sin\theta\sin\delta & \cos\theta & -\sin\theta\cos\delta \\ -\sin\delta & \sin\theta & \cos\theta\cos\delta \end{bmatrix}
 \end{aligned} \tag{2}$$

Since the tilt angles during the agricultural machinery operation can basically be regarded as small angles, it can be obtained that:

$$\sin\delta \approx \delta, \sin\theta \approx 0, \sin\theta\sin\delta \approx 0, \cos\theta \approx \cos\delta \approx 1 \tag{3}$$

It can be derived that:

$$F_1 = F_2 \approx \begin{bmatrix} 1 & 0 & \delta \\ 0 & 1 & -\theta \\ -\delta & \theta & 1 \end{bmatrix} \tag{4}$$

Therefore, regardless of whether the rotation occurs first around the X - axis or the Y - axis, under the condition that the tilt angles are small, the matrices are the same. When the chassis is horizontal, the coordinate system coincides with the moving coordinate system. Suppose point N is a certain point on the chassis when it is horizontal. Fix point N where the moving coordinate system coincides with the chassis. Thus, $N_{Z1}=0$. When the platform rotates by an angle δ relative to the Y - axis and by an angle θ relative to the X - axis, and the coordinates of point N in the reference coordinate system are (N_x, N_y, N_z) , can be obtained that:

$$\begin{bmatrix} N_x \\ N_y \\ N_z \end{bmatrix} = F \cdot \begin{bmatrix} N_{x1} \\ N_{y1} \\ N_{z1} \end{bmatrix} \tag{5}$$

$$N_z = -\delta \cdot N_{x1} + \theta \cdot N_{y1} + N_{z1} \tag{6}$$

Among them, with $N_{z1} = 0$, then $N_z = -\delta \cdot N_{x1} + \theta \cdot N_{y1}$, and the coordinate positions of each support point on the Z - axis can be calculated.

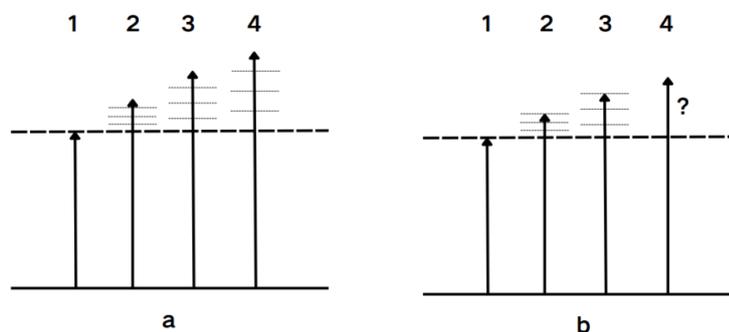

Fig. 2 -The leveling process of tracking the lowest point plane

The core of the leveling strategy in this study lies in dividing the four legs into four levels according to their height differences: the highest point, the second - highest point, the second - lowest point, and the lowest point. By subdividing the vertical height error of each leg relative to the lowest point into three intervals, during the initial adjustment stage, the displacement distances of the second - highest point and the second - lowest point relative to the lowest point are both equal to one - third of the distance of the lowest point. The lowest

point, the second - lowest point, and the second - highest point form a plane. During this process, the highest point needs to track the plane formed by the lowest point, the second - lowest point, and the second - highest point.

Assume that the coordinates of the four support points in the reference coordinate system are $a(X_a, Y_a, Z_a)$, $b(X_b, Y_b, Z_b)$, $c(X_c, Y_c, Z_c)$, and $d(X_d, Y_d, Z_d)$. According to the different positions of the four points, the following three cases can be summarized (as shown in Fig.3).

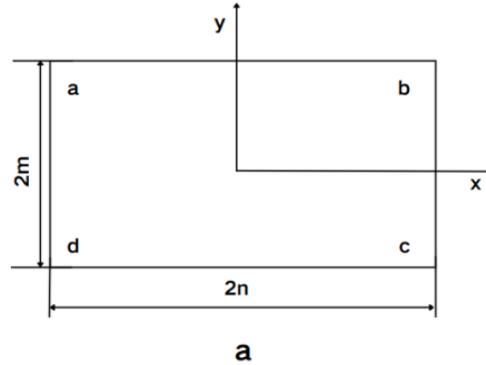

Fig. 3 - Basic Situation of the Chassis Plane

Assume that point **a** is the lowest point, point **b** is the second - lowest point, point **c** is the second - highest point, and point **d** is the highest point.

Determine the normal vector of the plane passing through points **a**, **b**, and **c**.

$$n = \begin{vmatrix} i & j & k \\ x_c - x_a & y_c - y_a & z_c - z_a \\ x_b - x_a & y_b - y_a & z_b - z_a \end{vmatrix} \tag{7}$$

$$= [y_c - y_a)\Delta z_b - (y_b - y_a)\Delta z_c]i - [(x_c - x_a)\Delta z_b - (x_b - x_a)\Delta z_c]j + [(x_c - x_a)(y_b - y_a) - (x_b - x_a)(y_c - y_a)]k$$

$$\Delta z_i = z_a - z_i = \delta(x_i - x_a) + \theta(y_a - y_i) \quad (i = a, b, c, d) \tag{8}$$

The normal vector of the plane formed by points **a**, **b**, and **c** in Figure 3 is:

$$n = -4mn\delta i + 4mn\theta j - 4mnk \tag{9}$$

Therefore, the equation of the plane is:

$$\delta(x - x_a) + \theta(y - y_a) - (z - z_a) = 0 \tag{10}$$

Assume that the moving speeds of points **b** and **c** are k ($i=b,c$). After the moving time t , the vertical position errors of points **b** and **c** relative to the lowest point are:

$$\Delta z_i(t) = \Delta z_i - tk\Delta z_i = (1 - tk)\Delta z_i \tag{11}$$

At this point, the plane determined by points **a**, **b**, **c** is:

$$-\delta(1 - tk)(x + x_a) + \theta(1 - tk)(y + y_a) - (z + z_c) = 0 \tag{12}$$

By substituting the x - and y - coordinates of point **d** into the formula of the plane formed, the z - coordinate of point **d** can be obtained.

$$z_d(t) = z_a - 2n\theta(1 - tk) \tag{13}$$

Therefore, the rising distance of **d** within time t is:

$$s_d = z_d(t) - z_d = 2n\theta tk \tag{14}$$

The rising speed of point **d**.

$$v_d = \frac{s_d}{t} = 2nek \tag{15}$$

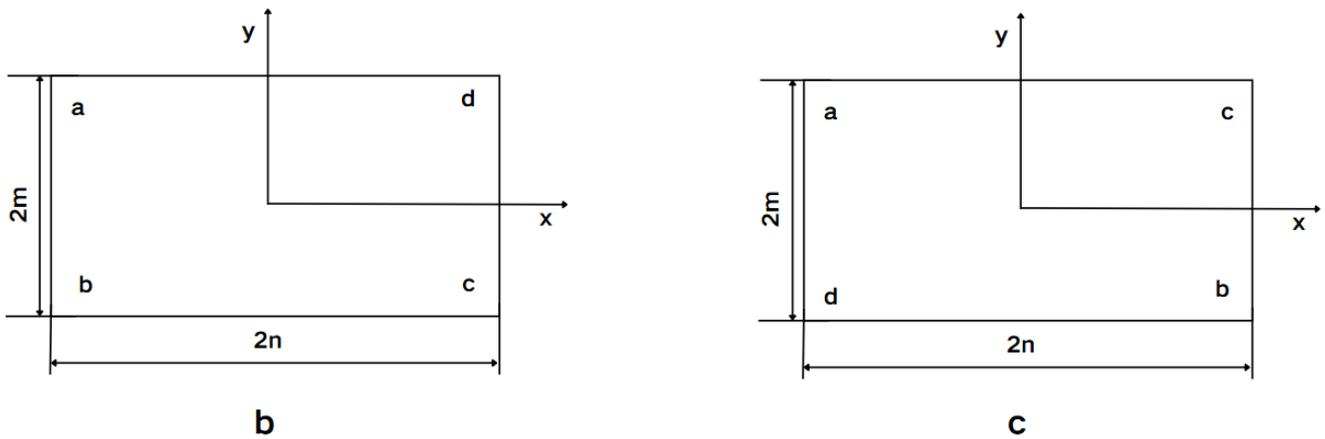

Fig. 4 - The other two basic situations

Similarly, the ascending speed of point **d** in Figure 4b $v_d=2n\delta k$, the ascending speed of point **d** in Figure 4c $v_d=(2m\delta + 2n\theta) k$ can be known.

Through predictive calculations for a variety of different situations, it was found that:

- (1) When the projected distance between points **a** and **d** on the horizontal plane is 2 m, the ascending speed of point **d** is the same as that in Figure 4a, that is, $v_d=2n\theta k$.
- (2) When the projected distance between points **a** and **d** on the horizontal plane is 2n, the ascending speed of point **d** is the same as that in Figure 4b, that is, $v_d=2n\delta k$.
- (3) When the projected distance between points **a** and **d** on the horizontal plane is equal to the diagonal distance of the plane, that is, $(2\sqrt{m^2 + n^2})$, the ascending speed of point **d** is the same as that in Figure 4c, that is, $v_d=(2m\delta + 2n\theta)$.

Therefore, it is only necessary to detect and process to calculate the positional relationship between the highest point and the lowest point, and then the movement speed of the lowest point can be determined.

Hydraulic System

The leveling system in this study consists of a detection system, a leveling mechanism, and a control system. The detection system is a dual - axis sensor. The dual - axis sensor is installed at the center point of the chassis and is used to detect the tilt angles of the chassis in the front - rear and left - right directions. The leveling mechanism is composed of a hydraulic system, which includes suspension hydraulic cylinders and direction valves respectively equipped at the four wheels.

As the core power source for adjusting the chassis attitude, the hydraulic system realizes the leveling function of the vehicle body through the telescopic movement of the hydraulic cylinders. In this study, the design of the chassis is mainly based on preset parameters, according to table 1.

Table 1

Preset Parameters	
Item	Parameter
Overall Vehicle Length	6000 mm
Entry 2	2400 mm
Wheelbase	2800 mm
Track Width	1400 mm
Predetermined Net Body Mass	5500 kg
Predetermined Full Load Mass of the Grain Bin	1500 kg

The hydraulic system mainly consists of key components such as the oil tank, filter, hydraulic pump, relief valve, two - position two - way solenoid valve, three - position four - way solenoid valve, one - way throttle valve, and hydraulic cylinder. The chassis designed in this research for the agricultural machinery field has a preset net vehicle body mass of 5500 kg. If it is applied to the harvesting machinery field, the additional weight when fully loaded with grains needs to be considered, and this load is estimated to be approximately 1500 kg.

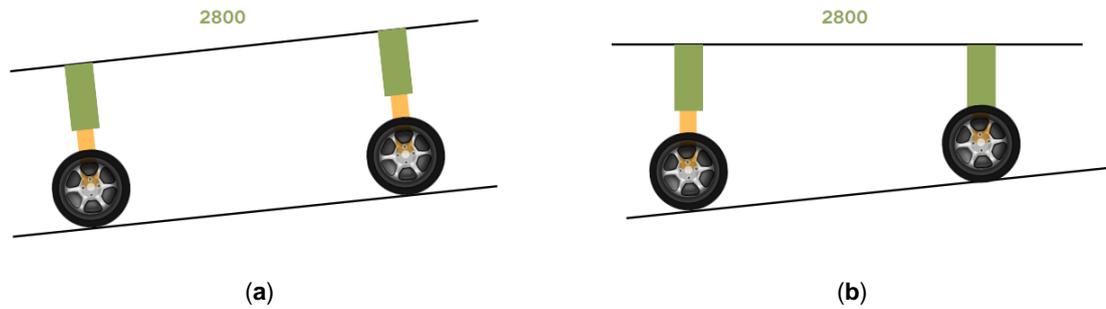

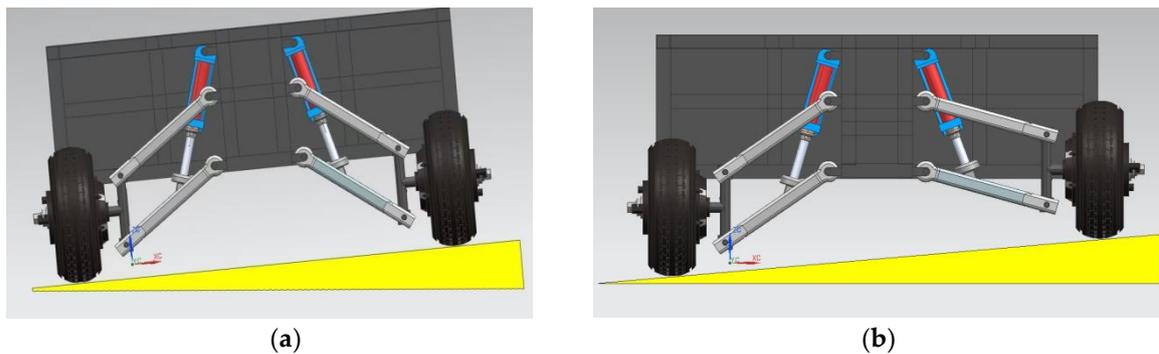

Fig. 5 - Schematic diagram of the leveling process in the longitudinal direction

During the actual operation of agricultural machinery, there are mainly four single - direction tilting conditions, namely forward tilt, backward tilt, left tilt, and right tilt, as well as four compound tilting conditions, including left - rear tilt, right - rear tilt, left - front tilt, and right - front tilt. Since the leveling is carried out in a way of tracking the plane formed by the four lowest points, regardless of the tilting condition, it only needs to determine the lowest point, the second - lowest point, the second - highest point, and the highest point. Taking Figure 5 as an example, in the case of backward tilt, the rear wheels are the lowest points. Then, the two front wheels need to track the rear wheels, and the hydraulic cylinders perform a retracting motion to lower the front part of the vehicle body, thus leveling the vehicle body. The same principle can be applied to other single - direction tilting situations.

Fig. 6-

Schematic diagram of the leveling process in the transverse direction

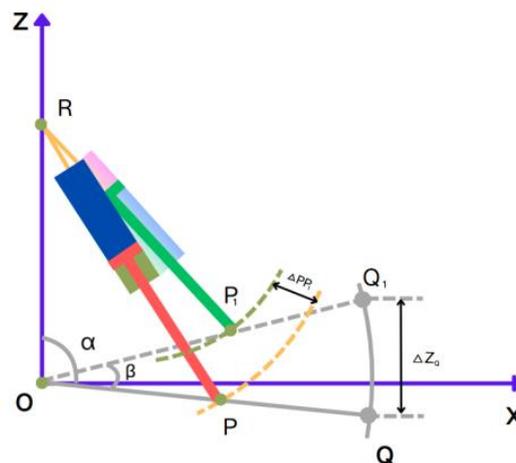

Fig. 7 - Schematic diagram of the leveling hydraulic mechanism

When there is a left - front tilt, the right - rear wheel is the lowest point and the left - front wheel is the highest point. During the leveling process, the distances between the other two wheels and the right - rear wheel are calculated. Subsequently, the hydraulic cylinders perform a retracting motion. The hydraulic cylinder of the left - front wheel retracts to track the plane formed by the other three points, reducing the distance between the vehicle body and the wheel, thus ensuring a stable leveling process. The same method can be applied to other compound - direction tilting situations.

The cosine law in triangle ORP.

$$\cos\alpha = \frac{|\overline{OR}|^2 + |\overline{OP}|^2 - |\overline{RP}|^2}{2|\overline{OR}||\overline{OP}|} \tag{16}$$

$$\alpha = \arccos \frac{|\overline{OR}|^2 + |\overline{OP}|^2 - |\overline{RP}|^2}{2|\overline{OR}||\overline{OP}|} \tag{17}$$

OQ₁ is obtained by rotating OQ around point O. Let the coordinates of point Q be (X_Q, Z_Q), and the coordinates of point Q₁ be (X_{Q1}, Z_{Q1}), where:

$$X_Q = \cos\left(\alpha - \frac{n}{2}\right) = |\overline{OQ}| \sin\alpha \tag{18}$$

$$Z_Q = |\overline{OQ}| = \sin\left(\alpha - \frac{n}{2}\right) = |\overline{OQ}| \cos\alpha \tag{19}$$

Derived from the rotation matrix:

$$Q_1 = (X_{Q1}, Z_{Q1}) = \begin{bmatrix} \cos\beta & \sin\beta \\ -\sin\beta & \cos\beta \end{bmatrix} \begin{bmatrix} X_Q \\ Z_Q \end{bmatrix} = \begin{bmatrix} \cos\beta & \sin\beta \\ -\sin\beta & \cos\beta \end{bmatrix} \begin{bmatrix} |\overline{OQ}| \sin\alpha \\ |\overline{OQ}| \cos\alpha \end{bmatrix} \tag{20}$$

Among them, the coordinate of point Q₁ in the Z-axis direction can be obtained by adding the required lifting amount to the coordinate of point Q in the Z-axis direction:

$$Z_{Q1} = Z_Q + \Delta Z_Q = |\overline{OQ}| \cos\alpha + \Delta Z_Q = -|\overline{OQ}| \sin\alpha \sin\beta + |\overline{OQ}| \cos\alpha \cos\beta \tag{21}$$

It can be simplified to obtain:

$$\cos\alpha + \frac{\Delta Z_Q}{|\overline{OQ}|} \cos\alpha \cos\beta - \sin\alpha \sin\beta = \cos(\alpha + \beta) \tag{22}$$

Thus, the size of the rotation angle β can be obtained as follows:

$$\beta = \alpha - \arccos\left(\cos\alpha + \frac{\Delta Z_Q}{|\overline{OQ}|}\right) \tag{23}$$

Based on the angles α and β as well as the lengths of sides OR and OQ₁ in triangle ORQ₁, according to the cosine theorem, the length of side RQ₁, which is the length of the hydraulic cylinder after extension and contraction, is:

$$|\overline{RP}_1| = \sqrt{|\overline{OR}|^2 + |\overline{OP}_1|^2 - 2|\overline{OR}||\overline{OP}_1| \cos(\alpha - \beta)} \tag{24}$$

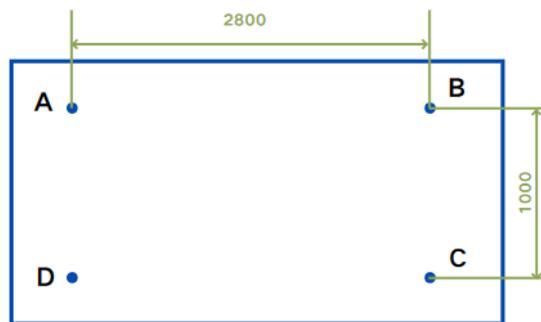

Fig. 8 - Schematic diagram of the chassis plane

As shown in the figure, the total length of the chassis in this paper is 6500 mm, and the width is 2400 mm. Among them, A, B, C, and D are hydraulic cylinders. The horizontal spacing between A and D is 1000 mm, and the longitudinal distance between A and B is 2800 mm.

This design simulates the maximum longitudinal leveling angle of ±8° and the maximum transverse leveling angle of ±12°.

1. Calculation of the Stroke of the Hydraulic Cylinder.

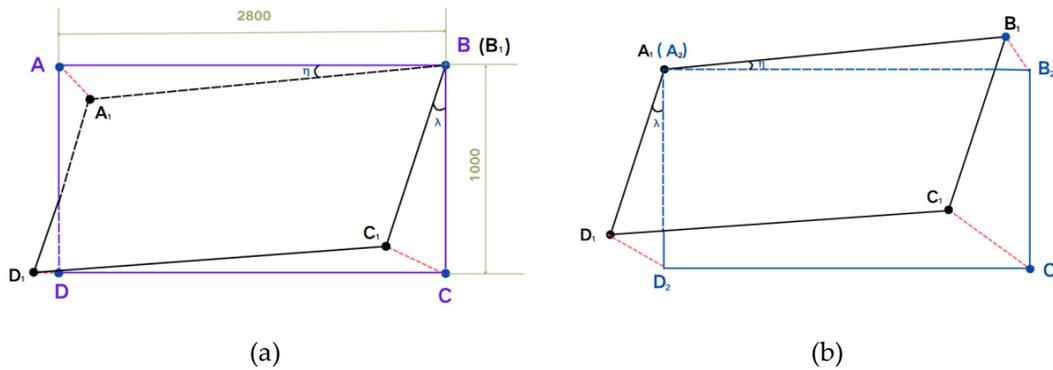

Fig. 9 - Schematic diagram of the chassis leveling process

As shown in the figure, plane ABCD is the placement diagram of the chassis in the default state. A₁B₁C₁D₁ is the placement diagram of the chassis after tilting when encountering an obstacle, and A₂B₂C₂D₂ is the result after leveling by means of the lowest point surface tracking method.

Point C is the highest point, and point A is the lowest point:

$|\overline{C_1C_2}| = |\overline{AA_1}| + |\overline{CC_1}| = 389\text{mm} + 208\text{mm} = 597\text{mm}$. Therefore, in order to achieve leveling with a longitudinal angle of 8° and a transverse angle of 12°, it is necessary to take mm.

Based on the schematic diagram of the motion model, with a value of $|\overline{OR}| = 500$ mm, the default length of the hydraulic cylinder being $|\overline{RP}| = 534$ mm, the default position being $|\overline{OP}| = 150$ mm, and α being $\alpha = 95^\circ$, by substituting the above data into the formula of the motion model, a value of $\Delta PP_1 = 162$ mm can be obtained. In order to achieve a leveling of 8° in the longitudinal direction and a left-right leveling of the hydraulic cylinder with a stroke not less than 12° in the transverse direction, the stroke should be approximately 162 mm. Therefore, the stroke of the hydraulic cylinder is set to 200 mm.

In this design, the mass of the vehicle body is 1500 kg, the preset full load weight is 5500 kg, and the total load mass is 7000 kg. Since the chassis coordinate system is located at the position of the center of gravity of the chassis, and the distances from the four support points to the center of gravity are basically the same, the loads on the four hydraulic cylinders are also basically the same, each being one-fourth of the total load on the chassis, that is, 1750 kg.

$$\sin \lambda = \frac{|\overline{CC_1}|}{|\overline{BC}|} = \frac{208}{1000} \tag{25}$$

$$\sin 12^\circ \approx 0.208 = \frac{|\overline{CC_1}|}{1000} \tag{26}$$

$$|\overline{CC_1}| = 208 \tag{27}$$

$$\sin \eta = \frac{|\overline{AA_1}|}{|\overline{AB}|} = \frac{|\overline{AA_1}|}{2800} \tag{28}$$

$$\sin 8^\circ \approx 0.139 = \frac{|\overline{AA_1}|}{2800} \tag{29}$$

$$|\overline{AA_1}| = 389 \tag{30}$$

$$G = mg \tag{31}$$

Substituting the load of a single hydraulic cylinder into the above formula, $G = 17.15$ KN is obtained.

In addition, the preset system pressure is 10 MPa, the back pressure is 0.5 MPa, and the mechanical efficiency is 0.8. By referring to the table, the speed ratio can be obtained as 1.33. When the speed ratio is 1.33, the ratio of the inner diameter of the cylinder barrel (the diameter of the rodless cavity) of the hydraulic cylinder to the diameter of the plunger rod of the hydraulic cylinder is 0.5. Through calculation, the inner diameter of the cylinder barrel of the hydraulic cylinder is 53.38 mm, and the diameter of the piston rod is 21.35 mm. According to the reference to GB/T 2348 - 1993, the inner diameter of the cylinder barrel of the hydraulic cylinder is 63 mm, and the diameter of the piston rod is 25 mm.

Table 2

Hydraulic Cylinder Dimension Diagram	
Item	Parameter
hydraulic cylinder travel	200mm
inner diameter of the hydraulic cylinder barrel	63mm
diameter of the piston rod	25mm

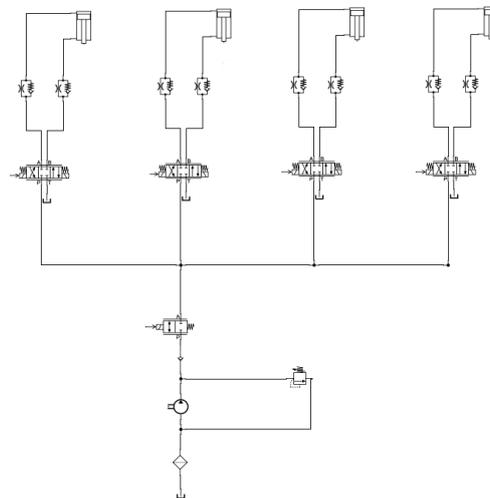

Fig. 10 - Hydraulic Schematic Diagram

1. When the vehicle body is stationary or leveling is not required, the two-position two-way solenoid valve is in the right position and in a cut-off state. Meanwhile, all four three-position four-way solenoid valves are in the middle position, the oil circuits are cut off, and none of the four hydraulic cylinders will operate.

2. When the hydraulic system enters the leveling working state: take the process where point a on the vehicle body is the highest point and point c is the lowest point as an example. At this time, after the two-position two-way solenoid valve is energized, it will be in the left position, and the main hydraulic oil circuit will be connected. Subsequently, the three-position four-way solenoid valves corresponding to **A**, **B**, and **D** are all energized and in the left position. Then, the hydraulic oil enters the rod chambers, and the hydraulic oil in the rodless chambers flows back to the oil tank. At this moment, the hydraulic cylinders **A**, **B**, and **D** perform contraction movements, and the vehicle body translates downward to achieve the leveling effect. Afterwards, if the vehicle body drives onto a flat ground and point C becomes the highest point while point A becomes the lowest point, then the three-position four-way solenoid valves corresponding to **A**, **B**, and **D** are all energized and in the right position. The hydraulic oil then enters the rodless chambers, and the hydraulic oil in the rod chambers flows back to the oil tank. At this time, the hydraulic cylinders **A**, **B**, and **D** perform extension and contraction movements, and the vehicle body translates upward to achieve the default balanced state.

Design and Simulation of the Control System

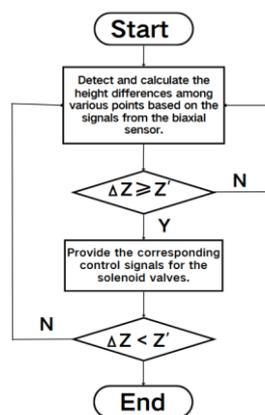

Fig. 11 - Control System Flowchart

The leveling logic of the control system is as follows:

① When the leveling starts, the dual-axis sensor collects the inclination angles of the vehicle body in the X-axis and Y-axis directions. And according to the above formula, the height of each point and the height position error in the vertical direction of the Z-axis from the lowest point are calculated.

② Judge the positional relationship between the highest point and the lowest point, and compare the relationship between ΔZ and Z' (where ΔZ represents the vertical height difference between the highest point and the lowest point, and Z' represents the threshold value for determining whether to carry out the leveling movement). If $\Delta Z \geq Z'$, the controller will send signals to each control valve to control the corresponding hydraulic cylinders to move. If $\Delta Z < Z'$, then return to the first step, and the dual-axis sensor will collect signals again to detect the position error among each point.

In order to verify the reliability and effectiveness of the adaptability of the chassis leveling parameters, this research uses the Simulink platform of MATLAB simulation software to conduct simulations and build simulation models according to the leveling strategy.

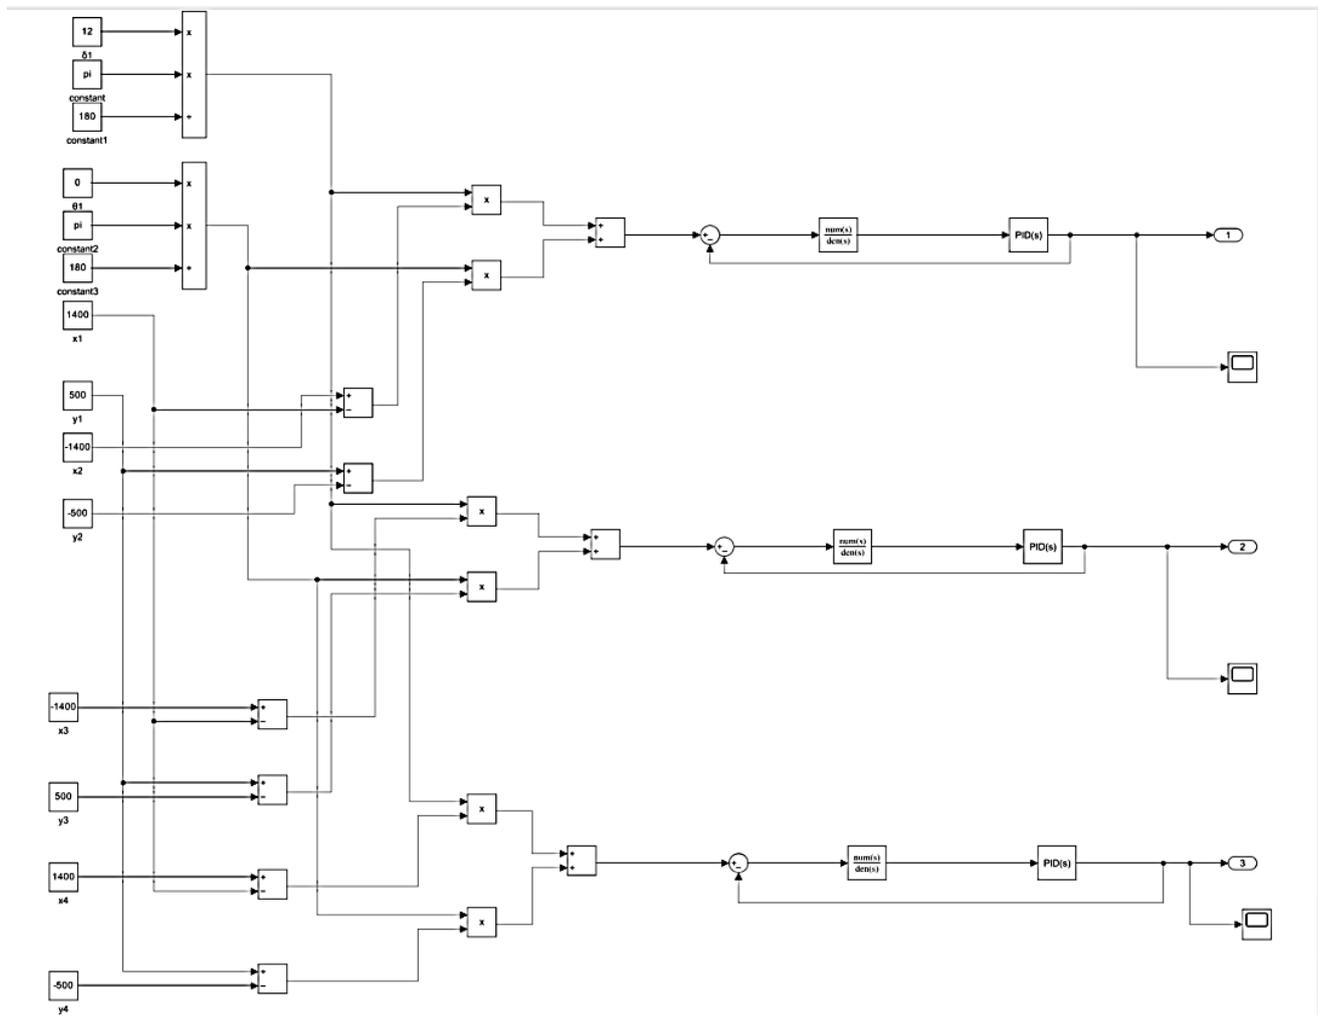

Fig. 12 - Simulation diagram on the Simulink platform

To preliminarily verify the correctness of the leveling control system, simulations will be carried out for different situations next.

1. When $\theta=8^\circ$ and $\delta=0^\circ$.

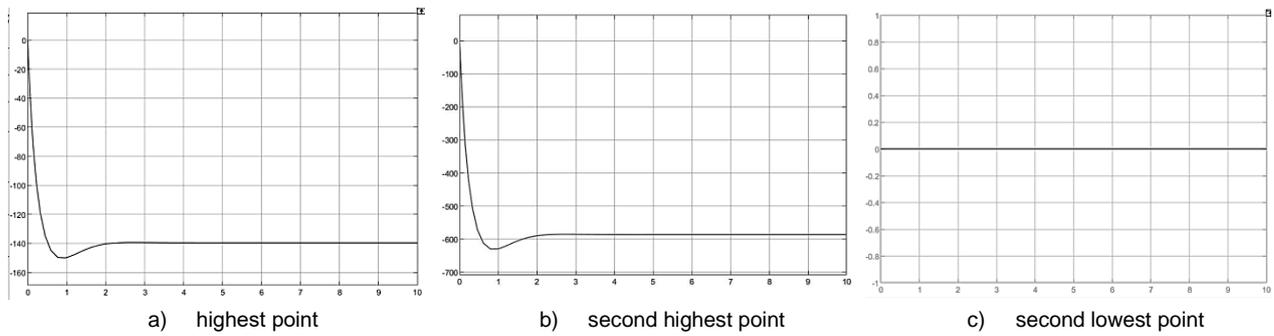

Fig. 13 - Simulation diagram on the Simulink platform

When $\theta = 8^\circ$ and $\delta = 0^\circ$, unilateral inclination occurs. The heights that need to be adjusted for the highest point and the second highest point are the same, and the heights of the lowest point and the second lowest point are the same. At this time, it is only necessary for the higher side to approach the lower side.

2. When $\theta=0^\circ$ and $\delta=12^\circ$.

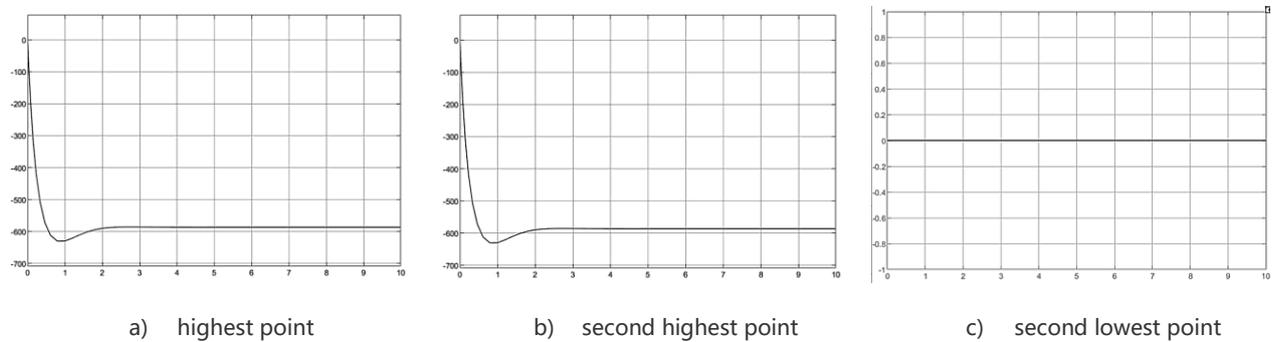

Fig. 14 - Simulation diagram on the Simulink platform

When $\theta = 0^\circ$ and $\delta = 12^\circ$, unilateral inclination occurs. The heights that need to be adjusted for the highest point and the second highest point are the same, and the heights of the lowest point and the second lowest point are the same. At this time, it is only necessary for the higher side to approach the lower side.

3. When $\theta=8^\circ$ and $\delta=12^\circ$.

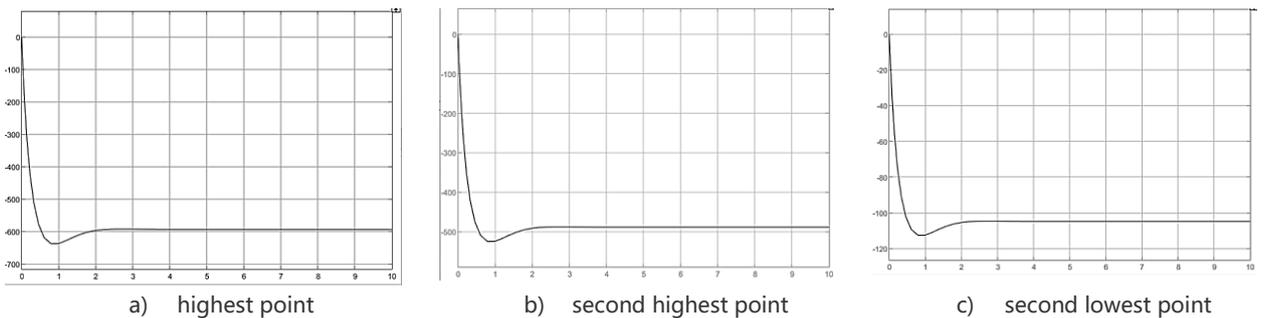

Fig. 15 - Simulation diagram on the Simulink platform

When $\theta = 8^\circ$ and $\delta = 12^\circ$, the highest point, the second highest point and the second lowest point appear. At this time, these three points approach the lowest point to complete the chassis leveling action.

4. When the angle is negative, the lowest point changes. Therefore, the simulation results are the same as when the angle is positive.

Simulation experiments on six angle conditions of inclination angles were carried out through MATLAB/Simulink. The experimental results show that each sub-process of the leveling control can work normally. The maximum range of the inclination angles is $\theta = -8^\circ$ to 8° , and $\delta = -12^\circ$ to 12° .

RESULTS

The effect of adaptive attitude adjustment will influence the performance of the whole machine during operation. Therefore, it is necessary to verify the chassis strategy and design through experiments.

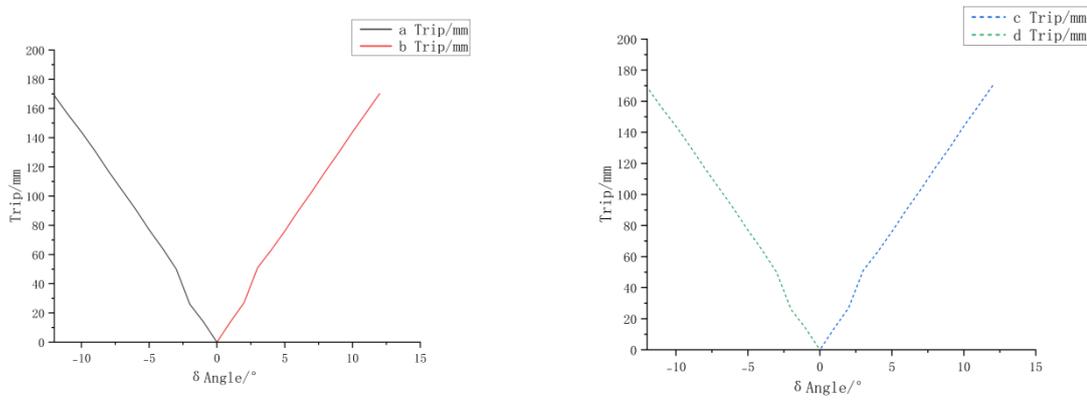

Fig. 16 - Experimental site diagram

To test the working performance of the chassis' attitude adjustment structure and attitude adjustment control system more accurately, four experiments will be carried out, and each experiment will be repeated three times. The average value will be taken and recorded.

Experiment One

Set the δ angle to incline in sequence as -12° , -10° , -8° , -6° , -4° , -2° , 0° , 2° , 4° , 6° , 8° , 10° , 12° , that is, add obstacle slopes on the left or right side according to the angles one by one to achieve the inclination of the target value of the chassis δ angle. Then immediately record the extension and contraction amounts of the attitude adjustment mechanism. Each experiment will be carried out three times to avoid contingency.

Fig. 17 -

(a) (b)
Experiment One: transversal direction tilt the stroke of each hydraulic cylinder

Experiment Two

Set the θ angle to incline in sequence as -8° , -6° , -4° , -2° , 0° , 2° , 4° , 6° , 8° , that is, add obstacle slopes in front of or behind the chassis according to the angles one by one to achieve the inclination of the chassis θ angle. Then immediately record the extension and contraction amounts of the attitude adjustment mechanism. Each experiment will be carried out three times to avoid contingency.

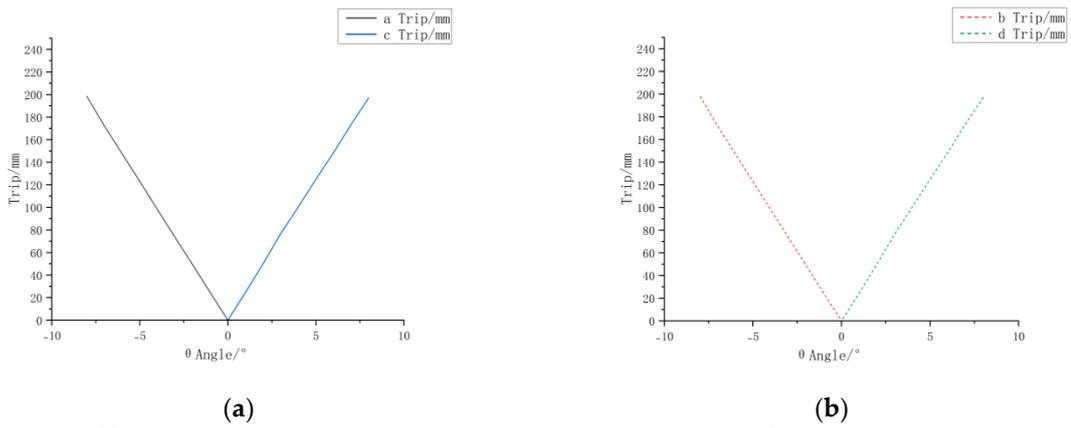

Fig. 18 - Experiment Two: longitudinal direction tilt the stroke of each hydraulic cylinder

Experiment Three:

Set the θ angle to incline in sequence as $-8^\circ, -6^\circ, -4^\circ, -2^\circ, 0^\circ, 2^\circ, 4^\circ, 6^\circ, 8^\circ$ and the δ angle to incline in sequence as $-12^\circ, -9^\circ, -6^\circ, -3^\circ, 0^\circ, 3^\circ, 6^\circ, 9^\circ, 12^\circ$ simultaneously, that is, add obstacle slopes according to the angles one by one to achieve the simultaneous inclination of the chassis θ and δ angles. Then immediately record the extension and contraction amounts of the attitude adjustment mechanism. Each experiment will be carried out three times to avoid contingency.

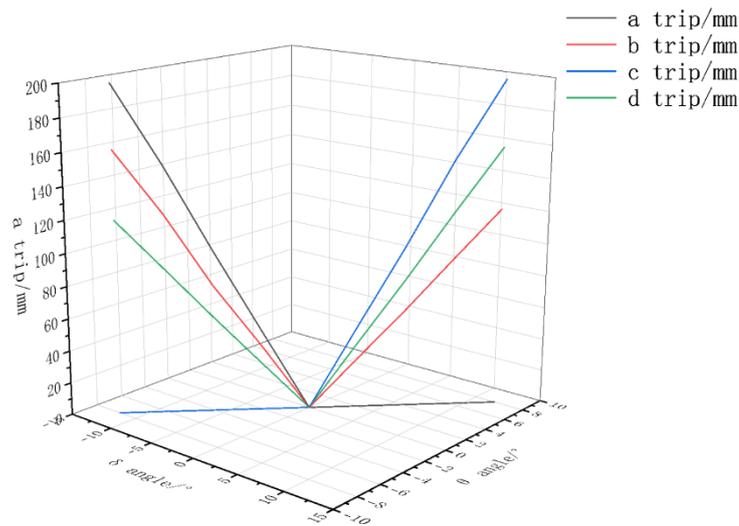

Fig. 19 - Experiment Three: The Moving Amount of Each Hydraulic Cylinder Stroke under Different Inclination Angles

Experiment Four:

Set the θ angle to incline in sequence as $8^\circ, 6^\circ, 4^\circ, 2^\circ, 0^\circ, -2^\circ, -4^\circ, -6^\circ, -8^\circ$ and the δ angle to incline in sequence as $-12^\circ, -9^\circ, -6^\circ, -3^\circ, 0^\circ, 3^\circ, 6^\circ, 9^\circ, 12^\circ$ simultaneously, that is, add obstacle slopes according to the angles one by one to achieve the simultaneous inclination of the chassis θ and δ angles. Then immediately record the extension and contraction amounts of the attitude adjustment mechanism. Each experiment will be carried out three times to avoid contingency.

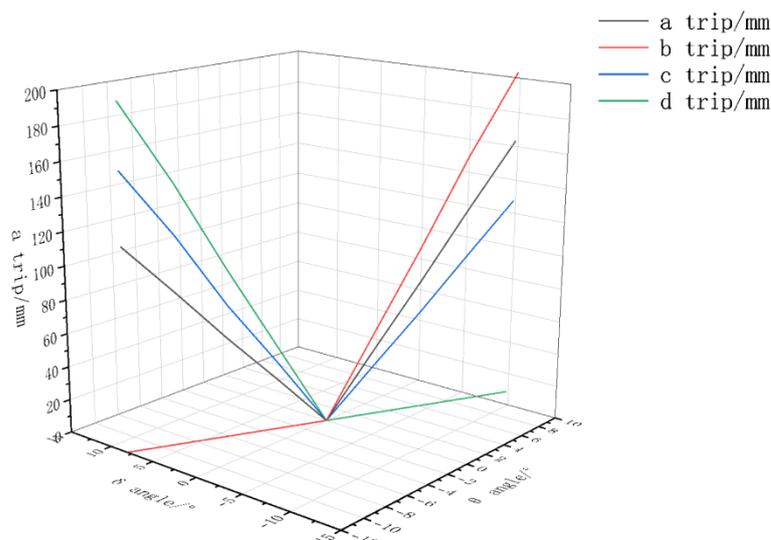

Fig. 20 - Experiment Four: The Moving Amount of Each Hydraulic Cylinder Stroke under Different Inclination Angles

CONCLUSIONS

The experimental results show that the chassis can perform leveling motion in the transverse direction within the range of $[-12^\circ, 12^\circ]$ and in the longitudinal direction within $[-8^\circ, 8^\circ]$. During the experiment, there was no instance of insufficient stroke in the hydraulic cylinder. Due to the implementation of the surface track leveling strategy, the chassis exhibited good stability throughout the leveling process, with no shaking or jolting. The chassis strategy and hydraulic cylinder stroke effectively meet the design requirements.

ABSTRACT

In response to the current challenges in the harvesting process of hybrid rice, where the threshing gap cannot adequately adapt to the varying threshing requirements, leading to high grain breakage rates, loss rates, and frequent clogging of the drum, a new threshing device for hybrid rice was designed by adjusting the gap of the concave screen. The concave screen was divided into a low-loss threshing section and a low-damage threshing section, with the addition of a hydraulic system to enable the adjustment of the threshing gap. A dynamic analysis of the rice at the spiral feeding inlet and within the threshing drum was conducted, determining that the adjustable range of the threshing gap is between 10 and 20 mm. A prototype of the low-loss threshing device for hybrid rice was built, and bench tests were performed with feed rate, drum speed, and threshing gap as influencing factors, while cleaning rate and breakage rate were used as response indicators in an orthogonal experiment to determine the optimal parameter combination. The optimal threshing performance was achieved at a threshing gap of 14.19 mm, a drum speed of 460.12 r/min, and a feed rate of 2.13 kg/s, resulting in a cleaning rate of 97.67% and a breakage rate of 0.295%. Subsequent verification tests under the optimal combination showed a cleaning rate of 96.2% and a breakage rate of 0.36%, meeting the harvesting standards for hybrid rice. This research provides theoretical support for the development of mechanized harvesting equipment for hybrid rice.

摘要

针对目前制繁种水稻收获过程中脱粒间隙无法很好的适应不同条件下水稻脱粒需求，脱粒过程中水稻籽粒破碎率、损失率及滚筒易堵塞等问题，从调节凹板筛脱粒间隙的角度出发，设计了一种制繁种水稻脱粒装置。将凹板筛设计为低损失脱粒段与低损伤脱粒段，通过加入液压系统能够实现脱粒间隙调节。对水稻在螺旋喂入口和脱粒滚筒内进行动力学分析，确定了脱粒间隙可调范围为10~20mm。试制了制繁种水稻低损失脱粒装置试验台，进行台架试验，以喂入量、滚筒转速、脱粒间隙作为影响因素，以脱净率和破损率作为响应指标进行正交实验，确定最优组合参数，获得脱粒装置在脱粒间隙14.19mm、滚筒转速460.12r/min、喂入量2.13kg/s的组合参数下脱粒效果最优，脱净率为97.67%，破损率为0.295%，并在最优组合下验证试验，结果表明脱净率为96.2%，破损率为0.36%，满足水稻制繁种收获标准，该研究可为制繁种水稻机械化收获装备的研制提供理论支持。

INTRODUCTION

Rice, as one of China's important food and economic crops, had a planting area of 28,949 thousand hectares and a yield of 206.6 million tons in 2023, according to statistics from the National Bureau of Statistics (Wei Li et al., 2024; Tian L. et al., 2020; Guo L. et al., 2024). The widespread adoption of rice harvesting machines has saved labor and resources, improved the efficiency of rice harvesting, and played an important role in grain harvesting. In seed breeding, an important aspect of agricultural production, the requirements for seed vitality and grain threshing are more stringent compared to regular rice harvesting during the rice harvesting process. Currently, common field rice-wheat combine harvesters are widely used for rice seed breeding harvesting, which often leads to high threshing losses and severe seed breakage.

Threshing, as an indispensable process, may result in increased loss and breakage rates when working parameters are poorly configured due to changes in feed rate, making it difficult to meet threshing requirements under different conditions (Teng, Y. et al., 2020). Therefore, reducing grain loss and breakage rates during rice seed breeding harvesting has become an urgent issue.

In recent years, researchers both domestically and abroad have conducted numerous studies aimed at reducing grain loss and breakage rates. Vlăduț N.V. et al., (2022), presented a mathematical model to characterize the threshing and separation process in an axial-flow thresher. Their paper aimed to provide a theoretical foundation for optimizing thresher design and performance. Bergkamp et al., (2015), designed a constant-pressure concave screen that, by incorporating a hydraulic cylinder to adjust the piston rod extension, achieved the effect of manually adjusting the threshing clearance, preventing situations where grain loss occurs due to excessive feed rates, and concluded that the constant-pressure concave screen is superior to traditional concave screens. Vlăduț N.V. et al., (2023), found that the loss (p_{ev}) is affected by the threshing rotor speed (n), implicit rotor peripheral speed (v_p), material feed speed (v_a), the space between the rotor and the counter - rotor (δ), material feed flow (Q), material density (ρ), and the length of the threshing device (L). Since ρ and L remain constant, they analyzed the variation of the loss with respect to v_p , Q , ρ , and v_a . By changing two parameters of the loss function (presented graphically), the study aimed to minimize the loss. Ivan Gh. et al., (2015), demonstrated that by optimizing the feeding process, the capacity of the tangential threshing system can be enhanced. This is achieved when the system can guide more materials carried by the feeder house conveyor during a full rotation of the threshing cylinder. The research indicates that to improve the feeding capacity of the threshing system in conventional cereal harvesters, it is necessary to match the speed, quantity, and spacing of the feeder house conveyor slats with the number of rods on the threshing cylinder and the speed of the tangential threshing cylinder. Matousek et al., (2017), designed a three-section combined adjustable concave screen, composed of three small concave screens as a whole, with the movement of the three small concave screens controlled by rotating connecting shafts, concluding that adjusting the threshing clearance can reduce loss rates. Miu, P.I. & Kutzbach et al, (2007) analyzed the movement trajectory of rice in the threshing device, established a kinematic mathematical model based on crop position and movement speed, determined the movement laws of rice in the threshing device, providing a theoretical basis for analyzing the proportion of grains and extraneous matter in the threshing device. Osueke et al, (2011), analyzed the effects of grain threshing force, threshing clearance, feed rate, and drum speed on the threshing process, optimizing the threshing analysis model and concluding that the threshing clearance and grain threshing force are the main factors affecting threshing quality. Dai, F. et al, (2011), designed a vertical axis flow cone-type threshing device by adding a conical short bar-tooth plate structure on the drum, concluding that this method accelerates the axial transport speed of breeding wheat and is less prone to blockages. Lian Y. et al, (2020), designed an adaptive control system for the threshing system of a rice-wheat combine harvester, concluding that the operational parameter control system effectively improves harvesting efficiency by studying the adaptive control system and comparing harvesting tests with and without controllers. Zhang Lu Ke et al, (2022), proposed a rice threshing and separating device blockage monitoring and diagnostic system, effectively preventing grain loss caused by drum blockages. Liu Wanru et al, (2023), established an impact mechanics model for collisions between rice grains and different threshing elements, concluding that the optimized curved rod tooth drum effectively reduces the power consumption of the drum and enhances the threshing performance. Teng Yuejiang et al, (2020), designed a segmented vertical flow threshing and separating device, providing a reference for the improvement and optimization of the threshing device of vertical flow rice harvesters through multi-objective optimization experiments aimed at problems such as high breakage rates, incomplete threshing, and inadequate separation.

In conclusion, current research on rice threshing devices primarily focuses on adjusting the overall threshing clearance of the device through the drum and concave screen. However, the inability to simultaneously meet the threshing conditions at the front and rear ends of the threshing device due to differences in grain density inside the device caused by feed rates hinders the reduction of grain loss and breakage rates. Therefore, in response to issues such as grain loss and breakage during rice seed breeding harvesting, this paper proposes the design of a threshing device for rice seed breeding, analyzes the movement patterns of rice during threshing, and, based on single-factor and multi-factor experiments, identifies the optimal operating parameters, aiming to provide a reference for the development of harvesting equipment for rice seed breeding trials.

MATERIALS AND METHODS

Overall Structure

The overall structure of the harvesting and threshing device for hybrid rice is shown in Figure 1. It mainly consists of a material transport device, material feeding port, cover plate, concave screen, threshing drum, backing plate, hydraulic cylinder, motor, and power transmission device, among others. The main parameters of the device are presented in Table 1.

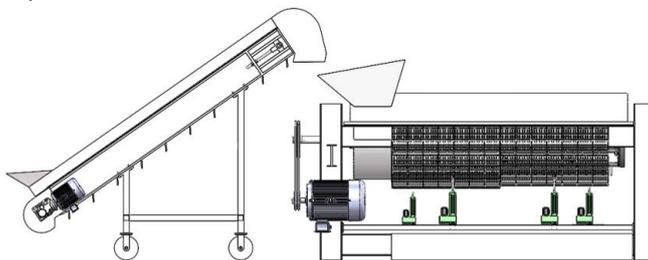

Fig. 1 – The overall structure of the segmented adjustable threshing device for hybrid rice harvesting

Table 1

The main parameters of the segmented adjustable threshing device for rice harvesting	
Parameter	Numerical value
Test bench dimensions (Length × Width × Height) / (m × m × m)	2.2×1.1×1.5
Length of concave screen (m)	1.8
Engine power (kW)	103
Type of concave screen	Grid type
Threshing gap adjustment range (mm)	5~10

When the threshing device begins to operate, rice is transported through the material conveying device into the spiral feeding inlet. From the spiral feeding inlet, it enters the threshing device for threshing, using a radial feeding and discharging method. The motor provides power to drive the power transmission device, which in turn drives the threshing drum to rotate and supports the concave screen's extension and retraction with the hydraulic cylinder. Under the combined action of the threshing drum and the concave screen, the rice undergoes multiple forces such as gravity, impact force, friction force, and centrifugal force to achieve the separation of grains from the stalks. Sensors within the threshing device are used to detect the feeding amount and grain density inside the drum, controlling the extension and retraction of the hydraulic cylinder to drive the two parts of the concave screen to move independently, adjusting the threshing gap. Ultimately, the rice grains fall into the grain bin, while impurities are discharged outside the threshing device, completing the threshing process.

Design and selection of key components

The threshing device of traditional rice harvesting machines has a fixed concave screen that is not adjustable, which cannot better meet the threshing requirements under different working conditions. When the feeding amount is too large, the grain density inside the threshing device increases, causing the rice material in the threshing drum to spiral forward in the feeding direction. As a result, the grain density in the front half of the threshing device is greater than that in the rear half, leading to a situation where an excessively large threshing gap reduces the cleaning rate, while an excessively small threshing gap increases the damage rate. To address this issue, a hydraulic system is introduced to support the concave screen and divide it into a low-loss threshing segment and a low-damage threshing segment, allowing for independent control of the two sections. This enables the adjustment of the appropriate threshing gap based on the varying grain densities, thus solving the problems of reduced cleaning rates and increased damage rates caused by uneven grain density within the threshing drum.

Dynamic analysis of rice at the helical feeding inlet

The spiral feed inlet serves as the starting point for rice entering the threshing device (Xu L., Li Y., & Ding L. et al, 2008), enabling the stable transport of rice into the threshing drum. To prevent blockages in the drum and grain loss caused by excessive feeding, a dynamic analysis of the rice is conducted at any point along the spiral feed inlet. As shown in Figure 2, the rice plant is treated as a particle O for the dynamic analysis within the spiral feed inlet. To ensure that the material moves along the spiral feed inlet and smoothly enters the threshing drum, the following conditions must be met:

$$T \cos \alpha > F_b \sin \alpha \tag{1}$$

$$F_b = f_1 T = T \tan \beta \tag{2}$$

In the formula, f_1 is the coefficient of friction between the material and the spiral feed inlet.

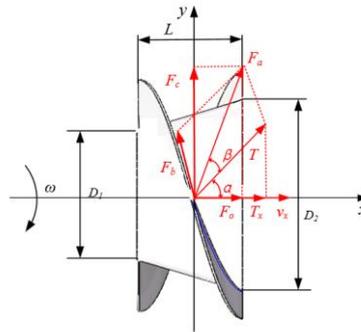

Fig. 2 – Kinetic analysis of rice at the screw feed inlet

where: ω is the angular velocity of rotation of the threshing drum, rad/s; D_1 is the diameter of the front end of the screw feeding inlet, cm; L is the length of the screw feeding inlet, cm; D_2 is the diameter of the rear end of the screw feeding inlet, cm; F_b is the friction between the rice and the screw feed inlet, N; T is the conveying force of the screw feed inlet to the rice, N; T_x is the component of T on the x-axis, N; F_a is the resultant force of F_b and T , N; F_o is the component of F_a on the x-axis, N; F_c is the component of F_a on the y-axis, N; v_x is the axial feeding speed of rice, m/s; α is the friction angle between the rice and the screw feed inlet, °; β is the helix angle of the screw feed inlet, °.

From equations (6) and (7), it can be concluded that to ensure the material moves axially along the spiral feed inlet, the axial thrust force must exceed the axial resistance, that is:

$$\cot \alpha > \tan \beta \tag{3}$$

Therefore, the β between the helix angle and the friction angle α should meet:

$$\alpha < \frac{\pi}{2} - \beta \tag{4}$$

As the main influencing factor of rice feeding speed v_x (Zeng, S., Zeng, L. et al, 2022), the helix angle β decreases when the β increases, the axial component T_x of T decreases, the feeding power P increases, the feeding speed decreases, and the feeding efficiency decreases. When β decreases, the axial component T_x of T increases, the feeding speed increases, and the feeding efficiency increases. In order to select the appropriate helix angle β , prevent the drum from clogging, and improve the feeding efficiency, the following are required:

$$P = T_x v_x \tag{5}$$

$$v_x = \omega r \tag{6}$$

In the formula, ω is the angular velocity of the drum, in rad/s; r is the radius of the drum, in mm.

Upon measurement, the friction α is 48.3°. According to equations (4), (5), and (6), the helical angle β is set to 35°.

Parameter design of the threshing drum

The structure of the threshing drum is shown in Figure 3. The threshing of rice is mainly accomplished through the cooperation between the rods and teeth of the threshing drum and the concave sieve. Considering that the moisture content of southern rice is relatively high, which can easily lead to damage during threshing, this paper selects cylindrical threshing rods to reduce the contact area with the rice, thereby lowering the damage rate. The length of the rods is 78 mm, and the distance between adjacent rods is 82 mm.

The diameter of the threshing drum determines the threshing trajectory. A smaller drum diameter reduces the threshing line speed, decreases the threshing capacity, and lowers the clean threshing rate of the rice. Conversely, a larger drum diameter increases the threshing line speed, enhances the threshing capacity, and raises the damage rate of the rice. Based on domestic standards for cylindrical threshing drums, the diameter D of the threshing drum is determined to be 500 mm.

The length L_l of the threshing drum is designed as:

$$L_l = \frac{q}{q_1} \tag{7}$$

In the formula, q is the feed rate, in kg/s, and q_1 is the threshing capacity of the drum per unit volume, in kg/(s·m).

The threshing device uses cylindrical rods, with q_1 set at 1 to 1.5 kg/(s·m) and q set at 2.5 kg/s. The length of the threshing drum is determined to be 2200 mm using formula (7).

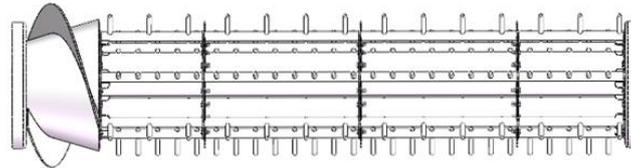

Fig. 4 – Structure diagram of threshing drum

Kinematic analysis of rice in the threshing drum

Due to the complex forces acting on rice during the threshing process, a dynamic analysis of rice threshing is conducted at low speeds to select an appropriate range for the threshing gap and drum rotational speed, thereby reducing damage to the rice grains. A coordinate system (xoy) is established with the center of gravity of the rice as the origin to analyze the force distribution on the rice, as shown in Figure 4.

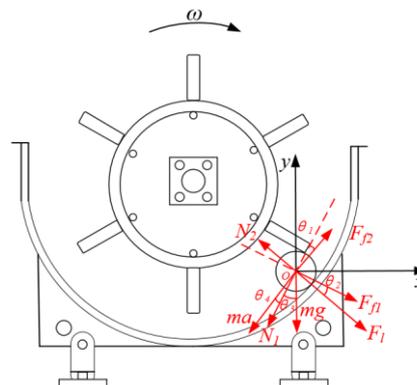

Fig. 5 – Kinetic analysis of rice in threshing drum

where: ω is the angular velocity of the threshing drum, in rad/s; N_1 is the impact force of the threshing rod teeth on the rice, in N; N_2 is the supporting force of the concave sieve on the rice, in N; F_{f1} is the frictional force between the threshing rod teeth and the rice, in N; F_{f2} is the frictional force between the concave sieve and the rice, in N; F_i is the centrifugal force acting on the rice, in N; m is the mass of the rice, in g; g is the gravitational acceleration, in N/kg⁻¹; a is the acceleration of the rice, in m/s²; θ_1 is the angle between the impact force N_1 and the frictional force F_{f2} , in degrees; θ_2 is the angle between the frictional force F_{f1} and the centrifugal force F_i , in degrees; θ_3 is the angle between the gravitational force mg and the impact force N_1 , in degrees; θ_4 is the angle between the direction of the rice’s acceleration and the impact force N_1 , in degrees.

According to Figure 5, the force analysis of rice during the threshing process is shown in formulas (8) and (9).

$$N_1 + ma \cos \theta_4 + mg \cos \theta_3 + F_i \sin \theta_2 = F_{f2} \cos \theta_1 + N_2 \sin \theta_2 \tag{8}$$

$$F_{f1} + F_i \cos \theta_2 + mg \sin \theta_3 + F_{f2} \sin \theta_1 = N_2 \cos \theta_2 + ma \sin \theta_4 \tag{9}$$

$$F_i = mr\omega^2 \tag{10}$$

$$F_{f1} = \mu_1 N_1 \tag{11}$$

$$F_{f2} = \mu_2 N_2 \tag{12}$$

In the formulas, r represents the rotation radius of the rice, in mm. μ_1 and μ_2 are the coefficients of friction between the rice and the threshing rod teeth and concave sieve, respectively, with $\mu_1 = 0.59$ and $\mu_2 = 0.54$.

Kinematic analysis of rice in the threshing drum

Before threshing the grains, the threshing device must first separate the rice from the straw. The grains are rubbed and peeled by passing through the threshing drum and concave sieve, then they enter the cleaning device through the concave sieve. Under the influence of the threshing drum and the flow guide plate, the straw moves forward in a spiral manner and is eventually discharged from the end of the threshing device (Chen L. et al, 2023; Chen J. et al., 2024; Wang J. et al., 2021).

To explore the motion laws of the material within the threshing device and ensure that the material moves axially within the threshing drum, preventing blockages and allowing for smooth discharge, an xoy coordinate system is established with the center of mass of the straw as the origin, as shown in Figure 6.

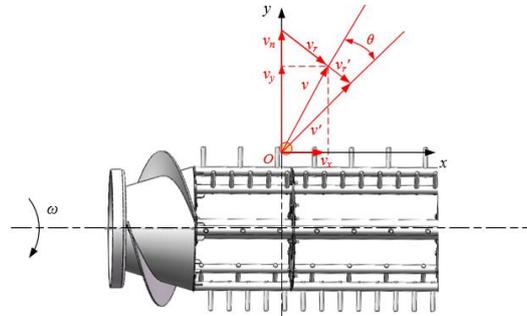

Fig. 6 – Kinematics analysis of straw in threshing device

where:

ω is the angular velocity of the threshing drum, in rad/s; v is the actual motion speed of the straw, in m/s; v_x is the component of speed v along the x-axis, in m/s; v_y is the component of speed v along the y-axis, in m/s; v_n is the pulling speed under the influence of the flow guide plate, in m/s; v_r is the sliding speed of the straw relative to the flow guide plate, in m/s; v_r' is the sliding speed in the absence of friction, in m/s; v' is the motion speed in the absence of friction, in m/s; θ is the angle of change in speed due to the action of friction, in degrees.

As shown in Figure 6, the velocity decomposition of the rice straw within the threshing device is represented by equations (15) and (16).

$$v_x = \frac{dn \left(\mu_3 + \frac{d}{2\pi r} \right)}{60 \left[1 + \left(\frac{d}{2\pi r} \right)^2 \right]} \tag{15}$$

$$v_y = \frac{dn \left(1 - \frac{\mu_3 d}{2\pi r} \right)}{60 \left[1 + \left(\frac{d}{2\pi r} \right)^2 \right]} \tag{16}$$

where: d is the pitch of the guide plate, in mm; n is the rotational speed of the drum, in rad/s; μ₃ is the coefficient of friction between the straw and the guide plate, where μ₃ = 0.18; r is the radius of the drum, in mm.

From equations (15) and (16), it can be seen that the motion speed of the straw is related to the pitch of the guide plate, the rotational speed of the drum, and the radius of the drum. When the central axis of the drum is fixed and the radius of the drum increases while the length of the threshing rod teeth remains unchanged, it can be approximated that the threshing gap increases. In this paper, the change in the radius of the drum is used to represent the change in the threshing gap.

When the drum rotational speed n increases, v_x and v_y also increase. This can be interpreted as an enhanced ability to separate grains from straw with the increasing drum speed, resulting in an increase in the instantaneous speed of the straw and a faster axial movement. When the radius of the drum r increases, the threshing gap enlarges, causing v_x and v_y to decrease, which can be explained as a reduction in the ability to separate rice grains from straw due to the enlargement of the threshing gap. When the pitch of the guide plate d increases, v_x and v_y decrease, which can be interpreted as a reduced conveying capacity for the straw with the increase in pitch, making it easier for the drum to become clogged.

In summary, to prevent the drum from clogging and to ensure the smooth progress of the threshing process, the drum rotational speed should be set between 260 and 660 r/min, and the threshing gap should be set between 10 and 20 mm.

Design of the concave plate sieve

During the threshing process, the concave plate sieve works in cooperation with the threshing drum to achieve the preliminary separation of rice grains and broken materials (Teng Y. *et al*, 2020). Traditional rice harvesters often have fixed structures for the concave plate sieve, and the fixed threshing gap cannot adapt to different working conditions, which can easily cause damage to the rice grains. Therefore, a segmented adjustable concave plate sieve has been designed, as shown in Figure 7. Based on the existing dimensions of the threshing segment of the threshing drum, this paper selects a bar-type concave plate sieve to increase grain passage, reduce collision intensity, and lower the damage rate. The length of the concave plate sieve is set at 2100 mm, divided into two parts, each measuring 1050 mm (Di Q. *et al*, 2021). The bars are made of steel plates that are 1010 mm long and 22 mm wide, with a wrap angle of 190°.

Two pads are installed in each part to connect the hydraulic cylinder with the concave plate sieve. When there are many grains, increasing the gap of the concave plate can effectively reduce the collision intensity between the concave plate sieve and the rice grains, while providing enough space for high-density rice to be threshed. Increasing the threshing gap not only improves the passage of grains but also reduces the damage caused by the squeezing of grains due to the clogging of the threshing device.

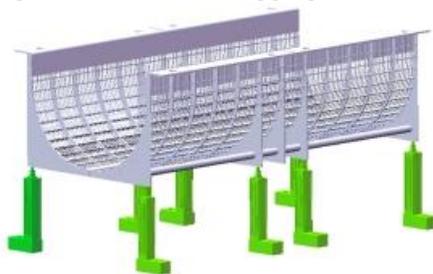

Fig. 7 – Structure diagram of concave plate screen

The hydraulic system, serving as the power device for adjusting the threshing gap, is designed with two oil inlets and sixteen oil outlets, ensuring simultaneous supply to four hydraulic cylinders with an error margin of less than 2%. When there is a need to adjust the threshing gap, the hydraulic system directs hydraulic oil into the hollow hydraulic cylinders through hydraulic rotary joints, with one side featuring a piston rod. By controlling the flow of hydraulic oil, the piston rod extends and retracts, thereby driving the movement of the concave plate sieve to modify the size of the threshing gap. When adjustment of the threshing gap is unnecessary, the hydraulic oil flow ceases, maintaining the piston rod of the hydraulic cylinder in a stationary state. The hydraulic system also remains static, ensuring that the position of the concave plate sieve does not change, thus guaranteeing a constant threshing gap.

The design of the adjustable hydraulic system allows for precise control when there is a need to modify the threshing gap, while maintaining stability when no adjustments are required.

Bench test and result analysis

To verify the working effect of the segmented adjustable threshing device, a test stand was fabricated for conducting bench tests. The test subjects selected were Shuyou No. 9 rice from the rice planting base in Xinlong Town, Dongfang City, Hainan Province, with basic parameters shown in Table 2.

Table 2

Parameters of basic physical characteristics of rice	
Parameter	Numerical value
Moisture content of rice grains / %	23.1
Moisture content of rice straw / %	74.4
Height of rice plant / cm	103.6
Thousand grain weight / g	27.1
Number of grains per ear	154

Experimental method

This experiment combines the design analysis of key component parameters, selecting threshing gap A, drum speed B, and feeding amount C as experimental factors, and selecting cleaning rate y_w and damage

rate y_p as evaluation indicators. Based on GB/T 5982-2017 "Test Methods for Threshers" and DB37/T2878.2-2016 "General Technical Requirements for Agricultural Product Harvesting Machinery", an orthogonal experiment is conducted.

The calculation formulas for cleaning rate y_w and damage rate y_p are as follows:

$$y_w = \frac{m_w}{m} \times 100\% \quad (17)$$

In the formula,

y_w is the cleaning rate, %; m_w is the weight of threshed grains, g; m is the total grain mass, g.

$$y_p = \frac{m_p}{m} \times 100\% \quad (18)$$

In the formula,

y_p is the damage rate, %; m_p is the weight of damaged grains, g; m is the total grain mass, g.

Fig. 8 – Test bench of segmented adjustable threshing device for rice harvesting

Single-factor experiment

Before conducting the orthogonal experiment, single-factor experiments should be carried out on the threshing gap A, drum speed B, and feeding amount C to determine the reasonable range of factor levels and the influence patterns of each factor on the threshing performance. Based on preliminary trials and the adjustable range of the device, the single-factor experimental ranges are set as follows: threshing gap A is 10–20 mm, drum speed B is 260–660 r/min, and feeding amount C is 1–3 kg/s.

When the threshing gap A is fixed at 15 mm, the drum speed B is set at 450 r/min, and the feeding amount ranges from 1 to 3 kg/s, the effects of feeding amount C on the cleaning rate y_w and damage rate y_p during the threshing process are shown in Figure 9. As illustrated in Figure 9, when the feeding amount is between 1–2 kg/s, both the cleaning rate and damage rate increase significantly with the rise in feeding amount; the cleaning rate rises from 93.1% to 99.2%, while the damage rate increases from 0.18% to 0.59%. However, when the feeding amount is between 2–3 kg/s, the cleaning rate shows a downward trend, decreasing from 99.25% to 94.5%. An excessively high feeding amount results in the threshing device being unable to effectively thresh the rice, leading to a decline in threshing efficiency, while the damage rate slowly increases from 0.59% to 0.8%. To ensure effective threshing, the selected feeding amount range is 1.5–2.5 kg/s.

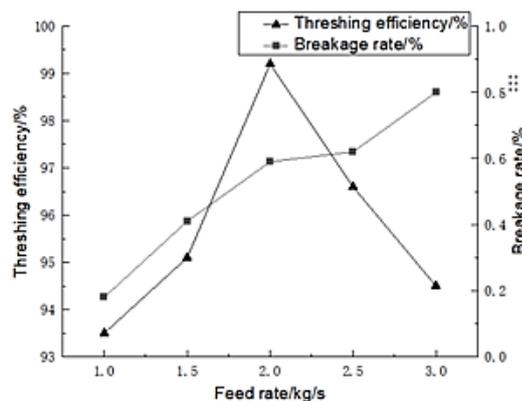

Fig. 9 – The impact of feed rate on threshing efficiency and damage rate

When the threshing gap A is fixed at 15 mm, the drum speed B ranges from 260 to 660 r/min, and the feeding amount is 2 kg/s, the effects of drum speed B on the cleaning rate y_w and damage rate y_p during the threshing process are shown in Figure 10. As illustrated in Figure 10, with the continuous increase in the drum speed, both the cleaning rate and loss rate show an overall upward trend. When the drum speed increases from 450 r/min to 550 r/min, the cleaning rate rises from 94.2% to 99.4%, indicating a significant upward trend. During this process, as the drum speed increases, the impact force on the rice becomes more pronounced, resulting in effective threshing. However, when the drum speed increases from 550 r/min to 660 r/min, the cleaning rate drops from 99.4% to 98.7%. The excessively high drum speed fails to achieve optimal threshing results, leading to grain loss. To ensure effective threshing, the selected drum speed range is set at 450–550 r/min.

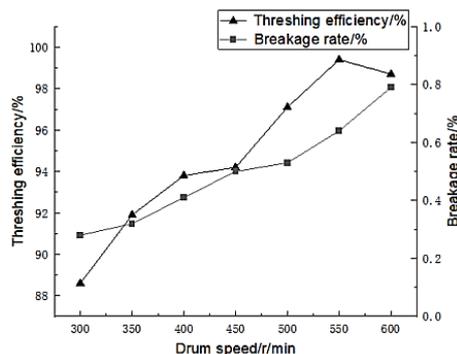

Fig. 10 – The impact of roller speed on cleaning rate and damage rate

When the threshing gap A is set between 10–20 mm, the drum speed B ranges from 260 to 660 r/min, and the feeding amount is 2 kg/s, the effects of threshing gap A on the cleaning rate y_w and damage rate y_p during the threshing process are illustrated in Figure 11. As shown in Figure 11, when the threshing gap is between 10–15 mm, the cleaning rate exhibits an upward trend, increasing from 95.5% to 99.6%. A good threshing gap allows the threshing rod teeth to fully contact the rice and effectively rub off the husk, thereby improving the threshing effect. At the same time, it reduces the collisions between the rice grains and the concave screen, with the damage rate decreasing from 0.95% to 0.32%. However, when the threshing gap is between 15 mm and 20 mm, the cleaning rate shows a downward trend, dropping from 99.6% to 94.3%. A larger threshing gap is unable to efficiently complete the threshing of rice, resulting in some rice not being fully rubbed and husked, which causes losses. Additionally, this leads to insufficient contact and collisions between the rice grains and the concave screen, causing the damage rate to further drop from 0.32% to 0.08%. To ensure effective threshing, the selected threshing gap range is set at 12–18 mm.

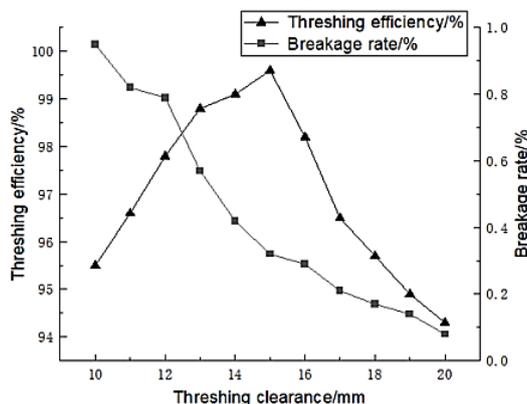

Fig. 11 – The impact of threshing gap on threshing purity and damage rate

RESULTS AND ANALYSIS

The experiment utilized a quadratic orthogonal design (Yang, R. et al., 2024), with the experimental factors being threshing gap A, drum speed B, and feeding amount C. The experimental indicators were the cleaning rate y_w and damage rate y_p . Based on the analysis of the previous experimental results, the value ranges for each experimental factor were determined: the threshing gap A is set at 12–18 mm, the drum speed B at 450–550 r/min, and the feeding amount C at 1.5–2.5 kg/s. The coding table for the levels of the experimental factors is shown in Table 3, and the experimental plan and results are presented in Table 4.

Table 3

Factor level coding table			
Material	Threshing gap A	Drum speed B	Feeding amount C
-1	12	450	1.5
0	15	500	2
1	18	550	2.5

Table 4

Test protocol and results					
Experiment number	Threshing gap A	Drum speed B	Feeding amount C	Cleaning rate / %	Damage rate / %
1	12	550	2	94.89	0.45
2	15	450	1.5	99.51	0.22
3	18	500	1.5	97.69	0.15
4	15	500	2	98.25	0.33
5	15	500	2	98	0.3
6	15	550	2.5	97.18	0.37
7	12	450	2	95.05	0.33
8	18	450	2	97.99	0.17
9	18	500	2.5	96.61	0.15
10	15	500	2	98.98	0.31
11	12	500	2.5	95.24	0.41
12	15	500	2	98.69	0.29
13	15	450	2.5	96.69	0.24
14	15	550	1.5	95.9	0.3
15	15	500	2	98.1	0.28
16	18	550	2	96.48	0.17
17	12	500	1.5	95.74	0.32

Using Design-Expert software, a quadratic regression analysis and multiple regression fitting were performed on the experimental data (Tian L. et al., 2020), along with variance analysis and significance testing of the experimental factors. As shown in Table 5, the experimental results indicate that the overall model for cleaning rate y_w and damage rate y_p is significant ($P < 0.01$), and the regression equation model for cleaning rate y_w and damage rate y_p is highly significant. Factors A, B, BC, and A^2 have a highly significant effect on cleaning rate y_w ($P < 0.01$), while factors C and B^2 have a significant effect on cleaning rate y_w ($0.01 \leq P < 0.05$). Factors AB, AC, and C^2 have no significant effect on cleaning rate y_w ($P \geq 0.05$). Similarly, factors A, B, BC, and A^2 have a highly significant effect on damage rate y_p ($P < 0.01$), while factors C and B^2 have a significant effect on damage rate y_p ($0.01 \leq P < 0.05$). Factors AB, AC, and C^2 have no significant effect on damage rate y_p ($P \geq 0.05$). The insignificant factors were included in the residual term, resulting in the regression equations for cleaning rate y_w and damage rate y_p as follows:

$$y_w = 8.99 + 7.15A + 0.2B - 12.89C + 0.041BC - 0.18A^2 - 0.26 \times 10^{-3} B^2 \tag{19}$$

$$y_p = -1.88 + 0.17A + 0.22 \times 10^{-2} B + 0.36C - 0.2 \times 10^{-3} AB - 0.015AC - 0.26 \times 10^{-2} \tag{20}$$

As shown in Table 5, the cleaning rate y_w and damage rate y_p have $P < 0.01$, indicating that the regression model is highly significant; the lack of fit term $P_w = 0.5313$ and $P_p = 0.5063$ ($P > 0.1$) are not significant. The regression equation fits well for both the cleaning rate and damage rate, with no other major factors affecting the experimental indicators. The quadratic relationship is significant, and the analysis results are reasonable.

Table 5

Response surface methodology

To observe the effects of threshing gap, drum speed, and feeding rate on the cleaning rate and damage rate of hybrid rice grain harvested, this study fixes the level of one factor and investigates the interaction between the other two factors.

Through interaction response surface analysis (Ge Y. et al., 2015), the first figure in Figure 12 shows the response cloud of the cleaning rate (y_w) under the interaction of drum speed and feeding rate. It can be seen from the figure that when the threshing gap is 15 mm, as the drum speed and feeding rate increase, the cleaning rate begins to rise. This phenomenon can be attributed to the fact that the increase in drum speed enhances the force exerted by the threshing elements on the rice, allowing for successful threshing and consequently leading to an increase in the cleaning rate. From this interaction response cloud, it can be concluded that the effect of drum speed on the cleaning rate is significantly greater than that of feeding rate on the cleaning rate.

Similarly, through interaction response surface analysis, the second figure in Figure 12 shows the response cloud of the damage rate (y_p) under the interaction of threshing gap and drum speed. It can be observed that when the feeding rate is 2 kg/s, as the threshing gap and drum speed increase, the damage rate decreases. This phenomenon can be explained by the fact that the increase in threshing gap enlarges the internal space of the threshing device, reducing the force at the contact point between the grains and the concave screen under the action of the threshing drum, thereby leading to a decrease in the damage rate of the grains. However, with the increase in drum speed, the damage rate increases due to the greater force exerted on the rice when it contacts the threshing elements, which may cause damage to the grains if the drum speed is too high during threshing. The interaction response cloud indicates that the effect of threshing gap on the damage rate is clearly greater than that of drum speed on the damage rate.

Through interaction response analysis, the third figure in Figure 12 shows the response cloud of the damage rate (y_p) under the interaction of threshing gap and feeding rate.

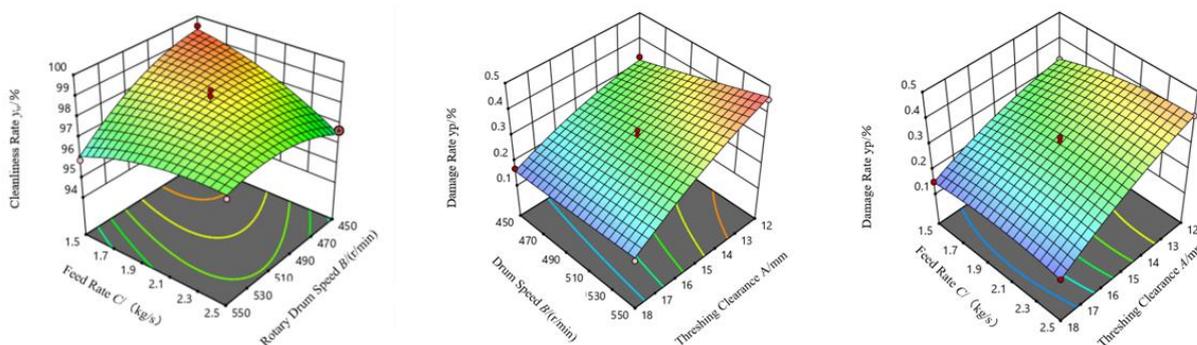

Fig. 12 – Interaction Response Plot

It can be seen that when the drum speed is 500 r/min, as the threshing gap and feeding rate increase, the damage rate decreases. This phenomenon can be explained by the fact that the increase in threshing gap enlarges the internal space of the threshing device, reducing the force at the contact point between the grains and the concave screen under the action of the threshing drum, thus leading to a decrease in the damage rate of the grains. As the feeding rate increases, the damage rate rises slightly, but the change is not significant, which can be attributed to the increased material density within the threshing device and the greater interaction

force between materials, resulting in slight damage. Therefore, it is evident that the impact of the threshing gap on the damage rate is significantly greater than that of the feeding rate on the damage rate.

Determination of optimal parameters

To increase the cleanliness rate (y_w) and reduce the damage rate (y_p), the maximization of cleanliness rate and minimization of damage rate are set as optimization objectives, seeking the best operating parameters, as shown in equation (19):

$$\begin{cases} \max y_w(A, B, C) \\ \min y_p(A, B, C) \\ 12 < A < 18 \\ 450 < B < 550 \\ 1.5 < C < 2.5 \end{cases} \quad (19)$$

Through optimization, the optimal parameters obtained are: threshing clearance of 14.19 mm, rotary drum speed of 460.11 r/min, and feed rate of 2.13 kg/s, resulting in a cleanliness rate of 97.67% and a damage rate of 0.295%, which meet the relevant threshing standards.

The adjusted parameters for the platform are: threshing clearance of 14.2 mm, rotary drum speed of 460 r/min, and feed rate of 2.1 kg/s. Experimental results indicate a cleanliness rate of 96.2% and a damage rate of 0.36%, with a relative error of less than 2 percentage points compared to the model optimization results.

CONCLUSIONS

(1) In response to the current challenges in the harvesting process of hybrid rice, where the threshing clearance cannot adequately adapt to the threshing requirements under different conditions, issues such as grain breakage rate, loss rate, and drum clogging during threshing are addressed. A threshing device for hybrid rice is designed from the perspective of adjusting the threshing clearance of the concave screen.

(2) A kinematic analysis of the threshing process is conducted. By analyzing the forces acting on the rice at the spiral feeding inlet and within the threshing drum, the selection of the concave screen and threshing drum is determined, aiming to reduce grain damage during threshing. Additionally, single-factor experiments are performed to establish the threshing clearance range of 12 to 18 mm, the drum speed range of 450 to 550 r/min, and the feed rate range of 1.5 to 2.5 kg/s.

(3) Using threshing clearance, drum speed, and feed rate as experimental factors, and cleanliness rate and damage rate as response indicators, an orthogonal experiment is conducted to establish a regression model for the relationship between threshing clearance, drum speed, feed rate, cleanliness rate, and damage rate. The results indicate that at a threshing clearance of 14.19 mm, a drum speed of 460.11 r/min, and a feed rate of 2.13 kg/s, the cleanliness rate is 97.67% and the damage rate is 0.295%. Verification through platform experiments shows that the cleanliness rate is 96.2% and the damage rate is 0.36%, with a relative error of less than 2% compared to the model optimization results. This demonstrates that this parameter combination can effectively improve the cleanliness rate of rice grains and significantly reduce the damage rate of rice grains.

ABSTRACT

Mold contamination of stored maize can cause significant economic losses, and it is crucial to effectively classify maize kernels without destroying their original structure. But existing studies have found it difficult to distinguish moldy maize. In this paper, a method for non-destructive detection of mold in maize using near-infrared spectral fingerprinting is proposed. The spectral raw data are initially acquired using a handheld near-infrared spectrometer. To enhance the signal quality, preprocessing is conducted, and a classification model is developed for full-band spectral data. In order to further optimize the model and enhance the classification accuracy, the feature wavelengths were extracted from the spectral data with effective preprocessing techniques in the full-band model. Finally, the maize kernel mold classification model is constructed. The classification accuracy of SG+SNV-SVM-ISFLA model can reach up to 97.22%, and the accuracy for the identification of asymptomatic moldy maize is 96.30%, which can realize the accurate grading of moldy maize and can well distinguish asymptomatic moldy maize. This work may significantly control the spread of molds in the food industry while improving storage economics and safety.

摘要

仓储玉米受到霉菌污染会造成重大经济损失, 因此在不破坏玉米原有结构的情况下对玉米进行有效分类至关重要。但现有研究发现, 轻微霉变玉米难以区分。本文提出了一种利用近红外光谱指纹的玉米霉变无损检测的方法。最初使用手持式近红外光谱仪获取光谱原始数据。为了提高信号质量, 进行了预处理, 并为全波段光谱数据建立分类模型。为了进一步优化模型并提高分类准确率, 对预处理后的数据进行特征提取。最后, 构建了玉米霉变分类模型。结果表明 SG+SNV-ISFLA-SVM 模型的分类准确率高达 97.22%, 对无症状霉变玉米的识别准确率为 96.30%, 可实现对玉米霉变的准确分级, 并能很好地区分无症状霉变玉米。这项工作可大大控制霉菌在食品工业中的传播, 同时提高贮藏的经济性和安全性。

INTRODUCTION

Maize, as an important crop, causes huge economic losses every year due to maize mold problems (Long et al., 2022a). Maize itself contains starch, proteins, sugar, amino acids and other nutrients for the reproduction of mold which provides the necessary nutritional conditions, while the temperature and humidity and other external factors in the storage room will also accelerate the reproduction of mold. The process of maize mold mainly produces aflatoxin, Deoxynivalenol (DON), fumonisins and other harmful substances. According to the estimation of the Food and Agriculture Organization (FAO) of the United Nations and a recent validation report, more than 25% of food crops are contaminated with mycotoxins due to the occurrence of molds (Long et al., 2022b; Zhang et al., 2020). In order to prevent and control the occurrence of molds in food, there is a need for the efficient identification of molds in maize kernels (Kang et al., 2022). Existing mold identification methods are difficult to distinguish asymptomatic moldy maize. Therefore, researching non-destructive mold identification methods while being able to accurately detect asymptomatic moldy maize is a key technical challenge currently being faced.

Traditional methods of identifying mold in crops are divided into physical and chemical methods. The physical methods mainly identify the degree of mold by observing their color, odor and touch, which are simple to operate, but are affected by subjective factors and cannot be accurately quantified (Milićević et al., 2010; Oyebanji et al., 1999).

The chemical methods are used to quantitatively analyze mold by preparing sample solution, which are highly sensitive and quantitative, but this method have high complexity and high demands for operators (Paraginski *et al.*, 2019). Visible light computer vision has been used by scholars for mold identification, which has the advantages of non-contact, high efficiency, rapidity and automation, but this technology cannot effectively identify asymptomatic moldy maize (Fei *et al.*, 2018; Qiang *et al.*, 2014; Sun *et al.*, 2022). The rapid development of spectroscopic technology provides a new method for quality detection of crops, and the identification of moldy maize by spectroscopy offers the possibility of effective identification of healthy maize and asymptomatic moldy maize (Bai *et al.*, 2020).

Near-infrared spectroscopy is often used for crop quality detection because of the fast analysis and high efficiency of the measurement process. Currently, the application of NIR spectroscopy to the detection of crop composition and diseases has achieved great results. The combined and multiplied frequencies of hydroxyl groups, such as O-H, N-H, C-H, and S-H, and C-O, are also in the NIR band (Cui *et al.*, 2019). Hydroxyl and single bond hydroxyl groups are the main groups that make up organic compounds, including oils, proteins, and sugars. Therefore, the light absorption of organic compounds in the near-infrared region is mainly the absorption of light with the multiplicative or combined frequency of hydroxyl groups. Jiahui Dai *et al.* (2024) used near infrared spectroscopy to quantitatively analyze the main active components of betel nut, and the results showed that R^2 values were close to 1, and the corresponding RPD values were all less than 3. Jiangming Jia *et al.* (2022) developed quantitative prediction models for sensory quality scores, total catechins and caffeine of different quality grades of Yuezhou Longjing tea using near-infrared spectroscopy. The results showed that the best prediction models for sensory scores, total catechins and caffeine were VCPA-IRIV + SVR, VCPA-IRIV + RF, and CARS + SVR. The relative percentage deviation (RPD) values were 2.485, 2.584 and 2.873, respectively. Jiahui Zhang *et al.* (2023) used a handheld miniature near-infrared spectrometer and applied 24 preprocessing methods in combination with a support vector machine (SVM) and a boosting algorithm. The results showed that the model exhibited high accuracy and stability during parameter tuning, with precision and F1 scores greater than 0.8 and a Kappa coefficient around 0.7. These findings confirm the feasibility of using near-infrared spectroscopy (NIRS) for the rapid identification of 'Dangshan' pear Mianhua reaction diseases. Pauline Ong *et al.* used visible and near infrared spectroscopy combined with a novel wavelength selection method called Modified Flower Pollination Algorithm (MFPA) to identify sugarcane diseases. The simplified SVM model developed utilized the MFPA wavelength selection method to obtain the best performance with an accuracy value of 0.9753, a sensitivity value of 0.9259, a specificity value of 0.9524 and an accuracy of 0.9487 (Ong *et al.*, 2023). Minhui An *et al.* (2023) used NIR to establish a prediction model for walnut mold and developed Support Vector Machine (SVM) and Extreme Learning Machine (ELM) with an accuracy of 100% for the identification of walnut mol. Hui Jiang *et al.* (2023) quantified aflatoxin B1 in moldy peanuts using two-dimensional convolutional neural network in NIR and the results showed that $R^2=0.99$, $RPD=8.3$, $RPIQ=9.3$. All of the above studies have validated the feasibility of NIR spectroscopy for crop composition analysis and disease detection as well as mold detection, but there is little research on early mold detection in maize, especially in healthy maize and asymptomatic mold.

Therefore, to address the challenge of distinguishing healthy maize from asymptomatic moldy maize, this paper proposes a method that utilizes SVM, PLS-DA, RF, KNN, and BP neural networks to analyze and determine the optimal classification model. By comparing the accuracy and F1 scores of these models, the most effective model-building approach is identified to achieve accurate classification of moldy maize. Additionally, this method enables the efficient detection of asymptomatic moldy maize, meeting the requirements of maize warehousing while enhancing its economic benefits.

MATERIALS AND METHODS

Samples

The samples for this experiment were taken from the same variety of maize that had been inoculated with molds in the breeding laboratory of Anhui Agricultural University and had been classified into four grades of moldy maize (grade 1, 2, 3, and 4), i.e., healthy maize, asymptomatic moldy maize, moderately moldy maize, and severely moldy maize, according to the method of LS/T 6132-2018, "Inspection of grain and oils—Storage fungal examination—Enumeration spores of fungi". A total of 683 maize kernel samples meeting the criteria were collected. This included 200 samples of grade 1, 153 samples of grade 2, 261 samples of grade 3, and 68 samples of grade 4. In accordance with an 8:2 ratio, all samples were randomly divided into a train set and a test set for the classification modeling study.

Near-infrared spectrum instrument

The instrument utilized to collect spectral data in this experiment is the handheld portable miniature near-infrared spectrometer "NIR-R210" created by Shenzhen Pynect Technology Co., Ltd. (Shenzhen, China). The spectral wavelength range spans from 900 nm to 1700 nm, comprising 228 bands for spectral detection, with a resolution of 3.89 nm and a signal-to-noise ratio (SNR) of 6000:1. The spectral data are collected by connecting the data line of the spectrometer to the computer. Prior to each measurement, the NIR spectrometer must undergo calibration using a black and white plate. Spectral data were acquired using the ISC-NIRScan-GUI (Windows v3.9.8-win64), supplied with the device.

Spectral data acquisition

For maximum measurement accuracy, the spectrometer underwent a 30-minute warm-up before measurement. The endosperm of each maize kernel was scanned with the endosperm side down, as illustrated in Fig. 1. Each sample underwent 5 scans, and the average of these 5 samples was considered as the final data. Each data file was named based on the sample number. Following the completion of spectral data acquisition, all files were imported. The data in each file included intensity, wavelength, absorbance, and reflectance. The absorption spectral data from the average of 5 scans were used as raw modeling spectral data.

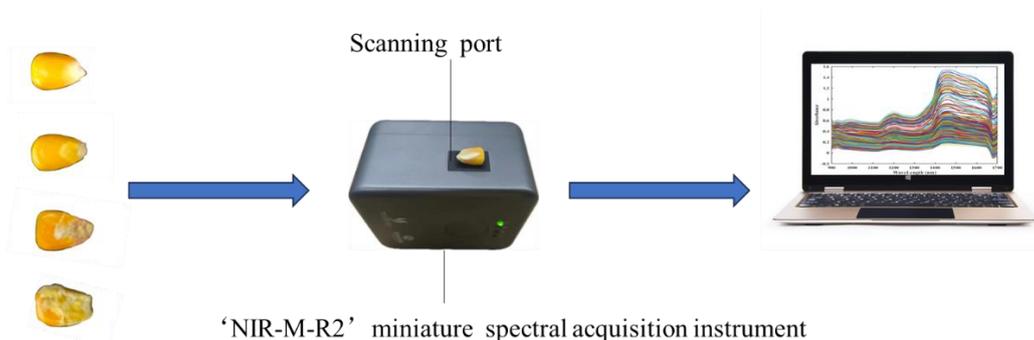

Fig. 1 - Spectral Data Scanning

RGB data acquisition

Due to the limitations of visible light cameras and the naked eye, detecting mold on asymptomatic moldy maize is challenging. Therefore, this paper adopts an electron microscope modeled as "HY-500BL" produced by Shenzhen HAYEAR Electronics Co., Ltd. to take pictures of moldy maize. It can find molds on the surface of asymptomatic moldy maize, as shown in Fig. 2. The collected microscopic photographs provide evidence that asymptomatic moldy corn is observable and allow for a secondary check of the classification results for asymptomatic mold.

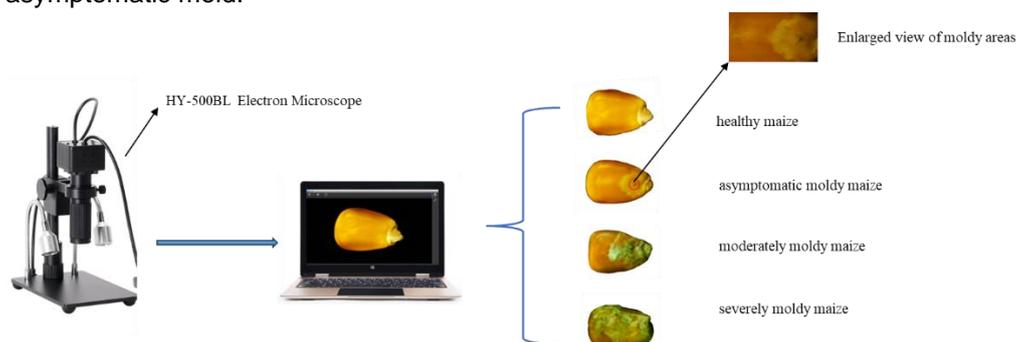

Fig. 2 - Plot of the extent of mold on maize under an electron microscope

Spectral processing method and feature wavelength extraction

During spectral data acquisition, certain disturbing factors unrelated to spectral information acquisition inevitably arise, such as the background noise of the experimental platform (Liu *et al.*, 2023). This leads to some irrelevant information in the raw spectral data. Studies have demonstrated that data preprocessing is effective in mitigating invalid information in spectral curves, enhancing the utilization rate of spectrally valid information, improving SNR of NIR, and subsequently enhancing the accuracy and stability of the regression

model established at a later stage (Xu et al., 2008). In this paper, Baseline Correction (BC) (Li et al., 2020), Multiplicative Scatter Correction (MSC) (Sun et al., 2019), Standard Normal Variate Transform (SNV) (Malavi et al., 2024), and Savitzky-Golay convolution smoothing (SG) (Lanjewar et al., 2024) were employed. Additionally, a combination of SG + SNV, SG + MSC, and SG + BC, constituting two single preprocessing algorithms, was explored to determine the optimal preprocessing method.

Specifically, BC eliminates the influence of the baseline by finding the flatter and more stable parts of the spectral data, and then subtracting or cancelling the resulting baseline from the original spectral signal by fitting the shape and position of the baseline, thus making the spectral signal features more prominent and clearer. As shown in Equation (1).

$$\begin{aligned} Y(\lambda) &= X(\lambda) - B(\lambda) \\ B(\lambda) &= a_0 + a_1\lambda + a_2\lambda^2 + \dots + a_n\lambda^n \end{aligned} \quad (1)$$

where:

$X(\lambda)$ represents the original spectral data, $B(\lambda)$ represents the fitted baseline, and $Y(\lambda)$ represents the corrected spectral data.

MSC selects a set of representative spectral data as a benchmark, averages all the spectral data of the benchmark to obtain the average spectrum, then compares each spectral data with the average spectral data, calculates the scaling factor, i.e., the scaling factor at each wavelength point, and applies the obtained scaling factor to the original sample spectral data, to obtain the scaling-corrected spectral data. As shown in Equation (2).

$$\begin{aligned} \bar{X} &= \frac{1}{N} \sum_{i=1}^N X_i \\ X_{ij} &\approx a_i \cdot \bar{X}_j + b_i \\ Y_{ij} &= \frac{X_{ij} - b_i}{a_i} \end{aligned} \quad (2)$$

where: \bar{X} represents the mean spectrum, N is the number of samples, X_i is the spectrum of the i -th sample, X_{ij} denotes the absorbance value of sample X_i at the j -th wavelength point, \bar{X}_j denotes the absorbance value of the reference spectrum at the j -th wavelength point, a_i is the slope, b_i is the intercept, Y_{ij} represents the corrected spectrum.

SNV is centered by calculating the average of the spectral intensities at each wavelength for each sample, and then subtracting the average of the corresponding wavelengths for each sample, which ensures that the average spectral intensity at each wavelength is zero. For each wavelength point, the standard deviation of the spectral intensities of all samples at that wavelength point was calculated, and for each wavelength point, the spectral intensities of all samples were divided by the standard deviation of the corresponding wavelength point. This ensured that the variance of the spectral data was relatively consistent for the purpose of standardization, as shown in Equation (3).

$$\begin{aligned} \bar{X}_i &= \frac{1}{n} \sum_{j=1}^n X_{ij} \\ \sigma_i &= \sqrt{\frac{1}{n-1} \sum_{j=1}^n (X_{ij} - \bar{X}_i)^2} \\ Y_{ij} &= \frac{X_{ij} - \bar{X}_i}{\sigma_i} \end{aligned} \quad (3)$$

where: \bar{X}_i represents the mean of the samples, n is the total number of wavelength points in the spectrum, X_{ij} denotes the absorbance value of the i -th sample at the j -th wavelength point, σ_i represents the standard deviation, and Y_{ij} represents the standardized data.

Finally, SG determines the order of the polynomial by choosing the size of the smoothing window, i.e. the number of neighboring data points to be processed at a time, and then determines the order of the polynomial, which determines the complexity of the polynomial to be fitted. The selected window is slid over the data from the first data point to the last data point and within each window polynomial fitting and smoothing of the data is done. Polynomial fitting is done by finding a polynomial by least squares that is as close as possible to all the data points within the window. Smoothing of the data is done by using the fitted polynomial to estimate the value of the window centroid i.e., the value of the smoothed data point, and the above operation is repeated until all the data points are processed, as shown in Equation (4).

$$P(x) = a_0 + a_1x + a_2x^2 + \dots + a_kx^k \quad (4)$$

$$Y_i = P(x) \cdot X_i$$

where: $P(x)$ represents the fitted polynomial, a_0, a_1, \dots, a_k denotes the coefficients of the fitted polynomial, and Y_i represents the smoothed data.

Following the preprocessing of spectral data, various feature extraction algorithms, including the Successive Projection Algorithm (SPA), Competitive Adaptive Reweighted Sampling (CARS), and Improved Shuffled Frog Leaping Algorithm (ISFLA), are utilized to identify characteristic wavelengths meeting the prediction criteria in the full-wavelength model. Subsequently, a model based on these extracted characteristic wavelengths is constructed to identify characteristic wavelengths. The model is further optimized to enhance accuracy.

The SPA algorithm first randomly selects a feature from the dataset as the initial feature. It then projects the remaining features onto the orthogonal complementary space of the already selected features, removing the influence of the selected features on the remaining ones. Afterward, the algorithm selects the feature that contributes the most to the model from the projected features. Finally, the newly selected feature is added to the set of selected features. Repeat the projection and selection steps until a predetermined number of features are selected, and the final set of selected features is representative and uncorrelated (Pang *et al.*, 2022; Vallese *et al.*, 2023).

CARS algorithm first randomly generates multiple feature subsets, each of which contains a random subset of the original features. For each feature subset, a PLS regression model is built and the regression coefficients are calculated for each feature. Based on the absolute value of the regression coefficients, weights are assigned to each feature. The larger the weight, the higher the importance of the feature to the model. Subsequently, a weighted sampling method was used to sample the features based on their weights. Features with higher weights have a higher probability of being retained. The relationship between the number of retained features and the prediction error in each iteration is calculated and a 'U' curve is plotted. Select the subset of features with the smallest prediction error, repeat the above process, continuously reduce the number of features, and recalculate the weights and feature selection in each round of iteration, and stop iterating when the predetermined number of iterations is reached or the selected subset of features is stable, and finally output the subset of features that contributes the most to the predictive ability of the model (Tang *et al.*, 2021; Xing *et al.*, 2021).

ISFLA algorithm starts by randomly generating a certain number of frogs, each frog representing a possible solution, which form the initial population. The frogs are sorted by fitness value and divided into subpopulations, each containing a number of frogs. A local search is then performed to determine the optimal frog and the worst frog in each subpopulation. The solution of the optimal frog is the best solution in the current subpopulation, and the solution of the worst frog is the worst solution in the subpopulation. The worst frog updates its position based on the solution of the optimal frog. Specifically, the worst frog moves closer to the optimal frog to increase its fitness value. If the updated position is better than the previous position, the position is accepted; otherwise, further attempts are made to update based on the global optimal solution. After all subpopulations complete the local search, all frogs are remixed to break the local optimum among subpopulations. After mixing, the subgroups are reclassified to continue the next round of local search. In order to avoid the local search from falling into local optima, ISFLA introduces an adaptive step-size adjustment strategy, which dynamically adjusts the step-size of the frogs' jumps based on the feedback during the search process. In some iterations, a more exploratory global search strategy is used to increase the ability of the algorithm to jump out of the local optimum. The local and global search processes are repeated until the stopping condition is satisfied, and the solution of the optimal frog in the whole frog population, i.e., the selected optimal wavelength, is finally output (Hsu and Wang, 2021; Kongsorot *et al.*, 2022).

Modeling method

The modeling methods utilized in this study comprise Support Vector Machines (SVM), Partial Least Squares Discriminant Analysis (PLS-DA), K Nearest Neighbor (KNN), Random Forest (RF), and Back Propagation Neural Network (BP).

The goal of SVM is to find a hyperplane that maximizes the interval between classes in order to classify the data. Specifically, a straight line (hyperplane) is computationally found to separate several classes of data while maximizing the distance between two classes of data points and the hyperplane. The closest data points to the hyperplane, known as support vectors, determine the position and direction of the hyperplane. The hyperplane is then adjusted to maximize the distance from the support vectors to the hyperplane. Finally, for new data points, their class is determined based on their position relative to the decision boundary (hyperplane) (Khairunniza-Bejo et al., 2021).

PLS-DA is a supervised learning method that combines Partial Least Squares Regression (PLS) and Linear Discriminant Analysis (LDA), and is commonly used for classification tasks, especially in high-dimensional, small-sample datasets. PLS-DA maximizes the variance of the samples on these variables by searching for latent variables, and minimizes the confounding between different classes, thereby achieving the classification purpose. Specifically, the input dataset X and the corresponding category labels Y are searched for a set of latent variables, T , so that these variables explain the maximum covariance between X and Y . Through an iterative approach, the weight vector W is computed to derive the latent variables $T = XW$, and a linear regression model of the latent variables T to the category labels Y is built, thus transforming the classification problem into a regression problem. Solve for the regression coefficient B so that $Y \approx TB$. Finally, use the results of the regression model to classify the new sample. The new sample is projected into the latent variable space and its category is determined based on the output of the regression model (Daniels et al., 2021).

KNN A simple and intuitive supervised learning algorithm mainly used for classification and regression tasks. KNN selects the nearest K neighbors by calculating the distances between the samples to be classified and the training samples, and then determines the class of the samples to be classified by the class information of these neighbors. Specifically, the input data consists of a feature matrix X and corresponding labels Y , where X is a sample dataset containing multiple features, and Y is the category label corresponding to each sample, and the Euclidean distance metric Manhattan distance, etc. are chosen to compute the distances between the samples. For the to-be-classified sample, calculate its distance from all the samples in the training set and select the nearest K samples as its neighbors. Finally, based on the categories of these K neighbors, the categories of the samples to be classified are decided by voting, and the category with the highest frequency of occurrence is selected as the final classification result (Cunningham and Delany, 2021). In this study, Euclidean distance is utilized to calculate the distances between points in the feature space. Cross-validation is employed to determine the optimal score of K (Uddin et al., 2022).

RF does this by generating multiple decision trees, each trained independently on a subset of the data, and then combining the predictions of these trees by majority voting. Specifically, the input dataset X and corresponding labels Y are input, multiple subsample sets are randomly selected from the original dataset with putback (i.e., Bootstrap sampling), each of which is used to train a decision tree, and during the construction of each tree, for each node split, a portion of the features are randomly selected to determine the optimal split thus increasing the diversity of the tree and reducing overfitting. Each decision tree is trained on the corresponding Bootstrap sample set to generate multiple different decision tree models, and finally, for new data points, the classification results of each decision tree are voted on and the category with the most votes is selected as the final prediction (Wang et al., 2021).

BP is a training algorithm for multilayer perceptron (MLP) which adjusts the network weights by calculating the errors and back propagating them so that the network is able to learn and approximate complex nonlinear functions. BP neural network consists of an input layer, a hidden layer, and an output layer, and each layer consists of a number of neurons. The core idea is to adjust the weights and bias of the network through the back propagation algorithm to minimize the error between the predicted output and the actual output, in which the input layer receives the input data, the hidden layer performs a linear transformation of the input data through the weights and bias, and then performs a nonlinear transformation through the activation function (e.g., sigmoid, ReLU, etc.), and the output layer performs a transformation of the output again through the weights and bias and through the activation function to get the final predicted output. The predicted output of the output layer is compared with the actual output (labels) and the error is calculated.

Starting from the output layer, the gradient of the error with respect to each weight and bias is calculated. By chain rule, forward propagation is performed layer by layer, calculating the gradient of each layer, and using gradient descent, the weights and biases of each layer are adjusted according to the calculated gradient to reduce the error. The process of forward propagation, error calculation and back propagation is performed repeatedly until the error converges to a preset threshold or the maximum number of iterations is reached (Wang *et al.*, 2023).

In this paper, spectral data were processed and modelled and analyzed using MATLAB 2023b.

Evaluation criteria

For the multi-class classification task of corn kernel quality detection, average evaluation metrics are more suitable. Therefore, this study uses accuracy, average recall, average precision, and average F1 score as evaluation metrics.

Acc is the ratio of the number of correctly classified samples to the total number of samples.

$$Acc = \frac{TP + TN}{TP + TN + FP + FN} \quad (5)$$

where:

TP and TN represent the true prediction of the positive sample and the true prediction of the negative sample, respectively. FP and FN represent the false prediction of the positive sample and the false prediction of the negative sample, respectively.

P is the arithmetic mean of the precision (P) of each category, which is defined in the following:

$$P = \frac{1}{k} \sum_i^k P_i = \frac{1}{k} \sum_i^k \frac{TP_i}{TP_i + FP_i} \quad (6)$$

where:

i represents the target classes, k is set to 4, as four types of corn kernels are classified, P is the proportion of the predicted positive samples that are actually positive.

R is the arithmetic mean of the recall (R) of each category. It is defined as follows:

$$R = \frac{1}{k} \sum_i^k R_i = \frac{1}{k} \sum_i^k \frac{TP_i}{TP_i + FN_i} \quad (7)$$

$F1$ is the weighted harmonic average of P and R scores, which is defined as follows:

$$F1 = \frac{1}{k} \sum_i^k \frac{2 \cdot P_i \cdot R_i}{P_i + R_i} \quad (8)$$

RESULTS

Analysis of original spectral curve

The spectral raw data were obtained using the experimental setup described above, as shown in Fig. 3(a). The overall shapes of the spectral curves of all the maize seed samples were similar. From Fig. 3(b), it can be clearly seen that there are obvious peaks at 930 nm, 1210 nm and 1460 nm, and clear troughs at 910 nm, 1220 nm and 1300 nm. The 930 nm peak corresponds to water absorption, associated with the first multiplicative frequency of the O-H bond stretching vibration in relevant carbohydrates. The 1210 nm peak corresponds to the first multiplicative frequency of the C-H bond stretching vibration in fats and oils within maize kernels, particularly fatty acids. The 1460 nm peak corresponds to C-H bond changes in fibers and polysaccharides inside the maize kernel.

Fig 3(c) shows that the absorbance of maize kernels with different degrees of mold is different, which is mainly due to aflatoxin, erythromycin, vomitoxin and other molds, which will change the hydroxyl (OH), hydrocarbon (CH) and carbonyl (C=O) groups of maize kernels. Because of the complex compounds contained in the maize kernels, the spectral profiles are more complicated and correspond to the octave and frequency information of different chemical bond vibrations, which is the main reason for the different spectral profiles of different molded maize. It was also verified that it is feasible to use microscopy to observe asymptomatic moldy maize.

Analysis of spectral data preprocessing results

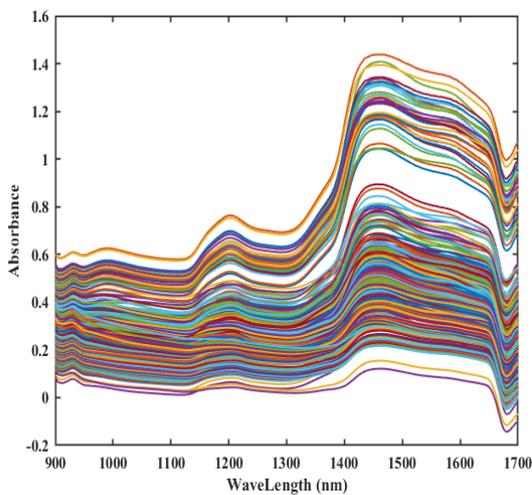

Preprocessing methods and combinations play a crucial role in reducing the interference of irrelevant information. The spectral data underwent preprocessing using SNV, MSC, SG, BC, SG+SNV, SG+MSC, and SG+BC. To ensure consistency in the observed sample data after applying different preprocessing methods, the resulting spectra were compared. The spectral curves resulting from the seven preprocessing methods are presented in Fig. 4, clearly demonstrating their distinct effects. From Fig. 4(a) and Fig. 4(b), it is evident that the spectral curves resulting from the SNV and MSC processing exhibit no significant or fluctuating trends. These methods, both belonging to the scattering processing category, effectively mitigate the scattering effect during spectral data acquisition. They enhance the signal-to-noise ratio of the spectral data, correct the spectral baseline shift, and do not impact the corresponding absorption data. The primary objective of SNV is to mitigate the scattering effect and eliminate optical range changes in the spectra. In contrast, MSC intends to correct the scattering effects due to uneven particle distribution and varied particle sizes on the sample surface. Fig. 4(c) illustrates the spectral curves obtained by applying the SG convolution smoothing method to the original spectral data. This method removes irrelevant noise from the spectra and results in a smoother curve than the original image. Fig. 4(d) displays the outcomes of BC baseline correction, revealing that the baseline drift of the spectral image improves significantly after correction. Additionally, the peaks and shapes of the spectral image are better aligned than those in the original image. This section analyses the relevance of the data preprocessing results. To evaluate the advantages and disadvantages of various preprocessing methods in this experiment, the next step is to model the preprocessed data.

Full-band based modeling

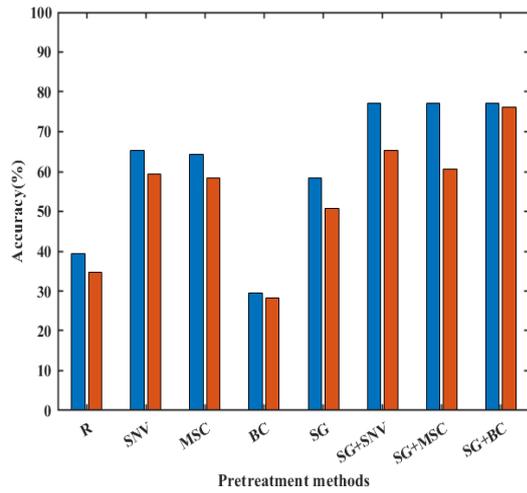

In this paper, five methods, SVM, PLS-DA, RF, KNN and BP, are used to model and analyze the spectral data after different preprocessing. Fig. 5 shows the comparison of accuracy and F1 value of each model with different preprocessing methods. From Fig. 5, it can be clearly seen that, except for the BP neural network and PLS-DA, the preprocessing effect of BC on the other models is poorer. This may be because the baseline and the signal sometimes overlap, leading to the removal of some real information during the BC process. On the other hand, the overall effect of the model after SG processing is better, mainly because SG removes high-frequency noise from the signal, making the spectral curves smoother and highlighting their key characteristics. In addition, for different models, SG+SNV, SG+MSC and SG+BC preprocessing methods all achieve good results, which indicates that the superposition of preprocessing methods is feasible.

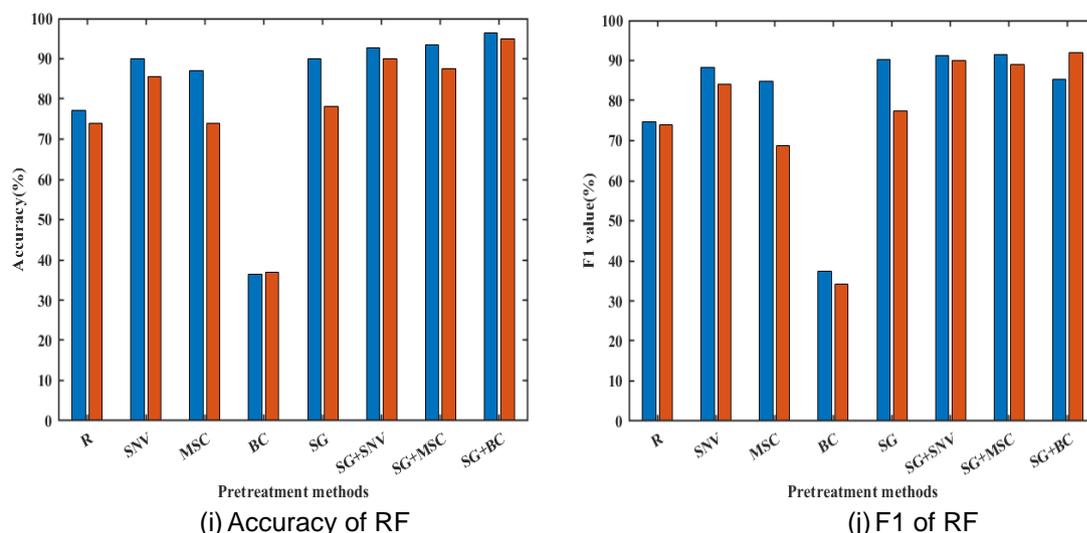

Fig. 5 - Accuracy and F1 with the testing dataset

As shown in Table 1, regarding the accuracy and F1 of each model, SVM and RF consistently outperformed PLS-DA, KNN, and BP in classifying the extent of mold in maize kernels. The best results obtained by SVM were based on spectral data after SG+SNV preprocessing with 97.98% accuracy and 97.55% F1 value for the training set, 93.48% accuracy and 94.63% F1 value for the validation set, and 88.57% identification accuracy for asymptomatic moldy maize, and the best results obtained by RF were based on spectral data after SG+BC preprocessing that the training set accuracy is 96.33% with F1 value of 95.43% and the validation set accuracy is 94.50% with F1 value of 94.98% and the recognition accuracy for asymptomatic moldy maize is 91.43%, which is slightly higher than the SVM modeling, and both models have high discriminative ability. For the identification of asymptomatic moldy maize, the SG+SNV-SVM model incorrectly identified four asymptomatic moldy maize as three healthy maize and one moderately moldy maize. The SG+BC-RF model incorrectly identified three asymptomatic moldy maize as one healthy maize and two moderately moldy maize, which due to the fact that the surface of the asymptomatic moldy maize is similar to that of the healthy maize, but its internal chemical composition is similar to that of moderate moldy maize, which can easily lead to model misidentification.

Despite PLS-DA achieving high accuracy and F1 values in the training set (97.44% for SG+SNV, 96.71% for SG+MSC, and 95.61% for SG+BC), PLS-DA's performance in the validation set was subpar (65.22% for SG+SNV, 73.83% for SG+MSC, and 67.25% for SG+BC). This disparity arises from the limitations of PLS-DA in handling highly correlated independent variables and category imbalances. On the other hand, KNN demonstrated overall lower effectiveness in modeling both raw and preprocessed data, reaching a maximum accuracy of only 77.25% for SG+BC in the training set and 76.48% in the validation set, significantly below the anticipated performance. This inefficiency is attributed to KNN's inapplicability to data with high dimensionality and unbalanced feature weights. For maize mold samples, SVM, RF and BP gave better classification results due to their robustness and good handling of non-linear and large-scale datasets.

Table 1

Classification results based on the SVM, PLS-DA, RF, KNN and BP models

Characteristic wavelength extraction

Based on the results of the established full-band model it can be seen that the model classification under SG+SNV and SG+BC preprocessing is better, so SPA, CARS, and ISFLA were used to extract the feature wavelengths from the spectral data after SG+SNV and SG+BC preprocessing. In the case of SG+SNV, three feature wavelength extractions were performed, yielding 107, 113, and 32 feature wavelengths, respectively. For SG+BC, 107, 109, and 33 wavelengths were extracted. As shown in Fig 6, the feature extraction wavelengths for SG+BC-SPA were concentrated in the range of 1150 nm-1250 nm and 1300 nm to 1700 nm, while those for SG+BC-CARS were mainly concentrated in the range of 980 nm-1220 nm and 1410 nm-1650 nm. For the SG+BC-ISFLA method, a reduced number of feature wavelengths were identified, yet they predominantly clustered within the spectral ranges of 1100nm-1300nm and 1300nm-1650nm. These findings suggest that the maize kernel mold-related compounds associated with these feature wavelengths are consistently concentrated within their respective mentioned ranges. Although the specific values of the extracted feature wavelengths may vary across spectral curves, the observed similarity in their distribution ranges underscores the consistent concentration of these compounds in the aforementioned spectral intervals.

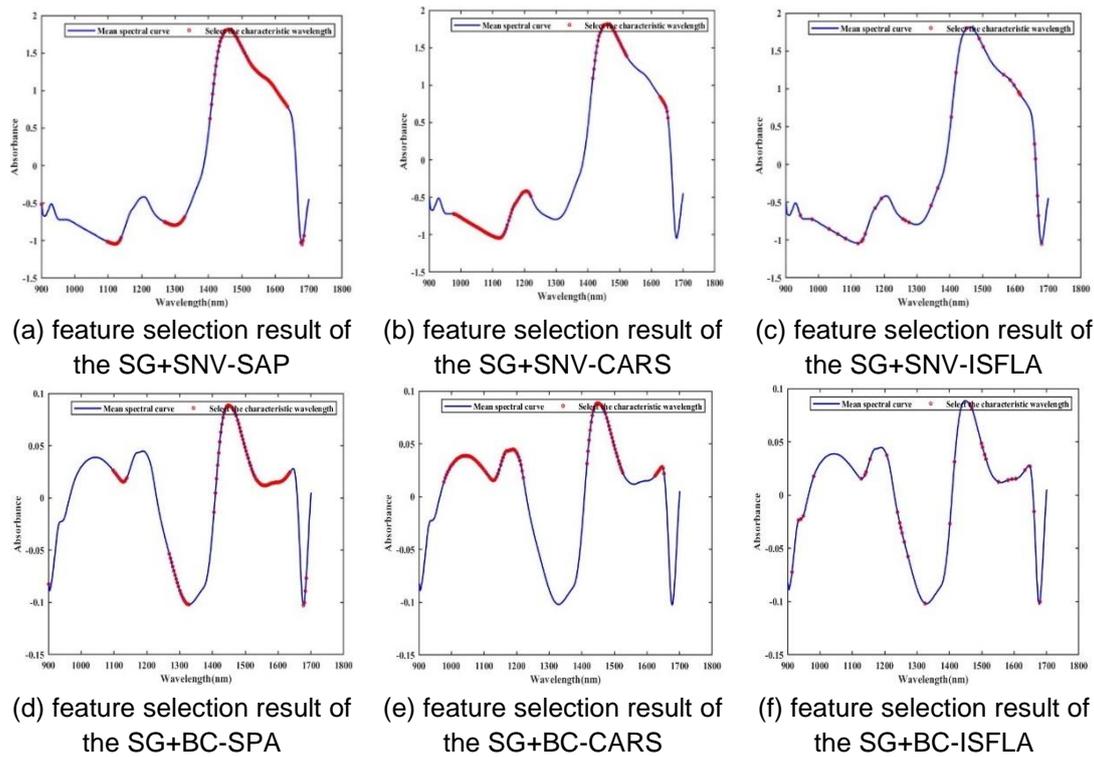

Fig. 6 -Feature extraction results

Modeling of characteristic wavelengths

According to Table 2, the models constructed after feature extraction demonstrate improvements in prediction accuracy and F1 value (Zhang et al., 2022). Specifically, for the SG+SNV-SVM model, ISFLA feature extraction yields the best results with an F1 value of 97.79%, indicating a 3.16% improvement over the pre-feature extraction performance. Conversely, SPA feature extraction shows the least favorable outcome for the SG+SNV-SVM model, resulting in a 0.63% increase compared to pre-extraction. In the case of the SG+BC-RF model, ISFLA feature extraction is the most effective, achieving an F1 value of 96.91% and a 1.93% improvement over the pre-extraction F1 value. However, SPA feature extraction for the SG+BC-RF model shows a minimal improvement of 0.09%, representing the least effective method. Finally, for the SG+BC-BP model, ISFLA feature extraction stands out with the highest F1 value of 95.20%, demonstrating a 3.32% improvement over pre-feature extraction. SPA feature extraction for SG+BC-BP achieves a 2.31% improvement compared to the other two methods. SG+SNV-SVM-ISFLA had the highest classification ability for moldy maize, with an F1 value of 97.22%. The recognition accuracy for asymptomatic moldy maize reached 96.30%, and this sample is a biological sample of high complexity, and the classification index of SG+SNV-SVM-ISFLA model is acceptable in this study.

In summary, while different feature extraction methods exhibit varying effects on the models, there is an overall enhancement in accuracy. This underscores the capability of the feature extraction process to eliminate irrelevant wavelengths and preserve information-rich features, thereby improving the predictive performance of the model.

Table 2

Modeling of maize grain mildew degree under different feature extraction methods.

Models	Characteristic Wavelength Extraction Method	Train set				Test set

CONCLUSIONS

The aim of this paper is to investigate the use of near-infrared spectral fingerprints to classify moldy maize while at the same time accurately identifying asymptomatic moldy maize thereby reducing the probability of early mass infection of stored maize. Firstly, different preprocessing methods are used for comparative analysis, and the results show that the modeling effect of the spectral data after a series of preprocessing methods, such as SNV, MSC, SG, etc., is better than that of the original data, and better results can be obtained by using a combination of multiple preprocessing methods to deal with the original spectra, among which the SG+SNV and SG+BC are the most effective. Secondly, the full-band spectral data classification model was constructed, and the experimental results showed that the accuracy of the SG+BC-RF model for moldy maize classification could reach 94.50%. Then, feature extraction is performed on the different preprocessed data. Finally, the data after feature extraction were modelled, and the experimental results showed that the SG+SNV-SVM-ISFLA model could classify moldy maize with an accuracy of up to 97.22%, and identify asymptomatic moldy maize with an accuracy of up to 96.30%, which meets the identification requirements. This work provides new perspectives and ideas for the classification of moldy maize and the identification of asymptomatic moldy maize, as well as new ideas for early mold safety monitoring of stored maize.

ABSTRACT

To ensure the stability of seeding depth for a corn planter unit under different soil moisture conditions, a control system was designed to adjust the seeding depth of the unit based on soil moisture content. Using a PLC controller as the control foundation, the system employs a hydraulic system as its actuator. Soil moisture content is detected by moisture sensors, and the PLC controller processes the analog signals from the sensors. The controller then adjusts the forward and reverse rotation and speed of one motor via a variable frequency drive, thereby controlling the vertical displacement of the depth-limiting wheel to regulate the seeding depth. At the same time, a pressure sensor provides feedback to the PLC controller to control the switching time of the solenoid directional valve, driving the hydraulic cylinder stroke. The profiling mechanism connected to the hydraulic system moves the depth-limiting wheel accordingly, achieving stability in the planter's seeding depth. The control system is further optimized using the Mamdani fuzzy PID algorithm. Experimental results demonstrate that the designed seeding depth control system is stable and reliable, accurately adjusting the seeding depth according to different soil moisture levels. When the unit operates at speeds of 8~10 km/h, the stability of the seeding depth reaches 90%, significantly improving the stability of the unit's seeding depth.

摘要

为了使玉米播种机单体在不同含水率土壤播种工作时保持播种深度的稳定性,设计了一种根据土壤含水率控制播种单体播种深度的控制系统。以 PLC 控制器为控制基础,系统采用液压系统作为其执行机构,通过水分传感器检测土壤含水率,PLC 控制器分析处理传感器检测所获得的模拟信号后,控制器通过控制变频器调节电机正反转和转速,实现对限深轮的上下位移,完成对播种深度的控制。同时压力传感器将信号反馈给 PLC 控制器控制电磁换向阀的开断时间来驱动液压缸行程,与之相连接的仿形机构带动限深轮一同运动,实现对播种机播深的稳定性调节。利用 Mamdani 模糊 PID 算法对控制系统进行优化。实验结果表明,所设计的播种深度控制系统稳定可靠,能根据不同土壤含水率精确控制播种深度,单体作业速度在 8~10 km/h 时,播深稳定性达到 90%,系统提高了单体的播种深度稳定性。

INTRODUCTION

At present, precision seeding technology is one of the important measures to save and increase efficiency of dry farming, reduce production cost and increase economic income for modern agriculture (Xu et al., 2023). There are many factors affecting the sowing quality of precision sowing, among which soil moisture content, pressure and sowing depth are one of the many factors, among which suitable and consistent sowing depth can effectively improve the yield of corn crops (Zhu et al., 2019; Fu, 2022).

Since the middle of the last century, countries began to study the control of sowing depth. Through a series of basic theoretical and experimental studies, a variety of excellent performance of sowing machines and tools have been developed (Li et al., 2018). Jia et al., (2018), designed an adaptive tillage depth monitoring system, which used the surface adaptive swing arm and optical encoder to measure the rotation of the swing arm, and then converted the measured angle into the tillage depth through a formula.

Xianliang LIU, M.S. Stud. Eng.; Rui ZHANG*, Prof. Ph.D. Eng.; Yubin ZHAI, M.S. Stud. Eng.; Wenjie LI, M.S. Stud. Eng.; Haozhe WEI, M.S. Stud. Eng.;

Nielsen *et al.*, (2018), designed two kinds of depth measurement systems based on angle sensor, linear displacement sensor and ultrasonic sensor and a set of electro-hydraulic control system. Ultrasonic detection technology was adopted and ultrasonic detector was installed on the trencher to complete real-time detection of the trench depth (Du *et al.*, 2021; Fu *et al.*, 2019). A CAN bus monitoring and evaluation system for down pressure and sowing depth of multi-row seeder were designed (Gao *et al.*, 2019; Romaneckas, 2022). A measuring device for sowing depth and sowing pressure with angle and shaft pin sensors was adopted, the design of hydraulic drive and zonal controlled pneumatic drive device was optimized, and real-time monitoring and quality evaluation of sowing pressure and sowing depth in precision sowing operations were achieved (Rao A.S., 2023; Suomi, 2024).

At present, new progress has been made in the development of precision sowing devices in China. However, the comprehensive effects of soil moisture content, sowing depth and soil compaction on seed emergence were less studied (Xu Bing *et al.*, 2023; Hao *et al.*, 2023; Wang *et al.*, 2023). Therefore, this paper proposes an automatic control system for sowing depth of corn seeder based on soil moisture content. PLC is used as the main controller of the control system, and water content sensor and pressure sensor are used as signal input, the three-phase motor and hydraulic cylinder as the actuator realize the real-time control of the sowing depth and the downforce, so as to realize the precise control of the sowing depth of the single seeder.

MATERIALS AND METHODS

System structure and working principle

The system is composed of PLC controller, moisture content sensor, pressure sensor, seeding monomer, proportional reversing valve, hydraulic cylinder, frequency converter and AC motor, as shown in Figure 1.

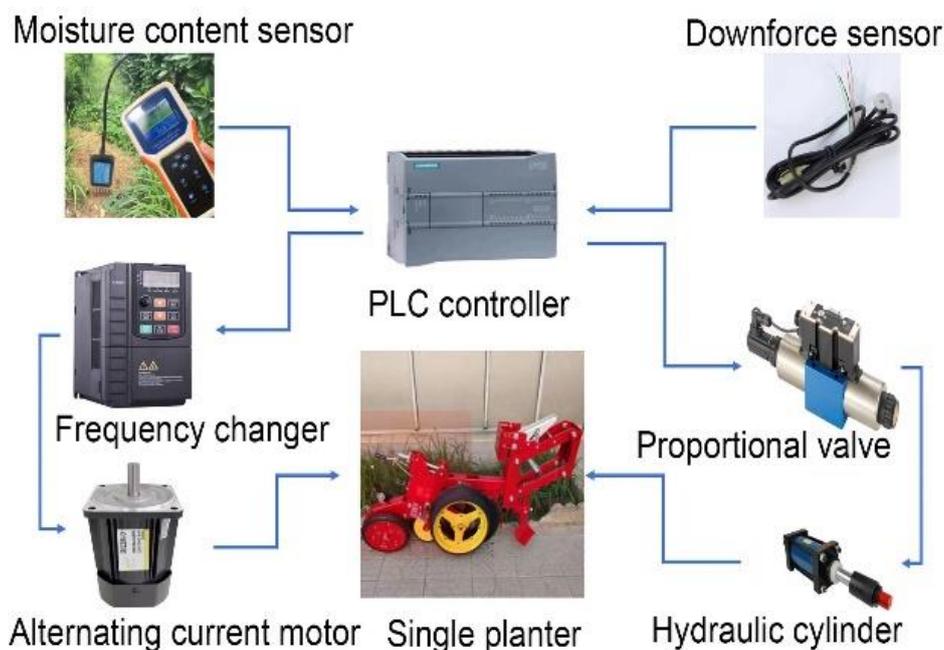

Fig. 1 - Composition of control system

The working process is as follows: PLC as the core processor of the system, equipped with analog input/output module, can collect the value of the moisture content sensor and pressure sensor, analyze and process the output control signal to the actuator, namely the frequency converter and solenoid valve. The adjustment mechanism of the system is divided into sowing depth adjustment and hydraulic feedback adjustment. The former collects soil moisture content through static moisture content sensor before the test starts, and the signal is output to the inverter after PLC processing, and the inverter controls the motor action, thus controlling the sowing depth of the seeder. The latter is to collect the signal of the lower pressure sensor, after the PLC controller analysis and processing, the result is output to the proportional valve, the proportional valve according to the signal range to control the hydraulic oil flow rate and flow, so as to control the expansion and stroke of the hydraulic cylinder, to achieve the real-time feedback action of the lower pressure, so as to achieve the stability control of the sowing depth.

PLC Controller

Siemens S7-1200PLC controller, model 6ES7214-1AG40-0XB0 is used. The controller comes with 24 digital I/O points, including 14 input points and 10 output points. In addition to the switching signal, it is necessary to use the input and output of the analog signal to control the acquisition of the sensor signal and the adjustment of the proportional valve. The control cabinet is shown in Figure 2. At the same time, TIA Portal V18 software was used for PLC configuration and programming. The Ethernet protocol was used to communicate with third-party devices, and I/O assignments are shown in Table 1.

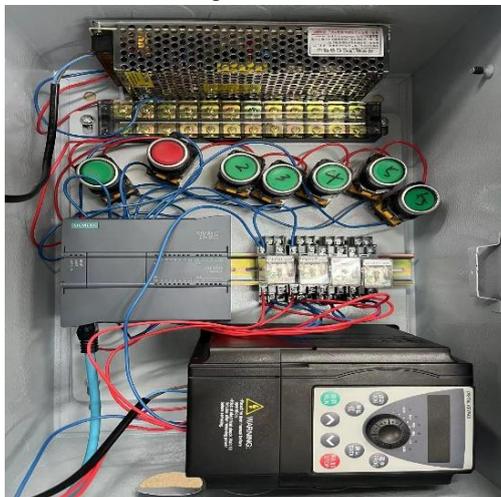

Fig. 2 - Electrical control cabinet

IW98	Pressure input		

Design of depth control system

First of all, the depth limiting wheel is used as a farming reference component, and the relative height difference between it and the trenching plate directly corresponds to the sowing depth. RS485 soil moisture content sensor is used as the detection mechanism, the measurement range is 0-100%, the accuracy is ±3%, the sampling frequency is 1Hz, and the PLC analog input module is connected. The actuator is a combination of frequency converter and three-phase motor, while the three-phase motor and the monomer are connected through a coupling, and their rotation can drive the movement of the monomer. The frequency converter is selected from Instar AE200 model (input 220VAC/50Hz, output 0-400Hz), and the motor is selected from Matsuoka three-phase 220V asynchronous motor (rated torque 5.2Nm).

Fig. 3 - Installation of frequency converter and motor

By observing the pressure sensor signal installed in the groove of the depth limiting wheel arm to reflect the change of pressure on the depth limiting wheel, the pressure sensor is directly connected to the PLC analog input module, and the pressure signal is fed back to the PLC controller. The output end of the PLC controller is connected to the proportional reversing valve. By receiving the voltage signal transmitted by the PLC controller to control the flow rate and direction of the oil in the solenoid valve, the hydraulic cylinder connected with it moves with the change of the position of the valve core, driving the parallel four-link copying mechanism to complete the upward and downward movement, controlling it to reach the predetermined pressure, and realizing the stable control of the depth. The stress analysis diagram of the pressure sensor is shown in Figure 4. The force analysis formula is shown in equation (1).

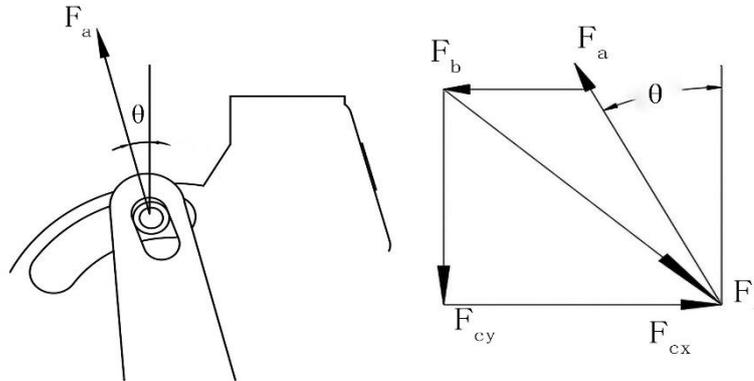

Fig. 4 - Force analysis diagram of pressure sensor

$$\begin{aligned} F_{cx} &= F_a \sin \theta + F_b \\ F_{cy} &= F_a \cos \theta \end{aligned} \quad (1)$$

where:

F_a - Reaction force of the depth limiting arm on the depth limiting block, N; F_b - Force of single frame on depth limiting block, N; F_c - Sensor force on depth limiting block, N; θ - the Angle between the depth limiting arm and the sowing unit frame, ($^\circ$); F_{cx} - F_c component in the horizontal direction, N; F_{cy} - F_c in the vertical direction, N.

The installation position of the force sensor is the limit pin of the depth limiting wheel, which does not rotate itself, and the force stability is limited only by the reaction force in the vertical direction of the deep wheel arm. Therefore, the sensor uses a high-precision micro-pressure sensor, the selected model is DYHW-108, the force range is 0 ~ 2000 N, the output voltage range is 0 ~ 10 V, and the working voltage is 15 ~ 30 V.

According to the weight of the single unit of the corn planter, the hydraulic cylinder of model MOB40X100 was selected. The inner diameter of the hydraulic cylinder D is 40 mm, the diameter of the piston rod is 20 mm, the maximum pulling force is 6.59 kN and the maximum thrust is 8.80 kN. The hydraulic cylinder can satisfy the motion control of the monomer. The installation position of hydraulic cylinder is shown in Figure 5. The oil source of the system adopts the hydraulic output after the tractor, and its output rated flow rate is generally 36 L/min, the rated working pressure is 12 MPa, and the safe working pressure is 15 MPa. Therefore, the pilot relief valve integrated block is used to stabilize the oil pressure in the cylinder, the rated flow rate is 36 L/min, the maximum pilot flow rate is 60 L/min, and the pressure range is 0 ~ 50 bar.

Fig. 5 - Installation position of hydraulic cylinder

Fuzzy PID control

In order to obtain more rapid and stable control effect, based on the traditional PID control theory, fuzzy control theory is introduced into the traditional PID control with the help of MATLAB. Fuzzy PID control has the characteristics of short response time, small overkill and good dynamic performance. According to the corresponding relationship between the pressure of the monomer and the displacement of the hydraulic cylinder, the pressure control of the monomer of the planter is transformed into the displacement of the hydraulic cylinder. After the fuzzy control algorithm processes the deviation between the given value and the output value of the system and the deviation change rate of the two through the proportion, integral and differential coefficients, the control system can get more accurate control effect.

A fuzzy PID controller suitable for the system was optimized and designed. A Mamdani dual-input-three-output fuzzy controller was constructed with the deviation e and the deviation change rate ec as inputs and the three PID control parameters k_p , k_i and k_d as outputs. e , ec , k_p , k_i and k_d are replaced by 5 fuzzy subsets respectively, namely, large positive deviation (NB), small positive deviation (NS), zero deviation (Z), small negative deviation (PS) and large negative deviation (PN). According to the actual situation, the argument domain of parameter change was set as $\{-6, -5, -4, -3, -2, -1, 0, 1, 2, 3, 4, 5, 6\}$. The input of the fuzzy controller is Gaussian membership function and the output is trigonometric membership function.

According to the parameter function of PID controller and expert experience, the fuzzy rules suitable for control system are optimized. The fuzzy rules of k_p , k_i and k_d are designed, as shown in Table 2~4.

Table 2

Kp fuzzy rules

PB	PB	PS	PS	PS	PB

Through the fuzzy rule table formulated by MATLAB software analysis and reasoning, the relationship diagram of input parameters e and ec and output parameters k_p , k_i and k_d is obtained, as shown in Figure 6.

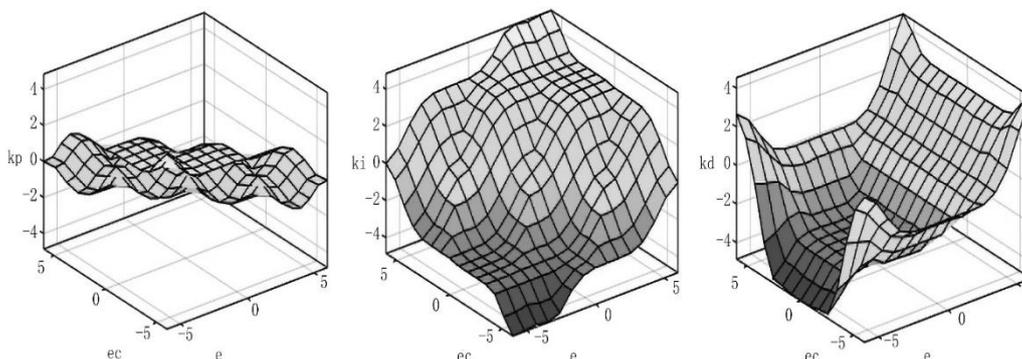

Fig. 6 - Fuzzy control relation surface

In order to verify the optimization effect of fuzzy PID control, a fuzzy controller model was built on Simulink simulation software, as shown in Figure 7. The simulation model of the pressure control system was established, as shown in Figure 8.

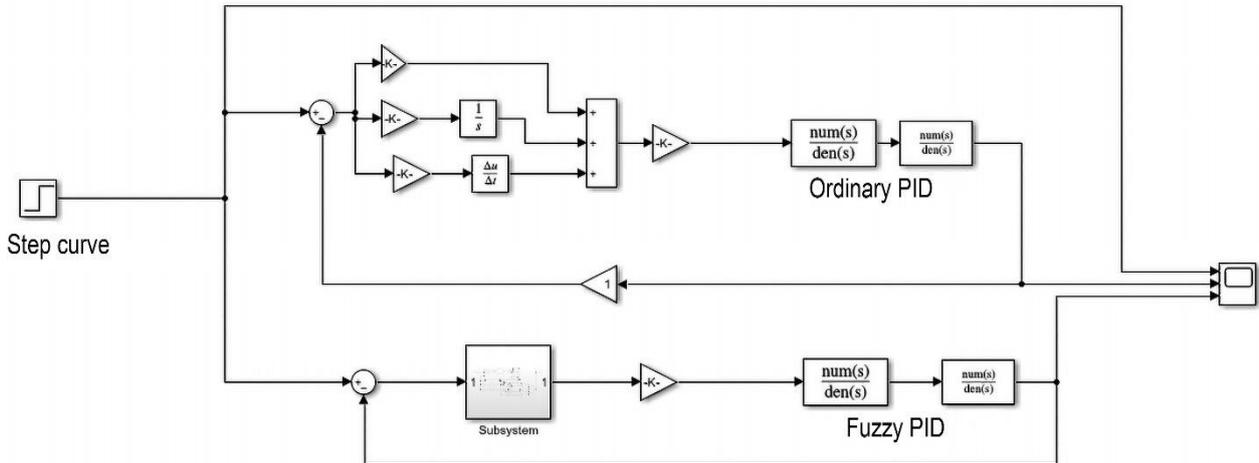

Fig. 7 - Fuzzy controller model

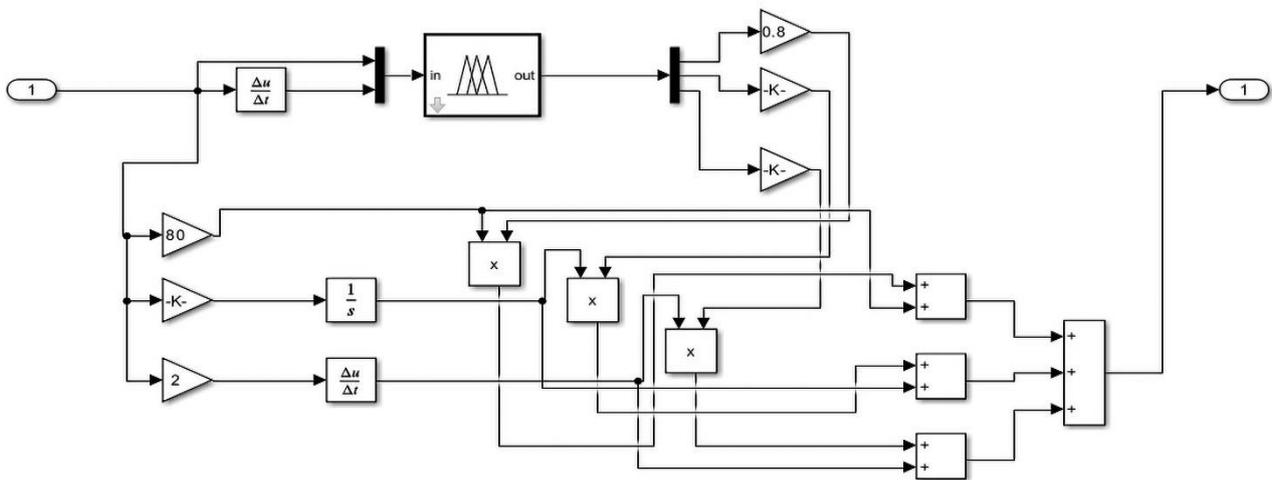

Fig. 8 - Simulation model of downforce control system

The above model is simulated by MATLAB software and the simulation results are observed through the scope window, as shown in Figure 9. As can be seen, compared to the traditional PID controller, the adjustment time of the system increases by 2.572s and the overshoot is reduced from 27% to 14% when using fuzzy PID control instead of the ordinary PID control. Fuzzy PID control can shorten the system response time to a certain extent on the premise of reducing system fluctuations, and the system control effect is significantly improved. This approach meets the stability requirements for sowing depth control.

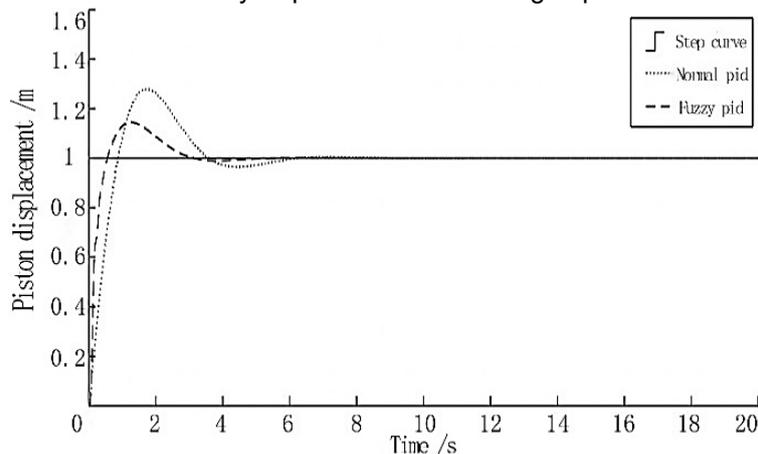

Fig. 9 - Step response curve of the system

RESULTS

A pre-experiment of soil moisture content was carried out before the field experiment. Three groups of variables (moisture content, pressure and sowing depth) were designed, and three levels were set for each group of variables. Without considering the interaction between the variables, the optimal values corresponding to the sowing depth and downforce under each group of moisture content interval were solved to achieve the highest corn emergence rate (The emergence rate is calculated by multiplying the ratio of the actual number of seedlings to the sowing amount by 100%). Multiple sets of data were measured through experiments and the emergence rate was obtained, as shown in Table 5. These results will be used as reference for subsequent tests of the control system.

Table 5

Soil moisture pretest				
number	Moisture content(%)	Downforce(N)	Sowing depth(cm)	Emergence rate(%)
1	16 ~ 18	250	5	61
2	16 ~ 18	500	6	79
3	16 ~ 18	750	7	86
4	18 ~ 20	250	5	82
5	18 ~ 20	500	6	92
6	18 ~ 20	750	7	74
7	20 ~ 22	250	5	88
8	20 ~ 22	500	6	65
9	20 ~ 22	750	7	77

The results showed that the optimal value of the lower pressure and the sowing depth were 750 N and 7 cm respectively in the range of 16% ~ 18% moisture content. The optimal value of the water content was in the range of 18% ~ 20% corresponding to the lower pressure of 500 N, the optimal value of the sowing depth was 6 cm. In the range of 20% ~ 22%, the optimal value of the lower pressure was 250 N, and the optimal value of the sowing depth was 5 cm.

In order to test the sowing depth control performance of the control system under different moisture content, the performance test was conducted in the test soil tank of Qingdao Agricultural University in the summer of 2024, as shown in Figure 10. The field environment of the soil tank was measured before the test. The measured soil volume density of 3 ~ 7 cm depth was 1.2 g/cm³, the average seed bed firmness was 2.5 kg/cm². The control system was installed in Weifang Letian Company's Grand stamping no-tillage seeder. The mechanical parallel four-link copying system was used in the control test, and the depth of the trencher was adjusted to the corresponding sowing depth according to the soil moisture content.

Fig. 10 - Soil tank test diagram

The standard operation speed of tractors in the field was 8 ~ 10 km/h. Two groups of controlled experiments were conducted. The first group adopted the sowing depth control system and added fuzzy control method, while the control group adopted ordinary mechanical copying. The corresponding relationship of different sowing depth was set according to the different moisture content of the earlier sowing data and each group of experiments was repeated six times to reduce errors. According to the agricultural industry standard NY/T 1768-2009 "Technical Specification for Quality Evaluation of no-till seeder", the average sowing depth, the qualified rate of sowing depth and the coefficient of variation of sowing depth were calculated. The test results are shown in Table 6 ~ 8.

Table 6

Consistency test results of sowing depth at different speeds (16% ~ 18% moisture content)				
Argument	Regulation mode	Tractor operating speed/(km/h)		
		8	9	10
Average sowing depth /mm	Control system	71	69	72
	Mechanical copying	65	62	63
Pass rate of sowing depth /%	Control system	96	95	93
	Mechanical copying	72	66	62
Coefficient of variation of sowing depth /%	Control system	10.4	12.3	13.4
	Mechanical copying	14.8	15.6	17.6

Table 7

Consistency test results of sowing depth at different speeds (18% ~ 20% moisture content)				
Argument	Regulation mode	Tractor operating speed/(km/h)		
		8	9	10
Average sowing depth /mm	Control system	62	58	63
	Mechanical copying	56	54	52
Pass rate of sowing depth /%	Control system	97	96	92
	Mechanical copying	75	68	65
Coefficient of variation of sowing depth /%	Control system	9.8	11.8	12.2
	Mechanical copying	14.1	15.4	16.9

Table 8

Consistency test results of sowing depth at different speeds (20% ~ 22% moisture content)				
Argument	Regulation mode	Tractor operating speed/(km/h)		
		8	9	10
Average sowing depth /mm	Control system	49	52	53
	Mechanical copying	53	57	62
Pass rate of sowing depth /%	Control system	95	94	93
	Mechanical copying	71	64	62
Coefficient of variation of sowing depth /%	Control system	10.5	12.5	13.6
	Mechanical copying	14.6	16.1	18.6

From Table 6 ~ 8, it can be seen that the qualified rate of sowing depth control system is higher than 90% at different speeds, and the qualified rate of sowing depth control system is obviously better than that of mechanical copying device. In summary, compared with ordinary mechanical copying device, the automatic sowing depth control system can maintain the stability of sowing depth at different operating speeds and with different compatibility. According to different moisture content, the monomer can be accurately controlled to reach the predetermined sowing depth, and the sowing depth control system has reliable performance.

CONCLUSIONS

Field tests on sowing depth control were conducted for three soil moisture content ranges of 16% ~ 18%, 18% ~ 20% and 20% ~ 22%. When the moisture content was within the range of 18% ~ 20% and the sowing depth was set at 60 mm, the qualification rate of sowing depth was the highest when the vehicle speed of the control system was 6 km/h. The qualified rates of the corresponding control system and mechanical profiling were 97% and 75%, respectively. Compared with the mechanical profiling mechanism, the sowing depth control system increased by 22 percentage points. Thus, the sowing depth control system is obviously superior to the traditional mechanical profiling device.

ABSTRACT

To address the high efficiency and precision seeding requirements for rice factory seedling cultivation, a whole tray air-suction dual-station high efficiency seedling cultivation and seeding assembly line was designed. Based on the whole-tray air-suction principle, the study focused on the design of a dual-suction seed tray dual-station precision hole-to-hole seeding device, a transverse seedling tray conveying device, and an automatic seed replenishment device. Nan Jing 46, Nan Jing 5055, and Koshihikari rice seeds were used for seeding performance experiments on the assembly line. The impact of workstation configuration and production efficiency on the empty hole rate, reseeding rate, damage rate, and seeding precision was analyzed. Experimental results showed that the dual-station precision seeding method significantly improved seeding efficiency. When the seeding efficiency reached 2000 trays per hour, the seeding rate of 1-3 seeds per hole was 90.1%, while the damage rate, empty hole rate and reseeding rate were 0.38%, 0.84%, 9.06% respectively. This study shows that combining the whole tray air-suction principle with transverse seedling tray conveying device, dual-station precision hole seeding device, and automatic seed addition device can significantly enhance the seeding efficiency while ensuring the seeding accuracy, achieving a seeding efficiency of over 2000 trays per hour. This study provides an important reference for further improving the seeding accuracy and efficiency of precision rice seedling cultivation and seeding assembly line.

摘要

针对水稻工厂化育秧的高效率精量播种需求, 本文设计了一种整盘气吸式双工位高效育秧播种流水线。基于整盘气吸式原理, 重点设计了双吸种盘双工位精量对穴播种装置、横向秧盘输送装置及自动加种装置。南粳 46、南粳 5055 及越光稻种子被用于流水线播种性能试验, 分析了工位配置和生产效率对合格率、损伤率、空穴率和重播率的影响。试验结果表明, 双工位精量对穴播种方式显著提高了播种效率。当播种效率达到 2000 盘/h 时, 每穴 1-3 粒的合格率为 90.1%, 损伤率、空穴率、重播率分别为 0.38%、0.84%、9.06%。该研究表明, 将整盘气吸式原理与横向秧盘输送装置、双工位精量对穴播种装置及自动加种装置相结合, 能够在保证播种效果的同时显著提升播种效率, 达到超过 2000 盘/小时的播种效率。这一研究为进一步提高水稻精量育秧播种流水线的播种精度和效率提供了重要参考。

INTRODUCTION

As one of the world's major food crops, improving rice production efficiency and yield was of great strategic significance for ensuring food security, coping with population growth and other key issues (Zang et al., 2024). Factory-based rice seedling cultivation was a modern agricultural technology that transferred the seedling cultivation process to a controlled factory environment, achieving a high degree of standardization and automation of sowing, growth, and management, thereby effectively improving the survival rate and quality of rice seedlings (Hou et al., 2020; Zhang et al., 2023; Karayel D., 2022). As an important equipment for factory-based rice seedling cultivation, the seeding assembly line for rice seedling cultivation could complete tray feeding, subsoil laying, hole pressing, seeding, watering, topsoil covering, tray stacking all at once (Singh R.C., 2005), which could significantly improve the production efficiency and quality of rice seedling cultivation (Sun et al., 2021; Ding et al., 2021).

Currently, scholars and enterprises accomplished a series of research progress in the field of factory-based seeding assembly line for rice seedling cultivation (Yang *et al.*, 2021). The mechanical groove wheel seeding method was applied in Japan's Kubota 2BZP-800 rice seedling cultivation and seeding assembly line (Cao *et al.*, 2021). It is suitable for flat seedling trays and could reach a seeding efficiency of 800 trays per hour. The mechanical drum seeding method was applied in the 2BD-300 and 2BD-600 rice seedling cultivation and seeding assembly line produced by Changzhou Yamike Company (Yuan *et al.*, 2020). It was suitable for bowl seedling trays, and the highest seeding efficiency could reach 600 trays per hour. The radial outer groove wheel seeding method was applied in Zoomlion's 2BP-780C rice seedling cultivation and seeding assembly line (Ma *et al.*, 2018; Zhang *et al.*, 2015). It was suitable for bowl seedling trays and the seeding efficiency could reach 780 trays per hour (Hou *et al.*, 2015). The precision seeding assembly line and automatic stacking device was designed by Ma Xu *et al.* for rice seedling cultivation, while the seeding efficiency could reach 800 trays per hour (Ma *et al.*, 2019). The air-suction drum rice seed metering device designed by Han Bao *et al.* had realized the functions of automatic seed filling in the sockets and pneumatic assisted seed suction, which greatly improved the uniformity of seeding and seed integrity (Han *et al.*, 2009).

However, traditional mechanical seeding equipment had problems such as low efficiency, easy seed damage, poor adaptability, and difficulty in accurately controlling the seeding amount and position, which affected the consistency of the seeding effect (Li *et al.*, 2021; Xing *et al.*, 2020; Li *et al.*, 2009). Seed metering device based on the principles of air suction rollers and air suction needles have rarely been applied in rice seedling cultivation and seeding. These methods exhibit low working efficiency and struggle to meet the requirements for large-scale promotion and application (Li *et al.*, 2008).

In view of the above problems, a rice seeding assembly line for rice seedling cultivation based on the whole-tray air suction principle was proposed, and its key components such as the tray sending device, seed metering device and tray stacking device were optimized and improved. Under the premise of ensuring seeding accuracy, the production efficiency of rice seedling cultivation and seeding had been greatly improved, providing a new technical path for the development of precise and high-efficiency rice factory-based seedling cultivation and seeding equipment.

MATERIALS AND METHODS

OVERALL STRUCTURE AND WORKING PRINCIPLE

The whole tray air-suction seeding assembly line for rice precision seedling cultivation was mainly composed of horizontal tray delivery device, bottom soil laying device, dual-station high-efficiency seeding device, sprinkler device, topsoil covering device, horizontal tray stacking device, automatic seed adding device, seed tray high pressure fan, electric control box and frame, as shown in Fig.1.

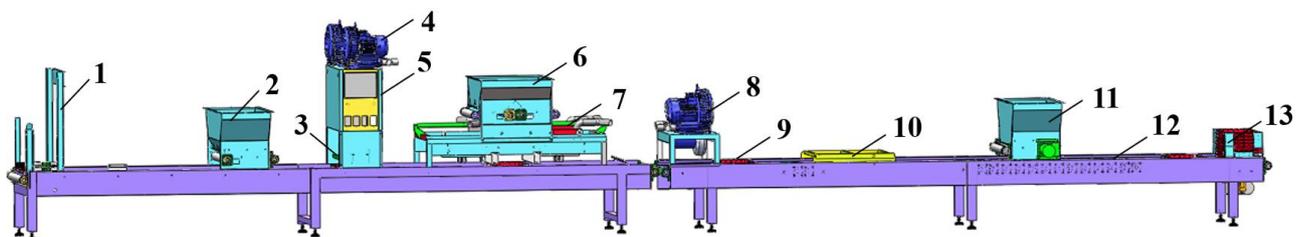

Fig.1 - Schematic diagram of the overall structure of the whole tray air-suction seeding assembly line for rice precision seedling cultivation

1. Horizontal tray delivery device
2. Bottom soil laying device
3. Hole pressing device
4. Left seed tray high pressure fan
5. Electric control box
6. Automatic seed adding device

8. Right seed tray high pressure fan
9. Seedling tray
10. Sprinkler device
11. Topsoil covering device
12. Frame
13. Horizontal tray stacking device

When the seed metering device was working, the power of the seeding assembly line was turned on to ensure that the air compressor and high-pressure fan were in normal working condition. Subsequently, the seedling trays were stacked on the horizontal tray delivery device. The start button on the electric control box was pressed, and then a group of seedling trays (including No. 1 seedling tray and No. 2 seedling tray) were continuously transported through the conveyor belt. When the seedling tray moved to the bottom soil laying device, the conveyor belt driven by the motor spread the nutrient soil evenly on the bottom of the seedling tray. Next, the seedling tray reached the hole pressing device, where it underwent a hole pressing process to form seed holes. Afterwards, when the seedling tray entered the dual-station high-efficiency seeding position, the cross-intermittent seeding method was used for whole-tray precision hole seeding.

Specifically, when the No. 1 seedling tray reached the seeding position, the left suction tray would discharge the seeds, and the right suction tray would suck the seeds. The No. 1 seedling tray moved forward after seeding, while the No. 2 seedling tray reached the seeding position. The right seed suction tray discharged seeds, and the left seed suction tray sucked seeds, thus completing the seeding of a group seedling trays. After the seeding operation, the seedling trays were watered, covered with topsoil and stacked in sequence, and finally the seedling trays that had been sown were removed. The above operation process was repeated to realize the continuous tray delivery - bottom soil laying - hole pressing - seeding - water sprinkling - topsoil covering - trays stacking operation of the seeding assembly line for rice seedling cultivation. The main design parameters of the seeding assembly line for rice seedling cultivation designed in this paper are shown in Table 1.

Table 1

Main design parameters of seeding assembly line		
Parameters	Unit	Values
working principle	/	whole tray air-suction
efficiency	tray/h	2000
qualification rate	%	≥85
empty hole rate	%	≤2
reseeding rate	%	≤15
damage rate	%	≤2
delivery method	/	horizontal tray delivery

KEY COMPONENTS DESIGN

Design of horizontal tray delivery and stacking device

(1) Design of horizontal tray delivery device

To ensure the seeding effect of the seed metering device, there was usually a limit to the speed of the seeding tray and the seeding assembly line. The highest efficiency of the traditional seedling cultivation and seeding assembly line could only reach 1000 trays/h. This paper proposed a horizontal tray delivery method, which adjusted the traditional vertical tray delivery method to a horizontal tray delivery method. The seedling tray delivery method is shown in Fig. 2.

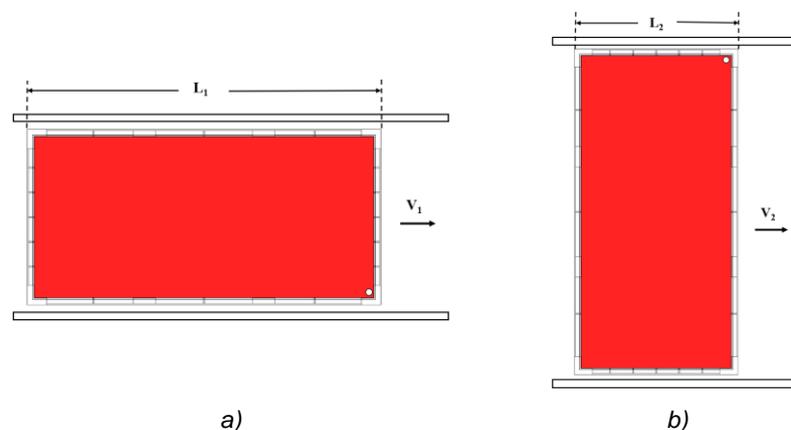

Fig. 2 - Seedling tray delivery method
 (a) horizontal delivery; (b) vertical delivery

The time t required for a single seedling tray to move was

$$t = \frac{L}{v} \tag{1}$$

Among them, L was the moving distance of the seedling tray, and v was the moving speed of the seedling tray.

The standard seedling tray size of 300mm*600mm was used in this experiment, that is, $L_1 = 2L_2$, $v_1 = v_2$.

Therefore:

$$t_1 = 2t_2 \tag{2}$$

When the horizontal tray delivery method was applied in the seeding assembly line for rice seedling cultivation, the seeding assembly line efficiency was doubled when the moving speed of the seedling tray remained unchanged.

The horizontal tray delivery device was composed of frame, upper cylinder, lower cylinder and chuck, as shown in Fig. 3. During operation, the upper cylinders on both sides extended out and the chuck was inserted between the two lowest seedling trays. The lower cylinders on both sides retracted, so that the lowest seedling tray automatically fell onto the conveyor belt of the assembly line, completing the automatic tray delivery. Then the lower cylinders on both sides extended out, the upper cylinders on both sides retracted, and the seedling tray fell on the chuck connecting the lower cylinders on both sides. Then the upper cylinders on both sides extended out, and the lower cylinders on both sides retracted to complete the next tray delivery operation.

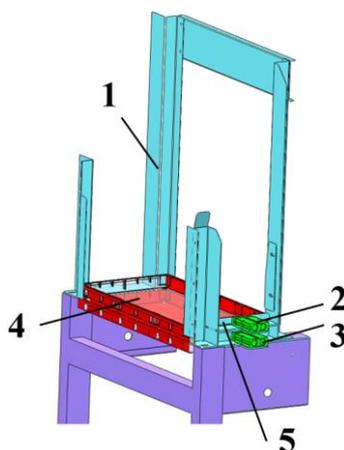

Fig. 3 - Horizontal tray delivery device

1. Frame; 2. Upper cylinder; 3. Lower cylinder; 4. Seedling tray; 5. Chuck

(2) Design of horizontal tray stacking device

The horizontal stacking device was composed of cylinder, frame, tray, and stacking chuck, as shown in Fig. 4. During operation, when the seedling tray reached the stacking position, the two stacking cylinders extended synchronously to move the seedling tray upward, and the stacking chuck was retracted into the through groove driven by the seedling tray. When the seedling tray moved to the upper side of the stacking tray chuck, the stacking tray chuck returned to the initial open state under the action of the spring. Then, the two cylinders retracted at the same time, and the seedling tray moved downward under its own weight and fell on the stacking tray chuck. When the next seedling tray was transported to the tray position, repeated the above process to complete the automatic stacking operation of seedling trays. The horizontal stacking device adjusted the stacking interval time according to the efficiency of the assembly line operation, and completed the automatic stacking operation.

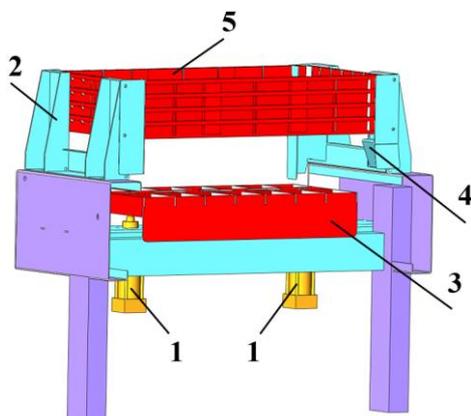

Fig. 4 - Horizontal tray stacking device

1. Stacking cylinder 2. Frame 3. Tray 4. Seedling tray 5. Stacking chuck

Design of dual-station high-efficiency seeding device and automatic seed adding device

Dual-station high-efficiency seeding device and automatic seed adding device are shown in Fig. 5. The dual-station high-efficiency seeding device realized interactive seeding with double suction seed trays, and the automatic seed adding device added seeds to the seed tray according to actual needs.

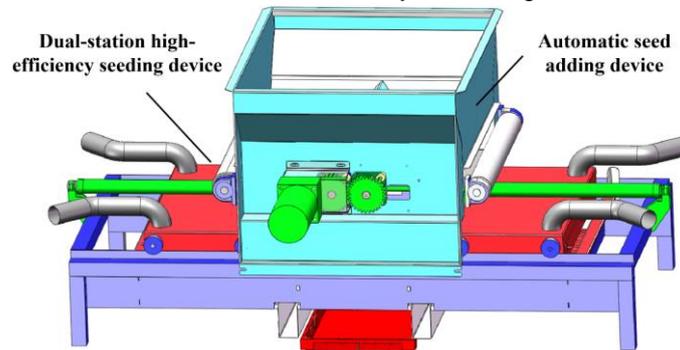

Fig. 5 - Dual-station high-efficiency seeding device and automatic seed adding device

(1) Design of dual-station high-efficiency seeding device

Dual-station high-efficiency seeding device is shown in Fig.6. The dual-station high-efficiency seeding device was mainly composed of seed suction station 1, seed suction station 2 and seeding station.

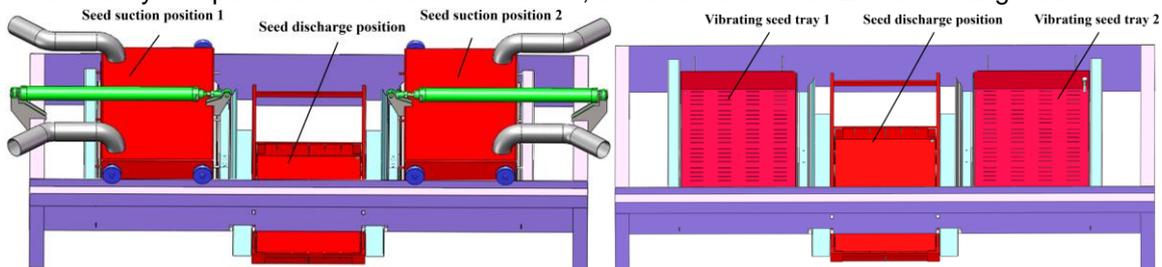

Fig. 6 - Structure diagram of the dual-station high-efficiency seeding device

In the horizontal single-station working mode, seeding work was completed by 1 seed suction tray, 1 seed suction position and 1 seed discharge position. While in the horizontal dual-station working mode, 2 seed suction trays cooperated with 2 seed suction positions and 1 seed discharge position to complete the interactive seeding work. The comparison of operation time under different working modes is shown in Fig.7.

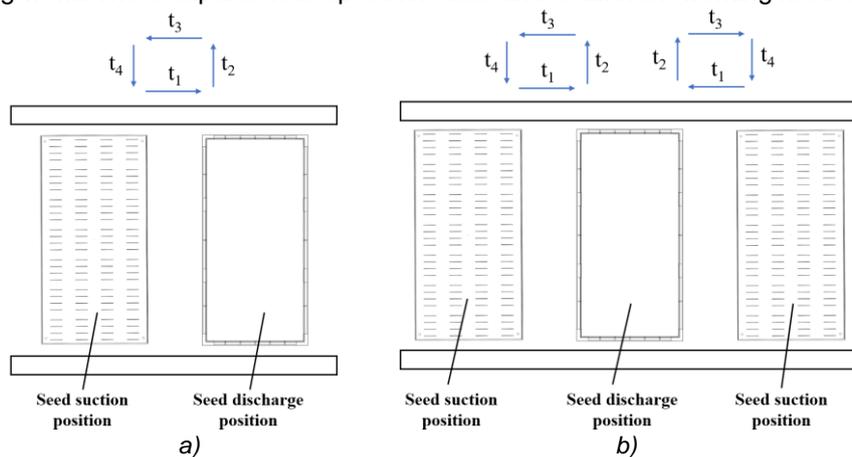

Fig. 7 - Comparison of operation time under different working modes

(a) Horizontal single-station;

(b) Horizontal dual-station

In the horizontal single-station working mode, the time required to complete the seeding of one seedling tray is T_s .

$$T_s = t_1 + t_2 + t_3 + t_4 \tag{3}$$

where t_1 is the time required for the seed suction position to move to the seed discharge position, t_2 and t_4 are the time required to complete seed discharge, t_3 is the time required for the seed discharge position to move to the seed suction position.

In the horizontal dual-station working mode, the time to complete the seeding of seedling tray No. 1 and seedling tray No. 2 when working independently was $2T_s$. When working interactively, the seeding position is shared, and only the seeding time t_2 does not overlap. When $t_1 + t_3 + t_4 \geq t_2$, the time required to complete the seeding for a set of seedling trays (two trays) is $T'_d = T_{d1} + T_{d2} = t_1 + t_2 + t_3 + t_4 = T_s$. Therefore, the time T_d required to complete one seedling tray seeding could be shown as Eq.(4).

$$T_d = T'_d = \frac{1}{2}T_s \tag{4}$$

During operation, the dual-station high-efficiency seeding device worked sequentially in reset state 1 → seeding state 1 → reset state 2 → seeding state 2. This process repeated itself to achieve interactive seeding of seed suction tray 1 and seed suction tray 2. The working principle diagram of dual-station high efficiency seeding is shown in Fig. 8.

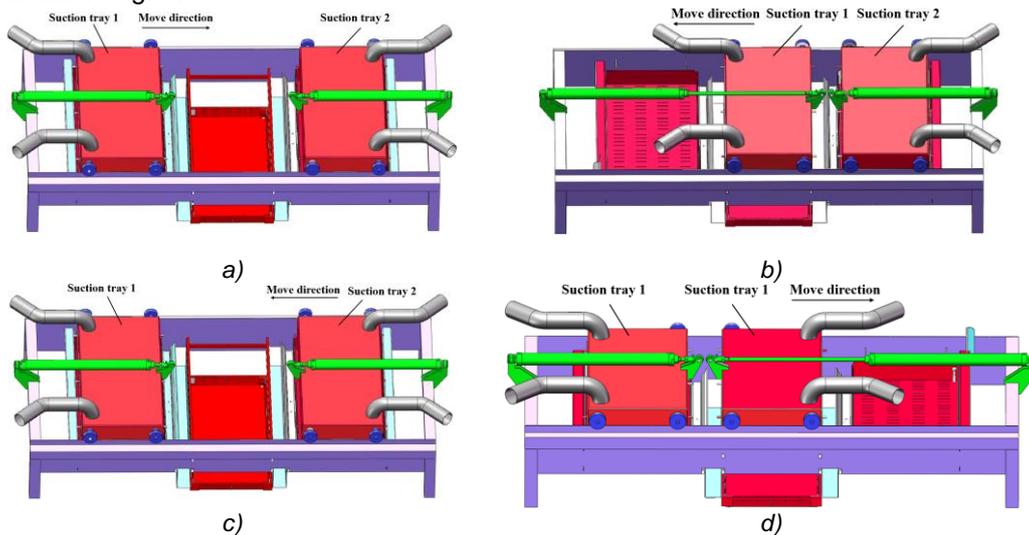

Fig. 8 - Working principle diagram of dual-station high efficiency seeding
 (a) Reset state 1; (b) Seeding state 1; (c) Reset state 2; (d) Seeding state 2

The physical object of dual-station high efficiency seeding device is shown in Fig. 9.

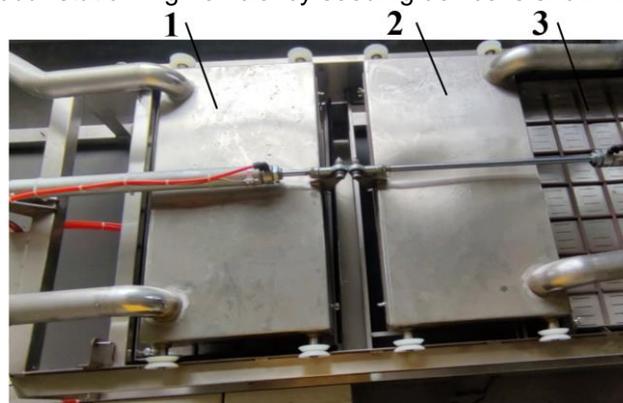

Fig. 9 - Physical object of dual-station high efficiency seeding device
 1. Seed suction tray 1; 2. Seed suction tray 2; 3. Vibrating seed tray 1

(2) Design of automatic seed adding device

The automatic seed adding device was located directly above the seeding station of the seeding frame and was connected to the dual-station high efficiency seeding device, as shown in Fig.10.

When the assembly line was working, seeds were manually placed into the seed box in advance (Liu et al., 2021). The seeds in the seed tray were continuously consumed during the operation (Wang et al., 2021). When receiving the seed addition command, the stepper motor drove the conveyor belt to move and deliver the seeds in the seed adding box to the vibrating seed tray at a preset rate, achieving automatic seed replenishment.

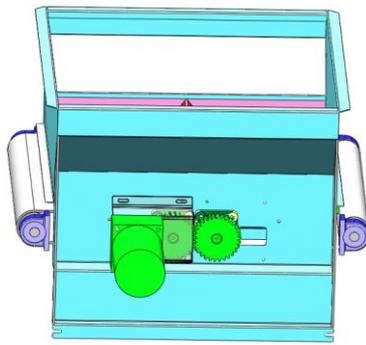

Fig. 10 - Automatic seed adding device

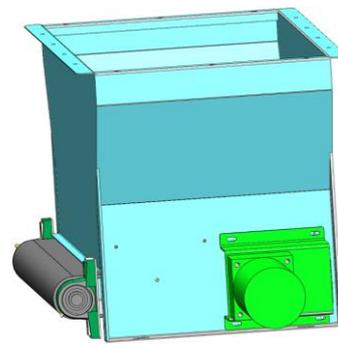

Fig. 11 - Soil laying device

Design of soil laying device

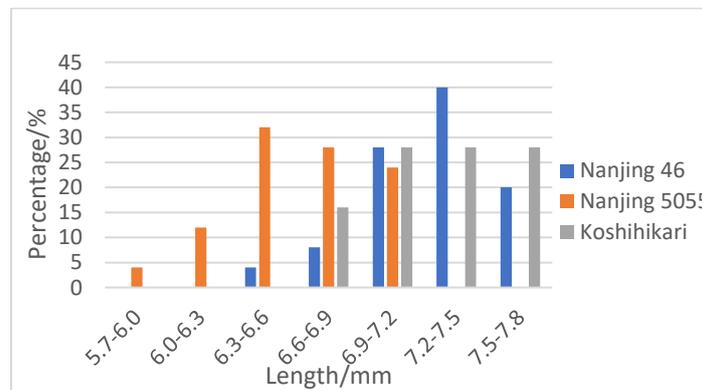

The soil laying device is shown in Fig.11. According to the difference in soil laying type for seedling tray, it could be divided into bottom soil laying device and topsoil covering device. When the seedling tray reached below the soil laying device, the stepper motor drove the conveyor belt on the soil spreading device through the reduction gear. The soil in the soil spreading device was added to the seedling tray along the conveyor belt to achieve uniform soil spreading. The soil thickness was determined by the opening of the outlet baffle and the speed of the stepper motor. According to the actual soil thickness requirements, the relevant parameters were adjusted to achieve uniform soil spreading on the seedling tray.

RESULTS

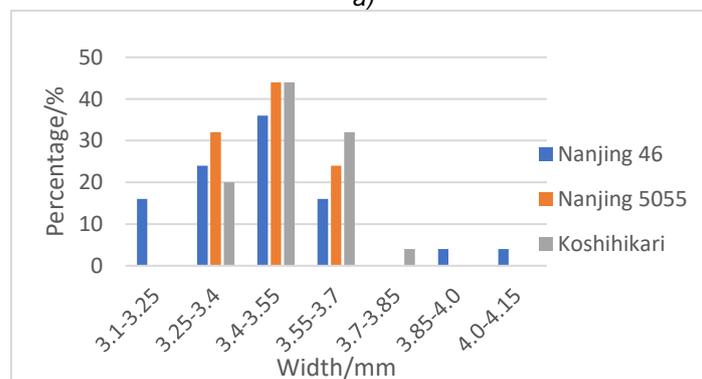

EXPERIMENT AND ANALYSIS OF SEEDING ASSEMBLY LINE

Experimental Materials

In order to verify the operating effect of this design, seeding performance tests and parameter optimization of the seeding assembly line for rice seedling cultivation were carried out. Three rice seeds varieties, namely Nanjing 46, Nanjing 5055, and Koshihikari, suitable for planting along the Yangtze River in Jiangsu Province, were used as experimental materials. 200 seeds of each variety were randomly selected, and the length, width and thickness of each seed were measured by a vernier caliper with an accuracy of 0.01 mm. The average of three times was taken to obtain the final size of the rice seeds. The rice seed size distribution is shown in Fig.12.

a)

b)

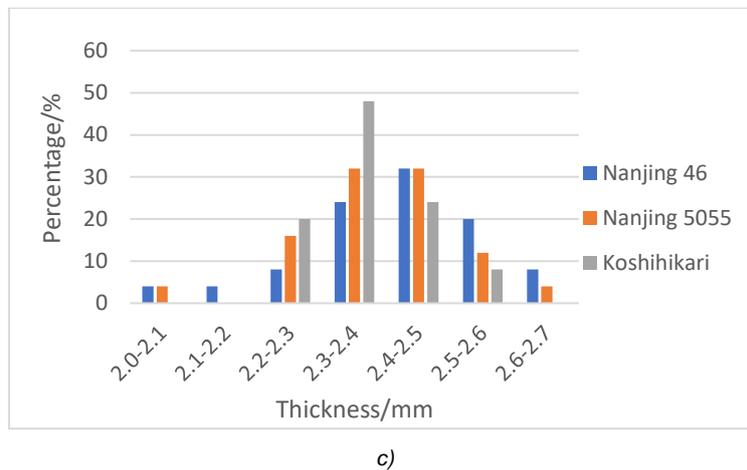

Fig. 12 - Distribution of different rice seed sizes
 (a) Length size distribution; (b) Width size distribution; (c) Thickness size distribution

Experimental Equipment

The experiment was carried out on the whole tray air-suction dual-station high efficiency seedling cultivation and seeding assembly line designed in this paper. 434-hole seed suction flat plate, 2-needle suction needle, and 434-hole standard seedling tray were used in this experiment. The physical product of the whole tray air-suction dual-station high efficiency seedling cultivation and seeding assembly line is shown in Fig.13.

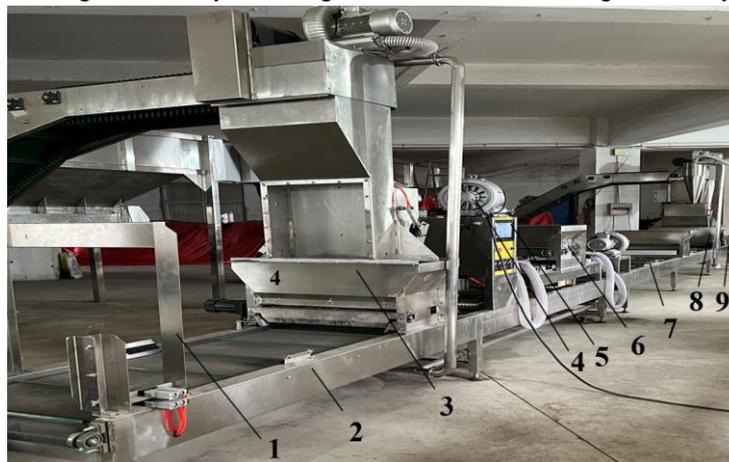

Fig. 13 - The physical product of the whole tray air-suction dual-station high efficiency seedling cultivation and seeding assembly line
 1. Horizontal tray delivery device 2. Frame 3. Bottom soil laying device 4. High pressure fan 5. Electric control box
 6. Dual-station high-efficiency seeding device 7. Sprinkler device 8. Topsoil covering device 9. Horizontal tray stacking device

The main control interface and parameter setting interface are shown in Fig.14 and Fig.15 respectively. The main control interface could realize switching between five interfaces: automatic, manual, query, precision seeding, and setting.

Fig. 14 - Main control interface

Fig. 15 - Parameter setting interface

At the same time, the main control interface could display the cumulative and current completed number of seedling trays. When a failure or emergency occurred, real-time alarm could be realized. Production efficiency could be displayed in real time and adjusted through a visual interface. The setting of vibration times, seeding times, seed scraping times and seed adding times could be realized by the parameter setting interface. At the same time, the functions of tray delivery, bottom soil laying, hole pressing, seeding, topsoil covering, precision seeding, water spraying 1, water spraying 2, automatic subsoil feeding and topsoil feeding could be enabled and disabled.

Test performance evaluation indicators

The production efficiency, qualification rate, reseeding rate and empty hole rate were taken as the main performance evaluation indicators of this equipment. The specific definition and calculation method are as follows:

(1) Production efficiency

Production efficiency refers to the number of seedling trays that can be seeded per hour on a stable seeding assembly line for rice seedling cultivation. During the experiment, seeding assembly line for rice seedling cultivation is started, and the time is measured by a stopwatch with an accuracy of 0.01 s, to obtain the number of seedling trays E_1 within 1 minute (Wang et al., 2023). Thus, the seeding efficiency of the assembly line is calculated from Eq.(5).

$$E=60 E_1 \quad (5)$$

where the unit of E is trays/h.

(2) Qualification rate

The qualification rate specified in this article is the percentage of holes with 2 ± 1 seeds per hole to the total number of holes in the seedling tray (Liu et al., 2021). Thus, the qualification rate P_1 is calculated from Eq.(6).

$$P_1 = \frac{N_1}{N_0} \times 100\% \quad (6)$$

where N_1 is the number of holes with 2 ± 1 seeds/hole, and N_0 is the total number of holes in the seedling tray.

(3) Reseeding rate

The reseeding rate specified in this article is the percentage of holes with 4 or more seeds per hole to the total number of holes in the seedling tray (Ni et al., 2022). Thus, the reseeding rate P_2 is calculated from Eq.(7)

$$P_2 = \frac{N_2}{N_0} \times 100\% \quad (7)$$

where N_2 is the number of holes with 4 or more seeds.

(4) Empty hole rate

The empty hole rate specified in this article is the percentage of holes with 0 seeds per hole to the total number of holes in the seedling tray (Hu et al., 2021). Thus, the empty hole rate P_3 is calculated from Eq.(8).

$$P_3 = \frac{N_3}{N_0} \times 100\% \quad (8)$$

where N_3 is the number of holes with 0 seeds.

Experiment on the whole tray air-suction seeding assembly line for rice precision seedling cultivation

Considering the similar seed sizes shown in Fig. 12, Nanjing 5055 rice seeds were used to conduct the experiment. Before the experiment, awns, deflated grains, and rice awns were removed from the seeds. The seeds were then soaked one day in advance to allow the buds to emerge. Two hours before the experiment, the seeds were taken out and evenly dried in a cool and dry place to remove moisture from the surface of the seeds. In order to verify that double-station sowing could promote the improvement of work efficiency. The experiment was divided into two groups, namely the single-station seeding mode and the dual-station high-efficiency seeding mode.

(1) Single-station seeding mode

Only part of the equipment of the double-station high-efficiency seeding device was started, which consisted of suction seed tray 1, vibrating seed tray 1 and seeding position (Liang et al., 2022). Before the experiment, preliminary experiments showed that the highest seeding efficiency could reach 1200 trays per hour (Hu et al., 2021). Therefore, seeding experiments were carried out sequentially at production efficiencies of 500, 600, 700, 800, 900, 1000, 1100, and 1200 trays per hour.

During the experiment, the seeds were evenly distributed in the seed boxes, the production efficiency was set, and the assembly line was started. When the assembly line was working stably, the seedling tray was placed on the horizontal tray delivery device to complete the seeding experiment (Ding et al., 2022).

Then, three consecutive seedling trays were randomly selected to obtain seeding effect data. The experimental results of different production efficiencies under the single-station seeding mode are shown in Table 2.

Table 2

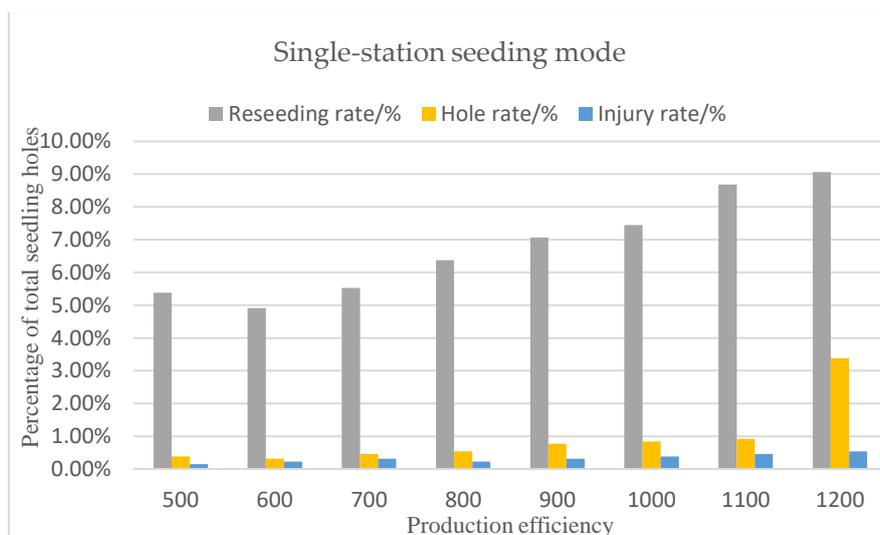

Experimental results of different production efficiencies under single-station seeding mode

No.	Production efficiency	Qualified rate (2±1) /%	Reseeding rate / %	Empty hole rate / %	Damage rate / %
1	500	94.24%	5.38%	0.38%	0.15%
2	600	94.78%	4.91%	0.31%	0.23%
3	700	94.01%	5.53%	0.46%	0.31%
4	800	93.09%	6.37%	0.54%	0.23%
5	900	92.16%	7.07%	0.77%	0.31%
6	1000	91.71%	7.45%	0.84%	0.38%
7	1100	90.40%	8.68%	0.92%	0.46%
8	1200	87.56%	9.06%	3.38%	0.54%

The changing trend of the operation effect in the single-station seeding mode is shown in Fig.16.

a) Qualified rate; (b) Reseeding rate, empty hole rate, damage rate

(2) Dual-station high-efficiency seeding mode

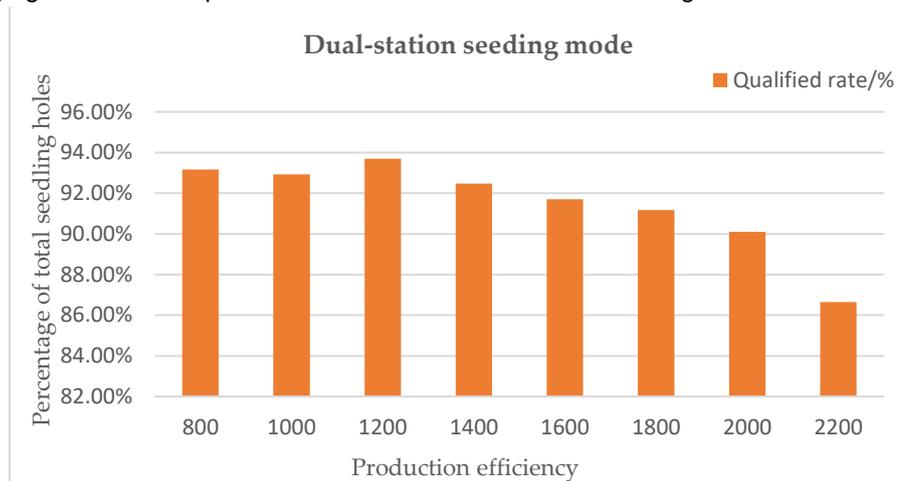

The seed suction tray 1, the vibrating seed tray 1, the seed suction tray 2 and the vibrating seed tray 2 of the dual-station high-efficiency seeding device worked together to realize interactive seeding and complete the entire seeding process (Khizhnyak V.I., 2021; Ramesh B., 2015). Before the experiment, preliminary experiments showed that the highest seeding efficiency could reach 2200 trays per hour. Therefore, seeding experiments were carried out sequentially at production efficiencies of 800, 1000, 1200, 1400, 1600, 600, 1800, 2000 and 2200 trays per hour (Sial F.S., 1984). The experiment was carried out again according to the above method and relevant results were obtained. The experimental results of different production efficiencies under the dual-station seeding mode were shown in Table 3.

Table 3

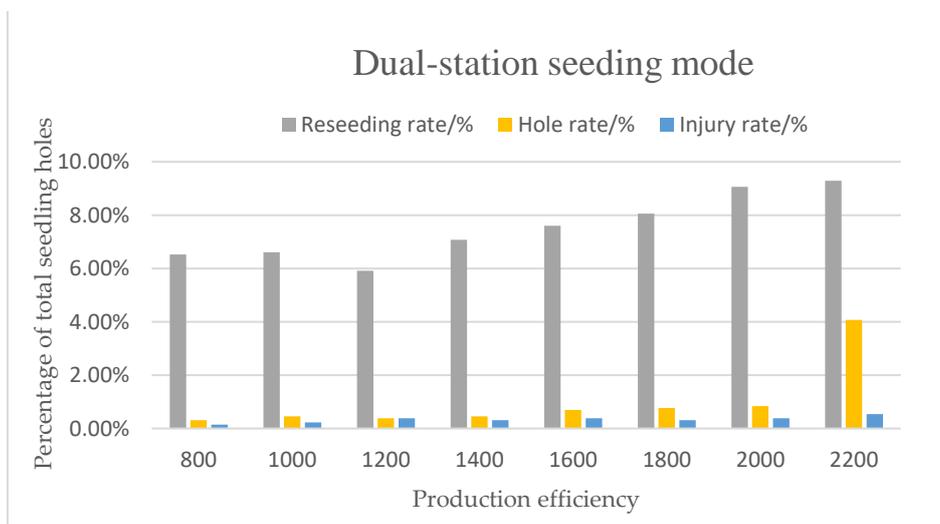

Experimental results of different production efficiencies under dual-station seeding mode

NO.	Production efficiency	Qualified rate (2±1) %	Reseeding rate %	Empty hole rate/%	Damage rate/%
1	800	93.16%	6.53%	0.31%	0.15%
2	1000	92.93%	6.61%	0.46%	0.23%
3	1200	93.70%	5.92%	0.38%	0.38%
4	1400	92.47%	7.07%	0.46%	0.31%
5	1600	91.71%	7.60%	0.69%	0.38%
6	1800	91.17%	8.06%	0.77%	0.31%
7	2000	90.10%	9.06%	0.84%	0.38%
8	2200	86.64%	9.29%	4.07%	0.54%

The changing trend of the operation effect in the dual-station seeding mode is shown in Fig.17.

a)

b)

Fig. 17 - The changing trend of the operation effect in the dual-station seeding mode
 (a) Qualified rate; (b) Reseeding rate, empty hole rate, damage rate

In the single-station seeding mode and the dual-station seeding mode, the experimental results showed the changing trends of the qualified rate, reseeding rate, empty hole rate and damage rate with the operation efficiency as shown in Table 2, Table 3, Figure 16 and Figure 17. In both working modes, the overall pass rate gradually decreased with the improvement of production efficiency. When the efficiency exceeded 1100 trays per hour (single-station mode) or 2000 trays per hour (dual-station mode), the pass rate would drop significantly. The reseeding rate and empty hole rate showed a gradual upward trend with the improvement of production efficiency, but the changes were not significant. When the number of trays per hour exceeded 1,100 (single-station mode) or 2,000 (double-station mode), the void rate would increase significantly and failed to meet the requirements for rice seedling cultivation and seeding. The principle of air suction seeding ensured that the damage rate did not change significantly with the increase of production efficiency.

Therefore, the dual-station seeding mode could improve operational efficiency while ensuring seeding accuracy. When the seeding efficiency reached 2000 trays per hour, the seeding rate of 1-3 seeds per hole was 90.1%, while the damage rate, empty hole rate and re-seeding rate were 0.38%, 0.84%, 9.06% respectively. It could meet the accuracy requirements of precision rice seedling cultivation and seeding.

CONCLUSIONS

Aiming at the common problems of low qualified rate of precision seeding and limited operation efficiency of rice seeding production line, this paper innovatively proposed the collaborative operation mode of "horizontal tray delivery—dual-station seeding". A whole tray air suction dual-station high-efficiency seeding device was designed, which adopted two sets of seed suction trays to work alternately with vibrating seed trays, combined with the optimization of the horizontal tray delivery mechanism, to compress the seeding tray movement time by 50%, and successfully achieved a breakthrough in seeding efficiency of 2000 trays/h. The experiment results showed that under the dynamic working condition of 800-2000 trays per hour, the qualified rate of 2±1 seeds/hole was more than 90.1%, and the hole rate and damage rate were kept within 0.84% and 0.38% respectively. Compared with the single-station mode, the dual-station interactive strategy improved efficiency by 81.8% while ensuring seeding accuracy. The integrated assembly line design realized the coordination of the processes of tray feeding, subsoil laying, hole pressing, seeding, watering, topsoil covering, tray stacking. It had been verified by Nanjing 46, Nanjing 5055 and Koshihikari rice seeds that it could meet the agronomic requirements of factory-based seedling cultivation and seeding of different rice varieties.

The research results have significantly improved the efficiency of mechanized rice planting. Through precision seeding, the amount of seeds used per acre will be reduced, and the rice yield per acre is expected to increase, providing technical support for ensuring food security. The proposed horizontal tray delivery mechanism and dual-station dynamic compensation strategy provide a transferable solution for the modular design of dryland seedling equipment for vegetables, flowers, etc. The interactive operation mode provides a new path to solve the problem of improving efficiency in the field of precision seeding, and has important reference significance for promoting the intelligent upgrading of precision agricultural equipment.

Keywords: Deep learning, millet downy mildew, spores, target detection, YOLOv8s

ABSTRACT

This paper proposes a lightweight spore detection method for millet downy mildew based on an improved YOLOv8s, aiming to enhance the accuracy and efficiency of spore detection. First, the backbone network of the YOLOv8s model was modified by replacing the original backbone with EfficientViT. The substitution of the EfficientViT backbone enables global receptive field and multi-scale learning, which helps to reduce computational costs. While maintaining high performance, this modification significantly improves computational efficiency. Second, a Frequency-Adaptive Dilated Convolution (FADC) module was added to the neck of the model. By adaptively adjusting the receptive field of dilated convolution, the FADC module optimizes the detection of different frequency information. It improves the detection of small objects without adding extra computational burden. Finally, the detection head was optimized to better adapt to the task of detecting millet downy mildew spores, resulting in enhanced detection speed and accuracy. The improved algorithm, named EFP-YOLOv8s, maintains the same mAP50 as the original YOLOv8s model while reducing the number of parameters by 37.8% and computational cost by 58.5%. By balancing high performance with reduced computational resource demands, the model achieves lightweight design, making it more deployable and scalable in practical applications.

摘要

本文提出了一种基于改进 YOLOv8s 的轻量化谷子白发病孢子检测方法，旨在提高孢子检测的准确性和效率。首先，针对 YOLOv8s 模型的主干网络进行了改进，将原有的主干网络替换为 EfficientViT。通过替换主干网络 EfficientViT 实现全局感受野和多尺度学习，有助于降低计算成本。在保持高性能的同时，显著提高了计算效率。其次，在模型的颈部添加了 FADC (Frequency-Adaptive Dilated Convolution) 模块，通过自适应地调整膨胀卷积的感受野，针对不同频率的信息进行优化。在不增加额外计算量的同时改善小目标的检测效果。最后，对检测头进行了优化，使其更加适应谷子白发病孢子的检测任务，提高了检测速度和准确性。改进后的算法 EFP-YOLOv8s 相比原 YOLOv8s 模型 mAP50 保持不变，参数量下降 37.8%，计算量下降 58.5%。该模型在保持高性能的同时，也降低了计算资源的需求，实现轻量化，更易于在实际应用中部署和推广。

INTRODUCTION

Millet downy mildew is a soil-borne and seed-borne systemic disease caused by **Sclerospora graminicola* (Wang et al., 2024). This disease affects the normal growth of cereal leaves and aggravates the tendency of leaf rot. It usually occurs at the 3-leaf stage of seedlings, and at the early stage of the disease, white spots are produced on the adaxial surface of the leaves, accompanied by a moldy layer on the dorsal surface with a grayish-white color, and the diseased grains show a leaflet shape (Cheng et al., 2020). During different growth stages after millet is infected, the disease manifests symptoms such as gray back, white tip, spear-like stalk, white hair, and hedgehog head. The brown powdery substance observed in these symptoms is the oospores of the downy mildew fungus (Yan et al., 2019). These oospores can rapidly multiply and infect plants under suitable conditions, leading to a significant decrease in grain yield and even causing crop failure (Yue et al., 2021). Therefore, timely and accurate detection of cereal white disease spores is of great significance in preventing and controlling the spread of the disease and ensuring the stability and safety of cereal production.

In the early stage, spore detection and counting mainly relied on manual observation and counting, such as hemocyte counting method and plate colony counting method (Li *et al.*, 2006). Although these methods can reflect the number of spores to a certain extent, they are cumbersome, time-consuming and laborious to operate, and the operation error between different personnel is large, which makes it difficult to meet the demand for high-precision and high-volume detection. To overcome these limitations, researchers began to explore more efficient and accurate counting methods. Spore counting methods based on PCR technology are highly accurate, but the operation is complicated, costly and also time-consuming (Wang *et al.*, 2024). In recent years, spore detection and counting methods based on emerging technologies such as fluorescent labeling, flow cytometry, and molecular chemistry have emerged (Liu *et al.*, 2023; Ren *et al.*, 2022; Aguayo *et al.*, 2018). These techniques not only significantly improve the sensitivity and specificity of spore detection, but more importantly, they are able to achieve high-precision quantification of spore counts, providing more reliable data support for scientific research and practical applications.

With the rapid development of computer vision and deep learning technology, image-based target detection methods show great potential in the field of plant disease detection. In 2018, the K-means clustering algorithm was used for image segmentation, image preprocessing, identification of contacted downy spores based on shape factor and area of the spores, and contacted downy spore outline segmentation based on the combination of concavity and contour segmentation. This approach aimed to achieve accurate and automatic detection and counting of spores (Lei *et al.*, 2018). In 2020, an improved U-Net architecture was proposed, reaching a segmentation rate of 91.4%. The new network architecture achieved a higher segmentation rate in the segmentation task of the wheat powdery mildew spore image dataset (Liang *et al.*, 2020). In 2023, a spin-up UNet++ feature extraction network was constructed, with an average recognition accuracy of 99.03%, which improved the segmentation rate by 10.35 percentage points compared to the original CenterNet model (Zhou J. *et al.*, 2023). In 2024, microscopic image processing and machine learning techniques were used to help identify spores of a fungus that can be used to infect pathogens. The method extracted texture, color and shape features of the spores and classified them using Random Forest algorithm with an accuracy of 95.38% (Nezhad *et al.*, 2024).

The YOLO (You Only Look Once) series of algorithms, with its high efficiency and accuracy, has achieved remarkable results in real-time target detection tasks. In 2020, it was proposed for Yolov3 algorithm to join the traditional morphological processing of spore recognition method in microscope images. The accuracy of the spore recognition algorithm increased to more than 94%, and the detection rate was more than 82% (Li X. *et al.*, 2020). In 2023, the number of parameters and computation of the model were reduced by incorporating FasterNet and NAM attention mechanism module into the base model YOLOv5m. It effectively improved the speed and accuracy of spore detection of cucumber downy mildew fungus (Qiao C. *et al.*, 2023). In addition, the Ghost convolution of CBAM attention mechanism was introduced to replace the CSP structure, improving the feature fusion network and utilizing a finer-grained mesh for the detection of dense and sticky small targets. The loss function was enhanced by assigning different weights to various output feature maps, and DIoU_NMS was used instead of NMS (Li M. *et al.*, 2023). In 2024, a small target detection layer was added to the original Yolov8 model, incorporating the focal attention mechanism and WIoU loss function. The average detection accuracy mAP @ 0.5 in the spore data set reached 96.8 % (Zhang D. *et al.*, 2024). Additionally, the backbone network of the original YOLOv8 model was replaced with PP-LCNet, the EMA attention mechanism module was introduced in the neck network, and the bounding box loss function was replaced with WIOU. These modifications reduced the number of floating-point operations per second while maintaining higher detection accuracy (Luo B. *et al.*, 2024).

Traditional deep learning models often suffer from high computational complexity, large number of parameters, and slow inference speed, making it difficult to meet the demand for real-time detection and mobile deployment in agricultural scenarios. Therefore, it is of great practical significance to improve the YOLO series of algorithms in a lightweight way. In 2024, the CG module was added to the original backbone of YOLOv5s along with the HS-FPN module, resulting in a significant reduction in the number of model parameters and accurate detection of various types of pathogen spores. YOLOv8s optimized feature extraction capability compared to YOLOv5, improving detection accuracy while maintaining a relatively lightweight structure (Cheng *et al.*, 2024). Additionally, by introducing GhostConv to replace standard convolution, constructing the LightC3 module, adopting BiFPN instead of the Concat operator, and integrating the SE attention mechanism, the computational burden and the number of model parameters were significantly reduced while maintaining high detection accuracy (Meng F. *et al.*, 2024).

A study for wheat grain counting achieved efficient detection and counting in complex scenarios by improving the YOLOv8's neck network into a BiFPN structure, further validating the effectiveness of the lightweight design (Ma N. *et al.*, 2024).

Given the characteristics of small, dense, and clustered targets in millet downy mildew spore images, as well as the relatively high computational costs and parameter counts of the aforementioned improved networks that hinder deployment, this study develops a lightweight detection model for millet downy mildew spores by integrating an EfficientNet-ViT backbone, a C2f_FADC neck module, and an optimized detection head. This model not only achieves excellent detection performance but also enables accurate identification of pathogen spores while maintaining high efficiency. It is anticipated that the findings of this study will provide robust support for the prevention and control of millet downy mildew and contribute to the advancement of intelligent and precise agriculture.

MATERIALS AND METHODS

Image Data Acquisition

First, millet plants with typical symptoms of downy mildew were selected from the field. The mature diseased panicles were excised using sterile scissors as samples. These samples were then filtered through a 0.04 mm mesh sieve to remove large particulate impurities from the suspension. Next, the collected diseased tissue sample was placed into a centrifuge tube containing an appropriate amount of sterile water, and the spores were fully shaken using a vortex shaker to disperse the spores in suspension as evenly as possible. Finally, an appropriate amount of spore suspension droplets was added to the microscope slide, and the coverslip was placed under the microscope, and the number of oospores in the field of view was observed under the microscope at 10×10 times the microscope. A total of 2042 images were obtained, with a resolution of 1800 pixels × 1350 pixels, in jpg format.

Image Preprocessing

The acquired spore images showed significant dense distribution and adhesion characteristics, which posed a challenge to the subsequent spore identification and counting work. In this paper, the methods of randomly adjusting saturation, adding Gaussian noise and changing brightness are used to simulate the complex and changeable environmental conditions in the field and various lighting conditions, shooting angles and noise interference factors that may be encountered in the actual detection scene, aiming to expand the data set from multiple dimensions. A total of 6126 images were obtained after expansion. The dataset was divided into a training set of 4926 sheets and a validation set of 1200 sheets according to the ratio of 8:2.

YOLOv8s model structure

YOLOv8 is a YOLO target detection and image segmentation model developed by Ultralytics (Redmon J. *et al.*, 2016). YOLOv8 introduces an Anchor-Free detection head, a new loss function, and a Task-AlignedAssigner positive and negative sample allocation strategy to improve the detection accuracy and speed of the model. In addition, YOLOv8 provides models with different scales, such as Nano, Small, Medium, Large and ExtraLarge, where YOLOv8x is the most accurate but runs the slowest with the largest model size, and YOLOv8n is the fastest with the smallest model size. Considering the accuracy and speed requirements of spore detection in real scenarios, YOLOv8s in YOLOv8 is chosen as the benchmark model for improvement.

Improvement of YOLOv8s model

First, the backbone network of the YOLOv8s model was improved by replacing the original backbone network with EfficientViT. EfficientViT combines the advantages of convolutional neural network (CNN) and Transformer, which has stronger feature extraction capability and higher computational efficiency, thus enhancing the accuracy of spore detection. Secondly, the FADC module is added to the neck of the model, which enhances the model's ability to learn spore features by introducing the attention mechanism, further improving the accuracy of detection. Finally, the detection head was optimized to better adapt to the task of detecting millet downy mildew spores, resulting in improved detection speed and accuracy.

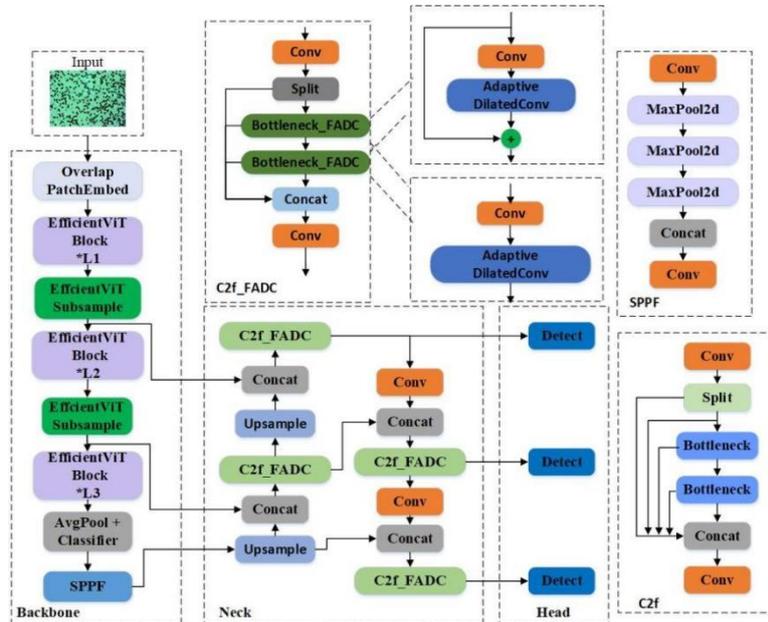

Fig. 2 - EFP-YOLOv8 model

EfficientViT

EfficientViT consists of three phases, each containing a number of sandwich structures, which are composed of 2N DWConv (spatially localized communication) and FFN (channel communication) as well as cascaded packet attention (Liu et al., 2023). Compared with the traditional Multi-Headed Self-Attention (MHSA), CGA performs head segmentation of the features before generating the query (Q), key (K) and value (V). This change not only improves the efficiency of computation, but also allows each head to focus on a different subset of features, thus enhancing the diversity and expressiveness of the model. To further enhance the model capacity, EfficientViT sums the output of each head with the input of the next head, realizing the effective transfer and fusion of feature information. Eventually, the outputs of multiple heads are stitched together and mapped through a linear layer to obtain the final output features.

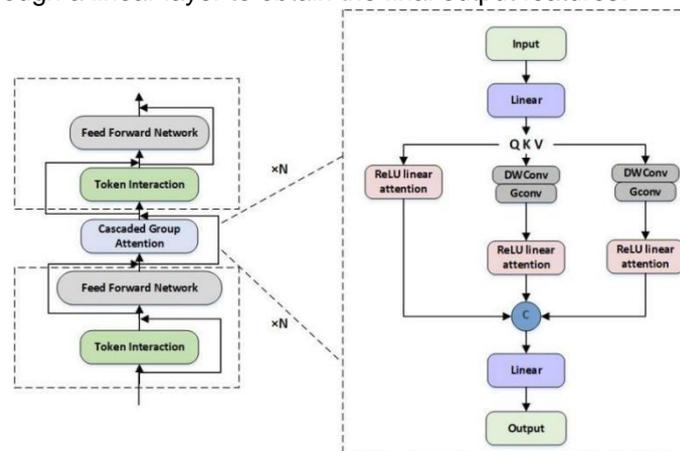

Fig. 3 - EfficientViT network structure diagram

In the Cascaded Grouped Attention (CGA) approach, the model splits the complete feature into multiple parts and provides these parts to each head separately for processing. This way of partitioning features not only saves computation, but also makes the attention computation more efficient.

Each head focuses on processing a different subset of features, which improves the diversity and robustness of the model. The computational formulas are shown in Eq. (1) to Eq. (3).

$$\tilde{X}_{mn} = \text{Attn}(X_{mn}Y_{mn}^Q, X_{mn}Y_{mn}^K, X_{mn}Y_{mn}^V) \tag{1}$$

$$\tilde{X}_{m+1} = \text{Con}[\tilde{X}_{mn}]_{n=1:h} Y_m^P \tag{2}$$

$$X'_{mn} = X_{mn} + \tilde{X}_{m(n-1)}, 1 < n \leq h \tag{3}$$

X_{mn} is the n -th partition of the input feature X_m , $X_m = [X_{m1}, X_{m2}, \dots, X_{mh}]$, $1 < n \leq h$, is the total number of heads, Y_{mn}^Q , Y_{mn}^K , and Y_{mn}^V are projection layers that partition the input features into different subspaces and Y_m^P is a linear layer that projects the connected output features with the same dimension as the input. X'_{mn} is the residual connection of the m -th head output and input.

C2F_FADC

The C2f module in YOLOv8 realizes the fusion of feature maps at different scales and improves the target detection performance by introducing the ELAN attention mechanism and Bottleneck design. The C2f_FADC module further introduces the attention mechanism and the deep convolution based on this foundation, which optimizes the computational efficiency of the model and enhances the focus on the key regions, improving the accuracy and robustness of the model in the complex scenario of the detection performance in complex scenes.

Frequency Adaptive Dilation Convolution (FADC) consists of three strategies: adaptive dilation rate (AdaDR), adaptive kernel (AdaKern), and frequency selection (FreqSelect) (Chen L. et al., 2024). AdaDR adjusts the dilation rate spatially, AdaKern operates on the convolution kernel weights, and FreqSelect directly balances the frequency power of the input features in order to encourage the acceptance of domain expansion.

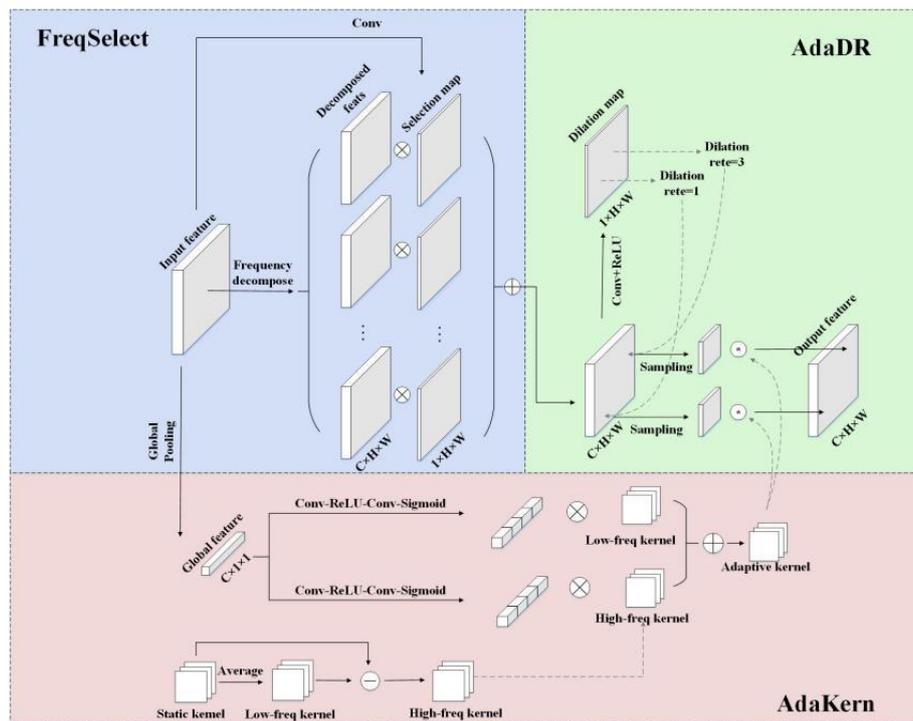

Fig. 4 - FADC network structure diagram

Adaptive Dilation Rate (AdaDR): Unlike the traditional fixed dilation rate, FADC can dynamically adjust the dilation rate according to the frequency characteristics of different image regions. In high-frequency regions, the FADC selects a smaller expansion rate to capture more detailed edge information, while in low-frequency regions, a larger expansion rate can be selected to expand the sensory field.

Adaptive Kernel (AdaKern): This module decomposes the convolutional weights into low-frequency and high-frequency components and dynamically adjusts the ratio between these components on a per-channel basis. By increasing the high-frequency portion of the convolutional weights, AdaKern is able to capture more high-frequency components, thereby increasing the effective bandwidth.

FreqSelect: The FreqSelect module optimally balances high-frequency and low-frequency components in the feature representation by re-weighting the spatial variance. It suppresses high-frequency components in the background to encourage the FADC to learn larger expansions, thereby expanding the range of the receptive field.

Detection head improvements

The main function of the detection head is to process the input feature map to detect targets in the image. It integrates and analyzes features of different levels and scales through techniques such as multi-scale feature fusion, thus adapting to the detection of targets of different sizes. In order to further reduce the number of model parameters without decreasing the detection accuracy, this paper introduces a local convolutional neural network PConv, so that the two convolutional branch inputs of the detection head share the same PConv and the output feature maps of the 1x1 Conv, which achieves the reduction of computational redundancy, and at the same time facilitates the effective sharing and utilization of features among different branches to optimize the performance and efficiency of the detection head.

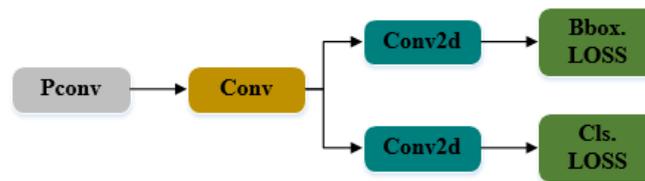

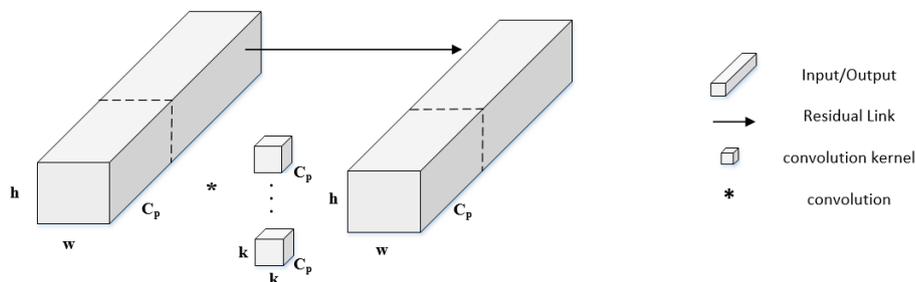

Fig. 5 -Detect structure diagram

PConv optimizes performance by reducing redundant memory accesses. When dealing with continuous or regular memory accesses, PConv can selectively apply a convolutional kernel that performs spatial feature extraction for only a portion of the input channel and leaves the remaining channels unchanged. This strategy significantly reduces memory accesses.

$$FLOPS = h \times w \times k_2 \times C_p^2$$

Fig. 6 - PConv structure diagram

The number of floating point operations FLOPs for PConv convolution is:

(6)

where h represents the height of the feature map; w represents the width; k represents the size of the convolution kernel; and C_p represents the number of channels. the number of floating-point operations for PConv convolution is only 1/16 of that for regular Conv convolution.

RESULTS

Parameter Configuration and Evaluation Indicators

For the hardware environment configuration, the CPU is Intel(R)Core(TM)i9-9900KFCPU@3.60GHz, the GPU model is Quadro P5000, the host memory is 125GB, and the video memory is 16GB. For the software environment setup, the 64-bit Linux operating system is used, and the programming language used is Python3.8. CUDA11.0 was used to complete the computational acceleration, and the deep learning framework Pytorch1.8.1 was used for training. The specific training parameters in the experiment are set as follows, the

resolution of the input image (image_size) is 640×640 pixels, the initial learning rate (learning_rate) is set at 0.01, the batch size (batch_size) is set at 16, and the number of iterations (epochs) is 100.

In this paper, the accuracy rate (Precision, P), meanAveragePrecision (mAP), the size of model parameters (Parameters), and the amount of model computation (GFLOPS) are used to evaluate the performance of the model.

The formula for each metric is as follows:

$$P = \frac{TP}{TP+FP} \quad (7)$$

$$R = \frac{TP}{TP+FN} \quad (8)$$

$$AP = \int_0^1 P(R) dr \quad (9)$$

$$mAP = \frac{1}{n} \sum_{i=1}^n AP_i; mAP = \frac{1}{n} \sum_{i=1}^n AP_i \quad (10)$$

In the formula TP is the number of spores correctly detected; FP is the number of background impurities mistakenly detected as spores; FN is the number of spores identified as impurities; R is the value of the recall rate under the current accuracy rate, which refers to the proportion of spores detected by the model to all actual spores; the area under the P - R curve plotted using the precision rate P and the recall rate R represents the average precision AP value of the category. The higher the AP value, the better the detection performance of the algorithm is considered to be.

Backbone network comparison test

In order to evaluate the advantages of replacing the backbone network with EfficientViT, three lightweight models, namely, Efficientnet, GhostNet, and MobileNetV3, are selected as the backbone network of the original model of YOLOv8s for the comparison experiments. The specific experimental results are shown in Table 1.

Table 1

Comparative experiments of different backbone networks

Model	Parameters /MB	GFLOPS	P/%	mAP50/%
YOLOv8s	11.1	28.4	97.1	97.6
YOLOv8s+Efficientnet	10	22.0	97.4	97.1
YOLOv8s+GhostNet	6.3	16.3	95.3	96
YOLOv8s+MobileNetV3	6.6	16.3	96	96.9
YOLOv8s+EfficientViT	8.4	20.4	96.9	97.1

From the analysis in Table 1, replacing the backbone network with GhostNet based on the YOLOv8s model reduces the computation and number of parameters by 4.8 and 12.1, respectively, but the $mAP50$ decreases by 1.8 percentage points. mobileNetV3 decreases in the number of parameters and computation, but decreases in P , $mAP50$, and R . EfficientNet network model has a 9.9% decrease in the number of parameters, a 22.5% decrease in computation, a 0.3 percentage point increase in precision, and decreases in both $mAP50$ and R . EfficientViT has faster detection with a very small decrease in precision, where the number of parameters decreases by about 24.3%, the computation decreases by about 28.2%.

Comparative experiments with different convolutions of the neck

From the analysis in Table 1, the experimental results show that C2f_FADC proposed in this paper performs better in terms of accuracy improvement. The number of C2f_Star_CAA parameters and the computation amount are increased compared to the base model. The introduction of C2f_RFACnv detection accuracy decreases and the computational amount rises, which is not in line with the experimental purpose of

this paper. In summary, the introduction of C2f_FADC not only realizes the lightweighting of the network, but also improves the detection accuracy of the model on the image target to achieve the purpose of the model optimization, which proves the validity of the improved method in this paper.

Table 2

Comparison experiment on different convolutions in neck				
Model	Parameters / MB	GFLOPS	P / %	mAP50/%
YOLOv8s+EfficientViT	8.4	20.4	96.9	97.1
YOLOv8s+EfficientViT+C2f_Star_CAA	9.4	22.6	96.6	97.2
YOLOv8s+EfficientViT+C2f_Faster_EMA	7	17.8	96.6	97.4
YOLOv8s+EfficientViT+C2f_RFACConv	8.4	20.6	96.2	96.9
YOLOv8s+EfficientViT+C2f_FADC	8.4	18.7	96.9	97.5

Optimized Detection Head Comparison Experiment

To further achieve lightweighting, PConv, RepConv, EMSConvP, and RepConv are used to improve the detection head, respectively. As can be seen from Table 3, the number of EMSConvP parameters decreases by 19.8%, and the computational volume decreases by 46.1%. the number of RepConv parameters rises, and the computational volume decreases by a small amount. The method using PConv to optimize the detection head compares the base model accuracy and mAP changes are not obvious, but the number of parameters decreases by 37.8% and the computation amount decreases by 58.5%, which is the best lightweight effect in the comparison experiments. The lightweight detection head in this paper has great advantages in model deployment ability and small target detection ability, and has high accuracy and fast calculation speed in grain powdery mildew spore detection.

Table 3

Improved detection head comparison experiment				
Model	Parameters / MB	GFLOPS	P / %	mAP50 / %
YOLOv8s	11.1	28.4	97.1	97.6
YOLOv8s+EfficientViT+C2f_FADC	8.4	18.7	96.9	97.5
YOLOv8s+EfficientViT+C2f_FADC+PConv	6.9	11.8	96.8	97.6
YOLOv8s+EfficientViT+C2f_FADC+EMSConvP	8.9	15.3	96.8	97.4
YOLOv8s+EfficientViT+C2f_FADC+RepConv	12.6	22.1	96.8	97.5

Comparison of different models

To further validate the advantages of the EFP-YOLOv8s model proposed in this paper for the detection of millet downy mildew spores, the improved model was compared with YOLO v5s, YOLO v6s, YOLO v8s, YOLOv9s, YOLOv10s, and the final results of the comparison are shown in Table 4. According to the experimental results, it can be seen that the accuracy rate and mAP50 value of each model are relatively close to each other, among which the base model YOLOv8s has the highest accuracy rate of 97.1%, but the number of parameters and the amount of calculation are too large. The improved model EFP-YOLOv8s decreased the accuracy rate by 0.3 percentage points compared with the original model, and the mAP remained unchanged, but the number of parameters decreased by 37.8% and the computational volume decreased by 58.5%. Compared with YOLOv5s, YOLOv6s, YOLOv9s, and YOLOv10s, EFP-YOLOv8s has the best combined accuracy and mAP, and the computational and parametric quantities are lower than the other models.

Table 4

Comparative experiments with different models				
Model	Parameters /MB	GFLOPS	P/%	mAP50/%
YOLOv5s	9.1	23.8	96.8	97.5
YOLOv6s	16.3	44	96.9	97.7
YOLOv8s	11.1	28.4	97.1	97.6

YOLOv9s	7.1	26.7	96.7	97.5
YOLOv10s	7.2	21.4	96.7	96.5
EFP-YOLOv8s	6.9	11.8	96.8	97.6

SPORE DETECTION AND TRAINING SYSTEM FOR FOXTAIL MILLET DOWNY MILDEW

In this study, a *Sporisorium scitamineum* spore detection system based on PyQt5 was developed, which comprises two main functional interfaces: the spore detection and counting interface, and the model training interface.

Spore detection and counting interface

This interface is designed to provide a convenient tool for efficient detection and precise counting of *Sporisorium scitamineum* spores. Users can select and upload spore image files stored locally through the interface to the system. The system utilizes deep learning algorithms to automatically recognize and label the spores in the images, displaying the labeled images in real-time on the interface. Upon completion of the detection, the interface automatically tallies the number of spores and presents the results clearly in the result display area. Additionally, users have the option to save the labeled images locally.

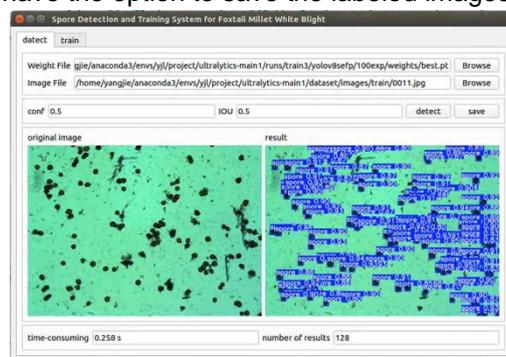

Fig. 7 - Spore detection and counting interface

Model training interface

This interface allows users to import customized spore image datasets for training or optimizing deep learning models. Users can flexibly set training parameters through this interface, such as learning rate, batch size, and number of training epochs, to enhance model performance. During the training process, the interface displays real-time training logs, aiding users in intuitively monitoring the model's training status. Additionally, the interface supports model saving and loading functionalities, enabling users to save trained models locally for direct use in subsequent detection tasks.

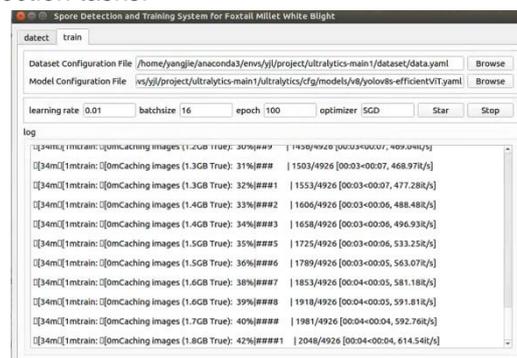

Fig. 8 - Model training interface

CONCLUSIONS

In this paper, a lightweight YOLOv8s model is proposed to replace the backbone network, introduce C2f_FADC and improve the detection head. Through comparative experiments, it is verified that the improved model maintains high precision detection accuracy compared to YOLOv8s while the number of parameters decreases by 37.8% and the computational amount decreases by 58.5%. The improved mAP50 is 97.6% and P reaches 96.8%, which gives certain advantages to the EFP-YOLOv8s model proposed in this paper compared with mainstream target detection networks.

This research result not only provides a new technical means for the prevention and control of cereal leucosis, but also provides ideas and methods that can be used for the detection of disease spores in other crops.

In the future, more advanced lightweight technology and optimization strategies will continue to be explored to further improve the detection performance and practicality of the model, and to promote the continuous development and application of intelligent technology in agriculture.

ABSTRACT

In order to clarify the working mechanism of forage crusher, the combined cutting and crushing forage crusher was taken as the research object, the mechanical analysis was carried out on the cutting and crushing process of alfalfa stalk, the dynamic model was established, and the relationship between the shear force and the relevant parameters of the cutting mechanism was defined. It was found that the cutting Angle, the installation Angle and the wedge Angle had important effects on the cutting effect and power consumption. The force of alfalfa stem in the grinding chamber is mainly related to the speed of the grinding shaft, the gap between the hammer and the rolling plate. With the output speed of motor, feeding amount, screen diameter and water content as test factors, productivity, silking rate, power consumption and average crushing length as evaluation indicators, the single factor test was carried out to determine the influence of each test factor on the evaluation indicators. The research results can provide reference for the optimization design of grass crusher.

摘要

为明确牧草粉碎机工作机理，以切割粉碎组合式牧草粉碎机为研究对象，对苜蓿茎秆切割和粉碎过程进行了力学分析，建立了动力学模型，明确了剪切力与切割机构相关参数的关系，得到动刀遇角、安装后角和楔角对切割效果和功耗具有重要影响；苜蓿茎秆在粉碎室内受力主要与粉碎轴转速、锤片和揉搓板间隙有关。以电机输出转速、喂入量、筛孔直径、含水率为试验因素，生产率、丝化率、功耗、平均粉碎长度为评价指标，进行了单因素试验，确定了各试验因素对评价指标的影响规律，研究结果可为牧草粉碎机的优化设计提供参考。

INTRODUCTION

Animal husbandry is an important part of agriculture and plays an important role in the national economy of our country (Zhang et al., 2021; Jiang et al., 2019). The production and supply of forage is the basis of the development of animal husbandry, which affects the scale and speed of animal husbandry development. China's grass planting area is close to 15 million mu, accounting for 8.2% of the arable land. The total annual output of forage is 90 billion kg, and the total output value is 12 billion US dollars (Chen et al., 2023; Wu et al., 2022; Wu et al., 2018).

Grass processing can be divided into cutting processing, crushing processing and kneading processing according to the crushing form (Wang et al., 2021; Zhao et al., 2019; Xu et al., 2020). The corresponding models are cutting mill, hammer mill and so on. The cutting mill breaks the grass by cutting, but the broken grass after processing is mostly round stem, and there are hard joints, which will lead to indigestion and palatability of livestock, which is not conducive to digestion and absorption of livestock (Li, 2023; Wang et al., 2024; Liu et al., 2019).

The hammer mill first pulverizes the grass to a certain extent through the impact of the hammer, and then throws the grass at a faster speed to the kneading board and the sieve plate in the crushing room, and is further crushed by the collision of the kneading board and the rubbing of the sieve plate, which has high crushing efficiency and wide adaptability (Ma et al., 2016; Wang et al., 2017; Liu et al., 2011).

¹Tao Chen, Ph.D.; Shu-juan Yi, Prof. Ph.D.; Song Wang, Ph.D.; Wen-sheng Sun, Ph.D.;

Because the forage with high water content has strong toughness, the force required when it is broken by blows and other effects is greater, and the whole forage is easy to wind the rotor when it is crushed, resulting in blockage (Fan et al., 2021; Wang et al., 2021; Jia et al., 2014). Therefore, the existing grinder still has some problems, such as low efficiency, poor crushing quality, and not being suitable for forage with large water content.

To solve the above problems, our team designed a cutting and crushing combined grass crusher, which preprocessed the grass before crushing, and cut it into small segments of a certain length by cutting. However, its working mechanism is not clear. This study conducted a theoretical analysis of the cutting and crushing process, explored the crushing mechanism of the crusher on grass, identified the factors influencing crushing quality, and performed an experimental study using these factors to analyze their impact on the crushing effect.

MATERIALS AND METHODS

Structure and working principle

Cutting and crushing cooperative grass kneading machine is mainly composed of feeding conveyor belt, conveyor chain plate, feeding mechanism, screening mechanism, kneading mechanism, cutting mechanism and other parts. The structure is shown in Fig. 1.

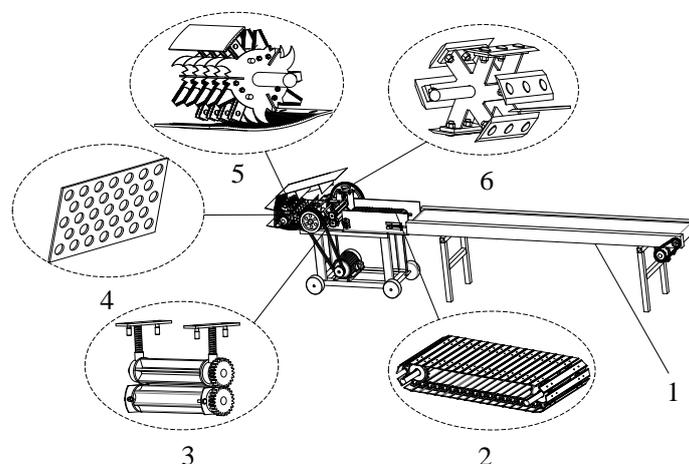

Fig.1 – Structural diagram of cutting and crushing cooperative forage kneader

1. Feeding conveyor belt; 2. Conveyor chain plate; 3. Feeding mechanism;
4. Screening mechanism; 5. Kneading mechanism; 6. Cutting mechanism

The kneading operation is mainly divided into the following stages: feeding stage, the whole grass is transported to the conveyor chain plate through the feeding conveyor belt, and the grass enters the cutting chamber by rotation of the feed roller. In the cutting stage, the grass is cut into a certain length under the shearing action of the rotating motion of the grass knife and the fixed knife, and the cut grass is pushed to the kneading chamber under the rotation of the grass knife. In the kneading stage, the grass section is broken into filaments under the synergistic action of the hammer and serrated knife, the kneading and tearing between the hammer and serrated knife and the kneading tooth plate, the impact and friction between the sieve plate, etc.

In the screening and sending stage, the broken grass that meets the kneading length is thrown to the outside of the kneading machine through the screen plate under the combined action of the air flow generated by the rotation of the kneading rotor and the centrifugal force. The broken grass that is larger than the kneading length needs is kneaded in the kneading chamber for the next time, and further broken through the same crushing method as the last kneading until the length meets the kneading demand.

Mechanical analysis of cutting process

The cutting process is realized by the combination of cutting knife and fixed knife, and the shear force generated on the stem and the thrust generated by the feed roller act on the stem together (Wu et al., 2022; Jiang et al., 2019; Wu et al., 2018). In order to facilitate the force analysis of the whole system, the following assumptions are made: the shape of alfalfa stalk is cylinder, the whole organization is uniform and continuous; the shear of the stem is balanced at every moment; the force analysis is based on a single shear. Consider alfalfa layer as a whole; the compression and deformation of the feeding roller on alfalfa were ignored.

The stress of alfalfa stem and tool in the cutting process was analyzed, as shown in Fig. 2.

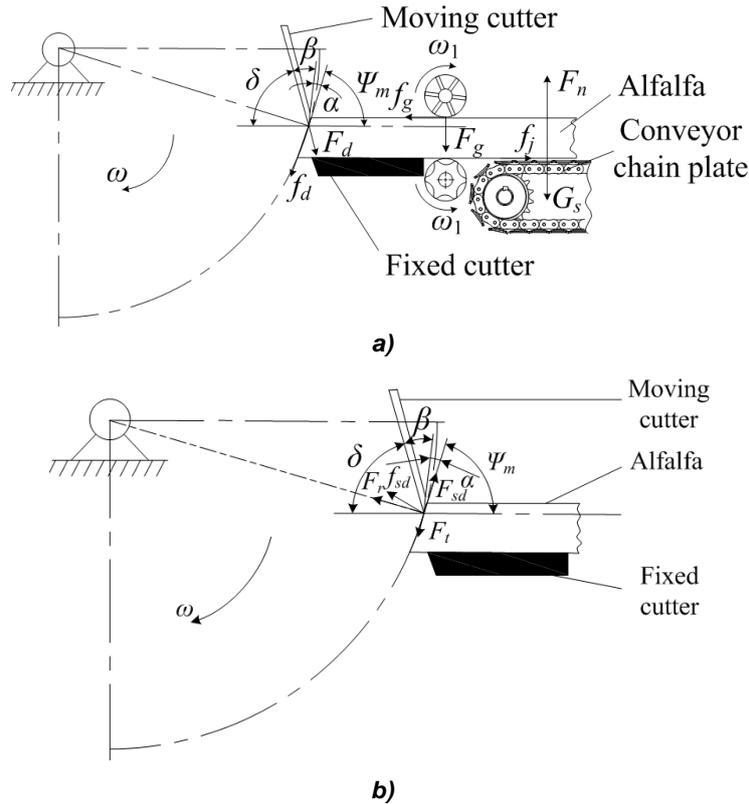

Fig. 2 – Force analysis of the chopping mechanism

a) Stress analysis of alfalfa stalk cutting process; b) Force analysis of the knife

In the process of cutting, the main forces on the stalk are: (1) the positive pressure F_d of the knife facing the stalk, the direction is perpendicular to the knife face down; (2) the friction force f_d of the knife facing the stalk, the direction is consistent with the direction of the knife movement; (3) the supporting force F_n of the feed tank and the fixed tool on the stalk, the direction is always perpendicular to the bottom surface of the feed tank and the fixed tool; (4) the direction of the pressure F_g and friction force f_g of the feeding roller on the stalk are vertically downward and consistent with the direction of the stalk feed, respectively; (5) the direction of gravity G_s on the stalk and friction f_j on the bottom of the feed tank facing the stalk are vertical downward and opposite to the direction of feed, respectively; (6) the tool is subjected to the force F_t and F_r provided by the cutting shaft, and the directions are respectively the tangential direction and the center direction of the tool moving path; (7) the tool is subjected to the friction F_{sd} of the stalk, and the direction is opposite to the direction of the knife movement; (8) the tool is subject to the supporting force f_{sd} provided by the stalk, and the direction is perpendicular to the tool face.

According to the horizontal force balance of alfalfa stalk, it can be obtained:

$$F_d \sin \delta = f_g + f_j + f_d \cos \delta \tag{1}$$

From the vertical force balance of the stem, it can be obtained:

$$F_d \cos \delta + G_s + F_g + f_d \sin \delta = F_n \tag{2}$$

With the cutting edge of the knife as the fulcrum, the moment of the stalk is balanced:

$$F_g L_1 + G_s L_3 + f_g (f - H_m) = F_n L_2 + f_j H_m \tag{3}$$

The horizontal component of F_d under the positive pressure of the blade facing the stalk is:

$$F_{d2} = f_g + f_j + f_d \cos \delta \tag{4}$$

The vertical component of F_d under the positive pressure of the blade facing the stalk is:

$$F_{d1} = F_n - G_s - f_d \sin \delta \tag{5}$$

The encounter angle of knife is:

$$\psi_m = 90^\circ - \sigma \tag{6}$$

The angle between the back cutter face and the horizontal direction is:

$$\delta = 180^\circ - \alpha - \beta - \psi_m \tag{7}$$

The shear force of cutting action on the stalk causing the stalk to break is:

$$\tau_s = \frac{F_n - G_s - F_g - f_d \sin(180^\circ - \alpha - \beta - \psi_m)}{S} \tag{8}$$

where: S is cross-sectional area of alfalfa stalk, m^2 ; α is installation rear angle of the tool, ($^\circ$); β is wedge angle of the knife, ($^\circ$); ψ_m is knife angle, ($^\circ$); H_m is vertical distance from any point on the knife path to the bottom of the feed tank, mm; L_1 is horizontal distance between the feed roll and the tool, mm; L_2 is the horizontal distance between the center of gravity of the alfalfa stem and the tool, mm.

Mechanical analysis of crushing process

Smashing process

The force analysis of alfalfa stem in the attack and breaking process is shown in Fig.3.

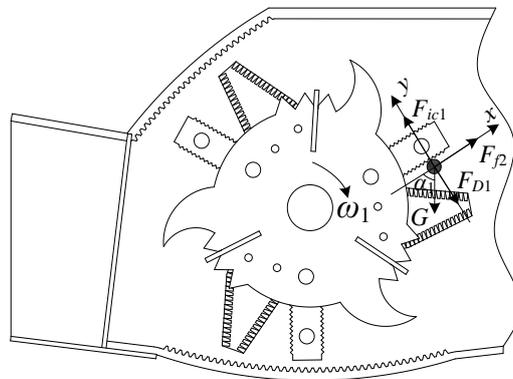

Fig. 3 – Force analysis of alfalfa stem during crushing

Alfalfa stems are mainly subjected to the combined action of four forces, namely gravity G , the striking force F_{D1} of the hammer on the alfalfa stalk, the friction force F_{f1} of the hammer on the alfalfa stalk and the Coriolis inertia force F_{ic1} of the alfalfa stalk. The center of the stalk is regarded as the center of mass, and all external forces act on the center of mass.

According to D'Alembert's principle, the balance equation of the impact force on alfalfa stalk can be obtained as follows:

$$\begin{cases} \sum F_x = 0, & F_{f1} - G \cos \alpha_1 = 0 \\ \sum F_y = 0, & F_{D1} - G \sin \alpha_1 - F_{ic1} = 0 \end{cases} \tag{9}$$

where:

$$\begin{cases} F_{f1} = \mu m_1 g \sin \alpha_1 \\ F_{ic1} = -m_1 a_c = -2m\omega_e v_{r1} \end{cases} \tag{10}$$

By combining equations (9) and (10), the following is obtained:

$$F_{D1} = 2m_1 \omega_e v_{r1} - m_1 g \sin \alpha_1 \tag{11}$$

where: F_{D1} is striking force of alfalfa stalk by hammer, N; G is alfalfa stem gravity, N; m_1 is alfalfa stalk mass, kg; F_{f2} is the friction force of alfalfa stem against the hammer, N; F_{ic1} is Coriolis inertia force, N; μ_1 is friction coefficient between alfalfa stem and sieve plate; ω_1 is angular velocity of the rotor, rad/s; v_{r1} is linear velocity at the end of the hammer, m/s; α_1 is the angle between alfalfa stem gravity and the X-axis, ($^\circ$).

According to Formula (11), when the internal structure of the kneading machine remains unchanged, the impact force F_{D1} of the alfalfa stem under the hammer is mainly affected by the angular velocity ω of the kneading rotor and the linear velocity v_{r1} of the hammer end. The greater the angular velocity of the kneading rotor ω_1 and the linear velocity of the end of the hammer piece v_{r1} , the greater the impact force on the alfalfa stalk, and the change of the two sizes depends on the change of the speed of the crushing shaft.

Impact crushing

The force analysis of alfalfa stems during impact crushing is shown in Fig. 4.

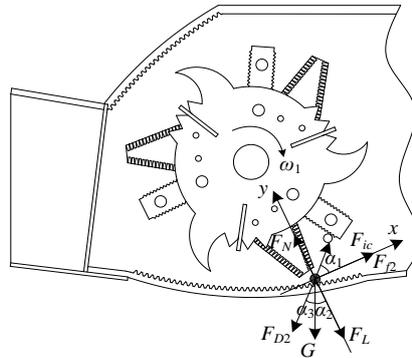

Fig.4 – Force analysis of alfalfa stem impact crushing process

According to D'Alembert's principle, the equilibrium equation of the impact force on alfalfa stalk can be obtained:

$$\begin{cases} \sum F_x = 0, & F_{D2} \sin(\alpha_2 + \alpha_3) - F_{ic2} \cos \alpha_4 - F_{f2} = 0 \\ \sum F_y = 0, & F_L + G \cos \alpha_2 + F_{D2} \cos(\alpha_2 + \alpha_3) - F_N - F_{ic2} \sin \alpha_4 = 0 \end{cases} \quad (12)$$

where:

$$\begin{cases} F_{ic2} = -2m_2\omega_{e1}v_{r1} \\ F_{f2} = \mu_2 \frac{m_2g}{\cos \alpha_2} \\ F_L = m_2 \frac{n^2}{r_1} \end{cases} \quad (13)$$

By combining equations (12) and (13) the following is obtained:

$$F_{D2} = \frac{(2\omega_{e1}v_{r1} \sin \alpha_4 - n^2) \cos \alpha_2 - r_1g(1 - \cos \alpha_2)}{\cos(\alpha_2 + \alpha_3)} \quad (14)$$

where:

F_{D2} is impact force on alfalfa stem, N; F_{f1} is friction force on alfalfa stem kneading plate, N; F_{ic2} is Coriolis inertia force, N; F_L is centrifugal force on alfalfa stem, N; n is spindle speed, r/min; r_1 is distance between the center of mass of alfalfa stem and the center of rotor, m; μ_2 is friction coefficient between alfalfa stem and kneading plate; α_2 is the angle between alfalfa stem and impact force, (°); α_3 is the angle between the alfalfa stem and the impact force (°); α_4 is angle between Coriolis inertia force and X-axis, (°); g is acceleration of gravity, m/s².

Rubbing crushing

The force analysis of alfalfa stems during rubbing and crushing is shown in Fig. 5.

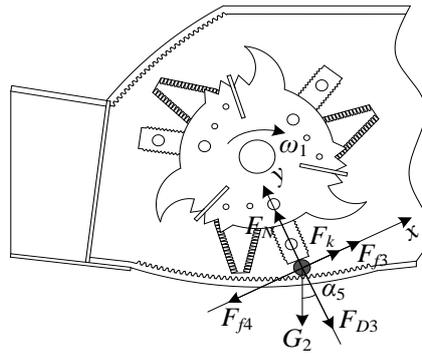

Fig. 5 – Stress analysis of alfalfa stem kneading and crushing process

According to the law of conservation of momentum:

$$Mv = Mv_1 + m_3v_2 \tag{15}$$

$$\begin{cases} v = \frac{\pi n_1 D}{60} \\ v_1 = \frac{\pi n_2 D}{60} \end{cases} \tag{16}$$

By combining equations (15) and (16), it is obtained:

$$v_2 = \frac{\pi MD(n_1 - n_2)}{60m_3} \tag{17}$$

where: M is weight of hammer, kg; v is linear velocity at the end of the hammer, m/s; v_1 is velocity after the hammer hits the alfalfa stalk, m/s; v_2 is alfalfa stalk speed after being hit, m/s; n_1 is rotational speed before the hammer hits the alfalfa stalk, r/min; n_2 is rotational speed after the hammer hits the alfalfa stalk, r/min.

According to D'Alembert's principle, the balance equation of kneading-force on alfalfa stems can be obtained as follows:

$$\begin{cases} \sum F_x = 0, & G \sin \alpha_5 + F_{f4} - F_k - F_{f3} = 0 \\ \sum F_y = 0, & F_{D3} + G \cos \alpha_5 - F_{ic3} = 0 \end{cases} \tag{18}$$

where:

$$\begin{cases} F_{f3} = \mu F_{D3} \\ F_{f4} = \mu m \frac{v^2}{D + \delta} = \mu \frac{m^2 \pi^2 D^2 (n_1 - n_2)^2}{3600(D + \delta)} \\ F_{ic3} = 2m\omega v_r \\ F_k = \frac{1}{2} C \rho S v_{r2} \end{cases} \tag{19}$$

By combining equations (18) and (19), it is obtained:

$$F_{D3} = \mu_2 \frac{M^2 \pi^2 D^2 (n_1 - n_2)^2}{3600m(D + \delta)} \tag{20}$$

where: F_{D3} is kneading force on alfalfa stem, N; F_{f3} is friction of the end of the hammer against alfalfa stalk, N; F_{f4} is friction of kneading board on alfalfa stalk, N; F_k is air resistance, N; F_{ic3} is Coriolis inertia force, N; δ is hammer plate clearance, m; C is air resistance coefficient; ρ is air density, kg/m³; S is alfalfa stem windward area, m²; v_{r2} is relative velocity of material to air, m/s

According to formula (20), the extrusion rubbing force on alfalfa stems is mainly affected by the rotational speed n_1 before the hammer hits the alfalfa stalk, the rotational speed n_2 after the hammer hits the alfalfa stalk, rotor diameter D , and the gap δ between the hammer and the kneading board.

It can be seen from the above analysis that the main factors affecting the kneading effect of alfalfa stem in the kneading room are the rotating speed of the kneading shaft and the gap between the hammer and the kneading board.

RESULTS AND DISCUSSIONS

The performance test of the designed crusher was carried out. Alfalfa was processed and collected in Duerbert County, Daqing City, Heilongjiang Province. The collected alfalfa was cut in full field at the bud stage, and there was no obvious mechanical damage. The average density of alfalfa was 996 kg/m^3 after many measurements and calculations. The experiment was conducted in the crop harvesting Laboratory of Heilongjiang Bayi Agricultural University, and the test site was shown in Fig. 6.

Fig. 6 –Test Site

1. Power consumption test device; 2. Crusher; 3. Feeding conveyor belt

According to the theoretical analysis results and in order to check the grinding effect of the machine on high water content alfalfa, productivity, silking rate, average crushing length and power consumption were selected as performance indexes, and a single factor test was carried out with motor rotation speed, screen diameter, feeding amount and water content as test factors. Alfalfa with required moisture content was obtained by natural drying. The evaluation indexes were calculated as follows:

Productivity

Feed the weighed alfalfa, record the feeding test time, weigh the output sample quality, and calculate the productivity:

$$y_1 = \frac{m}{t} \times 3600 \quad (21)$$

where: m is quality of alfalfa for testing; t is test time, s.

The test time t is short. In order to meet the test accuracy, the working time of this test is obtained from the data analysis of the torque-time curve of DYN-200 torque sensor.

Silk rates

Samples were collected at the outlet, at the same time interval for 3 times, each time no less than 200 g. All samples were mixed and weighed. Qualified alfalfa silk was screened and weighed, and its silk rate was calculated as:

$$y_2 = \frac{m_1}{m_0} \times 100\% \quad (22)$$

where: m_1 is quality of alfalfa silk in the sample, g; m_0 is alfalfa sample quality, g.

Average crushing length

By weighing 500 g samples of broken materials for measurement and classification: below 30 mm, 30~40 mm, 40~50 mm, 50~60 mm, 60~70 mm, 70~80 mm and above 80 mm, the average length of broken stems and the corresponding mass m_i between each grade are measured, weighed and measured 3 times, and the average value is taken. The average crushing length is calculated as:

$$\ln \bar{L} = \frac{\sum_{i=1}^n m_i \ln \bar{L}_i}{\sum_{i=1}^n m_i} \quad (23)$$

Power consumption

The power consumption is determined by the DYN-200 torque power sensor installed on the motor spindle. After each group of tests, the instantaneous torque, power and required time measured by the sensor are derived through the torque measurement system, and the instantaneous power of the effective working period is calculated to obtain the kneading power consumption. The calculation formula is as follows:

$$W_z = \int P(t) dt_z \quad (24)$$

where: W_z is kneading power consumption, kJ; $P(t)$ is instantaneous power, kW; t_z is kneading time, s.

Test results and analysis

According to the pre-test and the adjustable range of the machine, the rotation speed of the motor ranges from 150 to 600 r/min, the sieve diameter from 12 to 22 mm, and the feeding amount from 0.5 to 2.5 kg/s. According to the different water content requirements of the post-harvest processing of alfalfa, the water content of the single factor test ranges from 10% to 80%.

(1) Effect of motor rotation speed on performance evaluation index

The influence of motor rotation speed on performance evaluation index is shown in Fig. 7 (Sieve diameter is 16 mm, feeding amount is 1.5 kg/s, moisture content is 80%).

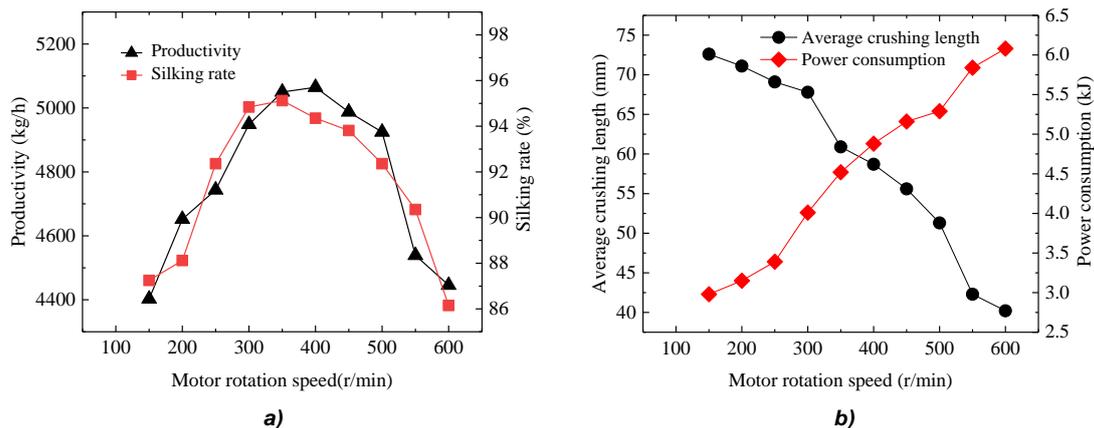

Fig. 7 – Influence of motor rotation speed on performance evaluation index

It can be seen from the figure, that with the increase of the motor rotation speed, the productivity and silking rate both increase first and then decrease, the average crushing length decreases, and the power consumption increases. The reason is that with the increase of the motor rotation speed, the chopping and crushing rotor speed will be accelerated, and the interaction frequency between alfalfa and the crushing parts can be increased per unit time, so the productivity and silk rate increase. The increase of interaction frequency also reduces the length of the stalk crushing and increases the power consumption. When the motor rotation speed is too large, the broken grass will rotate along with the crushing rotor, forming a circulation, which cannot be thrown out of the body through the screen in time through the centrifugal force, and will cause excessive crushing, and the silked alfalfa is too fine, so the productivity and silking rate show a decreasing trend. The motor rotation speed is in the range of 250~500 r/min, the productivity and the silk rate are at a high level, when the motor rotation speed exceeds 500 r/min, the productivity and the silk rate drop sharply, the average crushing length decreases sharply, and the power consumption rises sharply, so the motor rotation speed should not exceed 500 r/min. Considering the performance evaluation index comprehensively, the grinding performance is better in the range of 250~500 r/min.

(2) Effect of sieve diameter on performance evaluation index

The influence of sieve diameter on performance evaluation index is shown in Fig. 8 (motor rotation speed is 350 r/min, feeding amount is 1.5 kg/s, water content is 80%).

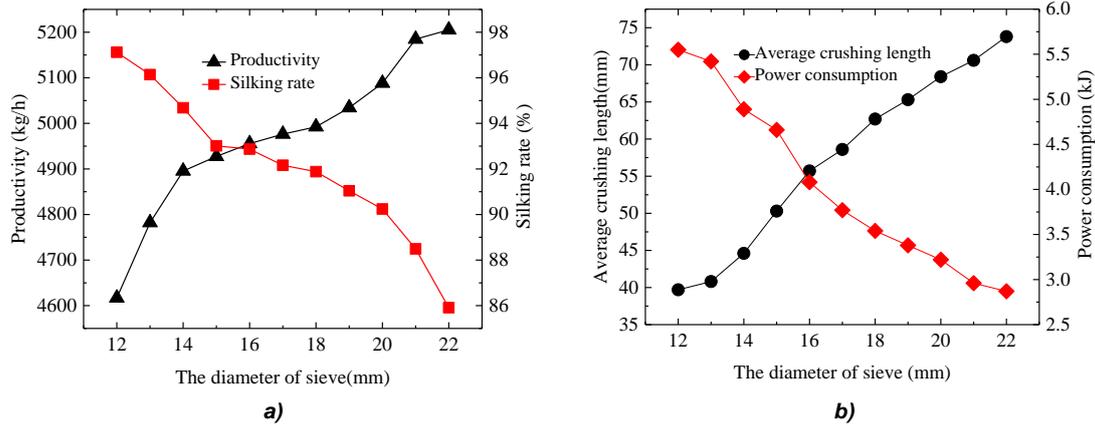

Fig. 8 – Influence of sieve diameter on performance evaluation index

It can be seen from the figure that with the increase of the screen diameter, the productivity and average crushing length show an increasing trend, while the silk rate and power consumption show a decreasing trend. The reason is that the larger the diameter of the sieve hole, the lower the limit of broken grass passing through the sieve hole, the longer the length of the stalk that can pass through the sieve, the more alfalfa can be fed in the same time, the higher the discharge efficiency, and the higher the number of crushing per unit time, so the productivity increases and the power consumption decreases.

However, some alfalfa whose length is longer than the requirement of crushing will pass through the sieve, resulting in a decrease in the silking rate and an increase in the average crushing length. When the sieve diameter is less than 14 mm, the broken grass through the sieve is more limited, so the productivity is low, the silk rate is high, the average crushing length is short, and the power consumption is large. When the screen diameter exceeds 20 mm, although the productivity is on the rise, the power consumption is low, but the silk rate drops sharply, and the average crushing length exceeds the crushing requirements. Therefore, the screen diameter should not exceed 20 mm. Considering the performance evaluation index comprehensively, the screen diameter ranges from 14 to 20 mm, the productivity and silk rate are relatively stable, and at a high level, the average crushing length is close to the crushing requirements, the power consumption is at a moderate level, and the crushing performance is better.

(3) Effect of feeding volume on performance evaluation indexes

The influence of feeding amount on performance evaluation index is shown in Fig. 9 (motor rotation speed is 350 r/min, screen diameter is 16 mm, water content is 80%).

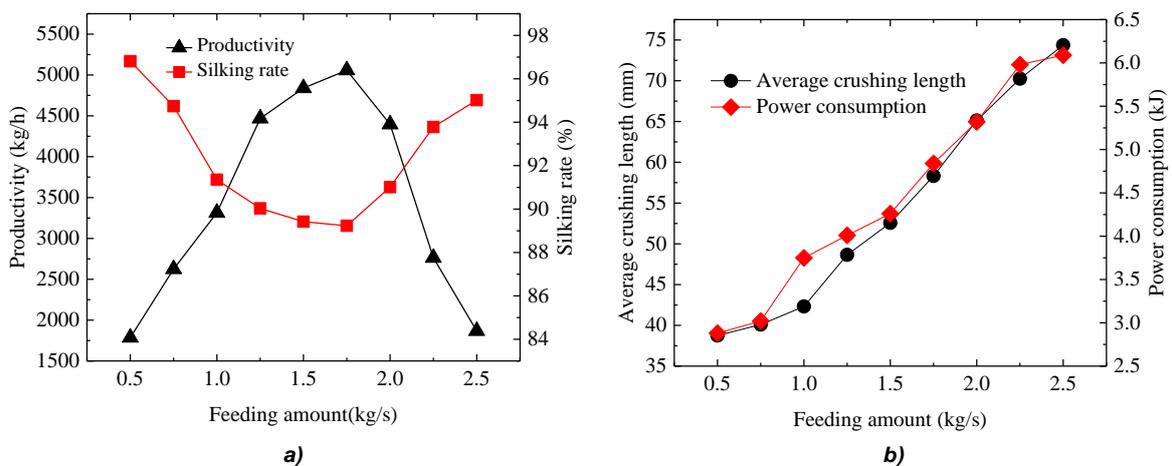

Fig. 9 – Influence of feeding amount on performance evaluation index

As can be seen from the figure, with the increase of feeding amount, the production first increased and then decreased, the silk first decreased and then increased, and the average crushing length and power consumption showed an increasing trend.

When the feeding amount is 0.5~1.75 kg/s, the feeding mechanism has self-adjustment ability, alfalfa can enter the machine smoothly, and the alfalfa in the cutting bin and crushing bin increases, so the productivity increases, the power consumption increases, the interaction frequency between a single alfalfa and the crushing parts decreases, so the silking rate decreases, and the average crushing length increases. When the feeding amount is greater than 1.75 kg/s, the self-adjustment ability of the feeding mechanism is weakened, part of alfalfa begins to accumulate at the feeding outlet, and the alfalfa in the cutting and crushing bin decreases, so the productivity decreases, and the interaction frequency between a single alfalfa and the crushing parts increases, so the silking rate increases. When the feeding amount exceeds 2 kg/s, the productivity begins to drop sharply. Considering the performance evaluation index comprehensively, the crushing performance is better in the range of 1~2 kg/s.

(4) Effect of moisture content on performance evaluation index

The influence of water content on performance evaluation index is shown in Fig. 10 (motor rotation speed is 350 r/min, screen diameter is 16 mm, feeding amount is 1.5 kg/s).

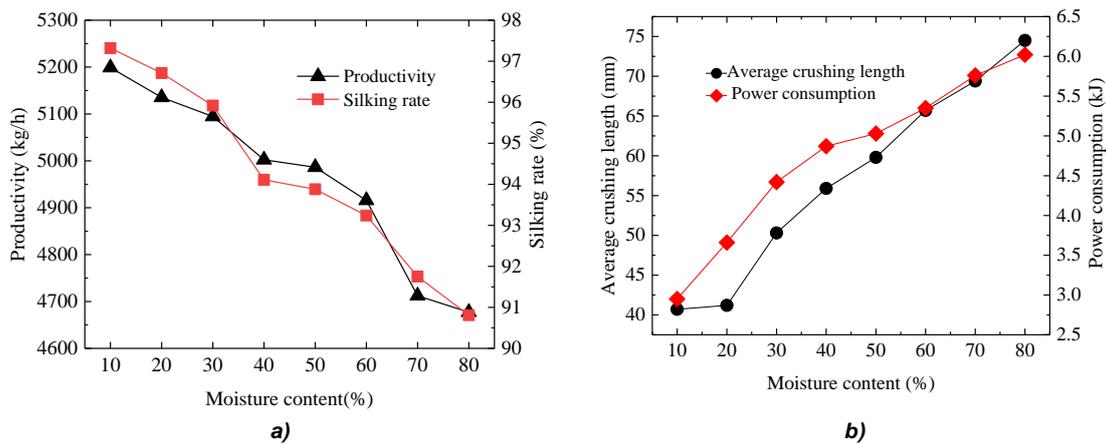

Fig. 10 – Influence of moisture content on performance evaluation index

As can be seen from the figure, with the increase of water content, both productivity and silking rate showed a downward trend. The average pulverizing length and power consumption are on the rise. The reason is that when the moisture content of alfalfa stems is low, it is brittle and easy to break, so the productivity is high and the power consumption is low. With the increase of moisture content, the toughness of alfalfa is greater, the adhesion between the internal components of the stems is enhanced, and the crushing force required is greater, and it requires multiple strikes, rubbing and impact to meet the requirements of crushing length, so the productivity and silking rate are gradually reduced. The average crushing length is long and the power consumption is large. However, the silking rate is always greater than 90%, which reflects that the machine can crush alfalfa with different moisture content.

CONCLUSIONS

(1) Dynamic analysis was carried out on the cutting process of alfalfa stalk, a dynamic model was established, and the relationship between shear force and relevant parameters of the cutting mechanism was defined. It was found that the cutting Angle, installation Angle and wedge Angle had important effects on the cutting effect and power consumption. The dynamic analysis of the grinding process of alfalfa stalk in the grinding chamber shows that the force of alfalfa stalk in the grinding chamber is mainly related to the rotation speed of the grinding shaft, the gap between the hammer and the kneading board.

(2) Through the single factor test, the influence law of motor output speed, sieve diameter, feeding amount and moisture content on productivity, silking rate, average length of silk kneading and power consumption are respectively explored. The test results show that with the increase of the output speed of the motor, the productivity and the spinning rate increase first and then decrease, the average length of the spinning wire decreases gradually, and the power consumption increases gradually. With the increase of the screen diameter, the productivity and the average length of the yarn increase gradually, and the silk rate and power consumption decrease gradually. With the increase of feeding amount, the production increases first and then decreases, the silk decreases first and then increases, and the average kneading length and power consumption increase gradually. With the increase of water content, the productivity and silking rate gradually decrease, and the average length and power consumption of the kneading wire gradually increase.

Keywords: Obstacle detection, Multi-scale detection, ResNet50, ROI Align

ABSTRACT

For the accurate detection of obstacles in complex farmland environments, ResNet50 is adopted as the backbone feature extraction network, feature pyramid network (FPN) is utilized to enhance the multi-scale feature fusion capability, and the region of interest alignment (ROI Align) strategy is introduced to improve the candidate box localization precision. The experimental results show that the precision, recall, and mean accuracy (mAP) of the improved model are 91.6%, 89.7%, and 93.8%, respectively, which are improved by 2.7, 2.3, and 3.1 percentage points compared with the original base network, and provide a technical reference for navigation and obstacle avoidance of unmanned agricultural machinery.

摘要

针对复杂农田环境中障碍物的准确检测, 采用 ResNet50 作为骨干特征提取网络, 利用特征金字塔网络 (FPN) 提升多尺度特征融合能力, 并引入感兴趣区域对齐 (ROI Align) 策略提高候选框定位精度。实验结果显示, 改进模型的精度、召回率和平均精度 (mAP) 分别为 91.6%、89.7% 和 93.8%, 相比于原基础网络, 提升了 2.7、2.3 和 3.1 个百分点, 为无人农业机械的导航避障提供了技术参考。

INTRODUCTION

Driven by the rapid development of agricultural machinery intelligence and automation, unmanned agricultural machinery has made significant progress. In order to ensure that these unmanned agricultural machines can operate safely and efficiently during operation and effectively avoid collision with obstacles such as utility poles, trees, buildings, etc., it is necessary to carry out accurate and fast identification of obstacles in the field. In farmland obstacle detection, deep learning detection algorithms have higher detection accuracy, stronger generalization ability and better adaptability than other detection algorithms, and can more accurately identify complex and changing obstacles in farmland, while maintaining stable detection performance under different light, climate and crop growth conditions.

Deep learning-based detection algorithms are divided into two categories: single-stage object detection algorithms (such as SSD and YOLO series) and two-stage object detection algorithms (such as Sparse R-CNN and Faster R-CNN). The latter, although more complex in process and relatively slower in speed, demonstrates higher accuracy. Research on obstacle detection in the field of machine vision has made significant progress.

He et al., (2022), improved the recognition accuracy by enhancing Mask R-CNN, employing Swin-Le Transformer for feature extraction and ME-PAPN for feature fusion. They integrated a multi-scale enhancement method to boost the detection capability of small targets, achieving a mean Average Precision (mAP) of 91.3% and an average detection time of 4.2 frames per second (FPS).

Rahman et al., (2022) implemented a transfer learning model based on the convolutional neural network MobileNetV2, which can be used on low-configured devices while maintaining a balance between detection speed and processing efficiency. The accuracy of obstacle detection reached 97.00%.

Xue et al., (2022) improved the Faster R-CNN object detection algorithm to identify obstacles in agricultural fields, effectively enhancing the speed of obstacle recognition while reducing false positives and missed detections. This improvement meets the real-time detection requirements for low-speed operations of tractors.

Du *et al.*, (2024), proposed an optimized obstacle detection method based on an improved YOLOv8. By removing the P5 layer and introducing DCNv2 to optimize the bottleneck, the model enhances the detection capability for small and irregular obstacles. The improved model achieved a 3.4% increase in mAP50, a 34.5% reduction in GFLOPs, a 77.4% decrease in parameters, and a 73% reduction in model size.

Han *et al.*, (2024) investigated an autonomous driving obstacle avoidance method based on YOLOv5 monocular vision. This approach combines a deep reinforcement learning path planning algorithm to dynamically generate safe driving paths. By introducing a monocular vision obstacle avoidance aggregation network, the MMA obstacle avoidance method is developed, achieving an accuracy that fluctuates between 78.76% and 88.26%.

Zhao *et al.*, (2024), proposed a real-time high-precision railway obstacle detection model based on a lightweight CNN and an improved Transformer (RH-Net). This model includes a Lightweight Feature Extraction Module (LEM) to minimize computational load, an Improved Transformation Module (IFM) that enhances the capability of extracting global contextual information, and an Enhanced Multi-Scale Feature Fusion Module (EFM) that optimizes the detection of obstacles of varying sizes.

Yang *et al.*, (2025) proposed the YOLO-Region model to solve the problem of oversensitive obstacle detection in unmanned electric locomotives in underground coal mines, the model backbone adopts the InceptionNeXt block and the NSPP module, extends the FPN+PAN architecture with the Impro-TSCODE header and introduces the repulsion loss to enhance the detection of occluded targets.

Researchers have made significant progress in the field of obstacle recognition, confirming the feasibility of target detection technology for obstacle detection. However, in today's era of unmanned farming, there is relatively little research on using drone equipment to capture images of agricultural fields for obstacle recognition. To address this gap, this paper selects the second-stage detection algorithm Faster R-CNN, which offers higher detection accuracy, for detecting obstacles in farmland. Given the complexity of agricultural environments, directly applying Faster R-CNN to unstructured agricultural scenes for obstacle detection may lead to decreased model accuracy, particularly under complex and variable weather conditions, where the effectiveness of obstacle detection can be significantly weakened. Therefore, this paper conducts targeted optimization based on the Faster R-CNN model, aiming to address the current issues of insufficient accuracy and poor robustness in deep learning models for obstacle detection in agricultural fields.

MATERIALS AND METHODS

Acquisition of images of farmland obstacles

This study adopts a combined ground and airborne acquisition of the dataset, i.e., combining ground-based cell phone acquisition with airborne UAV acquisition, as shown in Figure 1. Ground-based acquisition can obtain detailed and accurate information about obstacles, including the shape, size, and material of obstacles, which is suitable for complex terrain and dense obstacle areas, and can capture details that may be missed by aerial acquisition. Aerial acquisition can quickly cover a large area and improve acquisition efficiency, and it has unique advantages for high-altitude obstacles or areas that are difficult to reach on the ground. The combination of the two can result in a more complete and accurate obstacle dataset, which is useful for subsequent application and analysis.

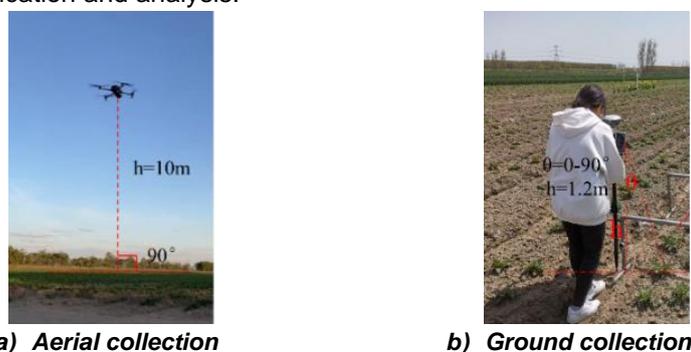

Fig. 1 – Data collection method

The dataset was collected from March to June 2023 through aerial photography and mobile imaging in Hebei and Shandong provinces, under varying lighting conditions during the morning, afternoon, and evening. The drone used was a DJI Mavic 3, which captured vertical aerial shots of the plots at an altitude of 10 meters and a flight speed of 7 m/s.

The drone automatically collected images at predetermined intervals along a designated flight path. Both longitudinal and lateral overlap rates were set at 70%. Each flight generated approximately 200 images. Simultaneously, mobile phones and cameras were employed to capture multi-angle views of the field obstacles, as illustrated in Figure 2. The types of obstacles were diverse, specifically including buildings, high-voltage power towers, trees, telegraph poles, water wells, personnel, and agricultural machinery, categorized into seven main groups.

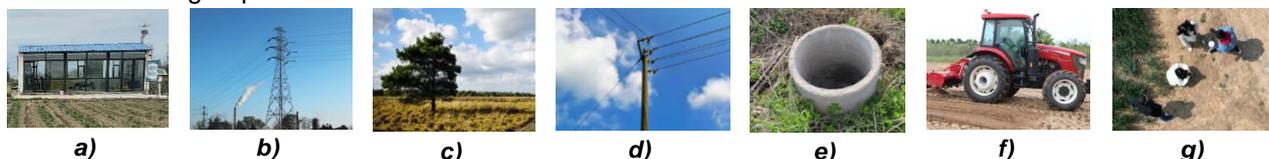

Fig. 2 – Example of dataset image

a) building; b) high-voltage power towers; c) tree; d) telegraph pole; e) water well; f) agricultural machinery; g) person

Data expansion

To improve the robustness and generalization performance of the dataset, an image enhancement strategy is implemented. As shown in Fig. 3, data enhancement includes random brightness adjustment to simulate different lighting environments, Gaussian noise addition, horizontal flip, and vertical flip to simulate diverse shooting angles. These methods not only increase the number of images, but also effectively reduce the overfitting problem during model training, and finally an expanded dataset containing 7707 obstacle images is obtained.

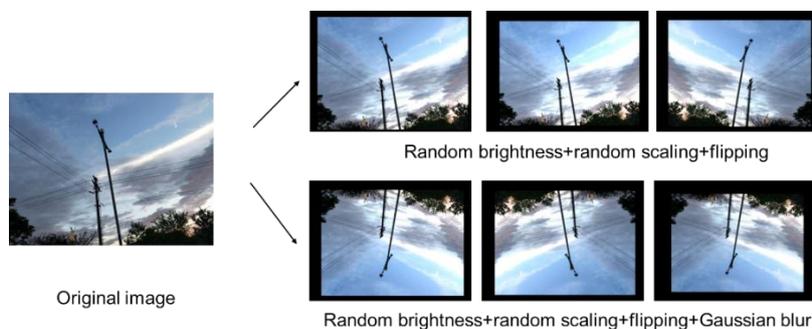

Fig. 3 – Data enrichment

Image annotation and dataset construction

Using the Labellmg image annotation tool, obstacles were annotated on the processed images. The dataset comprises 7,707 images with a total of 11,578 annotation tasks for obstacles. The training data was organized into the standard PASCAL VOC 2007 format. From the entire dataset, 6,823 images were randomly selected as the training set for model learning and parameter tuning, while 884 images were designated as the validation set to monitor the performance of the model in real-time during training, allowing for timely adjustments to the training strategy. A separate test set was established for the final evaluation of the model's recognition accuracy and generalization capability. This division ensures both the thorough utilization of the dataset and the objectivity and accuracy of the evaluation results.

Faster R-CNN model

Faster R-CNN, as a two-stage detection algorithm, has a more complex process and relatively slower running speed compared to one-stage algorithms such as the YOLO series and SSD (Single Shot MultiBox Detector), but it demonstrates a higher level of detection accuracy. Faster R-CNN consists of a feature extraction layer, a Region Proposal Network (RPN), and an RoI Pooling layer (Region of Interest Pooling). The detection process of Faster R-CNN is summarized as follows: First, the training images are resized to a uniform dimension and input into the network, where feature maps are generated via the feature extraction layer; second, the RPN network generates a series of anchor boxes on the feature map based on predefined Intersection over Union (IoU) thresholds; then, the anchor boxes produced by the RPN are combined with the feature map and sent to the RoI Pooling layer to obtain fixed-size (7x7) feature representations of the anchor boxes; finally, these feature representations are input into the classification and regression layers for bounding box regression predictions and object detection classification, resulting in accurate detection outcomes. The entire detection process is illustrated in Figure 4.

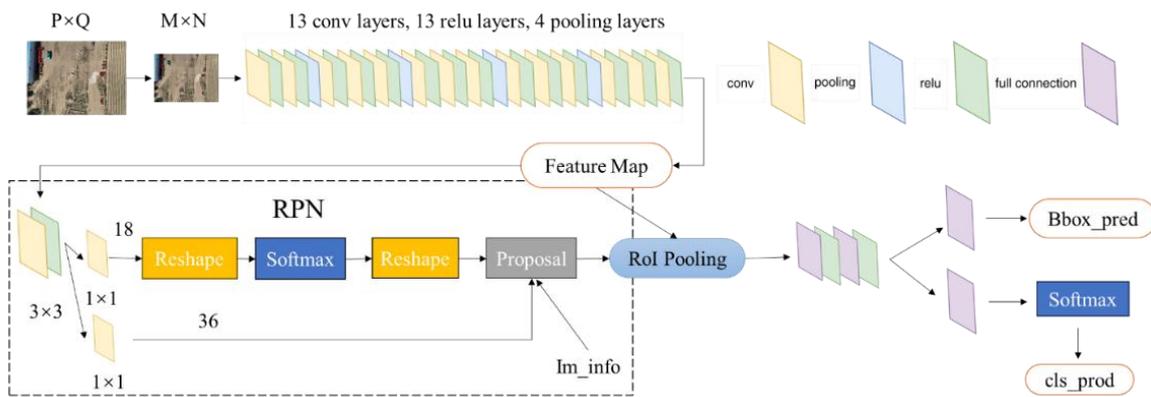

Fig. 4 – Faster R-CNN Detection Flowchart

Improved Faster R-CNN model

To enhance the obstacle detection capability of the Faster R-CNN model in complex agricultural environments, this study implemented the following key improvements: first, the original VGG16 feature extraction backbone used in Faster R-CNN was replaced with the more efficient ResNet50. Second, by introducing a Feature Pyramid Network (FPN), the fusion of high-level and low-level features was achieved, thereby enriching the information content of the feature maps. Finally, the ROI Align strategy was adopted to replace the original ROI Pooling layer, which improved the model's accuracy in candidate box localization. The architecture of the improved Faster R-CNN model is illustrated in Figure 5.

ResNet50 backbone network

To address the hardware resource limitations in agricultural environments, and to significantly enhance the feature extraction capability of the obstacle detection model while optimizing the deployment of the network model in practical production operations, this study adopted ResNet50 as a replacement for the original VGG16, serving as the new backbone network. The ResNet50 network effectively resolves the degradation problem in deep neural networks by introducing residual units. Its architecture, as shown in Figure 5, consists of five core components: conv1, conv2_x, conv3_x, conv4_x, and conv5_x. The conv1 component includes only one convolutional layer and one max pooling layer, which can be considered as the preprocessing stage of the network. The remaining four components (from conv2_x to conv5_x) are structurally similar, consisting of repeated stacks of residual structures such as ReB1 and ReB2.

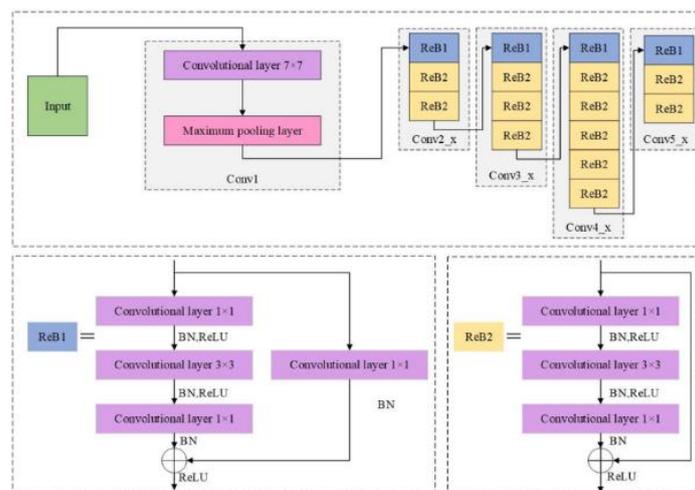

Fig. 5 – ResNet50 structure diagram

Feature pyramid network

Aiming at the problem of complex background and diverse scales of obstacle images jointly captured by UAVs and cell phones, this paper adopts the feature pyramid network FPN to improve the Faster R-CNN model. As shown in Figure 6, FPN fuses the rich semantic information of the high-level feature map with the rich spatial details of the shallow feature map to generate a richer and more accurate feature representation.

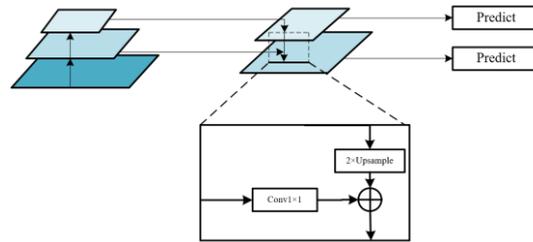

Fig. 6 – Feature pyramid network architecture

The structure combining the FPN network with the ResNet50 network is illustrated in Figure 7. First, the ResNet50 network performs bottom-up convolution operations to extract feature maps of varying scales and different channel numbers, denoted as {C2, C3, C4, C5}. Subsequently, these feature maps are fused through a top-down pathway. During the fusion process, the feature maps are first adjusted using 1x1 convolution operations, resulting in a new set of feature maps {M1, M2, M3, M4}. Then, adjacent feature maps M are fused using upsampling, followed by processing with 3x3 convolution operations, ultimately generating the feature map P. To control computational complexity, this paper only selects four feature maps of different scales for output during the feature extraction phase, namely {P2, P3, P4, P5}. Finally, all feature maps generated by the FPN are input into the Region Proposal Network (RPN), thus achieving effective fusion of high-level and low-level features, further enhancing the model's feature extraction capability.

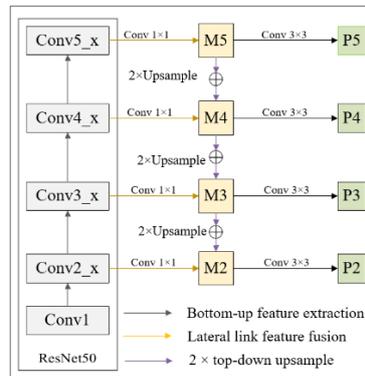

Fig. 7 – Feature pyramid network architecture

ROI Align

The operational process of ROI Align is illustrated in Figure 8. First, the predicted candidate regions are accurately mapped to the corresponding feature levels and thoroughly traversed. At this stage, each candidate region is meticulously divided into $k \times k$ uniform small grids, while ensuring the precision of boundary coordinates, effectively avoiding potential errors introduced during the quantization process. Subsequently, within each small grid, the specific values of four key sampling points are accurately calculated using bilinear interpolation. These values are then used as the basis for performing the maximum pooling operation, which determines the comprehensive feature representation of each grid. By integrating the ROI Align strategy, the model is not only able to flexibly adapt to uniform input size requirements when processing candidate regions but also achieve more precise and detailed localization, significantly enhancing the model's object recognition capability.

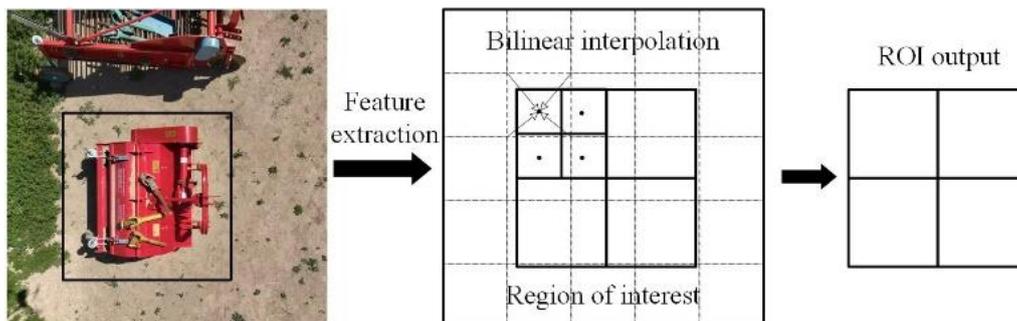

Fig. 8 – ROI Align Principle

The Faster R-CNN model architecture after the above improvements is shown in Fig. 9.

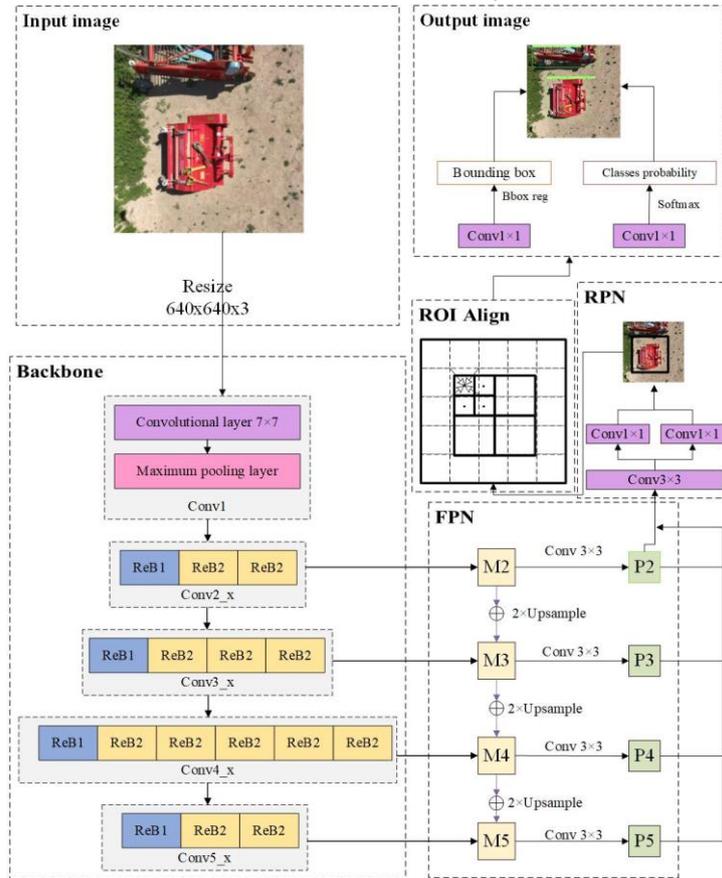

Fig. 9 – Improved Faster R-CNN model architecture

RESULTS AND ANALYSIS

Test environment

The experiments were conducted in the Anaconda environment under the Windows 10 operating system, utilizing the PyTorch framework for development and programming within PyCharm. The hardware setup included an AMD Ryzen 7 4800H processor, a Radeon Graphics 2.0GHz graphics card, an Nvidia GeForce RTX 2060 GPU, and 6GB of RAM.

Test evaluation indicators

In order to test the correctness of the algorithm, Precision (P), Recall (R), mean average precision (mAP) are used as model evaluation metrics. In terms of model complexity, the key factors considered are the parameter and FPS. Parameter indicates the computational memory resources consumed by the model, and FPS indicates the number of images that the model can process per second. The calculation formula is as follows.

$$P = \frac{T_p}{T_p + F_p} \tag{1}$$

$$R = \frac{T_p}{T_p + F_n} \tag{2}$$

$$AP = \int_0^1 P(R) dR \tag{3}$$

$$mAP = \frac{\sum_{i=1}^N AP_i}{N} \tag{4}$$

$$Parameters = r^2 \times a \times v + v \tag{5}$$

In the formula, *TP* denotes the number of samples where the positive class is predicted to be positive, *FP* denotes the number of samples where the negative class is predicted to be positive, *FN* denotes the number of samples where the positive class is predicted to be negative, *a* is the input size, *r* is the size of the convolution kernel, and *v* is the output size.

Comparative test analysis of different algorithms

To validate the effectiveness of the improved Faster R-CNN model used in this study for detecting obstacles in agricultural fields, comparative experiments were conducted under the same training environment and hyperparameter settings, contrasting the improved model with single-stage models in the deep learning domain (SSD, YOLOv8n) and two-stage models (Sparse R-CNN, Cascade R-CNN).

Table 1

Different model experiment results

Models	Precision/%	Recall/%	mAP@0.5%	Parameters/MB	FPS/(img/s)
Faster R-CNN	88.9	87.4	90.7	41.36	8.3
SSD	81.2	82.1	82.7	25.6	4.6
YOLOv8n	86.4	83.4	87.9	2.51	10.5
Sparse R-CNN	87.7	84.5	88.2	43.01	7.8
Cascade R-CNN	87.5	84.8	87.9	40.12	7.1
Our	91.6	89.7	93.8	41.45	8.7

According to the data in Table 1, Faster R-CNN demonstrates the highest accuracy, recall, and mean Average Precision (mAP) when compared to both single-stage and two-stage models, providing a solid foundation for further optimization of subsequent models. The improved Faster R-CNN model surpasses SSD, YOLOv8n, Sparse R-CNN, and Cascade R-CNN in mean Average Precision by 11.1, 5.9, 5.6, and 5.9 percentage points, respectively. In terms of accuracy, it also outperforms these models by 10.4, 5.2, 3.9, and 4.1 percentage points, respectively. Additionally, the improved Faster R-CNN exhibits excellent recall, exceeding these models by 7.6, 6.3, 5.2, and 4.9 percentage points. These data conclusively demonstrate that the improved Faster R-CNN model excels in extracting effective features and accurately predicting the coordinates and category information of obstacles.

Ablation test analysis

To evaluate the specific improvements in the performance of the basic Faster R-CNN model achieved by using ResNet50 as the backbone network, the Feature Pyramid Network, and the Region of Interest Align (ROI Align) strategy, ablation experiments were designed while keeping the dataset and experimental parameters consistent.

Table 2

Results of ablation experiment

Test	ResNet50	FPN	ROI Align	P/%	R/%	mAP@0.5%	Parameters/MB	FPS
1	×	×	×	88.9	87.4	90.7	41.36	8.1
2	√	×	×	89.5	88.1	91.9	41.14	8.3
3	√	√	×	90.7	88.5	93.2	41.14	8.7
4	√	√	√	91.6	89.7	93.8	41.25	8.7

As shown in Table 2, in Experiment 2, ResNet50 was used to replace the original VGG16 as the backbone network. Benefiting from the residual structure of ResNet50, the improved backbone network not only increased the number of convolutional layers but also achieved improvements of 0.6%, 0.7%, and 1.2% in accuracy, recall, and mean Average Precision (mAP), respectively, while reducing the number of parameters. In Experiment 3, the introduction of the Feature Pyramid Network (FPN) for multi-scale feature fusion allowed the feature maps to integrate high-level semantic information and low-level spatial information, thereby enhancing the model's capabilities in multi-scale and small object detection. This improvement resulted in increases of 1.2%, 0.4%, and 1.3% in accuracy, recall, and mean Average Precision, respectively. In Experiment 4, ROI Align was used to replace the original ROI Pooling. ROI Align improved the overall regression performance of the predicted bounding boxes, making them more precise when detecting obstacles. This enhancement led to increases of 0.9%, 1.2%, and 0.6% in accuracy, recall, and mean Average Precision, respectively. Overall, the results of the ablation experiments indicate that these improvements played a positive role in enhancing obstacle detection accuracy. Compared to the original Faster R-CNN model, the improved model not only reduced the number of model parameters and increased detection speed but also achieved increases of 2.7%, 2.3%, and 3.1% in accuracy, recall, and mean Average Precision, respectively.

Test results of different obstacles

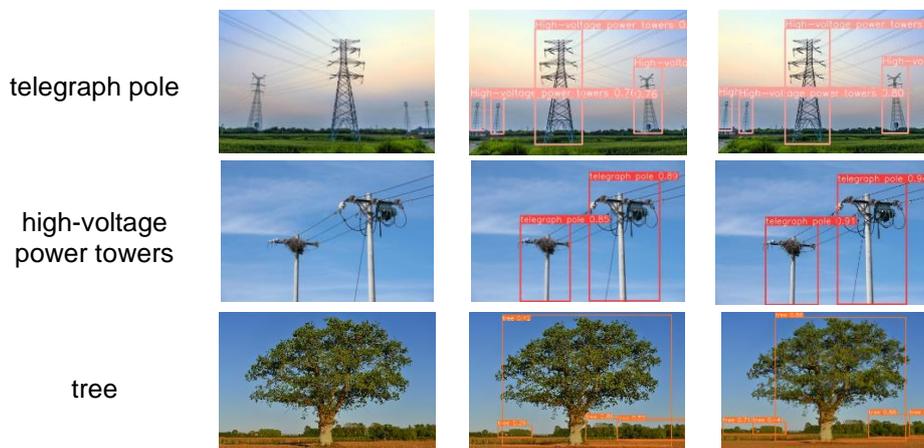

To clearly present the differences in performance between the original model and the improved model in detecting various categories of obstacles, the test results of both models were compared and the comparison results were displayed in Figure 10. Additionally, the mean Average Precision (mAP) of the obstacle detection results during the training process were statistically analyzed and they are listed in Table 3.

According to the data analysis in Table 3, the improved Faster R-CNN model, compared to its original version, shows only a slight improvement in agricultural machinery detection tasks, while achieving a significant increase in mean Average Precision (mAP) for other obstacle detection tasks. This improvement is reflected not only in the overall optimization of detection performance but also in the notable enhancement of specific obstacle detection. Taking utility pole detection as an example, the mAP@0.5 of the original model was only 82.1%, whereas after adopting the improved YOLOv8 model, the mAP@0.5 for utility pole detection increased to 89.8%. Although there remains a certain gap in detection accuracy for utility poles compared to other obstacles such as vehicles and pedestrians, the improved model has made significant progress compared to the original model. As shown in Figure 10, the improved Faster R-CNN model not only reduces the instances of missed detections and false positives compared to the original model, but it also enhances the confidence level of obstacle detection.

Table 3

Types of obstacles	mAP@0.5/%	
	pre-optimization	post-optimization
telegraph pole	82.1	89.8
high-voltage power towers	92.7	94.5
tree	91.3	93.8
building	92.5	94.6
person	89.4	93.7
agricultural machinery	95.1	95.2
water well	92.0	94.8
all	90.7	93.8

According to the data analysis in Table 3, the improved Faster R-CNN model, compared to its original version, shows only a slight improvement in agricultural machinery detection tasks, while achieving a significant increase in mean Average Precision (mAP) for other obstacle detection tasks. This improvement is reflected not only in the overall optimization of detection performance but also in the notable enhancement of specific obstacle detection. Taking utility pole detection as an example, the mAP@0.5 of the original model was only 82.1%, whereas after adopting the improved YOLOv8 model, the mAP@0.5 for utility pole detection increased to 89.8%. Although there remains a certain gap in detection accuracy for utility poles compared to other obstacles such as vehicles and pedestrians, the improved model has made significant progress compared to the original model. As shown in Figure 10, the improved Faster R-CNN model not only reduces the instances of missed detections and false positives compared to the original model, but it also enhances the confidence level of obstacle detection.

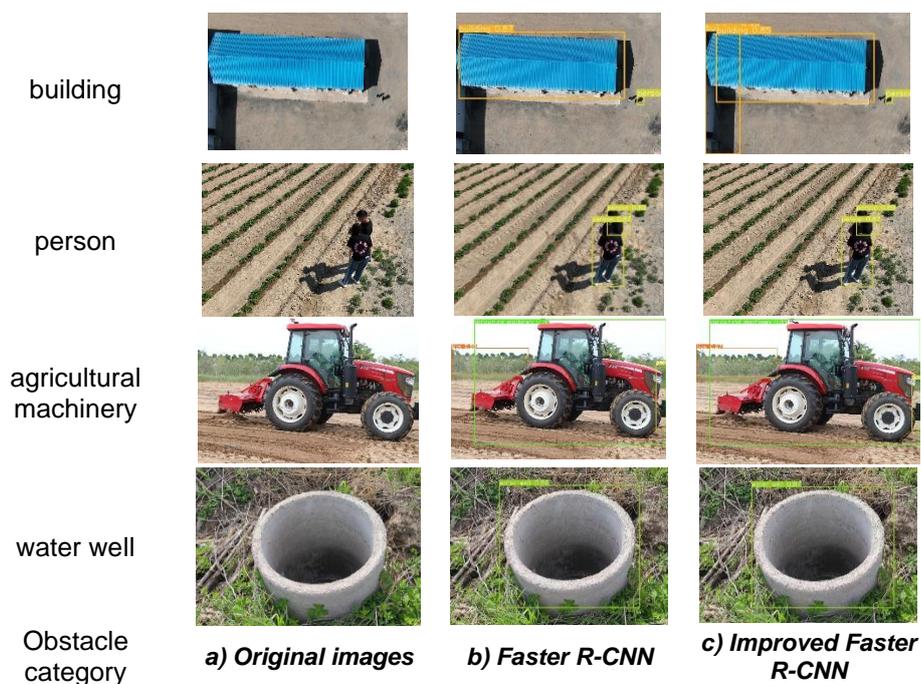

Fig. 10 –Comparison of Faster R-CNN and Improved Faster R-CNN Detection Results

As shown in Figure 10, the improved Faster R-CNN model not only reduces the instances of missed detections and false positives compared to the original model, but it also enhances the confidence level of obstacle detection.

CONCLUSIONS

This study developed a farmland obstacle detection model based on an improved Faster R-CNN model. Validation using the same obstacle dataset showed that the improved model achieved a recognition accuracy of 91.6% and a recall rate of 93.8%. In practical applications, the model's recognition rate for static obstacles such as utility poles, high-voltage towers, trees, buildings, agricultural machinery, and wells exceeded 90%. Simultaneously, the model's recognition rate for dynamic obstacles, such as people walking at a speed of 0.8 m/s, also remained at 90%, with an average detection frame time of 108 ms, meeting the requirements for real-time detection.

Keywords: Wheat grains, machine vision, YOLOv8n, attention mechanism, DWR module

ABSTRACT

Wheat grains are a common type of cereal variety, and due to their large quantity and high demand, traditional manual quality inspection requires a significant amount of labor with potentially inadequate results. To address this issue, this study focuses on intact, damaged, moldy, and shriveled wheat grains, and establishes a YOLO-wheat automatic wheat grain appearance quality detection model. First, a large number of wheat grain sample images were collected, preprocessed, and annotated. Next, YOLOv5n, YOLOv8n, and YOLOv10n wheat grain object detection models were established, and the optimal model YOLOv8n was selected as the base model for automatic wheat grain appearance quality detection. To further improve wheat grain detection performance, the Dilation-wise Residual (DWR) module was integrated into the YOLOv8n network structure to enhance feature extraction from the expandable receptive field in the higher layers of the network. Additionally, the TripletAttention attention mechanism was introduced, and this improved network was named YOLO-wheat. Experimental results showed that YOLO-wheat achieved an mAP value of 91.3% in wheat grain appearance quality detection, representing a 4.3% improvement compared to the previous version. This study provides technical support for automatic wheat quality detection.

摘要

小麦籽粒是一种常见的谷物类品种，且由于其数量多需求量大，在传统人工品质检测时耗费大量精力而效果不见得足够好。为解决上述问题，本研究以小麦完善粒、破损粒、发霉粒和干瘪粒为研究对象，建立 YOLO-wheat 小麦籽粒外观品质自动检测模型。首先，采集了大量小麦籽粒样本图像，并进行了数据预处理和标注整理。其次，建立了 YOLOv5n、YOLOv8n、YOLOv10n 小麦籽粒目标检测模型，从中选取最优模型 YOLOv8n 为小麦籽粒外观品质自动检测基础模型。为了进一步提升小麦籽粒检测性能，在 YOLOv8n 网络结构中使用 Dilation-wise Residual(DWR) 模块加强从网络高层的可扩展感受野中提取特征，并引入了 TripletAttention 注意力机制，将此网络命名为 YOLO-wheat。实验结果表明 YOLO-wheat 在小麦籽粒外观品质检测中 mAP 值为 91.3%，较改进前提升 4.3%。该研究可为小麦品质自动检测提供技术支持。

INTRODUCTION

In daily life, wheat is one of the most demanded and high-quality food products for human consumption (Zahra et al., 2023; Shewry et al., 2023), requiring both high quantity and quality standards. However, due to its large volume and the difficulty in distinguishing quality categories, traditional manual inspection methods are highly complex, time-consuming, and labor-intensive, often leading to unsatisfactory results. With the development of machine vision and deep learning technologies, the use of computers to achieve automated analysis of target detection images (Dhanya et al., 2022) has become a powerful tool to solve this problem, improving production efficiency and reducing labor costs. Therefore, machine learning and deep learning techniques can be utilized in combination with large datasets of labeled wheat grain samples to perform target detection on wheat grains through automated and intelligent methods, promoting the modernization and intelligent development of the agricultural industry. Furthermore, this can later be integrated with robotics to achieve intelligent agriculture (Soori et al., 2024).

Target detection tasks based on deep learning have been widely applied in agricultural production due to their high precision and rapid detection capabilities. In 2021, Wang Qiu jin et al., (2021), developed a wheat fusarium head blight grain recognition model based on feature band fusion images and deep learning algorithms. By comparing recognition accuracy, the optimal deep learning model was selected, enabling real-time online detection of fusarium-infected wheat grains.

In 2023, Wang Ling *et al.*, (2023), proposed a wheat grain counting method based on the YOLOv7-ST model. The YOLOv7-ST model accurately and quickly detected issues such as grain occlusion and adhesion under varying degrees of dispersion, significantly improving the efficiency of wheat seed testing. In 2024, Yu Zhaofu *et al.*, (2024) proposed a genetic algorithm-based optimizer designed for the YOLOv8 network, addressing the challenge of optimizing complex networks through intelligent algorithms, thus providing a better method for soybean grain recognition. Tomáš Zoubek *et al.*, (2024), conducted a comparative study of YOLO models for weed and crop recognition. By adjusting different parameters, the model was fine-tuned to address weed recognition challenges, and it was determined that different models showed improved performance for specific feature detection problems. In 2024, Ma *et al.* (2024), focused on wheat grains and proposed an improved YOLOv8-based wheat grain detection and counting method. Today, the applications of deep learning in agriculture are not limited to crop recognition. Yue *et al.*, (2024), proposed a lightweight pest detection method based on an improved YOLOv8 model, capable of identifying dynamic pests affecting crops. This method enhanced YOLOv8's feature extraction capabilities, addressing issues like low precision in small-object detection and improving the model's suitability for embedded deployment, providing valuable insights for the lightweight model in this study. In addition, YOLO models can be repeatedly modified to make them better suited for specific detection scenarios. For instance, Liu *et al.*, (2024), proposed a Fusion Transformer YOLO-based model for grape disease detection. Sangaiah *et al.*, (2024), developed UAV T-YOLO-Rice, an efficient and lightweight rice leaf disease detection model; and Ren *et al.*, (2024), introduced the FPG-YOLO model for detecting pollination stamens of "Yulu Fragrant" pears in unstructured environments. These studies demonstrate that target detection algorithms show excellent performance in agricultural modernization, especially in crop localization and recognition. Beyond agriculture, YOLOv8n-based models have also been improved for various applications. For instance, Li Bohao *et al.*, (2024), proposed an improved UAV aerial small-object detection algorithm model based on YOLOv8n. Qin *et al.*, (2024), developed a cable switch fault diagnosis model based on YOLOv8n; and Yang Ruijun *et al.*, (2024), designed a lightweight remote sensing image detection algorithm for military aircraft using YOLOv8n. These applications highlight that visual detection using the YOLOv8n base model has found use across diverse fields, providing inspiration for this study. However, research on detecting wheat grains of varying qualities remains relatively scarce, with low recognition accuracy. Therefore, this study focuses on detecting the quality of wheat grains, specifically intact grains, damaged grains, moldy grains, and shriveled grains, using deep learning methods for intelligent quality detection.

First, a large dataset of wheat grain images was collected and annotated using labeling. The detection performance of YOLOv5n, YOLOv8n, and YOLOv10n was compared, and the YOLOv8n model was ultimately selected as the base model. To further enhance the detection accuracy of the model, the Dilation-wise Residual (DWR) module, which is more suitable for small-object detection, and the TripletAttention attention mechanism were integrated into the YOLOv8n model. The enhanced model, named YOLO-wheat, was developed to achieve automated detection of wheat grain appearance quality.

MATERIALS AND METHODS

Data Acquisition and Pre-processing

In this study, a total of 684 images of intact grains, damaged grains, moldy grains, and shriveled grains were collected (Zhixiao *et al.*, 2020). These images included various scenarios such as white backgrounds, black backgrounds, different shooting angles, varying lighting conditions, different rotation degrees, and scattered stacking, aiming to realistically replicate various situations that may occur in practical application scenarios. Figure 1 shows some of the collected wheat grain images.

(a) White Background

(b) Black Background

Fig. 1 - Partial Data Collection

The images were annotated using labeling in the YOLO format. During annotation, the mouse was used to accurately draw bounding boxes on the images, ensuring that no wheat grains were missed. Each grain in the images was labeled according to its appearance quality, categorized into four classes: intact grains (denoted as "w"), damaged grains (denoted as "p"), moldy grains (denoted as "f"), and shriveled grains (denoted as "g"). The annotation results were then saved for subsequent operations.

Since images captured in a laboratory environment cannot fully reflect real-world scenarios, data augmentation techniques were applied to enrich the dataset. The collected images were further processed with random rotations, noise addition, brightness adjustments, and other image enhancement methods. These techniques were randomly combined to simulate various situations that might be encountered in practical algorithm application scenarios. Figures 2 and 3 show a comparison between the original wheat grain images and the augmented images under different backgrounds.

Fig. 2 - Comparison of Data Augmentation Effects for Wheat Grains on a Black Background

Fig. 3 - Comparison of Data Augmentation Effects for Wheat Grains on a White Background

The images were divided into a training set, validation set, and test set in a ratio of 7:2:1. The specific distribution is shown in Table 1. The dataset is categorized into two types: black background and white background. There are 348 images with a white background and 336 images with a black background. Among the white background images, the training set, validation set, and test set contain 243, 70, and 35 images, respectively. For the black background images, the training set, validation set, and test set contain 235, 67, and 34 images, respectively.

Table 1

Comparison of Experimental Parameters for Each Model					
Augmented dataset	White Background	Black Background	Augmented dataset	White Background	Black Background
Training Set	243	235	Training Set	243	235
Validation Set	70	67	Validation Set	70	67
Test Set	35	34	Test Set	35	34
Total	348	336	Total	348	336

YOLOv8n Model

The YOLO algorithm series has a long history of development (Jiang et al., 2020; Terven et al., 2023). Among them, YOLOv8n is a state-of-the-art, lightweight object detection model capable of processing images in real-time and identifying various objects within them. It demonstrates superior performance in addressing the issues designed in this study. For instance, in real-world application scenarios, it can provide rapid feedback, allowing operators sufficient time to address problems identified after detection. This makes it highly practical in terms of both usability and accuracy.

The YOLOv8n network model primarily consists of three components: the Backbone, the Neck, and the Head. In deep learning-based object detection algorithms, these three major components have distinct roles. The Backbone is mainly responsible for increasing the feature depth and level of abstraction of the input image, transforming it into feature maps that contain various information such as the location and shape of objects in the image. The Neck is primarily designed to aggregate feature information from different levels and is situated between the Backbone and the Head. The Head is used to predict the categories and locations of objects,

including their bounding boxes. The basic structure of a deep learning-based object detection algorithm follows the sequence: Input → Backbone → Neck → Head → Output.

DWR (Dilation-wise Residual) Model

The DWR module acts as a tool for extracting features at different scales in the higher layers of the network, significantly improving the algorithm's accuracy, its structure as shown in Figure 4. First, a multi-branch structure is used to expand the receptive field, where each branch employs a dilated depthwise convolution with different dilation rates. Second, a specially designed Simple Inverted Residual (SIR) module is used to extract features from the lower layers of the network. This module has only a small receptive field of 3x3 and adopts an inverted bottleneck structure to expand the number of channels, ensuring stronger feature extraction capability. Finally, based on the combination of the DWR module and the SIR module, the network DWRSeg was constructed. In this network, the decoder adopts a simple structure similar to FNC. The decoder uses strong semantic information from the last two stages to directly upsample the feature maps and then concatenate them with feature maps from earlier stages for the final prediction.

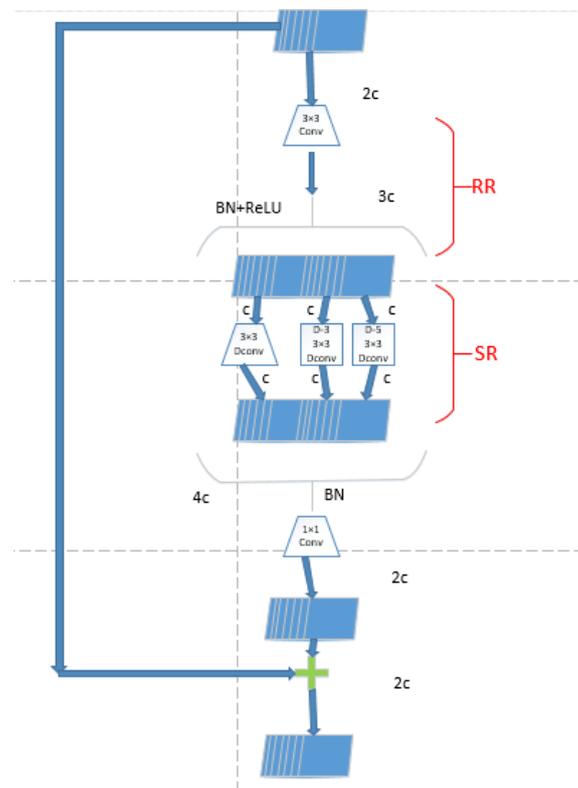

Fig. 4 - Diagram of the DWR Module

In summary, the introduction of the DWR (Dilation-wise Residual) module in the YOLO algorithm plays a crucial role in improving the accuracy of object detection. Its efficiency lies in the following key aspects: (1) Powerful receptive field expansion capability: The DWR module leverages the characteristics of dilated convolution to expand the receptive field of the convolution operation on the input image. This helps the network capture more extensive spatial information in the image. By expanding the receptive field, the model can better understand object features such as position, size, and shape, thereby improving the accuracy of object detection. (2) Multi-scale feature fusion: The DWR module introduces a residual connection mechanism to fuse feature information at different scales, enabling the network to comprehensively utilize feature representations from multiple levels. Through residual connections, the model can better learn semantic information across different scales, enhancing its ability to detect objects in complex scenes and small targets. (3) Enhanced network representation capability and learning efficiency: By incorporating residual connections and dilated convolution, the DWR module improves the network's representation capacity and learning efficiency. Residual connections help mitigate the vanishing gradient problem, accelerate the network's convergence process, and improve the model's learning efficiency.

Meanwhile, dilated convolution enhances the network's ability to learn contextual information from the image, enabling it to better understand global information in the image, thereby improving object detection accuracy. The introduction of this module allows the YOLO algorithm to achieve better performance in object detection tasks and demonstrates greater potential for practical applications.

TripletAttention Model

The Triplet Attention mechanism (Triplet Attention) refers to a mechanism in the field of deep learning that enables models to focus on multiple specific regions. It is a specialized attention mechanism designed for processing sequential data, extending the traditional bidirectional attention mechanism. It allows the model to simultaneously consider the past, present, and future information when calculating attention weights.

The YOLOv8-ALTE bridge crack detection algorithm proposed by *Yang et al. (2024)* incorporates the Triplet Attention mechanism into the shallow layers of the backbone feature extraction module. In the traditional bidirectional attention mechanism, the model generates attention weights based on the current input and achieves a more specific and detailed understanding of the context by comprehensively considering a series of historical and future information. The Triplet Attention mechanism introduces the representation of future information, enabling the model to balance the importance of past, current, and future information when calculating attention weights. Specifically, the Triplet Attention mechanism consists of three independent attention weight vectors, which represent the importance of past, present, and future information, respectively. These three attention weights are then combined to produce the final attention weight.

This mechanism is often applied to tasks such as image segmentation and object detection to help models better focus on important regions of the image, thereby improving model performance and accuracy.

In the field of deep learning, attention mechanisms are typically used to help models focus on important parts of the input when processing sequential data or images. By weighting and integrating information from different parts, attention mechanisms enhance the model's ability to process input effectively. Multi-head attention, on the other hand, learns multiple sets of different attention weights in various subspaces, allowing for a more comprehensive capture of the complex features of the input data. Triplet Attention combines these two mechanisms to help the model focus on three important regions in an image.

By learning three sets of different weight parameters, the model can independently focus on these three regions and better integrate their information to understand the image. This mechanism improves the model's ability to locate and recognize objects, thereby enhancing the performance of tasks such as object detection. The Triplet Attention mechanism offers several advantages, including a comprehensive understanding of context, reduced risk of information leakage and overfitting, and improved predictive performance. Therefore, this study primarily improves the YOLOv8n algorithm based on the Triplet Attention mechanism.

Improvement Method in This Study

The shape of wheat grains is inherently small, and factors such as adhesion further increase the difficulty of wheat grain detection. To enhance the model's ability to extract features of small objects, this study incorporates a Dilation-wise Residual (DWR) module into the C2F module of the YOLOv8n backbone network. In C2F module, the feature aggregation functionality is mainly implemented by the Bottleneck module. Therefore, in the process of algorithm improvement in this paper, the Bottleneck module is replaced with the DWR module to achieve a shift in the feature aggregation direction. This modification shifts the detection focus toward the feature extraction of small objects, strengthening the network's ability to extract features of wheat grains and improving the network's capability to learn image details and contextual information. This ultimately enhances the accuracy and robustness of the detection results. Additionally, the Triplet Attention mechanism is integrated into the YOLOv8n model after the 9th-layer SPPF module. This enables the network to focus more on multiple specific regions and capture the minute features of wheat grains, thereby enhancing the network's effectiveness in handling complex target scenes.

This makes the model's feature extraction and recognition capabilities more precise and reliable. The improved network is named YOLO-wheat (as shown in Figure 5). The YOLO-wheat model comprehensively understands the context, reduces the risks of information leakage and overfitting, and improves prediction performance, ultimately enhancing the recognition results.

From the above analysis, it is evident that the core parameters of YOLOv8n are superior, resulting in better detection outcomes. Therefore, this study adopts YOLOv8n as the baseline model and optimizes it further to achieve efficient detection of wheat grain quality.

Table 2

Model	P	R	mAP	mAP0.5:0.95	GFLOPs
YOLOv10n	72.7	76.2	81	65.5	6.5
YOLOv8n	79.7	79.7	87	66.3	7.6
YOLOv5n	73.7	82.7	85.5	65.9	7.1

Detection Results of the Improved Algorithm

To evaluate the effectiveness of the improved algorithm, experiments were conducted on the wheat grain dataset using the improved YOLO-wheat model and the baseline YOLOv8 model. The results are shown in Table 3. In the table, "w" represents the "intact" category, "p" represents the "damaged" category, "f" represents the "moldy" category, and "g" represents the "shriveled" category. As seen in the table, after applying the improved algorithm, the mAP value for the "intact" category increased from 93.3% to 95.6%, with an improvement of 2.3%. For the "damaged" category, the mAP value increased from 89.9% to 93.4%, with an improvement of 3.5%. For the "moldy" category, the mAP value increased from 84.2% to 87.5%, with an improvement of 3.3%. For the "shriveled" category, the mAP value increased from 80.2% to 88.9%, with an improvement of 8.7%. Overall, the mAP value for all categories improved from 87% to 91.3%, showing an increase of 4.3%. The mAP@0.5:0.95 metric improved from 66.3% to 75.8%. These results demonstrate that the proposed YOLO-wheat model achieves better detection performance for different categories of wheat grains.

Table 3

Model	Category	P	R	mAP	mAP0.5:0.95
YOLOv8n	w	85.9	87.1	93.9	74.4
	p	81.7	84.1	89.9	68.6
	f	77.4	75.1	84.2	61.2
	g	73.8	72.7	80.2	60.9
	all	79.7	79.7	87	66.3
YOLO-wheat	w	88.8	90	95.6	81.5
	p	90.3	87.3	93.4	77.5
	f	81.4	78.6	87.5	71.4
	g	84	74.7	88.9	72.9
	all	86.1	82.7	91.3	75.8

Ablation Experiment

As shown in Table 4 of the ablation experiment results, the baseline YOLOv8n algorithm achieves an mAP of 87%. After adding the DWR module to YOLOv8n, the mAP increases to 90%. When only the Triplet Attention is added, without the DWR module, the mAP reaches 89.1%. Finally, when both DWR and Triplet Attention are incorporated together, the model achieves the best recognition performance: Precision increases to a maximum of 86.1%, Recall rises to a maximum of 82.7%, and mAP reaches a peak of 91.3%. The experimental results demonstrate that adding either DWR or Triplet Attention individually enhances the network's feature extraction capability, but the performance is optimal when both are incorporated into the network.

Table 4

Baseline	DWR	Triplet Attention	P	R	mAP
√	×	×	79.7	79.7	87
√	√	×	84.6	81.8	90
√	×	√	82.3	82.7	89.1
√	√	√	86.1	82.7	91.3

Overall, YOLO-wheat has the following advantages over the original YOLOv8 model: With the addition of the Triplet Attention mechanism, the model can better and more accurately capture important information in images, improving the precision and performance of object detection, particularly for detecting the appearance and types of wheat grains. It also enhances the handling of both global and local information. The DWR module allows the algorithm to provide better feature extraction for complex and small objects by expanding the receptive field. In other words, the Triplet Attention mechanism helps balance the attention given to global and local information, making the model more effective at handling targets of different scales. The DWR module, on the other hand, offers better adaptability to complex backgrounds and higher precision for small targets.

Experimental results with different backgrounds

In real-world application scenarios, different backgrounds may be encountered. Therefore, during the data collection phase, wheat grains were collected with both white and black backgrounds to explore the impact of background color on the algorithm's accuracy. The detection results of wheat grains with different backgrounds using the YOLO-wheat algorithm established in this paper are shown in Table 5. From Table 5, it can be observed that compared to the white background, the Precision of wheat grains with the black background increased by 14.4%, and the mAP improved by 7.8%. Specifically, the mAP for intact grains increased by 3.1%, the mAP for damaged grains increased by 5.2%, the mAP for moldy grains increased by 12.7%, and the mAP for shriveled grains increased by 10.2%. This suggests that background color has a certain impact on wheat grain detection, with a more significant improvement in target detection when using a black background. In practical applications, setting the background to black would yield the best detection results.

Table 5

Detection results under different backgrounds					
Background	Category	P	R	mAP	mAP0.5:0.95
White background	w	84.3	94.4	92.1	71.8
	p	75.1	89.1	91.9	68.8
	f	75.9	73.9	82.2	59.2
	g	70.7	77.8	83.6	64.1
	all	76.5	83.3	87.5	66
Black background	w	96.9	83.3	95.2	65.9
	p	92.9	89.9	97.1	61.9
	f	88.5	88.6	94.9	61.7
	g	85.6	86.8	93.8	65.3
	all	90.9	87.2	95.3	63.7

Visualization of detection results

The trained YOLO-wheat model was used to validate the wheat grain dataset, and the detection results are shown in Figure 6. It can be observed that the improved algorithm in this study performs well in detecting both dispersed and clustered wheat grains under black and white backgrounds.

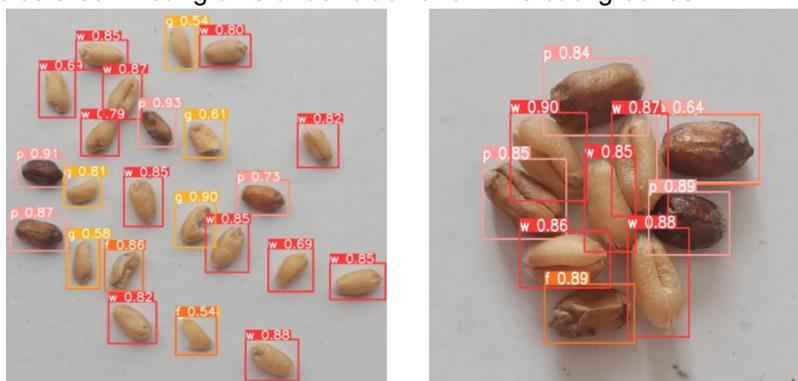

Fig. 6 - Visualization of detection results

CONCLUSIONS

With the development of machine learning and deep learning technologies, machine vision has become increasingly widespread in the agricultural sector. This study successfully developed an improved object detection model based on YOLOv8n, named YOLO-wheat, which aims to precisely locate the position and recognize the appearance quality of wheat grains. It provides technical support for intelligent wheat harvesting and recognition, as well as data collection for wheat yield analysis, making it suitable for related production environments.

(1) The dataset used in this study was constructed with black and white backgrounds as templates, incorporating image processing techniques such as random rotation, noise addition, and brightness adjustment. The goal was to simulate real-world environmental conditions and provide optimal templates for real detection environments. For example, detection should ideally be performed in a black background setting.

(2) This study employed the DWR module and the Triplet Attention module to enhance the recognition performance. YOLOv8n was used as the base model, with the DWR module placed in the C2F (Cross Feature Fusion) layer, and the Triplet Attention mechanism added after the SPPF (Spatial Pyramid Pooling Fast) layer to further improve the accuracy of the YOLOv8n model. The improved model achieved a mean Average Precision (mAP) of 91.3% for wheat grain quality detection, a 4.3% improvement over the original YOLOv8n model. This demonstrates that the proposed improvement enhances accuracy for small object detection.

This study focused on the appearance quality detection of a single type of wheat grain. However, the quality detection of multiple wheat varieties remains limited, highlighting the need for a more comprehensive dataset to increase sample diversity and improve the model's generalization capability. Finally, as this experiment is still in the algorithm research phase, further research and design of lightweight models or optimized algorithms for high-real-time scenarios may be needed before applying this in actual automated classification tasks.

ACKNOWLEDGEMENT

This research, titled "Wheat Grain Appearance Quality Detection Based on Improved YOLOv8n", was funded by The College Students Innovation Training Program of Shanxi Agricultural University (202410113026) and the Basic Research Program of Shanxi Province (202303021212115).

Keywords: Smart Agricultural Management Cloud Platform; Analytic Hierarchy Process (AHP); Fuzzy Comprehensive Evaluation (FCE); UI Design

ABSTRACT

UI design and user interaction optimization of smart agricultural management cloud platforms are key research directions for enhancing the overall value of the system. However, there is still room for improvement in terms of functionality and visibility of the platform interface. This study constructs a UI design evaluation model by combining the Analytic Hierarchy Process (AHP) and Fuzzy Comprehensive Evaluation (FCE), systematically evaluating and optimizing three UI design schemes of the platform. First, AHP was used to allocate weights to design factors, and then FCE was applied for comprehensive evaluation of each scheme, ultimately selecting the optimal one. Based on user heatmap data, the visual design of high-click areas was further optimized, improving the platform's score from 80.524 to 86.927. The study demonstrates that the combined AHP and FCE method has significant effects on UI design evaluation and optimization, providing scientific evidence and practical guidance for enhancing user experience in other smart agricultural management cloud platforms.

摘要

智慧农业管理云平台的 UI 设计与用户交互优化是提升系统整体价值的关键研究方向。然而，目前平台界面在功能性与可视性方面仍有改进空间。本研究通过结合层次分析法 (AHP) 与模糊综合评价法 (FCE) 构建了 UI 设计评价模型，对平台的三种 UI 设计方案进行了系统评估与优化。首先，采用 AHP 对设计因素进行权重分配，然后运用 FCE 对各方案进行综合评价，最终筛选出最优方案。基于用户热力图数据，进一步优化了高点击区域的视觉设计，使平台评分从 80.524 提升至 86.927。研究表明，AHP 与 FCE 结合的方法在 UI 设计评价与优化中具有显著效果，为其他智慧农业管理云平台的用户体验提升提供了科学依据和实践指导。

INTRODUCTION

With the integration of the Internet of Things (IoT) and big data technologies, smart agricultural management cloud platforms have emerged as the "brain" of agricultural production, enabling precise allocation of energy resources and driving industrial upgrades. The platform integrates multi-source data such as smart irrigation, greenhouse energy consumption, and agricultural machinery operations, achieving real-time monitoring of the entire agricultural production process. It provides data analysis and decision support, helping practitioners improve efficiency, reduce costs, and promote green, sustainable development.

The user interface (UI) design of the platform plays a crucial role in connecting users with the system. A high-quality UI design can enhance the user experience and ensure the efficient operation of the platform; whereas poor design can lead to operational difficulties, decision-making errors, and decreased platform effectiveness. Therefore, using scientific methods to evaluate and optimize UI design has become a key research focus in the field of smart agriculture. The interface design adheres to principles of simplicity, vitality, liveliness, and fashion, and must integrate users' functional, psychological, and interactive needs through icons, colors, and interactions. Continuously improving the design will further promote the development of smart agriculture (Huijun et al., 2020).

Jiyuan SUN, M.S.Agr; Bin QI, Assoc. Prof. Ph.D. Eng; Xiaoming Sun, M.S. Eng, Lecturer; Yuanqi LIU, M. S.Agr; Yuchao REN, M. S.Agr; Tengyun MA, M. S.Agr; Bohan ZHANG, M. S.Agr; Qiong Wu, Senior Art and Craft Specialist.

The methodological landscape has evolved through successive innovations in decision-making frameworks, beginning with the development of the Analytic Hierarchy Process (AHP) as a transformative tool for quantifying qualitative challenges (Yongfeng et al., 2012). Subsequent advancements emerged through the integration of grey relational analysis with fuzzy mathematical principles to create comprehensive product evaluation systems (Guodong et al., 2009), followed by the application of TOPSIS techniques for human-computer interface assessment (Huiliang et al., 2016). Recent technological implementations demonstrate enhanced sophistication, particularly in ergonomic evaluations combining AHP-fuzzy comprehensive methods with TRIZ-based optimization for agricultural drone controllers (Shuxing et al., 2022). Concurrent developments in consumer product research achieved breakthroughs through multimodal methodologies blending sensory analytics, morphological deconstruction, and fuzzy AHP for automotive seat design (Qinglan et al., 2025). The methodological frontier further expanded through hybrid architectures integrating AHP-entropy weighting with fuzzy assessment systems, establishing multi-criteria evaluation frameworks for micro-irrigation filtration technologies (Feng et al., 2025). This progression reflects three paradigm shifts: increased hybridization of classical decision tools, domain-specific framework adaptation, and theoretical-practical integration across engineering disciplines.

Traditional UI design evaluation methods often rely on user feedback and expert judgment, which makes it difficult to systematically and comprehensively reflect the strengths and weaknesses of the design. To address this issue, this paper introduces the combination of the Analytic Hierarchy Process (AHP) and Fuzzy Comprehensive Evaluation (FCE) to construct a scientific and objective evaluation model. AHP determines the weight of each evaluation indicator through expert scoring, while FCE uses fuzzy mathematics to handle the uncertainties and ambiguities in the evaluation process. This enables a comprehensive evaluation of the UI design for the smart agricultural management cloud platform, providing theoretical support and practical guidance for the development and improvement of the platform.

MATERIALS AND METHODS

Analytic Hierarchy Process (AHP)

The Analytic Hierarchy Process (AHP) was developed in the 1970s by the American operations researcher (Saaty et al., 2008). It is a scientific method that combines qualitative and quantitative approaches by determining weight factors, which decompose complex evaluation problems into quantifiable evaluation objects that can then be synthesized. By combining AHP with fuzzy mathematics, it is possible to better handle the uncertainty inherent in the UI design process of a smart agricultural management cloud platform, ultimately leading to the optimal design solution. The evaluation method and process are shown in Figure 1.

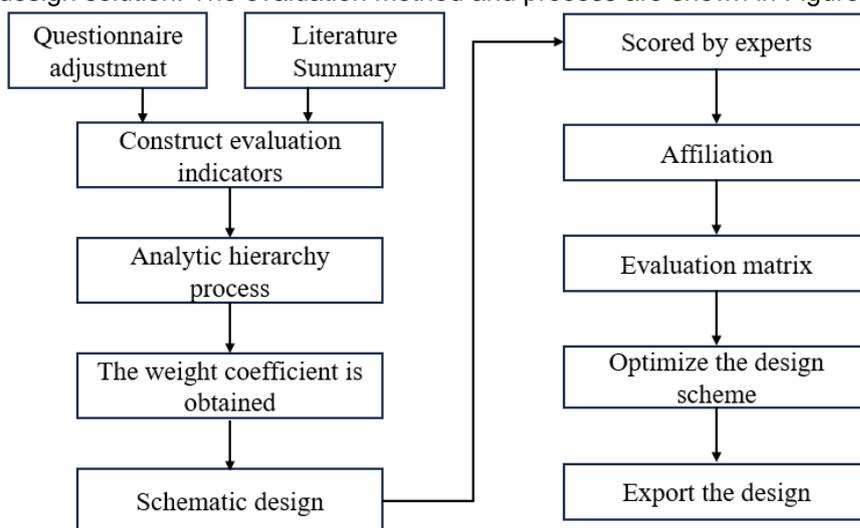

Fig. 1– Evaluation Method and Process

Hierarchical Structure Model of Agricultural Management Cloud Platform

The objectives, influencing factors, and analysis objects that need to be evaluated using the Analytic Hierarchy Process (AHP) are categorized into the highest, middle, and lowest levels according to their interrelationships. A hierarchical structure diagram is drawn (Tongxin et al., 2019).

The smart agricultural management cloud platform is placed at the goal level, with functionality experience and appearance as the criterion layer of the evaluation system (Xiangsheng et al., 2019). The criterion layer is further subdivided into seven indicator layers, as shown in Figure 2.

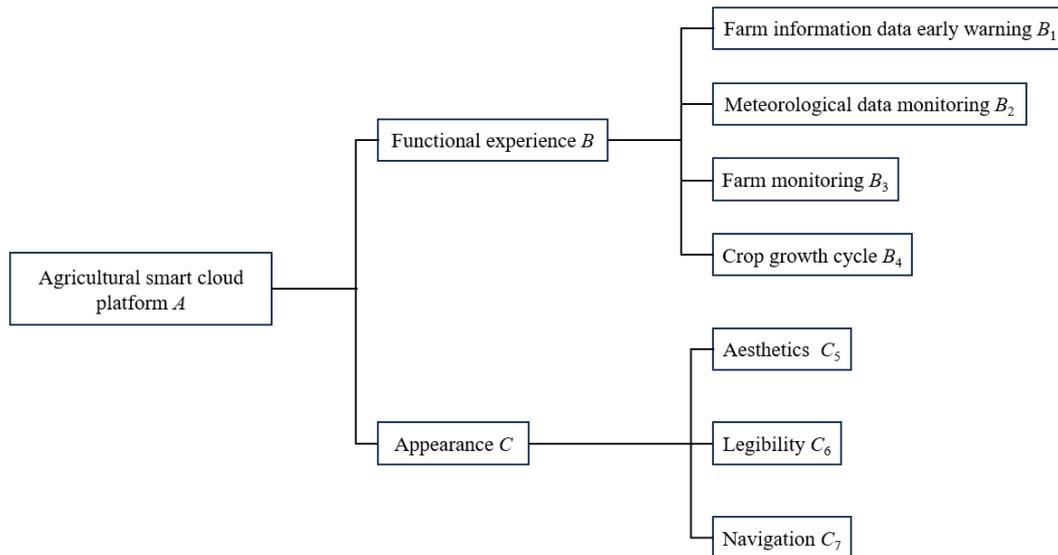

Fig. 2 – Design demand indicators for agricultural management cloud platform

Based on the design elements, the 9-point scale method can be used to construct a judgment matrix. The judgment matrix is used to compare pairwise relationships between indicators at the same level, with comparisons made at both the criterion layer and sub-criterion layer. A relative scale from 1 to 9 is assigned to each comparison, with the values reflecting the relative importance of the design elements. An example of the judgment matrix scale table is shown in Table 1 (Lin et al., 2024; Haibiao et al., 2019; Hui, 2019; Yimin et al., 2017; Qianrong et al., 2017).

Table 1

Judgment Matrix Scale		
Relative Importance Assignment (i/j)	Implication	Scaling instructions
1	Equal Importance	Indicator <i>i</i> is equally important as Indicator <i>j</i>
3	Slightly More Important	Indicator <i>i</i> is slightly more important than Indicator <i>j</i>
5	Strongly More Important	Indicator <i>i</i> is noticeably more important than Indicator <i>j</i>
7	Very Strongly More Important	Indicator <i>i</i> is strongly more important than Indicator <i>j</i>
9	Extremely Important	Indicator <i>i</i> is extremely more important than Indicator <i>j</i>
2, 4, 6, 8	The Intermediate Value of Two Adjacent Judgments	The importance is determined based on adjacent scale values
$A_{ij}=1/a_{ij}$	Reciprocal	

Arithmetic averaging is used to find weights

Based on the constructed judgment matrix, the arithmetic mean method is used to calculate the weight of each element. The steps are as follows:

- 1) Normalize each column of the judgment matrix so that the elements in each column are comparable in terms of their relative proportions. That is:

$$\bar{x}_{ij} = \frac{x_{ij}}{\sum_{i=1}^n x_{ij}} \quad (i = 1, 2, 3, \dots, n) \tag{1}$$

- 2) Sum the rows of the processed matrix to obtain the total sum of the elements in each row, and then calculate the average value of the relative weights of each element, that is,

$$\tilde{w}_i = \sum_{i=1}^n \bar{x}_{ij} \quad (i = 1, 2, 3, \dots, n) \tag{2}$$

3) Process the results after summation, and then the weight vector can be obtained.

$$w_i = \tilde{w}_i/n \tag{3}$$

Consistency Test

After obtaining the relative weights of each design element, a consistency test is required. Firstly, calculate the maximum eigenvalue of the judgment matrix based on these weights, and obtain the consistency index CI through this eigenvalue. Then, use the standard RI values in Table 2 to calculate the consistency test coefficient of the judgment matrix. This process aims to evaluate the consistency level among the various elements in the judgment matrix and ensure the reliability of the weight relationships.

1) The maximum eigenvalue of the judgment matrix.

$$\lambda_{max} = \sum_{i=1}^n \frac{(Aw)_i}{(nw)_i} \tag{3}$$

2) The consistency test values of each indicator.

$$V_{CI} = \frac{\lambda_{max}}{n-1} \tag{5}$$

3) The test coefficient of the judgment matrix

$$C_{CR} = \frac{V_{CI}}{V_{RI}} \tag{6}$$

In the formula:

n—Order of Judgment Matrix;

w—Eigenvector of the Normalized Judgment Matrix;

Aw—It is the product of matrix A and vector w, and the resulting new vector.

Table 2

Standard Value of RI

N	1	2	3	4	5	6	7	8	9
RI	0.00	0.00	0.52	0.89	1.12	1.26	1.36	1.41	1.46

Judgment matrix

Questionnaires were distributed to five experts. In accordance with the rules of the 9-point scale method, the experts were invited to evaluate and score each design element. Based on the scoring results provided by the experts, a judgment matrix was constructed, which reflects the experts' judgments on the relative importance among different elements. This judgment matrix will serve as the basis for weight calculation and consistency testing, supporting the systematic decision-making analysis process.

The judgment matrix of the intelligent agricultural management cloud platform is:

A	B	C
B	1	1/2
C	2	1

The judgment matrix among the various indicators of the functional experience criterion layer is:

B	B ₁	B ₂	B ₃	B ₄
B ₁	1	2	5	8
B ₂	1/2	1	3	4
B ₃	1/5	1/3	1	3
B ₄	1/8	1/4	1/3	1

The judgment matrix among the various indicators of the appearance - criterion layer is:

C	C ₅	C ₆	C ₇
C ₅	1	2	5
C ₆	1/2	1	4
C ₇	1/5	1/4	1

Results of Weights and Consistency Tests

Based on the calculations of Formulas (1) - (6), the weights of each evaluation indicator in the design of the intelligent agricultural management cloud platform were obtained, and the specific values are shown in Table 3. Through this weight distribution, it is possible to have a more comprehensive understanding of the contribution degree of each indicator to the design of the intelligent agricultural management cloud platform, so as to optimize the design in a more targeted manner (Ying et al., 2024).

Table 3

Index Weights of the Design Evaluation System for the Smart Agricultural Management Cloud Platform

Criterion layer	Weights of the Criterion Layer	Indicator layer	Weights of the Indicator Layer	Comprehensive Weight	λ_{max}	CR
Functional Experience B	0.3783	Farm Information Data Warning B1	0.5394	0.2040	4.0684	0.0256 < 0.1
		Meteorological Data Monitoring B2	0.2823	0.1067		
		Farm Monitoring B3	0.1206	0.0456		
		Crop Growth Cycle B4	0.0576	0.0217		
Appearance C	0.6217	Aesthetics C5	0.5695	0.3540	3.0246	0.0236 < 0.1
		Readability C6	0.3331	0.2070		
		Navigability C7	0.0974	0.0605		

The consistency ratio (CR) values in Table 3 are all less than 0.1, indicating that the judgment matrices have passed the consistency test and the data used are valid.

Design Scheme of the Smart Agricultural Management Cloud Platform

Based on the weight ranking of each item in the above text, a fuzzy comprehensive evaluation is conducted on the design scheme of the smart agricultural management cloud platform. Three different schemes are designed as evaluation objects, as shown in Figure 3 - Figure 5.

Fig. 3 – Preliminary Design Scheme 1 of the Smart Agricultural Management Cloud Platform

Fig. 4 – Preliminary Design Scheme 2 of the Smart Agricultural Management Cloud Platform

Fig. 5 – Preliminary Design Scheme 3 of the Smart Agricultural Management Cloud Platform

Fuzzy Comprehensive Evaluation of the Smart Agricultural Management Cloud Platform

The Fuzzy Comprehensive Evaluation Method is suitable for the comprehensive evaluation of multiple indicators and elements. It can reduce the problem of uncertainty in evaluation results caused by subjective factors, handle fuzzy information better, and enhance the effectiveness of decision-making results. The Fuzzy Comprehensive Evaluation Model is shown in Figure 6. The specific operation process is as follows:

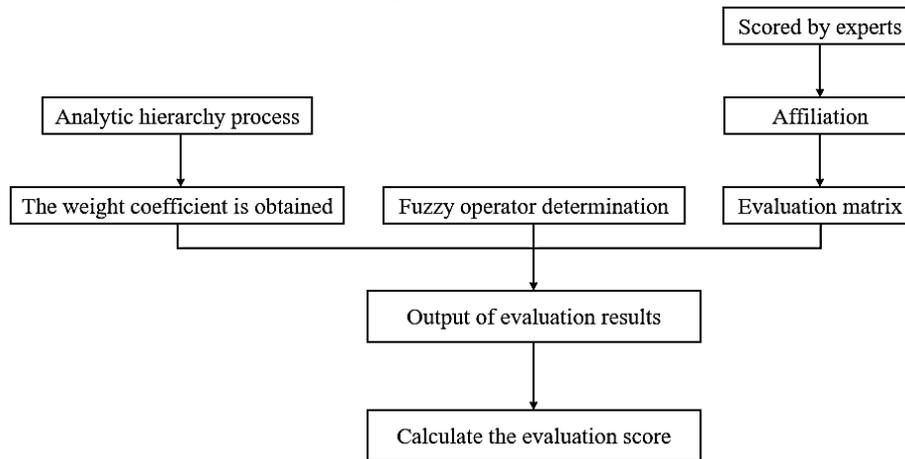

Fig. 6 – Fuzzy Comprehensive Evaluation Model

1) In this study, the UI design of the smart agricultural cloud platform is taken as the overall goal, with the goal layer being the UI design of the smart agricultural cloud platform. The evaluation is conducted from two sub-aspects, namely, functionality and appearance design, which form the criterion layer of the evaluation system. The criterion layer is further subdivided into seven indicator layers, as shown in Table 4.

2) The evaluation objects are categorized based on the various possible states, $M = \{M_1, M_2, M_3, \dots, M_N\}$, corresponding to four evaluation levels: 'Excellent', 'Good', 'Average', and 'Poor'. Then, corresponding numerical values are assigned to each evaluation grade, resulting in the value set $\{90, 80, 60, 50\}^T$. The score range and grade division criteria are as follows: Excellent for scores above 90, Good for scores between 80 and 89, Average for scores between 60 and 79, and Poor for scores below 69. These standards allow the evaluation objects to be assessed and assigned corresponding grades.

3) Weights reflect the relative importance of each indicator within the evaluation system, and the setting of these weights will directly influence the scientific validity of the final evaluation results. In this study, the AHP method is used to determine the weights for the evaluation system. As shown in Table 3, the weight for the criterion layer is $w_A = (0.3783, 0.6217)$, while the weight vector for the indicator layer is $w_B = (0.5394, 0.2823, 0.1206, 0.0576)$, and $w_C = (0.5695, 0.3331, 0.0974)$.

4) The fuzzy comprehensive evaluation matrix is composed of the degree of membership between each evaluation indicator and the evaluation set. For the three design schemes, fuzzy comprehensive evaluation matrices are established based on the scores provided by 20 experts for the criterion layer and indicator layer.

Table 4

Membership Degree of Indicators				
Scheme 1 R_{F1}	0	0.20	0.35	0.45
	0.05	0.10	0.45	0.40
	0	0.15	0.55	0.30
	0.05	0.15	0.40	0.40
Scheme 1 R_{F2}	0	0.20	0.55	0.25
	0.05	0.25	0.25	0.45
	0	0.35	0.35	0.30
Scheme 2 R_{S1}	0.15	0.35	0.25	0.25
	0.10	0.45	0.15	0.30
	0.15	0.30	0.25	0.30
	0.10	0.20	0.30	0.40
Scheme 2 R_{S2}	0.10	0.40	0	0.50
	0.10	0.30	0.15	0.45
	0.15	0	0.50	0.35
Scheme 3 R_{T1}	0.10	0.75	0.15	0
	0.25	0.50	0.15	0.10
	0.30	0.60	0.05	0.05
	0.10	0.75	0.10	0.05
Scheme 3 R_{T2}	0.25	0.65	0.10	0
	0.20	0.60	0.10	0.10
	0.30	0.55	0.15	0

After obtaining the fuzzy comprehensive evaluation matrix for each factor, the next step is to synthesize the matrix by combining the weights of each indicator w_i with the corresponding fuzzy comprehensive evaluation matrix, thus constructing a first-level evaluation matrix.

First-level Fuzzy Evaluation of Each Scheme

1. Scheme 1:

$$B_{B1} = R_{F1} \cdot w_B = [0.0170 \ 0.1628 \ 0.4052 \ 0.4149]$$

$$B_{C1} = R_{F2} \cdot w_C = [0.0167 \ 0.2313 \ 0.4306 \ 0.3215]$$

2. Scheme 2:

$$B_{B2} = R_{S1} \cdot w_B = [0.1330 \ 0.3635 \ 0.2246 \ 0.2788]$$

$$B_{C2} = R_{S2} \cdot w_C = [0.1049 \ 0.3277 \ 0.0987 \ 0.4687]$$

3. Scheme 3:

$$B_{B3} = R_{T1} \cdot w_B = [0.1665 \ 0.6613 \ 0.1350 \ 0.0371]$$

$$B_{C3} = R_{T2} \cdot w_C = [0.2382 \ 0.6236 \ 0.1049 \ 0.0333]$$

The first-level fuzzy evaluations of Scheme 1, Scheme 2, and Scheme 3 are as follows:

$$R_F = \begin{bmatrix} 0.0170 & 0.1628 & 0.4052 & 0.4149 \\ 0.0167 & 0.2313 & 0.4306 & 0.3215 \end{bmatrix}$$

$$R_S = \begin{bmatrix} 0.1330 & 0.3635 & 0.2246 & 0.2788 \\ 0.1049 & 0.3277 & 0.0987 & 0.4687 \end{bmatrix}$$

$$R_T = \begin{bmatrix} 0.1665 & 0.6613 & 0.1350 & 0.0371 \\ 0.2382 & 0.6236 & 0.1049 & 0.0333 \end{bmatrix}$$

Second-level Fuzzy Rating of the Smart Agricultural Management Cloud Platform

The second-level fuzzy evaluations of Scheme 1, Scheme 2, and Scheme 3 are as follows:

$$B_F = [0.0168 \ 0.2054 \ 0.4210 \ 0.3568]$$

$$B_S = [0.1155 \ 0.3381 \ 0.1463 \ 0.3969]$$

$$B_T = [0.2111 \ 0.6379 \ 0.1163 \ 0.0347]$$

Finally, the percentage scores for Scheme 1, Scheme 2, and Scheme 3 are 68.822, 71.498, and 80.524, respectively. The evaluation levels of Scheme 1 and Scheme 2 are "Average," while the evaluation level of Scheme 3 is "Good." Therefore, Scheme 3 is the best scheme.

RESULTS

Optimization of Evaluation Results

The evaluation level of the smart agricultural cloud platform is the result of the combined effect of the indicator layer weights and the scheme scores. In summary, by analyzing the indicator layer weights, two key indicators, 'Aesthetics' and 'Readability,' were identified as needing optimization. This provides a clear direction for UI optimization of the smart agricultural cloud platform. By combining actual user heatmaps, high-frequency click areas can be analyzed, and visual enhancements can be made in these areas to improve the platform's aesthetics and readability. The optimized interface will be re-evaluated using the fuzzy comprehensive evaluation system to verify the effectiveness of the improvements, ultimately yielding the optimized evaluation level. This method not only scientifically quantifies the improvement in user experience but also provides data support and practical guidance for future UI design optimization.

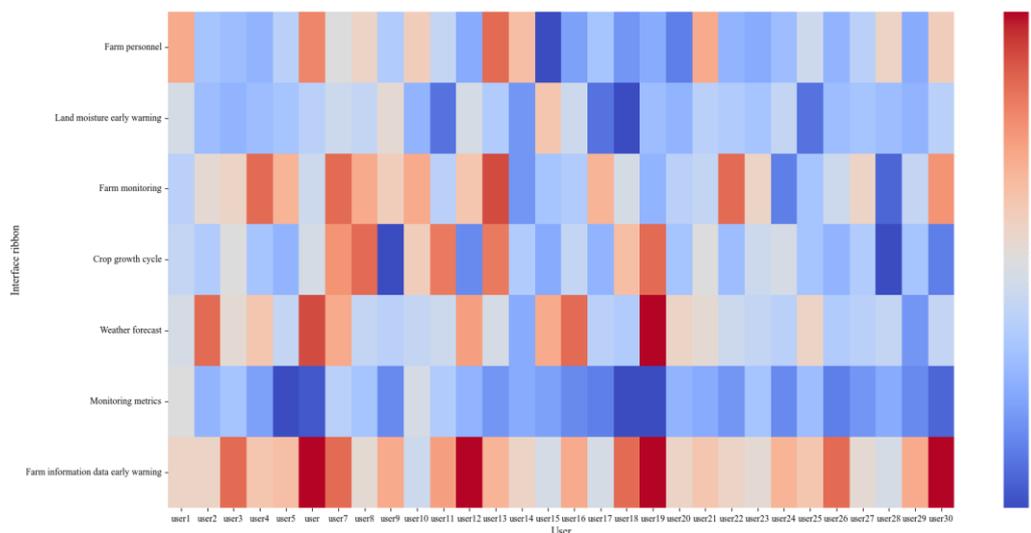

Fig. 7 – User Click Heatmap

Based on the analysis of the click heatmap in Figure 7, the area with the highest click frequency was identified as the "Farm Information Data Warning" section, while the area with the lowest click frequency was the "Land Use" section. In response to these high-click areas, improvements were proposed for the UI interface's "Aesthetics" and "Readability" indicators.

To further optimize the overall user interface (UI) effect, this study implemented a series of targeted improvements. Firstly, a visual optimization was applied to the functional area background by brightening the background tone, creating a fresher and more open visual experience, effectively enhancing operational convenience. At the same time, the interface at the top of the Smart Agricultural Management Platform dynamically displays weather scenes based on real-time weather conditions, not only enriching the interface's information but also greatly enhancing its visual appeal.

In terms of font design, to meet users' needs for information clarity, the font was adjusted to a bold style to ensure that users can quickly grasp the information while browsing, reducing visual fatigue and improving information retrieval efficiency. For the high-click area "Farm Information Data Warning," its design details were optimized. The alarm icon and related text colors were changed to prominent red, and the font size was increased and made bolder, creating a clear contrast with other information, highlighting the importance of the warning information, and making the key data in this area clearer and more readable. This ensures that users can quickly detect anomalies and take timely actions.

Considering the differences in user attention to different information modules, the low-click frequency "Regulatory Indicators" module was replaced with the "7-Day Weather Forecast." In this module design, a color-coding strategy was adopted to distinguish state information, with abnormal weather conditions highlighted in red text, helping users quickly identify key weather changes and enhancing the practicality and convenience of the information. Additionally, the "Farm Monitoring" module was subdivided into "Farm Greenhouse Monitoring" and "Farm Field Monitoring," with the display method of various farm information data optimized in the interface layout to increase visibility. Through reasonable layout and highlighting key data, users can quickly and accurately access the detailed farm information they need. The improved UI design interface is shown in Figure 8.

Fig. 8– Optimized Interface of Scheme 3

By using the established UI design evaluation system, the optimized UI of the smart agricultural management cloud platform was re-assessed, with the overall score increasing from 80.524 to 86.927, nearing the excellent level. This study focused on optimizing two key indicators: "Aesthetics" and "Readability." The optimization yielded ideal results, verifying the feasibility of this method in improving the human-computer interaction experience of the platform. In future optimization stages, the smart agricultural cloud platform can refer to this process and prioritize gradual improvements on the indicators that have the greatest impact on the final evaluation results.

CONCLUSIONS

Through the AHP method, the weights of interface design factors were quantified, and a comprehensive evaluation model was established using FCE. This model was used to compare and analyze three UI design schemes, ultimately selecting the optimal one. Based on this, the selected UI design was further optimized using user heatmap data and indicator layer weights. The following conclusions can be drawn:

1) During the UI design optimization process, the font size and color of the high-click areas were adjusted based on user click heatmaps, significantly improving the data visualization and user experience. This optimization not only simplified the operational workflow but also enhanced the overall operational efficiency and energy management efficiency. In particular, the optimization of the "Farm Information Data Alerts" section improved the clarity and readability of information in this area, thereby enhancing the functionality and real-time capabilities of the system.

2) The UI design score of the optimized smart agricultural management cloud platform increased from 82.396 to 87.471, demonstrating the scientific validity and effectiveness of the AHP/FCE method in evaluating the UI design of the platform and providing a reference for future smart agricultural management cloud platform designs.

3) The UI design evaluation and optimization system developed in this study provides valuable reference points for the decision-making stage of UI design. It helps identify and optimize deficiencies in design and offers data support and practical experience for future UI design improvements.

Keywords: Chinese cabbage, Mechanical harvesting, Clamping and conveying device, Design optimization, Finite element simulation test

ABSTRACT

To effectively solve the problem of high damage rates and low operating efficiency of clamping and conveying in the mechanized harvesting of Chinese cabbage, a "vertical clamping+flexible conveying" system was developed. Based on the measurement and analysis of the basic physical characteristics and static compression mechanical properties of Chinese cabbage, the "vertical clamping + flexible conveying" method was applied to arrange the clamping conveyor belts longitudinally. A combination of flexible feeding and soft clamping was used to achieve low-damage transportation. A dynamics coupling simulation model of the Chinese cabbage harvesting components was established. By adjusting the structural and operational parameters of the harvesting components, a simulation test of the Chinese cabbage harvesting operation was conducted to determine the kinematic and dynamic principles of the harvesting process. The designed and developed clamping conveyor device is installed on a cabbage harvester for field performance test verification. Field test results show that the field productivity of the cabbage harvester is 0.12 hm²/h, the average value of the clamping and conveying success rate is 96.38%, and the average value of the harvesting damage rate is 7.43%. The developed clamping and conveying device can effectively meet the requirements of high efficiency, and low energy consumption, low damage during harvesting, while also enhancing adaptability to Chinese cabbages of varying head diameters.

摘要

为提高大白菜机械化收获装备的作业性能,有效解决大白菜机械化收获过程中夹持输送损伤大、作业效率低的问题,研制了一种“立式夹持+柔性输送”夹持输送系统。基于测定分析大白菜基本物理特征参数和静载压缩力学特性,采用“立式夹持+柔性输送”方式对夹持输送带进行纵向排布,利用挠性喂入与柔性夹持的配合作业方法实现低损输送。建立大白菜株体-采收部件动力学耦合仿真模型,通过改变采收部件的结构参数和工作参数等,进行大白菜收获作业仿真试验,探明大白菜采收过程运动学、动力学规律。最后,将设计开发的夹持输送装置配置在大白菜收获机上进行田间性能试验验证。结果表明,夹持输送装置采用“立式夹持+柔性输送”的方式,可以实现对大白菜的高效低损输送,提高对不同球径大白菜的采收适应性。通过利用离散元法建立动力学耦合仿真模型,发现夹持输送过程大白菜所受合力大小呈现波动态势,表明夹取过程大白菜与夹持皮带的相互作用力呈动态变化。田间试验结果表明,大白菜收获机田间生产率为0.12hm²/h,夹持输送成功率均值为96.38%,采收破损率均值为7.43%,说明设计开发的夹持输送装置有效地满足高效、低能耗、低损伤的收获要求,提高了对不同球径白菜收获的适应性。

INTRODUCTION

Chinese cabbage (*Brassica pekinensis* (Lour.) Rupr.) is one of the vegetables with the largest planting area in China, accounting for about 15% and 19% of the total sown area and total output of vegetables in China (Hu et al., 2022; Liu et al., 2020). It has distinctive planting characteristics, because it has a high unit yield, storage, and transportation, long supply period, it is nutrient rich and has other advantages. In China to maintain the supply of vegetables, regulating market prices, and other aspects play a vital role (Ding et al., 2021). Chinese cabbage production methods are relatively rudimentary with low levels of mechanized harvesting and industrialization.

Currently, harvesting operations still rely entirely on manual labor, resulting in low efficiency, high labor intensity, and high operating costs. Additionally, the quality and efficiency of manual harvesting are difficult to control (Zhou *et al.*, 2023; Zhao *et al.*, 2018).

The countries that focus on cabbage harvester-related technology and equipment are mainly Japan, China, South Korea, and other countries. Most of the early cabbage harvester structures first used the spiral extraction device for extraction, and then a fixed single disk knife to complete the root-cutting harvesting, but extraction and root-cutting damage was relatively large (Park *et al.*, 2021). In order to reduce the extraction and root-cutting damage, Japan Yanmar and Osada Nouki jointly developed a tracked self-propelled cabbage harvester, which ensures the stability of the clamping and conveying process as well as the consistency of the root cutting, but the overall structure is more complex and the manufacturing cost is higher (Xu *et al.*, 2009). Researchers from Chungnam University in South Korea, Kim & Yeongsoo, (2020), developed a small tracked self-propelled cabbage harvester that demonstrated effective pulling and harvesting performance. However, its integrated pulling and conveying device, along with a complex conveyor mechanism, resulted in poor adaptability to different cabbage varieties (Park *et al.*, 2021). To enhance conveyance efficiency and stability during harvesting while reducing manufacturing costs, efforts have been made to optimize and improve the design of a tractor-mounted cabbage harvesting system (Ali *et al.*, 2019). Han *et al.* developed a tractor-mounted cabbage harvester, utilizing two tilt-mounted notched disks instead of a screw plucking device. This design proved highly efficient and well-suited for large-scale cabbage planting in northern China. However, the harvester required relatively high supporting power (Han *et al.*, 2021). Myat *et al.* designed a four-row cabbage harvester that employed a pulling shovel to extract the cabbages, followed by root transportation and cutting using V-shaped clamping belt and a single serrated disk. However, the harvesting process experienced issues such as root slanting cuts and missed cuts, leading to a high vegetable damage rate (Myat *et al.*, 2021).

Due to the tender leaves of cabbage, the clamping conveyor device will cause extrusion damage to the cabbage when clamping, so it is necessary to study the extrusion characteristics of cabbage before designing the conveyor device and design a flexible and adaptive clamping conveyor device to prevent excessive clamping. The most common types of clamping and conveying devices are double screw type and conveyor belt type (Li *et al.*, 2017; Ji *et al.*, 2023; Ding *et al.*, 2022). The double screw rod-type clamping and conveying device consists of a pair of counter-rotating screw rods. After the extraction device removes the cabbage, it is transferred to the double screw rods, where it is clamped and lifted through spiral motion (Ding *et al.*, 2018; Toncheva *et al.*, 2017). Conveyor belt-type clamping and conveying device mainly consists of two conveyor belts, with a spring tensioning mechanism designed inside the belts. This mechanism allows for secure clamping and transportation of cabbages of varying sizes (Zhou *et al.*, 2024). Shandong Agricultural University has developed a self-propelled cabbage harvester with broad adaptability. This harvester adopts a conveyor belt-type conveying and lifting system, utilizing an elastic tensioning mechanism to automatically adjust to cabbages with different physical characteristics (Zhang *et al.*, 2022).

It is necessary to improve and optimize the structural parameters of the clamping and conveying mechanism of the cabbage harvester, explore the interactions during the clamping and conveying process, and develop a low-damage, high-efficiency, and automated cabbage harvesting technology. The main objectives of this study are: (1) To determine and analyze the basic physical parameters and static load compression mechanical properties of cabbage; (2) To conduct kinematic and dynamic analysis of the cabbage clamping and conveying process, optimize the structural parameters, and complete the design of the clamping and conveying mechanism; (3) To establish a dynamically coupled simulation model of the Chinese cabbage harvesting components and analyze the kinematics and dynamics of the harvesting process; (4) To validate the machine prototype through field trials, verifying its actual field performance and identifying an optimized low-loss, high-efficiency, automated harvesting technology.

MATERIALS AND METHODS

Experimental materials and equipment

Chinese cabbage is the primary focus of harvesting machinery. Studying its basic physical characteristics and mechanical properties is essential for establishing a meaningful statistical scale model, providing a design basis and theoretical foundation for the development of cabbage harvesting equipment. Cabbages that had reached maturity and met harvesting standards were selected as test samples. To ensure reliability, only cabbages with an undamaged appearance and intact roots were chosen based on the principle of randomization and five-point sampling.

The test instruments and types of equipment used to measure the basic physical characteristic parameters of cabbage mainly include a tape measure, electronic digital display vernier caliper, electronic balance, beaker, measuring cylinder, and so on. Fifty plants were randomly selected for the measurement of basic physical characteristics and statistics. First of all, the electronic digital display vernier caliper was used to determine the total height of the cabbage plant, head height, head diameter, and other dimensions. Then, an electronic balance and electronic scales were used to measure the physical parameters of each sample three times, and the average value and standard deviation were calculated. These samples were placed horizontally between two rigid parallel plates, with 30 randomly selected cabbages tested using a GHS2000 universal testing machine under a specific loading rate. The instruments and equipment used for determining the basic physical characteristics and static compression properties of cabbage are listed in Table 1.

Table 1

Test equipment and instruments				
Equipment Name	Model Specification/Unit	Range	Accuracy	
Electronic Balance	CZ3002/g	0-300g	0.01	
Electronic Universal Testing Machine	GHS2000/N	0-2000	0.001	
Electronic Weigher	/kg	0-10kg	0.01	
Tape Rule	/m	0-3m	1	
Three-key Digital Vernier Calipers	SF2000/mm	0-200mm	0.1	

Physical and mechanical characteristics of Chinese cabbage

● Research on the physical characteristics of cabbage cultivation soil

Soil firmness was measured directly by a soil firmness meter, soil water content was measured by the drying method, and soil bulk weight was determined by the ring knife method. Soil physical properties were selected as evaluation indexes, including soil compactness, soil water content, and soil bulk density. Ten soil samples were randomly collected from the field using the five-point sampling method.

● Determination of basic physical characteristics of Chinese cabbage

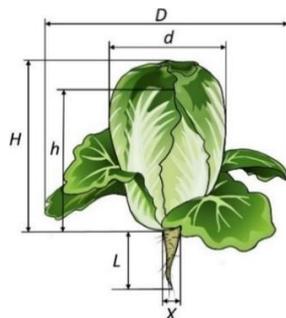

Fig. 2 - Terminology for the determination of basic physical properties of Chinese cabbage

D-Spread; d-Ball Diameter; H-Total Height; h-Nodule Height; X-Root Diameter; L-Root Length

After excluding immature and decayed cabbages from the experimental field, 50 cabbages were selected based on the principles of random sampling, diagonal sampling, and classification. In accordance with the design requirements of the cabbage harvesting equipment, the following parameters were chosen as evaluation indicators for the study of cabbage physical characteristics: total height of the whole cabbage plant (mm), nodule height (mm), spread (mm), nodule diameter (mm), total mass (kg), taproot diameter (mm) and taproot height (mm). The terminology used for determining the basic physical characteristics of cabbage is illustrated in Fig. 2, while the data collection process for these parameters is shown in Fig. 3.

Fig. 3 - The process of collecting basic physical characteristic parameters of Chinese cabbage

● **Determination of static load compression mechanical properties of Chinese cabbage**

This test was conducted to examine the radial static load compression mechanical properties of cabbage. The extrusion probe was applied to three different sections of the cabbage: the head, waist, and bottom, forming three test groups (Zhang et al., 2020; Du et al., 2019). To ensure test accuracy, the stress relaxation test of the cabbage required minimal deformation. A static measurement method was used, and the extrusion speed of the probe was set to 20 mm/min to apply pressure to the test samples.

The first group of Chinese cabbage samples (a total of 10) was placed horizontally on the fixed plate, and the bottom was fixed with a small amount of hot-melt adhesive, and the extrusion probe of the universal testing machine was placed squarely on the head of the test samples. Then, the test was carried out immediately using the GHS2000 universal testing machine at a lower loading rate of 20 mm/min. After the head-loading test was completed, the same method as described above was used to place the second group of samples (a total of 10). After the completion of the head loading test, the second group of samples (10 in total) was tested by the same method as described above, with the waist facing the extrusion probe of the universal testing machine to complete the test at a lower loading rate of 20 mm/min. Finally, the bottom of the third group of test samples was subjected to static loading compression test in the same way. When the first breakage of the exterior of the cabbage was observed, the loading was stopped, and the extrusion pressure on the test specimens was recorded to investigate the minimum extrusion pressure required for the cabbage to reach the breakage condition. Loading then continued until the cabbage was completely broken, at which point loading was stopped. This process aimed to examine the crack shape and direction in different parts of the cabbage under compression. The static compression mechanical properties test of the cabbage is shown in Fig. 4.

Fig. 4 - Static load compression mechanical characterization of Chinese cabbage plants

Structure and working principle of the whole machine

The current level of mechanization in cabbage harvesting is extremely low, mainly relying on manual labor. Additionally, harvested cabbage must not only meet agronomic production quality requirements but also minimize mechanical damage during the harvesting process to ensure a neat and visually appealing appearance (Sarkar et al., 2024; Kim et al., 2020).

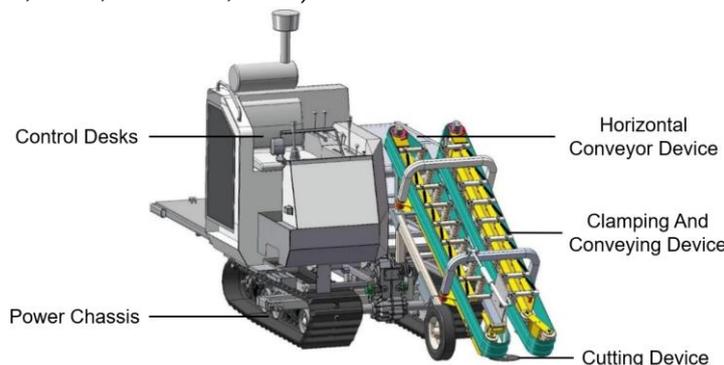

Fig. 5 - Schematic diagram of the single-row crawler-driven Chinese cabbage harvester structure

Based on the demand for mechanized harvesting of Chinese cabbage, the advantages and disadvantages of existing harvesting methods were comprehensively analyzed. The harvesting method selected for this study involves cutting the roots first, followed by clamping and conveying, and finally transporting the cabbage to the collection device. This study combines cabbage planting agronomy and harvesting requirements, developed a self-propelled cabbage harvester equipped with 52 kW engine. Through the design of well-matched root cutting device, clamping and conveying mechanism and lateral conveying device, the cabbage harvesting process can be completed in a single operation. The structure of the self-propelled cabbage harvester is shown in Fig.5.

During the working process of the harvester, the clamping conveyor device is first adjusted to an inclination angle of 20°~30° relative to the ground. The cutting device, driven by a hydraulic motor, completes the cutting of the cabbage roots. After the roots are cut, the cabbages are transferred through the clamping conveyor device to the lateral conveyor device, and finally, they are manually screened and loaded into baskets. The working process of the cabbage harvester is shown in Fig. 6. The main technical parameters of the harvesting machine are presented in Table 2.

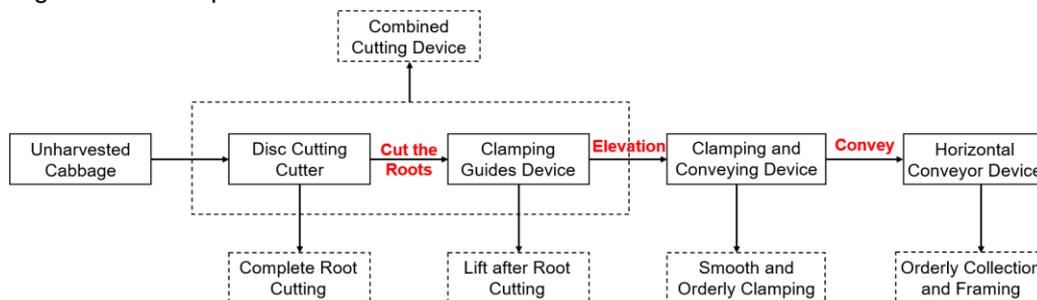

Fig. 6 - The working process of the cabbage harvester

Table 2

Main technical parameters of Chinese cabbage harvester

Technical Parameters	Numerical Value
Structural Form	Crawler-driven
Overall Dimensions /mm	4100×2000×2300
Auxiliary Power/kW	52
Output Speed/(r/min)	2500
Forward Speed/(m/s)	0-2
Number of Rows Harvested	1
Harvest Row Spacing/mm	400-500
Working Width/mm	550
Distance between Plants/mm	350-450
Machine Weight/kg	1520

Design and analysis of clamping conveyor device

Cabbage is transported using a horizontal parallel conveyor belt that clamps the top, which has poor adaptability to the uneven sizes of cabbage. Additionally, compression mechanical properties tests indicate that the radial clamping force on cabbage is relatively small, making it less likely to cause significant deformation or damage. Therefore, this design utilizes a pair of vertically arranged clamping belts, relying on friction to securely clamp the radial surface of the cabbage.

Due to the fragility of cabbage leaves, they are prone to mechanical damage. Therefore, based on the operating environment and the biological characteristics of cabbage. The structure of the clamping and conveying device designed in this program is shown in Fig.7.

The clamping and conveying device mainly consist of clamping belt, active pulley, driven pulley, tensioning pulley and driving hydraulic motor. The two active pulleys are symmetrically installed at the end of the clamping and conveying device. The driving hydraulic motor is installed on the frame above the active pulley and is connected to the driving shaft of the active pulley through a coupling. The driven pulley is suspended and installed at the front of the frame, positioned at the front end of the cutting disk, ensuring that the position of the pulleys remain in the same plane. The tensioning pulleys are installed on both side beams of the frame, with tensioning springs ensuring constant contact with the clamping belt, pushing it outward to

maintain proper tension. During operation, two independent hydraulic motors drive the active pulleys, effectively clamping the cabbage between the flexible clamping belts arranged longitudinally. The distance between the clamping belts allows the cabbage head to pass through, while the elastic tensioning wheel ensures that the flexible clamping belt adapts to cabbages of different sizes.

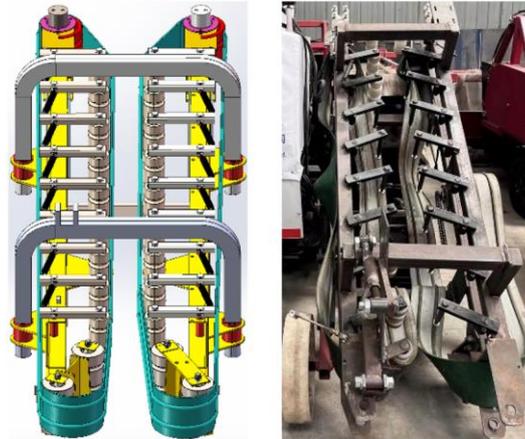

Fig. 7 - The structure of the clamping and conveying device

When the clamping position coincides with the center of gravity, the clamping stability reaches its maximum and the clamping effect is optimal. Therefore, the height of the clamping belt must be appropriately set to ensure compatibility with the cutting disk knife. The drive direction of the clamping belt has an inclination angle relative to the forward direction, which directly affects the accuracy of cabbage clamping and conveying. Based on existing research data, the optimal inclination angle range is determined to be 15° ~ 20°.

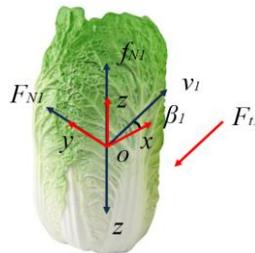

Fig. 8 - Chinese cabbage clamping conveying process force analysis

The force analysis of the cabbage in the clamping and conveying process is shown in Fig. 8. According to Fig. 8, the condition prevents the cabbage from tilting during the clamping and conveying process is:

$$\begin{cases} f_{N1} \geq mg \\ f_{N1} = F_{N1}\mu_{N1} \end{cases} \quad (1)$$

where: f_{N1} is the friction force; F_{N1} is the clamping force; μ_{N1} is the coefficient of static friction between the clamping belt and the cabbage; m is the mass of the cabbage.

The greater the clamping force and friction force provided by the clamping conveyor belt, the less likely it is to produce tilting and falling. However, excessive clamping force on the conveyor belt is likely to lead to clogging and exacerbate mechanical damage to the cabbage. To prevent excessive clamping force from damaging the outer leaves, the clamping force F_{N1} must remain below the maximum compression damage threshold. Based on the cabbage's external dimensions and weight parameters the average mass of a cabbage is set at $m = 2.3$ kg, and the static friction coefficient μ_{N1} is 0.57, resulting in a minimum required clamping force F_{N1} of at least 87.20 N.

To avoid slippage of the clamping conveyor belt, the initial tension F_0 after tensioning of the clamping belt is:

$$\begin{cases} F_0 = 500 \frac{P_c}{z v_1} (K_\alpha^{2.5} - 1) + q v_1^2 \\ P_c = (F_{t1} - F_{t2}) v_1 \end{cases} \quad (2)$$

where: F_0 is the initial tension of the clamping belt; P_c is the conveying power; z is the number of belt roots; K_α is the correction coefficient of the wrapping angle; v_1 is the linear velocity of the clamping belt; q is the mass of the clamping belt per unit length; F_{t1} , F_{t2} are the tensions of the tight and loose sides of the clamping belt, respectively.

In order to prevent cabbage from piling up and clogging at the feed opening, the clamping belt line speed v_1 should be greater than the forward speed of the harvester v_{m1} :

$$\begin{cases} v_1 \geq \frac{v_{m1}}{\cos\beta_1} \\ v_1 = \frac{\pi n_t D_1}{60} \end{cases} \quad (3)$$

where: v_{m1} is the forward speed of the harvester; β_1 is the angle between the clamping belt and the horizontal plane; D_1 is the diameter of the active pulley, mm; n_t is the rotational speed of the active pulley.

If the forward speed of the harvester v_{m1} is greater than the speed of the clamping conveyor, the cabbage will accumulate due to delayed conveyance, leading to clogging at the feed inlet. Conversely, if the forward speed of the harvester is lower than the speed of the clamping conveyor, clogging will not occur, ensuring smooth operation. As the speed of the active pulley n_t increases, the linear velocity v_1 of the clamping conveyor belt also increases, which enhances the efficiency of the clamping conveyor. However, to prevent cabbage accumulation and clogging at the feed inlet, the forward speed v_m of the harvester can be appropriately reduced and the inclination angle β_1 of the clamping conveyor belt can be adjusted accordingly.

In order to adapt to the main cultivar of cabbage “Si Jin” in Yucheng, Shandong Province, the maximum adjustable center spacing of the clamping and conveying device designed is set to 240 mm. The spacing of the feeding mechanism is set within the range of 140~200 mm, ensuring smooth passage for cabbages of varying ball diameters. Additionally, the following parameters are set: q is 0.25 kg/m, z is 1, K_a is 0.92, and β_1 is 15°, so that under non-blocking conditions, the active roller speed n_t is no less than 282.6 r/min, the linear speed of the clamping belt v_1 is no less than 1.72 m/s, the power of a single belt P_c is about 0.42 kW, and the minimum initial tension of the clamping belt F_0 is 212.76 N. The maximum adjustable center spacing of cabbage is 240 mm, while the feeding mechanism spacing is set within the range of 140~200 mm to ensure the smooth passage of cabbages of varying ball sizes.

Simulation and analysis of EDEM-based clamping conveying device

SolidWorks 3D design software was used to construct and simplify the harvesting component model. The three-dimensional model of Chinese cabbage was imported into EDEM for particle filling to determine the fixation mode of Chinese cabbage plant and soil. Harvesting simulation tests were conducted by modifying structural and working parameters.

The Chinese cabbage was simplified into two parts: the sphere and the rhizome. SolidWorks was used to create a 3D model of the cabbage, with parameter calibration based on real cabbage conditions. According to cabbage planting agronomy, a ridge soil ditch model was established, featuring a ridge top width of 650 mm and a plant spacing of 400 mm.

Table 3

Simulation model material parameters			
Materials	Densities/(kg/cm ³)	Poisson's Ratio	Shear Modulus/MPa
Chinese Cabbage	880	0.30	4.06
Soil	1360	0.40	1
Disk Cutting Cutter	7850	0.28	8.20×10 ⁴
Clamping Conveyor Belt	4000	0.25	1×10 ⁴

Table 4

Simulation model contact parameters			
Contact Type	Coefficient of Restitution	Coefficient of Static Friction	Coefficient of Kinetic Friction
Soil - Soil	0.20	0.40	0.30
Chinese Cabbage - soil	0.40	0.30	0.28
Chinese Cabbage - Chinese Cabbage	0.42	0.46	0.04
Soil - Disk Cutting Cutter	0.30	0.40	0.05
Disk Cutting Cutter - Chinese Cabbage	0.43	0.67	0.05
Clamping Conveyor Belt - Cabbage	0.50	0.50	0.01

The harvester model was simplified, retaining only the disk knife, clamping device, and traveling device. Based on the study of the basic physical parameters and mechanical properties of Chinese cabbage, the material parameters and contact parameters of the model were set. The working parameters of the cabbage harvesting components are shown in Fig. 9 and Table 5. The initial forward speed of the harvester was set to 0.1 m/s, the rotational speed of the disk knife to 100 r/min, and the speed of the conveyor belt to 100 r/min.

Arrangements for field experiment

● Experiment object

The developed self-propelled Chinese cabbage harvester was field-tested on November 18, 2024, at the planting demonstration base of Yatai Farm in Yucheng City, Dezhou City, Shandong Province. The experimental site followed a monoculture two-row open-field planting pattern. The agronomic parameters for cabbage planting were row spacing of 450 mm, plant spacing of 400 mm, and row top width of about 650 mm. The test subject was the Shandong Yucheng staple cabbage variety "Si Jin", with a total mature cabbage height ranging from 380 to 420 mm. The ball height varied from 270 to 290 mm, the spreading degree from 450 to 480 mm and the ball diameter from 160 to 180 mm. The total weight ranged between 2.1 and 2.5 kg. Additionally, soil firmness was measured at 13.46 MPa and soil moisture content was recorded at 24.75%.

● Indicators for the evaluation of experiment results

The field productivity, clamping and conveying success rate and the harvest damage rate were taken as the evaluation indexes of the performance of cabbage harvesting equipment.

(1) Field productivity

Chinese cabbage field productivity refers to the actual operating area covered by the harvesting equipment per unit time. Measurements should be taken in each test area, and the final value should be calculated as the average.

$$E = 3.6BV \quad (4)$$

where, E represents the field operation rate; B is the operating width of the cabbage harvesting equipment; V is the operating speed of the cabbage harvesting equipment.

(2) Clamping and Conveying Success Rate

The clamping and conveying success rate refers to the proportion of cabbages in the test area that were successfully cut at the roots, smoothly drawn into the clamping and conveying device, and transported without clogging, falling, or root loss due to cutting errors. The number of effectively clamped cabbages should be recorded during the test.

$$Q_p = \frac{N_p}{N} \times 100\% \quad (5)$$

In the formula, Q_P indicates the success rate of cabbage clamping and transportation; N_P is the number of effectively clamped and transported cabbages; N is the total number of harvested cabbages.

(3) Harvest Damage Rate

Harvest damage rate is the number of heavily damaged outer leaves and large deviations in cut root position as a proportion of the total harvest. $N_o = \frac{N_s}{N} \times 100\%$ (6)

In the formula, N_o represents the cabbage harvesting damage rate; N_s is the number of damaged cabbages during harvesting; N is the total number of harvested cabbages.

RESULT AND DISCUSSION

Measurement of physical and mechanical properties of Chinese cabbage

The measured soil compactness was (11.16 ± 3.20) kg/cm², soil water content was $(25.69 \pm 4.11)\%$, and soil bulk weight was (1.41 ± 0.26) g/cm³. The parameters of soil physical properties are detailed in Table 6. For Chinese cabbage, the total height H was (403.51 ± 22.05) mm, nodule height h was (277.32 ± 9.65) mm, spread d was (481.15 ± 33.10) mm, and nodule diameter d was (169.52 ± 9.05) mm. The total mass was (2.31 ± 0.18) kg, root diameter X was (28.78 ± 4.63) mm, and root length L was (103.76 ± 10.39) mm. The results of the basic physical characteristics of cabbage are presented in Table 7.

Table 6

Parameters of soil physical properties			
Test Indicators	Soil Compactness / kg·cm ⁻²	Soil Water Content /%	Soil Bulk Weight / g·cm ⁻³
Maximum Value	14.70	29.82	1.75
Minimum Value	8.30	21.61	1.24
Mean	11.16	25.69	1.41
Standard Deviation	1.63	2.07	0.14
Coefficient of Variation	0.15	0.08	0.10

Table 7

Basic physical characteristic parameters of Chinese cabbage							
Test Indicators	Total Height/mm	Nodule Height / mm	Spread / mm	Ball Diameter / mm	Total Mass / kg	Root Diameter/mm	Root Length / mm
Maximum Value	425.6	283.6	523.7	523.7	2.5	32.7	112.5
Minimum Value	381.5	264.3	457.5	457.5	2.1	23.4	91.8

In the static load compression mechanical properties test, cabbage samples were subjected to compression using an extrusion probe applied to the head, waist, and bottom of the cabbage. The resulting damage is illustrated in Fig. 10. By analyzing the crack direction after compression, the role of the clamping and conveying device in handling the cabbage can be determined, providing a theoretical basis for its design. The characteristic curves of squeezing force and displacement are shown in Fig. 11.

(a) Head Compression Results (b) Lumbar Compression Results (c) Bottom Compression Results

Fig. 10 - Damage diagram for static load compression test of Chinese cabbage plants

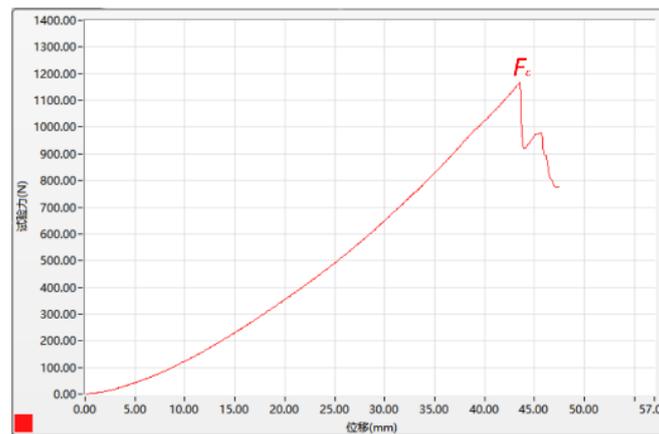

Fig. 11 - Characteristic curves of squeezing force and displacement

From the fitted curve graph, it can be seen that the cabbage strain rupture occurs when the compression displacement reaches 43.6 mm. The maximum compressive breaking force was 1166.1 N. The equation of the fitted curve for the shear characteristic test is:

$$F_p = 0.62x^2$$

where, F_p is the extrusion pressure on the cabbage strain; x is the displacement of the extrusion probe.

Simulation of Chinese cabbage harvesting process

Through the EDEM simulation interface, it can be observed that the disk cutter completes the root-cutting process at the moment when the cabbage is clamped at the front end of the clamping conveyor. The cabbage is then transported upward through the clamping conveyor, completing the entire harvesting process. From the test results, it can be seen that when the forward speed is 0.1~0.3 m/s, the rotational speed of the disk cutter is 100~300 r/min, and the rotational speed of the conveyor belt is 100~200 r/min, the cabbage root-cutting and clamping conveyor process can be successfully completed.

The harvesting process forces are shown in Figure 12. Test groups 1, 3, 5 and 7 were selected as controls. The maximum value of the combined force on the cabbage was 105.7 N. When the forward speed of the harvesting component, the rotational speed of the disk knife and the speed of the conveyor belt changed, the force on the cabbage also changed. The simulation test verified the rationality of the design of the harvesting components of the cabbage harvester. The rationality of the structural design of the device and the actual harvesting effect are further verified through subsequent field tests.

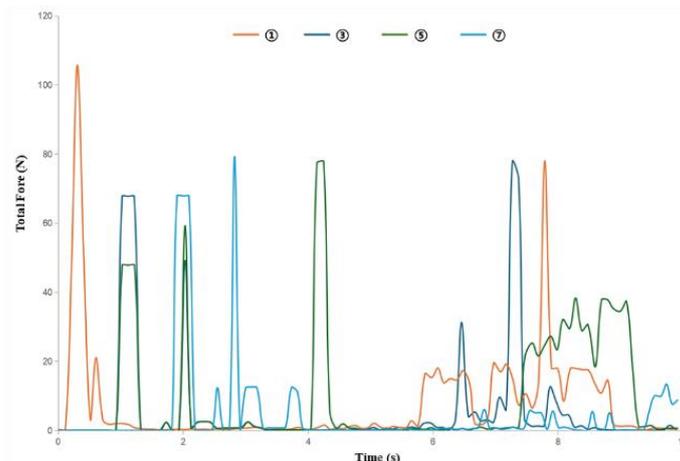

Fig. 12 - Analysis of the force results of the simulation test of Chinese cabbage

Results and analysis of the multifactorial test

Through preliminary theoretical analysis, the main influencing factors on the harvest performance index and their range of values were determined. A three-factor, five-level quadratic regression orthogonal rotary combination test was designed. The cutter speed, forward speed, and clamping belt speed were selected as the influencing factors, while the clamping and conveying pass rate was chosen as the evaluation index. The study aimed to determine the influence of factor interactions on the work performance index.

According to Table 9, the regression model for the clamping and conveying pass rate Q_p has a P -value < 0.0001 , indicating that the model is highly significant. The P -value for the lack-of-fit term is $0.2491 > 0.05$, and the correlation coefficient R^2 of the multiple regression equation is 0.9872 , demonstrating that the fitting accuracy of this regression equation is high. The effects of X_1 , X_2 , X_3 , X_{12} , X_{22} and X_{32} on the clamping qualification rate in the model are highly significant. It can be concluded that the order of influence of each factor on Q_p is: forward speed, cutter speed, and clamping belt speed.

Field harvesting performance experiments

Before conducting the field test, the test area was pre-cleared of dead, immature, and otherwise unsuitable cabbages for harvesting. A laser digital tachometer was used to calibrate key operating parameters of each component. The harvester’s cutting device parameters were set as follows: a cutter inclination angle of 11° , a cutter rotational speed of 215 r/min, and a working speed of 0.28 m/s for the cabbage harvesting test. The cabbage harvesting performance test included a total of five groups, with approximately 60 cabbages in each test area. The field test site operation is shown in Fig. 13.

Fig. 13 - Field experiments of Chinese cabbage harvester

During the field performance test of the harvester prototype, the overall performance remained stable. Each component functioned properly, causing minimal mechanical damage to the cabbage. The harvester demonstrated a high harvest integrity rate and met the required harvesting standards. Following the prototype test method, key operational evaluation indexes - including field productivity, clamping and conveying success rate, and harvesting pass rate - were calculated for each test area. The average of five test results was taken. The prototype achieved an average field productivity of 0.12 hm²/h, an average clamping and conveying success rate of 96.38%, and an average harvest breakage rate of 7.43%, meeting the design requirements for the cabbage harvesting model.

Discussion

- ***Experimental analysis of physical and mechanical properties of Chinese cabbage***

The cabbage samples used in this study for physico-mechanical property tests were produced in Shandong Province, located north of the Yangtze River. The cabbage plants were relatively tall, with most leaf bulbs being tightly packed. The overall bulb height ranged from 380 to 425 mm, the mid-diameter ranged from 158 to 177 mm, the average mass distribution was between 2.1 to 2.5 kg, and the plant height exceeded 260 mm. The physical and morphological parameters of cabbage exhibited significant variations in size and quality. Therefore, to enhance the versatility and adaptability of the harvesting machinery, it is essential to incorporate a floating adjustable feeding device and a clamping device structure.

- ***Experimental analysis of Chinese cabbage harvesting process simulation***

During the clamping and conveying process, the clamping belt exerts pressure on the cabbage, leading to deformation of the belt. The combined force exerted on the cabbage during the clamping process fluctuates, indicating that the interaction force between the cabbage and the clamping belt is dynamically changing. This fluctuation is primarily influenced by the flexible deformation of the clamping belt during contact.

- ***Experimental analysis of harvesting performance in the field***

Cabbage harvesting damage is mainly attributed to the following factors: cutting damage caused by variations in individual cabbage sizes and uneven soil conditions, leading to inconsistencies in the cutting position; handling damage - occurring when cabbage collides or is compressed in the collection box after being harvested. To minimize post-harvest losses, efforts should be made to retain 2-3 outer leaves of the cabbage during harvesting. Minor root and surface damage has minimal impact on subsequent sales. Therefore, the cabbage loss rate during harvesting is acceptable within a certain range.

CONCLUSIONS

This study focused on the structural design and analysis of the clamping and conveying device of a cabbage harvester, considering the basic physical properties of cabbage and the mechanical properties of static load compression. The discrete element method (DEM) was employed to simulate and analyze the clamping and conveying process. Additionally, field harvesting performance tests and practical feasibility analyses were conducted to verify the rationality and accuracy of the clamping and conveying device design. The main conclusions are as follows

- 1) To enhance the versatility and adaptability of cabbage harvesting machinery, a floating adjustable feeding device and a clamping conveyor structure were implemented to improve the harvester's adaptability.
- 2) The clamping and conveying device adopts a longitudinal arrangement, utilizing flexible feeding and flexible clamping to achieve low-loss conveying, thereby improving its adaptability to cabbages with different ball diameters.
- 3) A dynamic coupling simulation model of cabbage harvesting components was established, allowing for the analysis of kinematic and dynamic characteristics through cabbage harvesting process simulations.
- 4) The cabbage harvester developed in this study underwent field performance tests, and the results confirmed that the harvester meets the design requirements for the mechanized harvesting of Chinese cabbage.

ABSTRACT

To address the issue of increased fuel consumption and reduced efficiency caused by excessive slip of the drive wheels during tractor ploughing operations, this paper considered the time-varying, uncertain, and highly nonlinear characteristics of the tractor-operating unit. A nonlinear dynamic model was constructed and a nonlinear slip control method for the drive wheels was designed using sliding mode variable structure control (SMVSC). The method was validated and tested on both the MATLAB/Simulink platform and a hardware-in-the-loop (HIL) simulation platform based on dSPACE. The HILS results indicated that, compared to the fuzzy PID algorithm, under varying soil specific resistance pulses, the mean absolute deviation of slip rate was reduced by 0.013, and the response time decreased by approximately 1.3 seconds with the SMVSC method. In case of pulse variation in slip rate, the SMVSC method reduced the tracking response time by approximately 0.8 seconds and the average control overshoot by about 0.03. Under both experimental conditions, the SMVSC method demonstrated superior control performance, ensuring more stable tractor operation. These findings provide valuable insights for drive slip control in tractor ploughing operations.

摘要

为解决拖拉机犁耕作业时驱动轮过度滑转引起燃油消耗量增加和效率降低的问题, 本文考虑拖拉机作业机组时变、不确定和强非线性特征, 构建了非线性动力学模型并结合滑模变结构控制设计了驱动轮滑转非线性控制方法, 分别在 MATLAB/Simulink 平台以及基于 dSPACE 搭建的硬件在环仿真平台进行验证测试。硬件在环测试结果表明, 相比模糊 PID 算法, 在土壤比阻脉冲变化时, SMVSC 方法下滑转率的平均绝对值偏差减少了 0.013, 响应时间减少了约 1.3s; 在滑转率脉冲变化时, SMVSC 方法的跟踪响应时间减少了约 0.8s, 平均控制过冲减少了约 0.03。两种试验条件下, SMVSC 的控制效果更佳且能够使拖拉机保持较稳定的作业状态, 对于拖拉机犁耕作业中的驱动防滑控制具有一定的参考意义。

INTRODUCTION

With the intelligent and intensive development of modern agriculture (Giller *et al.*, 2015), the heavy tractors have become important tools for efficient operation in field planting (Janulevičius *et al.*, 2019). However, excessive slip of the drive wheels during ploughing operations can significantly reduce the field operation efficiency of heavy tractor unit and negatively affect soil quality (Rahmati *et al.*, 2020). With the deepening of the concept of "Green Agriculture" and the continuous improvement of soil protection requirements (Wang *et al.*, 2020; Holthusen *et al.*, 2018), the introduction and enhancement of intelligent slip control for tractor drive wheels will substantially improve tillage efficiency and optimize soil conditions.

At present, the research on the slip rate is mainly focusing on the measurement and identification method, mathematical modelling, control algorithm, etc. For example, there are relative researches on real-time monitoring of slip rate but not involving automatic control (Pranav *et al.*, 2010), and the traction resistance is adjusted by changing the plough depth at the level of force to meet the purpose of controlling slip rate within a certain range, that it is mainly used by PID, fuzzy control and other methods (Zhang *et al.*, 2016). In the process of mathematical modelling, most of the existing researches employ linearization methods to approximate the nonlinear characteristics of tractor, electro-hydraulic hitch system or operating unit.

Although there have been some further researches on more accurate drive anti-slip control, the strong nonlinear characteristics of the large complex inertial system are not completely considered (Watanabe M. and Sakai K., 2019), resulting in limited accuracy. Sliding mode variable structure control (SMVSC) is a control method which can solve the nonlinear problem. It is mainly used in the field of agricultural machinery automatic control, such as tractor automatic steering (He et al., 2023), path tracking control (Ji et al., 2023) and trajectory tracking considering slip (Zhang et al., 2022; Ding et al., 2022).

In the research on heavy tractor control, the experimental method is also an important part. Due to the difficulty in verifying the real-time execution capability of controllers through offline simulations, field experiments are often relied upon. However, these experiments are influenced by factors such as seasonality and crop growth cycles. Hardware-in-the-loop simulation (HILS), which runs simulation models on real-time processors, can simulate dynamic changes under various experimental conditions and evaluate the performance of control systems and controllers (Li et al., 2007; Paksoy et al., 2020). Now it is gradually trying to provide test solutions for special equipment in the agricultural field. Raikwar et al., (2019), developed a set of HILS test platform based on the automatic test of tractor embedded system to detect and evaluate the faults or defects of tractor electronic control units and control functions. Wu et al., (2019), developed a hardware-in-loop test platform using digital space as a tool to test and verify the efficiency of the power system management unit of electric tractor. Xu et al., (2021), proposed a layered multi-loop robust control architecture (LMLRC) for tractor path following control, and built a hardware-in-the-loop simulation platform with MicroAutoBox, PXI hardware, LabVIEW and other tools, based on which the dynamic effectiveness of the proposed controller was verified. Zhang et al., (2023), tested the proposed active torque distribution control strategy on the dSPACE hardware-in-the-loop simulation platform, demonstrating the controller's obvious advantages in reducing tractor slip, improving traction energy efficiency, and reducing motor energy consumption.

Based on the research of the "tractor-tool-soil" system, this paper has developed a dynamic model of a high-power tractor with electro-hydraulic hitch system during ploughing operations. A slip rate control strategy has been proposed based on this model and the SMVSC theory. Finally, offline simulations and hardware-in-the-loop tests have been conducted on the MATLAB/Simulink and dSPACE platforms, respectively, using a fuzzy PID control method for comparison. The experimental results of both methods have been compared, leading to the optimization of the anti-slip control for the drive wheels of high-power tractors.

MATERIALS AND METHODS

Description of the HILS

The HILS test platform is composed of two parts: software and hardware. The software part encompasses the mathematical model of a half-vehicle, the control algorithm, and the MATLAB-Simulink software. On the hardware side, the platform is equipped with a dSPACE DS1007 serving as the main processor, along with a power supply, an AD conversion board DS2002, a DA conversion board DS2103, a CAN module DS4302, and a controller based on the Freescale MC9S12XS128MAL. The schematic diagram of the entire system is presented in Figure 1.

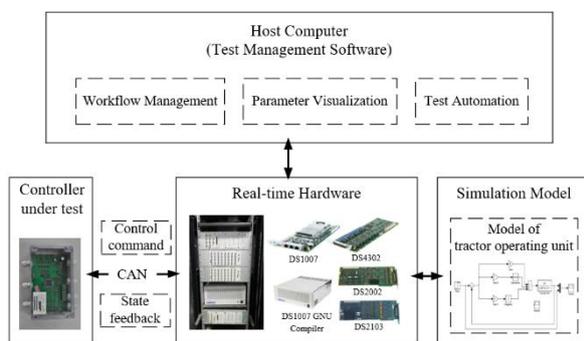

Fig. 1 - Schematic diagram of HILS

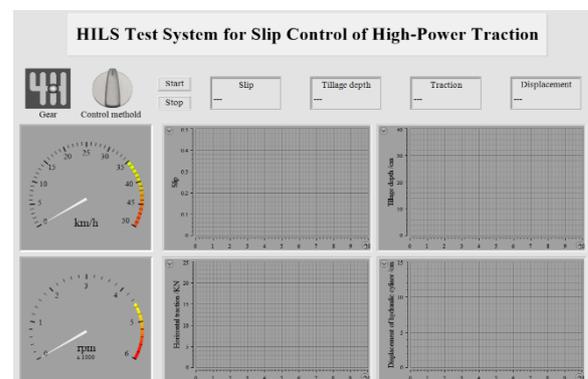

Fig. 2 - The human-machine interface of HILS

The specific functions of the system are as follows: the Tractor simulation model runs in the dSPACE real-time operating environment to simulate the dynamic response characteristics of the tractor under different working conditions; the test management software based on ControlDesk runs in the PC environment of the host computer to provide a good human-computer interaction interface, which can monitor system running state and controller performance in real time, display and dynamically modify system model parameters, and

realize workflow management and test automation. The dSPACE real-time processor interfaces with the controller through I/O interface (CAN bus) to realize the signal communication between the real-time model of tractor and the actual controller. In addition, the human-machine interface (as shown in figure 2) is designed based on the ControlDesk, including the functions of adjusting control parameters, displaying the status of the control system (tractor slip rate, tillage depth, etc.), tracking process response curve, etc.

The half-tractor model

In the mathematical modelling of heavy tractor electro-hydraulic hitch operation units, it is considered that the tractor works in the field mostly in a straight-line motion, and the field road environment is relatively flat. Therefore, the tractor's motion is simplified to linear motion in the longitudinal plane along the tractor's forward direction, ignoring the lateral movements such as sideslip and roll during forward movement. As shown in figure 3, the centre point of the rear axle is used as the coordinate origin to establish the x_0 - O - y_0 motion coordinate of the tractor's electro-hydraulic hitch operation units.

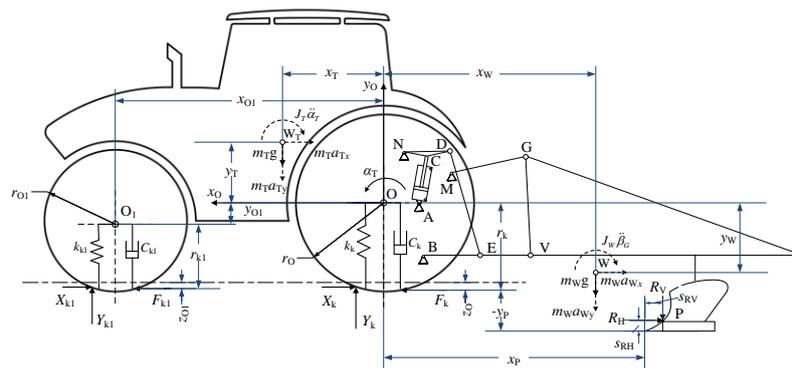

Fig. 3 - Simple diagram of kinematic and dynamic analysis for heavy tractor

● **Kinematics analysis**

The motion of the heavy tractor electro-hydraulic hitch operation unit is simplified into two parts: one is the tractor's translational motion in the forward direction with the base point O , the other is the rotational motion of the tractor's linkage around the base point O in the longitudinal plane, and the relative position relationship of the tractor's main points is expressed by the tractor's relative position relationship when driving on the flat ground. According to the basic theory of kinematics, for each main node of tractor and its linkage, its velocity can be expressed as the velocity projection component of the point and the base point O in the line direction, and its acceleration can be expressed as the vector sum of the acceleration of the base point O and the rotational acceleration of the point around the point O .

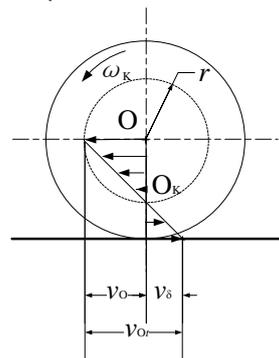

Fig. 4 - Rolling kinematics model with wheels slipping

When the tractor is ploughing, it has the characteristics of approximately constant speed linear operation, so its motion state is generally a rolling motion state with slip, as shown in figure 4. Assuming that during the movement, the instantaneous centre point of the speed of the tractor drive wheel is always above the soil ground in the field, the wheel slip rate of the rear-wheel drive tractor can be expressed as by equation (1):

$$\delta_k = \frac{v_{Or} - v_O}{v_{Or}} = \frac{r_O \omega_k - r_k \omega_k}{r_O \omega_k} = 1 - \frac{r_k}{r_O} \tag{1}$$

where: V_{O_i} and V_O are respectively the theoretical speed and instantaneous speed of the drive wheel in the forward direction, m/s; r_O and r_K are respectively the geometric radius and dynamic radius of the drive wheel, m; ω_K is the angular speed of the drive wheel, rad/s.

As shown in Fig. 5, based on the analysis of the geometric relationship model between the piston displacement of the lifting hydraulic cylinder and the position of hitch pole with changes of the farm tools' depth, the relationship between above three can be approximately obtained. On the basis of abovementioned geometric relation, the displacement of lifting hydraulic cylinder is $x_L=x_{LD}$ when the farming tool is in the predetermined tillage depth. The first-order and second-order differential relation of the angle and movement displacement of each member can be derived. Due to space limitations, the differential equations are no longer listed here.

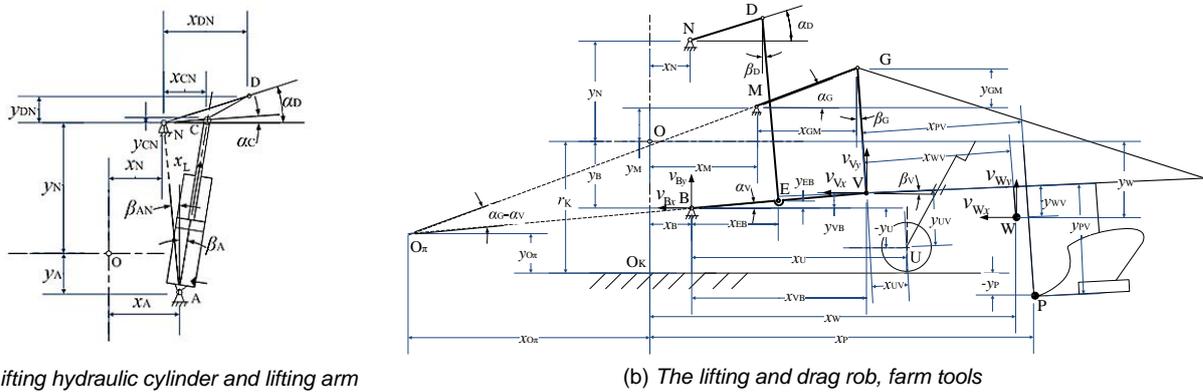

Fig. 5 - Simple diagram of kinematic and dynamic analysis for heavy tractor

NCD is the lifting arm; DE is the lifting rod; MG is the drag rob; BV is the horizontal bar; G and V are the hitch points connecting the upper and lower pull rods and farm tools; W is centroid of farm tools; x_L is the displacement of hydraulic cylinder piston; x_w, y_w are the horizontal and vertical distances from the rear wheel axis O to the centroid, m; $\alpha_c, \alpha_d, \alpha_v, \alpha_g, \beta_A, \beta_D, \beta_G$ are the angles between the corresponding member and the horizontal direction, rad; $\beta_A, \beta_D, \beta_G$ are the angles between the corresponding member and the horizontal direction, rad.

● **Dynamic analysis**

In Figure 3, the force analysis of the tractor's electro-hydraulic hitch operation unit shows that the external forces received by the tractor (including the hitch mechanism) mainly include: the tractor's gravity $m_T g$, the farm tools' gravity $m_W g$, the front wheels' vertical ground reaction Y_{K1} , the horizontal rolling resistance X_{K1} and the corresponding driving force F_{k1} , the rear wheels' vertical ground reaction Y_K , the horizontal rolling resistance X_K and the corresponding driving force F_K , and the farm tools' soil resistance R_H and R_V , the force F_G, F_{vx} and F_{vy} of the tool on the linkage at the upper and lower hitch points. Therefore, with the point O as the centre, the force and moment balance equations in the horizontal and vertical directions have been set up, as shown in equation (2).

$$\begin{cases} Y_K + Y_{K1} - R_V = m_T (g + a_{Ty}) + m_W (g + a_{Wy}) \\ F_K + F_{K1} - X_K - X_{K1} - R_H = m_T a_{Tx} + m_W a_{Wx} \\ R_H (r_K - y_P - s_{RH}) - R_V (x_P + s_{RV}) - (F_K + F_{K1}) r_K + X_{K1} y_{O1} - Y_{K1} x_{O1} \\ + m_T (g + a_{Ty}) x_T - m_T a_{Tx} y_T - m_W (g + a_{Wy}) x_W + m_W a_{Wx} y_W = J_T \ddot{\alpha}_T + J_W \ddot{\beta}_G \end{cases} \quad (2)$$

According to the above relevant kinematics and dynamics analysis, and referring to the previous research results and modelling methods, the kinematics and dynamics equations of each subsystem such as the tractor body, wheels, hitch mechanism and agricultural tools are brought into equation (2). The dynamic differential equations of tractor electro-hydraulic hitch ploughing unit are obtained, as shown in formula (3). In this formula, Y_K and $Y_{\Delta K}$ are intermediate variables; s_{O1} and s_o are respectively the compression deformation of front and rear tires, m; z_{o1} and z_o are respectively the soil subsidence caused by vertical load of front and rear tires, m; A_{K1} and A_K are the grounding area of front and rear tires, m^2 ; B_{K1} and B_K are respectively the grounding width of front and rear tires, m. The coefficients such as $m_{x_L e}, i_{x_L y_K}, J'_{x_L \alpha_L e}, l_{\alpha_T F_K}$ are respectively the intermediate equivalent mass, equivalent moment of inertia and other equivalent coefficients appearing in the process of solving the equation system, which can be expressed as expressions of known variables or constants. This study based on the author's previous work, utilizing the key dimensions and structural parameters of the tractor operating unit as outlined in reference (Zhang et al., 2020). Due to space constraints, further details are omitted.

$$\begin{cases}
 \ddot{x}_L = \frac{1}{m_{x_{1e}}} \left[p_L A_L + i_{x_{1F_K}} (F_K + F_{K1}) + i_{x_{1R_H}} R_H - i_{x_{1Y_K}} Y_K - i_{x_{1Y_{K1}}} Y_{K1} - i_{x_{1R_V}} R_V - m_{x_{1g}} g - J'_{x_{1\alpha_L}} a_T^2 - m_{x_{1\alpha_L}} \dot{x}_L \dot{a}_T - m'_{x_{1e}} \dot{x}_L^2 \right] \\

 \end{cases}$$

Slip Rate Controller Design

Through the analysis of the movement characteristics of the heavy tractor ploughing unit, it can be seen that when the soil conditions change suddenly, the tractor slip rate changes greatly, which will seriously affect the tractor's traction performance. Therefore, in view of the nonlinear characteristics of the heavy tractor electro-hydraulic hitch unit, considering the tractor traction efficiency, according to the slip rate control requirements under different ploughing conditions and considering the uniformity of ploughing depth, a slip rate control method with the optimal slip rate $\delta_{opt}=0.2$ as the control target was designed in this paper. The operation principle of the slip rate control system based on the optimal target is shown in figure 6. In this paper, the sliding mode variable structure control method is used to study, and the fuzzy PID control method is added to compare.

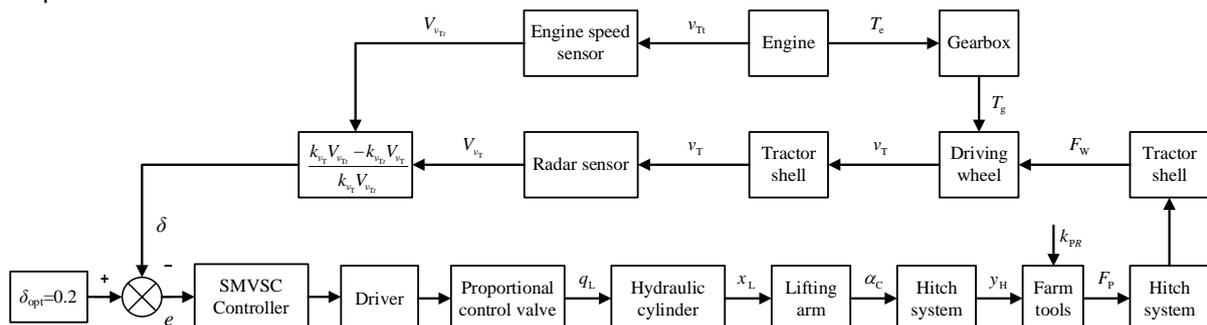

Fig. 6 - Diagram of control system working principle

● **Research on the SMVSC algorithm**

Because there are a lot of physical parameters and uncertainties which are difficult to obtain accurately in the tractor dynamics model, and the system equation has strong nonlinearity, the sliding mode variable structure control method is a nonlinear control method which adapts to the strong nonlinearity and is insensitive to the external disturbance, and has better robustness and higher reliability.

First, the output error is defined as:

$$e = \delta_K - \delta_{opt} \tag{4}$$

According to the sliding mode variable structure control theory, the switching function is defined as:

$$s(t) = Ce = C(\delta_K - \delta_{opt}) \tag{5}$$

where:

C is the sliding mode coefficient, and $C > 0$, setting $C = 1$.

The design of the sliding mode variable structure controller consists of two main aspects: on the one hand, it needs to be ensured that any position in the phase plane can reach the switching function $s=0$ in a finite time, and on the other hand, it needs to be ensured that it can converge to an equilibrium point on the switching function. According to the defined switching function and the basic principle of SMVSC, in the phase plane composed of the slip rate and the derivative of the slip rate, the switching line is a straight line with a slope of $-C$ and passing through $(\delta_{opt}, 0)$. The basic idea of SMVSC is to select an appropriate control variable, so that during the operation of the tractor, its phase trajectory $(\delta_K, \dot{\delta})$ continuously slides along the switching line to the control target $(\delta_{opt}, 0)$ by a predetermined control law. Derivation of equation (5) gives:

$$\dot{s}(t) = C\dot{e} = \dot{\delta}_K \tag{6}$$

Based on the requirement that points in the state space need to be allowed finite time to reach the termination point on the switching function $s=0$, the following conditions must be satisfied when designing the controller: when $s(t) > 0$,

$$\dot{s}(t) = C\dot{e} = \dot{\delta}_K < 0 \tag{7}$$

When $s(t) < 0$,

$$\dot{s}(t) = C\dot{e} = \dot{\delta}_K > 0 \tag{8}$$

Substituting the first-order differential equation expression of the slip rate that has been derived from the dynamic model into equation (6) gives:

$$\begin{aligned} \dot{s}(t) = (1 - \delta_K) & \left(\frac{\dot{\omega}_K}{\omega_K} - \frac{\dot{s}_O}{r_O - s_O} \right) + \frac{1}{\omega_K (r_O - s_O) (m_T + m_W)} \left\{ \frac{m_{x_O x_L}}{m_{x_L e}} p_L A_L + \left(i_{x_O R_H} + i_{x_L R_H} \frac{m_{x_O x_L}}{m_{x_L e}} \right) R_H \right. \\ & - \left(i_{x_O R_V} + i_{x_L R_V} \frac{m_{x_O x_L}}{m_{x_L e}} \right) R_V - \left(i_{x_O F_K} - i_{x_L F_K} \frac{m_{x_O x_L}}{m_{x_L e}} \right) F_K + \left(i_{x_O Y_K} - i_{x_L Y_K} \frac{m_{x_O x_L}}{m_{x_L e}} \right) Y_K + \left(i_{x_O Y_{K1}} - i_{x_L Y_{K1}} \frac{m_{x_O x_L}}{m_{x_L e}} \right) Y_{K1} \\ & \left. - m_{x_L g} \frac{m_{x_O x_L}}{m_{x_L e}} g + \left(m'_{x_O x_L} - m'_{x_L e} \frac{m_{x_O x_L}}{m_{x_L e}} \right) \dot{x}_L^2 + \left(m_{x_O \alpha_T x_L} - m_{x_L \alpha_T e} \frac{m_{x_O x_L}}{m_{x_L e}} \right) \dot{x}_L \dot{\alpha}_T - \left(J_{x_O \alpha_T} + J'_{x_L \alpha_T e} \frac{m_{x_O x_L}}{m_{x_L e}} \right) \dot{\alpha}_T^2 \right\} \tag{9} \end{aligned}$$

In order to ensure the stability of the sliding mode motion and the working quality, the dynamic effect of the convergence motion is improved by using the exponential approach law, and constant velocity approaches law is introduced to determine the convergence speed to be a certain non-zero speed when $s(\delta)$ continuously approaching 0, which ensures that the control system arrives at the switching manifold as soon as possible with this speed. The exponential approach law used is shown in equation (10).

$$\dot{s}(t) = -\varepsilon \operatorname{sgn}(s(t)) - ks(t) \tag{10}$$

where:

ε represents the law of constant velocity approach of the moving point, and $\varepsilon > 0$; k represents the law of exponential approach, and $k > 0$; $\operatorname{sgn}(s(t))$ represents the sign function.

Combine the vertical (9) and (10), and select the piston pressure $p_L A_L$ in the oil chamber of the lifting hydraulic cylinder as the equivalent control quantity, and get:

$$\begin{aligned}
 p_L A_L = & \omega_K (r_O - s_O) (m_T + m_W) \frac{m_{x_L e}}{m_{x_O x_L}} (-\varepsilon \operatorname{sgn}(s(t)) - ks(t)) - \omega_K (r_O - s_O) (m_T + m_W) \frac{m_{x_L e}}{m_{x_O x_L}} (1 - \delta_K) \left(\frac{\dot{\omega}_K}{\omega_K} - \frac{\dot{s}_O}{r_O - s_O} \right) \\
 & - \left(i_{x_L R_H} + i_{x_O R_H} \frac{m_{x_L e}}{m_{x_O x_L}} \right) R_H + \left(i_{x_L R_V} + i_{x_O R_V} \frac{m_{x_L e}}{m_{x_O x_L}} \right) R_V + \left(i_{x_O F_K} \frac{m_{x_L e}}{m_{x_O x_L}} - i_{x_L F_K} \right) F_K + \left(i_{x_L Y_K} - i_{x_O Y_K} \frac{m_{x_L e}}{m_{x_O x_L}} \right) Y_K \\
 & + \left(m'_{x_O x_L} \frac{m_{x_L e}}{m_{x_O x_L}} - m'_{x_L e} \right) \dot{x}_L^2 - \left(m_{x_O \alpha_T x_L} \frac{m_{x_L e}}{m_{x_O x_L}} - m_{x_L \alpha_T e} \right) \dot{x}_L \dot{\alpha}_T + \left(J_{x_O \alpha_T} \frac{m_{x_L e}}{m_{x_O x_L}} + J'_{x_L \alpha_T e} \right) \dot{\alpha}_T^2
 \end{aligned} \tag{11}$$

It can be seen from equation (11) that the expression is extremely complex. According to the dynamic characteristics of the motion of the electro-hydraulic hitch system and the characteristics of the sliding mode variable structure control theory, it is assumed that the tractor ploughing operation in the field is approximately constant speed operation, that is, the slip rate is kept near the optimal value with small fluctuation. Assume that the tractor engine speed is constant. Assuming that the tractor's pitching motion in the forward longitudinal plane is small, it is considered that the hydraulic cylinder push rod extends at a nearly uniform speed. Through simulation analysis and calculation, it can be further simplified:

$$p_L A_L = k_1 * (-\varepsilon \operatorname{sgn}(s(t)) - ks(t)) + k_2 v_O + k_3 R_H + k_4 R_V + k_5 F_K + k_6 Y_K + k_7 Y_{K1} \tag{12}$$

where: $k_1, k_2, k_3, k_4, k_5, k_6$ and k_7 are the coefficients related to tractor structural parameters, which are specifically expressed as follows:

$$\begin{aligned}
 k_1 = & \omega_K r_K (m_T + m_W) \frac{m_{x_L e}}{m_{x_O x_L}}, \quad k_2 = r_K \dot{s}_O \frac{m_{x_L e}}{m_{x_O x_L}} (m_T + m_W), \quad k_3 = -i_{x_L R_H} - i_{x_O R_H} \frac{m_{x_L e}}{m_{x_O x_L}}, \\
 k_4 = & i_{x_L R_V} + i_{x_O R_V} \frac{m_{x_L e}}{m_{x_O x_L}}, \quad k_5 = i_{x_O F_K} \frac{m_{x_L e}}{m_{x_O x_L}} - i_{x_L F_K}, \quad k_6 = i_{x_L Y_K} - i_{x_O Y_K} \frac{m_{x_L e}}{m_{x_O x_L}}, \quad k_7 = i_{x_L Y_{K1}} - i_{x_O Y_{K1}} \frac{m_{x_L e}}{m_{x_O x_L}}.
 \end{aligned}$$

The Lyapunov function is constructed based on the positive definite function to test the stability of the system employing the exponential convergence rate, and the Lyapunov function is:

$$V = \frac{1}{2} s^2 \tag{13}$$

Derivatives can be obtained:

$$\dot{V} = \frac{1}{2} \frac{d}{dt} s^2 = s \dot{s} < -\varepsilon |s| < 0 \tag{14}$$

where: $\varepsilon > 0$.

According to Lyapunov stability theory, it can be concluded that the designed control system is stable.

When the system enters the sliding mode motion and continuously switches along the sliding mode surface, in order to suppress the system "shaking" as much as possible, the continuous saturation function $sat(s)$ is used instead of the traditional constant velocity approach rate discontinuous symbol function $sgn(s)$, which is defined as follows:

$$sat(s) = \begin{cases} 1, & s > \psi \\ s/\psi, & |s| \leq \psi \\ -1, & s < -\psi \end{cases} \tag{15}$$

where: ψ is the thickness of the boundary layer.

The expression of the equivalent control variable $p_L A_L$ has been derived. The self-developed threaded plug-in proportional control valve was used for indoor testing. Based on the dynamic and static characteristics of the proportional control valve, the opening pressure of the proportional relief valve connected to the oil outlet of the proportional control valve was adjusted. The pressure difference between the load pressure of the proportional lowering control valve and the return oil pressure was controlled to maintain approximately 4 MPa and 9 MPa, respectively. By varying the input voltage of the proportional amplifier (driver), the steady flow of the proportional lowering valve under different driving voltages was obtained. Similarly, the steady flow of the proportional poppet under different driving voltages was measured. Through regression analysis and fitting of the test results, the relationship between control voltage and output flow was determined as follows:

$$U_{up} = \begin{cases} \frac{Q_{up}}{0.475\sqrt{\frac{2}{\rho}\Delta p}} + 3.87, & 0 \leq \frac{Q_{up}}{\sqrt{\frac{2}{\rho}\Delta p}} \leq 0.312 \\ \frac{Q_{up}}{0.475\sqrt{\frac{2}{\rho}\Delta p}} + 4.27, & \frac{Q_{up}}{\sqrt{\frac{2}{\rho}\Delta p}} > 0.312 \end{cases} \quad (16)$$

$$U_{down} = \begin{cases} 1.73 - \frac{Q_{down}}{0.48\sqrt{\frac{2}{\rho}(p_L - p_0)}}, & 0 \leq \frac{Q_{down}}{\sqrt{\frac{2}{\rho}(p_L - p_0)}} \leq 0.304 \\ 1.27 - \frac{Q_{down}}{0.48\sqrt{\frac{2}{\rho}(p_L - p_0)}}, & \frac{Q_{down}}{\sqrt{\frac{2}{\rho}(p_L - p_0)}} > 0.304 \end{cases} \quad (17)$$

where: U_{up} is the driving voltage of proportional poppet, V; U_{down} is the driving voltage of the proportional lowering valve, V; Q_{up} is the flow of hydraulic oil from the proportional lift valve into the hydraulic cylinder during the lifting process of the hydraulic cylinder, m³/s; Q_{down} is the flow from the hydraulic cylinder into the proportional descent control valve during the descent of the hydraulic cylinder, m³/s; Δp is the pressure difference between the two ends of the proportional directional valve, and the value has been set 1.5MPa; p_L is the load pressure of the hydraulic cylinder, Pa; p_0 is the return oil pressure, value 0 Pa; ρ is the density of hydraulic oil, kg/m³.

The flow continuity equation of hydraulic cylinder is shown in equation (18):

$$\dot{p}_L = \frac{\beta_e}{V_L} (q_L - A_L \dot{x}_L - C_{iL} p_L) \quad (18)$$

q_L can be obtained by combining equation (12) and equation (18). When the poppet valve is open, $q_L = q_{up}(U)$; when the drop valve is open, $q_L = -q_{down}(U)$. From the equations (16) and (17), the control voltage U of the electro-hydraulic proportional control valve can be obtained to implement the control.

● Incremental fuzzy PID control method

In order to highlight the advantages of SMVSC, PID control algorithm which is widely used in control field is selected for comparison. The fuzzy PID controller can improve the robustness of the system in the control process, taking the deviation e and the deviation change rate e_c of the slip rate as the input, and the three parameter correction quantities ΔK_P , ΔK_I and ΔK_D of the PID as the output. The domains of e and e_c are taken as [-0.6, 0.6], and the output variables ΔK_P , ΔK_I , ΔK_D are set according to experience as [-5, 5]. The tuning principles of PID controller parameters are:

(1) When e is larger and e_c is larger, in order to reduce the system response time and avoid system integral saturation, increase K_P and decrease K_I ;

(2) When e decreases gradually, in order to shorten the dynamic adjustment time, reduce overshoot and steady-state oscillation, K_P is reduced and K_I is increased;

(3) When the system begins to approach the target and enters steady-state, in order to obtain a good steady state, improve the ability to resist disturbance, increase K_D .

The fuzzy subsets of e , e_c , ΔK_I and ΔK_D are taken as {NB, NM, NS, ZO, PS, PM, PB}, representing {negative big, negative middle, negative small, zero, positive small, positive middle, positive big}, and the membership functions of all subsets are Gauss membership functions. Use MATLAB's fuzzy inference toolbox to build a fuzzy inference system and edit the membership of input and output variables.

RESULTS AND ANALYSIS

Offline simulation and analysis of control algorithm

According to the established system dynamics model and the designed control algorithm, the corresponding simulation model of slip rate control system is established in MATLAB/Simulink, and the entire system is analysed by off-line simulation. During the simulation process, the disturbance rejection characteristics of the sliding rate control system, that is the change of soil specific resistance input, and the dynamic response characteristics of the control target when the input setting value changes, are mainly

concerned. After several adjustments, the parameters of SMVSC are determined as $\varepsilon=1.2$, $k=0.01$, $\psi=0.01$, and the initial parameters of fuzzy PID controller are $K_P=12$, $K_I=0.5$, $K_D=1.5$. The initial conditions of the simulation are set as follows: the tractor gear is B2 gear, the initial displacement of the hydraulic cylinder piston rod is 8.83 cm, the initial ploughing depth of the tractor operation is 20 cm, and the simulation time is 50 seconds.

● **Soil specific resistance with pulse change**

The simulation takes $\delta_{opt}=0.2$ as the control target, takes the change of soil specific resistance as the external disturbance input, and sets the steady-state value of the soil specific resistance to 30000 N/m². At the beginning of the simulation, the soil specific resistance is added as a pulse signal with an amplitude of 8000 N/m², a period of 10s and a duty cycle of 50%. When the soil specific resistance changes, the simulation results are shown in Figure 7.

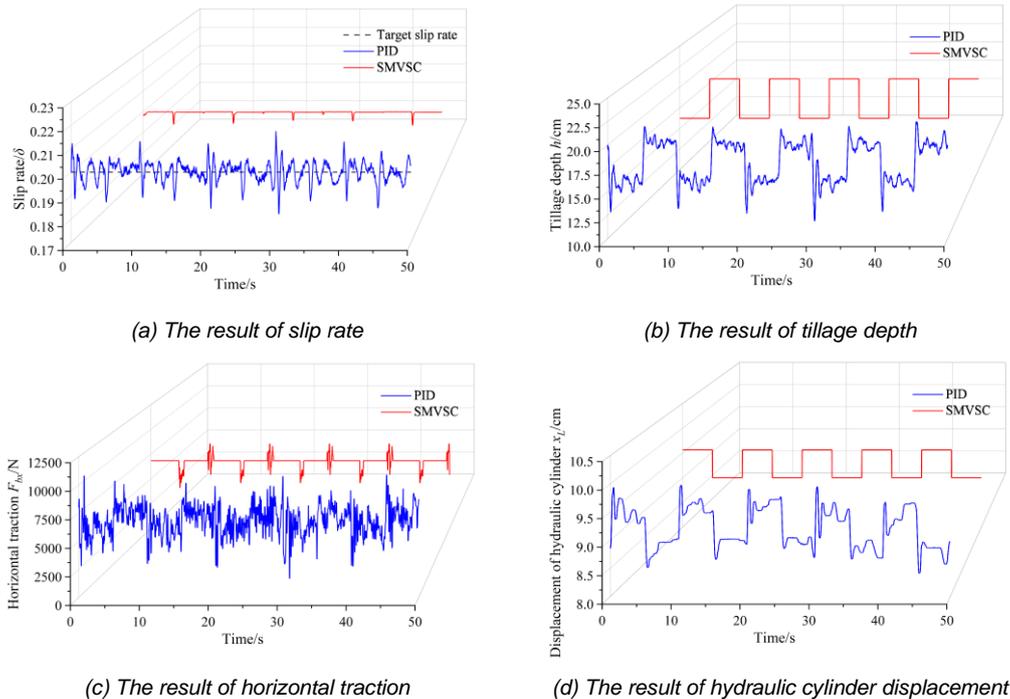

Fig. 7 - Simulation results of soil specific resistance with pulse change

According to Fig. 7 (a), when the specific resistance of soil changes step by step every 5 seconds, through the fuzzy PID control method, after a response time of about 1.5s, the slip rate can be basically controlled around 0.2, but the fluctuation is large, and the maximum error reaches 0.02. The results by the SMVSC method show that the sliding rate can be well controlled at 0.2, and the response time is very short, there is almost no overshoot at the beginning of the control. And the same time, the control target can be continuously and stably tracked in the control process, which can better resist the influence of soil specific resistance disturbance. In addition, when the specific resistance of soil is within 30000N cycle, the dynamic performance of tractor will be affected by random road excitation disturbance, so the fuzzy PID control algorithm can be adjusted according to the magnitude of deviation at any time. The slip rate has been near the target value of 0.2 by large steady-state error. But the SMVSC method has been proven to have a low steady-state error and better robustness against external disturbance, maintaining stability at 0.2 with almost no overshoot. The simulation results showed that when the soil conditions were changing, compared with the fuzzy PID control method, the SMVSC method had better disturbance rejection characteristics and faster response to the external disturbance, which verified the effectiveness and superiority of its control.

● **Control target value with pulse change**

In order to further understand the tracking performance of the control algorithm for the control target, the control target value input by the control system is varied under fixed soil conditions, and the dynamic response characteristics of the control system are analysed when the input undergoes a pulse change. The soil specific resistance is set to 30000 N/m², the initial value of the slip rate control target is 0.2, the control target change amplitude is 0.1, the period is 10s, and the pulse signal has a 50% duty cycle. The simulation results are shown in Figure 8.

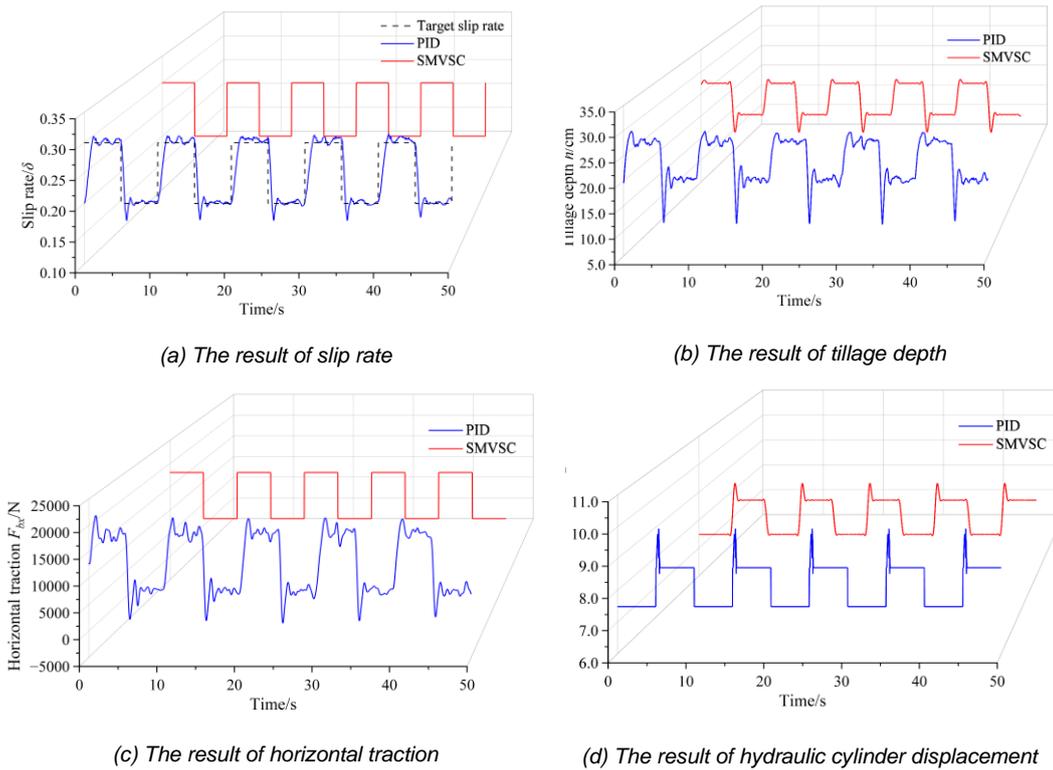

Fig. 8 - Simulation results of control target value with pulse change

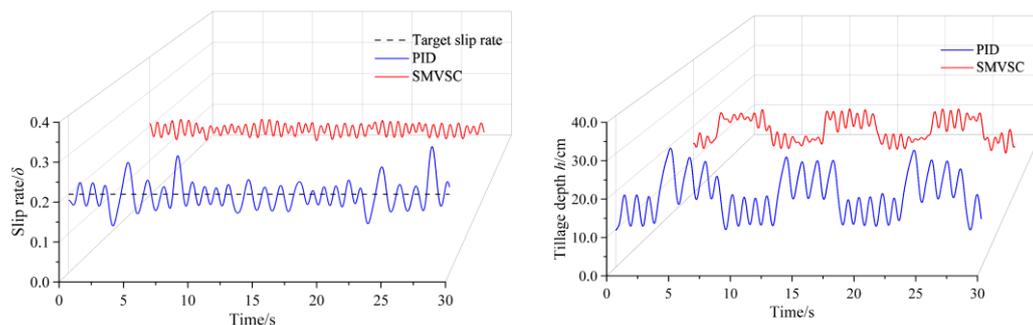

In the control process, the response time of fuzzy PID control was about 1.8s, and the maximum overshoot was 0.05, with a steady-state control error of about 0.01; there was almost no overshoot and steady-state control error by the SMVSC method. When the control target changed periodically between 0.2 and 0.3, the results showed that it reached the control target more quickly by the SMVSC method, the tracking performance of the control target is faster, and the error is smaller. It can be seen that, under certain conditions of the soil without external disturbance, when the control target changes, the dynamic tracking performance to the control target of the SMVSC is better, the response time is shorter than the fuzzy PID control, and there is almost no steady-state error, further proving the SMVSC method superiority.

HILS test and analysis of control algorithm

The HILS test system is used to experimentally investigate the slip rate control for a half-tractor model. According to the test conditions of off-line simulation, based on the HILS real-time simulation test platform, two different algorithms by SMVSC and fuzzy PID control are respectively carried out in the hardware-in-the-loop simulation test, corresponding to the analysis of the sliding rate control when the soil specific resistance pulse changes and the sliding rate control when the control target pulse changes.

● **Soil specific resistance with pulse change**

Setting the same test conditions as the offline simulation, the test duration is 30s, and the results are shown in figure 9.

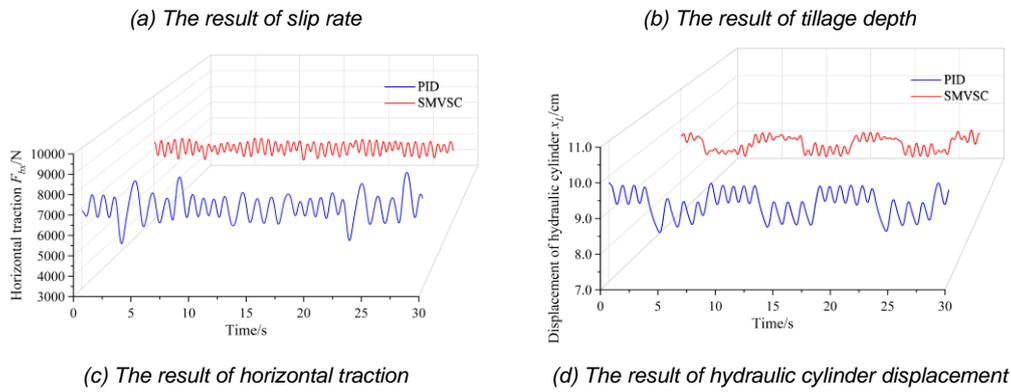

Fig. 9 - HILS results of soil specific resistance with pulse change

The absolute value deviation and variance of the mean value are used as the measurement indicators to evaluate the control effect of the slip rate, and to compare control accuracy of the two different control methods. At the same time, in order to better reflect the status of the ploughing operation under the control of slip rate, the data statistics of ploughing depth, hydraulic cylinder displacement and horizontal traction force were analysed. The analysis results are shown in table 1.

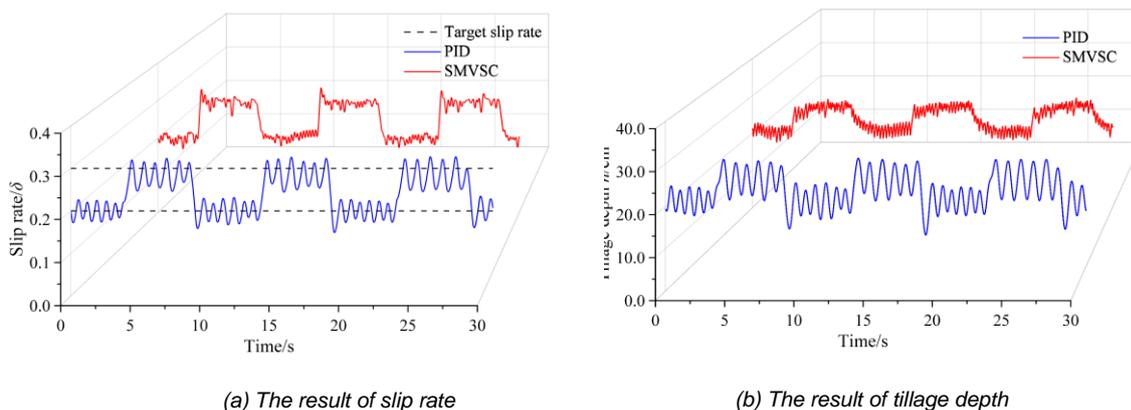

Table 1

Analysis about HILS results								
Methods	Slip rate		Tillage depth		Displacement		Horizontal traction	
	Mean Absolute Deviation	Variance	[cm]		[cm]		[N]	
			Max	Min	Max	Min	Max	Min
SMVSC	0.014	0.0002	25.22	11.92	9.67	8.81	7067.78	6350.24
PID	0.027	0.0011	31.46	9.70	9.81	8.40	8783.37	5224.83

By the SMVSC method, the maximum deviation of the slip rate control is 0.041, the mean absolute deviation is 0.014, and the slip rate variance is 0.0002. And by the fuzzy PID control method, the maximum deviation of the slip rate control is 0.121, the average absolute deviation is 0.027, and the slip rate variance is 0.0011. Although the slip rate was controlled around 0.2 through both algorithms, the deviation of the slip rate average absolute value under the SMVSC algorithm is reduced by 48%, the response time is reduced by about 1.3s, and the control deviation is smaller, and the fluctuation amplitude is far smaller than the fuzzy PID control algorithm. In addition, by the SMVSC, the adjustment change of plough depth is 5.26 cm, which is far less than 7.21 cm of fuzzy PID control, reducing about 27%; the adjustment change of hydraulic cylinder displacement is 1.15 cm, which is far less than 1.8 cm of fuzzy PID control, which is about 36%; the adjustment change of horizontal traction force is 1293.35 N, which is less than 2217 N of fuzzy PID control, which is about 42%. When the tractor realizes the optimal value control of slip rate, the adjustment amount is small, which makes the tractor keep in a more stable working state.

● Control target value with pulse change

The test conditions are set as above, and the results are shown in figure 10.

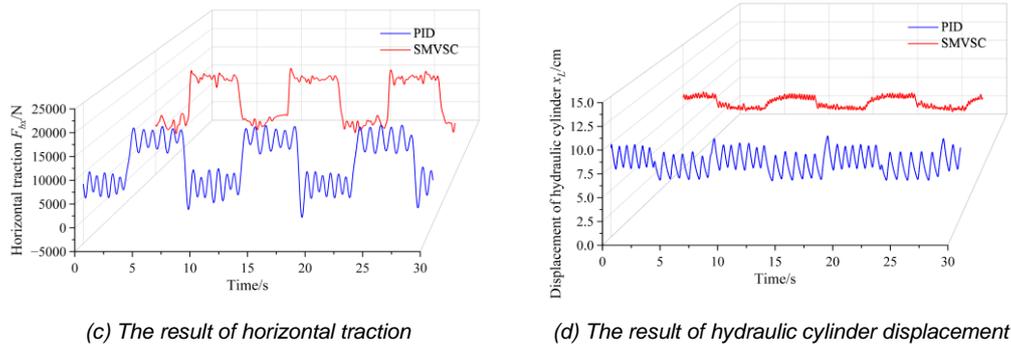

Fig. 10 - HILS results of control target value with pulse change

When the slip rate control target changes between 0.2 and 0.3, both algorithms can effectively track the dynamically changing slip rate target value, but the tracking response time of SMVSC method is reduced by about 0.8s less than that of fuzzy PID control, the average control overshoot is reduced by about 0.03, and the control deviation and fluctuation range are also significantly reduced. At the same time, the results by the SMVSC method show that, the displacement of the tractor hydraulic lift cylinder and the adjustment depth of the ploughing depth are significantly smaller than those obtained by the fuzzy PID control, and the fluctuation range of the horizontal traction force is also significantly reduced.

Compared with the integrated traction-slip ratio control method previously proposed by our team (Zhang *et al.*, 2016), the slip ratio control strategy developed in this study achieved superior target slip ratio tracking performance while maintaining minimal fluctuations in tillage depth and traction force. The proposed SMVSV method demonstrated significant improvements over existing slip ratio control approaches (Bai *et al.*, 2012; Soylyu *et al.*, 2021), reducing the system response time to within 1 second, decreasing the mean absolute deviation of slip ratio to 0.014 under soil specific resistance with pulse change, and significantly minimizing slip ratio overshoots along with fluctuations in tillage depth and traction force during target slip ratio adjustments with pulse change.

It can be seen that the method based on SMVSC has shorter response time, smaller control overshoot, and better dynamic tracking performance in the slip control process. As a robust control method, the control process of SMVSC method is independent of the state of the system and external disturbances, it has the advantages of parameter disturbance insensitivity and simple implementation. In view of the strong nonlinear and complex coupling characteristics of heavy tractor ploughing unit, SMVSC method has certain control advantages and better control effect than fuzzy PID control. While controlling the slip rate to the target value, the adjustment amount is smaller, which can maintain a more stable tractor field working condition.

CONCLUSIONS

(1) For the ploughing operation conditions, considering the nonlinear characteristics of the complex coupling system of the "tractor-tools-soil", a time-varying nonlinear dynamic model of the tractor's electro-hydraulic hitch system was developed, and the nonlinear motion characteristics of the system were clarified.

(2) Based on the theory of Sliding Mode Variable Structure Control (SMVSC), considering the strong nonlinearity, time-variability, and uncertainty characteristics of the dynamic system, the piston pressure in the hydraulic cylinder was selected as the control variable. A slip control algorithm for the tractor's drive wheels was designed, with a fuzzy PID algorithm used as a comparative benchmark. Simulations and analyses were conducted in MATLAB/Simulink.

(3) A hardware-in-the-loop simulation (HILS) test platform was developed to overcome the limitations of field experiment and to evaluate the real-time execution capabilities of the control algorithm. The results indicated that the SMVSC algorithm effectively achieved optimal slip rate control and a more stable operational state within the electro-hydraulic hitch system, characterized by reduced adjustment amplitudes. This advancement is significant for minimizing energy consumption and enhancing the quality of ploughing activities during operations.

Keywords: Path planning, Grid method, Improved whale optimization algorithm, Optimal traversal order

ABSTRACT

Path planning is crucial for agricultural machinery navigation. To address the issue of operational path planning in fields with obstacles, this paper proposes a method for obstacle avoidance path planning in farmland by combining an improved whale optimization algorithm with Dijkstra's algorithm. The population initialization is conducted using Tent mapping and a nonlinear convergence factor α^* is introduced to reduce the oscillation and instability of the traditional whale optimization algorithm. By using the grid method to model the environment of the target field, the field is divided into multiple regular subplots. The improved whale optimization algorithm is employed to determine the optimal traversal order of these subplots. Subsequently, Dijkstra's algorithm is applied to find the shortest path connecting the subplots, achieving global obstacle avoidance path planning for farmland. Taking a rectangular plot of land in Jiaolai Town, Jiaozhou City, Qingdao as the target area for this study, the experimental results indicate that this method achieves a coverage rate of 100% in the plot coverage path experiment. Additionally, the path redundancy rate is 4.87%, which represents a reduction of 1.63% compared to traditional algorithms. This research method is applicable to regular plots, but it still has limitations for irregular plots or those with curved boundaries.

摘要

路径规划是农机导航的关键。针对地块中存在障碍物的作业路径规划问题，本文旨在提出一种基于改进鲸鱼优化算法与 Dijkstra 算法相结合的农田避障路径规划的方法。本文通过利用 Tent 映射进行种群初始化，以及引入非线性收敛因子 α^* ，降低传统鲸鱼优化算法的振荡性以及不稳定性。通过栅格法对目标地块进行环境建模，将地块分成多个规则子地块，通过改进鲸鱼算法求解子地块最佳遍历顺序，再利用 Dijkstra 算法进行子地块之间连接最短路径，实现农田全局避障路径规划。以青岛市胶州市胶莱镇的一块矩形地块为本次研究目标地块，实验结果表明：本方法在目标地块覆盖路径实验中，地块覆盖率达到 100%，路径重复率为 4.87%，路径重复率较传统算法减少 1.63%。该研究方法适用于规则地块，对于不规则或边界为曲线的地块还存在局限性。

INTRODUCTION

Path planning is one of the key technologies for achieving autonomous navigation operations in agricultural machinery (Deng H et al., 2023). The rationality and efficiency of path planning directly impact the accuracy and quality of agricultural machinery operations. The presence of structured obstacles in fields, such as utility poles, buildings, and irrigation devices, poses a significant challenge in avoiding these obstacles and achieving comprehensive coverage in path planning for agricultural machinery navigation. For the problem of full coverage path planning in agricultural fields, there are currently two main approaches: local path planning and global path planning methods. Local path planning refers to the process of obtaining real-time information about obstacles surrounding the working path through perception sensors in situations where the field environment is unknown, with an emphasis on the safety and timeliness of the path (Chakraborty, S et al, 2022). Global path planning refers to the process of planning a global path when the environmental information of the field is known, aiming to achieve full coverage of the target area.

Currently, there is limited research on path planning for agricultural machinery both domestically and internationally. Regarding local path planning, Wang Zhen, (2023), utilized an improved ant - colony algorithm with embedded genetic operators to solve for the optimal path of virtual nodes. Taking the transportation cost and time cost of agricultural robots as the objective function, the effectiveness of the optimization model and the improved ant - colony algorithm was verified through case analysis. Li Fan, (2023), classified obstacles based on the relationship between the size of field obstacles and the working width of agricultural machinery. They proposed a method for obstacle avoidance using polyline techniques to bypass small obstacles by segmenting and merging the field. In 2023, someone proposed a method for constructing the shortest tangent obstacle avoidance path, which can quickly plan an obstacle avoidance path in the case of static obstacles (Huo Yinghui et al., 2023). For global path planning, Nilsson et al., (2020), represented the coverage trajectory of farmland as a virtual road network diagram consisting of main working area trajectories, headland passages, and turning trajectories. Finally, coverage path planning was conducted based on this diagram. Experimental results demonstrate that this method is applicable to various types of single fields; however, it is not suitable for fields with obstacles. Yakoubi et al., (2016), addressed the problem of complete coverage for cleaning robots using a genetic algorithm. They iteratively optimized the path length as the fitness function and employed genetic operators such as crossover and mutation to enhance fitness. This algorithm achieved complete coverage in simple environments; however, its drawbacks include low search efficiency in the later stages and poor convergence. Le proposed an algorithm for complete coverage path planning based on a spiral generation tree, utilizing genetic algorithms (GA) and ant colony optimization to solve the Traveling Salesman Problem (TSP). However, a notable drawback of this approach is the occurrence of dead zones in areas with a high density of obstacles. Additionally, the resulting path length and the number of turns are relatively unsatisfactory (Le et al., 2020).

In summary, regarding the path planning problem in plots with obstacles, both local path planning and full coverage paths have certain deficiencies. For example, existing local path planning methods often adopt the shortest tangent method and polyline method, where the obstacle avoidance strategies are overly simplistic, considering only a single obstacle, and lack universality in situations where multiple obstacles are present in the plot. The research on global path planning faces issues such as low algorithm efficiency, poor convergence performance, and an inability to handle areas with multiple obstacles. To address the above issues, this paper proposes a path planning method for obstacle-laden plots based on an improved whale optimization algorithm. Firstly, the target plot is modeled using a grid method. Then, the plot is segmented and merged based on the obstacles present, dividing it into multiple sub-plots that are free of obstacles. An intelligent algorithm is used to determine the traversal order of the sub-plots, while Dijkstra's algorithm is employed for path planning between the sub-plots. This ultimately achieves full coverage path planning for the entire plot.

MATERIAL AND METHODS

Construction of Operational Model

Grid Modeling of the Plot

In this study, a grid modeling method is utilized to create a representation of the target plot. This method defines the grid size based on key parameters such as the length, area, and obstacle information of the target plot, using the operational range of smart agricultural machinery as a reference. The entire environment is then divided into several square cells, referred to as grids, where each grid represents a specific area within the environment. These grids effectively capture obstacle information and clearly illustrate features of free space and other environmental characteristics, thereby simplifying the complex environmental data into a manageable set of two-dimensional grid representations (Deng et al., 2023).

The target plot is a farmland located in Jiaolai Town, Jiaozhou City, Qingdao, Shandong Province, with coordinates at 36.43°N latitude and 120.05°E longitude. The digital elevation model (DEM) data indicates that the plot has a total area of 130,040 square meters and a perimeter of 1.443 kilometers. The contour feature points of the field and the obstacles within the farmland have been marked (as shown in Figure 1). In this paper, based on the information of the target plot and the working range of the agricultural robot, a 20×20 grid model is constructed in MATLAB R2023a. The white grids represent the workable grids, the black grids represent the obstacle grids. A grid that contains obstacles but is not completely filled is defined as a partial - obstacle grid; a grid that is completely filled with obstacles is called a full - obstacle grid (as shown in Fig. 3).

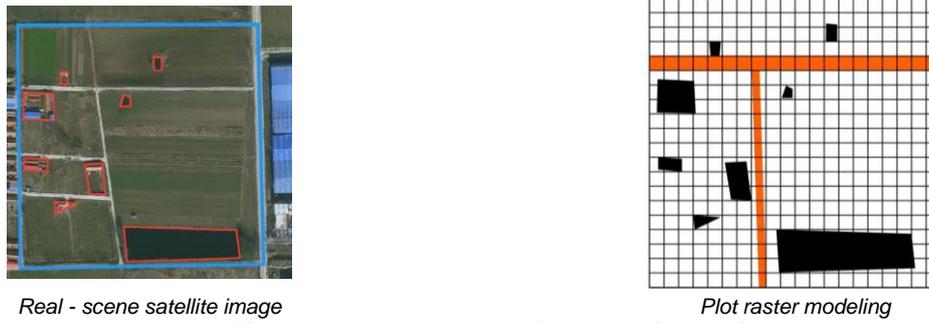

Fig. 1 – Overall structure of the cleaning device

Expansion of Obstacle Grids

Considering the varying shapes and sizes of obstacles in the field, some obstacles cannot fully occupy an entire grid cell, which increases the difficulty of algorithmic planning. Obstacles can also lead to path planning becoming trapped in local optima. Therefore, it is necessary to expand certain obstacles. When irregular obstacles do not occupy a full grid cell, their boundaries should be extended outward until the obstacles completely fill the grid cell they are in, thereby reducing the planning complexity. The specific rules for expanding obstacles are illustrated by the variations presented in Figure 2. According to these rules, the grid map in Figure 3 undergoes obstacle expansion, with the results shown in Figure 3.

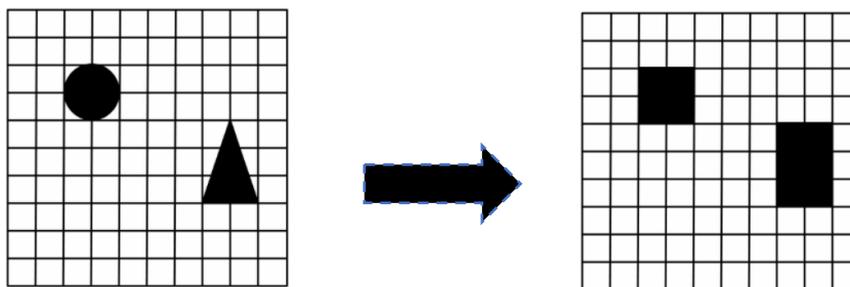

Fig. 2 – Obstacle Expansion Before and After

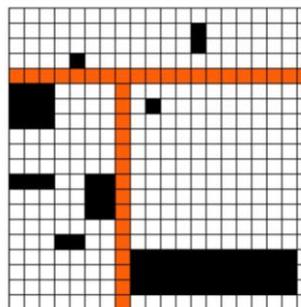

Fig. 3 – Obstacle Expansion Grid Map

Plot Division and Merging

This paper addresses obstacle avoidance path planning in farmland by partitioning the plots. The area decomposition method is employed to achieve this segmentation (*Tang et al., 2021*). Due to the presence of obstacles, the farmland is divided into multiple subplots, which can lead to an increased frequency of turns and lower coverage rates during agricultural operations. By utilizing the unit decomposition method, the farmland plots are segmented into multiple obstacle-free subplots (*Wang L. et al., 2024*).

The division of plots should be based on the grid map expanded above the obstacles. For each obstacle grid, parallel boundary lines to the X-axis and Y-axis are drawn from the two vertices at the bottom of the obstacle grid. These boundary lines extend outward until they encounter the next obstacle grid, and by repeating this process, the entire grid map can be segmented into multiple regular subplots. To reduce the operational redundancy and improve efficiency, adjacent subplots that have the same height or width should be merged to maximize the rectangular plots, thereby decreasing the number of subplots. The results of the plot division and merging are shown in Figure 4.

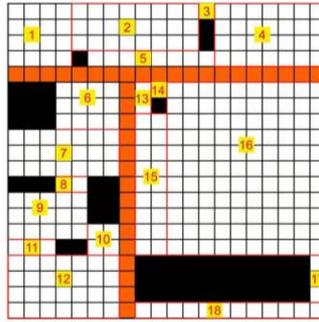

Fig. 4 – The results of the sub-plot division diagram

Sub-plot Traversal Order Planning

To achieve path planning for agricultural robots and reduce the rate of traversal duplication, it is essential to ensure that each defined sub-plot is planned exactly once in the global traversal path. This can be transformed into solving the Traveling Salesman Problem (TSP). The shortest path solution to the TSP corresponds to the optimal traversal order of the defined sub-plots. This study employs an improved whale optimization algorithm to determine the optimal traversal order among the sub-plots.

Traditional whale optimization algorithms

The whale optimization algorithm is a novel bio-inspired swarm intelligence algorithm, inspired by the foraging strategies of humpback whales (*Nadimi-Shahraki et al., 2023*). Within the framework of the whale optimization algorithm, each whale represents a feasible solution, and position updates are performed through encircling prey, bubble-net attacking, and random search.

(1) Encircling prey

In the encircling prey phase, it is assumed that the current best candidate is the target prey or an optimal solution close to the target prey (*Wei F. et al., 2023*). Once the best candidate solution is determined, all other whales will swim towards the direction of the best candidate solution, updating their positions in the process. The mathematical model for this process is as follows:

$$X(t + 1) = X_{best}(t) - A \cdot D \quad (1)$$

$$D = |C \cdot X_{best}(t) - X(t)| \quad (2)$$

In the formula, t represents the current iteration number; $X_{best}(t)$ denotes the position vector of the current best candidate solution, and $X(t)$ is the position vector of the current whale. The coefficients A and C are vector coefficients, which are calculated as follows:

$$A = 2ar - a = a(2r - 1) \quad (3)$$

$$C = 2r \quad (4)$$

$$a = 2 - \frac{2t}{T} = 2(1 - \frac{t}{T}) \quad (5)$$

In the formula, a is the convergence coefficient; r is a random vector within the range of $[0, 1]$, and T is the maximum number of iterations.

(2) Bubble Net Attack

Bubble net feeding is a unique predation behavior of humpback whales, which can be simulated using the following two mathematical models.

Constricting encirclement mechanism

The bubble net feeding technique is a unique foraging behavior of humpback whales used to capture prey, which can be simulated using the following two mathematical models.

Spiral position update

During this stage, the whales swim upstream in a spiral pattern, releasing bubble nets of varying sizes to capture prey. The mathematical model for this process is as follows:

$$X(t + 1) = D_{best} \times e^{bL} \times \cos(2\pi L) + X_{best}(t) \quad (6)$$

$$D_{best} = |X_{best}(t) - X(t)| \quad (7)$$

In this equation, D_{best} represents the distance between the current search individual and the current optimal solution; b is the spiral shape parameter; and L is a random number uniformly distributed in the range of $[-1, 1]$.

Assuming that humpback whales have an equal probability of adopting these two behaviors when attacking prey, this can be expressed using the following formula (8).

$$X(t + 1) = \begin{cases} X_{best}(t) - A, & p < 0.5 \\ D \cdot e^{bL} \cdot \cos(2\pi L) + X_{best}(t), & p \geq 0.5 \end{cases} \quad (8)$$

In the equation, P represents the probability of the predation mechanism, which is a random number within the range of $[0, 1]$.

(3) Searching for prey

To ensure that all humpback whales can thoroughly explore the solution space, they conduct random searches based on their relative positions (Yan Z. et al, 2023). When $|A| \geq 1$, the whales perform a global search, and the mathematical model is as follows:

$$D_{rand} = |C * X_{rand}(t) - X(t)| \quad (9)$$

$$X(t + 1) = X_{rand}(t) - A \cdot D \quad (10)$$

In this formula, D_{rand} represents the distance between the current search agent and a random agent, while X_{rand} denotes the position of the random agent at the current time.

Improve the whale optimization algorithm

Compared with traditional optimization algorithms and early meta-heuristic algorithms, the whale optimization algorithm has its main advantages in strong local search capability, a simple structure, and fewer required tuning parameters (Yang W. et al., 2023). However, the traditional whale optimization algorithm also faces issues such as getting easily trapped in local optima and premature convergence. Considering the advantages and disadvantages of the whale optimization algorithm, this paper aims to improve the initialization phase and the convergence factor.

(1) Improve the initialization phase

During the initialization phase, the quality of the whale population directly influences the performance of the algorithm. However, the whale optimization algorithm employs a random and uncertain strategy to generate the initial population, which fails to ensure the diversity of the population. This lack of diversity in the initial population negatively impacts the overall effectiveness of the algorithm. This paper proposes to incorporate Tent mapping into the initialization phase of the whale optimization algorithm. Tent mapping is characterized by its regularity, randomness, and strong traversability, making it an effective solution to the quality issues of the initial population in the traditional whale optimization algorithm. The Tent mapping formula is as follows:

$$X(t + 1) = \{\mu \cdot X(t), \quad 0 < X(t) < 0.5 \quad (11)$$

Assuming the initial whale population size is M , the population is represented as $X = \{X(t), 1, 2, 3, 4, \dots, M\}$. where $\mu \in (0,2)$ is the chaos parameter, and the chaotic effect is directly proportional to its value—the larger the value, the better the chaotic effect. When $\mu = 2$ the population exhibits good ergodicity and algorithmic solving speed, allowing for a more comprehensive search of a larger space within a certain range. This enables the selection of outstanding individuals from the current population as initial solutions, thereby improving the quality of the population and the performance of the algorithm.

(2) Incorporate the nonlinear convergence factor

To address the issues of the whale optimization algorithm easily falling into local optima and premature convergence, an analysis of the operational logic of three search mechanisms reveals that the efficiency of global and local search in the algorithm is determined by the magnitude of the vector coefficient $|A|$ (Chen X. et al., 2020). In the whale optimization algorithm, the convergence factor α exhibits a linearly decreasing trend. Therefore, when the number of iterations exceeds half of the maximum iteration count, $\alpha < 1$. In the iterative process, if the vector coefficient decreases prematurely to a low value, it increases the likelihood of the algorithm falling into a local optimum. To better balance the global search and local search capabilities of the algorithm, this study introduces a nonlinear convergence factor α^* , as shown in the following formula:

$$\alpha^* = 2 - \frac{2}{e^{-0.2 \cdot (t-T/2)}} \quad (12)$$

Let the maximum number of iterations be $T = 80$. The convergence factor curve is illustrated in the figure below. In the iteration data graph, during the early and mid-stages of the iteration process, the value of α^* remains at a high level to ensure the global search ability of the algorithm. In the later stages of the iteration, α^* rapidly decreases to ensure that the algorithm focuses on local search. The improved workflow of the Whale Optimization Algorithm is illustrated in Figure 6.

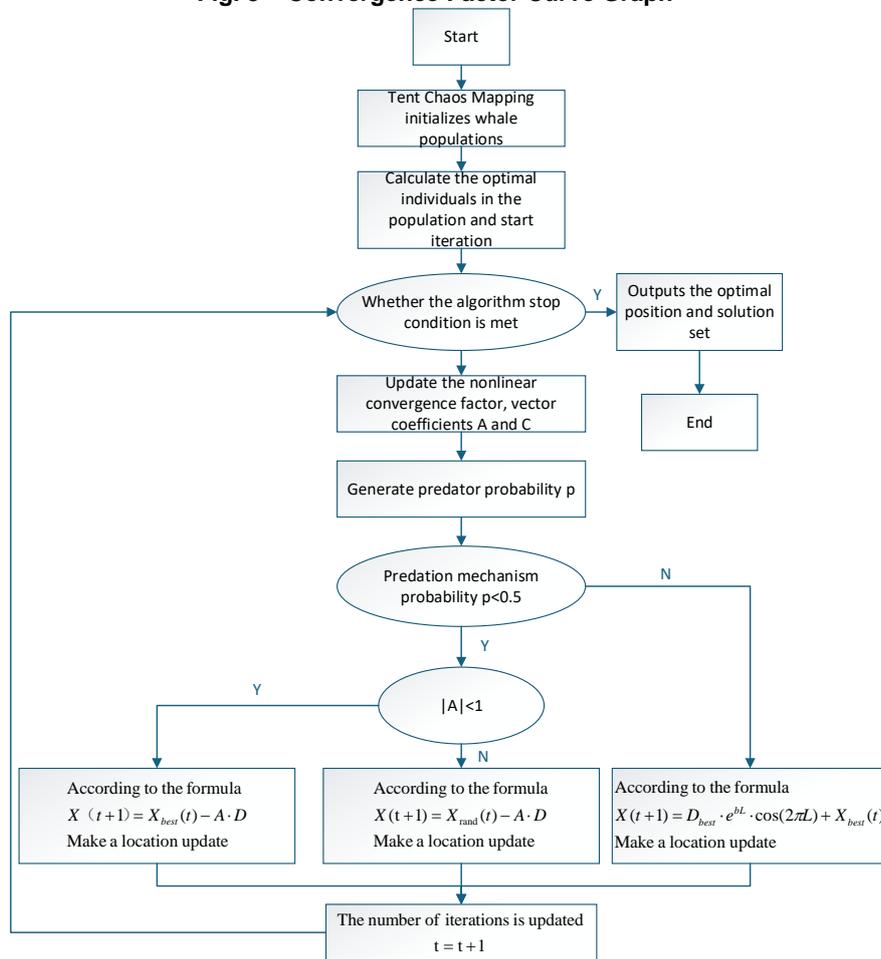

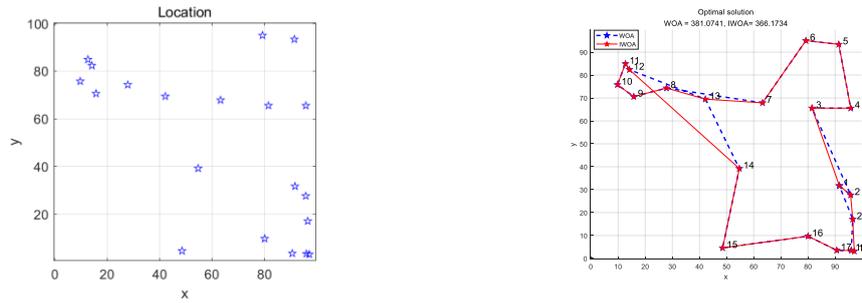

Fig. 6 – Algorithm Technical Roadmap

Improved simulation experiment of whale optimization algorithm

To demonstrate the superiority and advanced nature of the improved Whale Optimization Algorithm in solving the Traveling Salesman Problem (TSP), a comparative experimental method is employed. Both the traditional Whale Optimization Algorithm and the improved Whale Optimization Algorithm are utilized simultaneously to solve the TSP. This allows for a direct comparison of their performance and effectiveness in finding optimal or near-optimal solutions. Randomly generate coordinates for 20 cities and use the path length as the fitness value.

Figure 7a) shows the randomly generated coordinates of 20 cities, while Figure 7b) presents a comparison of the optimal traversal paths obtained using the improved whale optimization algorithm and the traditional whale optimization algorithm. This simulation was carried out in MATLAB R2023a on a Lenovo Legion Y7000 device.

a) Location
b) Traversal Path Comparison
Fig. 7 –Results of WOA and IWOA in Solving the TSP Problem

From Figure 7, it can be observed that the best fitness values for the Whale Optimization Algorithm (WOA) and the Improved Whale Optimization Algorithm (IWOA) are 381.0741 and 366.1734, respectively, indicating a reduction in fitness of approximately 3.9%. Based on the simulation results, it is evident that the solution obtained using the improved whale optimization algorithm for solving the Traveling Salesman Problem (TSP) with respect to the traversal order is significantly better than the results obtained using the traditional whale optimization algorithm.

Determine the optimal traversal order of the target sub-block

After validating the superiority of the improved whale optimization algorithm in addressing the traveling salesman problem, it is necessary to apply the improved whale optimization algorithm to the path planning for complete coverage of target plots. Based on the results of subplot division shown in Figure 4, for the convenience of planning the traversal order of regular subplots, the center coordinates of regular subplots will represent each subplot, and coordinate parameters will be used to indicate the specific locations of the subplots. Input the coordinates of the central points for each subplot; determine the optimal traversal order among the 18 subplots. The optimal traversal order between the target subplots is determined using both the traditional whale optimization algorithm and the improved whale optimization algorithm. The results are shown in the figure 8.

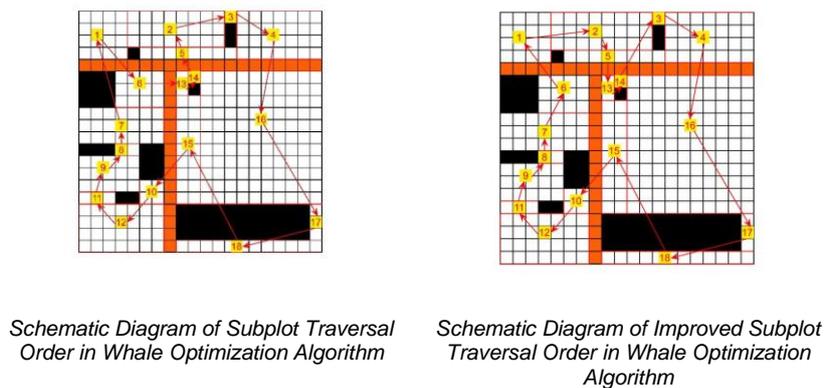

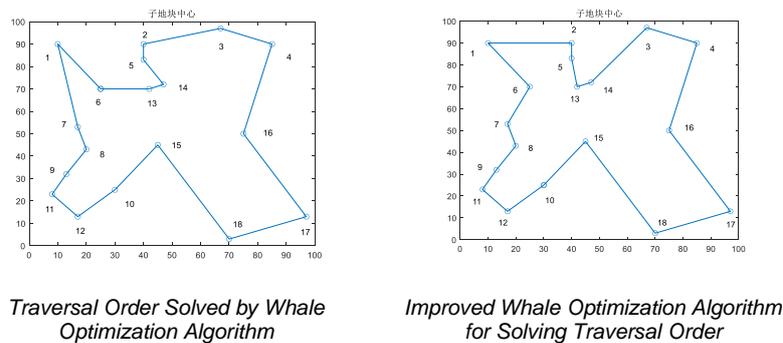

Fig. 8 –Comparison of traversal order results of subplots

Table 1

Comparison of traversal results from different algorithms		
The name of the algorithm	Traversal order	Fitness value
WOA	6-13-14-5-2-3-4-16-17-18-15-10-12-11-9-8-7-1-6	403
IWOA	16-17-18-15-10-12-11-9-8-7-6-1-2-5-13-14-3-4-16	401

According to the observations from Figure 8 and Table 1, the optimal traversal order obtained by the traditional whale optimization algorithm for the subplots is: 6-13-14-5-2-3-4-16-17-18-15-10-12-11-9-8-7-1-6, with a shortest distance of 403 meters. In contrast, the optimal traversal sequence derived from the improved whale optimization algorithm is: 16-17-18-15-10-12-11-9-8-7-6-1-2-5-13-14-3-4-16, resulting in a shortest distance of 401 meters.

Path Planning within Agricultural Subplots

Based on the grid layouts and the presence of obstacles, the plots are divided into multiple regular subplots that are free of obstacles. While irregular subplot structures are simpler, effective path planning for the regular subplots requires selecting appropriate agricultural machinery operating methods to achieve optimal results. Currently, the primary coverage methods for operations in regular plots include reciprocating and inward spiral traversal techniques, as shown in Figure 9. The objective of path planning is to enhance operational efficiency, reduce cost waste, and minimize issues such as re-tilling and missed tilling.

The inward spiral traversal method for path planning typically involves frequent turns, making it inconvenient to connect with adjacent subplots. This can lead to increased energy consumption and reduced operational efficiency. Therefore, this study opts for the reciprocating method for path planning of the subplots to enhance land utilization and reduce occurrences of re-tilling and missed tilling. The specific steps for reciprocating traversal are as follows: (1) Choose a starting point and set the coordinates of the starting point as (x_0, y_0) ; (2) Define the two edges of the rectangular plot as A and B ; (3) Determine the lengths of edges A and B , using the longer edge as the starting edge, with edge A aligned along the X-axis and edge B along the Y-axis. (4) If edge A is longer, the coordinates of the next point will be $(x_0 + 1, y_0)$. (5) If edge B is longer, the coordinates of the next point will be $(x_0, y_0 + 1)$.

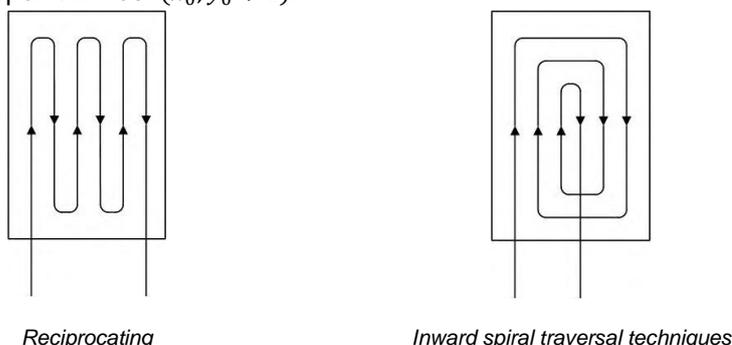

Fig. 9 – Coverage-Based Path Planning Method for Regular Plots

Subplot Connectivity Path Planning

After dividing the land into multiple subplots, agricultural robots complete traversal tasks within a single subplot area. They need to move from the current rectangular subplot to the next subplot based on the sequence of all subplots. In the path planning for connecting these two subplots, this study employs Dijkstra's algorithm for shortest path planning to reduce the redundancy of traversal paths and improve overall efficiency. The specific operational steps for using Dijkstra's algorithm for shortest path planning between points are as follows: First, read the data, set the source point a and the target point b , then mark the source point a and set $d_a = 0$, with $p_b = 0$; Subsequently, examine the distances between all marked points k and unmarked points h , and update $d_k = [d_k, d_k + m_{kh}]$. Here, m_{kh} represents the distance between points k and h . Select the unmarked point i with the smallest d_h , then find the point h^* among the marked points that is directly connected to i , and set $i = h^*$, followed by marking i . Continue this process in a loop until all points are marked. The algorithm can accurately generate the optimal path between two points, specifically achieving the shortest path from the starting point to the target point for agricultural robots.

RESULTS

Simulation of Path Planning for the Entire Agricultural Plot

All the experiments presented in this paper were conducted on a dedicated server operating under the Windows 11 system. The server is powered by an Intel(R) Core(TM) i5 - 9300H CPU, featuring a base clock frequency of 2.40 GHz and paired with 16 GB of RAM. For graphics processing, an NVIDIA GeForce RTX 4060 graphics card with 6 GB of video memory was employed. The programming and simulation tasks were accomplished using MATLAB R2023a as the development language.

In the previous sections, the traversal order between the target plot and its subplots has been determined using both the traditional whale optimization algorithm and the improved whale optimization algorithm. The starting point is determined within the initial plot, and a reciprocating planning approach is employed for the subplots of the initial plot. Subsequently, the next working area is accessed from the current regular subplot. The shortest path planning is performed using the aforementioned Dijkstra algorithm, facilitating the determination of the shortest, collision-free walking path from the traversal endpoint of the previous regular plot to the traversal starting point of the next regular plot. This process is repeated in a loop, ultimately achieving a complete coverage path planning for the entire farmland plot. The final results are compared as shown in the figure10.

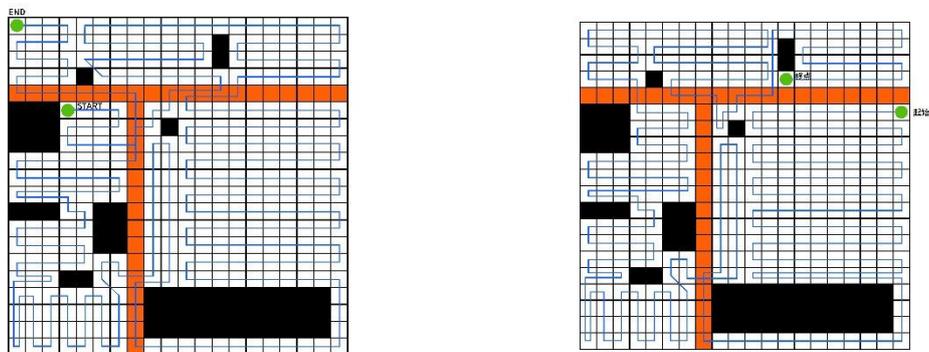

Diagram of Traditional Whale Optimization Algorithm for Path Planning

Diagram of Improved Whale Optimization Algorithm for Path Planning

Fig. 10 – Path Planning Comparison Diagram

Table 2

Comparison Diagram of Path Planning		
Path Planning Methods	Number of Covered Grids	Number of Duplicate Grids
Traditional Whale Optimization Algorithm and Dijkstra Algorithm	308	20
Improved Whale Optimization Algorithm and Dijkstra Algorithm	308	15

According to the observations from Figure 10 and Table 2, the entire grid consists of 20x20 cells, where black obstacles occupy 57 cells and roads occupy 35 cells, resulting in 308 free cells. The comparison shows that both algorithms achieve a coverage rate of 100%. Among them, the traditional whale optimization algorithm traverses 20 repeated cells, resulting in a traversal path redundancy rate of 6.5% and a path length of 4920 m. In contrast, the improved whale optimization algorithm traverses 15 repeated cells, achieving a traversal path redundancy rate of 4.87% and a path length of 4845 m. With the same coverage rate, the improved whale optimization algorithm reduces the path redundancy rate by 1.63% compared to the traditional algorithm. The experimental results indicate that the proposed method can effectively reduce path length, thereby validating the effectiveness of the research approach presented in this paper.

CONCLUSIONS

(1) This study proposes a stepwise path planning method for the entire agricultural plot area, which integrates an improved whale optimization algorithm with Dijkstra's algorithm. The method first employs the improved whale optimization algorithm to plan the traversal order of the segmented subplots, in order to determine the optimal traversal sequence for the subplots.

(2) To address the issues of local optimum entrapment and premature convergence commonly associated with the traditional whale optimization algorithm, this study utilizes Tent mapping for population initialization and introduces a nonlinear convergence factor. This approach balances the algorithm's global and local search capabilities, effectively mitigating local optima and significantly reducing search time. Experimental results using MATLAB indicate that, with 18 subplots, the improved whale optimization algorithm achieves a 4.07% reduction in average shortest path length and a 74.28% reduction in average iteration count compared to the traditional whale optimization algorithm.

(3) Using the path planning algorithm proposed in this study for full coverage of the target plots, MATLAB experiments reveal that the coverage rate of the paths generated by the improved whale optimization algorithm is 100%, with a repetition rate of 4.87%. This represents a reduction of 1.63% in repetition rate compared to the traditional whale optimization algorithm, thereby validating the effectiveness of the proposed method.

Keywords: *pyrolyzer, biochar, organic waste, carbon capture*

ABSTRACT

The three high-valuable products generated by the pyrolysis process are the biochar, the syngas, and the pyrolysis oil. The proportions of these products are influenced by several factors such as temperature, heating rate, and feedstock type. This research aimed to develop an innovative and improved pyrolysis reactor design, that can enhance both the quality and yield of biochar produced in thermochemical processes. The main objective was to enable the rapid conversion of various organic wastes, such as agricultural byproducts, wood chips, and other plant-based materials, into high-quality biochar. The experimental pyrolyzer model was designed with precise temperature control to optimize biochar properties and an intelligent process control system, which minimize emissions and maximize energy efficiency. This equipment not only contributes to sustainable waste management but also supports soil improvement by enhancing soil fertility and carbon sequestration in agricultural practices. The experimental results showed a high efficiency in obtaining a quality biochar within a short production time. Additionally, the biochar exhibited a water retention potential of up to 150% relative to the pre-treated biomass mass, while the energy consumption was estimated to be up to 15% lower compared to conventional methods.

REZUMAT

Cele trei produse de mare valoare generate de procesul de piroliză sunt biocharul, gazul de sinteză și uleiul de piroliză. Proporțiile acestor produse sunt influențate de mai mulți factori, cum ar fi temperatura, viteza de încălzire și tipul de materie primă. Prezenta cercetare a avut ca scop dezvoltarea unui proiect inovator de reactor de piroliză îmbunătățit, care poate îmbunătăți atât calitatea, cât și randamentul biocharului generat în procesele termochimice. Obiectivul principal a fost acela de a permite conversia rapidă a diferitelor deșeuri organice, cum ar fi produse secundare agricole, așchii de lemn și alte materiale pe bază de plante, în biochar de înaltă calitate. Modelul experimental de pirolizator este proiectat cu un control precis al temperaturii pentru a optimiza proprietățile biocharului și un sistem inteligent de control al procesului, care minimizează emisiile și maximizează eficiența energetică. Acest echipament nu numai că contribuie la gestionarea durabilă a deșeurilor, dar oferă și o îmbunătățire a solului, îmbunătățind fertilitatea solului și captarea carbonului în practicile agricole. Rezultatele experimentale au arătat o eficiență ridicată în obținerea unui biochar de calitate, într-un timp scurt de producție. Rezultatele experimentale au arătat o eficiență ridicată în obținerea unui biochar de calitate, cu un potențial de înmagazinare a apei de pana la 150% raportat la masa de tulpina înainte de tratare și un consum de energie estimat cu pana la 15% mai mic.

INTRODUCTION

Pyrolysis is a thermochemical process. It allows a controlled combustion of biomass in an oxygen-limited environment, generating both thermal energy and sterilized biochar (Amalina et al. 2023; Nenciu et al., 2024). Usually, upon completion of the thermochemical process, a significant amount of fixed carbon results in the form of biochar (between 10-20% of the initial mass), which can be used as an agricultural amendment. The gases generated during the process can be used to produce the thermal energy necessary to heat protected spaces or fruit dryers.

The industrial pyrolysis process offers a competitive alternative for the exploitation of numerous renewable energy sources, but also for the treatment and energy recovery of municipal, industrial or medical waste from various polluting industrial branches. The pyrolysis process is considered the most environmentally friendly thermochemical process, compared to combustion and incineration processes, because it has low emissions (Farag et al., 2024).

Biochar is an organic product resulting from the pyrolysis process of plant materials such as sawdust, straw or other agricultural waste. A common example of the use of pyrolysis is the conversion of plastic waste or biomass into liquid or gaseous fuels that can be used in various industrial or energy applications (Tomczyk et al., 2020; Wang et al., 2021). This process takes place at high temperatures, usually between 300 and 700 degrees Celsius, in an oxygen-limited environment (Amalina et al., 2022; Sun et al., 2017; Buss W, 2021). The resulting biochar has a porous structure and is considered a valuable soil amendment (Salma et al., 2024). Biochar contains approximately 98% carbon, which gives it chemical stability and the ability to retain nutrients in the soil. This composition makes it an effective amendment for improving soil quality (Woolf et al., 2010; Yang et al., 2021; El-Naggar et al., 2019).

The role of Biochar is to maintain moisture and stimulate beneficial microorganisms in the soil. These microorganisms are essential for plant health, as they contribute to the decomposition of organic matter and the availability of nutrients (Nidheesh et al., 2021). Among the most used materials are wood waste (Ahmad et al., 2017), agricultural residues (Zhang et al., 2022, Voicea et al., 2024), vegetable waste, manure (Wang et al., 2021; Jang et al., 2022; Nenciu et al. 2023), or industrial waste. Each of these raw materials has different characteristics that influence the final quality of the biochar produced. For example, the chemical composition and physical structure of biomass will determine the levels of fixed carbon and its ability to retain nutrients and water in the soil (Feng et al., 2021; Issaka et al., 2022; Oprescu et al. 2022).

The use of these raw materials not only helps create a valuable product such as biochar, but also contributes to the sustainable management of natural resources by recycling organic materials that might otherwise end up in landfills (Neogi et al., 2022; Voicea et al., 2024). The versatility of biochar highlights high potential in various industries, from agriculture and water treatment to animal husbandry. In a context where economic and commercial factors influence market dynamics, continuous innovation and research are essential to keep the biochar industry at the forefront of technological progress (Nenciu et al., 2024; Popescu et al., 2022).

Biochar has a complex porous network, which facilitates water absorption and retention, the size and distribution of the pores influence the water storage capacity, allowing it to retain moisture in the soil. It has many benefits such as: improving soil fertility (helps maintain moisture, which is essential for plant growth), reducing irrigation needs (by retaining water, biochar can reduce the frequency and amount of water needed for irrigation), stabilizing nutrients (preventing nutrient loss through leaching, thus maintaining a favorable environment for plants). Factors that influence the water storage potential are: the type of biomass used, pyrolysis conditions and interaction with the soil (Liu et al., 2015; Lone et al., 2015).

The objective of this work was to realize an improved design of a reactor for increasing the quality of biochar used in agricultural activities. After designing and building an Experimental Model of the equipment, it was tested for the treatment of plant waste from hemp and bamboo crops, in order to highlight the qualities of the obtained biochar and analyze the energy consumption.

MATERIAL AND METHODS

Experimental model design, customized for the pyrolysis of lignocellulosic biomass

This paper introduces an Experimental biochar production equipment designed and produced by the National Institute of Research - Development for Machines and Installations Designed for Agriculture and Food Industry - INMA Bucharest (Romania), distinguished by a series of innovative constructive elements. These advancements include enhancements in thermal efficiency, precise temperature control systems, and optimized batch management processes, all aimed at improving the quality and consistency of the resulting biochar. The equipment leverages smart control technologies for real-time monitoring and adjustment of critical parameters. This experimental setup is presented in figure 1.

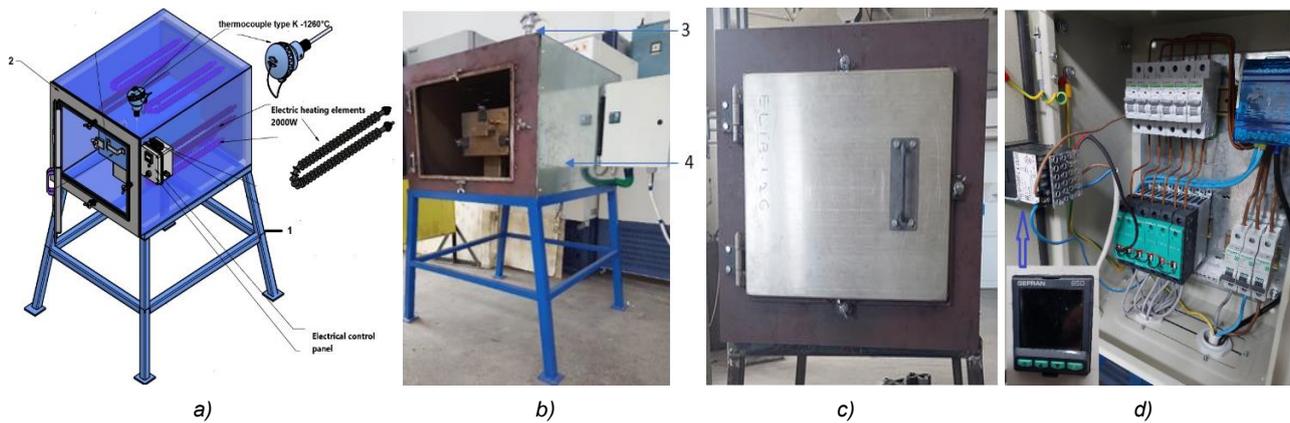

Fig. 1 – Experimental model for biochar production-general assembly

a) experimental model for biochar production; b) retort; c) equipment case; d) electrical control panel

The experimental model (figure 1-a) is customized for processing vegetable waste, consisting of a support (1) that supports a housing (2) with the actuation and control elements. This equipment features an automated system for managing the thermal process within a low-oxygen environment. The system incorporates an advanced electrical control panel (figure 1 d) that precisely regulates the combustion process, significantly reducing the time required to produce the biochar. To further enhance efficiency, the design allows for rapid replacement of the retort after each batch. By utilizing the residual high temperature within the enclosure from the initial production cycle, the new retort minimize downtime between batches. The casing (figure 1-c) is made of two galvanized tanks, suitable for corrosive industrial environments. The two casings are mounted concentrically and are insulated from each other with a ceramic fiber resistant to very high temperatures (up to 1260°C), in order to eliminate thermal energy losses. On the casing bottom and ceiling there are six electric resistances mounted around the retort (2000 W each). An overpressure valve and a high temperature thermocouple (3) are also mounted on the casing. The working temperatures are 300-500 °C for straw and other vegetable residues and 600 °C for forestry residues. The retort, illustrated in figure 2 (a), is constructed from high-temperature-resistant stainless steel (17 255 CSN, AISI 310). This material ensures durability and performance under intense thermal conditions. The retort is equipped with a discharge opening, featuring a frame (figure 2 -b) that supports three eye bolts (figure 2 -a) for securely attaching the biochar lid. For ease of handling and transportation, a handle is mounted on both the upper casing and the lid. With a capacity of 19 liters, the retort is designed to accommodate significant quantities of raw material, enhancing batch efficiency and overall productivity. The electrical resistances are presented in figure 2 b, c.

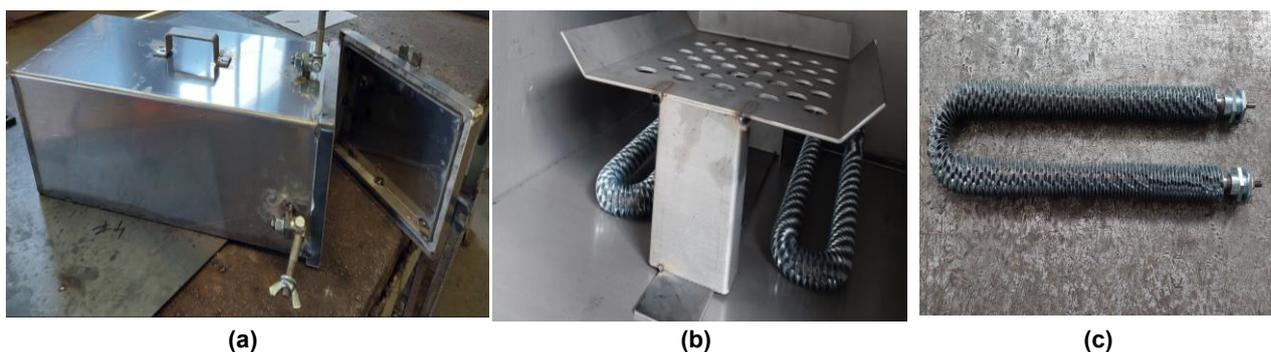

Fig. 2 - Heat treatment of organic material using a retort and electrical resistance

The present experiment evaluated hemp and bamboo stems. Their high lignocellulosic content makes them well-suited for this process, yielding porous biochar with excellent water retention properties. Hemp and bamboo are fast-growing and renewable resources that may serve as sustainable feedstocks for biochar production. The stems were harvested in August, being sectioned at 1 meter in length and stored in a dry room, as can be seen in figure 3.

Fig. 3 - Hemp and bamboo stems harvested for pyrolysis processing operations
(a) Hemp stalks and (b) bamboo stems

The stem pre-processing involved cutting the plants to a maximum length of 7 cm using a circular saw. The average moisture content of the bamboo and hemp was then determined using the oven-drying method. In this process, a sample was weighed (Figure 4a and b), dried in an oven at 105°C for 24 hours (Figure 4c), cooled in a desiccator, and then reweighed.

Fig. 4 - Raw material processing
a) hemp; b) bamboo; c) drying of the raw material

Thermochemical processing method of plant materials using pyrolysis

The processing method involves opening the upper lid of the retort and loading the shredded raw material, which was shredded to a length of approximately 7 cm, for a faster processing. Once the material is loaded, the electric resistance is activated in order to initiate heating. The thermic process begins for a period that varies depending on the granulation and moisture content of the raw material, typically ranging from 30 to 120 minutes. This approach ensures efficient pyrolysis tailored to the characteristics of the raw input material. To prevent biochar oxidation, the retort was cooled by immersion in cold water for 30 minutes, then extracted and temporarily stored in a desiccator to maintain its stability until further experimental analysis.

Assessing the Water Retention Capacity of Biochar

Biochar derived from different biomass sources exhibits varying water retention properties. To evaluate these characteristics, the water storage capacity of biochar produced from bamboo and hemp was analyzed. The biochar samples were placed in a vessel, weighed (Fig.5), and then immersed in water for 2 minutes. After this interval, the excess water was drained, and the samples were weighed again. This procedure was repeated five times to ensure accuracy, for 24 hours. This approach provided a comprehensive understanding of the water retention capabilities of biochar over different timeframes.

Fig. 5 - Different phases during the experiments to evaluate the water storage potential in biochar

In order to determine the dry biochar density, a 1000 ml vessel was filled with bamboo biochar and then weighed. This process was repeated 10 times for each type of material to ensure accuracy and account for potential variations in particle arrangement and compaction. The average values were then calculated to provide a more reliable density measurement, using equation (1).

$$\rho = \frac{m}{v} \tag{1}$$

where ρ is the density (kg/L), m is the biochar mass (Kg) and v is the biochar volume (L)

RESULTS

Given that the moisture content of hemp and bamboo varies along the stem length, three representative sections were analyzed for each feedstock: the lower, middle, and upper parts of the stem. Table 1 presents the moisture content of bamboo and hemp stems, from different plant parts, after being stored for three months following harvest.

Table 1

Plant part	Stem moisture average content %	
	Bamboo plant	Hemp plant
Lower part of the stem	17	21
Middle part of the stem	18	23
Upper part of the stem	15	22

The temperature during the pyrolysis process was carefully adjusted to minimize the loss of organic matter through gasification. This controlled approach aimed to optimize the conversion efficiency, ensuring a higher yield of biochar while preserving key carbon fractions. Figure 6 illustrates the temperature increase rate during the experiment, using the pyrolysis experimental model. This evaluation was particularly useful for equipment calibration when using organic materials that present different densities.

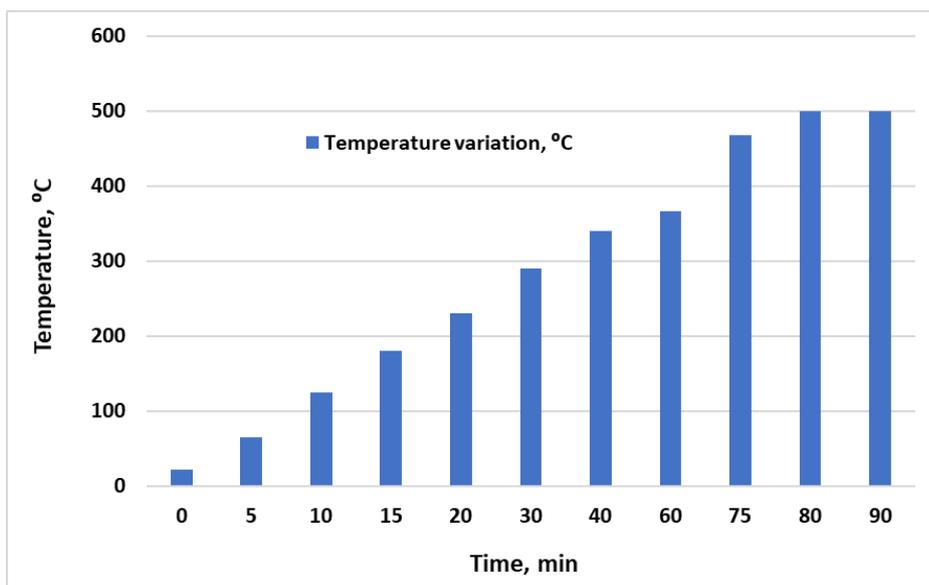

Fig. 6 - Temperature variation over time during pyrolysis equipment operation

The evaluation of biochar density after the completion of the process revealed a density for bamboo biochar of 0.2315 kg/L, while the density of hemp biochar was 0.0985 kg/L.

The cooled biochar was then weighed to evaluate the loss of material through gasification of organic material. It can be observed that the biochar obtained from bamboo lost 68.89% of its weight and the biochar obtained from hemp lost 81.96% of its weight. Hemp and bamboo stems were selected due to the shape of the stem, which has an inner hole that has a larger contact surface and allows a faster absorption of water (table 2).

Table 2

Feedstocks mass variation induced by the biochar production process

No.	Feedstocks for biochar production	Unprocessed material (kg)	Processed material (biochar) (kg)	Difference (%)
1	Bamboo biochar	0.8045	0.2503	68.89
2	Hemp biochar	0.4496	0.0811	81.96

Energy consumption per unit of time

In 1.4 hours needed to fully process the stems through pyrolysis, energy consumption reached 16.8 kWh. Based on average energy costs in Romania, this corresponds to approximately 4.1 EUR per batch. However, due to differences in plant density, the biochar yield per batch was 0.400 kg for hemp and 0.900 kg for bamboo.

Daily Productivity Calculation of Equipment

Considering that the equipment is fitted with two retorts (allowing for continuous operation without interruptions), the maximum productivity per hour is 0.29 kg/h for hemp and 0.64 kg/h for bamboo. Over an 8-hour workday, the total output reaches 2.29 kg for hemp and 5.12 kg for bamboo. Figure 7 illustrates the water storage capacity of the biochar mass, after it was immersed in water for 24 hours. The aim of the experiment was to evaluate the maximum water storage capacity within the biochar structure, simulating moisture retention in the soil.

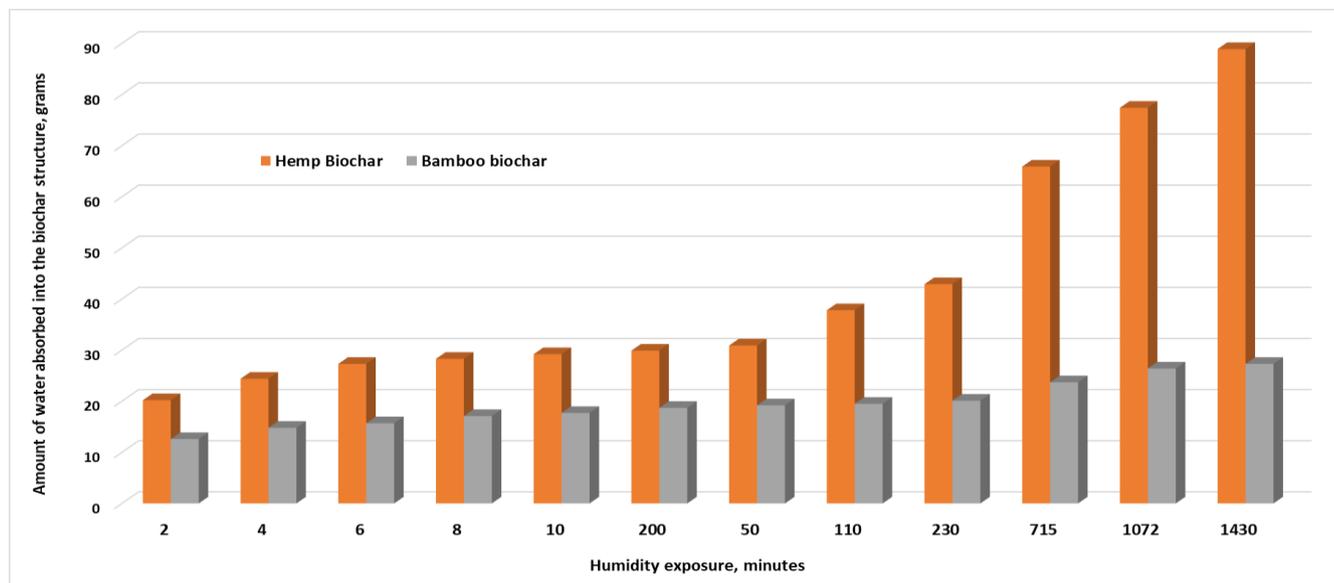

Fig. 7 - Water storage potential in biochar depending on water soaking time

Table 3 shows the water storage potential over time, the bamboo biochar stored a quantity of 27.3 grams in the 1430 min, that is 47.80%, and the hemp biochar stored a quantity of 88.9 grams, that is 150.17%.

An important indicator to consider is the percentage of water that each type of heat-treated material can retain relative to its own mass.

The stem fiber used to produce the biochar was found to play a crucial role in water storage capacity. Table 3 presents the water storage rate relative to the initial mass of each experimental plant. This analysis helps identify which structure offers the most effective storage solution.

Table 3

Water storage rate relative to the initial plant-mass

No.	Biochar type	Dry mass of biochar (gram)	Water storage potential as a percentage of biochar dry mass (%)									
			2 min	4 min	6 min	8 min	10 min	20 min	50 min	110 min	230 min	1430 min
1	Bamboo biochar	132.6	34.12	41.22	46.11	47.80	49.32	50.51	52.20	63.85	72.47	150.17
2	Hemp biochar	59.2	10.86	13.11	14.68	15.22	15.70	16.08	16.61	20.32	23.06	47.80

Discussions

Following the process of pyrolysis the material in the retort for biochar production, a significant difference was observed in the weight losses of the materials used. After cooling the biochar obtained from bamboo, it showed a weight loss of 68.89%, indicating that a considerable proportion of the original material was transformed into gases and vapors during the pyrolysis process. On the other hand, the biochar obtained from hemp had an even higher loss of 81.96%, thus suggesting that the gasification process was more pronounced for the latter. These results underline not only the efficiency of different biomasses in biochar generation, but also their high potential in the context of biochar production from organic waste. Analyzing these processes can provide valuable information for the optimization of biochar production and the efficient use of available resources.

Hemp biochar demonstrated a significantly higher water storage capacity compared to the bamboo biochar, having a better water storing potential (150.17% calculated in relation to the initial processed mass). These results suggest that hemp biochar could be more effective in improving soil water retention, which could be beneficial for agriculture, especially in arid conditions.

CONCLUSIONS

- The equipment allows a very fine adjustment of the temperatures, depending on the vegetable material, in order to customize the pyrolysis processes according to the structure of the vegetable waste. Thus, pyrolysis is improved for treating a variety of vegetable materials, keeping the high characteristics of biochar and avoiding overheating.

- The equipment consumes little energy compared to other equipment. On the one hand, this energy saving results from the advanced temperature regulation system (PLC and sensors) and on the other hand, due to the very good insulation of the thermal chamber-reactor. The circular arrangement of the electrical resistances also helps in efficient heating of the material.

- The retort type system helps to maintain a larger amount of biochar in the solid phase at the expense of gases and oils. Therefore, it is a better constructive design for the management of vegetable waste, for the purpose of use in agriculture. Constructive variants that maximize biogas and oils are more efficient for energy and industrial applications, but the proposed objective was to obtain a larger amount of biochar.

- All the adjustment of the equipment manages to increase the porosity, so that the biochar managed to store up to 150% water for bamboo (relative to the mass of the stem before treatment) and 47% water for hemp.

- The reduction in mass by 68.89% for bamboo stalks and 81.96% for hemp stalks is important because it reduces the costs of transporting the biochar from the farm to the agricultural land where it is applied.

- *The obtained biochar offers multiple benefits in agriculture and for the environment, such as:*

- Improving soil fertility: Biochar can retain nutrients and water in the soil, which improves soil fertility. It can also reduce nutrient loss through runoff.

- Reduction of carbon emissions: The production process of biochar involves the capture and storage of carbon from organic materials, due to its chemical stability, biochar can store long-term carbon in the soil.

- Improving soil structure: Biochar can improve soil structure, favoring the development of plant roots and improving its drainage.

- Remediation of degraded soils: Biochar can be used to remediate degraded soils, such as those that are saline or those affected by pollution.

- Promoting sustainability in agriculture: The use of biochar in agricultural practices can contribute to greater sustainability of agricultural systems, reducing reliance on chemical fertilizers and pesticides.

- Improving water retention: Biochar has the ability to retain water in the soil, which can be beneficial in water-scarce areas or during periods of drought. Adding biochar to sandy soils reduces irrigation requirements by up to 40%.
- Reduction of greenhouse gas emissions: By sequestering carbon in the soil and reducing methane and nitrous oxide emissions, biochar can help reduce greenhouse gas emissions from the soil.
- Improved plant health: Soils treated with biochar can support healthier crops that are more resistant to diseases and pests.

ACKNOWLEDGEMENT

This work was funded by the Ministry of Research, Innovation and Digitalization, within the NUCLEU Program, through Project 9N/ 01.01.2023 "Technology for valorization of plant residues in the form of biochar for improving soil quality" and by the Ministry of Agriculture and Rural Development (MADR), ADER Program - Contract ADER 25.3.1/20.07.2023 "Technology for valorization of poultry manure by obtaining biofertilizers rich in phosphorus".

DOI: <https://doi.org/10.35633/inmateh-75-36>**Keywords:** *Robotic arm, Picking claw, Blade length, Simulation, Morel***ABSTRACT**

To address the challenges of high labour intensity and expensive manpower in morel harvesting, a specialized morel picking machine was designed. It is capable of performing the tasks of grasping, cutting, and collecting morels. A three-degree-of-freedom robotic arm was incorporated to ensure precise positioning of the picking claw. The kinematic model of this arm was established to determine the operational radius for effective picking. A three-finger picking claw was developed, with the synchronous opening and closing of the three fingers through a wire-pulling mechanism and a four-bar linkage. Buffer elastic material was installed on the picking fingers, and cutting blades were placed at the fingertips. Simulation analyses were conducted to study the movement of the robotic arm's end, the forces acted on the picking arm, the hinge between the upper and lower arms, and the hinge at the lower arm's end, as well as the velocity of the picking claw's end. Single-factor experiments were employed to investigate the effects of the blade length of the picking finger on the picking success rate, the damage rate of mature morels, and the damage rate of immature morels. The results demonstrated that with a blade length set at 15mm, the picking success rate reached 96.2%, while the damage rates of mature and immature morels were 8.6% and 6.8%, respectively. These findings indicate that the machine can effectively meet the operational requirements for morel picking.

摘要

为解决羊肚菌采摘劳动强度大、人工成本高的问题,设计了一种羊肚菌采摘机,可以完成抓取、切断、收集作业。采用三自由度机械臂实现采摘爪的精确定位,建立了机械臂的运动学模型,确定了采摘作业半径。设计了三指结构采摘爪,通过拉线驱动与四杆机构实现三指同时闭合和松开。采摘手指上安装缓冲弹性材料,末端装有切割刀片。对机械臂末端运动、机械臂受力、大臂与小臂铰链处作用力、小臂末端铰链处作用力、采摘爪末端速度进行了仿真分析。通过单因素试验,研究了采摘手指刀片长度对采摘成功率、羊肚菌损伤率、未成熟羊肚菌损伤率的影响。结果表明,当刀片长度为15mm时,采摘成功率为96.2%,采摘损伤率为8.6%,未成熟羊肚菌损伤率为6.8%,基本满足羊肚菌采摘的作业要求。

INTRODUCTION

Morel mushrooms are rich in nutrients and trace elements, and are widely cultivated in China (Huang *et al.*, 2022; Liu *et al.*, 2017; Zhao *et al.*, 2009). Due to the unique growth environment of morels, their fragile texture, and significant variations in individual morphology, traditional manual harvesting methods are labour-intensive and inefficient (Huang *et al.*, 2023). As labour costs rise and the demand for high-quality picking increases, developing equipment that is suitable for the characteristics of morels is crucial for enhancing the economic benefits of the morel industry and increasing farmers' incomes.

Currently, numerous studies focus on the end effectors and grasping mechanisms of fruit and vegetable picking machinery; however, there are relatively few reports on morel picking machinery (Li *et al.*, 2014; Safeea *et al.*, 2019; Wang *et al.*, 2016; Gu *et al.*, 2012; Ding *et al.*, 2013). Yang developed a mushroom picking machine that achieved autonomous movement and stopping through a mobile platform. This machine collected mushroom data using a visual system and controlled the actuator to pick and load the mushrooms (Yang, 2020). Zhang investigated a portabella picking robot, which features a mobile lifting platform, adjustable guide rails, picking arms, flexible picking claws, as well as a visual recognition and positioning system, along with a measurement and control system (Zhang, 2019). Wang studied a morel harvesting machine that consists of a storage box, an air tube, a cutting device, and a blower fan. After the stem of the morel is cut off, it is sucked into the box.

Although the machine has a simple structure and high picking efficiency, it is prone to damaging the morels, and the fan consumes a significant amount of energy (Wang *et al.*, 2021). Wang developed a morel harvesting device that includes a sleeve and two blades. Through the interaction of the blades, the morels can be extracted from the soil, while the soil attached to the morels is expelled through holes in the blades (Wang, 2021). Yu designed a morel harvesting tool featuring scissors mounted on a support frame. The scissors are operated by an electric push rod, and a conveyor belt transports the morels into a receiving bucket (Yu, 2022). Additionally, Wang created a morel picking device equipped with a cylindrical component and a blade, with the blade affixed to the bottom of the cylindrical component and operated by a handle (Wang, 2019).

In this paper, to address the challenges of high labour intensity, susceptibility to damage, and high labour costs associated with morel harvesting, a morel picking machine that performs the functions of grasping, cutting, and collecting morels was designed. This machine not only ensures efficient harvesting operations but also effectively minimizes damage to the morels.

MATERIALS AND METHODS

Structure of the machine

Figure 1 illustrates the overall structure of the morel picking machine. It primarily consists of driving wheels, driven wheels, a mobile platform, a robotic arm rotation mechanism, an upper arm, a lower arm, electric push rods, and a picking claw, among other components. The mobile platform is powered by two DC motors, which allow the machine to move forward and backward during operation. The robotic arm is designed to achieve precise positioning of the picking claw, thereby facilitating the actions of picking, conveying, and collecting.

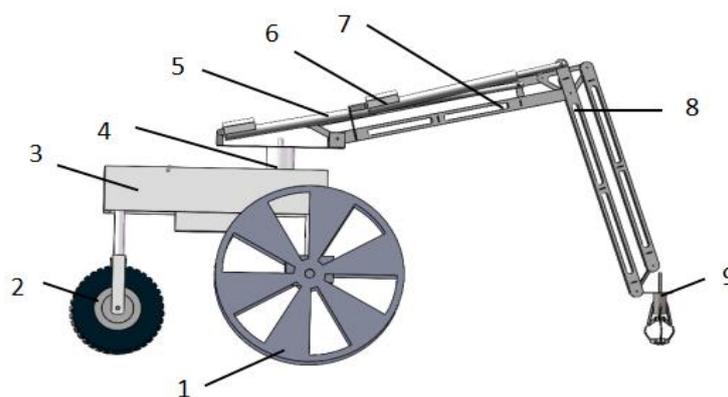

Fig. 1 - Schematic of the morel picking machine

1-driving wheels; 2-driven wheels; 3-mobile platform; 4-robotic arm rotation mechanism; 5-electric push rod for upper arm; 6- electric push rod for lower arm; 7- upper arm; 8- lower arm; 9- picking claw

Working principle of the machine

The machine is operated using a manual remote control. Once the machine is positioned for work, the rotating mechanism of the robotic arm is activated. The electric push rods of both the upper and lower arms facilitate the rotation of the arms, positioning the picking claw over the morels to be harvested. When the fingers of the picking claw close, a blade located at the tips of the fingers severs the stem of the morel, allowing it to be captured by the claw. Subsequently, the electric push rod for the upper arm contracts, elevating the upper arm. Meanwhile, the electric push rod for the lower arm rotates it by a specified angle, positioning the picking claw above the collection box. The fingers of the picking claw then open, depositing the picked morel into the collection box.

Design of the robotic arm

During the picking operation, the movement of the picking claw is simultaneously influenced by the trajectories of both the upper and lower arms (Jun, *et al.*, 2021; Zhang *et al.*, 2015; Zhang, 2019). To further analyse the angular and motion relationships among the upper arm, lower arm, and picking claw, the three-degree-of-freedom robotic arm was simplified, as illustrated in Figure 2 (Zhou, *et al.*, 2012; Yoshida *et al.*, 2022).

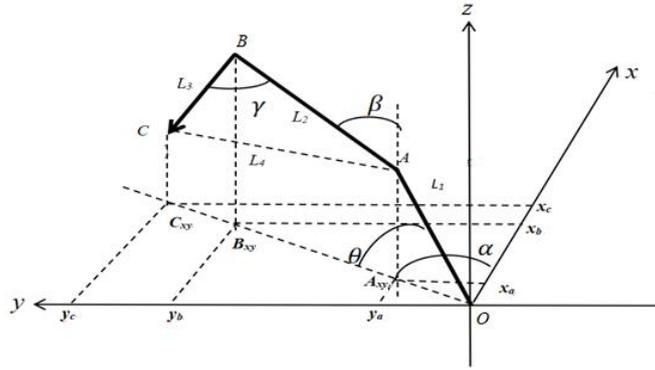

Fig. 2 - Simplified model of the robotic arm

In order to enable the picking claw at the end of the robotic arm to reach the designated picking range, the length of the upper arm was selected to be 800 mm, while the length of the lower arm was set at 650 mm, taking into account the overall structural dimensions of the machine. Using a right-handed coordinate system, the base of the robotic arm coincides with the xOy plane, and the centre of rotation for the robotic arm base is determined as the coordinate origin. The remaining components are arranged on the positive side of each coordinate axis (Zhang et al., 2020). OA represents the robotic arm rotation mechanism mounted on the base, enabling the arm to rotate around the z -axis. The length of OA is 400 mm. AB represents the upper arm, while BC represents the lower arm. θ is the angle between the robotic arm rotation mechanism OA and the xOy plane, α is the angle between the plane in which the robotic arm is situated and the xOz plane, β is the angle between the upper arm AB and the vertical direction, and γ is the angle between the lower arm BC and the upper arm AB .

Based on the geometric relationships illustrated in Figure 2, the following expression can be derived:

$$L_{OC_{xy}} = L_1 \cos \theta + L_2 \sin \beta + L_3 \sin(\gamma - \beta) \tag{1}$$

where:

$L_{OC_{xy}}$ represents the length of the projection of OC onto the xOy plane; L_1 represents the length of OA ; L_2 represents the length of AB ; L_3 represents the length of BC .

The coordinates of point A can be determined as follows:

$$\begin{cases} x_a = L_1 \cos \theta \cos \alpha \\ y_a = L_1 \cos \theta \sin \alpha \\ z_a = L_1 \sin \theta \end{cases} \tag{2}$$

The coordinates of point C can be expressed as follows:

$$\begin{cases} x_c = [L_1 \cos \theta + L_2 \sin \beta + L_3 \sin(\gamma - \beta)] \cos \alpha \\ y_c = [L_1 \cos \theta + L_2 \sin \beta + L_3 \sin(\gamma - \beta)] \sin \alpha \\ z_c = \sqrt{L_4^2 - (x_c - L_1 \cos \theta \cos \alpha)^2 - (y_c - L_1 \cos \theta \sin \alpha)^2} + L_1 \sin \theta \end{cases} \tag{3}$$

where, L_4 represents the length of AC .

According to the equations presented above, it can be concluded that when θ is 50° , α is 64° , β is 50° , and γ is 80° , the length of OC_{xy} is 1194 mm, which satisfies the requirement for a working radius greater than 1000 mm.

Motion simulation of the robotic arm

The motion trajectory of the robotic arm's end was simulated by importing the robotic arm model into Adams software, as shown in Figure 3.

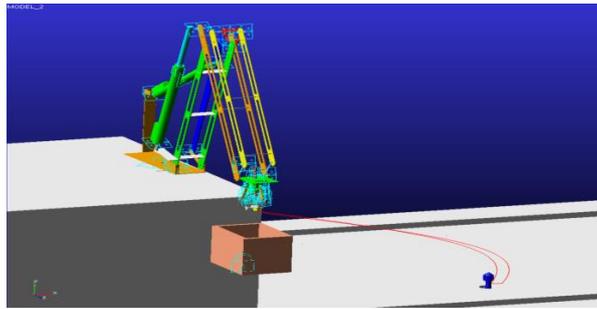

Fig. 3 - Simulation of the motion trajectory of the robotic arm's end

The variation in the mass centre coordinates of the robotic arm's end is shown in Figure 4. The labels "end.CM_Coordinate.X", "end.CM_Coordinate.Y", and "end.CM_Coordinate.Z" represent the coordinates of the centre of mass along the x, y, and z axes respectively. The label "end.CM_Coordinate.Mag" represents the distance from the robotic arm's end to the coordinate origin.

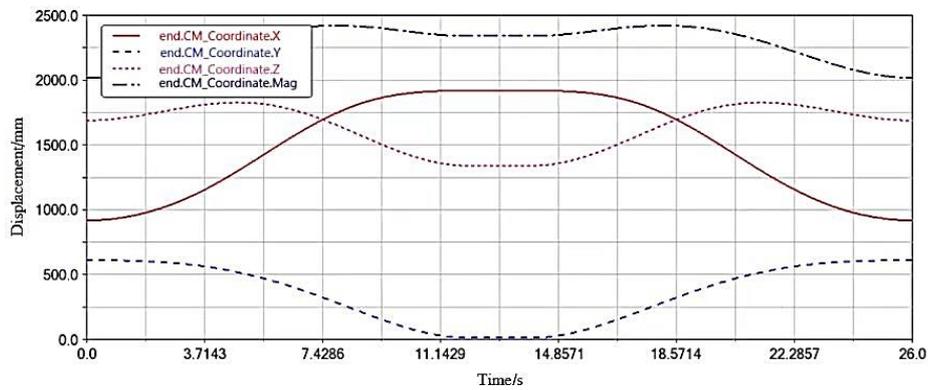

Fig. 4 - Variation in the mass centre coordinates of the robotic arm's end

The robotic arm's end is initially positioned above the collection box, with the y-axis coordinate of its centre of mass at 612.34 mm. Within 12 seconds, the end effector is manoeuvred to the picking position via the robotic arm rotation mechanism, the upper arm, and the lower arm. From 12 to 13 second, the robotic arm remains stationary while performing the picking action. At this moment, the y-axis coordinate of the mass centre of the robotic arm's end is 0.54 mm, indicating that the picking claw is nearly close to the ground. From 13 to 25 second, the robotic arm's end returns to its initial position, completing the collection action.

Force simulation of the robotic arm

An electric push rod with a stroke length of 400 mm and a thrust capacity of 1000 N was selected as the driving unit for the upper arm, while a push rod with the same stroke length of 400 mm and a thrust capacity of 480 N was chosen for the lower arm. The force acted on the robotic arm and the hinges at each connection were analysed using Adams software. Figure 5 illustrates the variation in the support force on the robotic arm. The labels "arm.Support_Force.X", "arm.Support_Force.Y", and "arm.Support_Force.Z" represent the component force along the x, y, and z axes respectively. The label "arm.Support_Force.Mag" represents the resultant force. As shown in Figure 5, the maximum support force reaches 493.76 N at 14 seconds.

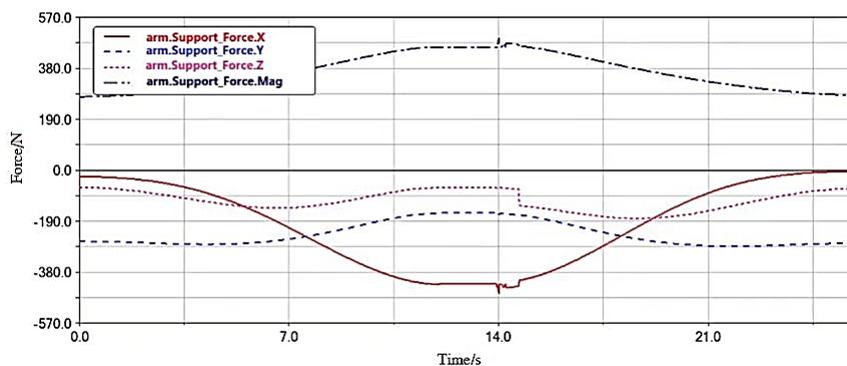

Fig. 5-Variation in the support force on the robotic arm

Figure 6 shows the variation in the force on the hinge connecting the upper arm and the lower arm. The labels “hinge.Force.X”, “hinge.Force.Y” and “hinge.Force.Z” represent the component forces along the x, y, and z axes respectively. The label “hinge.Force.Mag” represents the resultant force. As shown in Figure 6, the resultant force reaches its maximum value of 272.67 N at 26 seconds. The maximum force in the x-axis direction is 65.5 N at 18.2 seconds, the maximum force in the y-axis direction is 264.33 N at 26 seconds, and the maximum force in the z-axis direction is 54.28 N at 4.2 seconds.

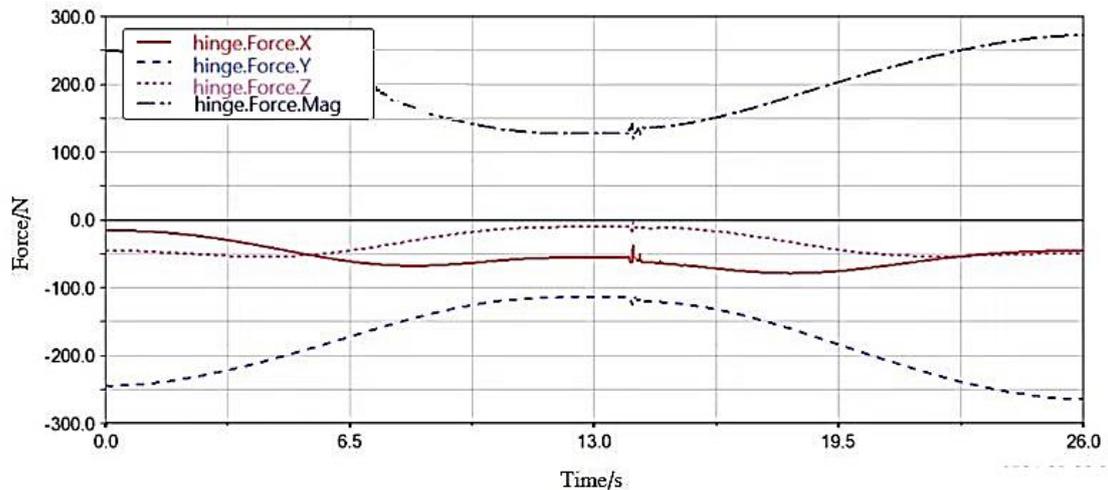

Fig. 6 - Variation in the force on the hinge connecting the upper arm and the lower arm

The robotic arm is constructed from 3 mm low-carbon steel plate. Force analysis indicates that the strength and stiffness of each component meet the necessary requirements. There is no significant deformation during operation, which effectively minimizes shaking and ensures accurate grasping.

Design of the picking claw

When manually picking morels, grasp the stem with the thumb, forefinger, and middle finger, then use a blade to cut it at a specific distance above the ground. This study examines the physical characteristics of morels and simulates the manual harvesting process. Compared to the double-finger structure, the three-finger end effector offers advantages such as high reliability, smooth movement, and resistance to detachment. Although the four-finger structure demonstrates effective grasping capabilities, it is difficult to control, complex in structure, and more expensive (Zhao et al., 2024; Chen et al., 2024). Based on a comprehensive analysis, this study adopts a three-finger structure. The picking claw comprises fingers, links, sliders, and blades, as shown in Figure 7.

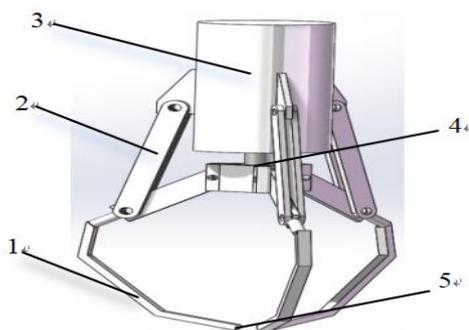

Fig. 7 - Schematic of the picking claw
1-finger; 2-link; 3-frame; 4-slider; 5-blade

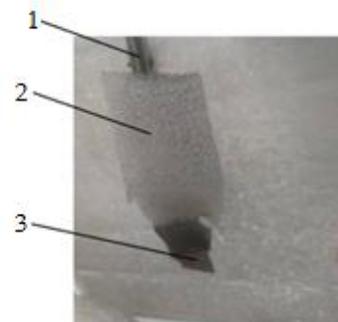

Fig. 8 - Composition of the picking finger
1-finger; 2-elastic foam; 3-blade

The frame of the picking claw is equipped with three fingers arranged uniformly at 120°. A servo motor is utilized to control the movement of these fingers. A power source simultaneously operates the fingers through a wire-pulling mechanism and a four-bar linkage, facilitating both closure and separation. When the servo motor rotates counterclockwise, the contraction of the cable drives the slider upward, causing the fingers to close. Conversely, when the servo rotates clockwise, the cable relaxes, and the fingers separate due to the action of a reset spring.

The reset spring is installed between the frame and the slider, featuring an elasticity coefficient of 1 N/cm, and a stretch of 3 cm. The fingers have a weight of 0.3 kg, while the other components collectively weigh

0.2 kg. The rotation speed of the servo is 120 °/s, and the required servo torque can be calculated to be 15 kg·cm. The selected servo model is the TD-8130MG, which has a torque rating of 29.5 kg·cm, thereby meeting the operational requirements.

The fingers are constructed from 45 steel. To accommodate morels of various sizes and prevent clamping damage, elastic foam was applied to the fingers as a buffer material. A triangular blade with a tip angle of 60 ° was selected and installed at the end of the finger, as illustrated in Figure 8.

The process of picking morels using the fingers was simulated. The variation in fingertip velocity was obtained, as shown in Figure 9. The labels “fingertip.Velocity.X”, “fingertip.Velocity.Y” and “fingertip.Velocity.Z” in the label represent the component velocity along the x, y, and z axes respectively. The label “fingertip.Velocity.Mag” represents the resultant velocity.

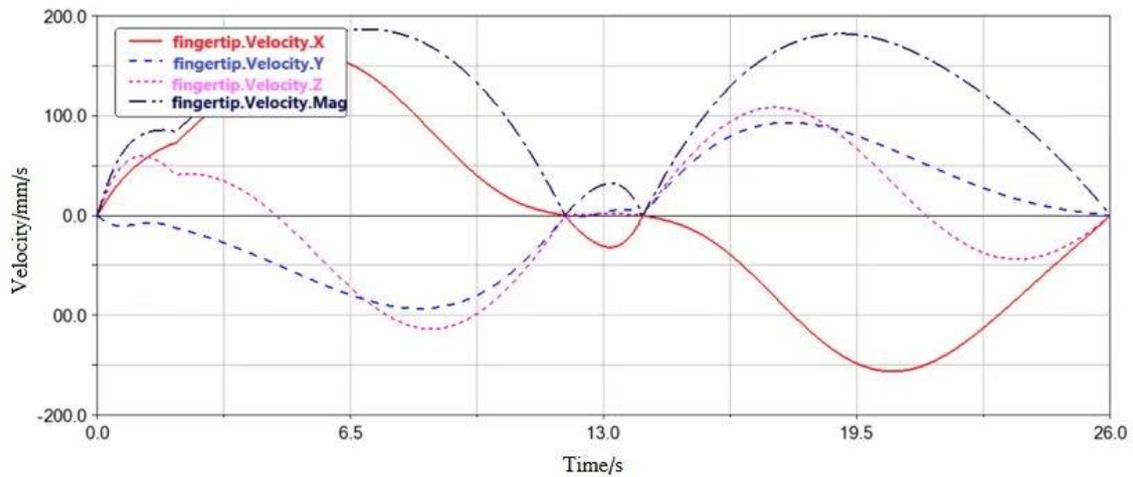

Fig. 9 - Variation in fingertip velocity

From Figure 9, it can be observed that at 12.5 seconds, the picking claw approaches the morel, and the velocity in each coordinate axis direction drops to zero, causing the picking claw to halt at the designated picking position. Between 12.5 and 13 second, the velocities along the y-axis and z-axis of the picking claw remain relatively constant, while the absolute value of the x-axis velocity increases. This indicates that the picking claw is performing a grasping operation on the morel in the x-axis direction. During the interval from 13 to 13.5 seconds, the absolute value of the x-axis velocity decreases, and the picking claw approaches the root of the morel at a reduced velocity for cutting operations. At 13.5 seconds, the velocity drops to zero, signifying the completion of the cutting and grasping actions. Throughout the entire picking process, the velocity of the picking claw changes relatively smoothly, with two brief pauses occurring when approaching the morel and after the cutting is completed. The impact generated by the fingertip is relatively small, which helps to reduce the damage rate of the morel.

Design of the mobile platform

Taking into account the planting environment of morels, the arrangement of all components, and the picking process, the mobile platform was designed to be 1140 mm long, 800 mm wide, and 600 mm high. The platform features a four-wheel support structure, with the front two wheels serving as the driving wheels and the rear two wheels functioning as the driven wheels. A DC motor transmits power through a chain drive to the output shaft, enabling the platform to move forward or backward (Wang et al.,2021). The following formula can be used to calculate the motor power.

$$P_e = \frac{1}{\eta} \left(\frac{mgfv}{3600} + \frac{mgiv}{3600} + \frac{C_d A v^3 m}{76140} + \frac{mga\delta v}{3600} \right) \tag{4}$$

where, P_e represents the motor power, kW; g represents gravitational acceleration, 9.8 N/kg; m represents the full load mass of the mobile platform, 100 kg; f represents the rolling resistance coefficient, 0.6; I represents the ground gradient; A represents the windward area in the forward direction, 1.2 m²; a represents the acceleration of the platform, with a maximum value of 0.5 m/s²; C_d represents the driving resistance coefficient, 0.7; v represents the platform velocity, 3 km/h; η represents the transmission efficiency, 0.9; δ represents the mass conversion coefficient of the platform, 1.2.

When the mobile platform ascends a slope with a gradient of 5% at a constant velocity of 3 km/h, the required motor power is 0.62 kW. When the platform accelerates at a rate of 0.5 m/s², the required motor power is 1.21 kW. Consequently, a brushless DC motor with a power of 1.5 kW was selected.

Prototype experiments

Experiments were carried out at a morel planting facility in Fushun, Liaoning Province, China. The diameter of a mature morel cap ranges from 30 to 60 mm, while the length of the cap varies between 40 and 100 mm. The diameter of the stem measures 20 to 40mm, and the stem length is typically between 50 and 70 mm. The mass of the morel is approximately 15 to 25 g. The experimental site is shown in Figure 10. The purpose of the experiment is to verify whether the robotic arm can accurately position the picking claw to the predetermined picking location, and to determine the optimal length of the blade mounted at the end of the picking finger. A 48V battery served as the power supply for the machine. The control system of the machine consists of a remote control, a receiver, an electronic speed controller, a motor, two electric push rods, and a steering engine. The remote control emits a 2.4GHz signal, which is then received and converted into a PWM (Pulse Width Modulation) signal by the receiver. The electronic speed controller achieves the start, stop, speed regulation of the motor, push rods and steering engine based on the received PWM signal. As a result, the position of the rotating mechanism, the upper arm, the lower arm can be adjusted to realize the picking process. The prototype is illustrated in Figure 11.

Fig. 10 – Experimental site

Fig. 11 – Experimental prototype

The primary factor affecting the picking efficiency is the blade length of the picking claw. If the blade is too short, it becomes challenging to cut the stem; conversely, if the blade is too long, it may inadvertently damage other immature morels. Consequently, four blade length levels were selected: 0 mm, 10 mm, 15 mm, and 20 mm. The index for the experiment included the picking success rate, the damage rate of mature morels, and the damage rate of immature morels. The calculation formulas are as follows:

$$\eta_c = n_c / n \quad (4)$$

$$\eta_d = (n_s + n_a) / n_c \quad (5)$$

$$\eta_z = n_j / n_z \quad (6)$$

where, η_c represents the picking success rate; η_d represents the damage rate of mature morels; η_z represents the damage rate of immature morels; n represents total number of picks; n_c represents the number of successful picks; n_s represents the number of morels with stem damage; n_a represents the number of morels with cap damage; n_j represents the number of damaged immature morels.

RESULTS

During the experiment, 15 mature morels were selected as a group at each level to calculate the experimental index values, with 4 groups being repeated. The damage to the morels caused by mechanical picking is shown in Figure 12.

The picking success rates at different levels are shown in Figure 13. When the picking claw is not equipped with blades, the claw's fingertip is unable to cut through the morel. In this case, the morel is grasped by the picking fingers and extracted from the soil by the robotic arm, leading to a lower success

rate. However, after the installation of the blades, the picking claw can effectively cut the root of the morel, resulting in a significant improvement in the picking success rate. Conversely, if the blade is excessively long, it may cause the picking claw to occupy more workspace, which can hinder smooth grasping movements and lead to a slight decrease in the picking success rate.

Fig. 12 - Morel damage

The damage rates of morels at different levels are shown in Figure 14. When the picking claw is not equipped with blades, the morel tends to break under tension, necessitating that the picking fingers exert additional pressure, which can easily lead to damage. Conversely, after the blades are installed, the morel can be severed with less force, significantly decreasing the damage rate. However, if the blade is excessively long, interference between the blade tips may occur when the claw is closed, potentially increasing the damage rate.

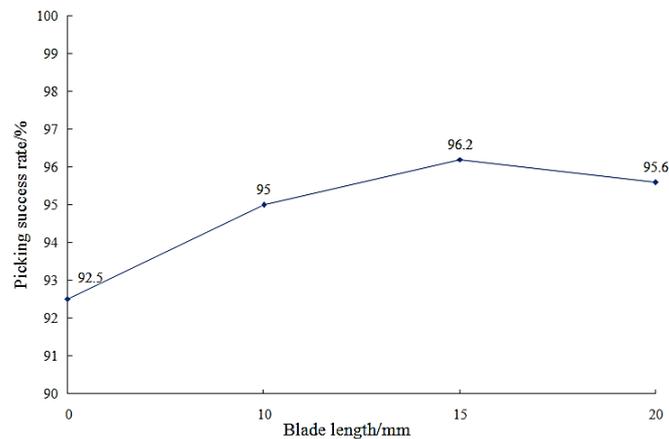

Fig.13 - Picking success rate at different blade lengths

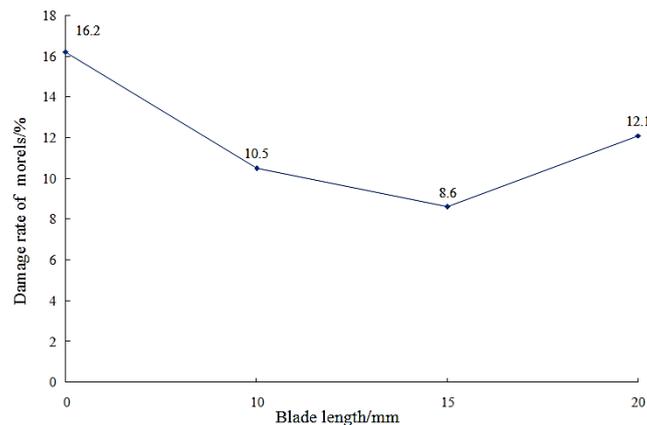

Fig. 14 - Damage rate of morels at different blade lengths

The damage rates of immature morels at different levels are shown in Figure 15. Immature morels are more fragile than mature ones and are typically found near mature morels, making them more susceptible to contact with the picking claw. In the absence of blades, the picking claw lacks sharp edges, which reduces the likelihood of damaging the surrounding immature morels. However, due to the complex and variable picking environment characterized by the irregular distribution of morels and the positional accuracy errors of the robotic arm, the blades are more prone to inadvertently contacting the immature morels during the cutting process, thereby increasing their damage rate.

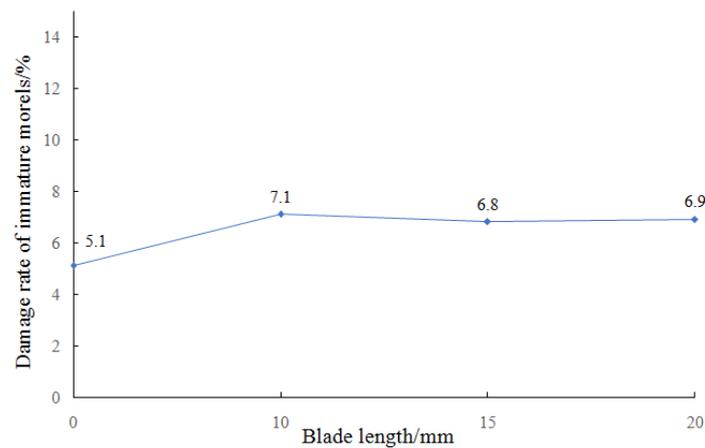

Fig. 15 - Damage rate of immature morels at different blade lengths

According to the experimental data, when the blade length at the end of the picking finger is set to 15 mm, the average picking success rate is 96.2%, the damage rate of morels is 8.6%, and the damage rate of immature morels is 6.8%. The picking machine can effectively grasp morels while maintaining a low damage rate, thereby meeting the requirements for morel picking operations.

CONCLUSIONS

The motion and force of the robotic arm and the picking claw during the picking process were analysed using Adams software. The simulation results proved the correctness of the theoretical model. The robotic arm adopts a three-degree-of-freedom structure, which can achieve precise positioning of the picking claw. The picking machine can perform positioning, cutting, and collection actions within 25 seconds. The picking claw is close to the ground when cutting the morel stem, ensuring the picking quality. The strength and stiffness of each component of the robotic arm meet the necessary requirements, ensuring both motion and grasping accuracy. The picking claw pauses briefly twice: once when approaching the morel and again after cutting. Furthermore, the velocity variation throughout the entire picking process is relatively smooth, which helps minimize damage to the morel.

Through single-factor experiments, the effect of the blade length of the picking finger on the picking success rate, the damage rate of morels, and the damage rate of immature morels was investigated. The results demonstrated that when the blade length was 15 mm, the picking success rate was 96.2%, the damage rate of morels was 8.6%, and the damage rate of immature morels was 6.8%. The picking machine ensures efficient picking operations while minimizing damage to both the picked morels and surrounding immature ones, thereby meeting the requirements for morel picking operations. However, this machine is just a prototype which requires manual operation. In future research, when combined with a visual recognition system for morels, it can work autonomously.

Keywords: Mechanical seed-metering device; Adzuki bean seeds; Physical parameters; Seed shape

ABSTRACT

To address the issue of seed filling in mechanical seed meters for different varieties of adzuki beans and to provide a basis for designing the shape and size of seed metering plate holes, a statistical analysis of the physical parameters of seeds from 10 adzuki bean varieties with significant morphological differences was conducted. The three-axis dimensions (length, width, and thickness) and the equivalent diameter of the seeds were found to approximately follow a normal distribution. The distribution and dispersion of each physical parameter were analyzed. A linear correlation analysis was performed between the equivalent diameter and the hundred-seed weight, showing a consistent overall trend. By measuring the hundred-seed weight, the relative equivalent diameter was determined, which was then used to select the appropriate seed metering plate diameter. The linear correlation coefficient analysis of the three-axis dimensions of different varieties indicated that, when modeling adzuki bean seeds for simulation, either the width or thickness could be selected as the primary dimension based on specific conditions.

摘要

为解决红小豆机械式排种器对不同品种红小豆的充种问题, 提供排种盘型孔结构设计参数依据, 选取形态差异较大的10种红小豆种植品种的种子物理参数进行数据统计分析。种子的三轴尺寸长、宽、厚及均径均近似服从正态分布, 分析确定了各物理参数的分布离散情况, 均径与百粒重整体变化趋势基本一致并进行线性相关分析, 通过测量百粒重得出相对均径从而选择排种盘直径, 不同品种三轴尺寸间线性相关系数分析结果表明, 仿真红小豆种子建模时可根据具体情况选取宽或厚作为主尺寸。

INTRODUCTION

Adzuki Bean, or Vermillion Beans, is the leguminous family's annual semi-twining herbaceous plant. The taste of the adzuki bean is sweet, and it is planted all over China. The stability of its production is of great significance in ensuring China's food security. Adzuki bean has a purple-red surface, plump grains, and is rich in protein, vitamins, and carbohydrates (Li et al., 2023), so consumers deeply favor it. Adzuki bean breeding technology (Liu et al., 2024) is an essential means of variety improvement and grain production increase. The adzuki bean mechanical plot breeding experiment (Dun et al., 2022) is the best method for breeding high-quality and high-yield new varieties, which is focused on the research and development of seeding machinery and equipment (Shang et al., 2021).

At present, the filling problem of the mechanical seed-metering device is still the core technical problem, which mainly studies the internal relationship between the hole of the seed metering plate and the adzuki bean seeds. Different varieties of adzuki bean seeds are sown in the breeding test field in the same region, and these seeds have different geometric dimensions and seed grain shapes. Therefore, it is necessary to measure and statistically analyze the geometric dimensions of different varieties of adzuki beans in the same region as a reference for the design of the hole shape of the seed-metering device (Lan et al., 2022). Domestic and foreign scholars have researched the physical properties of various agricultural materials. Dun Guoqiang et al., (2024), conducted EDEM discrete element simulation on the seed filling characteristics of the double swing plate type seed metering device of different soybean varieties and simulated the seeding process; Zheng Xiaoshuai et al., (2024), from Qingdao Agricultural University analyzed the geometric shape and size parameters of *Cyperus esculentus* seeds, measured the precise outline of *Cyperus esculentus* seeds by using the cross-sectional circular runout method, and established a discrete element simulation particle model of the

seeds. They also performed parameter calibration and seeding simulation through simulation experiments, data analysis, and fitting. Based on the geometric characteristics of pumpkin seeds, *Yu Yaxin et al., (2024)*, from Zhejiang Sci-Tech University calibrated the discrete element simulation contact parameters of pumpkin seeds and seed metering device, and determined the range of negative pressure and the number of holes in the seed metering plate through single factor tests. *Zhang Shengwei et al., (2022)*, used the Hertz-Mindlin with bonding model to establish a seed simulation model and calibrated the simulation parameters between mung bean seeds and contact materials to further optimize seed planting components. *Yan Jianwei et al., (2023)*, from Guizhou University took white radish seed particles as the research object, establishing a discrete element model of white radish seed particles using 3D scanning reverse modeling technology and EDEM software. They calibrated simulation parameters through physical tests and virtual simulation experiments. *Li Qichao et al., (2021)*, established a discrete element model of vegetable seeds and a seed-metering device model based on the physical parameters of three different types of small-particle vegetable seeds. Using discrete element software EDEM, they analyzed the seeding performance and examined the movement behavior of vegetable seeds during the seed filling process.

Wenxin Zhang et al., (2022), determined the basic physical parameters, contact parameters and angle of repose of germinated American ginseng seeds through physical experiments, and through the steepest climbing test, the optimal range of the significance parameter values was determined. *Ma Wenpeng et al., (2023)*, used the discrete element method to simulate and analyze the mechanized seeding process of sesame seeds. The contact parameters of sesame seeds were calibrated by combining the actual seed drop test and the simulated seed drop test. *Xu Bing et al., (2021)*, calibrated the simulated discrete element parameters of buckwheat seeds in combination with the simulation optimization design test and physical test. *Karaiev Oleksandr et al., (2021)*, mathematically modeled the calibration process of fruit stone culture seeds such as cherry, sweet cherry, cherry plum, almond, and apricot kernel, etc. *Xingye Chen et al., (2024)*, calibrated the contact parameters of the bean pod pepper seeds, took the repose angle as the response value, and simulated the discrete element model of the bean pod pepper seeds by using reverse engineering reconstruction technology. *Tianyue Xu et al., (2023)*, took ellipsoidal seeds such as soybeans, adzuki beans, and kidney beans as research objects and analyzed their size and shape. The results showed that the normal distribution can approximate the size dispersion, and thus a method of modeling ellipsoidal seeds as particles based on the multi-sphere method was proposed.

In summary, previous studies have conducted in-depth research on the physical parameters, the model establishment, and simulation parameter calibration of agricultural materials. However, there is still room for research on the physical parameters, seed shape measurement, and statistical analysis of a certain number of multi-variety adzuki bean seeds. Since the shape and size of adzuki bean seeds are relatively irregular and small, to ensure the accuracy of the experiment, several adzuki bean seeds were selected as research objects. Their length, width, and thickness were measured, followed by statistical analysis and calculations of their triaxial dimensional relationships, average diameter, sphericity, length-to-width ratio, length-to-thickness ratio, volume, density, and 100-grain weight. This analysis provides a reference for designing the seeding plate hole of the adzuki bean mechanical seed-metering device.

MATERIALS AND METHODS

Determination of material properties of Pak Choi seeds

Ten adzuki bean varieties grown in China were selected, namely, Pearl Red, Xianfeng Extremely Early, Shouhe Acacia, Shengyou, Pangda Agricultural, Kyoto, Jin Wangjie, Red Pearl, Dazhi, and Dahongpao. 100 seeds of each variety were randomly selected, as shown in Figure 1. A digital display vernier caliper (range 200 mm, accuracy 0.01 mm) was used to measure the triaxial dimensions (length l , width w , thickness t) of each adzuki bean seed (*Wang et al., 2018*). An electronic analytical balance (range 100 g, accuracy 0.001 g) was used to measure the 100-grain weight of adzuki bean seeds. 100 seeds of each variety were respectively taken for measurement, and the average value was taken 5 times (*Bai et al., 2024*). The actual operation diagram is shown in Figure 2. The average diameter d , sphericity S_p , length-to-width ratio R_{lw} , length-to-thickness ratio R_{lt} , volume v , and density ρ of the adzuki bean seeds were calculated.

The specific calculation formula (*Dun et al., 2023*) is as follows:

$$d = \frac{l+w+t}{3} \quad (1)$$

$$S_p = \frac{\sqrt[3]{lwt}}{\max(l \cdot w \cdot t)} \tag{2}$$

$$R_{lw} = \frac{l}{w} \tag{3}$$

$$R_{lt} = \frac{l}{t} \tag{4}$$

$$v = \frac{1}{6} \pi lwt \tag{5}$$

$$\rho = \frac{m}{v} \tag{6}$$

where: l is the seed length, mm; w is the seed width, mm; t is the seed thickness, mm; m is the seed quality, g; ρ is the seed density, g/cm³; v is the seed volume, mm³; S_p is the seed sphericity; R_{lw} is the ratio of seed length to width; R_{lt} is the ratio of seed length to thickness.

Fig. 2 - Measured physical parameters of adzuki beans

In order to analyze the population characteristic data of 100 seeds of each adzuki bean variety, the measured values and calculated values of the physical geometric parameters of the above varieties of seeds were calculated by mathematical statistics. The statistical parameters included each parameter's maximum, minimum, mean and coefficient of variation. The maximum and minimum values represented the distribution range limits of the parameter. The coefficient of variation is a commonly used statistic to measure the degree of data variation (Yang et al., 1993). The ratio of standard deviation to the mean value can eliminate the influence of measurement scale and dimension between different varieties of adzuki bean seeds. It is used to compare the dispersion degree of each parameter. The smaller the value, the more concentrated the overall distribution of the data, conversely, the larger the value, the more discrete the overall distribution. The statistical results of seed physical parameters of 10 kinds of adzuki bean seeds, such as Pearl red, Xianfeng Extremely Early and Shouhe Acacia, are shown in Table 1.

Table 1

Statistics of dimensions of adzuki bean seeds

Adzuki bean variety	Value	Length l/mm	Width w/mm	Thickness t / mm	Average diameter d / mm	Sphericity S _p	Length - width ratio R _{lw}	Length - thickness ratio R _{lt}	Volume v/ mm ³	Density ρ/g/cm ³	hundred-grain weight / g

RESULTS

Single seed parameter analysis

First, taking Pearl Adzuki beans as an example, the triaxial dimensions and shape parameters of 100 seeds of this variety were statistically analyzed. The statistical results are shown in Table 1. The average values and coefficients of variation of length l , width w , thickness t , and average diameter d of Pearl Adzuki beans are 6.05 mm, 5.29 mm, 4.86 mm, 5.40 mm, and 0.085, 0.055, 0.069 and 0.058, respectively. The triaxial dimensions and average diameter approximately obeyed the normal distribution. The normal distribution of triaxial dimensions of seeds is shown in Figure 3. The length l , width w , thickness t , and average diameter d of Pearl Adzuki seeds showed leapfrog jumps in the first 20%, 16%, 21%, and 24%, and the changes in the last 80%, 84%, 79% and 76% of the seeds were more gradual, indicating that there were fewer small seeds and more large seeds in Pearl Red varieties. The distribution of seed length l , thickness t , and average diameter d was basically consistent and relatively discrete. The sizes were concentrated in 5.5 mm~7.0 mm, 4.5 mm~5.5 mm, and 4.9 mm~5.9 mm, respectively. The size ranges were 2.35 mm, 0.92 mm, and 1.38 mm, respectively. The sizes varied greatly, and a certain proportion of over-large and over-small sizes existed. The seed width w was more concentrated, with a size range of 0.65 mm. The overall distribution was too smooth and basically symmetrical. The coefficients of variation of seed length l , thickness t , and average diameter d were 0.085, 0.069, and 0.058, respectively, while the coefficient of variation of seed width w was 0.055, significantly smaller than the first three. The overall distribution was significantly concentrated. The sphericity S_p of Pearl Red seeds ranged from 0.79 to 0.98, with an average value of 0.89 and a coefficient of variation of 0.052. The average length-to-width ratio R_{lw} and length-to-thickness ratio R_{lt} of the seeds were calculated to be 1.15 and 1.25, respectively. The length l and width w were basically the same, but both were significantly larger than the seed thickness t . The length-width cross-section of the seed was an ellipse, the length-thickness cross-section was an ellipse, and the seed shape was an approximately ellipsoid of unequal diameters.

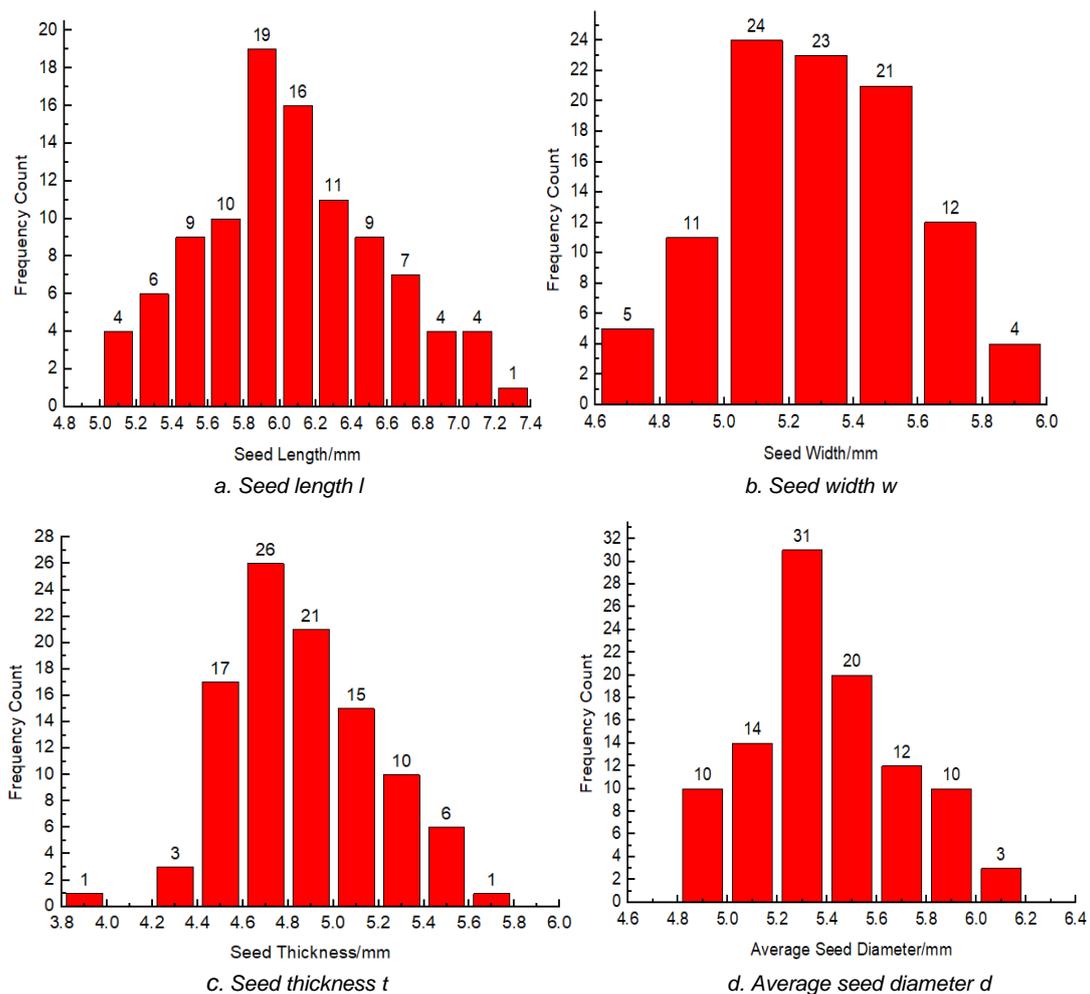

Fig. 3 - Seed grain triaxial and average diameter size distribution

In order to analyze the relationship between the length l , width w , and thickness t of adzuki bean seeds, origin 8.5 was used for parameter mapping (Chen *et al.*, 2024), and scatter plots of seed length and width, length and thickness, and width and thickness were drawn for linear fitting, as shown in Figure 4. The triaxial dimensions of adzuki bean seeds showed a linear positive correlation function relationship. The correlation coefficients of the linear fitting equations between the triaxial dimensions of length-width, length-thickness, and width-thickness were $R^2=0.1937$, $R^2=0.1567$, and $R^2=0.6424$. The Pearson coefficient between length-width and width-thickness was significantly greater than the linear correlation between length-thickness. Therefore, it can be determined that the width of the triaxial dimensions was the main dimension and the thickness was the secondary dimension. The seed width can be randomly generated according to the normal distribution during seed modeling, and the length and thickness dimensions can be calculated according to the functional relationship with the main dimension width. In this way, the size distribution of the adzuki bean seed population generated by simulation was closer to the actual situation.

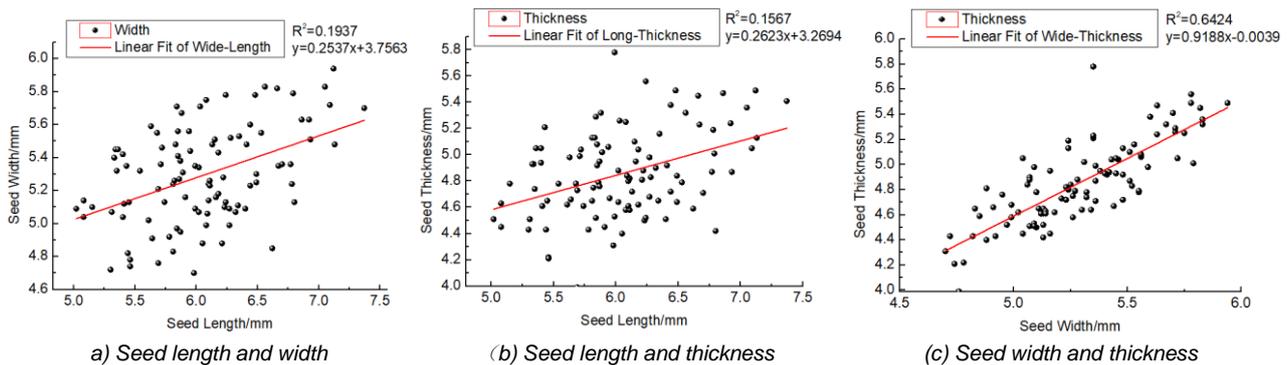

Fig. 4 - Scatter plot of the relationship between the triaxial dimensions of adzuki bean seed

Statistical analysis of different seed parameters

The measurement and statistical results of the parameters of a single variety of Pearl Red cannot represent the overall physical geometric parameters of adzuki bean seeds in the national planting area due to its variety of attributes and the particularity of regional environment planting. Therefore, as shown in Table 1, the physical parameters of 10 kinds of adzuki bean seeds were statistically analyzed. It can be seen from Table 1 that the physical parameters of 100 seeds in each adzuki bean variety obeyed the normal distribution. The coefficient of variation of length, width, thickness, and average diameter ranged from 0.049 to 0.104. The larger the coefficient of variation of the average diameter of adzuki bean seeds, the greater the degree of dispersion of the average diameter of seeds, the more irregular the seed shape, and the more it tends to be ellipsoidal. The coefficient of variation of sphericity ranged from 0.046 to 0.065, the coefficient of variation of length-to-width ratio and length-to-thickness ratio ranged from 0.066 to 0.098, the coefficient of variation of volume ranged from 0.144 to 0.216, and the coefficient of variation of density ranged from 0.058 to 0.134. The sphericity distribution was concentrated overall, followed by length-to-width and length-to-thickness ratios. The distribution of triaxial dimensions, average diameter and volume was relatively discrete, and the density distribution was the most discrete. The single-factor test method was adopted, and the experimental design expert software design-expert 8.0 was used. The adzuki bean varieties (10 kinds of adzuki bean seeds) and parameter values (maximum value, minimum value, average value) were used as experimental factors, and length, width, thickness, average diameter, sphericity, length-width ratio, length-to-width ratio, length-to-thickness ratio, volume, and density were used as experimental indicators. The statistical analysis of physical parameter tests was carried out, and the statistical results of the experimental indicators are shown in Table 2.

Table 2

Overall statistics of physical parameters of adzuki beans

Parameter	Minimum	Maximum	Average	Standard deviation	Coefficient of variation
Length / mm	4.81	10.65	8.08	1.082	0.134
Width / mm	4.22	8.68	5.93	0.516	0.087
Thickness / mm	3.99	7.69	5.85	0.575	0.098
average diameter / mm	4.76	7.99	6.62	0.658	0.099
Sphericity	0.68	0.997	0.81	0.052	0.064
Length-width ratio	0.82	1.84	1.36	0.141	0.103

Parameter	Minimum	Maximum	Average	Standard deviation	Coefficient of variation
Length-thickness ratio	0.83	1.81	1.38	0.132	0.085
Volume / mm ³	56.20	256.53	150.38	41.104	0.273
Density / g/cm ³	0.63	2.40	1.45	0.147	0.101

As shown in Table 2, the average length, width, thickness, average diameter, and variation range of the 10 kinds of adzuki bean seeds are 8.08 mm, 5.93 mm, 5.85 mm, 6.62 mm, 8.08±1.082 mm, 5.93±0.516 mm, 5.85±0.575 mm, and 6.62±0.658 mm, respectively. The seed length and width are close, and significantly larger than the seed thickness. The average diameter and the width of the seeds are close to each other. The coefficient of variation shows that the seed width distribution is relatively concentrated, and the seed length distribution is the most dispersed. In order to further explore the design structure of the seed metering plate hole, according to Tables 1 and 2, the factor index change trend chart was drawn using design-expert 8.0. The adzuki bean varieties were used as experimental factors, and the average diameter, 100-grain weight, and density of each variety were used as experimental indicators to analyze the changing trend of the adzuki bean seed average diameter, 100-grain weight and density parameters, as shown in Figure 5.

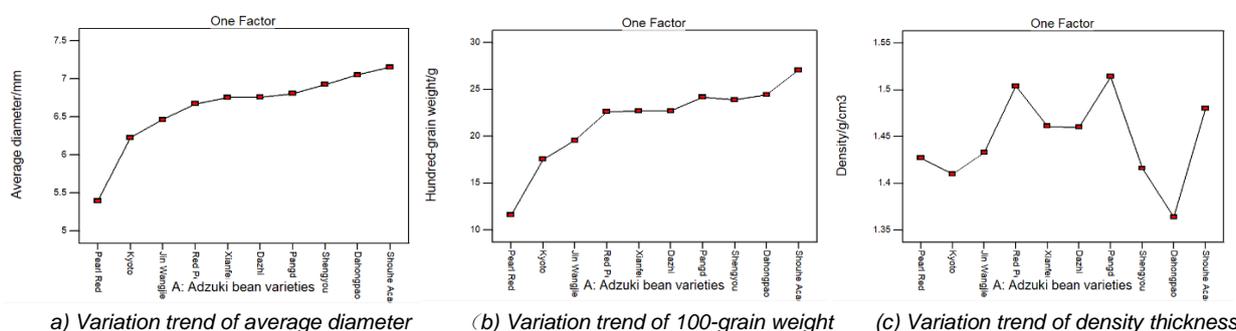

Fig. 5 - Variation trends of average diameter, 100-grain weight and density

As shown in Figure 5, the average diameter and 100-grain weight of different seeds have basically the same trend. The density of seeds of a few varieties (Shengyou, Dahongpao) is entirely opposite to the average diameter and 100-grain weight. The trends of seeds of other varieties (Kyoto, Red Pearl, Jin wangjie, Xianfeng Extremely Early, Dazhi, Pangda Agriculture, Shouhe Acacia) are basically consistent with their average diameter and 100-grain weight. Among them, the larger the average diameter of each adzuki bean variety, the larger the value of its 100-grain weight. Since the density range between the same beans is small, the density of specific varieties should be analyzed according to the specific variety combined with the average diameter and 100-grain weight. There is also a particular case in analyzing the average diameter and 100-grain weight trend. For example, although the average diameter of Shengyou's seeds is larger than that of Pangda Agriculture, the 100-grain weight is smaller than that of Pangda Agriculture, the floating trend of its value is not obvious. The main reason for this trend is that there are minimal exceptions in Shengyou adzuki bean seeds that lower the value of 100-grain weight, and it can be seen from the triaxial dimensions of the seeds and the range of the average diameter that the seed dimensions vary greatly.

The main parameters for designing the seed metering plate holes of the mechanical seed metering device are based on the average seed diameter increasing from 4.76 mm to 7.99 mm, with a variation of 3.23 mm. Therefore, the measured range of 100-grain weight is different, and the average diameter of each variety of seeds is calculated from the average length, width and thickness. The triaxial dimensions obey the normal distribution. Therefore, the external dimensions of adzuki bean varieties planted in the same area vary significantly, which puts forward necessary design requirements for the adaptability of the mechanical seed metering device to sowing varieties.

The seed metering plate with different hole sizes in the corresponding range can be accurately selected according to the 100-grain weight value in seed cleaning and replacement. As can be seen from Figure 6, there is a stable linear correlation between the 100-grain weight and the average diameter of adzuki bean seeds. Therefore, a linear equation was fitted between the 100-grain weight and the average diameter of 10 varieties of adzuki beans. The 100-grain weight of each variety of adzuki beans was set as the independent variable X, and the average diameter of each variety of seeds was set as the dependent variable Y.

Based on the principle of linear regression equation construction (Yu et al., 2024), the linear fitting equation was obtained as $y=0.1138x+4.1607$, and the Pearson coefficient R^2 was 0.9728. Therefore, when selecting the seeding plate, the 100-grain weight value x can be directly input to obtain the corresponding average diameter y , to select an appropriate seeding plate.

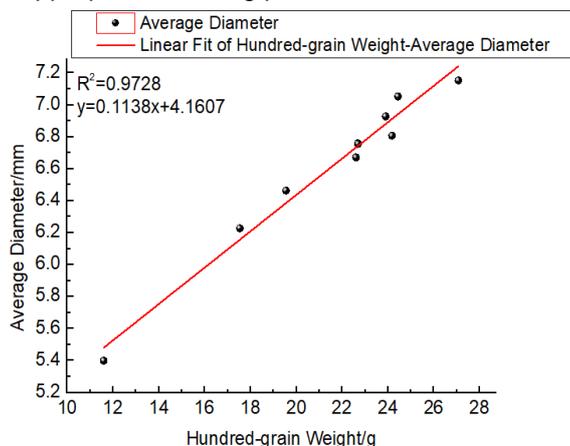

Fig. 6 - Linear fitting diagram of 100-grain weight-average diameter

Therefore, it will be very useful to study the overall statistical results of different seed physical parameters in the same region for the design of seed metering plate holes. Table 3 shows the results of the single-factor test ANOVA for physical parameters of different seed sphericity variation ranges.

Table 3

It can be seen from Table 3 that changes in the experimental factors, such as adzuki bean varieties, did not affect width, length-to-width ratio, or density ($P=0.237>0.01$, $P=0.1412>0.01$, $P=0.7434>0.01$). However, they had some effect on seed sphericity and length-to-thickness ratio ($0.01<P=0.0282<0.05$, $0.01<P=0.0456<0.05$), and an extremely significant impact on other physical parameters ($P<0.01$). The test factors had significant effects on all test indexes. In order to analyze the variation trends among the physical parameters of different varieties of adzuki beans, design-expert 8.0 was used to draw the variation trend diagram of factor indicators. The variation trend of the triaxial size and average diameter is shown in Figure 7.

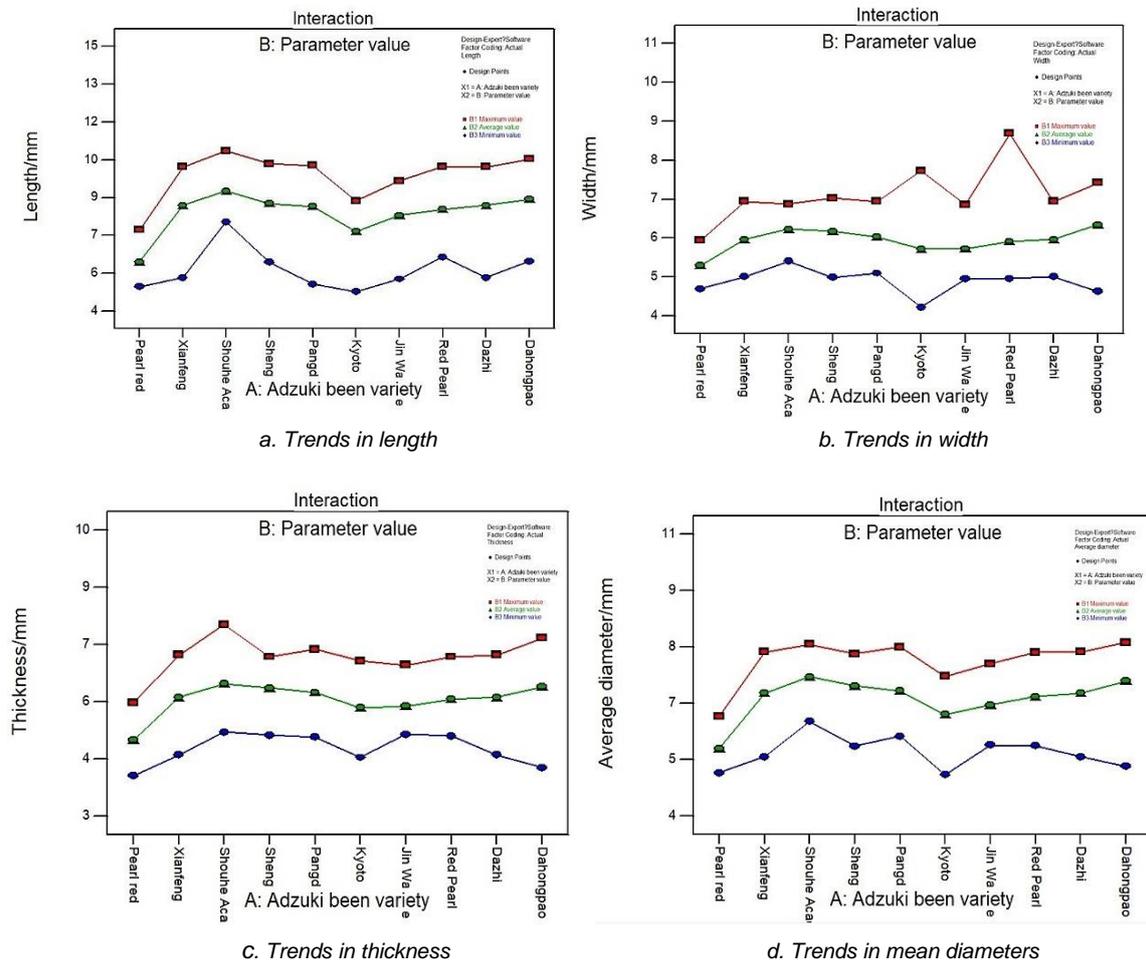

Fig. 7 - Variation trends diagram among different varieties

As can be seen from Figure 7, there are significant shape differences among different seeds. For each adzuki bean variety, the seed shape size parameter's mean value is basically equal to the mean value of the maximum and minimum values. However, there are some special cases, such as the average seed length of Shengyou, Pangda Agriculture, Kyoto and Jin wangjie tended to the maximum value. The average seed width of Kyoto, Red Pearl and Dazhi tended to the minimum value. The seed thickness of Xianfeng Extremely Early, Shouhe Acacia, Shengyou and Dahongpao tended to the maximum value, while the seed thickness of Jin Wangjie tended to the minimum value.

The main reason for this trend in triaxial size is that some parameters of the length, width and thickness of 100 seeds of each magenta adzuki bean seed obey asymmetric normal distribution. As shown in Figure 3, the length and thickness of Pearl Red seeds are asymmetrical. Seed width is a symmetrical normal distribution. The average diameter of seeds is the characteristic size of each seed population and the primary parameter of seed grain shape. It can be seen from Figure 7 that the overall change trend of the triaxial size of different seeds is basically the same, and the change trend of seed volume is also basically the same as that of the triaxial size, as shown in Figure 8.

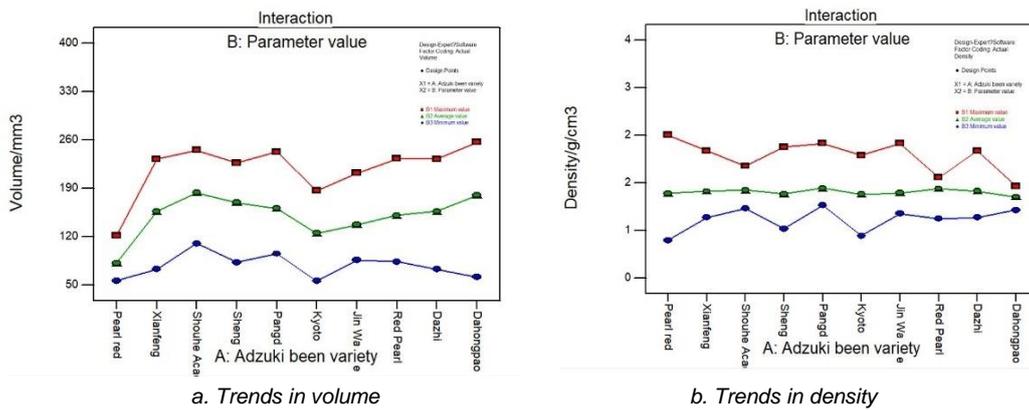

Fig. 8 - Variation trends diagram among different varieties

As shown in Figure 8, the volume of the 10 varieties of adzuki beans varies greatly. Except for Jinwangjie and Dahongpao, the average values are closer to the minimum value, and the volume change trend is basically consistent with the trend of the triaxial size change, with the average volume of 150.38 mm³ and the volume change range of 56.2 mm³–256.53 mm³. The coefficient of variation of the volume *v* of different varieties ranges from 0.052 to 0.216, the dispersion degree varies greatly, the greater the volume difference, the more comprehensive consideration is needed for the design of the seeding plate hole to determine the number of holes filled by the hole-direct seeding number of adzuki beans. The trend of adzuki bean seed density is entirely opposite to seed volume. The maximum and minimum density values are significantly different among different varieties, but the average value of seed density is very small, ranging from 1.364 g/cm³ to 1.514 g/cm³. Therefore, the influence of seed density on the seeding plate hole still needs to be considered in many aspects.

The variance analysis of the test results in Table 3 shows that the difference in sphericity among different varieties varies little, and its changing trend is shown in Figure 9.

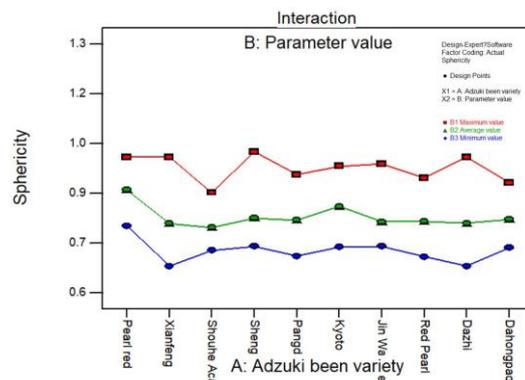

Fig. 9 - Sphericity variation trends among different varieties

It can be seen from Table 3 in Figure 9 that the average sphericity of 1000 seeds of 10 adzuki bean varieties is 0.81, and the sphericity range is 0.68–1.00. A small part of the seeds have a sphericity close to 1.00, which is a pure sphere, but most of them are non-equilinear ellipsoids and the maximum value of sphericity *S_p* is 1, with no significant change. The maximum and minimum values of sphericity *S_p* change gradually and obviously. The average value tends to the minimum direction. The variation coefficient of sphericity *S_p* for different varieties ranged from 0.046 to 0.065, and the dispersion degree changed little. The larger the sphericity, the more obvious the rolling effect of the seeds on the seed metering plate in the seed box, which is more conducive to filling the seed holes.

On the contrary, the smaller the sphericity, the lower the relative motion between seed particles, which is not conducive to filling the holes. For seeds filled into the hole, the smaller the sphericity, the better the seed storage and carrying effect of the hole. Therefore, the size of the seed sphericity requires some comprehensive and dialectical consideration for the design of the seed metering device. The stable state of the seed filling in the hole is the lowest center of gravity of the seed; that is, the smallest of the three axes is vertical, and the other two axes provide a reference for the diameter design of the hole to calculate the length-to-width ratio and length-to-thickness ratio of the seed, as shown in Figure 10.

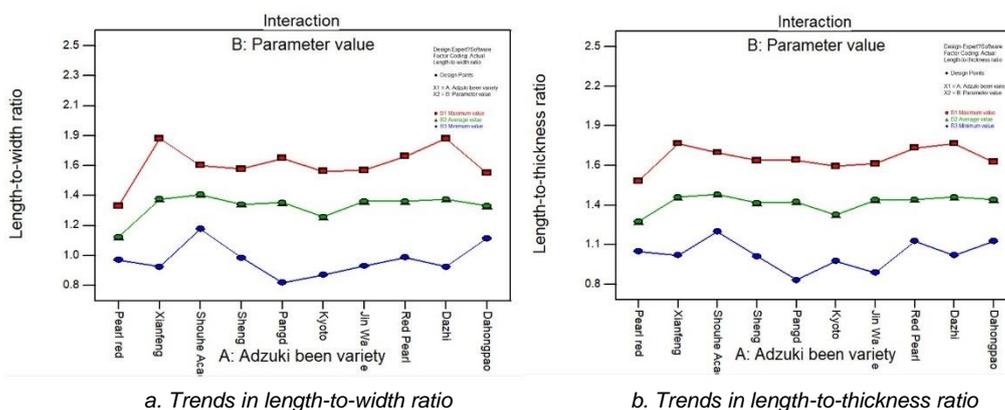

Fig. 10 - Variation trends diagram among different varieties

As shown in Figure 10, the average length-to-width ratio of the seeds of the 10 adzuki bean varieties is 1.36, the average length-to-thickness ratio is 1.38, the length-to-width ratio ranges from 0.82 to 2.21, and the length-to-thickness ratio ranges from 0.83 to 2.08. All unequal-diameter ellipsoid seeds appear in any shape, that is, the size of any axes of three axes has a maximum or minimum value, but each variety has its characteristics. For the length-to-width ratio of seeds, the overall average value is 1.36, and the length and width are basically equal. The minimum length-to-width ratio of Pearl Red, Xianfeng Extremely Early, Pangda Agriculture, Kyoto, Jinwangjie, and Dazhi Adzuki Bean is less than 1. The minimum values of the other varieties of adzuki beans are more significant than 1, but the maximum length-to-width ratio of all varieties of adzuki beans is greater than 1; For the length-to-thickness ratio of seeds, the average and maximum values are greater than 1 as a whole, and the minimum length-to-thickness ratio is less than 1 in some cases, such as Pangda Agriculture, Kyoto, and Jinwangjie Adzuki Bean, that is, the thickness of a small part of the seeds is greater than the length. In contrast, the length of all seeds of other varieties is greater than the thickness.

As shown in Figure 4, there is a stable linear correlation between the length, width and thickness of adzuki bean seeds. However, the Pearson coefficient R^2 of the fitted linear curve between different varieties' length, width and thickness are different. The fitting correlation coefficient R^2 of width-thickness of each variety is generally more significant than the fitting correlation coefficient of length-width and length-thickness. Most of the R^2 values of length-width are more significant than the R^2 values of length-thickness, and a small part is less than the R^2 value of length-thickness, such as Xianfeng Extremely Early, Kyoto, Red Pearl, and Dazhi Adzuki Bean. Therefore, the primary dimensions of the tri-axial dimensions calculated by different varieties are also different, directly affecting the model establishment of discrete element simulation seeds of the seed metering device. For this reason, the linear equations between the length, width and thickness of 10 kinds of adzuki beans are fitted, and the correlation coefficient R^2 is extracted as shown in Table 4. Except for Xianfeng Extremely Early, Kyoto, Red Pearl, and Dazhi Adzuki Bean, the main dimensions of other varieties are width. Seed modeling can be calculated according to the functional relationship with the actual main dimensions of adzuki beans, so that the size distribution of the simulated adzuki bean population is closer to the actual situation.

Table 4

Correlation coefficient R^2 of the linear equation of adzuki bean seeds

Correlation coefficient R^2 of linear equation				
Adzuki bean variety	Length-Width	Width-Thickness	Length-Thickness	Main dimension
Pearl Red	0.1957	0.6424	0.1567	Width
Xianfeng	0.2247	0.7200	0.2390	Thickness
Shouhe Acacia	0.1704	0.4571	0.1453	Width
Shengyou	0.1663	0.6262	0.1567	Width
Pangda Agricultural	0.2673	0.6363	0.2497	Width
Kyoto	0.1503	0.4986	0.2175	Thickness
Jin wangjie	0.2583	0.6557	0.2413	Width
Red Pearl	0.2178	0.4040	0.2784	Thickness
Dazhi	0.2356	0.7149	0.2395	Thickness
Dahongpao	0.5258	0.6979	0.3958	Width

CONCLUSIONS

(1) The physical characteristic parameters of seeds of 10 adzuki bean varieties were selected for statistical analysis. Length, width, thickness, average diameter, sphericity, length-to-width ratio, length-to-thickness ratio, volume, density, and 100-grain weight were statistically analyzed, and the maximum, minimum, mean, standard deviation and coefficient of variation of each parameter were obtained.

(2) The results of the analysis of the appearance parameters of Pearl Red Adzuki Beans showed that the triaxial dimensions of the seeds, length, width, thickness and average diameter all approximately obeyed a normal distribution. Subsequently, the statistical analysis of the seeds of multi-varieties adzuki beans, and the statistical test analysis results of different seed parameters showed that the average length and width of adzuki bean seeds of 10 varieties were basically the same and significantly greater than the average seed thickness, the analysis determined the discrete distribution of each physical parameter. Changes in adzuki bean varieties did not affect the width, the length-to-width ratio, or density. However, they had a significant impact on sphericity and the length-thickness ratio and had a very significant impact on other physical parameters. The overall change trend of the three-axis size was basically consistent with the 100-grain weight. For linear fitting of the 100-grain weight-average diameter, the equation and the Pearson correlation coefficient R^2 were obtained. The appropriate one can be directly selected according to the formula on the seeding plate. The volume change trend of seeds was basically consistent with the three-axis size, but the trend of both and density was basically consistent for the most part. There were also very few exceptions and a small part was completely opposite; this requires a specific design for the adzuki bean mechanical seed metering device to achieve the seed filling target of adzuki beans with different sizes. During the seed cleaning process, different hole sizes in the corresponding range can be selected based on the measured 100-grain weight value of the seeding plate.

(3) The average seed sphericity S_p was 0.89, and the average length-width and the length-thickness ratios of the seeds were 1.15 and 1.25, respectively. The length and width were basically the same, but both were significantly larger than the seed thickness t . The seed shape was an approximately ellipsoid of unequal diameters. The three-axis dimensions of the seed grains showed a linear positive correlation function relationship. The linear correlation of length-width was significantly greater than the linear correlation between length-thickness. However, the linear fitting correlation coefficients R^2 of length-width and length-thickness were relatively close. So, in practical applications, the primary size can be calculated based on the functional relationship of the actual size of adzuki beans so that the size distribution of the simulated adzuki bean population is closer to the actual situation.

Keywords: *Spartina alterniflora*; YOLOv8; Ecological Protection

ABSTRACT

In view of the difficulty and high cost of monitoring the invasion of small aggregations of *Spartina alterniflora* in coastal wetlands, this study proposes a SA-YOLO detection model. First, by adopting a lightweight cascade attention mechanism as the feature extraction part of the network, the model's ability to extract features from *Spartina alterniflora* images is optimized. Secondly, the convolution layer with an improved adaptive attention mechanism is added to optimize feature extraction, dynamically adjust the weight of the feature map, and reduce the amount of calculation. Thirdly, the improved adaptive convolution network is used to optimize the original neck layer, improve the model's ability to integrate *Spartina alterniflora* image features, and reduce the amount of calculation. Finally, a *Spartina alterniflora* recognition system is independently built. The system effectively implements the proposed method and realizes the detection and recording of *Spartina alterniflora* information. This study successfully verifies the effectiveness of the proposed method by conducting experiments on the actual collected *Spartina alterniflora* dataset. The test results show that the recall rate and accuracy of the proposed SA-YOLO *Spartina alterniflora* detection model are 94.5% and 92.4%, respectively, both reaching a high level. It can be seen that the model can complete the identification and detection tasks of *Spartina alterniflora*, providing a solution for the identification and information collection of *Spartina alterniflora* in coastal areas.

摘要

针对滨海湿地小聚集互花米草入侵监测难度大、成本高的问题，本研究提出了SA-YOLO检测模型。首先，通过采用轻量级级联注意力机制作为网络的特征提取部分，优化模型对互花米草图像特征提取能力；其次，加入改进自适应注意力机制的卷积层优化特征提取，动态调整特征图权重，降低计算量；再者，采用改进的自适应卷积网络对原有的neck层进行优化，提高模型融合互花米草图像特征的能力，降低计算量。最后，自主搭建了互花米草识别系统。该系统有效实施了提出的方法，实现了互花米草信息的检测与记录。本研究通过在实际采集的互花米草数据集上进行实验，成功验证了所提方法的有效性。测试结果表明，所提出的SA-YOLO互花米草检测模型的召回率和准确率分别为94.5%和92.4%，均达到较高水平。可见该模型能够完成互花米草的识别检测任务，为沿海地区互花米草识别与信息采集提供了一种解决方案。

INTRODUCTION

Spartina alterniflora is an important coastal wetland plant and a typical invasive alien species. It was introduced into China in 1979 (Jin et al., 2024). *Spartina alterniflora* has a well-developed root system, mainly composed of underground stems and adventitious roots, which are widely distributed in the soil. On the one hand, this gives *Spartina alterniflora* good soil fixation and growth capabilities; on the other hand, it compresses the living environment of local species, easily causing damage to the local ecosystem and reducing species diversity. In addition, *Spartina alterniflora* has strong reproductive capacity and grows rapidly. One is sexual reproduction, through the random drift of seeds, it begins to take root and grow when it encounters a suitable environment; the other is asexual reproduction through rhizome diffusion, which allows *Spartina alterniflora* to expand its population in a short period of time. The growth and reproduction characteristics of *Spartina alterniflora* increase the difficulty and uncertainty of its prevention and control, and it is difficult to grasp its growth location, time and other factors (Feng et al., 2024). As shown in Figure 1, this is the growth and distribution map of *Spartina alterniflora* in China produced by the Key Laboratory of Biodiversity and Ecological

Engineering of the Ministry of Education of Fudan University.

The growth environment of *Spartina alterniflora* is mainly in coastal wetlands, including intertidal zones of coastal mudflats such as estuaries and bays, and river beaches affected by tides (Li *et al.*, 2024). These areas are complex and difficult to access, which facilitates the random growth of *Spartina alterniflora* (Zhang *et al.*, 2024). At the same time, it is also the growth environment of reeds and other aquatic herbs. *Spartina alterniflora* is similar to reeds in appearance, but there are also significant differences between the two (Qiu *et al.*, 2022). *Spartina alterniflora* has long leaf lines and rough edges. Because of its secretion characteristics, its leaf surface often has white powdery salt frost, so it has good salt tolerance (Ma *et al.*, 2010). Only by achieving effective monitoring and management of *Spartina alterniflora* can it be beneficial to maintain the local ecological balance and protect the coastal wetland environment. The development of drone technology and the rapid update of computer vision have provided high-quality methods for monitoring. Neural network recognition can reduce the influence of subjective factors, save costs, eliminate accurate positioning, and improve the accuracy of recognition results (Qiu *et al.*, 2022).

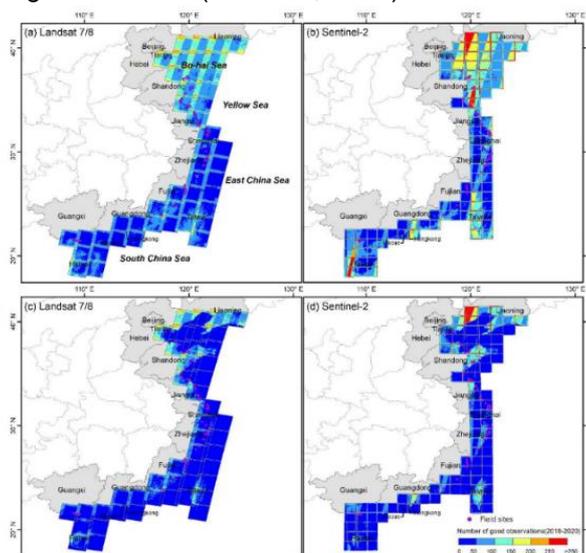

Fig. 1 – Distribution map of *Spartina alterniflora* in China

Tian *et al.* (2020) used the Zhangjiangkou National Nature Reserve in Fujian as the study area. Based on field surveys and drone aerial photography, they obtained training and validation samples of *Spartina alterniflora* for remote sensing image classification, and collected time series Sentinel-2 images of the start and end dates of the growing season in the study area from 2016 to 2018. Based on the spectral reflectance curves of different landform types in Sentinel-2 images, the vegetation index for extracting submerged *Spartina alterniflora* was established by using the characteristics of large differences in reflectance between submerged *Spartina alterniflora* pixels and pure water surface pixels in the red edge band. Then, an object-oriented random forest classification method was used to interpret *Spartina alterniflora* in the study area from 2016 to 2018. The seasonal expansion information of *Spartina alterniflora* was extracted, and the interpretation accuracy reached more than 92%. Li *et al.* (2024) conducted a hyperspectral inversion study on the functional traits of *Spartina alterniflora* in the Yancheng coastal wetland, confirming the great potential of hyperspectral technology in estimating functional traits. The accuracy and stability of the support vector machine constructed by selecting feature bands based on random forest importance score in inverting the functional traits of *Spartina alterniflora* leaves were verified. Zheng Hao *et al.*, (2023), used the Sentinel-2 NDVI dataset to obtain the vegetation phenology information of the study area in the core area of Yancheng Wetland Rare Bird National Nature Reserve, and identified the key phenological period for *Spartina alterniflora* extraction. Then, based on the multi-source and multi-temporal remote sensing data in the key phenological period, a feature set was constructed, and the landscape classification map was obtained by using five methods, ResNet18, MSRN2, CDCNN, SVM, and RF, and the accuracy was evaluated. Zhu *et al.*, (2020), combined deep learning with remote sensing data to achieve high-precision classification and dynamic monitoring of *Spartina alterniflora* in the coastal areas of Shandong Province.

Based on YOLOv8n, this study proposed an algorithm with high detection accuracy and fast detection speed, and actually deployed it on a self-built server to achieve timely monitoring and analysis of the growth of *Spartina alterniflora*, reduce the input of manpower and material resources, and provide solution experience

for the application of machine vision in the field of agricultural engineering.

MATERIALS AND METHODS

Data Acquisition and Pre-processing

The *Spartina alterniflora* dataset for this experiment was collected through web crawlers and field photography of some coastal wetlands, estuaries and river estuaries in Shandong Province. Images were collected from different angles, distances and time points. The collection equipment included mobile phones, Nikon Z30 micro-single cameras, etc. After screening and deletion, a total of 357 original images were obtained. In the actual dataset collection process, the image collection time was summer and autumn, so the dataset was divided into two categories of *Spartina alterniflora* in summer and autumn. The data set required for this experiment was enhanced by data enhancement and CutMix data processing under the Opencv library, and the original 357 images were enhanced to 1755 images by image translation, rotation, mirroring, and adjusting contrast and brightness, as shown in Figure 2.

After data enhancement, the Labellmg image annotation tool was used to annotate the images. They were divided into two major categories: summer *Spartina alterniflora* and autumn *Spartina alterniflora*, and the image annotation information file xml file was obtained, which was then converted into a txt format suitable for YOLO.

To meet the requirements for fast acquisition, processing, and recognition of *Spartina alterniflora*, this paper improves the original YOLOv8 network to achieve faster recognition and detection while improving detection speed and accuracy.

Spartina alterniflora recognition based on YOLOv8

The YOLOv8(*Github.com*) image recognition model consists of an input layer (Input), a backbone layer (Backbone), a bottleneck layer (Neck) and an output layer (Output). The image of *Spartina alterniflora* enters the Input and undergoes a batch resize operation to ensure the size consistency of the input image. The main network of SA-YOLO is used to extract features from images. The main network of the SA-YOLO model uses the cascaded attention mechanism EfficientVit (*Cai et al., 2022*) as the basic structure to complete the feature extraction of the *Spartina alterniflora* image. It mainly consists of four stages. The size of the feature map from input to output gradually decreases, forming a feature pyramid. First, the standard convolution layer performs upsampling preparation to extract the basic features of the *Spartina alterniflora* image; then, the image is subjected to deep convolution and weighted processing through a feature extraction module consisting of two MBConv modules, which helps capture the feature information of *Spartina alterniflora* in the image; finally, the image enters the two-layer EfficientVit Block module, which adopts a sandwich layout, uses MHSA (multi-head self-attention mechanism), and realizes channel information enhancement through parameter redistribution, strengthening the model's extraction of global information and local details of *Spartina alterniflora*. SPPF extracts the global feature information of *Spartina alterniflora* and performs global maximum pooling to enhance the receptive field. The feature fusion of the Neck part is enhanced, and the C2f convolution layer is optimized to DCNv4 (*Xiong et al., 2024*). This module has excellent expression and computing capabilities for complex backgrounds, and strengthens the model's feature expression and information extraction of *Spartina alterniflora* images. The SA-YOLO model structure is shown in Figure 2.

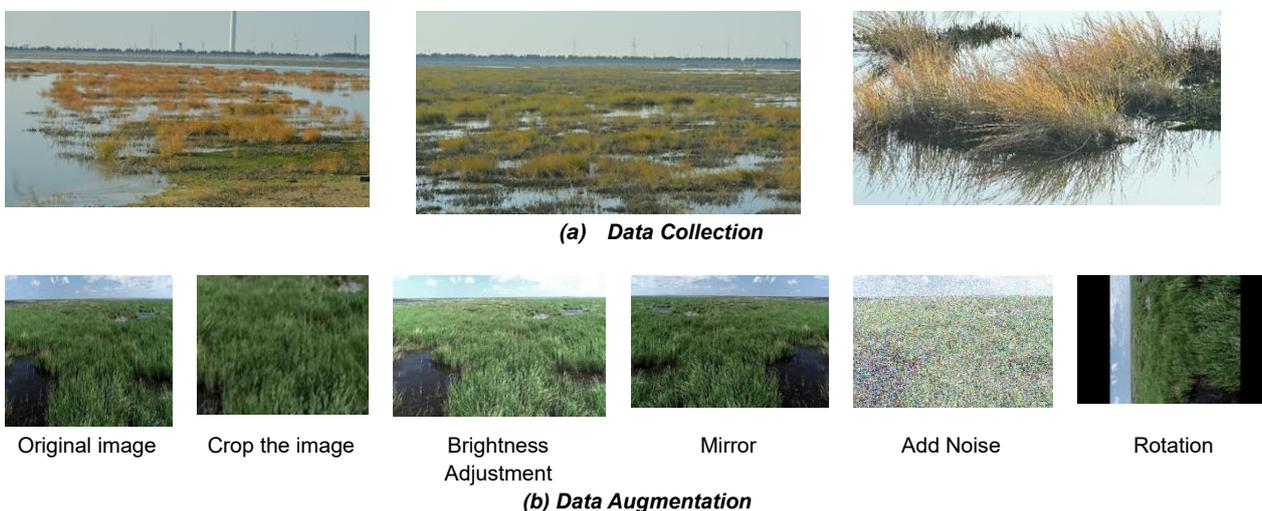

Fig. 2 - Dataset

SA-YOLO network improvement

This paper takes YOLOv8 as the basic model and proposes SA-YOLO for the growth environment and plant information elements of *Spartina alterniflora*. First, the lightweight EfficientViT network is used to replace the backbone to enhance the model's perception and feature extraction capabilities for higher-resolution images and expand the model's receptive field; when extracting features, the DCNv4 module is introduced to further reduce the model's computational workload while enhancing the model's feature fusion and expression capabilities, making the model more real-time and accurate while being lightweight. Compared with the original model, the improved SA-YOLO algorithm is not only lightweight, but also has higher computational efficiency and recognition accuracy.

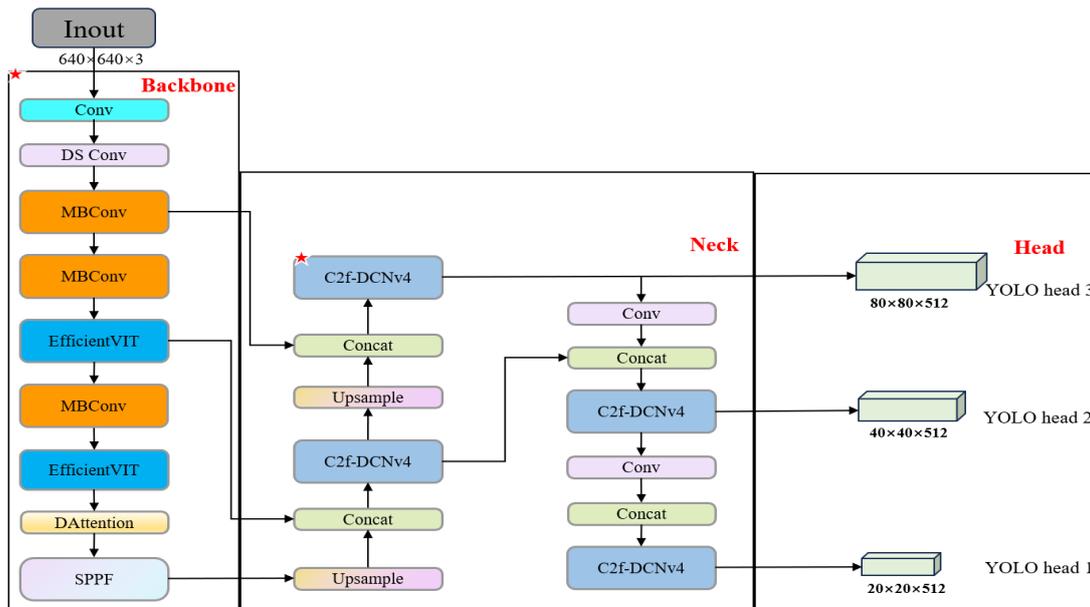

Fig. 3 -SA-YOLO Model structure

During the improvement process, the aim was to make the model have high-precision detection capability and strong feature extraction level for the input *Spartina alterniflora* images. The cascaded attention mechanism EfficientViT is introduced to replace the backbone network, so that the model has fast computing capabilities while maintaining high-precision detection. EfficientViT is a Vision transformer model for high-resolution dense prediction proposed by Cai et al., as shown in Figure 4 (a). By using ReLU linear attention to achieve global receptive field, lightweight and hardware-efficient operations can achieve the purpose of global receptive field and multi-scale learning.

EfficientViT uses EfficientViT block as the core module, as shown in Figure 4 (b), which consists of a sandwich structure (Sandwich Layout) and cascaded group attention (Cascaded Group Attention, CGA), that is, a lightweight MSA module and an MBCConv module. This basic module reduces the use of attention and alleviates the problem of memory access time consumption caused by attention calculation. At the same time, a layer of DWConv is added before each FFN as information interaction between local tokens and helps introduce inductive bias. The lightweight MSA module is mainly used to enhance the feature representation ability of the model, and plays an important role in the feature extraction and expression of *Spartina alterniflora* images in complex environments.

As shown in Figure 5, the lightweight MSA module (Rao et al., 2021) first performs multi-scale processing on the input *Spartina alterniflora* feature map to obtain feature representations of multiple scales, which cover different aspects from local details to global context information. Then, the ReLU linear attention mechanism is used to assign weights to these multi-scale features. After obtaining the weights, the lightweight MSA module applies these weights to the original multi-scale feature map for weighted fusion. Finally, the feature map processed by the lightweight MSA module will be sent to the subsequent network layer for further processing and prediction.

As shown in Figure 6, the MBCConv module (Mark et al., 2018) mainly consists of a 1x1 convolution layer (for dimensionality increase or decrease), a depthwise separable convolution, and a 1x1 pointwise

convolution. The 1x1 convolution layer in MBConv plays the role of dimensionality increase and dimensionality reduction.

As the core part of MBConv, the depthwise separable convolution applies a convolution kernel to each channel of the input feature map, and then fuses the information between channels of the output of the depthwise convolution through a 1x1 point-by-point convolution. Each convolution layer is usually followed by an activation function (ReLU6 (Mansuri et al., 2022) and a batch normalization layer. The activation function can increase the nonlinearity of the model and improve the expressiveness of the model, while batch normalization helps to accelerate the training process of the model and improve the stability of the model.

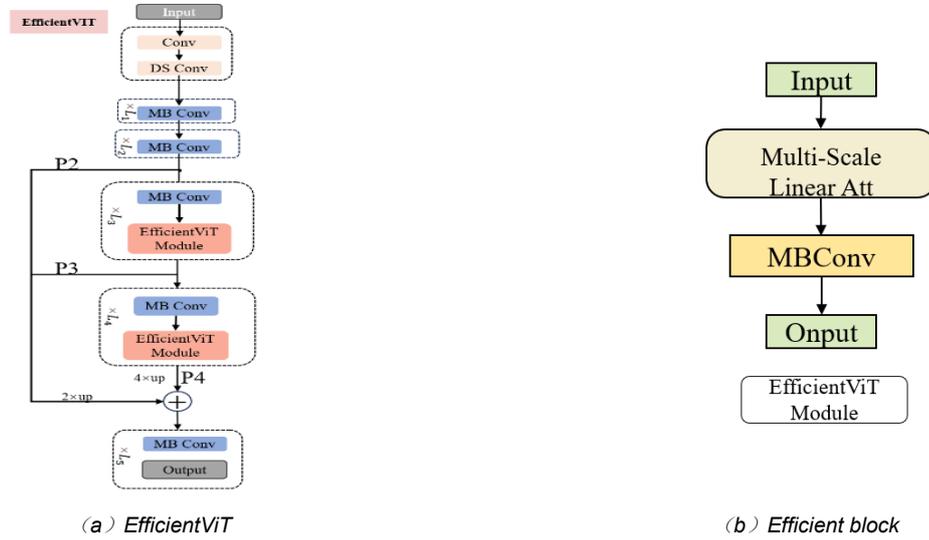

Fig. 4 - EfficientViT Model

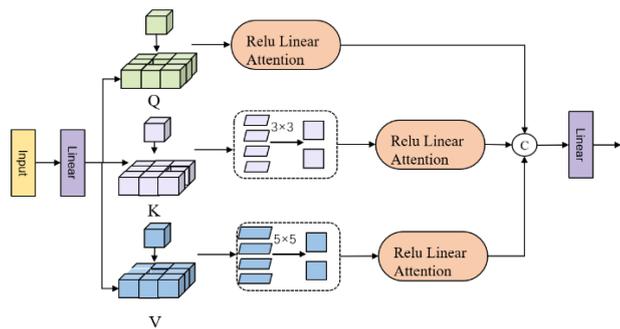

Fig. 5 -Lightweight MSA Module

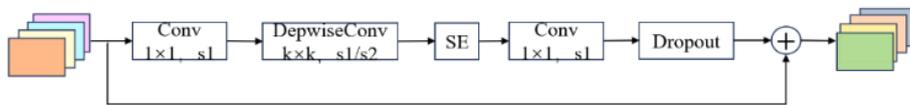

Fig. 6 - MBConv Model

C2f-DCNv4 convolution optimization

DCNv4 is a new type of deformable convolution network architecture. It adjusts the size of the convolution kernel by understanding different learnable offsets, so that the network focuses on the position and shape of *Spartina alterniflora* in the image. Compared with the previous generation, DCNv4 is optimized in two ways: when performing spatial aggregation, it no longer uses Softmax normalization processing and adopts a more flexible weight adjustment strategy; second, it adopts dynamic feature enhancement to convert the modulated scalar between 0 and 1 into an unbounded dynamic weight like convolution. The main structure of DCNv4 includes DCNv4Conv layer, batch normalization module and SiLU activation function (Jocher et al., 2021). After inputting the feature map, the channels are first grouped, where the input feature $x \in R^{(H \times W \times C)}$ (height H, width W and number of channels C), then each group is convolved to obtain the offset and weight, and finally the convolution results of all groups are spliced and output.

The output p_0 is calculated as follows:

$$y_g = \sum_{k=1}^k m_{gk} x_g(p_0 + p_k + \Delta p_{gk}) \tag{1}$$

$$y = \text{concat}([y_1, y_2, \dots, y_G]) \tag{2}$$

where: x_g and y_g represent the input features and corresponding output features of the g group respectively; m_{gk} represents the weight of the k -th sample point in the g group; p_k represents the k key node in the basic network; Δp_{gk} represents the offset relative to the basic network p_k ; concat represents the increase in the number of image feature descriptions.

The optimized structure of the C2f-DCNv4 module is shown in Figure 7. By introducing DCNv4 into C2f, the detection of *Spartina alterniflora* in complex growth environments is significantly improved, and it adapts to different changes in image sizes, thereby improving detection accuracy and robustness.

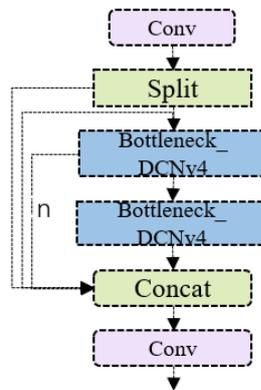

Fig. 7 - C2f_DVNV4 Model

Model deployment and hardware integration

This study conducted a field test on the proposed SA-YOLO model, and built a *Spartina alterniflora* recognition system based on the Flask framework and OpenCV to achieve real-time monitoring, target detection and statistical analysis of *Spartina alterniflora* in wetland environments.

This study tested non-dataset images collected in the field of *Spartina alterniflora*. Some of them were uploaded to the server locally after being taken by mobile phones and cameras, ensuring data security, preservation and reducing costs, and some were uploaded to the server in real time after being taken by drones. The server uses Flask as the backend framework and integrates the SA-YOLO model for target detection. During real-time uploading, in order to ensure efficient data transmission and real-time processing, data transmission supports Real Time Streaming Protocol (RTSP), which can push video streams to the server to achieve low-latency video processing and analysis.

As shown in Figure 8, the server receives the uploaded image. Subsequently, the system uses the SA-YOLO model for target detection. The processed detection results are re-encoded and pushed to the client through Flask's multipart/x-mixed-replace streaming transmission to achieve real-time monitoring and result display.

On the client side, users can view the identified video stream through a web browser and perform area annotation, target statistics, and parameter adjustments. In addition, the system provides historical data analysis and visualization functions, which can generate trend charts to analyze the growth distribution and changes of *Spartina alterniflora*, providing data support for ecological environment monitoring and governance.

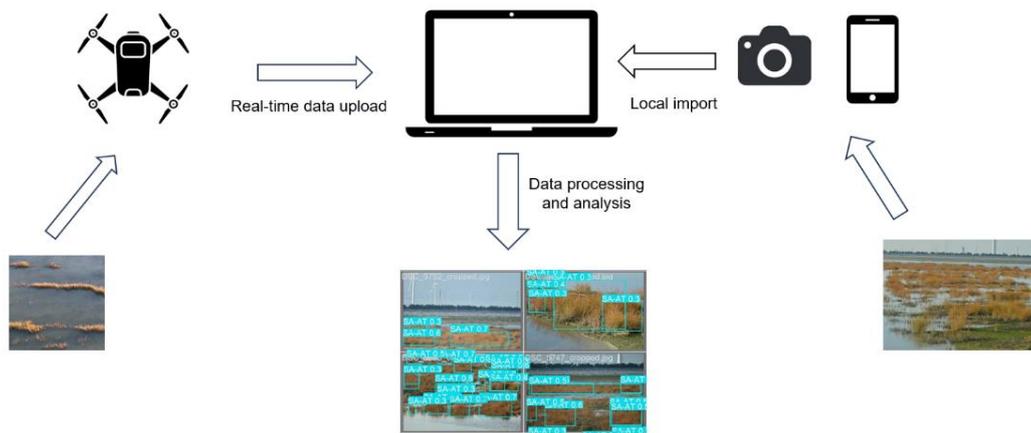

Fig. 8 - Working diagram of Spartina alterniflora identification system

RESULTS

The experiments and server deployments in this study were trained under the Windows 11 operating system. The CPU used was Intel i7-12600H, the GPU was NVIDIA RTX 3060 graphics card with 8 GB of video memory, the host memory was 16 GB, and the CUDA version was 11.8.

During the training process, according to the actual situation of the equipment, the batch size was set to 16, the number of process workers was set to 8, Adam with weight decay (AdamW) was used as the optimizer, the learning rate was set to 0.01, the momentum was set to 0.937, the weight decay coefficient was set to 0.1, and the number of training rounds was set to 300.

Model evaluation indicators

In order to fully verify the model's ability to identify and detect Spartina alterniflora, as well as the improved model's ability, precision *P* (Precision), recall *R* (Recall), and mean average precision (*mAP*) were used as indicators for evaluating the model.

The precision *P* represents the proportion of correctly predicted samples in all samples, as shown in Eq.(3):

$$P = \frac{T_P}{T_P + F_P} \times 100\% \tag{3}$$

The recall rate *R* represents the proportion of correctly predicted samples in all positive samples, as shown in formula (4):

$$R = \frac{T_P}{T_P + F_N} \times 100\% \tag{4}$$

The average precision *mAP* is the mean of the average precision (*AP*), and the average precision *AP* is the area of the *P-R* curve, as shown in formula (5):

$$mAP = \frac{\sum_{i=1}^N \int_0^1 P(R) dR}{N} \times 100\% \tag{5}$$

In the formula, *T_P* represents the number of correctly predicted positive samples, *F_P* represents the number of incorrectly predicted positive samples, *F_N* represents the number of incorrectly predicted negative samples, and *N* represents the number of categories. In this study, two categories of Spartina alterniflora are discussed, so *N*=2 at this time.

Ablation Experiment

In order to verify the model effect after replacing the backbone, the optimization degree of the model after adding the self-attention mechanism, and the effect of model feature fusion after adding deformable convolution, an ablation experiment was conducted.

Table 1

Ablation Experiment						
	EfficientVit	DAttention	C2f_DCNv4	<i>P</i> (%)	<i>R</i> (%)	<i>mAP</i> (%)
YOLOv8				89.3	87.1	90.2
1	√			90.4	89.6	92.1
2		√		88.1	86.9	90.5
3			√	89.6	88.2	91.8

4	√	√		89.7	88.6	91.7
5	√		√	91.3	90.7	92.6
6		√	√	91.5	90.8	92.2
SA-YOLO	√	√	√	92.4	94.5	93.1

Through ablation experiments, it can be seen that after replacing the backbone network, the accuracy, recall and average precision of the model in *Spartina alterniflora* recognition have all improved, indicating that the model has improved the feature extraction and receptive field of *Spartina alterniflora*. After replacing the deformable convolution, the model's detection ability has been further improved, as reflected in the accuracy and recall rates increased by 0.9% and 1.1% respectively, and the average precision value increased by 2.1%. Overall, the SA-YOLO algorithm proposed in this study is optimal.

Comparison of detection results by model

To verify the advantages of the improved model, it is compared with the original YOLOv8, YOLOv5, and YOLOv3. The performance comparison of different models is shown in Table 2.

Table 2

Model	Precision (%)	Recall (%)	mAP (%)
YOLOv8	89.3	87.1	90.2
YOLOv5	86.7	86.4	88.4
YOLOv3	85.1	85.3	87.6
SA-YOLO	92.4	94.5	93.1

As shown in Table 2, the accuracy and recall of the SA-YOLO model are both above 90%. In terms of accuracy, compared with the original YOLOv8, YOLOv5, and YOLOv3 networks, they are improved by 3.1%, 5.7%, and 7.3%, respectively. In terms of recall, SA-YOLO is 94.5%, which is improved to varying degrees compared with YOLOv8, YOLOv5, and YOLOv3, by 7.4%, 8.2%, and 9.2%, respectively. In terms of average precision, SA-YOLO is 2.9%, 4.7%, and 5.5% higher than YOLOv8, YOLOv5, and YOLOv3, respectively. From the comprehensive data, SA-YOLO has a significant improvement in the overall performance of the model, which is better than the other three models.

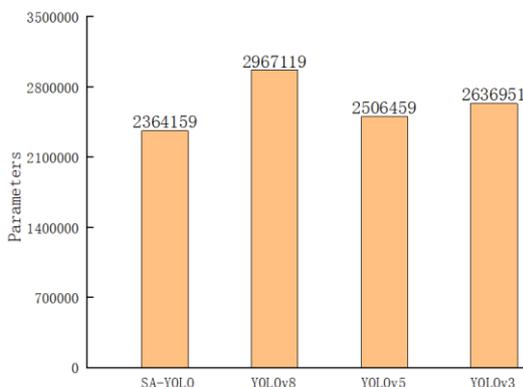

Fig. 9 - Comparison of parameters of each model

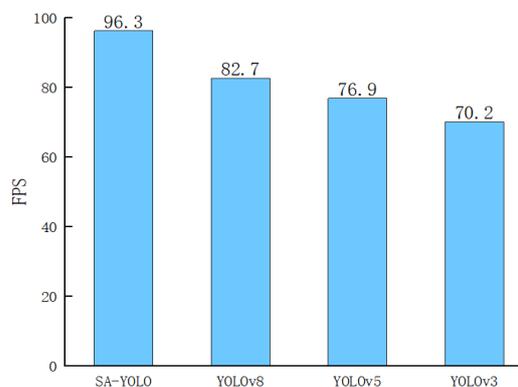

Fig. 10 – Comparison of detection speed FPS of each model

In Figures 9 and 10 the number of parameters and detection speed of different models in the process of detecting *Spartina alterniflora* is shown. Obviously, the SA-YOLO model generates fewer parameters during the detection process, but the detection speed and accuracy are far superior to other models. As shown in Figure 11, the detection results of *Spartina alterniflora* by the improved model have reached a higher level. Figure 12 shows the comparison of the recall rate and accuracy of YOLOv8 before and after the improvement.

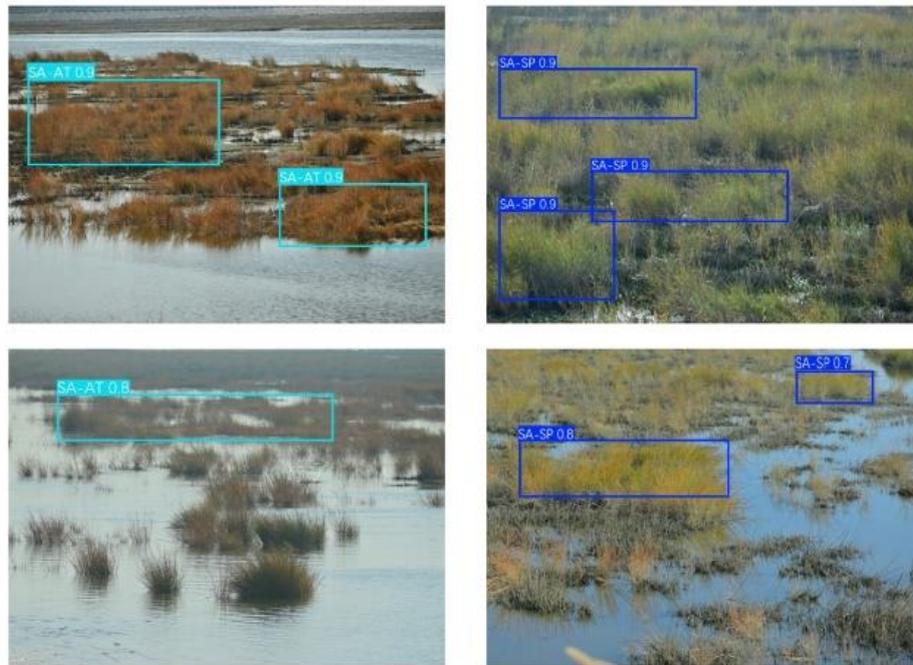

Fig. 11 –Some test results

The improved SA-YOLO model has better convergence ability and higher accuracy, which shows the effectiveness of the model improvement, especially after adding the cascaded attention mechanism and variable convolution, the model has better receptive field and recognition ability.

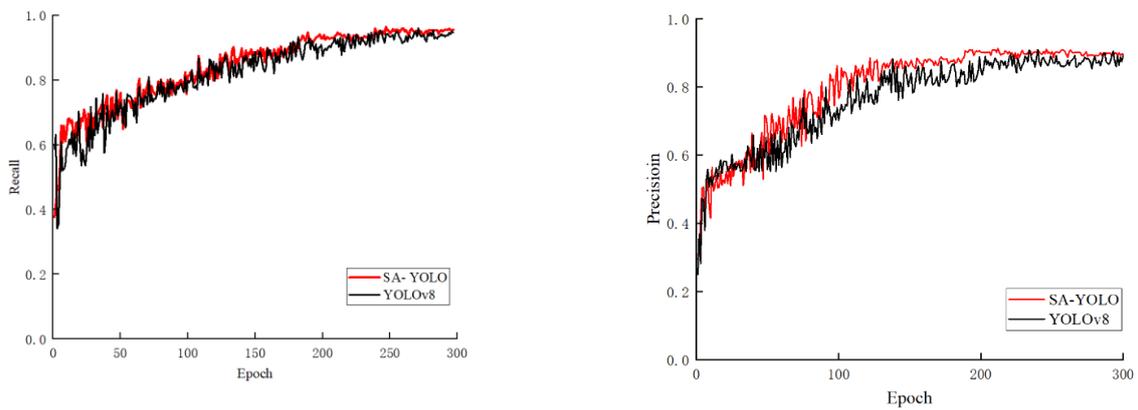

Fig. 12 – Recall and precision curve results

Comparison of the recognition and detection capabilities of each model for Spartina alterniflora in summer and autumn

As shown in Tables 3 and 4, the performance comparison of each model for the recognition of Spartina alterniflora in summer and autumn is shown.

Table 3

Detection Results of Different Models for Spartina Alterniflora in Summer			
Model	Precision (%)	Recall (%)	mAP (%)
YOLOv8	90.5	89.6	93.5
YOLOv5	87.3	88.7	90.2
YOLOv3	86.7	87.2	89.5
SA-YOLO	93.1	91.6	95.4

Table 4

Detection Results of Different Models for Spartina Alterniflora in Autumn			
Model	Precision (%)	Recall (%)	mAP (%)

YOLOv8	88.6	88.2	91.3
YOLOv5	87.5	89.1	89.3
YOLOv3	87.3	88.0	89.1
SA-YOLO	91.6	92.5	94.8

As shown in Tables 3 and 4, in the detection of data sets taken in different seasons but under the same weather conditions, the detection effects of each model for *Spartina alterniflora* in both seasons are good.

In the recognition of *Spartina alterniflora* in summer, the accuracy, recall rate and average detection precision of the SA-YOLO model are higher than those of the other three groups of models. The accuracy is 2.6%, 5.8% and 6.4% higher than YOLOv8, YOLOv5 and YOLOv3 respectively, and the recall rate is 2.0%, 2.9% and 4.4% higher respectively. The average precision is 1.9%, 5.2% and 5.9% higher respectively, which fully demonstrates that the proposed SA-YOLO model has the ability to detect *Spartina alterniflora*.

In the recognition of *Spartina alterniflora* in autumn, the expressiveness is not as good as that in summer, mainly because *Spartina alterniflora* grows more vigorously in summer, first of all, it has more characteristics in appearance, and secondly, it is also very different from the surrounding environment. In contrast, *Spartina alterniflora* in autumn is yellow in color and has sparse branches and stems, which is more integrated with the surrounding environment. However, SA-YOLO still has good recognition and detection capabilities. In terms of accuracy, it is 3.0%, 4.1%, and 4.3% higher than YOLOv8, YOLOv5, and YOLOv3, respectively. In terms of recall, it is 4.3%, 3.4%, and 4.5% higher, and in terms of average precision, it is 3.5%, 5.5%, and 5.7% higher.

System testing and effect evaluation

This study conducted multiple tests of the *Spartina alterniflora* information collection and identification system in November 2024 to verify the proposed SA-YOLO model for the *Spartina alterniflora* clusters in the coastal wetland area. As shown in Figure 13, it is an information image of *Spartina alterniflora* that was taken by a camera and uploaded locally by a computer.

Fig. 13 – Demonstration of the local upload effect of the *Spartina alterniflora* identification system

As shown in Figure 14, this study shows the effect of using drones to capture image pairs and achieve real-time uploading and processing. During the experiment, the drone and the computer were in the same Wi-Fi network to ensure the stability and real-time performance of data transmission.

Fig. 14– Real-time upload effect display of *Spartina alterniflora* identification system

CONCLUSIONS

The improved *Spartina alterniflora* detection model SA-YOLO based on YOLOv8 proposed in this study was trained and tested with a self-made dataset, which fully verified the effectiveness of the improvement. Multiple comparative tests were conducted, and the results showed that while SA-YOLO is lightweight, it has good performance in detection speed and accuracy of *Spartina alterniflora*. Its recall and accuracy reached 94.5% and 92.4%, and the mAP value of detection was 93.1%. Its comprehensive performance is higher than that of the original YOLOv8, YOLOv5, and Faster R-CNN.

In addition, this study also verified the actual deployment of the model, developed a *Spartina alterniflora* identification system, and conducted multiple field tests in stages. The results showed that both the *Spartina alterniflora* information images uploaded via the Internet and locally had good processing results and records.

Looking back at the entire research process, although the recognition and detection of *Spartina alterniflora* was achieved well, there is still room for improvement. First, the establishment of the *Spartina alterniflora* data set still needs further improvement; second, in terms of model deployment, there is a lot of room for server-side function expansion; third, you can try to combine the model with the *Spartina alterniflora* elimination machine.

This research is of great significance for the identification and detection of *Spartina alterniflora*, and is of great significance for future intelligent prevention and control of *Spartina alterniflora*, protection of the ecological environment and ecological diversity.

ABSTRACT

This study explores the use of deep neural networks for detecting and quantifying the cattle population in Mongolia using drone imagery, addressing the limitations of traditional methods that are labor-intensive and time-consuming. A custom dataset of aerial images featuring grazing cattle in Mongolia was developed, focusing on winter and spring seasons, to train and validate a model based on state-of-the-art object detection algorithms. Specifically, the You Only Look Once (YOLOv8) architecture was employed to detect cattle across diverse environmental conditions. Model performance was evaluated using widely accepted metrics, including precision, recall, F1 score, and the mean average precision (mAP). The findings demonstrate the effectiveness of the proposed approach, with the YOLOv8 model achieving a mAP of 97.3% at an IoU threshold of 0.5, highlighting its potential for efficient cattle detection and monitoring in Mongolia's unique environmental contexts.

INTRODUCTION

According to the preliminary results of the annual livestock census, by the end of 2023, Mongolia had 64.7 million head of livestock, including 5.4 million cattle (*National Statistics Office of Mongolia*). In the traditional setting, cattle farming typically occurs in a natural environment in Mongolia, where challenges like accidental drownings in rivers, snowbound or landslides may cause substantial damage and create serious challenges for cattle management (*Xu et al., 2020*). Consequently, monitoring cattle in Mongolia, including their behaviors and health, has emerged as a critical research area. The rapid progress in deep learning, particularly in methods involving convolutional neural networks (CNNs), offers effective solutions for detecting and classifying animals (*Radovic et al., 2017*).

Spanning the years 1980 to 2023 across all continents, a notable 71.4% of studies have been published since 2019, reflecting an increased focus on livestock detection in recent years (*Ocholla et al., 2024*). Furthermore, 69.2% of the studies relied on drones for detection and counting purposes, with alternative methods such as manned aircraft, satellites, and camera traps being used less frequently (*Ocholla et al., 2024*). The increasing popularity of drones is a result of innovations in embedded systems and electronic communication, which have reduced costs and enhanced their availability (*Olson and Anderson, 2021*).

Fig. 1 presents the distribution of studies on livestock detection and counting analyzed across various countries (*Ocholla et al., 2024*).

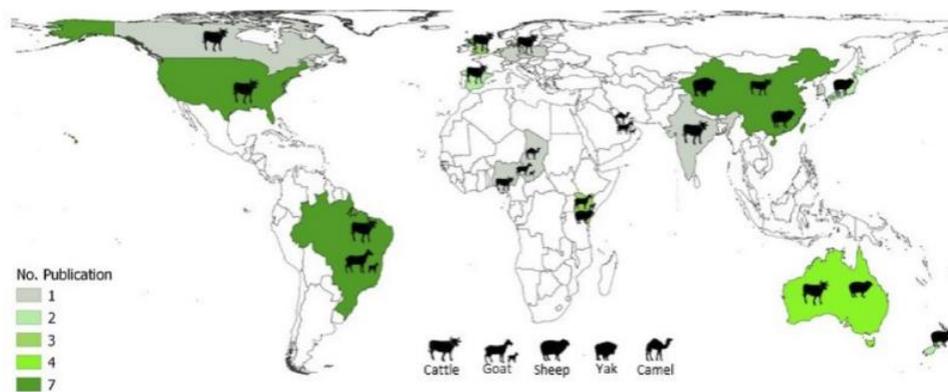

Fig. 1 - Country-wise distribution of studies on livestock detection and counting

Our research aims to leverage a cutting-edge object detection framework, specifically the YOLOv8 algorithm (Redmon *et al.*, 2016), to accurately detect and count grazing cattle in Mongolian grasslands using aerial images captured by drones.

Animal monitoring using remote technologies

Innovations in remote monitoring technologies have significantly improved data collection on animal behavior, enabling farmers to enhance meat quality, boost production efficiency, and ensure better health for livestock (Xu *et al.*, 2020). Farmers are employing wearable technologies, including RFID, GPS collars (Derek *et al.*, 2018), and smart ear tags (Kumar *et al.*, 2016), to track movement, behavior patterns, heart rate, body temperature, and other physiological indicators. These technologies play a crucial role in preventing illnesses and deaths among animals, thereby minimizing production losses (Xu *et al.*, 2020).

Motion-sensor cameras, commonly referred to as camera traps, offer a cost-effective method for recording animals' presence, locations, and activities (Verma and Gupta, 2018). These technologies collectively contribute to a more efficient and sustainable approach to animal monitoring and management in agricultural settings.

One significant drawback of existing ground-based techniques, such as smart ear tags and motion-sense cameras, is their constraint within large geographic areas and complex terrains, making it challenging to identify and track animals effectively (Gonzalez *et al.*, 2016). Combining drone technology with advanced machine learning models offers a promising approach to improving the management of livestock. Compared to traditional methods, drones demonstrate several unique advantages (Windrim *et al.*, 2019):

1. They are capable of operating at both low and extremely low altitudes.
2. They can acquire detailed, high-quality images even under varying weather conditions.
3. They can rapidly capture imagery across vast areas and challenging terrains that are otherwise difficult to access.

However, accurately and reliably counting animals in drone-captured imagery remains a crucial yet challenging task in intelligent livestock management (Wang *et al.*, 2021). The primary aim of this research is to explore deep learning approaches for the detection and quantification of animals, focusing on the automated analysis of cattle populations in drone-based images. Additionally, it highlights the potential of drone vision and object detection techniques to improve livestock management practices.

Drone-based animal detection and counting

CNNs (Lecun *et al.*, 2015) have proven to be an effective and reliable method for detection and counting tasks in image recognition, owing to its processing speed and accuracy. In recent years, advanced deep learning models such as Faster R-CNN (Ren *et al.*, 2015), Mask R-CNN (He *et al.*, 2017), and YOLO (Redmon *et al.*, 2016) have shown great promise in detecting and classifying objects across vast datasets, achieving higher accuracy, precision, and faster processing speeds.

Although these results are impressive, livestock monitoring still faces challenges in diverse and complex scenarios, including visual clutter (e.g., vegetation), strong lighting contrasts and shadows from farm structures, low target resolution, and high animal densities (e.g., tightly packed herds or feedlots) (Xu *et al.*, 2020). Therefore, a thorough evaluation of cattle-counting algorithms across various livestock farming environments in Mongolia is essential.

Deep learning algorithms for object detection are predominantly built on CNNs. These networks excel in image processing due to their capacity to extract hierarchical features directly from pixel-level data. These algorithms are specifically designed to identify and locate objects within images or videos (Lecun et al., 2015). Deep learning-based object detection methods can be classified into two categories: Two-Stage Detectors and One-Stage Detectors.

Two-Stage Detectors operate by initially generating potential regions of interest (Rois) within an image using techniques such as selective search or region proposal networks (RPNs). In the subsequent step, these Rois are classified, and their bounding boxes are adjusted for precision. Prominent examples of this category include R-CNN (Region-based Convolutional Neural Networks) (Girshick et al., 2014), Faster R-CNN (Ren et al., 2015), and Mask R-CNN (He et al., 2017). In contrast, One-Stage Detectors eliminate the need for a separate region proposal stage and directly predict bounding boxes along with class probabilities. Notable examples of this approach include YOLO (You Only Look Once) (Redmon et al., 2016) and SSD (Single Shot Multibox Detector) (Liu et al., 2016).

R-CNN and its variants, such as Faster R-CNN, are two-stage object detection frameworks known for their accuracy and detailed object localization but are slower and more computationally demanding. In contrast, YOLO is a single-stage algorithm optimized for real-time performance, making it ideal for applications requiring fast and efficient object detection, such as drone-based monitoring or video analysis (Xu et al., 2020).

Recent advancements in object detection methods have significantly enhanced the accuracy of monitoring livestock in pastures and open areas using drone-captured data.

The research done by João Vitor de Andrade Porto et al., (2021), highlights the application of Faster R-CNN for counting cattle in feedlots through aerial imagery, reporting an average precision of 89.7%.

Based on YOLOX, detection performance for counting cattle was improved through input resolution optimization, reaching a precision of 95.7% (Wang et al., 2023).

Mask R-CNN was applied to extract features and trained on drone-based imagery, achieving a classification accuracy of 96% for livestock (Xu et al., 2020).

Among the approaches discussed in the literature, YOLO stands out as a particularly promising method for cattle monitoring in real-time drone scenarios. The newer iteration, YOLOv8 (<https://ultralytics.com>), demonstrates significant improvements in speed, accuracy, and efficiency, making it a suitable benchmark for this study. This research aims to evaluate the feasibility and effectiveness of using YOLOv8 to detect and quantify cattle populations in diverse environmental conditions. The objectives of the study are as follows:

1. Apply the YOLOv8 model, pre-trained on the MS COCO dataset, to detect cattle in drone-captured images across various seasons.
2. Collect drone imagery of cattle during the winter and spring seasons to develop a custom dataset.
3. Train a custom YOLOv8 model using the collected dataset and evaluate its performance using standard metrics such as mAP, precision, recall, and F1 score.
4. Analyze cattle detection results across different seasons using the pre-trained and custom-trained models to validate the correctness and effectiveness of this research.
5. Offer insights into the applicability of deep learning object detection techniques for livestock monitoring and propose directions for future research in this domain.

Object detection techniques

Object detection is essential for this task, as it identifies and categorizes objects of interest by enclosing them within bounding boxes. The process typically involves two or three stages: generating bounding boxes to identify regions of interest, extracting features from these regions, and classifying objects to determine their categories. This study focuses on detecting a single class: cattle. In addition to detection, accurate localization of animals within images is crucial for effective counting and monitoring of livestock behavior.

Modern object detection models typically comprise two primary components: a backbone for feature extraction and a head for object classification and localization. The backbone processes input images and generates a feature map that supports the remaining network operations. The choice of backbone (e.g., VGG (Simonyan and Zisserman, 2015), ResNet (He et al., 2016), DenseNet (Huang et al., 2017), EfficientNet (Tan and Le, 2019)) depends on the detector's operating platform (CPU or GPU).

Object detection methods can be broadly categorized into two approaches: the two-stage approach, which employs region proposal algorithms, and the one-stage approach, which directly combines detection and classification tasks into a single step for real-time processing. This study focuses on the one-stage method

Fig. 4 - Drone-captured image of cattle in winter

Fig. 5 - Drone-captured image of cattle in spring

Many flight activities were conducted using the Potensic drone (www.potensic.com/atom.html), equipped with an integrated Sony camera, as shown in Fig. 6. The camera features a 1/2.3-inch CMOS image sensor capable of lateral and vertical rotation. It captures 4K videos and 12-megapixel photos with stabilization. Considering factors such as pixel resolution, photo capture delay, and operational convenience, videos were selected to create datasets of cattle in diverse scenes. The videos were recorded at 30 frames per second and saved in MOV format.

Fig. 6 - Image of the Potensic drone used for data collection

The drone performed 360-degree rotations above the cattle herd at altitudes ranging from 15 to 35 meters, capturing their posture from multiple angles. This approach significantly improved the accuracy of deep learning-based detection. Videos of varying lengths, up to 30 minutes, were recorded by the drone. However, as the YOLO training model requires image files, the OpenCV library was utilized in this study to extract frames from the videos. The most effective images for training were then carefully selected.

The winter dataset comprises 100 images containing a total of 1,563 cattle, with 70 images (1,376 cattle) allocated for training and 30 images (187 cattle) for testing. The spring dataset consists of 138 training images with 1,359 cattle, 17 testing images with 172 cattle, and 18 validation images containing 180 cattle. To ensure accurate labeling of ground truth data, the widely recognized image annotation and analysis platform Roboflow was utilized.

Our research is planned to continue over several years, with the aim of creating and sharing a benchmark drone-captured dataset of Mongolian livestock across all four seasons for scholarly purposes.

The Algorithm for detection and counting cattle

YOLOv8, developed by Ultralytics (<https://ultralytics.com>), is the newer version of the widely recognized model for real-time object detection and image segmentation. Leveraging advancements in deep learning and computer vision, YOLOv8 achieves exceptional performance in both speed and accuracy. Its optimized architecture enhances adaptability, enabling deployment across diverse applications and ensuring compatibility with a range of hardware environments, including edge devices and cloud-based systems.

YOLOv8 incorporates several key features that contribute to its high performance:

1. Mosaic Data Augmentation: This training technique merges four images into a single composite image, enabling the model to learn from varied object placements and contexts.
2. Anchor-Free Detection: This approach eliminates reliance on predefined anchor boxes by directly predicting object centers and bounding box dimensions, enabling more accurate and efficient object localization.
3. C2f Module: The C2f module enhances feature extraction by combining convolutional layers with feature fusion, thereby improving the model's accuracy in object detection.
4. Decoupled Head: YOLOv8 incorporates a decoupled head design that separates classification and localization tasks, enhancing both the model's efficiency and accuracy.

5. Loss Function: The model employs a modified loss function to optimize the training process and enhance object detection performance.

These features collectively enhance YOLOv8's advanced performance in fast and accurate object detection and image segmentation.

The implementation details

The YOLOv8 model was set up in a Python environment and initialized with a pre-trained model from the MS COCO dataset. Following the organization, formatting, and annotation of the collected cattle data, the model was trained on this dataset. The trained model was then tested and evaluated to measure its performance.

The training process was conducted on a 64-bit Windows 11 system equipped with an Intel Core i7-13620U CPU running at 2.4 GHz, 16 GB of RAM, and an NVIDIA RTX4050 GPU with 6 GB of dedicated memory.

To evaluate the performance of the proposed approach, precision, average precision (AP), and recall were utilized as evaluation metrics. Precision quantifies the ratio of true positive predictions to the total number of positive predictions (Equation 1), while recall measures the proportion of true positives relative to all actual positive instances (Equation 2). The precision-recall curve provides a comprehensive evaluation of the model's performance by analyzing the area under the curve across different IoU thresholds. Average precision, as defined in Equation 3, summarizes the precision-recall trade-off. IoU (Intersection over Union) quantifies the overlap between the predicted and ground-truth bounding boxes, expressed as the ratio of their intersection to their union, as specified in Equation 4.

$$P = \frac{\text{True Positives}}{\text{True Positives} + \text{False Positives}} \tag{1}$$

$$R = \frac{\text{True Positives}}{\text{True Positives} + \text{False Negatives}} \tag{2}$$

$$AP = \sum_{n=1}^N [R(n) - R(n - 1)] \times \max P(n) \tag{3}$$

where:

- N - the number of Precision-Recall (PR) points calculated;
- R(n) - the recall value at the n th point;
- P(n) - the precision value at the n th point.

$$IoU = \frac{A \cap B}{A \cup B} \tag{4}$$

RESULTS and DISCUSSIONS

The pre-trained Ultralytics YOLOv8 model is derived from the Microsoft COCO dataset, which predominantly features ground-level imagery. However, this model demonstrates limited suitability for detecting and counting objects in aerial images. An initial evaluation of the COCO-based pre-trained YOLOv8 model revealed inaccuracies, including misclassifications of cattle as birds in aerial imagery. As depicted in Fig. 8, these inaccuracies encompassed additional detections of shadows, missed cattle, and erroneous bird predictions, as further illustrated in Fig. 7.

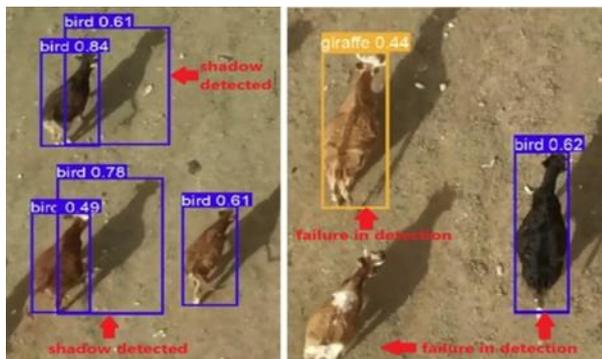

Fig. 7 - Examples of shadow and failure detections

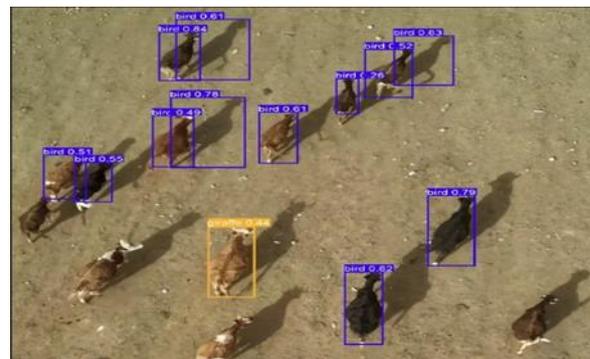

Fig. 8 - Predictions from the model pre-trained on the MS COCO dataset

The cattle detection model was trained on a custom-labeled dataset, resulting in high prediction accuracy. As demonstrated in Fig. 9, the custom-trained model accurately detected all cattle in the image with high confidence scores and no false positives, such as misclassifications involving shadows.

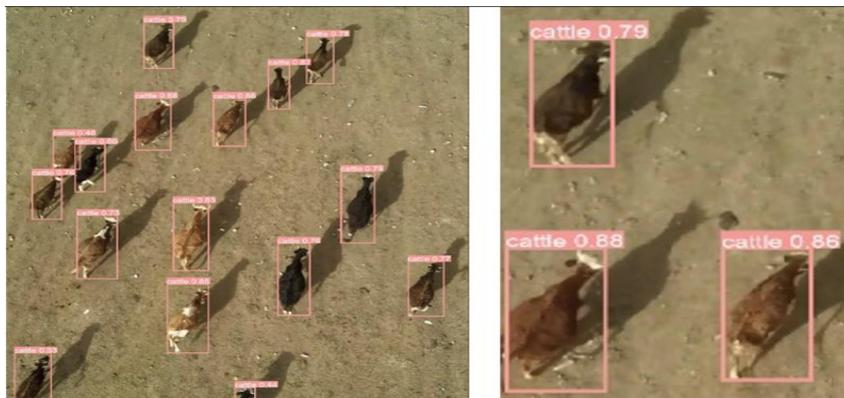

Fig. 9 - Prediction from the trained model with high confidence scores

Despite the blurriness of the images captured during winter, the trained model successfully detected cattle with high accuracy, as illustrated in Fig. 10.

Fig. 10 – Winter cattle detection results using the trained model

Comprehensively capturing a wide range of grazing cattle postures in natural environments is essential for deep learning-based object detection. In this study, low-altitude drones were employed to record 360-degree videos of cattle from multiple angles, ensuring the collection of diverse postural data. This approach was critical in achieving high model accuracy and reliable validation metrics. Unlike horses, which exhibit greater posture variability, cattle tend to graze in a more dispersed manner and display fewer postural variations due to their shorter necks, shorter legs, and robust bodies. These traits contributed to a more streamlined process for annotation, training, and validation in this research.

Accurate and comprehensive labeling of the full body of each cattle in the images, in addition to capturing diverse postures, is crucial for achieving effective object detection. This meticulous annotation process substantially contributes to improving the model's detection accuracy.

The performance of the trained model was assessed using evaluation metrics including mAP, precision, recall, and the F1 score. A comprehensive analysis of the results is presented in the following section.

1. Fig. 11 illustrates the Precision-Confidence Curve for the trained model. The plot indicates that the model achieves high accuracy beginning at a relatively low confidence threshold of 0.2 (20%), with precision generally improving as the confidence threshold increases. Precision attains its maximum value of 1.00 (100%) at a confidence threshold of 0.74 (74.0%), indicating a minimal occurrence of false positives at this level.

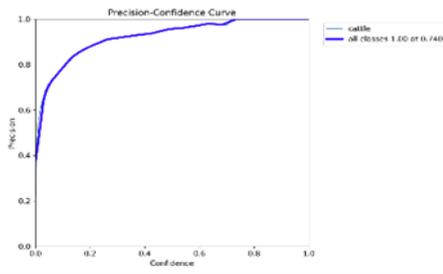

Fig. 11 - Precision-Confidence

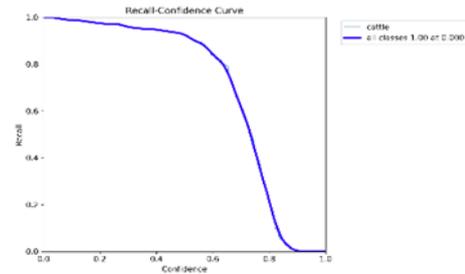

Fig. 12 - Recall-Confidence

- Fig. 12 presents the Recall-Confidence Curve for the trained model, highlighting its robust capability. Notably, the model achieves and sustains high recall levels at a confidence threshold of 0.7 (70%).
- Fig. 13 depicts the Precision-Recall Curve for the trained model. The metric 'All classes 0.973 mAP@0.5' indicates that the model achieves a mAP of 97.3% across all classes at an IoU threshold of 0.5 (50%), reflecting its overall detection performance.

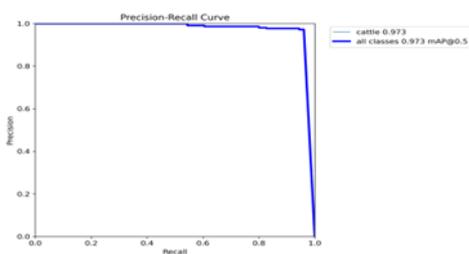

Fig. 13 - Precision-Recall

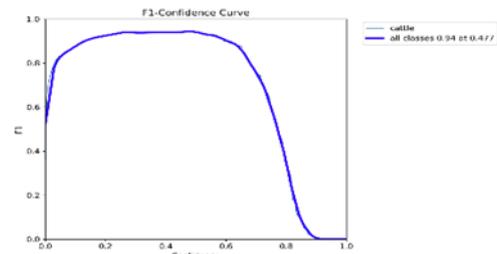

Fig. 14 - F1-Confidence

- Fig. 14 presents the F1-Confidence Curve for the trained model, highlighting its performance. An F1 score of 0.94 (94%) is achieved at a confidence threshold of 0.477 (47.7%), reflecting a well-balanced trade-off between precision and recall.

Upon completing the training phase, the YOLO validation function was employed to evaluate the model's performance. This validation process was conducted using 180 pre-annotated instances of cattle from 18 images in the dataset's validation set. The corresponding results are summarized in Table 1 below:

Table 1

Evaluation metrics of the trained model during validation

Class	Images [Number]	Instances [Number]	Precision [%]	Recall [%]	mAP@0.5 [%]	mAP@0.5:0.95 [%]
cattle	18	180	97.2%	96.1%	97.3%	59.9%

These metrics indicate excellent model performance, highlighted by high precision, recall, and an impressive mAP@0.5 score. The findings validate the model's effectiveness in accurately detecting and counting cattle in aerial images.

The confusion matrix for the single-class object detection model is depicted in the following figures. Fig. 15 presents the standard confusion matrix, while Fig. 16 illustrates the normalized version.

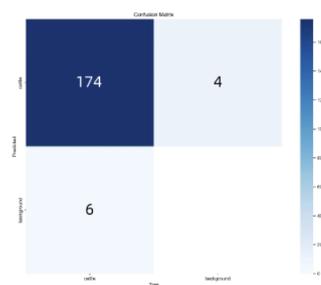

Fig. 15 - Standard confusion matrix

Fig. 16 - Normalized confusion matrix

CONCLUSIONS

The trained model achieved high performance metrics, validating the effectiveness of the proposed research methods and approach. This study demonstrates the feasibility of utilizing YOLOv8 for cattle detection and counting under diverse environmental conditions, contributing to advancements in livestock monitoring in Mongolia. Specifically, for counting large herds of livestock, this research provides robust evidence supporting a novel method that leverages deep learning-based object detection for high-precision identification in drone-captured images and accurate total counting.

Model predictions in this study indicate that the MS COCO-based model effectively learned the features of well-fed cattle during the summer but struggled to detect leaner Mongolian cattle in winter and spring. In contrast, the custom-trained model achieved high accuracy in identifying cattle across these seasons. This finding highlights the ability of deep learning approaches to capture significant feature variations associated with seasonal changes in cattle. Additionally, it underscores the potential of computer vision and deep learning to analyze the distinct characteristics of livestock under varying environmental conditions, offering valuable insights and methodologies to advance livestock research in Mongolia.

Mongolia's distinct four seasons-characterized by snow-covered winters, golden autumns, and lush green summers-combined with its varied terrain of rolling grasslands, alpine forests, and hills, pose unique challenges for cattle detection. Currently, the dataset comprises images collected and labeled during the winter and spring seasons. Over the next year, the dataset will be expanded through the collection of drone imagery capturing diverse cattle populations across all seasons and terrains in Mongolia. This initiative aims to develop a comprehensive aerial dataset of Mongolian cattle, facilitating the training of a high-accuracy detection and counting model optimized for diverse environmental conditions and landscapes throughout the country.

ABSTRACT

As an important facility structure in China, the solar greenhouse can provide a suitable environment for plant growth and development during winter, making it a viable structure for cultivating landscape flowers in cold regions. However, the impact of crop spacing in solar greenhouses on the thermal environment had received scant attention from researchers. Therefore, computational fluid dynamics (CFD) software was used to simulate the effect of crops on the thermal environment in solar greenhouses. The results of this study show that: the presence of crops in the greenhouse has a greater influence on the temperature in the solar greenhouse along the horizontal, vertical and longitudinal directions within the ranges of (3000, 8000 mm), (300 mm, at the film) and the distance from the inner surface of the east and west walls within the range of 10,000 mm; the presence of crops in the greenhouse has a greater influence on the internal temperature of the east wall, the west wall and the north wall; The influence of different planting densities of crops in the greenhouse on the internal temperatures of the solar greenhouse in the horizontal, vertical and longitudinal directions was within the ranges of (1000 mm, at the film), (600 mm, at the film), and the distance from the inner surface of the east and west walls was within the range of 6000 mm, respectively. This study can provide a theoretical basis for the cultivation and management of flowers in solar greenhouses in cold regions.

摘要

日光温室作为中国重要的设施结构，在冬季可提供植物生长发育的适宜环境，因此可在寒冷地区的日光温室中种植景观花卉。但是针对日光温室内花卉景观种植密度对温室热环境的影响较少，因此通过 CFD 模拟手段探究不同种植密度对温室湿热环境的影响。本研究结果显示：相对于无作物温室的温度，有作物温室的温度沿横向、竖向和纵向有较大变化的区域分别为 (3000,8000) mm、(300mm, 同跨度棚膜内表面高度处) 和距离东西墙体内部表面纵向距离为 10000mm 范围内；温室内作物不同种植密度对日光室内温度沿横向、竖向和纵向的影响范围分别为 (棚膜处,1000) mm、(600mm, 棚膜处) 和距离东西墙体内部表面距离为 6000mm 范围内。该研究可为寒冷地区日光温室花卉种植和管理提供理论依据。

INTRODUCTION

As the global population continues to grow, the demand for food shows a sharp upward trend, and facility horticulture, as a highly efficient agricultural production method, provides a highly promising solution to meet this challenge, while also helping to raise the income of the population (Cheng Weiwei., 2021). Among the many forms of facility horticulture, the development of solar greenhouses in China has been particularly remarkable, and they have become one of the key indicators of the level of agricultural modernization (Chen P et al., 2020). Daylight greenhouses, with their high-yield and high-efficiency production technology, have become an important way to improve crop yield and quality (Fu G.H. et al., 2016). However, the design and construction of solar greenhouses must fully consider the local climatic conditions, and China has a vast area with significant differences in climate. Therefore, an in-depth analysis of the thermal environment of solar greenhouses in Inner Mongolia can help promote the sustainable development of the greenhouse industry in this region (Hu Q.Q. et al., 2015).

The development of agricultural facilities and computer technology has led to the emergence of Computational Fluid Dynamics (CFD) as a powerful tool in the field of thermal environment index studies (He Z.G. et al., 2018; He Wei et al., 2022; Jia W.S. et al., 2016). Domenico et al., (2020), used TRNsys to perform simulations to select the best glazing for solar greenhouses considering different thermal phenomena, and the results showed that single pane glass/plastic materials are only recommended for tropical/hot climates, partially for dry (desert and semi-arid) climates and rarely for other climates. Li J.C., (2015), explored the effect of whether tomato was grown in the greenhouse on the microclimate environment in the solar greenhouse for the winter outdoor climatic conditions in Jinan, and found that the entrance wind speed had a small effect on the wind speed of the crop canopy, and that the temperature difference in the greenhouse was small and favourable to crop growth in the north-easterly winds, but did not consider the effect of transpiration. YU Wei et al., (2023), used CFD software for virtual identification and modelling of greenhouse temperature, and the results showed that the simulation results were in accordance with the temperature distribution law, indicating that the virtual and physical sensors can work together to monitor the greenhouse environment. Du Zhenyu et al., (2023), used CFD method to construct a numerical model of natural ventilation daylight greenhouse, explored the movement law of indoor airflow under the condition of natural ventilation and planting crops in spring, and the change rule of indoor temperature and humidity at different moments. The results show that: crops have a greater impact on the indoor airflow field, temperature and humidity field of the solarium; the temperature of the crop area in the solarium from 11:00 to 18:00 is too high, which does not satisfy the temperature range required by the 'four-stage variable temperature management'.

Most of the existing studies have focused on the environmental effects of the presence or absence of crops in solar greenhouses on the greenhouse environment, while few in-depth studies have been conducted on how different planting densities affect the greenhouse thermal environment, which was a key factor. In recent years, in order to improve the economic return of greenhouse cultivation, more and more greenhouse growers have begun to actively explore the landscape planting mode in traditional solar greenhouses (Shi L.J. et al., 2021). Taking the strawberry picking garden as an example, this model cleverly integrated the two major functions of crop cultivation and tourism, opening up a new development path for the greenhouse planting industry. However, under this innovative model, how to scientifically and reasonably plan the crop layout in the greenhouse (Sun B. et al., 2020), not only fully exploiting the utilisation potential of the greenhouse thermal environment to achieve efficient crop growth, but also ensuring that the tourists' sightseeing experience is not interfered with, and creating a comfortable and pleasant visiting environment, has become a key issue strengthening the further development of greenhouse planting industry. In this study, CFD simulation was used to accurately analyse the impact of different planting densities on the thermal environment in solar greenhouses, and to explore the intrinsic laws, with the aim of providing scientific, systematic and solid theoretical support for the optimization of greenhouse crop cultivation, and contributing to the sustainable development of greenhouse cultivation industry and the enhancement of its comprehensive benefits.

MATERIALS AND METHODS

Solar greenhouse geometry and grid model construction

Computational Fluid Dynamics (CFD) is a comprehensive discipline that integrates several fields such as mathematical modelling, fluid mechanics and computer science. It uses numerical analysis and fluid theory and other methods to carry out in-depth calculation, simulation and analysis of fluid objects, providing a powerful tool for solving complex fluid flow problems. The structure of CFD software consists of pre-processing, solver and post-processing. The pre-processing of CFD mainly includes the construction of the geometric model and mesh delineation, and a good pre-processing can greatly improve the accuracy of numerical simulation.

A geometrical model was constructed for a common solar greenhouse around the city of Hulunbeier in Inner Mongolia, China. The greenhouse was situated in a north-south orientation and measured 80 metres in length in the east-west direction. The dimensions of the greenhouse are as follows: a span of 10 metres, a ridge height of 5 metres, an earth wall on the north side of the building that was 4.5 metres high, and trapezoidal shapes on the north, east and west walls, with a lower base width of 8 metres and an upper base width of 2 metres. The intersection of the north wall, the west wall and the ground in the greenhouse was defined as the (0,0,0) point. SolidWorks modelling software was used for 1:1 three-dimensional modelling of the solar greenhouse, as shown in Figure 1.1.

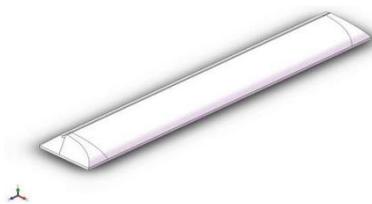

Fig. 1.1- 3D model of solar greenhouse

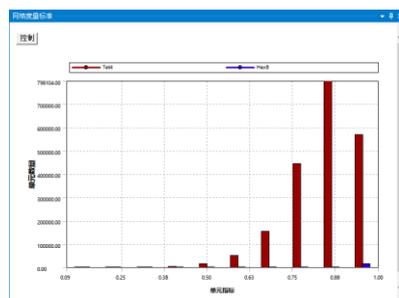

Fig. 1.2- Grid Quality

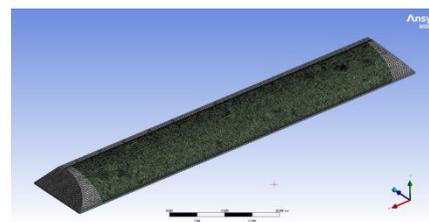

Fig. 1.3- Mesh Division

3D model meshing

Considering the boundary encryption and computational accuracy, a hybrid mesh is selected to process the model. The mesh size is 300 mm and the final mesh number was 1856226. The mesh quality is determined according to the mesh metric. The closer the mesh metric is to 1, the better the mesh quality. Grid division and grid quality were shown in Figure 1.2 and Figure 1.3.

CFD numerical modeling

Temperature change in a solar greenhouse is a dynamic and complex process influenced by factors such as construction, outdoor climate, growing conditions and internal ventilation. In order to improve the analysis efficiency and calculation accuracy, the CFD numerical model of temperature inside the solar greenhouse is reasonably simplified, assuming that the greenhouse is in a fully closed state except for the upper vent, ignoring the effect of humidity on the temperature, and that the parameters of each part of the material do not change with the temperature change.

Computational Fluid Dynamics (CFD) simulations are based on the three conservation laws of mass, momentum and energy, as well as the fundamental equations of fluid heat and mass transfer. In a confined space, the form of fluid flow is mainly affected by the Reynolds number (Re), which is manifested in two states: laminar and turbulent flow. In laminar flow, the fluid flows in layers, the flow velocity is stable, and the viscous force is dominant; while in turbulent flow, the fluid is in a disordered state, the flow velocity varies greatly, and the inertia force is dominant. The complex and dynamic fluid flow inside the solar greenhouse is usually regarded as turbulent flow. Therefore, turbulence models are widely used in the study of gas flow in greenhouses, among which the standard $k-\epsilon$ model is suitable for many scenarios and can obtain good results due to the assumption of turbulence isotropy.

In Fluent, radiation models include Rosseland model, P1 model, DTRM model, DO model, S2S model and solar radiation model. The simulation of the thermal environment of the solar greenhouse involves the radiative heat transfer processes such as the transmission of sunlight and the absorption and reflection of light by plants and soil, so the DO radiation model and the solar radiation model were preferred. In the simulation, the solar radiation calculator sets the solar orientation, irradiation intensity and material heat radiation parameters. The solar greenhouse is located at $49^{\circ}21'N$ latitude and $119^{\circ}25'E$ longitude, which is in the East 8 time zone. The solar radiation for this simulation was taken from the data at 17:00 on 26 January 2025 (a sunny day), the X-axis was reversed to due north, the Z-axis was reversed to due east in the coordinate system, the insolation coefficient was taken to be 1, and the light parameters were all set based on the solar calculator.

In CFD numerical simulation, porous media modelling is an effective tool for simulating the flow characteristics of fluids as they pass through complex regions containing solid particles or voids. In the simulation of the thermal environment of a solar greenhouse, considering the effect of the crop on air flow and heat transfer, it is a reasonable approximation to consider the crop as an isotropic porous medium. Considering the crop as a porous medium implies that structures such as the leaves and stalks of the crop are considered as a region with continuously distributed resistance. This treatment captures the crop's impedance to air flow, as well as the heat exchange process between the crop and the air.

Daylight greenhouses are subjected to differences in the distribution of solar radiation during the day, resulting in a temperature difference in the internal temperature, which leads to small changes in the air density inside the greenhouse. The Boussinesq assumption, which assumes that the air density varies so little in time and space that it can be approximated as a constant, simplifies the solution of the equations of hydrodynamics. The thermophysical parameters of the solarium envelope materials were shown in Table 1.

Boundary conditions and initial conditions

The setting of the boundary condition parameters has a great influence on the numerical simulation, and the boundary conditions and initial conditions are determined based on the experimental measured data and were set as follows:

(1) Setting of boundary conditions. The boundary conditions mainly include the setting of the boundaries of the front and rear roofs of the solar greenhouse, the east and west walls, the north wall and the soil. The interface between each part was set as a coupled wall. From 17:00 p.m. to 8:00 a.m. the next morning, the south roof was set as a layer of insulation.

(2) Setting of initial conditions. When constructing the thermal environment model of the solar greenhouse, the setting of initial conditions was a crucial step, which directly affected the accuracy and reliability of the simulation results. The experimental measurement data on 3 January 2024 were selected for model construction, and the initial temperature of the air inside the solar greenhouse was 16°C, respectively, and the outdoor temperature was applied to the outer surface of the greenhouse enclosure. In addition, the initial values of the north wall, soil, and crop surface temperatures were 22°C, 20°C, and 17°C, respectively.

Table 1

Material thermal property parameters of the solar greenhouse envelope

Parameters	PE	Wall	Soil	backward slope	Film	Crop
Densities[kg/m ³]	950	2000	1600	600	70	560
Specific heat capacity[J/(kg·K)]	1600	1050	1050	2500	1880	2100
Thermal conductivity[W/(m·K)]	0.34	0.8	0.75	0.29	0.04	0.19
Absorption coefficient	0.15	0.88	0.88	0.7	0.1	0.35
Scattering coefficient	0	0.12	0.12	0	0	0.1
Index of refraction	1.72	1.92	1.92	1.72	1.72	2.77

RESULTS AND DISCUSSION

Influence of the presence or absence of crops on the temperature distribution in solar greenhouse

Temperatures of greenhouses without crops and greenhouses with crop spacing of 1.5 m were selected for horizontal, vertical and longitudinal analyses, and temperatures of greenhouses with crop spacing of 1.5 m and 2 m were selected for horizontal, vertical and longitudinal comparisons.

Influence of the presence or absence of crops on vertical temperature changes in solar greenhouse

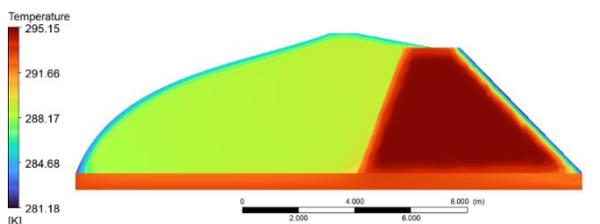

Fig. 3.1- Temperature cloud of X=36000mm north-south cross-section without crop

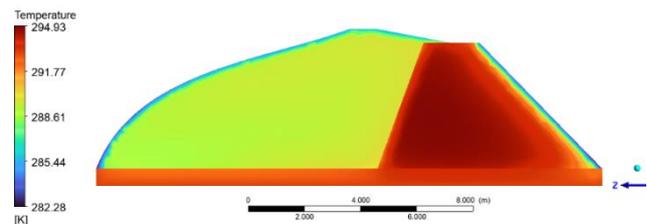

Fig. 3.2- Temperature cloud of X=36000mm north-south cross-section with 1.5m crop spacing

From Figures 3.1 and 3.2 above, in the specified parameters of $x=36000\text{mm}$, $z=0\text{mm}$, $y= (0, 5000)$ mm, the distribution law of vertical temperature was as follows: under constant working conditions, the temperature of the greenhouse with a crop greenhouse was higher than that of the greenhouse without a crop. In the range of $y=(0, 600)\text{mm}$, the temperature difference increased gradually, with a maximum temperature difference of 0.6°C , the minimum temperature difference was 0.06°C ; in the $y=(700, 4300)$ mm range, the temperature difference remained relatively stable, with a maximum temperature difference of 0.65°C ; in the $y=(4400, 4800)$ mm range, the temperature difference increased gradually, with a maximum temperature difference of 1.05°C and a minimum temperature difference of 0.65°C ; in the $y=(4900, 5000)$ mm range, the temperature difference decreased gradually, with a maximum temperature difference of 0.54°C and a minimum temperature difference of 0.04°C . The analysis indicated that the presence or absence of crops in the greenhouse exerted a negligible effect within the range of $y=(600, 4800)$ mm, yet it demonstrated a discernible effect within the ranges of $y=(0, 600)$ mm and $y=(4800, 5000)$ mm.

In the specified range of $x=36000$ mm, $z=5000$ mm, $y=(0, 3900)$ mm, the vertical temperature distribution law was as follows: under constant working conditions, the temperature of the greenhouse with crops was higher than that of the non-crop greenhouse. The temperature difference in the range of $y=(0, 100)$ mm gradually increased, and the maximum temperature difference was recorded at 0.49°C , while the minimum temperature difference was 0.06°C . In the range of $y = (200, 1200)$ mm, the temperature difference remains relatively smooth, with a maximum temperature difference of 0.48°C and a minimum temperature difference of 0.45°C . In the range of $y = (1300, 3500)$ mm, the temperature difference gradually increases, with a maximum temperature difference of 0.73°C and a minimum temperature difference of 0.46°C ; in the $y=(3600, 3900)$ mm range, the temperature difference decreased gradually, with a maximum temperature difference of 0.97°C and a minimum temperature difference of -0.12°C . The analysis indicated that the presence or absence of crops in the greenhouse exerted a negligible effect within the range of $y=(200, 3500)$ mm, yet it demonstrated a discernible effect within the ranges of $y=(0, 200)$ mm and $y=(3500, 3900)$ mm.

In the specified range of $x=36000$ mm, $z=9000$ mm, $y=(0, 1800)$ mm, the vertical temperature distribution law was as follows: under constant working conditions, the temperature of the greenhouse with a crop greenhouse temperature was indistinguishable from the temperature of the greenhouse without a crop. The temperature difference gradually increased in the range of $y = (0, 300)$ mm, with the maximum temperature difference of 0.55°C and the minimum temperature difference of 0°C . In the range of $y = (400, 900)$ mm, the temperature difference stayed relatively stable, with the maximum temperature difference of 0.66°C and the minimum temperature difference of 0.58°C . In the range of $y = (1000, 1800)$ mm, the temperature difference gradually decreases and the maximum temperature difference was 1.79°C and the minimum temperature difference was -0.13°C . From the above analysis, it can be seen that the presence or absence of crops in the greenhouse had a small effect in the range of $y = (300, 1000)$ mm, and a larger effect in the range of $y = (0, 300)$ mm and $y = (1000, 1800)$ mm.

As demonstrated in the preceding analysis, the presence or absence of crop temperature in the greenhouse exerted a lesser influence on the trellis at $x=36000$ mm and $y=300$ mm.

Effect of the presence or absence of crops on lateral temperatures in solar greenhouse

In order to explore the greenhouse, both with and without crops, the temperature along the transverse rule of change was to be analysed. For this purpose, the east-west span along the north-south cross-section was to be taken, with X set at 36000 mm, Y set at 0 mm, 1600 mm and 2400 mm, and Z set at $(-8000, 10000)$ mm on the temperature change curve.

From Figures 3.1 and 3.2 above, the change rule of temperature with crop temperature and without crop temperature at $y=0$ mm along the transverse direction was as follows: under the same working condition, the temperature of the greenhouse with crop was higher than the temperature of the greenhouse without crop; in the range of $z=(-8000,-6000)$ mm, the difference increased with the increasing of z , and the maximum difference was 0.6°C , and the minimum difference was 0.4°C ; in the range of $z=(-6000,2000)$ mm, the difference decreased with increasing z , the maximum difference was 0.8°C and the minimum difference was 0.07°C ; in the range of $z=(2000,10000)$ mm, the difference between the temperature of the greenhouse with crops and the temperature of the greenhouse without crops was maintained in the range of $(0.04, 0.07)^{\circ}\text{C}$. It can be seen that, considering the effect of the temperature difference of 0.5°C on the crop, the indoor crop had a greater effect on the internal temperature of the north wall, and a lesser effect on the temperature along the transverse direction at the soil surface of the indoor space.

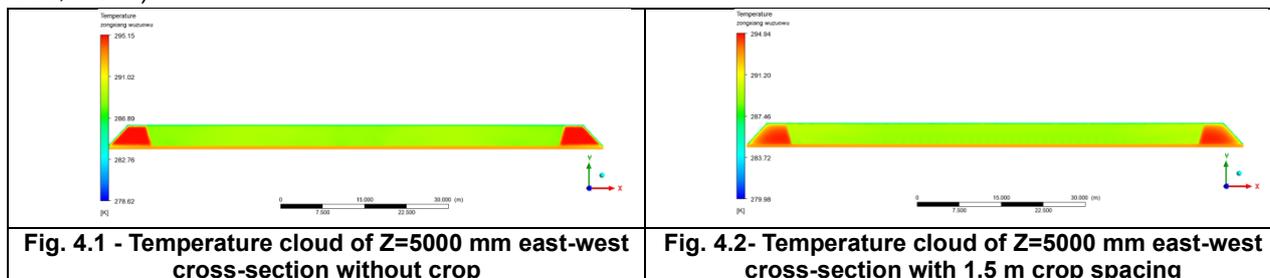

The change rule of temperature at $y=1600$ mm between the temperature with crop and the temperature without crop along the transverse direction was as follows: in the range of $z=(-6000, -2000)$ mm, the temperature of the greenhouse without crop was higher than the temperature of the greenhouse with crop; in the range of $z=(-6000, -5000)$ mm, the difference increased with the increased of z , and the maximum difference was 1.1°C , and the minimum difference was 1.0°C ; in the range of $z=(-5000, -2000)$ mm, the difference decreased with z , with a maximum difference of 0.6°C and a minimum difference of 0.3°C ; in the $z=(-1000, 9000)$ mm range, the temperature of the greenhouse with crops was higher than that of the greenhouse without crops; in the $z=(-1000, 0)$ mm range, the difference increased with z , with a maximum difference of 0.6°C and a minimum difference of 0.03°C ; in the range of $z = (0, 3000)$ mm, the difference decreased with increasing z , with a maximum difference of 0.62°C and a minimum difference of 0.45°C ; in the range of $z = (4000, 8000)$ mm, the difference stayed in the range of $(0.46, 0.64)^{\circ}\text{C}$ with increasing z ; in the range of $z = (8000, 9000)$ mm, the crop-free greenhouse temperature was higher than the temperature of the greenhouse with crops, with a temperature difference of 0.15°C . This shows that indoor crops had a greater effect on the interior of the wall at 5000 mm from the inner surface of the wall and on the interior space at 8000 mm from the inner surface of the wall.

The change rule of temperature at $y=2400$ mm between the temperature with crop and the temperature without crop along the transverse direction was as follows: in the range of $z=(-5000, -2000)$, the temperature of the greenhouse without crop was higher than the temperature of the greenhouse with crop, and the difference decreases with the increasing of z , with the maximum difference being 1.44°C and the minimum difference being 0.29°C ; in the range of $z=(-1000, 8000)$ mm, the temperature of the greenhouse with crop was higher than the temperature of the greenhouse without crop, in the range of $z=(-1000, 2000)$ mm, the difference decreased with increasing z , the maximum difference was 1.0°C , and the minimum difference was 0.53°C ; in the range of $z=(3000, 7000)$ mm, the difference was maintained in the range of $(0.60, 0.69)^{\circ}\text{C}$. In the range of $z=(7000, 8000)$ mm, the difference increased with increasing z and decreased with a maximum difference of 0.69°C and a minimum difference of 0.05°C . It was evident that indoor crops had a significant impact on the interior of the wall at 1000 mm from the inner surface of the wall and on the interior space at 7000 mm from the inner surface of the wall.

In summary, the presence or absence of crops in the greenhouse had a large effect on the temperature of the north side wall, and within the crop layer, the effect was larger at a distance of 3000 mm to 8000 mm from the inner surface of the north side wall.

Effect of the presence or absence of crops on longitudinal temperatures in solar greenhouse

To investigate the effect of crop presence on the longitudinal temperature distribution inside the greenhouse, an analysis was conducted along the east–west cross-section of the north–south span. Temperature variation curves were examined at $Z = 5000\text{mm}$, $y = 0$ mm, 1600 mm and 2400 mm, $x = (-8000, 80000)$ mm

As can be seen from Figure 4.1 and Figure 4.2, the change rule of temperature along the longitudinal direction of the greenhouse with and without crop temperature at $y=0$ mm was as follows: under the same working condition, the temperature of the greenhouse with crop temperature was higher than that of the greenhouse without crop temperature; within the range of $x=(-8000, -5000)$ mm, the temperature difference increased gradually with the increase of x , and the maximal temperature difference was 1.21°C ; within the range of $x=(-5000, 72000)$ mm range, the minimum temperature difference was 0.01°C , and the maximum temperature difference was 0.21°C ; in the $x=(72000, 78000)$ mm range, the temperature difference increased slowly as x increased, and the minimum temperature difference was 0.21°C , and the maximum temperature difference was 1.22°C ; in the $x=(78000, 80000)$ mm range, the temperature difference decreased gradually, the minimum temperature difference was 0.75°C and the maximum temperature difference was 1.22°C . It can be seen that, considering the effect of temperature difference of 0.5°C on the crop, the indoor crop has a greater effect on the temperature of the east and west walls, and a smaller effect on the temperature along the longitudinal direction at the soil surface of the indoor space.

The change rule of temperature at $y=1600$ mm along the longitudinal direction was as follows: in the range of width of the east and west walls, the temperature of the greenhouse without crops was higher than that of the greenhouse with crops; in the range of $x=(0, 72000)$ mm, the temperature in the greenhouse with crops was higher than that in the greenhouse without crops; in the range of $x=(0, 2000)$ mm, the difference of temperature was 1.2°C ; in the range of $x=(2000, 18000)$ mm range, the temperature difference gradually decreased, the maximum temperature difference was 1.2°C , and the minimum temperature difference was 0; in the $x=(18000, 34000)$ mm range, the temperature difference gradually increased, the maximum temperature difference was 0.51°C , and the minimum temperature difference was 0; in the $x=(34000, 40000)$ mm range, the temperature difference stayed constant, the temperature difference was 0.51°C ; in the range of $x=(40000, 56000)$ mm, the temperature difference decreased gradually, the maximum temperature difference was 0.51°C , and the minimum temperature difference was 0; in the range of $x=(56000, 72000)$ mm, the temperature difference decreased gradually, the maximum temperature difference was 1.45°C , and the

minimum temperature difference was 0. From the above analysis, it can be seen that, in the range of crop layers, the presence or absence of crops in the greenhouse has a greater effect on the temperature of the inner side of the east and west walls and on the temperature within the range of 10,000 mm from the longitudinal distance of the east and west walls.

The change rule of temperature at $y=2400$ mm along the longitudinal direction was as follows: in the range of the width of the east wall and the west wall, the temperature in the crop-free greenhouse was higher than the temperature in the crop greenhouse, and with the increase of the distance from the surface of the indoor wall, the temperature difference was gradually increasing, and the maximum temperature difference was 2.4°C , and the minimum temperature difference was 0.99°C ; in the range of $x=(0,72000)$ mm, the temperature in the crop greenhouse was higher than the temperature in the greenhouse without crops; in the range of $x=(0,18000)$ mm, the temperature difference gradually decreased, the maximum temperature difference was 1.3°C , and the minimum temperature difference was 0.07°C ; in the range of $x=(18000,22000)$ mm, the temperature difference stayed unchanged, and the temperature difference was 0.07°C ; in the range of $x=(22000,54000)$ mm, the temperature difference gradually increased, the maximum temperature difference was 0.66°C , the minimum temperature difference was 0.04°C ; in the range of $x=(54000,72000)$ mm, the temperature difference gradually decreased, the maximum temperature difference was 1.47°C , the minimum temperature difference was 0.04°C . From the above analysis, it can be seen that, the presence or absence of crops in the greenhouse had a greater impact on the temperature inside the east and west walls, and it has a greater impact on the temperature inside the wall at the longitudinal distance between the wall of 10000 mm and (34000,40000) mm range had a greater effect on the temperature.

Therefore, from the above analysis, it can be seen that the presence or absence of crops in the greenhouse had a greater effect on the temperature inside the east and west walls, and on the temperature within a distance of 10,000 mm from the surface of the wall, taking into account the effect of a temperature difference of 0.5°C on the crop.

Influence of different planting densities of crops on the temperature distribution in solar greenhouses

The study respectively simulated the temperature variation patterns in solar greenhouses with crop spacings of 1500 mm (actual) and 2000 mm. For the simulations, the temperature data at 17:00 on 26 January 2024 were selected as the initial boundary conditions. The temperature distribution maps at 08:00 were then analysed comparatively to assess the differences.

Influence on the vertical temperature of solar greenhouses

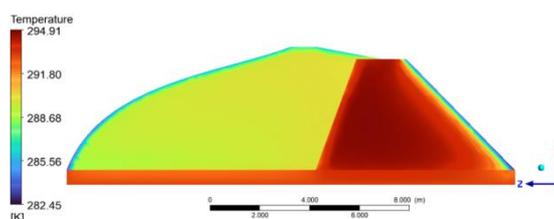

Fig. 5- Temperature cloud of $X=36000$ mm north-south cross-section with 2.0 m crop spacing

In order to investigate the vertical effect of different crop planting densities (1.5 m and 2 m, respectively) on the temperature in the greenhouse, $x=36000$ mm was taken in the greenhouse, and the difference in temperature between the crop planting density of 2 m and the temperature of the crop planting density of 1.5 m was analysed according to the difference in the height y when z was 0 mm, 5000 mm, and 9000 mm, respectively.

Taking $z=0$ mm, the temperature difference between the temperature at a crop planting density of 2 m and the temperature at a crop planting density of 1.5 m was analysed. Only when $y = (0, 800)$ mm, the temperature of crop planting density of 1.5 m was greater than the temperature of crop planting density of 2 m, the maximum difference was 0.2°C , and the minimum difference was 0.01°C ; when $y > 800$ mm, the temperature of crop planting density of 2 m was greater than the temperature of crop planting density of 1.5 m. The maximum temperature difference was 0.27°C and the minimum temperature difference was 0.15°C within the $y = (900, 4700)$ mm interval; when $y = (4800, 5000)$ mm, which is located in the vicinity of the film, the temperature difference gradually increases, and the maximum temperature difference was 0.69°C .

Taking $z=5000$ mm, the temperature difference between the temperature at a crop planting density of 2 m and the temperature difference at a crop planting density of 1.5 m was analysed. When $y = (0, 500)$ mm, the maximum difference in temperature between the two was 0.49°C ; when $y = (600, 1800)$ mm, the temperature difference between the two was more than 0.5°C , and the maximum temperature difference was 0.59°C ; when $y = (1900, 3400)$ mm, the maximum difference in temperature between the two was 0.49°C ; and when $y = (3500, 3900)$ mm, the maximum temperature difference between the two temperatures was 5.02°C and the minimum difference was 0.55°C .

Taking $z=9000$ mm, the temperature difference between the temperature at a crop planting density of 2 m and the temperature at a crop planting density of 1.5 m was analysed. When $y=(0, 1200)$ mm, the maximum temperature difference between the two temperatures was 0.3°C , and the minimum temperature difference was 0.23°C ; when $y=1300$ mm, the temperature difference between the two temperatures was the largest, which was 1.35°C ; when $y=1400$ mm, 1500 mm, the temperature of crop planting density of 1.5 m was greater than that of crop planting density of 2 m, and the difference in temperatures was 0.49°C respectively, 0.44°C ; when $y = (1600, 1800)$ mm, which was located in the vicinity of the film, the maximum difference in temperature was 0.59°C .

In summary, in the greenhouse when $x=36000$ mm, the temperature of crop planting density of 2 m was generally higher than the temperature of planting density of 1.5 m. However, there existed localized areas of contrast, where the temperature of crop planted at a density of 1.5 m was higher than the temperature of planted at a density of 2 m only at $z=0$ mm, $y<800$ mm, and at $z=9000$ mm, $y=1400$ mm, and 1500 mm. Further analysis showed that within the planting area, the effect of planting density on temperature was significant when $y>600$ mm, and the temperature difference could be up to 0.5°C or more. In addition, the effect of planting density on temperature was particularly pronounced in the area within 400 mm from the film, with lower temperatures near the film and larger temperature differences, especially at $z=5000$ mm, where the temperature difference at the film was the largest, reaching 5.02°C .

Influence on transverse temperature in solar greenhouses

The present study investigates the change rule of temperature along the transverse direction in the greenhouse with different planting densities. This study selected the data of different heights in the east-west spanning north-south direction in the greenhouse, and analysed the temperature within $z=(-8000, 10000)$ mm at $x=36000$ mm, $y=0$ mm, 1600 mm, and 2400 mm.

From the above figure, it can be seen that under the same working condition, in the greenhouse with crop planting densities of 2 m and 1.5 m respectively, the transverse temperature distribution pattern within $z=(-8000, 10000)$ mm at $x=36000$ mm and $y=0$ mm was as follows: the temperature difference within $z=(-8000, -5000)$ mm gradually increases, the maximum temperature difference was 0.1°C , and the minimum temperature difference was -0.02°C ; The difference in temperature values within $z=(-5000, -1000)$ mm remains unchanged, with a temperature difference of 0.05°C ; the temperature difference at $z=0$ mm was -0.26°C ; the difference in temperature values within $z=(0, 4000)$ mm remained unchanged, with a temperature difference of -0.06°C ; the difference in temperature values within $z=(4000, 8000)$ mm gradually increased, with a maximum temperature difference of 0.4°C ; the difference in temperature values within $z=(8000, 9000)$ mm gradually decreased, with a minimum temperature difference of 0.36°C ; and the temperature difference at $z=10000$ mm film was 0.72°C .

The change rule of temperature at $y=2600$ mm along the transverse direction was as follows: the temperature difference gradually decreased within $z=(-6000, -4000)$ mm, with the maximum temperature difference of -0.18°C and the minimum temperature difference of -0.01°C ; the difference in temperature values within $z=(-4000, -2000)$ mm stayed the same, with a temperature difference of 0.01°C ; the difference in temperature values within $z=(-2000, 3000)$ mm gradually increased, with the maximum temperature difference was 0.3°C ; the difference in temperature values within $z=(3000, 8000)$ mm gradually decreased, with a minimum temperature difference of 0.22°C ; and the temperature difference at $z=9000$ mm film was 0.58°C .

The change rule of temperature at $y=2400$ mm along the transverse direction was as follows: in $z = (-5000, -2000)$ mm within the temperature difference remained unchanged, the temperature difference was 0.03°C ; in $z = (-2000, 1000)$ mm within the difference in temperature values gradually increased, the maximum temperature difference was 0.29°C ; in $z = (1000, 7000)$ mm within the canopy gradually decreased, the minimum temperature difference was 0.21°C ; and the temperature difference at $z=8000$ mm film was 0.75°C .

In summary, the transversal air temperature distribution in the greenhouse was positively correlated with the planting density in the greenhouse, and the air temperature in the greenhouse with a planting density of 2

m was higher compared to the air temperature with a planting density of 1.5 m. The indoor air temperatures varied greatly in the range of 1 m near the film at the same height, with a difference value of more than 0.5°C; the wall temperatures varied greatly in the range of 1 m near the interior and exterior of the room, but with a difference of less than 0.25°C.

Impact on longitudinal temperature in solar greenhouses

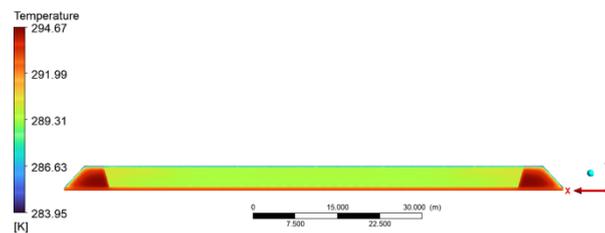

Fig. 6- Temperature cloud of Z=5000 mm east-west cross-section with 2.0 m crop spacing

In order to investigate the different crop spacing in the greenhouse on the indoor temperature along the longitudinal rule of change, the north-south span along the east-west cross-section was analysed, and the crop spacing of 2 m and 1.5 m, z=5000 mm, y=0 mm, 1600 mm, 2400 mm, x=(-8000,80000) mm at the temperature change curve was analysed.

From figures 4.2 and 6 above, under the same working condition, the greenhouse temperature of 2 m crop spacing and 1.5 m crop spacing at y=0 mm along the longitudinal rule of change was: in the range of east-west wall, the temperature of 2 m spacing was lower than 1.5 m spacing by 0.06°C on average; in the range of (1000,72000) mm, the temperature of 2 m spacing was higher than that of 1.5 m spacing, with the maximum temperature difference of 0.59°C and the minimum of 0.02°C. The temperature difference at 0 m was the largest at 3.19°C; in the range of (x=1000,72000) mm, the temperature difference was in fluctuation with the increase of x, with an average of 0.29°C, and the maximum was 0.59°C at 14000 mm, and the minimum was 0.02°C at 65000 mm; the temperature difference in the range of x=(73000,79000) mm did not vary much and averaged -0.07°C. Overall, crop spacing had a greater effect on temperatures in the range of 6000 mm and (10000, 16000) mm from the east-west wall and a smaller effect on temperatures within the wall.

The change rule of temperature along the longitudinal direction at y=1600 mm was as follows: in the range of east-west wall, the temperature of 2 m spacing was lower than that of 1.5 m spacing by 0.03°C on average; in the range of (0,73000) mm, the temperature of 2 m spacing was higher than that of 1.5 m spacing by 0.30°C on average. In the range of x=(0,73000) mm, the temperature difference was in a fluctuating state with an average of 0.30°C; in the range of x=(74000,79000) mm, the temperature difference decreased from -0.02°C to -0.07°C. Overall, crop spacing had a greater effect on the temperature within 6000 mm from the east-west wall and a lesser effect on the temperature within the east-west wall.

The change rule of temperature along the longitudinal direction at y=2400 mm was as follows: in the range of east-west wall, the temperature of 2 m spacing was lower than that of 1.5 m spacing by 0.03°C on average; the temperature difference increased with the increase of distance from the inner surface of the wall, and the maximum temperature difference was 0.29°C, and the minimum was 0.18°C. Within the range of x=(0,73000) mm, the temperature difference was in a fluctuating state, with an average difference of 0.24°C, and within the range of x=(74000,78000) mm range, the temperature difference increased from -0.04°C to -0.17°C. In conclusion, crop spacing had a small effect on the temperature inside the east-west wall and a large effect on the temperature within 5000 mm from the east-west wall.

Thus, from the above analysis, it can be seen that crop spacing has less effect on the temperature of the east and west walls, but more effect on the temperature within a distance of 6000 mm from the wall.

CONCLUSIONS

(1) The presence or absence of crops in the greenhouse has a greater influence on the temperature in the solar greenhouse along the horizontal, vertical and longitudinal directions within the ranges of (3000,8000) mm, (300 mm, at the film) and the distance from the inner surface of the east and west walls within the range of 10,000 mm;

(2) The presence or absence of crops in the greenhouse has a greater influence on the internal temperature of the east wall, the west wall and the north wall. The presence or absence of crops in the

greenhouse has a greater effect on greenhouse temperature than the density of crops grown in the greenhouse has on greenhouse temperature;

(3) The effect of different planting densities on the temperature of the greenhouse was less significant than that of different planting methods. The influence of different planting densities of crops on the internal temperatures of the solar greenhouse in the horizontal, vertical and longitudinal directions was within the ranges of (1000mm, at the film), (600 mm, at the film), and the distance from the inner surface of the east and west walls was within the range of 6000 mm, respectively.

Keywords: Single Axial Flow; Harvesters; Straw Crushing; Straw Spreading; operating effect

ABSTRACT

To identify the specific manifestations and influencing factors of the poor straw crushing and spreading effects in Northeast rice-growing areas, this paper focuses on the straw crushing and spreading device widely used on single axial flow harvesters. Experimental and theoretical analyses were conducted. The results indicate that the existing straw crushing and spreading devices, under different operating speeds and with various active blade types, exhibit crushing performance, spreading width, and spreading uniformity significantly below standard values. The primary issues are straw clumping, insufficient straw crushing, lateral bias in spreading, and inadequate spreading width. By establishing a theoretical model, the analysis reveals that the straw crushing effect is related to the characteristics of the straw itself, such as blade rotational speed, cutting angle, and support angle. In contrast, the spreading effect is associated with the motion direction of the straw leaving the threshing drum, straw ejection speed, and the arrangement of deflector plates. This paper clarifies the elements that need improvement in the operational effectiveness of the straw crushing and spreading devices attached to combine harvesters, providing a theoretical basis for subsequent enhancements.

摘要

为找到东北稻区秸秆粉碎抛撒效果差的具体表现形式及其影响因素, 本文以广泛使用的单纵轴流收获机装配的秸秆粉碎抛撒装置为研究对象, 开展试验和理论分析研究。试验表明, 现有秸秆粉碎抛撒装置在不同作业速度下, 采用不同动刀类型, 粉碎抛撒装置粉碎效果、抛撒幅宽和抛撒不均匀度都远低于标准值, 作业效果问题主要变现为: 秸秆成团、秸秆粉碎不充分、抛撒偏向一侧、抛撒幅宽不足。通过建立理论模型分析得出, 秸秆粉碎效果与秸秆自身特性, 粉碎刀转速、开刃角、支撑角有关; 抛撒效果与秸秆离开脱粒滚筒时运动方向、秸秆抛离速度、导流板布置有关。文章明确了联合收获机装配的秸秆粉碎抛撒装置作业效果需要提升的要素, 为后续改进提供理论依据。

INTRODUCTION

With the large-scale and intensive development of agriculture in China, single axial flow combine harvesters have become the mainstream products in the market due to their high efficiency and cost performance. These machines are particularly suitable for harvesting crops like rice (Gong et al., 2024; Zhang et al., 2021), which produce a substantial amount of straw and have gained significant usage in Northeast China (Wang et al., 2021). Returning straw to the fields can improve soil fertility, enhance soil structure, and increase grain yield (Wang et al., 2023; Zang et al., 2021), making it a critical measure for sustainable soil development (Wang et al., 2017). As a result, there is a growing demand for equipping combine harvesters with straw-crushing and spreading devices (Wang et al., 2022). However, in Northeast China's rice-growing areas, the ample and tough straw presents challenges, leading to poor crushing and spreading effects and unsatisfactory straw return quality (Sun et al., 2019).

Existing research on straw crushing and spreading (Jankauskas et al., 2023; Li et al., 2023; Sun et al., 2019; Vlăduț et al., 2023; Vlăduț et al., 2023; Wang et al., 2021; Wang., 2018; Wang., 2018) mainly focus on the design of the devices or the analysis of the product's application effects. There is a lack of detailed analysis of the causes of poor straw-crushing and spreading effects in this region.

More theoretical models must be developed to address these processes for the straw-crushing and spreading devices mounted on combine harvesters. This study conducts field experiments and theoretical analyses based on the original straw crushing and spreading devices of single axial flow combine harvesters. It aims to identify the specific problems and underlying causes in each stage of grinding and spreading while clarifying the aspects that need improvement, thus providing a foundation for future enhancements.

MATERIAL AND METHODS

Structure and Working Principle of the Straw Crushing and Spreading Device on Single Axial Flow Harvesters

The structure and spatial layout of the straw-crushing device mounted on this type of combine harvester are roughly illustrated in Fig.1. During operation, the straw crushing and spreading process can be divided into three stages:

(1) Straw Feeding Stage: Straw exits through the discharge opening of the threshing mechanism and slides down the collecting board to the entrance of the crushing device chamber.

(2) Straw Crushing Stage: After the straw enters the crushing device chamber, it is chopped up with the cooperation of the moving and fixed blades.

(3) Straw Spreading Stage: The crushed straw falls to the ground under the influence of the spreading device and its gravity.

Experimental Design

Field experiments were conducted during the rice harvesting period using the John Deere C100 single vertical axis flow combine harvester to explore the factors affecting the performance of rice straw crushing and spreading operations, as shown in Fig.2. The stubble height was approximately 30 cm during the operation, as illustrated in Fig.3. The experiment was carried out at Experimental Field No. 36 in the Jian Sanjiang Farm of Heilongjiang Province, with the rice variety being Longjing 31. The average plant height was 94.62 cm, and the average panicle length was 15.94 cm, while the straw moisture content measured 33.01%.

Fig. 2 - John Deere C100 and Stubble height

Fig. 3 - Smooth blade and serrated blade

Fig. 4 - Field test image

The harvester's original straw crushing and spreading device uses a high-speed rotating swing knife and a single-row fixed knife. Both the fixed and moving knives have smooth blades (no serrations). The rotational speed of the knife shaft is 2600 r/min. The test compares the shredding and spreading effects of the moving knives, which are smooth-blade knives and serrated blades. As shown in Fig.3, the test-crushing moving knives use the original smooth blade and the serrated blade available on the market. After the smooth blade knife operation was completed, the knife shaft with the serrated knife was installed to replace the smooth blade knife shaft, and the test operation continued. The header width of the harvester was 4.5 m, and the feeding rate was 9 kg/s.

The test speed is based on the gear position of the harvester, and the first gear's low speed, the first gear's high speed, the second gear's low speed, and the second gear's high speed are selected. The corresponding speeds measured by the stopwatch are 0.95 m/s, 1.12 m/s, 1.21 m/s and 1.38 m/s.

The test used straw crushing qualified rate (crushing length <15 cm) y_1 , straw spreading width (harvesting width 4.5 m) d , and spreading unevenness F_b as evaluation indicators. Fig.4 is a field test image.

The straw spreading width measurement method is: 5 measuring points are taken at equal intervals within the harvesting stroke of the combine harvester, and the width is measured and recorded at each measuring point. The straw sampling method is: one point is taken within the two working strokes of the combine harvester, and 5 sampling frames with an area of 90 cm × 50 cm are placed in sequence at each measuring point parallel to the direction of the harvester header, and all the straw in the sampling frame is collected. The straw crushing qualified rate and spreading unevenness are calculated according to the requirements of GB/T 24675.6-2009 "Conservation Tillage Machinery Straw Crushers (GB/T 24675.6-2009-2009)". The calculation formulas for straw crushing qualified rate y_1 and spreading unevenness F_b are respectively:

$$y_1 = \frac{M_{ai} - M_{bi}}{M_{ai}} \times 100\%, \quad i = 1, 2, \dots, 10 \quad (1)$$

$$F_b = \frac{1}{M} \sqrt{\frac{1}{9} \sum_{i=1}^{10} (M_{ai} - \bar{M})^2} \times 100\%, \quad i = 1, 2, \dots, 10 \quad (2)$$

where M_{ai} is the total mass of the straw at the sampling point, g; M_{bi} is the mass of the straw with a length less than 15 cm at the sampling point, g; and \bar{M} is the average mass of the straw at each measuring point, g.

RESULTS

Test results and analysis

Fig.5 shows the changes in various test indicators with harvesting speed. Referring to the straw crushing qualification rate requirements in GB/T 24675.6-2009, it can be seen from Fig.5a that the operating results of different types of crushing knives are not ideal when crushing rice straw in Northeast China, all are far less than 85%, and the lowest operating speed is 0.95 m/s, the qualified rate of straw crushing with different crushing knife types is only 72.02% and 63.48%. At the same time, as the operating speed increases, the qualified rate of straw crushing also has a downward trend. Under the same operating conditions, the smooth-edged crushing knife has a higher straw crushing qualification rate than the serrated knife. Through actual observation of the shape of the straw after different knife types, it was found that the straw incision showed more tearing after being crushed by the serrated knife. Fig.5b reflects that the change of the blade of the movable knife has no significant impact on the throwing width. It is observed that the straw throwing width of the modified machine is significantly different from the harvesting width, and as the operating speed increases, the throwing width decreases. Fig.5c shows that the throwing unevenness of both knife types is poor, which is far from the standard requirement of less than 30%. As the speed increases, the throwing unevenness slightly increases. According to the test, the operating effect of this model's straw crushing and spreading device could be better, and it needs to continue to be improved to solve the critical technical problem of straw crushing and spreading that restricts the quality of straw return to the field.

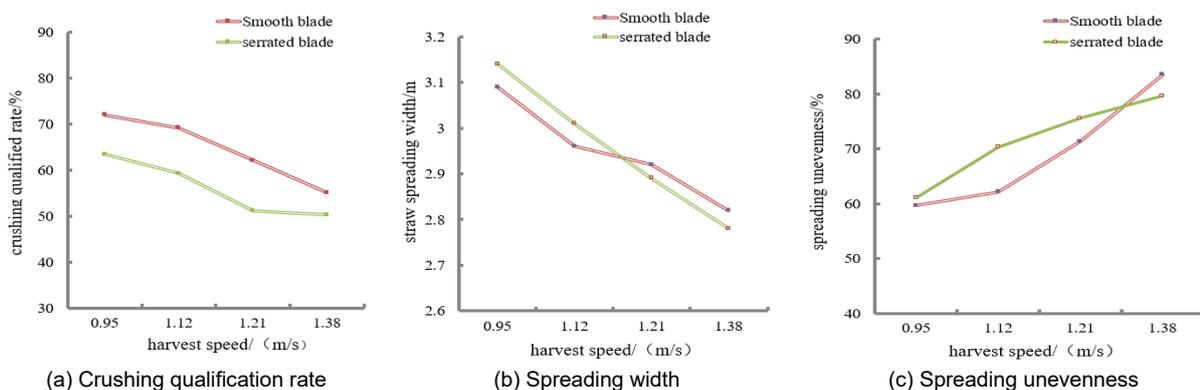

Fig. 5 - Variation of each test index with harvesting speed

Existing problems and theoretical analysis

Study on crushing problems

The straw scattered on the ground after the observation test is shown in Fig.6. After the observation operation, the straw mainly clumped together. As shown in Fig.6a, many straws were over 20 cm long, which severely impacted the subsequent straw burial and field return effectiveness (Sun et al., 2019). It was also found that the straw length did not meet the standard due to insufficient crushing. The straw shape exhibited one or more bends and damages along the straw shaft, as shown in Fig.6b. The main reason for this damage was that the moving and fixed knives failed to cut effectively into the straw. The excessive straw length also contributed to clumping.

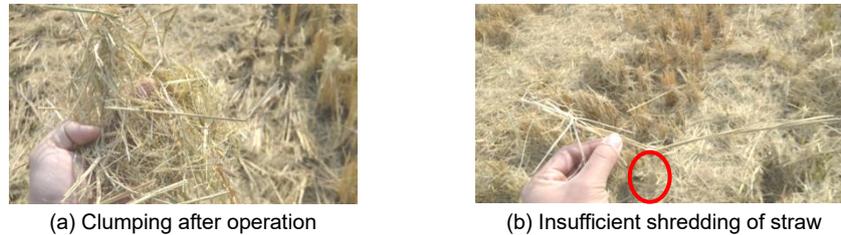

Fig. 6 - Straw scattered on the ground

(1) Analysis of straw cutting force

As an elastic body, straw undergoes two distinct stages during cutting: (1) the initial contact of the moving blade with the straw, leading to extrusion deformation, and (2) the continued movement of the moving blade, causing the straw to plastically deform before being cut. Effective straw cutting occurs in the second stage, making it crucial to study the force state of the moving blade during this phase. Establishing a mechanical model will aid in analyzing the key factors that influence the cutting effect in greater depth.

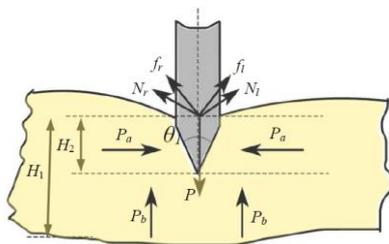

Fig. 7 - Model diagram of a moving knife cutting into a single straw

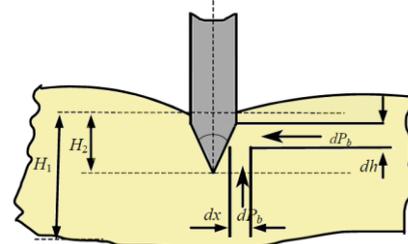

Fig. 8 - Schematic diagram of horizontal and vertical differential forces

As shown in Fig.7, a vertical cross-section model is established when the moving knife cuts into a single straw and the blade is sharpened on both sides. The force applied to the blade during the cutting process is analyzed. During the cutting process, the blade will be subjected to the extrusion force N_1 and N_2 of the straw stem on the blade, which is perpendicular to the sharpening surface in the opposite direction. Under the action of the extrusion force, friction forces f_1 and f_2 will be generated simultaneously. Because the sharpening is symmetrical, ignoring the differences in the microstructure inside the stalk, it can be assumed that $N_1=N_2$ and $f_1=f_2$. Therefore, it can be seen that the cutting force P on the straw at the moment the blade cuts in can be expressed as:

$$\begin{cases} P = 2(N_1 \sin \frac{\theta_1}{2} + f_1 \cos \frac{\theta_1}{2}) \\ f_1 = \mu N_1 \end{cases} \quad (3)$$

where θ_1 is the blade angle of the moving blade, °; μ is the friction coefficient of rice straw.

During the extrusion deformation process of the moving blade, the extrusion force N_1 acting on the grinding blade surface can be decomposed into the horizontal extrusion force P_a and the vertical extrusion force P_b of the straw on the blade (Koolen, 1994), so:

$$N_1 = P_a \sin \frac{\theta_1}{2} + P_b \cos \frac{\theta_1}{2} \quad (4)$$

To bring in factors related to straw characteristics, the extrusion pressure P_a and pressure P_b in the above formula can be obtained by integrating the differential forces in their respective directions (Zhao et al., 2015), as shown in Fig.8. As an elastic body, according to Hooke's law, the strain of straw after impact ϵ can be expressed as:

$$\varepsilon = \frac{\sigma}{E} = \frac{h_x}{H_1} \quad (5)$$

where σ is the stress when the straw is cut, N; E is the instantaneous elastic modulus of the straw when the knife cuts the straw; H_1 is the diameter of the straw before it is cut, mm; h_x is the thickness of the straw after it is squeezed, mm.

Therefore, the vertical squeezing force dP_b acting on the unit length of the straw can be expressed as:

$$dP_b = E\varepsilon \tan \frac{\theta_1}{2} dh_x \quad (6)$$

By integrating both ends of the above equation, the vertical extrusion force P_b can be obtained:

$$P_b = \frac{E}{H_1} \tan \frac{\theta_1}{2} \int_0^{H_2} h_x dh_x = \frac{E}{2H_1} H_2^2 \tan \frac{\theta_1}{2} \quad (7)$$

where H_2 is the thickness of the straw when it is plastically deformed by extrusion, mm.

Similarly, the horizontal extrusion force P_a can be obtained:

$$P_a = \frac{\nu E}{H_1} \int_0^{H_2} h_x dh_x = \frac{\nu E}{2H_1} H_2^2 \quad (8)$$

where ν is the Poisson's ratio of the straw.

Substituting equations 4, 7, and 8 into equations 3, the instantaneous cutting force P on the straw is obtained:

$$P = \frac{EH_2^2}{H_1} \left[\nu \left(\sin^2 \frac{\theta_1}{2} + \mu \sin \frac{\theta_1}{2} \cos \frac{\theta_1}{2} \right) + \tan \frac{\theta_1}{2} \left(\sin \frac{\theta_1}{2} \cos \frac{\theta_1}{2} + \mu \cos^2 \frac{\theta_1}{2} \right) \right] \quad (9)$$

When the instantaneous impact on the straw is more significant, the possibility of the knife cutting into the straw will be greater. According to Equation 9, the instantaneous cutting force on the straw is related to the characteristics of the straw itself. The friction coefficient of the straw and the resistance to bending of the straw impact the instantaneous force. The cutting angle of the moving knife also positively impacts the instantaneous force on the straw, so the cutting angle can be reasonably optimized when designing the blade. In addition, according to Formula 9, it can also be found that when the instantaneous extrusion thickness H_2 of the straw increases, the instantaneous cutting force of the straw increases significantly. Changes in the extrusion thickness H_2 are often related to the movable knife's rotational speed and the cutting blade's support angle. However, due to the straw's stable characteristics, when the movable knife's rotational speed reaches a specific value, the instantaneous extrusion thickness of the straw will not change. When the movable fixed knife supports cutting, increasing the straw cutting support angle can effectively prevent the movement of the movable knife caused by the poor bending strength of the straw, thereby obtaining a greater extrusion thickness. Therefore, when the cutting knife rotates at a certain speed, the straw support characteristics of the crushing knife can improve the straw-cutting effect.

Study on the spreading problem

The harvesting operation test found that the original straw crushing and spreading device had a poor operation effect, and the uneven spreading degree was significantly different from the national standard requirements. Through experimental observation, the main manifestations were: the straw spreading was biased to one side (along the left side of the operation direction), and the straw spreading power was insufficient, resulting in a small spreading width. As shown in Fig.9, the single longitudinal axial flow combine harvester had the phenomenon of straw spreading biased to one side during the crushing and spreading operation. During the operation, no straw was thrown on the right side of the spreading device (in the red frame of the Fig.9), so the straw after throwing was mainly distributed on the left side of the harvester center line, resulting in uneven spreading. As shown in Fig.10, the harvesting width of the entire harvester is D , m; the width of the thrown straw distributed on the left side of the harvester center line is expressed as d , m; in the actual operation process, it was observed that $d < D/2$ and the difference was significant, so the spreading width was small and insufficient to match the harvesting width.

Fig. 9 - Spreading to one side

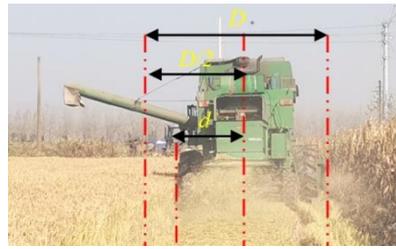

Fig. 10 - Spreading width is insufficient

Fig. 11 - Uneven straw feeding

(1) Study on the problem of spreading to one side

The movement of straw in the chamber of the crushing device is mostly tangential along the rotation of the crushing blade shaft (Mu, 2021). The spreading of straw to one side cannot be attributed to the axial movement of the straw during crushing. Instead, a possible cause is the uneven feeding of straw into the crushing device. To verify this hypothesis, the harvester crushing and spreading device was removed, and the straw flow state was observed after it left the threshing drum and before it entered the crushing device via the grass receiving plate. The straw flow direction is shown in Fig.11. It was observed that the straw flow was already biased to one side after leaving the drum and before entering the crushing device. The straw was not evenly distributed horizontally along the lower edge of the grass receiving plate, leading to the final uneven spreading of straw.

Considering that the straw crushing and spreading device equipped with the combine harvester operates on the straw discharged from the threshing device, the motion analysis of the state of the straw discharged from the threshing drum was carried out. Taking the straw flow with a specific volume as the research object, ignoring the entanglement, squeezing, and dragging effects caused by the continuous discharge between the straw flows, the surface velocity of the straw flow is decomposed. The x-axis direction is to the right in the width direction of the harvester; that is, the right direction is perpendicular to the forward direction of the harvester, and the z-axis direction is vertically upward. As shown in Fig.12, the straw flow will still maintain the tangential velocity v_1 rotating with the threshing drum and the movement velocity v_2 along the surface of the roller grass discharge board due to the centrifugal force of rotation and the support of the roller grass discharge board surface at the moment of separation. At the same time, the straw flow also accelerates a_0 due to its gravity at the moment of separation.

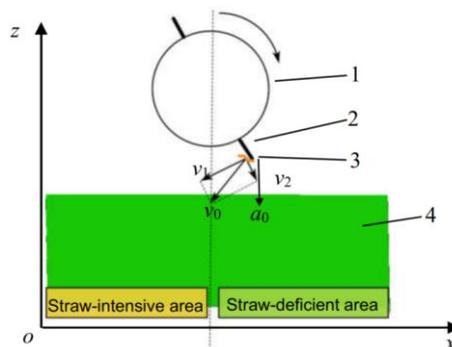

Fig. 12 - Kinematic analysis of the moment when the straw flow leaves the straw discharge plate

1. Threshing device; 2. Grass discharge board; 3. Straw flow; 4. Grass receiving board

Therefore, the instantaneous velocity v_0 of the straw flow leaving the roller straw discharge plate can be expressed as:

$$v_0 = \sqrt{v_1^2 + v_2^2} \quad (10)$$

In the formula, v_1 is the rotation speed of the threshing drum, m/s; v_2 is the movement speed of the straw along the surface of the drum discharge plate, m/s.

According to the literature (Chen et al., 2020; Li et al., 2021), it can be seen that the rotation speed of grain threshing equipment is generally 500~800 r/min, so the speed v_1 is larger than the speed v_2 . Therefore, according to the speed synthesis parallelogram rule, the direction of the speed v_0 is closer to the speed v_1 , which means that the discharged straw flow tends to move to the left.

Although there will be a vertical component force under the action of gravity during the period from when the straw flow breaks away from the straw discharge plate of the drum to when it starts to contact the crushing device and the straw plate, it will not significantly change the direction of the straw flow in a very short time. The continuous flow will form a dense area of straw on the left and a missing area of straw on the right at the bottom of the straw connecting plate of the crushing device. As shown in Fig. 12, this uneven straw feeding into the crushing device ultimately results in a deflected discharge, causing the crushed straw to be cast toward the left side.

From the above analysis, improving the uniformity of the transverse distribution of straw in the straw feeding and crushing device of a single longitudinal axis harvester is extremely important for reducing the unevenness of straw throwing. When optimizing the design, the direction of the straw falling off the drum can be guided, utilizing turbulence to counteract the tendency of the straw to move to the left. This approach helps ensure a more even distribution of straw when it is fed into the crushing device at the bottom of the straw plate.

(2) Research on the problem of insufficient throwing width

A dynamic model of the throwing width was established to study the factors influencing the throwing width of the straw crushing and throwing device assembled with the harvester. At the same time, it was assumed that the up and down rotation of the throwing device and the left and proper adjustment of the deflector did not affect the straw-throwing position. During the process of spreading straw in space, the right direction of the harvester width is used as the x-axis, the opposite direction of the working forward direction (i.e. backward) is used as the y-axis, and the vertical direction is used as the z-axis to establish a coordinate system and scatter the straw in the three-dimensional space. The motion is decomposed into *yoz* and *xoy* plane motions, as shown in Fig.13. v_c represents the operating direction and speed of the harvester, m/s; H_p is the height of the straw throwing point from the ground, m; w_c is the distance between the outermost deflector and the center line of the throwing device, m; w_b is the straw throw distance from the deflector. The movement distance along the x-axis after exiting, m; w_p is half of the width of the straw throwing width, m. The straw throwing speed is v_b , and the corresponding speeds decomposed into the x, y, and z axes are v_{b1} , v_{b2} , and v_{b3} .

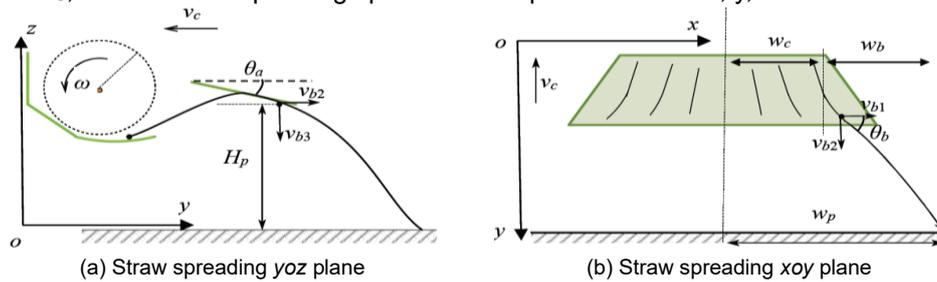

Fig.13 - Straw spreading trajectory of the straw crushing and spreading device

According to Fig.13b, the straw spreading width is twice w_p , and w_p can be expressed as:

$$w_p = w_c + w_b \tag{11}$$

From formula 11, it can be seen that the farthest distance determines the size of the straw spreading width. The straw is thrown under the guidance of the outermost guide plate. When the height H_p of the straw spreading point from the ground remains constant, the velocity v_{b1} of v_b along the x-axis determines the movement distance of the straw along the x-axis. The straw spreading motion can be analyzed using the theory of projectile motion. Referring to relevant literature (Brown, 2001), the motion equation of the straw along the x-axis during the spreading process is:

$$\begin{cases} \frac{d^2x}{dt^2} + k_a \left(\frac{dx}{dt}\right)^2 = 0 \\ k_a = \frac{\rho_a c_a A_a}{2m'} \end{cases} \tag{12}$$

where k_a is the air resistance factor; m' is the mass of the straw to be scattered, kg; ρ_a is the air density, kg/m³; c_a is the air damping coefficient; A_a is the resistance area caused by the shape and size of the straw, m².

To obtain the speed of the straw along the x-axis during the spreading process, equation 12 is integrated and solved. Assume that the initial conditions for spreading are: at spreading time $t=0$, $v_{bx}(0)=v_{b1}$, $x(0)=w_c$, and the speed of the straw along the x-axis at time t is solved as follows:

$$v_{bx}(t) = \frac{dx}{dt} = \frac{v_{b1}}{1 + k_a v_{b1} t} \quad (13)$$

The position coordinates of the straw along the x-axis during the spreading process can be expressed as:

$$x(t) = w_c + \int_0^t v_{dx}(t) dt = w_c + \frac{1}{k_a} \ln(1 + k_a v_{b1} t) \quad (14)$$

wherein, according to the spatial geometric relationship, the velocity v_{b1} along the x-axis can be expressed by the initial velocity of the straw spreading:

$$v_{b1} = \frac{\cot \theta_b}{\sqrt{1 + \tan^2 \theta_a + \cot^2 \theta_b}} v_b \quad (15)$$

Substituting equation 15 into equation 14, it can be obtained:

$$x(t) = w_c + \frac{1}{k_a} \ln\left(1 + \frac{k_a \cot \theta_b}{\sqrt{1 + \tan^2 \theta_a + \cot^2 \theta_b}} v_b t\right) \quad (16)$$

where θ_a is the installation angle of the spreading device, °; θ_b is the angle between the straw throwing speed and the x-axis, °.

Assuming that the time for the straw to fall to the ground after spreading is t_l , the value of w_c can be obtained by substituting it into the above formula. When the installation position of the spreading device is fixed, the installation angle is no longer adjusted, and external conditions remain constant due to the limited landing height, it can be considered that the straw landing time t and the air resistance factor k_a are fixed values. Under these conditions, the straw spreading distance w_p is only related to the throwing speed v_b and the angle θ_b between the throwing speed v_b and the x-axis. The magnitude of the straw throwing speed v_b is influenced by the airflow speed generated during the straw crushing process. The crushed straw will produce collisions and friction under the drainage action of the guide plate. This process can also increase the straw-throwing speed by reducing the kinetic energy loss. Therefore, a well-optimized guide plate layout angle can further enhance the spreading width.

CONCLUSIONS

Through an in-depth analysis of the problems existing in the operation of the original crushing and spreading device of the single longitudinal axial flow combine harvester, the factors requiring improvement in the straw feeding, crushing, and spreading stages were determined. The main conclusions of this study are as follows:

1. Through field test research, it was found that the problems existing in the operation of the straw crushing and spreading device equipped with the combine harvester in the rice-growing area of Northeast China were mainly manifested as straw clumping, insufficient straw crushing, spreading to one side, and insufficient spreading width.

2. A straw-crushing dynamics model was established, and the analysis revealed that the straw-crushing effect is influenced by the characteristics of the straw itself, the crushing knife speed, the blade angle, and the support angle. When the cutting knife operates at a certain speed, enhancing the support characteristics of the crushing knife on the straw can significantly improve the straw-cutting effect.

3. The kinematic models of the straw leaving the threshing drum and the guide plate were established respectively. The analysis showed that the straw flow discharged from the drum tended to move to the left, resulting in uneven straw feeding into the crushing device, which ultimately caused the crushed straw to be thrown to the left. When the installation position of the throwing device was fixed and the installation angle remained unchanged, the throwing width was influenced by the straw throwing speed and the installation angle of the guide plate.

Keywords: pelleted rice seeds; seed mechanics; simulation experiment; parameter calibration

ABSTRACT

The calibration of parameters for pelleted rice seeds (PR) is crucial for enhancing research on PR-related machinery and for executing high-speed precision hole sowing with unmanned aerial vehicles. This paper focuses on determining the fundamental physical and contact parameters of PR. A series of tests were conducted, including the Plackett-Burman test, the steepest ascent test, and the Box-Behnken test, using the stacking angle as the primary variable. These tests led to the identification of optimal combinations of simulation parameters. Specifically, the coefficients of rolling friction for the PR-PLA plate and PR-PR were measured at 0.137, while the coefficient of static friction for the PR-PLA plate was 0.336. This study provides a reference for calibrating simulation parameters of pelleted seeds and research on high-speed precision seeding.

摘要

丸粒化水稻种子的参数标定, 可以为丸粒化水稻相关机械的研究及无人机的高速精量穴播提供指导。本文以丸粒化的水稻为对象, 对其基本物性参数和接触参数开展测定。以堆积角为试验值进行 Plackett-Burman 试验、最陡爬坡试验和 Box-Behnken 试验, 获得最佳仿真参数组合 (丸粒化水稻种子-PLA 板滚动摩擦系数、丸粒化水稻种子-丸粒化水稻种子滚动摩擦系数及丸粒化水稻种子-PLA 板静摩擦系数分别为 0.137、0.137、0.336), 该研究能够为丸粒化种子的仿真参数标定及高速精量播种研究提供参考。

INTRODUCTION

Rice is one of the most vital food crops globally and serves as a crucial source of sustenance for over half of the world's population (Djavan. et al., 2025). It is not only a staple in many countries but is also used in a variety of recreational dishes (Ning, 2016).

Rice planting represents a crucial aspect of rice production, with the planting technology exerting a direct influence on yield (Cai. et al., 2023). Currently, three methods of mechanical planting are in use: potting transplanting, mechanical transplanting, and mechanized direct seeding. The first two of these require seedling transplanting, a relatively complex process that results in higher overall production costs for seedling transplanting (Xue et al., 2022). The mechanized direct seeding of rice has the potential to streamline the planting process, and it has gained significant traction in numerous countries and regions in recent years. The majority of existing rice direct seeding techniques employ the use of tractor-tractor seeders and drones. The method of tractor-tractor seeders is still primarily limited to strip seeding, with precision seeding also facing significant challenges, particularly in the precise separation of rice seeds from the population. Additionally, the use of ground machinery has been observed to have relatively low efficiency. While existing unmanned aircraft seeding is highly efficient, it remains primarily a sowing method with several limitations. These include the disorderly arrangement of seeds on the ground and the difficulty of rapidly and precisely separating them from the population. The unique physical characteristics of rice, including high flow resistance and adhesion, present a significant challenge to the rapid and precise separation of seeds from the population, which has been a key obstacle to the development of high-speed precision rice planting.

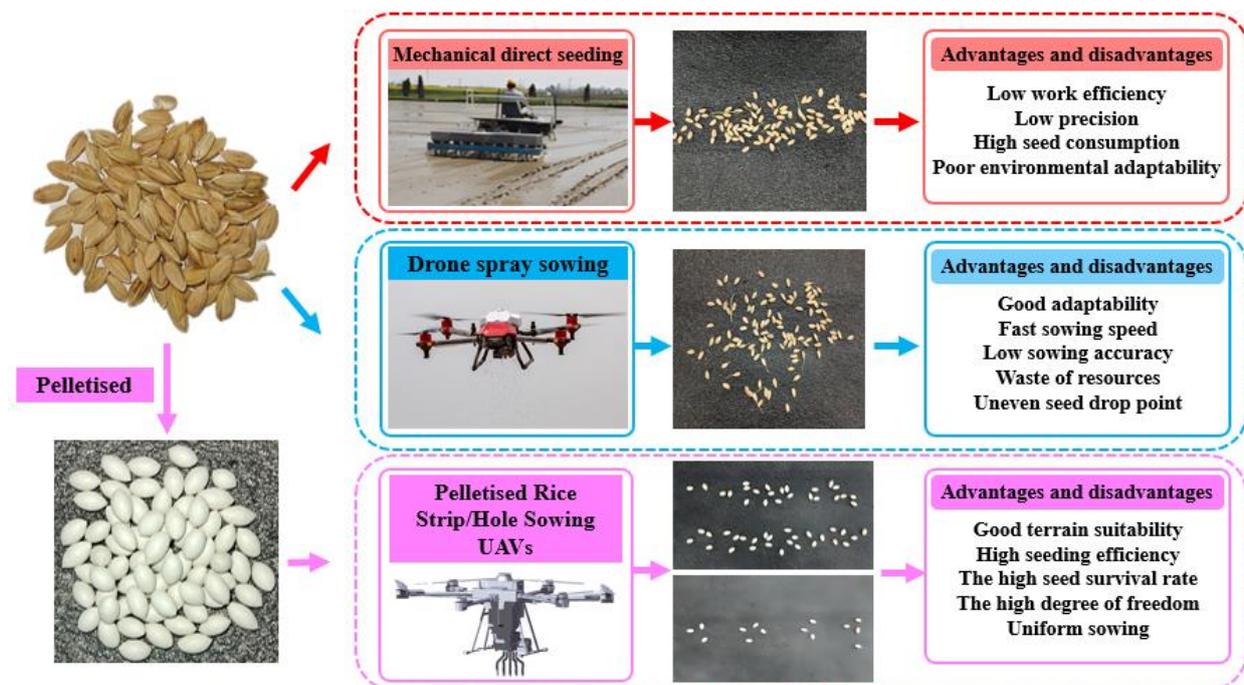

Fig. 1 - Comparison of direct seeding methods for rice

In light of the aforementioned considerations, our team proposed a method of pelleted rice seeds (PR), which can effectively solve the problem of rapid precision separation from the seed population, thus improving the sowing accuracy and sowing efficiency to carry out the subsequent high-speed precision planting of rice, as shown in Fig. 1, in the light of the characteristics of the physical structure of rice and planting needs. Seed pelleting treatment have been used in applications where germination, seedling emergence, resistance, and resistance to pests and diseases are improved (Ma et al., 2023; Yang et al., 2020; Wang et al., 2024). During the sowing process of PR, the forces between seeds and seeds and seeds and seed discharger are more complicated, and the parameter calibration of PRs can be carried out to find out their physical properties and promote the optimal design of pelleted seed discharger for precision hole sowing.

To date, researchers in both domestic and international settings have conducted simulations to calibrate discrete metamodelling about fertilizers, soils, seeds, and crops. In a previous study, Wen Xiangyu et al. (2020) proposed a friction factor calibration method based on the overall characteristics of granular materials. This method was then used to calibrate the discrete meta-simulation parameters between urea particles and PVC materials. This calibration was carried out according to the results of the analysis of variance (ANOVA) of different particle characteristics testing methods. In a further contribution to this field of study, Wang Xianliang et al. (2021) employed the Edinburgh Elasto-Plastic Adhesion nonlinear elastic-plastic contact model to calibrate the parameters of a discrete element simulation model of perennial no-tillage agricultural soil. Balevičius et al. (2011) conducted a sliding test to measure the static coefficient of friction between peas and Plexiglas. González-Montellano et al. (2012) investigated direct measurement methods for some parameters in discrete element simulation. Xuejie Ma et al. (2022) calibrated the contact parameters of alfalfa seed and coating powder as the main research objects and carried out the related discrete element simulation parameter calibration. Peng Zhang et al. (2022) simulated and determined the contact parameters such as stacking angle, collision recovery coefficient, static friction factor, etc., using Xinjiang cotton straw as the test material. As evidenced by the aforementioned research, the majority of discrete element simulation parameters have been calibrated for large seeds and soil. However, there is a lack of research on the calibration of discrete element simulation parameters for PR and other pelleted crop seeds.

In this paper, the discrete element simulation model of PR was calibrated and validated by combining physical tests with discrete element simulation. The angle of repose was used as the response variable. Furthermore, the Plackett-Burman test, the steepest-climbing test, and the Box-Behnken test were conducted sequentially. A two-sample t-test was conducted on the simulation results and experimental data using SPSS 23 software to ascertain the reliability of the simulation tests and identify the optimal combination of simulation parameters. This study serves as a reference for developing high-speed precision seeding of granular seeds, which aids in optimizing both the seeding equipment and the seed treatment process.

MATERIALS AND METHODS

Calibration of test materials and physical parameters

This paper is based on the study of early and mid-grain rice grown in large areas in southern and northern China. Hui Liangyu silk seed was used as an experimental subject to determine the external dimensions, thousand kernel weight, Poisson's ratio, and other basic physical properties of PR.

The PR exhibited an ellipsoidal shape, a compact texture, and a smooth surface. These characteristics could enhance the mobility and population separability of the seeds, as illustrated in Fig. 2. A total of 1,000 pill-PR were randomly selected and weighed using an electronic scale with an accuracy of 0.01 g to determine the thousand-grain weight. The seeds were divided into 10 groups and weighed separately, and the average value was calculated. The thousand-grain weight of the pill-PR was found to be 134.05 g. The external dimensions of the pill-PR were measured using a numerical vernier caliper (with an accuracy of 0.01 mm), as illustrated in Fig. 2. The mean diameter (D) and length (L) of the seeds were found to be 5.17mm×9.71mm, according to the measurement results.

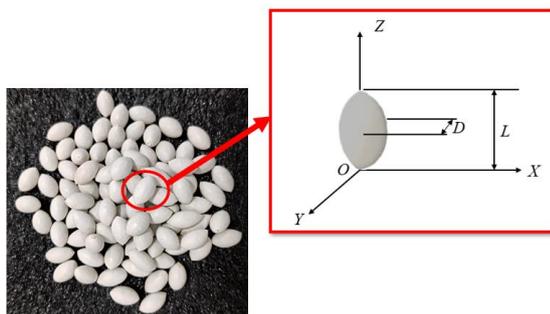

Fig.2 - Characteristic dimensions of PR

Fig.3 - Pressure deformation test of PR

One hundred PR were randomly selected and their original dimensions in radial (X-axis) and axial (Z-axis) directions were recorded. The compression deformation test of the PR was carried out using a universal material testing machine (UTM2501/50N, Shenzhen Sanshi Zongheng Technology), as shown in Fig. 3, with a test speed of 0.1 mm/min until the surface of the PR just broke (*Dun et al., 2024*). The radial deformation of the PR before and after the test was obtained using a universal material testing machine, and then the axial deformation of the PR was measured using electronic calipers (accuracy of 0.01 mm), and the Poisson's ratio of the PR was calculated to take the average value of 0.42.

A total of one hundred PR were randomly selected and their original dimensions in the radial (X-axis) and axial (Z-axis) directions were recorded. A universal material testing machine (UTM2501/50N, Shenzhen Sanshi Zongheng Technology) was employed to conduct pressure deformation tests on PR at a rate of 0.1 mm/min until the surface of the PR reached the point of rupture (*Dun et al., 2024*). The radial deformation of the PR was obtained using a universal material testing machine before and after the test. The axial deformation of the PR was then measured by electronic vernier calipers (accuracy of 0.01 mm), and the Poisson's ratio of the PR was calculated to yield an average value of 0.42.

Determination of exposure parameters

The contact parameters are primarily comprised of the static friction coefficient, rolling friction coefficient, collision recovery coefficient, and stacking angle (*Hou et al., 2020*). The contact parameters between the PR and the contact materials, as well as between the seeds themselves, represent crucial design parameters for a seed discharge device. In light of the engineering practice and the manufacturing materials of the seed discharger (*Xing et al., 2020*), this paper selects the contact parameters between the steel plate, the PLA material, and the PR, as well as the contact parameters between the PR.

Static Friction Coefficient Measurement Test

In this experiment, the static friction coefficients of PR were measured using the oblique method (*Cong, 2014*), which involved the use of steel plates and PLA plates. The coefficients were determined by observing the forces acting between the seeds, pellets, and plates. The test was conducted on a custom-built apparatus, and the dimensions ($L \times W \times H$) of the steel plate utilized for testing were 300mm×300mm×1mm, while the dimensions ($L \times W \times H$) of the PLA plate were 200mm×150mm×10mm, as illustrated in Fig. 4. The measurement will be taken along the long axis of the plate to be tested. The inclination angle of the plate will be increased

gradually until the PR begins to slide down its surface. This angle, which represents the sliding friction angle θ , will be recorded. Ten randomly selected PR seeds underwent three repetitions of the test to determine the tangent value of the sliding friction angle. This method was adopted to determine the static friction coefficient of the PR. The mean value of the static friction coefficient between the PR and the steel plate was 0.32, while the mean value of the static friction coefficient between the PR and the PLA plate was 0.34. To determine the coefficient of static friction between PR, the seeds were affixed to the PLA plate with tape, as illustrated in Fig. 4c. The resulting average value of the static friction coefficient between PR was 0.5.

Fig.4(a) - Test rig for coefficient of static friction between PR and steel plate

Fig.4(b) - Test rig for coefficient of static friction between PR and PLA plates

Fig. 4(c) - Test rig for inter-seed static friction coefficient of PR

Rolling Friction Coefficient Measurement Test

In this study, the side slope test method, as described by *Dun et al.*, (2024), was employed for the measurement of the variables under investigation. The underlying test principle is illustrated in Fig. 5. The apparatus comprises a PLA plate with a known inclination angle and a horizontal PLA plate. To conduct the rolling friction coefficient test between PR and the PLA plate, the PR is positioned on the inclined PLA plate, with an inclined rolling length of 30 mm. This allows the seeds to roll naturally under the influence of gravity, and the rolling distance of the seeds is then measured on the horizontal PLA plate. The rolling distance between the PR and the PLA plate is derived from the formula (1). The rolling friction coefficient between the PR and the PLA plate was determined through a series of 10 repetitions (*Wen et al.*, 2020). The resulting mean value was calculated to be 0.14.

$$mg \sin \theta \times h_0 = \mu_0 mg \cos \theta \times h_0 + \mu_0 mgh_1 \quad (1)$$

where:

m is the mass of PR, [Kg]; θ is the PLA plate tilt angle, [°]; h_0 is the rolling length of PR on an inclined PLA plate, [mm]; μ_0 is the coefficient of rolling friction between PR and PLA plates; h_1 is the rolling length of PR on a horizontal PLA plate, [mm].

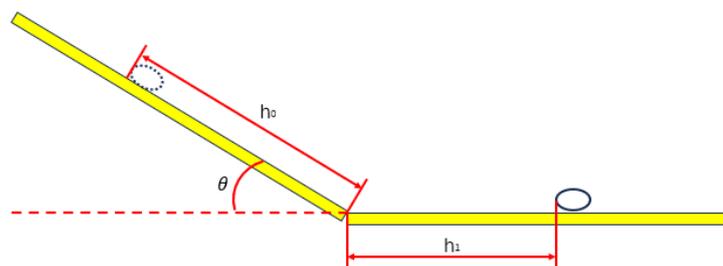

Fig.5 - Schematic diagram of side slope test

Replace the PLA plate in the above device with a steel plate, repeat the above test, and refer to the relevant literature (*Fan et al.*, 2024) to determine the rolling friction coefficient between the PR and the steel plate is 0.15.

In determining the rolling coefficient of friction between PR seeds, adhesive tape was used to uniformly fix the PR seeds onto two PLA boards. To account for the increase in rolling friction coefficient between the seeds, the angle of the inclined seed board was adjusted so that the sloping rolling length remained 30 mm. The above test was repeated 10 times, and following the relevant literature (*Wen et al.*, 2020), the average rolling coefficient of friction between PR seeds was determined to be 0.14.

Crash recovery factor

Mutual extrusion and collision are expected to occur between PR seeds and the seed discharger during the seed discharge process. To quantify this phenomenon, the interspecies collision recovery coefficient must be calculated (Hou *et al.*, 2020). This coefficient is defined as the ratio of the relative velocity of separation of two objects after a collision to their relative approach velocity before the collision. It is calculated using Equation (2) (Dun *et al.*, 2024). The collision recovery coefficient was determined through a free-fall test, the methodology of which is illustrated in Fig. 6. The distance between the funnel of the test bench and the PLA plate was set to 100 mm. The background plate had a spacing of 10 mm per frame, and a digital camera was used for high-speed photography, with the video slowed down by a factor of 10. The rebound height was measured after the seeds made contact with the PLA plate. Each set of data was tested 10 times, and the average value was calculated. The results yielded a collision recovery coefficient of 0.298 between PR and the PLA plate, 0.279 for interspecies collisions of PR, and 0.320 between PR and the non-steel plate.

$$e = \frac{|v_2 - v_1|}{|V_2 - V_1|} = \frac{|v_2|}{|V_2|} = \sqrt{\frac{h}{H}} \quad (2)$$

where:

V_1 is the initial velocity of the PR in free fall, i.e. $V_1 = 0 \text{ m/s}$; V_2 is the initial velocity of the PR before it touches the PLA plate, [m/s]; v_1 is the velocity of the PR when it bounces up at the highest point after colliding with the PLA plate, [m/s]; v_2 is the velocity of the PR after colliding with the PLA plate, i.e. $v_2 = 0 \text{ m/s}$; h is the height of the PR before free fall, [mm]; H is the highest height at which the PR bounces back from the free-fall collision with the PLA plate, [mm].

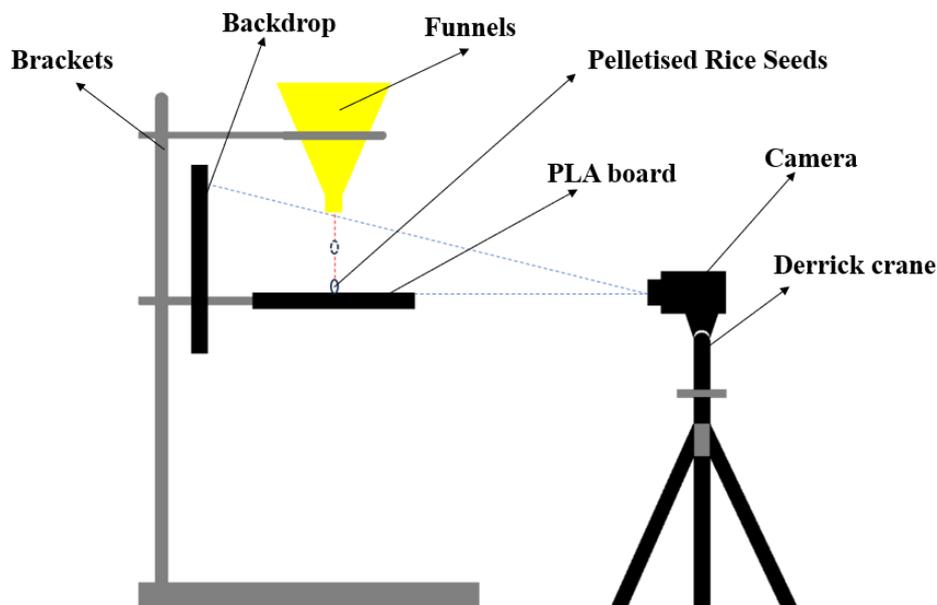

Fig. 6 - Schematic diagram of free fall test for PR

Stacking angle

The stacking angle is a macroscopic parameter that reflects the fluidity and friction characteristics of granular materials. Additionally, a seed stacking process occurs during the sowing of PR. To further verify the accuracy of the calibration parameters, the stacking angle was selected as a test index. In this experiment, the stacking angle was measured using the funnel method, as previously described in detail by Zhu *et al.*, (2022) and Al-Hashemi B.M.H. *et al.*, (2018). The test is shown in Fig. 7(a). The PR is placed into the funnel, where it falls into a pile on the PLA platform. The centerline of the camera is set to the same height as the PLA platform. Images of the PR stacking are captured using image processing software to measure the stacking angle, as illustrated in Fig. 7(b). This process is repeated 10 times to obtain an average angle, which represents the pill-PR stacking angle.

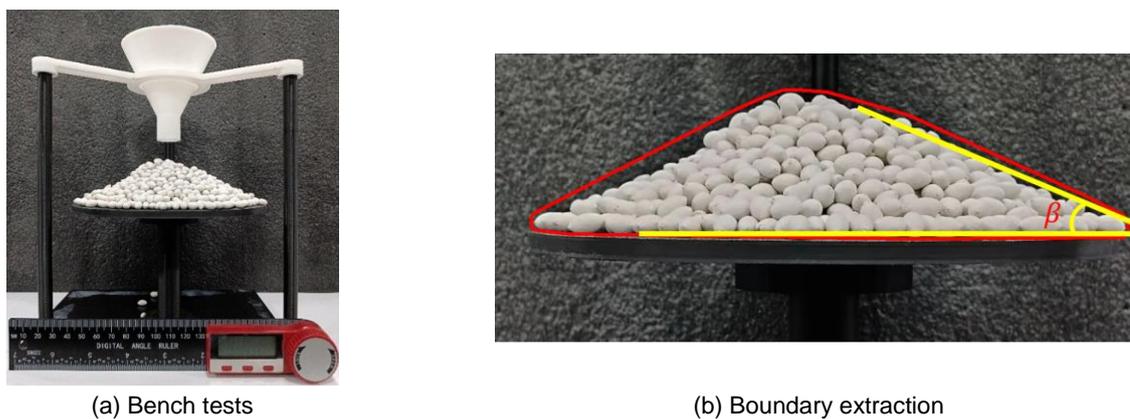

Fig. 7 - PR stacking angle test

Discrete elemental modeling of PR and calibration of simulation parameters

Development of a discrete meta-simulation model for PR

The external dimensions of the PR were determined through preliminary physical testing. Based on the test data obtained, the average dimensional values for each axis were calculated and then modeled using SolidWorks software. The generated models were saved in STL format and subsequently imported into EDEM software. As demonstrated in the related literature (Zhang *et al.*, 2017), the simulation modeling process is most significantly affected by the interaction between PR-PR, and PR-PLA plates, as well as the size and shape of the simulation model. The contour of the model, the rounded corners of the edges filled with PR, and the PR filled with spherical particles via EDEM software had minimal effect on the simulation results.

In the EDEM simulation test, the data obtained from the aforementioned test were inputted, and the stacking angle determination model was drawn according to the size of the actual stacking angle determination device, as illustrated in Fig. 8. A particle factory was constructed at the large aperture above the funnel for the dynamic generation of PR. The PR was generated in a fixed form (Hou *et al.*, 2020), with a generation rate of 1000 particles/s and a total of 600 particles. The grid size was three times the minimum particle radius (Hu, 2010). At the outset of the simulation, the PR was generated from the pellet plant situated above the funnel and subsequently descended under the influence of gravity. The seeds were generated in a continuous stream over 0.6 seconds, after which the simulation concluded at 2 seconds. The seeds coalesced into a seed pile on the chassis, and the stacking angle was subsequently determined through post-processing of the seed pile.

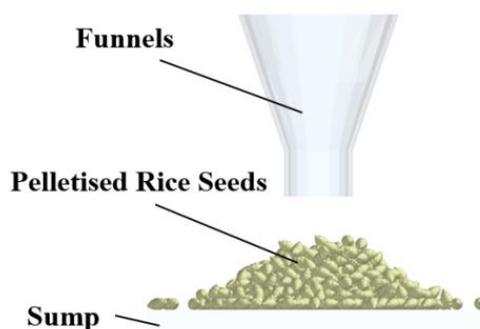

Fig. 8 - A simulation model for determining the stacking angle of PR

Discrete element simulation parameter calibration

Determination of the significant impact factor

The Design-Expert software was used in this study for the design of the Plackett-Burman experiment and data analysis. Plackett-Burman is a two-level design of experiments method that identifies significant parameters by comparing the difference between two levels of each parameter to the overall difference to determine the significance of the parameter (Bai *et al.*, 2023). The experimental parameters were identified based on the results of the physical tests described earlier. Parameters that had a significant effect on the response values were identified using the Plackett-Burman test (Li *et al.*, 2020). The maximum and minimum values of the seven test parameters listed in Table 1 were assigned +1 and -1, respectively. The Plackett-Burman test protocol and results are listed in Table 2.

Table 1

Plackett-Burman test parameter range table

Test parameters	Low level(-1)	High level(+1)
Poisson's ratio of PR (x1)	0.3	0.5
Rolling friction coefficient of PR-PLA plate (x2)	0.1	0.2
PR - Rolling Friction Coefficient of PR (x3)	0.1	0.2
Coefficient of static friction of PR-PLA plate (x4)	0.3	0.4
PR - Coefficient of static friction of PR (x5)	0.4	0.6
PR-PLA plate collision recovery coefficient (x6)	0.2	0.4
PR - Collision Recovery Coefficient of PR (x7)	0.2	0.4

Table 2

Plackett-Burman test program and results

Serial number	Test parameters							Stacking angle
	x1	x2	x3	x4	x5	x6	x7	
1	1	1	-1	1	1	1	-1	24.65
2	-1	1	1	-1	1	1	1	28.48
3	1	-1	1	1	-1	1	1	28.03
4	-1	1	-1	1	1	-1	1	25.77
5	-1	-1	1	-1	1	1	-1	23.31
6	-1	-1	-1	1	-1	1	1	17.63
7	1	-1	-1	-1	1	-1	1	18.10
8	1	1	-1	-1	-1	1	-1	19.05
9	1	1	1	-1	-1	-1	1	24.45
10	-1	1	1	1	-1	-1	-1	33.95
11	1	-1	1	1	1	-1	-1	34.61
12	-1	-1	-1	-1	-1	-1	-1	16.72

The data were imported into Design-Expert 13.0 software for analysis of variance (ANOVA) of the experimental results to determine the effect of each parameter. From the analysis, it was found that the coefficient of rolling friction of PR-PLA plate (X2), the coefficient of rolling friction of PR-PLA plate (X3) and the coefficient of static friction of PR-PLA plate (X4) had a significant effect on the stacking angle of PR, with P-values of 0.0726, 0.0024, and 0.0096, respectively. These values indicate a significant impact on the stacking angle, while the remaining parameters had relatively minor effects. Therefore, only the above three factors with significant effects were considered in the subsequent steepest climb test and Box-Behnken test.

Steepest climb test design

Based on the results of the Plackett-Burman test, the steepest climb test was conducted for the three selected significance factors (coefficient of rolling friction of PR-PLA plate, coefficient of rolling friction of PR-PLA seed, and coefficient of static friction of PR-PLA plate), and the relative error between the simulated stacking angle and the actual stacking angle was taken as the evaluation index to determine the optimum ranges of the above three test parameters (Liu et al., 2020). The design scheme and results of the steepest climb test are shown in Table 3.

For the simulation tests, all other insignificant parameters from the theoretical test results mentioned above were used: the PR Poisson's ratio 0.42, the PR-PR static friction coefficient 0.5, the PR-PLA plate collision recovery coefficient 0.298, and the PR-PR collision recovery coefficient 0.279.

Table 3

Steepest Climbing Test Design Options and Results

Serial number	x2	x3	x4	Stacking angle (°)	Relative error/%
1	0.1	0.1	0.3	15.82	0.323642582
2	0.12	0.12	0.32	20.22	0.135528003
3	0.14	0.14	0.34	25.3	0.081658829
4	0.16	0.16	0.36	27.24	0.164600257
5	0.18	0.18	0.38	29.24	0.250106883

According to the relative error results in Table 4, it can be seen that the rolling friction coefficient of PR and PLA plate and PR are both 0.14, and the static friction coefficient of PR-PLA plate is 0.34, the relative error between the simulated stacking angle and the actual stacking angle is small. It can be determined that the range of optimal intervals is in the vicinity of No. 3. Therefore, the follow-up will take No. 3 as the center point, and No. 2 and No. 4 as the low, high levels for subsequent Box-Behnken response surface tests.

Box-Behnken experimental design

In this paper, the Box-Behnken test design was performed using Design-Expert 13.0 software. This method fits a functional relationship between the parameters and response values to determine the interactions among the parameters. The solver is used to find the optimal values of the significant parameters (Bai et al., 2023). The Box-Behnken test for significance parameters was performed with No. 3 as the center point, No. 2 and No. 4 as the low (-1) and high (+1) levels, and all other parameters in the simulation test were set according to the parameters used in the steepest climb test. The test scheme and results are shown in Table 4.

Table 4

Box-Behnken experimental design scheme and results

Serial number	x2	x3	x4	Stacking angle (°)
1	-1	-1	0	23.77
2	1	-1	0	25.88
3	-1	1	0	25.54
4	1	1	0	27.62
5	-1	0	-1	24.81
6	1	0	-1	22.84
7	-1	0	1	23.45
8	1	0	1	26.71
9	0	-1	-1	24.98
10	0	1	-1	27.18
11	0	-1	1	26.89
12	0	1	1	27.16
13	0	0	0	23.57
14	0	0	0	23.15
15	0	0	0	23.90

The above test results were analyzed and fitted with multiple regression using Design-Expert 13.0 software to obtain the following second-order regression equations for the stacking angle of the PR simulation test:

$$\beta = 23.54 + 0.56A + 0.5675B + 0.575C - 0.2575AB + 1.31AC - 0.4325BC - 0.0687A^2 + 1.98B^2 + 0.9812C^2 \tag{3}$$

RESULTS

The results of Box-Behnken test ANOVA are shown in Table 5. From the analysis of the results in Table 5, it can be observed that factors A (x1), B (x2), C (x3), AC, B2, and C2 have a significant effect on the stacking angle, while the effect of AB, BC, A2 on the stacking angle is not significant. The p-value of this fitted model is 0.0013 (p<0.01), which indicates the relationship between the dependent and independent variables and its significance in the model; the lack-of-fit term P=0.5003>0.05, suggests that the model is well fitted. The coefficient of determination for the second-order regression equation of the stacking angle R^2=0.9775 and the adjusted coefficient of determination is R^2=0.9371, both of which are very close to one. In general, the

higher the coefficient of variation (CV), the lower the reliability of the test, In this test, the CV=1.56% which indicates that the fitted equation has a high degree of credibility and accurately represents real conditions, thereby verifying the test's reliability.

Table 5

Box-Behnken design Second order regression equation Analysis of variance

Source	Sum of squares	df	Mean Square	P-value
Model	33.2	9	3.69	0.0013
A (x1)	2.51	1	2.51	0.0098

Lack of fit	0.4805	3	0.1602	0.5003
Pure Error	0.2826	2	0.1413	
Cor Total	33.96	14		
<i>R² = 0.9775; Adjusted R² = 0.9371; CV = 1.56%</i>				

In the data analysis optimization module of Design-Expert 13.0 software, the second-order regression equations were refined by averaging the results from 100 sets of optimal combinations. The coefficient of rolling friction between PR and PLA plates was found to be 0.137, reflecting the interaction of the PR on the surface of the PLA plate as well as among the seeds themselves. Meanwhile, the coefficient of static friction for the PR against the PLA plate was measured at 0.336, indicating the maximum frictional force encountered when the PR remains relatively stationary before rolling. The remaining parameters, which were considered insignificant, were averaged based on physical tests. To validate the accuracy of these optimal parameter combinations, simulation tests were performed using EDEM, as depicted in Fig.9. The stacking angles recorded from three replicates were 24.15°, 23.97°, and 22.97°. A t-test analysis comparing the simulation results with the actual test values, conducted using SPSS 23 software, produced a p-value of 0.481, which exceeds the 0.05 threshold. In statistical terms, a p-value greater than 0.05 typically indicates no significant difference between the two data sets. Consequently, this result confirms that the outcomes of the simulation tests align closely with the real physical test values, further demonstrating the accuracy and reliability of the optimal parameter combination.

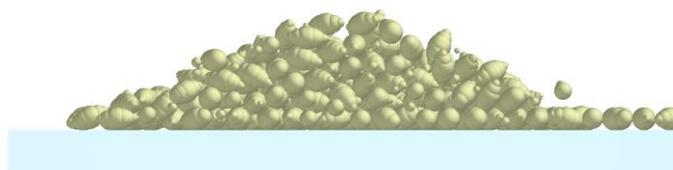

Fig. 9 - Validation of discrete element simulation of pile-up angle of PR

CONCLUSIONS

(1) The physical properties of the particulate material—including external dimensions, micrometric weight, and Poisson's ratio—along with the contact parameters, such as the static friction coefficient, rolling friction coefficient, and collision recovery coefficient, are established through physical testing. This process provides the essential parameters required for the discrete element simulation of the particle system.

(2) The Plackett-Burman test was performed according to the specified parameters to determine which factors most significantly affect the PR stack angle. The parameters under investigation include the rolling friction coefficient of the PR-PLA plate, the rolling friction coefficient of the PR-PR, and the static friction coefficient of the PR-PLA plate.

(3) The second-order regression equation for the stacking angle was derived using a Box-Behnken test. Following optimization and solving, the optimal simulation parameters identified are as follows: the rolling friction coefficient of the PR-PLA plate is 0.137, the rolling friction coefficient of the PR-PR plate is also 0.137, and the static friction coefficient of the PR-PLA plate is 0.336. Simulation experiments were conducted using these parameters, and a T-test analysis was performed to examine the correlation between the simulation results and the actual experimental values. The T-test analysis reveals no significant difference between the simulation results and the experimental values ($P > 0.05$), further confirming the authenticity and reliability of the simulation parameters after the experiments and calibration.

(4) This conclusion not only serves as a reference for research on PR and their high-speed precision sowing but also provides valuable insights for the practical application of these seeds in agriculture. This information can help optimize the seeding equipment design and seed handling process at a later stage, thus improving the efficiency and quality of agricultural production.

ABSTRACT

To address the issues of low precision and high cost in pig house environmental monitoring, an Internet of Things (IoT)-based pig house environmental monitoring system is proposed in this study. The system utilizes ESP32 as the main control chip of each sensor node, which is constructed in a star topology structure, realizing data transmission by using wireless communication technology. By incorporating the median filtering function and the Kalman filtering algorithm to perform data fusion of the same type of environmental parameters, the accuracy of the data is ensured. Based on the environmental suitability requirements of pigs, an evaluation index system for pig house environmental suitability is established, and comprehensive weight calculations are carried out by combining the entropy weight method and the improved analytic hierarchy process. Simulation experimental results demonstrate that the error of the temperature data after Kalman filtering fusion is merely 0.12%, fulfilling the monitoring accuracy requirements. The system can precisely evaluate the environmental suitability of pig houses, and it is applicable for monitoring pig house environments.

摘要

为解决猪舍环境监测精度低和成本高等问题, 本研究提出了一种基于物联网的猪舍环境监测系统。系统采用 ESP32 作为各传感器节点的主控芯片, 并通过星型拓扑结构搭建, 利用无线通信技术实现数据传输。通过引入中值滤波函数和卡尔曼滤波算法对同类型的环境参数进行数据融合, 确保数据准确性。基于猪只对环境的适宜度要求, 构建了猪舍环境适宜度评价指标体系, 并结合熵权法与改进层次分析法进行综合权重计算。仿真实验结果表明, 经过卡尔曼滤波融合后的温度数据误差仅为 0.12%, 满足监测精度要求。系统能够准确评价猪舍环境适宜度, 适用于猪舍环境监测。

INTRODUCTION

With the transformation of the agricultural industry structure, pig farming industry is evolving towards large-scale, intensive, and industrialized operations. This development is of great significance for optimizing the rural economic structure, improving agricultural efficiency, and increasing farmers' income (Han et al., 2010). However, currently, small and medium-sized pig houses still face challenges such as difficulties in implementing environmental monitoring technology and high monitoring costs. The quality of pig house environment is a crucial factor in ensuring the healthy breeding of pigs, directly influencing their growth, development, and reproductive ability (Spinka et al., 2017). It will lead to serious consequences, such as diseases and economic losses to farmers, if pigs grow in harsh environments for a long time (Chen et al., 2020; Li et al., 2023). Therefore, monitoring various parameters of the pigs' growth environment and improving the management level of pig farm environmental quality are of great significance for promoting the sustainable development of global pig farming industry (Li et al., 2024; Wang et al., 2024).

Numerous scholars have conducted research on the intelligent monitoring and control of pig house environmental quality to overcome existing problems. For example, Zeng et al., (2020), investigated a wireless multi-point, multi-source remote monitoring system for pig house environments, which can rapidly perceive the spatiotemporal distribution characteristics of pig house environmental parameters, providing valuable references for optimizing pig house environmental control.

Huang *et al.*, (2022), employed narrowband Internet of Things (IoT) and cloud platform technics to achieve remote monitoring and real-time regulation of multiple environmental factors such as temperature within pig house, effectively ensuring welfare of pigs and offering new design solutions for intelligent monitoring systems in pig farming. Nevertheless, these studies do not explore pigs' adaptability to pig house environment. Regarding the adaptability of pigs to pig house environment, many scholars have also carried out research (Xie *et al.*, 2024). For instance, Chen *et al.*, (2022), utilized an improved analytic hierarchy process combined with fuzzy comprehensive evaluation to establish a comprehensive evaluation system for pig house environment, which can evaluate the suitability of pig house environment in real-time and provide a good design solution for precise regulation and early warning of pig house environment. Wang *et al.*, (2023), applied a fuzzy comprehensive evaluation method to study an IoT-based environmental suitability evaluation system for fattening pig houses. This system can simultaneously collect data on multiple environmental factors in pig house and perform transmission, analysis, and display of these environmental data.

However, most of these studies typically adopt a single analytic hierarchy process (AHP) or entropy weight method for weight calculation, failing to comprehensively consider the deviation of subjective weight calculation methods and the one-sidedness of objective weight calculation methods (Xie *et al.*, 2016; Chi *et al.*, 2022; Xie *et al.*, 2024; Liu *et al.*, 2024).

To solve the aforementioned problem, this paper focuses on pig house environmental information monitoring as the research subject and combines Internet of Things (IoT) technology, wireless communication technology, and others to design an IoT-based pig house environment monitoring and application system (Gao *et al.*, 2016; Bai *et al.*, 2019; Zhou *et al.*, 2021; Wang *et al.*, 2024; Wang *et al.*, 2024). This system can remotely monitor environmental information such as temperature and relative humidity within pig house simultaneously. Additionally, to evaluate pig house environment more scientifically, the weight coefficient of the environmental evaluation index of pig house is calculated by integrating the subjective weight calculation method and the objective weight calculation method, thereby reducing the deviation and one-sidedness of the environmental evaluation. Finally, the fuzzy comprehensive evaluation method is utilized to assess the suitability of pig house environmental data. The suitability evaluation results can provide decision support for the precise regulation of pig house environment.

MATERIALS AND METHODS

Overall system plan

The experimental pig house is located at 11.32°E longitude and 37.19°N latitude. The internal view of the pig house is shown in Figure 1. The Internet of Things system for remote monitoring of the pig house environment mainly consists of three parts: the Information acquisition and perception layer, the Information wireless transmission layer, and the information processing and application layer. The overall structure of the system is illustrated in Figure 2. The pig house is monitored at 20 different points, each equipped with a set of sensor nodes. Thus, a total of 20 sets of sensor nodes and one set of sink node are installed in the monitoring area of the pig house.

Fig. 1 – Internal picture of pig house

Each set of sensor nodes is composed of the required environmental factor sensor, a data transmission interface, a main control chip and other structures, and it is powered by an independent power supply. These sensor nodes collect data on environmental factors within the pig house using their onboard main control chips and transmit the data via Wi-Fi to the sink node. The sink node performs data fusion on the received information from the sensor nodes and conducts corresponding evaluations based on a suitability evaluation model for the pig house environment, thereby enabling the analysis of environmental information throughout the entire pig house. Finally, the fused environmental factor data such as temperature and humidity are transmitted to the cloud platform via Wi-Fi, and the cloud platform uses the HTTP data transmission protocol to send this information to a WeChat mini-program, allowing users to view and access real-time environmental information about the pig house through either a PC or a mobile device.

ESP32 is used as the main control chip of the system. ESP32, which integrates a TCP/IP protocol stack enabling direct connection to Wi-Fi networks and also functioning as a hotspot, is utilized as the main control chip of this system. The sink node operates in softAP+Station mode, in this system. In this mode, the ESP32 main control chip can be used both as a terminal node and as a wireless access point, meeting the functional requirements of the sink node. Additionally, the ESP32 provides functions such as IIC interface, GPIO interface, UART serial port, and ADC interface, which can satisfy design requirements.

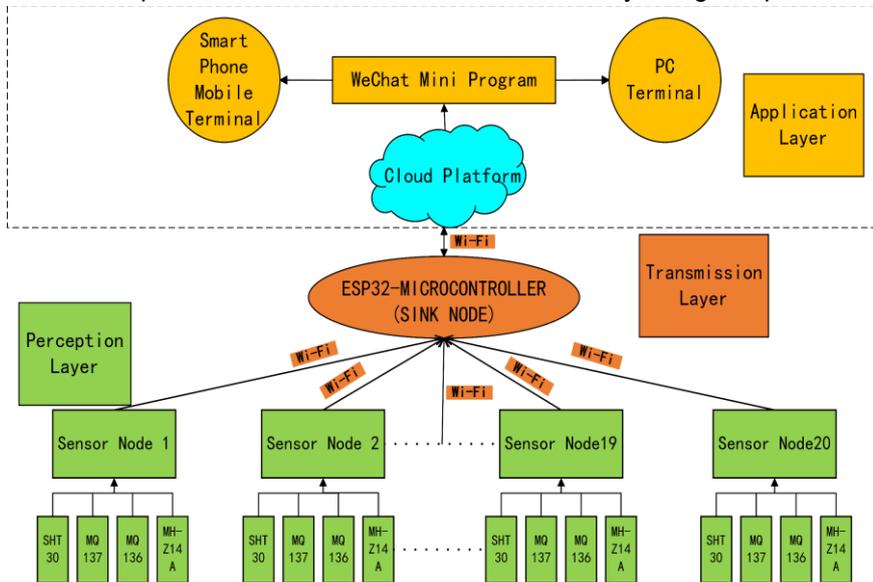

Fig. 2 – Overall system structure

System hardware design

(1) System sensor nodes hardware design

The temperature and relative humidity collection module adopts the SHT30 temperature and humidity sensor, which exhibits higher stability and reliability compared to other similar sensors. Its temperature measurement range is from -40°C to 125°C with an error margin of $\pm 0.2^{\circ}\text{C}$, and the relative humidity measurement range is from 0%RH to 100%RH with an error margin of $\pm 2\% \text{RH}$. It is connected to the ESP32 via an IIC interface. The ammonia gas collection module uses the MQ137 ammonia gas sensor, with a detection range of 5×10^{-6} to $5 \times 10^{-4} \text{ mg/m}^3$. The hydrogen sulfide collection module employs the MQ136 hydrogen sulfide sensor, with a detection range of 10^{-6} to 10^{-4} mg/m^3 . The carbon dioxide collection module utilizes the MH-Z14A carbon dioxide sensor, with a detection range of 0 to 10^{-2} mg/m^3 . The environmental information data within the pig house is processed by the ESP32 microcontroller and transmitted to the sink node via Wi-Fi. The connection circuit between the ESP32 MCU and the sensor is shown in Figure 3.

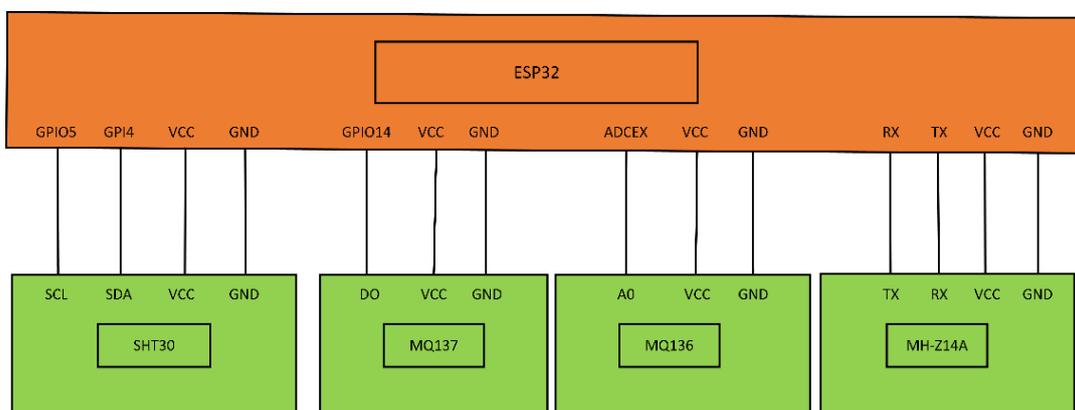

Fig. 3 – Interface between ESP32 and sensor

(2) System sink node hardware design

The main function of the sink node is to receive environmental information parameters collected from sensor nodes and it optimizes and fuses environmental data of the same type using a median filtering function and a Kalman filter algorithm. Meanwhile, it can display the current environmental information inside the pig

house and assess the current environment of the pig house in combination with a comprehensive evaluation model. The sink node adopts an ESP32 single-chip microcomputer along with an ILI9488 3.5-inch TFT display screen, allowing real-time viewing of the current environmental parameters on the display screen. The connection circuit between the ESP32 MCU and the TFT display is shown in Figure 4.

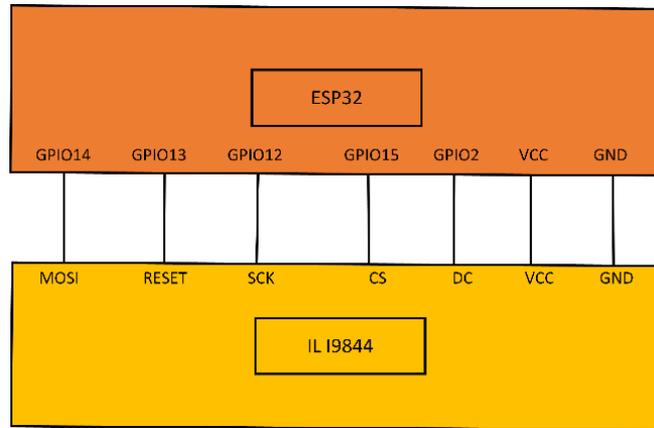

Fig. 4 – Schematic diagram of ESP32 MCU and ILI9488 display

Environmental parameter acquisition algorithm design

This paper's fusion algorithm is based on data collected by environmental parameter acquisition sensors, including temperature, humidity, ammonia gas concentration, hydrogen sulfide concentration, and carbon dioxide concentration. Before fusion, a median filter function is used to optimize the data and reduce the impact of random factors. Subsequently, a Kalman filter algorithm is applied to fuse the environmental data collected from the pig house. The main steps of the Kalman filter algorithm are as follows:

The system's current state prediction equation is as follows:

$$\hat{x}_{k/k-1} = A_{k-1/k-1} \hat{x}_{k-1/k-1} \quad (1)$$

where:

$\hat{x}_{k/k-1}$ is the predicted result of the system state at the current moment, $A_{k-1/k-1}$ is the system state transition matrix, and $\hat{x}_{k-1/k-1}$ is the optimal system state estimate from the previous moment.

There is a certain error between the predicted value and the true value, and the error covariance matrix equation is as follows:

$$P_{k/k-1} = A_{k-1/k-1} P_{k-1/k-1} A_{k-1/k-1}^T + Q_{k/k} \quad (2)$$

where:

$P_{k/k-1}$ is the system prediction state covariance matrix at the current moment, $P_{k-1/k-1}$ is the optimal prediction state covariance matrix from the previous moment, and $Q_{k/k}$ is the process noise covariance matrix.

The Kalman Gain equation is as follows:

$$K_{k/k} = P_{k/k-1} C_{k/k}^T (C_{k/k} P_{k/k-1} C_{k/k}^T + R_{k/k})^{-1} \quad (3)$$

where:

$K_{k/k}$ is the Kalman Gain, $C_{k/k}$ is the measurement matrix, and $R_{k/k}$ is the measurement noise covariance matrix.

The optimal state estimation equation for the system at the current moment is as follows.

$$\hat{x}_{k/k} = \hat{x}_{k/k-1} + K_{k/k} (y_{k/k} - C_{k/k} \hat{x}_{k/k-1}) \quad (4)$$

where:

$\hat{x}_{k/k}$ is the optimal state estimate at the current moment, and $y_{k/k}$ is the sensor measurement value at the current moment.

The covariance matrix update equation for the current moment is as follows:

$$P_{k/k} = [I - K_{k/k} C_{k/k}] P_{k/k-1} \quad (5)$$

where:

$P_{k/k}$ is the covariance matrix of the optimal state estimate at the current moment, and I is the identity matrix.

ENVIRONMENTAL SUITABILITY FUZZY COMPREHENSIVE EVALUATION MODEL

The comprehensive evaluation of the pig house is mainly carried out through sink node. The sink node receives data from sensor nodes and performs data fusion. Based on the fused values of various environmental parameters, a comprehensive weight calculation is performed by combining the entropy weight method and an improved analytic hierarchy process. Then, based on the data fusion values and weight set from the sink node, an evaluation of the suitability of the pig house environment is made.

Construction of the evaluation index system

The environmental factors that have the most significant impact on the growth, development, and reproduction of pigs include environmental temperature, relative humidity, ammonia gas concentration, carbon dioxide concentration, and hydrogen sulfide concentration. Therefore, this paper selects these five environmental parameters as the evaluation indicators for pig house environmental suitability. The degree of suitability is represented by 3 levels: Suitable (C), Relatively Suitable (M), and Unsuitable (B). Based on the environmental parameters of large-scale pig farms and the environmental management standards issued by the state, a pig house environmental evaluation index system is established, as shown in Table 1 (GB/T 17824.3-2008).

Table 1

Evaluation result set	Factor set				
	Temperature / °C	Relative Humidity/ %	Carbon dioxide / (mg·m ⁻³)	Ammonia gas / (mg·m ⁻³)	Sulfuretted hydrogen / (mg·m ⁻³)
Suitable	18~22	60~70	0~1000	0~2	0~2
Relatively suitable	16~18 or 22~27	50~60 or 70~80	1100~1200	5~10	4~6
Unsuitable	>27 or <16	>80 or <50	>1300	>20	>10

Evaluation modeling steps

The evaluation of pig house environmental suitability is conducted using a fuzzy comprehensive evaluation method that combines the entropy weight method, the improved analytic hierarchy process, and fuzzy set. The modeling steps are as follows:

- (1) Determine the factor set: Based on the established evaluation index system, determine the environmental factors that have the greatest impact on the healthy growth of pigs, and establish the evaluation factor set $I = \{u_1, u_2, u_3, u_4, u_5\}$. These include u_1 = temperature, u_2 = relative humidity, u_3 = ammonia gas concentration, u_4 = carbon dioxide concentration, and u_5 = hydrogen sulfide concentration.
- (2) Determine the evaluation result set: The evaluation result set is divided into three levels, denoted as $D = \{d_1, d_2, d_3\}$, where d_1 is Suitable (C), d_2 is Relatively Suitable (M), and d_3 is Unsuitable (B).
- (3) Establish the membership matrix and conduct single-factor evaluation: According to the evaluation standards for each indicator, determine the membership functions for each indicator. Use these membership functions to calculate the membership matrices for the five environmental factors: temperature, relative humidity, ammonia gas concentration, carbon dioxide concentration, and hydrogen sulfide concentration, corresponding to H_1, H_2, H_3, H_4 and H_5 . Combine these single-factor membership matrices to obtain the overall membership matrix H . Evaluate the pig house environment based on the maximum membership principle. The form of the membership matrix H is as follows:

$$H = \begin{bmatrix} H_1 \\ H_2 \\ H_3 \\ H_4 \\ H_5 \end{bmatrix} = \begin{bmatrix} h_{11} & h_{12} & h_{13} \\ h_{21} & h_{22} & h_{23} \\ h_{31} & h_{32} & h_{33} \\ h_{41} & h_{42} & h_{43} \\ h_{51} & h_{52} & h_{53} \end{bmatrix} = (h_{ij})_{5 \times 3} \tag{6}$$

where:

h_{ij} is the membership degree of the i -th evaluation indicator belonging to the j -th level.

- (4) The entropy weight method and an improved analytic hierarchy process (AHP) are used to determine the index weights. First, the collected data is standardized, and then the entropy values and information entropy redundancy of various environmental parameters within the pig house are calculated.

Based on this, the objective weight coefficient for each environmental parameter is derived. The improved AHP uses a 1-9 scales method for pairwise comparisons to obtain the importance ranking index of each environmental factor, establishing a comparison matrix. It then constructs an indirect judgment matrix and optimizes it to find the maximum eigenvalue and eigenvector, which are normalized to obtain the subjective weight coefficients. The subjective and objective weight coefficients are combined to obtain the comprehensive weight coefficient for each environmental factor. Finally, the comprehensive weight coefficient of each index is merged into a weight set ω .

(5) Fuzzy comprehensive evaluation. The comprehensive weight set ω calculated by entropy weight method and improved analytic hierarchy process is fuzzy synthesized with membership degree evaluation matrix H . By using a weighted linear transformation method, the fuzzy comprehensive evaluation result of the pig house environment is ultimately obtained.

$$Y = \omega \cdot H = \{y_1, y_2, y_3\} \tag{7}$$

where: Y is the comprehensive evaluation result matrix.

Consequently, the evaluation result matrix corresponding to the three suitability conditions of the pig house environment is obtained, and the suitability status of the pig house environment is determined based on the maximum membership principle.

Selection of membership function types

The key to evaluating the suitability of the pig house environment lies in determining the membership functions for the pig house environment. Based on the nature of the pig house environment evaluation factors, the functional relationship between membership degree and indicators needs to be constructed using continuous functions. In the evaluation of pig house environmental suitability, commonly used types of membership functions include ridge-shaped membership function, trapezoidal membership function, and triangular membership function. The ridge-shaped membership function optimizes the edges and corners of the trapezoidal membership function, which can reduce errors when calculating high membership degrees. Compared to the triangular membership function, the ridge-shaped membership function has better distinction between levels. Therefore, this paper uses the ridge-shaped membership function to calculate the membership degree matrix of evaluation factors such as temperature and humidity in the pig house environment. The expressions of the ridge-shaped membership function are shown in Formulas (8)-(10).

$$\text{Lower Type: } u(x) = \begin{cases} 1 & x \leq a \\ \frac{1}{2} - \frac{1}{2} \sin \frac{\pi}{b-a} \left(x - \frac{b+a}{2}\right) & a < x < b \\ 0 & x \geq b \end{cases} \tag{8}$$

$$\text{Middle Type: } u(x) = \begin{cases} 0 & x \leq a \\ \frac{1}{2} + \frac{1}{2} \sin \frac{\pi}{b-a} \left(x - \frac{b+a}{2}\right) & a < x < b \\ 1 & b \leq x \leq c \\ \frac{1}{2} - \frac{1}{2} \sin \frac{\pi}{d-c} \left(x - \frac{d+c}{2}\right) & c < x < d \\ 0 & x \geq d \end{cases} \tag{9}$$

$$\text{Upper Type: } u(x) = \begin{cases} 0 & x \leq a \\ \frac{1}{2} + \frac{1}{2} \sin \frac{\pi}{b-a} \left(x - \frac{b+a}{2}\right) & a < x < b \\ 1 & x \geq b \end{cases} \tag{10}$$

where: x represent the index values of the evaluation factors u_i , with its interval endpoints denoted as x_i 、 x_{i+1} . The membership degree of each evaluation level in the set of evaluation results is denoted as $u(x)$. The a , b , c , and d respectively represent the demarcation points in the set of evaluation results corresponding to various environmental factors in the pig house environment evaluation system. Each index value in the set

of evaluation factors has a corresponding fuzzy logical relationship. The ridge-shaped distribution membership functions of various environmental factors, established based on the pig house environment evaluation index system, are shown in Figure 5.

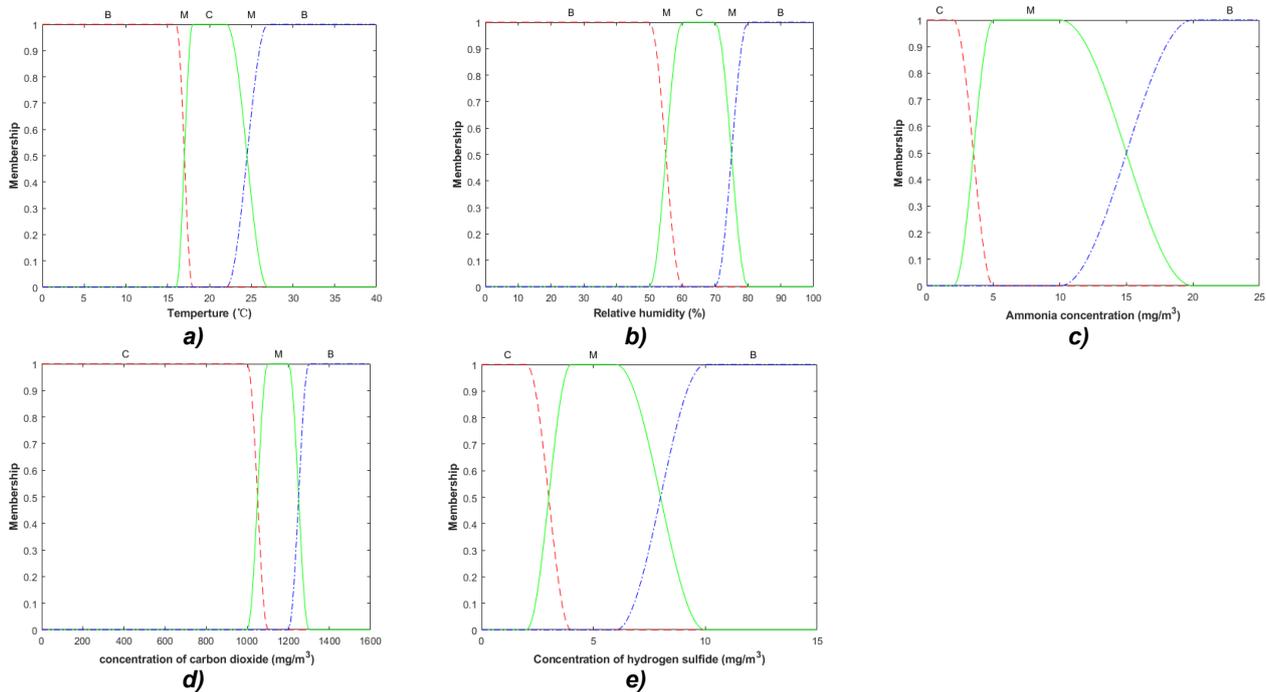

Fig. 5 – Membership function curves of each environmental factor
 a) Temperature; b) Relative humidity; c) Ammonia concentration;
 d) Concentration of Carbon dioxide; e) Concentration of hydrogen sulfide

In Figure a), b), c), d) and e), the three curves from left to right are the ring down type, the middle type and the ring up type.

Method for determining weight

(1) Weight calculation method based on the entropy weight method

Unlike the improved Analytic Hierarchy Process, which typically emphasizes subjective factors, the entropy weight method is a method of empowerment that objectively determines weight through observed values. The smaller the entropy value, the more disordered the information is, and thus its value in comprehensive evaluation is higher, resulting in a larger corresponding weight. For example, when there is a significant sudden increase in the temperature of the pig house, this algorithm will increase the weight of the temperature factor while reducing the weights of other factors with smaller changes. The algorithm process is as follows.

1) Standardize the data based on the following formula:

$$X'_{ij} = \frac{X_{ij} - \min(X_{1j}, X_{2j}, \dots, X_{nj})}{\max(X_{1j}, X_{2j}, \dots, X_{nj}) - \min(X_{1j}, X_{2j}, \dots, X_{nj})} + 1 \quad j = 1, 2, 3, \dots, m \quad (11)$$

2) Calculate the weight of the environmental parameter data for the j th item after standardization based on the following formula:

$$p_{ij} = \frac{X'_{ij}}{\sum_{i=1}^n X'_{ij}} \quad j = 1, 2, 3, \dots, m \quad (12)$$

3) Calculate the information entropy value of the environmental parameter for the j th item based on the following formula:

$$k = \frac{1}{\ln(n)} \quad (13)$$

$$e_j = -k \sum_{i=1}^n p_{ij} \ln(p_{ij}) \quad (14)$$

4) Calculate the information entropy redundancy of each environmental factor in the pig house based on the following formula:

$$f_j = 1 - e_j \tag{15}$$

5) Calculate the weight of each environmental parameter:

$$W_j^R = \frac{f_j}{\sum_{j=1}^m f_j} \quad j = 1, 2, 3, \dots, m \tag{16}$$

(2) Weight calculation method based on the improved analytic hierarchy process

Based on relevant research findings and the experience of livestock experts, the importances of evaluation indicators for multiple environmental factors in the pig house are determined as follows: environmental temperature, relative humidity, ammonia gas concentration, carbon dioxide concentration, and hydrogen sulfide concentration. The 1-9 scales method is used to compare these evaluation indicators with each other and construct a comparison matrix. The specific descriptions of the 1-9 scales method are shown in the table 2 below:

Table 2

Description of 1-9 scales	
Relative importance level	Scale significance
1	Equal importance
3	Slight importance
5	Obvious importance
7	Strong importance
9	Absolute importance
2, 4, 6, 8	The middle level of two adjacent levels

By conducting pairwise comparisons of environmental temperature (T), relative humidity (O), ammonia gas concentration (N), carbon dioxide concentration (E), and hydrogen sulfide concentration (HS), the importance of each factor is determined, resulting in a comparison matrix L . Then, the importance ranking index v_i for each factor is calculated, which are represented by the sum of each row in the comparison matrix L .

$$L = \begin{matrix} & T & O & N & E & HS \\ \begin{matrix} T \\ O \\ N \\ E \\ HS \end{matrix} & \begin{bmatrix} 1 & 2 & 3 & 4 & 3 \\ 1/2 & 1 & 2 & 3 & 2 \\ 1/3 & 1/2 & 1 & 3 & 2 \\ 1/4 & 1/3 & 1/3 & 1 & 1/3 \\ 1/3 & 1/2 & 1/2 & 3 & 1 \end{bmatrix} & \end{matrix} \quad i = 1, 2, 3, 4, 5 \tag{17}$$

where:

v_i is the importance ranking index for each factor indicator, and l_{ij} is the element in the i th row and j th column of the comparison matrix L .

Construct an indirect judgment matrix K reflecting the relative importance of each environmental factor. Let

$$q_m = \frac{v_{\max}}{v_{\min}} \tag{18}$$

where:

v_{\max} is the maximum ranking index, v_{\min} is the minimum ranking index, and q_m is the base point comparison scale. The indirect judgment matrix K is:

$$K = (k_{ij})_{5 \times 5} = \begin{cases} \frac{v_i - v_j}{v_{\max} - v_{\min}} (q_m - 1) + 1 & v_i - v_j \geq 0 \\ 1 / \left[\frac{v_i - v_j}{v_{\max} - v_{\min}} (q_m - 1) + 1 \right] & v_i - v_j < 0 \end{cases} \quad (i = 1, 2, 3, 4, 5) \quad (j = 1, 2, 3, 4, 5) \tag{19}$$

Transform the indirect judgment matrix K into an antisymmetric matrix S and then construct a quasi-optimal consistent matrix Z , the consistency requirement can be satisfied.

$$s_{ij} = \lg(k_{ij}) \quad (i = 1, 2, 3, 4, 5) \quad (j = 1, 2, 3, 4, 5) \tag{20}$$

where:

S is the antisymmetric matrix; s_{ij} is the element in the i th row and j th column of the antisymmetric matrix S ; k_{ij} is the element in the i th row and j th column of the indirect judgment matrix K .

$$z_{ij} = 10^{\frac{1}{n} \sum_{k=1}^n (s_{ik} - s_{jk})} \quad (i = 1, 2, 3, 4, 5) \quad (j = 1, 2, 3, 4, 5) \tag{21}$$

where:

z_{ij} is the element in the i th row and j th column of the quasi-optimal consistent matrix Z ; s_{ik} is the element in the i th row and k th column of the antisymmetric matrix S ; s_{jk} is the element in the j th row and k th column of the antisymmetric matrix S .

Finally, calculate the largest eigenvalue and the corresponding eigenvector of the quasi-optimal matrix Z , and normalize them as shown in equations (22) and (23) to obtain the required weight for each factor.

$$ZW = \lambda_{\max} W \tag{22}$$

$$W_j^A = \frac{W_j}{\sum_{j=1}^5 W_j} \tag{23}$$

where: λ_{\max} is the maximum eigenvalue of Z , and W is the relative weight vector.

After the aforementioned steps of the improved Analytic Hierarchy Process, the subjective weight of the evaluation index for each environmental factor is calculated, as shown in the table 3.

Table 3

Evaluation indicator weights of pig house environment	
Evaluation index	Weight
Temperature	0.4784
Relative humidity	0.2153
Ammonia gas	0.1468
Carbon dioxide	0.0562
Hydrothion	0.1033

(3) Combined weight calculation

Combine the subjective and objective weight values to obtain the combined weights. This calculation method can, to a certain extent, reduce the deviation of subjective weights and the one-sidedness of objective weights while leveraging their respective advantages, making the weight calculation more scientific. The comprehensive weights of the indices are calculated using the following formula:

$$\omega_j = \frac{W_j^A W_j^R}{\sum_{j=1}^n W_j^A W_j^R} \tag{24}$$

where:

ω_j is the comprehensive weight; W_j^A is the subjective weight calculated using the improved Analytic Hierarchy Process; W_j^R is the objective weight calculated using the entropy weight method. The comprehensive weights of the evaluation indicators are combined into a weight set ω , and ω satisfy $\omega = [\omega_T \ \omega_O \ \omega_N \ \omega_E \ \omega_{HS}]$.

RESULTS AND ANALYSIS

System data fusion effect test

Taking temperature as an example, the pig house temperature value measured by the precision temperature measuring instrument is used as the standard temperature.

During testing, each group of sensor node from 20 monitoring points in the pig house collected temperature data 10 times. The collected data from the sensor nodes are optimized using a median filtering function to reduce the influence of random factors. Subsequently, using MATLAB (2020a), the temperature data optimized by the median filtering function was compared with the temperature data processed by the algorithm discussed in this paper (a data fusion algorithm based on the median filtering function and Kalman filtering) and the standard temperature of 25.4 °C collected by a precision temperature instrument. The results are shown in Figure 6.

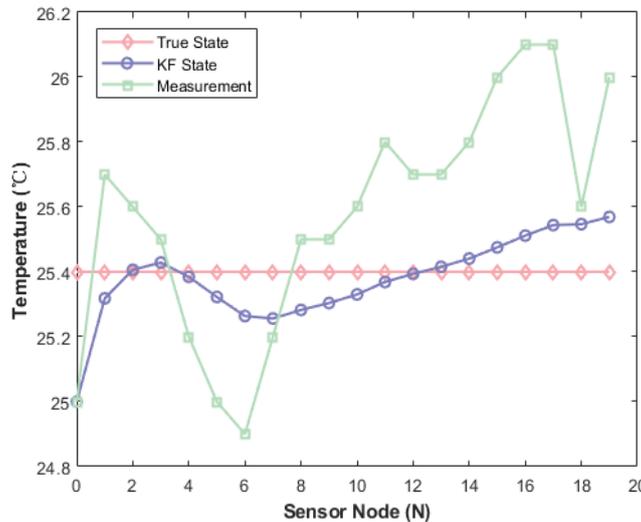

Fig. 6 – Comparison picture of the temperature values measured by three temperature measurement methods

From Figure 6, it can be seen that the average temperature measured by the 20 groups of sensor nodes is 25.57°C, while the average temperature after optimization by the fusion algorithm in this paper is 25.37°C, which is closer to the standard temperature of 25.4°C measured by the precision temperature instrument and the temperature data curve is smoother compared to that measured by the sensor nodes.

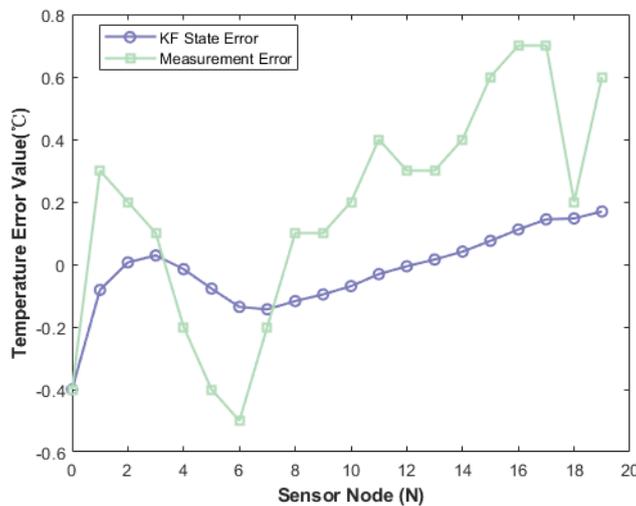

Fig. 7 – Error comparison results

From the error results comparison figure (Figure 7), it is evident that the measurement value error from the sensor nodes is 0.67% and the error range between -0.5°C and 0.7°C, indicating significant fluctuations. In contrast, the error value after applying the algorithm proposed in this paper is 0.12% and the error range is concentrated between -0.1°C and 0.2°C. The error comparison results demonstrate that the Kalman filtering data fusion algorithm proposed in this paper effectively improves the accuracy of sensor measurement data, indicating that the Kalman filtering algorithm meets the data processing requirements of this paper.

System operation test

The sensor nodes for collecting environmental information in the pig house are powered by an independent power source and use Wi-Fi for data transmission. Figure 8 show the historical data curves of pig house environment detection recorded every minute.

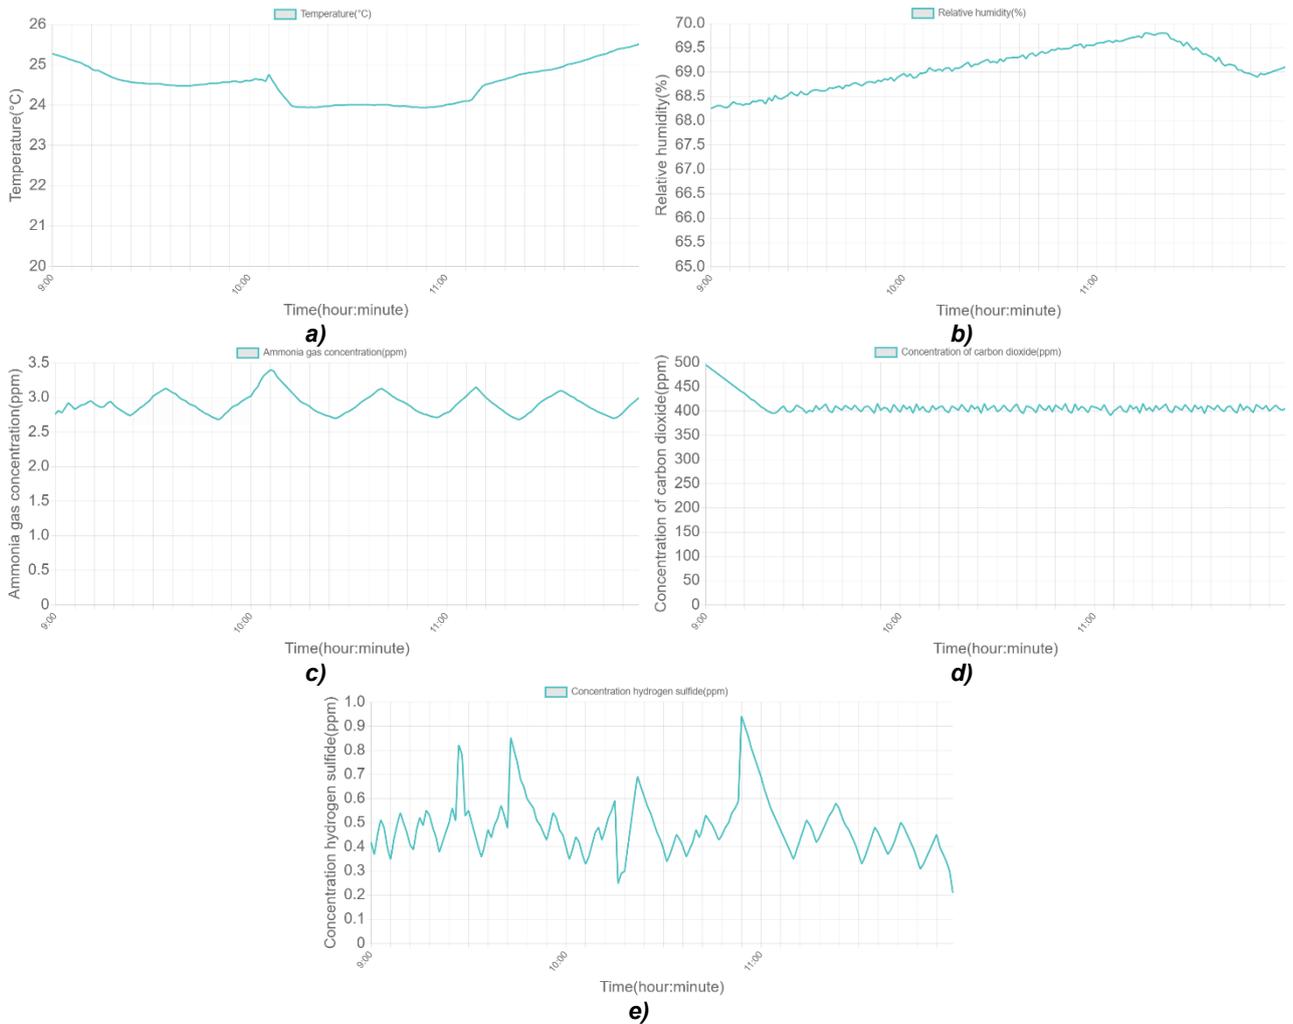

Fig. 8 – Historical data curves of environmental monitoring
 a) Temperature; b) Relative humidity; c) Ammonia concentration;
 d) Concentration of Carbon dioxide; e) Concentration of hydrogen sulfide

Environmental evaluation test

According to the collected 24h environmental factor data of pig house on October 11, 2024, the median filter function and Kalman filter data fusion algorithm were used to process these environmental data, and combined with fuzzy comprehensive evaluation, the membership curves of pig house environmental suitability evaluation at each time were obtained, as shown in Figure 9.

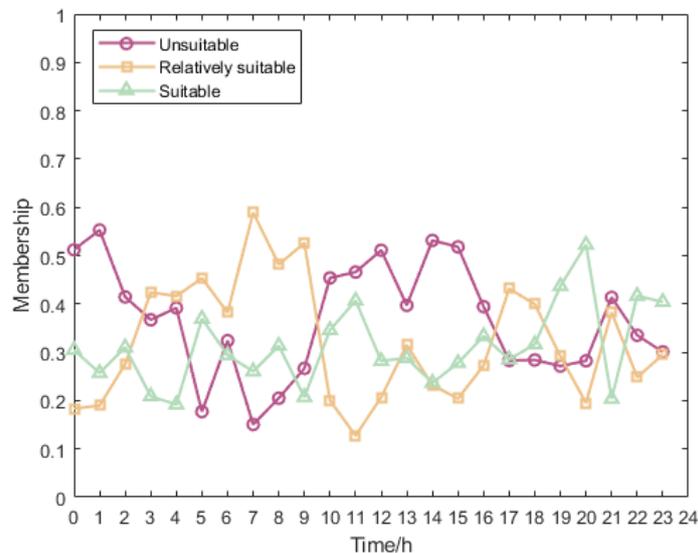

Fig. 9 – Membership degree curves of environmental suitability evaluation of pig house

From Figure 9, it can be seen that on this day, the combined proportion of suitable and relatively suitable conditions in the pig house environment is much greater than that of unsuitable conditions. The condition of the pig house environment is determined by multiple environmental factors and taking the data at 10:00 AM on a particular day as an example, the results after processing with the Kalman filter are as follows: temperature is 24.2°C, relative humidity is 66.82%, ammonia gas concentration is 5.3 ppm, carbon dioxide concentration is 1243 ppm, and hydrogen sulfide concentration is 0.05 ppm. By inputting these environmental factor data into the ridge-shape membership function, the membership matrix is obtained as shown in Eq. (25).

$$H = \begin{bmatrix} 0 & 0.59 & 0.41 \\ 0 & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 0.61 & 0.39 \\ 1 & 0 & 0 \end{bmatrix} \tag{25}$$

Through the comprehensive weight calculation method, the weight set at this time is derived as $\omega = [0.4625, 0.2109, 0.1466, 0.0551, 0.1249]$. Combined with Equation (15), a fuzzy comprehensive evaluation of the suitability of the pig house environment is conducted, resulting in evaluation outcome $Y = [0.1249, 0.6640, 0.2111]$, which corresponds to respectively the evaluation result set $D = \{\text{suitable, relatively suitable, unsuitable}\}$. According to the principle of maximum membership, at this time, the proportion of "suitable" in the evaluation result set is 0.1249, "relatively suitable" has the highest proportion at 0.6640, and "unsuitable" is 0.2111. Therefore, it is determined that the pig house environment at this time is "relatively suitable." The evaluation results of the pig house environment can be displayed on the remote monitoring page, as shown in Figure 10 and Figure 11. The system client can display the environmental information of the current measurement area and provide the current environmental suitability status. The visual interface of the cloud platform is consistent with the data display results of the WeChat mini program, which proves that the performance of each unit of the system is stable, the operation is normal, and the design objectives are met.

CONCLUSIONS

This paper designs a pig house environmental monitoring system based on Internet of Things technology, which can monitor the environmental data in the pig house in real time. The Kalman filter data fusion algorithm is adopted in the system to ensure the accuracy of monitoring data, and this data fusion algorithm is implemented in the main control chip of the sink node. The test results of temperature data show that the error of Kalman filter algorithm is only 0.12%, which meets the monitoring accuracy requirement. In order to achieve an accurate evaluation of the pig house environment, a fuzzy comprehensive evaluation system for pig house is constructed, avoiding the one-sidedness of single environmental factor evaluation methods. The system combines subjective and objective weight calculation methods, reducing the deviation of subjective weights and the one-sidedness of objective weights to a certain extent, making the weight calculation more scientific. The field tests indicate that the system operates stably, and the cloud platform can display real-time environmental data and suitability evaluation results of pig houses, meeting the system requirements.

Keywords: vapor compression refrigeration, phase change material, evaporator, defrosting, thermal energy storage

ABSTRACT

This article presents a preliminary thermodynamic evaluation of a vapor compression refrigeration system (VCRS) using phase change materials (PCM) for defrosting. The objective of this study was to highlight the potential of heat recovery during the operation of the VCRS and its subsequent use in the defrosting process. The system was analyzed energetically, considering both the cooling and defrosting cycles using PCM-RT 35 HC. Input data are given, and they were experimentally measured on a VCRS installed in a freezing chamber located in the university campus. The analysis includes the following refrigerants: R32, R404A, R134a, R290, R600a, R600, R1234yf, and R1234ze(E). The results indicate that as the defrosting time increases, the refrigerant flow rate required for PCM-based defrosting decreases. Furthermore, it was observed that R600 requires the smallest refrigerant flow rate for the defrosting process, while R404A requires the highest to defrost the same mass of ice. The analysis revealed that R32 is the most suitable refrigerant for PCM-based defrosting, followed by wet or dry refrigerants (R404A, R134a, R290) and, finally, isentropic refrigerants (R600, R600a, R1234yf, R1234ze(E)). Additionally, it is noted that as the condensing temperature increased, the recoverable heat increased for R32, R404A, R134a, and R290, but decreased for isentropic refrigerants such as R600a, R600, R1234yf, and R1234ze(E). This analysis was conducted using a computational model implemented in the Engineering Equation Solver software.

REZUMAT

Acest articol prezintă o evaluare termodinamică preliminară a unui sistem frigorific cu comprimare mecanică de vapori (IFV) cu degivrare pe bază de materiale cu schimbare de fază (MSF). Scopul acestei lucrări a fost acela de a evidenția posibilitățile de recuperare a căldurii în timpul funcționării sistemului IFV și utilizarea ulterioară a acesteia în procesul de degivrare. Sistemul a fost analizat din punct de vedere energetic atât pentru ciclul de răcire cât și pentru cel de degivrare cu MSF-RT 35 HC. Datele de intrare au fost măsurate experimental pe un sistem IFV ce echipează o cameră de congelare existentă în campusul universitar. Sunt luați în considerare agenții frigorifici: R32, R404A, R134a, R290a, R600a, R600, R1234yf și R1234ze(E). Rezultatele arată că dacă timpul de degivrare crește, debitul de agent frigorific necesar degivrării cu MSF, scade. De asemenea, se observă că în cazul agentului frigorific R600 s-a utilizat cel mai mic debit de agent frigorific pentru degivrare iar în cazul lui R404A, cel mai mare debit, pentru a degivra aceeași masă de gheață. Din analiză se constată că freonul R32 se pretează cel mai bine în cazul degivrării cu MSF urmat de freonii umezi sau uscați: R404A, R134a, R290 și în final de freonii izentropici: R600, R600a, R1234yf, R1234ze(E). Se constată de asemenea că odată cu creșterea temperaturii de condensare crește căldura recuperată în cazul lui R32, R404A, R134a, R290a și scade în cazul agenților frigorifici izentropici: R600a, R600, R1234yf și R1234ze(E). Această analiză s-a realizat folosind un model computerizat în software-ul Engineering Equation Solver.

INTRODUCTION

Significant greenhouse gas emissions are released into the atmosphere due to the extensive use of fossil fuels and industrial activities. Heating, ventilation, air-conditioning, and refrigeration (HVAC-R) systems that operate on the vapor compression refrigeration (VCR) cycle contribute substantially to these emissions. Depending on the country, HVAC-R systems account for 16% to 50% of a building's total energy consumption (Hepbasli, 2012) and approximately 33% of overall greenhouse gas emissions (Kharseh, et al., 2014). Greenhouse gas emissions from VCR systems can be divided into direct and indirect sources. Direct emissions, which result from refrigerant leaks, represent about 20% of the total, while indirect emissions, due to electricity consumption, equipment manufacturing, cooler production, defrost system, and material recycling, constitute the remaining 80% (Ragip, et al., 2023).

Refrigeration systems are a key component of the food industry. The most widely used refrigeration systems are the ones with vapor compression. A significant challenge for vapor compression refrigeration systems is the formation of ice on evaporator tubes, which poses a major operational issue. Ice formation begins when the surface temperature of the evaporator drops below both the freezing point of water and the dew point of the air, causing water vapor to condensate on the cold surface of the heat exchanger due to temperature differences. The water vapors that will eventually form the ice layer on the evaporator come from the food itself, from the moist air that enters the cold room when the door is opened or from other sources specific to each application. Relative humidity (RH) of the air inside the cold room also plays a crucial role in the ice formation process (Mohammed, et al., 2017).

The frost layer increases the thermal resistance between the air and the refrigerant, resulting in a decrease in cooling capacity. Additionally, the cooling capacity is further diminished due to a reduction in air-side volumetric flow. This occurs because the hydraulic diameter of the flow channel decreases while fan power remains constant (Le Gall et al., 1997). Consequently, both the refrigeration system's cooling capacity and its coefficient of performance (COP) are adversely affected (Al-Douri et al., 2024). Therefore, periodic defrosting is necessary.

As highlighted by Zhi-Ling et al., (2024), previous experimental studies evaluating defrosting heat supply in case of reverse cycle method indicate that 71% to 80% of the total heat required for defrosting is sourced from the indoor heat exchanger.

The most used defrosting methods for refrigeration systems have been detailed in the authors' previous research (Al-Douri et al., 2023). The defrosting method chosen for the given application has an influence on the air parameters (temperature, humidity) inside the refrigerating enclosure. The air parameters have a direct influence on the food products' quality. A defrost method based on a high operating temperature as electric defrosting for example, has as consequence a higher temperature inside the refrigerating enclosure at the end of the defrosting process. A defrosting method based on a low operating temperature like air defrosting for example has as consequence an increase in relative humidity inside of the refrigerating enclosure which can directly influence the quality of the food products. The PCM based defrosting method has a moderate operating temperature being suitable for applications from the food preservation industry. The current study focuses on an in-depth analysis of defrosting methods that employ phase change materials (PCM). Although most research in this field has been conducted at the level of heat pumps, the PCM approach has been investigated for its potential application to thermal energy storage (TES)-based defrosting methods in industrial refrigeration systems and beyond. According to the literature, TES-based defrosting methods are classified based on different energy sources into three categories: discharge heat storage, condensing heat storage, and subcooling heat storage.

For instance, to address the decline in heating capacity when the indoor heat exchanger is inactive, Wang et al. proposed operating the condenser and outdoor heat exchanger in parallel during defrosting mode. This configuration enables the PCM-HE to serve as a heat source for both space heating and defrosting. Zhang et al., (2014), demonstrated that heat dissipated from the compressor outlet of an air source heat pump, stored in the PCM-HE, can effectively melt frost on the outdoor coil. A similar discharge heat storage-based defrosting method has also been applied to air-cooled household refrigerators (Dobre et al., 2024; Zhongbao, et al., 2018).

In their work, Jian-kai et al., (2011), conducted an experimental comparison between the energy storage-based reverse cycle defrosting method and the traditional defrosting method for an air source heat pump. Under identical experimental conditions, the energy storage-based method reduced defrosting time by 60% and defrosting energy consumption by 48.1%.

Also, *Xin et al., (2021)*, reported that PCM-HEs could store sufficient energy during the heating phase and release it to melt and evaporate frost during the defrosting phase for a heat pump. Similarly, *Zhaozhong et al., (2023)*, demonstrated that for a split-air source heat pump (ASHP) unit utilizing phase change energy storage technology, the defrosting time could be shortened by 71.4–80.5%.

Zhang et al., (2014), also experimentally investigated the defrosting performance of a novel split-ASHP unit, where the compressor was encased in a PCM-HE to store dissipated heat. This innovative defrosting approach reduced energy consumption by 27.9% compared to the standard reverse cycle defrosting (SRCD) method (*Yang et al., 2019*).

Another experiment was conducted by *Miryam, et al., (2024)*, who utilized heat from the discharge of a heat pump compressor, stored in a PCM heat exchanger. During the defrosting process, the refrigerant passes through the PCM heat exchanger, vaporizes, and is then directed to the system's evaporator to remove the frost.

Zhongbao et al., (2017), performed an experimental study on defrosting methods using TES in a household refrigerator, comparing it with electric resistance defrosting. The experimental results demonstrated that the thermal storage defrosting system could reduce power consumption by 71% compared to the original electric heater defrosting method.

Overall, the energy storage defrosting method is one of the most promising ways to solve the frosting problem of the refrigeration systems.

MATERIALS AND METHODS

System description

The refrigeration system operates in cooling mode for 5,5 h. In this time interval a specific amount of ice is deposited on the evaporator coil. This amount of ice will be removed in the defrosting interval of 0,5 hours.

Functional parameters are presented in Table 1.

Table 1

VCRS characteristics			
Parameter	Value	Parameter	Value
Evaporating temperature t_o	-30°C	Cooling time $\tau_{cooling}$	5.5 hours
Condensing temperature t_c	33°C	Ice mass m_{ice}	1.4 kg
Cooling capacity \dot{Q}_o	4.5 kW	Heat storage capacity PCM RT 35-HC λ_{PCM}	240 kJ/kg
Defrosting time $\tau_{defrost}$	0.5 hours	Heat storage capacity Ice λ_{ice}	330 kJ/kg
Number of defrosts n	4	Pressure difference from p_8 to $p_6, \Delta p$	0.6 bar

The schematic and operating cycle of the VCRS are presented in Fig. 1 (a) and (b) respectively.

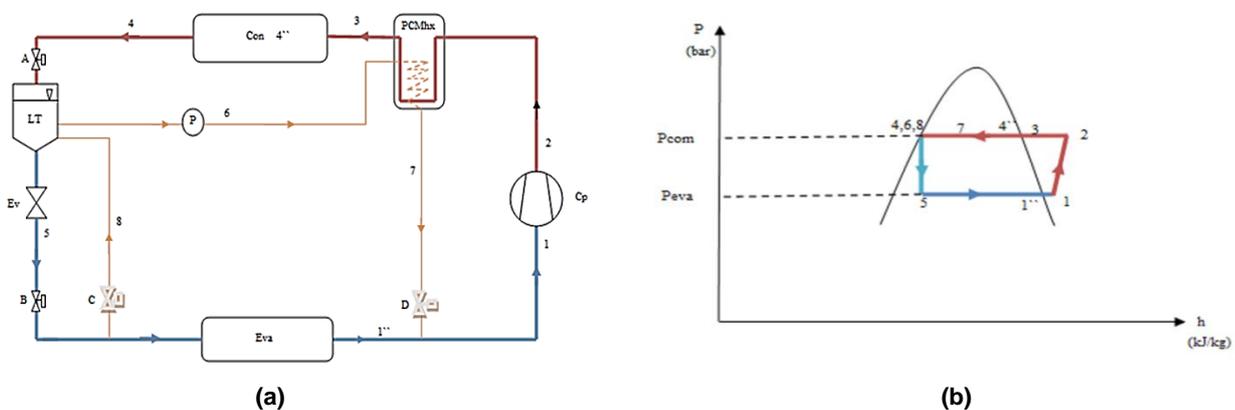

Fig. 1 - The schematic and operating cycle of the VCRS

(a) - Schematic view of the VCRS system with PCM; (b) - Thermodynamic cycle of the VCR system with PCM;

The authors' previous work (Al-Douri et al., 2023) presented an experimental study on the use of a PCM heat exchanger for defrosting the evaporator of a refrigeration system installed in the CG 005 room at the National University of Science and Technology POLITEHNICA Bucharest - Faculty of Mechanical Engineering and Mechatronics, Department of Engineering Thermodynamics. The study investigated the impact of several PCM types of SP 31, RT 35 HC, RT 54 HC, and SP 50 on the energy performance of the vapor-compression refrigeration system (VCR) for various refrigerants. The results demonstrated that RT 35 HC was the most suitable PCM, as the same amount of thermal energy was stored for a significantly smaller PCM mass compared to the other materials analyzed.

In the present work, the same refrigeration system with RT 35 HC-based PCM defrosting is analyzed, focusing on different aspects compared to the previous study.

Mathematical model

The evaporative pressure p_{eva} [bar], the condensing pressure p_{con} [bar], superheating degree Δt_{sh} are determined experimentally. With these values, the following thermodynamic states of the refrigerant can be determined:

$$\begin{aligned}
 \text{State 1''} &\rightarrow p_{eva}, \Omega, x=1 \rightarrow t_{1''}; h_{1''}; v_{1''}; s_{1''} \\
 \text{State 1} &\rightarrow p_{eva}, \Omega (t_1=t_{1''}+\Delta t_{sh}) \rightarrow h_1; v_1; s_1 \\
 \text{State 2} &\rightarrow p_{con}, \Omega (s_1=s_2) \rightarrow t_2; h_2; v_2 \\
 \text{State 3} &\rightarrow p_{con}, \Omega (t_3=t_c+\Delta t_{rec}) \rightarrow h_3; v_3; s_3 \\
 \text{State 4} &\rightarrow p_{con}, \Omega, x=0 \rightarrow t_4; h_4; v_4; s_4 \\
 \text{State 8} &\rightarrow p_{con}, \Omega, x=0 \rightarrow t_8; h_8; v_8 \\
 \text{State 6} &\rightarrow p_{con} + \Delta p, \Omega (h_6=h_8+|l_{8-6}|) \rightarrow t_6; h_6; v_6; s_6; p_6 \\
 \text{State 5} &\rightarrow p_{eva}, \Omega (h_5=h_6) \rightarrow t_5; v_5; s_5 \\
 \text{State 7} &\rightarrow p_{con} + \Delta p, \Omega, x_7=0.7 \rightarrow t_7; h_7; v_7; s_7
 \end{aligned} \tag{1}$$

where Δp is the rise of pressure from condensing pressure needed to circulate the liquid refrigerant on the defrosting loop, p_6 is liquid refrigerant pressure at the inlet of the PCMHx given by the defrost pump and p_{con} is the condensing pressure. Also, l_{8-6} represents the specific work of the defrost pump.

In eq. (1) the specific work required by the circulation pump is given by: $|l_{8-6}| = v_8 \Delta p$ and the refrigerant quality in state 7 is imposed $x_7=0.7$.

The mass flow rate of refrigerant \dot{m} can be written:

$$\dot{m} = \dot{Q}_0 / q_0 \tag{2}$$

$$q_0 = h_{1''} - h_5 \tag{3}$$

where: \dot{Q}_0 is the cooling capacity of the system and q_0 is the specific cooling capacity.

$$\tau_{\text{between defrost}} = (24 / n) \cdot 3600 \tag{4}$$

$$\tau_{\text{defrost}} = 30 \text{ min} \tag{5}$$

$$\tau_{\text{cooling}} = \tau_{\text{between defrost}} - \tau_{\text{defrost}} \tag{6}$$

where $\tau_{\text{between defrost}}$ is the time between 2 consecutive defrost cycles, τ_{defrost} is the time when the system is in defrost mode and τ_{cooling} is the time period when the system is in cooling mode, all three being in seconds.

In Eq. (4), n represents the number of defrosts that take place in 24 hours.

$$\dot{Q}_{\text{recovery}} = \dot{m} \cdot (h_2 - h_3) \tag{7}$$

$$Q_{\text{recovery}} = \dot{Q}_{\text{recovery}} \cdot \tau_{\text{cooling}} \tag{8}$$

$$\lambda_{\text{PCM}} = 240 \frac{\text{kJ}}{\text{kg}} \tag{9}$$

where $\dot{Q}_{recovery}$ is the heat flux that can be recovered from the refrigerant in the desuperheating process 2-3, $Q_{recovery}$ being the actual heat that can be recovered and λ_{PCM} is the heat storage capacity of PCM:

$$Q_{ice} = m_{ice} \cdot (c_{ice} \cdot (0 - t_{ice}) + \lambda_{ice}) \quad (10)$$

$$m_{ice} = 1.4 \text{ kg} \quad (11)$$

$$c_{ice} = 2.09 \text{ kJ/kg} \cdot \text{K} \quad (12)$$

$$t_{ice} = t_0 \quad (13)$$

$$\lambda_{ice} = 330 \text{ kJ/kg} \quad (14)$$

where Q_{ice} is the heat needed to melt the specific quantity of ice, (m_{ice}), c_{ice} is the specific heat of ice, t_{ice} represents the temperature of ice, which was taken equal to the evaporating temperature and λ_{ice} is the heat storage capacity for ice.

$$Q_{PCM} = m_{PCM} \cdot \lambda_{PCM} \quad (15)$$

$$Q_{PCM} = Q_{ice} \quad (16)$$

where Q_{PCM} is the heat that the mass of PCM (m_{PCM}) can absorb during defrosting period.

$$\dot{Q}_{ice} = Q_{ice} / \tau_{defrost} \quad (17)$$

$$\dot{Q}_{ice} = \dot{m}_{defrost} \cdot (h_7 - h_8) \quad (18)$$

where \dot{Q}_{ice} is the heat flux that can be absorbed in time $\tau_{defrost}$, h_7 and h_8 are the specific enthalpies at the exit and inlet of the evaporator during the defrost period [kJ/kg].

$$P_{cp} = \dot{m} \cdot (h_2 - h_1) \quad (19)$$

$$P_{p1} = |l_{8-6}| \cdot \dot{m}_{defrost} \quad (20)$$

$$|l_{8-6}| = v_8 \cdot \Delta p \quad (21)$$

where P_{cp} is the compressor power, h_2 and h_1 are the specific enthalpies at the exit and inlet of the compressor. P_{p1} is the power of the defrost liquid refrigerant circulation pump and v_8 is the specific volume of refrigerant after the evaporator exit on the defrost loop.

$$COP_{with\ pump} = \dot{Q}_0 / (P_{cp} + P_{p1}) \quad (22)$$

$$COP = \dot{Q}_0 / P_{cp} \quad (23)$$

where $COP_{with\ pump}$ represents the COP considering also the power of the defrost liquid refrigerant circulation pump and COP stands for the refrigeration cycle.

Based on the mathematical model presented before by Arora et al., (2008), Havelisky, (2000), Selbas, et al., (2006), a program has been developed in Engineering Equation Solver. Data resulted is expressed below for R600a, R600, R290, R32, R404a, R134a, R1234yf and R1234ze(E).

RESULTS

Figure 2 shows that when the defrosting time increases, the mass flow rate of defrosting refrigerant decreases for the same constant amount of ice ($m_{ice}=1.4$ kg), same evaporating temperature $t_0=-30^\circ\text{C}$ and the same quality $x_7=0.7$ at the exit of the PCMhx. Additionally, when defrost time is 30 minutes, refrigerant R600 displays the smallest refrigerant mass flow rate (0.0013 kg/s), while refrigerant R404A has the highest mass flow rate of roughly (0.0032 kg/s). For the defrosting time of 60 min increases the values of the defrosting refrigerant mass flow rate are much closer to each other compared to a defrosting time of 10 min.

Figure 3 and Table 2 show the COP values in function of the defrosting time for the analyzed refrigerants considering the same $t_0=-30^\circ\text{C}$ and quality $x_7=0,7$.

The coefficient of performance (COP) increases slowly with the increase of the defrosting time. It can be seen that the $COP_{with\ pump}$ of the refrigeration system with a PCM based defrosting is lower than the case of the refrigeration system without (COP). This is due to the fact that the power of the pump has a low value (see eq. 21 and eq. 22) which means that for both situations the coefficient of performance shows very close values.

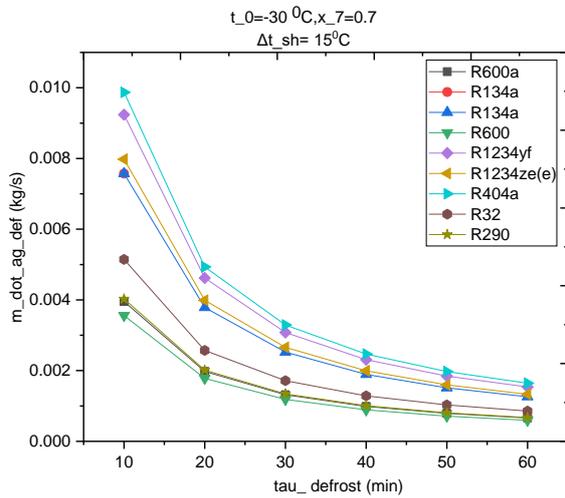

Fig. 2 – Mass flow rate of the defrosting agent versus defrost time

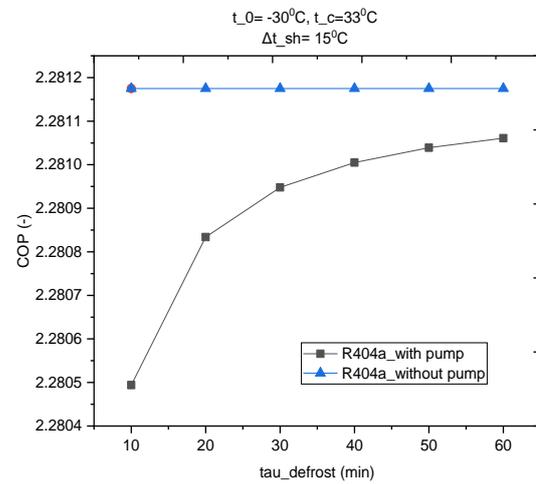

Fig. 3 - Comparison between COP with pump and COP without pump for R404a refrigerant

Table 2

Comparison between COP without pump and $COP_{with\ pump}$ for different refrigerants

Refrigerants	COP	$COP_{with\ pump}$	
		min	max
R600a	2.6743	2.6736	2.6742
R134a	2.6188	2.6182	2.6187
R600	2.7562	2.7556	2.7561
R1234yf	2.4059	2.4052	2.4058
R1234ze(E)	2.5684	2.5678	2.5683
R404A	2.2811	2.2804	2.2810
R32	2.5783	2.5778	2.5782
R290	2.5839	2.5831	2.5838

Table 2 shows that the influence of the defrosting time on the $COP_{with\ pump}$ and COP is the same with the specification that R600 has the highest coefficient of performance and R404A has the lowest for the same operating conditions: $t_0=-30^\circ\text{C}$, $t_c=33^\circ\text{C}$ and $x_7=0.7$.

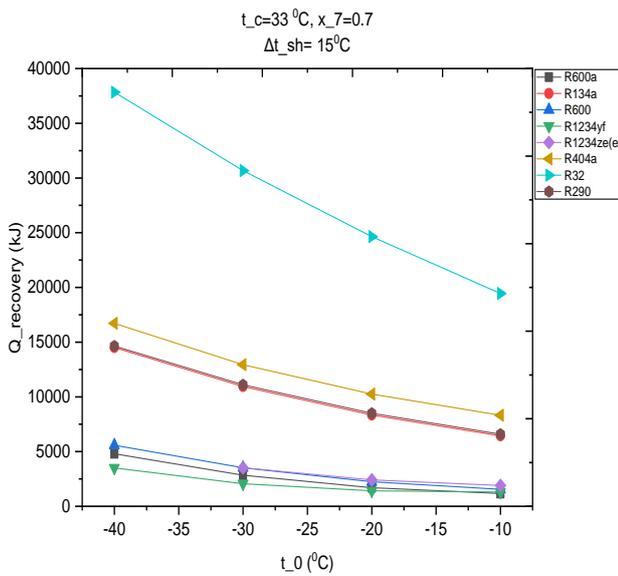

Fig. 4 – Variation of evaporation temperature with PCM heat recovery

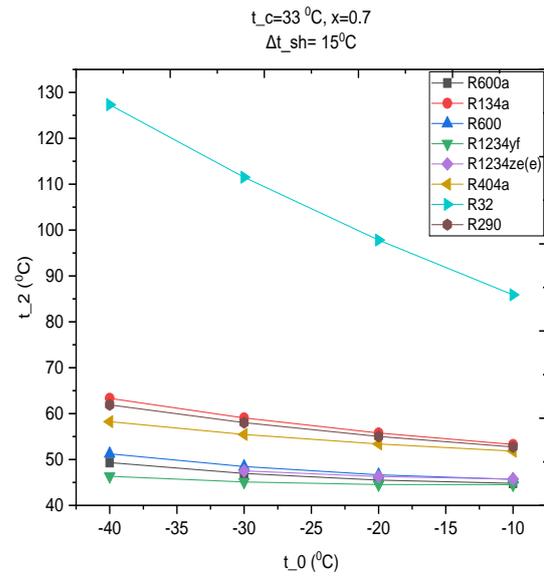

Fig. 5 - The correlation between discharge temperature t_2 and evaporation temperature t_0

Figure 4 shows the variation of the heat which can be recovered ($Q_{recovery}$) from the refrigerant depending on the evaporating temperature (t_0). The figure shows that increasing the evaporating temperature leads to a decrease of the recovered heat. Also, one can notice the heat recovered in the case when the refrigeration system operates at freezing temperatures (-15°C to -40°C) is higher compared to the case when it operates at refrigeration temperatures (-10°C to -15°C). This happens because when the evaporating temperature decreases the evaporating pressure decreases also which means higher compression ratio and as a result higher compressor discharge temperature t_2 (see Fig.5). It can be noticed that the highest heat recovery value can be achieved for R32 and the lowest one for R1234yf (see Fig.4).

The studied refrigerants fall into 3 groups: R32 with a $Q_{recovery}$ between 20000 kJ and 40000 kJ; R404A, R134a and R290 with a $Q_{recovery}$ between 7000 and 17000 kJ and R1234yf, R1234ze(E), R600 and R600a with a $Q_{recovery}$ between 1000 kJ and 5600 kJ.

As expected, the decrease in evaporating temperature results in an increase in discharge temperature t_2 as in the case of $Q_{recovery}$ (Fig 4). Three groups of refrigerants are distinguished: a) R32, b) R404A, R134a, R290 and c) R600, R600a, R1234yf, R1234ze(E). Group a) is characterized by the highest discharge temperatures (85°C-130°C), group b) between 55°C-65°C and group c) 45°C and 52°C. From the combined analysis of figures 4 and 5, it can be seen that R32 fits best to defrosting with PCM followed by groups b and c.

Table 3

Refrigerant $t_c=33°C; x_7=0,7, \Delta t_{sh}=15°C$	Q_{ice} (kJ)		$Q_{recovery}$ (kJ)	
	min(-10°C)	max(-40°C)	min(-10°C)	max (-40°C)
R600a	491,3	579	1165	4801
R134a	491,3	579	6439	14511
R600	491,3	579	1553	5579
R1234yf	491,3	579	1298	3504
R1234ze(E)	491,3	579	1898	3504
R404A	491,3	579	8323	16720
R32	491,3	579	19451	37839
R290	491,3	579	6593	14642

Data specified in Table 3 indicates that, for the operating conditions considered $t_0 \in [-10°C, -40°C]$, the recoverable heat is sufficient to achieve complete defrosting of the ice accumulated on the evaporator, even if the ice is subcooled and requires a greater amount of heat to melt.

Figure 6 shows that the increase of the condensing temperature t_c leads to an increase in the heat recovery. The influence of the condensing temperature on the recovered heat is different for the 3 groups of refrigerants. In figure 6 it can be observed that for R32 – from group a) and for group b), the increase in the condensing temperature leads to an increase of the heat that can be recovered. For instance, in the case of R32, it doubles from 30000 kJ to 60000 kJ, in case of R404A the increase being even greater. For group c), it can be seen that the recovered heat decreases while condensing temperature increases.

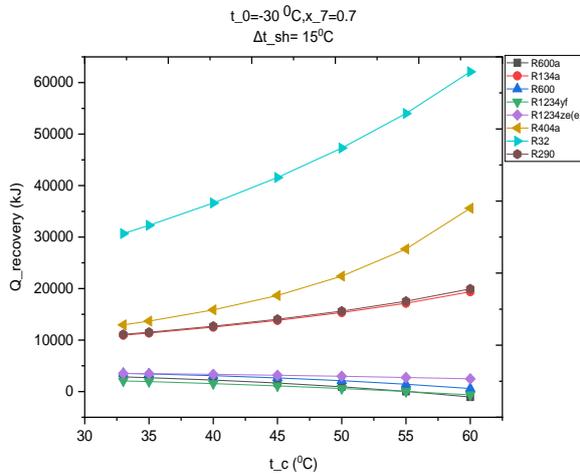

Fig. 6 - Variation of condensing temperature with PCM heat recovery

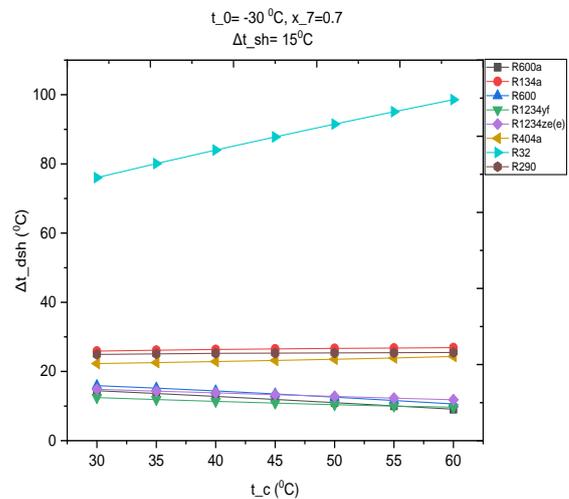

Fig. 7 - Influence of condensing temperature on the degree of desuperheating

According to Figure 7, for refrigerant R32, the desuperheating degree (Δt_{dsh}) increases with the condensing temperature, which justifies the results obtained in the case of heat that can be recovered (Fig. 6). The doubling of $Q_{recovery}$ is not only supported by the increase in Δt_{dsh} , but also by the properties of the refrigerant in terms of enthalpy values (h_2 and h_3). For refrigerants from group b), Δt_{dsh} is quasi-constant and the increase of $Q_{recovery}$ is generated by the enthalpy of the refrigerant. For group c), it is found that $Q_{recovery}$ is correlated with the decrease in Δt_{dsh} . It can be concluded that for certain refrigerants the increase in condensing temperature, in conditions of accumulation of a large amount of ice on the evaporator, can affect defrosting in the version with PCM.

It can be mentioned that the discharge temperature t_2 gives information about the type of PCM that can be used while Δt_{dsh} and $Q_{recovery}$ give information about the maximum amount of heat that can be recovered.

Table 4

Refrigerant $t_0=-30^{\circ}\text{C}; x_7=0.7,$ $\Delta t_{sh}=15^{\circ}\text{C}$	Q_{ice} (kJ)	$Q_{recovery}$ (kJ)			
		t_c (°C)	min	t_c (°C)	max
R600a	549.8	60	-1060	30	3036
R134a	549.8	30	10351	60	19377
R600	549.8	60	581.7	30	3648
R1234yf	549.8	60	-640.9	30	2248
R1234ze(E)	549.8	60	2475	30	3576
R404A	549.8	30	11947	60	35608
R32	549.8	30	28419	60	62103
R290	549.8	30	10497	60	19936

Upon careful analysis of Table 4, it is observed that for the group of refrigerants in category c), under tropical condensing temperatures, the recoverable heat decreases. For refrigerants such as R600a and R1234yf, the recoverable heat reaches negative values due to the fact that the refrigerants in category c) are isentropic. Consequently, the compression process leads to a discharge temperature t_2 lower than the condensing temperature, which means a reduction or even elimination of the desuperheating degree required for heat recovery. Under these conditions, it is no longer possible to recover heat from the refrigerant at the compressor discharge for the specified operating parameters.

Table 5

Refrigerant $t_0=-30^{\circ}\text{C}$; $x_7=0.7$, $\Delta t_{sh}=20^{\circ}\text{C}$	Q_{ice} (kJ)	$Q_{recovery}$ (kJ)			
		t_c ($^{\circ}\text{C}$)	min	t_c ($^{\circ}\text{C}$)	max
R600a	549.8	60	4334	30	6443
R600	549.8	60	5329	30	6807
R1234yf	549.8	30	6686	60	7934
R1234ze(E)	549.8	30	7344	30	8905

Table 5 presents the results obtained for a 20°C superheating degree. These results show a significant increase in recoverable thermal energy, thereby making PCM-based defrosting feasible for isentropic refrigerants.

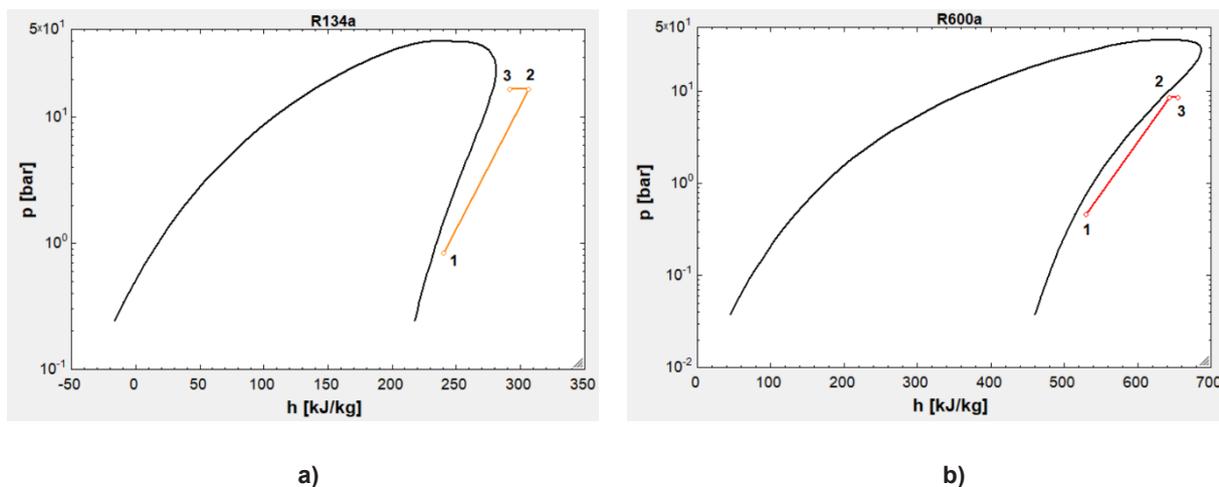

Fig. 8 – Compression and recovery processes for wet or dry refrigerants (a) and for isentropic refrigerants (b) in p-h diagram

Figures 8a and 8b illustrate two cases: (a) wet or dry refrigerants (e.g., R134a) and (b) isentropic refrigerants. The refrigerants R32, R404A, R134a, R290 from groups a) and b) are wet or dry. For these refrigerants the enthalpy in state 3 is lower than the enthalpy in state 2 making heat recovery possible. In Figure 8a and 8b the thermodynamic state 2 represents the state of the refrigerant at the compressor discharge and state 3 is the state of the refrigerant at the outlet of PCMhx.

In the case of isentropic refrigerants in group c): R600, R600a, R1234yf, R1234ze(E), the enthalpy of state 2 is lower than the enthalpy of state 3. Under these conditions, the possibility of recovering heat from the refrigerant at the compressor discharge is reduced to zero. Therefore, to enable PCM-based defrosting, it is necessary to increase the superheating degree before the compressor inlet.

Figure 9 shows the influence of the refrigerant quality over $COP_{with pump}$. From Figure 9 one can notice that for refrigerant quality values ranging from 0 to 0.1 the $COP_{with pump}$ increases abruptly and for values between 0.2 and 1 it increases much slower. The increase in $COP_{with pump}$ is attributed to the high-power input required by the liquid circulation pump during the initial phase of the defrosting process. As the liquid refrigerant circulates through the evaporator, its condensation rate progressively decreases, resulting in a gradually reduced flow rate of liquid refrigerant. Consequently, the power required to drive the pump decreases, leading to a slight yet linear increase in the $COP_{with pump}$.

Table 6 shows the effect of refrigerant quality on $COP_{with pump}$. It can be noticed that the refrigerant quality has a small impact on $COP_{with pump}$ and at the same time refrigerant R600 has the highest value out of all refrigerants analyzed in the present study. In Table 6 a higher number of digits have been used to point out the influence of the refrigerant quality (x_7) at the exit of the PCMhx on the $COP_{with pump}$. The influence of quality x_7 on $COP_{with pump}$ is not very strong and can be noticed after several digits depending on the refrigerant.

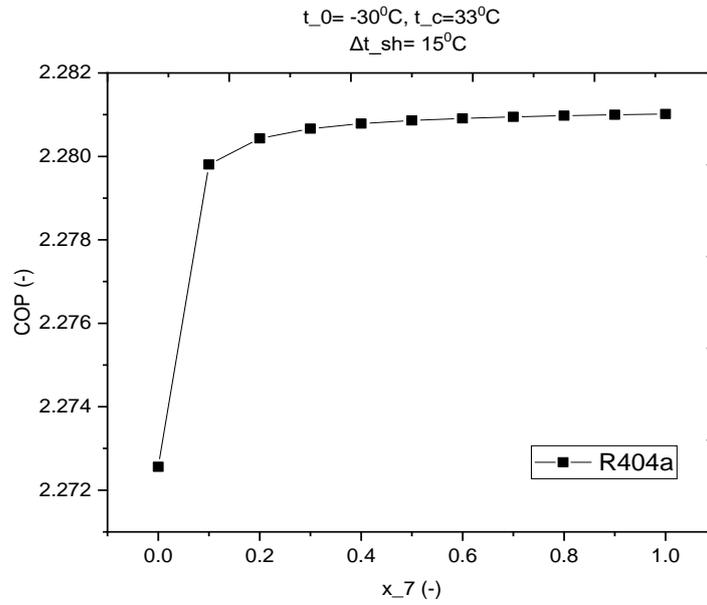

Fig. 9 - Influence of refrigerant quality over COP_{with pump}

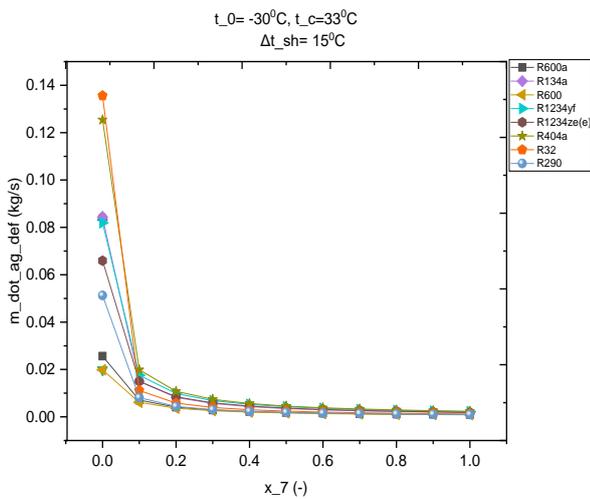

Fig. 10 - Effect of defrost refrigerant mass flow rate on refrigerant quality

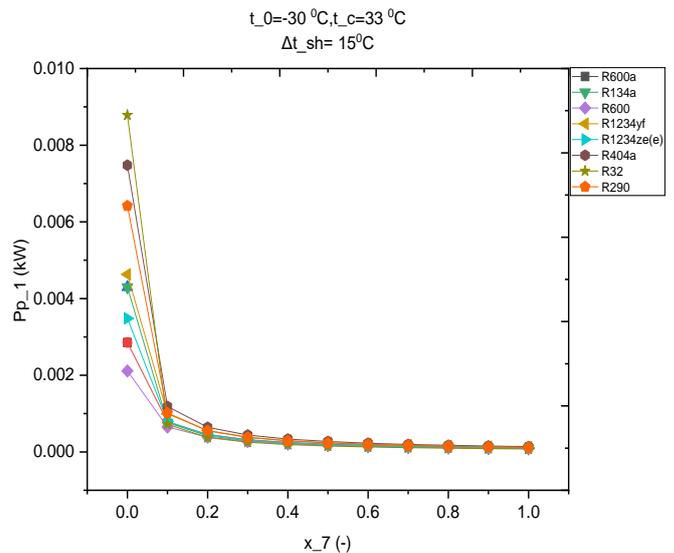

Fig. 11 - The relationship between pump power and refrigerant quality

Figure 10 shows the relationship between the mass flow rate of defrosting refrigerant and refrigerant quality x_7 . As expected, there is a significant correlation between these two parameters. The figure demonstrates that as the quality (x_7) increases, the mass flow rate of refrigerant required to maintain the same Q_{ice} decreases. This means that with a decrease in the mass flow rate of defrosting refrigerant the quality increases. Furthermore, the value of x_7 has an influence on the heat transfer from the PCMhx as well as on the power input of the pump, as shown in Figure 11.

Figure 11 shows the relationship between quality (x_7) and the power input of the defrost refrigerant pump. It shows that as x_7 increases from 0 to 1, the mass flow rate of defrost refrigerant decreases. This decrease leads to an increase in the work required to maintain the same pump power. This explains the fact that $COP_{with\ pump}$ of the refrigeration system with PCM based defrosting increases with the increase of x_7 , respectively the decrease of the defrosting refrigerant mass flow rate.

CONCLUSIONS

In this paper, the effect of using PCM heat storage for defrosting the evaporator of a refrigeration system was studied using different refrigerants. The impact of various refrigerants and system parameters on the energy performance of PCM-based defrosting was investigated under the same working conditions.

It was observed that as the defrosting time increases, the refrigerant flow rate required for PCM-based defrosting decreases. Among the refrigerants analyzed, R600 exhibited the lowest mass flow rate, while R404A the highest in order to defrost the same mass of ice.

Additionally, the $COP_{with\ pump}$ of the refrigeration system with PCM-based defrosting increases gradually with defrosting time, but it remains slightly lower than the system without defrosting, having comparable values in both cases.

The results indicate that an increase in the evaporating temperature leads to a decrease in the recoverable heat. However, for evaporating temperatures between -10°C and -40°C , the recoverable heat is sufficient to achieve complete defrosting of the ice accumulated on the evaporator.

In contrast, an increase in the condensing temperature improves the amount of recoverable heat for dry and wet refrigerants such as R32, R404A, R134a, and R290, but reduces it for isentropic refrigerants, including R600a, R600, R1234yf, and R1234ze(E).

Superheating plays a critical role in enhancing heat recovery. A higher superheating degree of significantly increases the recoverable heat, making PCM-based defrosting viable for isentropic refrigerants. Contrarily, the desuperheating degree varies with condensing temperature: it increases for R32, remains nearly constant for group b) refrigerants, and decreases for group c) refrigerants. This suggests that increasing the condensing temperature can influence the defrosting process differently depending on the refrigerant.

Previous analysis reveals that R32 is the most suitable refrigerant for PCM-based defrosting, followed by refrigerants in groups b) and c).

Additionally, the refrigerant quality at state 7 has a minimal influence on $COP_{with\ pump}$, with the highest value recorded for R600. As the refrigerant quality increases, the refrigerant mass flow rate required for defrosting decreases, resulting in lower power input for the circulation pump.

Keywords: corn kernel harvest; double longitudinal axial flow; large feeding amount; threshing

ABSTRACT

Traditional corn threshing devices face issues of high unthreshed grain rate and high breakage rate under conditions of high feeding rates. To address this, a high-throughput double longitudinal axial flow corn threshing device was designed in this study. Based on a stress analysis of the interaction between threshing components and corn ears, an arc-shaped plate tooth structure was developed to progressively increase the squeezing force between the plate teeth and the ears. A combined threshing element, integrating arc-shaped plate teeth and round-headed nail teeth, was designed to improve threshing cleanliness and minimize grain breakage under high feed capacity conditions. The crucial parameters of the threshing cylinder were determined by theoretical analysis. Threshing bench experiments were conducted to investigate the effects of feed rate, threshing cylinder speed, and guide plate angle on the device's grain breakage rate and unthreshed grain rate. Based on the findings, the optimal parameter ranges were identified. An orthogonal test involving three factors at three levels each was conducted to determine the optimal working parameters of the device. The results indicated that the ideal conditions were a feed rate of 16 kg/s, a threshing cylinder speed of 400 r/min, and a guide plate angle of 26°. Under these parameters, the grain breakage rate was 5.02%, and the unthreshed grain rate was 0.171%. The operational performance met the actual harvesting requirements. This research could offer a reference for the design of large-feed-rate threshing devices and related harvesters.

摘要

当前传统的玉米脱粒装置在大喂入量条件下,存在籽粒未脱净率高、破碎率高的问题,对此本研究设计了一种大喂入量双纵轴流玉米脱粒装置。基于脱粒元件与玉米果穗的受力分析,本研究设计了弧形板齿结构,逐步增加板齿与果穗之间的挤搓力,有利于脱下不同脱粒难度的玉米籽粒;本研究设计了“弧形板齿+圆头钉齿”组合式脱粒元件,满足了大喂入量条件下装置实现高脱净率和籽粒破碎;通过理论分析的方法确定了脱粒滚筒的关键参数。通过台架试验研究了该装置中喂入量、滚筒转速和导流板角度对籽粒破碎率和未脱净率的影响规律,并确定了较优参数区间。通过三因素三水平正交试验,确定了该装置的最佳工作参数为:喂入量为 16kg/s、滚筒转速为 400r/min、导流板角度为 26°,此时籽粒破碎率为 5.02%,未脱净率为 0.171%,作业性能满足了实际收获需求。该研究可为大喂入量脱粒装置和相关收获机设计提供参考。

INTRODUCTION

Corn occupies the largest sown area among grain crops in China and ranks second globally in production (**China, 2024). Currently, the main methods of corn harvesting are ear harvesting and direct grain harvesting (Tao et al., 2019). Threshing is an essential link in the process of direct grain harvesting. The grain breakage rate and the unthreshed grain rate are important references for assessing the effect of the threshing device and exert significant influence on the threshing quality.

The current research on corn threshing devices mainly focuses on reducing the grain breakage rate, enhancing the threshed grain rate, and threshing corn with high moisture content. Scholars have introduced innovative designs by integrating threshing theory and bionic principles, including the corn thresher element resembling a chicken beak (Xinping et al., 2015), the rigid-flexible coupling bionic threshing unit (Li et al., 2021), and the thumb-type threshing element (Jiale et al., 2023) by studying corn threshing theory and applying bionic principles. To address issues like incomplete threshing in existing axial flow threshers, scholars have developed a segmented threshing device (Yuejiang et al., 2020), the combined "threshing bow teeth and movable nail teeth" thresher separation device (Youliang et al., 2022). To reduce grain breakage caused by rigid thresher elements, optimized design yields plate teeth with protrusions (Xiaopeng et al., 2003) and elastic short rasp bars as threshing elements (Duanyang et al., 2019). These structural improvements optimize impact effects during threshing. Regarding the issue of the difficulty in threshing corn with high moisture content, numerous scholars have achieved significant progress through structural enhancements and parameter optimizations (Yujie et al., 2023; Qing et al., 2024; Jinliang et al., 2024). Some researchers explored the influence of feed rate, threshing cylinder speed and other factors on the threshing effect through experiments, and constructed relevant mathematical models, which provided reference for deep understanding of the threshing mechanism and obtaining the best working parameters (Srison et al., 2016; Cujbescu et al., 2021; Vlădut N. et al., 2022; Vlădut N. et al., 2023). Some researchers have used sensors and optimized control algorithms, which in turn provide timely and effective regulation of threshing parameters to achieve better threshing results (Maertens et al., 2004; Maertens et al., 2005; Abdeen M., 2022). To improve harvesting efficiency further, grain combine harvesters are gradually evolving towards larger scales. Therefore, threshing devices that can handle larger feed rates are needed. Currently, the research mainly concentrates on threshing devices with feed rates less than 12 kg, and there is relatively scarce research on those with feed rates greater than 12 kg. Meanwhile, the traditional threshing devices, under the circumstance of large feed rates, have issues such as high grain breakage rate and high unthreshed grain rate.

In response to the above problems, this study presents the design of a double longitudinal axial-flow corn threshing device incorporating variable-height combined threshing elements consisting of arc-shaped plate teeth and round-head nail teeth, a conical drum body, and adjustable guide vanes. Through bench experiments, the influence patterns of feed rate, threshing cylinder speed, and angle of the guide plate on grain breakage rate and unthreshed grain rate were investigated. The optimal parameter combination was acquired. This provides a reference for designing the double longitudinal axial flow threshing device with a large feeding amount.

MATERIALS AND METHODS

The Overall Structure and Working Principle of the Threshing Device

The Overall Structure

The overall structure comprises a feeding inlet, threshing drum, upper cover plate, grid concave plate screens, deflector adjustment mechanism, frame, gearbox, and motor. Notably, the rotation direction of the threshing drum on both sides is reversed, as illustrated in Figure 1.

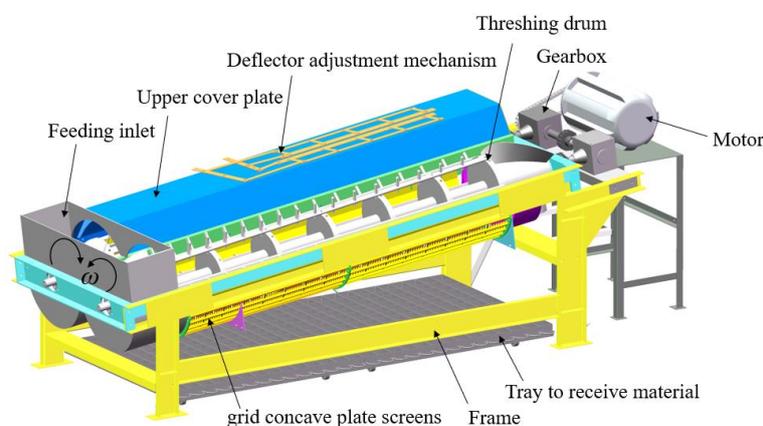

Fig. 1 - The Overall Structure of the Device

Under the harvesting condition of large feed-in volume, the double longitudinal axial-flow threshing drum has a lower rotational speed and a larger separation area than the single longitudinal axial-flow drum.

A lower rotational speed of the drum is conducive to reducing the impact force, thereby lowering the breakage of corn kernels. A larger separation area can decrease the thickness of the material layer, facilitating the timely separation of the threshed kernels out of the machine.

The Working Principle

During the threshing operation, corn ears are introduced through the feeding inlet and propelled into the threshing chamber on both sides of the double-longitudinal axial flow threshing device by the action of a screw feeding head. Under the combined influence of the threshing drum and upper cover plate, the corn ear moves toward the rear. It interacts with various components throughout this process, including threshing elements, conical drum bodies, grid concave plate screens, and striking and squeezing against other fruit ears to facilitate kernel separation from their cobs. The detached corn kernels are subsequently filtered through a grid of concave plate screens. At the same time, residual components such as cob cores and bracts are expelled via an outlet at the end of the threshing drum, thereby completing the threshing process.

The Design of Key Components

The design of the threshing drum

This paper designs a threshing drum of "variable-height threshing elements and conical roller body." The diameter of the addendum circle of the teeth at any cross-section of the threshing cylinder is a fixed value. The threshing components within the threshing cylinder combine arc-shaped plate teeth and round-headed nail teeth. The threshing drum is divided into four working zones based on its main functions: feeding, threshing, separation, and impurity discharge (Meizhou et al., 2020), as shown in Figure 2.

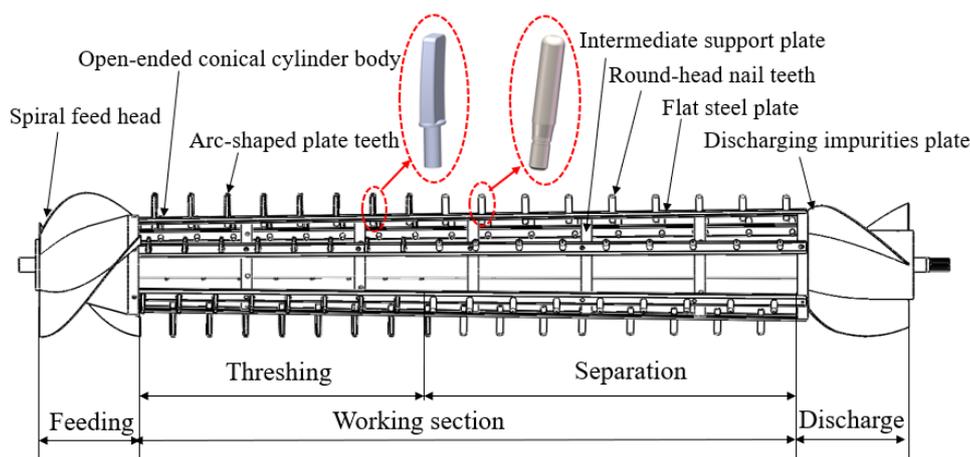

Fig. 2 - Structure diagram of threshing cylinder

Previous studies discovered that blockages mainly occurred in the first half of the threshing drum under significant feed rates. This paper employs a conical cylinder body to enhance the corn ears' accommodating capacity in the threshing cylinder's front half. Meanwhile, considering the relatively poor threshing effect at the front end of the conical cylinder body, longer threshing elements are installed at the small end of the conical cylinder body to improve the threshing capability at the front end of the conical cylinder body.

Most threshing and separation occur in the threshing section of the cylinder (Miu et al., 2008). Rigid threshing at this stage can cause a significant amount of breakage. Arc-shaped plate teeth let the cobs thresh under an oblique pushing force. This threshing action is conducive to reducing grain breakage. Round-headed nail teeth feature high efficiency, a high threshing cleanliness rate, and reduced losses due to the top gnawing of grains. When applied in the separation section of the threshing cylinder, they can guarantee the threshing cleanliness rate of the device under conditions of significant feed rates (Zheng et al., 2022). Meanwhile, the threshing section is designed to constitute 40% of the length of the working section, while the separating section makes up 60%. The threshing elements adopt a variable pitch arrangement that is dense at the front and sparse at the rear. In this paper, the spacing between the arc-shaped plate teeth is designed to be 138 mm, and the spacing between the round-headed nail teeth is 165 mm. The included angle between the flat steel and the axis of the roller is 30°. The distribution of the arc-shaped plate teeth and round-headed nail teeth is shown in Figure 3.

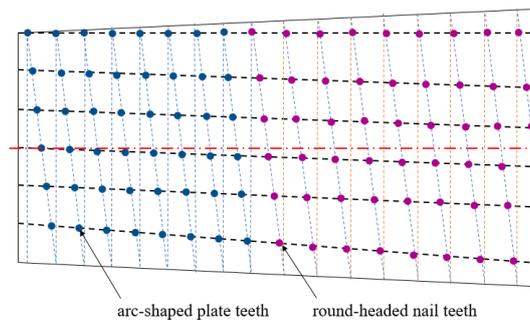

Fig. 3 - Schematic diagram of the arrangement of threshing elements on the threshing drum

The relationship between the length of the longitudinal axial flow threshing drum and the feed quantity is:

$$L = \frac{q}{q_0} \tag{1}$$

where: L denotes the working section length of the threshing drum, (m);

q represents the feeding amount of the threshing device, (kg/s);

q_0 represents the allowable feed rate per unit length in the threshing device, kg/(s·m). According to the recommendation in the "Agricultural Machinery Design Manual," q_0 is generally 3 to 4 kg/(s·m).

The unit is designed for a feed rate of 14~18 kg/s. Based on the calculation using formula (1), the value range of the unilateral threshing drum L is between 1.75 and 3.0 meters. Hence, the drum working section is designed to be 2.5 meters long.

The relationship between the diameter of the top circle of the threshing drum teeth D , the rotational speed n of the drum, and the linear speed v is as follows:

$$D = \frac{60v}{\pi n} \tag{2}$$

where: D is the diameter of the toothed top circle of the threshing drum, (m);

v is the threshing speed of the cylindrical axial roller, (m/s);

n is the rotational speed of the threshing drum, (r/min).

According to the recommendations in the "Agricultural Machinery Design Manual", the threshing speed of the cylindrical axial-flow drum (v) is 10 to 12 m/s and the threshing cylinder speed (n) ranging from 300 to 450 r/min, when substituted into Equation (2), the range of the top circle diameter of the threshing drum teeth is obtained as 430 to 760 mm. Hence, the design's top circle diameter D of the threshing drum is 550 mm. The threshing drum is a "constant-diameter drum," thus D is a fixed value.

The design of arc-shaped plate teeth and round-headed nail teeth

The corn cobs struck by the arc-shaped plate teeth will complete threshing under the continuously increasing squeezing and rubbing force, which is conducive to detaching corn kernels with different threshing difficulties. To guarantee the threshing cleanliness rate of the device, the round-headed spike teeth are designed to be arranged in the second half of the threshing drum. The structure of the arc-shaped plate teeth and the round-headed spike teeth is shown in Figure 4.

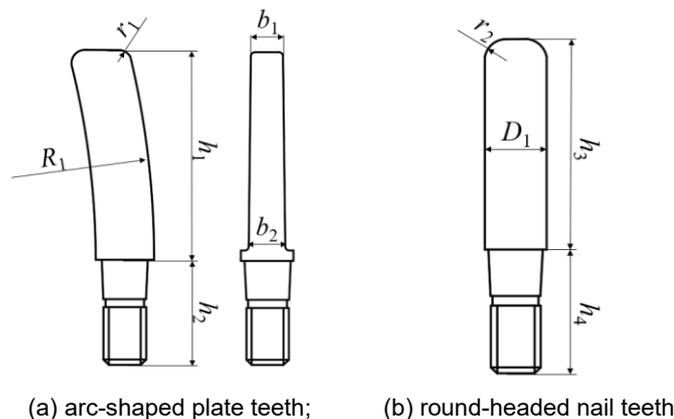

Fig. 4 - Threshing components structure

In Figure 4(a), h_1 is the working height of the arc-shaped plate teeth, taken as 75 to 95 mm; h_2 is the installation height; R_1 is the curve radius of the working surface of the arc-shaped plate teeth, taken as 344 mm; r_1 is the top fillet radius of the arc-shaped plate teeth, taken as 5 mm. b_1 is the top thickness of the arc-shaped plate teeth, taken as 12 mm; b_2 is the bottom thickness of the arc-shaped plate teeth, taken as 14 mm. In Figure 4(b), h_3 is the working height of the round-headed spike teeth, taken as 55 to 74 mm; h_4 is the installation height of the round-headed spike teeth; D_1 is the diameter of the round-headed spike teeth, taken as 20 mm; r_2 is the top fillet radius of the round-headed spike teeth. According to the theoretical research on the collision between the spike teeth and the corn cobs (Zhe, 2018), the calculation formula for the ball head radius is $R \geq 5$ mm. Therefore, in this paper, the top fillet radius r_1 of the arc-shaped plate teeth is designed to be 5 mm, and the top fillet radius r_2 of the round-headed nail teeth is 7 mm.

The threshing of corn cobs mainly occurs while moving from the upper cover plate to the bottom of the roller. During this process, the corn cobs struck by the arc-shaped plate teeth exist in two states: in contact with the concave screen or not in contact with the concave screen, as shown in Figure 5(a) and 5(b).

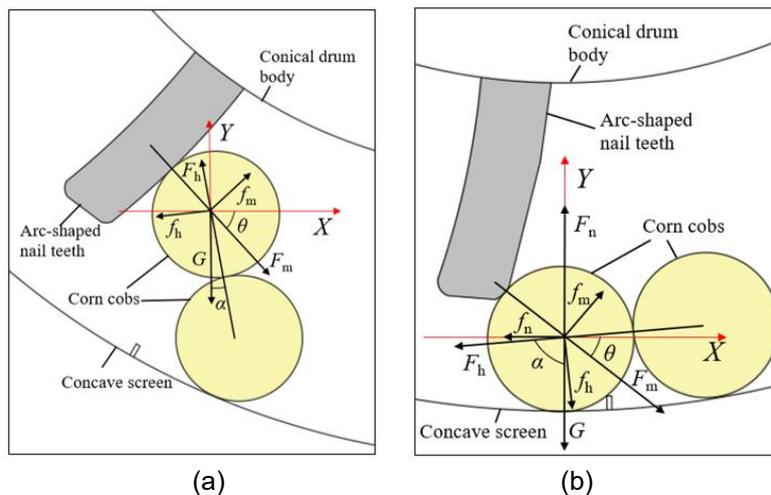

Fig. 5 - Force analysis diagram of corn cob

The force analysis of the corn cobs in these two states is carried out:

$$\begin{cases} F_{mx} = F_m \cos \theta \\ F_{my} = F_m \sin \theta \end{cases} \quad (3)$$

Figure 6(a) presents the schematic diagram of the state where the beaten ear of grain is not in contact with the concave sieve. Through the force analysis of it, the following can be obtained:

$$\begin{cases} F_x = F_{mx} + f_m \sin \theta - F_h \sin \alpha - f_h \cos \alpha \\ F_y = F_{my} - f_m \cos \theta - F_h \cos \alpha + f_h \sin \alpha + G \end{cases} \quad (4)$$

Figure 6(b) presents the schematic diagram of the contact state of the beaten ear of grain and the concave sieve. A force analysis of it yields:

$$\begin{cases} F_x = F_{mx} + f_m \sin \theta - F_h \sin \alpha - f_h \cos \alpha - f_n \\ F_y = F_{my} - f_m \cos \theta - F_h \cos \alpha + f_h \sin \alpha - F_n + G \end{cases} \quad (5)$$

where:

- F_m is the striking force of the arc-shaped nail teeth on the corn cob, (N);
- f_m - the friction force exerted on the corn cob by the arc-shaped nail teeth, (N);
- F_n - the supporting force of the concave plate screens on the corn cob, (N);
- f_n - the friction force of the concave plate screens on the corn cob, (N);
- F_h - the supporting force between the corn cobs, (N);
- f_h - the friction force between the corn cobs, (N);
- G - the gravity of the corn cob, (N);
- θ ($0^\circ < \theta < 90^\circ$) - the angle between the striking force of the arc-shaped nail teeth on the corn cob and the X-axis, ($^\circ$);
- α ($0^\circ < \alpha < 90^\circ$) - the angle between the supporting force between the corn cobs and the Y-axis, ($^\circ$).

When the corn cobs move from the upper cover plate to the bottom of the roller, affected by the impact force of the arc-shaped plate teeth and the gravity of the corn cobs, the relative position of the corn cobs and the threshing elements changes. During this process, θ gradually increases. As shown in Equation (3), the component force F_{mx} of the impact force of the arc-shaped plate teeth in the X-axis direction keeps decreasing, which slows down the axial movement speed of the corn cobs and enhances the rubbing contact between the corn cobs. At the same time, the component force F_{my} of the arc-shaped plate teeth in the Y-axis direction keeps increasing; that is, the downward pressure given by the arc-shaped nail teeth to the corn cobs gradually strengthens.

It can be inferred from Figure 5(a) and Equation (4) that to maintain the force equilibrium in the Y direction, F_h will constantly intensify, leading to a continuous increase in f_h . Combining Figure 5(b) and Equation (5), it is evident that F_h gradually strengthens, and consequently, f_h gradually rises. This rubbing and threshing process is gentle. Meanwhile, the arc-shaped plate teeth gradually squeeze the movable space of the corn cob. In this threshing process, the damage to the kernels is minor.

Design of conical drum body

The front end of the conical drum body has a smaller diameter, which enhances the grain accommodation capacity of the threshing device and strengthens the flexible contact among the corn cobs (Zhendong *et al.*, 2021). The threshing drum adopts an open type. The contact area between the open drum and the corn cobs is small, and the drum load is low, which is conducive to avoiding the problem of drum blockage caused by excessive feeding.

In this paper, the variation range of the working height of the threshing elements is designed to be 55 ~ 95 mm. As the length L of the threshing and separating section of the variable diameter open roller is 2.5 m, the taper β of the variable diameter roller body is:

$$\tan\beta = \frac{h}{L} \quad (6)$$

Hence, the taper of the conical drum body is 0.9° . This taper increases the gap at the feeding inlet by one layer of the thickness of the corn cobs compared to that at the discharge outlet, which is beneficial for smooth feeding and increasing the number of collisions between the corn cobs.

The design of the grid concave plate screens and the design of the adjustable upper cover plate with guide vanes

To prevent the uneven flow of corn cobs between the two threshing drums on both sides and influence the threshing effect, the threshing spaces of the two drums are not interconnected. Currently, the commonly used forms of concave plates include grid screens and punched screens. Grid screens have greater strength, and both the sieve porosity and separation efficiency are higher than those of punched screens. They are widely applied in existing combined harvesters. Therefore, this device employs a grid of concave plate screens. The double longitudinal axial flow grid concave plate screen is shown in Figure 6(a).

Adjusting the angle of the guide plate can control the axial movement speed of corn cobs and the material layer's thickness, significantly influencing the threshing effect. A combination guide plate with a fixed front section and an adjustable rear section is designed in the upper cover plate of the double longitudinal axial flow threshing cylinder. In this paper, the helix angle of the fixed guide plate is designed to be 24° . The helix angle range of the adjustable guide plate is designed to be 16° to 26° (Chen *et al.*, 2022). The structure of the unilateral upper cover plate is shown in Figure 6(b).

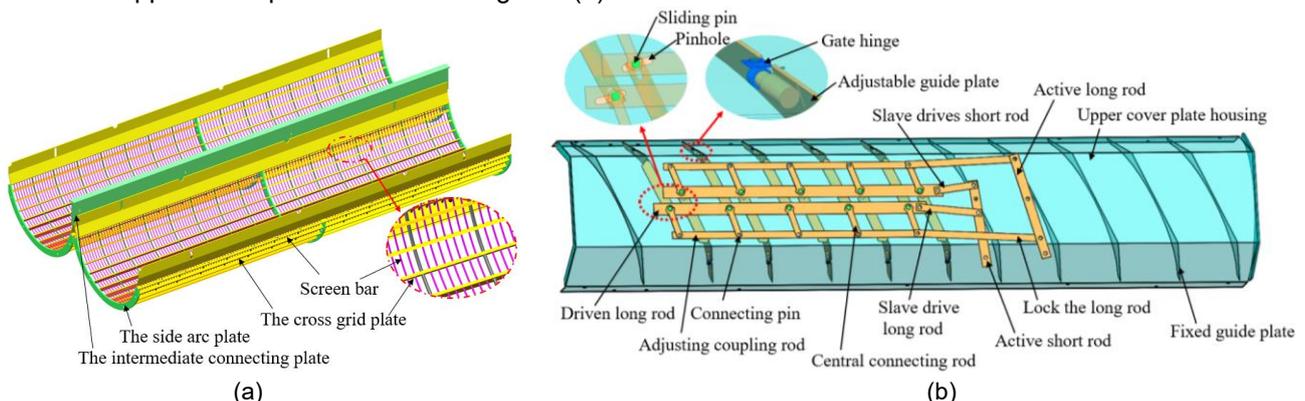

Fig. 6 - The Structural Diagram of the grid concave plate screens and the upper cover plate

One end of the adjustable guide plate is connected to the upper cover plate housing through a gate hinge, and the other end is connected to the driven long rod through a sliding pin. The other end of this driven long rod is connected to the active short rod. When the active short rod and the active long rod move simultaneously through force transmission, they cause a positional offset at one end of the adjustable guide plate. As a result, the angle of the adjustable guide plate changes, thereby controlling the axial movement speed of the corn cobs.

Experiment design

The existing research results (Chenlong *et al.*, 2022; Shulun *et al.*, 2024) indicate that the influences of the feed rate, the threshing cylinder speed, and the angle of the guide plate on the grain breakage rate are more significant than that of the threshing clearance. Hence, the feed rate, the threshing cylinder speed, and the angle of the guide plate were selected to research the device's threshing performance.

Test materials and conditions

In October 2024, a bench test was conducted at Shandong Tiankaizhongrui Machinery Technology Company Limited. The double longitudinal axial flow threshing roller was placed at an inclination of 7° to the ground, and the threshing clearance was 35 mm. The corn variety used in the experiment was "Liyuan296". The average moisture content of corn kernels was 31.3% using the LDS-1G model grain moisture detector. Thirty corn ears were taken for the physical characteristic experiments of the ears. The experimental data are as follows: the average ear length is 16.4 cm, the diameters at the middle and large ends are 49.7 mm, and the diameter at the small end is 46.9 mm. The test site is shown in Figure 7.

Fig. 7 - Testbed for double longitudinal axial flow with a large feeding amount

The threshing test of the corn threshing device

This paper conducts the corn threshing test by referring to GB/T 21961-2008 and GB/T 5982-2005. A platform scale weighs the corn cobs of the required weight and then spreads on the measurement area of the conveying device. After each test, the corn kernels in the receiving device are collected and thoroughly mixed for manual sampling, with each sample no less than 2 kg. The grain breakage rate Y_1 and the unthreshed grain rate Y_2 are calculated, and the calculation formulas are as follows:

$$Y_1 = \frac{m_s}{m_i} \times 100\% \quad (7)$$

$$Y_2 = \frac{m_j}{m_z} \times 100\% \quad (8)$$

where: m_s refers to the mass of broken grains in the sample, (g);

m_i is the total mass of grains in the sample, (g);

m_j represents the mass of unthreshed grains, (g);

m_z is the total mass of threshed grains, (g).

Single-factor test

The feed rate has a direct connection with the thickness of the material layer and thereby influences the threshing effect. The feeding quantities in this paper are set at levels 14 kg/s, 15 kg/s, 16 kg/s, 17 kg/s, and 18 kg/s respectively. The threshing cylinder speed is directly related to the striking force of the threshing components. Comprehensively considered, 300 r/min, 350 r/min, 400 r/min, 450 r/min, 500 r/min, 600 r/min, and 700 r/min were selected in this paper. The range of deflector angle adjustment for this device is 16 - 26°, and the deflector angles are horizontally set at 16°, 18°, 20°, 22°, 24° and 26° respectively.

Orthogonal test

According to the results of the single-factor experiments, the ranges of values for the test factors in the orthogonal experiments were determined. A quadratic orthogonal rotational combination experiment was carried out with three factors and levels. The three-factor level coding is presented in Table 1.

Table 1

Factors and levels of experiment			
Level	Experimental factor		
	Feed rate $X_1/(kg/s)$	Threshing cylinder speed $X_2/(r/min)$	The angle of the guide plate $X_3 / (^\circ)$
-1	15	350	22
0	16	400	24
1	17	450	26

RESULTS AND DISCUSSION

Bench tests were conducted under the experimental conditions set in this study. It was found that the unthreshed grain rate in each group was less than 0.3%, indicating a low level and demonstrating that the device performs well in terms of threshing cleanliness under these conditions. Therefore, the focus will subsequently shift to evaluating the corn grain breakage rate to further assess the threshing impact of the device.

The Results and Analysis of Single-Factor Experiment

The fixed values of the test parameters selected in this research are, respectively, the feed rate at 16 kg/s, the threshing cylinder speed at 400 r/min, and the angle of the guide plate at 16°. When carrying out the single-factor test of a certain factor, the parameters of the other two factors are selected as the fixed values. The experimental results are presented in Figure 8.

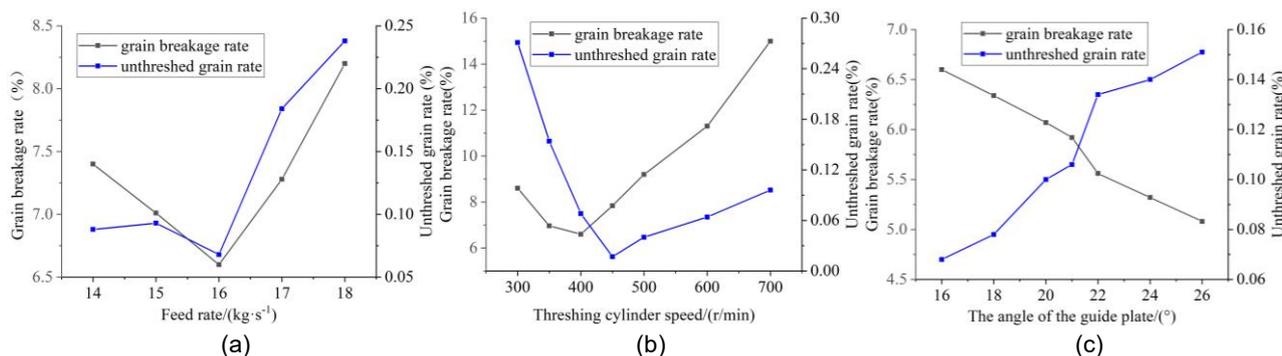

Fig. 8 - Diagram of the Results of the Single-Factor Experiment

In Figure 8(a) it is shown that with the increase in the feed rate, both the grain breakage rate and the unthreshed grain rate exhibit a trend of initially decreasing and then increasing. The reasons for this phenomenon are as follows: when the feed rate is relatively low, the corn cob being struck directly impacts the concave plate for rigid threshing, resulting in a higher grain breakage rate. Simultaneously, the axial movement speed increases rapidly upon impact due to less resistance. The threshing time is reduced, leading to a higher unthreshed grain rate. When the feed rate is relatively big, the material layer inside the roller is thicker. The threshed grains cannot be discharged from the machine in time, causing excessive impact. At the same time, it causes some corn cob to move to the impurity discharge section before the threshing is completed, resulting in a higher unthreshed grain rate.

In Figure 8(b) it is shown that as the threshing cylinder speed increases, both the grain breakage rate and the unthreshed grain rate demonstrate a trend of initially decreasing and then increasing. This is because when the threshing cylinder speed is low, the threshing time of the corn ears increases, and the number of strikes they receive increases, leading to a higher grain breakage rate. Meanwhile, the impact force of the threshing elements is small, causing some corn ears to be discharged from the machine before they are completely threshed, resulting in a higher unthreshed grain rate. At higher threshing cylinder speed, the threshing element strikes with high force, which results in higher kernel breakage and a rapid increase in the grain breakage rate. At the same time, it leads to a more incredible axial movement speed of the corn ears, causing some corn ears to be discharged from the machine before being completely threshed, resulting in a higher unthreshed grain rate.

It could be observed from Figure 8(c) that with the increase of the angle of the guide plate, the grain breakage rate shows a downward trend, while the unthreshed grain rate shows an upward trend. As the angle of the guide plate increases, the axial movement speed of the corn ears increases, which is conducive to the prompt discharge of the detached grains and avoids excessive impact, resulting in less grain crushing. Simultaneously, this behavior increases the probability of some corn ears being discharged from the machine before they are completely threshed, thereby increasing the unthreshed grain rate.

The Results and Analysis of the Orthogonal Experiment

Test Results and Analysis

The experimental scheme was designed based on the Box-Behnken module in the Design-Expert 13.0 software. With the grain breakage rate and the uncleaned grain rate as the experimental indicators, 17 experiments were carried out. The experimental scheme and results are presented in Table 2.

Table 2

Testing plan and results						
Experimental Number	Experimental Factors and Levels			Performance indicators		
	X_1 /(kg/s)	X_2 (r/min)	X_3 (°)	Y_1 %	Y_2 %	
1	16	350	22	6.21	0.252	
2	17	400	22	6.29	0.224	
3	16	400	24	5.41	0.143	
4	15	450	24	8.58	0.087	
5	15	350	24	7.49	0.274	
6	17	450	24	7.01	0.126	
7	16	400	24	5.32	0.194	
8	15	400	26	5.93	0.181	
9	16	400	24	5.62	0.092	
10	17	400	26	5.56	0.256	
11	16	400	24	5.23	0.154	
12	16	350	26	5.85	0.286	
13	16	450	26	6.73	0.046

Residual	7				
Lack of fit	3	5.17	0.0733	1.37	0.3735
Pure error	4				
Total error	16				

Note: *significant ($P < 0.05$), **very significant ($P < 0.01$)

It can be observed from Table 3 that X_1^2 and X_2^2 have an extremely significant effect on Y_1 ($P < 0.01$). X_2 , X_3 , and $X_1 X_2$ significantly influence Y_1 ($P < 0.05$). Other factors influencing Y_1 were insignificant ($P > 0.1$). Meanwhile, X_2 has an extremely significant influence on Y_2 ($P < 0.01$). Other factors influencing Y_2 are insignificant ($P > 0.1$). The $P < 0.05$ of the established regression model indicates that the relationship between the dependent variable of the regression model and the full set of independent variables is significant.

The P value of the lack-of-fit term is greater than 0.05, suggesting that the lack-of-fit is not significant, and the regression model fits the experimental results relatively well. Thus, the regression equation for the influence of each factor on Y_1 and Y_2 is obtained:

$$Y_1 = 5.97 - 0.22X_1 + 0.27X_2 - 0.66X_3 - 0.35X_1X_2 - 0.14X_1X_3 + 0.02X_2X_3 + 0.94X_1^2 + 1.27X_2^2 - 0.44X_3^2 \quad (9)$$

$$Y_2 = 0.11 + 0.019X_1 - 0.085X_2 + 0.04X_3 + 0.025X_1X_2 - 0.004X_1X_3 - 0.026X_2X_3 + 0.037X_1^2 - 0.016X_2^2 + 0.032X_3^2 \quad (10)$$

Response Surface Analysis

Through the data processing in the Model Graphs of the Analysis module, the interactive influences and influence rules of X_1 , X_2 , X_3 on the grain breakage rate are investigated. It can be known from Table 3 that the interaction effects of the three experimental factors on the unthreshed grain rate are not significant ($P > 0.05$). Thus, no further analysis is considered. The response surface results are presented in Figure 9.

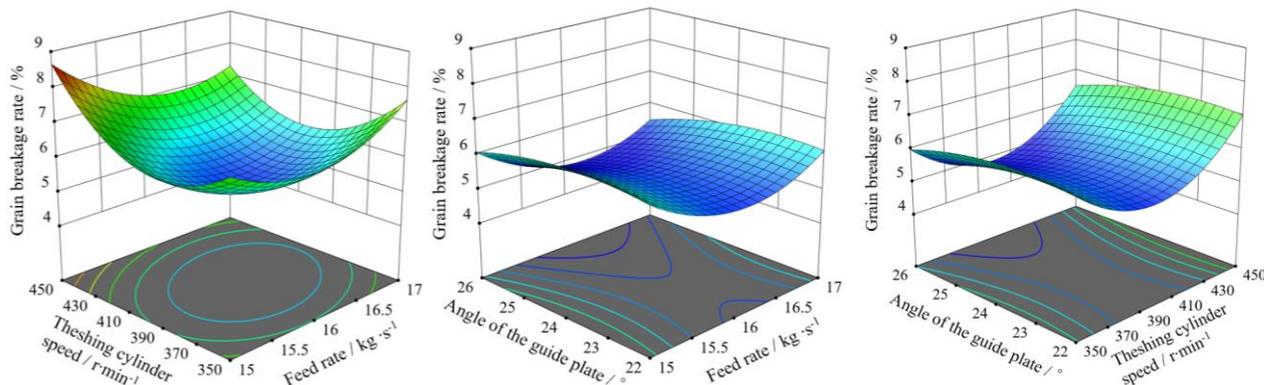

Fig. 9 - Response surface diagram of interaction factors

With the increase of the feed rate and the threshing cylinder speed, the grain breakage rate exhibits a trend of initially decreasing and then increasing, and the interaction effect of the two factors is significant. With the increase of the angle of the guide plate, the grain breakage rate shows a downward trend, while the interaction effect between the angle of the deflector plate and other factors is insignificant. This is because when both the feed rate and the threshing cylinder speed are at relatively low levels, the material layer of the corn ears is thin, and the axial movement speed of the corn ears is small. This circumstance results in, on the one hand, the impacted ears of grain directly hitting the concave screen for rigid threshing and, on the other hand, prolonging the threshing time of the ears of grain, leading to an increased breakage rate. When the feed rate and the threshing cylinder are both at relatively high levels, an overly thick material layer will impede the discharge of the detached corn kernels from the machine. Meanwhile, the excessive impact force endured by the corn ears causes the struck corn kernels to be directly crushed. Enlarging the angle of the guide plate enhances the materials' axial movement speed and reduces the material layer's thickness. This condition is conducive to the timely discharge of the already threshed corn kernels outside the machine, lowering the probability of excessive impact.

The Optimization of Threshing Parameters

The threshing effect was satisfactory. Hence, this paper's lowest grain breakage rate was taken as the optimization objective to optimize the threshing parameters. The multi-objective equation system was solved using the optimization solution module of Design Expert software. The optimal parameter combination was obtained: a feed rate of 16.057 kg/s, a threshing cylinder speed of 397.400 r/min, and an angle of the guide plate of 25.443°. The optimal parameters were simplified: a feed rate of 16 kg/s, a threshing cylinder speed of 400 r/min, and an angle of the guide plate of 26°. Multiple bench tests were carried out under this combination of parameters, and the average of the test results was taken. The actual grain breakage rate was 5.02%, and the unthreshed grain rate was 0.171%. The operational performance meets the actual harvesting requirements.

CONCLUSIONS

Existing threshing devices cannot meet the demand for large feeding volumes. This study focuses on three aspects - reducing impact force, increasing separation area, and controlling threshing time - to design a double longitudinal axial-flow corn threshing device suitable for large feeding volume conditions.

(1) Through the method of theoretical analysis, a threshing drum composed of a combined type of threshing elements of variable-height "arc-shaped plate teeth and round-head nail teeth" and a conical drum body was designed. The main structure and working process were analyzed, and the main structural parameters of the threshing drum were determined. This device satisfies the threshing requirements of high efficiency and low damage under the condition of large feed rates.

(2) The design of the arc-shaped plate teeth threshing element was based on a comprehensive analysis of the corn threshing process and mechanical considerations. It is capable of progressively increasing the squeezing and kneading force. An adjustable guide vane device was designed to control the axial movement velocity of corn cobs, thereby improving threshing performance.

(3) A large-capacity double longitudinal axial-flow threshing test rig was developed. The experiments indicate that the optimal parameter combination of this device is as follows: the feed rate is 16 kg/s, the rotational speed of the drum is 400 r/min, and the angle of the guide plate is 26°. At this point, the grain breakage rate is 5.02%, the unthreshed rate is 0.171%, and the operational performance meets the actual harvesting requirements.

Keywords: chili cleaning, bend lift conveyor, conveying efficiency, CFD-DEM

ABSTRACT

To improve the material conveying efficiency in the elbow lifting transportation process under negative pressure airflow and to solve pipeline material blockage issues, a chili cleaning device was used as the core model. CFD-DEM coupled simulation was employed to analyze the lifting process of non-spherical chili materials in the elbow pipe. Key parameter optimization was carried out through experimental design, determining the optimal parameter combination as a pipeline curvature of 2.03 and an air-to-feed ratio of 4.571. This combination achieved a conveying efficiency 4.406 times higher than the lowest efficiency case, and the uniformity of material transport under optimal parameters was verified through simulation. This study lays a solid foundation for the design of pipeline bends and the optimization of material conveying analysis.

摘要

为提高负压气流下弯管抬升输送过程物料输送效率，解决管道物料堵塞。以辣椒清选装置为核心模型，采用 CFD-DEM 耦合模拟，分析非球形辣椒物料弯管的提升过程。通过试验设计进行关键参数优化，确定最佳参数组合为管道曲率 2.03 和气送比 4.571。该组合的输送效率是最低效率情况下的 4.406 倍，并通过仿真验证了最佳参数组合下物料输送的均匀性。这为设备弯管的设计和物料输送分析的优化奠定了坚实的基础。

INTRODUCTION

Pneumatic conveying originated in Britain in the late 19th century. Since then, it has been extensively applied in diverse industries. Pneumatic conveying systems enjoyed a global market of nearly 30 billion U.S. dollars in 2021 (Hentschel, 2011; Hilgraf, 2023). Compared to traditional conveying methods, pneumatic conveying is characterized by high efficiency and low cost. With the continuous advancement of the industry, the demands for its conveying efficiency and performance are constantly escalating. However, pipeline conveying is merely a simple component of the device, which, therefore, lacks sufficient attention. This oversight seriously impacts the overall efficiency and operational effectiveness (Afkhami et al., 2015; Cong et al., 2018; Ma & Zhao, 2018).

Pneumatic conveying technology did not attract scholars' attention until the 1950s, although it was developed earlier in overseas countries. During the continuous development of pneumatic conveying technology industry, pneumatic conveying can be mainly categorized into dilute-phase pneumatic conveying, dense-phase dynamic pressure pneumatic conveying, dense-phase hydrostatic pneumatic conveying, and cylinder pneumatic conveying, among which dilute-phase pneumatic conveying methods are currently the most widely adopted. The existing analysis is primarily focused on spherical particles, simply constrained to the theoretical analysis of horizontal conveying or lifting conveying. With the gradual development of equipment in the multi-level direction, pneumatic pipeline is no longer limited to horizontal conveying, so there is an urgent need to provide theoretical support for the design of vertical-horizontal lifting.

Traditionally, design mode requires a lot of human and material resources. The coupled fluid mechanics and discrete element simulation technique, on the other hand, help to reduce the consumption of resources and is able to track and analyze the motion state of materials under the action of fluid from a microscopic perspective, which, hence, has been widely used in various types of pneumatic research. For example, Li Zhengquan and Chen Huimin analyzed the force between particles and pipe wall and the scouring effect on the pipe wall in pipelines using fluid mechanics and discrete element method (Li *et al.*, 2024). Gu Fengwei and Zhao Youqun analyzed the conveying device of straw no-tillage planter with the help of CFD-DEM coupled simulation and improved the homogeneity of straw casting and crushing (Gu *et al.*, 2022). Combining computational fluid dynamics and discrete element method, Hemin Zhao and Yongzhi Zhao effectively simulated the motion state of particles in horizontal channel pneumatic conveying (Zhao & Zhao, 2020). In summary, the reliability and applicability of the coupled CFD-DEM simulation technique have been fully verified. However, vertical-horizontal lifting process is rarely explored, and most of the existing research focuses on regular particles and lacks actual data to provide a basis for pipeline design.

By constructing a CFD-DEM coupled simulation model using chili peppers and chili pepper stalks as particle models, this paper investigates the conveying process of vertical-horizontal lifting in depth from the laws of air flow field and the motion state of particles and studies the conveying effect of materials under different structures (Chen *et al.*, 2020; Uzi & Levy, 2018). Combined with the experimental design, the optimal structure parameters are identified through experiments and simulation verification (Drescher *et al.*, 2025). The research results of this paper will provide valuable reference for the subsequent material lifting and conveying system and its structural design.

MATERIALS AND METHODS

Installations and Critical Areas

On the basis of previous research on chili cleaning device, this paper analyzed bending and lifting pipe of the chili mixture. The device consisted of conveyor belt, rotary feeder, conveyor pipe, rotary unloader, settling pipe and other components, as detailed in Fig. 1. Among them, the specific gravity sorting area (Fig. 1 (a)) and the inertia sorting area (Fig. 1 (b)) played the most critical role in operation. The chili was transported through the vertical-horizontal lifting pipe and then mixed. The detailed analysis will be performed in this paper to maximize the conveying efficiency and ensure the uniformity of conveying.

a. Specific gravity sorting area; b. Inertia sorting area

Theoretical analysis

The conveying pipeline needed to be rationally arranged, whose conveying efficiency would otherwise be affected, thereby potentially resulting in blockages, etc. Vertical - horizontal lifting pipelines are mainly divided into six types, as shown in Fig. 2 (a), where Pipeline 4 is the theoretically optimal route, which, however, is difficult to achieve in practice. Pipeline 2 is currently the most commonly used as it can be installed in a more standardized layout. Pipeline 2 has some single rounded corners designed into two rounded corners, which results in increased dissipation. Therefore, this paper presents an in-depth analysis and design of Pipeline 2.

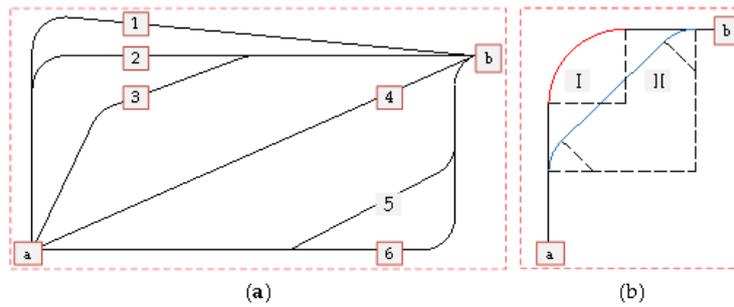

Fig. 2 - Pneumatic lifting conveying lines

a. Pneumatic lifting of the conveying pipeline arrangement; b. Schematic diagram of multiple corners of the pipeline

Conveying air velocity

Air velocity is one of the key parameters of chili cleaning device. According to the relevant provisions of the pipeline layout of the design institute, in the case of vertical or inclined pipe with elbows, the conveying air velocity should be 2.4 to 4.0 times the suspension velocity of the material. The floating speed of the material, V_p , was measured using suspension test bench provided by Qingdao Agricultural University (Gao et al., 2012; Ma Z. et al., 2011), as listed in Table 1.

Table 1

	Mixture material conveying speed		
	Overall dimensions [mm]	Suspension speed [m·s ⁻¹]	Conveying air velocity [m·s ⁻¹]
Chili	52.4~98.2	12.2-14.4	29.28~57.6
Chili stalks	21.5~43.1	9.1-10.5	21.84~42
Fractured stone	8~13	14.8~17.9	35.52~71.6

As the specific gravity sorting area is responsible for sorting out heavier impurities such as stones from the chili mixture, the conveying air velocity needs to be less than the minimum counterpart of stones and to meet the requirements in the conveying speed of chili peppers, stalk and other materials. Therefore, the optimal conveying air velocity of negative pressure at the inlet is 29.28~35.52 m·s⁻¹.

Curvature of bent pipe

The influence of the curvature generated in the material conveying process on the trajectory of the material was discussed.

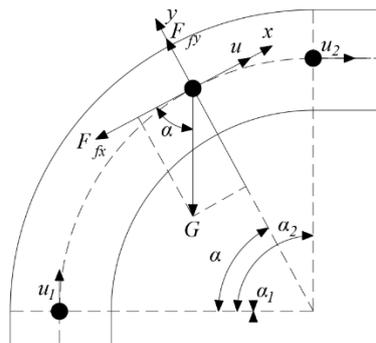

Fig. 3 - Material Bend Motion Analysis

The equations of motion are:

$$\begin{cases} -F_{fx} - G\cos\alpha = ma_x \\ F_{fy} - G\sin\alpha = ma_y \end{cases} \quad (1)$$

where F_{fx} , F_{fy} - airflow resistance components, (N); G - gravity, (N).

According to the boundary conditions, when particles were at Position 1, the angle of motion between the particles and the elbow was $\alpha_1=0^\circ$, and the velocity of the particles entering the bending phase was assumed to be $u=u_1$; when particles were at Position 2, the angle of motion between the particles and the elbow was $\alpha_2=90^\circ$, and the velocity of the particles entering the bending phase was assumed to be $u=u_2$.

The relationship between u_2 and α can be described as:

$$u_2^2 - e^{-f_w \alpha} u_1^2 = e^{-f_w \alpha} \frac{2gR}{4f_w^2 + 1} \{3f_w + e^{2f_w \alpha} [2(f_w^2 - 1) \sin \alpha - 3f_w \cos \alpha]\} \quad (2)$$

The final simplification of the above equation is obtained by combining the particles as they move from position 1 to position 2:

$$u_2 = e^{-\frac{\pi}{2} f_w} \sqrt{u_1^2 + \frac{2gR}{4f_w^2 + 1} [3f_w + e^{\pi f_w} (2f_w^2 - 1)]} \quad (3)$$

From eq. 3, it can be seen that the velocity of material movement is affected by the bending radius of the pipe.

Shape of Pipe

Pipes are commonly rectangular, circular and oval. Among them, circular pipes are more widely used for horizontal conveying. However, since the vertical-horizontal lifting process is very complex, this paper will examine and compare these three types of pipes in depth.

Gas-to-feed ratio

In the material conveying process, the material is vertically lifted and then horizontally conveyed through bending pipes. According to the relevant provisions about pipeline arrangement offered by the design institute, the air velocity of the material conveyed is mostly in the range of 12 m/s to 40 m/s, which is in line with the dilute phase pneumatic conveying speed conditions (Du et al., 2014; Huo et al., 2013). Under the condition of dilute-phase pneumatic conveying, gas-to-feed ratio is required to be between 1 and 5 (Hongxun, 1993), so as to meet the process requirements and performance indexes of the whole conveying system.

Experimental factors

Based on the above comprehensive analysis, the main factors affecting the material in the state of vertical-bend-horizontal conveying included pipe type, bend radius R, gas-to-feed ratio C. Curvature R/D was associated with elbow size, but was represented by radius R instead as the negative pressure of the pipe was constant and the cross-section size of the pipe had been determined. It will be further analyzed as a key influencing factor.

Simulation Settings

The simulation was coupled with ANSYS 2021r1 and EDEM 2020 software. The 'Mesh' module in ANSYS 2021r1 was used to delineate the mesh, and the Fluent module to analyze the flow field. In the Fluent module, the fluid medium was set to be air, and the k- ϵ model was employed to calculate the transient simulation method. The SIMPLE algorithm was used for computation. The material particles were generated and the mechanism was modelled using EDEM software. Data exchange between the two software packages was facilitated through a coupling plug-in, ensuring the accuracy and efficiency of the entire simulation (Alihosseini, Saegrov, & Thamsen, 2019; Zhao L. et al., 2016).

Simulation of particles and geometrical models

1) Particle physical parameters and contact parameters;

The physical properties of the chili mixture were measured based on the statistical principles of the physical parameters of the harvested chili mixtures. The characteristic properties of the material that could not be measured directly were obtained by EDEM calibration (Zhang et al., 2023). The parameters and contact coefficient of the material are listed in Table 2.

Table 2

Physical parameters of the material			
	Poisson's ratio	Shear modulus [MPa]	Density [kg·m ⁻³]
Chili	0.31	3.12	817.13
Chili handle	0.43	1.35	1024.45
Steel	0.29	79920	7860
	Coefficient of recovery	Coefficient of static friction	Coefficient of kinetic friction
Chili peppers-chili peppers	0.372	0.364	0.272
Chili peppers-chili stalks	0.277	0.452	0.341
Chili - steel	0.413	0.491	0.233
Chili stalk - chili stalk	0.362	0.682	0.578
Chili - steel	0.335	0.538	0.452

2) Particle modeling

In order to accurately simulate the actual working effect of the pipeline, particle modeling was conducted at a ratio of 1:1 between chili and chili stalk. By employing the SolidWorks finite element mesh module, the model was divided to generate node coordinates, and then the data was imported into EDEM software to construct the model for the particles of chili and chili stalk, as shown in Fig. 4.

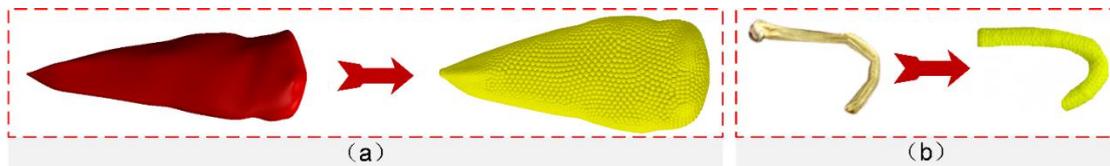

Fig. 4 - Particle-filled models
 a. Chili filler model; b. Chili stem filler model

3) Geometric modeling

A geometric model was established by SolidWorks software, and the mesh was delineated by the 'Mesh' module in Workbench, as shown in Fig. 5.

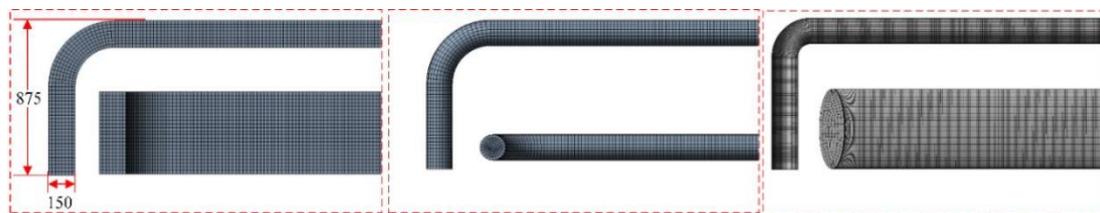

Fig. 5 - Geometric Modeling Mesh

Experimental

1) One-way test;

Using CFD-DEM coupled simulation technology and taking the uniformity of the airflow field, the stability of material conveying and the conveying efficiency as the evaluation indexes, this paper conducted the single-factor simulation analysis for the three key parameters, namely pipe type, curvature of elbow pipe R/D and air-to-feed ratio C . Among them, the pipe type included round, rectangular and oval; the curvature of elbow pipe R/D was set to be (1 ~ 5) because of common small curvature $R/D = 2$ and large curvature $R/D = 5$, and air-to-feed ratio C to be (1 ~ 5) according to the conditions of the rarefied-phase pneumatic conveying.

2) Orthogonal test;

According to the one-factor simulation results and agronomic requirements, curvature X_1 and air-to-feed ratio X_2 were taken as test factors, and material conveying efficiency Y as the evaluation standard (set 1s conveying 100 chilies as the unit efficiency). With the help of Design-Expert, two-factor three-level orthogonal test was performed (Cong et al., 2018).

The test factors are detailed in Table 3.

Table 3

Factor level coding table for chili pepper scavenging device test		
Encodings	Experimental factors	
	Curvature X_2	Gas to material ratio X_3
-1	1	1
0	2	3
1	3	5

In order to ensure the reliability of the CFD-DEM simulation, the optimal structural parameters were firstly obtained by simulation and experimental design analysis, and the pipe was processed according to the optimal combination of parameters to carry out the bending and lifting test on chili and chili stalk. During the test, the velocity at the key entrance and exit nodes was measured by a pipeline airflow speed transmitter, and compared with the velocity at the same locations obtained during the simulation to assess the reliability of the simulation results.

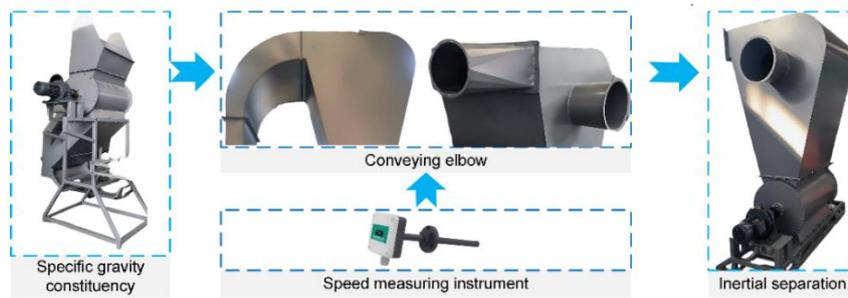

Fig. 6 - Of actual test setup

RESULTS

Analysis of the results of the one-way test

Analysis of pipe type simulation results

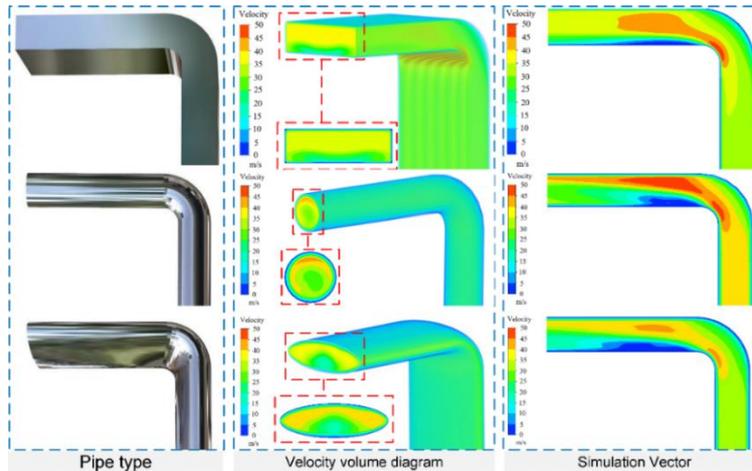

Fig. 7 - Pipeline fluid simulation volume diagram

As can be seen from the analysis of the cloud images for three types of elbow shown in Figure 7, airflow moved from the vertical area to the turning area in circular and elliptical elbows, mainly concentrating at the bottom and converging upward, which resulted in the turbulence in the horizontal area and therefore made it difficult to ensure the uniformity of material transportation (Liu et al., 2024; Wang et al., 2024; Zhang & Newell, 2024). In contrast, airflow movement in most areas remained unaffected when the airflow passed through the turning area in rectangular elbow due to the limitation of its own structure, so that airflow remained relatively stable in the material transportation process in the rectangular elbow, providing favorable conditions for the uniform and orderly transportation of the material.

Therefore, in terms of the airflow in the vertical and horizontal conveying processes, rectangular pipe was superior to oval and round ones. In the turning area, turbulence would not be produced in the rectangular pipe, which effectively ensured uniform airflow in the material conveying process and more stable airflow within the rectangular pipe from vertical to horizontal conveying.

Analysis of curvature simulation

The rectangular pipe was simulated, with air-to-feed set to be 2 and curvature R/D to be 1, 2, 3 and 4, respectively (Zhou et al., 2016). The simulation results are illustrated in Fig. 8.

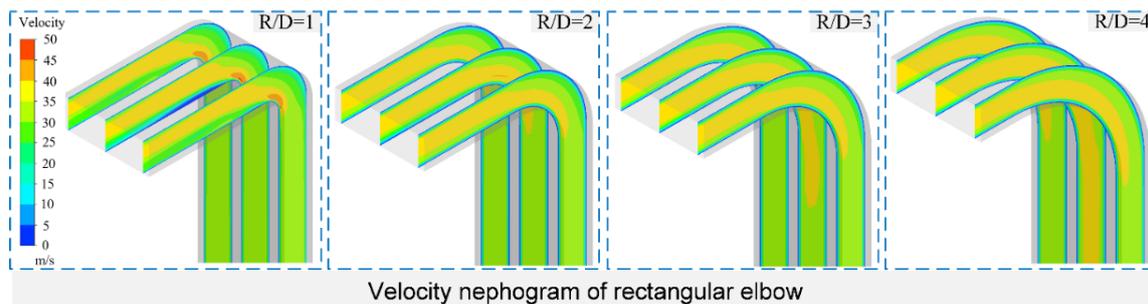

Fig. 8 - Curvature fluid simulation vector diagram

a. Velocity nephogram of rectangular elbow; b. Velocity nephogram of circular bend

As can be seen from Fig. 8, with the increase of the curvature R/D , the horizontal area of rectangular and round pipes did not change significantly, while the vertical area of high-velocity airflow area continued to expand towards the inlet.

As in the presence of negative pressure, when the airflow passes through the turning area, it would be attached to the lower wall of the turning area under the action of the Coanda Effect, thus generating adhesive flow. With the gradual increase of the curvature R/D , the turning trend of the airflow became more gentle and the adhesive flow of the steering process was cushioned. As a result, the high-velocity flow area was extended. Therefore, the larger the curvature R/D , the smoother the flow in the turning region.

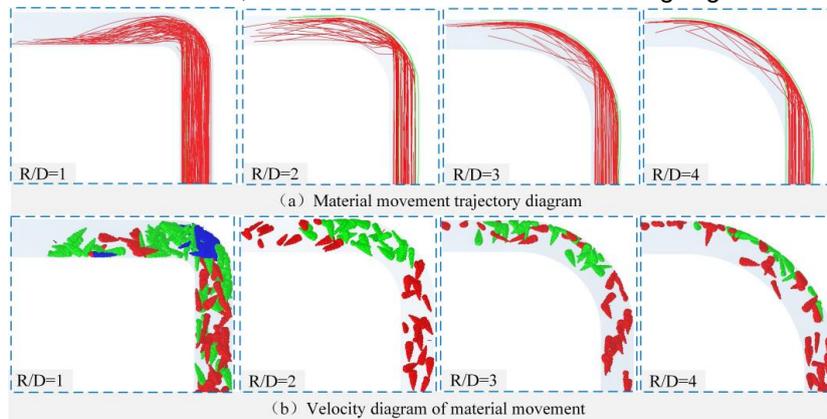

Fig. 9 - Particle coupling effect

a. Material movement trajectory diagram; b. Velocity diagram of material movement

As can be seen from Fig. 9, the larger the curvature R/D , the trajectory of the material was gradually concentrated at the top upon the completion of vertical and horizontal conveying. If a large number of materials were concentrated at the top of the pipe, then they would be unevenly distributed within the pipe, thus lowering the material conveying efficiency.

With the gradual increase of the curvature R/D , the number of collisions of material trajectory in the turning area obviously increased. The material would collide with the upper wall of the elbow under the action of the upward movement inertia when moving from the vertical area to the turning area. In addition, the turning area was enlarged, so that the materials would continue to collide repeatedly with the turning area following their initial collision, making the pipe very likely to be blocked.

For the sake of a comprehensive comparison, among the four common curvatures of rectangular pipes, the curvature $R/D = 2$ helped to ensure the uniform distribution of the materials in the pipe after they passed through the turning area and to effectively reduce the number of collisions between the materials as well as between the materials and the pipe wall, thus reducing the degree of damage to the materials.

Influence of air/feed ratio on conveying performance

A rectangular bend was simulated, with the curvature R/D being set to 2 and air-to-feed ratio to 1, 2, 3, 4 and 5, respectively (Ebrahimi & Crapper, 2017). The corresponding simulation results are shown in Fig. 10.

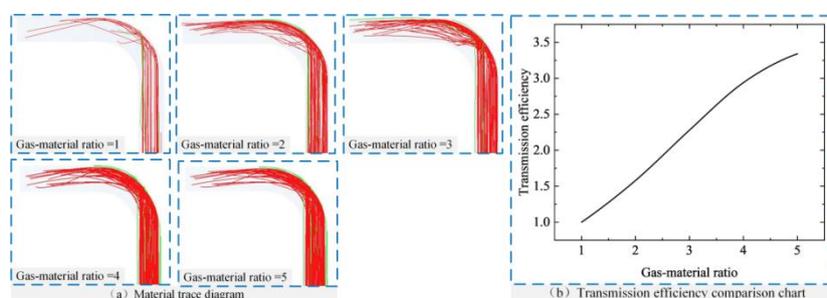

Fig. 10 - Particle coupling trace diagram

a. Material trace diagram; b. Transmission efficiency comparison chart

As seen in Fig. 10(a), increasing the air-to-feed ratio improved the uniformity of material conveying. With a higher air-to-feed ratio, the materials initially accumulated in the turning area, causing a reduction in speed. However, as the materials moved into the horizontal conveying section, they formed a more stable mass, leading to a more uniform trajectory.

As seen in Fig. 10(b), at a low air-to-feed ratio, the materials were not conveyed rapidly due to the occurrence of a winding phenomenon. As the air-to-feed ratio gradually increased, the cross-sectional area of the material exposed to the airflow became larger, enhancing the pulling force of the air on the material surface. This resulted in accelerated movement of the materials, thereby improving the efficiency of material conveying.

Analysis of orthogonal test

Experimental design and analysis were conducted using Design-Expert 13 software, with transportation efficiency as the evaluation indicator. The transportation efficiency of the least efficient combination was set as the baseline unit, represented as $Y_1=1$. The efficiency of the remaining combinations was then expressed as a multiple of the baseline according to the simulation results, i.e., $Y_1=n \times 1 (n \geq 1)$. The experimental results and ANOVA analysis are presented in Tables 4 and 5, respectively.

Table 4

Relationship between conveyor airflow speed and suspension velocity

Serial number	Factors		Performance indicators Gas to material ratio Y_1
	Curvature X_1	Gas-to-feed ratio X_2	
1	2	1	3.2
2	1	3	1.53
3	1	5	2.21
4	2	3	3.41
5	2	3	3.67
6	3	1	1.21
7	2	3	3.98
8	2	5	4.12
9	3	5	3.96
10	1	1	1
11	2	3	3.87
12	3	3	2.27

Table 5

ANOVA table for conveying efficiency

Source of variance	Square sum	Degrees of freedom	Mean square	F	P	Significance
Modelling	15.13	5	3.03	32.25	0.0001	Significant
X_1	1.21	1	1.21	12.95	0.0088	Significant
X_2	3.97	1	3.97	42.29	0.0003	Significant
X_1X_2	0.5929	1	0.5929	6.32	0.0402	Significant
X_2^2	8.15	1	8.15	86.82	< 0.0001	extremely significant
X_2^e	0.005	1	0.005	0.0529	0.8246	Insignificant
Residual	0.657	7	0.0939			
Lost proposal	0.4538	3	0.1513	2.98	0.1597	Insignificant
Inaccuracies	0.2032	4	0.0508			
Aggregate	15.79	12				

As shown in Table 6, the fit of the conveyor efficiency model was significant ($p < 0.1$), while the out-of-fit term was insignificant ($p = 0.1597$, $p > 0.05$). The terms X_1 , X_2 , and X_1X_2 had a significant effect on the chili clearing rate, with X_2^2 being extremely significant. After excluding the insignificant regression terms, the regression equation for conveying efficiency can be expressed as:

$$Y = 3.72 - 0.45X_1 - 0.8133X_2 - 0.3850X_1X_2 - 1.72X_1^2 \quad (4)$$

Air-to-feed ratio had a greater impact on material conveying efficiency than curvature. The interaction between air-to-feed ratio and curvature had a significant effect on conveying efficiency.

To determine the optimal levels of test factors, the optimization module of Design-Expert 13 software was used to establish a parameter optimization mathematical model. The model aimed to maximize conveying efficiency while considering the boundary conditions of each factor's test values. The objective function and constraints are as follows:

$$\begin{cases} \max Y(X1, X2) \\ \text{s. t } \begin{cases} 1 \leq X1 \leq 3 \\ 1 \leq X2 \leq 5 \end{cases} \end{cases} \quad (5)$$

According to the analysis, the optimal parameter combination was a curvature of 2.03 and an air-to-feed ratio of 4.571, resulting in a unit material conveying efficiency of up to 4.406.

Optimal combination of experimental and simulation results and comparison

Optimal simulation results

The simulation analysis results are shown in Fig. 11. As the materials were lifted from the vertical area to the turning area and then into the horizontal area, they were transported along the upper wall of the horizontal section due to changes in air resistance and gravity acting in the downward movement direction. Eventually, if the materials did not fall to the lower wall of the horizontal section, a uniform motion flow was formed, enabling stable horizontal conveying of the materials.

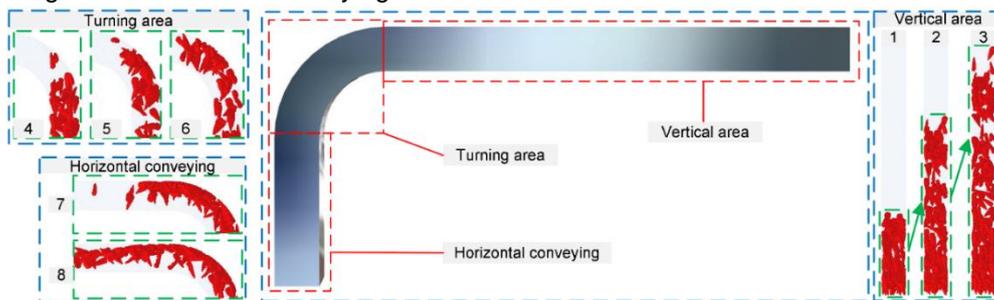

Fig. 11 - Schematic diagram of the motion state of the coupled simulated particles

Actual test results and simulation verification

The actual test was carried out in Jiaozhou, Qingdao, with a rectangular pipe shape, small curvature $R/D = 2.03$, and an air-to-feed ratio of 4.571. The materials used were chili peppers and chili stalks in the ratio of 10:1. The components of the test setup included an inertial sorting device, a centrifugal fan, and a curved conveying pipe.

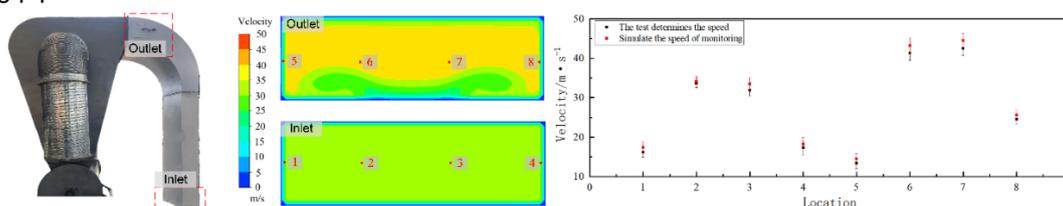

Fig. 12 - Comparison of actual test and simulation key position speed intention

As shown in Fig. 12, by comparing the simulation results of the velocity at the same positions at the inlet and outlet with the actual measurement results, it was found that the actual velocity was slightly lower than the simulated one. This deviation remained within a reasonable range due to the increasing energy consumption of airflow and material flow under the influence of external environmental factors in practical applications. Since the simulated speed closely matched the actual speed in both trend and magnitude, the simulation test results were proven to be highly accurate and reliable.

CONCLUSIONS

In this paper, the CFD-DEM coupled simulation technique was employed to simulate the material lifting and conveying state in a vertical-bend-horizontal pipeline. To achieve optimal material lifting and conveying efficiency, simulation analyses were conducted on pipe type, curvature, and air-to-feed ratio. Combined with

experimental design, the optimal pipe structure was determined to maximize material conveying efficiency. The following conclusions can be drawn:

- The comprehensive experimental design results indicate that material conveying efficiency is maximized when the curvature is 2.03 and the air-to-feed ratio is 4.571 for a rectangular pipe. Combined with the simulation results, this parameter combination ensures more uniform material transportation, meeting operational requirements.
- The CFD-DEM coupled simulation technique employed in this study significantly reduces design resource consumption while achieving ideal results. However, some deviations remain compared to actual tests. Nonetheless, the comparison of simulation and experimental speed measurements shows minimal errors at each point, effectively confirming the reliability of the simulation analysis.

DOI: <https://doi.org/10.35633/inmateh-75-47>**Keywords:** leek, harvesting machine, two rows, clamping conveying**ABSTRACT**

Aiming to address the limited space and the inapplicability of large harvesting equipment in Chinese greenhouses, a small electric double-row leek harvester was designed. This machine is capable of cutting, clamping, transporting, and collecting leeks simultaneously. A reciprocating cutting device was employed to accommodate varying row spacings. To make the machine suitable for small greenhouse environments, the parameters of the torsion clamping conveyor belt were optimized to reduce the overall size. Through theoretical analysis of the clamping and conveying system, the cutting mechanism, and the parameters for coordinated clamping-cutting operations, the structural design and working parameters were determined. A prototype was developed, and field experiments were conducted. The results showed that when the machine's forward speed was 0.3 m/s, the linear speed of the cutting knife was 0.66 m/s, and the conveyor belt speed was 0.42 m/s, the average damage rate was 4.87%, meeting the requirements for mechanized leek harvesting. This study provides a reference for the design of leek harvesters.

摘要

针对中国设施温室空间小、大型收获设备不适应等问题, 设计了小型电动双行韭菜收获机, 可一次性完成韭菜切割、夹持、输送、装框作业。采用往复式切割装置适应不同行距韭菜切割, 优化扭转夹持输送带参数, 减小整机尺寸, 适应温室小空间作业。通过对夹持输送装置、切割装置以及夹持-切割协同作业参数进行理论分析, 确定了夹持输送装置、切割装置的结构、工作参数。试制样机并进行了田间试验, 试验结果表明, 当机器前进速度为 0.3 m/s, 割刀线速度为 0.66 m/s、输送带速度为 0.42 m/s 时, 平均作业损失率为 4.87%, 满足韭菜机械化收获要求。本研究旨在为韭菜收获机的设计提供参考。

INTRODUCTION

Leek is native to China, with a perennial planting area of about 400,000 hm² and an annual output of about 2 million tons. Due to its special planting methods and different growth methods, it can be harvested at least 4–5 times a year (Gong *et al.*, 2018), but the mechanization level of leek harvest is low, mainly relying on manual sorting and boxing, which not only has low work efficiency, high labor intensity and high operating costs, but it is also difficult to guarantee the quality and efficiency of artificial harvest, affecting the development of leek industry (Zou *et al.*, 2022).

At present, the mechanical harvesting technology of leeks and other slender stalk leafy vegetables in foreign countries has been relatively mature (Wang *et al.*, 2021), such as the SLIDE TRAX SMALL parsley orderly harvesting machine from Hortech in Italy and the PO-335A leek harvester from ASA-LIFT in Denmark, which adopts a vertical clamping conveyor device with adjustable lifting and small clamping damage. However, the conveying device has a large structure and is not suitable for facility greenhouses (Liu *et al.*, 2019). The 4G-200 leek harvester of Korea Plant Company uses a twist clamping conveying belt to make leeks orderly spread in the same direction. The model is small and suitable for facility greenhouse operations, but it needs manual secondary sorting and boxing (Xu *et al.*, 2020). The mechanical harvesting technology of leek and other slender stalks of leafy vegetables in China is in the research stage. Some authors designed a leek harvesting machine with a two-stage conveying device (Feng *et al.*, 2023; Zhang *et al.*, 2022a; Liu *et al.*, 2023; Xin *et al.*, 2024; Xu *et al.*, 2024). The first-stage conveying device will transfer leek from vertical posture to horizontal posture, and the second-stage conveying device will transfer leek with horizontal posture to the collection device, which makes the leeks harvested this way more orderly. However, the overall length of the model is too long and the flexibility is poor.

Other researchers designed a small single-row leek harvester, which used a disc cutting knife and a twisting conveying belt to directly transport the cut leek to the ground behind the machine and lay it on the ground. The leek was manually picked up into the box (Zhao *et al.*, 2021; Zhang, 2024a). Su *et al.* (2020) extended the conveying distance of the conveyor belt and placed a collection box behind the machine to allow the leeks fall directly into the box. However, due to the significant height difference between the leeks and the box, the leeks tended to become disorganized after falling in.

Due to the long stems and leaves of leeks and the variation in row spacing, current leek harvesters primarily operate in a single row, using disc cutting knives and semi-cross torsion clamping conveyor belts, which result in low efficiency. Multi-row harvesters with high operation efficiency tend to be large in size and unsuitable for small plots in greenhouse facilities (Zhang *et al.*, 2024b). In this study, a small electric double-row leek harvester was designed. A reciprocating cutting knife was used, and the layout of the twisting clamping belt was optimized to shorten the clamping and conveying distance, thereby enabling double-row harvesting. The model is compact and offers high harvesting efficiency, making it suitable for greenhouse operations. The optimal structural parameters were determined through theoretical calculations of the clamping conveying device, cutting mechanism, and coordinated clamp-cutting operation. A prototype was developed, and field experiments were conducted to verify the rationality of the design parameters. This study provides a technical reference for the design of mechanized leek harvesters.

MATERIALS AND METHODS

Structure and Working Principle of the Harvester

The structure of the whole machine is shown in Fig. 1. It is mainly composed of a divider, a cutting device, a clamping conveying device, a collecting device, a travel device and a rack which can complete the cutting, clamping, conveying and boxing of leek at one time. The height of the reciprocating cutting knife can be adjusted up and down to meet the requirements of different cutting heights. Clamping conveying mechanism adopts double-row twisting clamping conveying mode to improve harvesting efficiency and orderliness. Conveying belt with sponge rubber strip is selected to reduce damage to leek. The main technical parameters of the machine are shown in Table 1.

Table 1

Main technical parameters of double-row electric leek harvester

Parameters	Unit	Values
Size of whole machine	mm	1800x900x880
Matched power	kW	0.5
Output Speed	r/min	330
Machine forward speed	m/s	0~0.75
Conveyor belt line speed	m/s	0~1.04
Working width	mm	660
Harvest height	mm	10~30

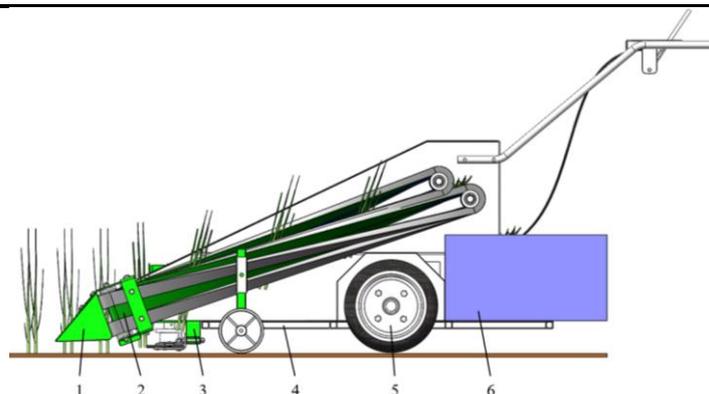

Fig. 1 - Structure diagram of double-row leek harvester

1 - Divider; 2 - Clamping conveying device; 3 - Reciprocating cutting device; 4 - Rack; 5 - Travel device; 6 - Collecting device

When the double-row leek harvester operates, the limiting wheel is first adjusted to align the divider of the harvester with the leek row, ensuring that the reciprocating cutting knife is parallel to the ground. During the machine's forward movement, the clamping conveyor first clamps the leek plant, and then the reciprocating cutting knife cuts the leek from the stem, and the clamping conveyor is transported backwards.

In the conveying process, to ensure the stability of the conveying and facilitate the subsequent collection, the clamping conveying belt is twisted, so that the state of the leek plant changes from vertical to horizontal, and the leek plants fall horizontally into the collection box in an orderly manner when it is transported to the end of the clamping conveying device.

Key component design

Clamping conveying device design

The clamping conveying device consists of two sets of torsion conveying mechanisms. Each mechanism is supported by two sets of belt rollers arranged at a 90-degree angle to each other, enabling the transition of the conveying direction from vertical to horizontal. Power is transmitted between the drive shaft and the driven shaft through a pair of spur gears with identical indexing diameters, ensuring synchronized rotation. The driven roller mounting rack can move forward and backward to adjust the tension of the conveyor belt, and left and right to adjust the belt gap. The structure of the clamping conveying device is shown in Fig. 2.

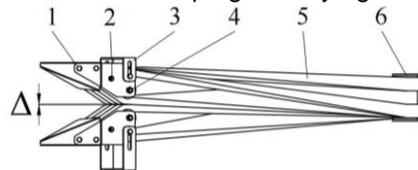

Fig. 2 - Structure diagram of clamping conveying device

1 - Driven roller guide roller holder; 2 - Guide roller; 3 - Fixed frame support frame; 4 - Driven roller; 5 - Conveying belt; 6 - Drive roller

During the conveying process, the gap between the upper and lower conveyor belts determines the size of the clamping force. Too large gap and too small clamping force will lead to misalignment or even dropping of the leeks during transport. Conversely, too small gap and too large clamping force will potentially cause damage to the leeks at the clamping point. To ensure orderly collection with minimal damage, the conveyor belt clearance was carefully designed. Experimental results on the physical characteristics of leeks showed that the diameter at the cutting position ranges from 5.09 to 7.76 mm. Mechanical property tests revealed that the critical compression force at which leeks become damaged is between 12.5 N and 18.95 N (Liu et al., 2022). Based on this, the initial gap between the upper and lower conveyor belts Δ was set to 3 mm, adjustable according to the planting density in a single row and stem diameter of the leeks during operation.

As shown in Fig. 3, to ensure reliable clamping and transportation of leek plants, the driving roller, driven roller, guide roller, and conveyor belt form a torsional clamping transport channel. Before the leeks enter the clamping conveying device, the gap between the upper and lower belts is small. As the leek plants enter the device, the sponges on the upper and lower conveyor belts are compressed and deformed by the leeks, causing the gap to widen. The leeks become "wrapped" by the sponge layers of the belts, which increases the number of contact points and improves clamping stability. This design effectively reduces damage to the leek plants.

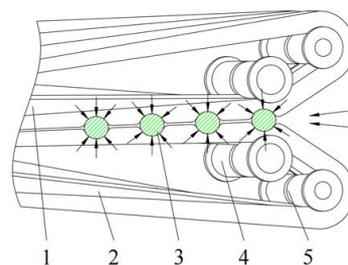

Fig. 3 - Schematic diagram of the transport process of the clamped part of leek plant

1 - Upper conveying belt; 2 - Lower conveying belt; 3 - Leek plant; 4 - Driven roller; 5 - Guide roller

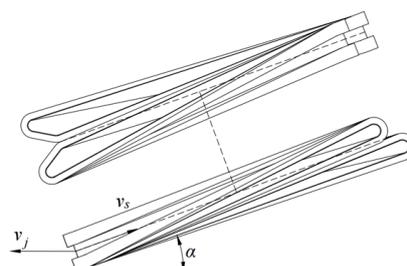

Fig. 4 - Speed analysis of transport process

To ensure smooth backward transmission of leeks and to prevent them from being pushed forward by the conveyor belt during harvesting, the belt speed must exceed the forward speed of the harvester (Li et al., 2023). Therefore, the conveyor belt speed and the machine's forward speed must satisfy the following condition:

$$v_s \cos \alpha > v_j \tag{1}$$

where:

α is the angle between the conveyor belt and the horizontal plane, ($^\circ$), $\alpha=20^\circ$ (Zhang et al., 2016); v_s is the conveyor belt speed, m/s; v_j is the machine's forward speed, m/s.

The minimum forward speed requirement for leek harvesting machinery is 0.2 m/s. According to equation (1), the speed of the driving roller must exceed 64 r/min. The designed speed range of the driving roller is 0~4495 r/min, corresponding to a conveyor belt speed range of 0~1.04 m/s. The design speed of the wheels is 0~55 r/min, corresponding to a forward machine speed of 0~0.75 m/s.

Cutting device design

Since the moisture content of the leek stem is as high as 84.5%, and considering the soft and easily damaged characteristics of the leek itself, this design selects a single-acting reciprocating cutting device, as shown in Fig. 5 (a). The cutting stroke $S=50$ mm, with a moving blade spacing $c=50$ mm, fixed blade spacing $c_0=50$ mm, top width $d=10$ mm, and edge height $h=55$ mm. The cutting knife length is 550 mm to meet the required harvesting width for leeks.

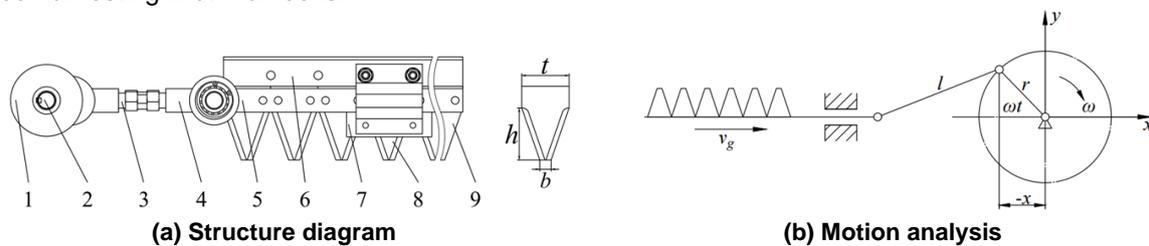

Fig. 5 - Cutting device

(a) 1 - Eccentric wheel; 2 - Power input shaft; 3 - Threaded connecting rod. 4 - Crank sleeve; 5 - Tool bar; 6 - Tool holder; 7 - Pressing edge plate; 8 - Moving blade; 9 - Fixed blade

Research indicates that as the angle θ increases, the cutting resistance will decrease, but if the angle θ exceeds a certain limit, the crop stems will slide out of the mouth of the moving and fixed blade, resulting in missed cutting or uneven stubbles (Shi et al., 2017). To reduce the above phenomenon and ensure that the reciprocating cutting device can cut normally at the moment of contact with the leek stem, the cutting process of the leek stem is analyzed, as shown in Fig. 6.

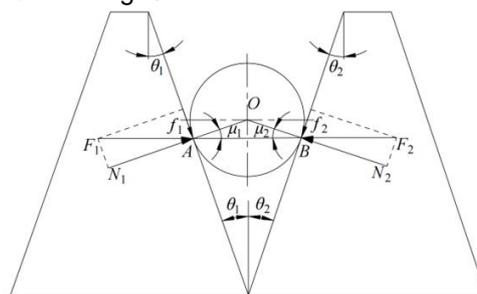

Fig. 6 - Force analysis diagram of blade clamping stem

As can be seen from Fig. 6., when the stems are clamped to maintain balance, the forces F_1 and F_2 must be equal in magnitude, opposite in direction, and on the same straight line:

$$\begin{cases} F_1 = N_1 \tan \frac{\theta_1 + \theta_2}{2} \leq N_1 \tan \mu_1 \\ F_2 = N_2 \tan \frac{\theta_1 + \theta_2}{2} \leq N_2 \tan \mu_2 \end{cases} \tag{2}$$

where: θ_1 - the cutting angle of the moving blade, ($^\circ$); θ_2 - the cutting angle of the fixed blade, ($^\circ$); μ_1 - the friction angle of the fixed blade to the stem, ($^\circ$); μ_2 - the friction angle of the moving blade to the stem, ($^\circ$); F_1 - the resultant force of the moving blade acting on the stem, N; F_2 - the resultant force of the fixed blade on the stems, N; N_1 - the normal force of the moving blade on the stems, N; N_2 - the normal force of the fixed blade on the stems, N;

After analysis, the following condition is obtained:

$$\theta_1 + \theta_2 \leq \mu_1 + \mu_2 \quad (3)$$

This inequality ensures the limiting condition for the clamping of the stem between the moving and fixed blades. Specifically, it means that the sum of the cutting angles θ_1 and θ_2 of the moving and fixed blade must not exceed the sum of the friction angles μ_1 and μ_2 between the blades and the stem. In this study, the values used were $\theta_1 = 19^\circ$, $\theta_2 = 18^\circ$.

During the operation of the cutting knife in the reciprocating cutting device, its absolute motion is a combination of reciprocating motion (as shown in Fig. 5. (b)) and linear motion:

$$\begin{cases} y = v_j t \\ x = r(1 - \cos \omega t) \end{cases} \quad (4)$$

where:

t is the time, s; y is the distance the machine travels in t time, mm; r is the crank radius, mm; x is the displacement of the moving blade in t time, mm.

The formula for calculating the forward distance of the moving blade is:

$$H = \frac{60v_j}{2n} = \frac{\pi}{\omega} v_j \quad (5)$$

where:

n is the rotational speed of the crank, r/min; H is the feed per revolution of the cutter, mm.

Based on geometric relations, the following equation can be derived:

$$y = \frac{H}{\pi} \arccos \frac{r-x}{r} \quad (6)$$

For leafy and stem vegetables like leeks, which require high cutting quality, a clean and smooth cut surface helps reduce damage and decay, extends shelf life, and enhances market value (Shan *et al.*, 2024).

The cutting diagram, drawn according to eq. (5), is shown in Fig. 7. I is the primary cutting area; III is the recutting area; b_1 is the average width of the fixed blade. The cutting device has no missed cutting zones and the repeated cutting area is relatively large, resulting in a neater and smoother cutting surface.

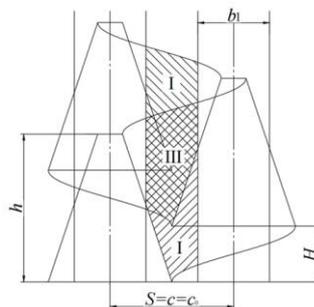

Fig. 7 - Cutting diagram of reciprocating cutting device

Clamping-cutting collaborative operation parameter design

Cutting leek plants while they are clamped is essential to ensure their orderly conveyance. After clamping and cutting, due to the combined effects of the machine's forward motion, the separation function of the divider, and the pulling action of the clamping conveyor belt, the leek plants may adopt unstable postures, such as leaning forward or backward in the direction of movement (Xin *et al.*, 2023). To ensure smooth clamping and transport after cutting, the relative positions of the clamping conveying device and the cutting device were carefully designed. Additionally, the postural changes of the leek plants in the forward direction of the machine were analyzed during the clamping-cutting process.

As the machine moves forward, the cutting knife contacts the clamped leek stems and performs a double-supported cutting action. For ease of analysis, a Cartesian coordinate system is established with the contact point O between the leek plant and the ground, at the clamping-uncut stage, as the origin. It is assumed that the clamping conveying device remains stationary relative to the ground, while the leek plant moves relative to the clamping conveying device at a speed v_j . The geometric relationship is illustrated in Fig. 8. Let the distance between the clamping point A and the front end of the cutting knife be l_g , the height of the cutting knife from the ground be h_1 , the height of the clamping point A from the ground be h_2 , the clamping-cutting time be t_1 , and the angles between the leek plant and the horizontal ground during clamping and cutting be β_1 and β_2 respectively.

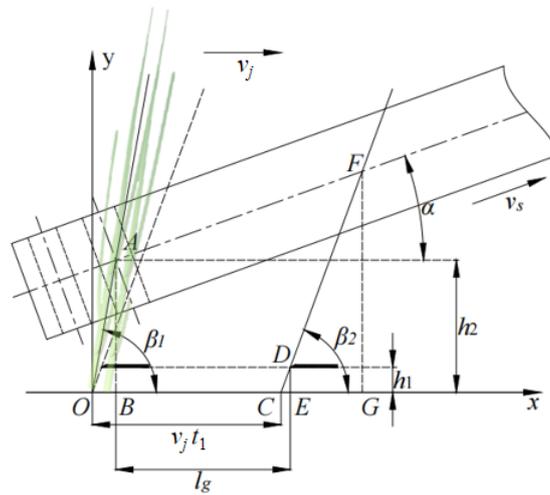

Fig. 8 - Analysis of the clamping-cutting process of leek plants

Since the motion of leek plant is the result of the combined movement of the harvester's forward speed v_j , and the clamping conveying speed v_s , the displacement equation of the clamping point F , during the clamping-cutting stage, relative to the clamping point A , in the clamping-uncut stage, is as follows:

$$\begin{cases} x_F = v_s t_1 \cos \alpha \\ y_F = v_s t_1 \sin \alpha \end{cases} \quad (7)$$

The clamping conveyor belt holds the leek stem at point A . To ensure the stem is securely clamped before cutting, it is necessary to determine the appropriate installation position of the cutting knife:

$$h_2 \cot \beta_1 \leq l_g \quad (8)$$

As shown in Fig. 9, during the clamping-cutting stage, the angle between leek plants and the ground satisfies the following trigonometric relationships in $\triangle CDE$ and $\triangle CFG$:

$$\begin{cases} \tan \beta_2 = \frac{h_1}{l_g + h_2 \cot \beta_1 - v_j t_1} \\ \tan \beta_2 = \frac{h_2 + v_s t_1 \sin \alpha}{h_2 \cot \beta_1 + v_s t_1 \cos \alpha - v_j t_1} \end{cases} \quad (9)$$

According to eq. (9), the angle between the leek plant and the ground in the clamping-cutting stage is:

$$\beta_2 = \arctan \frac{v_s t_1 \sin \alpha + h_2 - h_1}{v_s t_1 \cos \alpha - l_g} \quad (10)$$

According to eq. (10), the main parameters affecting the posture of leek plants during the clamping-cutting process are the linear speed of clamping conveying belt v_s , the height of cutting knife from the ground h_1 , the distance between clamping point A and the front end of the cutting knife l_g , and the angle between clamping conveying belt and horizontal plane α . Among them, the smaller the angle α between the clamping conveying belt and the horizontal plane. The smaller the inclination angle β_2 , the more inclined the clamping position of the clamping conveying belt relative to plant stems, the more unstable the clamping, and the greater the possibility of the clamping stem and leaf damage. If the angle α is too large, it may affect the overall height of the machine and interfere with the harvesting process (Hou et al., 2023). Research on the direction of stalk cutting showed that the cutting resistance and power consumption of skew cutting were reduced by 60% and 30% compared with perpendicular cutting. Using the skew cutting method at small angle to harvest vegetables with high water content such as leek can reduce damage to plants. In this study, the angle between the clamping conveying belt and the horizontal plane $\alpha = 20^\circ$, and the cutting knife installation position $l_g = 10$ mm, so as to ensure that clamping precedes cutting during harvester operation.

Field experiment

The prototype of double-row electric leek harvester was field-tested on July 22, 2024 at Shandong University of Technology in Zibo City, Shandong Province. The experiment equipment included the harvester, tape measure, stopwatch and other tools. The field experiment process is shown in Fig. 9.

Fig. 9 - Process of field experiment

This paper refers to the “Technical Specification for Quality Evaluation of Hand-held Stem and Leafy Vegetable Harvesters” (Ministry, 2020) and “Leafy Vegetable Harvesters” (Ministry, 2024), and related literature (Zhang *et al.*, 2022b; Kang *et al.*, 2020). Operation damage rate Z_s were used as performance evaluation experiment indexes of double-row electric leek harvester. The calculation formula is as follows:

$$Z_s = \frac{S_s}{S_j} \times 100\% \quad (11)$$

where: Z_s is the operation damage rate, %; S_s is the number of damaged leek plants; S_j is the number of effective clamping conveying leek plants.

According to preliminary experiments and theoretical analysis, machine's forward speed v_j , cutting speed v_g and conveying belt speed v_s , which affect operation damage rate, are selected as experimental factors. The experimental factors and levels are shown in Table 2.

Table 2

Experimental factors and levels				
Level	Machine's forward speed v_j (m/s)	Cutting speed v_g (m/s)	Conveying belt speed v_s (m/s)	
1	0.35	0.77	0.49	
0	0.3	0.66	0.42	
-1	0.25	0.55	0.35	

RESULTS

Design-Expert software was used to conduct a secondary rotary combination design experiment on the experimental data. The experimental schemes and results are shown in Table 3.

The experimental results were analyzed using Design-Expert software. The significance of the regression equation model was verified through analysis of variance and regression coefficient experiments. The results are presented in Table 4.

Table 4

Variance analysis of damage rate					
Source	Sum of Squares	Degree of freedom	Mean Square	F-value	p-value
Model	0.1251	9	0.0139	29.9	< 0.0001
v_j	0.0496	1	0.0496	106.69	< 0.0001
v_g	0.0013	1	0.0013	2.69	0.1451
v_s	0.001	1	0.001	2.18	0.1836
$v_j v_g$	0.0004	1	0.0004	0.8602	0.3845
$v_j v_s$	0.0006	1	0.0006	1.34	0.2843
$v_g v_s$	0	1	0	0	1

Residual	0.0033	7	0.0005		
Lack of Fit	0.0006	3	0.0002	0.2861	0.8341
Pure Error	0.0027	4	0.0007		
Cor Total	0.1284	16			

According to Table 4, the regression equation for the damage rate Z_s was obtained by excluding the insignificant terms from the regression equation.

$$Z_s = 12.776 - 17.265v_j + 26.9v_j^2 + 5.764v_g^2 + 15.765v_s^2 \quad (12)$$

The interaction between any two factors and their effect on Z_s was analyzed by fitting the response surface, with any factor in eq. (12) set to the zero level, as shown in Figure 8.

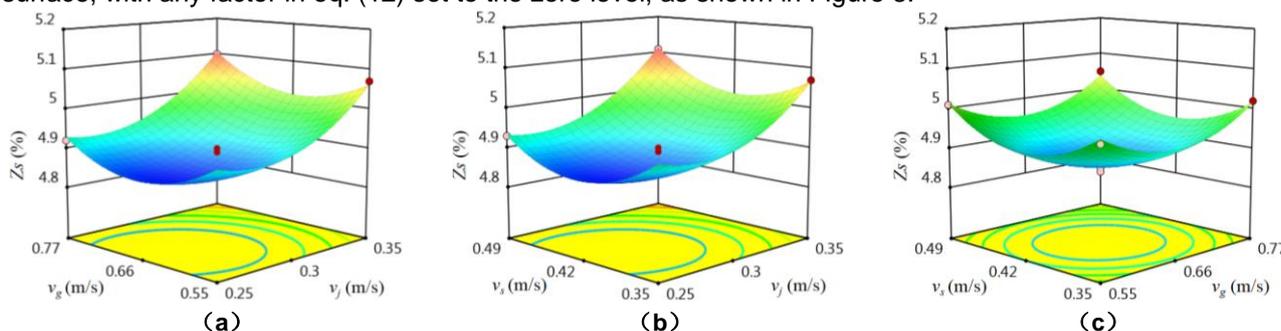

Fig. 8 - Response surfaces effect of factor interaction on experiment indicators

As shown in the response surface in Fig. 8, the factors affecting the operation damage rate from the largest to the smallest are machine's forward speed, cutting speed and conveying belt speed.

The Design-Expert software regression equation model was used to find the optimal parameters for the experiment impact factors: v_j at 0.3 m/s, v_g at 0.66 m/s, and v_s at 0.42 m/s. Under the optimal combination of parameters, the minimum operation damage rate Z_s was 4.84%.

The average operating damage rate was 4.87%, less than 5%, which meets the design requirements. The damage was mainly due to the tearing and breakage of the stubble, and the crushing damage caused by the plants detaching from the clamping conveying device at the end of the clamping conveying.

CONCLUSIONS

(1) Based on the agronomic and mechanized harvesting requirements of leek cultivation, a double-row electric leek harvester was developed. The machine primarily consists of travel, cutting, dividing, clamping, and conveying devices. It is capable of performing cutting, conveying, and collecting operations in a single pass, thereby reducing labor intensity and significantly improving harvesting efficiency.

(2) A clamping conveying device was designed, and the working conditions required to prevent leek plants from falling, clogging, or being crushed during the clamping and conveying process were analyzed. Based on this analysis, the structural parameters and conveying speed of the device were determined.

(3) A kinematic model of the single-acting reciprocating cutting device was established, and the structural parameters of the cutting mechanism were determined. The critical conditions required for smooth and complete cutting without omissions were analyzed, leading to the determination of the optimal working parameters for the cutting device.

(4) A field experiment and performance testing method were proposed, and the field experiment was successfully conducted. During both the harvesting operation and transfer process, the harvester met the operational and mobility requirements, demonstrating good power performance and passing ability. The results of the field experiment showed that the average operational damage rate was 4.87%, meeting the actual production and mechanized harvesting requirements for leek crops.

In view of the problems of low efficiency, poor crushing quality and inapplicability to high water content forage, the cutter and crusher rotor of hammer type forage grinder was designed, the cutter and crusher process was analyzed theoretically, and the parameters of cutter and crusher rotor were determined. The modal analysis of the cutting and crushing rotor was carried out by ANSYS Workbench, to verify the rationality of the rotor structure. The alfalfa with water content of 65% was taken as the processing object, and the quadratic orthogonal rotation combination test was carried out with the output speed of motor, sieve diameter and feeding amount as the test factors, and the productivity and silking rate as the evaluation indexes. Through the analysis of variance and target optimization of the test results by Design-Expert 12.0 software, the regression equation between the test factors and the evaluation index was obtained. With the goal of maximizing the productivity and silking rate at the same time, the output speed of the motor, the diameter of the sieve and the feeding amount were solved by multi-objective optimization, and the optimal parameter combination was determined as follows: the output speed of the motor is 443.77r/min, the diameter of the sieve is 14mm, and the feeding amount is 1.27kg/s. The verification test shows that the productivity is 5065.98 kg/h, and the silk rates is 94.87%. The device has high crushing efficiency, good quality, and can crush high water content forage, which meets the design requirements of forage mill.

摘要

针对现有的牧草粉碎机效率低、粉碎质量差、对高含水率牧草不适用等问题,对锤片式牧草粉碎机的铡切和粉碎转子进行了创新设计,对铡切和粉碎过程进行了理论分析,确定了铡切和粉碎转子的参数。利用 ANSYS Workbench 对铡切和粉碎转子进行了模态分析,验证转子结构的合理性。将含水率为65%的苜蓿作为加工对象,进行了以电机输出转速、筛孔直径、喂入量为试验因素,以生产率和丝化率为评价指标的二次正交旋转组合试验。通过 Design-Expert 12.0 软件对试验结果进行了方差分析及目标优化,得到了试验因素与评价指标之间的回归方程,以生产率和丝化率同时最大化为目标,对电机输出转速、筛孔直径、喂入量进行多目标寻优求解,确定最优参数组合为:电机输出转速 443.77r/min、筛孔直径 14mm、喂入量 1.27kg/s,验证试验表明,生产率为 5065.98kg/h、丝化率为 94.87%;该装置粉碎效率高、质量好,而且能够粉碎高含水率牧草,满足牧草粉碎机设计要求。

INTRODUCTION

As one of the important links of grass processing, crushing quality has an important impact on processing cost and livestock digestion effect (Wu et al., 2022; Wang et al., 2017). Crushing is to cut off the grass and expose its internal nutrients, which can not only improve palatability, but also increase the contact area with the stomach juice of livestock, shorten the rumination and chewing time, and reduce the energy consumed by the chewing of livestock. The crushed grass is easy to chew and has a good taste, which promotes the absorption of nutrients by livestock (Fang et al., 2021; Huan et al., 2021). The length of forage required by ruminants is 30~50mm, and crushing too long or too short is not conducive to digestion and absorption. In order to prevent too short after stirring cutting, the length of the crushed grass should be 50~70mm (Fan et al., 2021; Zheng et al., 2016; Li et al., 2019).

¹⁾Tao Chen, Ph.D.; Shu-juan Yi, Prof. Ph.D.; Song Wang, Ph.D.; Wen-sheng Sun, Ph.D.;

Grass processing can be divided into shredding processing, crushing processing and kneading processing according to the crushing form, and the corresponding models are guilloff type mill, hammer type mill, kneading type mill, etc. (Zhang *et al.*, 2024; Liu *et al.*, 2019). The cut type crusher breaks the grass by cutting, although it has the advantages of simple structure, low power consumption and high productivity, but the processed broken grass is mostly round rod, and there are hard joints, which will lead to indigestion and palatability of livestock, which is not conducive to digestion and absorption of livestock (Jiang *et al.*, 2019). Hammer mill first crushed the grass to a certain extent through the impact of the hammer, and then the grass was thrown to the kneading board and sieve plate at a faster speed in the crushing room, which was further crushed by the collision of the kneading board and the rubbing of the sieve plate. The crushing efficiency was high and the adaptability was wide, but the crushed grass was too fine, which could not make its fiber better retained. As a result, it has a low volume and cannot be stored for a long time (Liu *et al.*, 2011). Under the kneading action of the high-speed rotating hammer and tooth plate, the crushed grass is broken into soft and fluffy filamentous segments, exposing nutrients, increasing the contact area with the digestive system of livestock, and promoting digestion and absorption (Ma *et al.*, 2016).

In terms of forage processing machinery, foreign countries have complete types, relatively perfect functions and mature technologies, but they are mainly used in large-scale farmland and pasture, and are not suitable for the miniaturization and convenience of forage processing machinery in small-scale breeding areas in China. Domestic scholars have been committed to the research of grass processing machinery, more and more new models continue to emerge. Wang Defu *et al.*, (2017), used high-speed camera technology to analyze the crushing mechanism of the hammer mill, and conducted experimental research on crushing performance. They found that the crushing forms of the hammer mill were mainly percussion crushing, impact crushing and rubbing crushing, and the impact crushing and rubbing crushing had a greater impact in the crushing process. It is concluded that the linear speed of the end of the hammer and the water content of the material have great influence on the crushing effect of the hammer mill. Wang Tiejun *et al.* (2021), designed a feeding-adjustable straw breaking and kneading machine to solve the problem that the existing machine could not adapt to the whole bundle manually packed and the small square bundle mechanically pressed corn straw simultaneously. Through the analysis of the force and movement of straw in each device of the machine, the key structure of the whole machine is designed and matched with the drive system, and the kneading performance test is carried out to realize the localized kneading treatment of scattered bale straw in the village. You Yong *et al.* (2021) designed a 4-row herringbone roller crushing device based on the agronomic requirements of king grass harvester crushing, combined with the characteristics of strong tillering ability, large biomass and high-water content of king grass. The main structure and parameters of the crushing device are determined by theoretical analysis and calculation. The test shows that the length of the king grass broken by the device is uniform and the qualified rate of the stalk broken is high, which can meet the requirements of the king grass broken during the harvest period. Although after years of painstaking research by many scholars, the kneading quality of forage grass has been improved to a certain length, due to the strong toughness of forage grass with high moisture content, the force required when it is broken by blows and other effects is greater, and the whole forage grass is easy to wrap around the rotor when it is crushed, causing blockage. Therefore, the existing grinding machine still has some problems, such as low efficiency, poor kneading quality, and not suitable for forage with large moisture content.

In this paper, taking alfalfa as the processing object, the cutting and crushing rotors of hammer forage crusher are innovated. The forage is cut before it is crushed, and it is cut into small segments of certain length by means of cutting rotor. Thus, the crushing quality and production efficiency can be improved, and the high-water content forage can be crushed.

MATERIALS AND METHODS

Structure and working principle

The cutting and crushing combined grass crusher is mainly composed of motor, frame, conveying mechanism, feeding mechanism, cutting mechanism, crushing mechanism, screening mechanism, transmission system and other parts. The structure is shown in Fig.1.

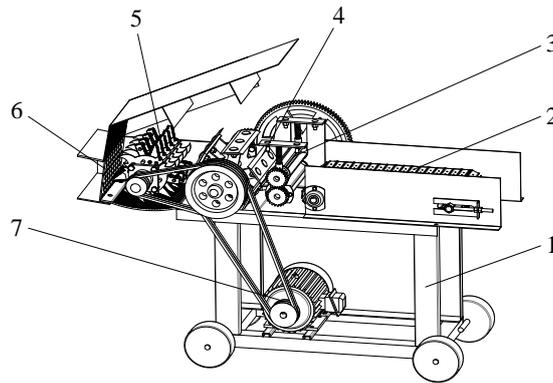

Fig.1 - Structure diagram of cutting and crushing cooperative grass crusher

1. Frame; 2. Conveying mechanism; 3. Feeding mechanism; 4. Cutting mechanism; 5. Crushing mechanism; 6. Sieve plate; 7. Motor

During operation, the whole grass is transported to the feeding mechanism through the conveying mechanism, and the feeding mechanism evenly feeds the grass into the cutting room to complete the feeding. The cutting mechanism breaks the grass into small segments of a certain length to complete the cutting. The crushing mechanism breaks the cut grass into filaments and completes the crushing. The crushed grass that meets the crushing length is thrown to the outside of the body through the screen plate through the dual action of the air flow generated by the rotation of the crushing rotor and the centrifugal force to complete the screening and throwing.

Force analysis and mechanism design of alfalfa during cutting process

The force analysis of alfalfa during cutting process is shown in Fig.2.

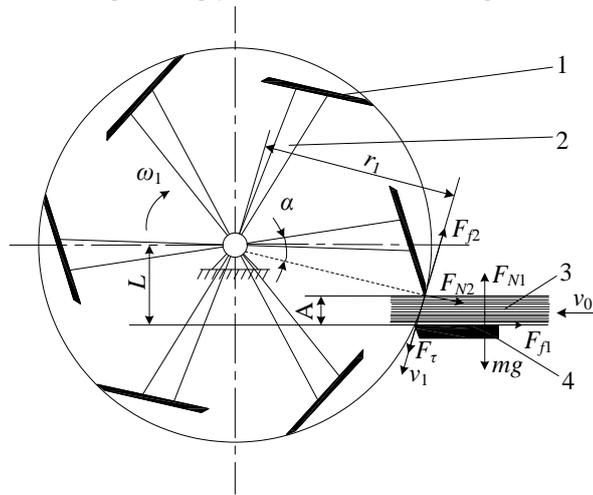

Fig. 2 - Analysis of the force and motion of alfalfa during the cutting process

1. Moving cutter; 2. Knife holder; 3. Alfalfa; 4. Fixed cutter

According to the cutting effect of moving and fixed knives on alfalfa, and the analysis of the force and movement of alfalfa in the process of cutting, the necessary conditions for cutting alfalfa are obtained:

$$F_{\tau} \sin \alpha \geq F_{f1} + F_{f2} \sin \alpha + F_{N2} \cos \alpha \tag{1}$$

It can be seen from Fig.2 that:

$$mg + F_{\tau} \cos \alpha + F_{N2} \sin \alpha = F_{N1} + F_{f2} \cos \alpha \tag{2}$$

$$F_{f1} = \mu_1 F_{N1} \tag{3}$$

$$F_{f2} = \mu_2 F_{N2} \tag{4}$$

where: α is the sliding cutting angle, ($^{\circ}$); m is alfalfa mass, kg; g is acceleration of gravity, m/s^2 ; F_{τ} is the cutting force of cutter on alfalfa, N; F_{N1} is the supporting force of cutter on alfalfa, N; F_{N2} is the positive pressure of a cutter on alfalfa, N; F_{f1} is the friction of cutter against alfalfa, N; F_{f2} is cutter friction on alfalfa, N; μ_1 is the friction factor between alfalfa and moving cutter; μ_2 is the friction factor between alfalfa and fixed cutter.

In this study, the design of the moving cutter and fixed cutter use the same material, the alfalfa and their friction factors are the same, that is, $\mu_1=\mu_2=\mu$, the joint vertical (1) ~ (4) can be obtained:

$$\mu + \frac{F_{N2} \cos(2\alpha) + mg \sin \alpha}{F_{N1} \cos \alpha} \leq \tan \alpha \tag{5}$$

$$\frac{F_{N2} \cos(2\alpha) + mg \sin \alpha}{F_{N1} \cos \alpha} \geq 0 \tag{6}$$

If formula (5) is established, the tangent value of alfalfa friction angle $\tan \varphi \leq \tan \alpha$ can be obtained, and the friction angle of alfalfa is generally $\varphi=24^\circ\sim 32^\circ$ (Chen et al., 2023), that is, $\alpha \geq 32^\circ$.

In order to facilitate the balanced sliding of alfalfa and reduce power consumption, the cutter should be inclined to install, but the inclination angle is too large to affect the dynamic balance and vibration, so the sliding angle is designed to be 32° , the circumferential interval of 60° is arranged with 1 blade cutter, the cutter shaft is arranged with 6 blades, guilloff cutter structure is shown in Fig.3.

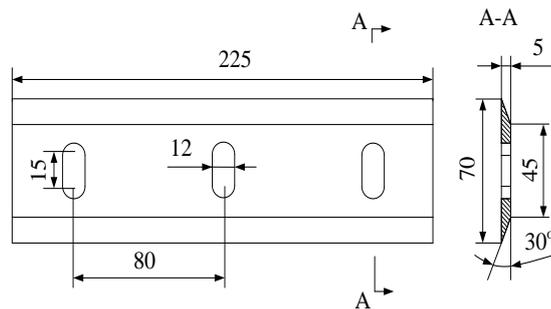

Fig. 3 - Structure diagram of the moving cutter

Force analysis and mechanism design of alfalfa in crushing process

The forces in alfalfa crushing process are shown in Fig.4.

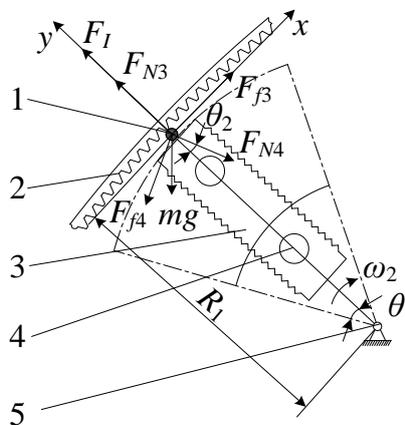

Fig. 4 - Stress Analysis of Alfalfa Silk Rolling Process
1. Alfalfa; 2. Kneading board; 3. Hammer; 4. Pin; 5. Crushing shaft

According to D 'Alembert's principle, alfalfa should meet the equilibrium state at the moment of crushing, and the equilibrium equation is established:

$$\begin{cases} \sum F_x = F_{f3} + F_{N4} \sin \theta_2 - F_{f4} \cos \theta_2 - mg \cos \theta_1 = 0 \\ \sum F_y = F_1 + F_{N3} - F_{N4} \cos \theta_2 - F_{f4} \sin \theta_2 - mg \sin \theta_1 = 0 \end{cases} \tag{6}$$

$$F_1 = m\omega_2^2 R_1 \tag{7}$$

$$F_{f3} = \mu_3 F_{N3} \tag{8}$$

$$F_{f4} = \mu_4 F_{N4} \tag{9}$$

Equations (6) ~ (9) can be obtained simultaneously:

$$\left\{ \begin{aligned} F_{f3} &= mg \cos \theta_1 + \left\{ \left[\mu_3 m \omega_2^2 R_1 + mg (\cos \theta_1 - \mu_3 \sin \theta_1) \right] \right. \\ &\quad \left. (\mu_4 \cos \theta_2 - \sin \theta_2) [(1 + \mu_3 \mu_4) \sin \theta_2 + (\mu_3 - \mu_4) \cos \theta_2]^{-1} \right\} \\ F_{f4} &= \mu_4 \frac{\mu_3 m \omega_2^2 R_1 + mg (\cos \theta_1 - \mu_3 \sin \theta_1)}{(1 + \mu_3 \mu_4) \sin \theta_2 + (\mu_3 - \mu_4) \cos \theta_2} \end{aligned} \right. \quad (10)$$

where:

ω_2 is the hammer angular velocity, rad/s; θ_1 - the horizontal angle between the alfalfa segment and the axis of the crushing shaft, ($^\circ$); θ_2 - the angle between the alfalfa segment and the axis of the kneading shaft and the direction of the kneading board's supporting force on the alfalfa, ($^\circ$); F_I - the centrifugal force in alfalfa section, N; F_{N3} - the supporting force of the hammer on alfalfa segment, N; F_{N4} - the support force of knead board on alfalfa segment, N; F_{f3} - the friction force of hammer against alfalfa segment, N; F_{f4} - friction force of kneading board on alfalfa segment, N; R_1 - alfalfa section turning radius, mm; μ_3 - friction factor between alfalfa segment and hammer piece; μ_4 - friction factor between alfalfa segment and kneading board.

Formula (10) shows that the friction force F_{f3} and F_{f4} during the grinding of alfalfa are related to the friction factor, position and angular velocity, etc. The trapezoidal teeth on the surface of the kneading plate near the hammer can increase the friction factor. The angular speed of the hammer is directly determined by the speed of the grinding shaft. When the machine power and transmission ratio are constant, the speed of the grinding shaft is mainly affected by the output speed of the motor. In order to clarify the influence of the output speed of the motor on the grinding effect of alfalfa, this paper optimizes it through experiments.

The hammer is designed as a rectangular zigzag shape, which increases the friction between the hammer and the material while striking and crushing the alfalfa, and can also produce better sliding and stabbing effects. The serrated knife is hexagonal, and the cutting edges on both sides of the knife are made into serrated edges to improve the strength and wear resistance of the blade. The structure of the hammer and serrated knife is shown in Fig.5.

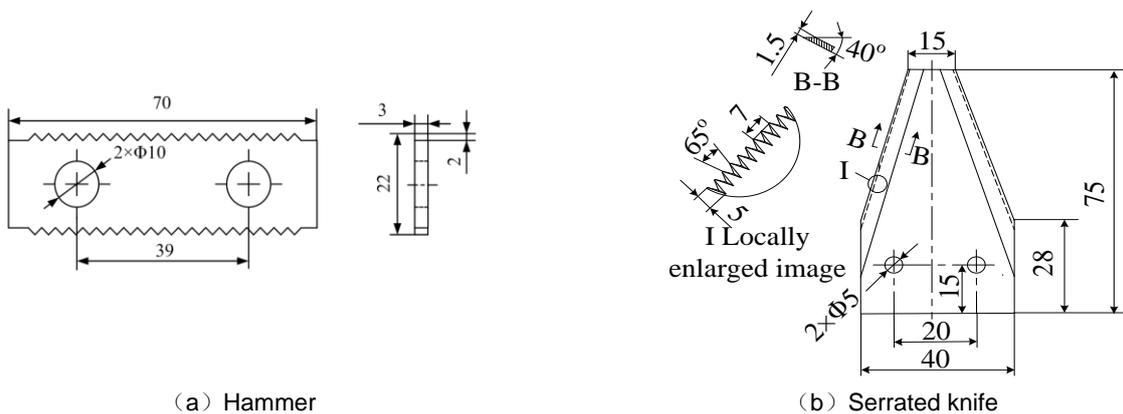

Fig. 5 - Structure diagram of hammer and serrated knife

Modal analysis

ANSYS Workbench software is used to analyze the mode of the cutting rotor and crushing rotor of the grinder, analyze its vibration characteristics and deformation, and ensure its reliability in the working process.

The modal analysis results of the cutting rotor are shown in Table 1 and Fig. 6.

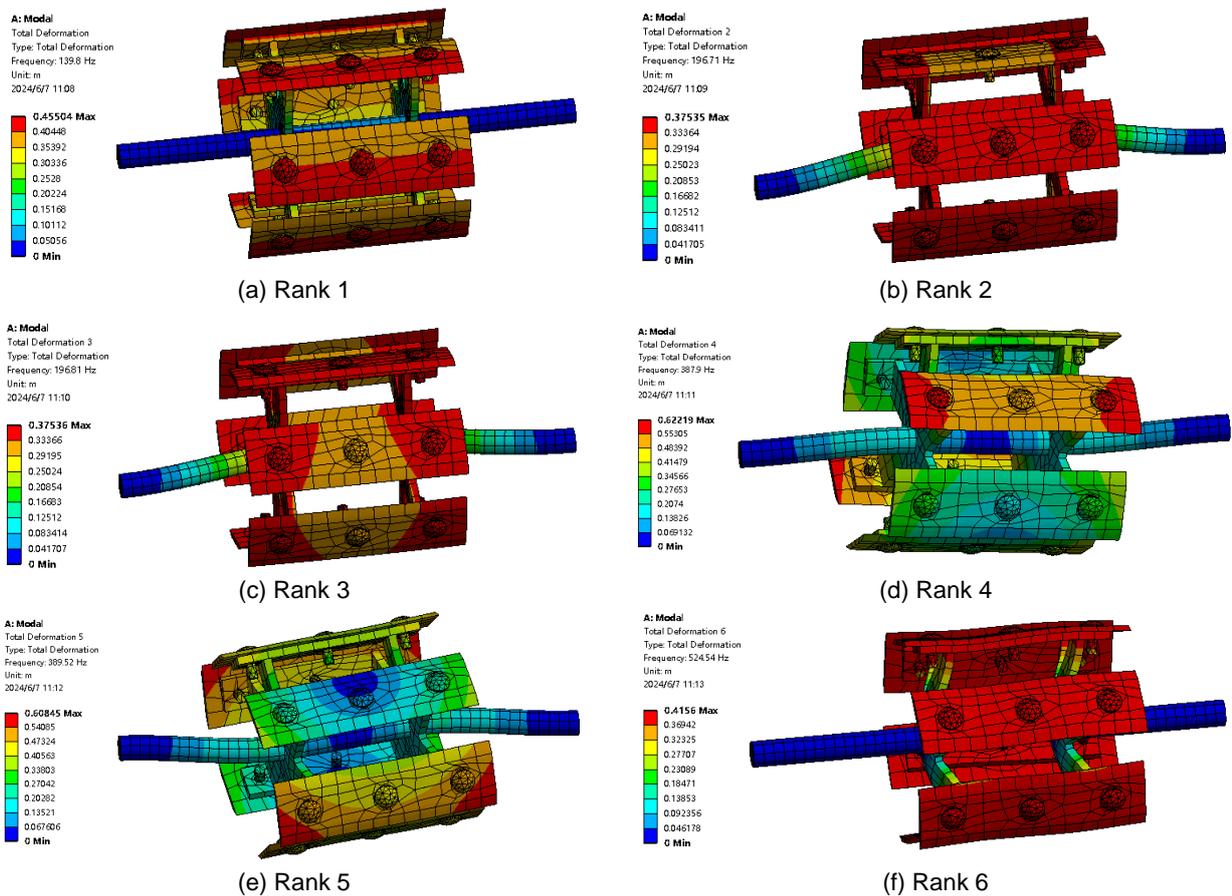

Fig. 6 - Cloud image of the first 6 modes of the cutting rotor

As can be seen from the Fig.6, the first-order vibration mode is represented by the deformation of the working edge surface of the cutter. The second order mode mainly shows the overall deformation of the rotor. The third order mode is mainly characterized by cutting tool deformation. The 4th-order mode mainly shows the deformation of cutting tool and tool holder. The 5th order mode is mainly tangential bending deformation. The 6th-order mode mainly shows the deformation of cutting tool and tool holder.

Table 1

Results of the first six modes of cutting rotor

Order	Intrinsic frequency/Hz	Maximum deformation/m	Main vibration mode
1	139.8	0.46	The working edge surface of the cutter is deformed
2	196.71	0.38	Integral rotor deformation
3	196.81	0.38	Cutter deformation
4	387.9	0.62	The cutter and tool holder are deformed
5	389.52	0.61	The cutting shaft is bent and deformed
6	524.54	0.42	The cutter and tool holder are deformed

In the process of rotor rotation, the excitation source mainly comes from self-rotation excitation. When the excitation frequency exceeds the natural frequency, the total performance of the rotor will have the risk of failure. The relation between the rotational speed of rotor and excitation frequency is

$$n = 60f \tag{11}$$

where: n is rotor assembly speed, r/min; f is rotary excitation frequency, Hz

The maximum working speed of the cutting rotor is 300r/min, and the maximum rotation excitation can be calculated to be 5Hz. Lower than the first order natural frequency 139.8Hz. Therefore, the designed cutter rotor can effectively avoid resonance phenomenon during high-speed rotation.

The modal analysis results of the crushed rotor are shown in Table 2 and Fig. 7.

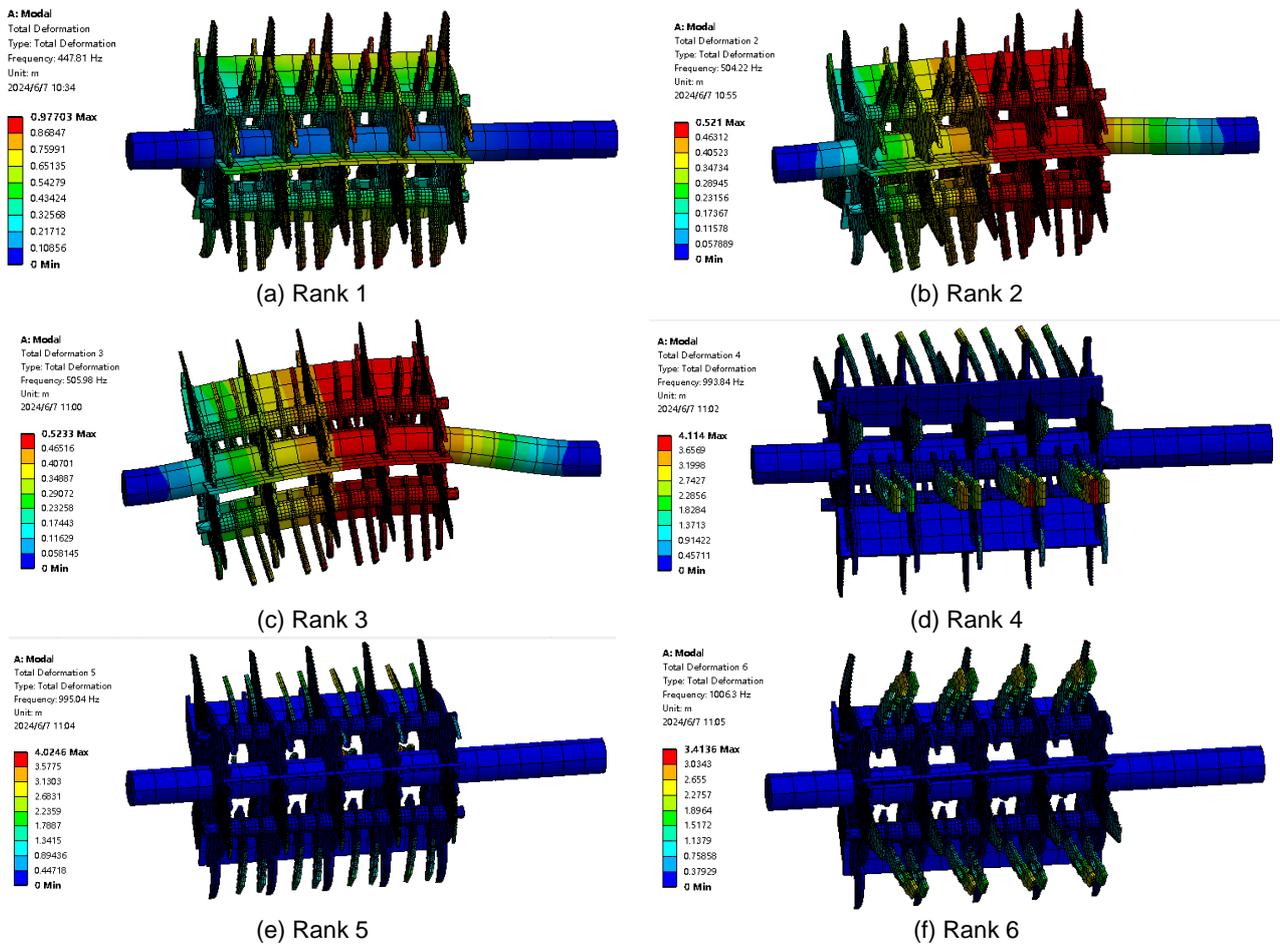

Fig. 7 - Cloud diagram of the first 6 orders of modal shapes of the crushing rotor

As can be seen from the Fig.7, the first-order vibration mode is manifested as the deformation of the outer edge of the hammer plate and the hammer frame plate. The second order mode mainly shows the deformation of rotor end and serrated knife. In the third order mode, the rotor is deformed as a whole. The fourth order vibration mode is mainly hammer deformation. The 5th order vibration mode is mainly hammer deformation. The 6-order vibration mode is mainly the hammer and serrated knife deformation.

Table 2

Results of the first 6 modes analysis of the crushed rotor			
Order	Intrinsic frequency/Hz	Maximum deformation/m	Main vibration mode
1	447.81	0.97	The edge of the hammer plate and the hammer frame plate is deformed
2	504.22	0.52	The rotor end and serrated knife are deformed
3	505.98	0.52	Integral rotor deformation
4	993.84	4.11	Hammer deformation
5	995.04	4.02	Hammer deformation
6	1006.3	3.41	Hammer and serrated knife deformed

The maximum rotational speed designed for the grinding rotor is 800r/min, and the maximum rotational excitation calculated by formula (11) is 13.33Hz. Lower than the first order natural frequency 447.81Hz. Therefore, the designed grinding rotor can effectively avoid resonance during high-speed rotation.

RESULTS AND DISCUSSIONS

The design of the kneading machine prototype was made and the performance test was carried out. Alfalfa was processed and collected at the dry grass planting base in Duerbert County, Daqing City, Heilongjiang Province. The alfalfa collected was free of diseases, pests and obvious mechanical damage. The average moisture content of alfalfa was determined by random sampling to be 65%. The test was carried out in the crop harvest Laboratory of Heilongjiang Bayi Agricultural University, as shown in Fig.8.

Fig. 8 - Test bench for cutting and crushing cooperative silk kneading machine

1. Crusher; 2. Feed conveyor belt

Productivity y_1

The weighed straw was fed, the time required to crush all the straw was recorded, and the productivity y_1 was calculated as:

$$y_1 = \frac{m}{t} \times 3600 \quad (12)$$

where: m is quality of straw for test, kg; t is test time, s.

Silking rate y_2

Samples were collected at the outlet at the same time interval for 3 times, each time no less than 200g. All samples were mixed and weighed. Qualified alfalfa silk was screened and weighed, and the silking rate y_2 was calculated:

$$y_2 = \frac{m_2}{m_0} \times 100\% \quad (13)$$

where: m_2 is quantity of alfalfa silk in sample, g; m_0 is alfalfa sample quality, g

The code of test factors is shown in Table 3, and the test scheme and results are shown in Table 4.

Error	6.72	8	0.84		
Sum total	253.26	22			

As can be seen from Table 3, the productivity regression model ($P < 0.0001$) is significant, while the lack of fit ($P = 0.1936$) is not, indicating that the model has a good degree of fitting and no misfit phenomenon occurs. The determination coefficient $R^2 = 0.9644$, the correction determination coefficient $R_{adj} = 0.9398$, which is very close to 1, and the coefficient of variation is 1.66%, indicating that the test data is reliable. The predicted value of the regression equation has a significant relationship with the actual value obtained through the analysis of the test results. The regression equation of each factor and evaluation index obtained after removing the non-significant item is shown as follows:

$$y_1 = 5115.98 + 76.08x_1 - 167.75x_2 + 51.56x_3 - 61.56x_1x_2 + 67.92x_1x_3 - 10.27x_2x_3 - 284.7x_1^2 - 131.08x_2^2 \quad (14)$$

According to Table 4, the silk rate regression model ($P < 0.0001$) was significant, while the lack of fit ($P = 0.8426$) was not, indicating that the model had a good degree of fitting and no misfit phenomenon occurred. The determination coefficient $R^2 = 0.9670$, the correction determination coefficient $R_{adj} = 0.9441$, which is very close to 1, and the coefficient of variation is 0.85%, indicating that the test data is reliable. The predicted value of the regression equation has a significant relationship with the actual value obtained through the analysis of the test results. The regression equation of each factor and evaluation index obtained after removing the non-significant item is shown as follows:

$$y_2 = 93.66 + 3.31x_1 + 0.47x_2 - 1.75x_3 - 0.85x_1x_2 + 1.45x_1x_3 + 0.91x_2x_3 - 0.72x_1^2 + 0.7x_2^2 + 0.57x_3^2 \quad (15)$$

Parameter optimization and test verification

In order to obtain the optimal parameter combination of the operating performance of the kneading machine, the multi-objective optimization algorithm in the Design-Expert 12.0 software was used to establish an optimization mathematical model with the maximum productivity and maximum silking rate as optimization objectives, as shown in Equation (16).

$$\left\{ \begin{array}{l} \max y_1(x_1, x_2, x_3) \\ \max y_2(x_1, x_2, x_3) \\ s.t. \left\{ \begin{array}{l} 250r/min \leq x_1 \leq 500r/min \\ 14mm \leq x_2 \leq 20mm \\ 1kg/s \leq x_3 \leq 2kg/s \end{array} \right. \end{array} \right. \quad (16)$$

The optimal parameter combination of the machine is as follows: the output speed of the motor is 443.77 r/min, the diameter of the screen is 14mm, the feeding amount is 1.27kg/s, the predicted productivity is 5078.28kg/h, and the silk rate is 94.93%.

In order to verify the reliability of the optimization results, the output speed of the motor was rounded to 445r/min, the feed volume was rounded to 1.3kg/s, and the screen diameter was selected to 14mm. The optimization results were verified. Each group of tests was repeated five times, and the average value of the five test results was calculated as the actual value of the evaluation index under this condition. The measured productivity is 5065.98kg/h, the silk ratio is 94.87%. The relative errors with the optimization results are 0.24% and 0.06%, respectively, indicating that the established mathematical model and the optimization results are accurate and reliable, and the kneading machine has good working performance.

CONCLUSIONS

(1) The cutting and crushing process of grass crusher was analyzed theoretically, and the key components such as cutting knife, hammer blade and serrated knife were designed. The modal analysis of cutting rotor and crushing rotor was carried out using ANSYS Workbench software, and the first 6 natural frequencies and corresponding vibration modes were obtained. The vibration mode of each order is analyzed in detail to avoid the damage of the whole machine due to the resonance phenomenon in the working process.

(2) Aiming at the simultaneous maximization of productivity and silking rate, the output speed, screen diameter and feeding amount of the motor were optimized by multi-objective solution, and the optimal parameter combination was obtained as follows: output speed of the motor was 443.77 r/min, screen diameter was 14 mm and feeding amount was 1.27 kg/s. The verification test showed that the productivity was 5065.98kg/h and the silking rate was 94.87%, which met the requirements of crushing alfalfa with high water content.

Keywords: Wheat harvester, Seed production and propagation, Cleaning device, Coupled simulation

ABSTRACT

To address the issues of high admixture and loss rates during seed production and harvesting operations with combine harvesters, a low-loss, high-purity cleaning device suitable for wheat seed production and harvesting was designed. Considering the actual conditions of seed production and harvesting operations, the structure and dimensional parameters of key components were optimized. Through theoretical analysis, a motion model of wheat seeds on the cleaning sieve was established, identifying the main factors affecting the cleaning performance as fan speed, sieve amplitude, and vibration frequency. The CFD-DEM coupling method was used to simulate and analyze the sieving process under the influence of airflow within the cleaning chamber. A three-factor, three-level quadratic regression orthogonal combination simulation test was conducted to establish a response surface regression model for the seed admixture rate and the seed loss rate. Multi-objective comprehensive optimization of the factors indicated that the optimal operating parameters of the cleaning device are a fan speed of 1143 rpm an amplitude of 28 mm, and a vibration frequency of 9.4 Hz. Finally, field trial verification was conducted by setting the working parameters based on the coupled simulation test data. The operational results of the optimized cleaning device showed a seed admixture rate of 1.47% and a seed loss rate of 1.07%, with all results meeting the relevant standards. This study can provide valuable theoretical support for the development of wheat seed production and harvesting machines.

摘要

为解决联合收获机在进行制繁种收获作业时混杂率、损失率较高等问题，设计了一款适用于小麦制繁种收获作业的低损高净度清选装置。结合实际制繁种收获作业情况，优化了关键部件的结构及尺寸参数。通过理论分析，建立了小麦种子在清选筛上的运动模型，确定了影响清选效果的主要因素为风机转速、清选筛振幅和振动频率。采用 CFD-DEM 耦合方法对清选室内部气流作用下的筛分过程进行模拟分析，开展了三因素三水平二次回归正交组合仿真试验，建立了种子混杂率和种子损失率的响应面回归模型，对各因素进行多目标综合优化，结果表明：风机转速 1143 rpm、振幅 28 mm、振动频率 9.4 Hz，是清选装置的最优工作参数。最后，以耦合仿真试验数据为基础设置工作参数，进行田间试验验证，优化后的清选装置作业结果为：种子混杂率 1.47 %、种子损失率 1.07 %，结果各项均满足相关标准。本研究可为小麦制繁种收获机的研发提供有价值的理论依据。

INTRODUCTION

Seed multiplication, as a sophisticated integration of breeding technology and propagation techniques, plays an indispensable strategic role in meeting the urgent demands of agricultural production by cultivating high-quality, high-yield seeds. It significantly contributes to enhancing agricultural productivity, ensuring food security, promoting green development, and fostering economic prosperity, thus exerting a profound impact on the sustainable development of global agriculture (Mehta et al., 2019; Török et al., 2019; Krishna et al., 2023).

However, there is currently a severe scarcity of intelligent operational equipment specifically designed for seed multiplication harvesting. This deficiency directly affects the cost and efficiency of seed production, becoming a bottleneck that hinders the rapid development of the seed industry. Compared to field crop harvesting, seed multiplication harvesting faces more complex challenges: factors such as the diversity of

experimental varieties and the close proximity between adjacent seed plots make the process arduous (Lalghorbani *et al.*, 2022; Parihar *et al.*, 2023; Cheli *et al.*, 2024). At present, there is no dedicated machine type for wheat seed multiplication harvesting, and combine harvesters are typically used as substitutes. Although the mechanized operation technology in the wheat industry has matured, it still struggles to meet the stringent requirements of seed multiplication regarding key technical indicators such as loss rate, seed damage rate, and breakage rate, necessitating further optimization and enhancement at critical mechanisms and technical levels.

Delaney *et al.*, (2012), employed the EDEM method to study the impact of particle models on sieving motion, discovering that using single spherical particles in sieving motion simulations is insufficient to accurately simulate the actual flow and separation of non-spherical particles.

Ivan *et al.*, (2015), investigated factors influencing threshing capacity in conventional grain combine harvesters, providing a theoretical foundation for enhancing operational efficiency.

Buryanov *et al.*, (2019), designed a threshing device with adjustable concave spacing, effectively reducing loads on blowers and cleaning sieves.

Hevko *et al.*, (2019), established a mathematical model for the cleaning and conveying system of root/tuber crops, offering theoretical guidance for cleaner design.

Safranyik *et al.*, (2019), investigated the movement patterns of spherical particles during the cleaning process and determined the optimal operating parameters of the cleaning sieve using analytical methods, while also employing DEM to analyze the impact of interactions among multiple particles moving on the sieve surface.

Mircea *et al.*, (2020), developed an internal helical coil to optimize cyclone separator performance in cleaning systems.

Vlăduț *et al.*, (2022), proposed a mathematical model describing threshing-separation processes in axial-flow threshers, establishing theoretical principles for device design and optimization.

Vlăduț *et al.*, (2023), determined optimal operating parameters for cleaning-threshing systems during harvesting by analyzing key influencing factors.

Marin *et al.*, (2023), evaluated the impact of primary vibration sources in grain harvesters on operators, delivering theoretical insights for machine design refinement.

Wang *et al.*, (2024), adopted a CFD-DEM coupling approach to simulate operations under different field conditions, analyzing how various design parameters affect operational outcomes. They then validated their findings through experiments, thereby determining the optimal design scheme for a new type of wheat harvester.

This paper is based on the study of grain combine harvesters and addresses the issues of high seed contamination and loss rates during seed multiplication operations. It proposes a cleaning device specifically suitable for seed multiplication harvesting. Through an integrated method combining coupled simulation and field experiments, the key structures and parameters of the cleaning device are optimized, aiming to provide valuable insights for the research of cleaning devices in wheat seed multiplication harvesters.

MATERIAL AND METHODS

OVERALL STRUCTURE DESIGN OF THE CLEANING DEVICE

The use of conventional grain combine harvester cleaning devices results in a high residue of seeds, which easily leads to the mixing of different seed varieties, making it difficult to meet the requirements for seed multiplication. Traditional centrifugal fans tend to cause material accumulation in front of the sieve area, and when the wind speed is high, the loss rate increases; conversely, when the wind speed is low, the residue amount is substantial. To enhance cleaning efficiency and achieve the expected targets for seed multiplication harvesting, a cleaning device suitable for wheat seed multiplication harvesting has been designed, as shown in the figure 1.

The main functional components of the cleaning device include a centrifugal fan, cleaning sieve, shaking plate, and auger. During operation, the wheat threshed mixture falls through the concave sieve of the drum onto the shaking plate and cleaning sieve. Under the impetus of the centrifugal fan, the material becomes fluidized. Light impurities such as bran and short stalks are directly expelled from the cleaning chamber by the fan. Stalks are discharged from the debris outlet through the reciprocating motion of the fan and cleaning sieve. The wheat grains fall into the grain collection auger, while a small portion of the inadequately cleaned threshed mixture undergoes secondary cleaning through the debris auger.

DESIGN OF KEY COMPONENTS OF THE CLEANING DEVICE

Design of Dual Air Duct Centrifugal Fan

As the core component of the pneumatic conveying system, the performance of the fan affects the operational efficiency of the machine. Most grain combine harvesters use single-outlet centrifugal fans, which are characterized by simple structure, easy installation, and high wind pressure, performing well in high-resistance environments. However, existing research indicates that during wheat mechanical harvesting, the threshed mixture is unevenly distributed on the sieve surface, exhibiting a “V” shape with thicker material at the front and thinner at the back, as well as more material on the sides than in the center (Li et al., 2012; Fu et al., 2024) This suggests that the airflow of single-outlet centrifugal fans has coverage blind spots, making it difficult to cover the entire sieve surface, which is unfavorable for cleaning operations. Therefore, it is necessary to design a centrifugal fan suitable for seed breeding harvesting, taking into account the characteristics of seed breeding harvesting and the distribution pattern of the wheat threshed mixture, to achieve the desired objectives.

Design of Radial Dual-Fan Impeller

The impeller is the core component of a centrifugal fan, and its rotation drives the airflow throughout the cleaning chamber. Therefore, its structural and dimensional parameters have a decisive impact on the performance of the fan. Impellers can be classified into forward, radial, and backward types based on the blade exit angle. To meet the operational requirements of seed breeding harvesting, a radial blade dual-fan impeller has been designed. The main design parameters of the impeller include the outer diameter D_1 , inner diameter D_2 , blade length B , blade thickness t , and the number of blades. The structure and main parameters of the fan impeller are shown in the figure 2.

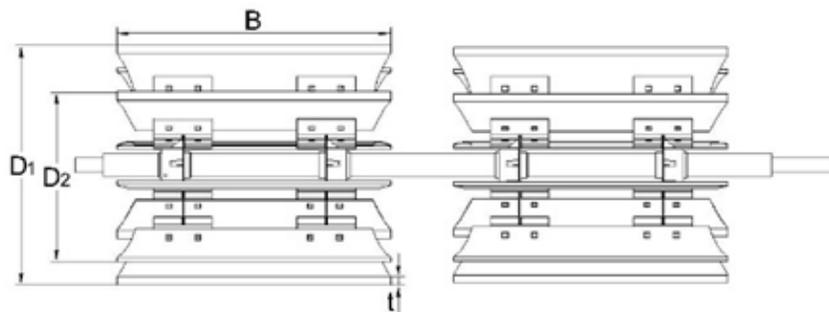

Fig. 2 – Fan Impeller Mode

Table 1

Fan Impeller Structural Parameters	
Parameter	Numerical value
Impeller diameter D_1 (mm)	400
Inner diameter of impeller D_2 (mm)	288
Blade length B (mm)	470
Blade thickness t (mm)	2
Blade quantity	8

Design of Blade Airfoil

The seed breeding and harvesting process is characterized by “tight schedules, heavy tasks, and high demands.” The fan in the cleaning system, which is responsible for sorting the mixture after threshing, must maintain stable operation for extended periods during the seed breeding and harvesting season. However, traditional straight blade designs often lead to unstable airflow separation and additional energy loss, directly resulting in decreased fan efficiency. To address this challenge, it is necessary to improve and upgrade the structural parameters of the fan blades (Zhang *et al.*, 2023). First, the blade bending angle should be adjusted. By utilizing fluid dynamics simulations and digital calculations, the optimal blade bending angle can be identified to ensure that airflow adheres more closely to the blade contour, thereby reducing flow separation and turbulence losses. Secondly, the leading edge of the blade has been modified to have a blunt angle. By optimizing the width ratio of the blade’s leading edge, pressure concentration is improved, and by adjusting the curvature of the blade’s leading edge to form a longer contraction passage, the range of efficient operating conditions for the blade is further expanded while ensuring stable operation under high-intensity conditions.

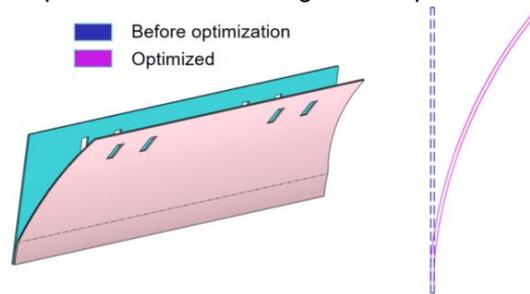

Fig. 3 – Comparison of Airfoil Before and After Optimization

Design of Fan Scroll Casing

The fan scroll casing serves the purpose of collecting and directing the accelerated airflow from the impeller, aiding in the circulation of airflow within the fan and converting part of the kinetic energy into static pressure energy. Due to the complex three-dimensional flow of gases inside a centrifugal fan, the scroll casing is filled with vortex structures of varying scales and intensities. Therefore, the scroll casing’s profile not only determines the guidance of airflow but also affects the flow loss within the fan, directly impacting the aerodynamic performance, output airflow, and pressure parameters of the entire fan. Currently, two widely used scroll profiles are the logarithmic spiral and the Archimedean spiral. The centrifugal fan scroll designed in this study is based on the Archimedean spiral, characterized by a smoothly curved equidistant spiral, which suppresses the formation of vortex regions within the scroll passage while maximizing airflow along the spiral. The main parameter calculations are shown in the table below, according to the Agricultural Machinery Design Manual:

Table 2

Fan Scroll Structural Parameters	
Parameter	Numerical value
Lower air outlet height L_1 (mm)	258
Upper air outlet height L_2 (mm)	84
Vertical distance H (mm)	186
Thread extension dimensions A	100
$R_1 = D_1/2 + (2/5)A$	240
$R_2 = D_1/2 + (9/10)A$	290
$R_3 = D_1/2 + (3/10)A$	230
$R_4 = D_1/2 + A/2$	250
$R_5 = D_1/2 + (4/5)A$	280

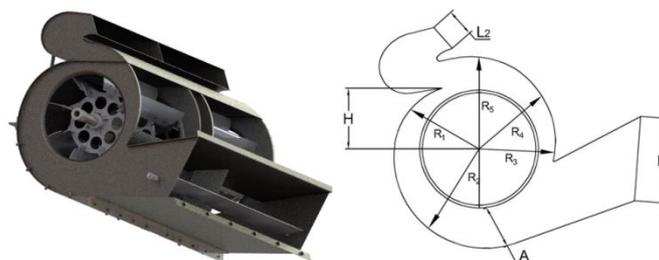

Fig. 4 – Fan Scroll Model

Design of Cleaning Sieve

As the core component of the cleaning device, the cleaning sieve plays a decisive role in the stratification and conveying movements of materials on the sieve surface. According to the shape and structure of the screen, cleaning sieves can be categorized into fish scale sieves, perforated sieves, bar sieves, etc. Among them, perforated sieves are mostly used for fine screening of small particles; bar sieves tend to experience hole blockage and beam fracture under high-intensity conditions; whereas fish scale sieves are composed of curved fish scale sieve plates with adjustable openings according to actual working conditions. They have a strong capability to convey residues without clogging easily, and the airflow on the sieve surface is uniform, which can meet the requirements of complex working conditions during seed production and harvesting.

Fig. 5 – Schematic Diagram of Cleaning Sieve

In cleaning operations, the mesh size is related to the feed rate. Referring to the "Agricultural Machinery Design Handbook," the formula for calculating the total length L of the sieve is:

$$L = \frac{F_z}{WF_s} \quad (1)$$

In the formula: F_z is the Machine feed rate; W is the Screen surface width; F_s is the feed rate that can be handled per unit area of the sieve.

Based on the actual feed rate and the actual grain quality on the sieve surface during the seed production and harvest process, the value of F_z is 4 kg/s, and the value of F_s is 2.4 kg/(s·m²). Considering the combination of the cleaning device with the frame and the single longitudinal axial flow drum threshing device, the sieve width is 1200 mm. Substituting these into the formula yields a value of L being 1390 mm. Taking into account that the mass of the material entering the cleaning device is approximately half of the drum's feed rate, the design of the cleaning sieve meets agronomic requirements.

Design of Eccentric Linkage Mechanism

The cleaning sieve achieves material stratification and movement towards the outlet through sieving motion. The specific motion process involves a deep groove ball bearing with an eccentric sleeve, which is positioned on the drive shaft using a shaft elastic retaining ring. The lower side of the connecting rod is fitted onto the deep groove ball bearing, while the upper side is hinged to the rocker arm with a bolt. The rocker arm is hinged to both the frame and the sieve base frame. A chain drive rotates the eccentric wheel at a constant angular velocity, and the connecting rod transmits this motion to the sieve frame, converting the rotational motion of the eccentric wheel into the reciprocating motion of the sieve frame. This motion pushes the material on the sieve surface towards the outlet and stratifies it. A schematic diagram of the structure is shown in the illustration.

Fig. 6 – Schematic Diagram of Eccentric Linkage Mechanism

Since the eccentric linkage mechanism is closed at both ends, it can be considered a closed-chain mechanism. Its degree of freedom analysis is as follows:

$$F = 3n - 2F_l - F_h \quad (2)$$

In the formula 2, F represents the degree of freedom of the mechanism; n represents the number of active components; F_l denotes the number of lower pairs; F_h represents the number of high pairs.

Analysis shows that there are 3 movable links, 4 lower pairs, and 0 higher pairs in this crank-link mechanism. Therefore, the degree of freedom is calculated as 1, meaning that only one input of power is required to enable the vibrating screen to achieve reciprocating motion.

MOTION ANALYSIS OF WHEAT SEEDS ON THE CLEANING SCREEN

After wheat seeds leave the shaking plate and enter the cleaning device, they move in the form of individual free particles. Therefore, when analyzing their forces in the airflow field, the focus should be on the individual behavior of wheat seed particles. When these particles fall onto the cleaning screen, the screen undergoes reciprocating motion, also known as simple harmonic motion, driven by a crank-rocker mechanism. During this process, the movement of materials on the screen surface primarily exhibits three states: forward sliding, backward sliding, and throwing. These movement states significantly affect the screening effect and separation efficiency of wheat from mixtures. Therefore, these motion characteristics must be fully considered in the design and optimization of cleaning devices.

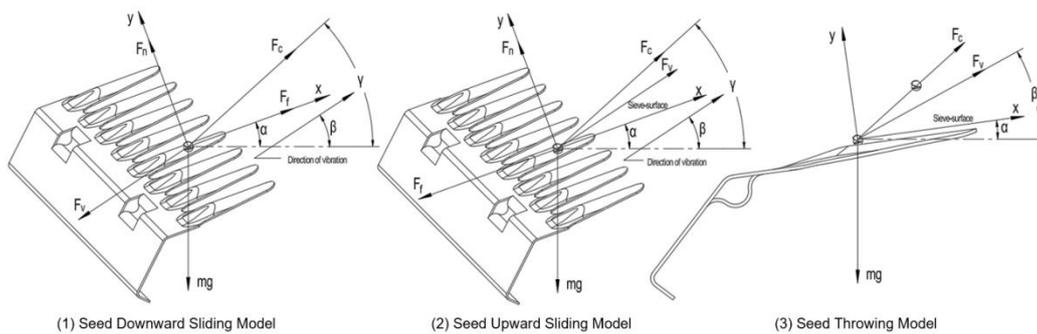

Fig. 8 – Analysis of Seed Motion States on the Cleaning Screen

Analysis of Seed Sliding Down the Screen Surface

According to D'Alembert's principle, when seeds are considered as rigid bodies and their motion on the screen surface is taken into account, a dynamic problem can be transformed into a static problem. By introducing inertial force, the main forces, constraint forces, and inertial forces of the particles formally constitute a system of equilibrium forces. In this context, a sliding motion model for the seeds can be established. When the seeds slide down the screen surface under the action of their inertial force and the direction of acceleration is positive, the motion model of the seeds can be described as follows:

$$F_c \sin(\gamma - \alpha) + F_n = mg \cos \alpha + F_v \sin(\beta - \alpha) \tag{3}$$

$$F_c \cos(\gamma - \alpha) + F_f = mg \sin \alpha + F_v \cos(\beta - \alpha) \tag{4}$$

In the formula, F_v denotes the inertial force; F_f denotes friction; F_c represents the wind power of the fan; α represents the inclination of the screen surface; β represents the vibration direction angle; γ indicates the airflow direction angle; φ denotes the friction angle.

Substituting the relevant parameters and performing rearrangement and simplification, the following is obtained:

$$\frac{\omega^2 r}{g} \cos \omega t = \left(\frac{V}{V_p}\right)^2 \cdot \frac{\cos(\gamma - \alpha + \varphi)}{\cos(\beta - \alpha + \varphi)} - \frac{\sin(\alpha - \varphi)}{\cos(\beta - \alpha + \varphi)} \tag{5}$$

In which, $\cos \omega t \leq 1$. The critical condition for the seeds to slide down the screen surface is:

$$\frac{\omega^2 r}{g} > \left(\frac{V}{V_p}\right)^2 \cdot \frac{\cos(\gamma - \alpha + \varphi)}{\cos(\beta - \alpha + \varphi)} - \frac{\sin(\alpha - \varphi)}{\cos(\beta - \alpha + \varphi)} \tag{6}$$

Analysis of Seed Sliding Up the Screen Surface

Similarly, when the seeds slide up the screen surface under the action of their own inertial force and the direction of acceleration is negative, the motion model of the seeds can be described as:

$$F_v \cos(\beta - \alpha) + F_c \cos(\gamma - \alpha) = F_f + mg \sin \alpha \tag{7}$$

$$F_n + F_c \sin(\gamma - \alpha) + F_v \sin(\beta - \alpha) = mg \cos \alpha \quad (8)$$

Substituting the relevant parameters and performing rearrangement and simplification, the following is obtained:

$$\frac{\omega^2 r}{g} \cos \omega t = \frac{\sin(\alpha + \varphi)}{\cos(\beta - \alpha - \varphi)} - \left(\frac{V}{V_p} \right)^2 \cdot \frac{\cos(\gamma - \alpha - \varphi)}{\cos(\beta - \alpha - \varphi)} \quad (9)$$

In which, $\cos \omega t \leq 1$. The critical condition for the seeds to slide up the screen surface is:

$$\frac{\omega^2 r}{g} > \frac{\sin(\alpha + \varphi)}{\cos(\beta - \alpha - \varphi)} - \left(\frac{V}{V_p} \right)^2 \cdot \frac{\cos(\gamma - \alpha - \varphi)}{\cos(\beta - \alpha - \varphi)} \quad (10)$$

Analysis of Seed Detachment from the Screen Surface

Analyzing the forces acting on seeds on the cleaning screen, it is evident that when the inertial force F_v is positive, and as the centripetal acceleration $\omega^2 r$ continuously increases, the support force F_n from the cleaning screen on the seeds decreases, gradually approaching zero.

At this point, the seeds, propelled by their own inertial force and the wind force from the cleaning fan, tend to be thrown off the surface of the cleaning screen. When the support force F_n exerted by the cleaning screen on the seeds equals zero, the seeds detach from the screen surface. Simultaneously, at the moment when the seeds begin to detach, sliding no longer occurs on the screen teeth, and the friction force disappears. At this moment, the motion model of the seeds can be described as:

$$F_N = mg \cos \alpha - F_v \sin(\beta - \alpha) - F_c \sin(\gamma - \alpha) \quad (11)$$

Substituting the relevant parameters and performing rearrangement and simplification, the following is obtained:

$$\frac{\omega^2 r}{g} \cos \omega t = \frac{\cos \alpha}{\sin(\beta - \alpha)} - \left(\frac{V}{V_p} \right)^2 \frac{\sin(r - \alpha)}{\sin(\beta - \alpha)} \quad (12)$$

In which, $\cos \omega t \leq 1$. The critical condition for the seeds to detach from the screen surface is:

$$\frac{\omega^2 r}{g} \geq \frac{\cos \alpha}{\sin(\beta - \alpha)} - \left(\frac{V}{V_p} \right)^2 \frac{\sin(r - \alpha)}{\sin(\beta - \alpha)} \quad (13)$$

In summary, the motion state of wheat seeds on the cleaning screen, apart from their own factors, is jointly determined by the airflow velocity and the acceleration ratio of the cleaning screen's motion (i.e., the fan speed and the vibration amplitude and frequency of the cleaning screen). To ensure cleaning performance, it is generally required that seeds can slide up and down on the screen surface while minimizing the occurrence of detachment from the screen. Therefore, finding the optimal combination of fan speed, amplitude, and vibration frequency is crucial for achieving good cleaning results. Due to the relatively complex motion patterns during the actual seed propagation and harvesting process, it is impossible to obtain accurate and effective dynamic data. Conducting numerical simulations of the airflow field in the cleaning chamber without material particles or vibration screening without airflow alone is incomplete. Therefore, it is necessary to use the coupled FLUENT and EDEM method, known as the CFD-DEM approach, to determine the optimal parameter range and combinations for key factors such as amplitude, airflow velocity, and airflow direction angle (Ding et al., 2022; Li et al., 2022).

RESULTS

RESEARCH ON THE MATERIAL MOVEMENT PATTERNS IN CLEANING DEVICES BASED ON CFD-DEM

To facilitate subsequent analysis, simulation models of the cleaning screen and the wheat threshing mixture were constructed using SOLIDWORKS and EDEM software. Orthogonal experiments were conducted with the seed impurity rate and seed loss rate as the main evaluation indicators, laying the foundation for further field trials and optimization of parameter combinations.

CFD Model of Cleaning Device

Firstly, considering the workload of coupled simulations and the computational capacity of the computer, a simplified 3D model of the cleaning chamber was constructed using SOLIDWORKS. Subsequently, the model in .STEP format from SOLIDWORKS was converted into a fluid domain model in .IGES format, which is recognizable by FLUENT, for meshing. The mesh was divided using a multi-module partitioning method, with the element size set between 0-1000 mm depending on the density. The total number of mesh elements was 45,422,210. The model after meshing is shown in the figure.

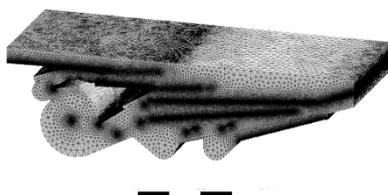

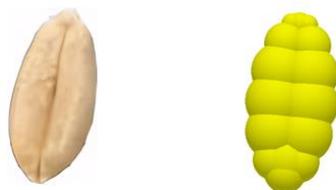

Fig. 9 – Schematic diagram of the cleaning room meshing

Then, the boundary conditions were set: both outlets of the centrifugal fan were assigned velocity-inlet boundary conditions, while the outlet was set as a pressure-outlet boundary. The fan impeller was configured with rotor-wall conditions, and the remaining areas were set as wall conditions. The k-epsilon model was chosen for the computational model, with the Standard Wall Function selected for the wall functions. The solution method employed was coupled, and the time step in FLUENT was set to 0.0004 s. After setting up, simulate the fluid domain model through simulation.

DEM Model of Wheat Threshing Mixture

Bags were placed at the grain outlet of the wheat harvester working in the field to collect the mixture threshed by the cleaning device. The proportions of wheat grains and stalks in the threshed mixture were measured to be 90.64% and 9.3%, respectively.

To construct a 3D model of wheat grains, 50 grains were randomly selected from the harvested wheat. Their average dimensions along the three axes were recorded using a vernier caliper, and the average values were calculated. Based on the results, the standard model dimensions for wheat grains were set to 6.76 mm×2.98 mm×2.88 mm. Using the obtained average dimensions of wheat grains, a 3D solid model was created with SOLIDWORKS software. The multi-sphere method was used in EDEM software to densely fill the 3D model, and a comparison between the filled particle model and actual wheat is shown in the figure.

(1) Wheat seeds (2) Discrete meta-model of wheat

Fig. 10 – Comparison Diagram of Wheat Seeds and Wheat Discrete Element Model

Similarly, 50 short stalks were randomly selected from the collected samples. After measuring their average dimensions along the three axes, the standard model dimensions for wheat stalks were determined to be a length of 23.54 mm, an outer diameter of 2.23 mm, and a wall thickness of 0.37 mm.

To ensure that the simulation experiments align with the actual conditions of seed production harvesting, mechanical properties and contact parameters between materials were determined by comprehensively referencing existing discrete element calibration literature for wheat grains and stalk particles, as well as data obtained from previous observations, measurements, and experimental studies. These parameters are shown in Tables 3 and 4.

Table 3

Material mechanical properties parameters			
Material	Poisson ratio	Shear modulus/pa	Density/kg-m ⁻³
Wheat seeds	0.3	2.6	1350
Short stalk	0.4	1	104
Cleaning sieve (Steel plate)	0.3	7800	7800

Table 4

Contact coefficient between materials			
Contact property	Restitution coefficient	Coefficient of static friction	Coefficient of rolling friction
Grain-Grain	0.2	1	0.01
Grain-Stem	0.3	0.5	0.01
Grain-Steel plate	0.45	0.35	0.01
Stem-Steel plate	0.3	0.36	0.01
Stem-Stem	0.22	0.5	0.01

The mass ratio measurement test was carried out on the mixture removed from the cleaning device obtained from the field. The mass ratio of each component of the mixture was 90.64 % of the grain mass and 9.3 % of the residual mass. Combined with the parameters of grain weight, grain and stem density, the number of particles generated in the simulation was calculated to be 4200 wheat grains and 450 wheat short stems, respectively. The particles were generated within 2.0 s.

Screening Simulation Process and Result Analysis

The figure below illustrates the cleaning states of the separation device at different time intervals, where the red spherical particles represent wheat seeds and the blue cylindrical particles represent short stalks.

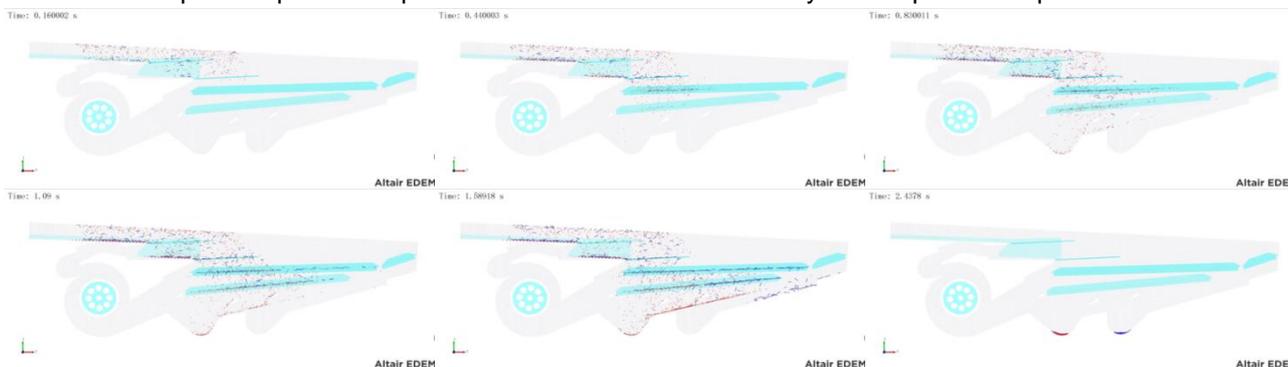

Fig. 11 – Simulation Time Frame Diagram of the Cleaning Chamber

Based on the illustration, it can be observed that at 0.16 seconds, the mixture particles begin to form in the particle generator and randomly fall onto the shaking plate. By 0.44 seconds, the particles come into contact with the cleaning screen and start moving towards the end of the screen due to the combined action of airflow and screening motion. At 0.83 seconds, some particles pass through the screen surface, and the wheat seeds, guided by the baffle plate, fall into the grain collection auger. By 1.09 seconds, a large number of mixture particles move towards the tail under the dual influence of airflow and screening motion, while light impurities are expelled out of the machine through the upper air outlet. At 1.58 seconds, the short stalks and light impurities are steadily discharged through the upper air outlet, and a large number of particles pass through the double-layer vibrating screen, guided by the baffle plates into the grain collection auger and the debris auger, respectively. By 2.4 seconds, the cleaning process is essentially complete; under the synergistic effect of airflow from the fan's dual outlets and screening motion, the vast majority of wheat seeds fall into the grain collection auger, with some entering the debris auger. These seeds, along with the debris, are transported by the auger above the vibrating screen for re-screening, with only a very small number of wheat seeds being expelled from the machine during the airflow and screening movements.

EXPERIMENTAL STUDY AND RESULT ANALYSIS OF WHEAT SEED SEPARATION AND CLEANING PERFORMANCE

Design of Experiments with Multiple Factors

To further investigate the combined effects of multiple factors on the performance of the cleaning device in wheat seed harvesting machines, the significance levels of various factors on the impurity rate and cleaning loss rate indicators are analyzed. This helps to determine the priority and influence order of each experimental factor on the test indicators and to identify the optimal parameter combinations. This analysis provides a theoretical basis for selecting factor levels in subsequent regression experiments. The experiment considers fan speed (X_1), amplitude (X_2), and vibration frequency (X_3) as experimental factors, and impurity rate (Y_1) and loss rate (Y_2) as the indicators of cleaning effectiveness, conducting a three-factor, three-level response surface experiment.

In the preliminary single-factor simulation experiments, impurity rate and loss rate were used as experimental indicators, while fan speed (900-1300 rpm), amplitude (10-50 mm), and vibration frequency (5-15 Hz) were considered as experimental factors. Specifically, when the fan speed was less than 1100 rpm material accumulation occurred, making it difficult for wheat seeds to pass through the sieve, resulting in an increased impurity rate. When the amplitude was less than 20 mm and the vibration frequency was less than 6 Hz, the separation effect between wheat seeds and short stalks was poor, leading to low cleaning efficiency. Conversely, when the amplitude exceeded 40 mm and the vibration frequency was greater than 10 Hz, there was significant fluctuation in the transport state of materials on the sieve surface, causing material splashing and a substantial increase in cleaning loss rate. Based on the analysis results of the single-factor experiments, the levels for fan speed were set at 1100 rpm, 1200 rpm, and 1300 rpm; the levels for cleaning sieve amplitude were set at 20 mm, 30 mm, and 40 mm; and the levels for vibration frequency were set at 6 Hz, 8 Hz, and 10 Hz. The coding table for experimental factor levels is shown in Table 5.

Table 5

Test code table			
Coding Level	Experimental factors		
	Fan speed X ₁ (rpm)	Amplitude X ₂ (mm)	Vibration frequency X ₃ (Hz)
-1	1100	20	6
0	1200	30	8
1	1300	40	10

Results and Analysis of Multi-Factor Experiments

The experimental setup and results are shown in the table. From the response surface experiment results, it can be seen that the range of seed admixture rate in this experiment is 1.15~1.96%, and the range of seed loss rate is 0.64~1.82%.

Table 6

Test design and results					
Experimental coding	Experimental factors			Hybridization rate of seeds Y ₁ /%	Losing seed rate Y ₂ /%
	Fan speed X ₁ (rpm)	Amplitude X ₂ (mm)	Vibration frequency X ₃ (Hz)		
1	1100	20	8	1.89	0.64
2	1300	20	8	1.29	1.02
3	1100	40	8	1.31	1.05
4	1300	40	8	1.17	1.92
5	1100	30	6	1.96	0.68
6	1300	30	6	1.34	1.23
7	1100	30	10	1.28	0.81
8	1300	30	10	1.21	1.74
9	1200	20	6	1.88	0.85
10	1200	40	6	1.29	1.36
11	1200	20	10	1.3	0.89
12	1200	40	10	1.15	1.82
13	1200	30	8	1.23	1.03
14	1200	30	8	1.19	0.99
15	1200	30	8	1.25	0.96
16	1200	30	8	1.27	0.94
17	1200	30	8	1.2	1.01

Perform a second-order multivariate regression fitting based on the simulation test data, and use Design-Expert 13 software to conduct regression analysis on seed admixture rate (Y₁) and seed loss rate (Y₂).

The regression equations for seed admixture rate (Y₁) and seed loss rate (Y₂) are:

$$Y_1 = 1.23 - 0.1788A - 0.18B - 0.1913C + 0.115AB + 0.1375AC + 0.11BC + 0.1148A^2 + 0.0723B^2 + 0.1047C^2 \tag{14}$$

$$Y_2 = 0.986 + 0.3412A + 0.3437B + 0.1425C + 0.1225AB + 0.095AC + 0.1050BC + 0.0283A^2 + 0.1433B^2 + 0.1007C^2 \tag{15}$$

To further analyze the impact of various experimental factors on the test indices, Design-Expert 13 software was used to obtain the response surface, as shown in the figure 12.

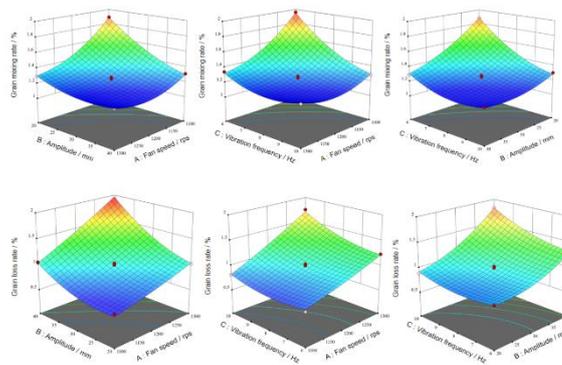

Fig. 12 – The response surface variation relationship of each factor to the test index

Experimental Optimization

In order to optimize the performance of the cleaning device and improve the effectiveness of seed harvesting, the fan speed, amplitude, and vibration frequency were subjected to parameter optimization design with the minimization of admixture rate and loss rate as the optimization objectives. The weight for admixture rate was set to five "+", and the weight for loss rate was set to three "+". The target values for the three factors were set within the optimization range, establishing a parametric mathematical model as follows:

$$\begin{cases} \min Y_1 \\ \min Y_2 \\ s.t. \begin{cases} 1100rps \leq X_1 \leq 1300rps \\ 20mm \leq X_2 \leq 40mm \\ 6Hz \leq X_3 \leq 10Hz \end{cases} \end{cases} \quad (16)$$

Using multi-objective parameter optimization in Design-Expert 13 software to analyze the mathematical model, the results indicate that the optimal operating parameters for the cleaning device are a fan speed (X_1) of 1143 rpm, an amplitude (X_2) of 28 mm, and a vibration frequency (X_3) of 9.4 Hz.

FIELD TEST

Building on the design of the cleaning device, its operating parameters were set according to the simulation test results and applied to the 4LX-1 wheat plot harvester. On June 22, 2024, a field trial was conducted at the Weifang Modern Agricultural Science and Technology Demonstration Park, harvesting the wheat variety "Zhengmai 113" at its optimal harvest time. The calculation formulas for seed admixture rate and seed loss rate are as follows:

$$P_z = \frac{M_z - M_m}{M_z} \times 100\% \quad (17)$$

$$P_s = \frac{M_b}{M_a + M_b} \times 100\% \quad (18)$$

In the formula: P_z represents the seed admixture rate, expressed as a percentage (%); M_z denotes the mass of the mixture in the grain collection auger, in g; M_m is the mass of seeds in the grain collection auger after impurities have been removed, in g; P_s represents the seed loss rate, expressed as a percentage (%); M_a is the harvested wheat seed yield per square meter, in g; M_b is the seed loss per square meter of wheat, in g.

Table 7

Serial number	Field test results	
	Low-loss and high-purity cleaning device	
	Hybridization rate of seeds/%	Losing seed rate/%
1	1.66	0.96
2	1.91	1.12
3	1.27	1.33
4	1.41	1.04
5	1.1	0.91
Mean value	1.47	1.07

The seed admixture rate and seed loss rate were calculated according to the formula, and the results are shown in the table. Under the optimal parameter combination of the optimized cleaning device, the average wheat admixture rate was 1.47%, and the average loss rate was 1.04%.

The operational results were similar to the simulation test results, with all indicators meeting the standards for seed production and harvesting. Therefore, the improved cleaning device is suitable for wheat seed production and harvesting operations.

Fig. 13 – Collection of Threshed Material and Field Test Diagram

CONCLUSIONS

(1) In this paper, a low-loss and high-purity cleaning device suitable for wheat breeding and harvesting operations was designed. The motion model of the sieve body and the material was established. It was determined that the operation effect of the cleaning device was affected by three important factors : fan speed, amplitude and vibration frequency.

(2) The CFD-DEM coupling simulation method was used to analyze the screening process of the separated mixture under the action of the fan, and the optimal structural parameters were obtained by combining the single factor test. The parameter combination was optimized with the minimum seed mixing rate and seed loss rate as the optimization objective, and the field verification test was carried out. The average mixing rate of wheat was 1.47 %, and the average loss rate was 1.04 %. The operation results were similar to the simulation test results, and all indicators met the relevant standards.

ABSTRACT

The processes of sowing and fertiliser application represent a significant aspect of agricultural production. In order to achieve efficient and precise seeding and fertiliser application, mass flow detection of seed and fertiliser particles can facilitate real-time monitoring and precise decision-making for intelligent seeding and fertiliser application. However, the diversity of seed and fertiliser particle types and particle flow modes presents a challenge for existing detection methods, particularly in meeting the varying operational requirements, especially for particle mass flow detection in low-altitude and high-speed sowing operations of agricultural drones. In such cases, the overlap and flow rate will have a significant impact on the detection results due to the large displacement and the continuous high-throughput dense phase of the particle flow. This paper provides a summary of the existing seed and fertiliser particle mass flow detection techniques and their underlying working principles. It compares the direct detection based on mass with the indirect detection methods based on velocity and concentration, and analyses their respective advantages, disadvantages and applicability. It also explores the possibility of optimising the existing detection methods for the specific needs of agricultural UAVs and considers the potential introduction of cutting-edge science and technology in order to develop an efficient, accurate and convenient detection system to meet the growing market demand.

摘要

播种和施肥是农业生产中的重要环节。在实现高效和精准化播种和施肥作业中，种肥颗粒的质量流量检测能够为智能化播种和施肥提供实时监控和精准决策。然而由于种肥颗粒类型和颗粒流动方式的多样性，现有检测方法较难满足不同的作业需求，尤其是农用无人机低空高速播撒作业中的颗粒质量流量检测，由于排量较大，颗粒流为连续高通量密相，重叠度和流动速度会对检测结果产生较大影响。本文总结了现有的种肥颗粒质量流量检测技术及其工作原理，比较了基于质量的直接检测与基于速度和浓度的间接检测方法，分析了各自的优缺点及适用性。针对农用无人机的特定需求，探讨了优化现有检测方法的可能性，并展望了引入前沿科学技术以研发高效、精准、便捷的检测系统，以满足日益增长的市场需求。

INTRODUCTION

Taking information and knowledge as the core elements, through the cross-border integration of modern information technology and agriculture such as the Internet, Internet of Things, big data, artificial intelligence and intelligent equipment, smart agriculture, which realises information perception, quantitative decision-making, intelligent control, precise inputs, and personalised services in the whole process of agricultural production, has become the development trend of modern agriculture in the world (Zhao, 2019). As the premise and foundation of smart agriculture, precision agriculture in the new situation needs to achieve the goals of positioning, timing and quantification, and provide low-input, high-quality and sustainable agricultural production through the monitoring and feedback of each operational link.

Sowing and fertiliser application are indispensable in agricultural production, and seed and fertiliser particle mass flow detection is an important foundation for precision operations such as precision sowing, precision fertiliser application and yield estimation. The detection of the mass flow rate of seed and fertiliser particles not only helps to know the actual sowing and fertiliser application information in the region and reduce the loss, but also realises the closed-loop control of the discharge rate, which helps to improve the effect of the precision variables of sowing and fertiliser application (Mahmud *et al.*, 2020). Therefore, the mass flow detection of seeding and fertiliser particles can provide basic data for realising the whole monitoring and intelligent management of agricultural operations, which can help the precise perception and intelligent decision-making of the agricultural production process (Lee *et al.*, 2015).

In recent years, research on seed and fertiliser particle mass flow detection technology has progressed rapidly, resulting in the emergence of numerous types of solid particle mass flow detection technologies and methods. Ding *et al.*, (2019), discussed the mechanical electromechanical alarm detection method, machine vision detection method, photoelectric sensing detection method, capacitive sensing detection method, and piezoelectric sensing detection method in their summary of the research progress of small and medium-sized seed sowing detection technology. They also highlighted the advantages and disadvantages of different detection methods and combined these with the requirements of precision agriculture to propose sowing detection indexes for different sowing modes. The existing particle flow detection technology can be classified into two main categories: mass flow detection and volumetric flow detection. The former encompasses techniques such as particle weighing, impact detection, and the measurement of particle volume over a fixed period and fixed volume of particle emission time (Liu *et al.*, 2018). In the field of solid particle pneumatic conveying, scholars have investigated a range of detection methods based on mechanical, optical, acoustic, electrical and correlation techniques (Bergeijk *et al.*, 2001). A significant proportion of the aforementioned methodologies have been extensively utilized within the domain of agricultural seeding and fertiliser application. However, there is a paucity of research pertaining to the detection of high-throughput dense-phase particle flows exhibiting low void fraction. The mass flow detection of continuous high-throughput dense-phase particle flows is imperative, given that particle motion and deposition are influenced by numerous factors during unmanned aerial dispersal.

The objective of this paper is to provide a comprehensive overview of the existing seed and fertiliser particle mass flow detection techniques, analyse the fundamental principles and limitations of the various detection techniques and their viability in UAV broadcasting applications and suggest potential avenues for further research into particle mass flow detection techniques in agricultural UAV broadcasting.

MATERIALS AND METHODS

Mass flow measurement technology

Direct detection method

In the context of direct measurement, the mass flow rate of a solid particle stream is obtained through the detection of either the instantaneous mass change of the particle stream itself or a sensitive variable that is directly correlated with the aforementioned mass flow rate change. The most commonly employed methods are those based on weighing and Coriolis force.

Weighing method

The majority of weighing methods rely on pressure transducers and their associated accessories to directly obtain particle mass changes. Typically, pressure sensors are employed to directly detect the mass change of the material box, thereby obtaining the real-time mass flow rate of particles (Wu *et al.*, 2014). Alternatively, a combination of pressure sensors and springs is utilised (Figure 1) (Yu *et al.*, 2019). This detection method has been widely employed in the measurement of grain yield, pneumatic conveying and other mass flow detection of grain flow (Qu, 2017). The weighing detection method based on belt scales is, in fact, a calculation of the average value of the mass flow rate of particles passing through each cross-section perpendicular to the direction of belt movement per unit time. The method is straightforward to implement physically, has no specific requirements regarding the physical properties of the particles being measured, and is highly applicable. However, it is susceptible to the influence of the rotational speed of the belt pulley and the distribution of particles above the belt, which can result in cumulative errors (Zhou and Zhang, 2009). The deformation and buffering of the spring can serve to counteract the interference of external factors, such as machine vibration. To achieve real-time detection and automatic calibration of fertiliser application, Li Ang

(2001), combined a load cell with a strain force transducer to measure the weight and dynamic behaviour of a fertiliser applicator. This combined detection method represents a significant advancement over traditional weighing techniques, offering enhanced precision in measurement. The weighing type is primarily based on the conveyor belt and spring assembly, which is typically employed for quality inspection in indoor seeding quality inspection test beds and roller grain transport lines. However, it is less frequently utilised in actual field operations.

Coriolis method

The Coriolis method is achieved by establishing the relationship between the Coriolis force generated during the vibration or rotation of the component and the mass flow rate of the particles (Geng *et al.*, 2005). As shown in Figure 2, the linear relationship between the moment generated by the Coriolis force and the mass flow rate as the particles rotate on the rotating metering disc can be expressed by the equation:

$$M = q_m \omega R^2 \quad (1)$$

where, M is the moment of the Coriolis force relative to the centre of rotation, $N \cdot m$; q_m is the mass flow rate, kg/s ; ω is the measurement of angular velocity, rad/s ; R is the measuring wheel outer diameter, m .

Considering the movement of particles on the metering disc and the variation in instantaneous mass distribution, this method yields better detection results under conditions of constant angular velocity and stable instantaneous particle flow. Coriolis-based detection methods convert particle mass and indirectly measure the force and momentum changes generated by particle motion. However, these methods are highly influenced by the flow rate and velocity of grain particles. Accurately capturing these mechanical changes is both the key challenge and the focus for improving detection accuracy.

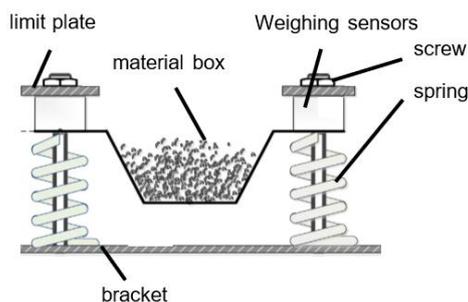

Fig. 1 - Weighing method based on pressure sensor

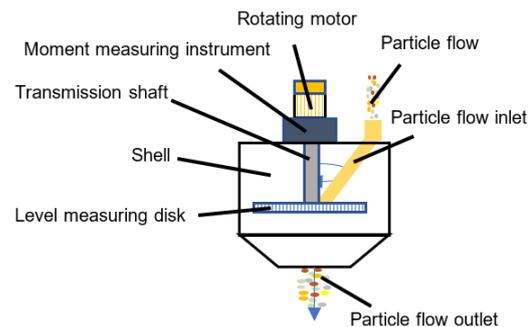

Fig. 2 - Coriolis force method based on rotation mode

Indirect detection method

Indirect measurement refers to determining the mass flow rate of particles by measuring the velocity or concentration of the solid particle stream. For a given particle, if its density and flow velocity are known, there is a correlation between the mass flow rate and the particle stream's concentration and velocity. Thus, the mass flow rate can be indirectly obtained by measuring these two parameters (Zheng and Liu, 2011; Zou Jing, 2015). In the following section, the correlation method is introduced taking into account two aspects: particle concentration detection and velocity detection.

Concentration-based detection method

Electrical method

This method mainly uses the charge change generated by the particle flow to obtain the particle concentration, including the capacitance method and the electrostatic method. The capacitance method refers to collecting the amount of output capacitance change generated when the particle flow passes between the poles of the capacitor and establishing the relationship between it and the particle flow rate according to the particle concentration to obtain the flow rate value (Zhou *et al.*, 2017).

The capacitance method has the advantages of stable operation, high reliability and strong resistance to dust contamination, but it has low sensitivity to the dense-phase particle flow with small concentration difference. In order to be able to accurately detect the capacitance variable generated by the dense-phase particle flow, the existing technology adopts new methods such as the differential capacitance principle or the construction of spiral capacitance sensors to improve the detection accuracy (Zhou *et al.*, 2014; Zhou L., 2014).

The electrostatic method is used to obtain the particle mass flow rate by detecting the amount of electrostatic charge generated by particle collision and friction and establishing the relationship between particle concentration and charge (Jia *et al.*, 2019; Wu *et al.*, 2019). In the actual pipe conveying particle flow, the collision between solid particles, the collision between particles and the pipe wall, and the friction between particles and the air flow generate a large amount of electrostatic charge.

The flow velocity of solid particles can be determined by inter-correlation velocimetry. The mass flow rate of solid particles can be calculated from their velocity and relative concentration (Qian *et al.*, 2012).

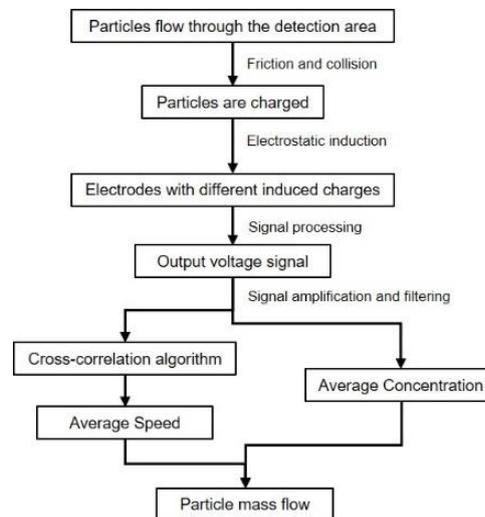

Fig. 3 - Electrostatic method

Research on detection technology based on this method has achieved some results. For example, Yan and Ma, (2000), used a pair of axially spaced metal rods mounted on the cross section of the pipe as electrostatic sensing elements and detected the mass flow rate by obtaining the alternating electrostatic signals caused by the particles flowing through the two rods in the pipe and developed a new type of detection instrument called 'StackFlow 2000', which can provide new opportunities for the application of electrostatic sensors. This method offers new possibilities for the development of electrostatic sensors. The distribution of the electrostatic sensing probes and the electrostatic response characteristics are the key factors affecting the detection results when using this method (Li Guanguan, 2016). Placement of multiple ring electrodes inside the particle flow tube to obtain the average flow velocity throughout the cross section of the measured tube area can improve the detection accuracy (Li *et al.*, 2014).

Volumetric concentration method

This method primarily utilizes the intermittent flow characteristics of particle streams. Changes in particle volume concentration are converted into voltage pulse signals, establishing a relationship between the number of voltage pulses and the number of particles. Based on this relationship, the particle mass flow rate can be calculated from the volume concentration. Common approaches under this method include the photoelectric method, piezoelectric method, and image-based method.

The photoelectric method primarily relies on the blocking effect of the particle flow on light intensity to detect changes in the light signal. A mapping relationship is established between the voltage pulses generated by light intensity fluctuations and the number of particles. Photoelectric sensors typically consist of a transmitter and a receiver, commonly using light-emitting diodes (LEDs) and phototransistors (Che *et al.*, 2017). During operation, as the particle stream passes between the transmitter and receiver, it causes variations in the light received, resulting in corresponding changes in the voltage signal. There is a clear correlation between the concentration of the particle stream and the voltage pulse signal. By counting these pulses, the number of particles can be estimated (Wu *et al.*, 2016; Qiu *et al.*, 2019; Karimi *et al.*, 2017). For continuous, dense, and high-throughput particle streams, the relationship between the induced voltage and flow rate can be established by constructing a distribution matrix of photoelectric sensors (Fig. 4) or dividing the particle channel into a grid (Fig. 5) to collect changes in multiple continuous voltage signals (Jiang *et al.*, 2021; Liu *et al.*, 2019). The relationship between induced voltage and flow rate can also be established by detecting changes in the thickness of the particle pile and using the relationship between the thickness of the particle pile and the mass

of the particles (Fig. 6) (Yin *et al.*, 2021), or by splitting a dense, high-throughput particle stream into multiple smaller streams using a discrete mechanism and detecting them in parallel with multiple sets of photoelectric sensors (Nong *et al.*, 2023; Xu *et al.*, 2022; Ding *et al.*, 2020). Swisher *et al.*, (2002), used a trapezoidal optical chamber to transmit laser light to an array detection unit composed of 32 photodiodes, allowing them to determine the instantaneous flow rate of fertiliser from an air-conveyor applicator based on the amount of light blocked by the granules. Regardless of the approach, whether using a photovoltaic line array or segmenting the granular stream, the key to improving this method lies in optimizing the photosensitive components (e.g., by using thin-faced lasers) and enhancing both the signal acquisition accuracy and the range of the photodiode sensors (Ding *et al.*, 2019; Ding *et al.*, 2021).

In the piezoelectric method, voltage pulse signals are generated by intermittent collisions between the particle stream and a piezoelectric element. These signals are detected and converted into particle counts. The frequency of collisions, and thus the number of voltage pulses, increases with the concentration of the particle stream. In other words, a higher particle concentration leads to more frequent impacts and a greater number of voltage signals. However, this method is less sensitive to particle streams with only slight changes in concentration. It also requires high-resolution detection capabilities to accurately respond to variations in particle concentration and to generate voltage pulse signals within an appropriate range.

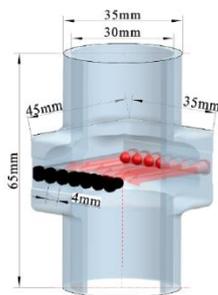

Fig. 4 - Mass flow detection method of continuous dense particle flow based on infrared sensor
(Jiang *et al.*, 2021)

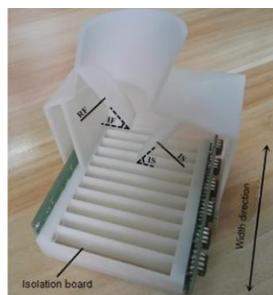

Fig. 5 - The dense particle flow is divided into a single row of small particle flow (Liu *et al.*, 2019)

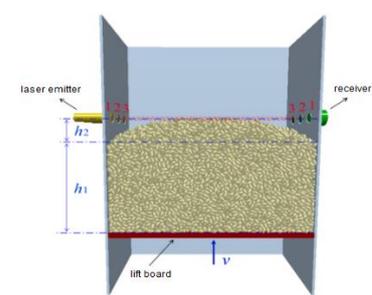

Fig. 6 - Photoelectric sensor array (Yin *et al.*, 2021)

The photoelectric and piezoelectric methods are relatively simple in principle and construction and have been widely used in fertiliser application and seeding (Jia *et al.*, 2018). Both methods essentially detect voltage pulse signals generated by the inductive element of the sensor and should be used in such a way as to ensure that a clear and stable signal is obtained as far as possible. For example, the detection accuracy of photoelectric sensors is susceptible to dust and other contaminants, and measures such as the installation of protective covers can be taken to ensure a clean detection environment (Ji *et al.*, 2016). Piezoelectric sensors are more sensitive to intermittent particle flow, and when detecting continuous particle flow, detection accuracy can be improved by using easily deformable materials (e.g. piezoelectric films), signal conversion and adaptive noise cancellation algorithms (Wang *et al.*, 2019; Xiong *et al.*, 2018).

The imaging method mainly uses high-speed camera technology to obtain images of the falling particle flow and counts the number of particles in unit space through image processing, which is also a volume concentration-based detection method (Back *et al.*, 2014). This method can obtain not only the particle flow information, but also the spatial motion trajectory of the falling particles (Yazgi and Degimencioglu, 2007). However, due to the high environmental requirements of this method, which requires a complex test bench to place the camera, light source, computer, etc., it is generally only used for laboratory testing (Lu *et al.*, 2019). In order to widen the scope of application, researchers have used a digital camera (Nikon, D70) and a charge-coupled device digital colour camera to capture images of seed and fertiliser particles, determine the number and size of particles, and experimentally verify the feasibility of these methods (Navid *et al.*, 2011; Back *et al.*, 2014).

The accuracy of image recognition is the basis of the image method. Since the image is mainly derived from the dynamic flow and static distribution of particles, and the number of particles is mostly used as the detection target, it will be affected by various factors such as light, vibration of the detection device, and overlapping of particle materials, and the detection error is relatively large. To improve the detection performance, neural networks and other image segmentation and feature extraction methods are also combined with image processing (Tan *et al.*, 2014; Zhao *et al.*, 2022).

In addition, to improve the detection accuracy of the existing detection system under the noise interference of field operations, the point cloud data collected by LiDAR has been used to characterise the geometric feature changes of particles as volume changes, and a related algorithm for calculating fertiliser emissions has been developed (Zhao *et al.*, 2021). This method requires processing and analysis of the point cloud data and is currently mostly used for indoor static particle flux detection platforms.

Attenuation method

This method mainly uses the principle that electromagnetic waves, sound waves, etc. are attenuated by the medium and the particle concentration is obtained by detecting the wave intensity before and after the emitted wave passes through the particle flow tube. Visible light, laser, microwave, X-ray, γ -ray and ultrasonic waves can be used as wave sources for the attenuation method. Using microwave as an example, the change in wave intensity through the particle flow can be characterised by the energy of the echo signal. By detecting the energy of the Doppler echo signal in the pipe, the density of the particle flow can be obtained, and then using the flow rate, the particle mass flow rate can be obtained (Isa and Wu, 2006). The traditional method of calculating the particle density is to use the power spectrum calculation to obtain the energy information of the signal. In the process of random signal acquisition, the power spectral density is commonly used to represent the distribution of the average power in the frequency domain, which can be used to obtain the total power P by integrating the operation over the entire frequency range, with the following equation:

$$P = \int_{f_{min}}^{f_{max}} s(f) d_f \quad (2)$$

where, P is the echo signal power; $s(f)$ is the power spectral density of the signal; f_{min} is the lower limit of the Doppler bandwidth; f_{max} is the upper limit of the Doppler bandwidth.

Power spectrum estimation methods include classical power spectrum estimation and modern spectrum estimation. Classical spectral estimation methods include the correlation function method (BT method) and the periodogram method, which is based on the FFT (Fast Fourier Transform) to estimate the power spectral density function, which is greatly affected by the transfer function and needs to be selected according to the actual situation (Deng *et al.*, 2014). Modern spectral estimation methods include AR model spectral estimation, MA model spectral estimation and ARMA model spectral estimation methods (Li Ying, 2015). When using this method, if the order of the parametric model is too low, it is difficult to accurately distinguish the frequency components, and if the order of the parametric model is too high, there is a possibility of distortion in the display of the true amplitude ratio, which affects the estimation of the true spectral peaks.

Velocity-based detection methods

Impulse momentum method

This method primarily utilizes the impact force generated by granule flow striking the force-measuring plate and force sensors, combined with the functional relationship between the impact force and the mass flow rate of granules, to determine the mass flow rate. The key to ensuring the detection accuracy of this approach lies in effectively extracting the valid deformation caused by the granule flow impact (Chen *et al.*, 2005; Zhou *et al.*, 2006). When the continuous particle flow passes through a fixed cross-section, the relationship between the cumulative particle mass W , the instantaneous mass flow rate m_i , the flow velocity v_i and the instantaneous flow rate Q_i is expressed as follows:

$$W = \sum_{i=1}^n Q_i(t) \Delta t = \sum_{i=1}^n m_i(t) v_i(t) \Delta t \quad (3)$$

If the continuous flow of particles hits the force plate continuously, the momentum of the moving particles will change after the collision with the force plate. Assuming that the velocity of the particles after the collision is zero, then the following formula is established:

$$I_i(t) = m_i(t) v_i(t) \quad (4)$$

From equation (4) it can be seen that if the particle collision momentum as well as the flow rate can be obtained, then the particle mass flow rate can also be obtained. The force plate deforms under the impact of the particle flow, the stress generated by the deformation is detected by strain sensors, and the relationship between the stress and the momentum can be determined by test calibration (equation 5).

$$I_i(t) = kU_i(t) \quad (5)$$

where, Δt is the timed sampling interval; $I_i(t)$ is the impulse of the particle flow, N·s; $m_i(t)$ is the mass of grain per unit length at any position on the conveyor belt at time t , kg; $v_i(t)$ is the instantaneous velocity of the grain at time t , m/s.

In order to resolve the issue of the test plate being vulnerable to a variety of factors, *Ding Yongqian (2009)*, investigated a pulse method based on velocity detection, which allows particles to flow through the test device by their own gravity and initial velocity without the need to maintain a constant velocity of motion. The method can calculate the particle flow rate based on the weight difference between two load cells and known structural parameters to determine the instantaneous mass flow rate and the total mass of particles to be detected. To improve the detection accuracy of the pulse method, *Fulton et al., (2009)*, simulated different field slopes experienced during field operations, investigated the effect of harvester traverse roll and pitch on the detection accuracy of existing mass flow sensors, and provided suggestions for optimising the detection method for different slopes. *Schrock et al., (1999)*, developed a new diaphragm grain mass flow sensor to isolate the grain from the load cell by using a flexible fabric-reinforced rubber diaphragm to reduce the possibility of cracking and entrapment of other contaminants behind the sensing element.

Pressure method

When faced with a continuous dense grain flow, the flow rate value can be obtained by collecting the continuously changing pressure generated by the grain flow acting on the pressure sensors and establishing the relationship between pressure and grain flow rate. As shown in Fig.7, multiple pressure sensors are arranged along the cross section of the particle flow between the two side walls of the deflector plate to establish the relationship between the instantaneous thickness of the particle flow and the pressure. Mathematical modelling methods are used to fit the thickness distribution equation of the cross section of the particle flow, and then the equation is integrated to obtain the instantaneous cross sectional area of the particle flow. The particle flow rate is used to establish the relationship between instantaneous mass and cross-sectional area, which in turn allows for the relationship between pressure and particle mass flow rate to be determined (*Geng et al., 2021*).

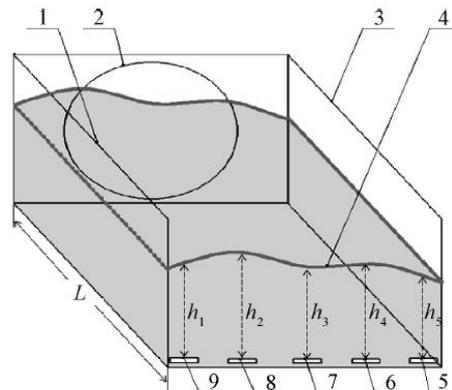

Fig. 7 - Schematic diagram of particle flow mass flow detected by piezoelectric sensor (*Xiong et al., 2018*)

1 - Right wall of the concave deflector plate; 2 - Tail of the grain collection elevator; 3 - Left wall of the concave deflector plate; 4 - Cross-section of grain flow; 5 - First reference position; 6 - Second reference position; 7 - Third reference position; 8 - Fourth reference position; 9 - Fifth reference position.

The method treats the flowing particle cluster as a solid mass of uniform density and establishes the relationship between particle flow pressure and flow velocity by detecting the force of the solid mass on the pressure sensor in real time, making it relatively friendly to dense phase particle flows and capable of obtaining large pressure signals. In addition to production measurement, the method can also be used in pneumatic conveying with a venturi to establish a relationship between the mass flow rate of solid particles by testing the difference in air flow pressure before and after gas-solid two-phase flow through the venturi (*Mailander and Moriasi, 2011*).

Doppler method

This method is a new non-destructive testing technique in which the measured element does not need to be in direct contact with the grain flow and there is no problem of corrosion and wear.

Moreover, in addition to microwaves, electromagnetic waves such as millimetre waves and lasers, as well as ultrasonic waves, can be used as the emitted wave source of this detection method (Yin Guang, 2012; Rafael et al., 2023). It has been widely used in grain particle flow detection (Penirschke et al., 2008). However, wave propagation is not only affected by the differential reflection caused by varying grain flow characteristics, but also by other factors that influence the reflected wave, which can interfere with the frequency shift (Pang et al., 2008). Developing appropriate detection structures and signal processing methods tailored to different grain characteristics is essential for ensuring the accuracy of this detection method.

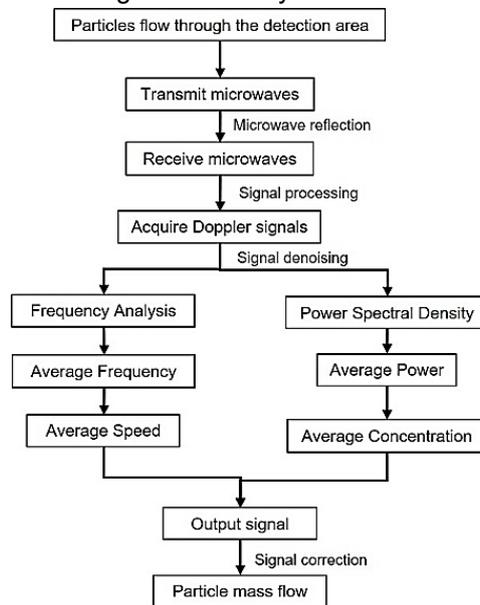

Fig. 8 - Microwave detection method based on doppler effect

Acoustic method

This method primarily involves acquiring acoustic signals generated by particle collisions and establishing their relationship with particle flow velocity, which is then used to calculate the mass flow rate (Wang et al., 2017). When the particle flow hits the steel plate during the free fall under gravity, the particle-particle collision and particle-steel plate collision can excite strong elastic waves, and the particle flow hitting the steel plate at different velocities will produce large differences in acoustic signals. Due to the damping effect of air and the relatively weak collisions between particles compared to collisions with a steel plate, acoustic signals are difficult to capture. However, an acoustic emission sensor can be used to detect the signals generated by the collision and friction of solid-phase particles with a steel plate (Wei et al., 2011). This method relies on acoustic signals produced during particle flow interactions, but when the particles are small or the collisions and friction are light, the resulting signals are weak and difficult to detect. Additionally, noise in the surrounding environment can further increase measurement errors. Therefore, accurately capturing and processing the effective acoustic signals generated by the particle flow is key to improving detection accuracy.

Summary of existing detection methods

The above detection methods obtain particle flow information from different angles, which can basically realise the detection needs in different scenarios, but they all have certain limitations (Figure 9). In the direct detection method, the detection element is in direct contact with the particles, which will definitely cause wear, corrosion and relaxation deformation of the sensor in the long run, and if it is in the pneumatic pipeline, it will also have a certain effect on the normal pressure drop in the pipeline, which will affect the efficiency of particle transport. In the indirect detection method, the concentration-based detection method is more sensitive to the particle concentration, and the light wave and acoustic wave are not only more demanding on the environment, which is affected by dust, impurities, temperature and humidity, but also the signal processing and analysis are relatively complicated. In particular, the detection of high-throughput dense-phase particle flow requires higher resolution and sensitivity of sensors, and the spatial distribution of sensors in the detection area as well as the post-signal processing techniques are more difficult than those of dilute-phase particle flow detection and require complex information conversion. The velocity detected by the velocity-based detection method is basically the average velocity of the particle flow, and the flow state and spatial distribution of the particles will directly affect the detection results, which can easily cause detection errors.

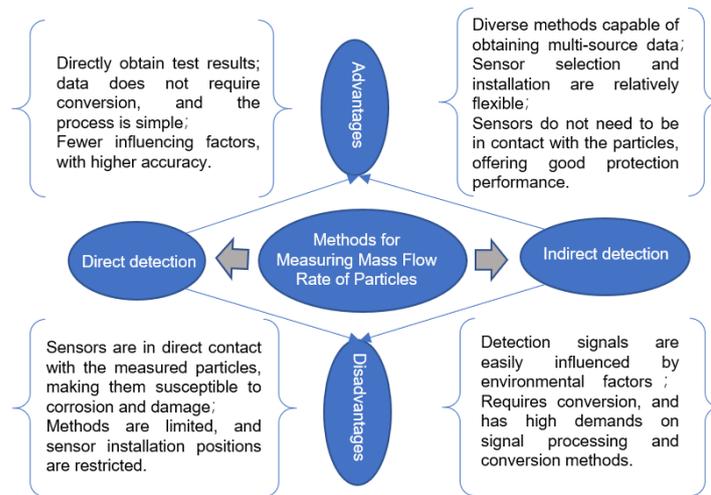

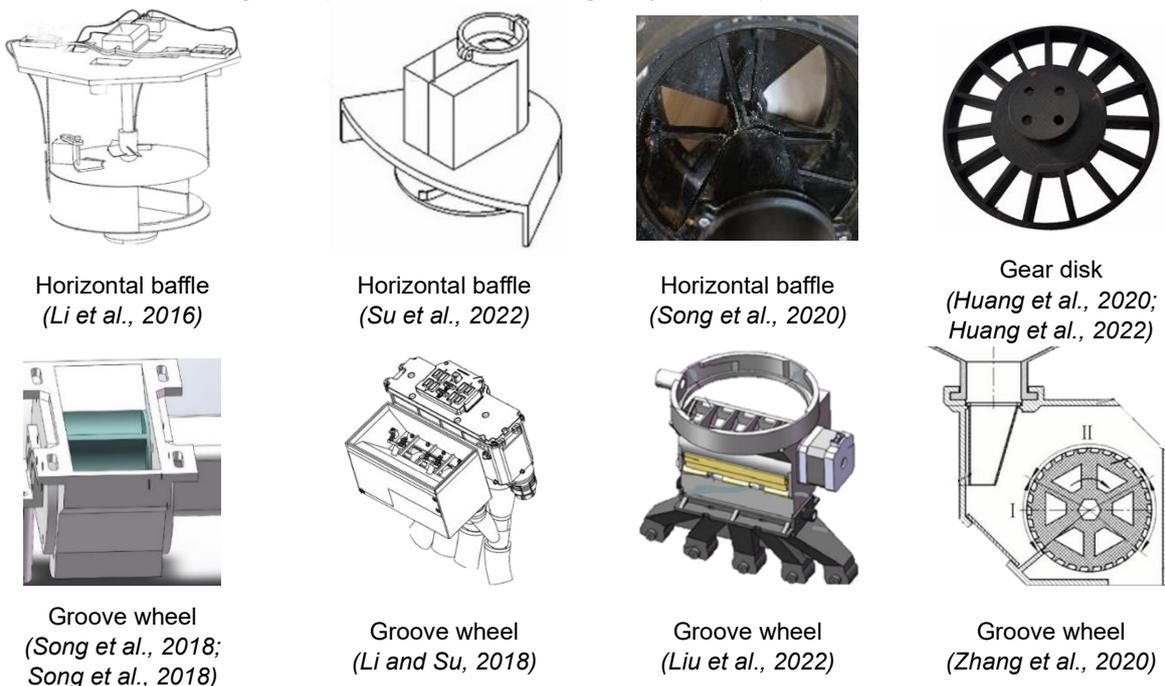

Fig. 9 - Comparison of different detection methods

In practice, the flow state and emission environment of seed and fertiliser particles are diverse, and there is still much room for improvement in the existing technology, and it is difficult to achieve good detection results using only the single method mentioned above. In order to improve the detection effect, researchers have attempted to fuse electrostatic sensors, differential pressure sensors and accelerometers, and constructed a data-driven model based on support vector machines to estimate the mass flow rate of a solid particle stream (Faisal et al., 2022). The machine vision system is characterised by its high precision, real-time capabilities, automation and intelligence. The image-based mass flow detection method of dense-phase particle flow is expected to yield significant achievements in the future (Liang Yongan, 2022; Wang Dingkan, 2022). The use of neural networks to model the relationship between the mass flow rate of solid particles and a variety of sensitive variables can also improve the detection effect (Ding Mingwei, 2022; Zhu Siqi, 2020).

Flow regulation and detection methods in drone seeding

The two main parts of the UAV spreading device are particle discharge and particle spreading, where the particle discharge method is related to the adjustable range of discharge and particle displacement adjustment, which mainly affects the particle discharge accuracy, and the particle spreading method is related to the particle diffusion trajectory and deposition range, which mainly affects the deposition width and uniformity (Song et al., 2020). Figure 10 shows the discharge mechanism in the existing UAV spreading device, which is mainly based on grooved wheels, horizontal baffles and centrifugal discs. It is typically installed at the bottom of the material box, having a simple structure and being easy to manipulate.

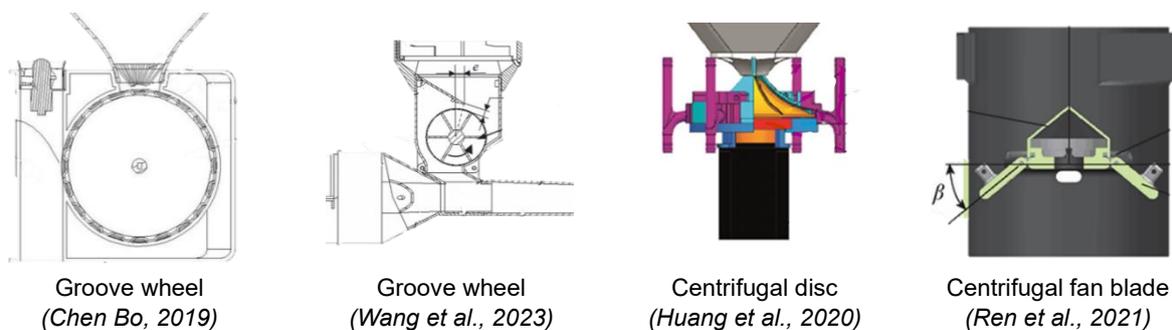

Fig. 10 - Method of displacement regulation and detection for UAV seeding

Song et al., (2021), designed a UAV variable fertiliser application system using an opposite laser sensor. The transmitting and receiving ends were fixed around the connecting pipe between the material box and the fertiliser discharger. Real-time detection of particle flow was achieved using the photoelectric principle, enabling mass flow detection of fertiliser particles. DJI Innovation employed a Hall sensor mounted on the agitator of the spreader. As the agitator rotates, the magnet on the Hall sensor interacts intermittently with magnetic strips on the side wall of the spreader. Variations in particle flow rate cause different levels of resistance as particles pass through the agitator, altering its rotation speed. These changes result in varying Hall sensor signals, which reflect the state of the particle flow (Huang and Zhang, 2020). To obtain more accurate detection results, Huang Junhao et al. developed a detection device based on differential weighing. The system uses multiple sensors to detect vibration noise and applies filtering techniques to improve detection accuracy (Huang et al., 2024).

RESULTS

Adaptation of different detection methods

The configuration of sensors, characteristics of detection components, and information processing techniques vary widely across different detection methods. Selecting an appropriate particle mass flow detection method tailored to specific discharge mechanisms is essential for accurately acquiring detection data and improving overall measurement precision. During UAV spreading operations, particle flow is highly susceptible to noise and vibration caused by the high-speed rotation of the rotors, which poses challenges to accurate mass flow detection. Additionally, conventional detection methods often fall short in terms of accuracy and resolution. Therefore, there is a pressing need to develop innovative detection technologies that offer strong anti-interference capability, high resolution, and rapid response time.
