11.	**DESIGN AND PARAMETER OPTIMIZATION OF A SEED STORAGE DEVICE OF A WHEAT PLOT SEEDER /** *小麦小区播种机存种装置的设计与参数优化* **Chen XUE, Liqing CHEN*), Zengbin CAI, Qi WANG** College of Engineering, Anhui Agricultural University, Hefei, Anhui / China	121

12.	**RICE SEED CLASSIFICATION BASED ON SE-ResNet50 /** *基于SE-ResNet50的稻种分类* **Zhen MA[1)], Sa WANG[1)], Hongxiong SU[1)], Juxia LI[*1)], Yanwen LI[1)], Zhifang BI[2)], Xiaojie LI[1)]** [1)] College of Information Science and Engineering, Shanxi Agricultural University, Taigu /China; [2)] Department of Basic Sciences, Shanxi Agricultural University, Taigu / China	131
13.	**SAFF-YOLO-BASED LIGHTWEIGHT DETECTION METHOD FOR THE DIAMONDBACK MOTH /** *基于SAFF-YOLO的白菜小菜蛾轻量化检测方法* **Miao WU [1,2,)], Hang SHI [1,2,)], Changxi LIU [1,2,)], Hui ZHANG [1,2,)], Yufei LI [1,2,)], Derui BAO [1,2,)], Jun HU [*1,2,)]** [1)]College of Engineering, Heilongjiang Bayi Agricultural University, Daqing / China; [2)]Heilongjiang Province Conservation Tillage Engineering Technology Research Center, Daqing / China	142
14.	**DESIGN AND TESTING OF A FULL-DEGREE-OF-FREEDOM CONSTRAINED SEED GUIDING DEVICE FOR ORDERED SEED FLOW /** *有序种子流全自由度约束导种装置设计与试验* **Xin DU*, Qianhao YU, Shufa CHEN, Qixin SUN, Yue JIANG, Jingyi MAO** Jiangsu Ocean University, Lianyungang / China	156
15.	**DESIGN AND EXPERIMENTAL STUDY OF A CRAWLER-TYPE PRECISION PESTICIDE APPLICATOR BASED ON DEM /** *基于DEM的履带式精准施药机设计与试验研究* **ZhiMing SHI[1,2)], Hang ZHAO[1,2)], ShouTai LI[3)], ZiWen CHEN[3)], JunJie CHEN[*1,2)], MingJin YANG [*3)]** Southwest University, College of Artificial Intelligence, Chongqing, China; [2)] National & Local Joint Engineering Research Center of Intelligent Transmission and Control Technology, Chongqing, China; [3)] Southwest University, College of Engineering and Technology, Chongqing, China	167
16.	**DESIGN AND OPTIMISATION OF ROTARY TILLER BLADE FOR ORCHARDS IN HILLY MOUNTAINOUS AREAS BASED ON THE DISCRETE ELEMENT METHOD /** *基于离散元法的丘陵山区果园圆盘式开沟刀具设计与优化* **Jing MI [1)], Huan XIE [*2)] Po NIU[*1)]** [1)]College of Mechanical Engineering, Chongqing Three Gorges University, Chongqing/China. [2)]Chongqing Three Gorges Vocational College, School of Automotive Engineering	177
17.	**DESIGN AND TESTING OF HYDRAULIC DRIVE SYSTEM FOR CRAWLER-TYPE TIGER-NUT HARVESTER /** *履带式油莎豆收获机液压驱动行走系统的设计与试验* **Zhe QU, Jianhao ZHANG, Jintao LE, Xilong WANG, Haihao SHAO, Huihui ZHAO, Zhijun L., Wanzhang WANG*** College of Mechanical and Electrical Engineering, Henan Agricultural University, Zhengzhou, China	187
18.	**DETECTION METHOD OF COTTON COMMON PESTS AND DISEASES BASED ON IMPROVED YOLOv5S /** *基于改进YOLOV5S的棉花常见病虫害检测方法* **Yulong WANG[1,2,3,#], Fengkui ZHANG[1,2,3,#], Rina YANGDAO[1,2,3], Ruohong HE[1,2,3], Jikui ZHU[1,2,3], Ping LI[1,2,3,*]** [1)] College of Mechanical and Electrical Engineering, Tarim University, Alar, Xinjiang, China [2)] Xinjiang Production and Construction Corps (XPCC) Key Laboratory of Utilization and Equipment of Special Agricultural and Forestry Products in Southern Xinjiang, Xinjiang, China [3)] Modern Agricultural Engineering Key Laboratory at Universities of Education Department of Xinjiang Uygur Autonomous Region, Xinjiang, China	199
19.	**DESIGN AND EXPERIMENT OF AN AIR-ASSISTED, GUIDED-GROOVE MAIZE SEED-GUIDING DEVICE BASED ON THE BRACHISTOCHRONE CURVE /** *基于最速降线的气辅-导槽式玉米导种装置设计与试验* **Wen-sheng SUN [1)], Shu-juan YI[*2)], Hai-long QI [2)], Yi-fei LI [1,3)], Yu-peng ZHANG [1)], Jia-sha YUAN [1)], Song WANG [1)]** [1)]College of Engineering, Heilongjiang Bayi Agricultural University, Daqing/P.R.China; [2)]Heilongjiang Beidahuang Modern Agricultural Service Group Zhongrong Agricultural Machinery Co., Ltd, Harbin / P.R.China; [3)]College of Engineering, Northeast Agricultural University, Harbin/P.R.China	210
20.	**DEM-BASED CALIBRATION OF SOIL CONTACT PARAMETERS PRIOR TO GRAPEVINE BURYING /** *基于离散元法的葡萄藤埋前土壤接触参数标定* **Beibei ZHANG[1)], Julaiti MAITIROUZI[*1)], Shixiang XING[1)], Hongcheng DENG[2)], Wenjing BAI[2)], Haileeqguli YASEN[2)]** [1)] College of Mechanical Engineering, Xinjiang University, Urumqi/China; [2)] Turpan Agricultural and Rural Mechanization Development Center, Turpan/China	223
21.	**RESEARCH ON ADVANCED COMPENSATION CONTROL STRATEGY FOR SOYBEAN COMBINE HARVESTER HEADER HEIGHT BASED ON AREA ARRAY LiDAR /** *基于面阵激光雷达的大豆联合收割机割台高度超前补偿控制策略研究* **Qingling LI[1,2)], Chao ZHANG[*1,2)], Shaobo YE [1,2)], Decong ZHENG[1,2)]** [1)] College of Agricultural Engineering, Shanxi Agricultural University, Taigu, China; [2)]Dryland Farm Machinery Key Technology and Equipment Key Laboratory of Shanxi Province, Taigu, China	237
22.	**ASSESSING THE ENVIRONMENTAL ADAPTABILITY BASED ON LASER DETECTION FOR DETERMINING GAS EMISSIONS FROM AGRICULTURAL SOURCES /** *评估使用激光探测确定农业源气体排放的局部环境的适应性* **Xiaofeng LIU[1)], Fuhai ZHANG[1)], Jingjing YU[1)], Jiayuan WANG[1)], Juan LIAO[2)], Qixing TANG[2*)]** [1)]Anhui Eco-Environment Monitoring Center, Hefei, China; [2)]School of Engineering, Anhui Agricultural University, Hefei, China	246

23.	**DETECTION OF EARLY BRUISING IN 'HUANGGUAN' PEAR BASED ON MCC-DeepLabV3+ MODEL / *基于MCC-DeepLabV3+模型的皇冠梨早期瘀伤检测*** **Congkuan YAN, Haonan ZHAO, Dequan ZHU, Yuqing YANG, Ruixing XING, Qixing TANG, Juan LIAO*)** School of Engineering, Anhui Agricultural University, Hefei, China	256
24.	**EFFECT OF MOISTURE CONTENT ON SOME PHYSICAL AND MECHANICAL PROPERTIES OF WHEAT (*Triticum aestivum* L.) SEEDS /** ***ስንዴ (Triticum aestuum L.) ዘሮች የሚያሳው የእርጥበት ይዘት በአንዳንድ የአካላዊ እና መካኒካላዊ ባህሪዎች ላይ ያለው ተጽእኖ*** **Amansis TESHOME[1a*)], Adesoji M. OLANIYAN[2)], Abebe FANTA[1a)], Habtamu ALEMAYEHU[1b)], Meseret ABEBE[3),] Dereje ALEMU[3)], Mubarak MOHAMMED[3)], Tasfaye ASEFFA[3)]** [1a)] Department of Agricultural Engineering, Haramaya Institute of Technology, Haramaya University, Dire Dawa, Ethiopia; [1b)] Department of Mechanical Engineering, Haramaya Institute of Technology, Haramaya University, Dire Dawa, Ethiopia; [2)] Department of Agricultural and Bioresources Engineering, Faculty of Engineering, Federal University Oye-Ekiti, Ikole Ekiti, Nigeria; [3)] Ethiopian Institute of Agricultural Research (EIAR); Melkassa Agricultural Engineering Research, Melkassa Agricultural Research Centre. Adama, Ethiopia	271
25.	**REVIEW OF EXPERIMENTAL RESEARCH INVESTIGATIONS AND THE WORKING PRINCIPLE OF SMALL VERTICAL AXIS WIND TURBINES /** ***REVIZIA INVESTIGAȚILOR DE CERCETARE EXPERIMENTALĂ ȘI PRINCIPIUL DE FUNCȚIONARE AL TURBINELOR EOLIENE MICI CU AX VERTICAL*** **Adrian PANDELE*), Bogdan Ovidiu DURAN, Dragos Mihail PREDA, Gheorghe VOICU*)** National University of Science and Technology POLITEHNICA Bucharest, Romania	282
26.	**RESEARCH ON THE INFLUENCE OF EXTRUSION PARAMETERS ON SOLID-LIQUID SEPARATION PERFORMANCE OF LIVESTOCK MANURE AND OPTIMIZATION OF PARAMETERS** ***畜禽粪污螺旋挤压脱水装置参数优化设计与试验*** **Weisong ZHAO[1,2,3)], Qimin GAO[1)], Chunsong GUAN*[1)], Binxing Xu[1,3)], Biao MA*[1,2)], Yan Gong[1,2)]** [1)]Nanjing Institute of Agricultural Mechanization, Ministry of Agriculture and Rural Affairs, Nanjing, China; [2)]Institute of Western Agriculture, the Chinese Academy of Agricultural sciences, Changji, China [3)]College of Mechanical and Electrical Engineering, Xinjiang Agricultural University, Urumqi, China	308
27.	**LOW-COST IOT-BASED INTELLIGENT SAFFRON MANAGEMENT SYSTEM /** ***低成本物联网智能藏红花管理系统*** **Wai Leong PANG[1)], Jieru WANG[1)], Hui Hwang GOH[1)], Swee King PHANG[1)], Hafisoh AHMAD[1)], Kah Yoong CHAN*[2)]** [1)] School of Engineering, Centre for Sustainable Societies, Taylor's University, Taylor's Lakeside, Subang Jaya, Selangor, Malaysia; [2)] Centre for Advanced Devices and Systems, Faculty of Artificial Intelligence and Engineering, Multimedia University, Persiaran Multimedia, Cyberjaya, Selangor, Malaysia	318
28.	**ANALYSIS AND CALIBRATION OF DISCRETE ELEMENT PARAMETERS FOR *YANHUSUO* BASED ON STACKING TESTS /** ***基于堆积试验的延胡索离散元参数分析与标定*** **Chun WANG[1,2)], Xiangyang LIU[1)], Yongchao SHAO[1)], Weiguo ZHANG*[1)]** [1)]College of Mechanical and Electrical Engineering, Northwest Agriculture and Forestry University, Yangling, China; [2)]College of Biological and Agricultural Engineering, Jilin University, Changchun, China	327
29.	**DESIGN AND EXPERIMENT OF HIGH LEVEL UNLOADING LARGE GRAIN COLLECTION BOX FOR FRESH CORN COMBINED HARVESTER /** ***鲜食玉米联合收获机高位卸粮大型集粮箱设计与试验*** **Xin ZHANG*), Tong YE, Haitao LAN, Jingwen WU, Jianguo CHANG** Heilongjiang Academy of Agricultural Machinery Engineering Sciences, Harbin, China	338
30.	**RESEARCH ON SPEED CONTROL OF AN ELECTRICALLY DRIVEN THRESHING CYLINDER IN A COMBINE HARVESTER BASED ON INERTIA PARAMETER IDENTIFICATION /** ***基于惯量参数辨识的联合收割机电驱动脱粒滚筒转速控制研究*** **Yushuai QIAN*, Li QUAN, Jiapeng DIAO, Lei XU, Zixuan XIANG, Xiaoyong ZHU** School of Electrical and Information Engineering, Jiangsu University, Zhenjiang, Jiangsu, China	353
31.	**STABILITY ANALYSIS OF FLAT-ELLIPTICAL GREENHOUSE SKELETON CONSIDERING INITIAL GEOMETRICAL IMPERFECTIONS / *考虑初始几何缺陷的平椭圆管大棚骨架稳定性分析*** **Hengyan XIE[1,*)], Cunxing WEI[2)], Xin ZHENG[1)], Wenbao XU[1)]** [1)]College of Civil Engineering and Water Conservancy, Heilongjiang Bayi Agricultural University, Daqing, China; [2)] College of Engineering, Heilongjiang Bayi Agricultural University, Daqing, China	369
32.	**OPTIMIZATION DESIGN AND TEST OF BAFFLE STRUCTURE PARAMETERS OF THE HQ-800 STRAW MILL / *HQ-800型秸秆粉碎机隔板结构参数优化设计及试验*** **Kai YONG [1)], Qing TANG [2,3*)], Zhewen SONG [3)], Lan JIANG [2)]** [1)]School of Smart Manufacturing, Wuhu Institute of Technology, Wuhu, China; [2)]Nanjing Institute of Agricultural Meshanization, Ministry of Agriculture and Rural Affairs, Nanjing, China; [3)]Sinomach Changlin Co.Ltd., Changzhou, China.	380

33.	**STUDY ON THE STRAW-SOIL DISTURBANCE CHARACTERISTICS OF A LIFT-TYPE WINGED CHISEL PLOW / *抬土式带翼凿式犁对秸秆-土壤扰动特性的研究*** **Juanjuan WU[1)], Xianliang WANG * [2 3)], Kun CHEN[2 3)]** [1)] School of Intelligent Manufacturing, Zibo Polytechnic University, Zibo, China; [2)] College of Agricultural Engineering and Food Science, Shandong University of Technology, Zibo, China; [3)] Institute of Modern Agricultural Equipment, Shandong University of Technology, Zibo, China	394
34.	**STUDY ON THE IMPACT-BLOCKING EFFECT BETWEEN GRINDING MEDIA AND WHEAT BRAN POWDER DURING THE VIBRATION CRUSHING PROCESS /** ***振动粉碎过程中磨介与小麦麸皮粉体间的冲击阻滞效应研究*** **Min CHENG*[2)], Haocong MENG[1)], Guangbo Xiang*[2)], Shihao ZHOU[1)], Mingxu Wang[1)], Baoguo LIU[1)]** [1)] School of Mechanical and Electrical Engineering, Henan University of Technology, Zhengzhou / China; [2)] School of Mechanical Engineering, Zhengzhou University of Science and Technology, Zhengzhou / China	404
35.	**METHODS AND EXPERIMENTAL STUDY ON THE DETERMINATION OF FRICTION AND MECHANICAL PROPERTY PARAMETERS OF VARIOUS RICE SEED VARIETIES UNDER DIFFERENT CONDITIONS /*不同状态下多种水稻种子摩擦与力学特性参数测定方法及试验研究*** **Hanqing LI[1)], Shengnan LIU*[1)], Guangwei WU[2)], Bingxin YAN[2)], Lin LING[1,2)],** [1)] College of Intelligent Manufacturing, Nanyang Institute of Technology / China [2)] Research Center of Intelligent Equipment Technology, Beijing Academy of Agriculture and Forestry Sciences / China [3)] College of Engineering Technology, Southwest University / China	416
36.	**DESIGN AND EXPERIMENTAL STUDY OF AN ADJUSTABLE WRAPPING MACHINE FOR RICE STRAW BALES OF DIFFERENT SIZES / *可调式秸秆包捆机的设计与试验研究*** **Liyan WU[1)], Huchao TAN[2)], Na ZHANG[1)], Hengyi WEI[1)], Zhenyu WANG[1)], Chunhua BAN[3)], Cuihong LIU*[1)]** [1)]College of Engineering, Shenyang Agricultural University, Shenyang / China [2)]Yantai Taihai Manoir Nuclear Power Equipment Co., Ltd., Yantai / China [3)]Liaoning Provincial Institute of Agricultural Mechanization / China	428
37.	**EFFECTS OF DIFFERENT VENTILATION VELOCITIES ON THE THERMAL ENVIRONMENT OF SOLAR GREENHOUSES / *不同通风速度对日光温室热环境的影响*** **Chuyuan ZHONG, Huiqun ZHOU** Horsh (FUjian) Food Co., Ltd, Fujian / China	441
38.	**EFFECTS OF ELECTRIC VOLTAGE AND WATER VOLUME ON OHMIC HEATING HYDRODISTILLATION (OHHD) OF NUTMEG LEAVES /** ***PENGARUH TEGANGAN LISTRIK DAN VOLUME AIR PADA HIDRODISTILASI OHMIK HEATING DAUN PALA*** **Imam SOFI'I[1)*], WINARTO[1)], Oktaf RINA[1)]** Department of Agricultural Technology, Politeknik Negeri Lampung, Bandar Lampung, Lampung / Indonesia	451
39.	**OPTIMIZATION DESIGN AND TEST OF INTERACTIVE ANTI-STICK GEAR FERTILIZER DISCHARGER FOR PINEAPPLE / *菠萝专用交互式防粘齿轮排肥器的优化与试验*** **Guoqiang DUN*[1)], Chunyu MA[2)], Xinxin JI[2)], Hailiang LI*[3)], Haochun CHENG[2)],** **Haitian SUN[3)], Chaoxia ZHANG[2)]** [1)] Harbin Cambridge University, Intelligent Agricultural Machinery Equipment Engineering Laboratory, Harbin / China; [2)] Northeast Forestry University, College of Mechanical and Electrical Engineering, Harbin/China; [3)] South Subtropical Crop Research Institute, Chinese Academy of Tropical Agricultural Sciences, Key Laboratory of Tropical Fruit Biology, Ministry of Agriculture & Rural Affairs, Key Laboratory of Hainan Province for Postharvest Physiology and Technology of Tropical Horticultural Products, Zhanjiang / China	461
40.	**RESEARCH ON THE VIBRATION AND FRUIT DROP CHARACTERISTICS OF CAMELLIA OLEIFERA BASED ON HIGH-SPEED PHOTOGRAPHY TECHNOLOGY /** ***基于高速摄影技术的油茶振动落果特性研究*** **Zhihao ZHU[1)], Xiaoyu CHAI *[1)], Lizhang XU[2)], Li QUAN[3)], Chaochun YUAN[4)], En LU[1)],** **Shuofeng WENG[3)], Shichao TIAN[1)], Guangqiao CAO[5)]** Chinese Academy of Agricultural Mechanization Science Group Co., Ltd., Beijing / China	475
41.	**RESEARCH ON TORQUE DYNAMIC COORDINATED CONTROL OF A NOVEL DUAL POWER SOURCE THRESHING DRUM OF COMBINE HARVESTER /** ***新型双动力源脱粒滚筒扭矩动态协调控制研究*** **Zhihao ZHU[1)], Xiaoyu CHAI *[1)], Lizhang XU[2)], Li QUAN[3)], Chaochun YUAN[4)], En LU[1)],** **Shuofeng WENG[3)], Shichao TIAN[1)], Guangqiao CAO[5)]** [1)]School of Agriculture Engineering, Jiangsu University, China [2)]Key Laboratory for Theory and Technology of Intelligent Agriculture Machinery and Equipment, Jiangsu University, China; [3)]School of Electrical and Information, Jiangsu University, China [4)]Automotive Engineering Research Institute, Jiangsu University, China [5)]Nanjing Institute of Agricultural Mechanization, Ministry of Agriculture and Rural Affairs, China	483
42.	**SUBSTANTIATION OF EQUIPMENT PARAMETERS FOR COMPACTING PLANT MATERIALS /** ***ОБОСНОВАНИЕ ПАРАМЕТРОВ ОБОРУДОВАНИЯ ДЛЯ УПЛОТНЕНИЯ РАСТИТЕЛЬНЫХ МАТЕРИАЛОВ*** **Dmitry MILKO[*)], Anna PEDCHENKO[1)], Tatyana KLEVTSOVA[1)], Alexander GVOZDEV[1)]** [1)] Melitopol State University / Russia	496

43.	**PREDICTION OF BOESENBERGIA ROTUNDA (L.) DRYING USING HOT AIR AND ULTRASONIC VIBRATION VIA EXTREME GRADIENT BOOSTING /** *การทำนายการอบแห้งของกระชายขาวด้วยลมร้อนและการสั่นสะเทือนความถี่สูงโดยใช้เทคนิคเอ็กซ์ตรีมเกรเดียนต์บูสติง* **Patipat THANOMPONGCHART[1)], Pakamon PINTANA[2)], Tossapon KATONGTUNG[3)], James C. ABSTRACT
Efficient cotton stalk recycling is crucial for agricultural sustainability. Traditional manual removal methods suffer from low efficiency and high labor intensity. Existing mechanical harvesters face limitations such as low removal rates, high stalk breakage rates, and significant omission rates. To address these challenges, this study focuses on optimizing a self-developed multi-row disc-type stalk puller. The conventional flat disc was redesigned into an obliquely angled disc with a bending angle. This 3D curved design enhances stalk constraint capability, thereby improving gripping stability and lifting height. A kinematic model was developed using the ADAMS dynamics simulation platform, revealing the relationships between motion trajectories and key structural parameters. Parametric analysis quantified the effects of disc diameter and bending angle on lifting height and working width. A three-factor, three-level orthogonal experimental design was implemented to evaluate the influence of speed ratio, disc diameter, and disc inclination on three performance indicators: removal rate (Y_1), breakage rate (Y_2), and omission rate (Y_3). The results showed that for Y_1 and Y_3, the primary influencing factors, in order of importance, were: disc diameter > bending angle > speed ratio; for Y_2, the order was: speed ratio > bending angle > disc diameter. The optimal parameter combination was determined to be: 600 mm disc diameter, 20° bending angle, and 0.7 speed ratio. Field tests achieved a pull-out rate of 95.7%, a breakage rate of 3.2%, and an omission rate of 1.1%. These findings provide both theoretical and technical support for enhancing the efficiency of mechanized cotton stalk harvesting.

摘要
棉秆高效回收对促进农业可持续发展具有重要意义，然而传统人工拔秆存在作业效率低、劳动强度大等问题，现有机械收获装置普遍存在拔净率低、断秆率高等技术瓶颈。针对现有棉花秸秆机械化收获存在的整株拔除率低、作业效率不高等问题，本研究基于自主研发的多行齿盘式拔秆机开展结构优化。通过将传统平面齿盘创新设计为带有折弯角的仰角齿盘结构，利用三维曲面增强茎秆约束能力，从机构学层面提升夹持稳定性和有效提拔高度。基于 ADAMS 动力学仿真平台，建立仰角齿盘运动学模型，揭示了运动轨迹与结构参数间的映射关系，通过参数化分析明确了齿盘直径、折弯角对提升高度和工作幅宽的量化影响规律。通过构建三因素三水平正交试验平台，系统研究速比、齿盘直径、齿盘倾角等关键参数对拔净率、拔断率和漏拔率的影响规律。试验结果表明：影响拔净率的参数从主到次排序为：齿盘直径 > 折弯角度 > 速比；影响漏拔率的参数从主到次排序为：齿盘直径 > 折弯角度 > 速比；影响拔断率的参数从主到次排序为：速比 > 折弯角度 > 齿盘直径。以拔除率为主要评价指标，得到最优参数组合是：齿盘直径=600mm、折弯角=20°、速比=0.7。验证结果表明，该参数组合下棉秆拔净率为 95.7%、拔断率为 3.2%、漏拔率为 1.1%。研究成果为进一步提高棉秆拔净率提供了理论依据和技术支撑。

INTRODUCTION
China is one of the world's major cotton producing countries, with the third largest cotton planting area in the world and abundant cotton stalk resources. Cotton stalk is a high-quality biomass resource with a wide range of applications such as building boards, chemical product raw materials (such as ethanol and

[1] *Weisong Zhao, Assistant researcher, Ph.D.; Jianhua Xie, Professor, Ph.D.; Mingjiang Chen, Researcher, Ph.D.; Chunsong Guan, Associate researcher, Ph.D.; Jia Zhang, Associate Professor; Zhenwei Wang, Assistant researcher;Yan Gong, Researcher.*

carboxymethyl cellulose), fuel and papermaking *(Agwa et al., 2020; Keshav et al., 2023; Nguyen et al., 2020; Wang Fangzheng et al., 2022)*. The comprehensive utilization of cotton stalks is an important measure to accelerate the green and low-carbon development of agriculture, and mechanized removal of these is the primary link in achieving numerous important uses *(Fernando Correa Da Costa and Cuiaba, 2010; Jiang et al., 2021; Liu Fei et al., 2019).*

The cotton stalk pulling device is a key component of the cotton stalk harvester. Many scholars have carried out work on the design of cotton stalk pulling technology and devices *(Cai Jialin et al., 2020; Chen Mingjiang et al., 2012; He Xiaowei et al., 2020; Tang Zunfeng et al., 2010; Xie Jianhua et al., 2023; Zhao et al., 2023)*. According to the structural form, the pulling devices include toothed discs type *(Ramadan, 2010)*, tire roller type *(Pan, 2014)*, clamping type *(Zhao Weisong et al., 2024)*, flexible belt type *(Cai Jialin et al., 2020)*, toothed roller type *(Zhang Aimin et al., 2016)*, etc. Among them, the toothed discs type stalk puller has a simple structure and affordable price. It is widely welcomed by Chinese farmers and has been applied to a certain extent. However, the operation effect of the toothed discs type stalk puller needs to be further improved, and there are still many cotton stalks that are missed or broken. In order to solve this technical problem, some scholars have carried out mechanism research, structural optimization design and other work. For example, *Wang Xiaoyu et al. (2011)* simulated the motion trajectory of the toothed discs type stalk puller and obtained the trajectory curve under the horizontal working condition of the toothed discs. *Ma Jichun et al., (2010),* further carried out the motion analysis of the toothed discs type stalk puller and explained the influence of different speed ratios on the motion law. *Chen Mingjiang et al. (2019)* used ADAMS to conduct an analysis of the operation process and parameter optimization of a multi-row toothed discs stalk puller. The results showed that the speed ratio was the key factor affecting the removal rate, and the optimal range was 0.55~0.8. *Zhao Weisong et al. (2022),* further conducted a study on the optimization of the toothed discs structure and established the response function of three influencing factors and assessment indicators. However, in the current reported results, the toothed discs are all planar designs, that is, the toothed discs are flat structures. This structure results in unsatisfactory clamping effect and lifting height of cotton stalks. In response to this problem, the goal of this study is to explore the motion law and operation effect of non-planar toothed discs structures, design a non-flat toothed disc, and conduct experimental research on motion trajectory analysis and key influencing factors.

MATERIALS AND METHODS

Overall structure and working principle

The traditional gear-disc type cotton stalk puller is driven by a ground wheel, which relies on the friction between the ground wheel and the ground to achieve power transmission. When operating at high speed, the ground wheel slips and the transmission is unstable, resulting in poor stalk pulling effect and a significantly reduced removal rate. The transmission ratio between the ground wheel and the toothed discs of the traditional toothed discs cotton stalk puller is a constant value, and the working parameters of the mechanism cannot be adjusted according to the changes in the cotton stalk harvesting period, which greatly limits the scope of application of the stalk pulling machinery.

The toothed discs type multi-row cotton stalk pulling device designed in this paper is mainly composed of a parallelogram hanging mechanism, a frame, a hydraulic motor and a speed sensor, a stalk supporter, toothed discs, a folding mechanism and other components, as shown in Figure 1.

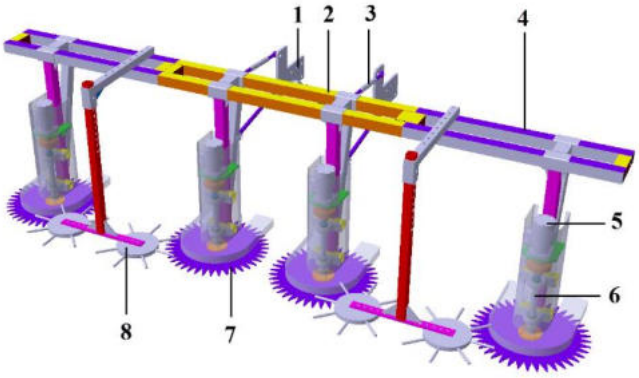

Fig. 1 - Structural diagram of multi-row cotton-stalk uprooting device

1. Hooking mechanism; 2. Fixed frame; 3. Telescopic rod; 4. Foldable frame; 5. Hydraulic motor; 6. Rotating shaft; 7. Non-flat toothed discs; 8. Crop support

The side frames can be folded during transportation, and are easy to assemble and disassemble. They can realize two-row or four-row operations, and the spacing between adjacent toothed discs is adjustable to meet the requirements for harvesting cotton stalks at different row spacings. The electro-hydraulic control technology can realize individual control of each gear disc, and the gear disc rotation direction and speed are adjustable.

Working principle: When working, the stalk pulling tooth plate rotates at a certain speed driven by the hydraulic motor. The tractor moves forward to feed the cotton stalks into the V-shaped tooth grooves on the tooth plate. The stalks are pulled out of the soil.

Key components and hydraulic transmission system design

Overall design of the gear-disc multi-row cotton stalk pulling stand

The overall structure of the gear-disc multi-row cotton stalk pulling stand is shown in Figure 2. It is mainly composed of a load-sensitive pump, an electro-hydraulic proportional valve, a display, a vehicle speed sensor, a cotton stalk pulling device, a tractor, etc. The gear speed and speed ratio are controllable and adjustable, and the gear speed, torque and other key operating parameters are monitored and recorded in real time through sensors, which is convenient for subsequent data mining and analysis.

Fig. 2 - Toothed disc multi-row cotton-stalk uprooting device

1. Hydraulic oil tank; 2. Tractor; 3. Hydraulic proportional valves; 4. Non-flat toothed disc; 5. Hydraulic motor

The cotton stalk pulling device is suspended at the front end of the tractor through a parallelogram mechanism. The pump is driven from the tractor's PTO via a coupling. Each disc is driven by a separate hydraulic motor, for a total of 4 discs, capable of removing 4 rows of cotton stalks per operation. The rack width of the toothed discs type multi-row cotton stalk pulling device is 2400 mm, the toothed discs spacing is adjustable, and it can operate when the cotton stalk row spacing is greater than 500 mm.

Hydraulic transmission system design

In order to achieve adjustable speed ratio during operation, the gear-disc multi-row cotton stalk pulling stand adopts electro-hydraulic control, as shown in Figure 3. The motor drives the stalk pulling gear to rotate, and the tractor moves forward to realize the cotton stalk pulling operation function. The speed sensor can transmit the gear speed signal to the controller. The control system CPU combines the vehicle speed signal and feeds back the control signal to the PVG proportional valve according to the system setting. The PVG proportional valve system controls the motor speed according to the signal.

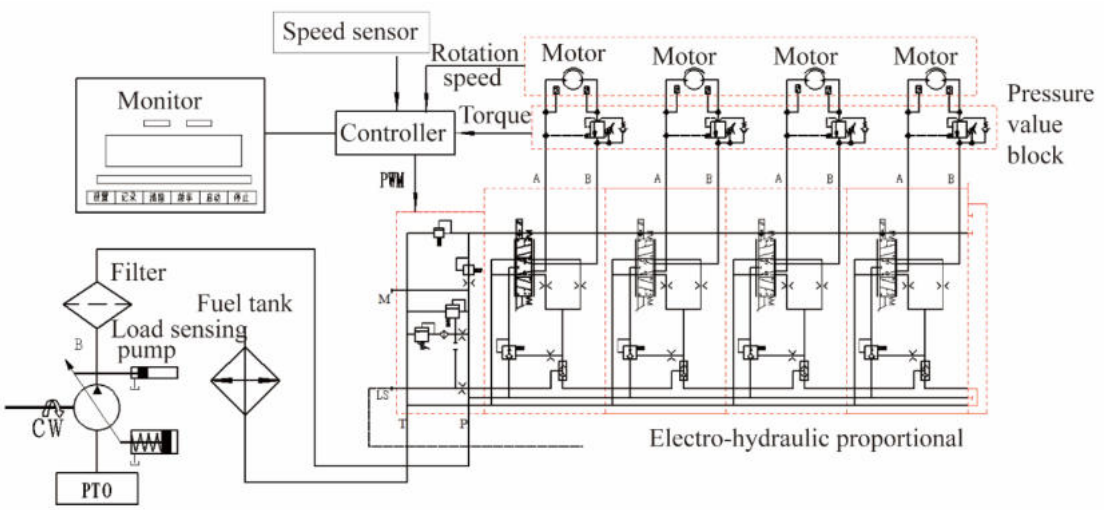

Fig. 3 – Diagram of electro-hydraulic control system

According to the electro-hydraulic control principle in Figure 3, the DANFOSS brand JR-L series load-sensitive pump, PVG16-4 proportional valve, OMP series hydraulic motor and speed sensor, HFBG-NN-0101 pressure measuring valve block, MC024-110 controller, and DP570 display were selected. The numerical range of the hydraulic motor and other modules was determined based on the stalk pulling torque.

According to the cotton stalk uprooting resistance, the stalk pulling torque of a single toothed discs is:

$$M=N\cdot L \tag{1}$$

where:

M is the pulling torque of a single toothed discs, N·m.

N is the pulling resistance of a single cotton stalk, the average value is 500 N, the max. value is 1000N.

L is the pulling arm length, 0.25 m.

The calculation shows that the average stalk pulling torque of a single toothed discs is 125 N·m, and the maximum is 250 N·m. Considering the 20% reserve torque, the maximum torque of a single toothed discs is 300 N·m. When the circumferential speed of the toothed discs ranges from 0 to 6 m/s, the theoretical speed is 0 to 229 r/min. Based on the above calculation results, the OMP 200 hydraulic motor and JR-L-S75C-LS load sensitive pump are selected.

Design and analysis of the elevation gear disc

The gear disc is an important component for clamping and pulling cotton stalks. Its main parameters are the gear disc diameter, tooth shape and tooth angle. The gear disc diameter not only affects its structural strength, but also affects the length of the cotton stalk pulling stroke. The tooth shape is designed as a "V"-shaped tooth groove. The V-shaped tooth groove has strong adaptability to the diameter and thickness of the cotton stalk and good pulling effect. The cotton planting patterns in Shandong Province, China mainly include 760 mm equal row spacing planting and wide and narrow row planting. The narrow row spacing is generally 500-600 mm. Considering the versatility of the test bench, the gear disc radius r is designed to be 250 mm. Too thin gear discs have insufficient strength, and too thick gear discs increase energy consumption and cost. The designed gear disc thickness is 5 mm. The diameter (root) of cotton stalks is mostly between 12 and 15 mm, and some are between 15 and 25 mm. The thinner the root, the easier it is to miss and break, and the thicker the root, the higher the removal rate. According to the geometric relationship in Figure 4, the V-shaped tooth groove must meet the following requirements when it can clamp the cotton stalk:

$$L_{\mathrm{BC}} \geq d_{max} \tag{2}$$

$$L_{\mathrm{AD}} \geq d_{max} \tag{3}$$

$$\angle \mathrm{BAC} = 2\angle \mathrm{BAD} = 2\tan^{-1}\frac{l_{BC}}{l_{AD}} \tag{4}$$

where:

L_{BC} - tooth width, mm; d_{max} - cotton stalk root diameter, taken as 25 mm.

L_{AD} - tooth depth, mm; $\angle$BAC - tooth angle, (°).

Increasing both the tooth width (L_{BC}) and tooth depth (L_{AD}) can enhance the adaptability of the non-flat toothed discs to cotton stalks of varying thicknesses. However, an increase in tooth width reduces the number of teeth, which may raise the probability of omission. Similarly, insufficient tooth depth (L_{AD}) can also increase the likelihood of omission. Based on Equations (2)~(4), when L_{BC} and d_{max} are both set to 25 mm and ∠BAC is set to 35°, the calculated tooth depth L_{AD} is 39.64 mm (>d_{max}), satisfying the required conditions. After rounding, L_{AD} is determined to be 40 mm. As shown in Figure 4, the toothed discs can meet the pulling out of cotton stalks with different root diameters. After the cotton stalks are pulled out, they fall down due to the loss of soil force on the root system. In order to enable the pulled cotton stalks to be smoothly separated from the toothed discs, an auxiliary separation component is designed. It is a curved component that can change the movement path of the cotton stalks so that the cotton stalks can be smoothly separated from the toothed discs.

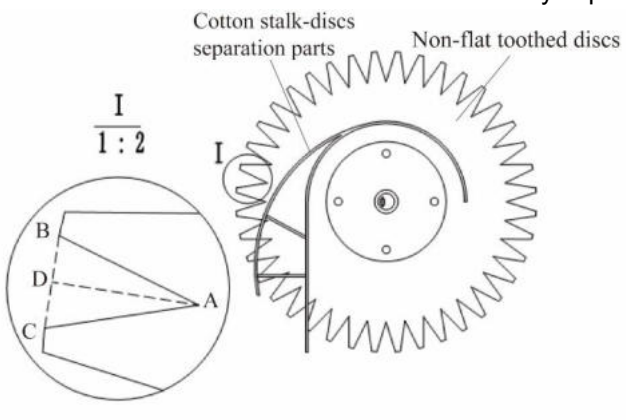

Fig. 4 – Non-flat toothed disc structure diagram

The clamping point (Point *O*, also the contact point) during stalk pulling was analyzed, as shown in Fig. 5. In traditional flat discs, the clamping point follows a trochoidal trajectory *(Chen Mingjiang et al., 2019)*. When discs are horizontally positioned (parallel to the ground), this trajectory becomes two-dimensional (parallel to the ground). Under these conditions, cotton stalks are typically pushed forward by the discs. This occurs because the clamping point lacks upward motion, eliminating vertical pulling forces. In order to optimize the trajectory of the clamping point, non-flat toothed discs were designed in this study. The objective of the design is to make the disc able to hold the cotton stalks firmly and to make the clamping point have an upward motion trajectory. The schematic structure of the non-flat toothed disc and its kinematic sketch are shown in Fig. 5.

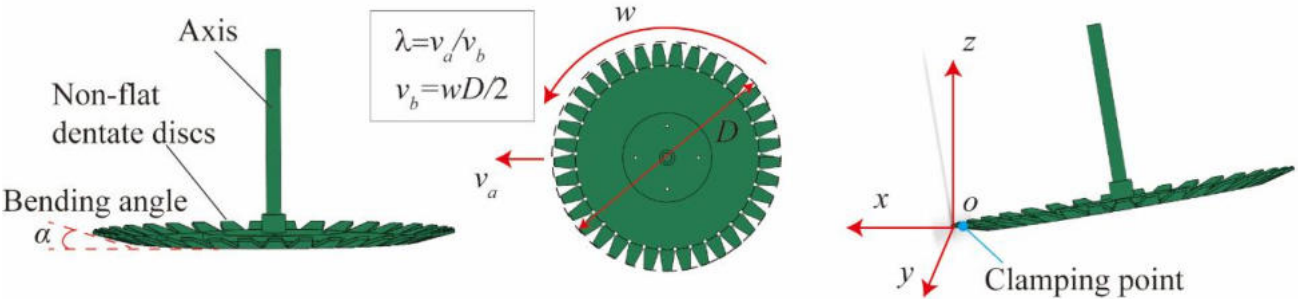

Fig. 5 - Non-flat toothed discs structural diagram and motion diagram

α is bending angle; λ is the ratio of the forward speed of the machine to the speed of the toothed disc, hereinafter referred to as the "speed ratio"; v_D is machine forward speed; w is angular speed of toothed discs; v_b is linear speed at clamping point; D is diameter of toothed discs.

To analyze the motion trajectory of clamping points on non-flat toothed discs and its impact on cotton stalk removal, ADAMS software was used for simulation. Under identical speed ratios, trajectories were simulated with varying disc diameters (D) and bending angles (α), as shown in Figure 6. Four parameter combinations were tested: D =500 mm, α=6°; D =500 mm, α=12°; D =600 mm, α=6°; D=600 mm, α=12°. It can be seen from Figure 6 that the overall movement trends of the trajectory curves of the four parameters are consistent, all of which are spiral lines. However, the curves do not overlap, indicating that both the toothed discs diameter D and the bending angle have an effect on the trajectory. On the whole, under the same bending angle conditions, the larger the diameter of the toothed discs, the larger the value of the curve in the z-axis direction, indicating a higher lifting height. Under the same gear disc diameter conditions, the larger the bending angle, the greater the lifting height.

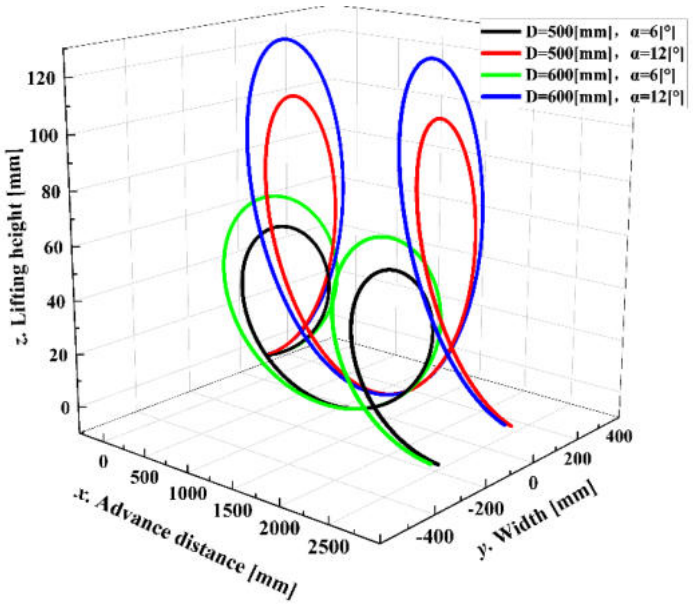

Fig. 6 - Motion trajectory of non-flat toothed discs

In order to further analyze the influence of the gear disc diameter and bending angle on the running trajectory, the x-y curve (Figure 7) and x-z curve (Figure 8) are drawn respectively. The x-y curve is used to analyze the variation of the gear disc working width, and the x-z curve is used to analyze the variation of the lifting height.

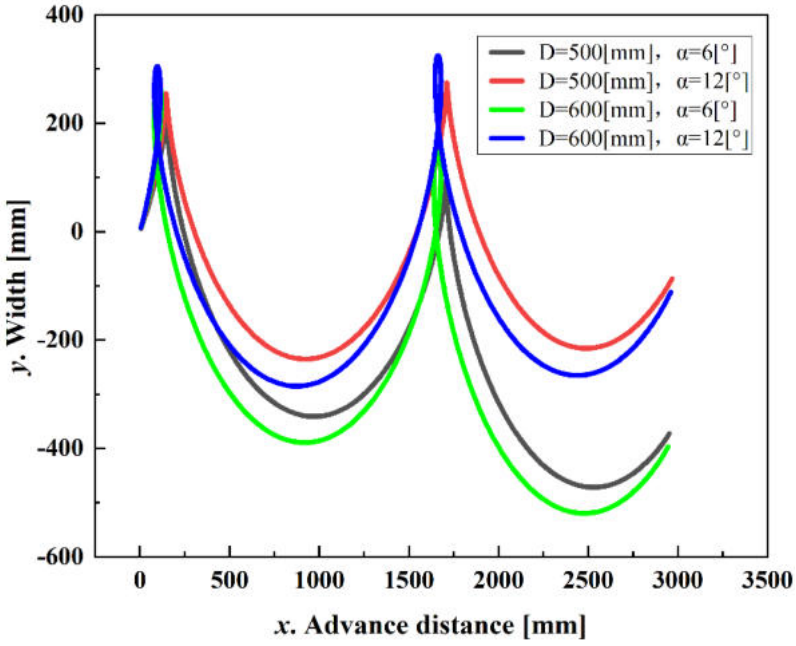

Fig. 7 - x-y curves

As can be seen from Figure 7, when the toothed discs diameters are the same (D=500 mm, D =600 mm), the toothed discs with a large bending angle (α=12°) have a small movement width, while the toothed discs with a small bending angle (α=6°) have a large movement width. The reason is that the large bending angle causes the projection diameter of the toothed discs on the horizontal plane to become smaller, so the movement width is reduced. A small movement width means a small effective working area, which easily increases the probability of missing cotton stalks. When the bending angle is the same, the movement width of the toothed discs with a diameter of 600 mm is greater than that of the toothed discs with a diameter of 500 mm. This shows that increasing the diameter of the toothed discs is an effective way to increase the movement width.

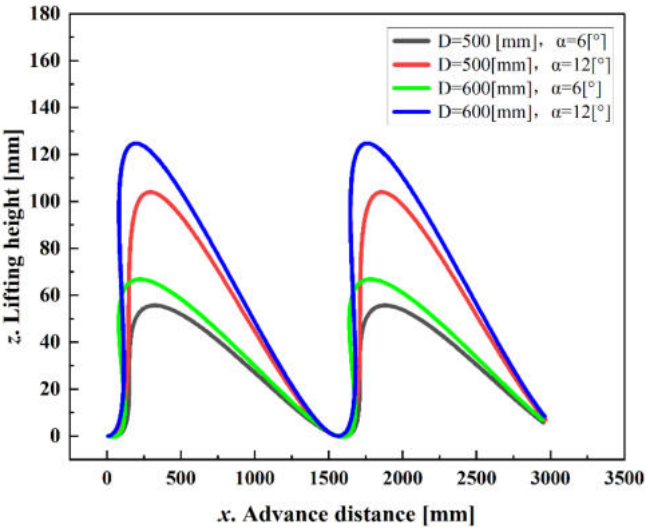

Fig. 8 - x-z curves

As can be seen from Figure 8, when the diameter of the toothed discs is the same, the toothed discs with a large bending angle has a larger lifting distance. This shows that under effective clamping conditions, the cotton stalk can be pulled to a higher height, which is conducive to the successful removal of the cotton stalk. At the same time, it can also be seen that increasing the bending angle (from 6° to 12°) produces a more obvious height increase than increasing the toothed discs diameter (from diameter = 500 mm to diameter = 600 mm).

Through the above research, it can be found that for non-planar toothed discs, the diameter and bending angle of the toothed discs have a greater impact on the movement width and lifting height. Therefore, this study selects three main influencing factors, namely, toothed discs diameter, bending angle and speed ratio, and studies the influence of each factor on the quality of cotton stalk removal through orthogonal experiments.

Experimental conditions

With the help of a self-made toothed discs type cotton stalk pulling test bench (*Chen Mingjiang et al., 2022*), all the tests were completed by replacing different toothed discs. The test site was the Binzhou Cotton Production Full Mechanization Agricultural Machinery and Agronomy Integration Demonstration Base in the National Agricultural Science and Technology Park of Binzhou City, Shandong Province. The test time was November 15-18, 2018, and the weather was cloudy. The cotton variety in the data collection area was Zhongmian 619, cultivated without film, with a planting row spacing of 760 mm, a plant spacing of about 200 mm, and a plant height of 900~1200 mm.

Experimental methods

The test was carried out with reference to GB/T8097-2008 "Test Methods for Harvesting Machinery Combine Harvesters" and DB37/T1856-2011 "General Technical Conditions for Toothed discs Type Cotton Stalk Pullers". Before the test, the toothed discs spacing was adjusted according to the cotton planting row spacing. The effective test length of each test was 30 m, and each group of tests was repeated 3 times. The experimental factors were toothed discs diameter, bending angle and speed ratio. The removal rate is the main test index for cotton stalk removal, and the non-removal rate mainly includes the breakage rate and the omission rate.

The calculation formula for the assessment index is shown below.

$$y_1 = \frac{N_1}{N} \times 100\% \quad (5)$$

$$y_2 = \frac{N_2}{N} \times 100\% \quad (6)$$

$$y_3 = \frac{N_3}{N} \times 100\% \quad (7)$$

$$y_1 + y_2 + y_3 = 100\% \quad (8)$$

In the formula, y_1, y_2 and y_3 are the removal rate, breakage rate and omission rate respectively; N_1, N_2 and N_3 are the number of cotton stalks successfully pulled, the number of cotton stalks broken and the number of cotton stalks missed respectively; N is the total number of cotton stalks, $N = N_1 + N_2 + N_3$.

RESULTS AND ANALYSIS

Based on the single factor test, the tooth disc diameter D, tooth disc inclination angle α and speed ratio λ were selected as influencing factors. The three different levels of factors were arranged according to the $L_9(3^4)$ orthogonal table for orthogonal test. The evaluation indicators were cotton stalk removal rate (y_1), breakage rate (y_2) and omission rate (y_3). Each group of experiments was repeated 3 times, and the experimental factor levels are shown in Table 2.

Table 1

Factors and levels

Levels	Toothed disc diameter, D [m]	Bending angle, α [°]	Speed ratio λ
1	0.5	0	0.5
2	0.6	10	0.7
3	0.7	20	0.9

The three-factor, three-level orthogonal test design scheme and results are shown in Table 2.

Table 2

Tests design scheme and results

No.	Factors			Response indicators		
	D	α	λ	Removal rate y_1 [%]	Breakage rate y_2 [%]	Omission rate y_3 [%]
1	1	1	1	83.31	4.73	11.96
2	1	2	2	90.89	3.95	5.16
3	1	3	3	92.31	6.05	1.64
4	2	1	2	93.69	1.11	5.20
5	2	2	3	95.06	1.43	3.51
6	2	3	1	93.24	5.41	1.35
7	3	1	3	76.74	13.52	9.74
8	3	2	1	82.82	2.30	14.88
9	3	3	2	89.71	2.94	7.35

The experimental results in Table 2 were subjected to range analysis using SPSS software. The range values characterize the relative influence weight of each factor on the evaluation metrics within the selected level ranges. Specifically, factors with larger ranges demonstrate stronger impact weights on the evaluation indicators under their respective level selections, as summarized in Table 3.

Table 3

Orthogonal test range analysis results

Parameters	y_1 [%]			y_2 [%]			y_3 [%]		
	D	α	λ	D	α	λ	D	α	λ
k_1	88.83	84.58	86.45	4.91	6.45	4.15	6.25	8.97	9.40
k_2	94.0	89.59	91.43	2.65	2.56	2.67	3.35	7.85	5.90
k_3	83.09	91.75	88.04	6.25	4.80	7.00	10.66	3.45	4.96
R	10.91	7.17	4.98	3.60	3.89	4.33	7.31	5.52	4.44
Factors of priority	$D>\alpha>\lambda$			$\lambda>\alpha>D$			$D>\alpha>\lambda$		
Optimal parameter combination	$D2\alpha3\lambda2$			$\lambda2\alpha2\ D2$			$D2\alpha3\lambda3$		

Note: k_1~k_3 refer to the mean values of each factor at its respective levels, %; R refers to range, %.

As shown in Table 3, the primary-secondary order of factors influencing cotton stalk removal rate was D > α > λ, while their influence on breakage rate followed the sequence λ > α > D, and the impact order on omission rate was D > α > λ. With removal rate serving as the primary evaluation metric, the optimal parameter combination was determined as $D2\alpha3\lambda2$.

In order to more intuitively show the influence of each factor level on the assessment indicators, Origin 9.0 is used to draw a horizontal indicator relationship diagram with the factor level as the horizontal axis and each assessment indicator as the vertical axis, as shown in Figure 9.

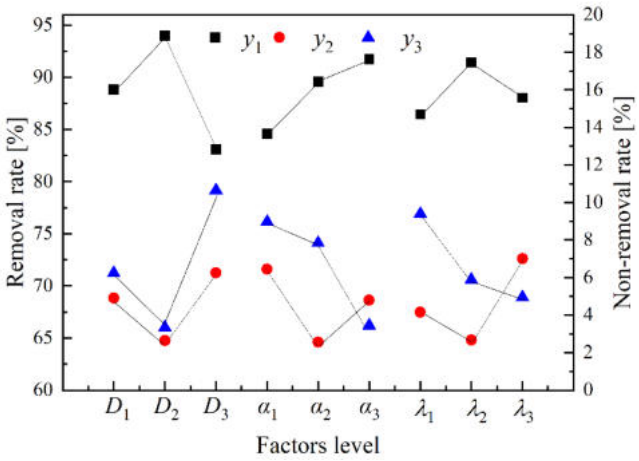

Fig. 9 – Relationship between each factor level and assessment index

An increase in both stalk breakage rate and omission rate directly reduces the removal rate; therefore, the removal rate was selected as the primary evaluation metric. When the removal rate is maximized, the optimal parameter combination is determined as D= 0.6 m, α =20°, and λ= 0.7, as shown in Table 3 and Figure 9. This parameter combination was used for a verification test, and the test was repeated 3 times to calculate the average value of the assessment index. The field environment and the non-flat toothed discs during the test is shown in Fig.10a, and the effect of cotton stalk uprooting is shown in Fig.10b. The test results show that under the $D2\alpha3\lambda2$ parameter combination, the cotton stalk removal rate is 95.7%, the breakage rate is 3.2%, and the omission rate is 1.1%. The test results show that the parameter combination is reasonable and can achieve a good stalk removal effect.

Fig. 10 - Cotton stalk removal test

CONCLUSIONS

(1) Based on the requirements and characteristics of cotton stalk uprooting operations, an optimized stalk removal device with non-flat toothed discs was designed. The key advantage of this device is that it imparts a significant upward motion trend to the cotton stalks during the removal process, thereby increasing the lifting height.

(2) ADAMS software was used to simulate and analyze the effects of three factors - disc diameter, bending angle, and speed ratio - on the motion trajectory of the gripping point, lifting height, and working width. The results show that the motion trajectory of the clamping point on the non-flat toothed discs follows a spiral pattern. Increasing the disc diameter helps improve the working width and reduce the omission rate, while increasing the bending angle is more effective than increasing the disc diameter for enhancing the lifting height.

(3) Following the orthogonal experiments carried out, an average cotton stalk removal rate of approx. 96% was obtained, using discs optimized in shape, dimensions and rotation speed. Thus, by using this type of discs, the performance of the cotton stalk removal device can be significantly improved.

ABSTRACT
To address the lack of contact parameters between Corydalis tuber and mechanical, or soil interfaces during planting, harvesting, and processing stages, this study calibrated discrete element simulation parameters for Corydalis tuber by combination of simulation tests and physical tests. 3D contour model of Corydalis tuber was obtained using 3D scanning technology, and a multi-sphere bonded particle model was constructed by automatic filling method. Simulation tests were conducted with the restitution coefficient, static friction coefficient, and rolling friction coefficient between Corydalis tuber and Q235 steel, as well as between Corydalis tuber and soil, as independent variables. The rebound height, friction angle, and rolling distance were considered as dependent variables. A second-order polynomial fitting method was used to analyze the experimental results. The actual test values were substituted into the polynomial equations to obtain simulation values for the contact parameters of Corydalis tuber with Q235 steel and soil, and these values were then validated against the experimental results. The findings indicate that the restitution coefficients of Corydalis tuber-Q235 steel and Corydalis tuber-soil were 0.728 and 0.44, respectively. The static friction coefficients of Corydalis tuber-Q235 steel and Corydalis tuber-soil were 0.41 and 0.76, respectively, while the rolling friction coefficients were 0.02 and 0.033, respectively. Under these conditions, the relative error between the simulation tests and physical tests was minimized. This study provides calibrated particle models and contact parameters for mechanical processing applications, including sowing, harvesting, and drying of Corydalis tuber.

摘要
针对延胡索在种植、收获、加工等环节中缺乏与机械、土壤接触参数的现状，本研究结合仿真试验与物理试验对延胡索进行离散元仿真参数标定。借用三维扫描技术获得延胡索的三维轮廓模型，采用自动填充法建立延胡索的多球粘结颗粒模型。分别以延胡索与 Q235 钢、土壤的碰撞恢复系数，静摩擦因数及滚动摩擦因数为自变量，以碰撞高度、摩擦倾角及滚动距离为因变量进行仿真试验，并进行二次多项式拟合。将实际试验值带入二次多项式，获得延胡索与 Q235 钢、土壤的接触参数仿真值，并与实际试验值进行校对。试验结果表明：延胡索-Q235 钢，延胡索-土壤的碰撞恢复系数分别为 0.728、0.44；延胡索-Q235 钢，延胡索-土壤的静摩擦因数分别为 0.41、0.76；延胡索-Q235 钢，延胡索-土壤的碰撞恢复系数分别为 0.02、0.033 时，仿真试验与实际试验相对误差最小。本研究可为延胡索播种、收获及烘干等机械加工提供颗粒模型与仿真接触参数。

INTRODUCTION
Corydalis tuber is one of the most widely utilized medicinal herbs in China. It is characterized by a flattened, spherical shape and typically thrives in loose soils, such as sandy or semi-sandy environments. Corydalis tuber contains over 30 types of alkaloids, including tetrahydropalmatine and corydaline (*He et al., 2007; Chen et al., 2008*). It exhibits notable pharmacological effects, such as analgesic, sedative, hypnotic, and anti-arrhythmic properties. In recent years, with the expanding applications of Corydalis tuber in the medical field, its demand has continued to rise, leading to increased profitability in its cultivation. Hanzhong City in Shaanxi Province is the largest Corydalis tuber cultivation area in China, with over 100,000 acres under cultivation, accounting for more than 70% of the nation's total production. Currently, the cultivation and harvesting of Corydalis tuber rely predominantly on manual labor, resulting in high labor intensity and elevated costs, which severely constrain the development of its cultivation industry.

To achieve full mechanization across all stages of Corydalis tuber cultivation, from planting to harvesting, has become an urgent necessity. Objective and accurate collection of the mechanical property parameters of Corydalis tuber is a prerequisite for the development of specialized mechanized equipment (*Han et al., 2017; Liu et al., 2018; Ma et al., 2013; Shi et al., 2014*).

The DEM simulates granular materials discretely, modeling each particle independently and assigning it mass, stiffness, and damping properties. The particles interact with each other through contact, and the dynamic forces and moments at the contact points are calculated using a contact mechanics model (such as the Hertz-Mindlin model), which in turn predicts the motion state of individual particles. This method has unique advantages in studying the plant-soil interaction in mechanized farming: First, it breaks through the continuum assumption and directly characterizes the particle-level stress transfer and displacement processes in the microscopic contact between the agricultural tool and the soil, accurately analyzing the soil fragmentation/compaction mechanism. Second, its multi-physics coupling capability can simultaneously simulate the stress deformation of mechanical components and the dynamic response of the soil, providing a cross-scale analysis basis for the structural optimization of agricultural machinery. This discrete granular dynamics feature makes it an important tool for shortening the research and development cycle of agricultural machinery.

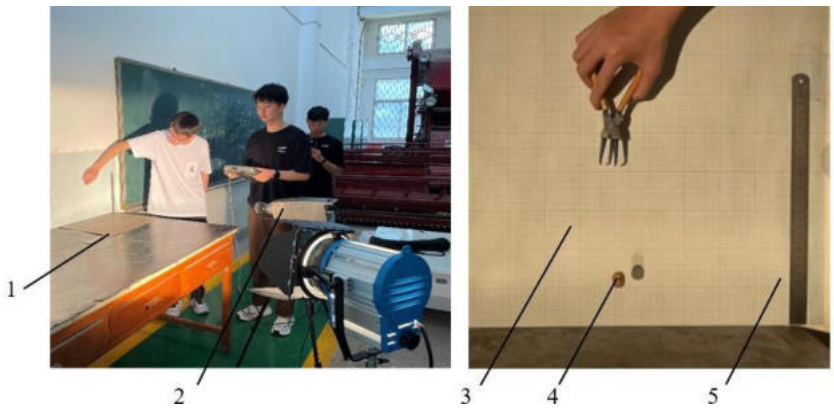
Originally developed to solve geotechnical problems, the discrete element method (DEM) is a numerical method for calculating the mechanical properties of granular materials. It simulates granular materials as individual particles and calculates the forces (such as contact and friction forces) and movements between the particles iteratively over time steps. It is particularly suitable for studying plant-soil interactions in mechanized farming because it can capture the discrete nature of soil particles and irregular shapes of crops (e.g., tubers), enabling precise modeling of dynamic processes such as soil penetration, root-soil adhesion, and mechanical harvesting collisions (*Wang et al., 2024*). In agricultural research, DEM has been widely applied to model interactions between crops (e.g., seeds, roots) and soil or machinery. For example, DEM has been successfully used to optimize soil-tool interactions in potato harvesting by simulating tuber-soil separation processes. (*Zhao et al., 2023*), and to design seed metering devices by analyzing seed motion under dynamic conditions. As a result, the potato tubers obtained by DEM simulation analysis are more stable, and the leakage rate and replay rate (coefficient of variation) are lower under reasonable seeding device structure design and working parameters (forward speed of machine, seeding speed, etc.) (*Chen et al., 2023*). Xu Bing et al., (*2021*) developed a discrete element model for buckwheat seeds using an automatic filling method, followed by parameter calibration. Based on this model, they conducted an optimized design of the three-stage vibration process for buckwheat. The optimized three-stage vibrating screen has higher clearance rate and lower impurity rate. Chen Zeren et al., (*2018*) classified corn seeds by shape and developed discrete element models for corn seeds using varying numbers of spheres in a filling method. This approach aimed to balance computational efficiency and accuracy. The results were validated through a "self-flow screening" experiment, demonstrating close alignment with actual outcomes. Recent studies on root crop mechanization (e.g., sugar beet harvesting) have further validated DEM's accuracy in predicting tuber damage rates under varying soil conditions (*Yang et al., 2023*). These applications demonstrate DEM's capability to capture granular behavior and complex mechanical interactions, which is critical for analyzing Corydalis tuber in soil environments. For example, analyze the uniformity and stability of Corydalis tubers seeding, harvest rate at harvest, loss rate, etc.

Due to the flattened, irregular shape of Corydalis tuber and its dynamic interactions with soil during mechanized harvesting, the discrete element method (DEM) is a preferred approach to capture these complex behaviors. Addressing the lack of particle contact parameters essential for designing key machinery for sowing and harvesting Corydalis tuber, this study employed 3D scanning technology to obtain a three-dimensional model of Corydalis tuber. Using an automatic filling method, a discrete element model for Corydalis tuber was established (*Sun et al., 2022; Wang et al., 2017; Xu et al., 2022; Yu et al., 2020; Xu et al., 2018*). Simulation experiments were conducted with this model to determine the coefficients of restitution, static friction, and rolling friction between Corydalis tuber and both soil and Q235 steel. These simulations were then compared with actual tests to obtain mechanical parameters closest to the true values.

MATERIALS AND METHODS

Determination of fundamental physical parameters

The experimental subject selected was Corydalis tuber, harvested in early May from a designated experimental field in Chenggu County, Hanzhong City, Shaanxi Province, China, cultivated with the "Zhehu



No.1" variety. Sampling was conducted using the five-point sampling method, and subsequent measurements of its physical characteristic parameters were performed. The density of Corydalis tuber was measured using the water displacement method, yielding a density of 1085 kg/m³. The moisture content of Corydalis tuber at harvest was determined using an Ohaus M23 rapid moisture analyzer. The average moisture content obtained was 61.27%.

Determination of contact parameters

During the harvest period, interactions occur between the Corydalis tuber, as well as between the particles and the soil or machinery. In discrete element simulations, the restitution coefficient, static friction coefficient, and rolling friction coefficient play crucial roles in determining the accuracy and reliability of the simulation. The soil selected for the experiment was that typically used for cultivating Corydalis tuber in the local region, while the material chosen for the machinery components was Q235 steel.

Determination of the restitution coefficients of Corydalis tuber - Q235 steel, Corydalis tuber - soil

The restitution coefficient refers to the ratio of the separation velocity to the approach velocity in the normal direction at the point of contact before and after a collision, depending solely on the materials involved. The restitution coefficients for Corydalis tuber colliding with Q235 steel and soil were determined through a free-fall test, as depicted in Figure 1. Corydalis tuber was dropped from a height of 200 mm, and upon collision with the Q235 plate or soil bed, they bounced back. The rebound height *h* was recorded using a high-speed imaging system, with a scale-marked grid paper and steel ruler placed behind the particles. To ensure the reliability of the experimental data, 10 sets of tests were conducted, with each set repeated three times, and the average value was taken.

(a) Free fall test (b) Positive perspective of the free fall test

Fig. 1 - Determination of restitution coefficients of Corydalis tuber – Q235 steel, Corydalis tuber - soil

1. Q235 steel; 2. High-speed camera; 3. Graph paper; 4. Corydalis tuber; 5. Ruler.

The coefficient of restitution can be calculated using the following formula:

$$e = \frac{v_4 - v_3}{v_2 - v_1} \quad (1)$$

$$v_4 = \sqrt{2gh} \quad (2)$$

$$v_2 = \sqrt{2gH} \quad (3)$$

in which:

e – the coefficient of restitution between Corydalis tuber and the colliding material;

v_1 – the velocity of the colliding material before the collision, [m/s];

v_2 – the velocity of Corydalis tuber before the collision, [m/s];

v_3 – the velocity of the colliding material after the collision, [m/s];

v_4 – the velocity of Corydalis tuber after the collision, [m/s];

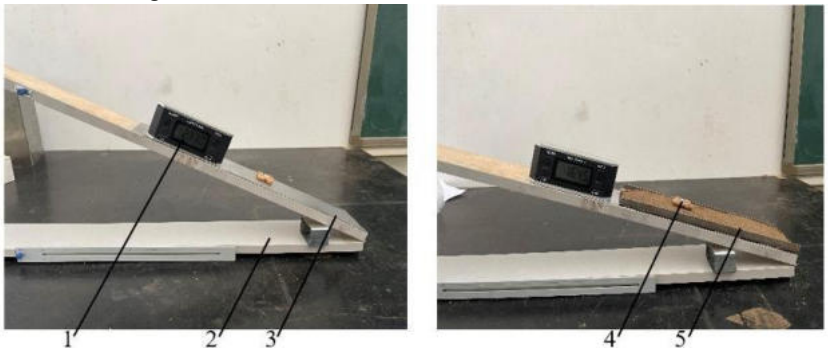
H – the height from which the object is dropped before free fall, [m];

h – the rebound height, [m];

g – the acceleration due to gravity, [m/s^2].

Both materials underwent 10 sets of experiments, and the results are presented in Table 1.

Table 1



Restitution coefficients of Corydalis tuber – Q235 steel, Corydalis tuber - soil

Number	Corydalis tuber-Q235 rebound height (m)	The coefficient of restitution	Corydalis tuber-soil rebound height (m)	The coefficient of restitution
1	0.0307	0.3916	0.0180	0.3000
2	0.0667	0.5774	0.0110	0.2345
3	0.0443	0.4708	0.0213	0.3266
4	0.0267	0.3651	0.0220	0.3317
5	0.0658	0.5730	0.0170	0.2915
6	0.0773	0.6218	0.0157	0.2799
7	0.0763	0.6178	0.0160	0.2828
8	0.0513	0.5066	0.0270	0.3674
9	0.0760	0.6164	0.0247	0.3512
10	0.0570	0.5339	0.0147	0.2708
The average value	**0.0572**	**0.5274**	**0.0187**	**0.3036**

By substituting the average rebound height of Corydalis tuber on Q235 steel and soil into Equation 2, 3 and 1, the coefficient of restitution of Corydalis tuber-Q235 is obtained as 0.5274, and the coefficient of restitution of Corydalis tuber-soil is 0.3036.

Determination of the static friction coefficients of Corydalis tuber - Q235 steel, Corydalis tuber - soil

The static friction coefficient refers to the ratio of the maximum static friction force to the normal force between two objects. The factors influencing the static friction coefficient mainly include the type of friction materials, the roughness of the contact surfaces, and so on. The static friction coefficients between Corydalis and Q235 steel, as well as between Corydalis and soil, were measured using the inclined plane method, as shown in Figures 2. Since Corydalis tuber have a flattened spherical shape, rolling is likely to occur during the experiment. To ensure accuracy and reduce experimental errors, four Corydalis tubers were bonded into a square shape using a hot glue gun. The inclined plane was equipped with an angle measurement device for easy reading and recording of data. For both materials, 10 sets of experiments were conducted, with each set repeated 3 times, and the average value was taken.

(a) Inclined plane method between Corydalis tuber and Q235 (b) Inclined plane method between Corydalis tuber and Soil

Fig. 2 - Determination of static friction coefficients of Corydalis tuber – Q235 steel, Corydalis tuber - soil

1. Angle measuring device; 2. Friction angle measuring instrument; 3. Q235 steel plate; 4. Corydalis tuber; 5. Soil plate.

The formula for calculating the static friction coefficient is as follows:

$$f = G\sin\theta \tag{4}$$

$$F_N = G\cos\theta \tag{5}$$

$$f = \mu F_N \tag{6}$$

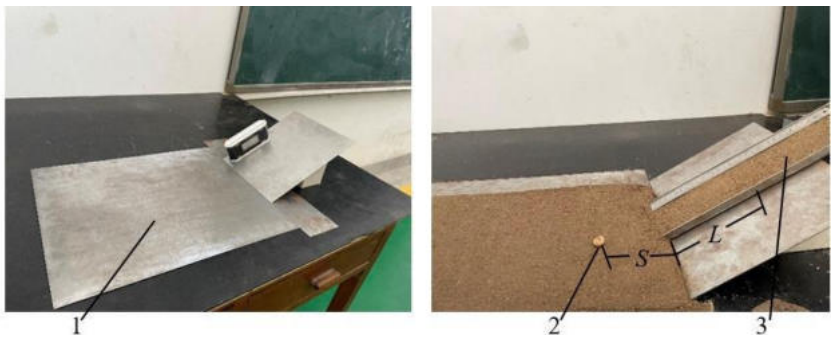
in which: f – the frictional force acting on Corydalis tuber, [N];
G – the gravitational force of Corydalis tuber, [N];
F_N – the support force acting on Corydalis tuber, [N];
μ – the static friction coefficient;
θ – the angle between the inclined plane and the horizontal surface, [°].

Both materials underwent 10 sets of experiments, and the results are presented in Table 2.

Table 2

Static friction coefficients of Corydalis tuber – Q235 steel, Corydalis tuber - soil

Number	Corydalis tuber-Q235 static friction angle (°)	The static friction coefficient	Corydalis tuber-soil static friction angle (°)	The static friction coefficient
1	25.95	0.4867	38.88	0.8064
2	26.12	0.4903	38.88	0.8064
3	26.50	0.4986	41.18	0.8749
4	28.05	0.5328	40.18	0.8632
5	24.42	0.4540	40.97	0.8683
6	25.48	0.4766	39.43	0.8224
7	24.05	0.4463	42.38	0.9126
8	25.25	0.4716	38.83	0.8050
9	28.52	0.5433	40.77	0.8622
10	27.89	0.5292	42.12	0.9041
Average value	26.22	0.4925	40.43	0.8525



In the ten groups of tests of these two types of materials, the static friction angle between Corydalis tuber and Q235 ranges from 24.05° to 28.52°, and the static friction angle between Corydalis tuber and soil ranges from 38.83° to 42.38°. The surface roughness of the corresponding material plate (Q235 steel plate or soil plate) has been ensured to be continuously consistent before each Corydalis tuber test, and the surface condition of the particles of the Corydalis tuber used for test is unchanged. The friction angle measuring instrument used for the test had an accuracy of $\pm$ 0.2°, and the corresponding angle was displayed during the measurement (two decimal places were retained by default). The experimental environment and the accuracy of the measuring instrument complied with the specifications.

By substituting the average static friction angle of Corydalis tuber on Q235 steel and soil into Equation 4, 5 and 6, the static friction angle of Corydalis tuber-Q235 is obtained as 0.4925, and the static friction angle of Corydalis tuber-soil is 0.8525.

Determination of the rolling friction coefficients of Corydalis tuber – Q235 steel, Corydalis tuber - soil

Rolling friction occurs when an object rolls without slipping or tends to roll on another object's surface, causing deformation at the contact point between the two materials, which generates resistance to rolling. In this study, the rolling friction coefficient between Corydalis and Q235 steel plate, as well as between Corydalis and soil, was measured using the bevel rolling method. The experimental setup is shown in Figure 3.

In the rolling friction factor measurement, the Corydalis tuber roll without sliding on the inclined plane, and the rolling resistance generated by the steel plate on the Corydalis tuber is essentially static friction. According to the results measured in Table 2, the average static friction angle between the Corydalis tuber and Q235 is 26.22°. And in order to facilitate the fixation of the inclined plane and horizontal plate of the steel plate, the angle between the inclined plane and horizontal surface was set to 30°, ensuring the plane interface was as smooth as possible. Corydalis tuber was placed at a distance of L = 35 mm, and with an initial velocity of 0 m/s, they were allowed to roll freely until they stopped. The horizontal rolling distance (S) of the Corydalis tuber was measured. Ten sets of experiments were conducted for each material, with each set repeated three times. The average rolling distance was taken as the final data. The shape of the Corydalis tuber is mostly irregular and flattened spherical, and the size is relatively small and highly variable, air resistance cannot be ruled out during testing, so it may have a slight effect on the test results in actual measurement.

(a) (b)

Fig. 3 - Determination of rolling friction coefficients of Corydalis tuber – Q235 steel, Corydalis tuber – soil

(a) Bevel rolling method between Corydalis tuber and Q235; (b) Bevel rolling method between Corydalis tuber and Soil

1. Q235 steel plate; 2. Corydalis tuber; 3. Soil plate.

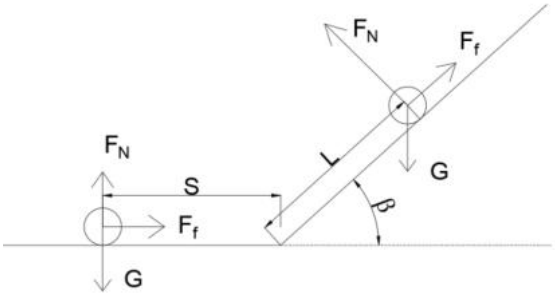


Fig. 4 - Force analysis of the Corydalis tuber rolling process

The force analysis of the rolling process of Corydalis tuber particles is shown in Figure 4. According to the law of conservation of energy during the entire rolling process, the rolling friction coefficient μ' can be calculated as follows:

$$0 - 0 = GL\sin\beta + (-\mu' G\cos\beta\, L) + (-\mu' GS)$$

$$GL\sin\beta = G(L\cos\beta + S)\mu'$$

$$\mu' = \frac{L\sin\beta}{L\cos\beta + S} \tag{7}$$

in which: β – the angle of inclination of the inclined plane, [°];

S – the distance traveled by Corydalis tuber while rolling on a flat surface, [m];

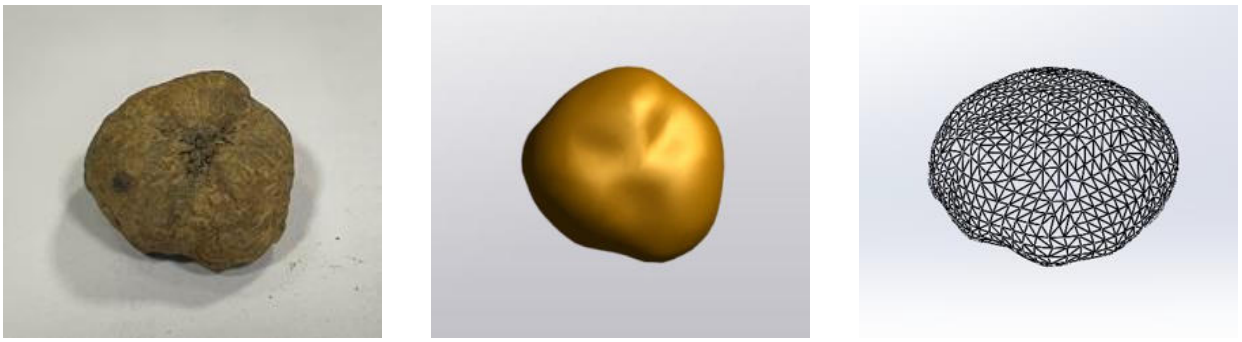
L – the distance traveled by Corydalis tuber while rolling on an inclined plane, [m];

μ' – the rolling friction coefficient of Corydalis tuber and materials.

Both materials underwent 10 sets of experiments, and the results are presented in Table 3.

Table 3

Rolling distances of Corydalis tuber – Q235 steel, Corydalis tuber - soil



Number	Corydalis tuber-Q235 rolling distance (mm)	Corydalis tuber-soil rolling distance (mm)
1	108.7	65.0
2	109.7	66.3
3	167.0	46.3
4	135.3	40.0
5	114.0	59.7
6	129.3	57.3
7	117.3	35.0
8	109.3	44.3
9	142.3	54.3
10	149.7	44.0
Average value	**122.1**	**49.7**

By substituting the average rolling distances of Corydalis tuber on Q235 steel and soil into Equation 7, the rolling friction coefficient of Corydalis tuber-Q235 is obtained as 0.115, and the rolling friction coefficient of Corydalis tuber-soil is 0.219.

Establishment of the Discrete Element Model for Corydalis tuber

3D model of Corydalis tuber

Given the highly irregular shape of Corydalis tuber, modeling using traditional three-dimensional software proves to be challenging (*Zhang et al., 2024*). In this study, advanced three-dimensional imaging technology was employed, utilizing the HandySCAN3D scanner to capture the three-dimensional morphology of Corydalis tuber (The surface roughness of the Corydalis tuber, deformation of the tuber and slight compression have negligible effects on the accuracy of the model.). The scanner has an accuracy of 0.0025 mm and a measuring rate of 1,300,000 measurements per second， then the contour model was saved in STL file format, as shown in Figure 5.

Fig. 5 - The 3D model of Corydalis tuber

Discrete element model

In this study, a multi-sphere bonded particle model was employed to establish the discrete element model for Corydalis tuber. The previously scanned contour model of Corydalis tuber was used as the filling space. Spherical particles with diameters of 1 mm, 2 mm, and 4 mm were utilized for the filling, with the respective quantities of spherical particles being 3,439, 426, and 61, as shown in Figure 6. In consideration of both the accuracy of the equilibrium simulation and simulation speed, spherical particles with a diameter of 2 mm were ultimately selected for the particle filling of Corydalis tuber.

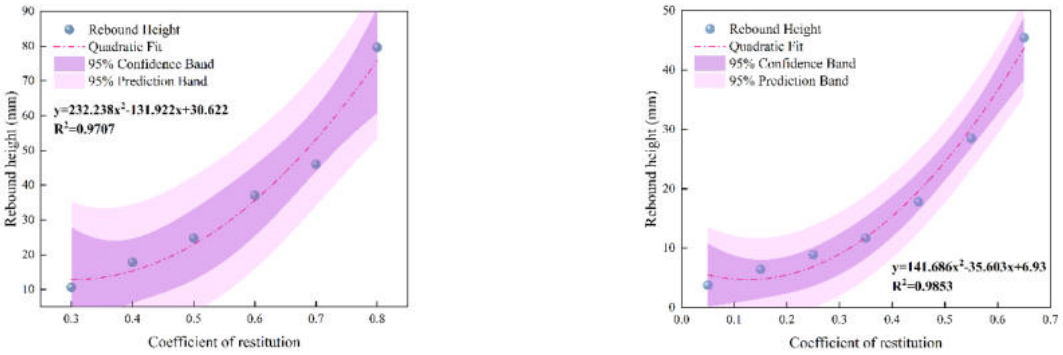
(a) 1mm (2) 2mm (3) 4mm

Fig. 6 - Multi ball bonding model

Calibration of contact parameters between Corydalis tuber, Q235 steel and soil

There exists a discrepancy between the parameters used in actual experiments and those in the simulations, making them unsuitable for direct application in subsequent mechanical simulation (*Zhao et al., 2024*). To enhance the accuracy and reliability of the discrete element simulations, calibration of the relevant parameters was performed through simulation experiments.

Calibration of the coefficient of restitution



Based on the coefficient of restitution of Corydalis tuber with Q235 steel and soil obtained from previous drop tests, the established discrete element model of Corydalis tuber was utilized to create simulation experiments under actual test conditions, as shown in Figure 7.

Fig. 7 - Drop test simulation

1. Corydalis tuber; 2. Baseplate.

In the simulation experiments, the static friction coefficient and rolling friction coefficient between the Corydalis tuber, Q235 steel, and soil were set to 0. Based on the results of the actual experiments, the coefficient of restitution for collisions between Corydalis tuber and Q235 was selected within the range of 0.3 to 0.8, while the coefficient of restitution for collisions between Corydalis tuber and soil was selected within the range of 0.05 to 0.65. The experimental results and the quadratic curve fitting results are shown in Figure 8.

(a) Corydalis tuber - Q235 steel (b) Corydalis tuber - soil

Fig. 8 - The fitted curves of the coefficient of restitution and rebound height from impact simulation tests of Corydalis tuber with Q235 steel and soil

To establish the functional relationship between the coefficient of restitution and rebound height for collisions between Corydalis tuber and Q235 steel, as well as soil, a quadratic polynomial fitting was performed.

The equation of the fitting curve is as follows:

$$y_1 = 232.238x_1^2 - 131.922x_1 + 30.622 \quad (8)$$

$$y_2 = 141.686x_2^2 - 35.603x_2 + 6.93 \quad (9)$$

in which: y_1 – the rebound height of Corydalis tuber and Q235 steel, [m];

x_1 – the coefficient of restitution between Corydalis tuber and Q235 steel;

y_2 – the rebound height of Corydalis tuber and soil, [m];

x_2 – the coefficient of restitution between Corydalis tuber and soil.

The coefficient of determination for regression equation y_1 was R^2 = 0.9707, and for y_2, it was R^2 = 0.9853. Both models had P << 0.05, indicating that the regression models were highly significant. Substituting the average rebound heights from the actual free-fall experiments, y_1 and y_2, into Equations (8) and (9) yielded the coefficient of restitution between Corydalis tuber and Q235 steel, x_1 = 0.728, and the coefficient of restitution between Corydalis tuber and soil, x_2 = 0.44. By setting x_1 and x_2 as the coefficients of restitution in the simulation experiments and repeating the trials 10 times, the average rebound height for Corydalis tuber and Q235 steel was 58.87 mm, and for Corydalis tuber and soil, it was 18.99 mm. The relative errors compared to the measured results from the actual experiments were 2.02% and 1.55%, respectively. This demonstrates that the calibrated simulation results were consistent with the experimental data. Ultimately, the coefficients of restitution for the discrete element simulation were determined to be 0.728 for Corydalis tuber and Q235 steel, and 0.44 for Corydalis tuber and soil.

Calibration of static friction coefficient

Based on the static friction angles of Corydalis tuber with Q235 steel and soil obtained from previous inclined plane tests (*Zhuang et al., 2023*), the established discrete element model of Corydalis tuber was utilized to create simulation experiments under actual test conditions, as shown in Figure 9.

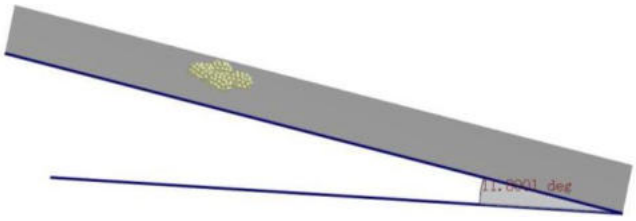


Fig. 9 - Ramp test simulation

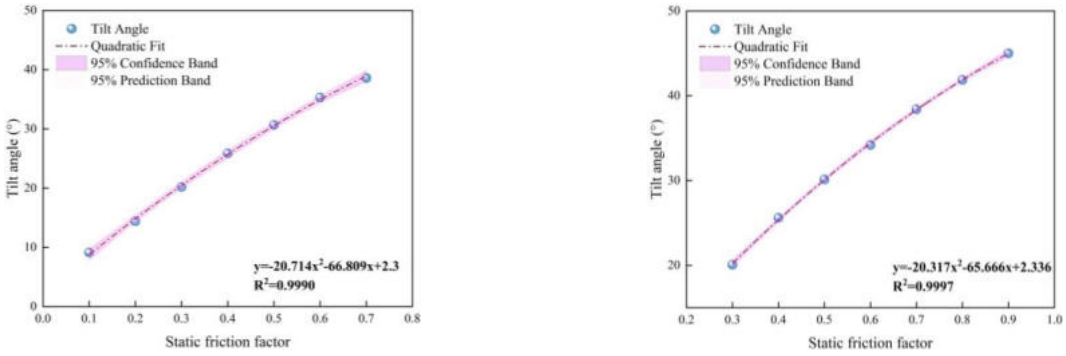
In the simulation experiments, the coefficients of restitution between Corydalis tuber and Q235 steel, as well as soil, were predefined. The rolling friction coefficients and inter-particle parameters for Corydalis tuber were set to 0. Based on the actual experimental results, the static friction coefficient ranges for Corydalis tuber with Q235 steel and soil were selected as 0.1~0.7 and 0.3~0.9, respectively, with an increment of 0.1. The experimental results and the quadratic curve fitting results are shown in Figure 10.

The fitted equations for the static friction coefficient curve between Corydalis tuber and Q235 steel, as well as soil, are as follows:

$$y_3 = -20.714x_3^2 + 66.809x_3 + 2.3 \quad (10)$$

$$y_4 = -20.317x_4^2 + 65.666x_4 + 2.336 \quad (11)$$



in which:

y_3 – the inclination angle (Corydalis tuber and Q235 steel), [°];

x_3 – the static friction coefficient between Corydalis tuber and Q235 steel;

y_4 – the inclination angle (Corydalis tuber and soil), [°];

x_4 – the static friction coefficient between Corydalis tuber and soil.

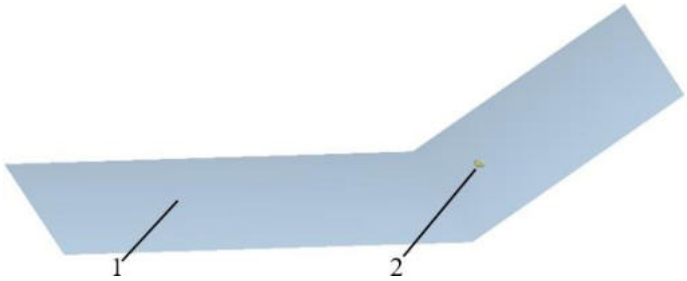
(a) Corydalis tuber - Q235 steel (b) Corydalis tuber - soil

Fig. 10 - The fitted curves of the static friction coefficient and inclination angle from simulation tests of Corydalis tuber with Q235 steel and soil

The coefficient of determination for regression equation y_3 was R^2 = 0.9990 with P = 0.0000009 << 0.05, and for y_4, it was R^2 = 0.9997 with P = 0.000000079 << 0.05, indicating that both models were highly significant. Substituting the average inclination angles from the actual inclined plane tests, y_3 = 40.52 and y_4 = 122.1, into Equations (10) and (11), yielded the static friction coefficients x_3 = 0.41 for Corydalis tuber with Q235 steel and x_4 = 0.76 for Corydalis tuber with soil. These static friction coefficients were then set as parameters for the simulation experiments, and 10 trials were conducted for each scenario. The resulting frictional inclination angle between Corydalis tuber and Q235 steel was 26.13°, with a relative error of 0.17% compared to the actual test. The frictional inclination angle between Corydalis tuber and soil was 40.46°, with a relative error of 0.41%. These results demonstrate that the calibrated simulation results closely aligned with the actual experimental data. Therefore, the static friction coefficients determined for the simulation experiments were finalized as 0.41 for Corydalis tuber with Q235 steel and 0.76 for Corydalis tuber with soil.

Calibration of rolling friction coefficient

Similarly, based on the rolling friction distances between Corydalis tuber and Q235 steel, as well as soil, measured in previous experiments, simulation experiments were constructed using the established discrete element model of Corydalis tuber under actual experimental conditions, as shown in Figure 11.



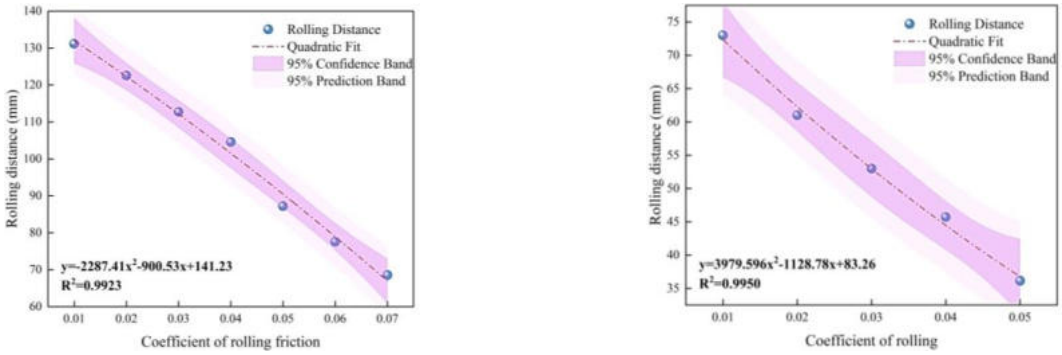


Fig. 11 - Rolling test simulation

1. Material plates; 2. Corydalis tuber.

In the simulation experiments, the coefficients of restitution and static friction coefficients between Corydalis tuber and Q235 steel, as well as soil, were predefined. The inter-particle contact parameters for Corydalis tuber were set to 0. The rolling friction coefficient range for Corydalis tuber and Q235 steel was selected as 0.01~0.07, and for Corydalis tuber and soil, it was 0.01~0.05, both with a step size of 0.01. The results of the simulation experiments and the fitted curves are shown in Figure 12.

(a) Corydalis tuber - Q235 steel (b) Corydalis tuber - soil

Fig. 12 - The fitted curves of the rolling friction coefficient and rolling distance from simulation tests of Corydalis tuber with various Q235 steel and soil.

The fitted equations for the rolling friction coefficient curve between Corydalis tuber and Q235 steel, as well as soil, are as follows:

$$y_5 = -2287.41x_5^2 - 900.53x_5 + 141.23 \quad (12)$$

$$y_6 = 3979.59x_6^2 - 1128.78x_6 + 83.26 \quad (13)$$

in which: y_5 – the rolling distance (Corydalis tuber and Q235 steel), [m];
x_5 – the rolling friction coefficient between Corydalis tuber and Q235 steel;
y_6 – the rolling distance (Corydalis tuber and soil), [m];
x_6 – the rolling friction coefficient between Corydalis tuber and soil.

The coefficient of determination for regression equation y_5 was $R^2 = 0.9923$ with $P = 0.000058 \ll 0.05$, and for y_6, it was $R^2 = 0.9950$ with $P = 0.00495 \ll 0.05$, indicating that both models were highly significant. Substituting the average rolling distances from the actual rolling tests, $y_5 = 122.1$ mm and $y_6 = 49$ mm, into Equations (12) and (13), the rolling friction coefficients were calculated as $x_5 = 0.02$ for Corydalis tuber with Q235 steel and $x_6 = 0.03$ for Corydalis tuber with soil. These rolling friction coefficients were then set as parameters for the simulation experiments, and 10 trials were conducted for each scenario. The resulting rolling distance for Corydalis tuber with Q235 steel was 118.5 mm, with a relative error of 3.04% compared to the actual test. The rolling distance for Corydalis tuber with soil was 48.375 mm, with a relative error of 2.73%. These results demonstrate that the calibrated simulation results were generally consistent with the experimental data. Therefore, the rolling friction coefficients determined for the simulation experiments were finalized as 0.02 for Corydalis tuber with Q235 steel and 0.033 for Corydalis tuber with soil.

CONCLUSIONS

(1) Through experiments measuring the restitution coefficient, static friction coefficient, and rolling friction coefficient between Corydalis tuber and Q235 steel, as well as soil, the actual experimental values for these parameters were obtained. These tests included measurements of the restitution coefficient, static friction coefficient, and rolling friction coefficient for Corydalis tuber under both conditions.

(2) A three-dimensional contour model of Corydalis tuber was obtained using 3D scanning technology. The contour model obtained by scanning cannot be directly used in subsequent discrete element simulation experiments. In order to improve the accuracy of discrete element particle modeling of Corydalis tubers and the simulation accuracy, a multi-sphere bonded particle model of the Corydalis tuber was generated using the automatic filling method in the EDEM software.

(3) The simulation test takes the restitution coefficient, static friction coefficient and rolling friction coefficient between the Corydalis tuber and Q235 steel, and between the Corydalis tuber and soil as independent variables, and the collision height, friction angle and rolling distance as dependent variables. A second-order polynomial fitting was performed based on the simulation results, and the actual experimental values were substituted into the polynomial equation to obtain the simulated contact parameter values of the Corydalis tuber with Q235 steel and soil. The values were then verified based on the actual experimental measurements, and the relative error between the two was less than 5%.

ABSTRACT

The germination of castor seeds was affected by different damage forms after shelling. Traditional methods could not express the change of mechanical damage characteristics on the surface of castor seeds. In the study, an improved migration learning algorithm for castor seed damage classification was adopted. The convolution kernel size of the first convolutional layer of the AlexNet model was modified, part of the convolutional layer was divided into two layers to increase the depth of the convolution model. Then a multi-scale convolution kernel was added to extract the damage characteristics of castor seeds. The results showed that combined with the hyperparameter optimization of convolutional layer stratification and the AlexNet model, the classification effect was improved. The average test accuracy was 98.10%. After the addition of multi-scale convolution, the average test accuracy was improved by 0.57%. The results show that the classification accuracy of cracked castor seeds is 71%, and the classification accuracy of castor seeds with missing shells is 63%. The classification accuracy of whole castor seeds is 67%. The verification of damage identification device for castor seeds was developed to verify the correctness of the algorithm. This study provided a theoretical and convolutional network model supported for the development of an online real-time damage classification detection system for castor seeds.

摘要

蓖麻种子发芽率主要是脱壳后不同形式的损伤引起。传统方法无法表达蓖麻籽表面机械损伤特征的变化。 本研究采用了一种改进的蓖麻种子损伤分类迁移学习算法，修改了 AlexNet 模型第一个卷积层的卷积内核大小。卷积层被分成两层，以增加卷积模型的深度。添加一个多尺度卷积核，以提取蓖麻种子的损伤特征。 结果表明，结合卷积层分层的超参数优化和 AlexNet 模型，分类效果得到了改善。 添加多尺度卷积后，平均测试精度提高了 0.57%。 实验结果显示，开裂蓖麻种子的分类准确率为 71%，缺失壳蓖麻种子的分类准确率为 63%。 整个蓖麻种子的分类准确率为 67%。 本研究为开发蓖麻种子的在线实时损害分类检测系统提供了理论支持。

INTRODUCTION

Castor plant is one of the world's top ten oil crops. Its seeds are rich in oil (35%-55% oil content depending on the species) and are also widely used as raw materials for detergent, cosmetics, medicines and biodiesel *(Acosta-Navarrete et al., 2017; Santos, 2019*). Because of its high viscosity, high ignition point, low freezing point, it is also made into lubricant and widely used in aviation, high-speed lathe and other industrial fields (*Li et al., 2018; Mosquera-Artamonov et al., 2018*). The damage of castor seeds in the process of shelling will directly affect germination and plant growth, and will also affect the yield of castor oil used for oil extraction. Therefore, it is very important to classify and detect damaged castor seeds, which needs to extract the defect features that affect the surface marks of castor seeds. The traditional conventional classification algorithms cannot meet the requirements of damage classification of castor seeds.

At present, convolutional neural network, transfer learning and other deep learning methods are attracting more and more attention. These learning methods have been widely used in image processing (*Kamilaris and Prenafeta-Boldú, 2018*), medical aviation, agriculture and other fields. In the field of agriculture, migration learning is often applied in the identification and classification of plant leaf diseases (*Huang et al., 2019; Rangarajan et al., 2018)*, the identification and location of crop pests (*DeChant et al., 2017; Thenmozhi and Srinivasulu Reddy, 2019)*, the identification and classification of crop fruits (*Liu et al., 2020)*, the location of plant organs and the prediction of growth potential (*Fengle and Zengwei, 2020; Liang et al., 2019; Yang, 2018)*, and so on. Relevant studies show that the pre-training model of migration learning has obvious advantages compared with traditional machine vision technology.

Through the classification of the integrity of different agricultural materials, it can be found that the classification method based on the depth model is more accurate and efficient than the traditional classification algorithms such as support vector machine, linear discriminant model, and artificial neural network (*Xie et al., 2020; Zhiheng et al., 2018; Zhu et al., 2020*). Through the improvement of AlexNet model, relevant studies have improved the accuracy and efficiency of classification, making the improved model more suitable for the objects needing classification (*Lv et al., 2020; Xiaoqing et al., 2019*). The surface stripes of castor seeds affected feature extraction and different damage features extraction required different algorithms, while traditional algorithms could not meet the classification of damage on castor seeds surface.

In this study, the AlexNet model was transferred to the classification of castor seed damage. The AlexNet network model was optimized by modifying the convolution kernel size of the first convolutional layer, layering partial convolution layers, and adding multi-scale convolution. It was optimized from batch size, learning rate to improve the test accuracy of the model. Finally, the modified AlexNet was verified by the damage identification device of castor seeds.

MATERIALS AND METHODS

Dataset construction

The typical variety of ZheBi No.4, widely planted in Tongliao Academy of Agricultural Sciences, Inner Mongolia, was selected as the test sample. The germination experiment showed that the two damaged types of seed shell missing and crack had the most significant effect on the germination of castor seeds. Therefore, castor seeds with these two damage types and whole (no damage) were classified.

In this study, an LT-USB 1080 CMOS industrial camera was used to shoot samples of castor seeds placed on white A4 paper under the indoor environment. The shooting distance was 5~10 cm, then 525 images were obtained. The resolution of the images was 1,920×1,080 pixels, and the images were cropped to 227×227 pixels of samples containing castor seeds. The image of castor seeds with seed shell missing castor seed, crackled castor seed and whole castor seed were flipped to expand the castor seed image data set. The seed shell missing castor seed, cracked castor seed, and the whole castor seed was named with 0_1.jpg, 1_1.jpg, and 2_1.jpg forms, respectively. In the training set, some castor seeds were shown in Fig. 1.

a. Seed shell missing castor seeds; b. Cracked castor seeds; c. Whole castor seeds (no damage)

Fig. 1 – Images of castor seeds of different types

AlexNet Model construction

The AlexNet model consists of five convolution layers, three maximum pooling layers, and three full connection layers, a total of eleven layers. The size of the input image is required to be 227×227×3 (227 pixels high, 227 pixels wide, 3 color channels). After convolution, the output image size is shown in equation (1) while after pooling, the output image size is shown in equation (2).

$$N_{out} = \frac{N_{in} - F + 2P}{S} + 1 \quad (1)$$

$$N_{out} = \frac{N_{in} - F}{S} + 1 \quad (2)$$

where, N_{out} is the image output size; N_{in} is the image input size; F is the size of the convolution kernel; P is the padding; S is the step size.

The image was input into the AlexNet model. Through the convolutional layer, local response normalization layer, and maximum pooling layer, the output image size is 27×27×96. In the second part, the data flow follows the convolutional layer, the maximum pooling layer, and the local response normalization layer successively, and the output image size is 13×13×256. The third part and the fourth part respectively contain a convolutional layer. After the convolution operation of two layers, the output image size is 13×13×384. The fifth part is the convolutional layer and the maximum pooling layer, then the output image size is 6×6×256. The sixth part and the seventh part are the full connection layer, each layer has 4096 neural units. To reduce overfitting, Dropout is added after the full connection layer. The eighth part is the output layer. The structural model is shown in Figure 2.

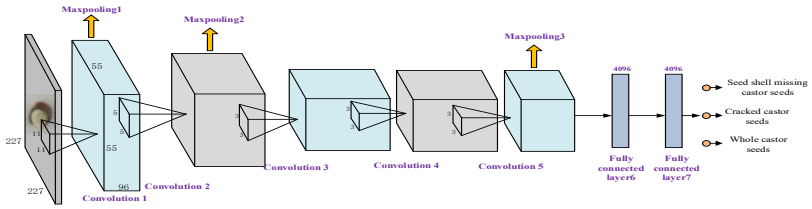

Fig. 2 - AlexNet network model diagram

The convolutional layer extracts the local features of the image through the convolution operation. After the feature map of the upper layer is processed by the convolution kernel, the feature map of the new layer can be obtained by the excitation function. The working process of the convolutional layer is as follows:

$$x_n^l = \sum_{i \in M_n} x_i^{l-1} * k_{in}^l + b_n^l \tag{3}$$

where, x^l_n is the n^{th} feature map of layer l; M_n is a set of feature mappings selected from the input feature mappings; k^l_{in} is the i^{th} element in the n^{th} convolution kernel of the layer l; b^l_n is the n^{th} offset of layer l; '*' is the convolution process.

The pooling layer is also called a downward sampling layer, which produces the sampling results of input feature maps and changes the size of features without changing the number of feature maps. The working process of the pooling layer is shown in equation (4):

$$x_n^l = f_{\text{down}}\left(x_n^{l-1}\right) + b_n^l \tag{4}$$

where, f_{down} (·) is the lower sampling function.

Evaluation Index

The accuracy of the classification algorithm is evaluated by the accuracy index, which is defined as equation (5):

$$a = \frac{N_C}{N_T} \times 100\% \tag{5}$$

where, a is the accuracy rate, %; N_C is the number of correctly classified samples; N_T is the total sample of training.

Operation platform

All the training and testing in this study are carried out on the same computer with the processor is Inter(R) Xeon(R) CPU E5-2643 v3 3.4 GHz, 32 G memory, AMD FirePro W7100 Graphics Adapter, and 8 GB of running memory, running under Windows 10 operation system.

Improvement of the AlexNet model method

Selection of the convolution kernel size

Convolution kernels are referred to as the local receptive field (LRF), which is a kind of filter. In this study, the convolution kernel size of the first convolutional layer in the AlexNet model is selected to learn the key features, to obtain better model performance. In this study, according to the literature(*DeChant et al., 2017; Liu, 2020*) and experimental experience, convolution kernel sizes of 5×5, 7×7, 9×9, 11×11, 13×13, and 15×15 were selected for training.

Convolution layer stratification

In this study, the convolutional layer 2 is divided into two layers, and the LRF size is modified to 3×3. The convolutional layer 3 is divided into two layers, and the LRF size is modified to 2×2. The convolutional layer 5 is divided into 2 layers, and the LRF size is modified to 2×2.

The parameters of each layer are shown in Table 1.

Table 1

Parameters of the convolutional network

CNN layers	Split layers	Output size	LRF size	Strides
Conv 1	Conv 1	55×55×96	11×11	4
Pooling 1	Pooling 1	27×27×96	3×3	2
Conv 2	Conv 2_1	29×29×256	3×3	1

CNN layers	Split layers	Output size	LRF size	Strides
	Conv 2_2	27×27×256	3×3	1
Pooling 2	Pooling 2	13×13×256	3×3	2
Conv 3	Conv 3_1	14×14×384	2×2	1
	Conv 3_2	13×13×384	2×2	1
Conv 4	Conv 4	13×13×256	3×3	1
Conv 5	Conv 5_1	14×14×256	2×2	1
	Conv 5_2	13×13×256	2×2	1
Pooling 3	Pooling 3	6×6×256	3×3	2

Adding multi-scale convolution

The structure of multiscale convolution is shown in Fig. 3.

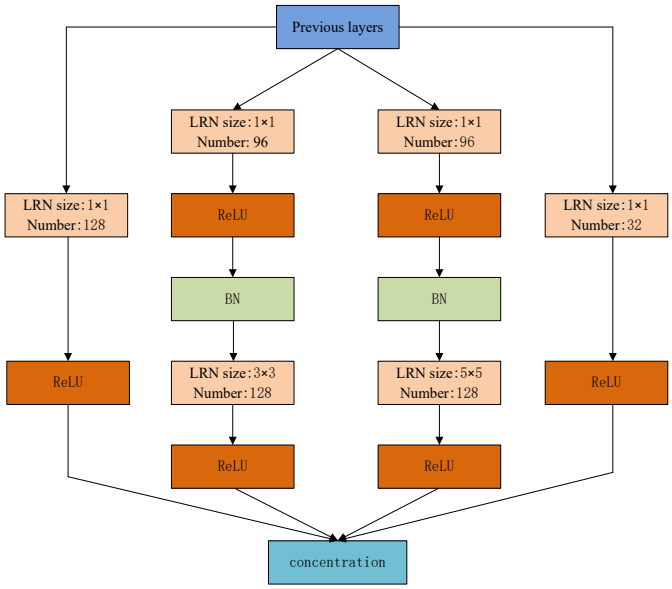

Fig. 3 – Structure of multi-convolution module

Multi-scale convolution has been widely used in VGG-Net, Inception series, GoogLeNet, and ResNet series. These networks have fully verified the superiority of multi-scale convolution in image recognition and target positioning. To learn better damage characteristics of castor seeds, a multi-scale convolution was added between convolutional layer 1 and convolutional layer 2. Three convolution kernels of different scales (1×1), (3×3), and (5×5), with the number of 32, 96, and 128 convolution kernels, were adopted to extract the sample image features in parallel. Then they merged into the same tensor and continue to pass them down.

RESULTS AND DISCUSSION

Influence of parameters on model performance

The influence of convolution layer 1 on the accuracy of model verification

In this study, the convolution kernel size of the first convolution layer of the AlexNet model was changed to learn the key features and obtain better model performance. The influence of the convolution kernel size on the recognition accuracy of the convolutional neural network is shown in Fig. 4.

When the convolution kernel size is 11×11, the average test accuracy is the highest. The results showed that there are significant differences in the shape characteristics among the data sets. So, the model network only needed to learn the shape features of the damage to ensure the fitting ability of the data. Therefore, the convolution kernel of convolutional layer 1 in this paper is selected 11×11.

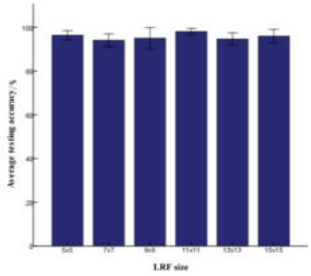

Fig. 4 – Average test accuracy under different convolution kernel sizes

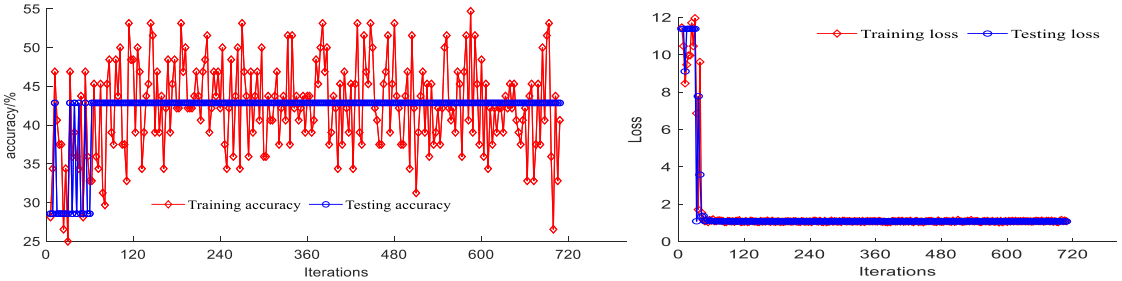
Influence of learning rate on model performance

As an important super parameter in supervised learning and deep learning, learning rate determines whether the objective function converges to the local minimum and when it converges to the minimum. An appropriate learning rate can make the objective function converge to the local minimum in an appropriate time. Fig. 5 shows the curves of training accuracy and loss value. It can be seen that when the learning rate is 0.1, the training accuracy oscillates back and forth around the minimum value, and the loss value fluctuates within a wide range. After convergence, the loss value is relatively large, resulting in the over-fitting phenomenon.



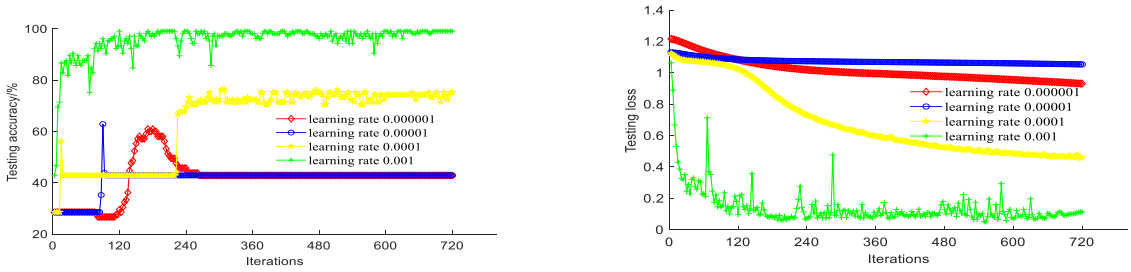


Fig. 5 – The curve of training, testing accuracy, and loss value with excessive learning rate

Fig. 6 is the graph of test accuracy and loss under different learning rates. When the learning rate is 0.00001 and 0.000001, the parameter to be optimized converges very slowly. After 700 iterations, the loss value converges slowly at close to 1. When the learning rate is 0.001, the model test accuracy is better, and the loss value converges near to 0. Therefore, this study chose a learning rate of 0.001 for training.

a) Test accuracy curve under different learning rates b) Test loss curve at different learning rates

Fig. 6 – Test accuracy and loss curves under different learning conditions

Influence of regularization on model accuracy

Regularization is an important means to control model complexity, combat over-fitting, and pursue a better prediction effect. In this study, L2 regularization is adopted to reduce the over-fitting phenomenon by adding a weight loss function. The regularization formula of L2 is shown as equation (6).

$$\Omega(\boldsymbol{\omega}) = \frac{1}{2}\boldsymbol{\omega}^T\boldsymbol{\omega} \tag{6}$$

where, ω is the weight vector.

Influence of stratification of the convolutional layer on the model

The convolutional layer is divided into two layers, which can increase the depth of the network and detect the characteristics of the object to be detected more deeply, then improve the accuracy of the test. After repeated calculations, the average test accuracy of the convolutional layer stratified model is 98.10%, which is 0.48 percentage points higher than the original AlexNet model of 97.62%.

Influence of multi-scale convolution on the model

After adding multi-scale convolution based on the AlexNet model, the average accuracy on the test set is improved by 0.57%, which indicates that the features extracted by the model after introducing multi-scale convolution can more accurately express the features of different damage types.

Comparison of different models

To further verify the recognition effect of the model, the recognition effect of common deep convolutive neural network models such as VggNet-16, GoogLeNet, ResNet-50, and ResNet-101 on damage types of castor seeds is compared in the same experimental conditions.

VggNet-16 model

In the VGG (Visual Geometry Group) network, by using a smaller convolution filter, increasing the depth of the model structure to 16 layers and reducing the number of parameters, which is also known as VggNet-16. The structure model is shown in Fig. 7. The VggNet-16 model is composed of a continuous convolution layer with a convolution kernel of 3×3 and a maximum pooling layer with a convolution kernel of 2×2. Then two full connection layers are added, and the last layer serves as Softmax output. In this study, VggNet-16 was used to classify the damage of castor seeds and compared them with the improved AlexNet model.

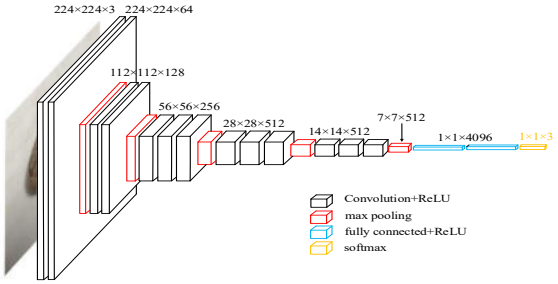

Fig. 7 – VggNet-16 network model diagram

GoogLeNet model

GoogLeNet is a deep convolution network model, which has achieved a good classification effect and improved computational efficiency in many applications. GoogLeNet is also known as the Inception Model. Its architecture consists of twenty-two layers, including 2 convolutional layers, 4 maximum pooling layers, 9 linear stacked Inception modules, and average pooling. Average pooling is applied at the end of the last inception module. Its structural model is shown in Fig. 8. In each initial module, multi-scale convolution such as 1×1, 3×3, and 5×5 are applied for dimension reduction. In this study, GoogLeNet was used to complete the task of castor seed damage classification and was compared with the improved AlexNet model.

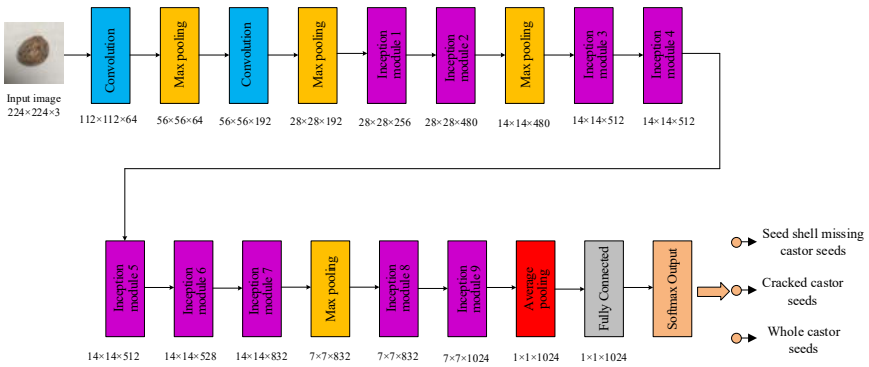

Fig. 8 – GoogLeNet The castor seed has two characteristic arcs, and the mechanical damage characteristics appear randomly on one of the network model diagram

ResNet-50 and ResNet-101 models

ResNet (Deep Residual network) has a good performance, its backpropagation will not encounter the problem of gradient disappearance. In this study, ResNet-50 and ResNet-101 were applied to complete the task of castor seed damage classification and were compared with the improved AlexNet model.

The output results of each model are shown in Table 2. It can be seen that the average test accuracy of the improved AlexNet model is 1.05% higher than that of the AlexNet model. The average test accuracy of the deep learning model based on VggNet-16 and GoogLeNet was slightly higher than the modified AlexNet model in this study. But the training efficiency was much lower than that of the model. VggNet-16 efficiency is 86.26% lower than modified AlexNet, and GoogLeNet efficiency is 56.72% lower than modified AlexNet.

The average test accuracy and training efficiency of ResNet-50 and ResNet-101 pre-training models are lower than modified AlexNet. Therefore, the model used in this study is more suitable for the classification of castor seeds damage types.

Table 2

Test accuracy under different depth models

DCNNS types	Test accuracy/%	Time/h
Modified AlexNet	98.67	1.16
AlexNet	97.62	0.63
VggNet-16	99.10	8.44
GoogLeNet	99.05	2.68
ResNet-50	96.83	4.80
ResNet-101	97.46	8.65

Design and verification of damage identification device for castor seeds

General composition of a damage identification device for castor seeds

The castor seed has two characteristic arcs, and the mechanical damage characteristics appear randomly on one of them. When castor seeds are placed naturally, only one of the character arcs can be picked up by the visual system. Therefore, it is necessary to carry out double-sided identification of castor oil seeds to ensure no damage to castor oil seeds missed detection. According to this requirement, when designing the damage identification device for castor seeds, the turning mechanism of castor seeds must be designed so that the two characteristic surfaces of castor seeds can be collected and recognized. At the same time, the system should include a castor seed conveying and identification mechanism for double characteristic surface detection of castor seeds. The three-dimensional structure diagram of the castor damage identification device is shown in Fig. 9.

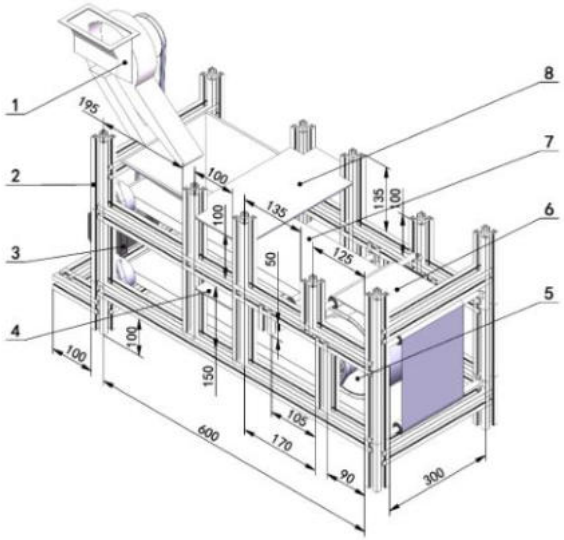

Fig. 9 – Stereo structure diagram of castor damage identification system

1.Castor seed planter; 2. Rack; 3. Electromotor; 4. Camera board Ⅱ; 5. Flipping roller; 6. Conveyor belt Ⅱ; 7. Conveyor belt Ⅰ; 8. Camera board Ⅰ

Experimental verification

In this study, the number of damage identified and classified was applied as the index to verify the rationality of the damage identification device for castor seeds. By comparing the accuracy of device identification with the actual damage accuracy, the superiority of the network model based on improved AlexNet is verified. The damage identification test device of castor seeds was developed. It can change the speed through the frequency modulator to obtain the appropriate speed.

It can verify the feasibility of the combination of the castor seed identification test device and the improved AlexNet model of castor seed damage classification method, it can also measure the stability of the identification performance of the castor seed identification device and verify the robustness of the interface algorithm.

The test equipment in this study is a self-developed damage identification test device for castor seeds. Fig.10 shows the experimental device for damage identification of castor seeds.

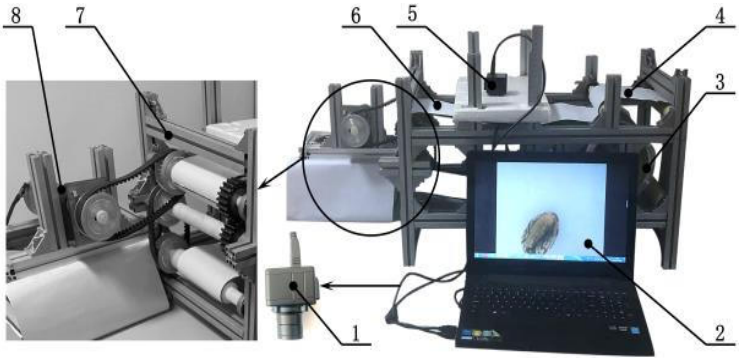

Fig. 10 – Experimental apparatus for damage identification of castor seeds

1. Camera Ⅱ; 2. Computer; 3. Flipping roller; 4. Conveyor belt Ⅱ; 5. Camera Ⅰ;
6. Conveyor belt Ⅰ; 7. Rack; 8. Electromotor

During the test process, castor seeds were placed on the conveyor belt of the castor seed damage device one by one in order through an artificially simulated seed planter. The photos of different types of castor seeds were taken by the camera and saved to the folder of the designated route. The type of castor seeds was verified through the interface of damage classification of castor seeds.

Since the first visual identification system can only verify one characteristic cambered surface of castor seed, three conditions should be taken into account on the process of validating the whole castor seed. When the castor seed is identified as a whole in the first visual system and cracked in the second visual system, the castor seed belongs to cracked castor seed. When the castor seed is identified as a whole in the first visual system and seed shell missing castor seed in the second visual system, it is identified as a seed shell missing castor seed. When the castor seed is identified as the whole in the first visual system and as whole in the second visual recognition system, it is identified as a whole castor seed. The verification results are shown in Fig.11.

a. Whole-Crack verification diagram b. Whole-Seed shell missing verification diagram

Fig. 11 – Verification of non-damaged (whole) castor seeds

Table 3

Repeat tests for each damage type device

Damage category	Predicted damage category			Classification performance			
	Crack	Seed shell missing	Whole	Accuracy / %	Actual damage rate / %	Theoretical damage rate / %	Damage rate difference / %
Crack	71	6	23	71.0	23.7	33.3	9.6
Seed shell missing	9	63	28	63.0	21.0	33.3	12.3
Whole	21	12	67	67.0	0.0	0.0	0.0

In this study, 100 castor seeds with cracks, 100 castor seeds with seed shells missing, and 100 castor seeds without damage (whole) were selected for verification. The verification results are shown in Table 3.

It can be drawn that the device can better identify and classify the three castor seeds. The accuracy of identification of cracked castor seeds was 71%, that of castor seeds with missing seed shell was 63%, and that of castor seeds with the whole shell was 67%. The damage rate of castor seeds was identified by damage. The actual crack damage rate was 23.7% in the process of identification, and the difference in damage rate was 9.6%. The damage rate of seed shell loss was 21.0%, and the difference in damage rate was 12.3%. It can be verified that the identification device and verification algorithm of castor seeds can meet the practical application.

CONCLUSIONS

To eliminate damage of castor seeds, an improved AlexNet model was proposed to classify castor seed damage types. The model was optimized by batch size, learning rate and regularization coefficient. The model was compared with other models and the damage identification device of castor seeds was used to test. The conclusions are as follows:

(1) Compared with other models, the improved AlexNet model has an average test accuracy of 1.05% higher than that of the original model under the same experimental conditions.

(2) The results of experiment show that the identification and classification accuracy of cracked castor oil seeds is 71%, and the identification and classification accuracy of castor seeds with missing shells is 63%. The classification accuracy of complete castor oil seeds is 67%.

(3) The damage rate of castor seeds was identified. The actual crack damage rate is 23.7% in the process of identification, and the difference in damage rate is 9.6%. The loss damage rate of seed shell is 21.0%, and the difference of damage rate is 12.3%, which verified that the identification device and verification algorithm of castor seeds could meet the practical application.

ABSTRACT
To address the challenges of complex farmland environment, an intelligent obstacle avoidance control algorithm for agricultural unmanned aerial vehicles (UAVs) is developed. The objective is to solve the problem of efficient obstacle avoidance in farmland scenarios characterized by dense dynamic obstacles and variable terrain. In this article, a target detection algorithm based on improved YOLOv5 (You Only Look Once v5) is proposed, and an intelligent obstacle avoidance system is constructed by combining reinforcement learning path planning and adaptive motion control strategy. Ghost module is introduced to improve the lightweight of YOLOv5, and the design of CIOU (Complete Intersection Over Union) loss function is optimized, which improves the detection accuracy of the model for small targets and dynamic obstacles. Experiments show that the error of path planning is reduced to less than 2.1 meters, and the time consumption is reduced by about 35%. In addition, fuzzy logic controller is used to realize adaptive PID control, which further enhances the flight stability of UAV in complex environment. The results show that the improved algorithm has excellent performance in many typical farmland scenes. This study provides theoretical and technical support for autonomous flight of agricultural UAV in complex farmland environment.

摘要
面向复杂农田环境，农业无人机智能避障控制算法的研究目的是解决其在动态障碍物密集、地形多变的农田场景中实现高效避障的难题。本文提出一种基于改进 YOLOv5（You Only Look Once v5）的目标检测算法，并融合强化学习路径规划与自适应运动控制策略，构建了一套智能避障系统。研究中引入 Ghost 模块对 YOLOv5 进行轻量化改进，并优化了 CIoU（Complete Intersection over Union）损失函数的设计，从而提高了模型对小目标及动态障碍物的检测精度。实验表明，路径规划误差控制在 2.1 米以内，规划耗时减少了约 35%。此外，通过采用模糊逻辑控制器实现自适应 PID 控制，进一步提升了无人机在复杂环境中的飞行稳定性。研究结果证实，所提出的改进算法在多种典型农田场景下均表现出优异性能。本研究为农业无人机在复杂农田环境中的自主飞行提供了有力的理论支持与技术保障。

INTRODUCTION
Precision agriculture technology has gradually become a key means to improve agricultural production efficiency and reduce resource waste. Under this background, agricultural UAV is widely used in many fields, such as farmland monitoring, crop spraying, sowing and fertilization, with its high efficiency, flexibility and intelligence *(Lu et al., 2023)*. In the complex farmland environment, autonomous flight of agricultural UAV faces many challenges, among which obstacle detection and obstacle avoidance are particularly prominent *(Liu et al., 2021)*. The farmland environment is complex, which is reflected in the diverse terrain, uneven distribution of vegetation and changeable weather conditions. For example, terrain such as slopes and ravines can affect the stability of UAV flight. Trees, shrubs, and other vegetation not only have a variety of species, but also vary in height and density. Changes in external factors such as wind speed and lighting increase the difficulty of perception and decision-making *(Zhao et al., 2020; Seiche et al., 2024; Dorbu et al., 2024)*. When working in the field, UAV will also face the coexistence of static obstacles (such as telephone poles and irrigation equipment) and dynamic obstacles (such as birds and other working machinery) *(Du et al., 2023)*. This puts forward higher requirements for the adaptability and intelligence of obstacle avoidance algorithm.

YOLOv5, as an efficient target detection framework, has attracted much attention because of its fast reasoning ability and high detection accuracy *(Brown et al., 2020)*. However, when it is applied to complex farmland environment, it exposes some problems. First, there are many kinds of obstacles in farmland, and the size difference is large, so the traditional YOLOv5 model has weak small target detection ability [8]. Second, the change of farmland illumination and weather interference will reduce the image quality and affect the model detection performance *(Yang et al., 2020)*. Third, the original architecture of YOLOv5 may not be real-time when it runs on an embedded platform with limited computing resources *(Yang et al., 2021)*. In view of the above challenges, this study proposes an improved YOLOv5 model, combined with intelligent obstacle avoidance control algorithm, to achieve efficient obstacle avoidance of agricultural UAV in complex farmland environment. The research is carried out from the following aspects: first, the Ghost module is introduced to improve the structure of YOLOv5 network, and the running speed of the model is improved on the premise of ensuring the detection accuracy. Secondly, the YOLOv5 loss function is optimized, and the CIoU loss function is used to replace the traditional IoU loss function. CIoU not only considers the overlapping area of the bounding box, but also introduces the constraints of aspect ratio and distance from the center point, which makes the model more accurate in detecting obstacles of different shapes in farmland. Thirdly, combined with binocular vision technology, depth information is used to enhance the three-dimensional perception ability of obstacles and provide more reliable data for path planning.

In the design of intelligent obstacle avoidance control algorithm, this study takes into account the dynamic characteristics of farmland environment and UAV motion constraints. Based on the detection results of the improved YOLOv5 model, the reinforcement learning algorithm is used for path planning, which enables UAV to dynamically adjust its flight path to avoid obstacles in complex farmland scenes. Adaptive control strategy is introduced to improve the robustness of UAV to uncertain environment. In case of strong wind interference or sensor data loss, the system can automatically adjust parameters to ensure flight safety. In addition, the possibility of multi-UAV cooperative obstacle avoidance is explored, and the real-time information sharing and cooperation of multi-UAVs are realized through distributed communication mechanism to improve the overall operation efficiency.

In order to verify the effectiveness of the method, this study built an experimental platform and tested it in a variety of typical farmland scenarios. The results show that the improved YOLOv5 model is superior to the original version in obstacle detection accuracy and speed, especially in small target detection and complex lighting conditions. Combined with intelligent obstacle avoidance control algorithm, UAV has good obstacle avoidance ability in dynamic obstacle dense environment, and the rationality and real-time performance of path planning have been greatly improved.

Theoretical basis

Target detection and deep learning

Target detection is an important way for agricultural UAV to perceive the environment. Its main task is to identify and determine the position of obstacles from the input images or videos *(Yang et al., 2021)*. Traditional target detection methods mostly rely on manual feature extraction (like HOG, SIFT, etc.) and classifiers (such as SVM). In the face of complex farmland environment, such methods usually expose the problem of poor generalization ability. The target detection algorithm based on deep learning has gradually become the mainstream by virtue of its strong feature learning ability and the advantages of end-to-end training *(Dai et al., 2020)*. Among them, YOLO (You Only Look Once) series algorithms emerge with high efficiency and real-time, especially YOLOv5 has great application potential in embedded devices.

However, YOLOv5 has some limitations in practical application, such as unsatisfactory detection effect on small targets and sensitivity to illumination changes, which are more prominent in farmland environment *(Varma et al., 2024)*. Take the telephone pole in the farmland as an example, it may only occupy a few pixels in the long-distance image. It is difficult for traditional YOLOv5 model to accurately capture the characteristics of such small targets. Moreover, the illumination conditions of farmland environment are changeable, especially on cloudy days or in the evening, the image quality will be obviously reduced, leading to the reduction of detection accuracy *(Gao et al., 2024)*. Therefore, this study is based on YOLOv5 to improve the applicability of the model in complex scenes by introducing Ghost module and optimizing the design of loss function.

Path planning and reinforcement learning

The purpose of path planning is to generate an optimal path from the starting point to the end point on the premise of ensuring flight safety. Traditional path planning methods mainly include graph-based algorithm (such as A * algorithm and Dijkstra algorithm) and sampling-based algorithm (such as RRT) *(Saeed et al., 2023)*. These methods perform well in static environment, but they face many problems in dynamic farmland environment. For example, obstacles in farmland may change at any time, and traditional offline planning methods are difficult to adapt to this dynamic change.

Therefore, this study adopts the path planning method based on reinforcement learning to deal with the uncertainty of complex farmland environment. Reinforcement learning is an unsupervised learning method, the core of which is to learn strategies through trial and error, so that agents can optimize decision-making behavior in the process of continuous interaction with the environment *(Zhu et al., 2024)*. In the application scenario of agricultural UAV, reinforcement learning can be used to solve the problem of dynamic obstacle avoidance.

Motion control and adaptive control

Motion control is the last step for agricultural UAV to perform obstacle avoidance task, and the goal is to transform the path planning results into specific flight instructions. Because the external interference in the farmland environment (such as wind speed, terrain fluctuation, etc.) may make the UAV deviate from the predetermined trajectory, it is necessary to design a robust motion control algorithm *(Liu et al., 2020)*. In this study, the method based on adaptive control is adopted to deal with the influence of external disturbance by adjusting the controller parameters online.

The basic principle of adaptive control is to dynamically adjust the control law according to the real-time state of the system to ensure the stability and performance of the system. In the application of agricultural UAV, fuzzy logic controller is introduced to adjust PID parameters adaptively. In addition, in order to further improve the control accuracy, the visual inertial navigation technology is combined to fuse the data of visual sensor and inertial measurement unit (IMU) to achieve higher precision attitude estimation and trajectory tracking.

Multisensor data fusion

In the complex farmland environment, it is often difficult for a single sensor to provide comprehensive environmental information *(Jiao et al., 2020)*. For this reason, multi-sensor data fusion technology has become the key to improve the sensing accuracy. Common sensors include lidar, binocular camera, infrared sensor and ultrasonic sensor, and each sensor has its own advantages and limitations *(Li et al., 2023)*. For example, lidar can provide high-precision distance information, but it is easily disturbed under strong light conditions; Binocular camera can generate three-dimensional depth map through stereo vision, but it requires high computing resources *(Muthanna et al., 2022)*.

In this study, the multi-sensor data fusion method based on Kalman filter is used to integrate the data of different types of sensors, so as to obtain more reliable and comprehensive environmental perception results. Kalman filter is a recursive estimation algorithm, the core of which is to gradually approach the real state of the system through two steps: prediction and update. In the application of agricultural UAV, Kalman filter is used to fuse the depth information of lidar and binocular camera to construct a unified environmental model.

Design of intelligent obstacle avoidance algorithm for agricultural UAV

Improved YOLOv5 target detection algorithm

Target detection is the first step for agricultural UAV to perceive farmland environment. Its core task is to identify and determine the position of obstacles from the input image *(Zhou et al., 2020)*. The traditional deep learning network, like YOLOv5, has excellent performance in the task of target detection, but in the complex farmland environment, there are still some situations, such as large consumption of computing resources and insufficient accuracy of small target detection *(Rienecker et al., 2023; Wenyu et al., 2024)*. In this study, Ghost module is introduced to improve the lightweight of YOLOv5 and optimize the design of loss function.

When traditional deep learning networks extract feature maps, there will be a lot of redundant and similar feature maps. However, these characteristic graphs are indispensable to the accuracy of the model, and they are all obtained by convolution operation and input to the next convolution layer for operation.

This process contains a lot of network parameters and consumes a lot of computing resources. Therefore, an attempt can be made to obtain these redundant feature maps at a lower computational cost. See Figure 1 for the main steps of Ghost module.

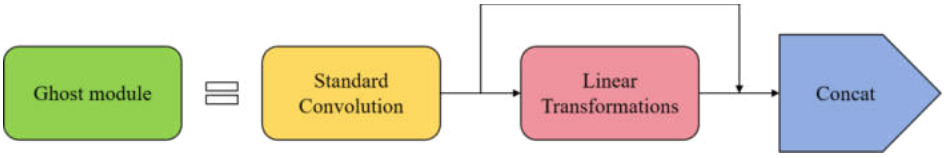

Fig. 1 - Ghost module

The working process of Ghost module is to generate a set of basic feature maps by using standard convolution layer, and then perform linear transformation (such as point-by-point convolution or depth-separable convolution) on these basic feature maps, and then generate a set of "phantom" feature maps *(Just et al., 2020)*.

Suppose the input feature map is $X \in \mathbb{R}^{H\times W\times C}$, where H and W represent the height and width of the feature map respectively, and C represents the number of channels. After the standard convolution layer processing, the basic feature map is as follows:

$$F_{base} = Conv(X) \tag{1}$$

Among them, $Conv(\cdot)$ stands for convolution operation.

Then, F_{base} is linearly transformed to generate a phantom feature map F_{ghost}, and its expression is:

$$F_{ghost} = \Phi(F_{base}) \tag{2}$$

$\Phi(\cdot)$ here stands for linear transformation operation, which generally adopts point-by-point convolution or depth-separable convolution.

The final output characteristic diagram is:

$$F_{out} = Concat(F_{base}, F_{ghost}) \tag{3}$$

$Concat(\cdot)$ refers to the splicing operation of feature graphs. In this way, Ghost module can expand the ability of feature expression without greatly increasing the number of parameters, so as to improve the detection efficiency of the model.

Based on Ghost module and Ghost-BottleNeck module, the CBL module and CSP_X module in YOLOv5s network structure are improved, and GBL(Ghost-Based Layer) and $GCSP_X$ (Ghost-based Cross-stage Partial Network) are obtained respectively. The improved YOLOv5s-Ghost network structure is shown in Figure 2.

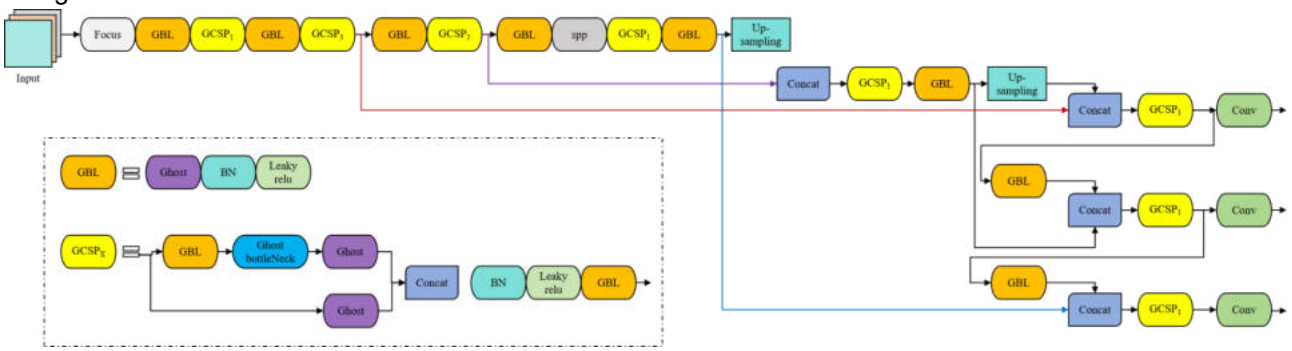

Fig. 2 -YOLOv5s-Ghost network structure

Compared with the original YOLOv5, YOLOv5s-Ghost model only uses a CSP_X structure. This reduces the complexity of the model to some extent and optimizes the feature fusion ability of the network. In addition, the information of gradient change is completely transmitted to the feature map, thus ensuring the accuracy of detection. For example, in the farmland environment, the size of obstacles such as trees and telephone poles is quite different, and the improved model can capture the spatial position of these targets more accurately *(Grau et al., 2020)*.

In order to further improve the bounding box regression performance of the model, CIoU (Complete Intersection Over Union) loss function is used to replace the traditional IOU loss function. CIoU considers the overlapping area between the prediction frame and the real frame, and also introduces the constraints of aspect ratio and the distance from the center point. It is defined as follows:

$$CIoU = 1 - IoU + \frac{\rho^2(b,b^{gt})}{c^2} + \alpha v \tag{4}$$

Where $\rho(b, b^{gt})$ represents the distance between the center point of the prediction frame b and the real frame b^{gt}, c represents the diagonal length of the smallest rectangle surrounding the two frames, and α and v respectively represent the weight and error term of the aspect ratio.
By introducing CIoU loss function, the model can better describe the three-dimensional spatial relationship of obstacles, thus improving the detection accuracy.

Path planning based on ORB feature point extraction

After obstacle detection, the next step is to plan the path based on the detection results. In this study, ORB (Orientated Fast and Rotating Brief) algorithm is used to extract the key feature points in the image, which is used to construct the environment map and guide the path planning. ORB algorithm is an efficient feature point extraction method, and its core steps include FAST corner detection and BRIEF descriptor generation.

Figure 3 shows the feature point extraction results of ORB algorithm in farmland environment. ORB algorithm can effectively capture the key feature points of obstacles, such as the outline of trees and the edge of telephone poles.

Fig. 3 - ORB feature point extraction results

Let the set of extracted feature points be $P = \{p_1, p_2, \ldots, p_n\}$, where each feature point p_i contains its coordinate (x_i, y_i) and descriptor d_i. In order to generate the environment map, the depth information z_i of each feature point is calculated by binocular vision technology, so as to construct a three-dimensional point cloud:

$$Q = \{(x_i, y_i, z_i)\}_{i=1}^{n} \quad (5)$$

Based on 3D point cloud Q, reinforcement learning algorithm is used for path planning, and the environment is modeled as a Markov decision process (MDP). In this framework, the state space AA represents the current position of UAV and the distribution of surrounding obstacles, and the action space represents the moving direction and speed of UAV. The reward function $R(s, a)$ is defined as:

$$R(s, a) = w_1 \cdot \text{Safety}(s, a) + w_2 \cdot \text{Efficiency}(s, a) - w_3 \cdot \text{Energy}(s, a) \quad (6)$$

where $\text{Safety}(s, a)$ represents the safety of the path, $\text{Efficiency}(s, a)$ represents the efficiency of the path, $\text{Energy}(s, a)$ represents the energy consumption, and w_1, w_2, w_3 is the weight coefficient.

Using reinforcement learning algorithm, UAV can quickly adjust its flight trajectory in dynamic environment and avoid collision with obstacles.

Adaptive motion control

The results of path planning need to be transformed into specific flight instructions by motion control algorithm. Because the external interference in the farmland environment (such as wind speed, terrain fluctuation, etc.) may cause UAV to deviate from the predetermined trajectory, it is necessary to design a robust adaptive control algorithm *(Shrestha et al., 2021)*.

An adaptive PID control method based on fuzzy logic controller is adopted in the research. Let the state variable of UAV be:

$$x(t) = [x_p, y_p, z_p, \theta]^T \quad (7)$$

where x_p, y_p, z_p represent the position of UAV and θ represents the yaw angle. The control objective is to minimize the position error:

$$e(t) = x_d(t) - x(t) \quad (8)$$

where $x_d(t)$ is the target position. The output of PID controller is:

$$u(t) = K_p e(t) + K_i \int_0^t e(\tau)d\tau + K_d \frac{de(t)}{dt} \quad (9)$$

where K_p, K_i, K_d are proportional, integral and differential coefficients respectively.

In order to cope with external interference, the fuzzy logic controller is used to adjust K_p, K_i, K_d adaptively. The input of fuzzy logic controller is the current flight state (such as yaw angle, pitch angle, etc.) and external interference intensity, and the output is the adjustment of PID parameters.

In order to further improve the reliability of environmental perception, multi-sensor data fusion technology is adopted in this study. Kalman filter is used to fuse the depth information of lidar and binocular camera, and a unified environmental model is constructed by combining the attitude data of IMU. The state update formula of Kalman filter is:

$$\hat{x}_k = \hat{x}_{k|k-1} + K_k(z_k - H\hat{x}_{k|k-1}) \quad (10)$$

where $\hat{x}_k$ is the estimated state, z_k is the observed value, and K_k is the Kalman gain matrix.

By fusing multi-sensor data, the system can obtain more comprehensive environmental information and provide reliable data support for path planning and motion control.

RESULTS AND DISCUSSIONS

Experimental setup

The hardware platform of this experiment is an agricultural UAV (DJI Matrice 300 RTK). It is equipped with binocular camera, lidar and IMU sensor. These devices are used to collect images and point cloud data in the actual farmland environment. It covers static obstacles (such as trees and telephone poles) and dynamic obstacles (such as birds and moving machinery). In terms of software, the improved YOLOv5s-Ghost model is used to perform the target detection task, and the path planning work is carried out in combination with reinforcement learning algorithm. All algorithms run on the embedded platform of NVIDIA Jetson Xavier NX to simulate the limitation of computing resources under real working conditions. The experimental data are taken from the images and point cloud data collected from the actual farmland environment. All the comparative experiments were carried out on the same hardware platform and the same farmland environment.

Result analysis

Figure 4 shows the time-consuming situation of different algorithms in path planning. When the information of farmland environment is simple and the number of obstacles is small, with the increase of the number of path planning nodes, the time required for the algorithm increases significantly. This is because in the low-complexity scenario, the increase in the number of nodes will cause a waste of computing resources, and the efficiency of path planning algorithm to deal with redundant information will also decrease. However, when the complexity of farmland environment gradually rises (such as more kinds of obstacles or dynamic obstacles), the advantages of multi-node begin to be reflected. This shows that the improved algorithm has stronger adaptability and higher efficiency when dealing with complex farmland environment.

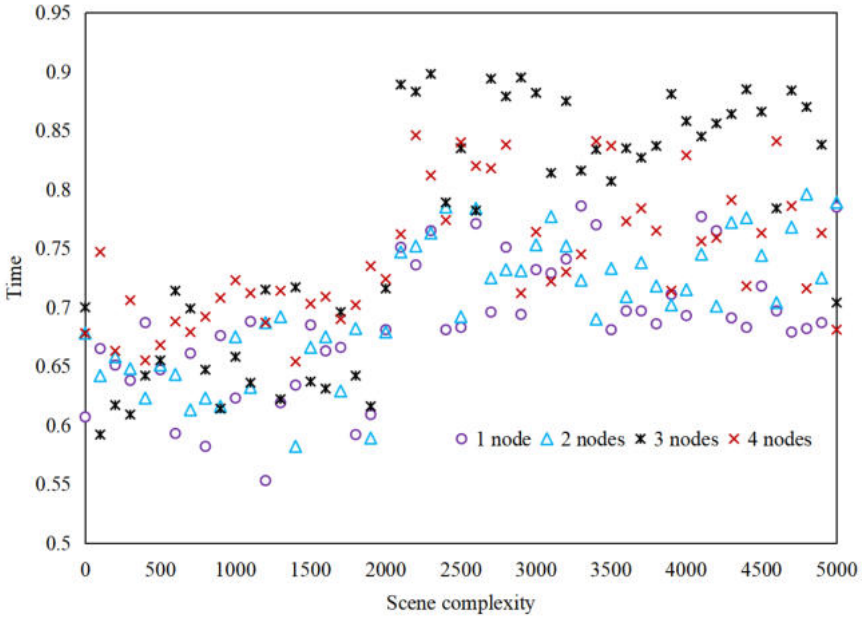

Fig. 4 - Path planning is time consuming

Further analysis shows that the average path planning time of the improved algorithm is about 35% less than that of the traditional Dijkstra algorithm. Compared with the original YOLOv5 model, it is reduced by about 20%. This is mainly due to the improvement of target detection accuracy of the improved YOLOv5 model and the advantages of reinforcement learning algorithm in identifying dynamic obstacles.

Figure 5 compares the errors of different algorithms in path planning. The results show that the traditional Dijkstra algorithm and the unoptimized YOLOv5 model have poor performance in error control. Especially in complex farmland scenes, or when the number of nodes is large, the paths generated by them often deviate from the optimal solution, which leads to failure of obstacle avoidance or low path efficiency. In contrast, the path planning algorithm based on the improved YOLOv5 greatly reduces the path planning error by optimizing the target detection accuracy and improving the dynamic obstacle recognition ability.

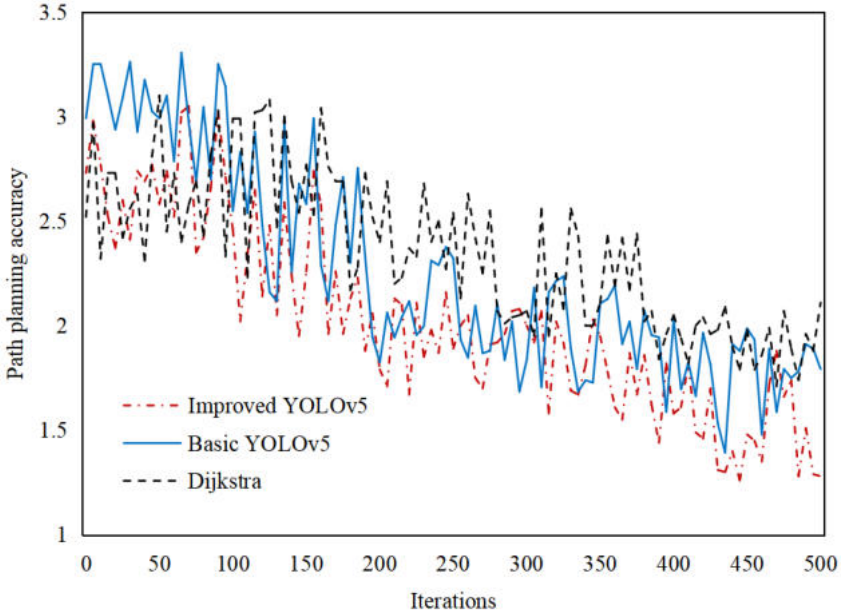

Fig. 5 - Path planning error

Figure 6 shows the comparison results of different algorithms in path planning accuracy. The path planning algorithm based on improved YOLOv5 has the highest accuracy, and its path planning accuracy can reach more than 96%. This result verifies the effectiveness and potential of the improved YOLOv5 in the application of agricultural UAV in complex farmland environment. By introducing Ghost module and CIoU loss function, the improved algorithm obviously improves the detection ability of small target obstacles (such as telephone poles) and dynamic obstacles (such as birds). In addition, the accuracy of the improved algorithm fluctuates little in complex scenes, showing strong robustness.

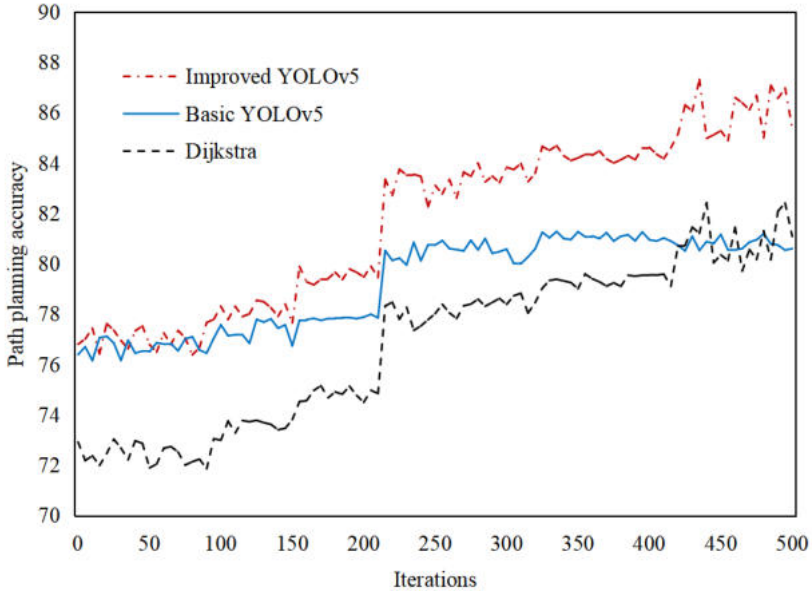

Fig. 6 - Path planning accuracy

It is not difficult to find from Table 1 that with the increase of scene complexity, the time-consuming growth rate of the improved YOLOv5 path planning is the smallest, which shows that it has higher efficiency in high-complexity scenes.

Table 1

Comparison of Path Planning Time Consumption for Different Algorithms

Scene Complexity	Dijkstra Algorithm	A* Algorithm	Unimproved YOLOv5	Improved YOLOv5
Low Complexity	0.85	0.72	0.68	0.58
Medium Complexity	1.23	1.05	0.92	0.75
High Complexity	2.15	1.87	1.54	1.12

Table 2 shows that the path planning error of the improved YOLOv5 in various scenarios is significantly lower than other algorithms. In the dynamic obstacle area, the error is only 2.5 meters, which is about 60% lower than the traditional algorithm.

Table 2

Comparison of Path Planning Errors for Different Algorithms

Scene Type	Dijkstra Algorithm	A* Algorithm	Unimproved YOLOv5	Improved YOLOv5
Dense Tree Areas	6.8	5.4	4.3	2.1
Dynamic Obstacle Areas	7.2	6.1	4.8	2.5
Comprehensive Scenes	6.5	5.7	4.5	2.3

Table 3 shows that the path planning accuracy of the improved YOLOv5 in all kinds of scenarios is over 95%, which is much higher than other algorithms. This result further proves the superiority of the improved algorithm in complex farmland environment.

Table 3

Comparison of Path Planning Accuracy for Different Algorithms

Scene Type	Dijkstra Algorithm	A* Algorithm	Unimproved YOLOv5	Improved YOLOv5
Dense Tree Areas	82	85	89	96
Dynamic Obstacle Areas	78	81	87	95
Comprehensive Scenes	80	83	88	96

Discussion

Based on these results, the improved YOLOv5 model usually has excellent performance in the accuracy of target detection and the efficiency and accuracy of path planning. Especially in the complex farmland environment, the improved algorithm greatly improves the detection ability of small target obstacles and dynamic obstacles by introducing Ghost module and CIoU loss function. In this way, it provides more reliable data support for path planning.

Moreover, the path planning algorithm based on reinforcement learning is particularly outstanding in dynamic scenes. It can quickly adjust the flight path to avoid collision. However, the experiment also revealed some problems. For example, in extreme weather conditions, such as strong wind or heavy rain, the quality of sensor data may decrease.

Future research will further optimize the anti-jamming ability of the algorithm, and also explore the potential application of more emerging technologies in agricultural UAV.

CONCLUSIONS

With the continuous progress of precision agriculture technology, agricultural UAV is more and more widely used in complex farmland environment. According to the characteristics of complex farmland environment, this article proposes a solution that combines the target detection algorithm based on improved YOLOv5 with the intelligent obstacle avoidance control strategy. It is found that the scheme has made significant breakthroughs in target detection accuracy, path planning efficiency and overall system robustness.

In the field of target detection, Ghost module is introduced to improve the lightweight of YOLOv5, and then the regression performance of bounding box is optimized by combining CIoU loss function. This greatly improves the detection ability of the model for small targets and dynamic obstacles. Experiments show that the detection accuracy of the improved YOLOv5 model can reach more than 96% in complex farmland environment, which is about 7% higher than that of the original model. Moreover, the path planning error of the improved algorithm when dealing with dynamic obstacles is only 2.1 meters, which is about 70% lower than the traditional Dijkstra algorithm.

In path planning and motion control, 3D point cloud data generated based on ORB feature point extraction and binocular vision technology provide high-precision input for path planning. Combined with reinforcement learning algorithm, real-time obstacle avoidance decision-making in dynamic environment is realized, and the time-consuming of path planning is reduced by about 35%. At the same time, the adaptive PID control strategy realized by fuzzy logic controller greatly improves the flight stability of UAV when it is disturbed by external interference. The experimental verification shows that the system is particularly outstanding in the comprehensive scene including obstacles such as trees and bushes.

However, there are still some limitations in this study. For example, in extreme weather conditions (such as strong wind or heavy rain), the quality of sensor data may decrease. Future research will further optimize the anti-interference ability of the algorithm, and explore the potential application of emerging technologies such as edge computing and federated learning in agricultural UAV.

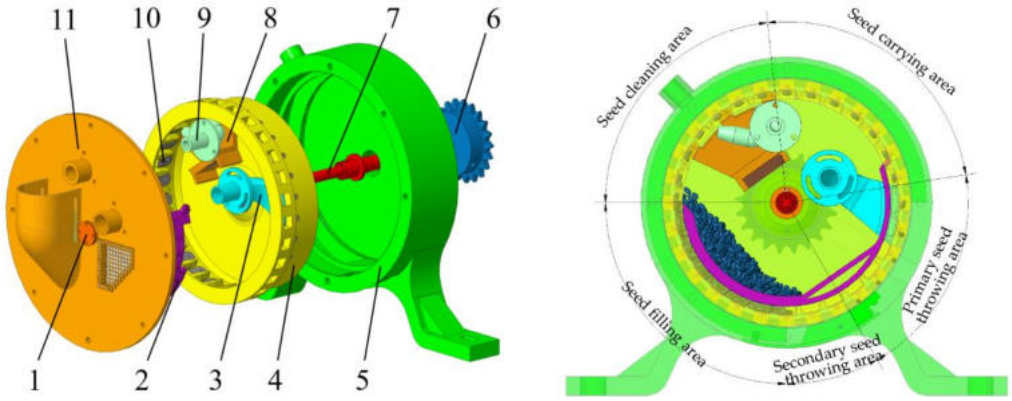
ABSTRACT
To address the poor seeding effect of inside-filling pneumatic high-speed precision seed-metering device for cotton, Computational Fluid Dynamics (CFD) and Discrete Element Method–Computational Fluid Dynamics (DEM-CFD) approaches were employed for simulation and optimization. The CFD technique was applied to analyze the influence of key structural parameters of the negative-pressure air chamber on the adsorption performance of the suction holes, while the DEM-CFD approach was used to investigate the motion of cotton seeds inside the seed-metering device during the seed-throwing stage. Based on these analyses, the optimal combination of structural and performance parameters of the seed-metering device was obtained. The simulation-optimized parameters were then validated through bench tests, which showed that at a suction hole diameter of 3.1 mm, a forward speed of 2.33 m/s (8.4 km/h), and a negative pressure of 3,178 Pa, the evaluation indexes were optimal: 96.25% qualification index, 1.83% multiple sowing index, and 1.92% missed sowing index. Further high-speed adaptability test showed that when the forward speed was 1.67~3.33 m/s (6~12 km/h), the qualification index remained greater than 91%, and both the multiple and missed sowing index were less than 5%, meeting the agronomic requirements of high-speed precision seeding for cotton.

摘要
针对内充气力式棉花高速精量排种器排种效果不佳的问题，采用 CFD 和 DEM-CFD 仿真分析方法对其进行了模拟与优化。利用 CFD 仿真分析了负压气室关键结构参数对吸孔吸附性能的影响，采用 DEM-CFD 气固耦合方法探究了投种环节排种器内部棉花种子运动规律，并获得了排种器关键结构与性能参数最佳组合。仿真优化后的参数经台架排种性能试验表明，当吸孔直径为 3.1 mm、前进速度为 2.33 m/s (8.4 km/h)、负压为 3178 Pa 时，其试验指标最优且为合格指数 96.25%，重播指数 1.83%，漏播指数 1.92%。进一步经高速适应性试验表明，当前进速度为 1.67~3.33 m/s (6~12 km/h) 时，合格指数均大于 91%，重播与漏播指数均小于 5%，满足棉花高速精播农艺要求。

INTRODUCTION
Cotton is an important economic crop in China, with a long history of cultivation *(Bie et al., 2018)*. With the acceleration of agricultural modernization, cotton growers are increasingly demanding high-speed and efficient agricultural machinery *(Dong et al., 2025)*. Sowing represents the first step of planting, the seed-metering device being a seeder key component, its seeding quality directly affecting the operational performance of the machine *(Li et al., 2025; Cortez et al., 2020)*. Cotton seed-metering devices are mainly classified into mechanical and pneumatic types. Mechanical seed-metering devices have simple structures but require high seed shape uniformity, having a tendency to damage seeds and suffer from low seeding accuracy under high-speed operation *(Yang et al., 2024; Li et al., 2025; Li et al., 2024)*. In contrast, pneumatic seed-metering devices, although structurally more complex, exhibit better adaptability to seed shape variations, higher seeding precision, and less seed damage, making them more suitable for high-speed seeding operations *(Zang et al., 2024; Li et al., 2021; Gao et al., 2023; Li et al., 2020; Yatskul & Lemiere, 2018; Pareek et al., 2023)*. At present, existing cotton precision seed-metering devices still suffer from poor seed-filling performance under high-speed conditions, with a typical missed sowing index greater than 10%, a qualification index lower than 75%, and the forward speed generally limited to less than 1.11 m/s (4 km/h) *(Zhang et al., 2021; Zhang et al., 2022; Xu, 2018)*.

Since the seed inside-filling type can make use of gravity, centrifugal force, and inter-seed interaction forces to improve the seed-filling performance, our research group previously designed an inside-filling pneumatic cotton high-speed precision seed-metering device. However, experimental results revealed that although the seed-filling performance was improved, the device still exhibited problems such as unstable seed adsorption and poor seed throwing quality under high-speed operation, leading to poor seeding performance. Therefore, the structural parameters of the seed-metering device still require further investigation and optimization.

In recent years, the Computational Fluid Dynamics (CFD) and Discrete Element Method–Computational Fluid Dynamics (DEM-CFD) techniques have been widely applied in the development of seed-metering devices *(Wang et al., 2025; Sun et al., 2025; Wan et al., 2022; Zhou et al., 2024; Guzman et al., 2020; Bustos-Gaytán et al., 2025)*. Guzman validated the feasibility of using DEM-CFD technique to simulate pneumatic seeder planting green field peas through the combination of simulation and experimentation, and investigated the effects of scaled-down seed tank and fluted roller, single run of a horizontal distributor tube, horizontal-vertical tube transition, and vertical seed manifold on the seed movement *(Guzman, 2024)*. Zha et al. designed a branched air-chamber type pneumatic seed-metering device to meet the varying seed rate requirements for different rice varieties, employing CFD technique to optimize the key structural parameters of the branched air chamber casing *(Zha et al., 2024)*. Cao et al. aimed to improve the operational performance of the mixing component in a horizontal air-assisted centralized wheat metering device. Using CFD and DEM-CFD methods, they investigated the influence of key structural parameters of the mixing component on internal airflow distribution and wheat conveying performance, and determined the optimal parameter combination *(Gao et al., 2024)*. Hussain et al. aimed to optimize the working performance of an air-suction maize seed metering device. CFD was used to investigate the effects of vacuum pressure, suction hole diameter, and seed disk speed on device performance, and the optimal parameter combination was obtained. This was subsequently validated through DEM-CFD coupling simulations and bench tests. At a vacuum pressure of 3.5 kPa, an operating speed of 1.94 m/s (7 km/h), and a suction hole diameter of 4 mm, the qualified index reached 95.98%, while the missed index was 1.5% *(Hussain et al., 2025)*. Zhao et al. combined the DEM-CFD gas-solid coupling method and high-speed camera to investigate the effects of key structural and performance parameters of a novel high-speed precision maize seed-metering device on the seeding performance, determining the optimal combination of operating parameters, and verifying the reliability of the seed-metering device under high-speed operation through bench and field tests *(Zhao et al., 2024)*. In summary, simulation techniques are currently widely applied in the development of seed-metering devices for grain crops such as peas, rice, wheat, and maize, while their application in the research and development of high-speed cotton seed-metering devices is not very developed. Moreover, existing studies have not clarified how the air chamber geometry affect the pressure uniformity at suction hole endface for inside-filling pneumatic seed-metering devices, nor have the DEM-CFD coupling simulation been utilized to define the seed throwing pressure and seed throwing port position angle required for stable seed throwing. Therefore, this study uniquely addresses these gaps by combining CFD and DEM-CFD simulations with experimental research to improve the seeding performance of inside-filling pneumatic cotton high-speed precision seed-metering device.



To improve the operational performance of an inside-filling pneumatic high-speed precision cotton seed-metering device, CFD simulations were conducted to analyze the influence of key structural parameters of the negative-pressure air chamber on the pressure at the suction hole end face, and the optimal parameter combination was determined. The DEM-CFD gas–solid coupling technique was then applied to investigate the motion behavior of cotton seeds inside the device during the seed-throwing stage, analyzing the effects of seed-throwing pressure on the initial and stable contact angles between the seeds and the inner wall of the back shell, and determining the optimal seed-throwing pressure and port position. Bench tests of the optimized device were carried out to identify the best combination of performance parameters affecting seeding quality, followed by high-speed adaptability verification. This study provides a reference for the optimization and further improvement of precision seed-metering devices.

MATERIALS AND METHODS

Overall structure and working principle

The inside-filling pneumatic high-speed precision cotton seed-metering device mainly consists of the front shell, seeding plate, suction-hole replacement plate, seed protection board, scraper, seed-cleaning air nozzle, seed-throwing air nozzle, seeding shaft, and back shell, as shown in Fig. 1(a).

As shown in Fig. 1, an arc-shaped groove is arranged on the inner wall of the back shell, which is assembled with the outer wall of the seeding plate to form an air chamber. The back shell is provided with an air outlet hole, which is connected to the air chamber and externally connected to a fan, so that the air chamber can be filled with negative pressure airflow. After cotton seeds enter the inner cavity of the seed-metering device through the seed inlet on the front shell, a seed cluster is formed. The cotton seeds in the lower layer of the seed cluster are adsorbed onto the suction holes under the action of airflow and rotate clockwise with the seeding plate. When the suction hole rotates into the seed cleaning area, excess seeds surrounding the suction hole are removed by the combined action of the scraper and seed cleaning air nozzle, falling back into the seed cluster. The single cotton seed stably adsorbed onto the suction hole is carried by the seeding plate through the seed carrying area and reaches the primary seed throwing area, where it is blown into the collection hole under the action of airflow from the seed throwing air nozzle. As the collection hole continues to move into the secondary seed throwing area, the seed is thrown out through the seed throwing port of back shell, thereby completing the entire seeding process.

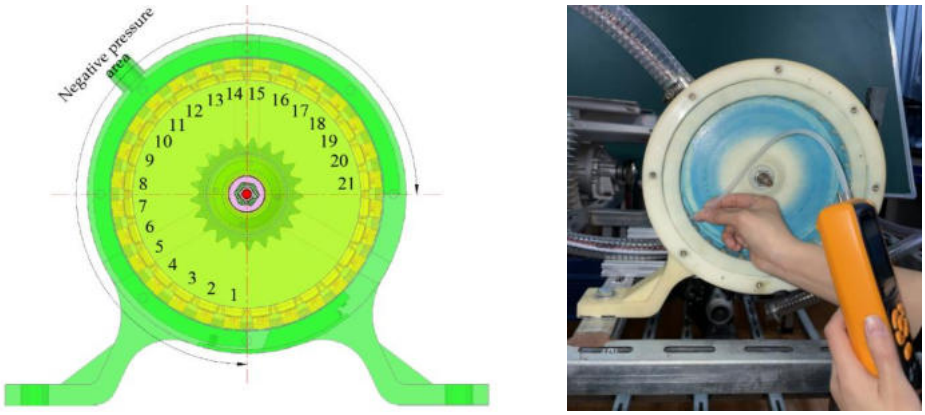
Simulation analysis method

CFD simulation method for the negative pressure air chamber

Construction and validation of the airflow field model

Using ANSYS Fluent 18.0 software to simulate the airflow field of the negative pressure air chamber, the airflow field model needs to be constructed firstly according to the actual structure and working principle of the seed-metering device, as shown in Fig. 2(a).



(a) (b)

Fig. 2 - Airflow field mesh model of the seed-metering device

(a) Overall schematic diagram of the mesh model, (b) Exploded schematic diagram of the mesh model

To improve the simulation efficiency, components such as the seeding shaft, seed protection plate, and scraper were omitted to simplify the computational domain. Based on the working principle of the seed-metering device, the airflow field model was divided into one dynamic zone (Rotary) and two static zones (Static_1 and Static_2), as shown in Fig. 2(b). According to the sliding mesh technique, pairs of interfaces were set up between the dynamic and static zones to realize the airflow communication and data exchange across the different regions. Due to the relatively regular geometry of the airflow field in the Rotary and Static_2 zones, structured meshes were applied in these regions. However, the airflow field in the Static_1 zone contains embedded seed cleaning and throwing air nozzles, making it unsuitable for structured meshes, therefore, instead were used unstructured meshes. After meshing the airflow field, the total number of cells was 342356, with the maximum skewness of 0.68. To verify the mesh-independence, two refined meshes with 459749 and 576813 cells were generated for simulation. The pressure differences at the suction hole endface among the three meshes were all less than 5%, indicating that the mesh density had little influence on the pressure at the suction hole endface and that mesh was independent.

In order to test the accuracy of the airflow field model of the seed-metering device, the pressure at the suction hole endface was selected as the evaluation index to carry out the airflow field simulation and physical comparison verification test. Before the test, the central plane of the partition plate between any two adjacent type holes was aligned with the vertical central axis of the seed-metering device, so that the 21 suction holes on the seeding plate were symmetrically and evenly distributed within the negative pressure zone, and sequentially numbered in a clockwise direction, as shown in Fig. 3(a). In the physical test, the pressure at the suction hole endface was measured using a digital differential pressure gauge (Shenzhen Wintact Electronics Co., Ltd., GM520 type, accuracy ±0.3% FSO (factory calibration within 12 months)), and the measurement method was illustrated in Fig. 3(b). The negative pressure at the air outlet was adjusted to –3000 Pa, and after the airflow stabilized, the pressure at suction holes 1–21 was measured and recorded in sequence. The simulation tests were conducted with reference to the physical test, and the boundary conditions were set as follows: the Outlet was set as a pressure outlet with a value of −3000 Pa, the Inlet_1, Inlet_2, and Inlet_3 were set as pressure inlets with the value of 0 Pa, and the rotation speed of dynamic zone was set to 0 r/min. The endface of the suction hole at the measurement points was set as wall. The standard k-ε turbulence model was employed and the pressure-based type solver was selected. The residual convergence criterion was set to 10^{-4}, and the time step was set to 0.003571429, with a total of 500 time steps. After both the physical and simulation tests were completed, the suction holes endface pressure values were compared to verify the accuracy of the airflow field model of the seed-metering device.

Simulation method

The negative pressure air chamber is directly connected to the suction holes, providing the required negative pressure to ensure that cotton seeds remain stably adsorbed on the suction hole endface during the normal operation of the seed metering device. The pressure at the suction hole endface can reflect the adsorption performance of suction hole, and investigating the effects of the structural parameters of the

negative pressure air chamber on the pressure at the suction hole endface can provide a basis for optimizing the parameters of the seed-metering device. The key structural parameters of the negative pressure air chamber mainly include the angle and position of the air outlet hole, and the width and thickness of the negative pressure air chamber.

(1) Effect of Air Outlet Hole Angle and Position on Suction Hole Endface Pressure

The air outlet hole serves as the airflow exit of the seed-metering device, with its angle and position parameters directly affecting airflow direction. These include the position angle, vertical inclination angle, and longitudinal (front–rear) inclination angle, which were therefore selected as test factors to investigate their effect on the pressure at the suction hole endface. Because the suction hole endface pressure is the key factor for stable adsorption of cotton seeds, increasing the endface pressure in the seed-filling area improved the filling performance of the seed-metering device, while reducing pressure variation between suction holes in the seed-cleaning and seed-carrying areas helped prevent missed seeding caused by abrupt pressure changes. Therefore, the average endface pressure in the seed-filling area and the standard deviation of endface pressure in the seed-cleaning and seed-carrying areas were selected as evaluation indexes, and a three-factor, three-level orthogonal test was conducted. The levels of each factor are shown in Table 1, and the angle arrangement was illustrated in Fig. 4. In the numerical simulation, the relevant parameters were set as follows: the Outlet was set as a pressure outlet with a value of −3000 Pa, the Inlet_1, Inlet_2, and Inlet_3 were set as pressure inlets with the value of 0 Pa, and the rotation speed of dynamic zone was set to 30 r/min. The standard k-ε turbulence model was employed and the pressure-based type solver was selected. The residual convergence criterion was set to 10^{-4}, the time step was set to 0.003571429, and the number of time steps was 570.

2. Test repeats for 3 times.

(2) Effect of Negative Pressure Air Chamber Width and Thickness on Suction Hole Endface Pressure

The thickness and width of the negative pressure air chamber determine the volume of the air chamber, as shown in Fig. 5, and its influence on the pressure at the suction hole endface can be explored to provide a reference for the optimization of the structural parameters of the seed-metering device. In the simulation test, the air chamber thickness and width were taken as test factors, and the pressure average at the suction hole endface in the seed filling area and pressure standard deviation at the suction hole endface in the seed cleaning and carrying areas were taken as evaluation indexes to carry out a two-factor test.

Based on the actual size of the seed-metering device, the air chamber width b_0 was set at three levels: 22 mm, 26 mm, and 30 mm, while the thickness c_0 was set at 12 mm, 16 mm, and 20 mm. In the flow field model, the position angle, up and down inclination angle, and front and rear inclination angle of the air outlet hole were all set to the optimal levels determined in the previous experiments. All relevant parameters in the Fluent software were kept consistent with the above orthogonal test.

DEM-CFD simulation method for the seed throwing link

In the primary seed throwing area, the cotton seeds adsorbed on the suction hole endface are blown from the filling hole into the collection holes under the airflow action from the seed throwing air nozzle outlet, and then rotated with the seeding plate to the secondary seed throwing area, and finally thrown out through the seed throwing port. The seed throwing air nozzle pressure determines whether cotton seeds can be smoothly blown into the collection hole. To reduce the required air pressure, the seed throwing air nozzle pressure should be selected as low as possible while ensuring the normal operation of the seed-metering device. After cotton seeds fall from the filling hole into the collection hole, collisions between them may cause a certain degree of bouncing. To avoid the impact of bouncing on the seeding performance of seed-metering device, the starting position angle (the angle between the plane formed by the starting edge of the seed throwing port and the center axis of the seeding plate, and the vertical center plane of the seeding plate) of the seed throwing port should be determined to ensure that the seeds have no significant bouncing against the inner wall of the back shell before seed throwing. Since the seeding plate is made of opaque toughness photosensitive resin, and the cotton seeds are coated, the external seed coating agent is easy to adhere to its contact and interfere with the line of sight, so it is not feasible to directly observe the movement of the seeds in the seed throwing area. Therefore, the DEM-CFD gas-solid coupling simulation test method was adopted.

Construction and validation of the cotton seed particle model

EDEM 2018 and ANSYS Fluent 18.0 software were used to perform DEM-CFD gas–solid coupling simulations of the seed-metering device. Bonded particle model (BPM) was adopted to construct cotton seed particles, meaning a single cotton seed consists of several independent fraction particles bonded together. The contact model between fraction particles was set as Hertz-Mindlin with bonding model, and a particle radius of 0.45 mm was chosen. In this study, the E`kangmian-10 cotton seeds (moisture content 11.06% wb, mass of 1000 cotton seeds 94.50 g, length 9.27±0.67 mm, width 5.14±0.37 mm, and thickness 4.50±0.33 mm) were selected as the test material, which can be divided into two categories of ellipsoidal and flat cotton seeds, with the quantity ratio of 22:3, the simulation model being shown in Fig. 6. The ellipsoidal and flat cotton seeds were composed of 146 and 127 fraction particles, respectively. The key components of the seed-metering device were all generated by 3D printing technology with resin materials. Among them, the front shell and seed protection board were made of fully transparent photosensitive resin, while the remaining parts were made of tough photosensitive resin.

Based on previous research and preliminary experiments, the intrinsic material parameters, contact parameters, and main computational parameters used in the coupling simulation are listed in Table 2 *(Hu et al., 2022)*.

	Density/(kg/m^3)	1.23
	Fluid time step/(s)	3×10^{-5}

Simulation method

Since the number of particles significantly affects the coupling simulation speed, one ellipsoidal and flat cotton seed was used in the DEM-CFD simulation for calculation, respectively. The seed-throwing pressure was selected as the test factor and set at four levels (500, 1000, 1500, and 2000 Pa) based on pre-tests. The initial contact angle—defined as the angle between the vertical center plane of the seeding plate and the vertical line connecting the center of the bonded particle closest to the vertical center plane with the centerline of the seeding plate at the moment the cotton seed first contacts the inner wall of the back shell—and the stable contact angle—measured when the seed shows no significant rebound after contact—were chosen as evaluation indices. These parameters were then used to conduct the coupling simulation test. Since a higher seeding plate rotational speed reduces the time during which the cotton seed is exposed to the airflow from the seed throwing air nozzle in the primary seed throwing area, making it more difficult for the seed to be smoothly blown into the collection hole, the rotational speed of the seeding plate was set to 35.71 r/min (corresponding to the designed maximum forward speed of 3.33 m/s (12 km/h)) to ensure the normal operation of the seed-metering device.

The remaining parameters were set as follows: the Inlet_1 and Inlet_2 were set as pressure inlets with the value of 0 Pa, the Outlet was set as pressure outlet with the value of -3000 Pa. The number of time steps was 100,000 and the simulation time was 3 s. The structural parameters of the negative pressure air chamber were set to the optimal combinations determined from the previous airflow field simulation tests.

The DEM-CFD coupling frequency was set to 3×10^{-5} s, the turbulence–particle coupling was set to two-way data transfer, and the Freestream model was adopted as the drag model. Each cotton seed type was simulated 10 times, the mean was used as the evaluation index, and the minimum value was used as the diagnostic indicator.

Seeding performance test method of the seed-metering device

To investigate the working effect of the simulation-optimized seed-metering device under high-speed operation, the seeding performance tests were conducted.

Test equipment

The test equipment consisted of a self-built performance test platform for the seed-metering device. The main components of the device were fabricated by 3D printing and installed on the platform, as shown in Fig. 7. The seed-metering device was driven by a DC motor through a speed reducer. The detection system employed a self-developed seed-metering device performance testing device for medium and large seeds, which mainly consisted of an LED photoelectric sensing system and a pulse recognition monitoring system, enabling real time monitoring and display of the seeding operation status *(Liu et al., 2021)*.

1. Fan Ⅰ; 2. Fan Ⅱ; 3. Pressure gauge; 4. LED photoelectric sensing system; 5. Pulse recognition monitoring system; 6. Seed-metering device; 7. DC motor; 8. Control system; 9. Lithium battery

Test method and evaluation indexes

Referring to GB/T 6973-2005 “Testing Methods of Single Seed Drills (Precision Drills)”, the seed-metering device performance testing device for medium and large seeds continuously detected and recorded the seeding time intervals under stable operation conditions. Every 251 seeds constituted one test group, and each group was repeated 3 times. The qualification index A_1, multiple sowing index D_1 and missed sowing index M_1 were taken as the evaluation indexes, and their calculation formulas were as follows:

$$\begin{cases} A_1 = \dfrac{n_1}{N}\times 100\% \\ D_1 = \dfrac{n_2}{N}\times 100\% \\ M_1 = \dfrac{n_3}{N}\times 100\% \end{cases} \quad (1)$$

where: n_1 is the number of seedings with the seeding time interval between 0.5 and 1.5 times the theoretical value; n_2 is the number of seedings with the seeding time interval less than 0.5 times the theoretical value; n_3 is the number of seedings with the seeding time interval greater than 1.5 times the theoretical value; N is the total number of seedings.

The experimental environmental conditions were a temperature of 25±2℃ and a relative humidity of 50±5%. All experimental runs were randomized.

Test design

Based on previous studies and pre-test, the main factors affecting the seeding performance of the seed-metering device are suction hole diameter, forward speed, and negative pressure. Among them, the conversion formula between forward speed and seeding plate rotational speed was as follows:

$$V_m = \frac{nKI_z}{60} \quad (2)$$

where: V_m is the forward speed, m/s; n is the rotational speed of seeding plate, r/min; K is the number of suction holes, value 28; I_z is the theoretical seed spacing, value 0.2 m.

Therefore, the above three factors were selected as test factors, and the qualification index A_1, multiple sowing index D_1, and missed sowing index M_1 were used as evaluation indexes to conduct the seeding performance tests of the seed-metering device.

(1) A Box-Behnken central combination test was carried out to investigate the effects of each test factor on the evaluation indexes and to determine the optimal parameter combination. According to the pre-test, it was found that the seeding performance was good when the suction hole diameter, forward speed and negative pressure were set to 2.7~3.5 mm, 1.67~3.33 m/s (6.0~12.0 km/h), and 2000~4000 Pa, respectively. Therefore, the levels of each test factor were selected as shown in Table 3. A total of 17 test groups were conducted, with each group repeated 3 times, and the average value was taken as the final evaluation index.

Table 3

The levels of test factors for Box-Behnken test

Levels	Test factors		
	Suction hole diameter X_1 / (mm)	Forward speed X_2 / (m/s)	Negative pressure X_3 / (Pa)
-1	2.7	1.67	2000
0	3.1	2.5	3000
1	3.5	3.33	4000

(2) Based on the optimal parameter combination obtained from the above tests, four levels of 1.67, 2.22, 2.78 and 3.33 m/s (6, 8, 10 and 12 km/h) were selected to carry out the high-speed adaptability test of the seed-metering device with forward speed as the test factor. Each group of tests was repeated 3 times, and the average of the results was taken as the final evaluation index.

RESULTS AND DISCUSSION

Validation of the airflow field model

The pressure registered values at the suction hole endface in both physical and simulation tests are shown in Fig. 8.

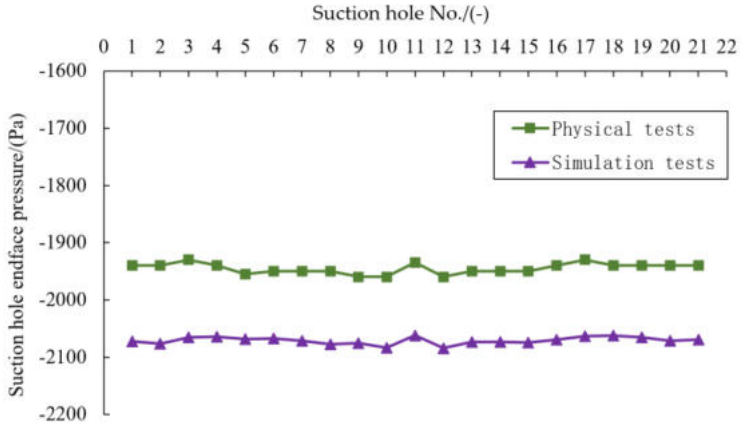

Fig. 8 – Pressure values at the suction hole endface in both physical and simulation tests

Note: 1. Simulation settings: Outlet −3000 Pa, Inlet(s) 0 Pa, dynamic zone rotation speed 0 r/min, residual convergence 10^{-4}, time step 0.003571429 s, 500 steps.
2. Test repeats for 3 times.

As can be seen from Fig. 8, the absolute values of the pressure at the suction hole endface in the physical tests were lower than the simulation values, which was mainly due to the airflow loss caused by the gap between the seeding plate and back shell. Since the seeding plate and the back shell were in axial linear contact, considering the difficulty of ensuring coaxiality due to the limited precision of 3D printing, a clearance of 0.6 mm was reserved between the back shell and the seeding plate to allow the seeding plate smooth rotation. Therefore, the absolute pressure values measured in the physical tests were all lower than those obtained from the simulation tests, but the relative errors between them were all less than 7.04%, indicating that the airflow field model was suitable for the subsequent simulation analysis of the seed-metering device.

Simulation analysis results

CFD simulation results *for the negative pressure air chamber*

Effect of Air Outlet Hole Angle and Position on the Suction Hole Endface Pressure

The design and results of the orthogonal test on the air outlet hole angle and position of the negative pressure air chamber are shown in Table 4, and the results of extreme difference analysis are shown in Table 5. As shown in the table, the factors influencing the pressure average at the suction hole endface in the seed filling area ranked in the following order: front and rear inclination angle θ_c, up and down inclination angle θ_b and position angle θ_a, and for this evaluation index, the optimal combination was $\theta_{c_2}\theta_{b_2}\theta_{a_1}$. The factors influencing the pressure standard deviation at the suction hole endface in the seed cleaning and carrying areas ranked in the following order: position angle θ_a, front and rear inclination angle θ_c and up and down inclination angle θ_b, and for this evaluation index, the optimal combination was $\theta_{a_2}\theta_{c_2}\theta_{b_2}$. Therefore, it can be concluded that the up and down inclination angle should be set to level θ_{b_2}, and the front and rear inclination angle should be set to level θ_{c_2}. However, the optimal value for the position angle remains uncertain and requires further determination through analysis of variance.

Table 4

Orthogonal test design and results

Test serial number	Test factors			Evaluation indexes

	θ_b	74.47	63.99	74.46	10.48	
	θ_c	67.79	67.11	78.02	10.91	

Note: 1. Simulation settings: Outlet −3000 Pa, Inlet(s) 0 Pa, dynamic zone rotation speed 30 r/min, time step 0.003571429 s, 570 steps. 2. Test repeats for 3 times.

The results of variance analysis are shown in Table 6. As can be seen from the table, for the pressure average at the suction hole endface in the seed filling area, the front and rear inclination angle had a significant effect on it, and the remaining two factors have no significant effect. For the pressure standard deviation at the suction hole endface in the seed cleaning and carrying areas, all the test factors had a highly significant effect, which was consistent with the results of the extreme difference analysis. Among the three test factors, the position angle had no significant effect on the pressure average at the suction hole endface in the seed filling area, with a contribution rate of 4.78%. However, it had a highly significant effect on the pressure standard deviation at the suction hole endface in the seed cleaning and carrying areas, with a contribution rate as high as 94.83%. Therefore, the selection of the position angle should be primarily based on the pressure standard deviation. Combined with the results of the extreme difference analysis, the optimal level for the air outlet position angle was determined to be θ_{a_2}. Since the factor combination $\theta_{a_2}\theta_{b_2}\theta_{c_2}$ was not included in the orthogonal test design, a simulation verification test was conducted for the airflow field model under this combination using the same method. After the simulation, statistical analysis showed that the pressure average at the suction hole endface in the seed filling area was 1257.64 Pa, which was lower than that of groups 2 and 9 in the orthogonal test, with a maximum pressure difference of 97.13 Pa. The pressure standard deviation at the suction hole endface in the seed cleaning and carrying areas was 8.92 Pa, which was lower than all standard deviations in the orthogonal test. This indicated that when the air outlet was located in the central plane of the negative pressure air chamber, the pressure at the suction hole endface in the seed filling area was not the highest, but the pressure variation in the seed cleaning and seed carrying areas was minimized, resulting in the most stable cotton seed adsorption. Since increasing pressure at the suction hole endface in the seed filling area can be achieved by adjusting the air outlet negative pressure, while reducing the pressure standard deviation at the suction hole endface in the seed cleaning and carrying areas was difficult to accomplish through changing external parameters, the optimal combination of air outlet angle and position was determined to be $\theta_{a_2}\theta_{b_2}\theta_{c_2}$, namely, the position angle of 135°, up and down inclination angle of 0°, front and rear inclination angle of 0°.

Effect of Negative Pressure Air Chamber Width and Thickness on the Suction Hole Endface Pressure

The results of the two-factor test on the negative pressure air chamber width and thickness are shown in Table 7. As observed, with the increase of thickness, the pressure average at the suction hole endface in the seed filling area gradually increased, while the pressure standard deviation at the suction hole endface in the seed cleaning and carrying areas gradually decreased. This was primarily because an increase in thickness enlarged the airflow circulation area within the air chamber. According to fundamental fluid dynamics theory, a smaller airflow circulation area results in greater resistance losses. Therefore, increasing the thickness of the negative pressure air chamber was conducive to reducing airflow losses and promoting the uniform distribution of suction hole endface pressure. As the width increased, the trend of the average pressure at the suction hole endface in the seed-filling area was not obvious, with only small differences observed, while the pressure standard deviation at the suction hole endface in the seed-cleaning and seed-carrying areas gradually decreased. The main reason is that the suction holes are located along the width of the air chamber, and their diameter is much smaller than the chamber width. Thus, airflow in this direction remained smooth. Consequently, width changes had little effect on the average pressure at the suction hole endface in the seed-filling area, whereas the increased circulation area promoted a more uniform pressure distribution. The results of variance analysis are shown in Table 8.

As can be seen from the table, thickness had a greater influence than width on both the pressure average at the suction hole endface in the seed filling area and the standard deviation in the seed cleaning and carrying areas, which was consistent with the above analysis. In order to obtain a higher pressure average at the suction hole endface in the seed filling area and a lower pressure standard deviation at the suction hole endface in the seed cleaning and carrying areas, the width and thickness of the negative pressure air chamber were selected as 30 mm and 20 mm, respectively.

DEM-CFD coupling simulation results for the seed throwing link

The single cotton seed throwing process is shown in Fig. 9. As illustrated in the figure, when the positive pressure of the seed throwing air nozzle was 1500 Pa, the cotton seed at the suction hole endface was blown into the collection hole under the drag force of the seed throwing air nozzle. At 1.581 s, the seed makes its first contact and collision with the inner wall of the back shell, and was subsequently bounced upward, followed by a second and third collision with the inner wall at 1.695 s and 1.752 s, respectively. After that, the seed no longer exhibited obvious bouncing behavior but instead moved along the inner wall until it was discharged at the seed-throwing port. This simulation phenomenon indicated that, after entering the collection hole, the cotton seed underwent multiple contacts and collisions with the inner wall of the back shell. Therefore, the starting position angle of the seed-throwing port should be set slightly backward to avoid degraded seeding performance caused by seed bouncing.

Note: 1. Simulation settings: Freestream model, Outlet −3000 Pa, Inlet_1 0 Pa, Inlet_2 0 Pa, Inlet_3 1500 Pa, dynamic zone rotation speed 35.71 r/min, solid time step 3×10^{-7} s, fluid time step 3×10^{-5} s, 100000 steps; 2. Test repeats for 10 times.

The DEM–CFD coupling simulation results for the seed-throwing process are presented in Table 9. As shown, when the seed-throwing pressure was 500 Pa, the outlet velocity of the seed-throwing air nozzle was 19.54 m/s, which was insufficient to blow the cotton seed into the collection hole. When the pressure was ≥1000 Pa, seeds were blown smoothly into the collection hole, and with increasing pressure, the nozzle outlet airflow rate also increased, accelerating seed entry. Consequently, the initial contact angle increased gradually, while the stable contact angles were consistently ≥37.23°, although no clear variation pattern was observed. Simulation and post-processing analyses further revealed no obvious regularity in the bouncing behavior of seeds within the collection hole. Based on this analysis, the seed-throwing pressure should be no less than 1000 Pa to ensure smooth seed delivery. However, considering the gap between the seeding plate and the back shell during actual operation, residual adsorption forces may still act on the seeds at the suction-hole end face after leaving the negative-pressure air chamber. Therefore, the seed-throwing pressure should be appropriately increased, and in this study, a value of 1500 Pa was selected. In addition, to minimize the bouncing of seeds in the collection hole and avoid adverse effects on seeding performance, the starting position angle of the seed-throwing port should be smaller than the minimum stable contact angle of the seeds (37.23°). Accordingly, an angle of 30° was adopted.

Table 9

Simulation test results of seed throwing link

Seed throwing pressure/(Pa)	Outlet velocity of seed throwing air nozzle/(m/s)	Initial contact angle / (°)	Initial contact angle minimum / (°)	Stable contact angle /(°)	Stable contact angle minimum / (°)

16	1	0	1	88.93	8.52	2.55
17	1	1	0	88.17	6.18	5.65

Note: 1. Air outlet hole position angle 135°, up and down inclination angle 0° and front and rear inclination angle 0°; air chamber thickness 20 mm and width 30 mm; seed throwing pressure 1500 Pa, seed throwing port starting position angle 30°; 2. Test repeats for 3 times.

In order to further analyze the significance of the effect of each test factor and its interaction on the evaluation indexes, Design-Expert 10.0.4 was used to carry out a multiple regression analysis on the test results and establish a quadratic regression model between the test factors and evaluation indexes. The significance analysis results are shown in Table 11. As can be seen from the table, the regression models were all highly significant (P≤0.01) and the lack of fit were all insignificant (P>0.05), so the regression equations were well fitted to the test data. For the qualification index, the linear terms X_2, X_3 and quadratic term X_2^2, X_3^2 had a highly significant effect on it (P≤0.01), interaction term X_1X_3, X_2X_3 and quadratic term X_1^2 had a significant effect on it (0.01<P≤0.05), and the remaining terms had no significant effect on it (P>0.05). For the multiple sowing index, the linear terms X_1, X_3 and quadratic term X_2^2, X_3^2 had a highly significant effect on it (P≤0.01), interaction term X_1X_3 and quadratic term X_1^2 had a significant effect on it (0.01<P≤0.05), and the remaining terms had no significant effect on it (P>0.05). For the missed sowing index, all the linear terms and quadratic term X_2^2, X_3^2 had a highly significant effect on it (P≤0.01) and the remaining terms had no significant effect on it (P>0.05). Moreover, the order of test factors affecting the qualification index was: negative pressure>forward speed>suction hole diameter. And the order of test factors affecting the multiple sowing index and missed sowing index was: negative pressure>suction hole diameter>forward speed. The quadratic regression equations between the test factors and evaluation indexes are as follows:

$$A_1 = 96.16 + 0.44X_1 - 2.10X_2 + 3.08X_3 - 0.34X_1X_2 - 1.99X_1X_3 + 1.83X_2X_3 - 2.26X_1^2 - 4.35X_2^2 - 6.75X_3^2 \quad (3)$$

$$D_1 = 1.77 + 1.53X_1 + 0.35X_2 + 1.6X_3 + 0.04X_1X_2 + 1.01X_1X_3 - 0.4X_2X_3 + 0.91X_1^2 + 2.03X_2^2 + 1.09X_3^2 \quad (4)$$

$$M_1 = 2.07 - 1.97X_1 + 1.76X_2 - 4.68X_3 + 0.3X_1X_2 + 0.98X_1X_3 - 1.42X_2X_3 + 1.35X_1^2 + 2.33X_2^2 + 5.66X_3^2 \quad (5)$$

where:

X_1, X_2 and X_3 represent the coded levels (−1, 0, +1), and the coding of actual factor levels is shown in Table 3.

*Note: 1. Air outlet hole position angle 135°, up and down inclination angle 0° and front and rear inclination angle 0°; air chamber thickness 20 mm and width 30 mm; seed throwing pressure 1500 Pa, seed throwing port starting position angle 30°; 2. Test repeats for 3 times; 3. P ≤ 0.01 (Highly significant, **); 0.01 < P ≤ 0.05 (Significant, *).*

So as to obtain the best combination of test factors, taking the maximum qualification index and the minimum multiple and missed sowing index as the final optimization objective, combined with the boundary conditions of each test factor, the established quadratic regression models were solved by multi-factor optimization.

The objective functions and constraints are as follows:

$$\begin{cases} \max A_1(x_1, x_2, x_3) \\ \min D_1(x_1, x_2, x_3) \\ \min M_1(x_1, x_2, x_3) \\ s.t. \begin{cases} 2.7\ mm \le x_1 \le 3.5\ mm \\ 1.67\ m/s \le x_2 \le 3.33\ m/s \\ 2000\ Pa \le x_3 \le 4000\ Pa \end{cases} \end{cases} \quad (6)$$

Using the optimization module of Design-Expert 10.0.4, the best combination of parameters was determined to be: suction hole diameter of 3.1 mm, forward speed of 2.33 m/s (8.4 km/h), and negative pressure of 3178 Pa. Under these conditions, the seeding performance was optimal, with a qualification index of 96.67%, multiple sowing index of 2.04%, and missed sowing index of 1.29%. To verify the reliability of the optimized parameters, the seeding performance test of seed-metering device was conducted for three repetitions. The average values of the evaluation indexes were as follows: qualification index of 96.25%, multiple sowing index of 1.83%, and missed sowing index of 1.92%, which were generally consistent with the predicted values from the software.

High-speed Adaptability Test

The high-speed adaptability test results of the inside-filling pneumatic cotton high-speed precision seed-metering device are shown in Table 12. As shown in the table, with increasing forward speed, the qualification index first increased and then decreased, the multiple sowing index first decreased and then increased, while the missed sowing index gradually increased, which was consistent with the previous analysis. When the forward speed ranged from 1.67 to 3.33 m/s (6–12 km/h), the qualification index exceeded 91%, and both the multiple sowing index and the missed sowing index remained below 5%. These values were superior to the agronomic requirements specified in JB/T 10293-2013 'Specifications for Single Seed Drills (Precision Drills),' which require a qualification index ≥75%, a multiple sowing index ≤20%, and a missed sowing index ≤10%. This indicates that the optimized seed-metering device meets the high-speed sowing requirements for cotton.

Table 12

High-speed adaptability test results

Forward speed/(m/s)	Qualification index/(%)	Multiple sowing index/(%)	Missed sowing index/(%)
1.67	94.34	3.98	1.68
2.22	95.66	2.61	1.73
2.33	96.25	1.83	1.92
2.78	94.81	2.75	2.44
3.33	91.43	4.55	4.02

Note: 1. Air outlet hole position angle 135°, up and down inclination angle 0° and front and rear inclination angle 0°; air chamber thickness 20 mm and width 30 mm; seed throwing pressure 1500 Pa, seed throwing port starting position angle 30°; 2. Test repeats for 3 times.

CONCLUSIONS

(1) The CFD simulation results of the negative-pressure air chamber showed that, in the orthogonal test of air outlet hole angle and position, the order of influence on the average pressure at the suction hole end face in the seed-filling area was: front–rear inclination angle > vertical inclination angle > position angle. For the pressure standard deviation in the seed-cleaning and seed-carrying areas, the order was: position angle > front–rear inclination angle > vertical inclination angle. The optimal parameter combination was a position angle of 135°, a vertical inclination angle of 0°, and a front–rear inclination angle of 0°. In the two-factor test of chamber thickness and width, thickness had a greater effect than width on both the average pressure in the seed-filling area and the standard deviation in the seed-cleaning and seed-carrying areas, with the optimal combination being a thickness of 20 mm and a width of 30 mm.

(2) The DEM–CFD simulation results of the seed-throwing process showed that, after falling into the collection hole, cotton seeds underwent multiple collisions with the inner wall of the back shell before moving along it. At a seed-throwing pressure of 1500 Pa, the seeds could be smoothly blown into the collection hole. Setting the starting position angle of the seed-throwing port to 30° reduced the adverse effects of seed bouncing within the collection hole on the seed-throwing performance.

(3) The results of the Box–Behnken test indicated that the factors influencing the qualification index ranked in the following order: negative pressure > forward speed > suction hole diameter. For the multiple sowing index and missed sowing index, the order was: negative pressure > suction hole diameter > forward speed. The optimal parameter combination was a suction hole diameter of 3.1 mm, a forward speed of 2.33 m/s (8.4 km/h), and a negative pressure of 3178 Pa. Bench tests verified the corresponding evaluation indexes, yielding a qualification index of 96.25%, a multiple sowing index of 1.83%, and a missed sowing index of 1.92%.

(4) The results of the high-speed adaptability test showed that, as forward speed increased, the qualification index first increased and then decreased, the multiple sowing index first decreased and then increased, and the missed sowing index gradually increased. When the forward speed was 1.67–3.33 m/s (6–12 km/h), the qualification index remained above 91%, while both the multiple and missed sowing indices were below 5%, thereby meeting the agronomic requirements for high-speed precision cotton seeding.

ABSTRACT
To address the autonomous navigation and operation requirements of agricultural robots in complex terrain environments of vineyards, this report proposes a point cloud Ground segmentation algorithm based on surface fitting, aiming to solve the problems of reduced segmentation accuracy and insufficient adaptability of traditional planar assumption methods in unstructured terrains such as sloped fields and ridge furrows. The core of the algorithm lies in adopting a point cloud representation method based on a non-uniform polar grid, which dynamically allocates face element sizes according to point cloud density and the width between vineyard ridges, effectively addressing the issues of point cloud sparsity and representability. Subsequently, the moving least square method is used to fit surface models. During the fitting process, strategies such as Gaussian weight function, cosine and sine basis functions, and set of orthogonal functions are introduced to shorten the algorithm's running time and reduce computational complexity. The algorithm's performance is evaluated on the public dataset KITTI and in real-world environments, and compared with algorithms such as RANSAC, GPF, R-GPF, and Patchwork. Experimental results show that the proposed algorithm outperforms other algorithms in both Precision and Recall. In practical environments, the algorithm can accurately and effectively segment complex vineyard environments, meeting the operational requirements of agricultural robots and providing technical support for the advancement of smart agriculture.

摘要
针对葡萄园复杂地形环境下农业机器人自主导航与作业的需求，本文提出了一种基于曲面拟合的点云地面分割算法，旨在解决传统平面假设方法在坡地、垄沟等非结构化地形中存在的分割精度下降与适应性不足的问题。算法的核心在于采用一种基于非均匀极坐标网格的点云表示方法，该方法根据点云密度以及葡萄园垄间宽度动态分配面元大小，有效解决了点云稀疏性和可表示性问题；随后用移动最小二乘法拟合曲面模型，在拟合过程引入高斯型权函数、正余弦基函数，正交函数集的策略，缩短算法运行时间，降低计算复杂度。在公开数据集 KITTI、葡萄园环境中评估算法性能，并于 RANSAC、GPF、R-GPF、Patchwork 等算法进行对比。实验结果表明，本文算法在 Precision 和 Recall 均优于其他算法；葡萄园环境中，该算法能准确、有效的分割葡萄园复杂环境，满足农业机器人的作业需求，为推进智慧农业提供了技术支撑。

INTRODUCTION
Agriculture, as the foundational industry underpinning socio-economic development, holds paramount significance in China—a nation with a millennia-old agrarian civilization. The development of agriculture not only determines national food security and social stability, but also serves as a pivotal driver for economic growth and rural revitalization.

In recent years, autonomous driving technology has been developing rapidly, and its research and application have become a core topic in the field of intelligent transportation systems *(Avcı et al., 2024)*. Driven by multiple factors such as algorithm optimization, hardware upgrading, and data-driven, self-driving vehicles have made significant progress in the key technical aspects of perception *(Cong et al., 2024)*, decision-making *(Wang et al., 2024)* and control *(Vidano et al., 2024)*. As the first step of an autonomous driving system, the accuracy of environment sensing is directly related to the performance and safety of the whole system. Among many sensors, LiDAR has become a key component for autonomous driving environment sensing with its advantages of high accuracy *(Wu et al., 2024)* and long-range measurement *(Bayer et al., 2021)*. Light Detection and Ranging (LiDAR for short) is an active remote sensing technology that utilizes laser pulses to measure distances in order to obtain three-dimensional positional information about the target object and

generate high-precision three-dimensional point cloud data. On this basis, the ground segmentation algorithm employs multi-dimensional feature analysis and deep learning framework to achieve accurate recognition of ground and non-ground points in complex terrain.

In a vineyard environment, the ground can have slopes or weeds, etc., that are more rugged than urban transportation surfaces. Weeds, fallen leaves, and highly reflective objects (metal supports, plastic film) can cause noise in LIDAR scans, and fragmented vegetation makes the ground segmentation unclear, as well as surrounding objects, blocking the fit, conventional ground segmentation algorithms selectively exclude it, and this algorithm is optimized for these characteristics. The main contributions are as follows:

1) Dynamic area optimization, improving the traditional fixed-area selection mode and adjusting the scanning focus according to the vineyard environment: the nearest area and the farthest area, it improves the plant recognition accuracy by 7.3%, reduces the leakage rate to 2%, and can detect obstacles as early as possible to provide safe time for the subsequent path planning.

2) Dual noise reduction technology, incorporating multipath reflection suppression and sensor dynamic compensation, the noise false detection rate is reduced by 78.8% and the terrain detection error is optimized by 61.7% under dense foliage and high temperature environments.

3) Design of fast surface fitting algorithms based on orthogonal basis functions: by replacing the traditional planar model with Legendre orthogonal polynomials and combining circular radial weight functions with matrix-free inverse least squares solving, the computational complexity is reduced from $O(n^3)$ to $O(n^2)$, which ensures the accuracy of complex terrain fitting while shortening the computation time of a single frame to 35ms to meet the real-time demand of 10 Hz for agricultural robots.

MATERIALS AND METHODS

Most of the traditional algorithms are adapted to urban traffic surfaces, and the orchard environment is relatively more complex. The ground segmentation algorithm proposed in this paper is based on concentric zone model (CZM), and several key modules are set up to realize the extraction of ground information from radar point cloud. CZM utilizes a uniform polar grid representation to divide the point cloud into multiple fan-ring regions with regularity and orientation, and the density of each region can be set by adjusting the parameters. Key modules include Reflected Noise Removal (S-RNR), Vertical Interference Removal (S-VIE), Sub-Regional Partitioning (SRP), Surface Model Fitting (S-SSF), Adaptive Thresholding (ATS), and Temporal Ground Recovery (TGR).

The overall framework is shown in Figure 1, and the following paragraphs highlight the definitions and rationale for the core modules.

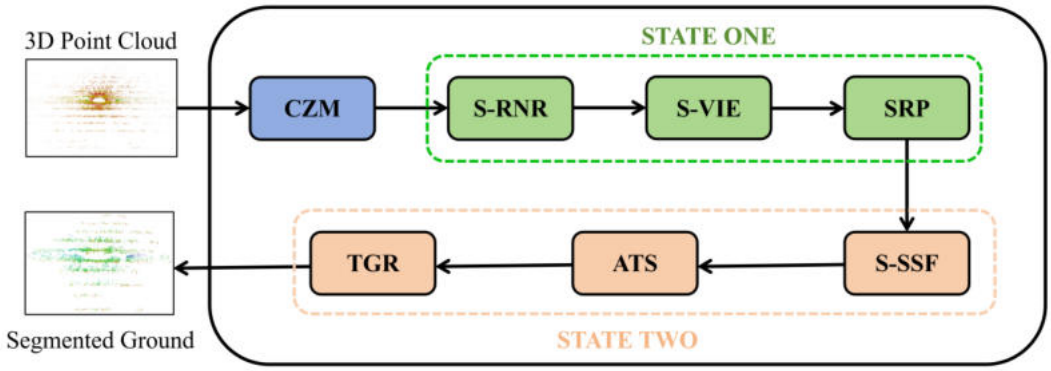

Fig. 1 - Module Flowchart

Concentric Zone Model (CZM)

When dealing with point cloud data of complex terrain, especially vineyard pavements, most of the traditional algorithms designed for flat urban pavements rely on fixed strategies such as adaptive binning and quadratic distributions and assume locally flat ground to simplify the computation. However, the ground is usually not flat and the density of the point cloud data varies with distance, which leads to under- or over-segmentation problems when conventional methods are ineffective in dealing with sparse and under-represented point clouds.

In response to these problems, a uniform polar grid model is proposed, which divides the point cloud collection into multiple sector-ring regions by radial distance and azimuth. However, there are two main problems with this method: the fan ring area near the center is small and has a sparse number of points, while the area away from the center is similarly underpopulated due to a sparse point cloud, both of which affect the accuracy of the ground plane fitting.

To overcome these limitations, the CZM was used. The model parametrically adjusts the density of the sector ring region in each ring band, taking into account the problem of LIDAR being dense in the near and sparse in the far, ensuring that the ring bands have a reasonable number of sector rings regardless of the distance from the center. The model is defined as follows:

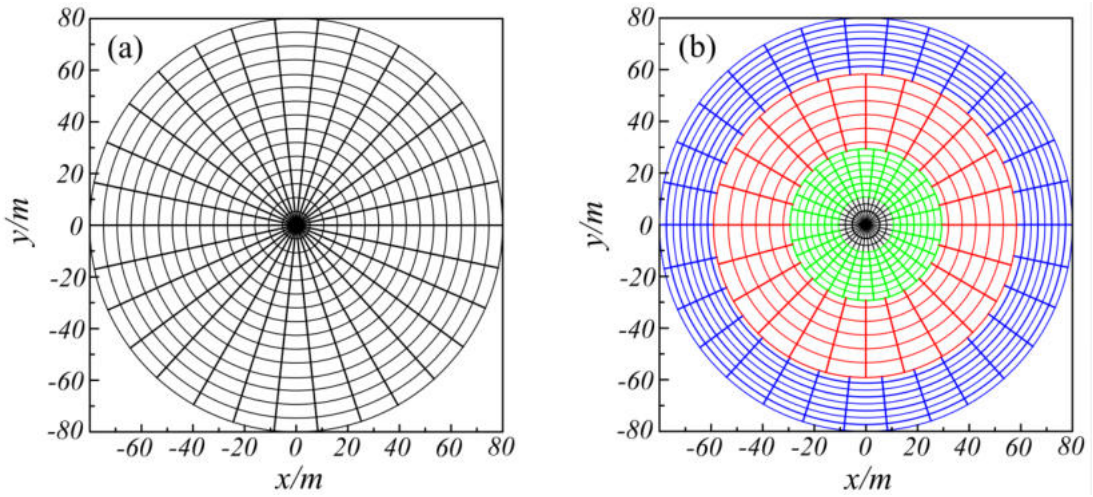

Fig. 2 - (a)Tradition modeling method; (b)concentric zone model

Compared with the traditional model definition Fig. 2(a), Fig. 2(b) is more applicable to the orchard environment by detailing the distant sparse point cloud and the point cloud in the vicinity of the LiDAR, the former confirms that obstacles can be detected in advance for subsequent path planning, while the latter detects obstacles at close range.

Reflected Noise Removal (S-RNR)

The presence of highly reflective objects (metal brackets, plastic films), radius effects (e.g., multiple reflections from plant leaves), and sensor noise in the vineyard point cloud collection can generate noise, these noise points can significantly affect the reliability of the fitted ground plane. Noise points also occur below the ground plane, as shown in Figure 3.

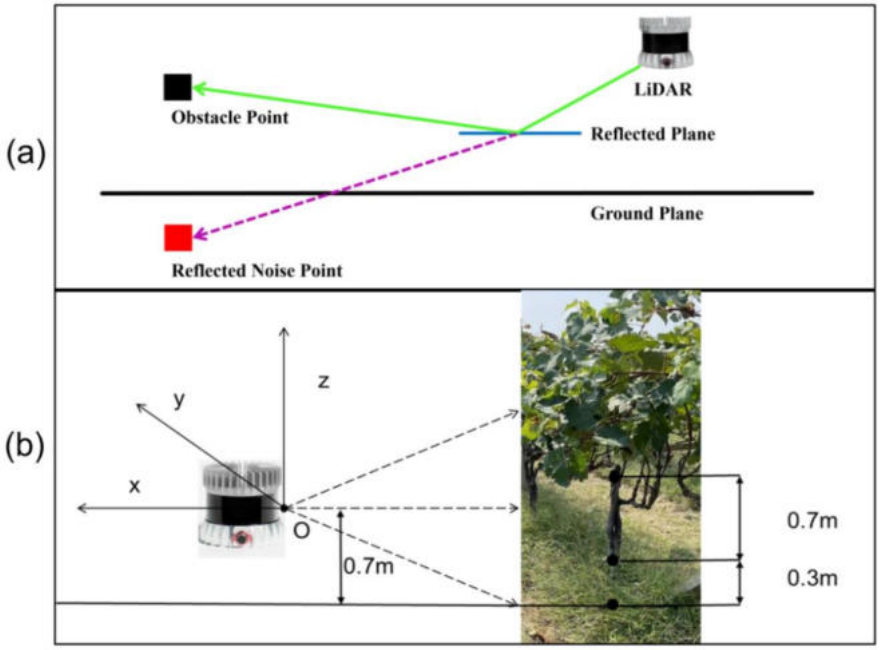

Fig. 3 - (a)Point Cloud Reflection Noise Schematic Diagram; (b)LiDAR Position Schematic Diagram

As shown in the figure, the height of the LIDAR mounted on the wheeled robot is 0.7 m. Let the height threshold be h, with the point O as the origin and the positive direction of the z-axis. Let the height of the point x in the vineyard LiDAR point cloud be z_x, then the equation of the non-ground point will be:

$$z_x > h \tag{1}$$

According to the actual measurement, the weed height of standardized planting vineyard is about 0.3 m, then the threshold is -0.4, then the vineyard LiDAR point cloud can be left when the height is greater than -0.4, otherwise it is separated as a ground point.

In order to solve the noise point problem, the algorithm employs the Regional Reflected Noise Removal (R-RNR) module and introduces the introduction of multipath effect suppression and sensor noise compensation. R-RNR performs reflection noise removal for each sector-ring region separately, searching for all points in the point cloud below a specified height one by one, and identifying points with reflection intensity below a threshold as reflection noise points. Multipath effect suppression establishes a three-frame sliding window that rejects transient points (e.g., vignette points from blade jitter) that persist for <0.3 seconds:

$$\mathrm{P_{valid}} = \{\mathrm{p_i} \mid \sum_{\mathrm{t=1}}^{3} \mathrm{I}\,(\mathrm{p_i} \in \mathrm{F_t}) \geq 2\} \tag{2}$$

Where $\mathrm{F_t}$ denotes the t-th frame point cloud, the suspected multipath point is detected by reverse ray detection, and if there is an occluder (e.g., a leaf point cloud) on the path from the sensor to the point, it is determined as a fictitious point and rejected. Sensor noise compensation, on the other hand, is applied by applying a nonlinear compensation model through a temperature sensor that collects the ambient temperature T in real time:

$$\mathrm{I_{corrected}} = \mathrm{I_{raw}} - \mathrm{k_1 e^{k_2 T}} \tag{3}$$

where $\mathrm{k_1}$=0.03 and $\mathrm{k_2}$=0.12 are the calibration parameters. And the point cloud motion compensation model was constructed by combining the IMU data, and the extended Kalman filter (EKF) was used to estimate the real spatial coordinates of each point:

$$\hat{\mathrm{x}}_\mathrm{t} = \mathrm{x_{meas}} - \int_{\mathrm{t-\Delta t}}^{\mathrm{t}} \mathrm{v}(\tau)\mathrm{d}\tau \tag{4}$$

where $\mathrm{v}(\tau)$ is the instantaneous speed of the agricultural vehicle.

Surface model fitting (S-SSF)

Moving least squares provides an effective polynomial approximation strategy for high-precision surface fitting of scattered point clouds, centered on minimizing the sum of squared node errors. When applied to LiDAR point cloud data, it generates smooth and close fitting surfaces. However, facing the huge amount of point cloud data, the traditional methods have high computational complexity. For this reason, the fast moving least squares method is used to simplify the coefficient matrix solution using weighted orthogonal functions (considering only diagonal elements and avoiding inverse), which significantly improves the computational efficiency and meets the real-time demand of automatic driving while ensuring the accuracy.

The fitting function is expressed as:

$$\boldsymbol{f}(\mathbf{x},\mathbf{y}) = \sum_{\mathbf{i=1}}^{\mathbf{m}} \boldsymbol{\alpha_i}\,(\mathbf{x},\mathbf{y})\mathbf{p_i}(\mathbf{x},\mathbf{y}) = \mathbf{p^T}(\mathbf{x},\mathbf{y})\boldsymbol{\alpha}(\mathbf{x},\mathbf{y}) \tag{5}$$

It can be simplified as follows:

$$f(\mathrm{t}) = \sum_{\mathrm{i=1}}^{\mathrm{m}} \alpha_\mathrm{i}\,(\mathrm{t})\mathrm{p_i}(\mathrm{t}) = \mathrm{p^T}(\mathrm{t})\alpha(\mathrm{t}) \tag{6}$$

where $\mathrm{t}=(\mathrm{x},\mathrm{y})$ and the coordinates t as a function of:

$$\alpha(t) = [\alpha_1(\mathrm{t}), \alpha_2(\mathrm{t}), \ldots\ldots, \alpha_\mathrm{m}(\mathrm{t})]^T \tag{7}$$

The basis function is a complete polynomial of order k and m is the number of terms in the product function:

$$\mathrm{p}(\mathrm{t}) = [\mathrm{p_1}(\mathrm{t}), \mathrm{p_2}(\mathrm{t}), \ldots\ldots, \mathrm{p_m}(\mathrm{t})]^\mathrm{T} \tag{8}$$

For surface fitting, a two-dimensional basis function is required, and the basis function $\mathrm{p}(\mathrm{t})$ takes the form:

Linear base: $\mathrm{p}(\mathrm{t}) = [1, \mathrm{x}, \mathrm{y}]^\mathrm{T}$

Secondary base: $p(t) = [1, x, y, x^2, xy, y^2]^T$

In the moving least squares approximation, the coefficient is determined by minimizing the weighted sum of squares of the errors of the nodes of the approximation function in a neighborhood of point x:

$$J = \sum_{I=1}^{n} w(x)[f(t) - Z_I]^2 = \sum_{I=1}^{n} w(x)[\sum_{i=1}^{m} p(t_I)\alpha(t_I) - Z_I]^2 \quad (9)$$

where n is the number of nodes affected in the neighborhood of x, Z_I is the value of the node at $t = t_I$, and $x = t - t_I$ is the difference between the two points, $t\text{-}t_I = \sqrt{(x - x_I)^2 + (y - y_I)^2}$, $w(x) = w(t\text{-}t_I)$ is the weight function of node t_I.

When the above equation equals zero, J reaches a minimum value and hence the following can be obtained:

$$\sum_{I=1}^{n} w(x)[\sum_{i=1}^{m} p(t_I)\alpha(t_I) - Z_I]^2 = 0 \quad (10)$$

$$\sum_{I=1}^{n} w(x) \sum_{i=1}^{m} p(t_I)\alpha(t_I) = \sum_{I=1}^{n} w(x) * Z_I \quad (11)$$

$h(x)$ and $g(x)$ are introduced to simplify the expression:

$$(h, g) = \sum_{i=1}^{n} w(x - x_i)h(x_i)g(x_i) \quad (12)$$

$$\alpha_1(t)(p_i, p_1) + \alpha_2(t)(p_i, p_2) + \cdots .. + \alpha_n(t)(p_i, p_n) = (p_i, Z), i = 1,2 \ldots, m \quad (13)$$

Organized into a system of linear equations, also known as normal equations:

$$\begin{bmatrix} (p_1, p_1) & (p_1, p_2) & \cdots & (p_1, p_m) \\ (p_2, p_1) & (p_2, p_2) & \cdots & (p_2, p_m) \\ \cdots & \cdots & \cdots & \cdots \\ (p_m, p_1) & (p_m, p_2) & \cdots & (p_m, p_m) \end{bmatrix} \begin{bmatrix} \alpha_1(t) \\ \alpha_2(t) \\ \cdots \\ \alpha_m(t) \end{bmatrix} = \begin{bmatrix} (p_1, Z) \\ (p_2, Z) \\ \cdots \\ (p_m, Z) \end{bmatrix} \quad (14)$$

Solving the above system of linear equations yields the reformation coefficient a(t) at node t. If the basis function $p_i(t)(i = 1,2,3, \ldots, m)$ is taken to be the set of orthogonal functions of the point set $\{x\}$ and the weight $\{w_i(i = 1,2,3, \ldots, m)\}$, we obtain:

$$(p_k, p_j) = \sum_{i=1}^{n} w_i\, p_k(t_i)\, (t_i) = \begin{cases} 0 & , (k = j) \\ A_k & , (k \neq j) \end{cases} (k, j = 1,2 \ldots m) \quad (15)$$

Then the matrix can be obtained:

$$\begin{bmatrix} (p_1, p_1) & 0 & \cdots & 0 \\ 0 & (p_2, p_2) & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & \cdots & (p_m, p_m) \end{bmatrix} \begin{bmatrix} \alpha_1(t) \\ \alpha_2(t) \\ \cdots \\ \alpha_m(t) \end{bmatrix} = \begin{bmatrix} (p_1, Z) \\ (p_2, Z) \\ \cdots \\ (p_m, Z) \end{bmatrix} \quad (16)$$

Then one can solve for $\alpha_i(t)(i = 1,2,3 \ldots, m)$:

$$\alpha_i(t) = \frac{(p_i, Z)}{(p_i, p_i)} \quad (17)$$

Collation is available:

$$f(t) = \sum_{i=1}^{m} p_i(t) \cdot \frac{\sum_{I=1}^{n} w(t - t_I)\, p_i(t_I)}{(p_i, p_i)} = \sum_{I=1}^{n} O_I^k(t) Z \quad (18)$$

where the form function is:

$$O_I^k(t) = w(t - t_i) \sum_{i=1}^{m} \frac{p_i(t) p(t_I)}{(p_i, p_i)} \quad (19)$$

By integrating the set of orthogonal functions, matrix inversion can be avoided, thereby resolving the problem of matrix irreversibility, reducing the computational time of the least squares method, and lowering overall algorithmic complexity.

In the moving least squares method, the choice of the weight function is crucial, and in a complex orchard environment, the appropriate weight function greatly affects the smoothness of the fitted ground. The weight function $w(t\text{-}t_i)$ in the moving least squares method should be tightly supported, that is, the weight

function is not equal to zero in a subdomain of x, and is zero outside of this subdomain, which is called the support domain of the weight function (i.e., the region of influence of x).

Therefore, a circular support domain with radius r was selected for the weight function, where $d = t\text{-}t_i$, $\bar{r} = \frac{d}{r}$.

This choice ensures that the function values at each node are influenced only by data points within the circular support domain, while points outside this region have no impact. Due to the compact support of the weight function, only the data points within the region of influence affect the value at point x. The weight function $w(t\text{-}t_i)$ is required to be non-negative and monotonically decreasing as d^2 increases. In this study, a two-part Gaussian-type weight function is used in place of the traditional three-part moving least squares (MLS) weight function. This modification results in a smoother fit, reduces fitting time, and lowers algorithmic complexity.

The Gaussian-type weight function is shown in equation (20):

$$\bar{w}(\bar{r}) = \begin{cases} \frac{e^{-\beta^2\bar{r}^2} - e^{-\beta^2}}{1 - e^{-\beta^2}}, & \bar{r} \le 1 \\ 0, & \bar{r} > 1 \end{cases} \quad (20)$$

RESULTS

Data set

In this paper, tests are performed using datasets collected by two different devices.

1) KITTI point cloud public dataset, the data acquisition equipment for the U.S. Velodyne company HDL-64 type 3D mechanical rotation Lidar, with 64 lasers, acquisition frequency of 10 Hz, each frame produces about 130,000 scanning points, the effect of the dataset is shown in Figure.

2) The vineyard dataset was collected using the OSI-64 LiDAR, which has a measurement range of 120 meters, a vertical viewing angle of 45°, a horizontal viewing angle of 360°, a rotation angle of 360°, a vertical angular resolution of 0.52°, a horizontal resolution of 1024, and 131072 sampling points per second, with data effects as shown in Fig.4.

Algorithm testing

1) Hardware platform

In this study, the KOMODO-03 general-purpose tracked robot mobile chassis developed by Extreme Robotics Technology Co. The chassis is fully electrically powered with a 48V 50Ah Li-ion battery power system with a maximum operating voltage of 54.6 V and a discharge cut-off voltage set at 43 V. The power section consists of two DC brushless motors and two 15:1 gearboxes. The computer is equipped with an AMD R7-4800H processor, 16 GB RAM and a single NVIDIA GeForce GTX1650ti GPU.

The mobile chassis structure is shown in Figure 5.

1. External Monitor; 2. Jetson AGX Xavier; 3. Crawler-Type Mobile Chassis; 4. Dual-Antenna GNSS-RTK; 5. 64-Line 3D LiDAR.

2) Measurement indicators

For the evaluation of segmentation accuracy, it is mainly evaluated from Precision, Recall and F1 Score, and the calculation method of each evaluation index is shown below:

$$\mathrm{Precision} = \frac{N_{TP}}{N_{TP} + N_{FP}} \tag{21}$$

$$\mathrm{Recall} = \frac{N_{TP}}{N_{TP} + N_{FN}} \tag{22}$$

$$F1 = 2 * \frac{\mathrm{Precision} * \mathrm{Recall}}{\mathrm{Precision} + \mathrm{Recall}} \tag{23}$$

where: N_{TP} is the number of ground points correctly labelled; N_{FN} is the number of ground points incorrectly labelled as non-ground points; N_{FP} is the number of non-ground points incorrectly labelled as ground points; and N_{TN} is the number of non-ground points correctly labelled.

KITTI dataset testing

The Semantic KITTI dataset is a large-scale dataset designed for autonomous driving scenarios, and in order to validate the accuracy of the algorithms in this paper for ground point cloud segmentation, this dataset was used to evaluate the performance of the proposed algorithms versus existing algorithms for ground segmentation.

In this experiment, the first 100 frames were selected (i.e., numbered 01 to 100) from the KITTI dataset as the test object, and each frame contains about 130,000 cloud data points. In order to make a clear comparison of the point cloud data, the non-ground point cloud was labelled as red and the ground point cloud as green, and the effect of the delineation of the road information was visualized by rviz.

The effect diagram of road information division is shown in Fig. 6, and the algorithm of this paper is compared with four ground segmentation algorithms of RANSAC *(Martin et al., 1981)*, GPF *(Dimitris et al., 2017)*, R-GPF *(Hyungtae et al., 2021)* and Patchwork *(Hyungtae et al., 2021)*. The comparison test is shown in Fig. 7, and the segmentation accuracy is shown in Table 1.

Table 1

Ground segmentation accuracy

Algorithm	Precision	Recall	F1 Score
RANSAC	0.8452	0.8389	0.8417
GPF	0.9256	0.7962	0.8551
R-GPF	0.7678	0.8862	0.8228
Patchwork	0.9279	0.9245	0.9267
Ours	0.9469	0.9458	0.9479

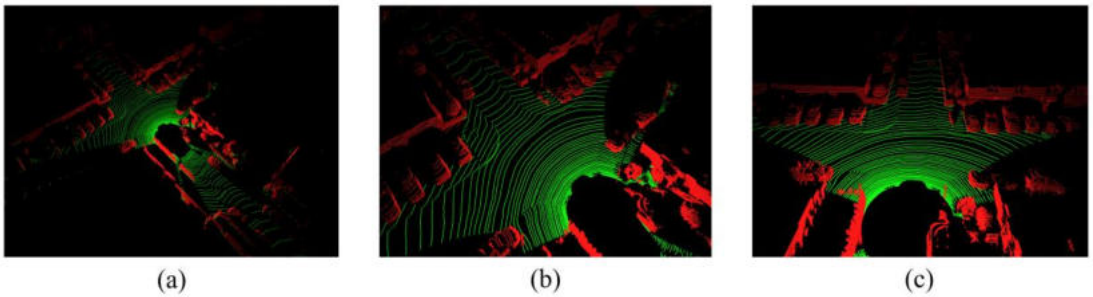

Fig. 6 - (a)Urban environment scene; (b), (c) Local vehicle scene

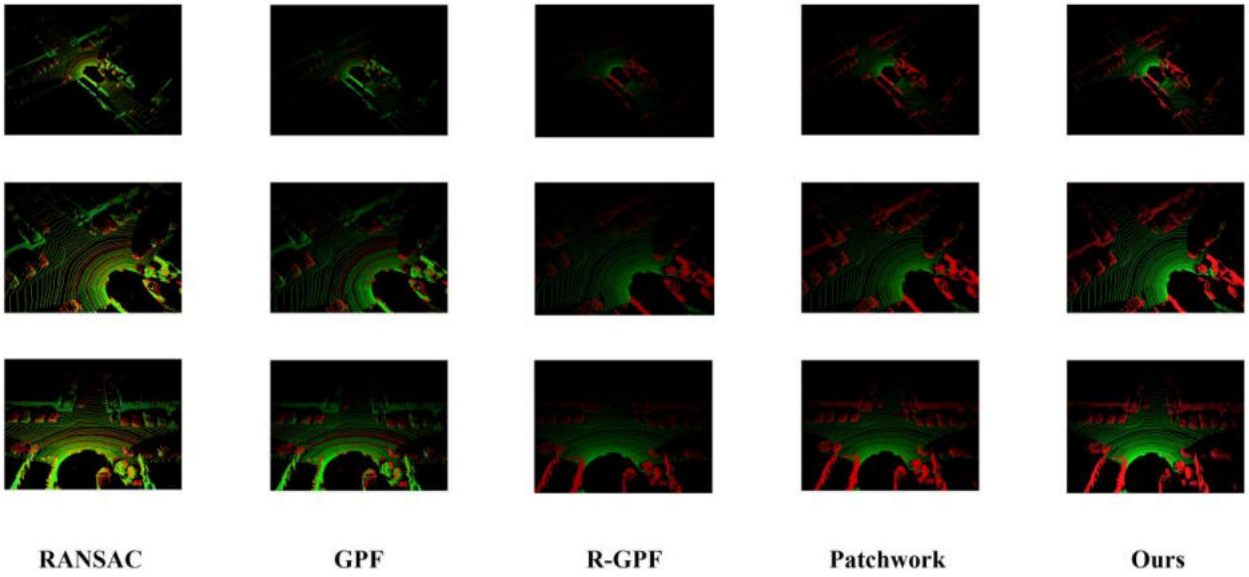

Fig. 7 - KITTI data set comparison test

In Fig. 7, the green point cloud represents the ground point cloud and the red point cloud represents the non-ground point cloud, and it can be seen by the global segmentation information as well as the local segmentation details that the algorithm in this paper is better than the other four algorithms. The ground segmentation accuracy in Table 1 shows that the algorithm in this paper is better than the above four algorithms in terms of segmentation accuracy, precision, recall, and accuracy in road tests in urban environments.

Vineyard Data Testing

The initial design of the algorithm in this paper is applied to the vineyard, using the OSI-64 LiDAR in the actual vineyard scene to collect data, and the original data and the algorithm of this paper to segment the environment comparison, the comparison effect graph is shown in Figure 8.

Figure 8 shows the real environment algorithm test, the test scene is a vineyard road, and 8(a)(d) shows the actual scene, where there is a human-type obstacle in (a), which is used to test the segmentation effect of the algorithm. Figure 8(b)(e) shows the unsegmented point cloud scene of the vineyard. Figure 8(c)(f) shows the scene after segmentation by the algorithm, and it can be seen from the segmentation effect that the algorithm in this paper can segment accurately.

Fig. 8 - Real environment algorithm testing

CONCLUSIONS

Aiming at the problem of insufficient performance of traditional methods for point cloud segmentation in complex scenes in vineyards, this paper proposes a surface-fitting ground segmentation method. By using orthogonal function basis to improve the moving least squares method, the computational complexity is reduced so as to improve the speed of surface fitting, Gaussian-type weight function is introduced to solve the problem of non-smoothness of the fitted surface, and the sine-cosine basis function is introduced, which is more able to restore the original shape of the vineyard ground. By improving the search area range of the radar so that the point cloud focuses on the farthest and nearest regions, obstacles can be detected as early as possible, providing sufficient time for path planning. Dual noise reduction technology is used to integrate multipath reflection suppression and sensor dynamic compensation to reduce the false detection rate of noise and enhance the robustness of ground segmentation in vineyard scenes.

The superiority of this approach is validated through experiments on the KITTI dataset and real vehicles. The results show that the method achieves accurate segmentation of ground point cloud, which is better than RANSAC, GPF, R-GPF and Patchwork algorithms. The segmentation precision can reach 0.9469 and the recall can reach 0.9458.

In future work, multimodal data fusion of LiDAR with visual and inertial measurement unit (IMU) data will be explored to enhance the robustness of the algorithm in complex environments such as rain, fog, and nighttime conditions. Additionally, the algorithm will be extended to other agricultural scenarios, including terraces and orchards, to evaluate its generalization performance.

Keywords: *stem detection, improved yolov8, occlusion recognition, orchard*

ABSTRACT

Accurate detection of apple stems is crucial for robotic cutting. This study proposed an improved YOLOv8-stem method for apple stem detection in overhead imagery under occlusion conditions. First, several improvements were made to the YOLOv8 neural network: the conventional convolutional process within the intermediate neck layer was substituted with the AK Convolution mechanism, a small object detection head was added, and ResBlock+CBAM attention mechanism was incorporated. Second, stem occlusion was determined by analyzing the positional relationship between the detected bounding boxes of stems and apples. The experimental results showed that compared to the original YOLOv8, this method improved apple stem detection accuracy by 6.0% (from 79.9% to 85.9%) and increased harvesting completeness from 84.2% to 93.2%.

摘要

准确检测苹果茎对于机器人切割至关重要。本研究提出了一种改进的 YOLOv8 茎检测方法，用于遮挡条件下俯视图像中的苹果茎检测。首先，对 YOLOv8 神经网络进行了几项改进：用 AK 卷积机制取代了中间颈层内的传统卷积过程，增加了一个小目标检测头，并引入了 ResBlock+CBAM 注意力机制。其次，通过分析检测到的茎和苹果边界框之间的位置关系来确定茎的遮挡。实验结果表明，与原始 YOLOv8 相比，该方法将苹果茎检测准确率提高了 6.0%（从 79.9%提高到 85.9%），收获完整性从 84.2%提高到 93.2%。

INTRODUCTION

Apples are the third largest fruit in terms of area planted and production globally *(Vasylieva et al., 2021)*. Manual apple harvesting is a time-consuming and labor-intensive task, and improving the competitiveness of the apple market requires addressing this challenge. Leaving apple stem too long during harvesting can cause surface scratches on the apples during transportation and storage, which can affect their freshness and appearance. Fruits stored without their stems exhibited greater weight loss, higher decay rates, and increased vitamin C loss *(Ozturk et al., 2020)*. Small apple stems and complex growing environments, overlapping fruits, branch and leaf shading, and light variations pose challenges to accurate target identification *(Chen et al., 2019)*.

In recent years, a lot of related works had been done by scholars at home and abroad for small target recognition of fruit stems in complex orchard environments. The YOLO family of algorithms had become a leader in target detection due to its rapid development and excellent performance. However, YOLO algorithms were mainly designed to detect and recognize full-size objects, and their performance was not as good when facing special-size objects, especially small targets *(Liu et al., 2023; Liu et al., 2022)*. To address this issue, Wu et al. introduced the YOLO-Banana model for precise identification of bananas and to determine the fruit axis and cutting point. They enhanced the Bottleneck module of YOLOv5 and employed an edge-detection algorithm to segment the fruit axis's contour, allowing them to pinpoint the cut-off location *(Wu et al., 2022; Wu et al., 2021)*. In situations where the fruit stem was covered, *Yu et al.* enhanced Mask R-CNN to address the issues of limited robustness in traditional algorithms when operating in unstructured environments *(Yu et al., 2019)*.

To investigate the method for identifying picking points in cases of partial occlusion, *Xiong et al. (2018)* conducted a study on locating grapes in the presence of disturbances. Other researchers employed stereovision and image processing techniques to detect and determine the locations of grape clusters and picking points, subsequently performing size measurements and enclosure calculations for the grapes *(Luo et al., 2021; Lufeng et al., 2017)*. The analysis of these studies revealed that there were fewer network improvements for short targets such as apple fruit stems, and for the localization of picking points covering the stems, most of them directly segmented the image of the target to be picked, which could produce large errors in the localization of the picking points.

This study concentrated on the detection of apple stems and sought to enhance the conventional YOLOv8 algorithm *(Jocher et al., 2023)*. It presented an enhanced YOLOv8-based method designed specifically for detecting apple stems in overhead imagery. To achieve this, high-quality datasets of apple fruits and stems were collected from a top-down perspective to provide positive samples for network training. In the annotation of training targets, both apples occluded by tree branches and apple stems were annotated as separate categories. When utilizing YOLOv8 for the detection of apples occluded by branches, the presence of an apple stem within the annotated apple bounding box was verified. If a stem was present, it was recognized normally; if not, it was determined that the stem was occluded by branches, necessitating a modification of the camera's position and angle. The YOLOv8 architecture was enhanced by incorporating a detection head specifically designed for small objects, the conventional convolutional process within the intermediate neck layer was substituted with the AK Convolution *(Zhang et al., 2023)* mechanism introducing a 160×160 detection feature map. A ResBlock+CBAM attention mechanism *(Woo et al., 2018)* module was incorporated to enhance the model's feature extraction capabilities for small target objects, thereby adapting to the characteristics of the apple stem dataset. The mean average precision (mAP) value and the harvesting completeness were calculated to evaluate the effectiveness of the stem detection, where the harvesting completeness was determined by applying the detection algorithm to apple stem images and computing the ratio of successfully detected stems to the total number of stems present in the dataset. This study provided a reference for designing a precise cutting vision system for harvesting robots.

MATERIALS AND METHODS

Collection and preprocessing of apple stem data

This study investigated the real orchard environment and the growth of apple stems in Shandong, China, and collected an apple dataset.

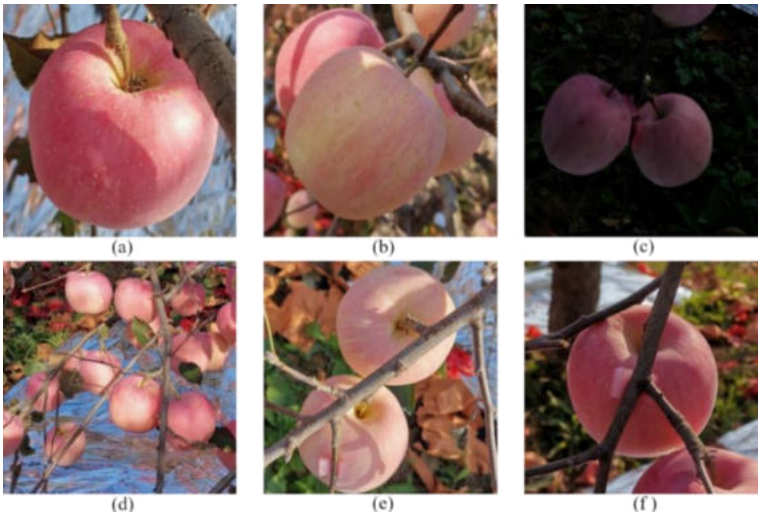

Fig. 1 - Apple images in different conditions

The images of apple stems were collected from apple orchards in Yantai, Shandong, China on October 15th and 16th, 2023. In order to minimize the risk of overfitting the network model, this study collected different distances, including close range (0.3 meters to 1 meter) and long range (1 meter to 3 meters). Images were taken at different times (morning, noon, and evening) to obtain rich and diverse data. Finally, the image dataset was cropped and organized. It was concluded that the apple stem's integrity was highest when viewed from an overhead (top-down) or horizontal perspective. A total of 1671 images of apple stems were collected.

As shown in Figure 1, this was a typical set of apple stem images in a complex environment, this study also collected images of fruit stems completely covered to cope with the special situation of complex orchard environments. All the experimental images were adjusted to a uniform size of 640×640, and then the image transformation module provided by the PyTorch framework was used to enhance the data.

Improved YOLOv8-stem Network Architecture

In order to accurately and quickly identify small objects such as apple stems, this study replaced the original convolutions with AKConv in the 3th and 5th layers of the network, based on the YOLOv8n model. Additionally, it incorporated a 160×160 small object detection head to increase sensitivity to smaller targets. Integrating the CBAM attention mechanism into the P4 and P5 feature maps improved feature representation, suppressed irrelevant information, improved object detection performance, and boosted the network's adaptability to objects of varying scales. The following sections will detail the working principles and technical aspects of each module. The altered network architecture is shown in Figure 2.

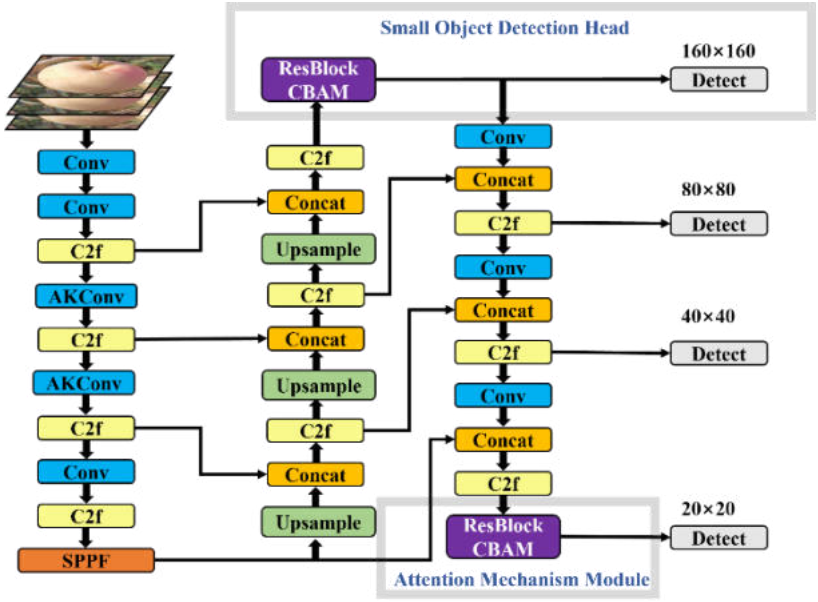

Fig. 2 - YOLOv8-stem Network

Replace the convolution module with AKConv

AKConv assigned initial sampling coordinates to convolutions of varying sizes and modifies the sample shape using learnable offset values. The third and fifth layers typically represent the deep feature extraction stage of the network, with higher resolution and channel numbers. Replacing AKConv in these layers can help the network focus more on extracting high-level and abstract features, thereby enhancing the network's capability to extract features from apple stems and manage occlusion scenarios.

Adding Small Target Detection Head

In the standard YOLOv8 object detection model, the output consists of three layers: P3, P4, and P5, each with three default detection heads. However, the standard model may perform poorly in detecting small objects. Therefore, a new 160x160 detection feature map was introduced for detecting objects larger than 4x4.

ResBlock＋CBAM

When using CBAM in ResNet improved the expressiveness of the feature maps in both the channel and spatial dimensions, thus enhancing the performance of the model. The high-level semantic information and multi-scale information of P4 and P5 made them particularly suitable for detecting small objects. By incorporating the CBAM attention mechanism into the P4 and P5 layers, the model's ability to represent features was enhanced, irrelevant information was suppressed, and target detection performance was improved, thus improving the model's detection and recognition capabilities for apple stems. This weighting mechanism allows the model to be more generalizable, adapting to apple stems of different sizes, shapes, and positions, thereby improving the model's robustness and accuracy.

Experimental Results and Analysis

In experiments to improve various backbone networks, DSConv *(Gennari et al., 2019)* convolution provided better accuracy and continuity in the segmentation of medical tubular structures, but the accuracy of apple stem detection decreased by 31.3%. Replacing the backbone network with ODConv *(Li et al., 2022)* moderately improved accuracy by 0.3% without changing the number of parameters. The results indicated that neither DSConv nor ODConv could effectively extract fruit stem features in highly crowded and complex environments. Bifpn was used to achieve bidirectional fusion of deep and shallow features, but the model parameters and accuracy of identifying fruit stems remained almost unchanged *(Tan et al., 2020)*. The CARAFE *(Wang et al., 2019)* network, which incorporated a kernel prediction module and a content-aware recombination module to generate larger up-sampling kernels, showed a decrease in accuracy of 0.25%. Vanillanet *(Chen et al., 2024)* performed well in terms of parameter and model computation by scaling the neural network model, but its accuracy control was mediocre. On the other hand, the improvement by replacing the backbone network with AKConv showed excellent performance, with a slight decrease in parameters and model computation while increasing detection accuracy (mAP@0.5/% increased by 2.2). This method effectively balanced model parameters and performance. Experimental results are shown in Table 1.

Table 1

Detection accuracy of each model in dataset (%)

Backbone	mAP@0.5/%	mAP@0.5-0.95/%	Params/M	FLOPs/G
Yolov8n(base)	0.799	0.362	3011027	8.2
Yolov8- DSConv	0.486	0.181	2996959	29.6
Yolov8-ODConv	0.802	0.359	2999036	8.1
Yolov8- Bifpn	0.804	0.342	3005852	8.1
Yolov8- CARAFE	0.774	0.332	4053191	8.3
Yolov8-Vanillanet	0.789	0.334	1731635	5.0
Yolov8- AKConv	**0.821**	**0.363**	**2965337**	**8.0**

Among the improvements in various attention mechanisms, LSKA *(Lau et al., 2024)* did not improve accuracy but reduced the model's parameter count. The EMA *(Ouyang et al., 2023)* module focused on retaining feature information on each channel, resulting in a slight increase in accuracy by 2.1%, with no increase in model computation. The parameter-free attention module SE *(Hu et al., 2018)* showed a small improvement in accuracy, while the global attention mechanism GAM *(Liu et al., 2021)* demonstrated a modest rise in the number of parameters while achieving an accuracy improvement of 3.9%. CBAM widely applied in many improvement studies, effectively improved accuracy in this study by combining feature channel and spatial principles to adapt to the complex and multi-feature environment in this scenario. Compared to the base accuracy, mAP@0.5/% improved by 4.6%, and the parameter count and the model's computations were roughly equivalent to those of the original model. Experimental results are shown in Table 2.

Table 2

Various attention mechanisms

Attention mechanism	mAP@0.5/%	mAP@0.5-0.95/%	Params/M	FLOPs/G
Yolov8n(base)	0.799	0.362	3011027	8.2
Yolov8-C2f-LSKA	0.794	0.338	2351555	6.6
Yolov8n+EMA	0.825	0.355	3006515	8.1
Yolov8n+SEAttention	0.808	0.368	3227923	8.4
Yolov8n+GAM	0.838	0.337	3687123	9.5
Yolov8n+CBAM	**0.845**	**0.346**	**3014406**	**8.1**

After testing a variety of attentional mechanisms for detecting small objects, the parts with significant improvements were selected and incorporated. Comparative experiments revealed that the YOLO network algorithm demonstrated strengths with respect to the three improvement modules from current cutting-edge research. However, additional ablation experiments were required to confirm the efficacy of each enhancement module. The findings from these experiments could be found in Table 3.

Table 3

Module ablation experiment

AKConv	CBAM	Head	mAP@0.5/%	mAP@0.5-0.95/%	Params/M	FLOPs/G
✓			0.821	0.362	2965337	8.0
	✓		0.845	0.342	3014406	8.1
		✓	0.826	0.352	2977588	12.5
	✓	✓	0.835	0.347	3239726	8.9
✓	✓	✓	0.859	0.347	3998948	14.6

These three improvements enabled the YOLO model to achieve higher recognition accuracy for small objects with specific apple stem shapes in orchard environments, where occlusion and scene complexity are common. Notably, this enhancement in performance was achieved with only a minimal increase in the number of parameters. Ultimately, compared with the baseline model, the improved YOLO achieved a 6.0% increase in mAP@0.5 on the dataset. The results of the ablation experiments are presented in Table 5. A comparison of detection outcomes before and after the network modifications, as shown in Figure 3, illustrates the effectiveness of the architectural changes. The visual results highlight clear improvements in detection accuracy and robustness achieved through the proposed enhancements.

Evaluation metrics

This study comprehensively evaluates the model's performance using precision (P), recall (R), gigafloating-point operations per second (GFLOPs), and the mean Average Precision (mAP) across all target categories at an IoU threshold of 0.5. The formulas for calculating precision, recall, and average precision (AP) are as follows:

$$P = \frac{TP}{TP + FP} \tag{1}$$

$$R = \frac{TP}{TP + FN} \tag{2}$$

$$AP = \int_0^1 P(R)dr \tag{3}$$

The mean Average Precision (mAP) is calculated as the total of the average precisions for all labels divided by the number of classes.

$$mAP = \frac{\sum_{i=1}^{k} AP_i}{k(classes)} \tag{4}$$

Where n denotes the total number of categories, k is the number of detections, and AP represents the average precision for each category.

RESULTS

Experimental Environment

Experiment setup: The operating system of the experimental platform was Windows 10. The CPU was an Intel(R) Core (TM) i5-12490F, with 16GB of RAM. The GPU was an Nvidia GeForce RTX 4060 Ti with 8GB of VRAM. The CUDA version used by torch vision is 11.7, and the deep learning framework was PyTorch-GPU 2.0.1+cu118. To ensure the fairness and rationality of the experiments, all ablation experiments were conducted in the same experimental environment.

Dataset Preparation

In apple stem images captured from various overhead angles, single-angle camera detection may fail to accurately identify the stem when the field of view is partially obstructed by overlapping branches or fruits. Such occlusions can prevent the camera from capturing the full shape and position of the apple stem, negatively impacting subsequent harvesting or processing tasks. To address this challenge, a specialized labeling strategy was adopted for the dataset used in this study. Apple stems visible from a top-down perspective were labeled as *Apple stem*, while apples obscured by branches were labeled as *Masked apple*. Additionally, apple stems captured from the top-down view were annotated together with apple eyelets to enhance the feature representation of the stem. This custom-labeled dataset formed the basis for training and evaluating the proposed detection algorithm designed to identify apple stems in occluded environments.

This study trained a model to recognize two types of objects: apple stems and apples obscured by tree branches. After detection, it was further determined whether the bounding box of the obscured apple contains the coordinates of the apple stem. If the coordinates of the stem are not within the bounding box of the obscured apple, it could be concluded that the stem is obscured by a branch. Otherwise, it was considered exposed. When tree branches obstruct the apple and cover the stem, the detection angle and position could be adjusted to better observe the stem, thereby more accurately detecting the initially unrecognized stem and providing a technical solution for apple harvesting.

There were a total of 2816 *Apple stem* labeled targets and 1321 *Masked apple* labeled targets in the original 1671 images before data augmentation. It should be noted that because the *Masked apple* was larger and more distinctive in the images, it was not involved in the statistics of the YOLOv8 network structure optimization results. The performance evaluation was conducted only for the target recognition effect of the *Apple stem*. The training of the *Masked apple* category was performed to validate and provide statistics for the specific case when the apple was covered by branches and the fruit stem was also covered. The dataset categorization is shown in Table 4.

Table 4

Classification of data sets

Classification of data sets	Number	Use of data sets
Apple stem	2816	Network Modification Performance Evaluation
Masked apple	1321	Identify and count obscured apples

This study employed K-Fold cross-validation as the evaluation method for the machine learning model. The original dataset was divided into 5 subsets (K=5). In each iteration, one subset was used as the validation set, while the remaining four subsets (K-1) were used as the training set. This process was repeated five times, ensuring that each subset served as the validation set exactly once. After each iteration, the model's performance metrics were calculated on the validation set, and the average of these results was taken as the overall performance evaluation on the entire dataset. The training results presented in the subsequent experiments were obtained using this K-Fold cross-validation approach.

Validate the network model

In order to more intuitively test the apple stem detection performance of the modified network model, this study compared the apple stem detection performance of YOLOv8n and YOLOv8 stalk. The comparison of the detection results is shown in Figure 3.

Fig. 3 - The comparison of detection results

There are a total of three sets of apple stem detection comparisons in the comparison chart. Overall, in terms of detection performance, the improved YOLOv8 stalk has increased the recall rate and overall confidence of apple stem detection.

After comparing the original YOLOv8 model, this study validated the superiority of the improved YOLOv8 stalk model by training and testing it on the same dataset as other detection models such as faster R-CNN, SSD, YOLOv5, YOLOv3, etc. From Table 5, it can be seen that the improved YOLOv8 stalk model has the highest average accuracy compared to other models, with an increase of 5.4 percentage points in average accuracy compared to the original YOLOv8n network.

Table 5

Comparison of the effectiveness of different network models

model	mAP @0.5/%	mAP @0.5-0.95/%	Params/M	FLOPs/G
YOLOv3-tiny	76.2	33.6	4.3	18.9
YOLOv5n	80.1	35.7	1.9	4.5
YOLOv8n	80.3	36.0	3.0	8.2
Faster R-CNN	80.8	35.8	104	268.3
SSD	82.2	35.4	93	195.3
YOLOv8-stalk	85.7	36.7	4.0	14.6

Detection Results and Analysis of Occluded Stems

After modifying the network, the deep learning model achieved higher recognition accuracy for apple stems, but it could not address the issue of incomplete harvesting caused by branches obscuring the apple stems. Therefore, the modified network was used to detect cases where apple stems were obscured by branches to observe the recognition and improvement effects. This study categorized the cases of obscured apple stems into three types: stems inside the corresponding obscured apple box but not recognized, stems inside the corresponding obscured apple box and recognized, and stems inside a non-corresponding apple box. This last category included cases where the stem was recognized or not recognized within the non-corresponding apple box. The number of stems not recognized was the focus for angle adjustment and re-detection to improve the actual harvesting rate. The following images show the detection results for these three different scenarios. Different occlusion scenarios of the stems are shown in Figure 4.

Fig. 4 - Different occlusion scenarios of the stems

This experiment was conducted using the trained inference model on 428 new scene images of apple stems collected from an apple orchard, which were different from the training dataset. Among these new images, 576 apples were annotated as obscured apples (Actual number of occluded apples). After prediction by the model, there were 565 predicted obscured apples (Predicted number of occluded apples). The number of stems recognized within the corresponding obscured apple bounding boxes (Fruit stems not covered by branches) was 485, and the number of stems inside the corresponding obscured apple boxes but not recognized (Fruit stems obstructed by branches) was 52. Other cases included 28 stems inside non-corresponding apple boxes (Other situations).

The statistical results are presented in Table 6.

Table 6

The statistical results

Category	number
Images of apple orchard scenes	428
Actual number of occluded apples	576
Predicted number of occluded apples	565
Fruit stems not covered by branches	485
Fruit stems obstructed by branches	52
Other situations	28

After analyzing the data of predicted obscured apples in the apple orchard scene images, in the case of 576 actually obscured apples, if the stems are also obscured, the deep learning network will not detect the obscured apples from a single camera angle, resulting in 52 stems inside the corresponding obscured apple box but not recognized. When this situation is detected, it can be inferred that the stems are obscured. In this case, changing the position and angle of the single camera to re-recognize the obscured stems can improve the picking efficiency from 576/485=84.2% to 576/ (485+52) =93.2% according to the theoretical statistical data. Moreover, as the apples with recognized stems inside the corresponding obscured apple box are picked, the situation where the stems are recognized inside non-corresponding obscured apple boxes will decrease, further improving the picking efficiency.

CONCLUSIONS

This study presented an enhanced YOLOv8-stem approach for detecting apple stems in overhead imagery under occlusion conditions. First, two datasets comprising apples and apple stems obstructed by tree branches were collected. Second, the YOLOv8 neural network was improved by substituting the conventional convolutional process within the intermediate neck layer with the AK Convolution mechanism. A small object detection head was added, introducing a 160×160 detection feature map, and a ResBlock+CBAM attention mechanism was incorporated. Third, the likelihood of missed detections was decreased by utilizing the coordinates of the apples and apple stems obstructed by tree branches identified by the enhanced YOLOv8-stem model. The experimental results showed that compared to the original YOLOv8 model, this method significantly improved both the detection accuracy of apple stems and the completeness of harvesting. The enhanced stem detection model achieved an average precision of 85.9%, representing a 6.0% improvement over the baseline YOLOv8 model (from 79.9% to 85.9%), and the harvesting completeness increased from 84.2% to 93.2%. This approach demonstrated promising applications in precise apple harvesting and automated fruit picking systems.

Keywords: *YOLOv8-pose, strawberry identification, fruit stem, key point detection, red ripe stage*

ABSTRACT

To solve the problems of low precision in locating stem picking points and difficulty in recognizing occluded strawberry during the operation of strawberry picking robots, this paper proposed an improved YOLOv8-pose method for strawberry fruits identification and key points detection at the red ripe stage. Based on the YOLOv8-pose human posture estimation model, three categories (strawberry, stem, and picking points) were annotated. The acquired images were divided into training, validation, and test sets in an 8:1:1 ratio. In order to improve the feature extraction ability of the model for small targets, shuffle attention (SA) mechanism was added into the backbone network of YOLOv8-pose. Additionally, a comparative analysis was conducted to assess the impact of six attention mechanisms of CBAM (Convolutional block attention module), SimAM (Simple attention module), GAM (Global attention module), EMA (Efficient multi-scale attention), SK (Selective kernel attention), and SA on the detection results. Experimental results show that the proposed method can quickly and accurately detect strawberry fruits and key points for picking. The Precision (P), Recall (R), and mean average precision (mAP)50 values for both bounding boxes and key points based on SA mechanism were 99.7%, 100.0%, and 99.5% respectively, which were superior to the other attention mechanisms. Compared with YOLOv5-pose and YOLOv8-pose models, the improved model had the best P, R, and mAP50 values, and its memory usage was 6.4MB, which was also optimal. The improved method can provide crucial technical support for precise robotic strawberry picking.

摘要

为解决草莓采摘机器人作业中果梗采摘点定位精度低和遮挡草莓识别困难等问题，本文以红熟期草莓为研究对象，提出一种改进的 YOLOv8-pose 草莓果实识别及采摘关键点检测方法。以 YOLOv8-pose 人体姿态估计模型为基础，标注了草莓、果梗、采摘点 3 个类别。将采集的图像按 8:1:1 的比例划分成训练集、验证集和测试集。为了提高模型对小目标的特征提取能力，在 YOLOv8-pose 的骨干网络中添加了 shuffle 注意力机制，并对比分析了 CBAM（Convolutional block attention module），SimAM（Simple attention module），GAM（Global attention module），EMA（Efficient multi-scale attention），SK（Selective kernel attention）以及 SA 六种注意力机制对检测结果的影响。实验结果表明，本文提出的方法可以对草莓果实及采摘关键点进行快速准确检测，基于 SA 注意力机制的边界框和关键点的检测精确率（Precison，P），召回率（Recall，R），平均精度均值（Mean average precision，mAP）mAP50 均为 99.7%，100.0%和 99.5%，均优于其他注意力机制；与 YOLOv5-pose、YOLOv8-pose 模型相比，改进模型的 P，R，mAP50 值都是最优的，模型的内存占用量为 6.4MB，也是最优的，该模型可以为机器人精准采摘提供重要的技术支持。

INTRODUCTION

With various nutrients such as amino acids, vitamins, minerals, strawberry is known as the “queen of fruits” *(Hu et al., 2024)*. At present, strawberry picking still rely on manual labor, which is time-consuming and costly *(Wang et al., 2022)*. The implementation of intelligent strawberry picking is of great significance for improving picking efficiency, reducing labor costs, minimizing fruit damage, and enhancing fruit quality. The

[2] *Jinlong Wu, Ph.D.Stud.; Ronghui Miao, Ph.D.Stud.*

harvesting of strawberry picking robots is mainly achieved by cutting fruit stems *(Ma et al., 2025)*. However, the diameter of strawberry stem is relatively small, and affected by complex backgrounds such as lighting and obstruction from branches and leaves, making it difficult to identify and locate strawberry. Accurate positioning fruits and stems are of great significance for improving the intelligence and automation of strawberry picking robots.

In recent years, with the development of deep learning technology, researchers at home and abroad applied deep learning algorithms to the recognition and detection of various fruits, and have achieved certain results. *Gai et al.* (*2024*) proposed a blueberry identification algorithm named TL-YOLOv8 based on the YOLOv8 algorithm to improve the detection accuracy, by introducing an improved MPCA (Multiplexed coordinated attention) in the last layer of the backbone network, the feature extraction capability during the training process was enhanced. *Gao et al. (2025)* proposed a novel YOLOv8n-CA method for tomato maturity recognition, which defines four maturity stages: unripe, turning color, turning ripe, and fully ripe, and the experimental results showed that the YOLOv8n-CA model had a computational complexity of 6.9 GFLOPs, and a weight file size of just 4.90 MB. *Chen et al. (2024)* proposed a lightweight target detection method called LFA-YOLO to address the problem of leakage and misdetection in the detection of lychee fruit anthracnose due to the complexity of the agricultural environment, and it achieved a mAP50 of 88.61%, with precision and recall rates of 90.18% and 82.77% respectively. In the application of strawberry recognition and detection, an improved YOLOv5 object detection model was proposed, the ghost module was used to optimize the backbone network, thereby reducing the number of parameters and complexity of the model, and the experimental results indicated that this model can provide a more accurate and efficient detection method for strawberry *(Peng et al., 2025)*. An improved YOLOv5s-based method for rapid detection of strawberry ripeness in greenhouse was proposed, shuffle block was introduced as the feature extraction network in the backbone to lightweight the model, the results showed that the average precision of the improved YOLO-ODM model can reach 97.4%, indicating that this lightweight method can detect the ripeness of strawberry quickly and accurately *(Chen et al., 2023)*. A combination of improved YOLOv4 and traditional image processing technology for strawberry stem recognition in complex picking scenarios was proposed, and this model can accurately locate the picking points and demonstrate better applicability in practical picking scenarios *(Huang et al., 2023)*. However, most of the aforementioned researches mainly focused on object detection of fruits and maturities for strawberry, the detection of key points for picking were relatively few, which cannot be directly applied to strawberry picking operations. Meanwhile, the maturities of strawberry can be divided into four stages: green ripe, white ripe, color change, and red ripe. Among these, the red ripe stage is the complete ripening stage, with uniform red color on the surface, soft texture, and unique aroma. Therefore, identifying the red ripe strawberry and picking points are key steps for strawberry picking robots.

This paper takes red ripe strawberry as research object, refers on the human posture estimation model, and proposes an improved YOLOv8-pose model for detecting key points of fruit and stem. In order to improve the feature extraction ability of the model for small targets (fruit stems, picking points), SA mechanism was added to the backbone network. This study can achieve the prediction of picking point for stems, providing technical support for machine picking of strawberry.

MATERIALS AND METHODS

Data collection

The experimental strawberry images were collected from strawberry planting base in Xianggu village, Taigu District, Jinzhong city, Shanxi province in March 2024. The datasets were carried out using a Huawei P40 Pro camera. The vertical distance between the shooting device and the ground was 150 mm - 250 mm. A total of 158 images were collected, with an image resolution of 3000 pixels × 4000 pixels. The experimental processing platform was configured with Intel Core (TM) i9-9900K @ 3.60GHz, 16GB of memory, and NVIDIA GeForce RTX 2080Ti main graphics card for GPU acceleration. Figure 1 shows the collected strawberry images, which include complex environment such as single fruit, multi fruit, fruit occlusion, and branch and leaf occlusion.

(a) Multi fruit + fruit obstruction (b) Multi fruit + no fruit obstruction (c) Single fruit (d) Single fruit + leaf obstruction

Fig. 1 - Sample images of strawberry

Dataset annotation

This paper used posture estimation model to achieve strawberry identification and key points detection on fruit stems. YOLOv8 is capable of performing complex tasks such as instance segmentation *(Fan et al., 2024)*, object detection *(Kumar and Muhammad, 2023)*, image classification, posture estimation *(Ma et al., 2024)*, and key points detection. Among them, posture estimation can obtain the positions of key points in the images, and the positions are usually represented by two-dimensional coordinates (x, y) or 3D coordinates (x, y, visible), and it is mainly used to recognize various postures of the human body *(Peruzzi et al., 2025)*. In YOLOv8, there are 1 category and 17 key points, the category name is "person", and each key point represents a different part of human body. The mappings of each index to the corresponding body joint are: 0: nose; 1: left eye; 2: right eye; 3: left ear; 4: right ear; 5: left shoulder; 6: right shoulder; 7: left elbow; 8: right elbow; 9: left wrist; 10: right wrist; 11: left hip; 12: right hip; 13: left knee; 14: right knee; 15: left ankle; 16: right ankle. Figure 2 shows the key points of human body.

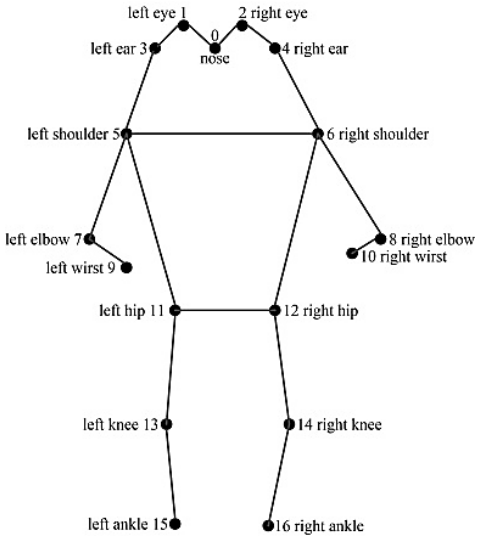

Fig. 2 – Key points of human body

Based on the posture estimation model of human body, a strawberry recognition and stem key points detection model was constructed. In this paper, the annotation tool Labelme was used to annotate the strawberry image datasets, and three types of labels were annotated: strawberry (in rectangle), stem (in point) and pick (in point). The annotation results were shown in Figure 3. The principle of labeling is: only the red ripe strawberry fruits will be labeled, and fruits that are too heavily obscured will not be labeled; the center point of the fruit stem was selected as key point; the picking point is marked at a distance of 1 cm from the stem. The format of the annotation file was JSON, in order to ensure that the datasets required for the experiment meets of COCO format, the annotated files need to be converted to TXT format.

Dataset production

After screening, a total of 98 images were selected for model training, validation, and testing. Then the image datasets were divided in an 8:1:1 ratio. Eighty percent (78 images) were randomly selected as the training sets for model training and parameter optimization. The remaining twenty percent (20 images) were used as validation and testing sets to verify the performance of the model.

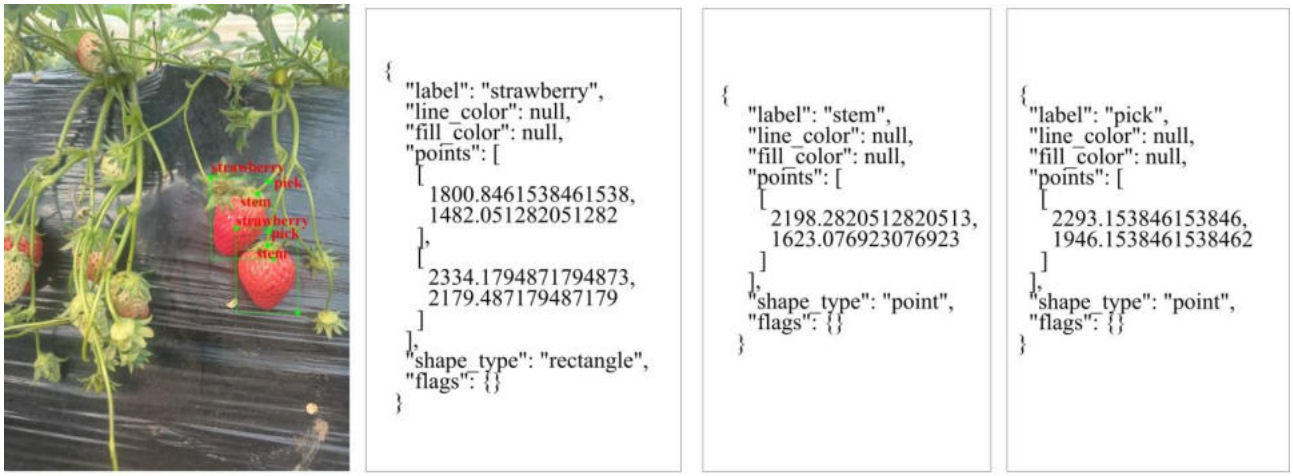

Fig. 3 – Annotation results

Dataset augmentation

YOLOv8 provides some dataset automatic augmentation methods to improve the generalization ability and detection performance of the model, and the main augment strategies include RandAugment, AutoAugment, and AugMix *(Sanat et al., 2023)*. Among them, RandAugment is a commonly used technique that enhances training data by randomly selecting a series of image transformations (such as brightness adjustment, contrast change, rotation, cropping, etc.), thus enabling the model to better learn various features and patterns in the images *(Lee et al., 2023)*. Some of the hyperparameter settings are as follows: the “hsv_h” (proportion of image hue augmentation) is 0.015; the “hsv_s” (proportion of image saturation augmentation) is 0.7; the “hsv_v” (proportion of image value augmentation) is 0.4; the “translate” (proportion of image translation) is 0.1; the “scale” (gain of image scaling) is 0.5; the “fliplr” (probability of image flip left-right) is 0.5, the “mosaic” (probability of image mosaic) is 1.0, etc. Figure 4 shows the data augmentation result, randomly applying image enhancement operations with a certain probability and intensity can generate diverse training samples. And it performs stably on different datasets and model sizes, especially suitable for resource limited scenarios.

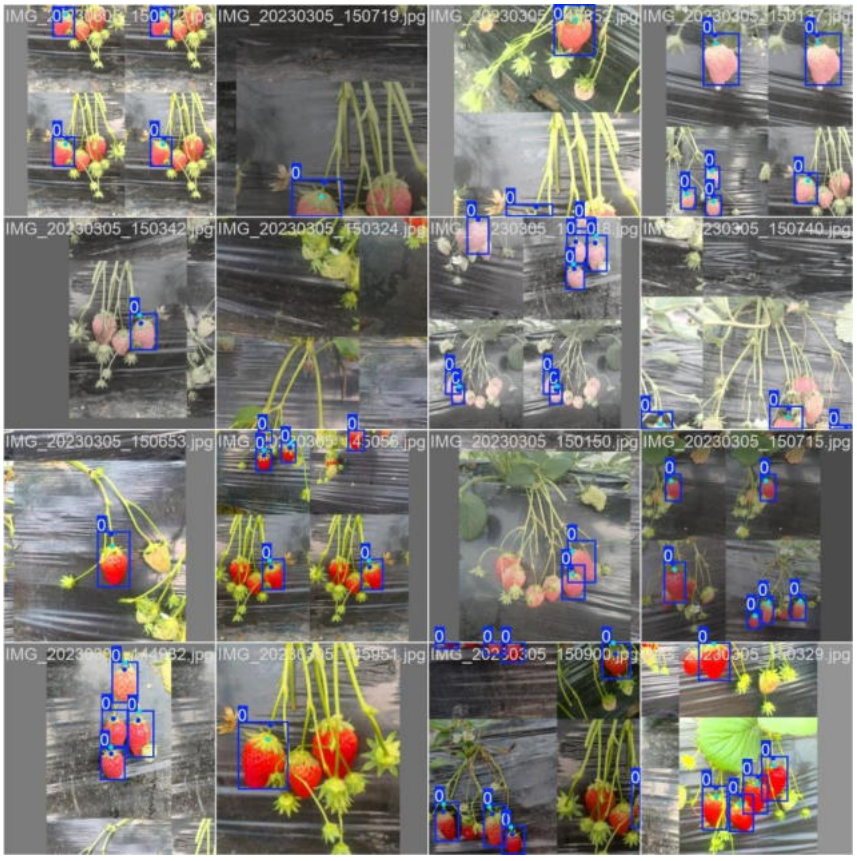

Fig. 4 – Dataset augmentation result

Strawberry identification and picking key points detection model

This paper constructed a model for strawberry identification and fruit stem key points detection based on the improved YOLOv8-pose network. In order to improve the feature expression ability, SA mechanism was added into the backbone network of YOLOv8-pose. Figure 5 shows the network structure of the improved YOLOv8-pose model.

YOLOv8-pose model

With advantages of higher detection accuracy and speed, new backbone network structure, anchor free detection head, and new loss function *(Jo et al, 2024)*, YOLOV8 model can achieve tasks such as object detection, instance segmentation, and key points detection, and it has been widely used in security monitoring, autonomous driving, smart homes and industrial automation. The structure of YOLOv8 mainly consists of three parts: Backbone, Neck, and Head.

a. Backbone: responsible for feature extraction. A series of convolutional and deconvolution layers are adopted to realize deep feature extraction. The introduction of residual connections and bottleneck structures can improve the performance of the network *(Zhai et al., 2024)*. Compared with YOLOv5, C2f module is introduced to replace the original C3 module, which can achieve light weighting with fewer parameters. Moreover, the depth wise separable convolution and dilated convolution techniques can further enhance feature extraction capabilities.

b. Neck: located between the backbone and head parts, responsible for feature fusion enhancement. The spatial pyramid pooling fusion (SPPF) can fuse features maps from different stages of backbone to enhance feature representation capabilities *(Dong et al., 2024)*.

c. Head: responsible for generating the final detect results. This section uses simple convolutional and upsampling layers, combined with the feature maps from the neck part to achieve object detection.

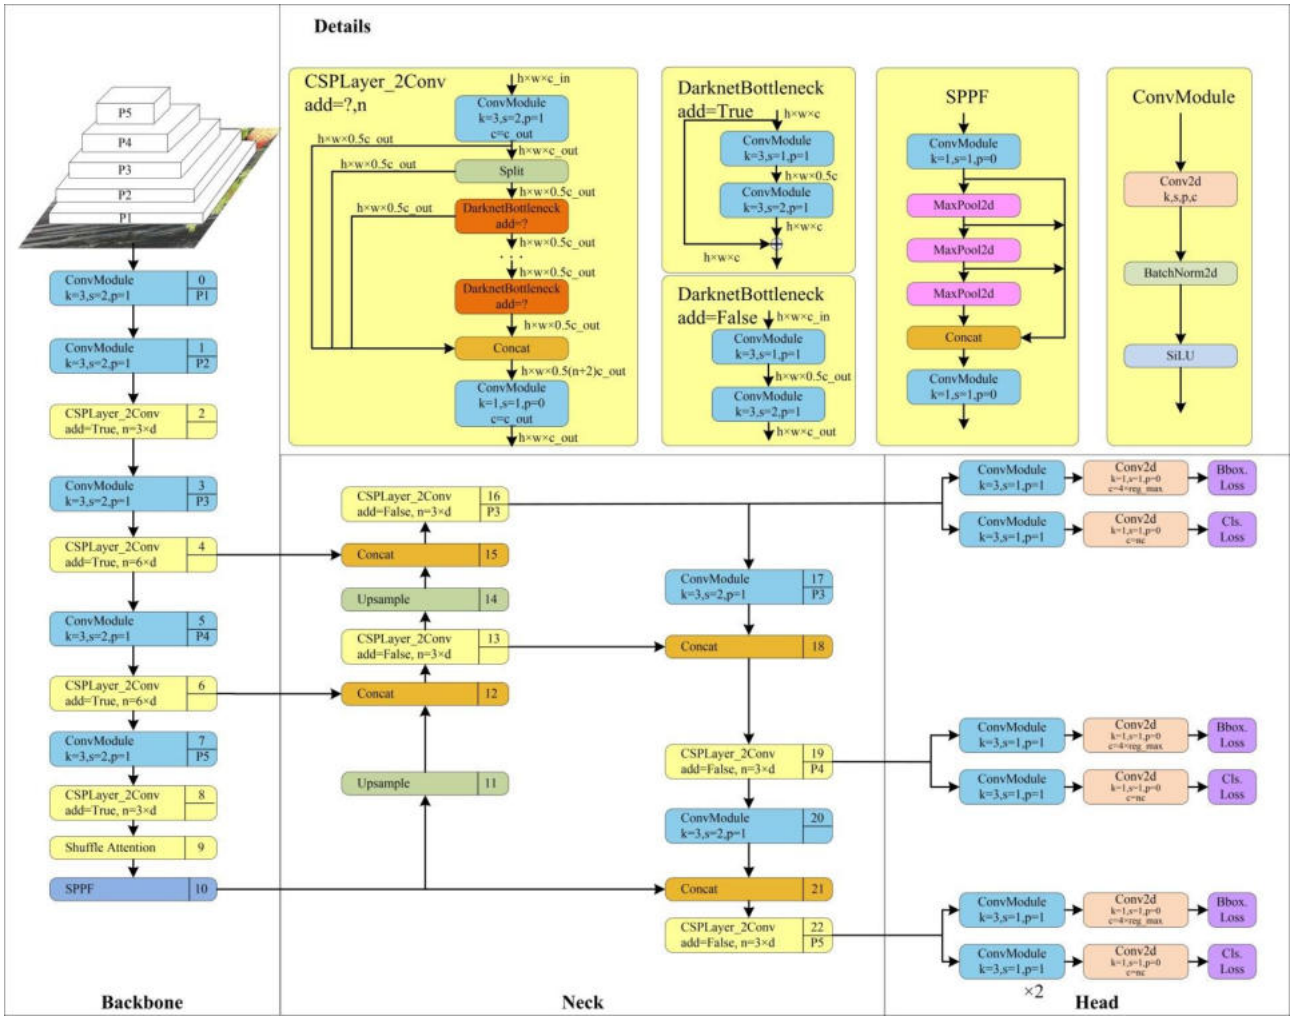

Fig. 5 – The network structure of the improved YOLOv8-pose model

SA mechanism

Attention module can focus on useful feature information and suppress unimportant feature. SA mechanism is capable of selectively weighting the information within the feature maps *(Zhang and Yang, 2021)*. By introducing this mechanism, YOLOv8 model can be made more stable and accurate in finding the position and classifying the tested object. The advantages of SA mechanism are: it efficiently combines spatial and channel attention mechanisms, thus improving the performance of the model; by dividing the channel dimensions of the input feature map into multiple groups, the computational cost is effectively reduced; by using channel rearrangement technique, the expression ability of channel features is enhanced.

The structure of SA is shown in Figure 6. The processing procedure of SA module mainly includes: (1) Making the input feature map into G groups to obtain sub features of each group; (2) Use spatial attention and channel attention to obtain information of the sub features; (3) Channel shuffle operation is used to fuse the features from different groups. The blue parts represent the spatial attention mechanism, and the green ones represent the channel attention mechanism. In Figure 6, X is the feature map; c, h and w represent the number of channels, spatial height and width respectively; the number of channels for each group is c/g; the number of channels for each attention branch is $c/2g$; GN is group normalization.

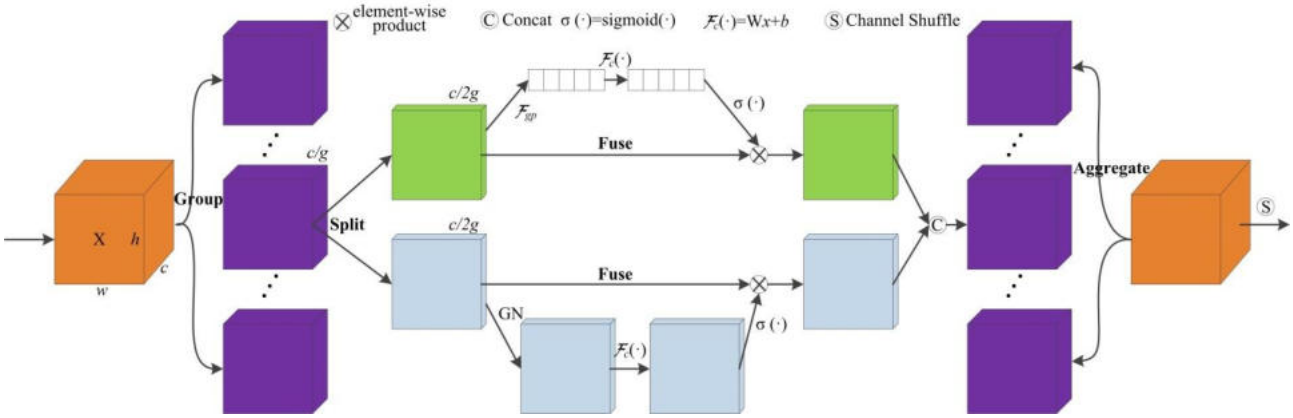

Fig. 6 – SA mechanism structure diagram.

Model evaluation

In order to evaluate the performance of identification and detection, mAP, P and R were selected as evaluation indicators. Among them, mAP refers to the average precision at different recall rates. P represents the proportion of samples predicted as positive cases that are actually positive cases. R represents the proportion of samples correctly identified as positive cases by the model among all actual positive cases. The calculation formulas for evaluation indicators are shown in equations (1) to (3).

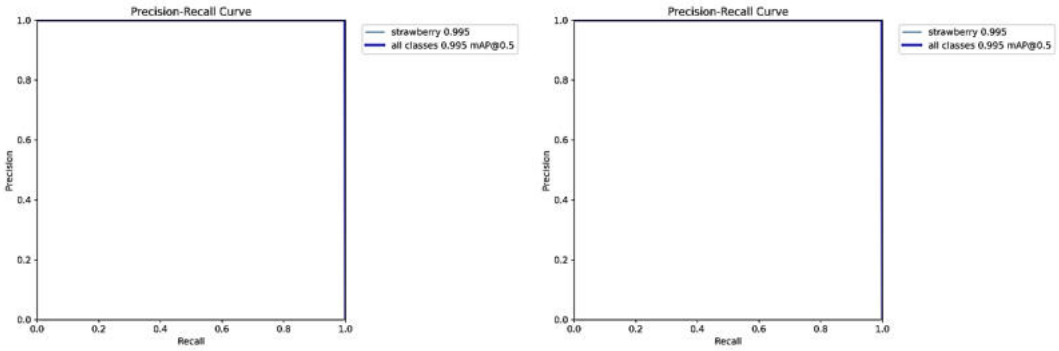
$$mAP = \frac{\sum_{i=1}^{C} \int_0^1 P_i dR_i}{C} \quad (1)$$

$$P = \frac{TP}{TP + FP} \quad (2)$$

$$R = \frac{TP}{TP + FN} \quad (3)$$

In which:

C is the number of categories; TP (True positives) is the number of correctly identified positive samples; TN (True negatives) is the number of correctly identified negative samples; FP (False positives) is the number of samples incorrectly identified as positive; FN (False negatives) is the number of incorrectly identified negative samples.



Model parameters

In the improved YOLOv8-pose model, the batch size is 16; the epoch is 200; the initial learning rate is 0.01; the momentum is 0.937. Batch size represents the number of training set images input for each batch; epoch represents the number of iterations of model training; learning rate is a parameter that controls the size of the gradient descent step in each iteration update; momentum can accelerate the update of model parameters.

RESULTS AND DISCUSSION

Identification and detection results of the improved YOLOv8-pose

Figure 7 shows the PR curves of box and pose on the training sets. PR curve is a common method used to evaluate the performance of the classification models. The horizontal axis of the PR curve is precision, and the vertical axis is recall. The closer the PR curve is to the upper right corner, the better the performance of the model. It can be seen that the mAP50 values for both box and pose were 0.995, which were close to 1, indicated that the model had a better balance between precision and recall, and its performance was good.

(a) Box PR curve *(b) Pose PR curve*

Fig. 7 - PR curves on the training sets

Figure 8 shows the loss curves on the training sets. The loss functions of YOLOv8-pose mainly includes five types of losses: bounding box loss (box_loss), key point loss (pose_loss), key point confidence loss (kobj_loss), classification loss (cls_loss), and distribution focal loss (dfl_loss). Bounding box loss represents the deviation between the predicted bounding box and the actual bounding box. Key point loss represents the deviation between the predicted key point positions and the actual positions. Key point confidence loss is used to measure the confidence level of the model in predicting key points, and it is adjusted by comparing it with the true confidence level. Classification loss represents the deviation between the predicted category and the true category. Distribution focal loss is used to optimize the predicted distribution of bounding boxes. As shown in figure 8, with the increase of training epochs, the loss value continuously decreased and tended to stabilize, indicated that the performance of the model was gradually improving in the classification and prediction tasks.

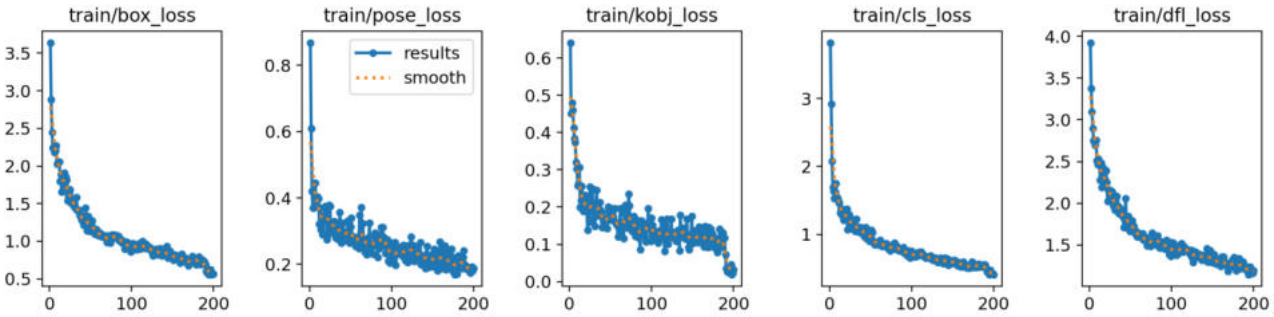


Fig. 8 - Loss curves on the training sets

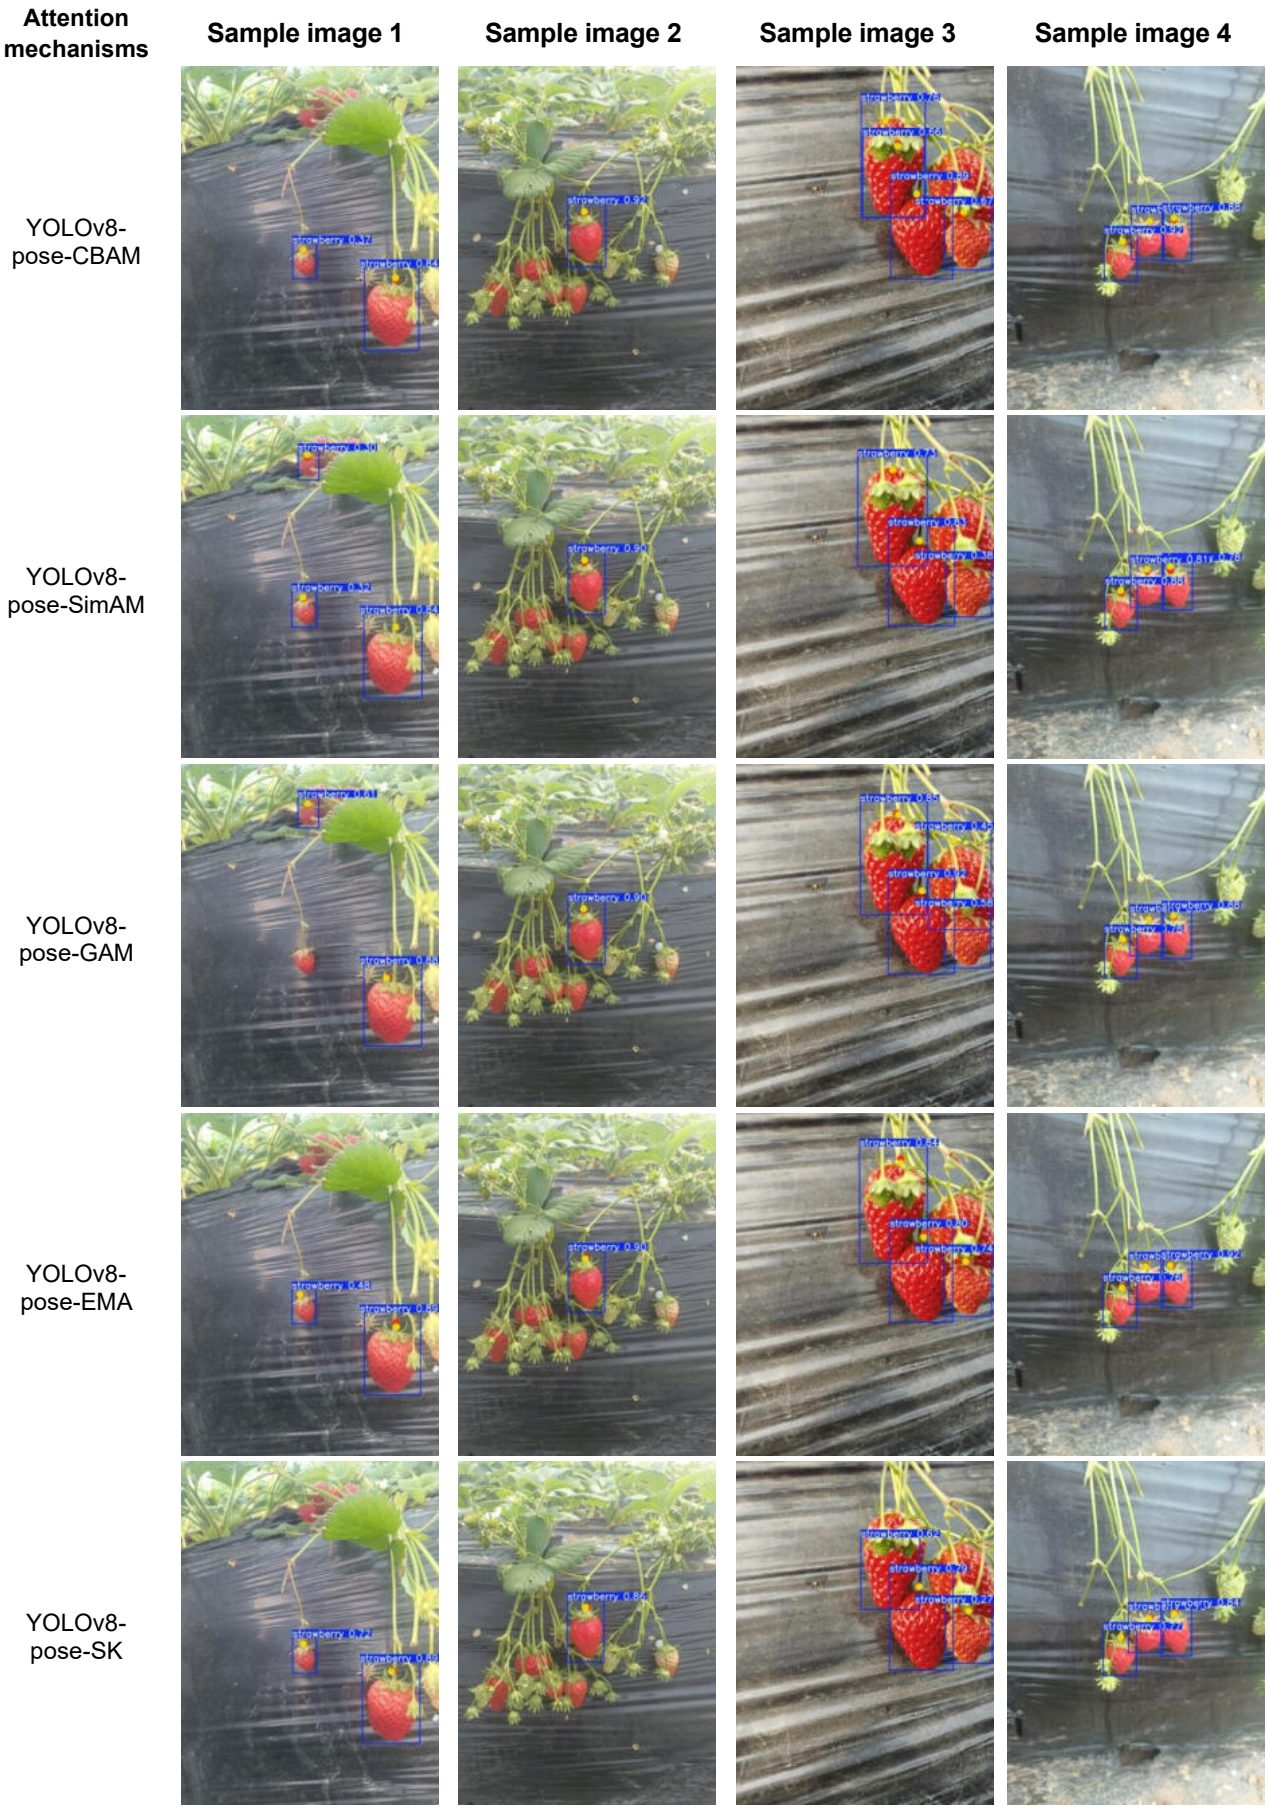
Figure 9 shows the identification and detection results of strawberry. In the recognition results, the blue rectangle represents the identified results of strawberry at red ripe stage; the red and yellow points present the picking and stem key points. It can be seen that the improved model can accurately identify the strawberry at red ripe stage, because it only has one target in this paper, the detection and recognition rate is relatively high. There is a certain overlap between the stem and picking points, due to the small color difference of key points, the detection results are not ideal.

Fig. 9 – The prediction results of the improved YOLOv8-pose model

Identification and detection results of different attention mechanisms

In order to verify the impact of attention mechanisms on the performance of the model, six attention mechanisms of CBAM *(Woo, et al., 2018)*, SimAM *(Yang, et al., 2021)*, GAM *(Liu et al., 2021)*, EMA *(Zhang et al., 2024)*, SK *(Peng et al., 2020)* and SA were set for comparative experiments.

Table 1 shows the detection results of different attention mechanisms. Here, mAP50 represents the average accuracy of the model when the IoU (Intersection over union) threshold is 0.5, while mAP50-95 represents the average accuracy when the IoU ranging from 0.5 to 0.95. And mAP50-95 provides a more comprehensive evaluation of the performance under different degrees of overlap.



From table 1, it can be seen that the indicators of all the attention mechanisms can reach 81% or above, and the detection results were good; the detection results of YOLOv8-pose-EMA and YOLOv8-pose-SK were relatively poor; the memory usage of YOLOv8-pose-SK was 17.5MB, which was the highest among all the attention mechanisms; the box and pose P, R, mAP50 of SA were all 99.7%, 100.0% and 99.5%, and the memory usage of YOLOv8-pose-SA was 6.4MB, these values were all optimal.

Figure 10 shows the partial identification and detection results of different attention mechanisms. It can be seen that all models were able to identify strawberry fruits and key points of picking with high accuracy; the model of YOLOv8-pose-GAM had a certain of miss detection. Due to the fact that both the stem and picking point are green, there was a certain overlap in the results.

Table 1

Detection results of different attention mechanisms

CONCLUSIONS

Faced with the characteristics of small stem diameter and easy damage to the flesh of strawberry, in this paper, an improved YOLOv8-pose method was proposed for strawberry fruit identification and key points detection method at red ripe stage. Based on the YOLOv8-pose human posture estimation model, three categories of strawberry, stem, and picking points were annotated. In order to improve the feature extraction ability of the model for small targets, SA mechanism was added into the backbone network of YOLOv8-pose. Experimental results show that the proposed method can quickly and accurately detect strawberry fruits and key points of picking, and can provide crucial technical support for precise robotic strawberry picking.

At present, there are varieties of strawberry, and the method in this paper is only suitable for detecting red strawberry. It may have certain limitations in identifying and locating strawberry in other colors. Subsequent research will introduce white strawberry or pink strawberry to enrich the images, so that improving the generalization ability and adaptability to different strawberry. Generally, intelligent fruit and vegetable picking robots are composed of vision, control, execution and walking systems. Among them, the visual system plays a crucial role in harvesting robots. As the “eyes” of the picking robots, it can accurately identify the position, size, and maturity of the target fruit through image recognition and object detection technology, and provide precise guidance for the execution system. The future research direction is to combine the method proposed in this paper with RGBD depth cameras to further obtain three-dimensional information of fruits, and guide the robotic arm to perform picking operations.

ABSTRACT
The influence of the device's structure and operating parameters, along with the material properties of millet, on threshing and separation performance forms the theoretical basis for designing and researching a single longitudinal axial flow threshing and separation device specifically adapted to millet. Therefore, a theoretical model for grain threshing and separation in a single longitudinal axial flow threshing device was established based on variable mass theory. To validate the theoretical model, single-factor tests were conducted on the feeding rate, rotational speed, and water content of Longgu 31 millet. The error analysis between the experimental and calculated values indicates that within a moisture content range of 17.14% to 32.93%, feeding rates varying from 1 to 3 kg/s, and rotational speeds ranging from 700 to 1000 r/min, the R-squared values consistently exceed 0.97. This indicates an excellent fit of the theoretical model. The theoretical model will serve as a valuable reference for the design and investigation of the single longitudinal axial flow separation device.

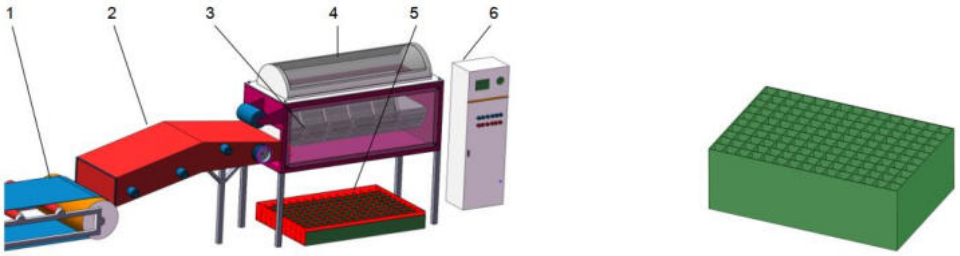
摘要
谷子的物料特性和装置的结构参数、工作参数对脱分性能的影响，是适应谷子特性的单纵轴流脱分装置设计和研究的理论依据。因此，应用变质量理论建立了谷子在单纵轴流脱分装置内的脱分理论模型，并构造了脱粒参数和分离参数的表达式。为了验证理论模型，选取龙谷 31 号为试验对象，在搭建的单纵轴流脱粒分离试验台上开展了谷子的喂入量、转速、含水率单因素试验，并将试验数据与模型计算数据进行误差分析，对比结果表明：当含水量为 17.14%-32.93%、喂入量为 1-3kg/s，转速为 700-1000r/min 时，试验数据与模型计算数据的 R-Squared 误差均大于 0.97，理论模型的拟合度好。因此，理论模型将为单纵轴流脱离分离装置的设计和研究提供参考。

INTRODUCTION
Currently, the grain combine harvester has become an indispensable agricultural machine for field operations. As a critical component, the threshing device plays a pivotal role in determining the overall performance of the harvester. Consequently, numerous scholars have devoted significant effort to optimizing this essential mechanism.

The tangential flow threshing device was utilized in early harvesting machinery, and its theoretical model has been well-established. The effects of structural design, operational parameters, and material properties on the threshing and separation efficiencies of the tangential flow threshing device were elucidated (*Wan et al., 1990; Zhang et al., 1994*). Due to its longer threshing time and superior threshing and Separation performance, the axial-flow threshing and Separation device has become predominantly used in grain combine harvesters in recent years. Consequently, scholars have conducted extensive theoretical and experimental research on the threshing and Separation performance of axial-flow devices. The authors investigated the effects of structural and operational parameters of the axial flow threshing device on threshing rate and separation rate through experimental research, and subsequently optimized these parameters (*Liu et al., 2021;*

Jun-hui Zhang, Ph.D.; Lin Zhao, Ph.D.; Shu-juan Yi, Prof. Ph.D.; Dong-ming Zhang, Ph.D.; Xin Zhang, master degree

Wu et al., 2022; Zhang et al., 2025; Liu et al., 2023). Through theoretical analysis, a separation probability model for the vertical axial flow threshing and separation device was developed. The results demonstrate that the structural and motion parameters of the drum significantly influence separation efficiency (*Dong et al., 1988*). In recent years, with millet and other coarse grain crops are more and more recognized by the public, millet harvesting process mechanization requirements are higher and higher. Research on the mechanical properties of millet grains and stems has progressively deepened, providing a solid foundation for the development of threshing devices specifically adapted to the unique characteristics of millet (*Zhang et al., 2018; Zhang et al., 2019; Yang et al., 2015*). Through experimental studies on the threshing process of millet, it was concluded that the rasp bar type axial flow method is most suitable for threshing and separating millet due to its specific characteristics (*Liang et al., 2015; Kang et al., 2017*).



In conclusion, while extensive experimental research has been conducted on the longitudinal axial flow threshing and separation process, there is a notable deficiency in the literature regarding theoretical models of this process. It is imperative to elucidate the impact of grain material characteristics, structural parameters, and operational parameters of the threshing device on the performance of the longitudinal axial flow threshing and separating system. This research will provide a theoretical foundation for designing and developing a longitudinal axial flow threshing and separating device tailored to the specific characteristics of millet.

MATERIALS AND METHODS

Structure and working principles of the single longitudinal axial flow threshing and separation device

The single longitudinal axial flow threshing and separation device is shown in Fig. 1(a). This device primarily comprises the feeding mechanism, threshing cylinder, cover plate, material collection trolley, and control system.

When the device is working, millet is fed into the axial threshing and separation device through the feeding device, and the action process of grain in the single longitudinal axial flow threshing and separation device can be divided into two distinct phases: threshing and separation. The threshing process is completed by rubbing and striking between the rasp bar-nail teeth combined threshing components, the concave plate and the material in the drum. The threshed seeds overcome the resistance of the stalk layer, pass through the grid of the concave plate, and fall into the material collection trolley, thereby completing the separation process.

(a) Primarily comprises of the device *(b) Material collection trolley*

Fig. 1 - Diagram illustrating the single longitudinal axial flow threshing and separation device

1 – Conveyor; 2 – Feeding mechanism; 3 – Threshing cylinder; 4 – Cover plate; 5 – Material collection trolley; 6 – Control system

The material collection trolley (as showed in Fig. 1(b)) consists of a 14×16 matrix of collection buckets, with each bucket measuring 10cm×10cm. During the single longitudinal axial flow threshing and separation device test, this trolley is employed to gather materials threshed from different locations within the device.

Theoretical model for the single longitudinal axial flow threshing and separation device

The cumulative separation rate is a critical metric for evaluating the performance of the axial flow threshing and separation device. This parameter is influenced by the physical properties of the grain, as well as the structural and operational parameters of the threshing and separation device. In the process of investigating their relationship, the following assumptions were made to streamline the calculations.

① The probability of grain being threshed and separated in the single longitudinal axial flow threshing and Separation device varies along the axial position. This variation is influenced by the characteristic parameters of the grain as well as the structural and operational parameters of the device.

② The probability of grains being threshed within an axial differential element is directly proportional to the quantity of unthreshed grains within that infinitesimal segment.

③ The likelihood of threshed grains being separated is directly proportional to the quantity of threshed but unseparated grains contained within the differential elements.

The coordinate system (as show in Fig. 2) was established on the single longitudinal axial flow threshing and separation device.

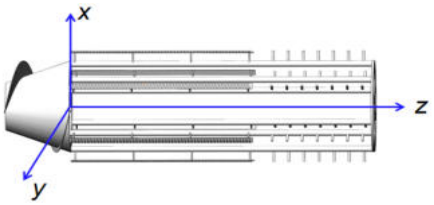


Fig. 2- The coordinate system of the single longitudinal flow threshing and separation device

(1) Threshing and separation model of the rasp bar section

The length of the rasp bar section was expressed as z_1 (as shown in Fig. 3). The total grain mass per unit length in the single longitudinal axial flow threshing and separation device was set as unit 1. The ratio of grain to grass was denoted by γ. And the cumulative threshing rate at the distance z from the feeding inlet was set as *T(z)*. When $0 \le z \le z_1$, the axial micro segment was located in the rasp bar part of the combined threshing and separation component. According to the second assumption, the cumulative threshing rate increment *dT* in differential element *dz* can be expressed as follows.

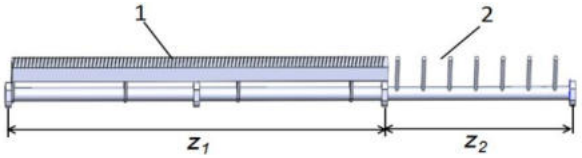

Fig. 3 - The configuration of the rasp bar-nail tooth threshing element
1 – Rasp bar section; 2 – Nail tooth section

$$dT(z) = a_{11}\frac{\gamma}{1+\gamma}\big(1 - T(z)\big)dz \tag{1}$$

where a_{11} is the threshing parameter of the rasp bar section. It is related to the characteristic parameters of millet, the structural parameters and working parameters of the single longitudinal axial flow threshing and separation device.

According to the actual working situation, the cumulative threshing rate of millet is zero when z equals zero. That is $T(z)\big|_{z=0} = 0$. By applying the method of separation of variables and integrating the differential equation in Equation (1), the cumulative threshing rate was obtained as follows:

$$T(z) = 1 - exp\left(-\frac{a_{11}\gamma}{1+\gamma}z\right) \tag{2}$$

The cumulative separation rate at the distance z from the feeding inlet was set as $F(z)$. According to the third assumption, the cumulative separation rate increment dF in axial differential element dz can be expressed as follows:

$$dF(z) = a_{12}\frac{\gamma}{1+\gamma}\big(T(z) - F(z)\big)dz \tag{3}$$

where a_{12} is the separation parameter of the rasp bar section.

According to the actual working situation, the cumulative separation rate of millet is zero when z equals zero. That is $F(z)\big|_{z=0} = 0$. Substituting this into Equation (3), the following expression is obtained:

$$F(z) = 1 + \frac{a_{12}}{a_{11} - a_{12}}exp\left(-\frac{a_{11}\gamma}{1+\gamma}z\right) - \frac{a_{11}}{a_{11} - a_{12}}exp\left(-\frac{a_{12}\gamma}{1+\gamma}z\right) \tag{4}$$

It can be seen from Equation (2) and (4) that both the cumulative threshing rate and the cumulative separation rate of the rasp bar section are an exponential function of the axial coordinate z.

(2) Threshing and separation model of the nail tooth section

The length of the nail tooth section was expressed as z_2 (as shown in Fig. 3). When $z_1 \le z \le z_1+z_2$, the axial micro-segment was located in the nail tooth section of the combined threshing and separation component. According to the second assumption, the cumulative threshing rate increment dT in differential element dz can be expressed as follows.

$$dT(z) = a_{21}\frac{\gamma}{1+\gamma}\big(1 - T(z)\big)dz \tag{5}$$

where a_{21} is the threshing parameter of the nail tooth section.

According to Equation (2), when $z = z_1$, the cumulative threshing rate can be determined and subsequently integrated into Equation (5). Then, by applying the method of separation of variables, the cumulative threshing rate of the nail tooth section can be obtained.

$$T(z) = 1 - exp\left(-\frac{a_{21}\gamma}{1+\gamma}z - \left(\frac{a_{11}\gamma}{1+\gamma} - \frac{a_{21}\gamma}{1+\gamma}\right)z_1\right) \tag{6}$$

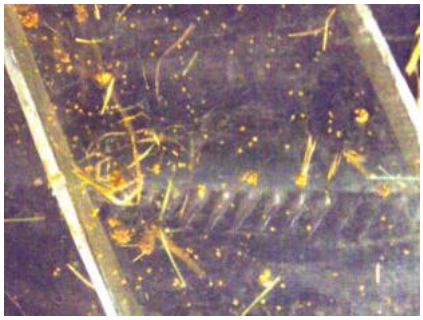
According to the third assumption, the cumulative separation rate increment dF in axial differential element dz can be expressed as follows:

$$dF(z) = \frac{a_{22}\gamma}{1+\gamma}\big(T(z) - F(z)\big)dz \tag{7}$$

where a_{22} is the separation parameter of the nail tooth section.

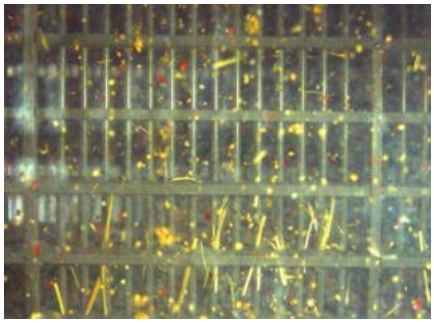
From Equation (4), it can be seen that when $z = z_1$, the cumulative separation rate can be determined and then the expression for the cumulative separation rate can be derived as follows:

$$\begin{aligned} F(z) = 1 + \frac{a_{22}}{a_{21}-a_{22}}exp\left(-\frac{a_{21}\gamma}{1+\gamma}(z-z_1) - \frac{a_{11}\gamma}{1+\gamma}z_1\right) \\ + \left(F(z_1) - 1 - \frac{a_{22}}{a_{21}-a_{22}}exp\left(-\frac{a_{11}\gamma}{1+\gamma}z_1\right)\right)exp\left(-\frac{a_{22}\gamma}{1+\gamma}(z-z_1)\right) \end{aligned} \tag{8}$$



It can be seen from Equations (6) and (8) that both the cumulative threshing rate and the cumulative separation rate of the nail tooth section are an exponential function of the axial coordinate z.

Construction of the threshing parameters and the separation parameters



From the derivation of the cumulative threshing rate $T(z)$ and the cumulative separation rate $F(z)$, it is evident that both the threshing parameters a_{11}, a_{21} and the separation parameters a_{12}, a_{22} are dimensionless quantities. In order to determine the threshing parameters and the separation parameters, the threshing process and the separation process of the single longitudinal axial flow threshing and separation device were analyzed.

(1) Construction of the threshing parameters

In the threshing and separation space, there is a periodic impact and rubbing between the rasp bar-nail tooth threshing element and the grain material through the high speed rotation of the threshing component. The grain will be separated from main stem when the acting force between the rasp bar threshing element and the grain material exceeds the connection force of grain and petiole, petiole and branch, branch and main stem. Then the threshing process of the grain will be completed (as Figure 4a).

(a) Threshing process of the grain

(b) Separation process of the grain

Fig. 4 - Threshing and separation process of the grain

The interaction force between the rasp bar section and grain material is mainly determined by the number of rasp bars, the number of transverse lattice on the concave plate and the relative linear velocity between rasps bar and grain material. The connection force of grain and petiole, petiole and branch, branch and main stem is related to the moisture content of millet. According to the analysis of the influencing factors in the threshing process and the theory of dimensional analysis, the following expression of the threshing parameter a_{11} was constructed.

$$a_{11} = c_{10} + c_{11}\frac{n_1 n_2}{h} + c_{12}\frac{n_1 n_2}{hv} \tag{9}$$

where n_1 is the number of rasp bar, n_2 is the number of concave panels, v is the linear velocity of the bar, h is the moisture content of grain, c_{10}, c_{11} and c_{2} are undetermined coefficients.

The interaction force between the nail tooth section and grain material mainly depends on the number of nail teeth, the diameter of nail teeth, the distance between nail teeth and the relative linear speed of the material. According to the theory of dimensional analysis, the following expression of the threshing parameter a_{21} was constructed.

$$a_{21} = c_{20} + c_{21}\frac{n_0 n_1 d_0}{l_0 h} + c_{22}\frac{n_0 n_1 d_0}{l_0 h v} \tag{10}$$

where n_0 is the number of nail teeth in a single combined threshing component, d_0 is the diameter of the nail teeth, l_0 is the distance between nail teeth, c_{20}, c_{21} and c_{22} are undetermined coefficients.

(2) Construction of the separation parameters

The threshed grains need to pass through the stem layer in the single longitudinal axial flow threshing and separation device and then through the grid gap of the concave plate to complete the separation process (as shown in Figure 4b). The resistance of grains passing through the stem layer is proportional to the thickness of the stem layer *(Yi et al., 2008; Vlăduţ et al., 2022)*. The thickness of the stem layer in the threshing separation space mainly depends on the size of the threshing and separation device, the feeding rate of millet, the density of grains and the movement time of grains in the threshing separation space. Therefore, it is assumed that the probability of the grain passing through the stalk layer is inversely proportional to the resistance of the stalk layer. And the resistance of the straw layer is directly proportional to the feeding rate and it is inversely proportional to the roller radius, rotational speed and grain density. The larger the area of grid holes in the concave plate, the easier it is for the seeds to separate through the concave plate. Therefore, it is assumed that the probability of the grain passing through the concave plate is directly proportional to the area of the grid hole of the concave plate. According to the theory of dimensional analysis, the following parameter expressions are constructed.

$$a_{12} = c_{10} + c_{11}\frac{\rho(2R - n_2 l_1)(l - n_3 d_1)}{q} + c_{12}\frac{\rho(2R - n_2 l_1)(l - n_3 d_1)v}{q} \tag{11}$$

where ρ is the density of the grain, n_3 is the number of concave strips, d_1 is the diameter of a concave strip, l_0 is the length of threshing drum, l_1 is the width of the transverse lattice of the concave plate, q is the feed rate, C_{10}, C_{11} and C_{12} are undetermined coefficients.

In the nail tooth section, the stirring effect of nail teeth makes the material in the threshing space loose and increases the probability of grains passing through the stem layer and being separated from the concave plate gap. The separation parameter of the nail teeth is also influenced by the number of nail teeth, their height and the distance between them. According to the theory of dimensional analysis, the following parameter equation is constructed.

$$a_{22} = C_{20} + C_{21}\frac{\rho n_0 n_1 h_0(2R - n_2 l_1)(l - n_3 d_1)}{l_0 q} + C_{22}\frac{\rho n_0 n_1 h_0(2R - n_2 l_1)(l - n_3 d_1)v}{l_0 q} \tag{12}$$

where h_0 is the height of nail teeth, C_{20}, C_{21} and C_{22} are undetermined coefficients.

Fitting test and validation test

Longgu 31 was selected as the test material to carry out the single longitudinal axial flow threshing and separation test in the harvest laboratory of Heilongjiang Bayi Agricultural University (as shown in Fig. 5). The ratio of grain to grass was 1.61. The grain density was 1053 kg/m^3.

(1) Fitting test

There were undetermined coefficients in the threshing parameters a_{11}, a_{21} and the separation parameters a_{12}, a_{22} of the single longitudinal axial flow threshing and separation theoretical model. In order to determine these undetermined coefficients, a single longitudinal axial flow threshing and separation device was built and laboratory tests were carried out. Then the undetermined coefficients in the theoretical model could be determined by fitting equation (4) and (8) with the test data.

The feeding rate was 1.5kg/s. And the grain moisture content was 25% ± 1%. The rotational speed was 800 r/min. All the experiments were repeated 3 times.

(a) Experiment preparation *(b) Experiment in progress*

Fig. 5 - Laboratory testing of threshing and separation performance for Millet

(2) Validation test

To validate the theoretical model, single-factor experiments were conducted on moisture content, feeding rate, and rotational speed. The moisture content of millet was varied between 17% and 32%. The feeding rate was set within the range of 1.5 kg/s to 3.0 kg/s. The rotational speed was tested in the range of 600 to 1000 r/min.

The material receiving trolley was used to collect threshed material from different axial coordinates. The millet in each bucket was separated, weighed, and the weight recorded. At the same time, the mixed millet and unthreshed millet were collected at the straw outlet, weighed, and the weight recorded. Formula (13) was applied to calculate the separation rate of the receiving bucket numbered *i*, and formula (14) was used to calculate the cumulative separation rate at coordinate *z*.

$$F_i = \frac{m_i}{\sum_{i=1}^{14} m_i + m_{mixed} + m_{unthreshed}} \times 100\% \quad (13)$$

$$F(z_i) = \frac{\sum_{j=1}^{i} m_j}{\sum_{i=1}^{14} m_i + m_{mixed} + m_{unthreshed}} \times 100\% \quad (14)$$

RESULTS

The fitting results of undetermined coefficients for threshing parameters and separation parameters

The variation data of the cumulative separation rate along the axis, obtained under the aforementioned test conditions, were presented in Table 1.

Table 1

Single longitudinal axial flow threshing separation laboratory test data of millet

z	Cumulative separation rate			
	Test one	Test two	Test three	Mean value
[m]	[%]	[%]	[%]	[%]
0.00	0.0000	0.0000	0.0000	0.0000
0.01	7.0721	6.8296	6.2932	6.7316
0.02	19.9198	17.7207	18.9419	18.8608

0.05	66.9131	66.4892	71.4036	68.2686

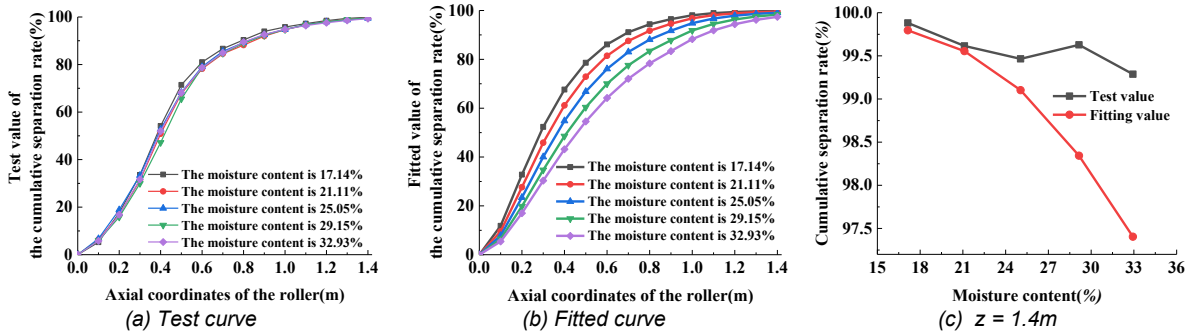
z	Cumulative separation rate			
	Test one	Test two	Test three	Mean value
[m]	[%]	[%]	[%]	[%]
0.06	78.1907	78.2470	80.8602	79.0993
0.07	84.7583	85.2418	86.6465	85.5489
0.08	88.9557	88.4965	90.2538	89.2353
0.09	91.7402	92.3759	93.5216	92.5459
0.10	94.1897	94.7856	95.4434	94.8062
0.11	96.3431	96.6883	97.1033	96.7115
0.12	98.0653	97.6089	98.1360	97.9368
0.13	99.0231	98.5088	98.7495	98.7605
0.14	99.6204	99.3768	99.3977	99.4650

Curve fitted in MATLAB was utilized to fit the data. The fitted process was divided into two segments: the rasp bar section and the nail tooth section, as the cumulative separation rate was a piecewise function. For $0 \le z \le z_1$, the cumulative separation rate of the rasp bar section was fitted using the test data. Consequently, the values of the undetermined coefficients in the threshing and separation parameters were obtained. The equations of a_{11} and a_{12} were then determined as follows:

$$a_{11} = -2.918 + 0.02976\frac{n_1 n_2}{h} - 0.4989\frac{n_1 n_2}{hv} \tag{15}$$

$$a_{12} = 3.867 + 0.01523\frac{\rho(2R - n_2 l_1)(l_0 - n_3 d_1)}{q} + (8.031e - 05)\frac{\rho(2R - n_2 l_1)(l_0 - n_3 d_1)v}{q} \tag{16}$$

Based on the established threshing parameter a_{11} and separation parameter a_{12} in the rasp bar section, parameter fitting for the nail tooth section was carried out. Consequently, the undetermined coefficients a_{21} and a_{22} were obtained. The equations for a_{21} and a_{22} were then determined as follows:



$$a_{21} = 8.165 - 2.464\frac{n_0 n_1 d_0}{l_0 h} + 4.999\frac{n_0 n_1 d_0}{l_0 hv} \tag{17}$$

$$a_{22} = -3.662 + 0.02495\frac{\rho n_0 n_1 h_0(2R - n_2 l_1)(l - n_3 d_1)}{l_0 q} + (5.037e - 04)\frac{\rho n_0 n_1 h_0(2R - n_2 l_1)(l - n_3 d_1)v}{l_0 q} \tag{18}$$

Error Analysis of Calculated Values and Validation Experiments

To validate the accuracy of the theoretical model, a single-factor experiment of millet was conducted using the single longitudinal axial flow threshing and separation device. The factors selected for testing included millet moisture content, feeding rate, and rotational speed. For each varying factor, the separation rate within the buckets was measured, and cumulative separation rate curves as functions of the axial coordinate were plotted. These experimental curves were subsequently compared with the fitted curve obtained from the theoretical model.

(1) Evaluation of the fitting effect of moisture content as a single factor

(a) Test curve (b) Fitted curve (c) z = 1.4m

Fig. 6 - Cumulative separation rate curve under varying moisture content conditions

Table 2

Error analysis table for single factor test of moisture content

	Error	Moisture content [%]				
		17.14	21.11	25.05	29.15	32.93
Rasp bar section	SSE	0.0926	0.0514	0.0049	0.0245	0.0848
	R-Squared	0.9769	0.9863	0.9987	0.9934	0.9777
Nail tooth section	SSE	0.0015	0.0014	0.0001	0.0039	0.0169
	R-Squared	0.9997	0.9997	0.9999	0.9993	0.9969
Rasp bar-Nail tooth	SSE	0.0934	0.0522	0.0049	0.0264	0.0931
	R-Squared	0.9893	0.9938	0.9994	0.9968	0.9890

The rotational speed was set to 800 r/min, the feeding rate was maintained at 2 kg/s, and the moisture content levels of the millet samples were 17.14%, 21.11%, 25.05%, 29.15%, and 32.93%. The experimental results and fitted values of the cumulative separation rate under different moisture contents were illustrated in Fig. 6. Table 2 presents the SSE and R-Squared values for both the fitted and tested data, specifically detailing the errors for the rasp bar section, the nail tooth section, and the combined rasp bar-nail tooth configuration.

As shown in Fig. 6a) and b), the experimental and fitted values of the cumulative separation rate exhibit exponential distributions with the axial coordinates. On the same axial coordinate, as water content increases, the magnitude of change in the fitting value exceeds that of the test value. As illustrated in Fig. 6c), upon completion of the threshing separation process, both the experimental and fitted values of the cumulative separation rate exceed 97%. As the moisture content increases, both the measured cumulative separation rate and the fitted cumulative separation rate exhibit a downward trend. However, the magnitude of change differs: the measured value decreases by 0.6%, while the fitted value decreases by 2.39%. As shown in Table 2, the SSE values for the rasp bar section, nail tooth section, and the combination of rasp bar - nail tooth components are all less than 1, while the *R-squared* values exceed 0.97. This indicates that the established threshing separation model fits well with changes in moisture content. However, the *R-squared* values for the rasp bar section are consistently lower than those for the nail tooth section, indicating that the model fits the rasp bar section less accurately compared to the nail tooth section.

(2) Evaluation of the fitting effect of feeding rate as a single factor

When the moisture content of millet was 25.0±0.2% and the rotational speed was set to 800 r/min, a single-factor experiment on feeding rate was conducted using the single longitudinal axial flow threshing and separation device. The feeding rate tested were 1.5 kg/s, 2.0 kg/s, 2.5 kg/s, 3.0 kg/s, and 3.5 kg/s. Fig. 7 presents the tested and fitted values of the cumulative separation rate under these different feeding quantities. Table 3 presents the *SSE* and *R-Squared* values for both the fitted data and test data in the single-factor experiment concerning feeding rate.

(a) Test curve *(b) Fitted curve* *(c) z = 1.4m*

Fig. 7 - Cumulative separation rate curve under varying feeding rate conditions

Table 3

Error analysis table for single factor test of feeding rate

	Error	Feeding rate [kg/s]				
		1.0	1.5	2.0	2.5	3.0
Rasp bar section	SSE	0.1031	0.0049	0.0157	0.0266	0.0120
	R-Squared	0.9704	0.9987	0.9960	0.9931	0.9966

	Error	Feeding rate [kg/s]				
		1.0	1.5	2.0	2.5	3.0
Nail tooth section	SSE	0.0076	0.0001	0.0022	0.0071	0.0052
	R-Squared	0.9986	0.9999	0.9996	0.9987	0.9990
Rasp bar-Nail tooth	SSE	0.1084	0.0049	0.0172	0.0319	0.0163
	R-Squared	0.9862	0.9994	0.9980	0.9963	0.9980

As shown in Fig. 7a) and b), the experimental and fitted values of the cumulative separation rate exhibit exponential distributions with the axial coordinates. As illustrated in Fig. 7c), upon completion of the threshing separation process, the measured cumulative separation rate exceeded 98.30%. The lowest fitted value was 94.76% at a feeding rate of 3.0 kg/s, resulting in a discrepancy of -3.54% between the fitted and measured values. As shown in Table 3, the *R-Squared* values for both the nail tooth section and the rasp bar-nail tooth combination element exceed 0.98. The minimum R-Squared value for the rasp bar section is 0.97, with all fitting values exceeding 0.95. The aforementioned results indicate that the function model exhibits satisfactory fitting performance in response to variations in feeding rate. However, the fitting accuracy for the rasp bar is comparatively lower than that for the nail tooth.

(3) Evaluation of the fitting effect of rotational speed as a single factor

When the moisture content of millet was 25.0 ± 0.20% and the feeding rate was 2.5 kg/s, a single-factor experiment on rotational speed was conducted using the single longitudinal axial flow threshing and separation device. The tested rotational speeds included 600 r/min, 700 r/min, 800 r/min, 900 r/min, and 1000 r/min. Fig. 8 shows the measured and fitted values of cumulative separation efficiency under different rotational speeds. Table 4 shows the *SSE* and *R-Squared* values for both the fitted and test datasets in the single-factor experiment related to rotational speed.

(a) Test curve (b) Fitted curve (c)z = 1.4m

Fig. 8 - Cumulative separation rate curve under varying rotational speed conditions

Table4

Error analysis table for single factor test of rotational speed

	Error	Rotational speed [r/min]				
		600	700	800	900	1000
Rasp bar section	SSE	1.3940	0.0624	0.0049	0.0534	0.0884
	R-Squared	0.6211	0.9827	0.9987	0.9860	0.9763
Nail tooth section	SSE	0.7390	0.0168	0.0001	0.0006	0.0046
	R-Squared	0.8653	0.9969	0.9999	0.9999	0.9992
Rasp bar-Nail tooth	SSE	1.8879	0.0722	0.0049	0.0537	0.0911
	R-Squared	0.7741	0.9913	0.9994	0.9937	0.9891

It can be observed from Fig. 8a) and Fig. 8b) that at the rotational speed of 600 r/min, the fitted curve significantly deviates from the test curve. Furthermore, as shown in Fig. 8(c), when the rotational speed is 600 r/min and z = 1.4, the fitted cumulative separation rate is 83.09%, resulting in a difference of -16.59% compared to the test value. As illustrated in Table 4, when the rotating speed is 600 r/min, the *SSE* values for the rasp bar section and the rasp bar-nail tooth combination exceed 1.

Additionally, the *R-Squared* values for the rasp bar, nail tooth, and rasp bar-nail tooth combination are 0.62, 0.86, and 0.77, all of which are significantly lower than the threshold of 0.95. Consequently, the function model exhibits poor fitting performance at this rotating speed. When the speed is set to 700 r/min, 800 r/min, 900 r/min, and 1000 r/min, the *SSE* values are all below 0.1, while the *R-Squared* values exceed 0.97. Therefore, the function model demonstrates excellent fitting performance.

CONCLUSIONS

(1) Based on the material characteristics of millet, a threshing and separation model utilizing a single longitudinal axial flow threshing separation device was developed. Analysis revealed that both the cumulative threshing rate and the cumulative separation rate of the rasp bar section and the nail tooth section exhibited exponential relationships with the axial coordinate. By examining the threshing and separation processes of millet within the single longitudinal axial flow threshing and separation device, functional expressions for the threshing parameters and separation parameters were formulated.

(2) A single longitudinal axial flow threshing and separation test platform was developed to perform fitting tests. The undetermined coefficients of the threshing and separation parameters were determined through data fitting using Matlab. This process clarified the influence of structural and material parameters on both the cumulative threshing rate and cumulative separation rate of the single longitudinal axial flow threshing and separation device.

(3) A single-factor test was conducted using the longitudinal axial flow threshing and separation device. Through the error analysis of the single-factor test curve and the fitting curve, it was found that when the moisture content ranged from 17.14% to 32.93%, the feed rate was between 1 and 3 kg/s, and the rotational speed was within 700-1000 r/min, the R-Squared values for both the calculated and experimental cumulative separation rate function models exceeded 0.97. This indicates that the model exhibits excellent fit and theoretical capability.

ABSTRACT
Crop diseases significantly diminish agricultural production, resulting in economic losses. Early detection and species identification remain major challenges. This paper introduces a lightweight Convolutional Neural Network (LCNet) designed for the detection of corn diseases, including blight, common rust, and gray leaf spot, using an efficient, low-latency model. The suggested architecture consists of three convolutional layers, three pooling layers, and one fully linked layer. Experimental findings indicate that LCNet surpasses the pre trained architecture MobileNetV2, DenseNet201, ResNet50, and different past study with an average accuracy of 94.65%. This method enables prompt disease identification, assisting farmers in averting significant crop losses while minimizing human labor in oversight and administration.

ABSTRACT IN HINDI (हिन्दी)
फसल की बीमारियाँ कृषि उत्पादन को काफी कम कर देती हैं, जिसके परिणामस्वरूप आर्थिक नुकसान होता है। इनका शीघ्र पता लगाना और प्रजातियों की पहचान प्रमुख चुनौतियाँ बनी हुई हैं। यह पेपर एक हल्के कन्वोल्यूशनल न्यूरल नेटवर्क (एलसीनेट) का परिचय देता है, जिसे एक कुशल, कम-विलंबता मॉडल का उपयोग करके ब्लाइट, सामान्य जंग और ग्रे लीफ स्पॉट सहित मकई रोगों का पता लगाने के लिए डिज़ाइन किया गया है। सुझाई गई वास्तुकला में तीन संकेंद्रित परतें, तीन पूलिंग परतें और एक पूरी तरह से जुड़ी हुई परत शामिल हैं। प्रायोगिक निष्कर्षों से पता चलता है कि एलसीनेट 94.65% की औसत सटीकता के साथ पूर्व प्रशिक्षित आर्किटेक्चर मोबाइलनेट वी2, डेंसनेट201 रेसनेट50, और विभिन्न पिछले अध्ययनों से आगे निकल जाता है। यह विधि शीघ्र रोग की पहचान करने में सक्षम बनाती है, जिससे किसानों को फसल के महत्वपूर्ण नुकसान को रोकने में सहायता मिलेगी जबकि निरीक्षण और प्रशासन में कम से कम मानव श्रम की आवश्यकता होगी।

INTRODUCTION

The fast proliferation of plant diseases manifests an alarming risk to global crop production, especially for staple crops such as corn, which is a fundamental food supply for millions globally (*Khan et al., 2024*). Traditional disease detection approaches, dependent on human field inspections, are both time-intensive and deficient in the precision required for early-stage diagnosis (*Hossain et al., 2023*). Recent breakthroughs in artificial intelligence and deep learning have enabled the creation of automated, high-precision models for plant disease categorization, therefore markedly improving early detection capabilities (*Hassan et al., 2021*). Convolutional Neural Networks (CNNs) have become the predominant method owing to its capacity to extract hierarchical characteristics from leaf pictures, facilitating the recognition of intricate disease patterns *(Li et al., 2021*). CNNs have emerged as a preeminent method in image-based illness classification, owing to its capacity to acquire hierarchical information, hence enhancing both accuracy and dependability. Several CNN architectures, including MobileNetV2 (*Sandler et al., 2018a*), ConvNet (*Liu et al., 2022*), and EfficientNet (*Howard et al., 2017*) etc. have been applied in previous research to detect and classify plant diseases with high precision. Recent research was used CNN-based deep learning models to improve the categorization of plant leaf diseases. In their study, *Amin et al., (2022*) suggested an end-to-end deep learning system for the detection of corn leaf diseases. Their methodology used two pre-trained convolutional neural networks, EfficientNetB0 and DenseNet121, to derive deep feature representations from corn leaf photos. The retrieved features were concatenated to build a more informative feature set, enhancing model performance. Moreover, data augmentation methods were used to enhance the variety of training samples.

The model was trained and evaluated using the PlantVillage dataset, with an exceptional classification accuracy of 98.56%, surpassing other models such ResNet152 (98.37%) and InceptionV3 (96.26%). Similarly, *Khan et al., (2024*), examined the use of deep transfer learning for the fine-grained categorization of corn leaf diseases. They used four pre-trained deep learning architectures-VGGNet, InceptionV3, ResNet50, and InceptionResNetV2-to identify complex disease patterns in corn leaves. ResNet50 demonstrated exceptional performance, with a validation accuracy of 87.51%, a precision of 90.33%, and a recall of 99.80%, underscoring its proficiency in precise illness detection. This research highlights the capability of deep learning methodologies in enhancing plant disease categorization, facilitating the development of more effective and efficient diagnostic models.

This research presents a LCNet developed for the classification of corn leaf diseases, based on recent advancements. The proposed model improves computational efficiency with a streamlined architecture of three convolutional layers, three pooling layers, and one fully connected layer, therefore significantly reducing the number of trainable parameters while maintaining satisfactory classification accuracy. The key contributions of this study lie in the development of a lightweight CNN-based model specifically designed for the detection of corn leaf diseases, which are summarized as follows:

1. Develop a compact and Lightweight CNN model tailored for the detection of corn diseases such as blight, common rust, and gray leaf spot.
2. The architecture comprising three convolutional layers, three pooling layers, and a fully connected layer to achieve a balance between accuracy and computational efficiency.
3. Achieve superior classification performance with LCNet, outperforming models like MobileNetV2, DenseNet201, and ResNet50, with an average accuracy of 94.65%.
4. Facilitate early and precise identification of crop diseases, aiding farmers in preventing major yield losses while reducing reliance on manual monitoring.
5. Conduct thorough experimental evaluations and comparative studies to validate the proposed model's effectiveness against established deep learning approaches.

The remainder of this paper is organized as follows: The next section provides a review of related studies. The subsequent section details the datasets, methodology, and research framework. Following this, the experimental results are presented and compared with previous works. Lastly, the final section summarizes the conclusions and outlines potential future research directions.

LITERATURE SURVEY

Recent years have seen considerable interest in the early identification and categorization of agricultural diseases with deep learning methods. Conventional techniques for disease diagnosis, including physical examination by agricultural specialists, are often time-consuming, labor intensive, and susceptible to inaccuracies. Researchers have investigated numerous CNN-based algorithms for automated illness diagnosis to tackle these problems. Notable designs, such MobileNetV2 (*Howard et al., 2017*), EfficientNet (*Tan et al., 2019*), and ConvNet *(Liu et al., 2022*) etc. have been widely used owing to their superior accuracy and resilience. Nonetheless, these models sometimes entail substantial computing expenses, rendering them less appropriate for real-time applications in resource-limited agricultural settings.

The article written by *Prasetyo et al., (2023*), focuses on classifying corn plant leaves to distinguish healthy leaves from three disease types: Northern Leaf Blight, Common Rust, and Gray Leaf Spot, using a CNN model based on the ResNet-9 architecture to develop a strong classification system. The dataset included 9,145 photos, allocated into 80% for training and 20% for testing. The researchers performed an epoch comparison to ascertain the ideal model performance across five values: 5, 25, 55, 75, and 100 epochs. The optimal accuracy was attained after 100 epochs, which was then used for the final model training. Furthermore, hyperparameter tweaking experiments were conducted, concentrating on the number of workers (num_workers = 4) and batch size (batch_size = 32), which enhanced the model's performance. The final model had a classification accuracy of 99%. The research study done by *Rachmad et al., (2023*), examined the use of CNN for the early identification and categorization of corn illnesses, with the objective of reducing production losses in Indonesia, a nation heavily reliant on corn. The research used a collection of corn leaf photos gathered from agricultural areas in the Madura Region, focusing on four categorization categories: healthy, gray leaf spot, blight, and common rust. A variety of CNN designs, such as SqueezeNet, AlexNet, ResNet-101, ResNet-50, and ResNet-18, were assessed for their efficacy in illness categorization.

The research used Adam optimization with a learning rate of 0.0001, training models for five epochs with 100 iterations, and implemented a 70:30 division for training and testing. Among the evaluated designs, ResNet-50 exhibited exceptional performance, with an accuracy of 95.59%. These results underscore the capability of CNN-based models in automating corn disease identification, enabling early intervention to reduce agricultural losses.

Ariska et al., (2024), investigated the use of CNN for the automated categorization of corn leaf diseases, using a dataset of 2,145 photos of leaf blight and 1,574 images of leaf spot, capitalizing on the network's capacity to extract and integrate local features for efficient disease detection. The model attained a remarkable classification accuracy of 99%, culminating in a final training accuracy of 99.06% and a validation accuracy of 98.50%. The research proposes further improvements by integrating contemporary architectures like EfficientNet B3 with transfer learning or MobileNet to boost accuracy and processing efficiency. These results highlight the efficacy of CNN-based solutions in precision agriculture, enabling early disease identification and enhanced crop management tactics. *Waheed et al., (2020*), examined the worldwide importance of corn and the adverse effects of diseases such as common rust, gray leaf spot, and northern corn leaf blight, highlighting the need for accurate and prompt disease identification to enhance crop output and quality. The suggested DenseNet model attained an impressive accuracy of 98.06%, surpassing conventional Convolutional Neural Network (CNN) designs like EfficientNet, VGG19Net, NASNet, and Xception Net, while using less parameters. This efficiency indicates the model's applicability for real-time use in agricultural contexts. The research highlights the effectiveness of enhanced deep learning models in diagnosing agricultural diseases, facilitating more sustainable and productive farming methods.

The investigation done by *Ahila Priyadharshini et al., (2019)*, presents a deep learning methodology using a modified LeNet architecture for the categorization of corn leaf diseases. The proposed CNN model is trained on corn leaf images from the PlantVillage dataset, differentiating among four categories: three disease classifications and one healthy category. The experimental findings indicate the model's efficacy, with an accuracy of 97.89%. These results underscore the efficacy of deep learning in agricultural disease diagnosis, providing an economical and precise option for automated crop health monitoring. The work underscores the significance of CNN-based models in precision agriculture, establishing a basis for future research on the optimization and implementation of these systems in practical agricultural contexts. The paper of *Zhang et al., (2021),* presents a CNN model enhanced with a Multi-Activation Function (MAF) module to improve detection accuracy for corn illnesses. Considering the constraints posed by limited illness datasets, the study employs image preprocessing methods to facilitate data augmentation. Furthermore, transfer learning and a warm-up training technique are used to expedite the learning process. The suggested model effectively identifies three corn diseases-maculopathy, rust, and blight-attaining a validation accuracy of 97.41%. To evaluate the efficacy of the MAF module, baseline testing and ablation experiments were performed on many CNN architectures. The findings indicate that the incorporation of the MAF module significantly enhances CNN performance, with optimal results achieved by the amalgamation of Sigmoid, ReLU, and Mish activation functions on ResNet50, resulting in a 2.33% increase in accuracy. The results illustrate the efficacy of optimized CNN models in agricultural contexts, providing a dependable and efficient method for automated corn disease identification.

MATERIALS AND METHODS

The present study adopts a deep learning-based methodology for the automated detection of corn leaf diseases using a lightweight Convolutional Neural Network (LCNet). The proposed framework involves several key stages, including data acquisition, preprocessing, dataset partitioning, model design, training, and performance evaluation (Fig. 1). A diverse set of corn leaf images representing diseases such as blight, common rust, and gray leaf spot was utilized to ensure accurate classification. The LCNet architecture was specifically designed to be computationally efficient, incorporating multiple convolutional and pooling layers to extract relevant features while maintaining low-latency predictions (Fig. 2). The model’s performance was benchmarked against well-known deep learning models such as MobileNetV2, DenseNet201, and ResNet50. Standard evaluation metrics accuracy, precision, recall, and F1-score were employed to assess the model’s effectiveness. Developed using deep learning frameworks, the experimental results demonstrated that LCNet achieved superior classification accuracy with reduced computational overhead, making it a suitable candidate for real-time deployment in agricultural environments.

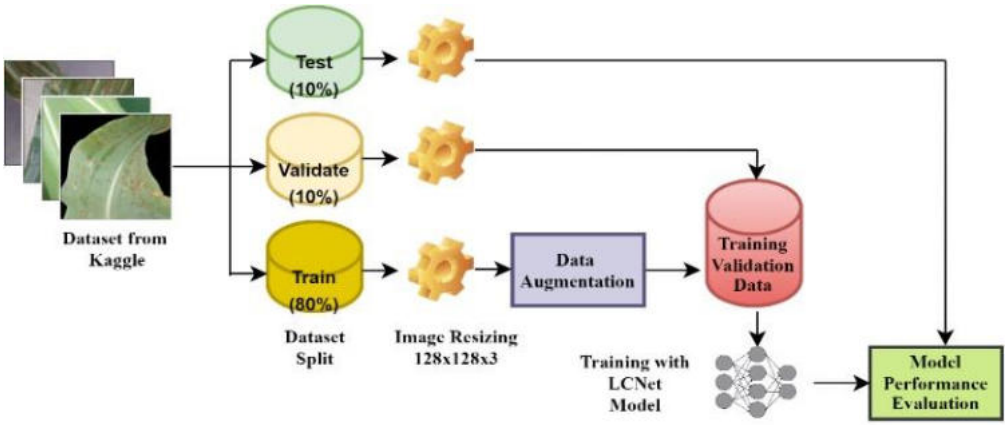

Fig. 1 - Proposed Methodology for CNN based Corn Leaf Disease Classification

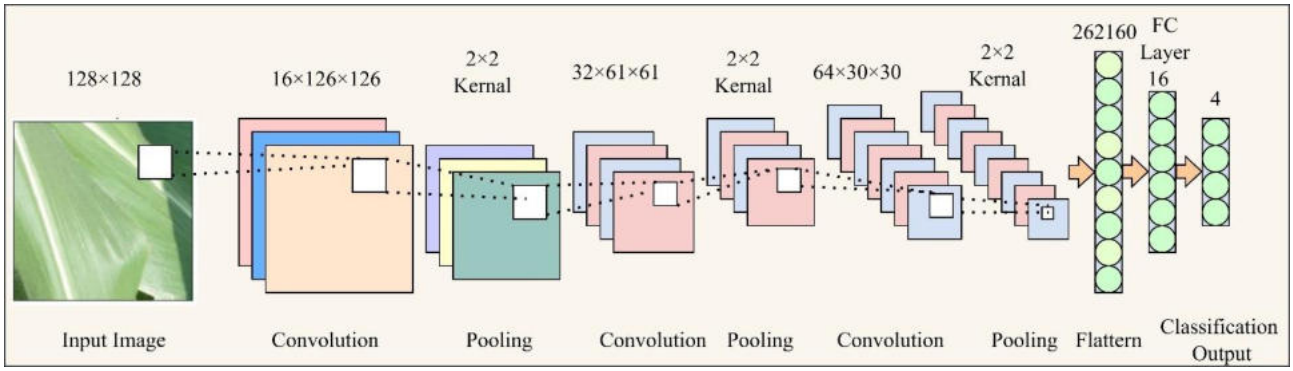

Fig. 2 - Proposed LCNet Model

A. Datasets:

The suggested LCNet model along with existing deep learning architectures, namely MobileNetV2, DenseNet201, and ResNet50, was trained and assessed using a dataset of corn leaf images. These models were employed to classify and identify diseases in previously unseen images. This work used a dataset of 4,188 corn leaf images obtained from Kaggle, classified into four categories: three disease types-common rust, gray leaf spot, and blight-and one healthy category.

To standardize input dimensions, the pictures were scaled to 128×128 pixels for the proposed CNN model. Pixel values were normalized by dividing each by 255, facilitating network weight initialization and enhancing model convergence during training. To facilitate efficient model training and assessment, the dataset was partitioned into training, validation, and testing subsets with an 80:10:10 distribution, a strategy derived from *Sahu et al., (2021*). As a result, 3,348 photos were designated for training, 419 for validation, and 421 for testing. The distribution of the corn dataset is clearly illustrated in (Figs. 3-4). This organized data segmentation enabled effective model training, reducing overfitting and ensuring the model generalizes well to new data. This technique seeks to provide an efficient and precise corn disease detection system with enhanced computing performance.

B. Transfer Learning via popular deep learning pre-trained models:

Training a network from scratch requires a lot of time and resources. Transfer learning is one of the solutions to this problem. It is a set of techniques rather than a single strategy (*Atila et al., 2021*), in which certain pre-trained network weights are employed during training, to handle different problems. According to the requirement of the new problem, the bottom layer of the trained model was replaced by a new layer.

ResNet50: TheResNet50 is a deep convolutional neural network model developed to tackle the difficulties associated with training very deep networks, especially the vanishing gradient issue. It belongs to the Residual Network (ResNet) family, proposed by *He et al., (2016)*, and has 50 layers, making it very efficient for picture classification and identification applications. The fundamental novelty of ResNet50 is its implementation of residual learning via skip connections, enabling

information to circumvent certain levels and directly reach deeper layers. This approach guarantees that deeper networks may be trained effectively without experiencing performance deterioration. The ResNet50 design comprises convolutional layers, batch normalization, ReLU activation, pooling layers, and fully connected layers, with residual blocks crucial for ensuring steady gradient propagation. Each residual block has three convolutional layers (1×1, 3×3, and 1×1), which enhance feature extraction and facilitate dimensionality reduction. ResNet50 utilizes identity mappings to facilitate the learning of intricate patterns while ensuring computational efficiency. One significant feature of ResNet50 is its capacity to attain high accuracy in picture classification tasks while incurring comparatively lower computing expenses than deeper models. It has been extensively used in medical image analysis, object identification, autonomous driving, and transfer learning because of its proficiency in generalizing across diverse domains. ResNet50, pre-trained on extensive datasets such as ImageNet, may be fine-tuned for applications, making it a potent and versatile instrument for diverse computer vision tasks.

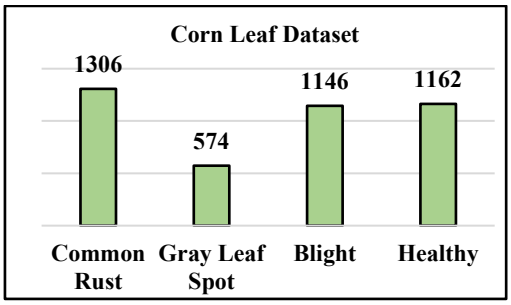

Fig. 3 - Corn Leaf Dataset

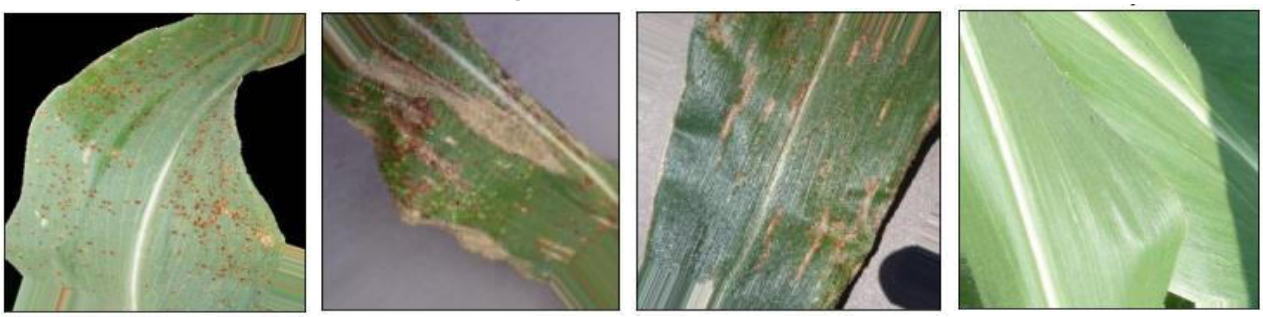

Fig. 4 - Image from Corn Leaf Dataset

(a) Common Rust Disease; (b) Blight Disease; (c) Gray Leaf Spot Disease; (d) Healthy images

DenseNet: This deep learning architecture was designed to enhance feature propagation and address the challenge of vanishing gradients commonly encountered in convolutional neural networks (CNNs). Introduced by *Huang et al., (2017*), DenseNet improves network performance through the implementation of dense connections, where each layer is directly connected to all subsequent layers within a dense block. Unlike traditional CNNs that follow a sequential information flow, DenseNet promotes the reuse of feature maps across layers, thereby improving gradient transmission and supporting efficient feature learning. Its structure comprises densely connected blocks separated by transition layers that incorporate batch normalization, 1×1 convolutions, and average pooling, which help regulate network complexity and reduce the number of parameters. This design leads to higher accuracy with fewer parameters compared to deeper architectures like ResNet. DenseNet is available in various configurations, such as DenseNet-121, DenseNet-169, DenseNet-201, and DenseNet-264, which indicate the number of layers. A significant advantage of DenseNet is its ability to deliver strong performance with reduced computational and memory demands, making it highly suitable for tasks like image classification, medical image processing, and object detection. Additionally, DenseNet models pre-trained on large-scale datasets like ImageNet are widely applied in transfer learning, allowing them to be fine-tuned for domain-specific problems. The model's efficient feature reuse mechanism reduces redundancy and enhances learning capabilities, positioning it as an optimal choice for high-accuracy applications with limited computational resources.

MobileNetV2: MobileNetV2, is a streamlined and effective convolutional neural network architecture tailored for mobile and embedded applications, providing a compromise between precision and computing economy. It was introduced by (Sandler et al., 2018b), with the integration of inverted residuals and linear bottlenecks, therefore markedly enhancing performance and reducing computing complexity. The fundamental innovation of MobileNetV2 is the depth wise separable convolution, which reduces the number of parameters and computations. It preserves a streamlined architecture while attaining competitive accuracy, making it exceptionally appropriate for picture classification, object identification, facial recognition, and AI-driven mobile apps. Its efficacy facilitates implementation on low-power devices, including smartphones, IoT devices, and edge computing systems. MobileNetV2, pre-trained on extensive datasets such as ImageNet, may be fine-tuned for specific applications, enabling significant versatility across several domains. It is extensively used in deep learning applications that need rapid inference and low resource usage, owing to its optimal balance between accuracy and computational economy.

Hyper-Parameters:

Hyperparameters are crucial for enhancing the training process of deep learning models. In this study, all pre-trained models were trained with a learning rate of 0.001 and used the Adam optimizer with a momentum value of 0.999. The ReLU activation function was used in all layers to improve non-linearity, while the softmax function was employed in the output layer to enable multi-class classification. The suggested LCNet model was trained using certain hyperparameters, guaranteeing effective learning and performance. The comprehensive setup of these parameters is shown in Table 1.

Table 1

Different hyper-parameters selected in the proposed CNN model

Hyper-parameter	Description
Learning rate	0.0001
Batch size	32
Number of epochs	250
Dropout	0.3
Optimizer	Adam
Momentum	0.999
Activation function	ReLu

C. Performance Matrices:

The suggested model's performance was assessed using several measures, including accuracy, precision, recall, and F1 score. Where, assessing accuracy and recall is an essential component of machine learning model evaluation, since it quantifies the balance between false positives and false negatives. Precision quantifies the ratio of accurately predicted positive samples to the total expected positives, reflecting the model's dependability in positive classifications. Conversely, recall measures the model's efficacy in identifying true positive samples inside the dataset. Furthermore, the F1 score, denoting the harmonic mean of accuracy and recall, was computed to provide a balanced assessment of model efficacy. An elevated F1 score indicates that the model achieves an effective equilibrium between accuracy and recall, making it a reliable instrument for classification endeavors.

These assessment measures guarantee that the proposed model accurately and reliably differentiates across various classes.

$$Accuracy = \frac{(TP+TN)}{(TP+TN+FP+FN)} \quad (1)$$

$$Precision = \frac{TP}{(TP+FP)} \quad (2)$$

$$Recall = \frac{TP}{(TP+FN)} \quad (3)$$

$$F1 - Score = 2 \times \frac{(TP \times FP)}{(TP+FP)} \quad (4)$$

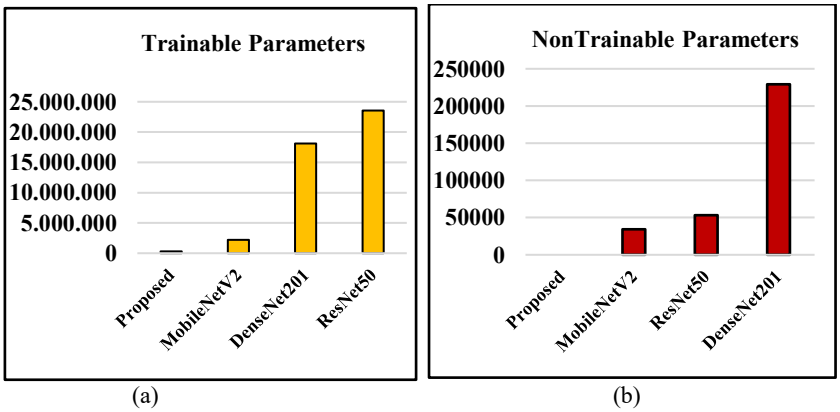
where: TP is True Positive, TN is True Negative, FP is False Positive, FN is False Negative

D. Hardware and Software Used:

This section presents and examines the outcome of the suggested strategy. The Keras library was employed in this study to create the suggested approach's structure. The Python-based Keras library provides a high-level API for creating deep learning architectures that can be built on top of other numerical computing libraries like TensorFlow. The proposed CNN model was trained with NVIDIA DGX A100 machine. The specification of the system is shown in Table 2:

Table 2

NVIDIA DGX A100 machine specification



Specification	Description
GPU	8xNVIDIA A100 Tensor core GPUs
GPU Memory	320 GB
Performance	5 peta FLOPS AI 10petaOPS INT8
CPU	Dual AMD Rome 7742, 128 cores, 2.25 GHz(base), 3.4 GHz(max boost)

RESULTS

This research assesses the efficacy of LCNet in identifying corn diseases, comparing its performance with three widely used pre-trained convolutional neural networks: MobileNetV2, ResNet50, and DenseNet201, as illustrated in Fig. 5-6 and Table 3, and compared with previous studies in Table 4. The assessment was grounded on critical performance criteria, including validation accuracy, validation loss, and computing efficiency, quantified by trainable and non-trainable parameters. All models were trained under identical parameter configurations, with a learning rate of 0.001, the Adam optimizer, and a momentum of 0.999, to provide an equitable comparison.

ResNet50 exhibited robust performance, with a validation accuracy of 91.27% and a validation loss of 0.2448. It necessitated 23,542,788 trainable parameters and 229,056 non-trainable parameters, making it computationally demanding. MobileNetV2 attained a validation accuracy of 90.19%, although recorded the greatest validation loss of 0.5175. It surpassed ResNet50 in efficiency, requiring 2,228,996 trainable parameters and 34,112 non-trainable parameters. DenseNet201 had the lowest validation accuracy at 87.88%, accompanied by a validation loss of 0.3413. Notwithstanding its reduced accuracy, it exhibited a markedly elevated computational burden, using 53,120 trainable parameters and 18,100,612 non-trainable parameters. The suggested LCNet model surpassed all pre-trained architectures, with the maximum validation accuracy of 94.65% and the lowest validation loss of 0.1559 as shown in Fig. 7. Moreover, LCNet exhibited exceptional computational efficiency, necessitating just 285,812 trainable parameters, making it an optimal selection for resource-limited settings.

The findings demonstrate that LCNet achieves an optimum equilibrium between precision and computing efficiency, making it suitable for real-time agricultural applications. The substantial decrease in trainable parameters indicates that LCNet can function efficiently on edge devices with constrained processing capabilities, hence guaranteeing its practical applicability for early disease detection in crops. The approach facilitates prompt disease detection, hence promoting proactive strategies to mitigate crop losses and enhance agricultural output.

CONCLUSIONS

This research presents an effective deep learning-based approach for classifying corn leaf diseases using a dataset of 4,188 images categorized into four groups: Common Rust, Gray Leaf Spot, Blight, and Healthy. A novel model, LCNet, was introduced and its performance was evaluated against established pre-trained architectures-MobileNetV2, DenseNet201, and ResNet50-as well as comparative studies from existing literature. LCNet demonstrated superior performance with a validation accuracy of 94.65% and a validation loss of 0.1559, outperforming MobileNetV2 (90.19%), DenseNet201 (87.88%), and ResNet50 (91.27%). These findings confirm LCNet's effectiveness in achieving high classification accuracy and efficient computation for corn leaf disease recognition. Looking ahead, future work will focus on fine-tuning model parameters through the Optuna optimization framework to further improve predictive accuracy. Additionally, the development of a lightweight mobile application is planned to support real-time, on-field disease detection, offering a practical and cost-effective tool for farmers and agricultural professionals.

ACKNOWLEDGEMENT

This study has been funded by the Department of Science and Technology (DST) under the project bearing reference number "DST/Reference No. T-319/2018-19." The authors sincerely acknowledge the support and financial assistance provided by DST, which played a crucial role in the successful completion of this research.

ABSTRACT
To improve the seed separation uniformity in the seed storage device of a wheat plot seeder, this paper investigates the key factors influencing its performance. First, the working principle of the seed storage device and the movement of seeds are analyzed, and the lifting mechanism of the seed storage tube is controlled by an electric pusher. Based on this analysis, the relevant parameter factors are identified. Next, EDEM software is used to simulate the seed storage process and determine the optimal combination of parameters. A three-factor, three-level central composite design experiment is conducted, with the inner diameter of the seed storage tube (D), the lifting height (L), and the lifting speed (V) as the test factors. The coefficient of variation of seed distribution uniformity (m_1) is used as the performance index. The optimal values determined for the parameters are D = 0.06 m, L = 0.015 m, and V = 0.05 m/s. Finally, bench experiments are carried out to verify the results. The experimental findings show that the average coefficient of variation for seed distribution using the traditional lifting lever is 6.46%, while the optimized parameters reduce it to 4.12%, significantly improving seed separation uniformity and meeting the seeding requirements.

摘要
为提高小麦小区播种机存种装置的分种均匀性，对小区播种机存种装置的相关试验因素进行了研究。首先，分析了存种装置的工作原理和种子的运动，通过电动推杆控制存种筒的升降；在此基础上，确定了存种装置的相关参数因素。其次，利用EDEM软件对存种装置进行仿真，以存种筒的内径(D)、上升高度(L)和上升速度(V)为试验因素，以种子分散均匀性变异系数(m_1)为性能指标进行三因素三水平的中心组合设计实验，确定各参数因子的最优组合为 D=0.06m, L=0.015m 和 V=0.05m/s*；最后，通过台架实验对优化参数进行了验证。试验结果表明，传统提升杆的平均种子分散均匀性变异系数为 6.46%，而优化参数下的平均种子分散均匀性变异系数为 4.12%，提高了种子分散均匀性，满足播种要求。*

INTRODUCTION
Seeds are the fundamental core of agriculture, playing a crucial role in agricultural development. Plot seeding is a key step in the breeding process, and its operational quality directly influences seed selection and breeding outcomes, making it highly significant for food security (*Shang et al., 2021; Zhou et al., 2022; Wang et al., 2022; Feng et al., 2024*). In this context, the wheat plot seeder is a specialized machine used in field experiments to breed high-quality crop varieties. The Austrian company WINTERSTEIGER introduced the world's first plot precision seeder in 1980, which employed suction seeding technology to precisely place individual seeds - an innovation that had a revolutionary impact on agricultural production. As a leading model for plot seeding, the wheat plot seeder performs seeding operations through manual feeding, cone filling, grid tray transportation, seed discharge via the outlet, and distribution using a centrifugal seed divider. Both in China and abroad, plot seeding is commonly conducted using such machines, significantly reducing manual labor requirements (*Cheng et al., 2018; Gao et al., 2022; Okeyo et al., 2020*).

In breeding trials or actual production, it is often necessary to sow multiple crop varieties within a single plot, with each variety requiring a relatively independent and appropriately sized area. The quality of seeding is directly linked to the subsequent growth and development of the crops. Uneven seeding can result in irregular plant distribution within the test plot, thereby compromising the accuracy and reliability of experimental results (*Beckman et al., 2022; Kovács et al., 2023*).

To enhance seeding performance, researchers both domestically and internationally have conducted extensive studies (*Karayel et al., 2022; Yatskul et al., 2018; Zhao et al., 2022; Yuan et al., 2024*).

Gong et al., (2011), proposed an electronic control system for plot seeders and identified the optimal distributor speed for sowing different seed types. *Cheng et al., (2019),* analyzed the effects of three key factors - seed distributor speed, seed separation angle, and seed separation distance - on seeding uniformity, and optimized the corresponding parameters. *Yang et al., (2019),* developed a magazine-type seeding device for plant-row drill planters to address issues of excessive manual labor and low operational efficiency. *Chen et al., (2020),* designed a three-leaf automatic cleaning and seed-changing air-suction seeder for soybean breeding, capable of quickly clearing and replacing residual seeds between plots without requiring machine stoppage. *Liu et al., (2023)*, investigated the forces acting on buckwheat seeds, identifying key influencing factors such as seed displacement, rotation rate, and seed gap layout, and determined the optimal parameter combination through experiments. *Yu et al., (2023),* explored the effects of distributor rotational speed, the number of distributor bosses, and boss length on seeding performance, providing a theoretical foundation for further improvements in seed distributor design. These studies have significantly contributed to enhancing the operational performance of plot seeders. However, uneven seed distribution remains an issue in actual sowing operations, which continues to limit overall work efficiency.

The seeding process initiated by the seed storage device is the first and foundational step in the overall operation of a plot seeder. It plays a critical role in ensuring the effectiveness and uniformity of the entire seeding process. In response to the challenges outlined above, this study focuses on the seed storage device of the plot seeder, aiming to enhance seed distribution uniformity. The findings of this research provide a theoretical and practical foundation for improving the uniformity of wheat seeding in plot trials.

MATERIALS AND METHODS

Structure of seed storage device

The XBJ-150 wheat plot seeder is selected as the research subject, with Figure 1 illustrating the overall machine structure and the configuration of its seed storage device. The seed storage system consists primarily of a seed storage tube and an electric pusher. During operation, wheat seeds are loaded into the seed storage device. The seed storage tube is raised via wireless remote control, allowing the seeds to slide evenly along the conical surface into the slots of the conical lattice disc seed-metering device (*Cheng et al., 2021*). Once all the seeds have been dispensed, the seed storage tube is lowered, again via wireless remote control, until it returns to its original position.

Analysis and determination of experimental factors

As the seed storage tube rises, the wheat seeds slide uniformly into the slots of the conical lattice disc seed-metering device along the cone surface. Figure 2 presents a stress analysis of the forces acting on wheat seeds during their movement along the conical surface. The equations governing this stress analysis are as follows:

$$F_r cos\alpha + \mathrm{mgsin}\alpha - f = \mathrm{m}a_x \quad (1)$$

$$F_r sin\alpha - \mathrm{mgcos}\alpha + F_N = \mathrm{m}a_y \quad (2)$$

where: F_r is the centrifugal force (N); F_N represents the supporting force exerted by the cone on the wheat seeds (N); f is the friction force between the cone surface and the wheat seeds (N); and mg is the gravitational force acting on the seeds (N).

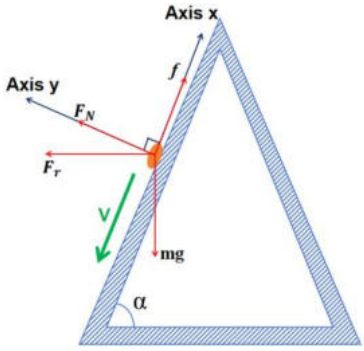

Fig. 2 - Force analysis of wheat seeds moving on the cone

The inner diameter and lifting height of the seed storage tube are key parameters that significantly influence the performance of the seed storage device. The uniform distribution of seeds into the slots of the metering device has a direct impact on seeding quality. The inner diameter of the seed storage tube determines the accumulation height of seeds under a fixed seed quantity. If the diameter is too small, resulting in a high seed accumulation, the vibration-induced adjustment of seed flow is effective. However, excessive seed accumulation can compromise the stability of seed motion when the tube is lifted, thereby negatively affecting distribution uniformity. Conversely, if the diameter is too large and the seed accumulation height is too low, it becomes difficult to generate relative motion within the wedge-shaped slot. This weakens the effect of vibration adjustment, also leading to poor seeding uniformity.

The lifting height of the seed storage tube determines the quantity of seeds that can slide out per unit time once the tube reaches its predetermined height. A smaller lifting height results in reduced seed interference, which can promote stable flow. However, the limited height may also restrict seed movement, increasing the risk of blockage and negatively impacting distribution uniformity. Conversely, when the lifting height is increased, the influence of the seed storage tube on seed flow is reduced, allowing a larger quantity of seeds to be released. However, this also results in a more uniform initial motion state among the seeds, leading to greater mutual interference during descent, which can likewise compromise uniformity.

The lifting speed of the seed storage tube also plays a critical role in maintaining seed distribution uniformity. When the lifting speed is too slow, the seeds remain in contact with the tube for a longer duration, making them more susceptible to interference from the tube wall. This can lead to blockages and uneven seed flow, thereby reducing uniformity. Conversely, if the lifting speed is too fast, the influence of the tube on the seeds is minimized, but the rate at which seeds exit the storage tube increases sharply. This can cause heightened mutual interference among the seeds during their movement, which also negatively affects uniformity.

Therefore, it is necessary to comprehensively consider the influence of the inner diameter, the lifting height, and the lifting speed of the seed storage tube on the uniformity of seed storage to achieve the best seeding effect. The optimal combination of three factors, namely the inner diameter of the seed storage tube (D), the lifting height of the seed storage tube (L) and the lifting speed of the seed storage tube (V), is selected to improve the uniformity of seed dispersion in the slot. According to the structure, working principle and working efficiency of the seed storage device of the wheat plot seeder (*Liu et al., 2010*), it is determined that the diameter of the seed storage tube ranges from 0.04 m to 0.08 m, the lifting height of the seed storage tube ranges from 0.005 m to 0.025 m, and the lifting speed of the seed storage tube ranges from 0.02m/s to 0.08m/s.

Determination of physical characteristics parameters of wheat seeds

The Jimai 22 wheat variety is widely sown in China, especially in northern Anhui. Therefore, the Jimai 22 wheat variety was selected for research. Moreover, 1000 grains are randomly selected and divided into three groups to weigh (W). Then 100 wheat seeds are randomly selected to measure and calculate the average length (l), width (w) and thickness (t), as shown in Table 1.

Table 1

Weight and dimension statistics of 1000 seeds of Jimai 22

Research factor	Group 1	Group 2	Group 3	Average
W/g	44.7	43.8	45.8	44.1
l/mm	6.29	6.39	6.37	6.35
w/mm	3.41	3.38	3.32	3.37
t/mm	3.12	3.16	3.08	3.12

Simulation test

The establishment of simulation model

Based on the results, a three-dimensional model of wheat seeds is established in CATIA software, and the model is imported into EDEM software. Multiple spherical combinations are used to fill the wheat seeds with particles, resulting in the wheat seed model shown in Figure 3.

Fig. 3 - Seed model of grain filling

The establishment of seed storage device model

A three-dimensional model of the seed storage device is built by CATIA software and imported into EDEM software, as shown in Figure 4.

Fig. 4 - Model of seed storage device

The inner wall of the seed storage tube is made of resin, and the surface cone of the conical lattice disc seed-metering device is made of steel. The parameters of seed, resin and steel obtained through literature search and calculation are shown in Table 2 (*Li et al., 2018; Zhu et al., 2019; Diao et al., 2024)*.

Table 2

Relevant parameters of simulation model

Relevant parameters	Seed	Resin	Steel
Poisson's ratio	0.29	0.39	0.3
Shear modulus /Pa	5.01e+8	7.19e+8	7.00e+10
Density /(kg·m^{-3})	1350	1240	7800
Relevant parameters	Seed	Resin	Steel

The parameters of the contact relationship between steel and the wheat seed and between resin and the wheat seed are shown in Table 3.

Table 3

Contact parameters between materials in the simulation model

Contact parameters	Seed-seed	Resin-seed	Steel-seed
Recovery coefficient	0.50	0.50	0.60
Coefficient of static friction	0.58	0.20	0.50
Coefficient of dynamic friction	0.08	0.02	0.01
Contact parameters	Seed-seed	Resin-seed	Steel-seed

Experimental design

According to the three factors obtained in Section 2.2, the optimal parameter combination is obtained using the three-factor and three-level orthogonal test method with the seed scattered uniformity coefficient of variation (m_1) as the evaluation index (*Liu, 2011)*. The seed scattered uniformity coefficient of variation (m_1) can be calculated as:

$$m_1 = \frac{\sqrt{\sum_{i=1}^{n}(M_i - \sum_{i=1}^{n} M_i/n)^2/(n-1)}}{\sum_{i=1}^{n} M_i/n} \quad (3)$$

where i represents the number of the slot of the conical lattice disc seed-metering device; M_i denotes the seed quality in slot number i; n represents the number of slots, n=40.

The relevant parameters of the simulation model are set. Seeds are added into the seed storage tube and an orthogonal experiment is conducted with a designed seed quantity of 0.15 kg.

Table 4 presents the factor level encoding table.

Table 4

Table of factor levels for orthogonal tests

Encoding	D/m	L/m	V/(m/s)
+1	0.04	0.005	0.02
0	0.06	0.015	0.05
-1	0.08	0.025	0.08

After the simulation seeding experiment is completed, the *Analyst Tree* interface is used to generate a grid group in each slot of the conical lattice disc seed-metering device. This allows for the measurement of wheat seed mass in each slot and the calculation of the seed distribution uniformity coefficient of variation, as shown in Figure 5.

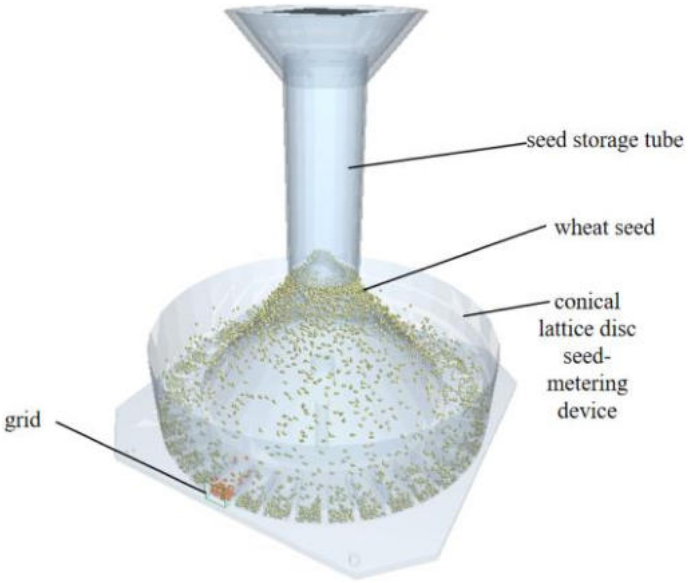

Fig. 5 - The diagram of the simulation experiment

Bench test

To verify the effectiveness of the optimal parameters, the seed storage device is improved according to the optimal parameters analyzed in the previous section. The original lifting lever is replaced with an electric pusher and compared with the traditional lifting lever. Eight sets of tests are conducted on the JPS-12 seed planter performance test bench in the Intelligent Agricultural Machinery Equipment Engineering Laboratory of Anhui Agricultural University, and the seed scattered uniformity coefficient of variation is calculated, as shown in Figure 6.

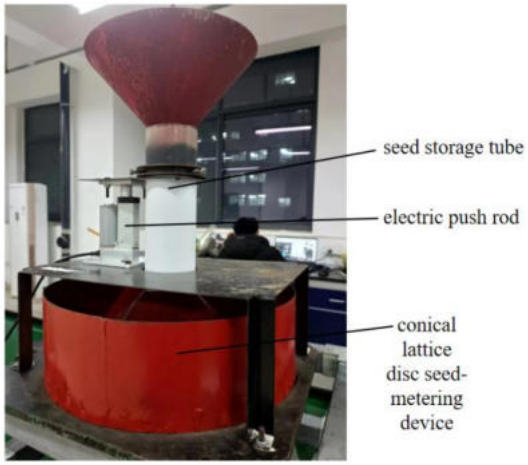

Fig. 6 - The diagram of the bench test

RESULTS

Simulation test results

The seed scattered uniformity coefficient of variation in the orthogonal test is shown in Table 5.

Table 5

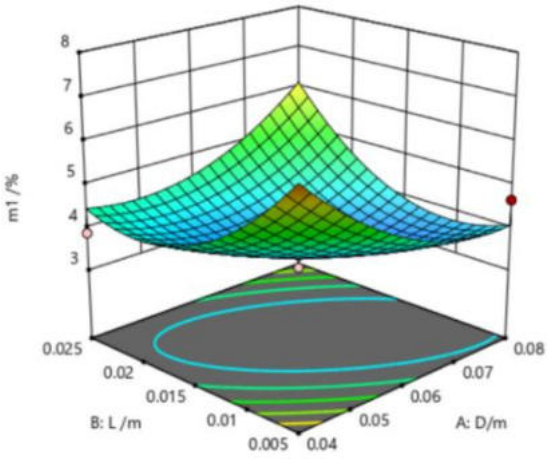
Statistics of coefficient of variation of orthogonal test

Number	D/m	L/m	V/(m/s)	m_1/%
1	0.04	0.005	0.05	5.87
2	0.06	0.015	0.05	3.62
3	0.06	0.025	0.02	5.67
4	0.06	0.015	0.05	3.05
5	0.08	0.015	0.08	5.98
6	0.06	0.005	0.02	5.08
7	0.04	0.015	0.08	5.24
8	0.08	0.005	0.05	4.65
9	0.08	0.025	0.05	5.84
10	0.06	0.015	0.05	3.46
11	0.04	0.025	0.05	3.87
12	0.08	0.015	0.02	4.43
13	0.06	0.005	0.08	4.98
14	0.04	0.015	0.02	5.67
15	0.06	0.025	0.08	6.01
16	0.06	0.015	0.05	3.97
17	0.06	0.015	0.05	3.34

According to the simulation results in Table 5, the average of m_1 (μ) is calculated as 4.749%, and the standard deviation (σ) is 0.998%, so the standard deviation ranges, μ±σ, μ±2σ and μ±3σ, are [3.742%, 5.747%], [2.744%, 6.745%] and [1.746%, 7.743%], respectively. That is, when the three factors are orthogonally combined at the three levels, the probabilities of m_1 within the above three intervals are approximately 68%, 95% and 99.7%. Design Expert 13 software (DSP 13) is used to analyze the simulation data, and the dimensionless factor encoding regression equation was obtained as follows:

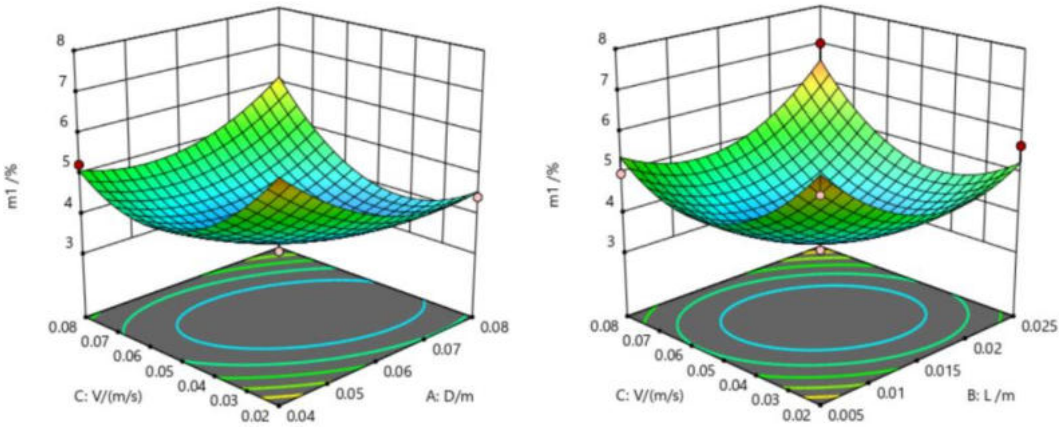
$$Y_1=3.49-0.2187X-0.0238Y+0.045Z+1.05XY+0.745XZ$$
$$-0.61YZ+0.7323X^2+1.09Y^2+1.36Z^2 \quad (4)$$

where X represents the inner diameter of seed storage tube. Y denotes the lifting height of the seed storage tube. Z represents the lifting speed of the seed storage tube.



The regression equation analysis is shown in Table 6, and the coefficient of variation model is highly significant (P<0.01), with a mismatch term of P=0.3822>0.05, indicating that the regression equation is well fitted. According to Table 6, the influence of each experimental factor on the coefficient of variation, in descending order, is as follows: the height of the seed storage tube, the inner diameter of the seed storage tube and the speed of the seed storage tube.

Table 6



Statistics of coefficient of variation of orthogonal test

Source	Sum of Square	Freedom	Mean Square	F	P

Figure 7 displays the influence of various factors interacting with each other on the coefficient of variation (m_1). Figure 7a shows the effect of L and D on the coefficient of variation. When L is constant, with the increase of D, m_1 decreases first and then increases. When D is constant, with the increase of L, m_1 decreases first and then increases. Figure 7b shows the effect of V and D on the coefficient of variation. When V remains constant, with the increase of D, m_1 decreases first and then increases. When D remains constant, with the increase of V, m_1 decreases first and then increases. Figure 7c shows the effect of V and L on the coefficient of variation. When V is constant, with the increase of L, m_1 decreases first and then increases. When L is constant, with the increase of V, m_1 decreases first and then increases.

(a) The impact of L and D on m_1

(b) The impact of V and D on m_1 (c) The impact of V and L on m_1

Fig. 7 - The influence of the interaction of various factors on the coefficient of variation

The regression equation for the impact of significant factors on the seed scattered uniformity coefficient of variation is as follows:

$$m_1=26.88-371.28D-744.46L-254.58V+5237.5DL+1241.67DV$$
$$+2033.33LV+1380.625D^2+10872.5L^2+1830.625V^2 \quad (5)$$

Using the objective function m_{1min}, the optimal parameter combination was determined through optimization in MATLAB/Simulink. The resulting optimal values for the three factors are: inner diameter D=0.06 m, lifting height L=0.015 m, and lifting speed V=0.05 m/s.

Bench test results

Table 7 displays the results of the comparative experiment between the traditional lifting lever and the electric pusher, which indicates that the average scattered uniformity coefficient of variation for using traditional lifting levers is 6.46%, and for using the electric pusher, it is 4.12%. Compared to traditional lever lifting, the improved method significantly improves the uniformity of wheat seeds and meets operational requirements, which proves the feasibility of the optimal parameter combination.

Table 7

Result of the bench test

Number	m_1/%	
	Before optimization	After optimization
1	5.61	4.58
2	6.94	3.66
3	6.64	3.89
4	5.71	5.13
5	6.44	3.61
6	6.39	3.16
7	7.17	4.28
8	6.82	3.77
Average	6.46	4.12

CONCLUSIONS

(1) Taking the seed storage device of the wheat plot seeder as the research object, the working principle and experimental factors related to the seed storage device are analyzed. An electric pusher is used instead of a traditional lifting lever to control the lifting of the seed storage tube. And the experimental factors related to the seed storage device are determined, namely the inner diameter of the seed storage tube (D), the lifting height of the seed storage tube (L), and the lifting speed of the seed storage tube (V).

(2) Through analysis, the ranges of the test factors are determined to be [0.04 m, 0.08 m], [0.005 m, 0.025 m] and [0.02 m/s, 0.08 m/s], respectively. A three-factor and three-level simulation experiment is conducted with the seed scattered uniformity coefficient of variation as the performance index. It is determined that the influences of each test factor on the coefficient from large to small are L, D, and V, and the optimal solution of experimental parameters is determined to be D=0.06 m, L=0.015 m, and V=0.05 m/s.

(3) Under the verification test, the range of the seed scattered uniformity coefficient of variation is [3.16%, 5.13%], with an average value of 4.12%. Compared with the traditional lifting lever, its coefficient of variation is reduced by 2.34%. Under the optimized combination of working parameters, the device achieves a relatively high working performance.

ABSTRACT
Traditional rice seed classification methods rely on manual observation of morphological features, which are inefficient and limited in accuracy. To improve the efficiency and accuracy of rice seed classification, this paper proposes a deep learning-based rice seed classification method using the SE-ResNet network architecture. This architecture integrates SENet into ResNet50, enabling the model to capture and learn sensitive differential features among rice seeds. Through comparative experiments, the classification accuracies of SE-ResNet50, ResNet, and AlexNet on the rice seed dataset were 89.58%, 72.97%, and 76.35%, respectively. The results demonstrate that SE-ResNet50 significantly outperforms ResNet and AlexNet in classification accuracy, validating its superiority in rice seed classification tasks.

摘要
传统的稻种分类方法依赖人工经验对形态特征的观察，效率低且准确性有限。为提高稻种分类的效率及精度，本文提出了一种基于深度学习的稻种分类方法，采用 SE-ResNet 网络结构，该结构将 SENet 集成到 ResNet 中，使其能够捕捉并学习稻种之间的敏感性差异特征。通过对比实验，SE-ResNet50、ResNet50 和 AlexNet 三种网络结构在稻种数据集上的分类准确率分别为 89.58%、72.97%和 76.35%。结果表明，SE-ResNet50 的分类准确率明显高于 ResNet50 和 AlexNet，验证了其在稻种分类任务中的优越性。

INTRODUCTION
Rice, as one of the most important global food crops, plays a pivotal role in agricultural production and food security. With the growing global population and increasing demand for food, improving rice yield and quality has become a critical goal in agricultural research. Among these efforts, the classification and identification of rice seeds are key to achieving precision agriculture and variety improvement. Accurate rice seed classification not only aids in seed quality control and variety identification but also provides scientific support for rice cultivation, processing, and trade.

In recent years, with the advancement of computer technology and machine vision, deep learning has gradually been applied to the agricultural domain. Significant progress has been made in rice seed classification. Traditional methods primarily rely on manual observation and morphological feature measurements, such as grain length, width, and shape. However, these methods suffer from subjectivity and inefficiency. In contrast, machine learning and deep learning-based approaches can automatically extract features from rice seed images and achieve efficient classification. *Kamilaris et al., (2018),* systematically compared deep learning with traditional methods and found that deep learning significantly outperforms traditional methods in agricultural tasks, establishing its theoretical superiority. *Carneiro et al., (2024)* systematically analyzed 37 recent studies that employed deep learning (DL) and machine learning (ML) models for grape variety identification, aiming to provide a detailed analysis of the classification process and highlight the strengths and limitations of each method. Based on this, researchers have explored various dimensions of convolutional neural networks (CNNs). *Sladojevick et al., (2016)* and *Lu et al., (2017),* employed basic CNN architectures for plant disease recognition, achieving average accuracies of 96.3% and 95.48%, respectively, demonstrating the versatility of CNNs in complex agricultural scenarios.

[1] *Zhen Ma, Lec.; Sa Wang, M.Sc.Stu.; Hongxiong su,, M.Sc.Stu.; Juxia Li, Prof; Yanwen, Li, Prof.; Zhifeng Bi,Lec.; Xiaojie Li, UG.*

Dymann et al., (2016), and *Reyes et al., (2015),* further expanded the application of CNNs, with the former achieving 86.2% accuracy in classifying 22 plant species and the latter focusing on vein pattern recognition in legumes, both overcoming the limitations of traditional manual feature extraction.

To enhance model performance, researchers have proposed various improvement strategies. *Zhang et al., (2019),* designed the GPDCNN model, which optimizes global pooling and dilated convolution to increase the receptive field while maintaining low computational complexity, significantly improving cucumber disease recognition. *Lu et al., (2017),* visualized feature hierarchies using deconvolution networks, enhancing model interpretability and discriminative power. Meanwhile, transfer learning has become an effective approach to address small-sample problems. *Pereira et al., (2019),* achieved efficient grape variety classification using a fine-tuned AlexNet model, while *Too et al., (2019),* systematically evaluated advanced architectures such as VGG, ResNet50, and DenseNet, finding that DenseNet achieved 99.75% accuracy in classifying 38 plant leaf categories with excellent anti-overfitting properties. *Dong et al., (2024),* addressed the challenge of identifying Camellia oleifera varieties caused by genetic diversity and morphological similarities by constructing a dataset of 30,890 leaf images and developing a deep learning model based on the Convolutional Block Attention Module (CBAM) and RegNetY-4.0GF. *Sun et al., (2023),* improved the EfficientNetv2 network model by introducing a transfer learning mechanism, the adaptive moment estimation optimization algorithm, and the MultiMarginLoss function, addressing the issue of low classification efficiency for southern medicinal plant leaves under complex backgrounds. They achieved a recognition accuracy of 99.12%, representing a 1.17% improvement over the initial model. *Zou et al., (2024*), developed a pepper anthracnose fruit classification and recognition model based on MobileNet V2 and created a mobile-based pepper fruit anthracnose recognition system, addressing the challenge of real-time diagnosis of pepper fruit anthracnose in offline field environments. *Peng et al., (2024*), optimized the YOLOV7 model and proposed the WineYOLO-RAFusion model to achieve more comprehensive and accurate recognition of wine grape varieties. Through data augmentation, transfer learning, and parameter fine-tuning, the MobileNet V2 model achieved a precision rate of 97.31% on the test set, with a recognition time of only 75 ms per image. Although these improved models significantly enhance applicability, they are not well-suited for rice seed classification.

To address these limitations, this paper introduces the SE-ResNet50 model, combining deep learning with feature channel recalibration mechanisms to improve the accuracy and efficiency of rice seed classification. Comparative experiments validate the superiority of SE-ResNet50 in rice seed classification tasks, providing new technical support for agricultural intelligence.

MATERIALS AND METHODS

Dataset Construction

For this experiment, a publicly available dataset of rice seed images was employed. The dataset includes four types of rice seeds: AKITAKOMACHI, KOSHIHIKARI, THAI HOM MALI, and YANGDAO-8, as illustrated in Figure 1. To enhance the generalizability of the model and augment the diversity of the dataset, data augmentation techniques, including random rotation and mirroring, were employed. As a result, the dataset was expanded to a total of 5189 images. The collected seed samples were systematically divided into training and validation sets at an 8:2 ratio, as shown in Table 1.

(a) AKITAKOMACHI (b) KOSHIHIKARI (c) THAI HOM MALI (d) YANGDAO-8

Fig. 1 - Examples of images for each category in the dataset
(a) represents the AKITAKOMACHI class, (b) represents the KOSHIHIKARI class, (c) represents the THAI HOM MALI class, (d) represents the YANGDAO-8 class.

Table 1

Dataset Distribution

Category	Training Set	validation Set
AKITAKOMACHI	976	244
KOSHIHIKARI	1056	263
THAI HOM MALI	1150	287
YANGDAO-8	971	242

Dataset Construction

SE-ResNet50-Based Rice Seed Classification Model

The SE-ResNet50 model proposed in this paper integrates the SE module into ResNet50. The SE module dynamically adjusts the weights of feature channels through Squeeze and Excitation operations, enhancing the network's ability to extract important features.

ResNet50 Overview

ResNet50, or Residual Network, is an innovative deep learning model architecture widely used in computer vision *(He et al., 2019; Veit et al., 2016; Rawat et al., 2017)*. ResNet50's deep network structure (over 100 layers) and exceptional performance have demonstrated its broad applicability in various computer vision tasks. The core innovation of ResNet50 is the introduction of residual learning to address the performance degradation problem caused by increasing network depth. This is achieved through the design of residual blocks, which allow direct information transfer between layers. Each residual block consists of multiple residual units, each comprising two convolutional layers and a skip connection that directly passes the input to the output. This skip connection not only helps maintain network stability but also enhances the network's ability to handle more complex data. The structure of the residual block is shown in Figure 2.

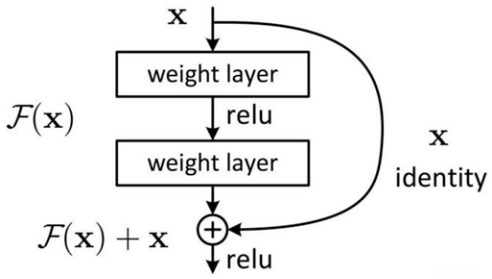

Fig. 2 - Structure of the Residual Block

The diagram summarizes the basic structure of a Residual Network (ResNet50), addressing the vanishing gradient problem in deep neural network training by introducing a skip connection.

The introduction of residual blocks significantly reduces the number of parameters and computational complexity in deep neural networks. Depending on the network depth, residual blocks can take different forms. Typically, ResNet50 employs two main types of residual blocks: the identity mapping module and the downsampling module.

The identity mapping module directly adds the input to the output when the dimensions of the input and output are the same. This process can be mathematically represented as:

$$F_{(x)} = x + H_{(x)} \tag{1}$$

where:

x is the input, $F_{(x)}$ is the output of the residual block, and $H_{(x)}$ is the nonlinear transformation within the residual block. In the identity mapping module, $H_{(x)}$ is typically an identity transformation, that is $H_{(x)} = x$, hence the output $F_{(x)}$ is equal to the input x plus its own value, thus achieving an identity mapping.

The downsampling module is used when the dimensions of the input and output feature maps do not match. This operation reduces the dimensionality of the input feature map to match the output, ensuring the continuity and effectiveness of the network structure. This is typically achieved through convolutional operations. The mathematical representation of the downsampling module is as follows:

$$F_{(x)} = W_{downsample} \cdot x + H_{(x)} \tag{2}$$

where:

x is the input, $F_{(x)}$ is the output of the residual block, $H_{(x)}$ is the nonlinear transformation within the residual block, and $W_{downsample}$ is the weight matrix of the downsampling operation.

These two modules are alternately combined to form the ResNet50 architecture, which is commonly used in constructing deep residual networks. Depending on whether the input and output dimensions are the same, either the identity mapping module or the downsampling module is selected, facilitating the training of deep networks and improving model performance. The structure of ResNet50 is shown in Figure 3.

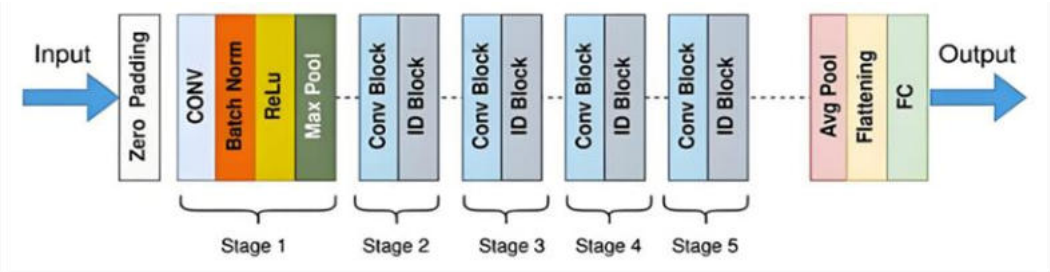

Fig. 3 - Structure of ResNet50

Figure 3 illustrates the overall structure of the ResNet50 model, detailing how data is processed at each stage of the network. The initial stage includes zero padding, a convolutional layer (CONV), batch normalization (Batch Norm), ReLU activation, and a max pooling layer (Max Pool). These layers are used to extract preliminary features from the image and reduce the size of the feature map. In stages 2 to 5, multiple residual blocks, including "Conv Block" and "ID Block," are used to capture deeper features while addressing the vanishing gradient problem through skip connections, thereby improving the network's learning efficiency. Each stage typically begins with a "Conv Block" to adapt to changes in feature map size and reduce computational complexity through bottleneck design. This is followed by several "ID Blocks" for further feature extraction without altering the feature map size. The network ends with a global average pooling layer (Avg Pool) to reduce the feature map to a fixed-size vector. This is followed by a flattening operation to convert the pooled output into a one-dimensional array. Finally, a fully connected layer (FC) maps the extracted features to the probabilities of each class.

Introduction of the SENet-Block Module

The SENet-block module integrates the Squeeze-and-Excitation (SE) module into traditional convolutional neural network blocks *(Hu et al., 2018; Wang et al., 2017; Vaswani et al., 2017)*. This integration enhances the feature representation capability of the network by dynamically adjusting the importance of feature channels, allowing the network to focus more on useful information. Although the SENet-block module may vary across different network architectures, the core idea remains the same: adding the SE module after traditional CNN blocks. The differences between rice seeds are often subtle, and with the development of hybrid rice varieties, these differences have become even more blurred, making the classification of rice seed varieties increasingly challenging. To address this issue, the introduction of the SENet-block module has proven to be an effective solution. The structure of the SENet-block module is shown in Figure 4.

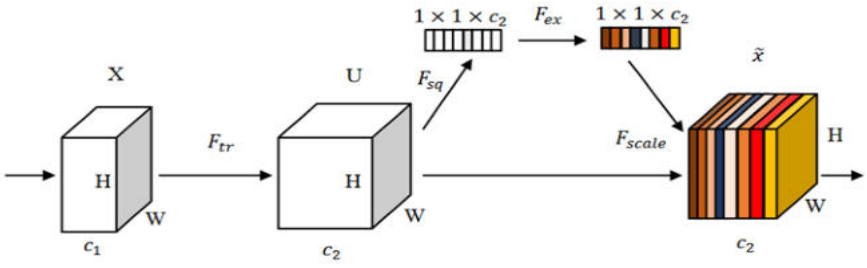

Fig. 4 - Structure of the SENet-Block Module

Figure 4 illustrates the workflow of the SENet (Squeeze-and-Excitation Network) module. First, the input feature map undergoes a Squeeze operation, which compresses the spatial information of each channel through global average pooling. Next, the Excitation operation generates weights for each channel through two fully connected layers. Finally, the Scale operation multiplies these weights with the original feature map to produce the recalibrated output feature map. This process dynamically adjusts the channel weights, enhancing the network's ability to focus on important features and thereby improving model performance.

Squeeze Operation

Through global average pooling, the feature map U is compressed, merging the $H \times W$ spatial information of each channel into a single value, generating a $1 \times 1 \times C_2$ channel descriptor. The purpose of this step is to extract global information from each channel.

The formula for global average pooling is:

$$s_c = \frac{1}{H \times W} \sum_{i=1}^{H} \sum_{j=1}^{W} u_c(i,j) \quad (3)$$

where:

S_c is the output feature of channel C, $H \times W$ is the spatial dimension of the feature map U, $\sum_{i=1}^{H} \sum_{j=1}^{W}$ indicates the summation of all spatial positions (i,j) in the feature map U, $u_c(i,j)$ is the value of the feature map U at channel C and position (i,j).

Excitation Operation

The channel descriptor is first processed by two fully connected layers. The first fully connected layer typically reduces the dimensionality and applies a ReLU activation function. The second fully connected layer maps the dimensionality back to the original number of channels C_2 and uses a sigmoid function to output the weight for each channel. This can be expressed as:

$$z = \sigma(g(s,W)) = \sigma(W_2 \times \delta(W_1 s)) \quad (4)$$

where:

s is the compressed channel descriptor obtained from the Squeeze operation, W_1 and W_2 are the weight matrices of the two fully connected layers, δ represents the ReLU activation function, σ is the sigmoid activation function, and z is the weight for each channel.

Scale Operation

The weights output from the Excitation step x (one weight per channel) are multiplied with the corresponding channels of the original feature map U. This step enhances the channels that the model deems important and suppresses the less important ones. The formula for this step is as follows:

$$\tilde{x}_c = z_c \cdot u_c \quad (5)$$

where:

$\tilde{x}_c$is the recalibrated feature map for channel C, z_c is the weight for channel C, and U_c is the original feature map for channel C.

The above content details the complete structure and operational process of the SENet-block module. By embedding the SENet-block structure into ResNet50, the advantages of deep residual networks addressing the vanishing gradient problem through skip connections—are combined with the feature channel recalibration strategy of SENet-block, significantly enhancing the overall performance of the network. This integration not only preserves the residual learning advantages of ResNet50 but also optimizes the network's ability to process feature information through the feature channel recalibration mechanism, thereby effectively improving network performance.

SE-ResNet50 Network Structure

SE-ResNet50 is a convolutional neural network architecture that integrates the Squeeze-and-Excitation (SE) module into ResNet50. This structure enhances the expressive power and performance of ResNet50 by adding a channel attention mechanism. By introducing the SE module, the network's ability to represent features is improved without significantly increasing computational cost, particularly in image classification and other visual tasks. The SE-ResNet50 model retains the advantages of the original ResNet50, such as using skip connections to train deep networks, while also enhancing the emphasis on channel-level features through the integration of the SE module. This makes the network more effective in handling complex images or other high-dimensional data.

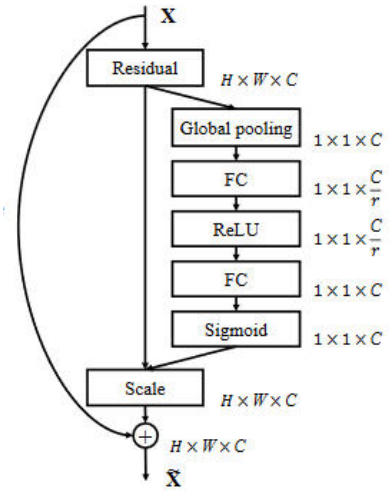

Fig. 5 - Structure of the SE-ResNet50 Residual Block

Figure 5 illustrates the working principle of the SE module combined with skip connections. First, the input feature map X (with dimensions $H \times W \times C$) is compressed through global average pooling into a channel descriptor of size $1 \times 1 \times c$, extracting global information from each channel. Next, the descriptor is processed by two fully connected layers (FC): the first layer reduces the dimensionality to $C \div r$ and applies a ReLU activation function to introduce nonlinearity; the second layer restores the dimensionality to C and generates weights for each channel using a sigmoid activation function. Finally, these weights are multiplied with the original input feature map through a scaling operation, producing the recalibrated feature map x which retains the original dimensions $H \times W \times C$. This process dynamically adjusts the channel weights, enhancing the network's ability to focus on important features and thereby improving model performance without altering the feature map dimensions.

Rice Seed Classification System

To enhance the usability and operational efficiency of the algorithm, this study has developed a rice seed classification application, realized through a dedicated graphical user interface (GUI). Utilizing an object-oriented programming approach, the Qt framework has been employed for the design of this application. The Qt framework facilitates comprehensive interface design by instantiating objects, configuring their properties, and establishing event bindings. This not only achieves separation of the front-end and back-end but also enables real-time target detection. The framework provides an extensive suite of GUI development tools, encompassing over 620 classes and nearly 6,000 functions and methods.

During the operation, users can import the images of seeds that need to be classified into the system by clicking the "Upload Image" button. Subsequently, by clicking the "Start Detection" button, the system will automatically execute the classification process, as illustrated in the figure 6.

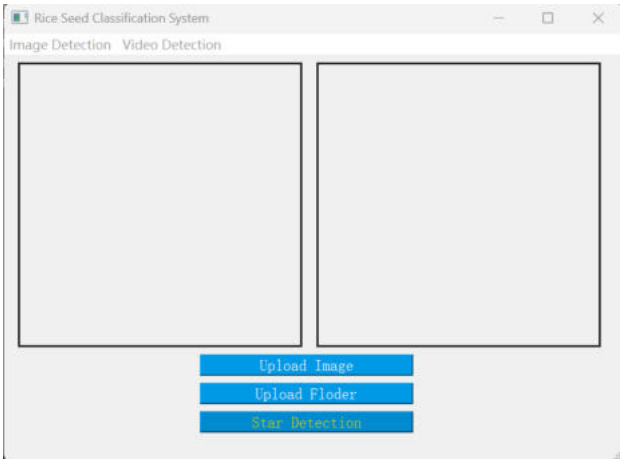

Fig. 7 - Rice seed classification system

Network Model Training

Experimental Platform and Training Parameters

The experimental environment runs on Windows 10 (64-bit) with 16 GB of RAM, an NVIDIA GTX1650Ti GPU, and an Intel(R) Core(TM) i5-10200H CPU @ 2.40GHz processor. The programming platform is Anaconda 4.12.0, with CUDA 10.1, and the development environment is PyTorch, using Python 3.8.

All models in this experiment were trained on the same training set with identical parameters for rice seed classification. The number of epochs was set to 100, the learning rate was 0.0125, and the batch size was 16, ensuring the fairness and comparability of the experimental results.

Model Evaluation Metrics

This method provides four key metrics—True Positives, False Positives, True Negatives, and False Negatives—to reveal the model's performance across different categories, offering a comprehensive understanding of its effectiveness.

Based on these four metrics, more complex evaluation metrics can be derived, such as precision, recall, and F_1 score. $\mathrm{Precision}$ represents the ratio of correctly predicted positive instances to all predicted positive instances. Recall reflects the ratio of correctly predicted positive instances to all actual positive instances. The F_1 score is the harmonic mean of precision and recall, providing a balanced measure between the two. These evaluation metrics collectively form a comprehensive framework for assessing model performance. The formulas for these metrics are as follows:

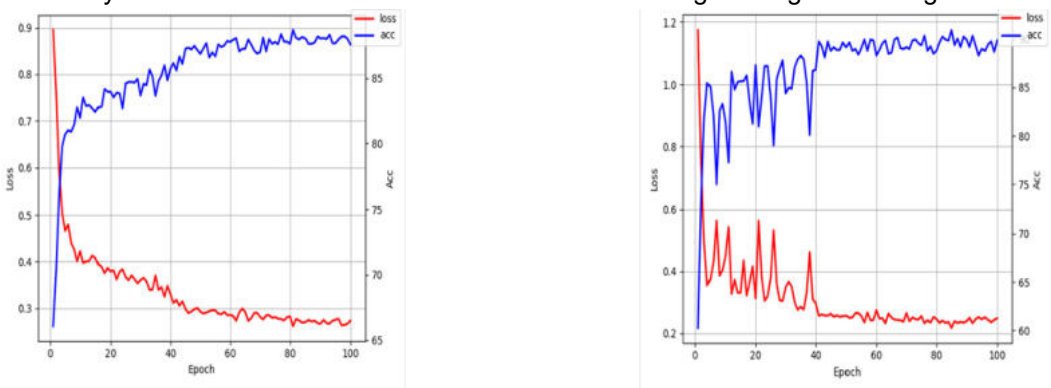
$$\mathrm{Precision} = \frac{TP}{TP+FP} \tag{6}$$

$$\mathrm{Recall} = \frac{TP}{TP+FN} \tag{7}$$

$$F_1 = \frac{2\times \mathrm{Precision}\times \mathrm{Recall}}{\mathrm{Precision}+\mathrm{Recall}} \tag{8}$$

For multi-class classification, $\mathrm{Precision}$ is calculated as the ratio of true positives for each class to the sum of true positives and false positives for that class. Recall is calculated as the ratio of true positives for each class to the sum of true positives and false negatives for that class. The overall evaluation metrics are as follows:

$$\mathrm{Precision}_{\mathrm{micro}} = \frac{\sum_{i=1}^{n} \mathrm{TP}}{\sum_{i=1}^{n} \mathrm{TP} + \sum_{i=1}^{n} \mathrm{FP}} \tag{9}$$



$$\mathrm{Recall}_{\mathrm{micro}} = \frac{\sum_{i=1}^{n} \mathrm{TP}}{\sum_{i=1}^{n} \mathrm{TP} + \sum_{i=1}^{n} \mathrm{FN}} \tag{10}$$

$$\mathrm{F1}_{\mathrm{micro}} = \frac{2\times \mathrm{Precision}_{\mathrm{micro}} \times \mathrm{Recall}_{\mathrm{micro}}}{\mathrm{Precision}_{\mathrm{micro}} + \mathrm{Recall}_{\mathrm{micro}}} \tag{11}$$

RESULTS AND ANALYSIS

SE-ResNet50 Model

The accuracy and loss curves of the SE-ResNet50 model during training and testing are shown in Fig.7.

(a) Training set results (b) Testing set results

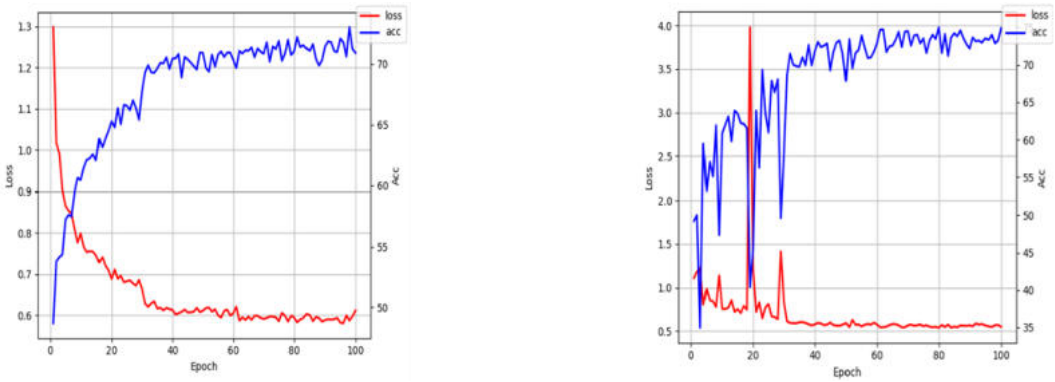


Fig. 7 - Accuracy and Loss Curves of the SE-ResNet50 Model

Figure 6 shows the loss and accuracy curves of the SE-ResNet50 model during training and testing. On the training set, the loss (blue curve) initially decreases rapidly and stabilizes around 0.3 after 100 epochs, while the accuracy (red curve) increases quickly and stabilizes around 95%. On the testing set, the loss (blue curve) also decreases rapidly initially but exhibits more fluctuations, stabilizing around 0.4. The accuracy (red curve) on the testing set increases quickly but fluctuates more, stabilizing around 85%.

From Figure 6, it can be observed that the SE-ResNet50 model exhibits excellent convergence performance during training, with the loss decreasing rapidly and stabilizing. The model shows no signs of overfitting or underfitting, indicating good generalization ability. When applied to the classification task of four types of rice seed images, the model achieves an accuracy of 89.58% on the testing set.

ResNet50 Model

The accuracy and loss curves of the ResNet50 model during training and testing are shown in Fig. 8.

(a) Training set results (b) Testing set results

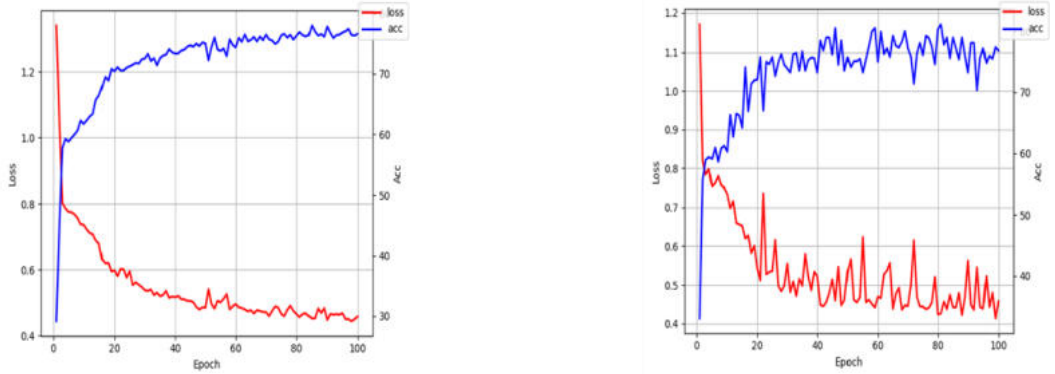

Fig. 8 - Accuracy and Loss Curves of the ResNet50 Model

Figure 7 shows the loss and accuracy curves of the ResNet50 model during training and testing. On the training set, the loss (blue curve) decreases rapidly initially and stabilizes around 0.4 after 100 epochs, while the accuracy (red curve) increases quickly and stabilizes around 70%. On the testing set, the loss (blue curve) decreases rapidly initially but exhibits more fluctuations, stabilizing around 0.5. The accuracy (red curve) on the testing set increases quickly but fluctuates more, stabilizing around 60%.

From Figure 7 it can be observed that the ResNet50 model converges more slowly and fails to achieve the expected performance level. The model's performance on both the training and testing sets is suboptimal. When applied to the classification task of four types of rice seed images, the ResNet50 model achieves an accuracy of only 72.97%.

AlexNet Model

The accuracy and loss curves of the AlexNet model during training and testing are shown in Figure 9.

(a) Training set results (b) Testing set results

Fig. 9 - Accuracy and Loss Curves of the AlexNet Model

Figure 8 shows the loss and accuracy curves of the AlexNet model during training and testing. On the training set, the loss (blue curve) decreases rapidly initially and stabilizes around 0.4 after 100 epochs, while the accuracy (red curve) increases quickly and stabilizes around 70%.

On the testing set, the loss (blue curve) decreases rapidly initially but exhibits more fluctuations, stabilizing around 0.5. The accuracy (red curve) on the testing set increases quickly but fluctuates more, stabilizing around 60%.

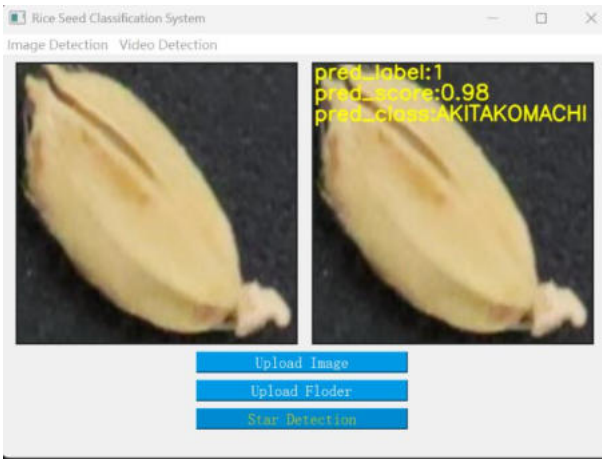
From Figure 8, it can be observed that the AlexNet model also converges more slowly and fails to achieve its best performance. The model's performance on both the training and testing sets is suboptimal. When applied to the classification task of four types of rice seed images, the AlexNet model achieves an accuracy of 76.35%.

Comparison of Different Networks

To validate the impact of different networks on model accuracy, this study conducted experiments using SE-ResNet50, ResNet50, and AlexNet. The comparison results are shown in Table 2.

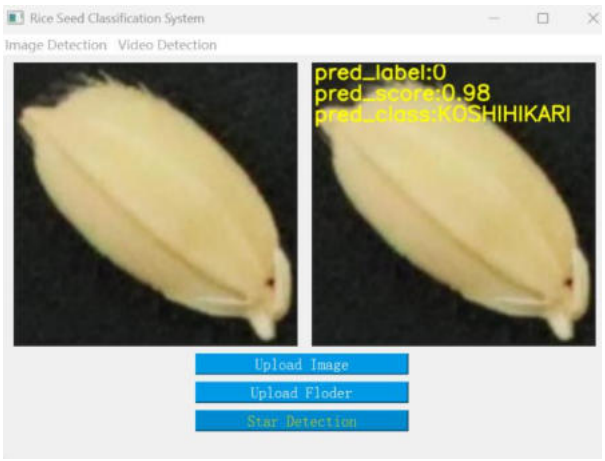
Table 2

Comparison of Experimental Results



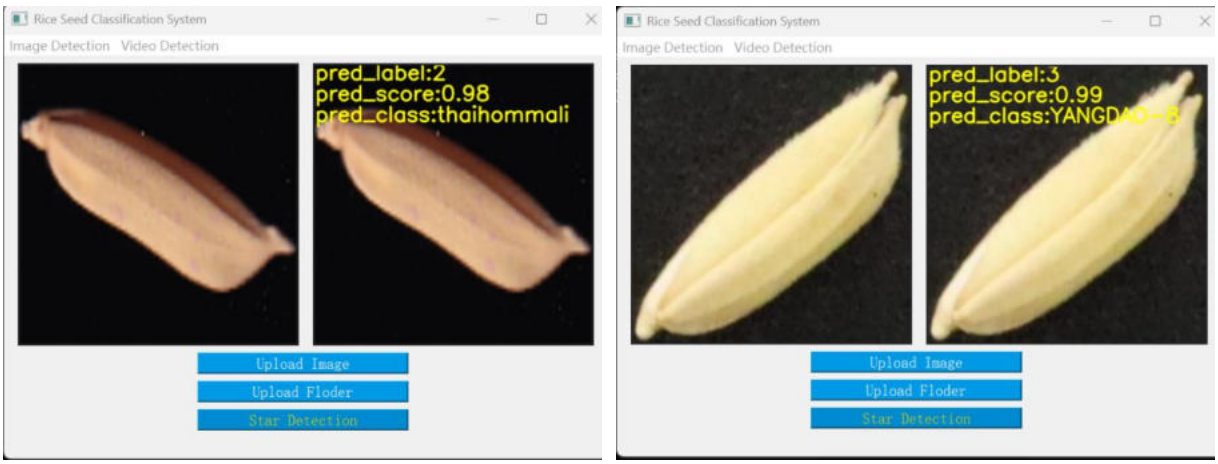
Model	Precision	Recall	F_1 Score
SE-ResNet50	0.8950	0.8922	0.8928
ResNet50	0.7212	0.7202	0.7194
AlexNet	0.7484	0.7582	0.7511

Table 2 shows the performance comparison of SE-ResNet50, ResNet50, and AlexNet in the rice seed image classification task. SE-ResNet50 achieves the best performance in precision (0.8950), recall (0.8922), and F1 score (0.8928), significantly outperforming ResNet50 (precision: 0.7212, recall: 0.7202, F1 score: 0.7194) and AlexNet (precision: 0.7484, recall: 0.7582, F1 score: 0.7511). These results demonstrate that SE-ResNet50 achieves significantly higher accuracy in rice seed image classification compared to the unmodified ResNet50 and AlexNet networks, highlighting the superiority of the selected network model in this task. Specifically, the deeper network layers and feature recalibration strategy (i.e., SENet) of SE-ResNet50 enable it to achieve better classification results in fine-grained image classification tasks such as rice seed classification.



These experimental results comprehensively and convincingly demonstrate that SE-ResNet50 offers higher accuracy and stability in rice seed image classification, validating its significant advantages in classification performance.

Results Presentation of the Rice Seed Classification System



Rice Seed Classification System visually presents the application effectiveness of the constructed intelligent classification model through its user interface (UI), emphasizing the classification process and output results of test set samples. The core interface design focuses on structured output presentation, including (pred_label, pred_class, pred_score), as illustrated in Fig.10. Experimental results demonstrate that the system effectively validates model performance. By visually correlating confidence scores (pred_score) with variety labels (pred_class), it provides an intuitive assessment basis for evaluating the practical applicability and classification accuracy of the model in real-world scenarios. This capability further facilitates subsequent model optimization and system deployment decisions.

CONCLUSIONS

This study innovatively proposes an SE-ResNet network architecture and develops a rice seed classification system, effectively addressing the technical limitations of traditional methods and existing deep learning models in fine-grained agricultural image recognition. The main contributions include:

(1) The novel integration of Squeeze-and-Excitation (SE) blocks into ResNet50 architecture significantly enhances the model's discriminative feature extraction capability for morphologically similar rice seeds through channel attention mechanisms. The proposed system achieves outstanding performance with precision of 0.8950, recall of 0.8922, and F1-score of 0.8928 on a dataset comprising 5,189 images across four varieties.

(2) A Qt framework-based graphical user interface (GUI) application system was developed, enabling real-time rice seed classification and structured output presentation (including category code pred_label, variety name pred_class, and confidence score pred_score), providing an intelligent tool for seed quality control and breeding decision-making.

These research outcomes offer an effective technical solution for agricultural intelligence development. Future studies will focus on expanding the system's applications in smart agriculture through the incorporation of multimodal sensor data and model lightweight design.

Keywords: *YOLO11; Diamondback moth; Lightweight; Real-time detection*

ABSTRACT

The diamondback moth (Plutella xylostella) is a destructive pest that severely compromises Chinese cabbage production. Infestations caused by this pest significantly reduce both yield and quality, making efficient and accurate detection crucial for cultivation management. To address the challenges of detecting small targets and extracting phenotypic features in complex environments, this study proposes SAFF-YOLO—a YOLO11-based pest detection algorithm specifically designed for diamondback moths in Chinese cabbage fields. First, the loss function was refined to enhance the model's learning capacity for pest samples, optimizing it for precision-driven bounding box regression. Second, Alterable Kernel Convolution (AKConv) was incorporated into the backbone network, strengthening feature extraction capabilities while reducing model parameters. Third, Single-Head Self-Attention (SHSA) was integrated into the C2PSA (Channel and Position Spatial Attention) module, enhancing the backbone network's feature processing efficacy. Fourth, the neck network employed Frequency-aware Feature Fusion (FreqFusion) as the upsampling operator, specifically designed for precise localization of densely distributed targets. Finally, the Feature Auxiliary Fusion Single-Stage Head (FASFFHead) detection module was implemented to boost multi-scale target detection adaptability. Experimental results demonstrate that SAFF-YOLO achieved detection metrics of 90.7% precision, 89.4% recall, and 92.4% mAP50 for diamondback moths in Chinese cabbage, representing improvements of 7.4%, 8.0%, and 8.4% respectively over YOLO11. With only 7.3 million parameters and computational cost of 12.8 GFLOPs, this corresponds to 60.1% and 40.7% reductions compared to the baseline model. These results confirm an optimal balance between model lightweighting and high detection accuracy. Under complex field conditions characterized by small and densely distributed targets, severe background interference, and intense illumination, SAFF-YOLO consistently demonstrates robust detection capabilities, effectively reducing both false negative and false positive rates while maintaining high operational robustness. This research provides a practical solution for real-time diamondback moth detection in field-grown Chinese cabbage.

摘要

小菜蛾是严重危害白菜生产的害虫，其导致的虫害会使白菜产量、质量严重下降，因此高效、准确地检测小菜蛾对白菜栽培至关重要。针对复杂环境下小菜蛾检测存在目标小、表型特征提取困难等问题，本研究提出了基于 YOLO11 的白菜小菜蛾害虫检测算法 SAFF-YOLO。首先，改进损失函数来增强模型对害虫样本的学习能力，使其更适合边界框回归的准确性需求；引入可变核卷积（Alterable Kernel Convolution，AKConv）作为主干网络，增强了特征提取能力，减少了模型参数的数量；将单头自注意力（Single-Head Self-Attention，SHSA）集成至 C2PSA（Channel and Position Spatial Attention）模块中，提高了骨干网络的特征处理能力；颈部网络使用频率感知特征融合（Frequency-aware Feature Fusion，FreqFusion）作为上采样算子，旨在更好的对密集目标识别定位；最后通过 FASFFHead（Feature Auxiliary Fusion Single-Stage Head）检测头增强模型对不同尺度目标的检测能力。试验结果表明，SAFF-YOLO 对白菜小菜蛾的检测准确率、召回率、平均精度均值（mean average precision，mAP50）达到 90.7%、89.4%和 92.4%，对比 YOLO11 各提高了 7.4%、8.0%和 8.4%，且参数量为 7.3M，每秒浮点运算次数（Giga Floating-point Operations Per Second，GFLOPs）为 12.8，相较于基准模型分别降低 60.1%和 40.7%，实现了模型轻量化和较高检测精度的平衡。在小菜蛾小且密集、背景干扰严重、光照强烈等复杂环境下，SAFF-YOLO 均能较好地识别出目标个体，有效地降低漏检率和误检率，具有较好的鲁棒性。本研究可为田间白菜小菜蛾实时检测提供有效技术支持。

INTRODUCTION

Globally cultivated Chinese cabbage (Brassica rapa subsp. pekinensis) serves as a nutritionally essential vegetable crop. However, expanding cultivation and climate change have escalated phytopathological threats (*Ritonga et al., 2024; Li et al., 2016; Zhang et al., 2024; Shi et al., 2025*). The diamondback moth (*Plutella xylostella*), a devastating pest for Chinese cabbage, imposes substantial economic losses on farmers and challenges sustainable agricultural production systems annually (*Ahmed et al., 2022; Shehzad et al., 2023; Li et al., 2016*). Adult diamondback moths exhibit phloem-feeding behavior and rapid reproduction rates, impairing normal plant development and causing yield reduction in Chinese cabbage (*Rahman et al., 2019*). Larval chewing damage during growth stages induces extensive defoliation and leaf perforation, with severe infestations leading to complete leaf skeletonization (*Hussain et al., 2020; Hu et al., 1997*). Morphologically distinct between life stages, adults are flight-capable with predominantly gray-brown to dark brown coloration, while larvae exhibit green or pale yellow pigmentation that enables adaptive concealment within host plants. This phenotypic divergence creates significant detection challenges across developmental phases of diamondback moth (*Chen et al., 2011*). Consequently, developing rapid and accurate detection methods for diamondback moth in Chinese cabbage, coupled with effective monitoring of pest population dynamics, to implement targeted control measures, enables comprehensive pest management across critical growth stages - seedling, rosette, and heading phases - thereby safeguarding crops from significant yield losses. This constitutes an urgent agricultural priority demanding immediate resolution.

The rapid advancement of artificial intelligence has positioned machine learning and deep learning-based object detection algorithms as pivotal technologies in plant disease and pest identification research (*Chakrabarty et al., 2024*). At present, representative two-stage object detection methods such as Faster RCNN (*Ali et al., 2023; Hou et al., 2023; Wang et al., 2017*) and representative single-stage object detection methods such as SSD (*Zhai et al., 2020; Lyu et al., 2021*), YOLO are widely used for the detection and recognition of targets such as crop diseases and pests *(Wang et al., 2024; Dongfang et al., 2024*). To address the challenge of early identification of pests and diseases such as coffee leaf rust and miner pests, *Fragoso et al., (2025)*, proposed a real-time detection solution based on the YOLO series models (versions 8 to 11). The models were trained using the BRACOL dataset. Results demonstrated that YOLOv8s exhibited the optimal inference speed, with its qualitative predictive performance being significantly superior to other versions. While maintaining high accuracy, it meets the requirements for real-time field monitoring, thereby delivering robust technological support for the sustainable management of coffee cultivation. Slim *et al., (2023)*, proposed an intelligent pest detection system based on the YOLOv5 deep learning model by employing transfer learning and data augmentation techniques, the system addressed the challenge of insufficient training data. A companion mobile application was developed to assist farmers in real-time pest identification, localization, and quantification. This system significantly reduced farm inspection costs while also providing efficient, data-driven decision-making support for pest management. Liang et al., (*2024*) proposed an optimized YOLOv8n architecture for corn pest detection, incorporating Deformable Attention (DAttention) and Spatial and Channel Reconstruction Convolution (SCConv) modules. Trained on a dedicated corn pest dataset, this approach maintains high detection accuracy at 71 frames per second (FPS), enabling rapid and precise field-level infestation monitoring.

In field agriculture, micro-dense pests constitute the predominant infestation type. To address small-target detection challenges, optimizing object detection network architectures has emerged as the primary technical approach *(Wen et al., 2022*). *Teixeira et al.,* (*2023*), used the YOLOv5 deep learning model to achieve efficient recognition on the Pest24 dataset in response to the challenge of automatic detection of agricultural pests. Their experiments revealed that the relative scale of insects is a critical factor influencing detection accuracy. This approach provides a novel solution for pest detection in scenarios characterized by dense small objects, while also highlighting that enhancing the detection capability for small-sized insects represents a promising future research direction. Addressing the challenge of citrus disease detection, *Dananjayan et al., (2022),* developed the meticulously annotated CCL'20 dataset, and systematically evaluated the performance of seven state-of-the-art CNN detectors. Experimental results demonstrated that Scaled YOLOv4 P7 achieved the fastest inference speed for early-stage disease prediction, while CenterNet2 with Res2Net-101 DCN-BiFPN significantly outperformed others in detection accuracy for early-stage diseases, leveraging multi-scale feature fusion and attention mechanisms to excel particularly in identifying small-target lesion areas. This framework provides an efficient technical solution for real-time citrus disease diagnosis, effectively balancing the dual demands of inference speed and detection accuracy.

Tian et al., (*2023*), proposed MD-YOLO (Multi-scale Dense YOLO) featuring fused feature extraction/aggregation pathways with DenseNet blocks and adaptive attention modules. Deployed on sticky insect boards, this IoT-embedded system detects three lepidopteran pest species with validated field performance, demonstrating practical applicability.

While object detection algorithms have demonstrated considerable success, significant challenges persist in small-target detection research. When detecting minute pests, inherent complexities include multi-scale targets, dense clustering, and frequent occlusion scenarios. Although algorithmic advances have mitigated feature degradation caused by edge information loss and background interference, such accuracy improvements typically incur increased computational complexity that exceeds the capabilities of edge deployment platforms (*Liu et al., 2020; Lippi et al., 2021; Song et al., 2023*). To address these constraints, SAFF-YOLO is proposed—a lightweight architecture for diamondback moth detection in Chinese cabbage—which maintains high detection accuracy while substantially reducing computational footprint for efficient edge device implementation.

MATERIALS AND METHODS

Data Acquisition and Processing

The primary image acquisition for our diamondback moth dataset was conducted in Anda City, Suihua Municipality, Heilongjiang Province. To ensure data reliability and enhance dataset diversity for robust model generalization, 1,772 raw images were compiled in lossless PNG format, supplemented with carefully selected web-sourced imagery to augment phenotypic variation and ecological representativeness.

To ensure model fidelity, data acquisition employed multiple device platforms including iPhone 15 Pro and Honor 30 Pro, capturing images at dual resolutions (1280×720 and 4096×3072 pixels) thereby enhancing the recognition system's robustness and generalization capabilities across diverse imaging conditions and hardware configurations.

The initial dataset comprises raw images categorized into diamondback moth larvae and adults, supplemented through comprehensive data augmentation techniques including geometric transformations (translation, rotation), photometric adjustments (saturation/exposure modulation), random occlusion, and Gaussian noise injection. As depicted in Figure 1, these augmentations simulate diverse field conditions to enhance dataset variability while improving model sensitivity to phenotypic variations, ensuring sustained high recognition accuracy in complex real-world environments.

Fig. 1 - Data Enhancement

A final dataset of 4,794 images was selected to ensure data quality and diversity, which was then divided into training, validation, and test sets at an 8:1:1 ratio. To ensure annotation accuracy, this study employed the open-source labeling software LabelImg to manually annotate diamondback moth specimens in images, ultimately establishing the Plutella xylostella Dataset.

SAFF-YOLO-based lightweight detection method for the diamondback moth

YOLO11 is an advanced single-stage object detection model whose architecture comprises three core components: a backbone network, a neck network, and a detection head. Building upon its predecessors, YOLO11 incorporates significant optimizations—including a more powerful backbone network to enhance feature extraction efficiency and an innovative neck design featuring an enhanced EfficientDet-inspired FPN architecture to improve multi-scale object detection capabilities. The detection head employs a refined design that achieves precise prediction of object categories and locations, enabling efficient and accurate identification and localization of diverse targets even in complex, dynamic scenarios. The overall architectural layout of the YOLO11 model is illustrated in Figure 2.

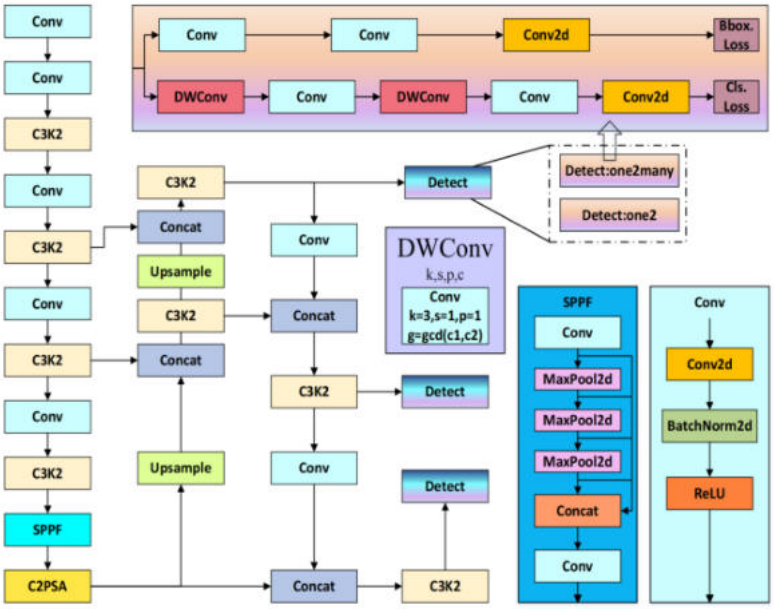

Fig. 2 - YOLO11 network structure

Despite its capability to accurately detect and identify targets, support multi-class object detection, and perform real-time tracking, YOLO11 remains challenged in achieving precise detection of early-stage small-scale pest infestations in field conditions. Specifically for diamondback moth detection, it struggles to extract phenotypic characteristics and accurately identify small targets. To address these limitations, this study proposes SAFF-YOLO (an enhanced YOLO11-based algorithm) for detecting diamondback moth infestations in Chinese cabbage fields, which significantly improves performance in agricultural pest detection tasks. The architecture of the proposed model is illustrated in Figure 3.

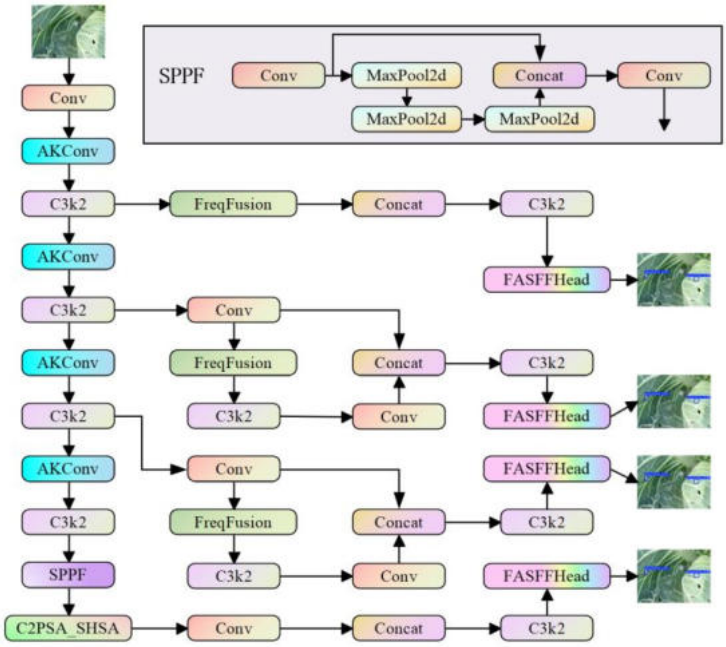

Fig. 3 - Structure of the SAFF-YOLO network

The original loss function was replaced with the Unified-IoU (UIoU) loss function (*Luo et al., 2024*), which dynamically adjusts the model's focus on prediction boxes of varying quality to optimize bounding box regression accuracy in object detection, thereby enabling more precise pest localization. The AKConv lightweight convolutional module was introduced to replace partial network structures *(Zhang et a., 2023*), enhancing feature extraction capability while reducing model parameters. Furthermore, SHSA and C2PSA modules were integrated into a unified SHSA_C2PSA module (*Yun et al., 2024*), which augments the backbone network's feature processing capacity, improves small-target detection performance, and reduces computational redundancy and memory access costs.

The neck network employs FreqFusion as its upsampling operator (*Chen et al., 2024*), enhancing localization in dense object scenarios while reducing computational complexity and improving processing speed. Within the detection head, the adaptive spatial feature fusion (ASFF) method was integrated with the P2 detection layer, evolving into a novel FASFFHead module (*Liu et al., 2019*). This integration mitigates feature loss during cross-scale fusion and implements secondary feature extraction for small targets, thereby enhancing model recognition accuracy.

Improvement of Loss Function

In the context of diamondback moth detection, the YOLO11 model faces challenges due to target density, minute scale, occlusion, and partial body visibility, leading to suboptimal recognition performance. To address this limitation, the original Complete Intersection over Union (CIoU) loss was replaced with the Unified-IoU (UIoU) loss function. This novel approach dynamically reallocates model focus from low-quality to high-quality prediction boxes through adaptive weight assignment, enhancing detection performance on both high-precision and densely clustered datasets while maintaining training efficiency. The mechanism effectively captures spatial relationships and overlapping region information among targets. The UIoU computation is formalized in Equation (1).

$$L_{UIoU} = 1 - IoU + \frac{\rho^2(b,b^{gt})}{c^2} + \alpha v \tag{1}$$

where ρ denotes the Euclidean distance between two points, b represents the center coordinate of the prediction box, b^{gt} indicates the ground truth box center, c is the diagonal length of the smallest enclosing rectangle, α serves as a scaling coefficient for balance, and v incorporates the aspect ratios of both prediction and target boxes into the sigmoid function. This formulation fulfills a dual role: (1) thresholding values to prevent excessive oscillation, and (2) quantifying aspect ratio consistency between boxes. The formal definitions of α and v are given in Equations (2) and (3), respectively.

$$\alpha = \frac{v}{(1-IoU)+v} \tag{2}$$

$$v = \left(\frac{1}{1+e^{-\frac{\omega 1}{h1}}} - \frac{1}{1+e^{-\frac{\omega}{h}}}\right)^2 \tag{3}$$

In the formula, $\omega 1$ and ω represent the lengths of the target box and the predicted box, while h_1 and h represent the widths of the target box and the predicted box.

The derivative calculation of UIoU is shown in equations (4) and (5).

$$\frac{\alpha v}{\alpha \omega} = 2\left(\frac{1}{1+e^{-\frac{\omega^{gt}}{h^{gt}}}} - \frac{1}{1+e^{-\frac{\omega}{h}}}\right)\left[\frac{1}{1+e^{-\frac{\omega}{h}}}\left(1 - \frac{1}{1+e^{-\frac{\omega}{h}}}\right)\right]/h \tag{4}$$

$$\frac{\alpha v}{\alpha h} = 2\left(\frac{1}{1+e^{-\frac{\omega^{gt}}{h^{gt}}}} - \frac{1}{1+e^{-\frac{\omega}{h}}}\right)\left[\frac{1}{1+e^{-\frac{\omega}{h}}}\left(1 - \frac{1}{1+e^{-\frac{\omega}{h}}}\right)\right] \times \frac{\omega}{h^2} \tag{5}$$

UIoU achieves adaptive weight allocation for prediction boxes of varying quality through strategic scaling of both prediction and ground truth boxes. This approach eliminates redundant bounding box computations while maintaining geometric integrity. After acquiring the bounding box dimensions (height, width) and center coordinates, UIoU applies scale factors to proportionally expand or contract these dimensions. This controlled scaling dynamically modulates the model's attention across prediction box qualities—where box contraction intensifies focus on high-quality predictions, thereby enhancing precision detection performance for well-defined targets.

AKConv

Convolutional kernels have achieved remarkable success in deep learning, yet they exhibit two inherent limitations. First, the confinement to local receptive fields restricts their capacity to capture global contextual information, while their fixed sampling patterns further limit adaptability. Second, conventional square-shaped kernels with fixed dimensions cause parameter counts to increase quadratically with kernel size. These rigid sampling geometries and kernel shapes struggle to adapt to the diverse target morphologies and scales across datasets and spatial locations (*Zhang et al., 2023*).

To overcome these limitations, AKConv (Adaptive Kernel Convolution) is introduced, which employs a flexible convolutional mechanism permitting kernels with arbitrary parameter counts. By dynamically adjusting kernel shapes to accommodate diverse image characteristics, this approach enhances model adaptability and computational efficiency. Consequently, AKConv not only improves model performance but also reduces parameter quantities. The architectural configuration of the AKConv module is illustrated in Figure 4.

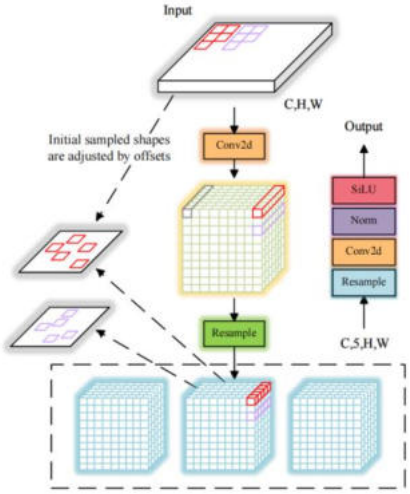

Fig. 4 - AKConv structure diagram

AKConv introduces a novel coordinate generation algorithm that dynamically adapts sampling shapes to varying images and targets. This algorithm generates initial sampling coordinates for kernels of arbitrary sizes and geometries (Fig.5), significantly enhancing flexibility in detecting multi-scale targets. To accommodate target variations, AKConv adjusts sampling positions of non-rectangular kernels through learned offsets, thereby improving feature extraction accuracy.

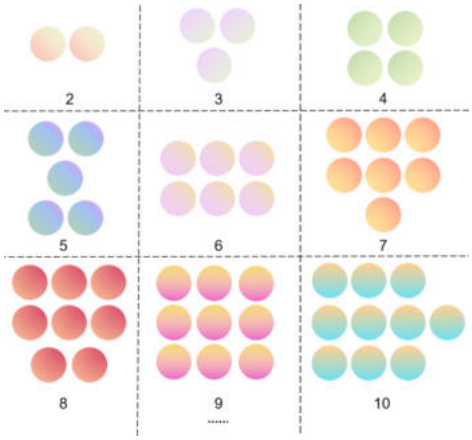

Fig. 5 - Adaptive initial sampling shape

Unlike traditional convolutional kernels that employ regular sampling grids, AKConv targets deformable kernels with irregular geometries. This innovation necessitated the development of an arbitrary-size convolution algorithm that generates initial sampling coordinates P_n for convolutional kernels (*Wu et al., 2024*). The algorithm first generates a regular sampling grid, subsequently constructs an irregular grid for residual sampling points, and finally concatenates both components into a unified sampling structure.

Within this framework, the top-left coordinate (0,0) serves as the sampling origin. Given initial coordinates P_n and kernel parameters ω for irregular convolution, the convolutional operation at position P_0 is formally defined by Equation (6).

$$ConvP_0 = \sum \omega \times (P_n + P_0) \quad (6)$$

AKConv resolves the fundamental mismatch between irregular sampling coordinates and fixed-size convolution operations through its algorithmic innovations.

Traditional convolution suffers from quadratic growth in both parameter count and computational load with increasing kernel size, leading to inefficiency in resource-constrained environments. In contrast, AKConv's unique design reduces model parameters and computational overhead, enabling dynamic complexity adjustment according to task requirements and hardware capabilities. Furthermore, AKConv adapts to spatial feature variations through offset-adjusted kernel positioning, effectively handling non-rigid deformations, occlusions, and complex backgrounds. This capability significantly enhances detection robustness for subsequent diamondback moth identification. The schematic representation of this adaptation process is illustrated in Fig. 6.

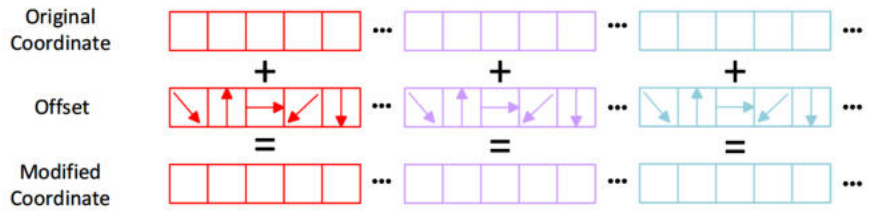

Fig. 6 - Offset adjustment sample shape

Single-Head Self-Attention

Accurate extraction of spatial location information is critical in object detection tasks. In pest-containing images where natural backgrounds dominate, convolutional kernels process non-target regions, introducing substantial redundant information that compromises pest recognition accuracy. The Single-Head Self-Attention (SHSA) mechanism addresses this by applying attention to a subset of input channels (CP=rC), reducing computational redundancy while integrating global and local features to enhance efficiency and precision. As illustrated in Fig. 7, SHSA operates by: (1) applying a single-head attention layer to a channel subset (CP=rC), where r denotes the reduction ratio) for spatial feature aggregation, while (2) preserving original information in remaining channels.

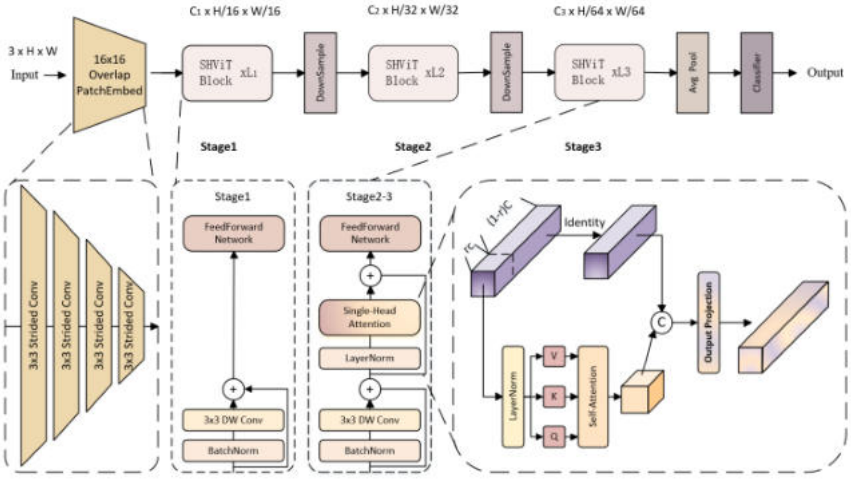

Fig. 7 - Structure of SHSA attention mechanism

The calculation formulas for its operation are shown in equations (7) to (10).

$$SHSA(X) = Concat\left(\widetilde{\mathrm{X}}_{att},\ X_{res}\right)W^{Q} \quad (7)$$

$$\widetilde{\mathrm{X}}_{att} = Attention\left(X_{att}W^{Q},\ X_{att}W^{K},\ X_{att}W^{V}\right) \tag{8}$$

$$Attention\left(Q,\ K,\ V\right) = Softmax\left(QK^{T}/\sqrt{d_{qk}}\right)V \tag{9}$$

$$X_{att},\ X_{res} = Split\left(X,\ \left|C_{p},\ C - C_{p}\right|\right) \tag{10}$$

where W^{Q}, W^{K}, and W^{V} denote projection weight matrices, dqk represents the dimensionality of queries and keys, and Concat signifies the concatenation operation. To maintain memory access consistency, the initial C_p channels serve as representative proxies for the complete feature map. Moreover, SHSA's final projection operates across all channels—not solely the initial C_p subset—ensuring efficient propagation of attention features to residual channels.

Frequency-aware Feature Fusion

Feature extraction of diamondback moths is challenged by small target regions, uneven density distribution, and low image resolution, resulting in insufficient valid information. However, dense image prediction requires high-precision category information and spatial boundaries. Conventional feature fusion methods underperform in maintaining category feature consistency and preserving boundaries, often causing significant intra-class feature variations and boundary ambiguity.

FreqFusion is a frequency-aware feature fusion framework comprising three core modules: an Adaptive Low-Pass Filter Generator (ALPF), an Offset Generator, and an Adaptive High-Pass Filter Generator (AHPF). The ALPF predicts spatially adaptive low-pass filters to mitigate intra-class inconsistency; the Offset Generator predicts feature offsets to refine internal representations and boundary characteristics; while the AHPF extracts high-frequency details for precise boundary delineation. As illustrated in Fig.8, these modules operate synergistically to resolve intra-class inconsistencies and boundary ambiguities in dense image prediction. Through frequency-aware feature refinement, this integrated mechanism enhances model performance.

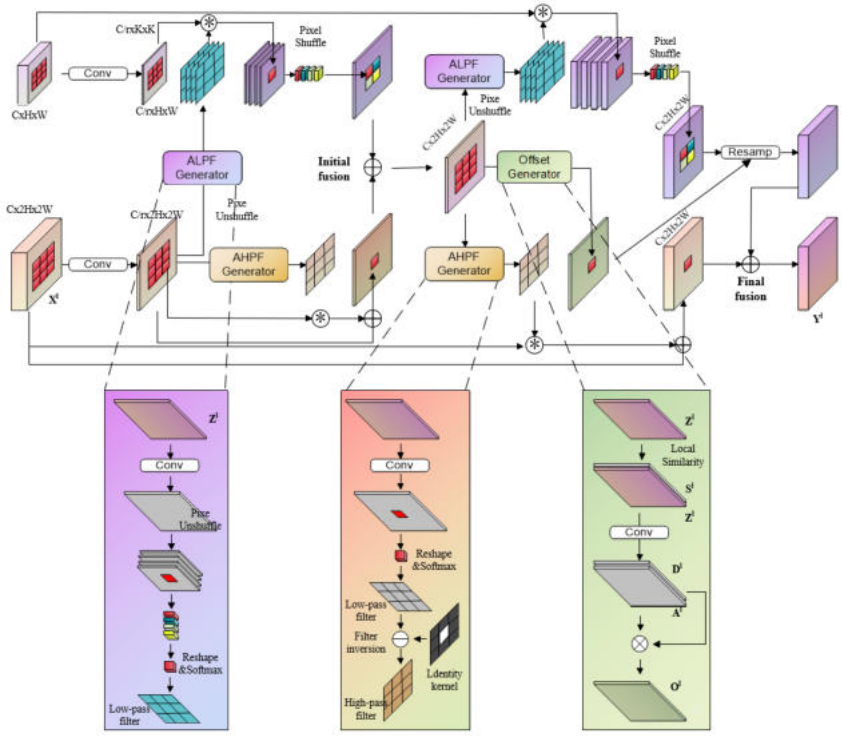

Fig. 8 - FreqFusion structure diagram

The generation calculation formula for FreqFusion is shown in Equations (11) and (12).

$$Y_{i,j}^{l} = \tilde{Y}_{i+u,j+v}^{\ l+1} + \tilde{X}_{i,j}^{\ l} \tag{11}$$

$$\tilde{Y}^{\,l+1} = \mathcal{F}^{UP}\left(\mathcal{F}^{LP}(Y^{l+1})\right),\ \tilde{X}^{l} = \mathcal{F}^{HP}(X^{l}) + X^{l} \tag{12}$$

In this formulation, $\mathcal{F}^{UP}$ denotes the low-pass filter predicted by the ALPF generator, while (u, v) represents the offset values predicted by the Offset Generator for feature coordinates at (i, j), and $\mathcal{F}^{UP}$ signifies the high-pass filter generated by AHPF. These components collectively resolve class inconsistency and boundary displacement by: (1) adaptively smoothing high-level features using spatially adaptive low-pass filtering, (2) replacing inconsistent features through resampling of adjacent class-consistent features, and (3) enhancing high-frequency boundary details in low-level features.

Feature Auxiliary Fusion Single-Stage Head

In object detection, conventional YOLO series achieve efficient detection through multi-scale feature fusion. While the YOLO11 detection head demonstrates advantages, it exhibits limitations in complex scenes or small object detection. The FASFFHead addresses this by: (1) introducing auxiliary feature layers and a feature selection module, (2) fusing multi-level features to enhance network sensitivity towards multi-scale and complex objects, and (3) improving extraction and representation of multi-scale features for superior discriminative feature capture. As illustrated in Fig. 9, the FASFFHead primarily consists of two key components: a Shallow-level Feature Fusion module (SFB) and a High-level Feature Extraction module (HFE), operating through the following mechanism.

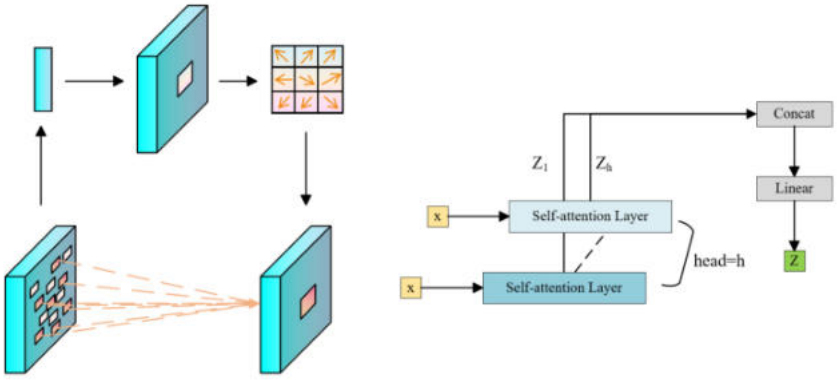

Fig. 9 - FASFFHead structure diagram

Within the SFB module, shallow-level and high-level features are integrated through a cascaded residual network and feature pyramid structure. This fusion preserves detailed spatial information from shallow features while incorporating global semantic context from high-level features, thereby enriching feature maps and enhancing representational capacity. The HFE module subsequently processes these fused features through depthwise convolutional layers to extract deep contextual information, while employing a Spatial Pyramid Pooling (SPP) layer to capture multi-scale representations. This dual mechanism significantly improves detection capability for objects across varying scales.

By synergistically combining SFB and HFE modules, the FASFFHead effectively fuses auxiliary features with high-level representations from the backbone network. This integration substantially boosts detection performance, simultaneously enhancing feature expressiveness while improving model robustness and generalization capability for practical object detection applications.

RESULTS AND ANALYSIS

Test environment and evaluation index

To ensure experimental validity, detailed hardware and software configurations are specified in Table 1.

Table 1

Software and Hardware Environment Configuration Table

Configuration Parameter	Configuration Item
CPU	16 vCPU Intel(R) Xeon(R) Platinum 8352V CPU @ 2.10GHz
RAM	120GB
GPU	NVIDIA GeForce RTX 4090 24GB
Operating system	Ubuntu 18.04
CUDA	12.4
Compiled language	Python 3.9
Deep learning framework	PyTorch3.8.0
Epochs	200
Batch size	32

The evaluation employs three metrics: $mAP@50$, precision (P), and recall (R). Precision quantifies the proportion of true positives among all positive predictions, while recall measures the proportion of actual positives correctly identified. Their computational formulations are given by Equation (13) and Equation (14), respectively.

$$P = \frac{T_P}{T_P + F_P} \tag{13}$$

$$R = \frac{T_P}{T_P + F_N} \tag{14}$$

where F_N denotes the number of false negatives (missed detections), F_P represents false positives (detections with IoU below the threshold), and T_P indicates true positives (detections with IoU ≥ threshold).

For mAP computation, the average precision (A) corresponds to the area under the Precision-Recall (P-R) curve, calculated as specified in Equation (15).

$$A = \int_2^1 P(R)dR \tag{15}$$

Performance comparison test of different models

To evaluate the pest recognition and detection performance of the SAFF-YOLO model, comparative experiments were conducted against prevalent object detection models: Faster R-CNN, SSD, YOLOv8, YOLOv9, YOLOv10, and YOLO11. Identical experimental setups (hardware/software configurations) were maintained across all models to ensure methodological rigor and validity. Model performance was comprehensively assessed using five metrics: precision, recall, mean average precision (mAP), floating-point operations (FLOPs), and parameter count. Comparative results are presented in Table 2.

Table 2

Training effect of different models

Model	Precision(%)	Recall(%)	mAP0.5(%)	GFLOPs	Model Size(MB)
Faster-RCNN	82.1	80.3	83.7	124.2	71.6
SSD	80.1	77.9	80.7	61.1	39.2
YOLOv5	81.3	76.8	81.8	5.9	4.4
YOLOv8	82.0	79.9	84.6	6.9	5.4
YOLOv10	81.7	78.4	82.3	6.6	5.2
YOLO11	83.3	81.4	84.0	21.6	18.3
SAFF-YOLO	90.7	89.4	92.4	12.8	7.3

According to Table 2, the SAFF-YOLO model demonstrates mAP@50 improvements of 8.7%, 11.7%, 10.6%, 7.8%, 10.1%, and 8.4% over Faster R-CNN, SSD, YOLOv5, YOLOv8, YOLOv10, and YOLO11, respectively. These gains indicate superior target localization accuracy, enhanced recognition capability for pests in complex backgrounds and dense populations, and higher confidence scores with improved reliability in detection outcomes.

Ablation Experiments

Targeting diamondback moth infestation detection, this study progressively enhanced the YOLO11 architecture. Each modification underwent statistical analysis to validate efficacy in pest recognition, with quantitative results detailed in Table 3.

Table 3

SAFF-YOLO model ablation experiments

Model	Precision(%)	Recall(%)	mAP0.5(%)	GFLOPs	Model Size(MB)
YOLO11	83.3	81.4	84.0	21.6	18.3
YOLO11-U	85.0	83.5	85.8	21.6	18.3
YOLO11-UA	83.1	82.3	85.1	5.5	4.4
YOLO11-UAB	86.2	83.7	86.7	5.4	4.3
YOLO11-UABC	88.6	87.3	89.6	6.1	4.3
SAFF-YOLO	90.7	89.4	92.4	12.8	7.3

Note: U represents replacing the UIoU loss function; A represents the AKConv improvement; B represents the SHSA improvement; C represents the FreqFusion improvement

Stage 1: UIoU replacement improved precision, recall, and mAP50 of baseline YOLO11 by 1.7%, 2.1%, and 1.8% respectively. Stage 2: AKConv modification reduced parameter count by 76% and computational load by 16.1 GFLOPs versus baseline. Stage 3: Integrating SHSA and FreqFusion modules increased mean average precision by 1.7-2.9 percentage points without computational overhead, enhancing all metrics.

Final integration: Incorporating the FASFFHead module, SAFF-YOLO demonstrated significant improvements over YOLOv11 across all evaluated metrics: a 40.7% reduction in model size, an 8.8 GFLOPs decrease in computational cost, and respective gains of 7.4% in precision, 8.0% in recall, and 8.4% in mAP50. This demonstrates SAFF-YOLO's superior accuracy and robustness when detecting micro-scale pests in dense infestations with scale variations and homogeneous backgrounds.

Model visualization analysis and comparison

Comparative detection results for diamondback moths using YOLOv5, YOLOv8, YOLO11, and SAFF-YOLO are presented in Fig. 10, validating SAFF-YOLO's superior performance in this study. Visual evidence demonstrates SAFF-YOLO's enhanced robustness in complex environments with significant interference, effectively reducing false positives and misclassifications prevalent in baseline YOLO variants. Under challenging conditions featuring small target pests and high identification difficulty, comparator models exhibit frequent false detections, duplicate identifications, and low-confidence predictions. SAFF-YOLO significantly outperforms these models through improved environmental adaptability and superior discriminative feature representation capabilities.

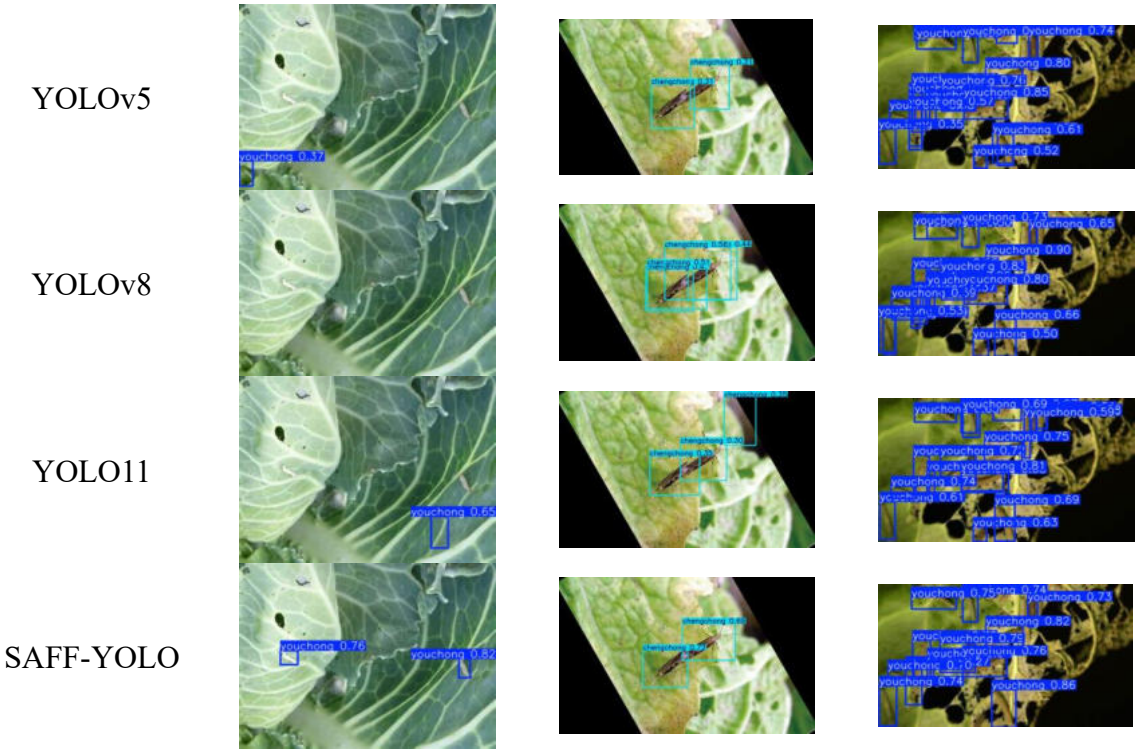

Fig. 10 - Target detection results of different models for the little Chinese cabbage diamondback moth

SAFF-YOLO: Diamondback Moth Pest Detection System

This study designed and implemented a visualization detection system for diamondback moths using the PyQt framework, as illustrated in Fig.11. PyQt integrates Python's concise syntax with Qt's robust functionality, offering comprehensive GUI components, cross-platform compatibility, and efficient signal-slot mechanisms. This architecture ensures consistent and stable user interfaces across diverse operating systems.

The application implements two core functionalities:

1) Pest image import module: Supports four input modalities: single image import, batch directory import, video file processing, and real-time camera-based detection.

2) Detection visualization interface: Presents detection metadata including inference duration, target count, pest classification, confidence scores, and bounding box coordinates. Post-detection, the system generates a comprehensive report listing target serial numbers, file paths, categories, confidence values, and positional coordinates.

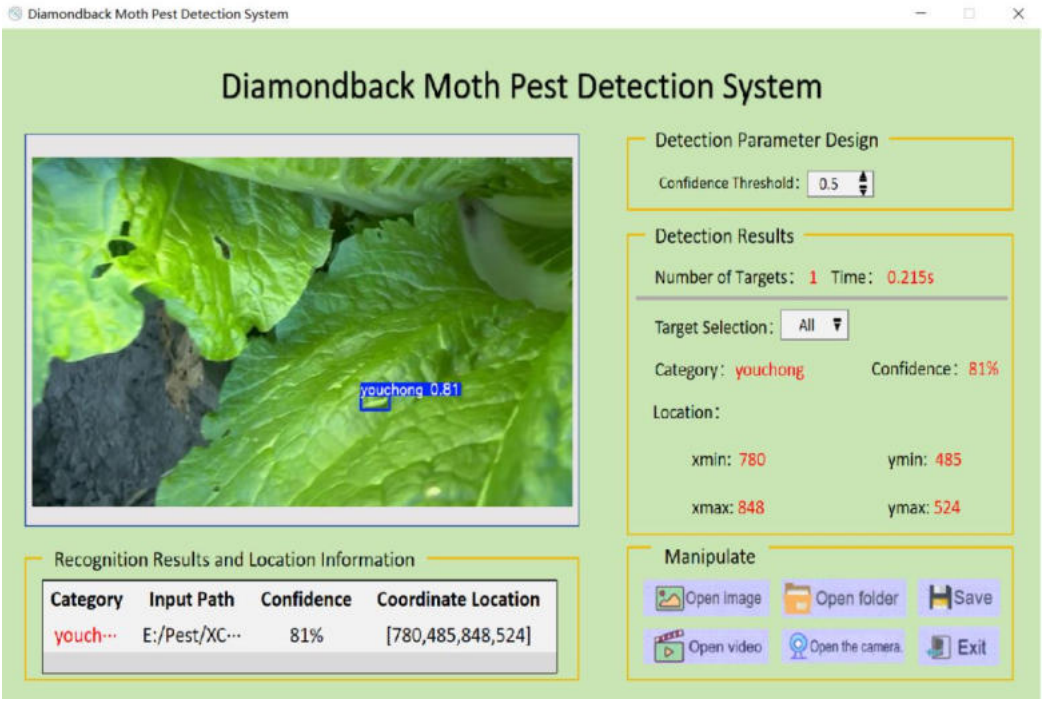

Fig. 11 - Diamondback Moth Pest Detection System

CONCLUSIONS

This study addresses key challenges in Chinese cabbage pest detection—including scale variation, target density, and phenotypic feature extraction difficulties—by proposing SAFF-YOLO: an efficient algorithm for diamondback moth detection on Chinese cabbage plants. The architecture modifies the YOLO11 framework through: (1) replacing the baseline loss function with UIoU to enhance discriminative learning of moth characteristics; (2) integrating AKConv lightweight convolutions and embedding SHSA attention within the C2PSA module to strengthen feature extraction while reducing parameters; (3) implementing FreqFusion as the neck network's upsampling operator for dynamic computation allocation and precise spatial localization; and (4) incorporating the FASFFHead for multi-scale detection capability enhancement. Experimental results demonstrate SAFF-YOLO's 11 MB model size reduction and 8.8 GFLOPs computation decrease versus YOLO11, while achieving 7.4% precision, 8.0% recall, and 8.4% mAP improvements—confirming superior efficiency and accuracy in cabbage moth detection. This approach enables precise localization of infestations for timely intervention in cabbage cultivation, offering valuable references for pest management in related agricultural systems.

ABSTRACT
To improve the uniformity and stability of seed guidance in ordered seed flow and meet the requirements of precision sowing operations, a brush-type seed guiding device capable of constraining all degrees of freedom of the seeds was designed. Bench tests were conducted to optimize the factors affecting performance, namely the nut-bolt head spacing, the brush-to-housing gap, and the brush belt speed. Through single-factor experiments, the influence of each factor on seed guidance performance was clarified, and reasonable value ranges were determined. Combined with a response surface test, a multiple quadratic regression model was established to describe the relationship between these factors and the variation coefficients of pass rate, missed seeding rate, and seed spacing. The results show that optimal seed guidance performance is achieved when the nut-bolt head spacing is 39.15 mm, the brush-to-housing gap is 0.22 mm, and the brush belt linear velocity is 0.644 m/s. This study provides a theoretical foundation and data support for the development of precision sowing technology and its associated seed guiding devices.

摘要
为提高有序种子流导种均匀性与稳定性，满足精量播种作业要求，设计了一种可约束种子全部自由度的毛刷式导种装置，对影响其工作性能的螺母-螺栓头间距、毛刷-外壳间隙和毛刷带线速度等因素进行了台架试验优化。通过单因素实验阐明各因素对导种性能的影响规律，并确定因素的合理取值范围。结合响应面试验，建立了各因素与合格率、漏播率和粒距变异系数间的多元二次回归模型。结果表明，当螺母-螺栓头间距为 39.15 ㎜、毛刷-外壳间隙为 0.22 ㎜、毛刷带线速度为 0.644 m/s 时，导种性能最佳。本研究可为精量播种技术及配套导种装置的研制提供理论基础与数据支撑。

INTRODUCTION
In 2024, the corn planting area and total output in China reached 44.74 million hectares and 294.92 million tons, respectively, consistently securing the top position among the three major grain crops for several years. Nevertheless, China's corn yield remains at only 6.59 tons per hectare, significantly lower than the 11.11–12.04 tons per hectare achieved by the United States and other developed countries (*Awad et al., 2022*). The full mechanization of corn sowing in China has made sowing quality a critical factor influencing corn yield (*Liao et al., 2020*). While significant research has focused on precision seed metering devices within single-seed sowing technology, studies specifically addressing the seed guiding mechanism remain scarce (*Du et al., 2023*). As a result, the seed guiding process has become a limiting factor in improving the quality of high-speed sowing operations. This highlights an urgent need for the development of an efficient seed guiding mechanism tailored to high-speed sowing requirements (*Fanigliulo et al., 2022*).

The seed guiding device is a core component of precision seeders, directly influencing seeding accuracy and efficiency, particularly at high operating speeds. To overcome this bottleneck, recent research has focused on optimizing seed guide designs to improve seed motion stability and placement accuracy.

Key technological strategies include:

Pneumatic-assisted seed guiding: utilizing airflow to guide and constrain seed trajectories. Examples include air-delivery auxiliary seed guides (*Li et al.*, *2025*), guidance restraint-airflow blowing devices (*Liu et al.*, *2025*), and conical spiral airflow high-speed guides (*Zhang et al.*, *2024*). These systems improve seeding uniformity through the optimization of airflow parameters (*Karayel et al.*, *2022*). Internationally, companies like Amazone and Vaderstad employ positive-pressure airflow ejection mechanisms. Air-assisted guidance has also been adapted for specialized applications, such as hill-seeding of sesame (*Wang et al.*, *2023*). Mechanical structure optimization: Researchers have developed novel geometries aimed at minimizing seed bouncing and collisions. These include converging groove-guided seed tubes (*Jia et al.*, *2024*), seed tubes based on the brachistochrone principle (*He et al.*, *2022*; *Li et al.*, *2024*), and belt-type systems. For example, *Chen et al. (2012)* designed a belt-based mechanism to ensure precise seed trajectory and improved spacing uniformity, while *Liu et al. (2017)* developed a sowing synchronous belt device for systematic seed transport to the seedbed. Performance monitoring and simulation: Employing technologies like photoelectric sensors for real-time monitoring of belt-type devices (*Wang et al.*, *2024*) and leveraging DEM-CFD coupling for advanced design and optimization (*Li et al.*, *2024*; *Ma et al.*, *2023*).

Despite being the most prevalent mechanism currently, the reliance of the gravity-based seed guide tube (*Im et al.*, *2023*) on seed descent along the inner wall induces significant bouncing and spacing non-uniformity at high operating speeds. This limitation highlights the urgent need for continued optimization through pneumatic assistance, innovative mechanical designs (including belt-type systems), and simulation-monitored approaches. While scholars domestically and internationally have made progress in mitigating the seed guide's impact on spacing consistency (*Du et al.*, *2024*; *Kumar-Patel et al.*, *2021*; *Ospanova et al.*, *2024*), persistent challenges remain in effectively preventing collisions between seeds and the seeding mechanism's inner wall, particularly under high-speed conditions. These collisions disrupt the initial stable seed flow, leading to uneven spacing, reseeding, or seed loss.

To address this specific bottleneck, this study introduces a seed discharge mechanism engineered for orderliness and smoothness, employing full-degree-of-freedom constraints. The core objective is to minimize spacing deviations induced within the seed guiding process itself, thereby refining precision sowing theory and advancing seeding machinery toward higher speed and precision.

MATERIALS AND METHODS

Overall structure and working principle

This study introduces an advanced mechanism for the high-speed and seamless delivery of maize, employing a fully constrained seed guiding system with a full range of degrees of freedom. This innovative approach is integrated with a high-speed precision seed discharger designed in the preceding phase (*Du et al.*, *2023*). The comprehensive configuration of both the seed discharger and the delivery mechanism is illustrated in Figure 1. The structure primarily consists of the following components: mounting base, housing, seed cleaning brush, air inlet, seed inlet, internal filling plate, brush belt drive motor, inner filling plate drive motor, compression spring, seed pushing wheel, belt-driver wheel, brush belt housing, brush belt, timing belt, belt-driven wheel, tensioning device, and coupling.

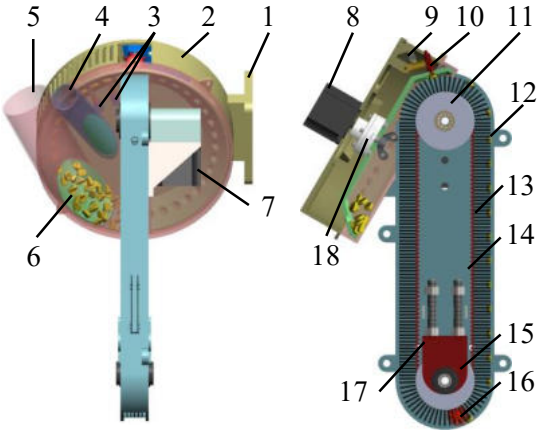

Fig. 1 – Schematic diagram of the structure of the seed-guiding device

1. Mounting base; 2. Housing; 3. Seed cleaning brush; 4. Air inlet; 5. Seed inlet; 6. Inner charging disk; 7. Brush belt drive motor; 8. Inner charging disk drive motor; 9. Pressure spring; 10. Seed pushing wheel; 11. Active belt wheel; 12. Brush belt housing; 13. Brush belt; 14. Synchronous belt; 15. Passive belt wheel; 16. Seed combing rollers; 17. Tensioning device; 18. Coupling

During operation, maize seeds are guided into the seed-filling chamber through the seed inlet by the seed dispenser. The filling process begins with the clockwise rotation of the inner filling disk, driven by a motor via a coupling. Under the combined effects of gravity, centrifugal force, inter-seed interaction, and airflow pressure, seeds are guided into designated holes. Excess seeds are removed by the seed cleaning brush and returned to the filling chamber, ensuring that each hole contains only one seed. Next, the seed tray advances to the seed pushing area, where the air holes at the bottom align with the seed holes to create a sealed path. The seed pushing wheel then rotates, pressing the seeds out of the holes and embedding them into the brush belt. The bristles of the brush constrain the seed's movement, securing it within the guiding system. Driven by a motor, the brush belt transports the seed to the seed outlet. There, the brush housing opens to release the seed, completing the guided delivery process.

Test design

This study utilized "Zhengdan 958" maize seeds as the experimental material to evaluate seed guiding performance, employing the JPS-12 multifunctional seeding test platform. To simulate the relative motion between seeds and the ground during field sowing, the seed guiding device was securely mounted onto the stationary frame of the test platform. The platform's conveyor belt was operated at linear speeds ranging from 3.6 km/h to 14.4 km/h. To minimize seed bounce and displacement upon landing, a 1-2 mm layer of grease was applied to the belt surface. The experimental setup is shown in Figure 2.

Test indicators

To assess the operational effectiveness of the seed-guiding device, evaluation criteria based on GB/T 6973-2005 were employed. The evaluation focused on criteria such as qualification, multiplicity, and missed seeding rate. The calculation formulas for each performance index are as follows:

To evaluate the operational performance of the seed-guiding device, assessment criteria were applied in accordance with the national standard GB/T 6973-2005. The evaluation focused on key performance indicators, including qualification rate, multiple seeding rate, and missed seeding rate. The calculation formulas for each performance index are presented below:

$$\begin{cases} Y_1 = \dfrac{n_1}{N} \times 100\% \\ Y_2 = \dfrac{n_0}{N} \times 100\% \\ X_a = \dfrac{\sum_{i=1}^{N-1} X_i}{N-1} \\ C = \dfrac{\sqrt{\dfrac{\sum_{i=1}^{N-1} X_i \left(X_i - X_a\right)^2}{N-1}}}{X_a} \times 100\% \end{cases} \quad (1)$$

Y_1 is the qualified rate, %; Y_2 is the missed seeding rate, %; X_a is the average seed spacing, cm; C is the coefficient of variation of seed spacing, %; n_1 is the number of qualified seed holes (holes); n_0 is the number of empty holes (holes); N is the total number of seed holes tested (251 holes); X_i is the distance between two adjacent seeds, cm.

After conducting three repetitions for each treatment, involving the statistical analysis of 251 holes within corn seed rows, average values were calculated. The data was then organized to derive the qualified rate, missed seeding rate and coefficient of variation of seed spacing (COV).

RESULTS

Influence of synchronous belt tension

The tension of the synchronous belt was adjusted by regulating the distance between two left-handed bolt heads and a nut, as illustrated in Figure 3(a). To evaluate the seeding performance of the synchronous belt under varying tension conditions, a one-factor bench test was conducted at an operating speed of 10 km/h and an air pressure of 1.6 kPa. The experimental variable was the distance between the nut and the bolt head, which was set at five levels: 38.0 mm, 38.5 mm, 39.0 mm, 39.5 mm, and 40.0 mm. The objective was to assess the qualified seeding rate, multiple seeding rate, and missed seeding rate of the seed discharging mechanism. The test results are presented in Figure 3(b).

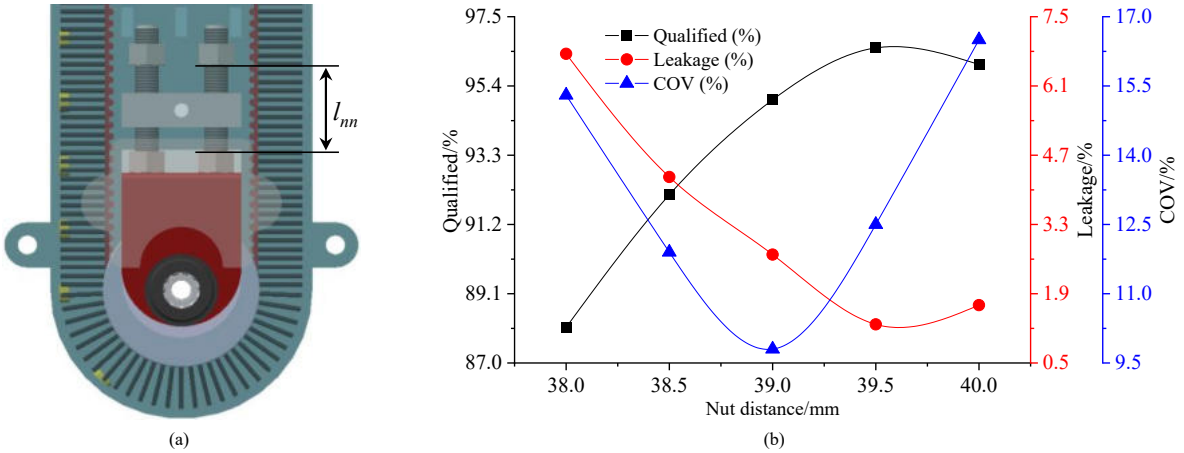

Fig. 3 – Tension adjustment-nut distance and effect of nut spacing on seed displacement performance

As depicted in Figure 3(b), the qualified rate shows a gradual increase with an increment in the distance between the nut and the bolt head. This phenomenon arises because heightened tension prevents the drive belt from easily skipping teeth, facilitating a smoother movement of the bristles carrying the seed. Consequently, this smoother movement reduces the likelihood of seed displacement from the bristles, resulting in decreased missed seeding and reseeding rates. Notably, when the distance between the nut and the bolt head reaches 40.0 mm, the rates of single seed, reseeding, and missed seeding are comparable to those at 39.5 mm, yet the tension force becomes excessively high.

As shown in Figure 3(b), the qualified seeding rate increases progressively with the expansion of the distance between the nut and the bolt head. This trend is attributed to the increased belt tension, which minimizes the risk of tooth-skipping by the drive belt and promotes smoother motion of the bristles that transport the seeds. Improved motion stability reduces the likelihood of seed displacement from the bristles, thereby lowering both missed seeding and multiple seeding rates. However, when the distance reaches 40.0 mm, the qualified, missed, and multiple seeding rates are similar to those observed at 39.5 mm, although the resulting belt tension is excessively high, potentially introducing mechanical strain or inefficiencies.

Influence of brush-housing gap

As shown in Figure 4(a), the clearance between the bristles of the brush belt and the housing plays a critical role in maintaining seed positioning accuracy during transportation. If the gap is too wide, seeds may become dislodged due to vibrations during movement. Conversely, if the gap is too narrow, excessive friction and resistance between the bristles and the inner wall of the housing can hinder the normal operation of the drive belt. To investigate this effect, a one-factor bench test was conducted at an operating speed of 10 km/h and an air pressure of 1.6 kPa. The gap between the bristles and the housing was adjusted to five levels: -2 mm, -1 mm, 0 mm, 1 mm, and 2 mm. The results are presented in Figure 4(b).

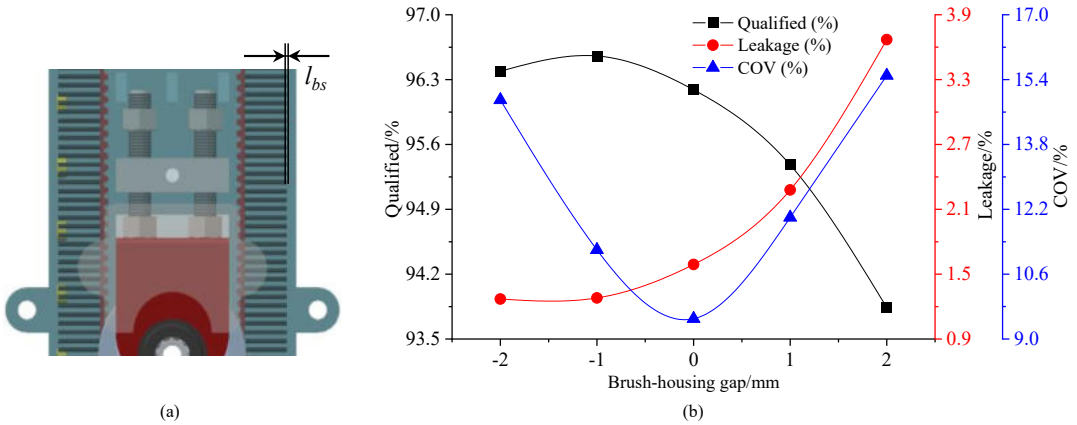

Fig. 4 – Schematic diagram of the clearance between the bristles and the housing, and the effect of the bristle-housing gap on seed discharge performance

As illustrated in Figure 4(b), an excessively large gap results in seed dislodgement during transport, leading to increased missed seeding and multiple seeding rates. Conversely, when the gap is too small, the multiple seeding rate also increases - likely due to the seeds being tightly wrapped by the bristles, which hinders their timely release during the discharge process. Notably, when the gap was set to -1 mm, the qualified seeding rate reached its highest value, while both the multiple and missed seeding rates were at their lowest. Therefore, -1 mm is identified as the optimal bristle-housing gap for ensuring stable and accurate seed discharge performance.

Influence of brush belt linear speed

A single-factor bench test was conducted under the conditions of a 10 km/h operating speed, 1.6 kPa air pressure, and a bristle-to-housing clearance of -1 mm. The test variable was the linear speed of the brush belt, set at five levels: 0.3 m/s, 0.6 m/s, 0.9 m/s, 1.2 m/s, and 1.5 m/s. The results of this test are shown in Figure 5.

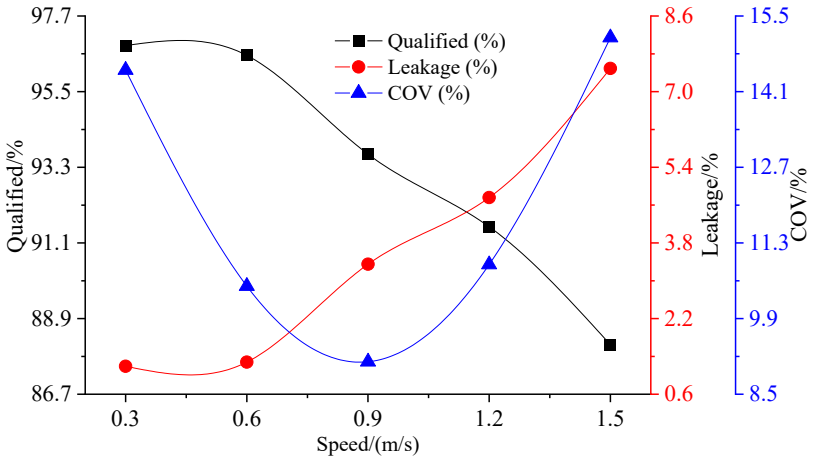

Fig. 5 – Influence of brush belt linear speed on seed displacement performance

As shown in Figure 5, a gradual decline in the qualified seeding rate is observed with increasing brush belt linear speed. This trend is attributed to the increased relative motion between the seed discharge disk and the brush belt, which hampers the ability of the seed pushing wheel to accurately embed seeds into the bristles in a timely manner. As a result, both missed seeding and multiple seeding rates increase. At a brush belt speed of 0.6 m/s, the seed guiding device achieves its highest qualified seeding rate, along with the lowest rates of multiple and missed seedings.

Interactions among the factors

To investigate the interaction effects of nut-bolt head spacing, brush-housing gap, and brush belt linear velocity on seed guiding performance, a Box–Behnken experimental design was employed. The study focused on three performance indicators - qualified seeding rate, missed seeding rate, and seed spacing uniformity - to quantitatively assess the influence of each factor and their interactions on the seed guiding mechanism.

The test scheme and test results are shown in Table 1.

Table 1

A quadratic multiple regression was fitted to the qualified rate to obtain the regression equation:

$$Y_1 = -7465.72 + 384.50 l_{nn} - 3.02 l_{bs} - 19.07 v_m + 0.07 l_{nn} l_{bs} + 0.54 l_{nn} v_m - 0.01 l_{bs} v_m - 4.89 l_{nn}^2 - 0.17 l_{bs}^2 - 3.84 v_m^2 \quad (2)$$

The interaction effects of brush belt speed and nut-bolt head spacing on the qualified seeding rate are illustrated in Figure 6. As the brush belt speed increases, the qualified rate of the seed guide shows a gradual decline. In contrast, with increasing nut-bolt head spacing, the qualified rate initially rises and then falls. Overall, the optimal seed guiding performance is achieved when the brush belt speed is between 0.3 and 0.6 m/s and the nut–bolt head spacing is between 39 mm and 40 mm.

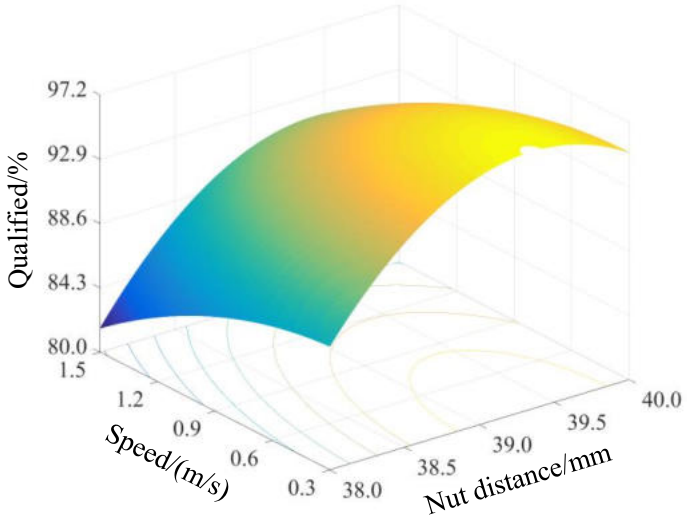

Fig. 6 – Response surface analysis of the interaction effects of factors

The results of the ANOVA for the missed seeding rate are shown in Table 3.

Table 3

A quadratic multiple regression was fitted to the missed seeding rate to obtain the regression equation:

$$Y_2 = 2203.69 - 112.33l_{nn} - 15.57l_{bs} + 16.59v_m + 0.41l_{nn}l_{bs} - 0.50l_{nn}v_m - 0.14l_{bs}v_m + 1.43l_{nn}^2 + 0.17l_{bs}^2 + 3.74v_m^2 \quad (3)$$

The interaction effects of the brush-housing gap and nut-bolt head spacing on the missed seeding rate are shown in Figure 7(a). As the brush-housing gap increases, the missed seeding rate gradually rises. In contrast, with increasing nut-bolt head spacing, the missed seeding rate first decreases and then increases. Overall, the lowest missed seeding rate is observed when the brush-housing gap is between -2 mm and -1 mm, and the nut-bolt head spacing is within the range of 39-40 mm.

The interaction effects of brush belt speed and nut-bolt head spacing on the missed seeding rate are presented in Figure 7(b). The missed seeding rate increases progressively with higher brush belt speeds. Similarly, as the nut-bolt head spacing increases, the missed seeding rate initially decreases and then increases. In general, optimal performance - with the lowest missed seeding rate - is achieved when the brush belt speed is maintained between 0.3 and 0.6 m/s, and the nut-bolt head spacing is in the range of 39-40 mm.

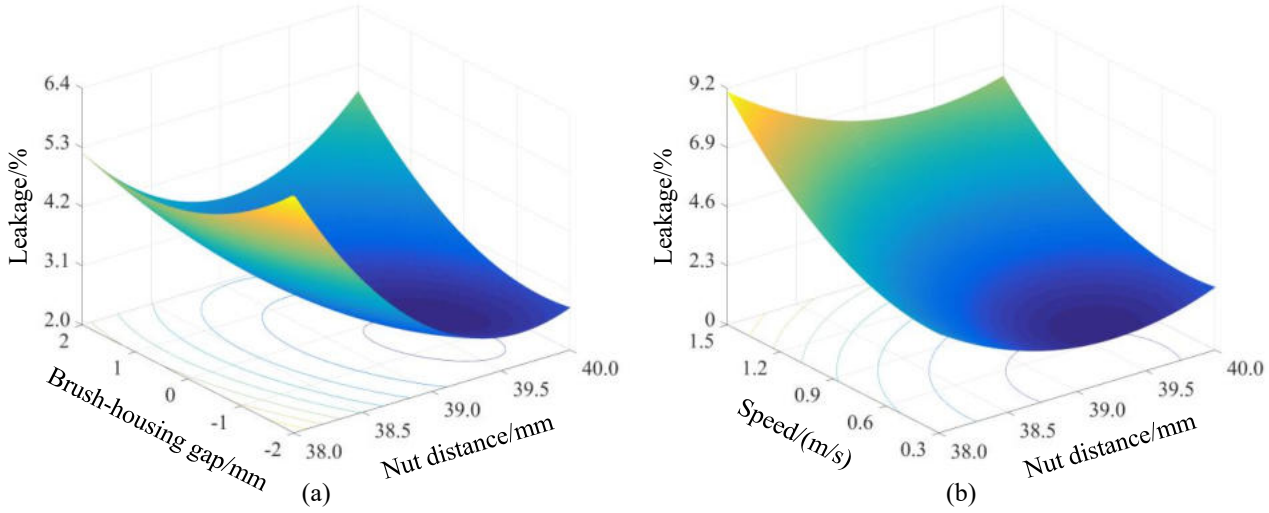

Fig. 7 – Response surface analysis of the interaction effects of factors

The results of the ANOVA for the COV are shown in Table 4.

Table 4

Cor Total	168.86	16			

*Note: ** indicates highly significant (p<0.01) and * indicates significant (p<0.05).*

A quadratic multiple regression was fitted to the COV to obtain the regression equation:

$$C=5957.22-306.25l_{nn}-0.28l_{bs}+61.71v_m-0.01l_{nn}l_{bs}-1.88l_{nn}v_m+0.29l_{bs}v_m+3.95l_{nn}^2+0.67l_{bs}^2+7.56v_m^2 \quad (4)$$

The interaction effects of brush belt speed and nut-bolt head spacing on the COV of seed spacing are shown in Figure 8(a). The COV initially decreases and then increases with rising brush belt speed and nut-bolt head spacing. The lowest COV values are observed when the speed is between 0.6 and 0.9 m/s and the nut-bolt head spacing ranges from 38.5 to 39.5 mm. Figure 8(b) illustrates the interaction effects of brush belt speed and brush-housing gap on the COV. A similar trend is observed: the COV decreases at first and then increases with increasing values of both variables. The optimal performance - reflected by the lowest COV - is achieved when the brush belt speed is between 0.6 and 0.9 m/s and the brush-housing gap is between -1 mm and 1 mm.

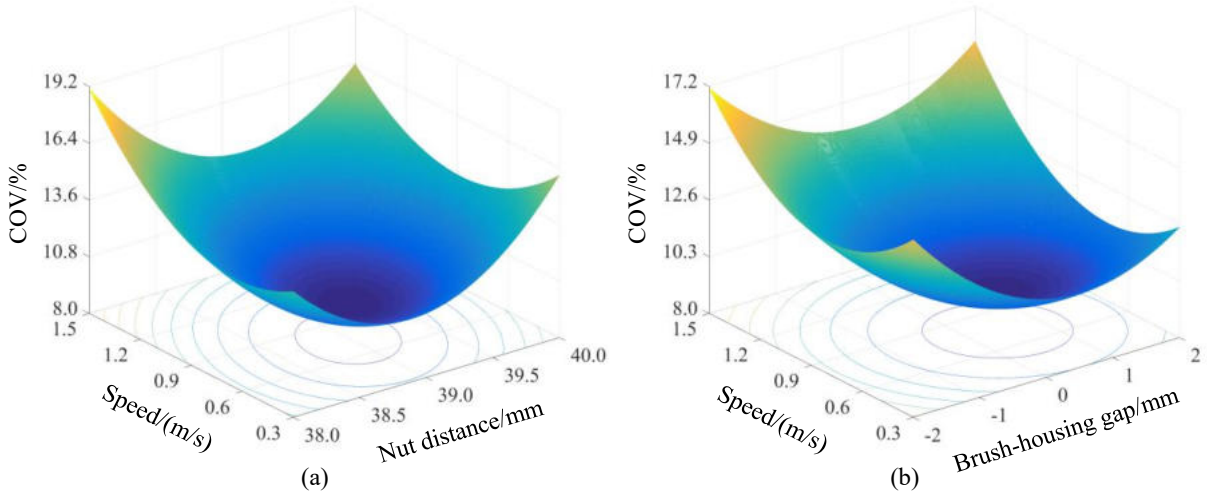

Fig. 8 – Response surface analysis of the interaction effects of factors

To identify the optimal combination of influencing factors within the defined constraint ranges, a multi-objective optimization was performed based on the regression model of seed guiding performance. The evaluation indices included the maximum qualified seeding rate, the minimum missed seeding rate, and the minimum coefficient of variation (COV) of seed spacing.

The optimization problem was formulated with the objective function and corresponding constraints defined as follows:

$$\begin{cases} \max Y_1\left(l_{nn}, l_{bs}, v_m\right) \\ \min Y_2\left(l_{nn}, l_{bs}, v_m\right) \\ \min C\left(l_{nn}, l_{bs}, v_m\right) \\ s.t. \begin{cases} 38 \text{ mm} \le l_{nn} \le 40 \text{ mm} \\ -2 \text{ mm} \le l_{bs} \le 2 \text{ mm} \\ 0.3 \text{ m/s} \le v_m \le 1.5 \text{ m/s} \end{cases} \end{cases} \quad (5)$$

The regression model was optimized and solved using Design-Expert 10 software. The optimal parameter combination was found to be a nut-bolt head spacing of 39.15 mm, a brush-housing gap of 0.22 mm, and a brush belt speed of 0.644 m/s. Under these conditions, the predicted values for the qualified seeding rate, missed seeding rate, and COV were 96.35%, 1.89%, and 9.72%, respectively. To validate the model, the bench test was repeated three times using the optimized parameters. The experimental results yielded a qualified seeding rate of 96.76%, a missed seeding rate of 2.15%, and a COV of 10.09%. The close agreement between the predicted and measured values confirms the high reliability and accuracy of the regression model.

CONCLUSIONS

This study aimed to address the problem of seed bouncing and displacement caused by collisions between corn seeds and the seed guide tube during planting, which disrupts the orderly flow of seeds. To overcome this issue, a seed guiding device was developed to constrain the seeds in all degrees of freedom, utilizing a flexible brush to ensure stable seed transport. A one-factor test was conducted to determine the optimal parameter ranges for nut-bolt head spacing, brush-housing gap, and brush belt speed, and to evaluate their individual effects on seed guiding performance. Subsequently, quadratic regression models were established using response surface test to analyze the effects of these parameters on the qualified seeding rate, missed seeding rate, and COV. Optimization results indicated that the best seed guiding performance was achieved at a nut-bolt head spacing of 39.15 mm, a brush-housing gap of 0.22 mm, and a belt speed of 0.644 m/s, resulting in a qualified seeding rate of 96.35%, a missed seeding rate of 1.89%, and a COV of 9.72%.

ABSTRACT

This study is based on the discrete element method to design a tracked precision solid particle pesticide applicator and establish a coupling model between the pesticide application device and particle swarm EDEM. Simulation shows that particle characteristics significantly affect the uniformity of pesticide application. The coefficients of variation for particles 1, 2, and 3 are 4.25%, 4.63%, and 5.57%, respectively, with relative deviations of 8.51%, 9.28%, and 11.33%. After response surface testing optimization, the measured coefficient of variation of the prototype was 8.25% and the relative deviation was 18.07%, both of which met industry standards.

摘要

本研究基于离散元法设计履带式精准固体颗粒施药机，建立施药装置-颗粒群 EDEM 耦合模型。仿真表明：颗粒特性显著影响施药均匀性，颗粒 1、2、3 的变异系数分别为 4.25%、4.63%、5.57%，相对偏差 8.51%、9.28%、11.33%。响应面试验优化后，样机实测变异系数 8.25%、相对偏差 18.07%，均达行业标准。

INTRODUCTION

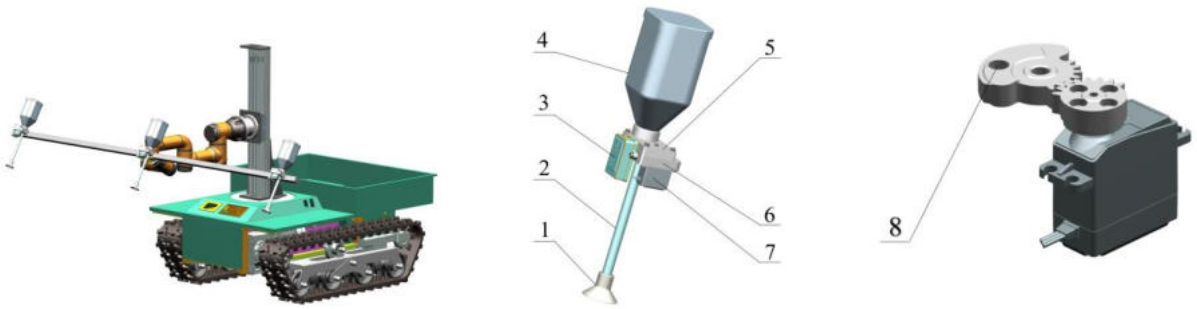
Liquid pesticide spraying is the dominant method for pest control in China; however, its effectiveness is limited by issues such as high droplet drift rates, low pesticide utilization efficiency, and environmental pollution (*Nation H.J.*, 1972). As modern agriculture transitions toward precision and intelligent technologies, solid granular pesticides have demonstrated significant potential for applications such as corn borer control and soil disinfection due to their ability to be applied directly to target areas, high resistance to drift, and prolonged efficacy (*Ministry of Agriculture and Rural Affairs, 2022*). However, existing solid granular pesticide application equipment faces technical challenges such as poor quantitative accuracy, uneven discharge, and limited terrain adaptability, restricting its widespread adoption (*Jiang Y.Y. et al., 2021*). Therefore, overcoming these challenges and enhancing the accuracy and adaptability of pesticide applicators are crucial for advancing precision spraying technology.

In recent years, with the rapid development of intelligent agriculture, precision pesticide application technology has been widely adopted. Research in this area primarily focuses on variable pesticide application control, operational parameter optimization, and equipment improvement (*He X.K., 2020*). *Zhai Changyuan et al. (2024)* designed a precision variable spraying monitoring system based on traceability management, which enables real-time detection of pesticide type, ratio, spraying volume, spray pressure, and operating speed, integrating precision pesticide application with traceability management. Gou Yujiang et al. developed a handheld variable fertilizer spreader and constructed a regression model using discrete element simulation experiments to optimize fertilization parameters and improve spreading uniformity. Dong Jiwei et al. designed a crawler-type target-matching pesticide spreader to meet the operational needs of orchards in hilly and mountainous areas. Its lifting and closing mechanism allow flexible adjustment of spraying distance and height, adapting to different fruit tree types. Currently, research on fertilizer and pesticide application equipment with wheeled chassis in plain areas is relatively advanced, with significant progress in variable pesticide application

ZhiMing SHI, M.S. Eng.; Hang ZHAO, M.S. Eng.; ShouTai LI, M.S. Eng.; ZiWen CHEN, A. Prof.; JunJie CHEN, M.S. Eng.; MingJin YANG, Prof.

and operational optimization technologies. However, under the complex terrain conditions of hilly and mountainous areas, research on the coupling mechanism between crawler walking systems and solid granular pesticide discharge mechanisms remains limited (*Hazra D.K. et al., 2019*).

Based on discrete element method (DEM) numerical simulation technology, this study designs a precision quantitative solid granular pesticide applicator suitable for hilly and mountainous areas. By integrating response surface tests, key operational parameters were optimized, and the effects of factors such as operating speed, material port diameter, and application angle on application uniformity were examined. The findings not only provide theoretical support for the development of precision pesticide application equipment in hilly and mountainous areas but also contribute to reducing pesticide use, minimizing environmental pollution, and promoting precision agriculture. This research is of great significance for the intelligent transformation of China's plant protection machinery.



MATERIALS AND METHODS

Machine structure and workflow

Machine structure

To address the complex agricultural environments in hilly and mountainous regions, this study developed a crawler-type precise quantitative solid particle sprayer. The system includes a crawler chassis power platform, a robotic arm, a rotating lifting mechanism, a spraying system, and a control system. The gear transmission component is manufactured by a CNC universal gear grinding machine (YW7232CNC). The power platform uses a self-propelled crawler chassis, known for its superior obstacle-crossing ability and stability, enhancing mobility in challenging terrains (*Qi X.Y. et al., 2015*). The robotic arm features a multi-joint structure for precise control of the spraying device's motion, and combined with the rotating lifting mechanism, it allows for fine-tuned multi-directional adjustments, improving spraying accuracy in diverse crop environments. The spraying system consists of three electronically controlled devices (Fig. 1a), with adjustable spraying spacing for synchronized multi-channel operation, boosting efficiency. The pesticide application device (Fig. 1b) includes a dispensing port, guide pipe, IoT module, material box, loading and unloading module, and servo motor. Solid granular pesticides are evenly dispensed via a rotating material tray (Fig. 1c), ensuring precise coverage and optimal pesticide use. The control system integrates robotic arm motion, pesticide application activation, and operational parameter adjustment. Operators can input commands or use preset programs for precise pesticide application to meet various operational needs.

The concept of targeted pesticide application originated from the manual handheld pesticide application process. In order to improve the utilization rate of granular drugs and reduce the transport and loss in ineffective spaces, the nozzle is aimed at the center of the seedlings during manual pesticide application, and the handheld spray rod is aimed at the seedlings for pesticide application. The tracked precision quantitative solid particle pesticide applicator adopts an automated targeted pesticide application method, and multiple components in the system work together to achieve efficient, precise, and environmentally friendly pesticide application. The pesticide application operation starts from the action of the robotic arm and the pesticide application device. The robotic arm can precisely control the movement of the pesticide application device to ensure that the pesticide is spread in the correct position. Solid particle pesticides are released to the target through the feeding port to ensure precise coverage of the target area. The parameter settings of the pesticide applicator, including the application amount, operating speed, and application angle, are adjusted through the control platform (*Meshram A.T., 2022*).

Workflow

The crawler-type precision quantitative solid particle applicator developed in this study employs an automated targeted application strategy to ensure efficient, precise, and environmentally friendly pesticide delivery. Targeted application technology originates from the manual handheld precision application method, in which the nozzle remains aimed at the center of the crop throughout the process, enhancing pesticide utilization efficiency and minimizing unnecessary dispersion. The application process is executed by the robotic arm in conjunction with the application device. During operation, the robotic arm precisely adjusts the position of the application device, ensuring the directional release of solid particle pesticides through the drop port for even coverage of the target crop (*Chen Z.W. et al., 2023*). The control system enables intelligent adjustment of application parameters, including dosage, operating speed, and application angle, to accommodate various environmental conditions and agronomic requirements.

Simulation and experiment

Discrete Element Simulation Model

In EDEM software, common particle contact models include the Hertz-Mindlin (no-slip) model, the Hertz-Mindlin with bonding model, the Hertz-Mindlin with JKR (Johnson-Kendall-Roberts) model, and the Linear Cohesion model. These models are suited to different granular materials and conditions. The Hertz-Mindlin with JKR model is preferred for simulating pesticide particle contact due to its ability to characterize particle bonding and agglomeration. Unlike the Linear Cohesion model, which only accounts for normal bonding forces and ignores tangential forces, the JKR model considers both normal and tangential bonding, making it more accurate for complex bonding materials (*Nie C.X. et al., 2022*).

Pesticide particles, with small size, high surface roughness, and moisture content, tend to agglomerate and adhere due to electrostatic and intermolecular forces. The JKR model effectively captures this behavior, which is further intensified in humid climates like those in southwestern regions. Traditional rigid or non-adhesive models are inadequate for such conditions. Thus, this study uses the JKR model to better simulate the flow and application behavior of pesticide particles, providing a solid theoretical foundation for designing and optimizing precision pesticide application equipment (*Wang S. et al., 2024*).

Particle Characterization

To accurately characterize the different physical properties of Imidacloprid pesticide particles and ensure the reliability of the simulation, key parameters such as particle density, moisture content, angle of repose, and particle size distribution were measured (Fig. 2). These parameters are essential for constructing the discrete element simulation model.

Fig. 3 - Test equipment

a) Repose angle measuring device; b) Electronic balance; c) Halogen Moisture Analyzer; d) Standard test sieve

Particle density was determined using the drainage method, as per GB/T 24528 and GB/T 13477.2-2002 standards. The density was calculated by measuring the particle volume after drainage and combining it with the mass measured by a high-precision electronic balance. Each group was measured three times, and the average value was taken for stability. Moisture content was measured using an FBS-760A halogen moisture analyzer, which heated and dried the samples while automatically recording water evaporation and mass changes. Each group was measured three times, and the average value was used to minimize error. The angle of repose was measured using the natural piling method, where particles fell through a funnel to form a cone, and the angle between the cone and the horizontal plane was recorded. This experiment was repeated 10 times to ensure reliability. Particle size distribution was determined by sieving 1000 g of particles using standard test sieves (GB/T 6003.1-2012). The mass retained on each sieve was recorded to calculate mass percentages. All experiments followed national standards, with multiple repetitions to ensure accuracy and reliability. The measurement tools and results are shown in Fig. 3 and Table 1.

Table 1

Test particle parameter measurement results

Item		Measurements		
		Particles 1	Particles 2	Particles 3
Particle size analysis (mass percentage passing through the sieve/%)	0.25mm	0	0	0
	0.50mm	5.98	12.38	0
	1.00mm	69.33	22.14	13.50
	1.60mm	16.35	47.12	42.47
	2.00mm	8.34	18.36	38.55
	2.50mm	0	0	5.48
Bulk density /（kg/m³）		5.85×103	0.55×103	2.66×103
Moisture content /%		0.170	3.533	0. 54
Angle of repose /（°）		18.6	23.4	32.5
Air humidity during the test /%		68	72	72

Simulation test

Discrete Element Simulation

In this study, the Hertz-Mindlin with JKR model was used to describe the interaction forces between particles and equipment, enabling a more accurate simulation of particle adhesion. Considering the particle size distribution of actual Imidacloprid pesticide particles, the spherical particle modeling method in EDEM software was employed to construct simulation models of particles with various shapes (Fig. 4). The experimental design included single-sphere, double-sphere, three-sphere, four-sphere, and irregular multi-sphere models, based on the actual particle distribution ratio to ensure the simulated morphology closely matched real particle characteristics (*Xie K. et al., 2024*). The simulation model parameters are listed in Table 2. This approach effectively characterizes particle morphology and simulates their motion within the equipment, providing a reliable basis for particle flow analysis and optimization of drug application equipment. Model parameters were set based on experimentally measured data, improving the accuracy and reliability of the simulation results.

	Static friction coefficient	0.25	0.35	0.30
	Dynamic friction coefficient	0.01	0.05	0.01

Simulation Experiment Design

To verify the design rationality of the spraying mechanism, to further explore the interaction between the spraying mechanism and pesticide particles, and to provide a scientific basis for the design of key parameters of the spraying machine, a simulation experiment was conducted using EDEM software. Based on typical spraying operation conditions in hilly and mountainous areas, the rotation speed of the spraying machine's material plate was set to 60 r/min, the material port diameter was set to 7 mm, and the spraying angle was maintained at 0° to ensure the uniformity of the testing process. Three types of pesticide particles with different material properties were selected for the experiment, covering various particle sizes, densities, and surface morphologies to simulate common pesticide formulations. By keeping the spraying machine's operating parameters constant and adjusting only the particle characteristics, the adaptability and reliability of the spraying machine under different particle types were studied (*Yin Y.S. et al, 2018*).

Field trials

To verify the operational performance of the precision quantitative solid particle sprayer, the experimental design followed industry standards, including the "JB/T 9782-2014 General Test Methods for Plant Protection Machinery" and the "GB/T 21157-2007 Test Methods for Granular Pesticide or Herbicide Spreaders." The focus was on evaluating the performance stability and uniformity of the sprayer. The experiment used the Box-Behnken experimental design method, with operating speed, feed port diameter, and spraying angle as the main influencing factors, and coefficient of variation and relative deviation as response variables.

Design-Expert 13 was used to conduct a three-factor, three-level experimental design, construct a response surface model, and optimize the operating parameters of the precision spraying equipment. Operating speed directly affects the uniformity and efficiency of spraying; feed port diameter determines the unit spraying amount of solid drug particles and is the core parameter of precision spraying; spraying angle, i.e., the vertical angle between the feed port and the crop to be sprayed, affects the distribution range and uniformity of the particles.

This study uses the coefficient of variation and relative deviation as key evaluation indicators to fully reflect the spraying performance of the equipment. By optimizing the combination of various factor levels, data support was provided for the parameter optimization of precision pesticide application equipment, laying a theoretical foundation for reducing pesticide usage, improving pesticide utilization, and promoting the application of precision pesticide technology. The test factors and levels are shown in Table 3, and the field test is shown in Fig. 5.

Table 3

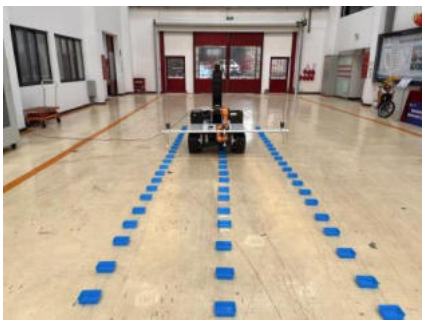

Fig. 5 - Field test of pesticide sprayer

RESULTS

Evaluation indicators

According to the "Test Method for Granular Pesticide or Herbicide Spreader GB/T 21157-2007," this study selected the coefficient of variation (CV) and relative deviation (RD) as evaluation indicators to quantitatively analyze the spreading uniformity and application accuracy of granular spraying equipment. The coefficient of variation (CV) reflects the uniformity of the granule spreading amount in different areas; the smaller the value, the higher the uniformity. The relative deviation (RD) evaluates the degree of deviation between the actual application amount and the target application amount, which is an important indicator for measuring the performance of precision spraying. Through rigorous experimental design and data analysis, this study comprehensively evaluates the performance of equipment spraying and provides a scientific basis for optimizing spraying parameters and improving spraying accuracy.

The average mass $\overline{M_n}$ of a single row of pellet boxes is calculated as follows:

$$\overline{M_n} = \frac{1}{n}\sum M_i \tag{1}$$

where n is the number of particle collecting boxes; M_i is the mass of granules collected by the ith particle collecting box.

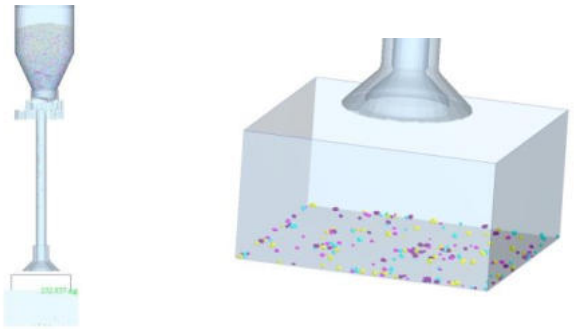
The coefficient of variation (CV) calculation formula is:

$$CV_n = \frac{s}{\overline{M_n}} \tag{2}$$

where s is the standard deviation, calculated as follows:

$$s = \sqrt{\frac{1}{n-1}\sum (M_i - \overline{M_n})^2} \tag{3}$$

The relative deviation (RD) of each row is calculated as:



$$RD_n = \frac{M_{i,\max} - M_{i,\min}}{\overline{M_n}} \times 100 \tag{4}$$

Simulation Results Analysis

The simulation test of the pesticide applicator was carried out based on EDEM software, and the results are shown in Figure 6. The simulation analysis shows that the spreading uniformity and stability of the pesticide applicator are greatly affected by the characteristics of the pesticide granule material. The coefficients of variation of granule 1, granule 2, and granule 3 are 4.25%, 4.63%, and 5.57%, respectively, and the relative deviations are 8.51%, 9.28%, and 11.33%, respectively (Fig. 7), all of which meet the industry standard requirements specified in the "Technical Specifications for Quality Evaluation of Fertilizer Machinery NY/T1003-2006." The simulation results show that the increase in particle size, density, surface profile, and friction coefficient will lead to a decrease in spreading uniformity and stability. Among them, the coefficient of variation of particle 3 is relatively high, indicating that its spreading distribution is more discrete, which may be related to the increase in the friction coefficient between particles leading to a decrease in fluidity.

Under fixed operating parameters, the pesticide applicator has the best adaptability to particle 1, and its coefficient of variation and relative deviation are both low, indicating that the pesticide applicator is suitable for particles with small particle size, smooth surface, and low friction coefficient.

In comparison, the simulation results of particle 3 reveal the limitations of the existing design when dealing with high-density, large-size particles. It is difficult to effectively overcome the inertia and friction resistance of the particles by relying solely on the particle gravity and the material inlet diameter, resulting in a decrease in spreading uniformity.

Analysis of field test results

According to the Technical Specifications for Quality Evaluation of Fertilizer Machinery (NY/T 1003-2006), the coefficient of variation for granular sprayers should be ≤13% (MARA., 2006). The maximum coefficient of variation was 8.25%, and the average relative deviation was 18.07%, both of which met the industry standard requirements (Table 4). The test data were imported into Design-Expert13 software for variance analysis (Table 5) and response surface analysis (Fig. 8, Fig. 9). From the univariate analysis, operating speed, feed port diameter, and application angle all had a significant effect on the coefficient of variation. Operating speed had the most significant effect, followed by feed port diameter, while the effect of the application angle was relatively small but still statistically significant. This indicates that the variation in the coefficient of variation is primarily affected by operating speed, while feed port diameter and application angle also influence spraying uniformity to some extent. The interaction analysis showed that the interaction effects of operating speed × feed port diameter and feed port diameter × application angle were not significant, while the interaction effect of operating speed × application angle was significant. The response surface analysis showed that at low operating speeds, increasing the feed opening diameter significantly reduced the coefficient of variation, indicating that appropriately increasing the feed opening diameter could improve uniformity. However, at high operating speeds, the effect of increasing the feed opening diameter on the coefficient of variation tended to stabilize. The effect of application angle on the coefficient of variation was more significant at high operating speeds, indicating that optimizing the application angle could improve spreading uniformity at high-speed operation. At low operating speeds, the effect of the application angle was relatively small. Under conditions of extreme application angles and larger feed opening diameters, the coefficient of variation increased slightly, indicating that excessively large application angles may lead to decreased spraying uniformity.

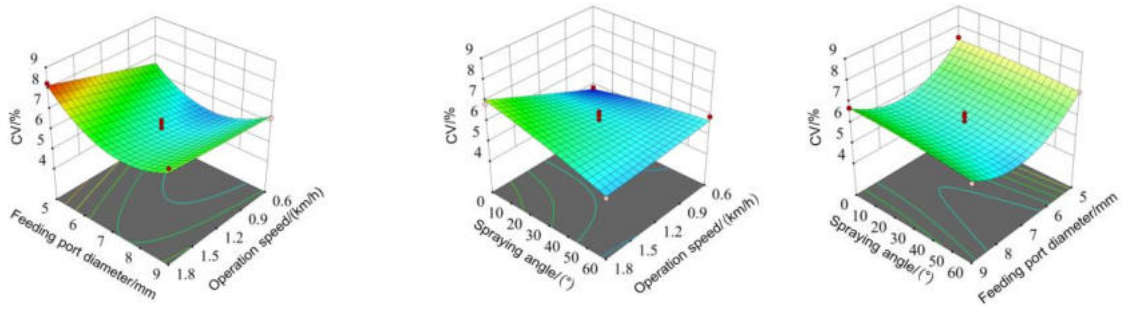
13	1.2	7	30	5.92	16.58
14	1.2	7	30	5.16	16.65
15	1.2	7	30	5.53	18.48
16	1.2	7	30	6.32	17.19
17	1.2	7	30	6.15	18.38



As shown in Table 5 and Fig. 9, the effects of operating speed, orifice diameter, and application angle on relative deviation are statistically significant, with P values of 0.0125, 0.0237, and 0.0342, respectively. From the perspective of the F-value, operating speed has the most significant effect, followed by orifice diameter, while the effect of application angle is relatively small. The two-factor interaction analysis showed that operating speed × orifice diameter and orifice diameter × application angle significantly affected relative deviation (P values of 0.0030 and 0.0114, respectively).

a) *b)* *c)*

Fig. 8 - Response surface plot of the effect of two-factor interaction on the coefficient of variation

a) Feeding port diameter × Operating speed; b) Spraying angle × Operation speed; c) Spraying angle ×Feeding port diameter

The response surface analysis showed that at low operating speeds, increasing orifice diameter had a greater effect on relative deviation, while at high operating speeds, the effect of increasing orifice diameter on relative deviation gradually weakened. This indicates a synergistic effect between the two, but the intensity of the effect is influenced by operating speed. In addition, the interaction between orifice diameter and application angle on relative deviation shows a nonlinear relationship. When the orifice diameter is small, adjusting the application angle has a smaller effect on relative deviation, while when the orifice diameter is large, the effect of changing the application angle on relative deviation becomes more significant. This indicates that when optimizing application parameters, the matching relationship among operating speed, feed port diameter, and application angle should be considered comprehensively to improve application accuracy and reduce deviation.

CONCLUSIONS

This study provides a theoretical basis for the research and development of precision pesticide application equipment in hilly areas, as well as technical support for reducing pesticide use, reducing environmental pollution, and promoting the development of precision agriculture. Discrete element method (DEM) was used to design and optimize a crawler-type precision pesticide applicator. Through simulation and field tests, the effects of pesticide particle characteristics and key operating parameters on application uniformity and accuracy were evaluated. The main findings are:

1. Particle material properties significantly affect application performance. The coefficients of variation for different particles were 4.25% (Particle 1), 4.63% (Particle 2), and 5.57% (Particle 3), with corresponding relative deviations of 8.51%, 9.28%, and 11.33%. Small-size, low-density, and smooth-surfaced particles exhibited good fluidity within the applicator and high spreading uniformity. In contrast, larger and denser particles were more significantly affected by gravity and friction, leading to accumulation at the material port, resulting in uneven spreading and affecting the accuracy of pesticide application.

2. Response surface analysis optimized key parameters such as operating speed, material port diameter, and application angle. Operating speed had the most significant effect on uniformity and accuracy, followed by material port diameter, with application angle having a smaller effect. At low speeds, increasing port diameter improved uniformity, while at higher speeds, optimizing the application angle reduced deviation and improved precision.

3. Field tests showed a maximum coefficient of variation of 8.25% and an average relative deviation of 18.07%, both meeting industry standards. The consistency between simulation and test data confirms the feasibility and stability of the designed applicator for precise pesticide application.

ABSTRACT
This study investigates the excessive energy consumption of traditional furrowing cutters used in sticky, heavy soils of orchards located in hilly and mountainous regions. A novel furrowing cutter was designed, taking the wetland rotary bending cutter as a reference. The bending radius, bending angle, and alpha angle were selected as design variables. Quadratic orthogonal regression and discrete element method (DEM) simulations were employed to analyse tool–soil dynamic interactions and assess the influence of key parameters on furrowing power consumption. Response surface analysis revealed that at a bending radius of 30.02 mm, bending angle of 109.97°, and alpha angle of 51.74°, the optimised cutter reduced power consumption by 12.9%, from 0.85 kW to 0.74 kW.

摘要
本研究针对丘陵山区果园粘重土壤条件下传统开沟刀具存在的高能耗问题，以湿地旋耕弯刀为参考，设计了一种适用于丘陵山区果园的开沟刀具。通过选择刀具弯折半径、弯折角度和阿尔法角作为控制变量，结合二次正交回归实验和离散元法（DEM）仿真，分析刀具与土壤的动力学交互特性，探讨关键参数对开沟功耗的影响机制。响应曲面分析结果表明，在弯折半径 30.02 mm、弯折角 109.97°、阿尔法角 51.74°的条件下，优化后的刀具功耗由 0.85 KW 降低至 0.74 KW，减少了 12.9%。

INTRODUCTION
Fertiliser application is crucial to fruit tree management, directly influencing yield and quality. Common fertiliser application methods include water-fertiliser integration, open furrow application, and fertiliser spreading, each with inherent limitations. Water-fertiliser integration can cause soil salinisation, while spreading results in fertiliser wastage and lacks precise depth control. Open furrow fertiliser application meets fruit tree nutrient requirements but remains hindered by high energy consumption and low operational efficiency. In China, premium orchards are primarily found in hilly and mountainous regions, including Sichuan, Guangdong, Guangxi, Shaanxi, and Gansu. These areas have low mechanisation levels, with manual labour remaining predominant due to complex terrain and varying soil properties. Given labour shortages and rising costs, developing mechanised furrowing and fertiliser application technologies tailored to complex terrain is increasingly critical *(Asl and Singh, 2009; Chen P. et al., 2024; Fu et al., 2024; Wang et al., 2015).*

In mechanised furrowing and fertiliser application in orchards, the furrowing tool, as a key component in direct soil contact, plays a crucial role in operational efficiency and power consumption. Extensive research has been conducted globally. *Kang et al., (2017)*, optimised the blade structure, significantly reducing operating power consumption; *QIN et al., (2021)*, proposed a combined cutting and throwing furrowing tool for tea garden mechanisation, effectively enhancing soil-throwing performance; *Barr et al., (2020)*, optimised the tool-soil interaction process using DEM simulation, significantly reducing tool power consumption and providing technical support for optimisation. However, orchard soils in hilly mountainous areas are sticky and heavy, with severe sloughing. The issues of high-power consumption and inefficient furrowing in traditional tools remain unresolved.

Jing Mi, M.S. Stud; huan xie, Assoc. Prof; Po Niu, Assoc. Prof. Ph.D. Eng.

The cutter's structural parameters are critical for enhancing operational efficiency and reducing energy consumption. Inspired by the design of the wetland rotary ploughing curved cutter, this cutter is widely used in wetland and orchard operations due to its superior cutting performance, reduced tangling, and effective soil penetration. Building on these characteristics, this study develops a furrowing cutter tailored for orchard soils in hilly mountainous regions. By optimising the bending radius, bending angle, and alpha angle, soil contact efficiency is improved, and power consumption is reduced.

MATERIALS AND METHODS

Main structure and parameters of furrowing tool

The cutter's structural parameters are essential for enhancing operational efficiency and reducing energy consumption *(Ma et al., 2021; Xiao et al., 2024; Zhang et al., 2022)*. This study adopts the design principles of wetland rotary ploughing curved cutters, which are widely used in wetland and orchard operations for their superior cutting performance, reduced tangling, and effective soil penetration. Building on this concept, a furrowing cutter optimised for orchard soils in hilly mountainous regions was developed. The bending radius, bending angle, and alpha angle were refined to enhance soil contact efficiency and minimise power consumption.

Figure 1 presents a schematic diagram of a furrowing cutter designed based on the wetland rotary ploughing curved cutter concept.

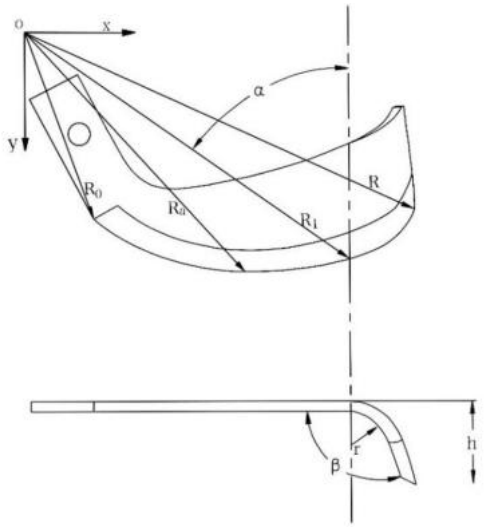

Fig. 1 - Schematic diagram of furrowing tool structure

O - center of rotation, R - radius of rotation, R_0 - radius of the starting point of the side-cutting edge, R_1 - radius of the end point of the side-cutting edge, R_a - radius of any point on the side-cutting edge, α - angle between the radius of the end point of the side-cutting edge and the bend line, r radius of bend, β is the angle of bend, h is the working width.

The main structural parameters of the furrowing tool are shown in Table 1.

Table 1

Main structural parameters of furrowing tool

Parametric	Numerical
Radius of rotation [*R*]	245 [mm]
Radius of the starting point of the side-cutting edge [R_0]	110 [mm]
Radius of the end point of the side-cutting edge [R_a]	220 [mm]
Bending radius [*r*]	45 [mm]
Bending angle [*β*]	135 [°]
Alpha angle [α]	40 [°]
Working width [*h*]	35 [mm]

DEM-based coupled tool-soil modelling

To ensure simulation accuracy, this study selected typical orchard soil from hilly mountainous regions as the simulation environment. The parameters were set based on experimentally measured soil physical properties and supplemented with data from the literature. The soil is primarily compacted clay with fine particles that are difficult to measure directly.

Therefore, reasonable assumptions regarding its physical properties were incorporated into the simulation *(Chen, M. et al., 2024; Chertkiattipol and Niyamapa, 2010; Hao et al., 2023; Wang et al., 2023)*. The Hertz-Mindlin with JKR model was employed to simulate soil particle contact, with a particle size of 5 mm. The simulation parameters for the tool and soil are presented in Table 2.

Table 2

Parameters of the tool-soil coupling model

parametric	numerical	parametric	numerical
Machine forward speed [m/s]	0.3	Soil-soil recovery factor	0.28
Tool speed [rpm]	300	Soil-Fe recovery factor	0.6
Soil density [kg/m³]	2500	Soil-soil static factor	0.5
Poisson's ratio for soil	0.32	Soil-steel static factor	0.5
Soil shear modulus [Pa]	1×10^{6}	Soil-soil rolling factor	0.37
Steel density [kg/m^3]	7850	Soil-steel rolling factor	0.05
Shear modulus of steel [Pa]	7.962×10^{10}	Fe Poisson's ratio	0.3

Lateral cutting-edge curve

During operation, the side-cutting edge vertically cuts the soil, with cutting performance primarily determined by the design of its curve. For furrowing depths of less than 30 cm*(Li et al., 2018)*, the Archimedean spiral is commonly selected as the side-cutting edge curve. Consequently, this study adopts this curve, expressed by the following equation:

$$\rho = \rho_0 + a'\theta \tag{1}$$

ρ_0-polar diameter at the start of the helix, [mm];

a'-increase in polar diameter for every 1 radian increase in the polar angle of the helix, [mm];

θ -arbitrary polar angle on the helix, [°].

To prevent soil compaction by the bladeless section during furrowing, ρ_0 must satisfy the following equation:

$$\rho_0 = \sqrt{R^2 + S^2 - 2S\sqrt{2Ra - a^2}} \tag{2}$$

S - cutting pitch, [mm];

a - furrowing depth, [mm];

R - furrowing knife turning radius, [mm].

The turning radius of the tool is a critical design parameter. Based on the requirements for orchard furrowing in hilly mountainous regions, the maximum gyration radius is set to 245 mm, with a soil-cutting pitch of 30 cm. The pole diameter at the helix's starting point, ρ_0 is calculated as 110 mm.

To ensure a smooth transition between the helix and the tangent edge, the pole diameter at the endpoint, ρ_n is typically 10–20 mm smaller than the gyration radius. Thus, the endpoint pole diameter is designed as 220 mm.

The polar angle θ_n at the helix endpoint is related to the slip shear angle by the following equation:

$$\theta_n = \tan\frac{\rho_n - \rho_0}{\rho_n}\tau_n \tag{3}$$

τ_n-slip angle at the end of the helix, [°].

Considering the requirements of orchards in hilly mountainous regions, the terminal slip cut angle is designed as τ_n=55◦, with a calculated increment of a'=3.14, thereby determining the side-cutting edge helix.

Tangent Curve and Tangent Height

The tangent edge is a spatial curve. To ensure a flat furrow bottom, the curve is positioned on the outer cylindrical surface of the knife stick, where it appears as a circular arc in the side view and transitions smoothly into the side cutting edge *(Fang et al., 2016; Yang et al., 2024)*. In hilly and mountainous orchards, the soil is compacted, requiring the knives to possess soil-breaking capabilities.

Liu et al., (2019), demonstrated that the optimal soil breakage rate and power consumption occurred when the tangent face height was 60 mm. Consequently, in this study, the end face height was set at 60 mm to satisfy the operational requirements of Class I rotary tillage knives. The bending radius, bending angle, and alpha angle influence cutting force and power consumption A smaller bending radius increases efficiency but also friction, whereas a larger radius reduces friction but affects cutting depth. Larger bending angles enhance dispersion efficiency but increase power consumption. The alpha angle influences cutting stability; a smaller angle promotes stable cutting, while a larger angle increases cutting depth but also resistance*(Liu et al., 2024; Zeng et al., 2024)*.

The tool's bending radius r is 30 mm, the alpha angle α is 47°, the bending angle β for the positive cutting part is 120°, the width of the top surface of the side-cutting edge C_1 is 5 mm, and the thickness of the edge C_2 is 1.5 mm.

At this stage, the main dimensional design of the cutter disc-type furrowing tool is essentially complete, and the final three-dimensional representation of the tool is shown in Figure 2.

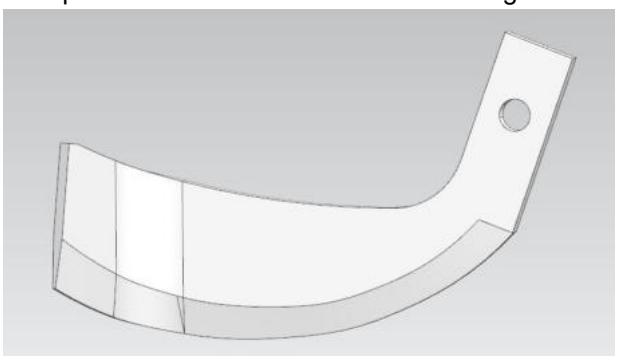

Fig. 2 - Schematic diagram of tool structure

EDEM simulation experiment

The furrowing tool model, based on the tool and soil described in the previous section, is created in UG, saved in STL format, and imported into EDEM. The tool-soil coupling model is then configured according to the physical material properties outlined earlier.

The furrowing tool-soil coupling model, established using the above method and parameters, is shown in Figure 3.

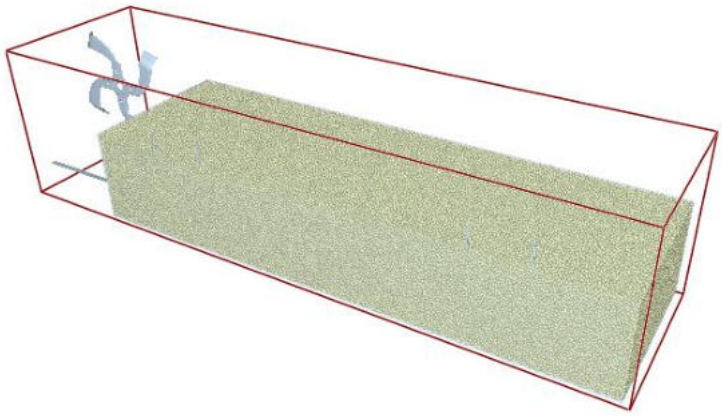

Fig. 3 - Schematic diagram of tool-soil simulation model

As EDEM cannot directly measure the power consumption of the tool, the torque applied to the tool must first be measured and then converted into power consumption using the following formula:

$$P = \frac{T \cdot n}{9549} \tag{4}$$

P - power consumption, [kW];

T - torque, [N·m];

n - tool speed, [rpm].

Quadratic regression orthogonal experimental design

The orthogonal combination design includes a two-level test m_c, asterisk test $2m_\gamma$ and zero-level experiment m_0. The total number of tests, n is calculated using the following equation (*Xiao et al., 2024*):

$$n = m_c + 2m_\gamma + m_0 \quad (5)$$

In accordance with the orthogonality requirement, the arm length parameter, denoted as γ, must satisfy the following relationship:

$$\gamma = \sqrt{\frac{\sqrt{(m_c + 2m + m_0)m_c} - m_c}{2}} \quad (6)$$

The present experiment was a three-factor, two-level full-scale trial, which resulted in $\gamma = 1.353$.

In the context of the given factors, the arithmetic mean is defined as the zero level of factor x_j, denoted x_{j0}, where x_{j2} and x_{j1} represent the upper and lower levels of factor x_j, respectively. Let $x_{j\gamma}$ and $x_{-j\gamma}$ denote the upper and lower asterisk arm levels of factor x_j, respectively. These values correspond to the upper and lower levels of factor x_j.

$$x_{j0} = \frac{x_{j1} + x_{j2}}{2} = \frac{x_{j\gamma} + x_{-j\gamma}}{2} \quad (7)$$

Therefore, the variation in this factor is as follows:

$$\Delta_j = \frac{x_{j\gamma} - x_{j0}}{\gamma} \quad (8)$$

It can be shown that a linear variation in each level of factor x_j leads to the following coding of the levels:

$$z_j = \frac{x_j - x_{j0}}{\Delta j} \quad (9)$$

The factor levels and their corresponding coding results for this experiment are shown in the table 3.

Table 3

Test Factors and Levels

Code	X_1 (Bending radius)	X_2 (Bending angle)	X_3 (Alpha Angle)
γ（1.353）	40	135	52
1	38.6955	131.0864	50.6955
0	35	120	47
-1	31.3045	108.9135	43.3045
$-\gamma$（-1.353）	30	105	42
Δ_j	3.6954	11.0864	3.6954

The test programme and the results obtained from the calculations are presented in the table below.

RESULTS AND DISCUSSION

Analysis of experimental results

Table 5

Analysis of variance

	SS	DF	MS	F-value	P-value	VIF
Model	0.0257	9	0.0029	23.28	0.0002	
A-X_1	0.0017	1	0.0017	13.80	0.0075	1
B-X_2	0.0128	1	0.0128	104.54	＜0.0001	1
C-X_3	0.0035	1	0.0035	28.25	0.0011	1
AB	0.0000	1	0.0000	0.1687	0.6935	1
AC	0.0011	1	0.0011	8.66	0.0216	1
BC	0.0004	1	0.0004	3.32	0.1112	1
A2	0.0024	1	0.0024	19.67	0.0030	1
B2	0.0014	1	0.0014	11.54	0.0115	1
C2	0.0024	1	0.0024	19.52	0.0031	1

Note: P≤0.01 (highly significant), P≤0.05 (significant).

The F-value of the model in the table 5 is 23.28, indicating that the model is significant. The P-value is less than 0.05, further confirming the model's significance. The significant factors include A, B, C, AC, A^2, B^2, and C^2. SS represents the sum of squares, DF is the degrees of freedom, MS is the mean square, and VIF is the Variance Inflation Factor. A VIF value of 1 indicates that the factors are orthogonal. The ANOVA analysis demonstrates that the overall model is significant. The effect of B-X_2 on power consumption is the largest, followed by C-X_3 and A-X_1. Additionally, the interaction between A and C also significantly affects power consumption.

The regression coefficients and goodness of fit can be derived from the ANOVA, and the regression equations are as follows:

$$Y = 0.9069 + 0.0120X_1 + 0.0317X_2 - 0.0178X_3 + 0.0016X_1X_2 + 0.0115X_1X_3 - 0.0093X_2X_3 - 0.0183X_1^2 - 0.0139X_2^2 - 0.0216X_3^2 \quad (10)$$

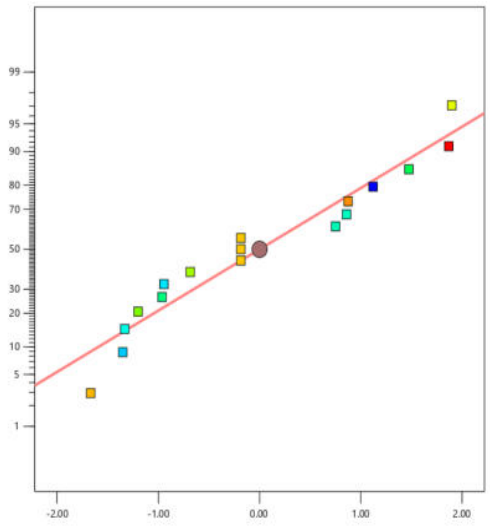
The results of the significance and confidence analyses for the regression equations are as follows:

Table 6

Confidence analyses of regression equations

Parametric	Numerical
R^2	0.9603
Adjusted R^2	0.9093
P	0.0004

The regression equation had an R^2 of 0.9606 and an adjusted R^2 of 0.9093, with a P-value of 0.0004, indicating that the equation was well-fitted and had a significant effect. The normality of the standardized residuals was verified for the regression model, and these residuals were plotted against the standard distribution, as shown below.



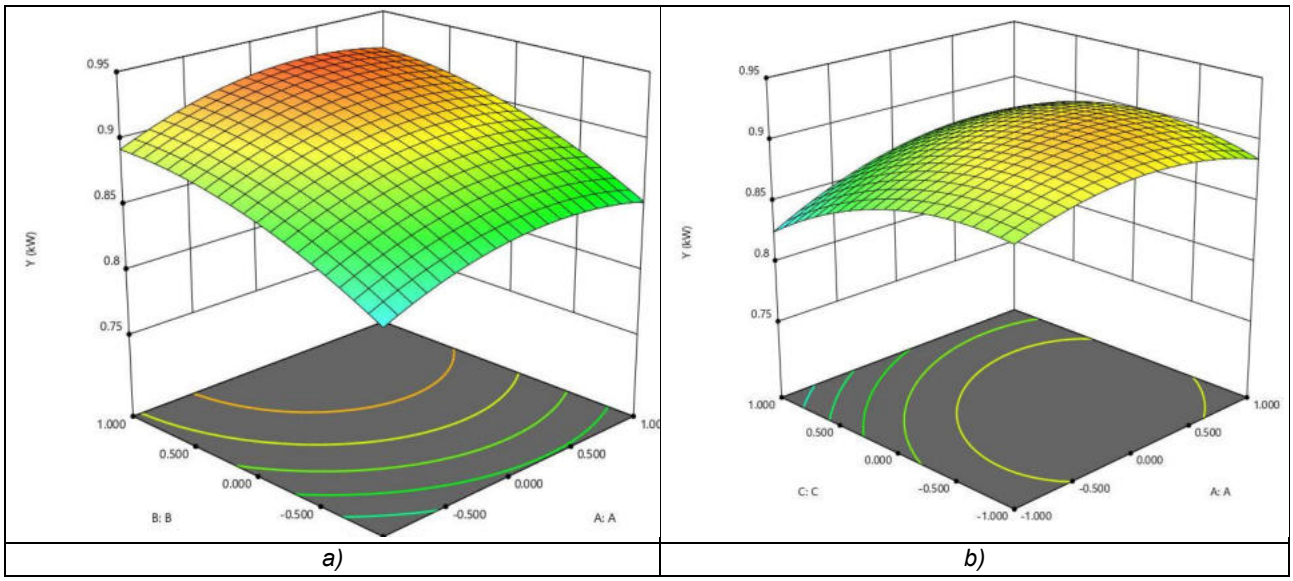


Fig. 4 - Distribution of residual studies

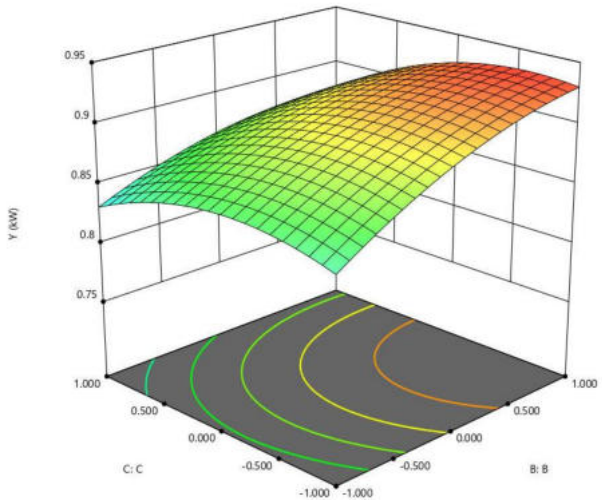
As shown in the Figure 4, the points are distributed along a nearly straight line, indicating that the results are approximately normally distributed. This supports the credibility of the model and aligns with the assumptions of the analysis of variance (ANOVA).



Interaction Effect of Tool Structure Parameters on Power Consumption

In this study, response surface methodology was used to optimise the furrowing tool parameters and analyse the effects of factors and their interactions on power consumption, with the results presented through response surface plots. The response surface of the A (X_1) bending radius and B (X_2) bending angle on power consumption was plotted while keeping the C (X_3) alpha angle at the 0 level. The results show that power consumption increases with the A (X_1) bending radius, with the growth rate slowing at 35 mm and decreasing after reaching a maximum at 36 mm. Power consumption also increases with the B (X_2) bending angle, while it decreases as the C (X_3) alpha angle increases.

The bending radius determines the contact area between the tool and the soil, as well as the force characteristics during the cutting process. A smaller bending radius concentrates the cutting force and reduces the thickness of the soil cutting layer but may result in a larger reaction force. In contrast, a larger bending radius allows the tool to penetrate deeper into the soil, though it may increase power consumption. The bending angle affects both the direction and efficiency of the shear force applied by the tool. Smaller bending angles are suited for shallow cutting but may cause soil build-up and disturbance. Larger bending angles are more suitable for deeper cutting and aid in breaking up compacted layers. The alpha angle influences both the depth of cut and the direction of soil dispersion. Smaller alpha angles enable the tool to cut deeper into the soil but may increase power consumption.

Analysis of tool optimisation results

The objective of the optimisation is to minimise the furrowing power through the rational selection of tool structure parameters. Consequently, a regression equation was established with the goal of minimising power, to reflect the relationship between tool structure and power consumption, providing a quantitative basis for optimisation.

The constraints for the optimisation process are as follows:

$$\begin{cases} X_1 = [-1.353, 1.353] \\ X_2 = [-1.353, 1.353] \\ X_3 = [-1.353, 1.353] \end{cases}$$

The optimal solution is obtained by solving the following equation:

$$\begin{cases} X_1 = -1.33373 \\ X_2 = -1.19486 \\ X_3 = \ \ 1.21368 \end{cases}$$

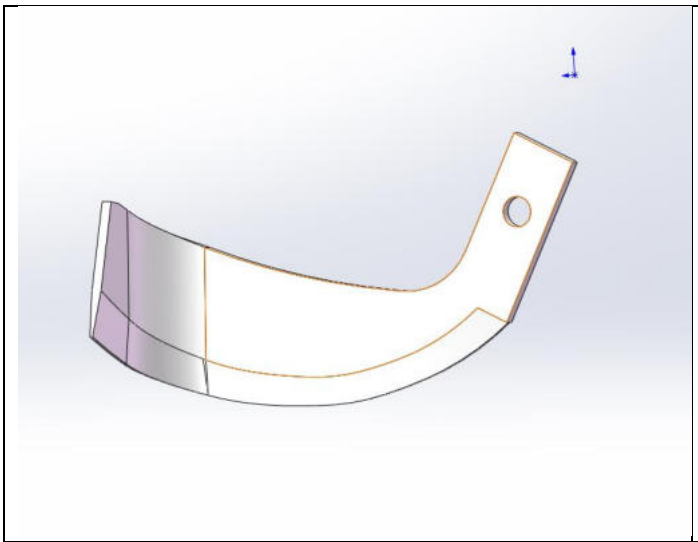

Fig. 6 - Optimised tool model

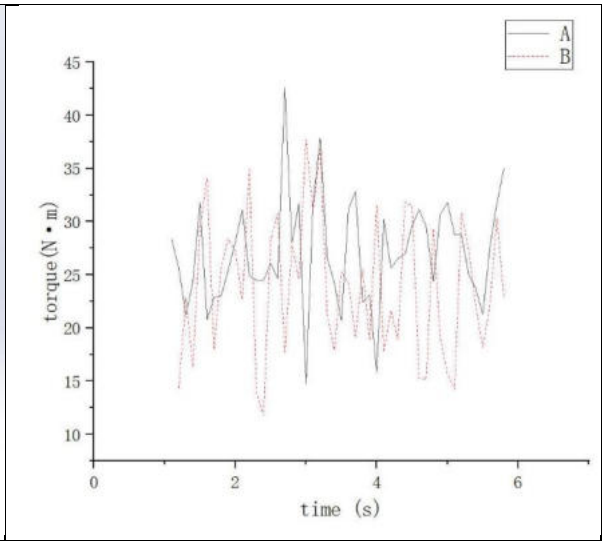

Fig. 7 - Comparison of torque before and after optimization

The optimised furrowing torque graph was generated from EDEM post-processing and plotted using Origin to compare pre-optimisation (torque-A) and post-optimisation (torque-B) values. The results indicate a significant reduction in furrowing torque. After optimisation, the average furrowing torque decreased to 23.90 N·m, while the corresponding furrowing power was 0.75 kW, with a relative error of 1.35%. Compared to the pre-optimisation power of 0.85 kW, furrowing power consumption was reduced by 12.90%.

CONCLUSIONS

This study used a wetland rotary ploughing cutter as a prototype to design a furrowing cutter for orchards in hilly mountainous areas, considering the characteristics of sticky soil. The bending radius, bending angle, and alpha angle of the knives were optimised using quadratic orthogonal regression experiments. The interaction between the knives and soil was analysed through discrete element method (DEM) simulation, with the Hertz-Mindlin with JKR model selected for soil-particle contact modelling. Power consumption during furrowing was used as the evaluation index. Based on the regression analysis and simulation results, the power consumption of the optimised tool is 0.74 kW, 12.9% lower than the pre-optimised value of 0.85 kW. These results demonstrate that by optimally adjusting the tool structure, power consumption can be significantly reduced and working efficiency improved, providing a theoretical basis for the design of orchard furrowing and fertiliser application machinery in hilly mountainous areas.

Keywords: *tiger-nut harvester, crawler, hydraulic drive, field trial*

ABSTRACT
Tiger-nut is widely cultivated in sandy soils across China, and the mechanization level for harvesting remains low. Harvesters are mainly medium- and small-sized tractor-drawn models, which exhibit weak driving capability, a large turning radius, and poor stability. This paper presents the design of a crawler-type tiger-nut harvester hydraulic-driven travel system, with the required hydraulic motor displacement of 44.65 mL·r^{-1} and hydraulic pump displacement of 44.58 mL·r^{-1}. Experimental results from the harvester showed that the harvester's linear travel deviation rate ranged from 1.19% to 2.10%, with an average travel speed of 1.08 m·s^{-1} and the average value of radius for forward left turn and forward right turn is 2740 mm and 2748 mm. The harvester can achieve bidirectional stepless speed regulation in the field, ensuring stable harvesting performance and meeting the design requirements for the tiger-nut harvester.

摘要
油莎豆多种植于中国的沙土地，目前油莎豆机械化收获水平低，现有收获机以中小型牵引式为主，存在驱动能力弱、转弯半径大和行驶稳定性差等问题。本文设计了一种履带式油莎豆收获机液压驱动行走系统，计算得出所需的液压马达排量为 44.65 mL·r^{-1}，液压泵排量为 44.58 mL·r^{-1}。样机试验结果表明：收获机直线行走偏移率为 1.19%-2.10%，平均行走速度为 1.08 m·s^{-1}，前进左转和前进右转的半径平均值分别为 2740 mm 和 2748 mm。收获机在田间能够实现双向无级调速，收获作业性能稳定，满足油莎豆收获机设计要求。

INTRODUCTION
Tiger-nut, often referred to as the "king of oilseed crops," contains rich nutrients in its underground tubers, which can be used to extract edible oil, sugars, and produce beverages, offering significant economic value *(Roselló-Soto et al., 2018; Edo et al., 2024; Wang et al., 2021; Cantalejo et al., 1997)*. China currently relies on imports for more than 70% of its oilseed crops. In the context of the current international situation, the development of the tiger-nut industry holds great strategic importance in addressing Chinese edible oil security issues *(Zhang et al., 2020; Zhang et al., 2024)*.

Mechanized harvesting is a critical and challenging phase in the full mechanization process of tiger-nut production. To optimize harvesting, tiger-nut is best cultivated in sandy soils. Tiger-nut harvesters are generally classified into two types based on their travel mechanism: towed and self-propelled *(Shang et al., 2004)*. In foreign countries, tiger-nut harvesters are typically towed by high-horsepower tractors to perform digging and transportation tasks. However, these harvesters have large structures with limited functions and require coordination with transport vehicles for synchronized harvesting, making them unsuitable for small-scale farms. Currently, the majority of tiger-nut harvesters in China are small- and medium-sized towed models, which suffer from issues such as weak driving power, large turning radius, and poor stability. These shortcomings negatively impact the digging, cleaning, and screening quality, severely limiting the development of the tiger-nut industry *(Xu et al., 2016; Wei et al., 2023)*.

[1] *Zhe Qu, Associate Professor. Ph.D. Eng.; Jianhao Zhang, M.S. Stud. Eng.; Jintao Le, M.S. Stud. Eng.; Xilong Wang, M.S. Stud. Eng.; Haihao Shao, M.S. Stud. Eng.; Huihui Zhao, Lecturer. Ph.D. Eng.; Zhijun Lv, Lecturer. Ph.D. Eng.; Wanzhang Wang, Professor. Ph.D. Eng.*

The tracked travel system provides low ground pressure, high adhesion, strong load-bearing capacity, and a small turning radius *(Jun et al., 2013; McBride et al., 2000; Leggieri et al., 2022)*. The hydraulic drive system enables stepless speed regulation, offering smooth transmission, ease of operation, and rapid response *(Lv et al., 2024; Guo et al., 2025; Zhao et al., 2025)*. By combining the advantages of both systems, a smooth and efficient harvest of tiger-nut can be achieved. Therefore, this paper presents the design of a crawler-type self-propelled tiger-nut harvester with a hydraulic drive system, to enhance the harvester's adaptability and ensure the stability of the harvesting operation.

MATERIALS AND METHODS

Structure and technical parameters of the machine

The developed tiger-nut harvester comprises an excavating device, cab, lifting device, engine, material box, feeding device, screening device, drive system, crawler travel device, and other components. The overall structure of the machine is shown in Fig. 1, and the main parameters are shown in Table 1.

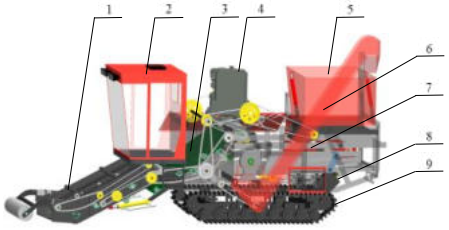

Fig. 1 - The whole structure of tiger-nut harvester

1. Excavating device; 2. Cab; 3. Lifting device; 4. Engine; 5. Material box; 6. Feeding device; 7. Screening device; 8. Drive system; 9. Crawler travel device

Table 1

The main technical parameters of tiger-nut harvester

Parameters	Values
Unladen mass [kg]	7500
Full load mass [kg]	10000
Overall dimensions [mm]	6800×2500×3200
Rated engine power [kW]	103
Rated engine speed [r·min^{-1}]	2300
Working width [mm]	1800
Harvesting speed [m·s^{-1}]	0-0.3
Travel speed [m·s^{-1}]	0-1

The general structure of the hydraulic drive system

The key components of the hydraulic drive system designed in this paper include a hydraulic stepless speed changer, reducer, direction cylinder, and other elements, as shown in Fig. 2.

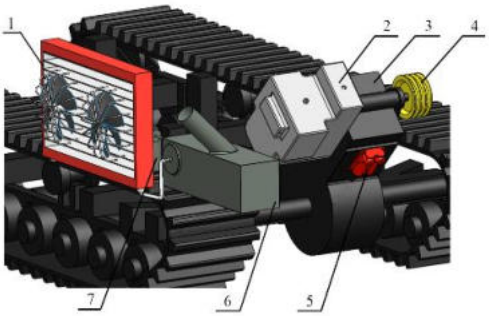

Fig. 2 - The overall structure of the hydraulic drive system

1. Radiator; 2. Stepless speed changer; 3. Reducer; 4. Power input; 5. Direction cylinder; 6. Hydraulic oil tank; 7. Filter

The basic parameters of the hydraulic drive system are shown in Table 2.

Table 2

Basic parameters of hydraulic drive system

Parameters	Values
Transmission mode	stepless gearbox
Steering type	unilateral brake steering
Pump power input method	a leather drive belt
Hydraulic pump displacement [mL·r^{-1}]	46
Maximum system pressure [MPa]	32
Rated system pressure [MPa]	16
Hydraulic motor displacement [mL·r^{-1}]	46
Hydraulic pump input speed [r·min^{-1}]	2300
Low speed reduction ratio	90
High speed reduction ratio	30

Working principle of hydraulic drive system

The working principle of the hydraulic drive system designed in this paper is illustrated in Fig. 3.

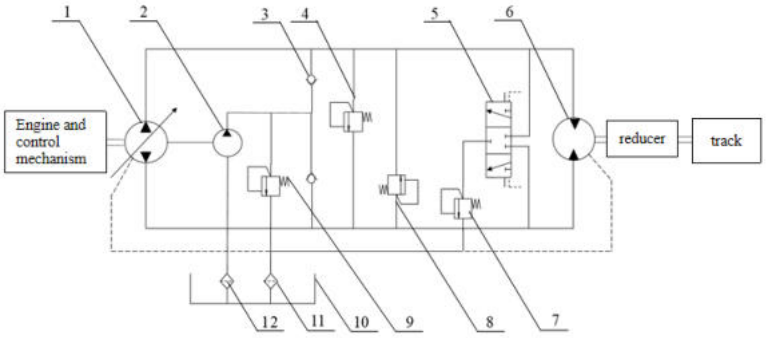

Fig. 3 - Hydraulic schematic of the drive and travel system

1. Variable pump; 2. Charge pump; 3. Check valve; 4. High pressure relief valve; 5. Flush valve; 6. Hydraulic motor; 7. Low pressure relief valve; 8. High pressure relief valve; 9. Charge relief valve; 10. Hydraulic oil tank; 11. Oil return filter; 12. Oil suction filter

The hydraulic pump in the hydraulic drive system is a bidirectional piston variable displacement pump, while the charge pump is a gear pump. The hydraulic pump is connected directly to the power input shaft, supplying hydraulic fluid to the system. The hydraulic motor is a bidirectional piston fixed displacement motor, with its output connected to a reducer, converting hydraulic energy into mechanical output. The charge pump, charge relief valve, and other components form the charge circuit, which replenishes hydraulic fluid in the system and maintains stable system pressure. The flush valve, low pressure relief valve, and oil return filter form the flushing circuit, which aids in reducing system temperature and ensuring proper lubrication. The check valve and high pressure relief valve together make up the protection circuit, maintaining stable system pressure. The system operates as follows: The engine drives the hydraulic pump via a belt, powering the hydraulic system. The hydraulic pump draws fluid from the oil tank, converting the engine's mechanical energy into hydraulic energy. As the oil flows through the circuit, it drives the hydraulic motor, which generates rotational speed and torque, converting hydraulic energy back into mechanical energy. Once the hydraulic motor discharges the oil, the oil flows directly into the intake of the hydraulic pump, starting the next cycle. If the system experiences low pressure or oil leakage, the charge circuit replenishes the oil. To adjust speed or reverse the motion, the operator uses the control handle to adjust the servo control valve. This action moves the servo cylinder, which adjusts the tilt angle of the hydraulic pump's swashplate, changing the pump's displacement and flow rate, enabling continuous variable speed control. When the system is idle, the hydraulic fluid returns to the oil tank through the flushing circuit.

Design of key components of hydraulic drive system

- **Traction Performance Analysis and Calculations**

The traction performance of a travel system is the traction work capacity exerted under specified ground conditions and its efficiency. The force model of the harvester while traveling is shown in Fig. 4.

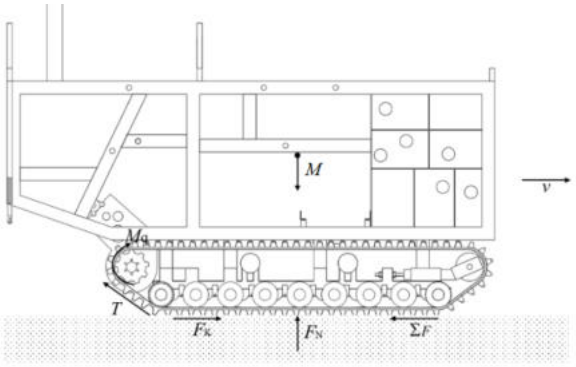

Fig. 4 - Force model of the tracked travel device during operation

From the mechanical model, it can be seen that under the action of the driving moment M_q, the track generates a tension T with the value:

$$T = \frac{M_q}{r_q} = \frac{i_1 \cdot \varphi_e \cdot M_e}{r_q} \quad (1)$$

where:

φ_e is the engine-to-drive-wheel mechanical efficiency, 0.95;

M_q is the drive-wheel torque, [N·m];

r_g is the drive-wheel radius of 0.16 [m] *(Han et al., 2023)*;

Neglecting the friction loss of tension T, the track attachment force F_k is equal to the track tension. The normal operation of the tiger-nut harvester in the field requires overcoming the rolling resistance F_p from the ground, the inertial resistance of the system F_i, the internal resistance of the system F_f, and the ramp resistance F_z and the digging resistance F_c when traveling on a ramp. Rolling resistance is mainly the normal and tangential forces generated by contact with the ground and the deformation of the tracks and the ground under full gravity, which is related to the resistance coefficient and the weight of the whole machine. The main working environment of the tiger-nut harvester is sandy loam soil, and the rolling resistance coefficient is taken as 0.15 *(Pan et al., 2014)*.

$$M = mg \quad (2)$$

$$F_p = f\ M\ \cos\alpha \quad (3)$$

where:

M is the gravity of the harvester, [N];

m is the mass of the harvester when fully loaded, [kg], calculated as 10000 kg;

α is the slope of the ramp, taken as 20°;

g is the acceleration of gravity, [m·s^{-2}];

f is the rolling resistance coefficient;

The rolling resistance F_p = 14095.39 N was calculated.

Inertial resistance is calculated by the following formula:

$$F_i = \frac{2Mv}{gt} \quad (4)$$

where:

v is the travel speed during operation, taken as 0.4 [m·s^{-1}];

t is the acceleration time, taken as 3 s;

The inertial resistance F_i = 2666.67 N was calculated.

The internal resistance of the system is related to the overall lubrication and precision and is calculated from the mass of the whole machine and the internal resistance coefficient:

$$F_f = \partial M \tag{5}$$

where:

∂ is the internal friction drag coefficient, typically 0.05-0.07 *(Ji et al., 2013)*, taken as 0.07;

The internal resistance F_f= 7000 N was calculated.

When the harvester travels uphill or downhill, the component of gravitational force acting along the slope direction generates resistance. This resistance is related to the slope and is calculated using the following formula:

$$F_z = M \sin\alpha \tag{6}$$

The ramp resistance F_z = 34202.01 N was calculated.

When the tiger-nut harvester operates in the field, the travel system is simultaneously subjected to digging resistance. The maximum digging depth of the harvester's digging mechanism is 200 mm, and the digging width corresponds to the full working width of 1800 mm (*Lv et al., 2022; Zhang et al., 2021*). The digging resistance F_c is calculated as follows:

$$F_c = 2\tau h_c W \tag{7}$$

where: τ is the coefficient of integration per unit of transverse area of the soil mound *(Han et al., 2023)*, taken as 5 N·cm^{-2};

h_c is the depth of excavation, [mm];

W is the width of excavation, [mm];

The excavation resistance F_c = 36000 N was calculated.

The maximum traction required by the system is equal to the sum of all resistance forces:

$$F_q = F_p + F_i + F_f + F_z + F_c \tag{8}$$

where:

F_q is the total tractive force, [N];

The total tractive force F_q = 93964.07 N was calculated.

The ground adhesion F_φ was calculated by the following equation:

$$F_\varphi = \varphi M \tag{9}$$

where: φ is the adhesion coefficient factor taken as 1.0 *(Liu et al., 2022)*;

The ground adhesion F_φ = 100000 N was calculated.

A comparative analysis of the calculated data shows that the total traction force F_q is smaller than the ground adhesion force F_φ, indicating that the system meets the calibration requirements and the harvester will not experience slippage during field operation.

The drive wheel speed and driving torque are calculated according to the following formula:

$$n_q = \frac{60v}{2\pi r_q} \times 10^3 \tag{10}$$

$$M_q = \frac{1}{2} \sum F \cdot r_q \times 10^{-3} \tag{11}$$

where:

n_q - maximum speed of the drive wheel, [r·min^{-1}];

r_q - radius of the drive wheel, 160 [mm];

M_q - driving torque, [N·m];

The drive wheel speed n_q = 24 r·min^{-1} and the drive torque M_q = 8000 N·m were calculated.

- **Determination of travel system operating pressure**

The operating environment of the crawler-type tiger-nut harvester consists of sandy loam. The hydraulic system's working pressure is initially set at 14 MPa, with a maximum pressure of 32 MPa *(Dong et al., 2005)*.

- **Parameterization of hydraulic motors**

The hydraulic motor output speed n_m, torque M_m and displacement V_m are as follows.

$$n_m = n_q \cdot i_1 \tag{12}$$

$$M_m = \frac{M_q}{i_1 \cdot \eta_1 \cdot \eta_2} \tag{13}$$

$$V_m = \frac{2\pi M_m}{\Delta P \cdot \eta_3} \tag{14}$$

The synthesized equation yields:

$$V_m = \frac{\pi F_q r_q}{\Delta P \cdot \eta_1 \cdot \eta_2 \cdot \eta_3 \cdot i_1} \tag{15}$$

where:

i_1 is the low-speed reduction ratio (field operation reduction ratio), 90;

η_1 is the hydraulic motor mechanical efficiency, taken as 0.95;

η_2 is the reduction gearbox mechanical efficiency, taken as 0.99;

η_3 is the hydraulic motor volumetric efficiency, taken as 0.95;

ΔP is the system pressure, MPa;

Bringing in the data, it was calculated that the motor speed m_n = 2160 r·min^{-1}, the torque applied to the motor M_m = 94.51 N·m, and the motor displacement V_m = 44.65 mL·r^{-1} during the stable operation of the harvester in the field.

- **Calculation of hydraulic pump parameters**

In the selected hydrostatic (HST) transmission system, the hydraulic pump and hydraulic motor are connected in an integrated closed-loop configuration. By ignoring system flow losses and using the motor displacement along with the desired operating speed, the system flow rate can be calculated. This flow rate is then used to determine the required displacement of the hydraulic pump V_p:

$$Q_m = \frac{n_m \cdot V_m}{1000\eta_3} \tag{16}$$

$$Q_p = Q_m \tag{17}$$

$$V_p = \frac{1000Q_p}{\eta_p \cdot \eta_4} \tag{18}$$

Available:

$$V_p = \frac{n_m \cdot V_m}{\eta_p \cdot \eta_3 \cdot \eta_4} \tag{19}$$

where:

Q_p is the hydraulic pump flow rate, [L·min^{-1}];

n_p is the pump power input speed, [r·min^{-1}];

η_4 is the hydraulic pump volumetric efficiency, 0.99;

The hydraulic pump output flow rate Q_p = 101.52 L·min^{-1} and the hydraulic pump displacement V_p = 44.58 mL·r^{-1} were calculated.

The displacement of the charge pump is 20-25% of the displacement of the variable pump, and the charge pressure is less than 3 MPa.

$$V_p' = (0.2 \sim 0.25) V_p \tag{20}$$

The charge pump displacement V'_p was calculated to be 8.92-11.15 mL·r^{-1} based on the data.

- **Other hydraulic components**

When designing and selecting tubing, fittings, and hydraulic fluid, the process should adhere to relevant national standards *(Standardization Administration of the People's Republic of China, 2021; Standardization Administration of the People's Republic of China, 2022)*, while considering factors such as connection reliability, sealing performance, pressure loss, and overall cost.

The inner diameter of the fuel line is calculated as follows:

$$d = \sqrt{\frac{4q}{\pi v_0}} \times 10^3 \quad (21)$$

where: d is the diameter of the hydraulic pipe, [mm];

q is the flow rate of the hydraulic fluid, [$m^3 \cdot s^{-1}$];

v_0 is the flow rate of the hydraulic fluid, taken as 4 $m \cdot s^{-1}$;

The calculated inner diameter was d = 18.3 mm. According to standard requirements, the hose inner diameter was specified as 20 mm, and appropriate tube fittings were selected accordingly.

- **Selection of hydraulic drives**

Based on the hydraulic principles and component parameters used in the design calculations, a Heckert HT series variable pump with a displacement of 46 $mL \cdot r^{-1}$ and a rated pressure of 16 MPa was selected, along with an integrated hydraulic drive unit consisting of a hydraulic pump and motor. The configuration is shown in Figure 5, and the corresponding parameters are listed in Table 3.

Fig. 5 - Hydraulic drive device

Table 3

Hydraulic drive device parameters

Parameters	Values
System displacement [$mL \cdot r^{-1}$]	46
Charge pump displacement [$mL \cdot r^{-1}$]	10
Rated pressure [bar]	160
Maximum pressure [bar]	320
Control system	mechanical servo
Maximum speed [$r \cdot min^{-1}$]	3300

RESULTS

Performance Tests

- **Site testing**

The field tests focused on evaluating the harvester's straight-line travel performance, response characteristics, and parking brake effectiveness on slopes, as well as measuring its maximum travel speed and operational stability.

- **Travel straightness test**

The straight-line movement test of the harvester is conducted according to the GB/T 15370.4-2012 standard *(Standardization Administration of the People's Republic of China, 2012)*. A 20 m correction zone and a 30 m test zone are defined within the test field. The test factors include the hydraulic pump displacement (maximum and intermediate displacements) and load size (no load, 200 kg load, and 500 kg load). The deviation rate is used as the performance indicator to assess the straightness of the movement process.

The travel offset rate was calculated based on the formula:

$$\Delta C = X_1 - X_2 \quad (22)$$

$$H = \frac{|\Delta C|}{S} \quad (23)$$

where: X_1 is the perpendicular distance between the track and the reference straight line before the test, [m];

X_2 is the perpendicular distance between the track and the reference straight line after the test, [m];

H is the offset rate, [%]; ΔC is the offset, [m]; S is the test distance, [m].

The results of the offset rates obtained for different operating conditions are shown in Table 4.

Table 4

Offset test results

Hydraulic pump displacement	Number of tests	Unladen	200 kg Load	500 kg Load
		Offset rate [%]	Offset rate [%]	Offset rate [%]
Maximum displacement	1	0.14	0.15	0.12
	2	0.09	0.12	0.19
	3	0.15	0.20	0.11
Intermediate displacement	1	0.10	0.15	0.12
	2	0.18	0.13	0.16
	3	0.16	0.12	0.14

The field test results show that the deviation rate of the harvester ranges from 0.09% to 0.20%, significantly lower than the standard requirement of 6%, demonstrating that the harvester exhibits excellent straight-line movement and that the hydraulic drive system fulfills the performance criteria. Additionally, the deviation rate remains relatively consistent across different displacements, indicating that the displacement of the hydraulic pump has a minimal effect on the straight-line movement performance. Furthermore, the deviation rate remains relatively consistent under different loads, suggesting that the hydraulic drive system demonstrates robust adaptability to different load conditions.

- **Travel speed measurement test**

The travel speed measurement test is conducted to verify the speed control stability of the designed hydraulic drive system and to determine the maximum field travel speed. The theoretical maximum travel speed of the designed harvester is calculated using the following formula:

$$n_{qm} = \frac{n_m}{i_2} \tag{24}$$

$$v_m = \frac{2\pi r_q \cdot n_{qm}}{60} \tag{25}$$

where: n_{qm} is the theoretical travel speed of the driving wheel, [r·min^{-1}];

n_m is the output speed of the hydraulic motor, [r·min^{-1}];

i_2 is the high speed reduction ratio, 30;

v_m is the maximum theoretical travel speed, [m·s^{-1}];

The maximum theoretical travel speed of the crawler-type tiger-nut harvester was calculated to be 1.18m·s^{-1}.

In the test field, a 50-meter distance was measured as the travel speed measurement interval. Buffer zones for acceleration and deceleration were marked 10 meters before and after the measurement interval. The central 30-meter section was divided into six equal intervals, each 5 meters in length. The time to traverse each 5-meter interval was recorded, and the speed for each interval, as well as the average speed over the entire section. The harvester was tested in an unloaded state under high gear conditions, with the control lever for speed pushed to its maximum, and the test was repeated three times. The 18 speed measurements obtained from the six segments across the three tests were processed as shown in Fig. 6.

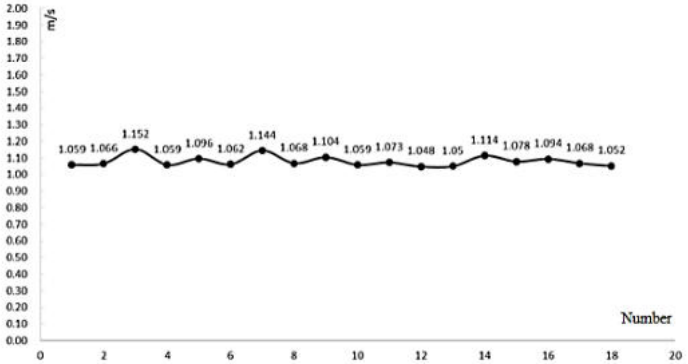

Fig. 6 - Speed stability analysis

As shown in Figure 6, the measured field travel speed ranged from 1.05 to 1.15 m·s^{-1}, with an average speed of 1.08 m·s^{-1} and a standard deviation of 0.03 m·s^{-1}. The overall data exhibited minimal fluctuation, with no significant outliers, indicating good speed stability of the hydraulic drive system. However, due to internal leakage within hydraulic components, track slippage, and other influencing factors, the maximum measured travel speed was slightly lower than the theoretical value of 1.18 m·s^{-1}. Nonetheless, the maximum travel speed of the harvester meets the design requirements, and the travel process remains stable and reliable.

- **Starting and braking performance tests**

The time required for the harvester to accelerate from rest to maximum speed is defined as the startup acceleration time, which reflects the responsiveness of the hydraulic drive system. The time for the harvester to decelerate from maximum speed to a complete stop is termed the braking deceleration time. Three measurements were conducted, and the average value was taken. The average values are shown in Table 5.

The relationship between the drive wheel speed monitored by the tachometer and the travel speed is described by the following equation:

$$n_q = \frac{60}{2\pi r_q} v \tag{26}$$

As can be seen from the speed test results in Fig. 6, the maximum travel speed obtained in the field test was 1.15 m·s^{-1}, which was substituted into the data to calculate the driving wheel speed at the maximum speed of 64.46 r·min^{-1}.

Table 5

Starting and braking performance measurement results

Ordinal number	Start-up acceleration time [s]	Brake deceleration time [s]
1	3.1	1.5
2	3.7	0.8
3	3.3	1.2
Average value	3.4	1.2

As shown in Table 5, the hydraulic drive system of the harvester demonstrates good startup and braking performance. The startup time is close to the simulation response time of 2.8 seconds, which also validates the accuracy of the simulation. The higher measured response time compared to the simulation may be due to the manual stopwatch measurement, which could introduce errors in reaction time.

- **Ramp parking brake test**

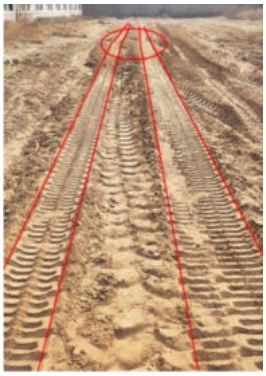
The ramp parking brake performance test was conducted in accordance with GB/T 3871.6-2006 *(Standardization Administration of the People's Republic of China, 2006)*. The harvester was driven steadily onto a ramp, and the engine was then shut off to perform parking brake tests in both uphill and downhill conditions. Each test maintained a parking duration of 3 minutes. The test setup is illustrated in Figure 7.

Fig. 7 - Ramp braking test

a. Uphill parking brake test *b. Downhill parking brake test*

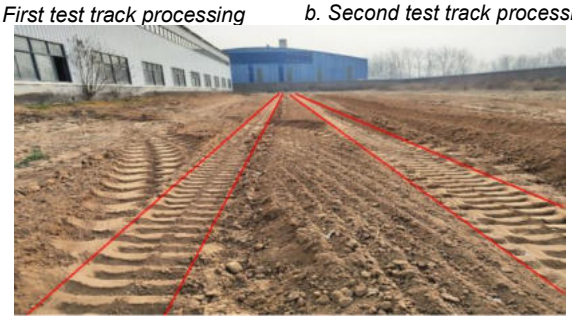
The test results showed that the harvester remained stationary during the entire ramp parking duration, demonstrating excellent parking stability. This meets the test requirements and indicates that the hydraulic system provides reliable parking brake performance on slopes.

Field trials



To comprehensively evaluate the performance of the harvester and its hydraulic drive system, field tests on straight-line driving and turning performance were conducted after the simulations and field trials of the hydraulic system.

- **Linear travel test**



In a test field, the harvester was driven at maximum speed without adjusting the control handle to further assess the straight-line driving performance of the designed drive system. Three sets of tests were conducted, and the track marks were processed to evaluate the straight-line performance. The results are shown in Fig.8.

a. First test track processing

b. Second test track processing

c. Third test track processing

Fig. 8 - Field straight-line travel test

According to the field straight-line driving performance test, the harvester's deviation rate ranges from 1.19% to 2.10%. The sideways slipping of the harvester, caused by soft soil and subsidence, leads to a slightly higher deviation rate compared to the field test, but it still meets the national standard requirements. The test results indicate that the harvester has good straight-line driving performance, meeting the requirements for tiger-nut harvesting.

- **Field steering trials**

In order to verify the steering ability and steering radius of the harvester in the field, three tests were conducted with forward left and right turns respectively, and the steering test and radius measurement process are shown in Fig. 9, and the results are shown in Table 6.

Fig. 9 - Field turning test

Table 6

Field Turning Test Results

Serial number	Left Turning Radius [mm]	Right Turning Radius [mm]
1	2714	2807
2	2763	2726
3	2742	2711
Average value	2740	2748

The theoretical radius R_t is 2720 mm when steering in the field, and the average value of radius for forward left turn and forward right turn is 2740 mm and 2748 mm. There is a track offset within the permissible range when steering, and it can be accomplished by unilateral braking steering in the field as required.

CONCLUSIONS

(1) To improve the adaptability of the tiger-nut harvester and ensure stable harvesting operation, a hydraulic drive system for the crawler-type harvester was designed. The required displacement of the hydraulic motor was calculated to be 44.65 mL·r^{-1}, and the displacement of the hydraulic pump was determined to be 44.58 mL·r^{-1}. A unified hydrostatic drive unit with a displacement of 46 mL·r^{-1} and a system pressure of 16 MPa was selected.

(2) Field evaluations demonstrated that the harvester exhibits a straight-line deviation rate of 1.19–2.10% and an average travel speed of 1.08 m·s^{-1}. The effective implementation of the steering mechanism, which reliably regulates turning performance under various field conditions, confirms the system's capacity to achieve stable and efficient harvesting operations.

(3) Field trials in sandy loam soils show that the hydraulic drive system performs stably under varying loads and speeds, with low deviation and precise turning. These results confirm its reliability for tiger-nut harvesting and support further optimization and industrial application.

Keywords: *Cotton, pest and disease, YOLOv5s, lightweight, target detection*

ABSTRACT

To address the low recognition accuracy and slow detection speed of cotton leaf pests and diseases in natural environments, a detection method based on an improved YOLOv5s model was proposed. The enhanced model integrates the Ghost module and the C3Faster module to increase inference speed and reduce model complexity, achieving lightweight performance without significantly compromising accuracy. To counteract the tendency of common cotton pest and disease features to be lost in complex natural scenes, a Coordinate Attention (CA) mechanism was introduced to improve the network's recognition and localization capabilities. The parameters, FLOPs, and weight file size of the improved model were reduced to 65.5%, 66.2%, and 67.1% of those of the original YOLOv5s model, respectively. On a self-built dataset, the improved YOLOv5s model achieved a mean average precision (mAP) improvement of 10.5%, 0.2%, and 0.4% compared to YOLOv4, YOLOv5s, and YOLOv7, respectively. The model was deployed on a Jetson Orin NX development board with CUDA acceleration, achieving a real-time detection speed of 76.3 frames per second.

中文摘要

针对自然环境中棉花叶片病虫害识别精度低、识别速度慢的问题，提出了一种基于改进YOLOv5s的检测方法。该方法基于YOLOv5s模型，通过结合Ghost模块和C3Faster模块来提高推理速度，实现模型轻量化，而不会显著影响准确性。由于棉花常见病虫害的特征在自然环境中很容易丢失，因此添加了CA注意机制模块，以帮助轻量级网络提高识别和定位能力。改进后的模型参数、FLOP和权重文件大小分别为YOLOv5s的65.5%、66.2%和67.1%。将自建数据集与YOLOv4、YOLOv5s和YOLOv7进行比较，结果表明，改进的YOLOv5模型的平均准确率分别提高了10.5%、0.2%和0.4%。改进后的模型部署在Jetson Orin NX开发板上，并使用CUDA加速。加速模型检测速度为76.3帧/秒。

INTRODUCTION

Cotton is the seed fiber of malvaceous cotton plants in subtropical regions and is one of the most important economic crops in the world. China's cotton planting area and yield account for 9.82% and 23.76% of the world, respectively, with Xinjiang having the largest cotton planting area and yield. In 2024, China's cotton planting area reached 2,838.3 thousand hectares, with a total output of 6.164 million tons. Xinjiang accounted for 2,447.9 thousand hectares of the planting area and 5.686 million tons of the total yield, representing 86.2% and 92.2% of the national totals, respectively. The yield and quality of cotton are affected mainly by pests and diseases. The common pests and diseases of cotton in Xinjiang mainly include yellow wilt disease, aphids, and brown spots *(Chen et al., 2018; Lou et al., 2018; Zhao et al., 2023).* Currently, cotton pests and diseases in Xinjiang mainly rely on the application of plant-protection machinery. During operation, the precision of spraying is poor, making it difficult to accurately and effectively prevent different types of pests and diseases.

Yulong WANG, Master Student; Fengkui ZHANG, lecturer; Rina YANGDAO, Master Student; Ruohong HE, Master Student; Jikui ZHU, lecturer; Ping LI, Professor.

As the computer technology progresses, prevention and control of cotton pests and diseases have evolved from being initially determined by experienced experts to using computer technology and deep learning algorithms to determine pest and disease varieties and control measures. To apply the target detection technology to plant protection machinery, the first step is to solve the problems of a large model, slow recognition speed, and low recognition accuracy.

The YOLO algorithm has been widely used in the detection of crop pests and diseases due to its fast inference speed and high accuracy. YOLO is highly suitable for real-time agricultural applications by directly predicting object classes and positions on feature maps (*Ganesan and Chinnappan, 2022; Amarasingam et al., 2022; Apacionado and Ahamed, 2023; Wang et al., 2023a; Cruz et al., 2022*). In recent years, various YOLO-based models have been applied to crops such as rice, corn, tomato, and cotton (*Masykur et al., 2023; Chen and Yang, 2023; Azath et al., 2021; Susa et al., 2022; Sangaiah et al., 2024*). To improve the detection accuracy in complex field conditions, several enhancements have been proposed. *Shi et al. (2023)* introduced the SimAM attention mechanism into YOLOv5s, improving the accuracy except the model size. *Liu et al. (2023)* upgraded YOLOv7 with deformable convolutions, SENet, and Focal-EIOU loss, enhancing the performance at the cost of increased complexity. *Li and Wang (2020)* used image pyramids in YOLOv3 to boost multi-scale detection without reducing model weight. *Zhang et al. (2023)* applied CBAM to YOLOv7 for cotton disease detection to increase the accuracy without reducing FLOPs. *Wang et al. (2023b)* proposed YOLOv4-G using GhostNet and Ghost modules to improve the accuracy, while the memory usage remained high.

To address the problems of large amounts of calculation and difficult feature extraction in the detection model, an improved model based on YOLOv5s was proposed. The lightweight is convenient for the model to be deployed on mobile devices, and the attention mechanism is added to improve the ability to extract important features of the image, providing a theoretical basis for the automation prevention and control of cotton common pests and diseases.

MATERIALS AND METHODS

Image acquisition

Common pests and diseases, such as cotton yellow wilt disease, aphids, and brown spots were selected as the research objects. The cotton pest and disease image dataset were collected from June to September 2023 at the cotton experimental station of Tarim University, using an iPhone14 camera. To meet the diversity of the natural environment, images of different weather conditions were collected at different times, including sunny days, windy days, morning, noon, etc. A total of 2322 cotton pest and diseases were collected. To improve the robustness of model training and avoid overfitting, the collected pictures were horizontally flipped and randomly cropped to expand the dataset. Finally, 4232 pictures of cotton pests and diseases were obtained. The expanded data were screened and pictures with excessive blur, inconsistent features, and excessive differences in actual shooting were deleted. A total of 4000 pictures were selected as the image dataset for cotton pests and diseases. There were 797 pictures of yellow wilt disease, 1065 pictures of aphids, 1422 pictures of brown spots, and 716 pictures of healthy leaves. Some of the collected images are shown in Fig. 1.

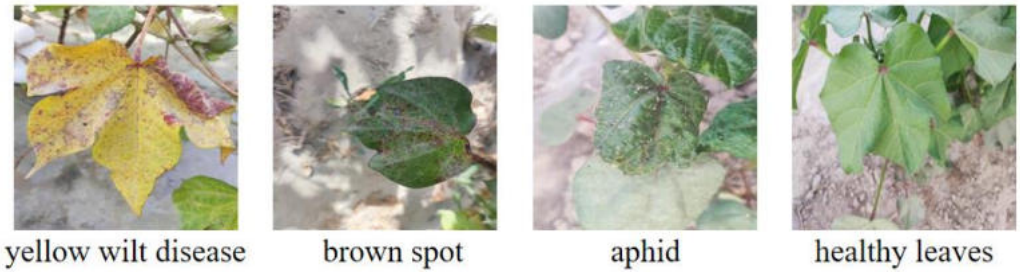

Fig. 1 - Pictures of cotton common pests and diseases

Dataset producing

The cotton pest and disease dataset were labeled with Libeling. Libeling is an open-source data labeling tool that can label tow formats: VOC and YOLO. These 4000 images in the dataset were manually labeled as yellow wilt disease, aphid, brown spot, and healthy leaves. The storage format is a VOC tag format and the file format is an xml file. The code was used to convert the xml format annotation file into a txt format annotation file, which was randomly divided into a training set and a verification set at a proportion of 80%. There were 3203 pictures in the training set and 797 in the verification set.

YOLOv5s algorithm network model

YOLOv5s is a target detection network model in the YOLOv5 series with small model parameters. Because of its small model volume and fast inference speed, it is particularly suitable for real-time target detection tasks deployed on mobile devices or edge computing devices. The model consists of four parts: the input end, Backbone Network, Feature fusion Network Neck and Head Network. In this study, enhancements to the YOLOv5s model are presented, and the architecture of the improved network is illustrated in Fig. 2.

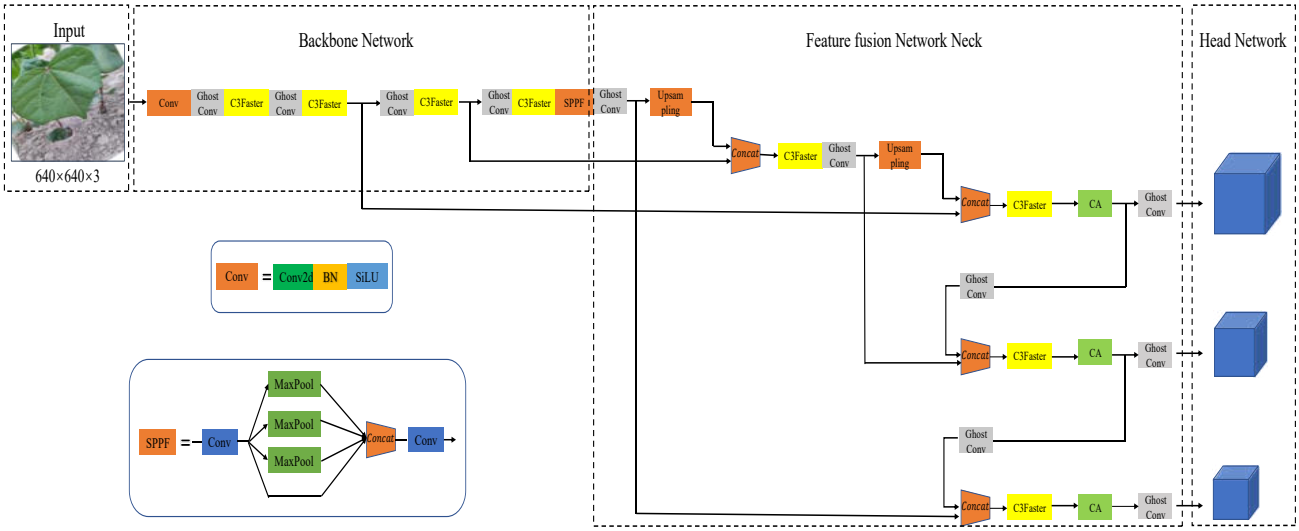

Fig. 2 - Improved YOLOv5s network model structure

Note: The Conv module consists of Conv2d + BN + SiLU, where BN denotes Batch Normalization and SiLU is the activation function. Concat represents tensor concatenation, SPPF stands for Spatial Pyramid Pooling-Fast, and Maxpool denotes the Max Pooling operation. Ghost Conv is the convolution module within the Ghost module used in this study, highlighted with a gray background in the figure. C3Faster refers to the C3Faster module employed in this study, highlighted with a yellow background in the figure. CA represents the CA attention mechanism module used in this study, highlighted with a green background in the figure.

The input end is primarily used for adaptive anchor frame calculation, adaptive image scaling, and mosaic data augmentation *(Passos et al., 2023)*. Mosaic data enhancement is an extension of YOLOv4, which can increase data diversity and model robustness and improve small target detection performance by splicing, flipping, and color gamut changes on four random images. The main structure of the backbone includes Conv, C3, and SPPF modules. After the image enters the neural network through the input end, the backbone network extracts feature and continuously narrows the feature map. The role of the feature fusion Network Neck is to obtain relatively shallow features from the Backbone Network and then stitch them together with deep semantic features. The Head Network contains three prediction branches, which extract feature information to predict targets of different sizes and obtain the category, confidence, and location information of the predicted targets *(Lan et al., 2024).*

Introducing lightweight modules Ghost and C3Faster

In practical applications, it is often necessary to deploy the model on mobile devices to achieve real-time detection. Mobile devices do not possess the computing power of computers. At this point, it is necessary to reduce the calculation time and improve the calculation speed of the model to successfully deploy the model. Based on the YOLOv5s model, all convolutions except the first ordinary convolution are replaced by Ghost Conv, and all C3 modules in the original model are replaced by C3Faster to realize the lightweight of the model and improve the calculation speed while ensuring accuracy.

The Ghost module *(Zeiler and Fergus, 2014)* is a novel plug-and-play component. Since Ghost convolution constitutes the core of the Ghost module, this paper exclusively employs Ghost convolution and refers to the module accordingly. The Ghost module is distinguished by its ability to generate more feature maps using fewer parameters. Initially, intrinsic feature maps are produced through conventional convolution. Subsequently, Ghost feature maps are generated via linear transformation *(Li et al., 2019).* Finally, the intrinsic feature maps and the Ghost feature maps are concatenated to form the final output. The specific structures are shown in Fig. 3.

FasterNet is used to improve the feature expression ability and receptive field coverage while maintaining light weight and high speed *(Shi et al., 2024)*. The network consists of four stages, and its architecture is illustrated in Fig. 4. Based on the YOLOv5s model, the C3Faster module is proposed. It replaces all C3 modules of the original model with C3Faster to reduce the redundancy of calculations and memory

access, thereby improving the efficiency of the neural network. It also improves the efficiency of the floating-point operation per second of the model through partial convolution PConv, thereby achieving high-speed operation on mobile devices while ensuring accuracy.

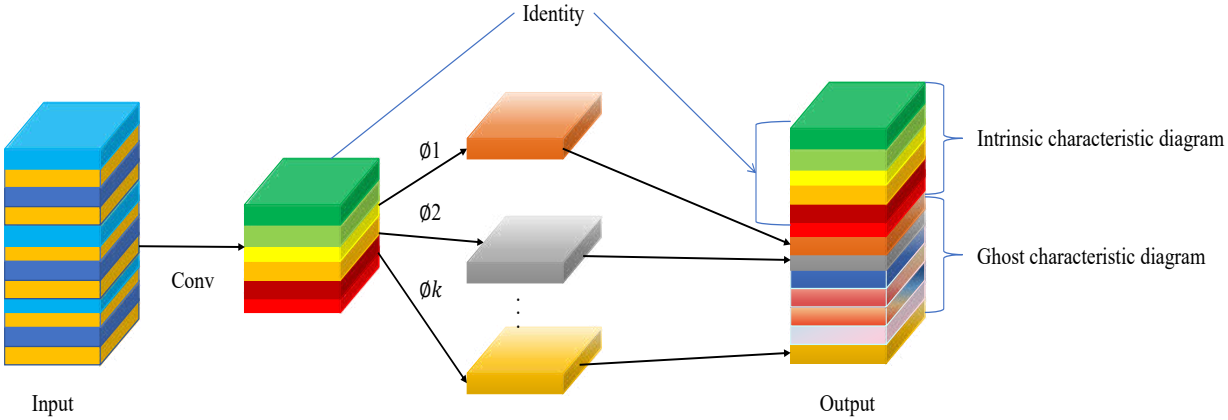

Fig. 3 - Ghost module

Note: Conv represents standard convolution, ∅ denotes linear transformation operations, and Identity signifies the identity mapping.

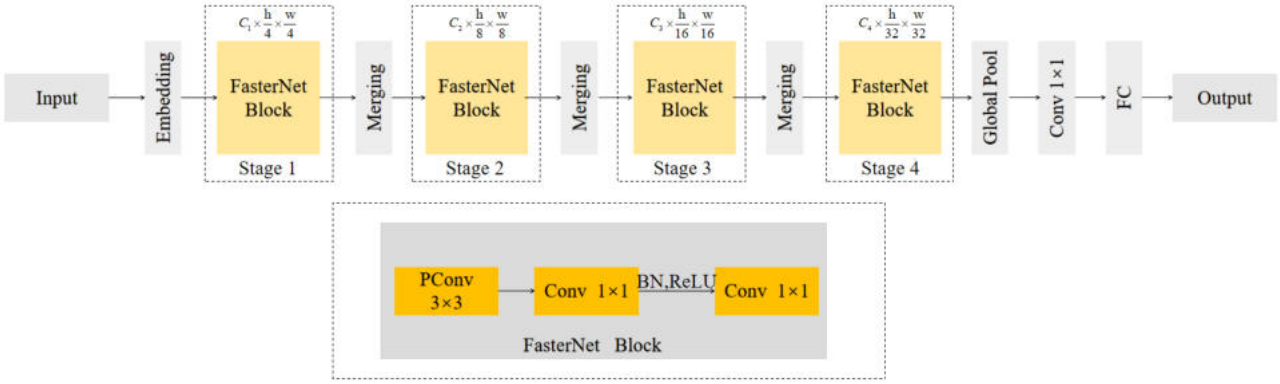

Fig. 4 - FasterNet network architecture

Note: C_x denotes the number of image channels; h represents image height; w represents image width; FasterNet Block refers to a specific module; PConv stands for partial convolution; Conv denotes standard convolution; BN represents Batch Normalization; and ReLU signifies the activation function.

Introducing CA attention mechanism module

In the natural environment, cotton leaves grow densely, and the background is complex. It is difficult for the YOLOv5 model to extract important features of pests and diseases, and the detection results will be misjudged or unrecognized. To improve the extraction effect of the YOLOv5s model on small features, in the neck part of the feature fusion network, a CA (Hou et al., 2021) attention mechanism module was added after other C3 2_1 modules to help the lightweight network rise points. A flowchart of the CA attention mechanism module is shown in Fig. 5(a).

To capture remote spatial interaction with precise location information, global average pooling is decomposed. The specific formula is as follows:

$$z_c^h(h) = \frac{1}{W} = \sum_{0 \le i < W} x_c(h,i) \tag{1}$$

$$z_c^w(w) = \frac{1}{H} = \sum_{0 \le j < H} x_c(j,w) \tag{2}$$

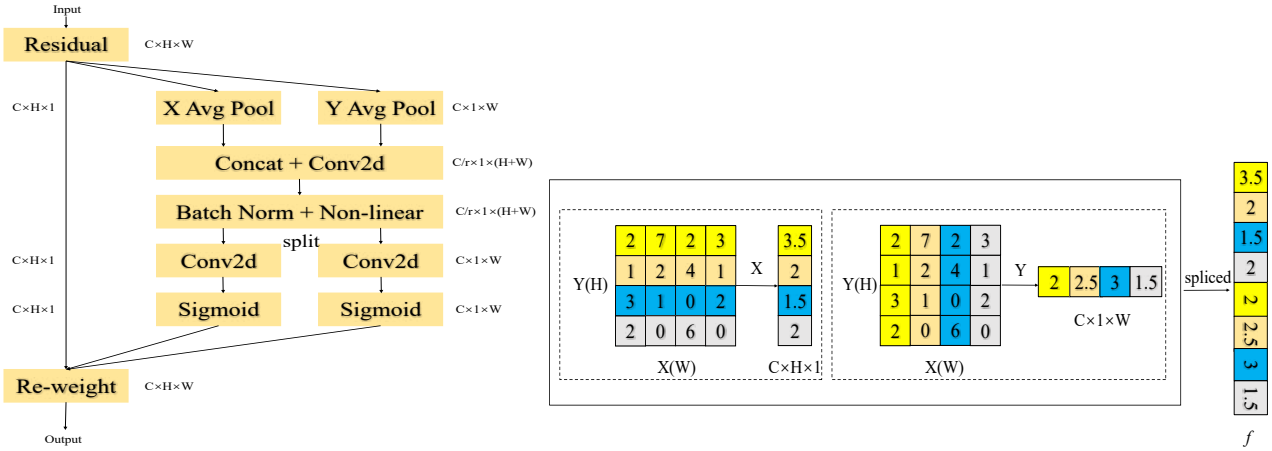
where z_c^h is the height feature diagram representing the output of channel *c*, z_c^w is the width feature diagram representing the output of channel *c*, $x_c(h,i)$ is the input of channel *c* along the *h* direction, and $x_c(j,w)$ is the input of channel *c* along the *w* direction. An input feature diagram with a size of C×H×W is collected in the X- and Y-directions, respectively, and those with a size of C×H×1 and C×1×W are generated, respectively, as shown in Fig. 5(b).

After obtaining the two-feature diagrams, the generated C×H×1 and C×1×W feature diagrams were transformed, spliced, and calculated as follows:

$$f = \delta(F_1([Z^h, Z^w])) \tag{3}$$

where δ is a nonlinear activation function and F_1 is a convolution transformation function. After splicing z^h and z^w, the feature map shown in Fig. 5(b) was generated. F_1 operation (using a 1×1 convolution kernel for dimensionality reduction) and activation operation are performed to generate feature diagram f.

A feature diagram f is generated, and the split operation is performed along the spatial dimension, which is divided into f^h and f^w. A 1×1 convolution was used to increase the dimension, and then the sigmoid activation function was combined to obtain the final attention vectors g^h and g^w. The formula used is as follows:



$$g^h = \sigma(F_h(f^h)) \tag{4}$$

$$g^W = \sigma(F_W(f^W)) \tag{5}$$

where σ is the sigmoid activation function, and F_h and F_w are the dimension-up operations. The output formula of the final CA attention mechanism module is as follows:

$$y_c(i,j) = x_c(i,j) \times g_c^h(i) \times g_c^w(j) \tag{6}$$

where $y_c(i,j)$ is the output of channel *c*, $x_c(i,j)$ is the input of channel *c*, $g_c^h(i)$ is the attention vector of channel *c* along the *h* direction, and $g_c^w(j)$ is the attention vector of channel *c* along the *w* direction.

a. CA attention mechanism module flow chart b. C×H×1 and C×1×W characteristic diagram and characteristic diagram *f*

Fig. 5 - CA attention mechanism module

Note: In Figure 5-a, C denotes the number of channels, H represents image height, W represents image width, X Avg Pool refers to horizontal average pooling, Y Avg Pool refers to vertical average pooling, Conv2d denotes the 2D convolution operation, Non-linear represents the non-linear activation function, Sigmoid is the activation function, and Re-weight stands for the weight file. In Figure 5-b, spliced refers to the concatenation operation.

Training environment deployment and parameter adjustment

The hardware environment in this experiment was a CPU 13th Gen Intel (R) Core (TM) i9-13900KF, 3.00GHz, running memory 32.0GB, GPU Nvidia GeForce RTX 4090, operating system Windows 11-64 bit. Deep learning frameworks such as PyCharm2021, Pytorch1.11, and Python3.8, were used to optimize, train, and evaluate the model.

The training parameters of the model were an image input size of 640 × 640, training of 500 rounds, batch size of 16, and maximum working core of 16. The optimizer used was the stochastic gradient descent method, the initial learning rate was 0.001, the learning rate momentum was 0.937, and the weight attenuation coefficient was 0.0005.

Evaluation index

The precision, P, recall rate, R, and mean average precision, mAP, in the training results were used to measure the recognition performance of the model. Parameters, weight file, and FLOPs were used to measure the complexity of the model. Precision P represents the proportion of correctly detected samples to all detected samples. The formula is as follows:

$$P = \frac{TP}{(TP + FP)} \tag{7}$$

The recall rate R denotes the proportion of correctly detected samples to all samples that are expected to be detected and is calculated as follows:

$$R = \frac{TP}{(TP + FN)} \tag{8}$$

The average accuracy mean mAP is the average of the APs of all classes. The average accuracy AP is the area of the P–R curve as a measure of the performance of the multiclass target detection model. The formula is as follows:

$$mAP = \frac{\sum_{i=1}^{N} \int_0^1 P(R)dR}{N} \times 100\% \tag{9}$$

where TPrepresents the number of true positives (samples correctly detected by the model), FP represents the number of false positives (samples incorrectly detected by the model), FN represents the number of false negatives (samples that should have been detected but were missed), and N represents the number of detection categories. The constructed dataset included three types of cotton pests and diseases, along with healthy leaves as a separate category, resulting in a total of four classes ($N = 4$).

RESULTS AND ANALYSIS

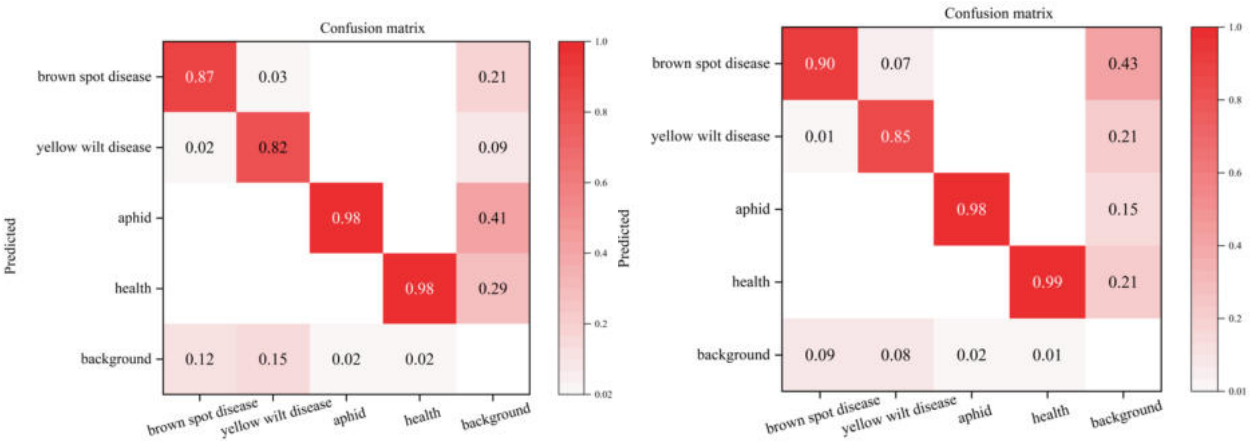
Performance comparison of YOLOv5s-FasterCA model ablation test

To clarify the influence of the Ghost, C3Faster, and CA attention mechanism modules on the performance of the YOLOv5s model, ablation tests were conducted using a self-made dataset of common pests and diseases in cotton. The test results are listed in Table 1. It can be seen from Table 1 that in the original network, using the Ghost module and C3Faster module instead of the ordinary convolution module and C3 module can significantly reduce the model parameters, calculation, and weight file, with little reduction in the precision P, recall rate R, and mean average precision mAP. From the experimental results, it can also be seen that only when the CA attention mechanism module is added are the precision P and mean average precision mAP of the original network model increased by 0.7% and 0.4%, respectively. The recall rate R is slightly decreased, and the parameters, floating-point calculation, and weight file are also slightly increased.

Table 1

YOLOv5s model ablation test

Ghost module C3Faster module	CA attention mechanism	Precision *P* / %	Recall rate *R* / %	Mean average precision *mAP* / %	Parameters / ×10⁶M	Weight file size / MB	FLOPs / G
×	×	88.7	92.4	93.4	7.03	13.7	16.0
√	×	88.3	91.8	92.7	4.58	9.14	10.5
×	√	89.4	92.1	93.8	7.06	13.8	16.1
√	√	89.5	91	93.6	4.61	9.20	10.6



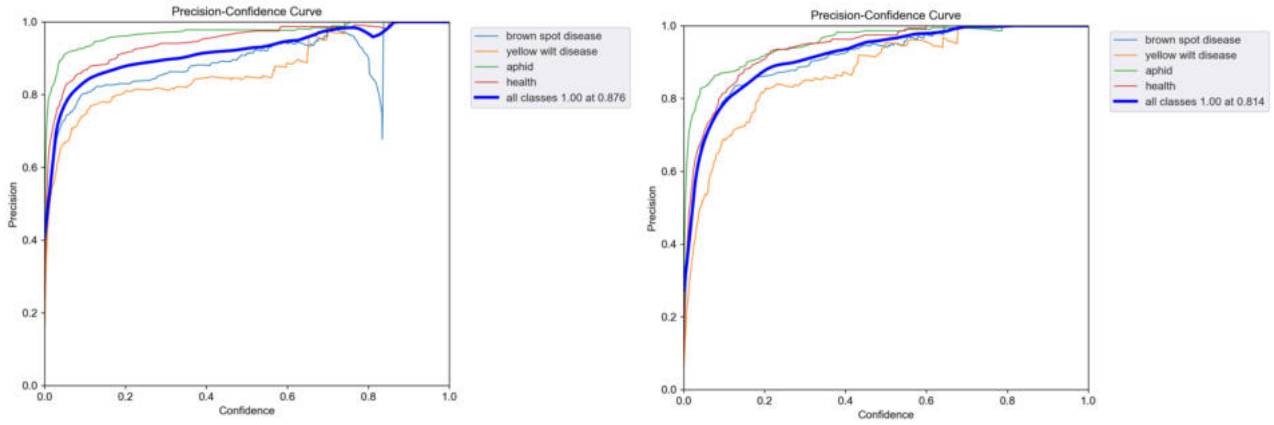
Note: √ indicates the inclusion of the module, while × denotes its exclusion.

Through the ablation test results, under the premise of realizing the lightweight model and ensuring recognition accuracy, the YOLOv5s-FasterCA model is obtained by adding the Ghost, C3Faster, and CA attention mechanism modules to the YOLOv5s model. In the detection and recognition of common cotton pests and diseases, the model parameters were 4.61 × 10^6 M; the FLOPs were 10.6G, and the weight file was 9.20 MB. Compared with the original model, the above parameters were reduced by 34.5%, 33.8%, and 32.9%, respectively, and the accuracy and average accuracy were improved by 0.8% and 0.2%, respectively. This indicates that the YOLOv5s-FasterCA model can improve the recognition accuracy of common cotton pests and diseases while meeting the lightweight requirements.

Performance comparison between YOLOv5s-FasterCA model and original model

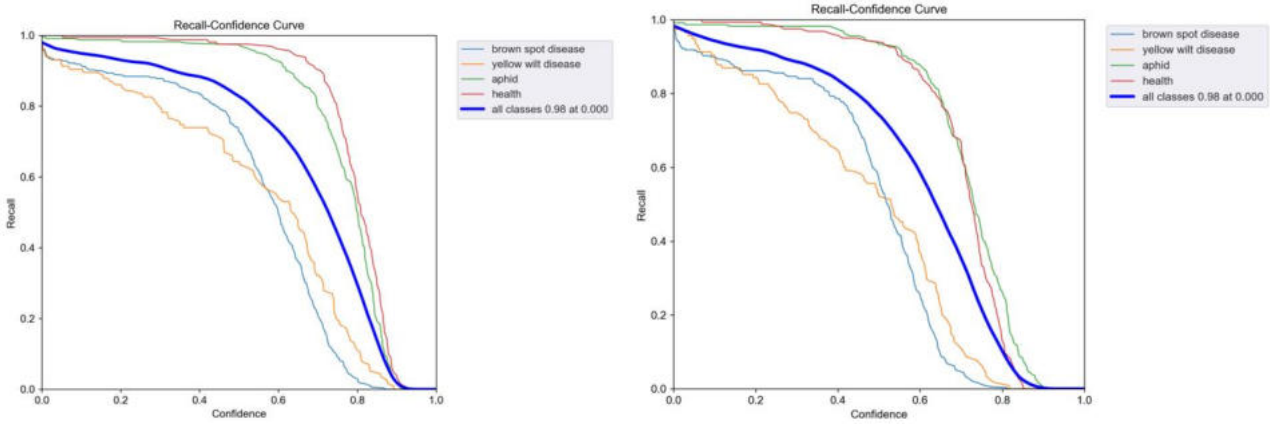
To further verify the performance of the improved model, the YOLOv5s original model and YOLOv5s-FasterCA models were used to train and test the dataset of common cotton pests. The model performance was measured by a confusion matrix diagram, P _ curve diagram, R _ curve diagram, and PR _ curve diagram.

From Fig. 6(b), the improved model has a 3% increase in the probability of detecting brown spot disease, a 1% decrease in the probability of misjudging yellow wilt disease, and a 3% increase in the probability of detecting yellow wilt disease compared to Fig. 6(a). There was no change in the probability of aphid detection or a 1% increase in the probability of detecting healthy leaves. It can be seen from the confusion matrix that compared with the original model that the improved model can improve the precision and reduce the probability of misjudgment, indicating that the improved model is better than the original model.



(a) YOLOv5s (b) YOLOv5s-FasterCA

Fig. 6 - Confusion_matrix

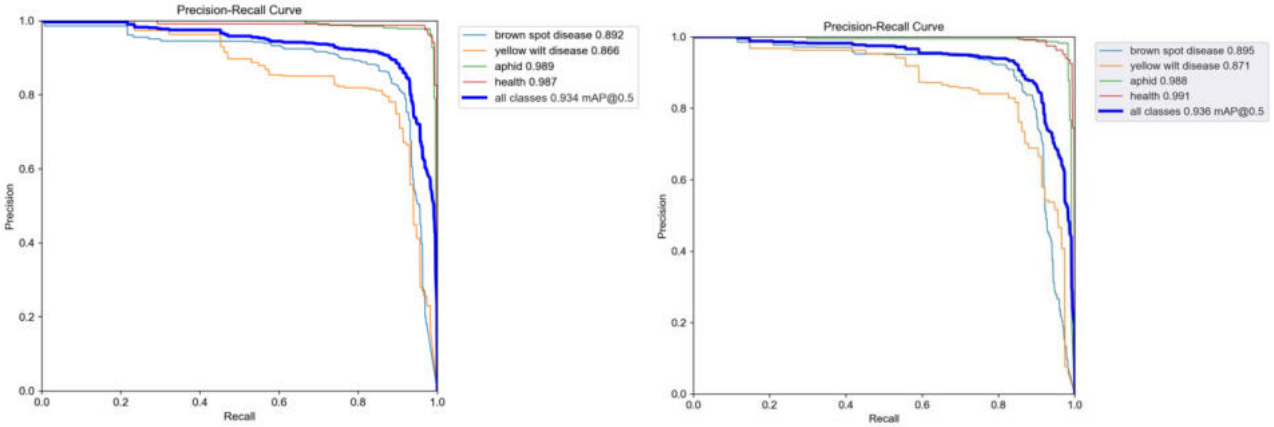


To compare the accuracy and confidence of the improved and original models, the P _ curve graph was used to display the changes in the recognition accuracy of the model for each category under different confidence thresholds.

As shown in Fig. 7(b), the highest confidence of the improved model was 0.814, which was 0.062 lower than that of the original model (Fig. 7(a)). This indicates that the improved model can achieve optimal accuracy when the confidence level is 0.814. Compared with the original model, it can reduce the possibility of missed detection when the confidence threshold is low.

(a) YOLOv5s (b) YOLOv5s-FasterCA

Fig. 7 - P _ curve comparison diagram



(a) YOLOv5s (b) YOLOv5s-FasterCA

Fig. 8 - R _ curve comparison diagram

To compare the precision and recall rates of the improved model and the original model, the R _ curve diagram was used to display the probability of recall of each category when the confidence was a certain value.

It can be seen from Fig. 8 that when confidence is small, category detection is more comprehensive. Through comparison, it was found that when the confidence level was 0.98, the recall rates of the improved model and the original model were 0.

To compare the accuracy and recall rate of the improved and original models, the PR_curve diagram shows the changes in accuracy with the recall rate. From Fig. 9(b), compared with Fig. 9(a), the improved model has a 0.3% higher accuracy in detecting brown spot disease, a 0.5% lower accuracy in detecting yellow wilt disease, a 0.1% lower accuracy in detecting aphids, a 0.4% higher accuracy in detecting healthy leaves, and a 0.2% improvement in accuracy for all types of mAP.

(a) YOLOv5s (b) YOLOv5s-FasterCA

Fig. 9 - PR _ curve comparison diagram

Performance comparison between YOLOv5s-FasterCA model and different models

The improved YOLOv5s-FasterCA model was compared with YOLOv4, YOLOv5s, and YOLOv7 on a self-built dataset. All models were trained using the same dataset and identical training parameters, and the results are shown in Table 2.

The mean average precision of the YOLOv5s-FasterCA model was 10.5%, 0.2%, and 0.4% higher than that of the other three models. The detection time of a single image was 1ms slower than that of the original model (which can be ignored). This indicates that the detection accuracy and recognition speed of the model meet the requirements for the real-time detection of common cotton pests and diseases.

Table 2

Performance comparison of different models

Modules	Precision P/%	Recall rate R/%	Mean average precision mAP/%	Parameters/×10^{6}M	Weight file size /MB	FLOPs/G	Detect/ms
YOLOv4	78.8	79.42	83.1	64.33	249.7	60.4	37
YOLOv5s	88.7	92.4	93.4	7.03	13.7	16.0	7
YOLOv7	90.2	92.6	93.2	70.83	135	188.9	41
YOLOv5s-FasterCA	89.5	91	93.6	4.61	9.20	10.6	8

Fig. 10 - Comparison of model detection effects in natural environment

Identification of common pests and diseases of cotton in natural environment

It can be seen from Table 2 that the model parameters, weight files, and FLOPs calculations of YOLOv4 and YOLOv7 are too large to meet the lightweight requirements of the model. Only the YOLOv5 and the improved YOLOv5s-FasterCA models were deployed on the Jetson Orin NX development board to detect common cotton pests and diseases under the same natural environment in the test dataset. The results are shown in Fig. 10. The detection results indicate that the YOLOv5s model may fail to identify certain pest and disease types under complex background. In contrast, the improved YOLOv5s-FasterCA model can significantly reduce false detections and missed detections, demonstrating better performance in accurately identifying common cotton pests and diseases, even in challenging environments. Furthermore, after acceleration with CUDA, the YOLOv5s-FasterCA model achieved a detection speed of 76.3 FPS on the Jetson Orin NX development board, meeting the requirements for real-time detection.

CONCLUSIONS

(1) An improved target detection model, YOLOv5s-FasterCA, was proposed by integrating Ghost and C3Faster modules to replace the standard convolution and C3 modules in the original YOLOv5s. The Coordinate Attention (CA) mechanism was introduced. The improved model achieved a precision of 89.5% and a mean average precision (mAP) of 93.6%, 0.8% and 0.5% higher than the original YOLOv5s respectively. In addition, the parameter count, FLOPs, and weight file size of the model were significantly reduced, meeting the requirements for lightweight deployment.

(2) The comparative experiments showed that the mAP of YOLOv5s-FasterCA was 10.5%, 0.2%, and 0.4% higher than those of YOLOv4, YOLOv5s, and YOLOv7, respectively. Although the improvement in single-frame inference time compared to YOLOv5s was minimal (reduced by approximately 1ms), the enhanced model demonstrated excellent detection performance in complex natural environments. It can effectively reduce false and missed detections of common cotton pests and diseases under real field conditions.

(3) The recognition accuracy and robustness of the YOLOv5s-FasterCA model are improved in unstructured field environments. With CUDA acceleration, it achieved a real-time detection speed of 76.3 frames per second on the Jetson Orin NX development board, making it suitable for mobile deployment scenarios with limited computing resources. However, when encountering unseen or unmarked types of pests and diseases, the model may exhibit decreased recognition performance or misclassify them as known categories. Future work will improve generalization ability by expanding datasets and implementing anomaly detection strategies.

ABSTRACT

To address the issue that existing seed-guiding devices struggle to meet the high-speed operational requirements of delta-row planters for dense maize planting, a seed-guiding device with air assistance and a guided groove was designed based on the principle of the brachistochrone. The overall structure and working principle of the device are described, and the curved segment of the seed guide tube was optimized using the brachistochrone principle while accounting for frictional effects. Computational fluid dynamics (CFD) simulations were conducted to analyse the flow field characteristics of the seed guide tube at inlet airflow velocities of 63.48, 60.64, 57.73, 54.69, 51.50, and 48.15 m/s. A multi-factor test was performed using chamber pressure and operating speed as test factors, with the qualified index of grain spacing and the coefficient of variation as evaluation metrics. Comparative tests were conducted using a traditional guided-groove seed guide tube and a brachistochrone-based seed guide tube without a guided groove. Results showed that the optimal parameter combination for the newly designed device was a chamber pressure of 3.124 kPa and an operating speed of 12.0 km/h. Under these conditions in the bench test, the qualified index reached 97.04%, and the coefficient of variation was 6.18%, outperforming the other two types of seed-guiding devices. These findings demonstrate that the seed-guiding device based on the brachistochrone principle can significantly improve the seeding quality of delta-row planters for dense maize planting under high-speed operation.

摘要

针对现有导种装置难以满足玉米品字形密植播种机高速作业需求的问题，基于最速降线原理设计了一种气辅-导槽式导种装置。阐述了导种装置的总体结构与工作原理，根据考虑摩擦力下的最速降线原理对导种管曲线段进行了优化设计，得到了曲线段轮廓的解析方程。通过 CFD 仿真试验探究了导种管在入口流速分别为 63.48、60.64、57.73、54.69、51.50、48.15m/s 时的流场特性。以腔室压力与作业速度为试验因素，以粒距合格指数、粒距变异系数为试验指标开展了多因素试验，确定了导种装置最优参数组合并对其进行了试验验证，同时开展了与传统导槽式导种装置、无导槽最速降线式导种装置的对比试验。结果表明：该导种装置的最优工作参数组合为腔室压力 3.124 kPa、作业速度 12.0 km/h，台架验证该参数组合下的粒距合格指数为 97.04%、粒距变异系数为 6.18%，并且较另外两种导种装置表现出了更优的导种性能，说明基于最速降线原理设计的气辅-导槽式导种装置可以进一步提高玉米密植播种机在高速作业条件下的播种质量。

INTRODUCTION

Maize precision planting refers to the process of sowing single maize seeds into a predetermined soil seedbed position with a precision planter according to the sowing density required by local agronomy, in accordance with consistent row spacing, uniform grain spacing and precise depth *(Zhao et al., 2024; Sun et al., 2024)*.

[1]*Wen-sheng Sun, Ph.D.; Shu-juan Yi, Prof. Ph.D.; Hai-long Qi, bachelor degree; Yi-fei Li, Ph.D.; Yu-peng Zhang, master degree; Jia-sha Yuan, master degree; Song Wang, Ph.D.*

The seed-guiding mechanism is one of the final links in the maize precision planting process, ensuring that seeds enter the soil in a uniform and orderly manner. It not only maintains the orderly state of seeds achieved in the preceding steps but also directly influences the uniformity of seed distribution in the field *(Yatskul et al., 2018; Liao et al., 2020)*. However, the random movement of maize seeds from the seed-metering device into the seed-guiding unit, combined with collisions within the guide, disrupts the smooth flow of seeds. This results in deviations from the intended placement in the seedbed, ultimately reducing sowing quality.

Extensive research has been carried out by agricultural machinery companies and researchers to address the issue of maize seed misplacement caused by collisions during the seed-guiding process. The U.S.-based company Precision Planting developed a belt-type seed-guiding device that uses a conveyor belt to transport maize seeds from the seed-metering device to the seed outlet. By matching the conveyor speed with the planter's operating speed, the system ensures consistent seed spacing under varying operating conditions. The Swedish company Vaderstad introduced an airflow-projection seed-guiding device, which utilizes positive pressure airflow to constrain and rapidly project seeds into the soil through a seed guide tube, enabling high-speed maize planting. *Dong Jianxin et al., (2023),* designed a guided seed-casting mechanism that optimizes the seed guide trajectory, enhancing the seed placement accuracy of attitude-controlled drive-guided seed-metering devices under high-speed conditions. *Li Yuhuan et al. (2020)* achieved linear seed-throwing of maize under high-speed conditions by incorporating a seed-pushing mechanism into an air-suction high-speed precision seed-metering device, in coordination with specially shaped holes on the seed-metering plates. *Liu Rui et al. (2023)* designed a seed-guiding device based on the Venturi principle, utilizing positive pressure airflow assistance to effectively address the issue of seeds failing to enter the seedbed in an orderly, single-grain manner due to violent collisions. The brachistochrone theory, which addresses the optimization of velocity and path selection *(Adetifa et al., 2021)*, has also been applied in the optimal design of curved structures in agricultural machinery components. *Tang Han et al. (2023)* applied the brachistochrone theory to the structural design of the curved section of the seed guide tube in an internally-filled, air-blowing seed-metering device. Bench tests showed that, under a working pressure of 4.5 kPa and a working speed of 41 r/min, the seed spacing qualified index and the coefficient of variation reached 96.56% and 9.58%, respectively. Similarly, *Jia Xian et al. (2024)* optimized the seed-guiding curve of a gravity-type seed guide tube based on the brachistochrone principle. Bench test results indicated that the coefficient of variation was reduced by approximately 3% compared to that of a traditional gravity-type seed guide tube within the operating speed range of 9.0 to 14.4 km/h. However, due to the high installation precision and compatibility required between the seed-guiding device and the seed-metering unit, current seed-guiding devices struggle to meet the operational demands of high-speed delta-row planters for dense maize planting.

To improve the seeding quality of high-speed delta-row planters for dense maize planting, a seed-guiding device with air assistance and a guided-groove structure was designed based on the principle of the brachistochrone. The curved segments of the seed guide tube were optimized using the brachistochrone curve while accounting for friction, and were combined with a guided-groove structure to constrain seed movement under high-speed positive pressure airflow. This study provides a technical reference for enhancing the performance of seed-guiding devices in high-speed planters for dense maize planting.

MATERIALS AND METHODS

Overall structure and working principle

As shown in Fig. 1, the seed-guiding device primarily consists of a pressure relief wheel and its connecting frame, a seed-discharge tube, a transition tube, a seed guide tube, and suppression wheels. To coordinate with the seed discharge operation of the seed-metering device *(Sun et al., 2024)*, key components such as the pressure relief wheels, seed-discharge tube, transition tube, seed guide tube, and suppression wheels are symmetrically arranged. Two identical pressure relief wheels are installed inside the corresponding shaped holes at the seed-unloading points of the two seed-metering plates. These wheels serve to block airflow and ensure that seeds are smoothly discharged from the plates into the seed-discharge tube. To maintain the sealing integrity of the air-pressure seed-metering system and to allow smooth transfer of seeds detached from the plates, the seed-discharge tube is integrated into the device shell. The transition tube serves to connect the seed-discharge tube with the seed guide tube.

As the core working part of the whole seed-guiding device, the seed guide tube consists of linear and curved segments, and the upper and lower combined guided-groove structures are set to produce a restraining

effect on the movement of the seeds passing through the seed guide tube. The key structural parameters of the seed guide tube *(Yi et al., 2025)*, such as the outer diameter d_1 of the tube body is 21 mm, the inner diameter d_2 of the tube body is 17 mm, the length L_1 of the seed guide tube is 550 mm, the width H_1 is 100 mm, the length L_2 of the linear section is 310 mm, the length L_3 of the curved section is 240 mm, the guided-groove height L_4 is 355 mm, the width w_1 of the upper guided-groove is 1.3 mm, the width w_2 of the lower guided-groove is 2.2 mm. According to the agronomic requirements of narrow-wide-row delta-row dense planting area of maize in Heilongjiang province, the spacing L of narrow-single-row is 18~20 cm, the spacing L_0 of narrow-double-row is half of the spacing L, and the spacing H of narrow-row is 13 cm. Therefore, the row spacing of the two seed guide tubes is 13 cm.

The seed-guiding device can be divided into three functional zones based on the working process: the seed-delivery zone, the seed-attracting zone, and the seed-attaching zone. After the seed-metering device delivers seeds to the seed-unloading points, the pressure relief wheel blocks the inner side of the corresponding holes at these points, causing the seeds to lose the pressure attachment force. As a result, the seeds enter the seed-delivery zone vertically under the combined action of gravity and airflow. Within the seed-delivery zone, seeds sequentially pass through the seed-discharge tube, the transition tube, and the straight segment of the seed guide tube, accelerating as they fall. When the seeds enter the seed-attracting zone, a pressure difference is generated between the inside and outside of the tube due to the influence of the guided-groove structure. This pressure difference creates an additional pressure field that causes the seeds to move toward the end of the seed guide tube while simultaneously shifting toward the guided groove under the action of this pressure field. Once the seed is stably attached to the guided groove, it enters the seed-attaching zone, where it moves along the inner sidewall of the groove toward the seed-throwing point under the combined forces of gravity, airflow, and friction. Finally, the seed exits the seed guide tube at the seed-throwing point and is pressed into its predetermined position in the seedbed by the suppression wheels, completing the seed-guiding process. Through the staggered discharge timing of the seed-metering device and the orderly regulation provided by the seed-guiding device, maize seeds are accurately placed in the seedbed to form a narrow-row, delta-row sowing pattern.

Design of curved segments of the seed guide tubes

Under high-speed operating conditions of planters for dense maize planting, the movement of seeds upon detachment from the seed-metering plates becomes highly random. This increased randomness leads to a higher frequency of seed collisions within the seed-guiding device, ultimately reducing seeding uniformity *(Fanigliulo et al., 2022; Ma et al., 2023)*.

Studies have shown *(Li et al., 2023)* that the curve structure designed based on the principle of the brachistochrone is conducive to the improvement of irregular seed mobility and seed-throwing uniformity.

Therefore, in this study, the structural design of the curved segments of the seed guide tubes was carried out based on the principle of the brachistochrone.

As shown in Fig. 2, according to the principle of the brachistochrone, the equation of the curve trajectory (l_1) that takes the shortest time for the maize seed to go from point *A* to point *B* when friction is not considered is:

$$\begin{cases} x = R_1\left(\frac{\pi\theta_1}{180} - \sin\theta_1\right) \\ y = R_1(1-\cos\theta_1) \end{cases} \quad (1)$$

where:

R_1 is the radius of the circle in the *Axy* coordinate system, m; θ_1 is the rolling angle of rotation of the circle in the *Axy* coordinate system, (°).

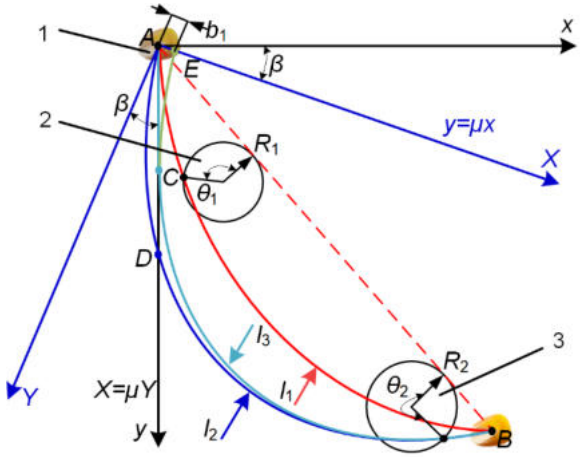

Fig. 2 - Schematic diagram of the combined brachistochrone curve

1. maize; 2. circle in the Axy coordinate system; 3. circle in the AXY coordinate system.

The velocity v_1 at any point during the fall of the seed is:

$$v_1 = \frac{ds}{dt} = \frac{\sqrt{1+y'^2}}{dt}dx \quad (2)$$

where:

s is the length of any curve arc, m; *t* is the time, s; y' is the first-order derivative of the curve trajectory equation.

Assuming that the seed slides tightly against the surface without bouncing, the angle *φ* of the seed during the fall tends to zero. After considering friction, the change ΔE in kinetic energy of the seed during its descent from point *A* according to the kinetic energy theorem is:

$$\Delta E = d\left(\frac{1}{2}mv_1^2\right) = mgdy - \mu mg\cos\varphi ds \Rightarrow v_1 = \sqrt{2g(y-\mu x)} \quad (3)$$

where:

m is the mass of the seed, m; g is the acceleration of gravity, m/s^2; *μ* is the rolling friction coefficient between the maize seed and the seed guide device; *φ* is the angle between the normal direction of the seed's location and the vertical direction, (°); x, y are the coordinates of the seed's position in the *Axy* coordinate system, m.

The time T taken by the seed to travel from point *A* to point *B* can be expressed as:

$$T = \int dt = \int_0^{x_B} \frac{\sqrt{1+y'^2}dx}{\sqrt{2g(y-\mu x)}} \quad (4)$$

Eq. (4) is solved by rotating the *Axy* coordinate system clockwise by an angle *β* to obtain the *AXY* coordinate system under friction, and:

$$\beta = \arctan\mu \quad (5)$$

$$y - \mu x = \frac{Y}{\cos\beta} \quad (6)$$

Eq. (4) is then transformed into:

$$T = \int_0^{x_B} \sqrt{\frac{(1+Y'^2)\cos\beta}{2gY}}\,dX \tag{7}$$

where:

x_B is the horizontal coordinate of point *B*, m.

However, from Fig. 2, it can be seen that the curve *AD* (l_2) enters the *x*<0 region, and the velocity of the seed at point *D* is less than its free fall velocity from point *A*, indicating that the curve *AD* is not the optimal path. When the brachistochrone curve is translated from point *A* to point *E* along the direction of the *X*-axis, the seed falls from point A to point C along the boundary $X = \mu Y$, and then along the curve *CB* to point *B*, the time T used is:

$$T = \sqrt{\frac{2y_C}{g}} + \int_0^{x_B} \frac{\sqrt{1+y'^2}dx}{\sqrt{2g(y-\mu x)}} \tag{8}$$

where:

y_C is the longitudinal coordinate of point *C*, m.

But the position of point C is not fixed, and there may be changes when it occurs:

$$\delta T = \frac{1}{\sqrt{2gy_C}}\left(1 - \frac{y'}{\sqrt{1+y'^2}}\right)\delta y_C \tag{9}$$

When the time T takes the minimum value, the point C needs to satisfy the condition:

$$\begin{cases} \delta T = 0 \\ y' = \infty \end{cases} \tag{10}$$

At this time, the brachistochrone curve *CB* is tangent to the *y*-axis, and its trajectory equation in the *AXY* coordinate system is:

$$\begin{cases} X = R_2\left(\frac{\pi\theta_2}{180} - \sin\theta_2\right) + b_1 \\ Y = R_2(1-\cos\theta_2) \end{cases} \tag{11}$$

where: X, Y is the position coordinate of the *AXY* coordinate system, m; R_2 is the radius of the circle in the *AXY* coordinate system, m; θ_2 is the rolling angle of rotation of the circle in the *AXY* coordinate system, (°); b_1 is the amount of translation of the brachistochrone curve along the *X*-axis direction, m.

Also, the coordinates of point *C* satisfy the following conditions:

$$\begin{cases} X_C = R_2\left(\frac{\pi\theta_C}{180} - \sin\theta_C\right) + b_1 \\ Y_C = R_2(1-\cos\theta_C) \\ X_C = \mu Y_C \\ \left.\frac{dX}{dY}\right|_C = \frac{1-\cos\theta_C}{\sin\theta_C} = \mu \end{cases} \tag{12}$$

where: X_C, Y_C is the positional coordinate of point *C* in the *AXY* coordinate system, m; θ_C is the rolling angle of rotation of the circle in point *C*, (°).

Obtained from Eq. (12):

$$\mu = \tan\frac{\theta_C}{2} = \tan\beta \tag{13}$$

And then there's:

$$b_1 = R_2(2\mu - 2\arctan\mu) \tag{14}$$

The μ is 0.0931 *(Sun et al., 2024)*, and substituting into Eq. (13) yields θ_C of 10.64° and β of 5.32°, and then substituting into Eq. (14) yields $b_1/R_2 = 5\times10^{-4}$. According to the above dimensional parameters of the seed guide tube, the coordinates of the point *A* in the *Axy* coordinate system are (0, 0), and the coordinates of the point *B* are (0.1, 0.24). According to the coordinate transformation formula:

$$\begin{bmatrix} X \\ Y \end{bmatrix} = \begin{bmatrix} \cos\beta & \sin\beta \\ -\sin\beta & \cos\beta \end{bmatrix}\begin{bmatrix} x \\ y \end{bmatrix} \tag{15}$$

the coordinates of point *A* in the *AXY* coordinate system are found to be (0, 0) and the coordinates of point *B* are (0.122, 0.230). Substituting the coordinates of point *B* in the *AXY* coordinate system and $b_1/R_2 = 5\times10^{-4}$ into Eq. (11) yields the rolling angle θ_B at point *B* as 84.45°, R_2 as 0.255, and b_1 as 1.27×10^{-4}. The analytical equation (l_3) for the combined brachistochrone curve AB considering friction is obtained as:

$$\begin{cases} AC: Y = 10.74X \\ CB: \begin{cases} X = 0.255 \times \left(\dfrac{\pi\theta_2}{180} - \sin\theta_2\right) + 1.27 \times 10^{-4} \\ Y = 0.255 \times (1 - \cos\theta_2) \end{cases} \end{cases} \quad (16)$$

By substituting θ_C into Eq. (16), the coordinates of point *C* in the *AXY* coordinate system are calculated as (4×10^{4}, 4×10^{-3}), and the value range of the θ_2 is 10.64~84.45°. Based on the analytical equation (l_3), the curve corresponding to the seed guide tube trajectory was plotted, as shown in Fig. 3. The curved segment of the seed guide tube was then designed in accordance with this trajectory equation.

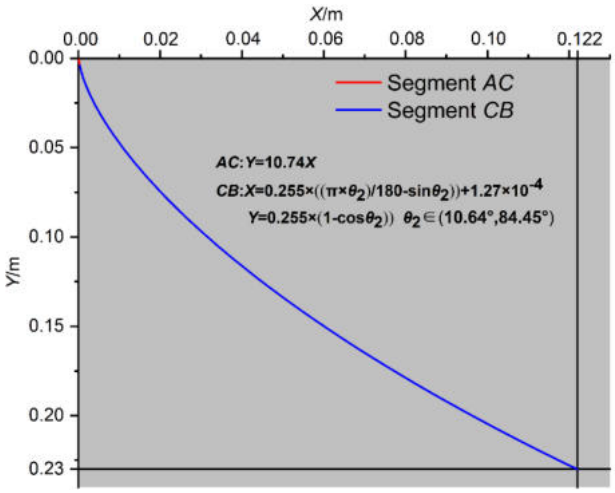

Fig. 3 - Schematic diagram of the outline of the curved section of the seed guide tube

Simulation tests

As shown in Fig. 4, the fluid domain of the seed guide tube is extracted by Space Claim software, and the inlet and outlet of the tube are labelled as "Inlet" and "Outlet", respectively. The labelled model is imported into Fluent Meshing module for meshing. In order to improve the mesh quality of the model, the minimum and maximum values of the surface mesh size were set to 0.5 and 1.5 mm, respectively, and the poly mesh was used for volume mesh-filling. The meshed model is imported into the Fluent solver module, and the widely used standard K-epsilon turbulence model is selected for the simulation. In the Solution Methods, the second-order equations are used for the pressure and momentum equations and the first-order upwind equations are used for the turbulent kinetic energy and turbulent dissipation rate equations. In the Run calculation, the time-step is set to be 1×10^{-2} s, and the total simulation time is set to be 2 s. According to the repeated test results of the actual experiment, the flow velocity v_r of the Inlet was set as 63. 48, 60.64, 57.73, 54.69, 51.50 and 48.15 m/s, respectively, and the pressure of the Outlet was set as 0 Pa to carry out the single-factor simulation experiment, so as to explore the flow field characteristics in the seed guide tube under different inlet velocities.

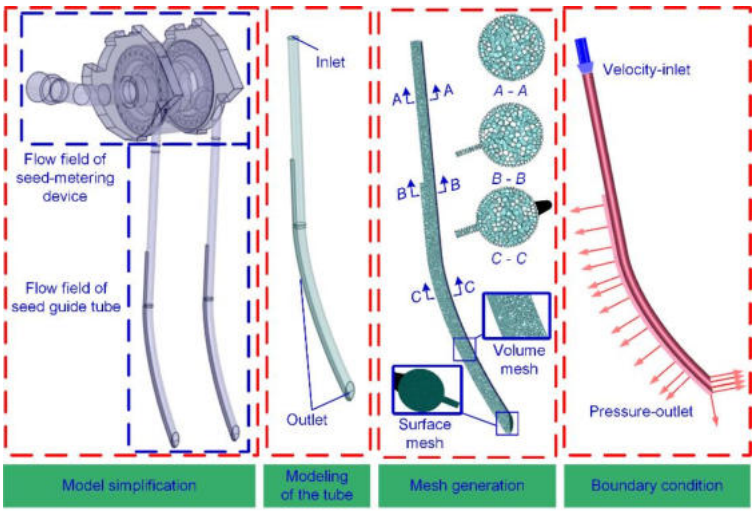

Fig. 4 - Establishment of CFD simulations

Bench tests

In order to determine the optimal working parameter combination of the seed guide device based on the principle of the brachistochrone, and to check its performance improvement effect compared with the traditional seed guide tube with guided-groove and the seed guide tube without guided-groove based on the brachistochrone, the bench performance test was carried out in the High-speed Precision Sowing Lab of the College of Engineering, Heilongjiang Bayi Agricultural University at an ambient temperature of about 20°C and a seed bed oil belt temperature of about 25°C. The test conditions and seeding effect are shown in Fig. 5, and the main devices include seed-supply device, air-pressure seed-metering device, HTB multi-stage blower (Shanghai Liangjin Electromechanical Equipment Co., Ltd, Shanghai), JPS-16 seed-metering device test bench (Heilongjiang Agricultural Machinery Engineering Research Institute, Harbin, Heilongjiang, Mean error of grain spacing measurement ≤2 mm), frequency converter, DP2000 intelligent pressure and wind velocity air volume meter (Shanghai YIOU Instrument Equipment Co., Ltd, Shanghai, resolution 1Pa), as well as three types of seed guide tubes. Among them, the JPS-16 test bench can collect the seed grain spacing falling on the surface of the seed bed oil belt after sowing through computer vision technology, and output the statistical results of the detection indexes using the image acquisition and processing system. The typical maize variety "Dika C2235" planted in Heilongjiang region of China was used for the test seed *(Sun et al., 2024)*, and the related material characteristics are shown in Table 1.

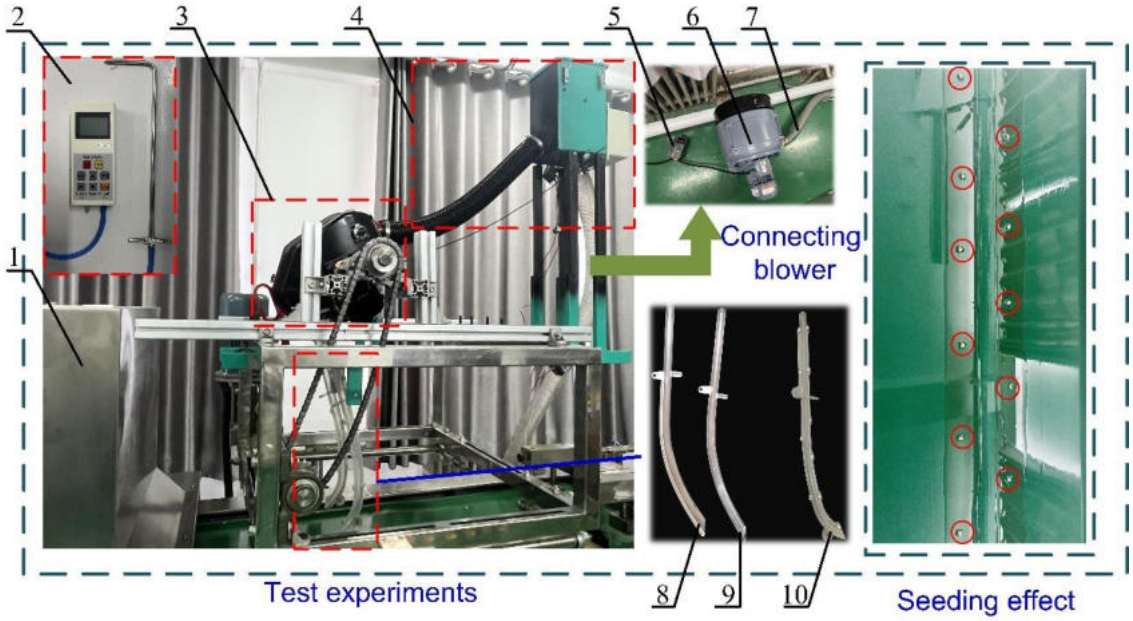

Fig. 5 - Bench test

Table 1

Basic material characteristics of maize seed

Types	Seed picture	Moisture content / %	Thousand grain weigh / g	Density / g·cm^{-3}	Pile angle/(°)	Length/mm	Width / mm	Thickness / mm
Dika C2235 (big-rounded)		12.4	342.3	1.198	22.42	10.24±0.59	9.74±0.54	7.24±0.61

Based on the actual test conditions, the chamber pressure P_f of the seed-metering device was set in the range of 2.7~4.2kPa, and the operating speed v_p was set in the range of 12.0~16.0 km/h. A two-factor, five-level multi-factor experiment was conducted. The coding of the test factors is shown in Table 2, where *X*1 and *X*2 represent the coded values of chamber pressure P_f and operating speed v_p, respectively.

Table 2

Experimental factors and level codes in multi-factor experiment

Coded values	Experimental factors	
	***X*1/ kPa**	***X*2/ (km/h)**
-1.414	2.70	12.0
-1	2.92	12.6
0	3.45	14.0
1	3.98	15.4
1.414	4.20	16.0

Referring to the international standard ISO 7256/1 (1984) and JB/T10293-2001 "Technical Conditions for Single Grain (Precision) Seeders" *(Tang et al., 2023; Tang et al., 2024)*, the qualified index Q_1 and the coefficient of variation Q_2 were selected as the evaluation indexes of the test, and their calculation formula is as follows:

$$\begin{cases} Q_1 = \dfrac{n_q}{N_1} \times 100\% \\ Q_2 = \sqrt{\dfrac{\sum(x - x_p)^2}{(N_1 - 1)x_p^2}} \times 100\% \end{cases} \quad (17)$$

where:

n_q is the number of qualified grain spacing; N_1 is the total number of intervals; x is the grain spacing measured in the test, m; x_p is the average grain spacing measured in the test, m.

The conversion relationship between the working speed n_p of the seed-metering device and the operating speed v_p of the planter is given by:

$$n_p = \frac{60 v_p}{ZL} \quad (18)$$

where: Z is the number of the holes in the seed-metering plates.

The test was conducted by randomly counting the 250 consecutive seed grain spacings adjacent to the sown homogeneous section, and each set of test was replicated 5 times to calculate the qualified index Q_1 and the coefficient of variation Q_2 under different treatments.

RESULTS AND DISCUSSIONS

Results of the simulation experiments

As shown in Fig. 6 a, in order to investigate the flow field distribution of the seed guide tube at different inlet flow velocities, the pressures and flow velocities of different lengths H_2 in the negative direction of the *y*-axis from the inlet of the seed guide tube at 2 s were extracted, and the cloud diagrams of the pressures and flow velocities of the axial plane of the seed guide tube in the *z*-axis direction as well as the vertical cross sections at distances of 100 mm, 200 mm, and 300 mm from the inlet of the tube were intercepted, respectively. The pressure and velocity curves for different lengths H_2 at each velocity-inlet of the tube are shown in Fig. 6 b. The results of the pressure and velocity cloud diagrams in the axial plane and the vertical cross sections are shown in Fig. 6 c and Fig. 6 d, respectively.

In Fig. 6 b, it can be seen that along with the increase of the length H_2, the trends of pressure and velocity curves at different velocity-inlets are basically the same. The velocity curve shows a slow upward trend within the range of 0~380 mm from the length H_2, and a rapid decrease followed by a gradual increase and then a gradual decrease within the range of 380~550 mm. The velocity ranges for inlet-velocities of 48.15, 51.50, 54.69, 57.73, 60.64 and 63.48 m/s in the *y*-axis direction were 36.87 ~ 56.23 m/s, 39.85 ~ 60.04 m/s, 42.71 ~ 63.66 m/s, 45.47~ 67.11 m/s, 48.13 ~ 70.41 m/s, and 50.72 ~ 73.63 m/s, respectively. When the length H_2 ranges from 0 to 321 mm, the pressure decreases rapidly at first and then decreases slowly. When the length H_2 ranges from 321 to 550 mm, the pressure generally shows a fluctuating upward trend. As the inlet velocity increases, the maximum pressure differential along the y-axis also increases, with values of 484.11, 546.29, 608.66, 670.80, 732.73, and 795.78 Pa corresponding to the respective inlet velocities listed above.

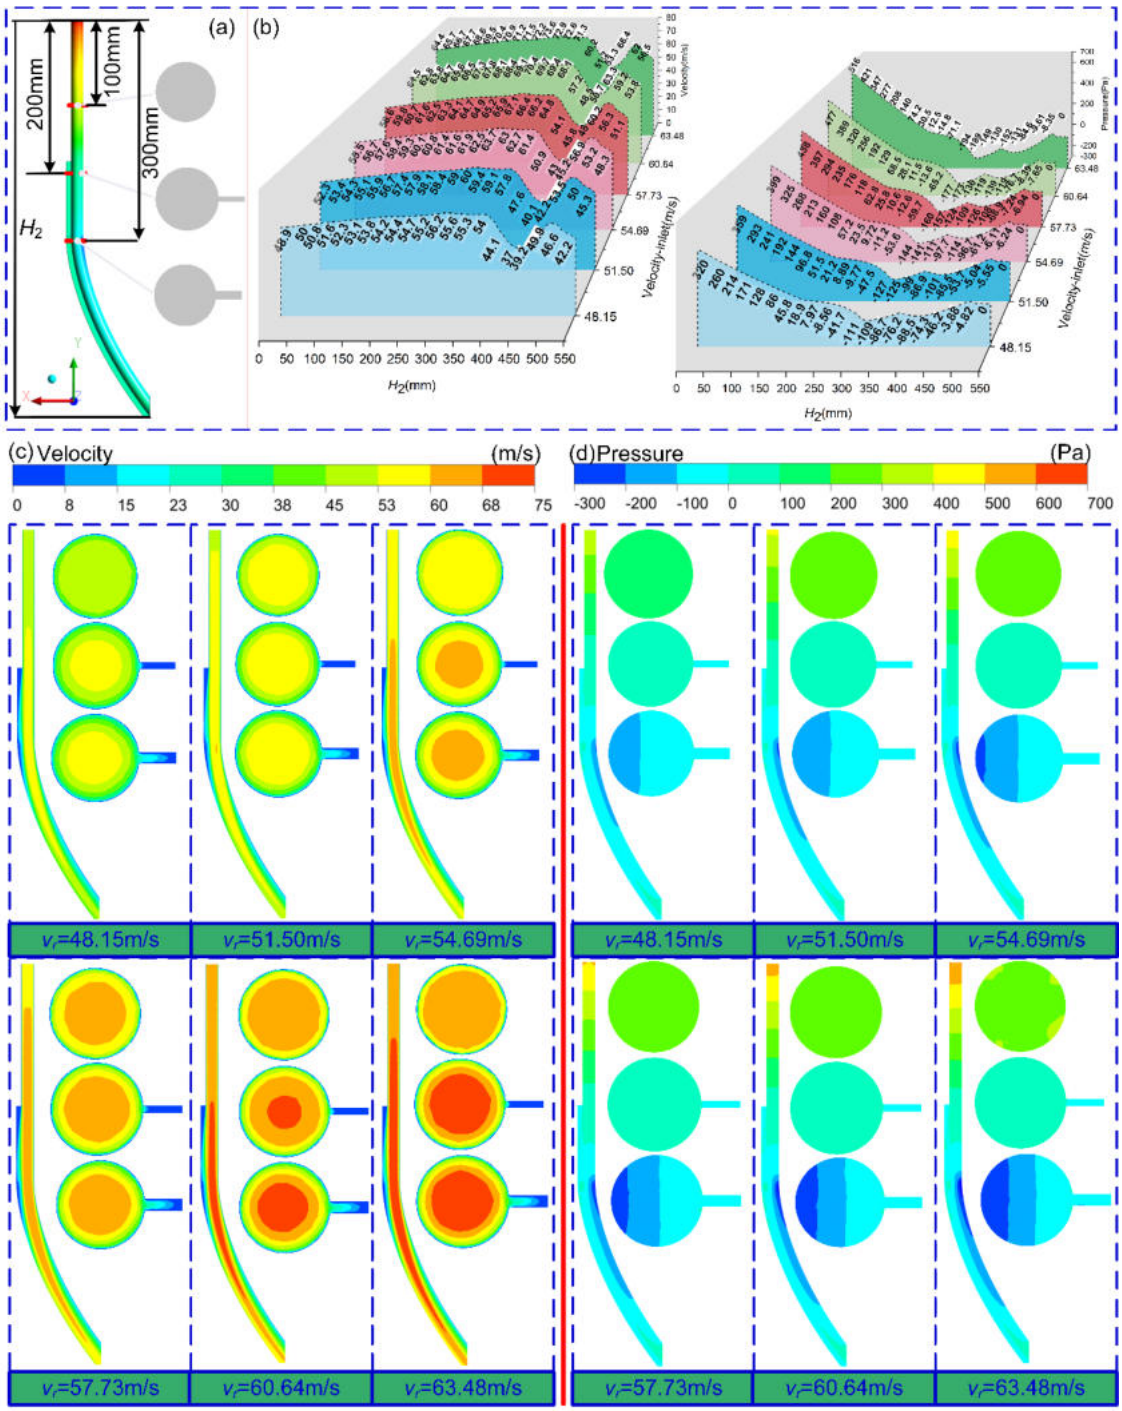

Fig. 6 - Results of CFD simulations

As shown in Fig. 6c, the velocity cloud diagrams in the axial plane reveal that as the inlet velocity increases, the overall flow velocity throughout the flow field also increases. Additionally, the area occupied by the high-velocity zone expands accordingly. However, the increase in flow velocity near the upper guided-groove is less pronounced compared to that observed near the lower guided-groove. Furthermore, the flow velocity near the end of the tube shows a tendency to decrease, which can be attributed to the increase in the vertical cross-sectional area at the tube's outlet. For the velocity cloud diagrams of the vertical cross-sections, the flow velocity is highest near the center of each section. The flow velocity distribution is more uniform in sections without a guided groove, whereas sections with a guided groove exhibit a greater velocity gradient. Notably, the velocity gradient near the lower guided-groove is more pronounced than that near the upper guided-groove, indicating that the curved segment of the lower guided-groove exerts a stronger adsorption effect on the seeds than the linear segment of the upper guided-groove. Furthermore, as the inlet flow velocity increases, the central flow velocity in each vertical cross-section also increases. Specifically, the central flow velocity in sections with a guided-groove trough reaches 68~75 m/s when the inlet velocity ranges from 60.64

to 63.48 m/s. In contrast, the flow velocity at the edge of the guided-groove trough remains largely unaffected by changes in inlet velocity, consistently ranging between 0 and 8 m/s.

It can be seen from Fig. 6 d that for the pressure cloud diagrams in the axial plane, the change of the velocity-inlet has a greater influence on the pressure gradient of the linear segments, and has a smaller influence on the pressure gradient of the curved segments. With the increase of the velocity-inlet, the pressure gradient range of the linear segment increases from 0~400Pa to 0~600Pa, while the area of the cloud of the curved segment, which only has a pressure gradient range of -300~-100Pa, exhibits a trend of gradual expansion. For the pressure maps of each vertical cross section, along with the increase of the velocity-inlet, the pressure distributions of the sections without guided-groove and the sections of upper guided-groove did not show obvious difference, but the sections of lower guided-groove showed an obvious pressure gradient evolution: the area of the maps with the pressure gradient range of -100~0Pa gradually decreased, while the area of the maps with the pressure gradient range of -300~-200Pa continued to increase. This indicates that increasing the velocity-inlet will obviously increase the pressure difference near the lower guided-groove, which will help to improve the stability and reliability of the seed guide tube in the process of seed-attracting and seed-attaching.

Results of the bench experiments

According to the range of factors in Table 2, the bench test was designed and conducted based on the central composite design, and the test results were obtained, as shown in Table 3.

Table 3

Results of the multi-factor experiments

Number.	Experimental factors		Experimental indexes	
	*X*1/ kPa	*X*2/ (km/h)	Q_1/ %	Q_2/ %
1	2.92	12.6	96.23	7.06
2	3.98	12.6	95.54	7.92
3	2.92	15.4	93.42	10.86
4	3.98	15.4	92.83	9.32
5	2.70	14.0	94.82	10.09
6	4.20	14.0	94.08	8.76
7	3.45	12.0	97.07	6.36
8	3.45	16.0	92.01	11.16
9	3.45	14.0	95.93	9.42
10	3.45	14.0	95.62	9.47
11	3.45	14.0	95.91	9.81
12	3.45	14.0	95.88	9.79
13	3.45	14.0	95.69	9.83

The results were processed and analysed using Design Expert 12 software, and the analysis of variance of the quadratic equation was obtained, as shown in Table 4.

Table 4

Analysis of variance of the quadratic equation

Source	Q_1				Q_2			
	Sum of squares	df	*F*-value	*p*-value	Sum of squares	df	*F*-value	*p*-value
Model	26.02	5	86.47	< 0.0001**	22.27	5	37.10	< 0.0001**
*X*1	0.6766	1	11.24	0.0122*	0.8198	1	6.83	0.0348*
*X*2	20.08	1	333.74	< 0.0001**	17.96	1	149.61	< 0.0001**
*X1 X*2	0.0025	1	0.0415	0.8443	1.44	1	11.99	0.0105*
$X1^2$	3.17	1	52.75	0.0002**	0.2649	1	2.21	0.1811
$X2^2$	2.77	1	45.95	0.0003**	1.94	1	16.13	0.0051**
Residual	0.4213	7			0.8405	7		
Lack of fit	0.3415	3	5.71	0.0627	0.6786	3	5.59	0.0649
Pure error	0.0797	4			0.1619	4		
Cor total	26.44	12			23.11	12		

Note: * indicates a significant impact; ** indicates a highly significant impact.

In Table 4, the *p*-value of the regression model of the qualified index Q_1 and the coefficient of variation Q_2 were all less than 0.01, indicating that the regression model was highly significant, and the *p*-value of the lack of fit were all greater than 0.05 as non-significant, indicating that the regression model was well fitted.

In the analysis of variance of the Q_1, the $X2$, secondary terms $X1^2$ and $X2^2$ showed highly significant effects, the $X1$ showed significant effects, and interaction terms $X1X2$ showed insignificant effects. The magnitude of the effect of each factor on the Q_1 was $X2>X1$. After excluding the insignificant factors, the quadratic regression equation of the Q_1 was:

$$Q_1 = 23.00735 + 16.0239X1 + 7.7066X2 - 2.40178X1^2 - 0.31525X2^2 \quad (19)$$

In the analysis of variance of the Q_2, the $X2$ and secondary terms $X2^2$ showed highly significant effects, the $X1$ and interaction term $X1X2$ showed significant effects, and secondary term $X1^2$ showed insignificant effects. The magnitude of the effect of each factor on the Q_2 was $X2>X1$. After excluding the insignificant factors, the quadratic regression equation of the Q_2 was:

$$Q_2 = -91.077 + 10.59639X1 + 10.85005X2 - 0.8X1X2 - 0.251087X2^2 \quad (20)$$

Based on the results of the multi-factor experiment, the highest Q_1 and the lowest Q_2 are used as the optimization objectives, and the optimization equation is established within the factor range:

$$\begin{cases} maxQ_1 \\ minQ_2 \\ s.t. \begin{cases} 2.7\text{kPa} \geq X1 \geq 4.2\text{kPa} \\ 12\text{km/h} \geq X2 \geq 16\text{km/h} \\ 1 \geq Q_1(X1, X2) \geq 0 \\ 1 \geq Q_2(X1, X2) \geq 0 \end{cases} \end{cases} \quad (21)$$

It was calculated that when the chamber pressure was 3.124 kPa and the operating speed was 12.0 km/h, the predicted values of the Q_1 and the Q_2 of the seed-guiding device were 96.709% and 6.08%, respectively. Under this parameter combination, 5 repetitive bench tests were carried out, and the results were shown in Table 5. At the same time, in order to check the performance improvement effect under this parameter combination compared with the traditional seed guide tube with guided-groove (Type B) and the seed guide tube without guided-groove based on the brachistochrone (Type C), five repetitive bench tests were carried out under the same conditions for these two types of seed guide tube, and the comparative results are shown in Table 5.

Table 5

Bench validation and comparative test results

Test number	Type of seed guide tube	Q_1/ %	Q_2/ %	Deviation from the Q_1 predicted value /%	Deviation from the Q_2 predicted value /%
1	A	97.04	6.11	0.33	0.03
	B	94.36	7.22	-2.35	1.14
	C	90.76	7.93	-5.95	1.85
2	A	97.11	6.19	0.40	0.11
	B	94.45	7.37	-2.26	1.29
	C	91.03	8.23	-5.68	2.15
3	A	96.84	6.27	0.13	0.19
	B	93.97	7.13	-2.74	1.05
	C	90.22	8.36	-6.49	2.28
4	A	97.22	6.09	0.51	0.01
	B	94.53	6.93	-2.18	0.85
	C	90.49	7.96	-6.22	1.88
5	A	96.97	6.22	0.26	0.14
	B	93.78	7.24	-2.93	1.16
	C	89.94	8.47	-6.77	2.39
Statistical results	A	97.04±0.13	6.18±0.07	0.33	0.10
	B	94.22±0.29	7.18±0.15	-2.49	1.10
	C	90.49±0.38	8.19±0.21	-6.22	2.11

Note: *A* indicates the seed guide tube with guided-groove based on the brachistochrone, *B* indicates the traditional seed guide tube with guided-groove, and *C* indicates the seed guide tube without guided-groove based on the brachistochrone.

In the table, the Q_1 and the Q_2 of the seed guide tube with guided-groove based on the brachistochrone (Type A) under the optimal parameter combination are 97.04±0.13% and 6.18±0.07%, 95% confidence Interval ≈ [96.88%, 97.20%] and 95% confidence Interval ≈ [6.09%, 6.27%], respectively, and the deviation of the results from the prediction is less than 0.4% with a relatively small error. This parameter combination further improves the seed-guiding performance of the seed-guiding device, which indicates that the results of the parameter optimization have a certain reliability. In addition, the Q_1 of the type A increased by 2.82% and 6.55%

compared with type B and C, and the Q_2 of the type A decreased by 1.00% and 2.01% compared with type B and C, which indicates that the seed guide tube with guided-groove based on the brachistochrone has a better seed-guiding performance. In addition, a high-speed camera was used in the experiment to measure the time for seeds to pass through type A, type B and type C as 0.029s, 0.035s and 0.033s, respectively, and the type A and type C were faster than the type B. This indicates that the seed guide tube designed based on the theory of the brachistochrone is able to shorten the time of the seed-guiding process effectively.

CONCLUSIONS

In order to improve the seeding quality of the planter for maize dense planting when it operates at high speed, a seed-guiding device with air-assisted and guided-groove is designed based on the principle of the brachistochrone. The flow field characteristics of the seed guide tube were investigated using CFD simulation. When the flow velocity at the inlet of the seed guide tube was 63.48, 60.64, 57.73, 54.69, 51.50, and 48.15 m/s, the flow velocity in the *y*-axis direction ranged from 36.87 to 56.23 m/s, 39.85 to 60.04 m/s, 42.71 to 63.66 m/s, 45.47 to 67.11 m/s, 48.13 to 70.41 m/s, and 50.72 to 73.63 m/s, respectively, and the maximum differential pressure was 484.11, 546.29, 608.66, 670.80, 732.73, and 795.78Pa, respectively. The two-factor and five-level central combination test was conducted under the conditions of 2.7~4.2 kPa of chamber pressure and 12~16 km/h of operating speed. The test results showed that the seed-guiding performance of the designed seed-guiding device was optimal under the parameter combinations of 3.124 kPa of chamber pressure and 12.0 km/h of operating speed, and the deviation between the results of the bench validation test and the results of the prediction was less than 0.4%. In addition, under the optimal parameter combination, the device's qualified index increased by 2.82% and 6.55%, and the coefficient of variation decreased by 1.00% and 2.01%, respectively, compared with that of the traditional seed guide tube with guided-groove and the seed guide tube without guided-groove based on the brachistochrone. This study shows that the combination of "airflow assisted + guided-groove structure + the brachistochrone" can effectively control the seed movement in the seed guide tube, and further improve the seeding uniformity and stability of the seed-guiding process of the maize delta-row dense planting planter under high-speed operating conditions.

ABSTRACT
To address the lack of simulation parameters when applying discrete element simulations to guide the optimal design of grapevine burying machines, this study focused on the soil conditions in Xinjiang. The soil was divided into three layers, and the static and dynamic angle of repose characteristics of each layer were investigated using the Hertz-Mindlin with Johnson-Kendall-Roberts (JKR) contact model. First, the Plackett-Burman test was used to eliminate parameters that had no significant effect on the static and dynamic angles of repose. Then, the steepest ascent test was applied to narrow the parameter ranges, followed by the Box-Behnken test to develop regression models between the repose angles and the significant parameters. The results showed that the soil-soil restitution coefficient, soil-soil rolling friction coefficient, soil-steel static friction coefficient, and JKR surface energy were the key parameters influencing the static and dynamic repose angles. Experimental validation demonstrated that the average relative errors between the simulated and measured angles of repose using the optimized parameters were 0.92% and 0.32%, respectively, confirming the validity of the selected parameters. This study provides an important reference for the design optimization of grapevine burying machines and for discrete element simulation of other cohesive particulate materials.

摘要
针对应用离散元仿真指导葡萄埋藤机优化设计时仿真参数缺乏的问题。以新疆土壤为研究对象，将土壤分为三层，以 "Hertz-Mindlin with Johnson-Kendall-Roberts"为接触模型，研究了不同土层的静/动态休止角特性。首先利用 Plackett-Burman 检验排除对静/动态休止角影响不显著的参数，利用最陡爬坡检验缩小参数区间范围，利用 Box-Behnken 检验得到静/动态休止角与显著性参数之间的回归模型。结果发现，土-土恢复系数、土-土滚动摩擦系数、土-钢静摩擦系数和 JKR 表面能是影响静/动态休止角的主要参数。通过实验验证，最优离散元模拟参数的静/动态休止角与实测值的平均相对误差分别为 0.92% 和 0.32%，验证了所选参数的有效性，该研究为葡萄埋藤机的优化设计以及其他粘性颗粒物料的离散元模拟提供了重要参考。

INTRODUCTION
In Northwest China, much of the agricultural land in arid irrigated regions is used to cultivate grapes as a specialty crop. In 2021, Xinjiang alone accounted for 1.85 million acres of grape cultivation, producing 3.5 million tons, ranking first in both production and planting area nationwide *(Wang et al., 2024)*. Grapevine burying is a key winter protection technique for grapes in northern China, with its production costs comprising nearly 50% of the annual expenses. Turpan, as the largest grape-growing base in Xinjiang, has seen a rapid increase in mechanized vine-burying, and while the current mechanization level is relatively high, there remain significant shortcomings in terms of efficiency, cost, and adaptability. A major challenge lies in the lack of advanced machinery to further improve productivity (*Shen et al., 2024*). Therefore, the design of suitable agricultural machinery is crucial. In this context, soil modeling plays a vital role in the development and optimization of such equipment, as it contributes to increased production efficiency and reduced operational costs. However, no discrete element simulation models currently exist for soil prior to grapevine mulching and burial. Thus, it is essential to construct a discrete element parameter model of the soil.

To analyse the interaction between soil-engaging components and soil, numerical simulation is commonly used to establish an accurate soil model (*Smith et al., 2014*).

Xinjiang region is an irrigated area with high evaporation in the surface layer, and there is a large difference in water content between the surface soil and the subsoil, which has a large impact on the contact parameters of the discrete element model (*Li et al., 2019*).

Some scholars have conducted layered sampling of cold-proof soil during grapevine clearing to determine the moisture content of different soil layers. Based on this data, they combined it with simulation tests of the soil's angle of repose to complete discrete element parameter calibration, achieving results with minimal error *(Yang et al., 2023)*. Some scholars have constructed a particle model of mulberry soil under specific moisture conditions based on the soil particle size distribution. Using this model, the discrete element parameters of the soil were calibrated, and the results were found to be reliable (*Song et al., 2022*). The combination of static and dynamic angles of repose for calibrating discrete element particles has been widely applied in fields such as food, pharmaceuticals, industrial materials, and agricultural soils, yielding promising results. The calibrated soil simulation results closely match experimental measurements and meet the intended testing objectives (*Zhang et al., 2024; Luana et al., 2017; Li S. et al., 2024*). In addition, some researchers have applied scaling theory to calibrate the contact parameters in discrete element simulations of wheat flour, using the Plackett-Burman test, steepest ascent test, and Box-Behnken design, with the static angle of repose as the response variable (*Li et al., 2019*).

Most existing soil discrete element simulation parameter calibrations rely on a single static angle of repose as the response variable, without incorporating a combination of static and dynamic angles of repose to evaluate soils with varying moisture content. However, in real-world operations, soil exhibits both static and dynamic behaviours, and using both angles of repose as response variables offers a more accurate representation of the soil's actual mechanical state during field operations (*Zeng et al., 2019*). In Xinjiang, field soil conditions are typically assessed prior to grapevine burying, and in some areas, pre-irrigation is performed to ensure sufficient soil moisture. This results in more cohesive soil, which helps improve the performance and effectiveness of the grapevine burying operation (*Maitadudulili.et al., 2016*).

In this study, the Hertz-Mindlin with Johnson-Kendall-Roberts (JKR) contact model was selected to calibrate the contact parameters of the soil DEM model for different soil layers. The Plackett-Burman (PB) experimental design was first used to screen for significant factors and to analyse their effects on the static and dynamic angles of repose. Subsequently, a Box-Behnken experimental design with multi-objective optimization was applied to determine the candidate discrete element parameter sets for each soil layer. Finally, the calibrated discrete element simulation parameters were experimentally validated. The resulting optimal DEM parameters provide accurate input data for the simulation of grapevine burying operations, and also serve as a reference for discrete element modeling of other cohesive particulate materials.

MATERIALS AND METHODS

Materials and Instruments

The samples of vineyard soil were taken from the planting base of Thompson Seedless in Lianmuqin Township, Shanshan County, Turpan City, Xinjiang Uygur Autonomous Region (42.87°N,89.98°E). Based on the depth of soil disturbance during vineyard operation, the 60 cm soil profile affected by machinery was divided into three layers: the upper layer (0-20 cm), the middle layer (20-40 cm), and the lower layer (40-60 cm). Tests on the soil characterization parameters were conducted in accordance with the Chinese standard GB/T 50123–1999, Standard for Geotechnical Test Methods.

Test apparatus included the following equipment: an FCE-3000 electric constant temperature blast drying oven; a standard ring knife (specifications: diameter 50.46 mm, height 50 mm); a JJ623BF electronic balance (range: 620 g, precision: 1 mg); a standard test sieve set conforming to GB/T 6003–1997, with mesh sizes from top to bottom of 2.0 mm, 1.0 mm, 0.5 mm, 0.25 mm, and 0.075 mm; customized cylinder 1 (inner diameter 40 mm, height 100 mm); customized cylinder 2 (inner diameter 100 mm, height 100 mm); 65Mn iron sheet; 42 stepper motor; flange coupling; metal support; aluminium alloy profiles; a 200-type standard inspection sieve machine; aluminium box; camera; and food preservation bags, among other auxiliary tools.

Intrinsic parameter measurements

The ring knife method was used to measure soil density. In the field, the soil surface was paved and compacted, and the soil was taken with a ring knife, which was placed in an aluminium box and a food preservation bag to preserve the soil sample. After picking out the plant stalks and other impurities in the soil, the total mass of the ring cutter and soil was determined using an electronic balance and recorded as m1, and the mass of the empty ring cutter was determined as m0. Five-point sampling method was used to sample the

soil in three layers, and the average density of soil in the three layers from the top to the bottom was 172.23 kg/m^3, 177.35 kg/m^3, and 177.69 kg/m^3, and the average density of the soil was taken to be 175.76 kg/m^3.

$$\rho = \frac{m1-m0}{v} \quad (1)$$

where: ρ is the soil density (g·cm^{-3}); v is the volume of the ring knife (cm^3); m_1 is the mass of the ring knife and soil *(g);* and m_0 is the mass of the ring knife (g).

The drying method was used to determine soil moisture content. First, the mass m' of the empty aluminium box was measured using an electronic balance. Then, soil was added, and the total mass m' of the box and moist soil was recorded. The box was placed in a preheated oven at (107±2)℃ for 8 hours, cooled to room temperature, and weighed again to obtain the mass after drying.

$$\omega = \frac{m_1 - m_2}{m_1 - m} \quad (2)$$

where:

ω is the moisture content of the soil (%);

m_1 is the mass of the aluminium box and the soil (g);

m_2 is the mass of the aluminium box and the dry soil (g);

m is the mass of the aluminium box (g).

Sieving method was used to measure the particle size distribution of the soil. Soil collected from the field was first dried in a drying oven to remove impurities and pulverized, and then sieved using standard test sieves and oscillating sieves to measure the mass of the soil at different particle sizes and calculate the percentages as shown in Table 1.

Table 1

Soil particle size distribution

Particle radius/mm	Mass/g	Percent/%
≥2	17.48	8.74
2-1	8.34	4.17
1-0.5	11.68	5.84
0.5-0.25	41.50	20.75
0.25-0.075	111.60	55.80
0.075-0	9.40	4.70

According to the soil texture classification standard GB/T 17296, soil with a sand content greater than 50% is classified as clayey soil. Based on this standard, the soil in the study area was identified as clayey sandy loam (*Chen et al., 2017*).

Using the drying method and the addition of pure water, three soil moisture content gradients - 8.39%, 10.74%, and 12.40% - were prepared for the angle of repose tests. A dried soil sample with mass m_3 was measured, and pure water with mass m_1 was added. The mixture was stirred thoroughly and allowed to stand for 24 hours. The actual moisture content ω_x was then determined using the drying method and calculated as follows:

$$\omega_x = \frac{m_s}{m_s+m_3} \quad (3)$$

where*:*

ω_x is the water content of the soil (%);

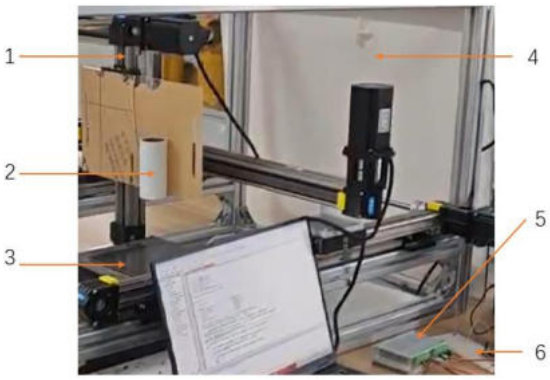
m_s is the mass of water required to configure the sample (g);

m_3 is the sample mass (g).

Static angle of repose measurement

Common methods for measuring the static angle of repose include the cylinder lifting method and the funnel method (*Han et al., 2020; Zhen et al., 2020*). Given that the soil in this study contains some moisture and exhibits relatively cohesive texture, the hollow cylinder method was considered more suitable for accurately determining the static angle of repose. The test was conducted by placing a 65Mn steel plate horizontally on the test machine platform. The cylinder test apparatus was then connected, and the cylinder was positioned vertically on the steel plate and filled with the test soil.

The test machine was activated to lift the cylinder at a uniform speed of 25 mm/s (*Thomas et al., 2018*). A camera was used to record the formation of the soil pile for each moisture content condition. The test was repeated four times for each condition to ensure repeatability. The actual test setup for measuring the static angle of repose is shown in Fig. 1.



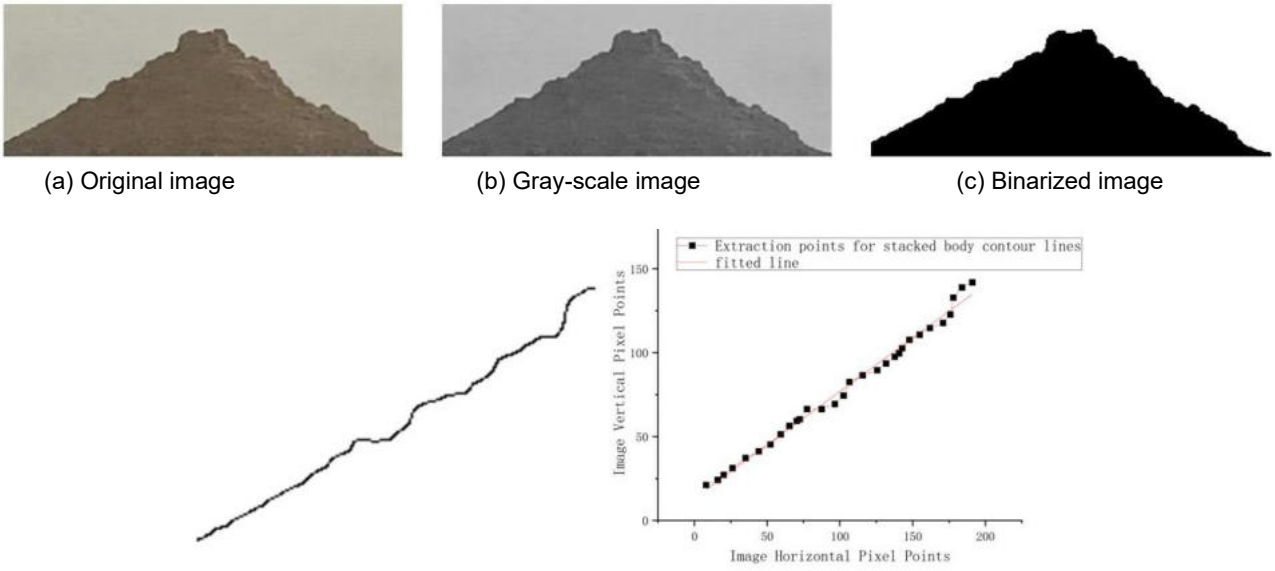


Fig. 1 - Static angle of repose measurement

1. Slipway; 2. Cylinder; 3. Cushion; 4. Background Board; 5. Driver; 6. Controller.

Image processing was used to determine the soil accumulation angle values (*Luo et al., 2018*). First, the original image was cropped to an appropriate size, and then processed through grayscale conversion and binarization. The boundary coordinates of the soil pile were extracted using the image digitizing function in Origin software (Fig. 2d). For each set of coordinates, linear fitting was performed, and the corresponding scatter plots and fitted lines were generated to obtain the fitting equations. The slope of each fitted line was then used to calculate the accumulation (stacking) angle. The arctangent (inverse tangent) of the slope was converted into an angle value (Fig. 2e). The final stacking angle was obtained by averaging the angles from both sides of each image. The image processing procedure and results are illustrated in Fig. 2.

(a) Original image (b) Gray-scale image (c) Binarized image

Fig. 2 - Calculation process of static angle of repose of soil

Dynamic angle of repose measurement

The dynamic angle of repose is defined as the maximum angle between the slope of the soil mass and the horizontal plane before collapse occurs, i.e., when the internal forces between soil particles can no longer counteract gravity as the soil ascends with the rotation of the drum. It serves as a key parameter for characterizing the dynamic flow behaviour of soil. A custom-built device was used to measure the dynamic angle of repose, as illustrated in Figure 3.

The apparatus consists of a rotating drum (100 mm in diameter and 100 mm in length, with a steel sheet affixed to the inner wall), a motor, controller, and coupling. The measurement procedure was as follows: a specified amount of soil was loaded into the drum until the fill level reached 25% of the drum volume.

The motor was then activated to rotate the drum at a constant speed of 7 r/min, as recommended in relevant literature (*Zhou et al., 2023*). A video camera positioned directly in front of the drum recorded the rotation process in real time to capture the dynamic angle of repose. After repeating the experiment for five times, the average values of the dynamic angle of repose α of the three layers of soil were obtained as 42.7°, 43.91° and 45.7°, respectively.

Contact model

The water content of the soil before burying the vine is not low, and the soil particles will have a certain degree of adhesion between them. The Hertz-Mindlin with JKR model is used as a particle contact model, which is suitable for simulating the particulate materials that are prone to adhesion and agglomeration effects. Therefore, discrete element simulation was carried out using the Hertz-Mindlin contact model with JKR cohesion model, which assumes that the adhesion force acts within the contact area of the particles and contributes to the contact surface manifolds, thus obtaining a larger contact area than predicted by the Hertz-Mindlin theory. In the JKR model, the normal elastic contact force F_{JKR} of the particles is expressed as:

$$F_{JKR} = \frac{4E^*}{3R^*}\alpha^3 - 4\sqrt{\pi\gamma E^*\alpha^3} \tag{3}$$

$$\delta = \frac{\alpha^2}{R^*}\left[1 - \sqrt{\frac{4\pi\gamma R^3}{E^*\alpha^3}}\right] \tag{4}$$

where: E^* is the equivalent elastic modulus; R^* is the equivalent particle radius; α is the normal overlap; γ is the particle surface energy; δ is the tangential overlap.

The first term in Eq. (3) is the normal contact force based on the Hertz-Mindlin theory, and the second term is the particle adhesion force based on the JKR theory; when the particle surface energy $\gamma = 0$, the JKR model will degenerate into the Hertz-Mindlin model.

Principle of particle stiffness reduction

The Rayleigh time step refers to the length of time for 2 collision operations between particles, which is an important factor affecting the computational efficiency of DEM simulation. The formula for the Rayleigh time step is:

$$t_R = \frac{\pi r}{(0.163\upsilon + 0.877)}\sqrt{\frac{\rho}{G}} \tag{5}$$

where: t_R is the Rayleigh time step; r is the particle radius; υ is the particle Poisson's ratio; ρ is the particle density; G is the particle shear modulus.

To ensure the efficiency and accuracy of the simulation, 10% to 30% of the Rayleigh time step is usually chosen as the computational time step. From Eq. (5), it can be seen that the shear modulus of the particles is the main factor affecting the time step, and the reduction of particle stiffness allows the use of a larger time step in the simulation, which reduces the number of computational iterations and thus improves the computational speed. With the introduction of reduced stiffness particles in the JKR model, more overlap of particles occurs during kinematic collisions. If the surface energy of the particles remains constant, the kinetic energy lost in the collision will increase. In order to ensure that the result of the motion of the particles after the collision remains unchanged, so that the separation energy required by the 2 particles in contact remains constant, the reduction of particle stiffness must be balanced by the reduction of the surface energy of the particles, and the conditions to be satisfied are:

$$\gamma_{mod} = \gamma \left(\frac{G_{mod}}{G}\right)^{2/5} \quad (6)$$

where: γ_{mod} and G_{mod} are the surface energy and shear modulus of the modified particles respectively.

With the reduction of particle stiffness and the increase of time step, the calculation speed is improved, but the range of particle stiffness reduction should be limited. In order to prevent the particle stiffness from decreasing too much and causing too much overlap, the particle shear modulus after decreasing the stiffness should be kept above 10^7 Pa (*Lommen et al., 2023*).

Discrete element simulation parameter calibration

According to the theory of particle scaling, the related literature proposes that if the density of the particles corresponding to the scaled model is kept constant, the intrinsic parameters of the particles corresponding to the scaled model are the same as those of the original model, but the contact parameters of the particles with the particles and the particles with the touching soil parts corresponding to the scaled model can't be obtained directly according to the equations, and the related parameters need to be calibrated by simulation tests (*Feng et al., 2009*).

In order to reduce the amount of simulation data and improve the simulation efficiency, the soil particles are simplified into a single sphere model, and then the scaling theory is used to scale the particles of different particle size ranges into appropriate sizes, referring to the relevant literature (*Zhen et al., 2024; Yang et al., 2023; Li et al., 2024*) and the GEMM database, to determine the range of values of intrinsic parameters of the soil and the relevant contact parameters are shown in the following table.

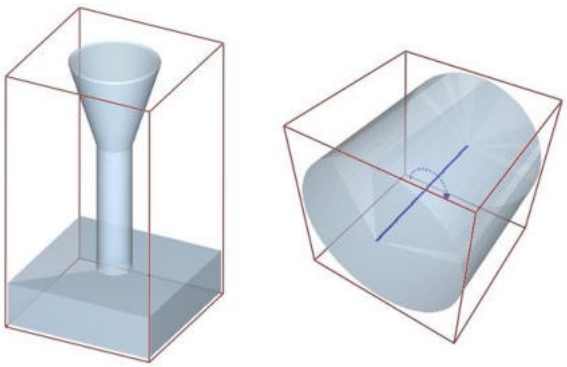

Table 2

Scaling model parameter value range

Parameters	Value	Unit
Soil density	175.7567	**kg·m^{-3}**
Poisson's ratio for soil	0.33	
Soil shear modulus A	10-10 0	**MPa**
Coefficient of restitution between soil particles B	0.15-0.75	
Coefficient of static friction between soil particles C	0.2-1.16	
Coefficient of rolling friction between soil particles D	0.05-0.15	
Steel density	7850	**kg·m^{-3}**
Steel Poisson's ratio	0.3	
Steel shear modulus	7.9×10^4	**MPa**
Coefficient of restitution between soil-steel E	0.25-0.65	
Coefficient of static friction between soil-steel F	0.30-0.80	
Coefficient of rolling friction between soil and steel G	0.20-0.40	
Surface energy (JKR) H	0.1-0.3	**J·m^{-2}**

Discrete element simulation modeling

In SOLIDWORKS software, the 3D geometric model of the static and dynamic angle of repose measurement device was built according to the scale of 1:1 with reference to the dimensions of the measurement device, saved in STL format and imported into EDEM software. The 3D geometric model of the measurement device is shown in Fig. 4.

(a) Static angle of repose model (b) Dynamic angle of repose model

Fig. 4 - Geometric model of the static and dynamic angle of repose determination device

The initial conditions of the simulation were set as follows: the particle sizes of the enlarged spherical particles were set to 2.5 mm, 5 mm and 10 mm, and the generation mode was dynamic. The static angle of repose model establishes a particle factory at the top of the funnel, with a total particle mass of 0.167 kg, and the generation rate is set to 0.5 kg of particles per second. In the dynamic angle of repose simulation model, a particle factory was established inside the cylinder to simulate the soil particles. A total particle mass of 0.209 kg was used, corresponding to a 25% fill rate of the drum volume, consistent with the experimental setup. After the particles settled into a stationary state, a rotational axis was introduced at the centre of the model, and the rotational speed was set to 7 r/min. The computational time step for both the dynamic and static repose angle models was set to 2.5 ms. After the particles stabilized, a rotational axis was added to the centre of the model, and the rotational speed was set to 7 r/min. The computational time step for both models was defined as 20% of the Rayleigh time step, and the mesh size was set to three times the diameter of the smallest spherical particle. Once the simulation reached a stable state, the angle of repose was measured using the EDEMPY measurement tool. The discrete element simulation parameters included the intrinsic properties of the particles, the 3D geometric model, the contact parameters between particles, and the contact parameters between particles and the geometry. The 3D geometry was modeled using 65Mn material, and the range of contact parameter variation was determined through preliminary experiments.

Simulated static/dynamic angle of repose determination

To accurately determine the angle of repose of the simulated particle pile, the simulation result files were analysed using the EDEMPY library, a Python-based post-processing tool for discrete element simulations. Measurement principle: First, a radial array of cylindrical containers is defined. The highest particle in each container is then identified. The centre-of-mass coordinates of these particles are extracted and subjected to least-squares linear fitting. The angle between the resulting fitted line and the horizontal plane is calculated, representing the angle of repose. This measurement principle is illustrated in Fig. 5 and Fig. 6. To improve measurement accuracy, only the stable region of the pile was selected for analysis. In addition, measurements were performed along multiple radial directions (eight directions in this study), and the average angle of repose was calculated. A schematic of the multi-directional measurement method is shown in Fig. 7.

RESULTS

Plackett-Burman test for discrete element simulation parameters

Not all parameters set for the discrete element simulation have a significant effect on the angle of repose. To identify the key influencing factors, a parameter screening test was conducted using the Plackett-Burman design in Design-Expert software. The static and dynamic angles of repose were used as response variables, while the eight parameters to be calibrated, along with two dummy variables (as shown in Table 3), were selected as the test factors. This design allowed for the evaluation of each factor's significance on the angle of repose and facilitated the identification of the most impactful parameters for further optimization.

Table 3

Plackett-Burman test scheme and results

Serial number	Experimental factors								Static angle of repose / (°)	Dynamic angle of repose / (°)
	A	B	C	D	E	F	G	H		
1	-1	-1	1	-1	1	1	-1	1	33.33	55.35
2	1	-1	1	1	1	-1	-1	-1	39.44	47.88
3	1	1	1	-1	-1	-1	1	-1	23.57	40.61
4	1	-1	1	1	-1	1	1	1	*45.01*	*61.13*
5	1	-1	-1	-1	1	-1	1	1	31.38	51.45
6	1	1	-1	-1	-1	1	-1	1	27.82	63.35
7	-1	-1	-1	-1	-1	-1	-1	-1	26.82	46.56
8	-1	-1	-1	1	-1	1	1	-1	46.79	50.82
9	-1	1	-1	1	1	-1	1	1	39.27	51.39
10	-1	1	1	1	1	-1	-1	1	32.28	51.25
11	-1	1	1	-1	-1	1	1	-1	27	47.04
12	1	1	-1	1	1	1	-1	-1	36.35	57.19

The test results in Table 3 were analysed by ANOVA, and the significance of each test parameter on the static angle of repose and dynamic angle of repose was obtained as shown in Tables 4 and 5. From Table 4, it can be seen that the rolling friction coefficient of soil-soil D has a $p < 0.01$, which is very significant on the simulation results; soil-soil coefficient of restitution B, soil-steel static friction coefficient F, are significant on the simulation results. The smaller the soil-soil coefficient of restitution, the greater the energy loss during collision of soil particles, which will limit the movement between soil particles and make the static accumulation angle increase. The remaining parameters have p-values greater than 0.05, the effect on the simulation results is extremely small. From Table 5, it can be seen that the soil-steel static friction coefficient F, JKR surface energy H is extremely significant on the dynamic angle of repose with p-value less than 0.01, and p-value of the rest of the parameters is greater than 0.05, the effect on the dynamic angle of repose being extremely small.

Steepest Ascent Test

The steepest ascent test is used to accurately determine the centre point of the test factor levels, enabling the initial response region to quickly approach the optimal response region. Based on the results of the parameter screening tests, the factors with P-values less than 0.05 in Tables 4 and 5 were selected for the steepest ascent test. The selected parameters were gradually increased according to the chosen ascent step size, while the remaining parameters were held constant at intermediate levels: soil shear modulus (1×10^7 Pa), soil-soil static friction coefficient (0.68), soil-steel restitution coefficient (0.45), and soil-steel rolling friction coefficient (0.30). The test results are presented in Table 6. As shown in the table, both the static and dynamic angles of repose increased progressively with higher values of the selected test factors.

Table 6

Steepest Ascent Test Scheme and Results

Serial number	Experimental factors				Static angle of repose / (°)	Dynamic angle of repose / (°)
	B	D	F	H		
1	0.75	0.05	0.5	0.1	25.62	35.61

6	0.15	0.2	0.8	0.3	42.05	67.49

Box-Behnken test and regression analysis

In order to obtain the mathematical regression model of the angle of repose with the significant influencing factors (soil-soil restitution coefficient, soil-soil rolling friction coefficient, soil-steel static friction coefficient, and JKR surface energy), a response surface test was conducted using the Box-Behnken method. According to the results of the steepest ascent test, the parameter values of test No. 2 in Table 7 were selected as the intermediate level, and the parameter values of No. 1 and No. 3 were selected as the low level and high level, respectively, for the experimental design. The test scheme and results are shown in Table 7.

Table 7

Tables 8 and 9 show the analysis of variance (ANOVA) for the static and dynamic angle of repose in the test, respectively. As can be seen from Tables 8 and 9, the p-values (p-value is the probability of obtaining the observed value of the test statistic and other values that are more unsupportive of the original hypothesis when the original hypothesis is true) of the two fitted models are less than 0.01, indicating that the relationship between the angle of repose and the resulting regression equations is highly significant; the p-values of the out-of-fit terms are all greater than 0.05, indicating that the regression equations are not out-of-fit, and they have a predictive significance; the coefficients of determination for the static angle of repose are 0.9946 for static angle of repose and 0.9926 for dynamic angle of repose, indicating a good fit. For the static angle of repose, the p-values of the soil-soil restitution coefficient B, the soil-soil dynamic friction coefficient D, the soil-steel static friction coefficient F, the JKR surface energy H, and the interaction terms BF, BH, DF, and DH are less than 0.01, which are extremely significant on the static angle of repose; the p-values of each of the quadratic terms, except for H2 and the quadratic term BD are all greater than 0.05, which indicates that these two factors were not significant on the static angle of repose, and all other factors had significant effects on the static angle of repose. For the dynamic angle of repose, the p-values of soil-soil rolling friction factor D, soil-steel rolling friction coefficient F, JKR surface energy, interaction term BF, and secondary terms B2, D2, F2, and H2 are less than 0.01, which are extremely significant on the dynamic angle of repose, and the p-values of soil-soil restitution coefficient B and interaction term BH are less than 0.05, which have a significant effect on the dynamic angle of repose. and the other factors were not significant on the dynamic angle of repose.

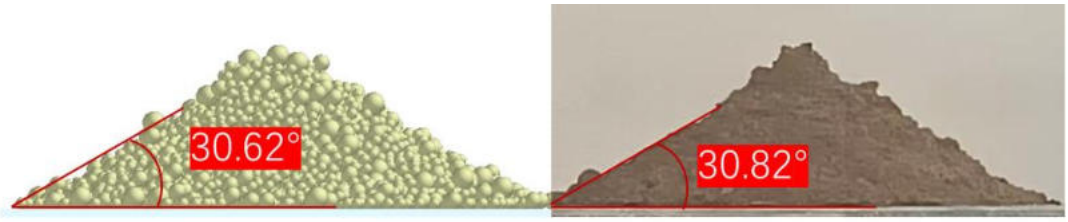
The quadratic regression equation for the dynamic angle of repose (DAoR) was developed by removing the statistically insignificant terms, while ensuring that the model remained significant and exhibited a good fit to the experimental data:

$$DRA = 51.59 - 0.4058B + 0.6392D + 3.47F + 5.88H + 1.18BF + 0.775BH - 0.7789B^2 - 1.16D^2 - 1.19F^2 - 2.38H^2 \quad (8)$$

Determination and validation of discrete element simulation parameters

The experimentally measured soil angles of repose were used as response targets to optimize the regression equations, and the resulting combinations of discrete element simulation parameters were input into EDEM software for validation. Figure 8 presents a comparison between the simulated and experimental values of the optimized parameter sets for each soil layer. The average relative errors for the static angle of repose and dynamic angle of repose were calculated as 1.56% and 0.984%, respectively. These results indicate that the simulated values closely matched the experimental measurements, with no significant differences, thus confirming the accuracy and reliability of the calibrated parameter combinations. Although the angles of repose for each group were relatively similar, different combinations of discrete element simulation parameter values resulted in variations in particle contact interactions and force chain distributions.



These differences led to distinct stacking morphologies in the simulated particle assemblies. Therefore, among the five DEM parameter combinations tested for each soil layer, the one that produced a stacking morphology most closely resembling the actual experimental observation was selected as the preferred combination. The selected optimal DEM parameter values for each soil layer are as follows: soil-soil restitution coefficient (B) is 0.734, 0.556, 0.643, soil-soil rolling friction coefficient (D) is 0.082, 0.086, 0.095, soil-steel static friction coefficient (F) is 0.564, 0.511, 0.525 and the JKR surface energy (H) is 0.102, 0.117, 0.122.

(a) (b) (c)

Fig. 8 - Comparison between simulated and experimental values using the optimized discrete element simulation parameter combinations

The static and dynamic angles of repose for the upper soil layer are shown in Figures 9 and 10. As illustrated, there is no significant difference between the simulation results and the actual experimental observation. The measured static angle of repose was 30.82°, and the dynamic angle of repose was 42.70°, while the simulated values were 30.62° and 42.75°, respectively. The relative errors for the static and dynamic angles of repose were 0.65% and 0.12%, which are both very low. These results confirm that the optimized discrete element simulation parameter combination is accurate and reliable, and thus suitable for use in subsequent simulation studies.

CONCLUSIONS

The computational efficiency of discrete element simulations was significantly improved by scaling particle size and reducing particle stiffness. The results of the Plackett-Burman test indicated that, within a certain value range, factors such as particle shear modulus, particle-steel restitution coefficient, particle-steel kinetic friction coefficient, and particle-particle static friction coefficient did not significantly affect the angle of repose. In the Box-Behnken response surface test, the static and dynamic angles of repose were used as dual response indices to optimize the discrete element simulation parameters. This approach led to more accurate simulation results, with particle behaviour more closely resembling actual soil conditions. In this study, the static and dynamic angles of repose were adopted as macroscopic response indicators for calibrating the discrete element simulation parameters of simplified soil particles. Optimal parameter combinations were determined through the Plackett-Burman and Box-Behnken tests, and subsequently validated through experimental comparison. The main conclusions are as follows:

(1) The average static and dynamic angles of repose of the soil were measured using a custom-built device, yielding values of 30.82°, 32.35°, and 33.77° for the static angle, and 42.7°, 43.91°, and 45.7° for the dynamic angle, corresponding to the upper, middle, and lower soil layers, respectively.

(2) The Plackett-Burman test identified that the soil-soil restitution coefficient, soil-soil rolling friction coefficient, and soil-steel static friction coefficient significantly influenced the static angle of repose, while the soil-steel static friction coefficient and JKR surface energy were significant factors for the dynamic angle of repose.

(3) The Box-Behnken test was employed to establish second-order regression models for both static and dynamic angles of repose. These models were optimized using the experimentally measured angle values as targets. The resulting optimal parameter combinations, validated through experiment, were as follows: soil-soil restitution coefficients were 0.734, 0.556, 0.643, soil-soil rolling friction coefficients were 0.082, 0.086, 0.096, soil-steel static friction coefficients were 0.564, 0.511, 0.525, JKR surface energies were 0.102, 0.117, 0.122.

(4) The simulated static angles of repose for the three soil layers were 30.62°, 32.51°, and 33.2°, and the simulated dynamic angles were 42.75°, 43.95°, and 45.96°, respectively. The corresponding relative errors for the static angle were 0.65%, 0.09%, and 2.03%, and for the dynamic angle were 0.28%, 0.12%, and 0.56%. These small errors confirm that the calibrated discrete element simulation parameters are accurate and reliable, and can be confidently used in subsequent DEM simulations.

Keywords: *Area array LiDAR, soybean combine harvester, header height，Bang-bang control*

ABSTRACT
For the automatic control of soybean harvester header height, this study uses Area array LiDAR for header height detection. An improved quartile range algorithm is used to dynamically remove outliers under crop residue interference. Linear, quadratic, and cubic nonlinear terrain fitting models are established based on the surface undulation characteristics of soybean fields. The Huber loss function is introduced to enhance the robustness of parameter estimation. The balance between model complexity and fitting goodness is quantified using Bayesian information criterion (BIC), and the model intercept term with the smallest BIC value is selected as the terrain reference height. Aiming at the hysteresis characteristics of valve controlled asymmetric hydraulic cylinders, a telescopic dual-mode transfer function model is established, and a Bang-bang switch lead compensation strategy with position threshold is proposed. By predicting the trend of terrain changes, the electromagnetic directional valve is triggered in advance when the height error of the header exceeds the set threshold, effectively reducing the system response delay. Field comparative experiments have shown that at a working speed of 1m/s, the automatic control mode significantly improves the uniformity of cutting compared to the manual mode. When the cutting threshold is set to 20, 25, and 30 mm, the coefficient of variation of cutting height is reduced by 2.13%, 1.71%, and 0.55%, respectively. Moreover, the automatic mode maintains a gentle distribution characteristic within the threshold range of 15-35 mm, verifying the strong robustness and control accuracy advantages of the designed system in complex farmland environments.

摘要
针对大豆收割机割台高度自动控制，本研究采用面阵激光雷达进行割台高度检测，利用改进四分位距算法实现作物残茬干扰下的离群点动态剔除，并依据大豆田地表起伏特征建立线性、二次及三次非线性地形拟合模型，通过引入 Huber 损失函数增强参数估计鲁棒性，结合贝叶斯信息准则（BIC）量化模型复杂度与拟合优度的平衡关系，择优选取 BIC 值最小的模型截距项作为地形基准高度。针对阀控非对称液压缸的迟滞特性，建立伸缩双模态传递函数模型，提出带位置阈值的 Bang-Bang 开关超前补偿策略：通过预判地形突变趋势，在割台高度误差超过设定阈值时提前触发电磁换向阀动作，有效降低了系统响应延迟。田间对比试验表明，在 1m/s 作业速度下，自动控制模式较手动模式显著改善割茬均匀性，当割茬阈值设置为 20、25 及 30mm 时，割茬高度变异系数分别降低了 2.13%、1.71%及 0.55%，且自动模式在 15-35 mm 阈值范围内始终维持平缓分布特征，验证了所设计系统在复杂农田环境中的强鲁棒性与控制精度优势。

INTRODUCTION
The losses during soybean harvesting mainly include header losses, threshing and separation losses, of which header losses account for about 80% of the total losses (*Lian et al., 2024*). Crop cutting and missed cutting are related to the contour and height adjustment of the header. If the position of soybean pods is low, the cutting knife is prone to miss the soybean pods, causing loss of harvest on the cutting platform. If the height of the cutting blade is lowered, it is easy to shovel soil into the cutting table when the blade is in contact with the ground, causing soil to mix with soybean seeds and resulting in "mud flower face" loss, which affects the quality of soybean harvest *(Liu, 2022)*. Therefore, during harvesting, the cutting table should be adjusted in a timely manner according to the height of the soybean bottom pod to achieve cutting table imitation. At present, the detection methods for the height of the cutting table can be basically divided into contact and non-contact methods. For the contact detection method, the Cleodolphi team introduced a position sensor in the height detection of the harvester chassis and used a pressure sensing system to provide real-time feedback on the contact status of the cutter head with the ground (*Cleodolphi et al., 2017*). The combine harvester header

adjustment system developed by Liao Yong achieves dual sensor collaborative detection, capturing crop height information through E18-D80NK infrared diffuse reflection photoelectric sensor, and accurately obtaining header height data with KTC pull rod potentiometer displacement sensor (*Liao et al., 2018*). Li Zerui improved the traditional cutting table system for soybean harvesting characteristics, and designed a floating cutter that achieved adaptive adjustment within a small range through mechanical profiling (*Li et al., 2022*). Zhou developed an intelligent cutting platform system based on angle sensing for the special cultivation mode of soybean under film mulching drip irrigation in Xinjiang. Field test data showed that the relative error of height detection of the device remained stable within 5% (*Zhou et al., 2024*). Non-contact surface parameter detection mainly includes ultrasonic waves, machine vision, infrared sensing, etc. Pasi et al constructed a soil wheel multi ultrasonic sensor fusion measurement system, which controlled the terrain contour detection error within ± 10 mm through multi-source data fusion algorithm (*Pasi et al., 2015*). The ultrasonic dynamic plant measurement system has been validated through orthogonal experiments, and its measurement accuracy is significantly improved compared to traditional floating wheel devices (*Chang et al., 2016*). Huang Yiqi's team proposed a 3D coordinate reconstruction method based on Otsu adaptive thresholding algorithm, which achieved sub centimeter level (MAE<3 mm) terrain detection accuracy through feature point cloud spatial registration (*Huang et al., 2017*). Huang Min proposed a sugarcane ridge height detection scheme based on frequency modulated continuous wave radar. The device can maintain a maximum error level of 3.02 cm under complex working conditions with a vegetation cover thickness of 10 cm and a detection distance of 170 cm (*Huang et al., 2021*). Its penetrating detection mechanism provides an innovative solution for terrain measurement under vegetation cover conditions.

However, the above-mentioned technical systems generally adopt a discrete single point sampling mechanism, which makes the measurement data susceptible to local random noise interference and unable to accurately characterize the macroscopic terrain characteristics of the work area. Based on this, this study proposes a terrain perception system based on area array LiDAR, which uses fusion point cloud feature extraction and introduces a Bang-bang switch advance compensation strategy with position threshold: when the terrain undulation is detected below the preset threshold, the system state remains stable, and only triggers hydraulic actuator adjustment when significant terrain changes are identified.

MATERIALS AND METHODS

Data acquisition and processing of area array LiDAR

This study used Nooploop's TOFSense-MS surface array LiDAR for header height detection, with a ranging range of 1.5c m ~ 4 m and a distance resolution of 1 mm. The data was transmitted through UART interface using NLink protocol, and an 8 × 8 spatial height matrix was constructed in real time to generate a three-dimensional point cloud map. To address the issue of data anomalies caused by crop residues, terrain changes, and sensor noise in the work environment, an improved quartile range algorithm is adopted for outlier detection:

$$Q_1 = P_{25}(h), \quad Q_1 = P_{75}(h), \quad IQR = Q_3 - Q_1 \tag{1}$$

Keep the data range as [Q1-1.5IQR, Q3+1.5IQR], and remove outliers outside the range. Establish three types of terrain fitting models based on the surface topography characteristics of soybean fields:

Linear model:

$$h = \beta_0 + \beta_1 x + \beta_2 y + \varepsilon \tag{2}$$

Quadratic model (including curvature term):

$$h = \beta_0 + \sum_{k=1}^{2}(\beta_k x^k + \gamma_k y^k) + \beta_3 xy + \varepsilon \tag{3}$$

Third order model (high-order nonlinearity):

$$h = \beta_0 + \sum_{k=1}^{3}(\beta_k x^k + \gamma_k y^k) + \beta_4 xy + \beta_5 x^2 y + \beta_6 xy^2 + \varepsilon \tag{4}$$

Among them, (x, y) are the coordinates of the LiDAR array, ε is the residual term, and the model complexity dynamically adjusts with the complexity of the crop field terrain. Huber loss function is used for anti-interference parameter estimation:

$$\min_{\beta}\sum_{i=1}^{n}\rho(\frac{r_i}{\sigma}),\rho(r)=\begin{cases}0.5r^2 & |r|<c\\ c|r|-0.5c^2 & |r|>c\end{cases} \quad (5)$$

The applicability of the model is evaluated based on Bayesian Information Criterion (BIC):

$$BIC = n\ln(\hat{\sigma}^2)+k\ln(n) \quad (6)$$

In the formula, n is the effective data amount, K is the number of model parameters and $\hat{\sigma}^2$ is the robust regression residual variance. The model with the lowest BIC value is selected, and the intercept term of this model is extracted as the fused height value. The left image below displays the original sensor data, which contains four noticeable outlier points. After processing using the method described above, the influence of these anomalies is effectively mitigated.

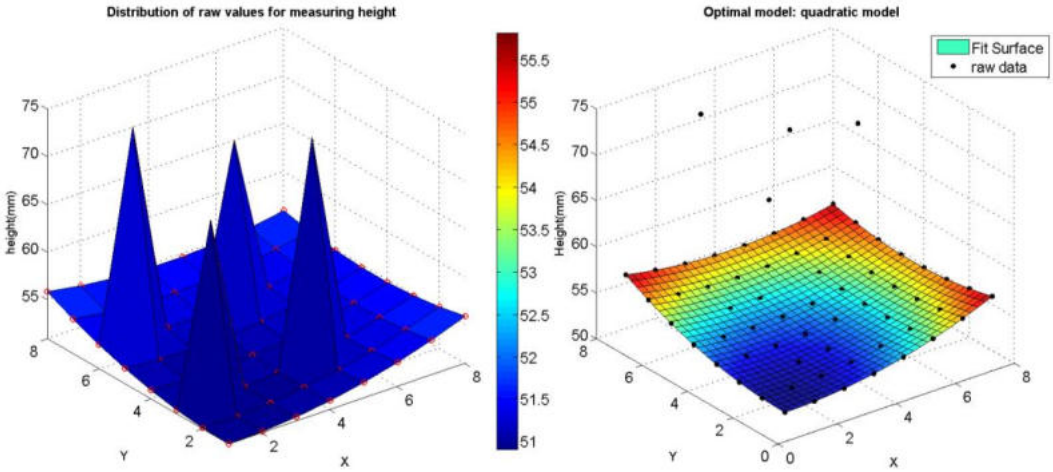

Fig. 1 - Comparison of Front and Rear Processing of Area Array LiDAR Data

Figure 2 illustrates a closed-loop position control system based on the STM32F103ZET6 development board. TOFSense-MS LiDAR data is transmitted to the STM32 master control unit via serial communication. The microcontroller executes control algorithms to drive the H-bridge module, thereby regulating the on/off states and fluid direction of the electromagnetic directional valve, which ultimately achieves header height adjustment. The serial port screen provides a Human-Machine Interface (HMI) supporting parameter configuration, real-time data monitoring, and status display functions.

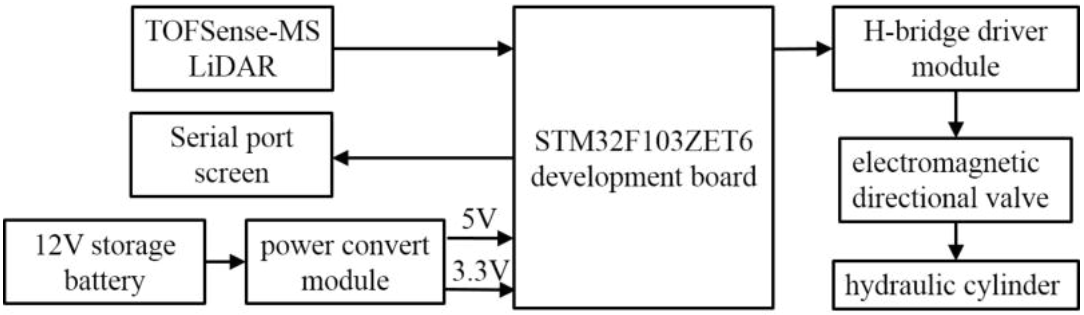

Fig. 2 - Closed-loop position control system

Modeling and analysis of valve controlled asymmetric cylinder system

The height adjustment of the cutting table adopts an asymmetric hydraulic cylinder as the execution unit, and the lifting control is achieved by an electromagnetic directional valve. Compared to proportional valve systems, electromagnetic directional valves have significant engineering applicability in the field of agricultural equipment due to their simple structure, low maintenance costs, and strong resistance to pollution. However, its discrete switch control characteristics result in inherent delay in valve core switching, directly affecting the dynamic response performance of the hydraulic cylinder. To optimize the control accuracy of the system, it is necessary to establish a dynamic model of the valve controlled asymmetric cylinder. The structural diagram is shown in Fig 3.

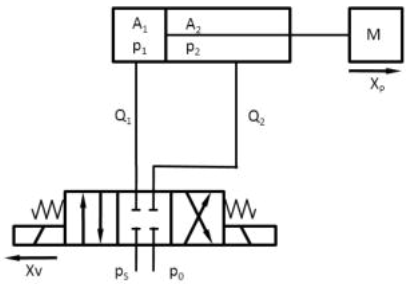

Fig. 3 - Structural diagram of valve controlled asymmetric cylinder system

Assuming the ratio of the two cavity areas is n, that is:

$$n = \frac{A_2}{A_1} \tag{7}$$

Define the load pressure as P_L and the load flow rate as Q_L. When the hydraulic cylinder enters steady state, there are:

$$p_L = \frac{p_1 A_1 - p_2 A_2}{A_1} = p_1 - n p_2 \tag{8}$$

$$Q_L = Q_1 = \frac{Q_1 + n Q_2}{1 + n^2} \tag{9}$$

Due to the different open-loop gains of the extension and retraction of asymmetric hydraulic cylinders, it is necessary to establish basic equations for each case separately. The linear equation for the flow rate of a four-way valve controlled asymmetric cylinder is as follows (*Ye et al., 2015*):

$$Q_L = K_q x_v - K_c p_L \tag{10}$$

$$K_q = \frac{\partial Q_L}{\partial x_v} = \begin{cases} K_{q1} = C_d w \sqrt{\frac{2}{\rho} \frac{(p_s - p_L)}{1 + n^3}}, & x_v > 0 \\ K_{q2} = C_d w \sqrt{\frac{2}{\rho} \frac{n p_s + p_L}{1 + n^3}}, & x_v < 0 \end{cases} \tag{11}$$

$$K_c = -\frac{\partial Q_L}{\partial p_L} = \begin{cases} K_{c1} = C_d w x_v \sqrt{\frac{1}{2\rho} \frac{1}{(1 + n^3)(p_s - p_L)}}, & x_v > 0 \\ K_{c2} = C_d w x_v \sqrt{\frac{1}{2\rho} \frac{1}{(1 + n^3)(n p_s + p_L)}}, & x_v < 0 \end{cases} \tag{12}$$

In the formula: C_d is the valve port flow coefficient; ω is the gradient of the throttle area of the solenoid valve; X_v is the displacement of the reversing valve core; p_1 is the rodless chamber pressure; p_2 is the rodless chamber pressure; P_S represents the fuel supply pressure; ρ represents the density of hydraulic oil.

Assuming that the initial volumes of the two chambers of the piston are the same and the leakage is ignored, the flow continuity equation can be derived:

$$Q_L = A_1 \frac{dx_p}{dt} + \frac{V_t}{2(1 + n^2)\ \beta_e} \frac{dp_L}{dt} \tag{13}$$

$$A_1 P_L = m \frac{d^2 y}{dt^2} + B_c \frac{dy}{dt} + K y + F \tag{14}$$

$$x_p = \frac{A_1 K_q x_v - (K_c + \frac{V_t}{2(1 + n^2)\beta_e} s) F}{(K_c + \frac{V_t}{2(1 + n^2)\beta_e} s)(m s^2 + B_c s + K) + A_1^2 s} \tag{15}$$

Neglecting elastic load, viscous damping, and external load forces, it can be obtained:

$$x_p = \frac{A_1 K_q x_v}{(K_c + \frac{V_t}{2(1+n^2)\beta_e} s)(ms^2) + A_1^2 s} = \frac{\frac{K_q}{A_1} x_v}{s(\frac{V_t m}{2A_1^2(1+n^2)\beta_e} s^2 + \frac{K_c m}{2A_1^2} s + 1)} \quad (16)$$

Table 1

Valve-controlled asymmetric cylinder power structure parameters

Parameter Name	Symbol	Parameter Value	Parameter Name	Symbol	Parameter Value
Effective area of rodless cavity	A_1	1.2566×10^{-3}m^2	Discharge Coefficient	C_d	0.61
Effective area of rod cavity	A_2	0.8765×10^{-3}m^2	Area gradient	ω	0.0047
Area ratio	n	0.6975	Liquid elastic modulus	β_e	6.85×10^{8}Pa
Energy pressure	P_s	8×10^{6}Pa	Oil density	ρ	850kg/m^3
Return oil pressure	P_0	0	Effective volume	V_t	1.2566×10^{-4}m^3

According to the technical manual, the opening time of the 4WE6J61B solenoid valve is 20-45 ms and the closing time is 10-25 ms, both of which are 25 ms. Other parameter settings are shown in Table 1. Therefore, the transfer function when the hydraulic cylinder is extended can be:

$$H_1(S) = \frac{271.0481}{5.8613\times10^{-6}s^3 + 0.001s^2 + s} e^{-0.025s} \quad (17)$$

Similarly, the transfer function when the hydraulic cylinder retracts is:

$$H_2(S) = \frac{226.3698}{5.8613\times10^{-6}s^3 + 0.0012s^2 + s} e^{-0.025s} \quad (18)$$

Analysis of Bang-Bang switch lead compensation strategy with position threshold

The input of an electromagnetic directional valve can be represented as the set $U=\{U+, 0, U-\}$, corresponding to the hydraulic cylinder rising, holding, and falling respectively. Set the height of the header as $h_0(t)$, measure the height value of the sensor as $h(t)$, and the header elevation error e is defined as $h_0(t) - h(t)$. When | e | is less than the position threshold ε, the electromagnetic directional valve does not operate. When e is greater than the position threshold ε, it indicates that the ground elevation increases and the header position is lower, and the header needs to rise. When e is less than the position threshold - ε, it indicates that the ground elevation decreases and the header position is higher, and the header needs to descend. The algorithm flow chart is shown in Fig. 4.

The control algorithm expression is:

$$U = \begin{cases} U_+ & e > \varepsilon \\ 0 & |e| < \varepsilon \\ U_- & e < -\varepsilon \end{cases} \quad (19)$$

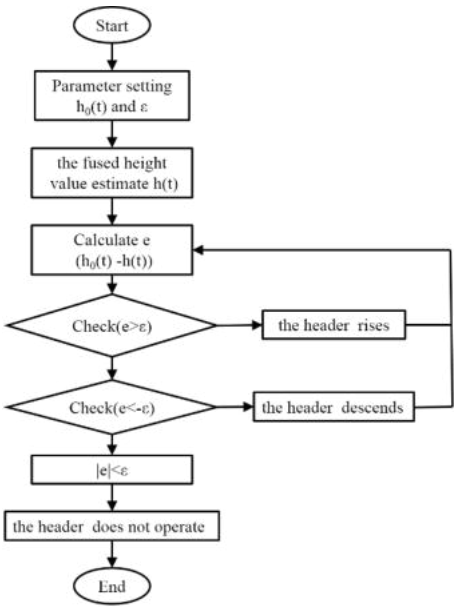

Fig. 4 - Algorithm flow chart

Set the header height to 20 cm and simulate ground height changes using a filtered white noise time-domain road input model, the expression is as follows (*Li et al., 2016*):

$$\dot{q}(t) = -2\pi n_{00} u q(t) + 2\pi n_0 \sqrt{G_q(n_0) u} W(t) \tag{20}$$

In the formula, n_{00} is the lower cut off spatial frequency, taken as 0.011m^{-1}; u is vehicle speed; $q(t)$ is random elevation displacement for road surface; n_0 is reference spatial frequency; $G_q(n_0)$ is the roughness coefficient of the road surface; W(t) is Gaussian white noise with a mean of 0.

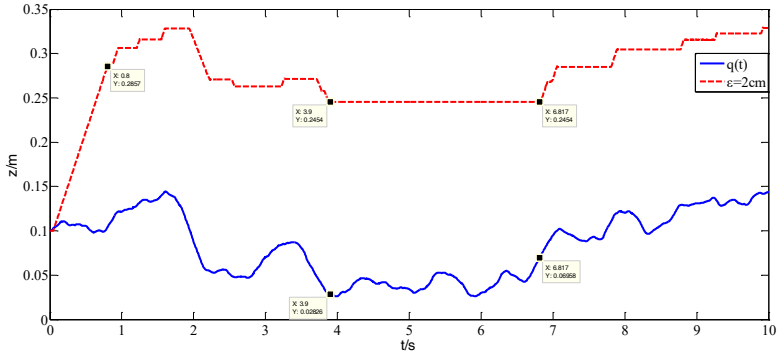

Fig. 5 - Ground elevation (random variation) and cutting height curve

Matlab is used to simulate the variation of the header height and the results are shown in Fig. 5. The position threshold ε is selected as 20 mm. During the time period of 0-0.8 s, due to the fact that the header height is less than 20 cm above the ground, the hydraulic cylinder rises. From 3.9 to 6.817 s, although the ground elevation changes between 2.8 cm and 6.9 cm, the magnitude of the change does not exceed the threshold. At this time, the header height remains at 24.54 cm and does not move. Overall, it shows a control effect of not adjusting the small undulating road surface, and only adjusting it for large undulations.

Field experiment testing

A comparative experiment of soybean harvesting was conducted at the Taigu Shenfeng Experimental Base. The experiment set up a manual and automatic dual-mode control group. The cutting height was used to invert the dynamic changes in the cutting table height, with a constant operating speed of 1 m/s, a preset cutting height of 200 mm, and a working interval length of 30 m. In manual mode, the cutting height will remain at the preset value and will not be adjusted in real-time during the operation process. In automatic mode, the cutting threshold is set to 15 mm, 20 mm, 25 mm, 30 mm, and 35 mm respectively.

Extract 50 sets of cutting height samples continuously from the stable operation section of the harvester, and select the average cutting height and cutting height coefficient of variation (CV). The kurtosis coefficient k is used as a measurement indicator, and its calculation formula is as follows:

(a) Soybean Harvest Experiment (b) Measurement of cutting height

Fig. 6 - Field experiment on height control of soybean sun cutting machine cutting table

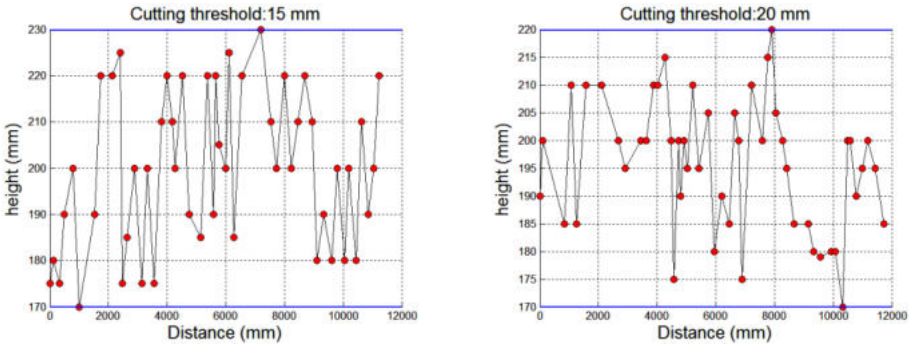
$$\bar{L} = \frac{\sum_{i=1}^{n_1} L_i}{n_1} \tag{21}$$

$$C.V = \frac{\sqrt{\frac{\sum_{i=1}^{n_1}(L_i - \bar{L})^2}{n_1 - 1}}}{\bar{L}} \tag{22}$$

$$k = \frac{n(n+1)\sum_{i=1}^{n_1}(L_i - \bar{L})^4 - 3[\sum_{i=1}^{n_1}(L_i - \bar{L})^2]^2(n-1)}{(n-1)(n-2)(n-3)s^4} \tag{23}$$

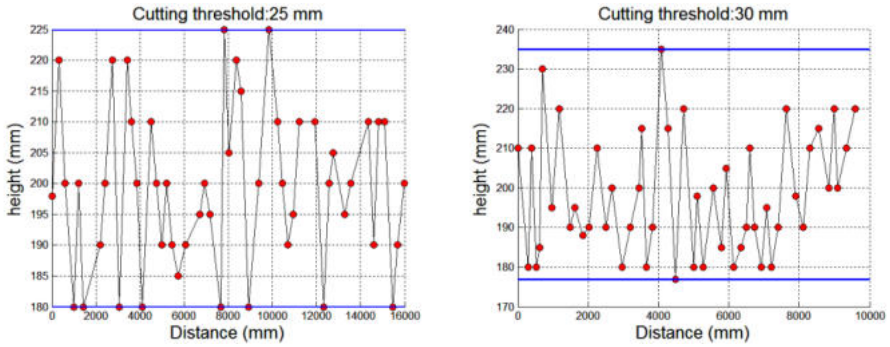
In the formula: n_1 is the total number of measured cuttings; L_i is the i-th measurement of cutting height, mm; m_i is the i-th weighing mass, kg.

RESULTS



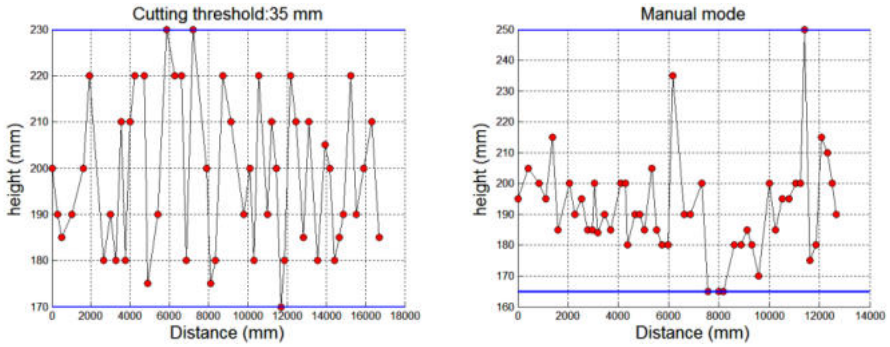
Some measurement data are shown in Table 2, and the distribution of cutting height is shown in Fig. 7.

Table 2



Measurement values of cutting height (top 10 groups)

Cutting threshold / mm	Measurement point cutting height /mm									
	1	2	3	4	5	6	7	8	9	10
15	175	180	175	190	200	170	190	220	220	225
20	190	200	185	210	185	210	210	200	195	200
25	198	220	200	180	200	180	190	200	220	180
30	210	180	210	180	185	230	195	220	190	195
35	200	190	185	190	200	220	180	190	180	210
Manual mode	195	205	200	195	215	185	200	190	195	185



The experimental data processing results are shown in Table 3. In manual mode, the absolute error between the average cutting height and the preset cutting height is less than 8 mm, while in automatic mode it is reduced to 5 mm. Compared with manual mode, when the cutting threshold is set to 20, 25, and 30 mm, the coefficient of variation of cutting height is reduced by 2.13%, 1.71%, and 0.55%, respectively. The kurtosis coefficient analysis further reveals that manual mode presents a peak distribution (kurtosis=3.4635), while automatic mode maintains a gentle distribution feature within the threshold range of 15-35 mm (kurtosis interval: -1.2306 to -0.6541), indicating that the system effectively suppresses the occurrence of extreme deviation values.

（a）The cutting threshold is 15 mm （b）The cutting threshold is 20 mm

（c）The cutting threshold is 25 mm （d）The cutting threshold is 30 mm

（e）The cutting threshold is 35 mm （f）Manual mode

Fig. 7 - Distribution of cutting height

Table 3

Analysis of Experimental Data Processing Results

Cutting threshold / mm	Average cutting height $\bar{L}$	Coefficient of variation of cutting height C.V / %	Kurtosis coefficient
15	199.7	8.49%	-1.2306
20	195.88	6.04%	-0.6541
25	199.36	6.46%	-0.701
30	198.12	7.62%	-0.6658
35	198.3	8.35%	-1.1811
Manual mode	192.08	8.17%	3.4635

CONCLUSIONS

(1) By integrating the high-resolution 3D terrain detection capability of Nooploop TOFSense-MS area array LiDAR, combined with an improved quartile range algorithm, outliers caused by interference sources such as crop residues and sensor noise are dynamically removed. Linear, quadratic, and cubic terrain fitting models are constructed based on Huber robust regression framework. By quantifying the trade-off between model complexity and terrain adaptability using Bayesian Information Criterion (BIC), the intercept term with the smallest BIC value is selected as the reference height to achieve accurate representation of complex farmland terrain.

(2) Aiming at the nonlinear hysteresis characteristics of valve-controlled asymmetric hydraulic cylinder systems, a telescopic dual-mode transfer function model is established, and a Bang-Bang switch lead compensation strategy based on position threshold is proposed. By predicting the trend of terrain changes, the electromagnetic directional valve is triggered to act in advance.

(3) Field comparative experiments show that at a working speed of 1 m/s, the coefficient of variation of cutting height in automatic control mode is significantly reduced compared to manual mode (when ε=20mm, C.) V=6.04%，The automatic mode maintains a gentle distribution feature within the threshold range of 15-35 mm, with a decrease of 26.1%. The research results provide theoretical support and engineering practice paradigm for intelligent control of high-precision agricultural equipment, which can be further extended to the optimization of imitation systems in multi crop harvesting scenarios such as corn and wheat.

ABSTRACT

In the context of agricultural emissions in China, it is common for fields to be bordered by row windbreaks, which - when located downwind of emission sources - can complicate gas flux measurements. To address this challenge, the environmental adaptability of a laser-based detection system for quantifying gas emissions from agricultural sources was evaluated through a controlled gas emission field simulation experiment. Using methane as a representative gas, a flux measurement system based on open-path laser absorption spectroscopy was developed. The study employed an artificially simulated methane volatilization source and two measurement devices to conduct experiments under three conditions: an ideal environment, a laser path positioned downwind of the source, and a laser path set directly above the source. Results show that the standard deviations of the ratio Q_{bLS}/Q were 0.0277, 0.0283, and 0.0256, respectively. The corresponding maximum fluctuation amplitudes were 7.3%, 7.4%, and 5.9%. These findings suggest that for a row windbreak located downwind of an emission source, selecting an optimal measurement strategy - such as positioning the optical path above, across, or near the vertical downwind axis of the source - can minimize environmental interference and enhance the reliability of methane flux measurements in agricultural settings.

摘要

针对我国农业排放问题，田间地头常常会设置一排防风林。假设防风林位于被测源的下风向，这可能会使测量变得复杂。鉴于这种情况，在气体排放田间模拟实验中，以甲烷为例，对基于激光探测确定农业源气体排放的环境适应性进行了评估。建立了基于开放光路激光吸收光谱技术的甲烷通量测量系统。通过使用人工模拟的甲烷挥发源和两套测量装置，分别开展了理想环境下、源下风向以及源上方环境下的实验。结果表明，理想环境下 QbLS/Q 的标准偏差为 0.0277。源下风向得到的 QbLS/Q 标准偏差为 0.0283。源上方设置得到的 QbLS/Q 标准偏差为 0.0256。QbLS/Q 的最大波动幅度分别为 7.3%、7.4%和 5.9%。由此可见，对于一排防风林，假设其位于被测源的下风向，通过优化测量方法可降低气体通量的估算误差。在测量实际大面积面源时，从源的下风向进行测量，并且可以将光路设置在源垂直下风向的上方，穿过源或靠近源。这种测量方法减少了上风向防风林造成的局部环境干扰，从而实现测量。

INTRODUCTION

The methods for measuring agricultural non-point source emission flux include: vertical radial plume mapping method *(Qian et al., 2023; Obaideen et al., 2022)*, Tracer Correlation method *(Vechi et al., 2023)*, box method, Eddy Correlation method *(Dong et al., 2016)*, Inverse dispersion method *(Flesch et al., 2018)*, and so on *(Flesch et al., 2018; Erland et al., 2022)*. There are big differences in applicability, accuracy, and space-time resolution *(Ghorbani et al., 2017)*. Laser absorption spectroscopy is a widely used technique for large-scale gas sensing applications, including quantitative analysis of gas concentration *(Goldsmith et al., 2012; Harris et al., 2002; Hashmonay et al., 2008; Liu et al., 2015; McBain et al., 2005; Xin et al., 2017)*. The flux detection method combined with tunable diode laser absorption spectroscopy and the backward Lagrangian stochastic (BLS) technology can achieve high time resolution agricultural gas emission, and has high accuracy in agricultural non-point source gas flux monitoring.

However, the precondition is to assume that the measurement conditions are idealized. In the actual agricultural gas emissions measurement process, complex external disturbance conditions, various structures (buildings, trees, etc.) introduce vortices, jets, and sheltered zones *(Viguria et al., 2015; Wilson et al., 2005; Wilson et al., 2003)*.

Comprehensive wind field measurements are generally impractical, and wind modeling is a complex task that may lack accuracy. In an experiment using a 1.25 m-high windbreak fence to enclose the tracer, Flesch concluded that local wind complexity can be neglected when measurements are taken at distances greater than 5h from the fence *(Wilson et al., 2001)*. However, this conclusion may not be applicable to the context of agricultural emissions in China, where windbreaks - often rows of trees - are commonly found along the edges of fields, as illustrated in Fig. 1. It is assumed that the windbreak is located downwind of the emission source, which may introduce additional complexities into the measurement process.

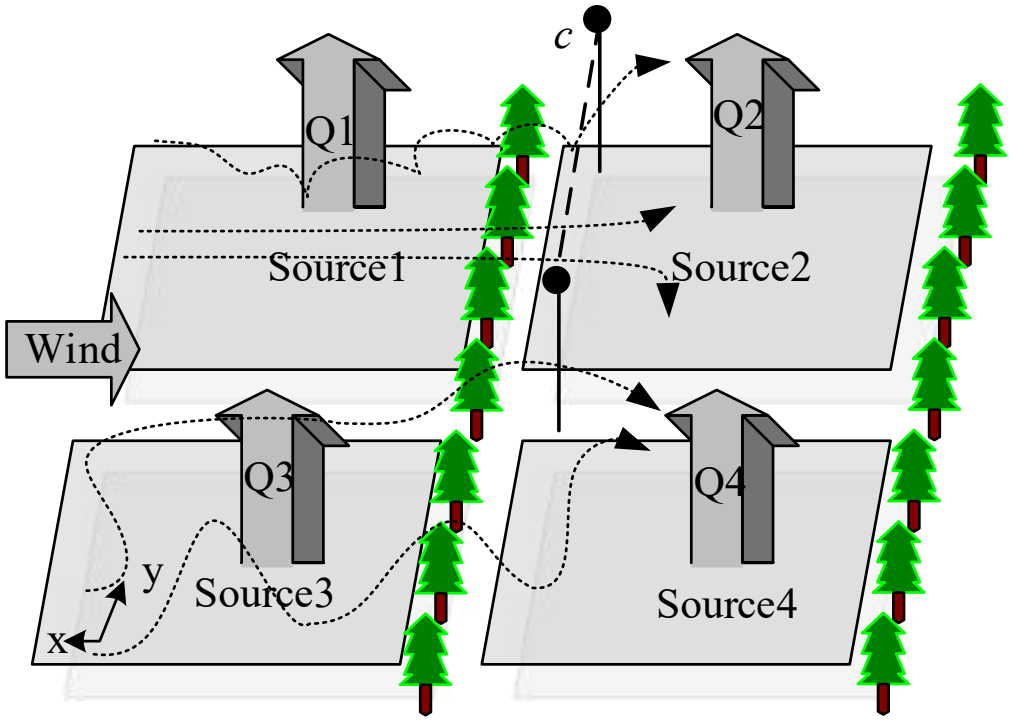

Fig .1 - Windbreaks complicate measurement

In response to this situation, an outdoor field simulation experiment of methane emissions was conducted to evaluate the environmental adaptability of laser-based detection methods for quantifying gas emissions from agricultural sources.

MATERIALS AND METHODS

Measurement principle

According to Beer-Lambert's law, the measured concentration can be expressed as:

$$c = \frac{A}{A_0}\frac{L_0}{L}c_0 \tag{1}$$

Where:

c_0 is the concentration of the standard gas;

L_0 is the optical path length of the standard gas, (cm);

A_0 is the integral absorbance of the standard gas;

L is the actual optical path length of the experimental system, (cm);

A is the fitted integral absorbance.

It is known that the regional source emits gas at a uniform but unknown rate Q (kg/m^2/s). The average gas concentration c is measured at point M within the plume. The emission rate Q can be inferred from the concentration at M and $(c_0/q)_{SIM}$, the ratio of the concentration rise over background at M to the source emission rate [19-20]. As shown in Eq. (2), c_b is the background gas concentration.

$$Q = \frac{c - c_b}{(c/Q)_{SIM}} \tag{2}$$

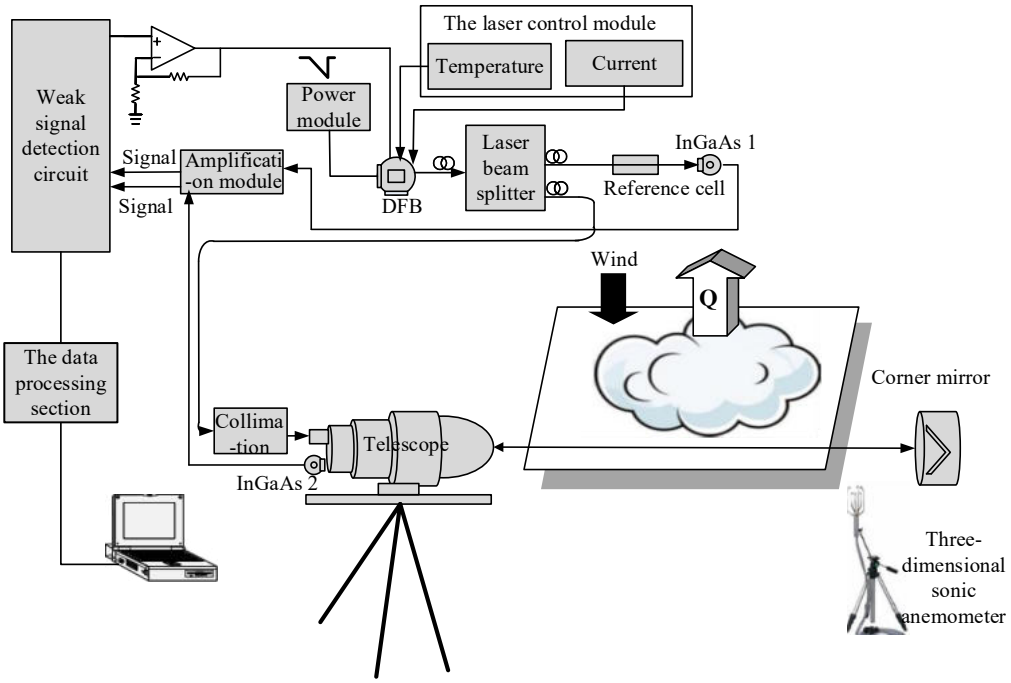

Fig. 2 - Block diagram of the system

The system block diagram is shown in Fig 2, which mainly includes a laser absorption spectrum detection device and a three-dimensional sonic anemometer. The laser absorption spectrum detection device is used to detect the methane gas concentration *(Wang et al., 2022)*. The three-dimensional sonic anemometer is used to measure three-phase orthogonal wind speed components (Ux, Uy, Uz).

The laser absorption spectrum detection device consists of a laser and its control module, an optical structure section, a reference optical cell, a calibration section, a weak signal detection circuit, and a data processing unit. A DFB laser with a center wavelength of 1653 nm - corresponding to a near-infrared single absorption line of CH_4 - is used as the detection light source. The laser control module (LDC3724B) is employed to adjust the laser's output wavelength. Driven by the scanning signal, the output wavelength of the laser is rapidly scanned around the target absorption line. The single-mode laser beam is evenly split into reference and probing optical paths. The reference beam is directed into the reference optical gas cell via the optical structure section to calibrate the standard gas. The probing beam is transmitted to the transceiver telescope of the optical structure, then reflected by a corner mirror and focused onto InGaAs photodetector 2. After passing through the weak signal detection circuit and the data processing section, the concentration of CH_4 gas is retrieved through spectral inversion.

By combining the integrated line concentration with meteorological data, the BLS model is employed to estimate gas emissions.

The height of the laser detection optical path is taken as the laser path height. A gas simulation volatilization device is used to simulate uniform methane emission.

The methane volatilization source consists of a weight sensor, a gas flow meter, high-purity sample gas, and an artificial simulated source, as illustrated in Fig. 3.

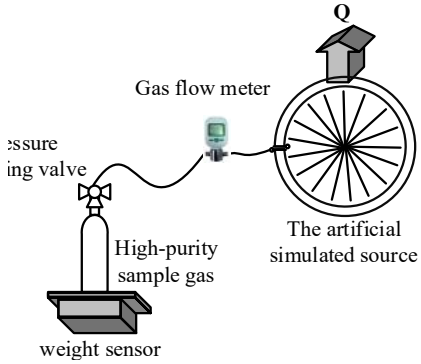

Fig. 3 - Gas simulation volatility device diagram

The weight sensor has a measuring range of 30 kg, and the measurement accuracy is 1 g, which meets the measurement needs of gas weight changes. High-purity sample gas is controlled by the gas flow meter to ensure uniform gas discharge at a uniform speed. It is sent to two connected 3x1.5 m artificial simulated sources, which are made of polyvinyl chloride with an inner diameter of 18 mm. The simulated source is provided with a diameter of 1 mm diffusion holes at every 0.3 m above it to simulate methane gas emission.

The high-purity sample gas used is methane gas (99.9% purity), which is released from the high-pressure gas cylinder at a rate of 5-40 L/min. In order to avoid the marginal effect of methane volatilization, the flux measurement is started after 5 minutes of gas release, and the duration of each release is not less than 30 minutes.

Evaluative experiment

The experiment is conducted on the experimental base adjacent to Science Island, Hefei, China. The monitoring area can be regarded as a uniform underlying surface.

Building the experimental environment

To eliminate the influence of environmental factors on the measurement results, and in alignment with the prevailing wind direction, two sets of methane flux measurement instruments - based on open-path laser absorption spectroscopy and constructed as described in Section 2 - are positioned according to the geometric layout shown in Fig. 4. Device 1 is located in an area affected by a tree, while Device 2 is placed in an assumed ideal environment, free from obstruction. Prior to the measurement experiments, a consistency analysis is conducted between the two instruments to ensure they operate under equivalent conditions. The BLS model is used to estimate the emission rate, with simulations performed using WindTrax software. A three-dimensional sonic anemometer is installed at a height of 1.35 m above the ground to record wind data.

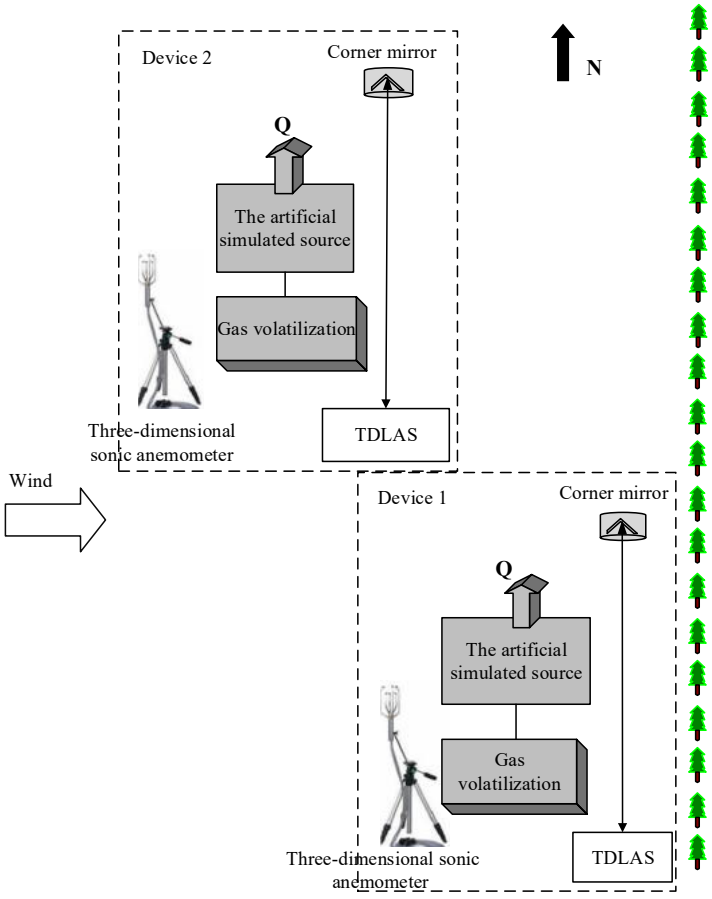

Fig. 4 - Instrument environment diagram

The experimental site is shown in Fig. 5. Both sets of instruments began data collection simultaneously. The artificial simulated sources used in the experiment have identical areas and shapes, and the distance between each laser path and the edge of the emission source is the same. However, due to slight positional deviations, the measurement locations are not identical, and weather conditions may differ slightly between the two setups.

Experiments are conducted under varying environmental conditions. The ratio of Q_{bLS} to the actual release rate Q is calculated and compared to 1 to evaluate the influence of environmental complexity.

Fig. 5 - The experimental site

Experimental design scheme

Considering the feasibility of actual measurement processes, Device 1 in the experiment is tested using two different configurations for setting up the laser path. In the first configuration, the laser path is placed at a distance of at least 0.5×x from the downwind direction, where *x* is the distance between the emission sources. In the second configuration, the laser path is positioned directly above the source and passes over it. All other construction conditions are assumed to remain unchanged.

During the first setup experiment, the measurement results from both devices are recorded simultaneously. After completing the measurement, the gas simulation volatilization device is turned off, and the system is left undisturbed for 30 minutes to minimize the residual effects of methane volatilization. The background methane concentration is then measured and assessed. Once the measurement conditions are confirmed to be stable, the second setup experiment is initiated.

In the second setup experiment, only the measurement laser path of Device 1 is altered, while the conditions for Device 2 remain unchanged and continue to represent an ideal environment. During this phase, gas emission is again simulated using the gas simulation volatilization device.

RESULTS

Methane concentration measurement consistency between two instruments

Before the measurement experiments, a consistency analysis was conducted to verify that the two instruments operate under equivalent conditions. In the laboratory, a 20 m multi-reflection gas cell was placed in the detection optical path to measure a fixed CH_4 concentration of 40 ppm. During the measurement process, after the gas was injected into the chamber, the inlet and outlet of the multi-reflection cell were sealed, ensuring that the gas concentration remained constant throughout the experiment. Both instruments continuously measured the fixed concentration for 240 minutes. The recorded signals were processed using 50-point averaging to retrieve the concentration values. The correlation coefficient for consistency between the two instruments was 0.991, while the relative errors compared to the standard gas concentration were 0.023 and 0.017, respectively. A follow-up consistency analysis was conducted in a simulated environment. Under the same experimental conditions, a rotatable thin phase screen plate was used to simulate atmospheric turbulence, incorporating a pseudo-random phase distribution that follows Kolmogorov spectrum statistics. The CH_4 concentration was maintained at 40 ppm throughout the experiment. Both instruments continuously measured the fixed concentration for 200 minutes. As in the previous test, the recorded signals were processed using 50-point averaging to retrieve the concentration values. The consistency correlation coefficient between the two instruments was 0.982, and the relative errors compared with the standard gas concentration were 0.059 and 0.067, respectively. These results indicate that both instruments demonstrate good consistency. Although the correlation decreased and the relative errors increased in the simulated turbulent environment, this degradation is attributed to environmental noise. Nonetheless, both instruments are capable of accurately and consistently measuring line concentration.

Analysis of experimental results from two instrument setups with different laser paths

Experiments were conducted under different environmental conditions using two distinct laser path configurations. The two instruments were tested simultaneously. The ratio of Q_{bLS} to the actual release rate Q was calculated and compared to 1. The results obtained from the two laser path configurations are presented in Tables 1, 2, and 3.

Table 1

Measurement results of Device 2 under ideal environmental conditions

It can be seen from the measurement results in Fig. 6 and Fig.7.

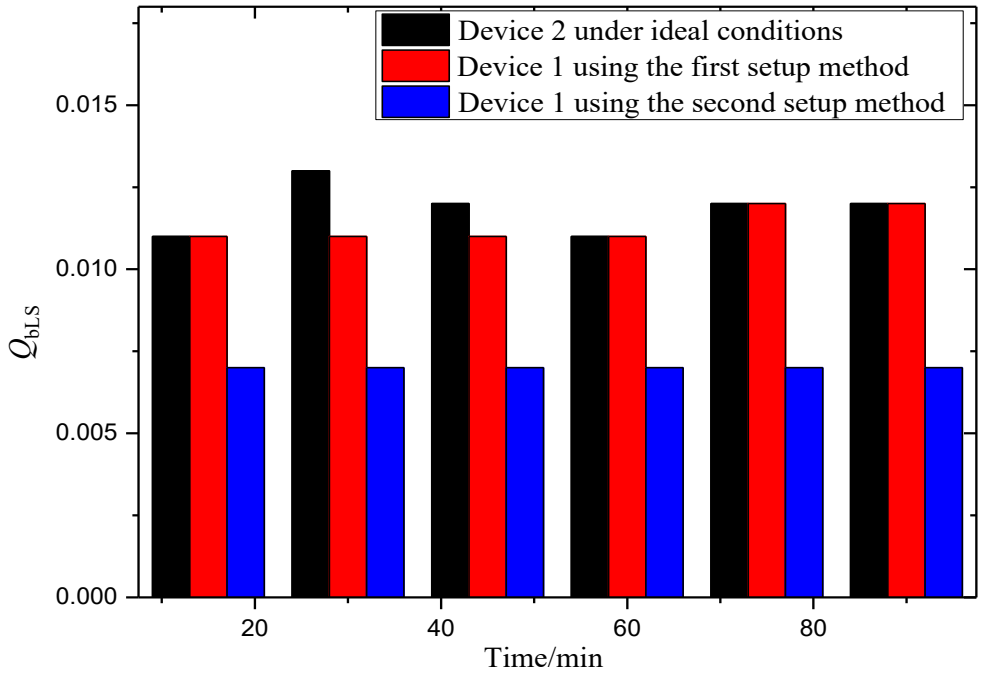

Fig. 6 - Measurement results Q_{bLS} for the two devices

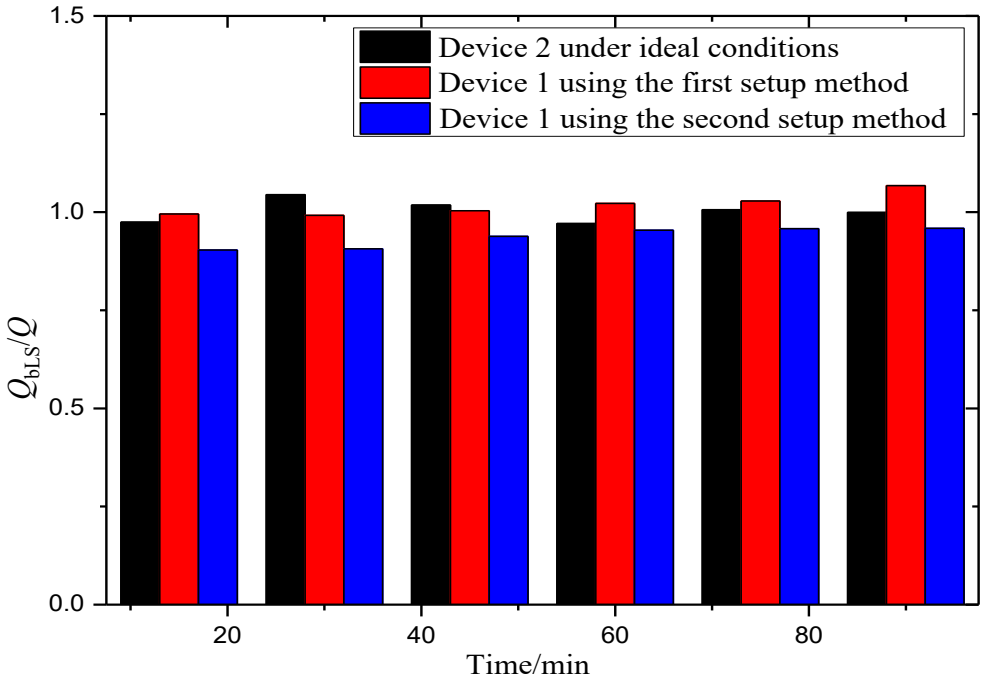

Fig. 7 - Measurement results Q_{bLS}/Q for the two devices

The results indicate that the standard deviation of Q_{bLS}/Q in the ideal environment is 0.0277. For Device 1, the standard deviation is 0.0283 when the laser path is placed downwind of the source, and 0.0256 when the laser path is placed directly above the source. The maximum fluctuation amplitudes of Q_{bLS}/Q are 7.3%, 7.4%, and 5.9%, respectively. Although Device 2, operating under ideal conditions, yields a Q_{bLS}/Q ratio closest to 1 - indicating the highest accuracy - both setup methods used with Device 1 remain within an acceptable error range. Among them, the second setup (with the laser path above the source) performs better. These results suggest that in the presence of a row windbreak assumed to be located downwind of the emission source, the estimation error in gas flux can be effectively reduced by selecting an optimal measurement configuration.

When measuring an actual large-scale surface source, measurements are taken from the downwind direction of the source. The optical path can be set directly above, across, or near the vertical downwind direction of the source.

CONCLUSIONS

In the process of measuring agricultural gas flux emissions, the presence of windbreaks can introduce environmental interference and complicate measurements. To address this issue, a methane flux measurement system based on open-path laser absorption spectroscopy was developed. Experiments were conducted under three conditions: an ideal environment, a setup with the laser path downwind of the source, and a setup with the laser path directly above the source. The results show that the standard deviation of Q_{bLS}/Q in the ideal environment is 0.0277, compared to 0.0283 when measured from the downwind direction of the source, and 0.0256 when measured directly above the source. The corresponding maximum fluctuation amplitudes of Q_{bLS}/Q are 7.3%, 7.4%, and 5.9%, respectively. These results indicate that for a row windbreak located downwind of the emission source, measurement accuracy can be improved by selecting an optimal measurement configuration.

When measuring emissions from a large-scale surface source, the recommended approach is to position the optical path in the downwind direction - either above, across, or near the vertical axis of the source. This configuration reduces local environmental interference from windbreaks located upwind and enables accurate measurement of farmland gas emissions.

Keywords: *early bruise detection, MCC-DeepLabV3+, near infrared imaging, semantic segmentation, 'Huangguan' pear*

ABSTRACT
Due to their delicate and thin skin, 'Huangguan' pears are very vulnerable to pressure and impact during picking, packing and transportation, which can cause bruising. Early detection of bruises allows for timely identification of affected fruits to reduce potential food safety risks. However, early bruises in 'Huangguan' pears, particularly those that occur within the 30 minutes, often show no visible differences in external features compared to healthy tissue, making conventional techniques such as manual and machine vision sorting ineffective. Accordingly, a near-infrared (NIR) camera imaging technique combined with deep learning segmentation algorithm for early bruise 'Huangguan' pears detection is proposed in this study. Firstly, a near-infrared camera imaging system is applied to collect early bruise images of 'Huangguan' pears, and then a lightweight segmentation model based on the DeepLabV3+ architecture, referred to as MCC-DeepLabV3+ is presented. In the MCC-DeepLabV3+ model, MobileNetV2 is used as the backbone network, reducing the parameter size and enhancing deployment efficiency. Additionally, the coordinate attention (CA) mechanism is integrated into the shallow feature extraction and ASPP modules to improve the extraction of positional information across various features, minimizing the discrepancy between segmented areas and the actual bruised regions. Furthermore, a cascade feature fusion (CFF) strategy is incorporated into the encoder to reduce segmentation edge discontinuities and ensure effective multi-level semantic fusion, improving segmentation accuracy. The experimental results show that the proposed model has achieved a mIoU of 95.68%, and mPrecision of 97.58% on the self-built dataset of early bruising in 'Huangguan' pears. Compared to benchmark models such as U-Net, SegNet, PSPNet and HRNet, the proposed model demonstrates superior segmentation performance, offering promising support for the development of nondestructive detection techniques for agricultural product quality.

摘要
由于黄冠梨的表皮细腻而娇嫩，在采摘、包装和运输过程中非常容易受到压力和冲击，这可能导致瘀伤。早期发现瘀伤可以及时识别受影响的水果，有助于减少潜在的食品安全风险。然而，皇冠梨的早期瘀伤，特别是那些在 30 分钟内发生的瘀伤，与健康组织相比，通常在外部特征上没有明显的差异，这使得人工和机器视觉分类等传统技术的效果不佳。因此，本研究提出了一种结合深度学习分割算法的近红外(NIR)相机成像技术用于早期皇冠梨瘀伤检测。首先，采用近红外相机成像系统采集黄冠梨的早期瘀伤图像，然后，提出了一种基于 DeepLabV3+架构的轻量级分割模型，称为 MCC-DeepLabV3+。该模型采用 MobileNetV2 作为骨干网络，减少了参数大小，提高了部署效率。此外，将坐标注意（CA）机制集成到浅层特征提取和 ASPP 模块中，提高了不同特征之间的位置信息提取，最大限度地减少了分割区域与实际损伤区域之间的差异。在编码器中引入级联特征融合（CFF）策略，减少了分割边缘不连续，保证了有效的多级语义融合，提高了分割精度。实验结果表明，在自建的黄冠梨早期瘀伤数据集上，该模型的 mIoU 和 mPrecision 分别达到了 95.68%和 97.58%。与 U-Net、SegNet、PSPNet 和 HRNet 等基准模型相比，该模型显示出优越的分割性能，为水果早期无损检测技术的发展提供了有力的支持。

INTRODUCTION

"Huangguan" pear is a high-quality pear variety widely grown in China, which has become an important cash crop in many areas because of its attractive appearance, delicate texture and high yield. However, the soft structure and high water content of 'Huangguan' pears make them susceptible to physical trauma or impact damage during harvesting, packing and transport, resulting in early tissue bruising. Bruising is usually defined as damage to the subcutaneous tissue of fresh produce that does not result in rupture of the epidermis *(Al-Dairi et al., 2024*). Early bruises in 'Huangguan' pears are cosmetically indistinguishable from healthy tissue and are difficult to detect with the naked eye, but they provide an ideal environment for microbial colonisation. If early damage is not detected and treated in a timely manner, the resulting microorganisms may spread and infect other healthy fruits, thus seriously affecting product quality and economic value *(Opara et al., 2014)*. Traditionally, testing the quality of 'Huangguan' pears in packinghouses has relied on manual inspection by trained professionals *(Patel et al., 2024)*, but this method is highly subjective and suffers from limitations such as time-consuming, labour-intensive and the possibility of secondary damage to the fruit *(Li et al., 2024)*. To cope with these shortcomings, machine vision technology based on RGB images is widely used *(Manavalan, 2020; Arumuga et al., 2023; Tian et al., 2024)*. The technology achieves a reduction in labour costs and the rate of misjudgement as well as an increase in detection speed during the inspection process by capturing RGB images of fruits and combining them with image processing algorithms *(Du et al., 2020)*. However, since the RGB image inspection method relies on surface visible light information, its detection effect is mainly limited to surface defects visible to the naked eye and restricted to early bruises or internal damage hidden under the fruit skin *(Li et al., 2021)*. Therefore, this method still has significant shortcomings in meeting the needs of early bruise detection.

It is well known that when fruit undergoes physical trauma, the pulp tissue is damaged and a series of complex physiological and biochemical reactions occur at the site of injury, altering the density and vibrational strength of the molecular bonds *(Li et al., 2018)*. These changes affect the sugar and water content, which leads to alterations in optical properties, making it possible to utilize optical properties for early identification of internal damage. Several studies have used hyperspectral imaging to extract spectral information to evaluate the intrinsic and extrinsic qualities of fruit. *Zhu et al., (2016)* applied hyperspectral imaging and chemo-metrics to predict the integrated quality of tomato non-destructively and determine the optimal harvesting period. *Wu et al., (2023)* used HSI combined with spectral and texture features to detect and classify early damage of Lingwu longdate based on 1D convolutional neural network (1D-CNN). *Liu et al., (2023)* used hyperspectral imaging, transfer learning and convolutional neural network modelling techniques to detect early mechanical damage in pears, and the resulting model achieved an accuracy of 96.61% on the test set, which was 3.64% higher than the pre-fine-tuning network. The above studies show that HSI performs well in fruit damage detection, but it faces challenges in practical applications such as high equipment cost, complex data processing and high computational resource requirements *(Mei et al., 2023)*. Compared with hyperspectral imaging and processing, NIR imaging offers simpler data processing, eliminating the need to analyse large amounts of spectral band information, which significantly simplifies data processing and reduces inspection costs. Due to the higher absorption of NIR light by bruised tissue, NIR cameras are able to acutely capture subcutaneous damage that cannot be identified by the naked eye and visible light, and visualise healthy tissue and damaged areas by combining spectral information with spatial information *(Ünal et al., 2024)*. In addition, the high sensitivity of NIR cameras to changes in key components such as moisture and sugar, as well as their small size and light weight, make them ideal for early bruise detection in fruit.

Based on near infrared imaging, traditional machine learning techniques are combined for fruit damage detection. *Nandi et al., (2016),* proposed an automatic mango ripeness grading method based on support vector machines (SVM) and fuzzy learning, achieving a grading accuracy of 87%. *Hu et al., (2018)* developed an algorithm for bruised apple identification using 3-D infrared imaging, featuring a vertex-based local binary pattern (vmLBP) for feature extraction and SVM for classification. The algorithm achieved a 91.83 ± 0.46% accuracy, outperforming traditional methods. However, the performance of machine learning models is highly dependent on feature selection, requiring manual elimination of redundant features or identification of the most representative information to minimize the effect of irrelevant input variables *(Li et al., 2022)*, which is not only time-consuming but also depends on expert knowledge. In contrast, due to its powerful feature learning capabilities, deep learning has become an alternative technology in several areas of agriculture *(Attri et al., 2023)*, such as pest and disease detection *(Shafik et al., 2024)*, crop yield estimation *(Barbosa et al., 2021)*, water management *(Chen et al., 2021)*, and soil analysis *(Zhong et al., 2021)*.

Deep learning automatically learns important features from images through multi-layer neural networks, significantly simplifying the feature extraction process, thereby eliminating the reliance on experts to manually select features *(Wu et al., 2020)*.This process not only improves classification accuracy but also reduces human intervention. In recent years, deep learning has demonstrated notable advantages in computer vision and agricultural applications. *Yuan et al., (2022),* developed an early bruise detection system for apples by combining near-infrared imaging with deep learning, achieving an accuracy rate exceeding 99%. The powerful learning and inference capabilities of deep learning give it a clear edge in fruit damage detection tasks, enabling more accurate and efficient automated detection.

Based on the analysis of the aforementioned detection methods and deep learning techniques, this paper proposes a method for early bruise detection in 'Huangguan' pears that integrates near-infrared imaging technology with deep learning algorithms. DeepLabV3+ *(Chen et al., 2018),* as a basic framework for segmentation model is employed for detecting damaged regions in near-infrared images of 'Huangguan' pears, with MobileNetV2 *(Sandler et al., 2018)* chosen as the backbone network to reduce the model's parameter size. Additionally, the coordinate attention (CA) *(Hou et al., 2021)* mechanism is introduced at both shallow and deep feature levels within the encoder to enhance the model's ability to detect bruise regions and improve segmentation accuracy. Furthermore, the cascade feature fusion (CFF) *(Zhao et al., 2018)* strategy is incorporated to better integrate shallow and deep semantic features, thereby enhancing the continuity of edge detection. Experimental results demonstrate that the improved model achieves early bruise detection in 'Huangguan' pears with a model size of only 6.103MB, while key metrics, such as mIoU and mPrecision, reach 95.68% and 97.58%, respectively, significantly improving both detection efficiency and accuracy.

MATERIALS AND METHODS

Experimental samples and damage device

The skin colour of 'Huangguan' pears closely resembles the colour of bruising in its early stages, making bruise identification particularly challenging. Bruise samples of 'Huangguan' pear were prepared as shown in Figure 1.

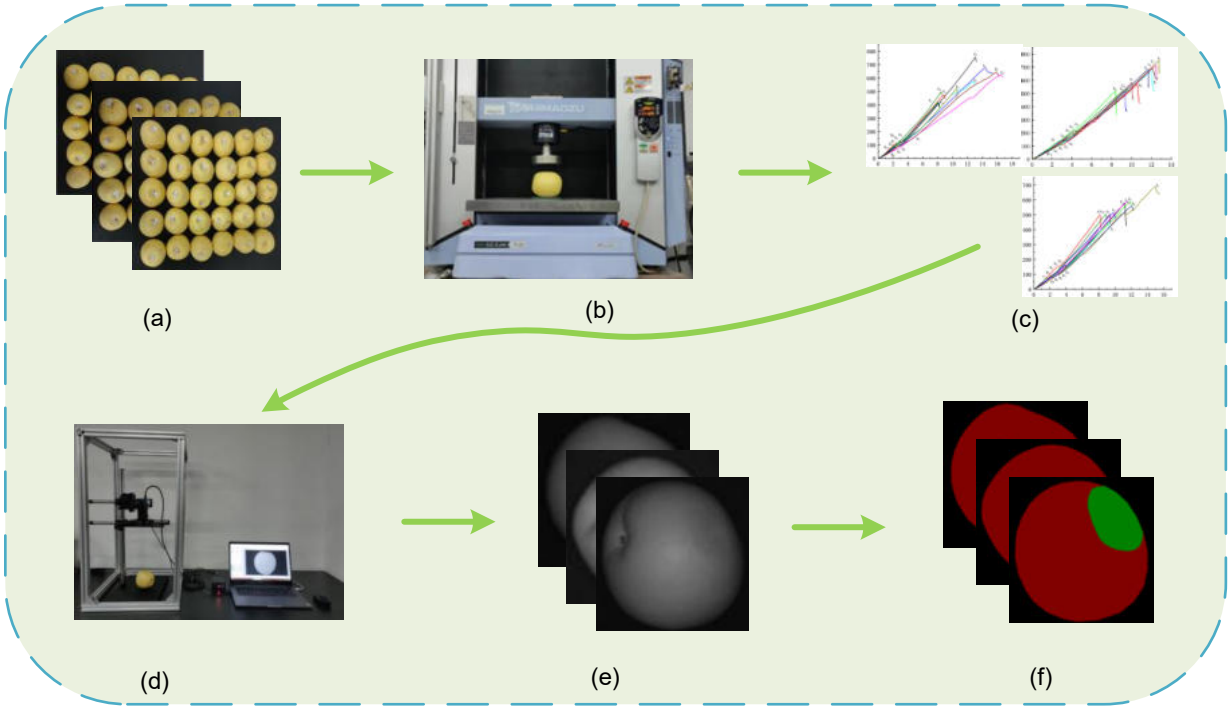

Fig. 1 - Process of bruise sample and data preparation

A total of 120 'Huangguan' pears, free of damage and disease, were purchased from a supermarket and stored at room temperature. These pears were categorized into three groups based on size: large, medium, and small, as shown in Figure 1(a). The diameters of the large pears ranged from 90 to 100 mm, medium pears from 80 to 90 mm, and small pears from 70 to 80 mm.

Since early-stage bruises on 'Huangguan' pears are not visible to the naked eye, it is difficult to obtain naturally bruised pears. Therefore, the bruised pear samples were artificially created. To simulate various levels of compressive bruising, a universal testing machine was used to perform mechanical compression tests, as shown in Figure 1(b). First, ten pears from each size group were randomly selected for preliminary compression tests to determine their biological yield and rupture points, providing a reference for pressure control during the bruise sampling process. The results, shown in Figure 1(c), indicated that the rupture force range for large pears was between 515.73 N and 749.91 N, for medium pears between 457.87 N and 755.73 N, and for small pears between 414.91 N and 689.29 N. Then, it was determined that the maximum lower bound of the rupture force range was 515.73 N, and the minimum upper bound was 689.29 N. For the subsequent bruise sampling, 90 pears were subjected to forces ranging from 520 to 680 N. To simulate varying degrees of internal bruising that 'Huangguan' pears may experience during harvesting and transport, a universal material testing machine applied pressure to the equatorial region of the pears. The pressure was initially set at 520 N and incrementally increased by 10 N until it reached 680 N.

Near infrared camera imaging system and image acquisition process

A NIR camera employed as the imaging device in this experiment is the IUA4100KPA model, manufactured by Hangzhou Jiecheng Instrument Co., Ltd., which features a Sony sensor with a resolution of 2688 × 1520 pixels and a maximum frame rate of 90 frames per second. The lens used is a C-M0418IR (3MP) high-definition industrial lens produced by FordTech, ensuring high-resolution, high-quality image capture suitable for precise detection of surface bruises on 'Huangguan' pears. The imaging system, shown in Figure 1(d), comprises a ring light source, a dark box, and a stand, providing stable and uniform illumination. The camera and lens are positioned at the centre of the ring light source, with the samples placed on a black background plate. The height and aperture of the lens were adjusted for optimal imaging conditions, and the camera's aperture and focal length were fine-tuned to ensure clarity and high resolution. This imaging system minimizes environmental interference and provides consistent, accurate image acquisition, laying a robust foundation for subsequent image processing and analysis.

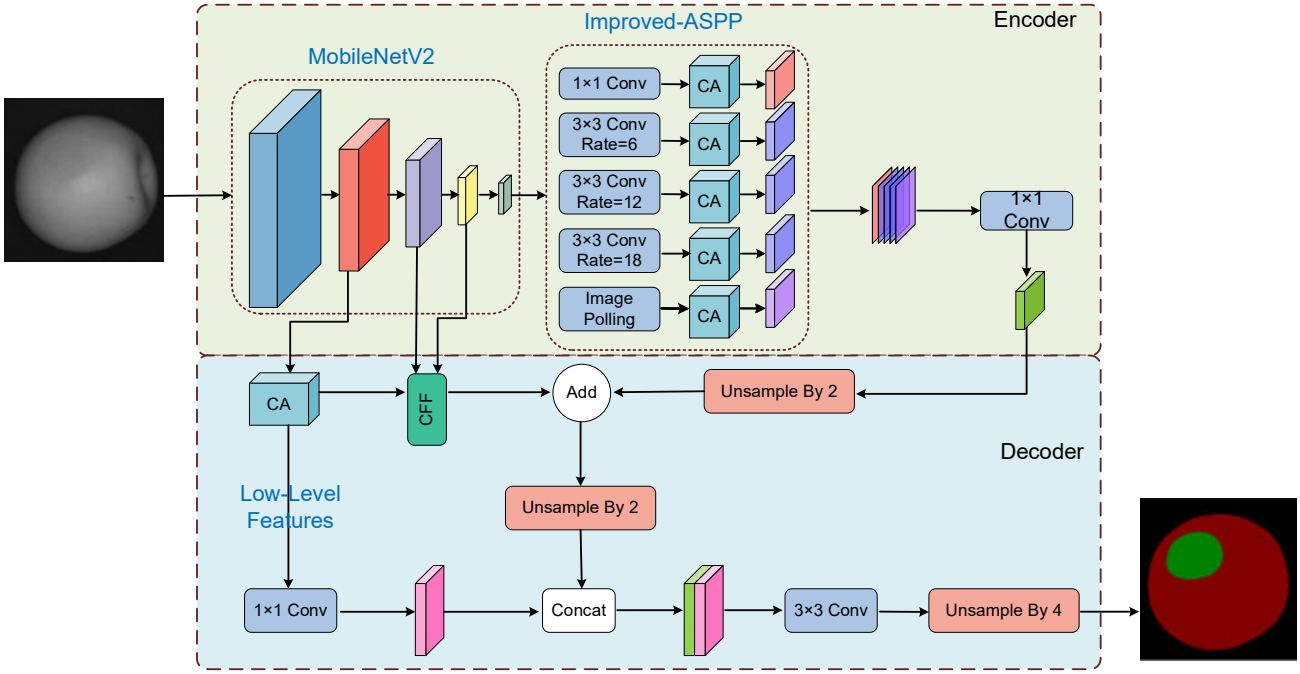
Immediately after pressure application and bruise induction, NIR images were captured and subsequently collected at 10 min, 20 min, and 0.5 hour intervals to enrich the sample set. To ensure the diversity and comprehensiveness of the dataset, images were taken from multiple angles and positions. After removing unclear or substandard images, a final dataset consisting of 2700 high-quality NIR images of bruised 'Huangguan' pears was obtained, as shown in Figure 1(e). These images were annotated using LabelImg software, where the intact regions of the pears were marked in red, and the bruised regions were highlighted in green. A visualization of the labelled images is shown in Figure 1(f). The dataset was ultimately divided into training, validation, and test sets in an 8:1:1 ratio, comprising 2160, 270, and 270 images, respectively.

DESIGN OF BRUISE SEGMENTATION MODEL

DeepLabV3+ is a state-of-the-art deep learning-based semantic segmentation model designed to address the challenges of spatial information loss and low-resolution outputs commonly encountered in traditional convolutional neural networks for segmentation tasks. Its key innovations include the incorporation of atrous convolution and encoder-decoder architecture, which significantly enhance feature extraction capabilities and improve the resolution of segmentation results. In the model architecture, the input image is first processed by the backbone network, Xception, which extracts hierarchical features: shallow features that retain spatial details and deep features that encode rich contextual semantics. The deep features are then refined through the atrous spatial pyramid pooling (ASPP) module, which employs atrous convolutions with varying dilation rates and global pooling to effectively capture multi-scale contextual information and enrich feature representation. During the decoding stage, low-resolution deep feature maps are upsampled and fused with high-resolution shallow feature maps. This fusion process, followed by additional convolutional operations, restores the spatial resolution of the feature maps to match that of the input image, ultimately producing precise and high-quality segmentation outputs.

Although DeepLabV3+ demonstrates strong performance in multi-scale feature processing and output resolution enhancement, it exhibits certain limitations when applied to the segmentation of early bruise regions in near-infrared images of 'Huangguan' pear. The early bruise regions have minimal visual differences compared to healthy areas, particularly at the boundaries, making them challenging to distinguish, which leads to segmentation discontinuities and missed detections around these boundaries.

Furthermore, the high computational complexity of Xception as the backbone network restricts the model's scalability and efficiency in processing large-scale mass near-infrared datasets. To address these challenges, this paper proposes an improved model, MCC-DeepLabV3+. First, the original Xception backbone is replaced with MobileNetV2, which significantly reduces both the parameter count and computational complexity while retaining robust feature extraction capabilities. Second, a coordinate attention (CA) mechanism is integrated into the shallow features and ASPP modules of the backbone network. This enhancement improves the model's ability to capture spatial information at multiple feature levels, thereby increasing segmentation accuracy and mitigating missed detections. Finally, a cascaded feature fusion (CFF) strategy is introduced during the fusion of shallow and deep features. This strategy ensures a more effective integration of multi-level semantic information, addressing edge discontinuities and further improving the overall segmentation quality. The architecture of the improved model is illustrated in Figure 2.



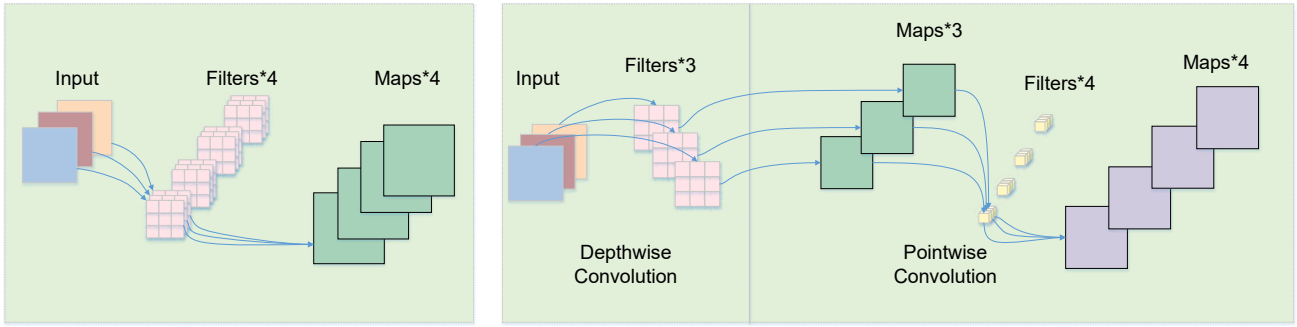


Fig. 2 - The structure of the improved DeepLabV3+ model for bruise 'Huangguan' pear detection

Lightweight backbone network

The Xception network, employed in DeepLabV3+, possesses robust feature extraction capabilities. However, its architecture, composed of numerous stacked convolutional layers, involves extensive multi-level computations, leading to a high parameter count and significant computational complexity. This computational burden presents a bottleneck for the early bruise segmentation task of 'Huangguan' pears, where rapid processing of large-scale near-infrared images is required. To address this issue, the MCC-DeepLabV3+ model replaces Xception with MobileNetV2. MobileNetV2 is a lightweight network architecture that leverages depthwise separable convolutions instead of standard convolutions, significantly reducing the parameter count and computational complexity. Additionally, its inverted residual structure minimizes feature redundancy while maintaining high representational power, enabling efficient feature extraction with a low computational cost.

(a) standard convolution *(b) depth separable convolution*

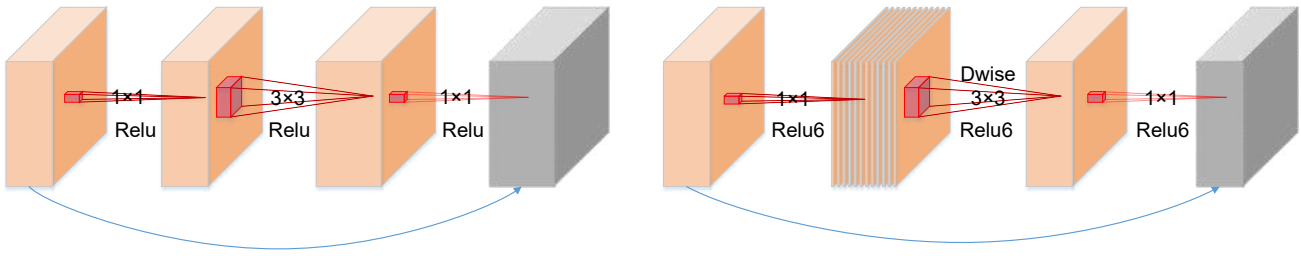
Fig. 3 - Structures of standard convolution and depth-separable convolution

Depthwise separable convolution is the core operation in MobileNetV2 for achieving model lightweighting. It decomposes the standard convolution operation into two independent steps: depthwise convolution (DW) and pointwise convolution (PW), effectively reducing the computational load of the model. As shown in Figure 3, compared with standard convolution, depthwise separable convolution is divided into two parts: first, depthwise convolution performs convolution independently on each input channel to extract spatial features; then, pointwise convolution applies 1×1 convolutions to perform point-by-point operations, linearly combining features from different channels and fusing spatial and channel information. This decomposition significantly reduces the computational complexity.

Specifically, as shown in Figure 3, depthwise convolution (DW) extracts spatial features by independently processing each input channel, while pointwise convolution (PW) fuses spatial and channel information through 1×1 convolutions. The computational complexity of depthwise separable convolution can be represented by the following two formulas:

$$C_{DW} = M \times D_F \times D_F \times D_K \times D_K \quad (1)$$

$$C_{PW} = M \times N \times D_F \times D_F \quad (2)$$



where D_F is the dimension of the feature map, D_K represents the size of the convolution kernel, M is the number of input channels, and N is the number of output channels.

Under equations (1) and (2), the total computation of the depth separable convolution can be expressed as Eq.(3). In contrast, the standard convolution is computationally intensive, which is calculated as Eq.(4). Comparing Eq. 3 and Eq. 4, it can be seen that the computational complexity of the depth-separable convolution is reduced to $\frac{1}{N}+\frac{1}{D_K^2}$ of the standard convolution, which allows MobileNetV2 to maintain a high feature extraction capability while reducing the computational effort.

$$C_{DS} = C_{DW} + C_{PW} = M \times D_F \times D_F \times D_K \times D_K + M \times N \times D_F \times D_F \quad (3)$$

$$C_{SC} = M \times N \times D_F \times D_F \times D_K \times D_K \quad (4)$$

In addition, MobileNetV2 introduces a novel inverted residual block, optimized based on traditional residual networks. While traditional residual networks mitigate the vanishing gradient problem through skip connections, the inverted residual block enhances computational efficiency and feature representation through a “dimensionality enhancement-extraction-dimensionality reduction” design, as illustrated in Figure 4. Specifically, the 1×1 convolution is used to reduce dimensions initially, followed by 3×3 depthwise separable convolution for feature extraction, and finally, another 1×1 convolution to restore the feature dimensions. The use of a linear activation function Relu6 helps to minimize feature loss during dimensionality reduction and improves the efficiency of information flow. Thus, by introducing deeply separable convolutions and inverted residual structures, MobileNetV2 reduces the model’s parameter count while maintaining strong feature extraction capabilities.

Fig. 4 - The structure of inverted residual network

Introduction of CA attention mechanism

In semantic segmentation tasks, the traditional DeepLabV3+ model relies on shallow features to provide spatial information and utilizes the ASPP module to extract multi-scale contextual information. However, this architecture exhibits certain limitations. Firstly, shallow features are different to capture the global positional information of bruise regions due to their small receptive fields. Secondly, the ASPP module demonstrates relatively weak capability in capturing spatial location information, although it focuses on aggregating cross-scale semantic features.

These challenges are exacerbated in the segmentation of early bruises in 'Huangguan' pears, where the subtle visual differences between healthy and bruised regions, combined with blurred boundaries, significantly increase the segmentation difficulty. To address these issues, this paper introduces the coordinate attention (CA) mechanism into the shallow feature and ASPP modules of the MCC-DeepLabV3+ model to enhance their spatial localization capabilities. In the shallow feature extraction stage, the CA mechanism strengthens the representation of local spatial details in bruise regions by leveraging cross-channel information modeling and orientation-awareness properties. In the ASPP module, the CA mechanism compensates for its inherent limitations in capturing spatial location information, enabling the model to more accurately perceive the boundary positions of bruise regions. This enhancement effectively improves the spatial localization capability of the model, thereby increasing the accuracy and continuity of boundary segmentation for early bruise regions in 'Huangguan' pears. Therefore, the introduction of the coordinate attention (CA) mechanism enables the encoding of channel relationships and remote dependencies based on precise location information, and the structure is shown in Figure 5.

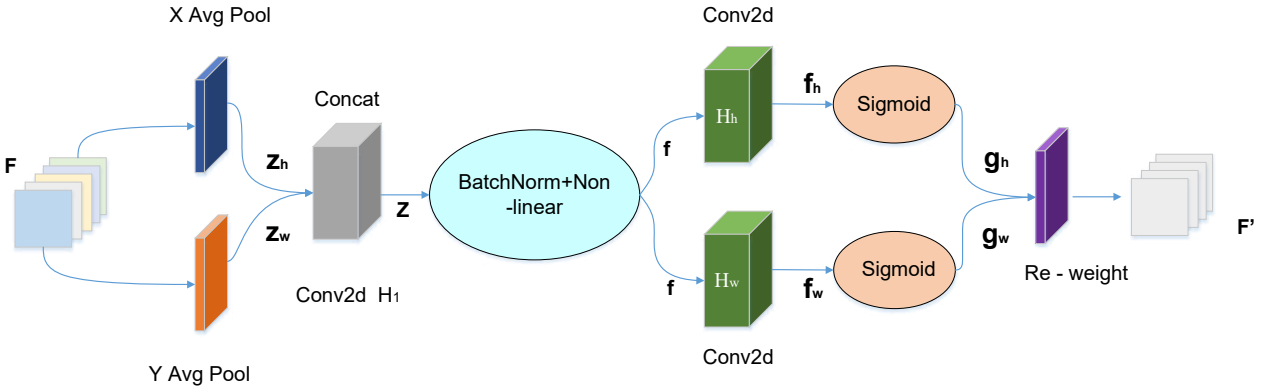

Fig. 5 - Structure of the coordinate attention mechanism module

From Figure 5, to globally encode the height H and width W directions of the input feature map **F**, the CA mechanism implements a global average pooling operation along the H and W directions, respectively, which generates the corresponding two 1D feature maps $\mathbf{z_h}$ and $\mathbf{z_w}$, as follows:

$$\mathbf{z_h}(h)=\frac{1}{W}\sum_{i=0}^{W}x_c(h,i)\ ,\ \mathbf{z_w}(w)=\frac{1}{H}\sum_{j=0}^{H}x_c(j,w) \tag{5}$$

where $\mathbf{z_h}$ and $\mathbf{z_w}$ denote the aggregation results of the feature map in the H and W directions, respectively. The $\mathbf{z_h}$ and $\mathbf{z_w}$ obtained above are spliced and downscaled by a 1×1 Conv H_1 operation to generate an intermediate feature map **Z** of size $C/r\times1\times(W+H)$, where r is the channel reduction ratio. Next, batch normalization and nonlinear activation operations are applied to **Z** to obtain the processed feature map **f**, where δ denotes the nonlinear activation operation.

$$\mathbf{Z}=\mathrm{H}_1\left[\mathbf{z_h},\mathbf{z_w}\right] \tag{6}$$

$$\mathbf{f}=\delta\left[\mathrm{BN}(\mathbf{Z})\right] \tag{7}$$

Then, **f** is split into $\mathbf{f_h}$ and $\mathbf{f_w}$ in both H and W directions and the attention weights $\mathbf{g_h}$ and $\mathbf{g_w}$ are computed by 1×1 Conv H_h, H_w operations and Sigmoid activation function, respectively:

$$\mathbf{g_h}=\sigma\left[\mathrm{H_h}\left(\mathbf{f}_h\right)\right]\ ,\ \mathbf{g_w}=\sigma\left[\mathrm{H_w}\left(\mathbf{f_w}\right)\right] \tag{8}$$

where σ denotes the Sigmoid function.

Finally, the input feature maps are multiplied with the generated attention weights $\mathbf{g_h}$ and $\mathbf{g_w}$ in the X and Y directions, respectively, to obtain the final feature maps after fusing the attentional information:

$$\mathbf{F}^{'}=\mathbf{F}\otimes\mathbf{g_h}\otimes\mathbf{g_w} \tag{9}$$

Integration of CFF module

In DeepLabV3+, the backbone network generates features at varying levels of abstraction during feature extraction. Shallow features are particularly effective for pixel-level localization tasks and ability to excel at capturing edge details and local information due to their high resolution. In contrast, deep features are progressively abstracted and aggregated through a multi-layer network, encapsulating rich global semantic information, which helps in understanding overall image context and category differentiation. Effective fusion of shallow and deep features is the key to achieving a more comprehensive and robust feature representation. However, the traditional DeepLabV3+ decoder employs a simple concatenation method for feature fusion, which inadequately addresses the distinct characteristics and synergistic relationships between shallow and deep features. This limitation can result in the loss of critical detail information, particularly in challenging scenarios such as segmenting bruised areas with blurred boundaries. Consequently, issues such as edge discontinuities and breaks may arise, significantly compromising segmentation accuracy.

To address these challenges, this study introduces the cascaded feature fusion (CFF) module to more effectively integrate shallow and deep features. The core processes of the CFF module are illustrated in Figure 6. First, the shallow feature map $\mathbf{F_1}$ undergoes a 3×3 dilated convolution with a dilation rate of 2 to adjust the channel dimensions. Simultaneously, the deep feature map $\mathbf{F_2}$ is upsampled by a factor of two using bilinear interpolation, followed by the same dilated convolution operation to align its dimensions and receptive field with $\mathbf{F_1}$. This approach not only ensures feature resolution consistency but also expands the receptive field, enabling the capture of richer contextual information while reducing computational overhead. Next, batch normalization is applied to both feature maps to standardize data distribution, which accelerates network training and enhances model convergence. Finally, the normalized $\mathbf{F_1}$ and $\mathbf{F_2}$ are element-wise added, and the result is processed through a ReLU activation function to produce the fused feature map, denoted as $\mathbf{F_{12}}$.

The integration of the CFF module enables a more effective combination of the edge detail information from shallow features and the global semantic information from deep features. This enhancement significantly improves segmentation accuracy for bruised areas while ensuring smoother and more continuous boundary delineation. Moreover, the optimized design of the CFF module reduces computational costs, thereby improving overall segmentation efficiency.

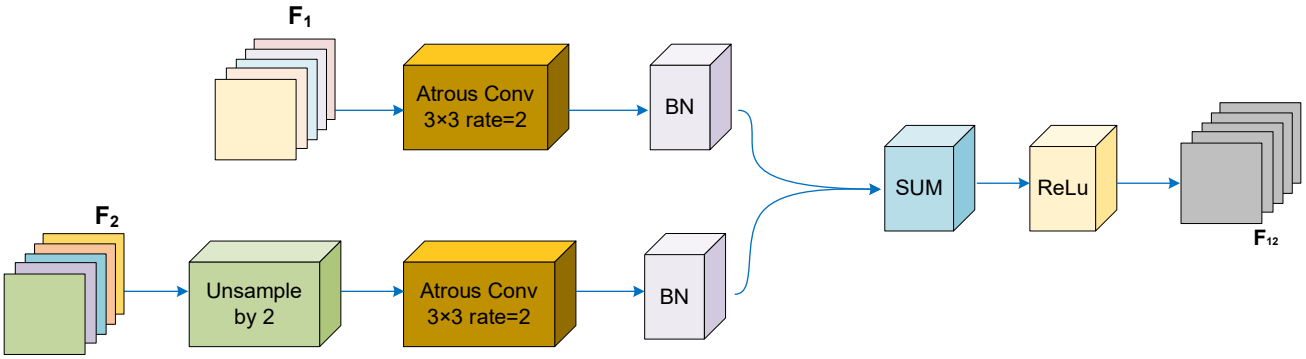

Fig. 6 - Structure of the cascaded feature fusion module

RESULTS AND ANALYSIS

Experimental setup and evaluation metrics

The experiment uses Windows11 operating system. The hardware platform employs Intel I7-11700K CPU and NVIDIA GeForce RTX 4080 GPU with 32G video memory. Network construction, debugging, training and testing are carried out under the Pytorch framework based on the Python language, in which the torch version is 1.13 and the CUDA version is 12.1. The size of the input image is set to 512×512, and the batch size and the number of iterations are set to 2 and 300, respectively, for the training process. In the experiment, the initial learning rate is set to 0.01, and the model is optimized by using SGD. The network is initialized by loading pre-training weights.

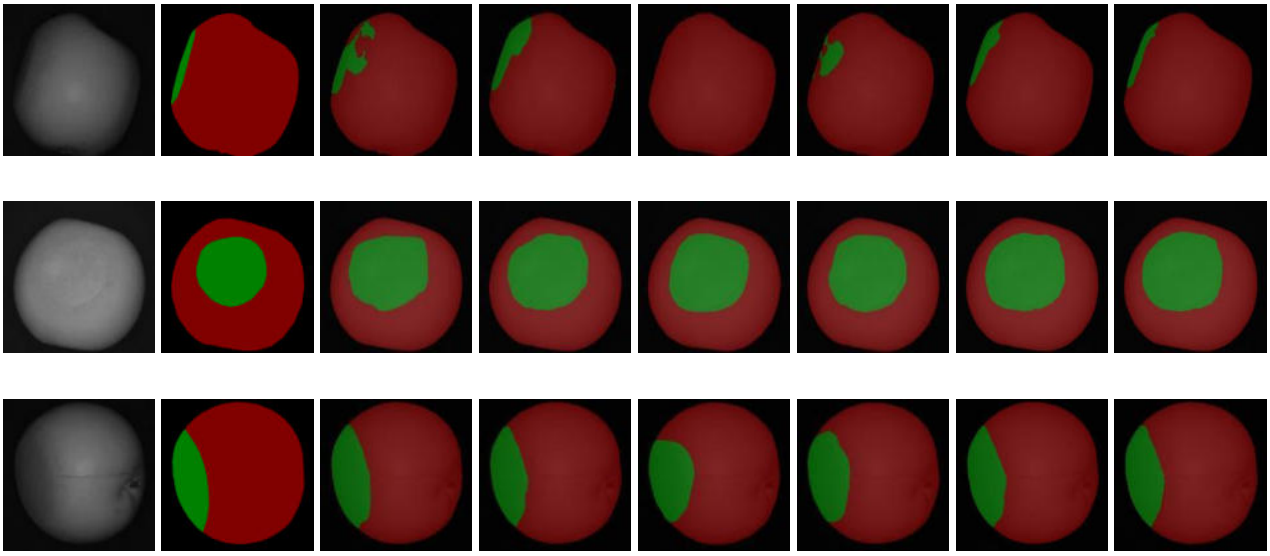
For quantitatively comparing the performance of semantic segmentation network models in detecting bruises on 'Huangguan' pears, four evaluation metrics were used: mean Intersection over Union (mIoU), mean Pixel Accuracy (mPA), mean Precison (mPrecision) and mean Recall (mRecall). mIoU is the ratio of the intersection to the union of the ground truth and predicted labels, averaged over all classes. mPA represents

the proportion of correctly classified samples, providing an intuitive measure of overall performance. mPrecision refers to the proportion of true position samples among those predicted as positive by the model, which serves as an evaluation of the model's accuracy in predicting positive cases. mRecall measures the model's ability to correctly identify positive samples, indicating the proportion of true positive samples correctly predicted from all actual positive samples. The four evaluation metrics are defined as follows:

$$mIoU = \frac{1}{k+1}\sum_{i=0}^{k}\frac{TP}{TP+FP+FN} \tag{10}$$

$$mPA = \frac{1}{k+1}\sum_{i=0}^{k}\frac{TP+TN}{TP+TN+FP+FN} \tag{11}$$

$$mPecision = \frac{1}{k+1}\sum_{i=0}^{k}\frac{TP}{TP+FP} \tag{12}$$



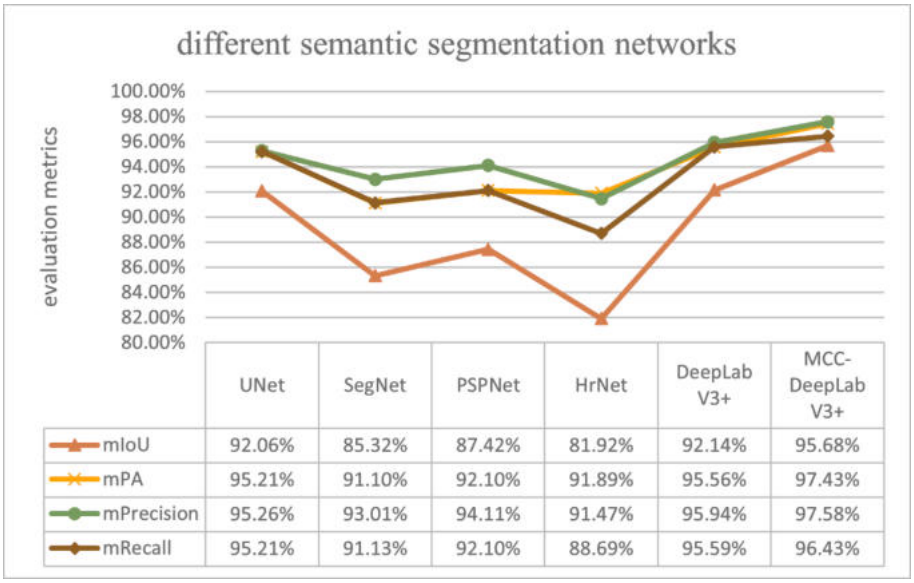
$$mRecall = \frac{1}{k+1}\sum_{i=0}^{k}\frac{TP}{TP+FN} \tag{13}$$

In the above formulas, TP (True Positive) refers to cases where the prediction is positive and the ground truth is also positive. FP (False Positive) denotes situations where the prediction is positive but the ground truth is negative. FN (False Negative) refers to instances where the prediction is negative but the ground truth is positive. TN (True Negative) indicates cases where both the prediction and the ground truth are negative.

Comparison experiment of different models

To verify the effectiveness of the proposed MCC-DeepLabV3+ model in early bruise segmentation of 'Huangguan' pears, it is compared with five classical segmentation models: UNet (*Ronneberger et al., 2015*), SegNet (*Badrinarayanan et al., 2016*), PSPNet (*Zhao et al., 2017*), HrNet (*Sun et al., 2019*), and DeepLabV3+. The experiments were conducted using the same parameter settings and test conditions, and the performance of each model in detecting bruises was visualized through segmentation results.

Figure 7 illustrates the segmentation performance of different models on randomly selected test data.



(a) Input *(b) Groud-truth* *(c) UNet* *(d) SegNet* *(e) PSPNet* *(f) HrNnet* *(g)DeepLab V3+* *(h) Ours*

Fig. 7 - Comparison of segmentation results of different networks

UNet performs poorly in locating bruise regions. In UNet, the upsampling process often introduces noise and skip connections that tend to mix high-level features leads to frequent misclassification of healthy tissue as bruise regions. SegNet suffers from significant loss of spatial information due to multiple pooling operations during the decoding stage, especially when precisely segmenting boundary regions. PSPNet is prone to missing bruise features, indicating insufficient sensitivity to the characteristics of bruise regions. HrNet retains high-resolution feature maps through its multi-resolution parallel network branches, capturing global context information.

However, this design may overlook local details, especially when the contrast between the background and bruise areas is low, leading to misclassification of the background as bruise regions. Among the five models, DeepLabV3+ achieves relatively better performance. However, its spatial convolutions have limited capacity to preserve spatial location information, leading to some healthy regions being misclassified as bruise areas. In Figure 7(h), the proposed MCC-DeepLabV3+ model demonstrates more precise bruise segmentation compared to the other five models, significantly reducing misclassification and omission errors. It closely aligns with the ground truth shown in Figure 7(b), delivering more reliable and accurate segmentation results.

To further validate the performance of the proposed MCC-DeepLabV3+ model, mIoU, mPrecision, and mRecall metrics were evaluated on the 'Huangguan' pear bruise dataset, with results summarized in Figure 8. MCC-DeepLabV3+ achieved superior performance across all metrics, with mIoU, mPA, mPrecision, and mRecall reaching 95.68%, 97.43%, 97.58%, and 96.43%, respectively, outperforming all comparison models. For instance, in terms of mIoU, the proposed model demonstrated improvements of 3.93%, 12.14%, 9.45%, 16.80%, and 3.84% over UNet, SegNet, PSPNet, HrNet, and DeepLabV3+, respectively. These results show that the proposed model's robustness and effectiveness in achieving high segmentation accuracy and accurately detecting bruise regions. The above qualitative and quantitative comparison results show that MCC-DeepLabV3+ performs excellently in the task of early bruise segmentation in 'Huangguan' and pear. It effectively addresses the limitations of classical segmentation models, such as inaccurate bruise localization, insufficient boundary smoothing and incorrect segmentation. With higher segmentation accuracy and enhanced robustness, the model provides a practical and efficient solution for bruise detection in industrial applications.

	UNet	SegNet	PSPNet	HrNet	DeepLab V3+	MCC-DeepLab V3+
mIoU	92.06%	85.32%	87.42%	81.92%	92.14%	95.68%
mPA	95.21%	91.10%	92.10%	91.89%	95.56%	97.43%
mPrecision	95.26%	93.01%	94.11%	91.47%	95.94%	97.58%
mRecall	95.21%	91.13%	92.10%	88.69%	95.59%	96.43%

Fig. 6 - Comparison of segmentation performance of different semantic segmentation networks

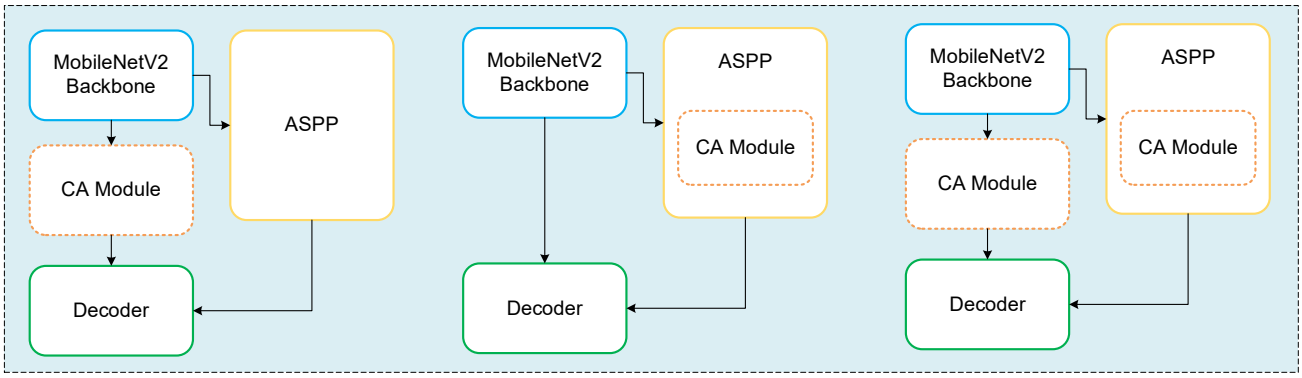


Fig. 7 - The structure of CA attention mechanisms in different positions

To determine the optimal application of the attention mechanism in DeepLabV3+, three different encoder architectures shown in Figure 9 were designed and evaluated on the custom 'Huangguan' Pear dataset. These architectures include: incorporating the attention mechanism only after the shallow feature output from MobileNetV2 (referred to as "CA after MobileNetV2"), integrating it solely within the ASPP module ("CA in ASPP"), and applying it to both MobileNetV2 output and the ASPP module ("CA after MobileNetV2 and in ASPP"). Figure 10 illustrates the segmentation results of the three structures, while Table 1 presents their performance metrics.

As shown in Table 1, Structure 3 achieved the highest performance across all metrics, with mIoU, mPA, mPrecision, and mRecall reaching 95.22%, 96.93%, 96.41%, and 95.57%, respectively. Specifically, as depicted in Figure 10, structure 1 enhances the extraction of local features but lacks reinforcement of deep semantic features, leading to inadequate global information capture. This limitation reduces segmentation accuracy, particularly for irregular bruise morphologies, which are prone to misclassification. Structure 2 (in ASPP) improves global contextual perception and optimizes the receptive field across multi-level features, enabling more accurate contour detection. However, it struggles with fine boundary delineation. In contrast, structure 3 combines the strengths of both approaches. The attention mechanism applied after MobileNetV2 refines edge features and improves detail segmentation, while the mechanism in the ASPP module strengthens global semantic feature representation and ensures effective spatial information capture. This dual-attention mechanism achieves a balanced integration of global and local features, significantly enhancing overall segmentation performance and edge detail accuracy. By combining subjective visual evaluations with objective performance metrics, it is evident that the dual-attention mechanism substantially improves the performance of DeepLabV3+ in 'Huangguan' pear bruise segmentation. This approach not only preserves the integrity of global semantic features but also restores fine edge details, thereby enhancing both segmentation accuracy and model robustness. Therefore, it was selected as the final design in this study.

Table 1

Comparison of network segmentation performance after adding attention mechanism at different locations

Network type	mIoU	mPA	mPrecision	mRecall
Structure 1	92.06%	95.21%	95.26%	93.21%
Structure 2	92.14%	95.56%	95.94%	94.59%
Structure 3	95.22%	96.93%	96.41%	95.57%

Ablation experiment

To verify the contribution of each module in 'Huangguan' pear bruise detection, this study conducts ablation experiments using a self-constructed dataset, with DeepLabV3+ as the base framework. By comparing the effects of embedding the MobileNetV2 backbone network, the Coordinate Attention (CA) mechanism, and the Cascaded Feature Fusion (CFF) module, the effectiveness and individual contributions of these modules are thoroughly evaluated. The test effect graphs and performance metrics for different module combinations are shown in Figure 11and Table 2, respectively.

Firstly, the backbone of DeepLabV3+ was replaced from Xception to MobileNetV2, reducing the model parameters from 54.71M to 5.82M, nearly a tenfold decrease. This number of parameters has decreased, but the mIoU, mPA, mPrecision, and mRecall metrics improved from 91.24% to 93.52%, 95.56% to 96.55%, 95.94% to 96.56%, and 95.59% to 96.55%, respectively, demonstrating the effectiveness of the lightweight design. The efficient depthwise separable convolutions and inverted residual structure of MobileNetV2 significantly reduce the parameter count while maintaining robust feature extraction capabilities, offering a practical solution for resource-constrained industrial applications. Next, the CA mechanism was embedded in both the output of MobileNetV2 and the ASPP module, keeping the model parameters unchanged at 5.82M. However, the performance improved further, with mIoU, mPA, mPrecision, and mRecall reaching 93.54%, 96.59%, 96.64%, and 96.57%, respectively. The CA mechanism effectively enhances the model's ability to capture global spatial information by combining spatial coordinates with channel attention. Specifically, it strengthens long-range dependencies through global average pooling in the horizontal and vertical directions, improving the model's capability to handle complex bruise shapes while significantly reducing omissions and misclassifications. This demonstrates the critical role of the CA mechanism in enhancing the spatial feature representation of the model. Finally, the introduction of the CFF module slightly increased the model parameters to 5.87M but improved performance. Compared to the initial network with Xception as the backbone, the mIoU, mPA, mPrecision, and mRecall improved by 1.65%, 1.10%, 0.77%, and 1.07%, respectively. The CFF module employs a cascaded feature fusion strategy, combining fine-grained details from shallow features with global semantics from deep features, enhancing the model's ability to capture multi-level features, improving segmentation accuracy.

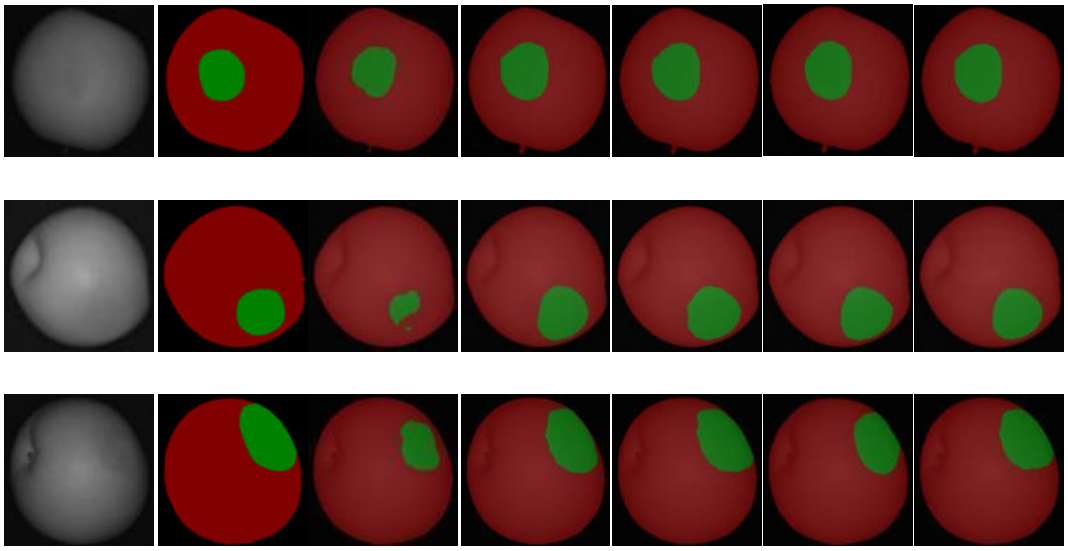

Table 2

The segmentation performance comparison of different modules

DeepLabV3+	Backbone		CA	CFF	Params (M)	mIoU (%)	mPA (%)	mPrecision (%)	mRecall (%)
	Xception	MobileNetV2							
√	√				54.71	92.14	95.56	95.94	95.59
√		√			5.82	93.52	96.55	96.56	96.55
√		√	√		5.82	93.54	96.59	96.64	96.57
√		√		√	5.87	93.66	96.61	96.68	96.61
√		√	√	√	6.10	95.68	97.43	97.58	97.43

Figure 11 illustrates the segmentation performance of the model on the test set after the progressive addition of different modules. Comparing Figure 11(c) and Figure 11(d), it can be observed that replacing the backbone network with MobileNetV2 resulted in clearer segmentation of bruise regions, enhancing the model's initial segmentation capability. Further comparison between Figure 11(d) and Figure 11(e) shows that the introduction of the CA attention mechanism significantly improved the model's feature extraction capability, leading to more precise segmentation and clearer delineation of bruise contours. Comparing Figure 11(e) and Figure 11(f), the inclusion of the CFF module enhanced the handling of edge details in early bruise region segmentation, effectively avoiding issues such as edge blurring or irregularities. Overall, the segmentation results of the proposed model (Figure 11(g)) are more closely aligned with the ground truth (Figure 11(b)), demonstrating the effectiveness of the combined modules in improving segmentation accuracy and detail preservation.

The above objective metrics and subjective segmentation results from the ablation experiments demonstrate that the MobileNetV2 backbone significantly reduced the model's parameters, improving segmentation efficiency. The CA mechanism enhanced the model's ability to represent spatial positional information, resulting in more accurate segmentation. Meanwhile, the CFF module, by integrating multi-level features, further improved the localization accuracy and detail preservation in bruise regions. Together, these three modules achieve a balance between lightweight design and high performance.

CONCLUSIONS

This paper introduces a lightweight semantic segmentation network, MCC-DeepLabV3+, designed for early bruise detection in ‘Huangguan’ pears using near-infrared (NIR) imaging technology and deep learning techniques. A universal testing machine was employed to generate real early bruises, and a corresponding dataset of early bruising in ‘Huangguan’ pears was prepared. The proposed network adopts MobileNetV2 as the backbone, which effectively reduces the parameter size of the original Xception model, thereby addressing the issue of model complexity. Furthermore, a Coordinate Attention (CA) mechanism is integrated into both the shallow feature extraction stage and the Atrous Spatial Pyramid Pooling (ASPP) module, significantly enhancing the model’s segmentation performance and improving its ability to process edge details. The introduction of the Cascaded Feature Fusion (CFF) module further optimizes the integration of shallow detail features with deep semantic information, which is crucial for improving accuracy in detecting early bruises.

To assess the performance of the proposed model, a series of comparative experiments with classical segmentation networks such as UNet, SegNet, PSPNet, HrNet, and DeepLabV3+ was conducted. The evaluation focused on key metrics, including mIoU, mPA, mPrecision, and mRecall, as well as a detailed analysis of the segmentation results on the test set. Our findings reveal that MCC-DeepLabV3+ consistently outperforms the other models across all evaluated indices, demonstrating superior segmentation reliability and performance in detecting early bruises in ‘Huangguan’ pears.

In terms of attention mechanisms, the impact of adding CA attention mechanisms at various stages of the network, specifically at the shallow input of the MobileNetV2 backbone and within the ASPP module, was explored. Our results indicate that incorporating CA attention mechanisms at both locations simultaneously significantly improves model performance, compared to models with either individual or no attention mechanisms. This reinforces the importance of integrating attention mechanisms at multiple stages of the network to enhance segmentation results.

To further validate the effectiveness of the proposed enhancements, ablation experiments were conducted, which confirmed that MCC-DeepLabV3+ outperforms various combinations of individual improvements.

The model's segmentation results closely align with the ground truth labels, showcasing its ability to accurately detect early bruises in 'Huangguan' pears. This advancement provides a new, efficient, and precise approach for early bruise detection, which can be effectively applied in automated fruit quality detection and precision agriculture.

In conclusion, the enhanced MCC-DeepLabV3+ network introduced in this paper offers significant improvements in the accuracy and efficiency of early bruise detection in 'Huangguan' pears. While the proposed model demonstrates impressive performance, there remains potential for further optimization. Future research will focus on refining both the accuracy and speed of detection to further enhance the practicality and effectiveness of this approach for real-world applications in agriculture. Additionally, addressing challenges such as the detection of complete overlap between bruises in densely packed pears will be a key area for future improvement.

ABSTRACT

The selection of design, improvement, and utilization of seed planting, harvesting, and postharvest implements depends on the grain physical and mechanical property information of the specific crop type and variety. However, this information is lacking for wheat varieties produced in different regions of Ethiopia. The objective of the study was to generate data on the physical and mechanical properties of grains from selected wheat varieties. Three wheat varieties (Danda'a, Jalanne, and Kakaba) were selected. A factorial combination of 3 × 5 treatment levels was adapted with three replications. The variables studied were the grain size, shape, weight, bulk density, angle of repose, and coefficient of friction. The data were subjected to analysis of variance (ANOVA), and the Dunnett multiple range test was used to separate the means. Significance was accepted at a 95% confidence interval ($p < 0.05$). As moisture increased, the grain's dimensions, shape, thousand kernel weight, coefficient of friction, and angle of repose all increased while bulk density decreased. The bulk density decreased from 0.73 to 0.54 g/cm³ as moisture increased from 8.50% to 28.50%. The study indicated large variations in the treatments used. The mean values for grain length, surface area, and volume increased from 5.786 ± 0.253 to 6.525 ± 0.361 mm, 38.514 ± 2.997 to 49.627 ± 3.201 mm², and 22.531 ± 2.644 to 32.933 ± 3.201 mm³, respectively. Similarly, thousand kernel weight, repose angle, and friction coefficient increased from 26.70 to 42.00 g, 23.20 to 34.70°, and 0.4142 to 0.8391, respectively. Variations in grain properties indicate the necessity for diverse design and calibration criteria for seed planting, harvesting, and postharvest equipment tailored to different wheat varieties at different moisture levels.

INTRODUCTION

Wheat (*Triticum aestivum L.*) is among the most important staple food crops and a major diet that is consumed by more than 2.5 billion people globally (*Bentley et al., 2022*). It is a staple food in all parts of the world, supplying 35% of food and providing 20% of the calories (Statista, 2022). In Ethiopia, wheat is one of the most important food grain crops. The grain is used for food utilization in different forms such as bread, porridge, soup, *injera, nifro, tella, arki,* and other industrially processed products like pasta and macaroni *(Nigussie et al., 2015*). Furthermore, farmers use wheat grain for marketing to generate income, and the straw is used as animal feed and bedding. Ethiopia's annual wheat production is about 5.80 million tons, with mean productivity of three tons per hectare (ton ha^{-1}) (CSA, 2021), which is relatively lower than the attainable yield of five tons ha^{-1} (*Zegeye et al., 2020*). Wheat accounts for about 17.00% of the total cereal grain produced in Ethiopia, making it the third most important cereal crop after teff and maize (CSA, 2021).

Certain physical attributes and engineering properties of the materials should be considered significant and crucial engineering data when designing machinery, structures, processing systems, and controls that will be used in the production, handling, and processing of food and agricultural products (*Mohsenin, 1986*). The engineering characteristics of wheat with various moisture contents must be understood to develop a machine for handling, transporting, and planting (*Tabatabaeefar, 2003*). Knowledge of the mechanical and physical characteristics of grains is necessary for the design, operation, adaptation, modification, and enhancement of any equipment. In general, the physical and mechanical characteristics of the grains from particular crop types and varieties determine and influence these processes (*Krishnakumar, 2019*). Depending on the crop type and variety, the grains of any food crop differ in terms of size, shape, mass, volume, surface area, density, porosity, angle of repose, coefficient of friction, hardness, resistance to compressive and shear forces, and force-deformation relationship (*Adinoyi et al., 2017; Surpam et al., 2019*). Variations in the location of the production environment, such as climate, soil, and cultural techniques, also impact the mechanical and physical properties of grains (*Mohite et al., 2019*). Furthermore, the grain moisture content has a major impact on how these characteristics vary, suggesting that the physical and mechanical properties are characterized as a function of the grain moisture levels (*Masane et al., 2016*).

For seed planting, threshing, cleaning, and grading, the grain's size and shape, defined by its three-dimensional (3D) parameters, are essential (*Kenghe et al., 2015; Surpam et al., 2019*). The design, selection, and proper functioning of equipment used for handling, storing, and processing grains of certain crop kinds and varieties are influenced by the mechanical characteristics of the grain, such as its coefficient of friction and angle of repose (*Fayed et al., 2020*). The significance of physical and mechanical properties, along with the characteristic variability of the grains, cannot be undermined for the widely diverse wheat cultivars adapted to different agro-ecological zones of Ethiopia and produced under varying cultural practices of the farming communities across various regions of the country.

Therefore, a comprehensive understanding and knowledge of the physical and mechanical properties of wheat grains from particular cultivars or varieties are necessary for the proper selection, design, fabrication, testing, improvement, evaluation, and operation of the machinery required for wheat harvesting, threshing, cleaning, grading, storage, conveying, milling, seed planting, and other tasks. Although it is crucial for the selection, design, improvement, and operation of seed planting, harvesting, and postharvest tools, there have been very few studies on the mechanical and physical characteristics of grains, and there is generally insufficient information on the mechanical and physical characteristics of wheat grains produced in Ethiopia.

Since the physical and mechanical characteristics of wheat grains are essential for the selection, design, development, and use of seed planting, harvesting, and postharvest tools, this study was conducted to generate data that can fill the gaps in this knowledge. The current study aimed to determine the mechanical and physical characteristics of wheat seeds at various moisture content.

MATERIALS AND METHODS

Location of the Study

The study was conducted at the Melkassa Agricultural Research Centre (MARC) in the East Shoa Zone, Oromia Regional State, Ethiopia, in 2024.

Materials and Sample Preparation

In this study, the three most important varieties of wheat - Danda'a, Jalanne, and Kakaba, were used. The Danda'a and Jalanne varieties were obtained from Kulumsa Agricultural Research Center and the Kakaba variety was sourced from a farm at Haramaya University, Ethiopia. The samples were manually cleaned to remove foreign matter, dust, dirt, and broken and immature grains. A digital oven drying machine (Universal

Oven Model of Memert Brand, Germany) was used for testing. The initial moisture content of the samples was determined by oven drying at 104 ±2ºC for 24 hours (*AOAC, 2005*). Samples at desired moisture levels were prepared by adding calculated amounts of distilled water, thoroughly mixing, and then sealing in separate polyethylene buckets. The quantity of distilled water was calculated using the following equation:

$$W_2=W_1\left(\frac{M_1-M_2}{100-M_1}\right) \quad (1)$$

where: W_2 – mass of water added (g), W_1 – total seeds mass (g), M_1 –initial moisture content (%), and M_2 – final moisture content (%).

The samples were stored in a refrigerator at 4ºC for 12 days to allow the moisture to distribute uniformly throughout the samples. Before starting a test, the required quantities of the sample were allowed to warm up to room temperature (*Tabatabaeefar, 2003*). All physical and mechanical properties of wheat seed were measured at moisture levels of 8.50%, 13.50%, 18.50%, 23.50%, and 28.50% (w.b) for all seed varieties, with three replications at each moisture level.

Methods

Treatment variables

Wheat varieties and grain moisture levels were the independent variables. The physical and mechanical properties of the grains were determined at five different wet-based (w.b) grain moisture levels ranging from 8.50% to 28.50% with the levels selected at 5.00% intervals. The moisture range was chosen based on the recommended optimum moisture levels at harvesting, threshing, marketing, and safe storage (*John, 2021*). The 3 × 5 factorial combinations of treatments (3 varieties and 5 moisture levels) were arranged in a Completely Randomized Design, with the appropriate number of replications for each specific parameter.

Determination of physical properties

Grain size

The length, width, and thickness in the three dimensions (3D), designated by L, W, and T, were measured by randomly sampling 100-grain kernels at each selected grain moisture level using a digital vernier caliper with a resolution of 0.01 mm. The mass of each sampled grain was also recorded using an analytical balance, and this measurement was repeated for all the involved varieties. The representative geometric mean diameter, surface area, and degree of sphericity were calculated from basic dimensions using the following Equations 2 to 6 (*Mohsenin, 1986; Adinoyi et al., 2017; Krishnakumar, 2019*).

$$\text{Geometric mean diameter: } D_g=(L\times W\times T)^{\frac{1}{3}} \text{ [mm]} \quad (2)$$

$$\text{Surface area: } A_s=\pi D_g{}^2 \text{ [mm}^2\text{]} \quad (3)$$

$$\text{Volume: } V=\frac{\pi\times L\times W\times T}{6} \text{ [mm}^3\text{]} \quad (4)$$

$$\text{Aspect ratio: } R_a=\frac{W}{L} \quad (5)$$

$$\text{Sphericity: } S=\frac{(L\times W\times T)^{\frac{1}{3}}}{L}\times 100 \text{ [\%]} \quad (6)$$

Thousand kernel weight (TKW)

The grains were counted using a digital counter and placed into a cylinder container of known weight. Thousand kernel weight (TKW) was measured by counting 1,000 seeds with a seed counter and weighing them on an electronic balance to an accuracy of 0.001 g. The cylinder with grain was weighed using a digital balance. This procedure was repeated three times at each moisture level.

Bulk density (ρ_b): Bulk density was calculated from the mass and volume of a circular container with a known volume, which was filled with the wheat samples. After filling the container, excess seeds were removed by passing a flat metal across the top surface with five zigzag motions. The grain was then carefully filled from a height of 150 mm into a 500 mL graduated cylinder of known weight. It was repeated three times. The cylinder was weighed with its content, and the difference above the cylinder weight was used to calculate the bulk density using Equation 10 (*Khanahmadzadeh et al., 2021*):

$$\text{Bulk density: } \rho_b=\frac{M_b}{V_b} \text{ [g cm}^{-3}\text{]} \quad (7)$$

where: M_b = mass of bulk grains (g); V_b - the container volume (cm^3).

Determination of mechanical properties

Angle of repose

The flow characteristics of solids is the angle of repose, which is associated with inter-particulate friction or the resistance to movement between particles. It is also related to the density, surface area, shape of the

particles, and the coefficient of friction of the materials (*Sen et al., 2020*). Two cylindrical containers: one hollow and placed on top of a closed side, were used in the setup for the experiment for measurements of the repose angle. The measurements of the repose angle were taken using equation (8), as provided by *Baryeh (2002)*, *Mohsenin (1986)*, and *Saparita et al. (2019).*

$$\text{Angle of repose: } \theta = tan^{-1}\left(\frac{H}{R}\right) \quad (8)$$

where: H - depth of the slope (mm) and R - the bottom horizontal span of the slope (mm).

Coefficient of friction

The coefficient of static friction was determined using a plywood box with 350 mm in length, 190 mm in width, and 35 mm in height, featuring an open base and top faces. The box was placed on a graduated angular tilting table, on which the test surface plate was fixed. Friction was measured against aluminum, galvanized iron sheets, glass, mild steel, painted surfaces, plastic, plywood, and rubber. A hollow metal cylinder, 50 mm in diameter and 50 mm in height, open at both ends, was filled with seeds at the desired moisture content and placed on an adjustable tilting surface, ensuring that the cylinder did not come into contact with the surface. The surface was then raised gradually until the filled cylinder began to slide down (*Razavi and Milani, 2006; Khanahmadzadeh et al., 2021*). The tilt angle (α) was read from an angular scale when the box began to slide down on the test surfaces and was replicated three times at each moisture level. The coefficient of static friction was calculated using Equation (9).

$$\text{Coefficient of friction: } \mu = tan\,\alpha \quad (9)$$

Data Analysis

The data collected were organized into the required forms for every parameter and subjected to statistical analysis. Minitab 18th edition software was used for statistical analysis. Both descriptive statistics and Analysis of Variance (ANOVA) models were employed as needed, depending on the specific behavior of each parameter. The descriptive method was used to analyze the grain mean dimensions with standard deviations. Analysis of variance was applied to the bulk grain properties, using the Dunnett multiple comparison test with the least significance difference (LSD) at a 5% probability level. Mean line graphs, trend line equations, and coefficients of determination (R^2) were generated for some of the property variables.

RESULTS AND DISCUSSION

Physical Properties

Table 1 summarizes the measured and determined dimensions of 100 kernels from each wheat variety with a moisture content ranging from 8.50 to 28.50%. For the three wheat seed (*Triticum aestivum L*) varieties: Danda'a, Jalanne, and Kakaba, the physical parameters and ANOVA values are shown. The evaluated physical parameters include length, width, thickness, geometric mean diameter, surface area, volume, aspect ratio, and sphericity. The table presents the mean ± standard deviation for each parameter.

Table 1

Descriptive Statistics Wheat varieties dimension, geometric mean diameter, surface area, volume, aspect ratio, and sphericity at Moisture Content Levels from 8.50% to 28.50%.

Wheat Variety	Variable	Moisture Content Level (%)				
		8.50	13.50	18.50	23.50	28.50

Principal Dimension - Significant differences were observed among the measured parameters as moisture content increased. As moisture content rose, the size of the wheat kernels also grew. The dimensions (length, width, and thickness) of all varieties increased with rising moisture content. This growth was probably caused by small air voids on the kernels, which may have formed from the swelling effect of the added water. Similar findings were reported for barley grain by *Tavakoli et al., (2009),* sorghum grain by *Mwithiga and Sifuna (2006)*, and *Birehanu et al., (2024)*.

The findings confirm that the principal dimensions of wheat grains from the three varieties increased with an increase in moisture content (Table 1). The average seed length for Danda'a, Jalanne, and Kakaba increased from 5.975±0.39 to 6.362±0.307 mm, 6.050±0.399 to 6.525±0.361 mm, and 5.786±0.253 to 6.315±0.289 mm, respectively, as moisture content increased from 8.50% to 28.50%. Similarly, the average seed width for Danda'a, Jalanne, and Kakaba increased from 2.969±0.194 to 3.311±0.306 mm, 2.958±0.242 to 3.321±0.211 mm, and 2.954±0.187 to 3.218±0.266 mm, respectively, at the same moisture level. The average seed thickness for Danda'a, Jalanne, and Kakaba increased from 2.453±0.184 to 2.814±0.230 mm, 2.579±0.198 to 2.907±0.186 mm, and 2.514±0.150 to 2.965±0.194 mm, respectively, as the moisture content increased from 8.50% to 28.50%. These results align with the findings of *Majdi and Taha (2007)*, who reported that axial dimensions and mean diameter increase with the moisture content of green wheat. Changes in seed dimensions with increasing moisture are important to consider when designing equipment. As indicated in the literature, the physical properties of seeds change with the moisture content. Parameters such as moisture content, external friction, and material density are key factors influencing technological processes (*Kaliniewicz et al., 2018*). Variations in seed dimensions may also result from differences in the seeds' ability to absorb water, as well as variations in chemical composition, morphological structure, and endosperm structure. The water absorption capacity of cereal seeds is crucial not only during storage but also during conditioning before sowing.

Mean diameter. The geometric mean diameters varied among the different wheat varieties at similar moisture levels, with all test varieties showing a linear increase in diameter as moisture content increased (Table 1). The average geometric mean diameter for Danda'a, Jalanne, and Kakaba increased from 3.512±0.156 to 3.894±0.222 mm, 3.581±0.172 to 3.974±0.128 mm, and 3.499±0.136 to 3.916±0.185 mm, respectively, as moisture content increased from 8.50% to 28.50%. The geometric mean diameter is a useful parameter in the design of the metering cells. The metering cells for wheat planters should be designed based on the geometric mean diameter of 3.974±0.128 mm. The increase in the grain's geometric mean diameter may have been due to an overall increase in grain size resulting from the rise in moisture content. This diameter is primarily used in equipment designing, while the equivalent mean diameter represents the average size of bulk grain in a package (*Simonyan et al., 2007*).

Seed surface area and volume. Both surface area and volume for a seed showed significant increases with rising moisture content, with a notable variation among the varieties at similar moisture levels (Table 1). The mean seed surface area for Danda'a, Jalanne, and Kakaba increased from 38.805±3.457 to 47.761±5.346 mm^2, 40.352±3.879 to 49.627±3.201 mm^2, and 38.514±2.997 to 48.264±4.502 mm^2, respectively, the moisture content increased from 8.50% t0 28.50%. Similarly, the mean seed volume for Danda'a, Jalanne, and Kakaba increased from 22.803±3.054 to 31.191±5.140 mm^3, 24.192±3.484 to 32.933±3.201 mm^3 and 22.531±2.644 to 31.639±4.386 mm^3, respectively, at the same moisture levels. A similar linear increase in sorghum grain volume, from 29 to 38 mm^3, was reported by *Kenghe et al., (2015)* for a grain moisture increase from 10.94 to 24.22% (db.). Additionally, *Birehanu et al., (2024),* also observed a linear increase in grain volume with rising moisture levels.

Aspect ratio and Sphericity. The mean aspect ratio and sphericity of wheat seed showed a linear relationship with seed moisture content (Table 1). The seed aspect ratio showed non-significant increases for the Kakaba variety but slightly significant (P = 0.05) increases for Danda'a and Jalanne. The mean aspect ratio of Danda'a and Jalanne increased from 0.492±0.044 to 0.521±0.046, and 0.490±0.049 to 0.511±0.048, respectively, as moisture content increased from 8.50 to 28.50. Similarly, the mean seed sphericity for Danda'a, Jalanne, and Kakaba increased from 58.208±3.049 to 61.232±2.626%, 59.351±3.225 to 61.026±2.906%, and 59.856±2.870 to 62.064±2.685%, respectively, at the same moisture content levels. The shape of the Kakaba seed was the most spherical compared to the Danda'a and Jalanne. The increase in sphericity was attributed to the swelling of the grain kernels with additional water intake, where the thickness (minor diameter) increased more than the major and intermediate diameters (*Birahenu et al., 2024*).

Bulk Density. The experimental results showing the relationship between bulk density and moisture content are presented in Figure 1. A linear decrease in bulk density was observed with increasing moisture content, and this trend was statistically significant at the 5% significance level. The bulk density of Danda'a, Jalanne, and Kakaba varieties decreased from 0.71 to 0.61 g cm^{-3}, 0.73 to 0.64 g cm^{-3}, and 0.70 to 0.54 g cm^{-3}, respectively, as the moisture content increased from 8.50 to 28.50%. This decline in bulk density suggests that the mass increase due to moisture absorption was less than the corresponding volumetric expansion of the bulk, as previously noted in soybean samples (*Tabatabaeefar, 2003*). An inverse relationship between bulk density and moisture content has also been reported by various other studies (*Garnayak et al., 2008; Shahbazi, 2015; Birahenu et al., 2024*). The models fitted to the data using regression analysis showed that the bulk density decreased linearly with increases in the moisture content for all cultivars. Therefore, the following equations were derived for the relationship between bulk density (ρ, g cm^{-3}) and moisture content (M, %), for each variety.

Danda'a variety: $\rho_D = 0.7597 - 0.005780M$, $R^2=0.927$

Jalanne variety: $\rho_J = 0.7461 - 0.004189\ M$, $R^2=0.769$

Kakaba variety: $\rho_K = 0.7857 - 0.00963\ M$, $R^2=0.739$

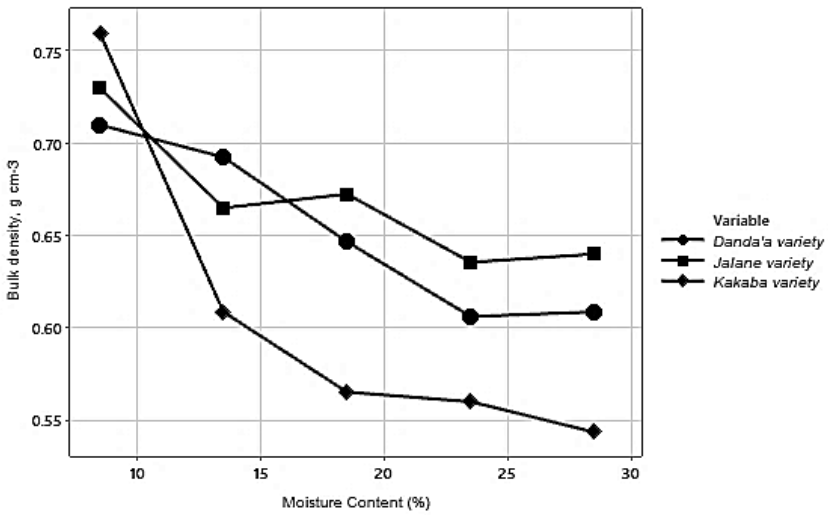

Fig. 1- Effect of moisture content on bulk density of wheat seed varieties

Thousand Kernel Weight. The results obtained for the thousand-kernel weight of wheat with an increase in moisture content are shown graphically in Figure 2. It was observed that the thousand-kernel weight increased linearly with an increase in moisture content, and this change was significant at the 5% significance level. The figure reveals that, for all the wheat seed varieties considered, the thousand-kernel seed mass increases as the moisture content increases. The thousand-kernel weight of the Danda'a, Jalanne, and Kakaba varieties increased from 28.70 to 35.00 g, 31.30 to 42.00 g, and 26.70 to 38.00 g, respectively, as the moisture content increased from 8.50 to 28.50%. The thousand-kernel weight means showed a significant variation among the test varieties, and it also increased linearly with an increase in grain moisture content. The thousand-kernel weight of Jalanne exceeded that of the Danda'a and Kakaba varieties by about 13.11% and 11.73%, respectively. The means of thousand-kernel weight at 13.50% (wb) were 36.30 g, 32.30 g, and 30.00 g for Jalanne, Kakaba, and Danda'a, respectively. The 13.50% moisture is the standard level recommended for wheat grain marketing (*John, 2021*). A mean increase in thousand-kernel weight from 20.67 g to 22.01 g was also reported for sorghum, with a corresponding moisture increase from 8.70% to 21.80% (wb) (*Sabar et al., 2020*). Regression analysis was used to find and fit the best general models to the data. The results showed that as the moisture content of the seeds increased, the thousand-grain weight of wheat increased linearly. Thus, the dependence of the thousand-kernel mass of wheat seeds (TKW, g) on the seed moisture content (M, %) was expressed by the following best-fit equations for each variety:

Danda'a variety: $TKW_D = 26.11 + 0.2720M$, $R^2=0.834$

Jalanne variety: $TKW_J = 28.18 + 0.4680M$, $R^2=0.912$

Kakaba variety: $TKW_K = 23.47 + 0.5260M$, $R^2=0.935$

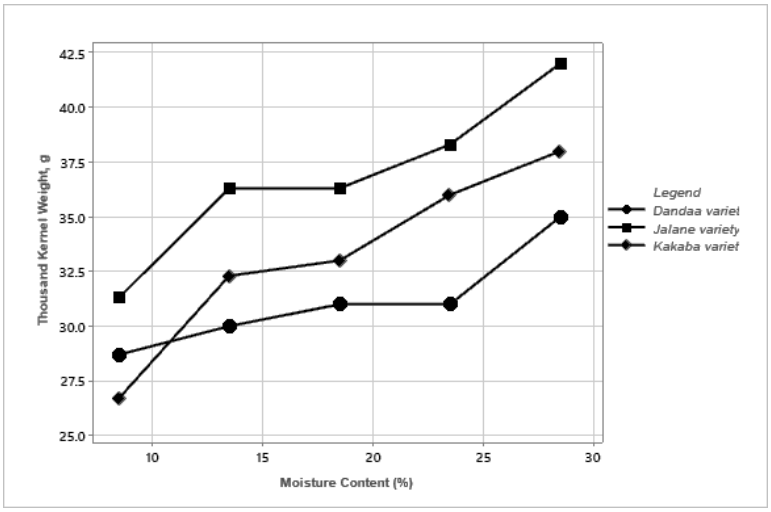

Fig. 2 - Effect of moisture content on thousand kernel weight of wheat seed varieties

Mechanical Properties

Repose Angle. The variation observed in the angle of repose of wheat seeds with increasing moisture content is shown graphically in Figure 3. It was observed that the angle of repose increased linearly with an increase in moisture content, and this change was found to be significant at the 5% level. The angle of repose exhibited a linear increase with significant differences at higher moisture content levels, regardless of the wheat variety tested. The mean repose angle increased for Danda'a from 23.20 to 34.70°, for Jalanne from 24.10 to 32.30°, and for Kakaba from 24.50 to 32.31°, as the moisture content increased from 8.50% to 28.50% (Figure 3). Overall, the angle of repose ranged from 23.20° to 34.70°, indicating flow characteristics classified as good to fair. Angles of repose between 25° to 30°, and 31° to 40°, have been reported to correspond to good and fair, flow properties, respectively (*Sen et al., 2020; Birhanu et al., 2024*). Therefore, the observed values in this study suggest that all wheat varieties demonstrated flowability ranging from good to fair under varying moisture conditions.

At higher moisture content within the experimental range, the grains tended to clump together, resulting in increased pile stability and reduced flowability, which in turn led to higher angles of repose. The observed increase in the angle of repose for the wheat seed varieties was primarily attributed to the expansion in seed size and mass at elevated moisture levels. Additionally, higher moisture content made the seed surfaces stickier, reducing their ability to roll over one another - an effect also reported by *Razavi et al. (2007)*.

Regression models fitted to the experimental data indicated a linear increase in the angle of repose with moisture content for all wheat varieties. The following equations describe the relationship between the angle of repose (θ, °) and moisture content (M, %) for each variety:

Danda'a variety: $\theta_D = 17.85 + 0.5780\ M$, $R^2=0.993$

Jalanne variety: $\theta_J = 21.39 + 0.3940\ M$, $R^2=0.971$

Kakaba variety: $\theta_K = 22.19 + 0.3680\ M$, $R^2=0.951$

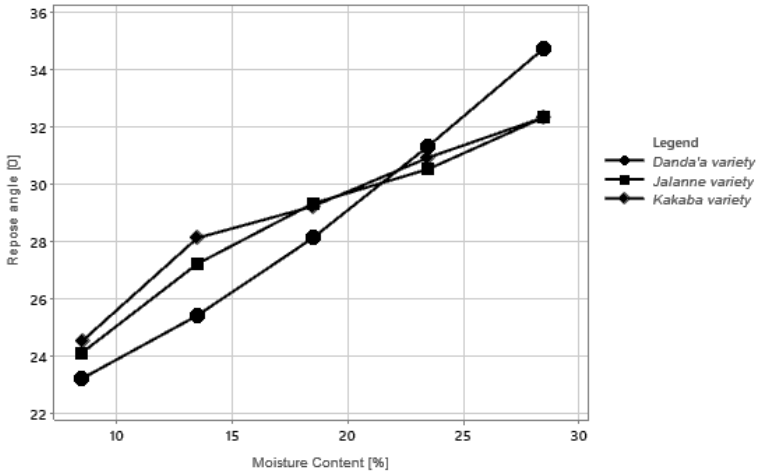

Fig. 3 - Effect of moisture content on the repose angle of wheat seed varieties

Static coefficient of friction

The static coefficient of friction for wheat seed was determined for eight different structural surfaces, as presented in Table 2. It was observed that the static coefficient of friction increased with an increase in moisture content across all surfaces. The values of the static coefficient of friction ranged from 0.4142 to 0.8391 on various surfaces for all wheat seed varieties tested at the specified moisture content levels.

Moisture content played a significant role in influencing μ, with higher moisture levels typically increasing friction due to enhanced adhesive forces between grains and surfaces. However, at the upper moisture range (near 28.50%), some smoother surfaces exhibited slight reductions in μ, possibly due to a lubricating effect from excess moisture. Varietal differences were also notable: Danda'a displayed broad friction ranges, suggesting high sensitivity to surface type, while Jalanne unexpectedly showed high friction on plywood, possibly due to grain morphology. Kakaba, unlike the other varieties, had plastics as the second-highest friction surface, indicating unique grain-surface interactions. These findings have practical implications for grain handling and storage systems, where rubber linings could be used to prevent slippage, while smoother surfaces like aluminum or painted materials might be preferred for applications requiring reduced friction. Further research could explore dynamic friction under movement or the effects of surface wear over time to optimize post-harvest processing and machinery design.

Across all moisture contents, the highest static coefficient of friction was observed on the compressed rubber surface. This could be attributed to the more unpolished surface of the compressed rubber compared to the other materials used. It was also noted that moisture had a greater effect on the static coefficient of friction than the material surface itself. This is likely due to increased adhesion between the grain and the material surface at higher moisture content. Similar results were reported by *Sahoo and Srivastava (2002)*, *Ozarslan (2002), Tabatabaeefar (2003), Bulent Coskun et al. (2005)*, and *Shepherd and Bhardwaj (1986)* for okra, cotton, lentil, wheat, sweet corn, and pigeon pea seeds, respectively. *Parde et al., (2003),* reported that the friction coefficient against the plywood, galvanized steel, and concrete surfaces for the Koto buckwheat cultivar increased significantly from 0.26 to 0.31, 0.25 to 0.29 and 0.38 to 0.43, respectively, with increases in moisture content from 14.8% to 17.9%, which were lower values than compared to the current findings.

The variation between the current findings and previously reported studies could be attributed to differences in seed variety, study location, and other related factors. The increase in grain moisture content likely caused an increase in the grain's surface roughness, which reduced its slipping characteristics and led to higher friction between the grains and the surfaces. These differences could provide important insights for the design of postharvest equipment, such as hoppers, storage structures, and auger conveyors (*Mohite et al., 2019*).

Table 2

Descriptive Statistics of Wheat varieties of static coefficient of friction

Static coefficient of friction, μs						
Surface	**Variety**	**Moisture Level (%)**				
		8.5	**13.5**	**18.5**	**23.5**	**28.5**
Aluminum	Danda'a	0.4627	0.4877	0.4986	0.5317	0.7399
	Jalanne	0.4663	0.4877	0.4986	0.5774	0.7002

Rubber;	Danda'a	0.6452	0.4452	0.6873	0.7002	0.8243
	Jalanne	0.6536	0.7002	0.6873	0.7536	0.8391
	Kakaba	0.6452	0.6552	0.6745	0.7002	0.7133

The relationships between the static coefficient of friction and moisture content for compressed aluminum, galvanized, glass, mild steel iron, painted, plastic, plywood, and rubber are represented by the following equations:

Aluminum
Danda'a: $CoF_a = 0.3227 + 0.01197M$, $R^2 = 0.721$
Jalanne: $CoF_a = 0.3398 + 0.01115M$, $R^2 = 0.846$
Kakaba: $CoF_a = 0.3684 + 0.008068M$, $R^2 = 0.894$

Galvanized steel
Danda'a: $CoF_g = 0.3334 + 0.01450M$, $R^2 = 0.975$
Jalanne: $CoF_g = 0.3525 + 0.01114M$, $R^2 = 0.985$
Kakaba: $CoF_g = 0.3464 + 0.01280M$, $R^2 = 0.985$

Glass
Danda'a: $CoF_{gl} = 0.4079 + 0.009610M$, $R^2 = 0.962$
Jalanne: $CoF_{gl} = 0.4179 + 0.005386M$, $R^2 = 0.961$
Kakaba: $CoF_{gl} = 0.4118 + 0.008578M$, $R^2 = 0.971$

Mild steel iron
Danda'a: $CoF_{ms} = 0.4365 + 0.01018M$, $R^2 = 0.999$
Jalanne: $CoF_{ms} = 0.4379 + 0.007188M$, $R^2 = 0.895$
Kakaba: $CoF_{ms} = 0.3826 + 0.01225M$, $R^2 = 0.939$

Painted
Danda'a: $CoF_p = 0.2673 + 0.01632M$, $R^2 = 0.98$
Jalanne: $CoF_p = 0.4163 + 0.007026M$, $R^2 = 0.93$
Kakaba: $CoF_p = 0.3624 + 0.0109\ M$, $R^2 = 0.976$

Plastic (Mica)
Danda'a: $CoF_pl = 0.4075 + 0.01003M$, $R^2 = 0.927$

Jalanne: $CoF_{pl} = 0.3687 + 0.01016M$, $R^2 = 0.960$
Kakaba: $CoF_{pl} = 0.4043 + 0.01016M$, $R^2 = 0.925$

Plywood (MDF)
Danda'a: $CoF_{pw} = 0.3981 + 0.009466M$, $R^2 = 0.932$
Jalanne: $CoF_{pw} = 0.5215 + 0.006168M$, $R^2 = 0.928$
Kakaba: $CoF_{pw} = 0.3714 + 0.009958M$, $R^2 = 0.995$

Rubber
Danda'a: $CoF_{ru} = 0.4336 + 0.01226M$, $R^2 = 0.497$

Jalanne: $CoF_{ru} = 0.5697 + 0.008488M$, $R^2 = 0.859$
Kakaba: $CoF_{ru} = 0.6106 + 0.003624M$, $R^2 = 0.981$

where: CoF - coefficient of friction a - aluminum, g - galvanized, gl - glass, ms - mild steel iron, p - painted, pl - plastic, pw - plywood, ru - rubber, and M - moisture content.

CONCLUSIONS

The study investigated the physical and mechanical properties of different wheat varieties at varying moisture levels, aiming to enhance process and equipment design for improved wheat grain yield and quality. Significant differences were observed among the test wheat varieties in terms of grain properties, and these properties varied with changes in moisture content.

Key findings include:

- All test varieties showed an increase in grain size as moisture content increased, with the Jalanne variety exhibiting the largest mean values for grain size and all other studied properties.
- As moisture content increased, grain dimensions, shape, thousand kernel weight, coefficient of friction, and angle of repose also increased, while bulk density decreased. Specifically, bulk density decreased from 0.73 to 0.54 g/cm³ as moisture content increased from 8.50% to 28.50%.
- Grain length, surface area, and volume increased significantly, with mean values rising from 5.786±0.253 mm to 6.525±0.361 mm, 38.514±2.997 mm² to 49.627±3.201 mm², and 22.531±2.644 mm³ to 32.933±3.201 mm³, respectively.
- Thousand kernel weight, repose angle, and friction coefficient also showed increases, highlighting the impact of moisture on these parameters.

In conclusion, the study emphasizes the need for varied design and calibration criteria for equipment used in seed planting, harvesting, and postharvest handling, based on the different physical and mechanical properties of wheat at various moisture levels. These findings suggest that to minimize seed damage and losses during operation, it is essential to tailor equipment design and operation to account for the grain's physical and mechanical properties at different moisture contents. This approach will optimize the efficiency and effectiveness of machinery used in wheat production.

ACKNOWLEDGEMENT

The author expresses gratitude to the Department of Agricultural Engineering and Food Process Engineering from Awash Melkassa Agricultural Research Centre for the provision of laboratory facilities and technical support, Haramaya University, and Kulumsa Agricultural Research Centre for the provision of certified wheat seed varieties, and Haramaya University for financing this study through grant number HURG_2023_03_05_12.

Keywords: *small vertical axis wind turbine, working principle, experimental testing wind turbines evaluation,*

ABSTRACT
This review paper provides a comprehensive analysis of the working principles of wind turbines, with a specific focus on experimental research studies for Vertical Axis Wind Turbines (VAWTs). Wind turbines are essential in harnessing renewable energy, and understanding their operational mechanisms is crucial for optimizing efficiency and performance. The paper outlines the basic working principles of both Horizontal Axis Wind Turbines (HAWTs) and VAWTs, with a deeper exploration of the latter due to its unique advantages in urban and low-wind conditions used in agriculture. The review critically examines recent experimental research on VAWTs, including various design modifications, aerodynamic performance studies, and energy efficiency improvements. Key parameters such as blade shape, turbine configuration, and site-specific factors are discussed, drawing on findings from experimental setups in laboratory and field conditions. The paper also highlights challenges in scaling VAWTs, including structural integrity, noise reduction, and cost-efficiency. Future trends and advancements in VAWT technology are considered, aiming to enhance their viability as a competitive solution for renewable energy generation in households, companies and agricultural farms. Cost-effectiveness, noise reduction, and structural durability remain significant barriers to the widespread adoption of VAWTs, despite promising advancements. This underscores the need for additional research into scalable designs, advanced materials, and optimal configurations for a variety of environmental conditions.

ABSTRACT
Această lucrare de oferă o analiză cuprinzătoare a principiului de funcționare ale turbinelor eoliene, cu un accent special pe studiile experimentale de cercetare pentru turbinele eoliene cu ax vertical (VAWT). Turbinele eoliene sunt esențiale în valorificarea energiei regenerabile, iar înțelegerea mecanismelor lor operaționare este crucială pentru optimizarea performanțelor. Lucrarea conturează principiul de bază de lucru atât ale turbinelor eoliene cu ax orizontal (HAWT) cât și al clor cu ax vertical (VAWT), cu o explorare mai profundă a acestora din urmă datorită avantajelor unice în condiții urbane și de vânt scăzut ce pot fi utilizate in agricultura. Studiul examinează critic cercetările experimentale recente privind VAWT, inclusiv diverse modificări de proiectare, studii de performanță aerodinamică și îmbunătățiri ale eficienței energetice. Sunt discutați parametri cheie, cum ar fi forma palei, configurația turbinei și factorii specifici locului, bazându-se pe constatările din configurații experimentale în condiții de laborator și de teren. Lucrarea evidențiază, de asemenea, provocările în scalarea VAWT, inclusiv integritatea structurală, reducerea zgomotului și eficiența costurilor. Sunt luate în considerare tendințele și progresele viitoare în tehnologia VAWT, cu scopul de a spori viabilitatea acestora ca soluție competitivă pentru generarea de energie regenerabilă în gospodarii, companii si ferme agricole. Eficiența din punct de vedere al costurilor, reducerea zgomotului și durabilitatea structurală rămân bariere semnificative în calea adoptării pe scară largă a VAWT-urilor, în ciuda progreselor promițătoare. Acest lucru subliniază necesitatea unor cercetări suplimentare privind designurile scalabile, materialele avansate și configurațiile optime pentru o varietate de condiții de mediu.

INTRODUCTION

Wind energy is a key pillar in the global transition toward renewable and sustainable energy systems, offering a clean and inexhaustible alternative to fossil fuels (*Arutyunov et al., 2017*). With increasing concerns over climate change, energy security, and environmental sustainability, wind turbines have gained widespread adoption as reliable sources of electricity generation. Advances in turbine technology continue to improve efficiency and reduce costs, thereby accelerating their integration into both large-scale power grids and small, decentralized energy systems (*Franković et al., 2001*).

Wind turbines function by converting the kinetic energy of moving air into mechanical energy, which is subsequently transformed into electrical energy (*Hau et al., 2006*). This process involves several key stages:

- *Wind capture*: The turbine blades, designed with aerodynamic profiles, intercept wind flow and convert it into rotational motion. The efficiency of this process depends on wind speed, blade geometry, and orientation (*Kusiak et al., 2010*).
- *Mechanical energy conversion*: The rotational energy of the blades is transferred through the rotor hub and main shaft to a generator, where it is transformed into electrical energy via electromagnetic induction (*Cheng et al., 2014*).
- *Electricity generation*: Within the generator, a system of magnets and copper coils produces an electric current as the rotor turns, which is directed to the grid for consumption (*Kan et al., 2021*).
- *Energy conversion and control*: Most turbines produce alternating current (AC), which is conditioned—typically through transformers or inverters—to match grid requirements. Advanced control systems adjust rotor orientation and blade pitch to optimize performance under varying wind conditions (*Yaramasu et al., 2015*).
- *Transmission and distribution*: Generated electricity is routed through substations and delivered to end users via the electrical grid. In larger wind farms, this process may involve energy storage systems and voltage regulation to maintain grid stability (*Hossain, 2021*).

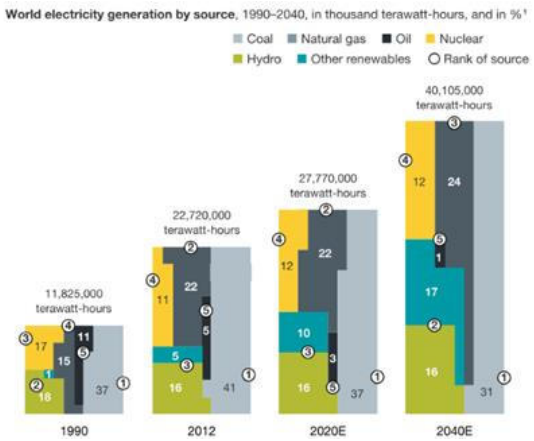

Fig. 1 - Evolution of electricity generation sources
(*www.mckinsey.com*)

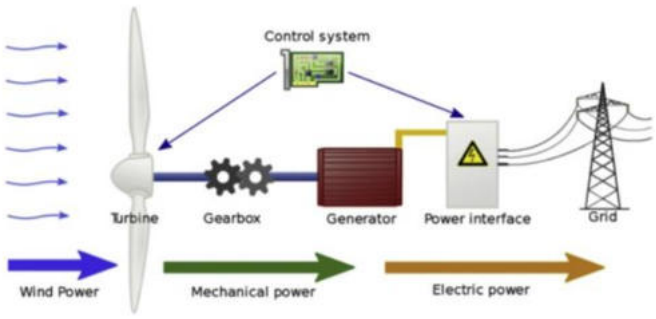

Fig. 2 - The operating principle of wind turbines
(*Gupta et al., 2021*)

While the basic principle remains consistent across all wind turbines, their configurations vary significantly, influencing their efficiency, cost, and suitability for different environments. The two primary types are horizontal-axis wind turbines (HAWTs) and vertical-axis wind turbines (VAWTs).

HAWTs are the most prevalent, particularly in utility-scale wind farms. In these systems, the rotor shaft is aligned horizontally, and the blades rotate in a vertical plane (*Mohammadi et al., 2016*). The blade design, often modeled after aircraft wings, optimizes lift-to-drag ratio for maximum energy capture at high altitudes (*Dal Monte et al., 2013*). These turbines are known for their high efficiency and scalability, though they can be challenging to maintain due to their large size and offshore or remote locations.

Table 1

Advantages and disadvantages of Horizontal Axis Wind Turbines (*Eftekhari et al., 2022*)

Advantages	Disadvantages
- *High efficiency*: HAWTs are generally more efficient than other types of wind turbines. - *Proven technology*: They have been in operation for decades, and their performance is well known. - *Large-scale production*: HAWTs can be scaled up for large wind farms, making them ideal for commercial energy production.	- *Complicated maintenance*: HAWTs are often located in remote or offshore locations, requiring significant maintenance and repair costs. - *Noise and visual impact*: These turbines can be noisy and are sometimes criticised for their visual impact on landscapes.

In contrast, VAWTs feature vertically oriented blades that rotate around a shaft perpendicular to the ground. Common designs include the Savonius and Darrieus models. A key advantage of VAWTs is their ability to capture wind from any direction, eliminating the need for yaw mechanisms. Their compact and accessible design makes them well-suited for turbulent, low-wind urban environments (*Kragten, 2004*).

Table 2

Advantages and disadvantages of Vertical Axis Wind Turbines (*Kragten, 2004*)

Advantages	Disadvantages
- *Omnidirectional*: VAWTs can capture wind from any direction, eliminating the need for the turbine to be constantly adjusted. - *Lower maintenance expenses*: Because the mechanical components of VAWTs are located closer to the ground, they are easier to maintain than HAWTs. - *Suitability for urban areas*: Their compact design and ability to operate in turbulent and low-speed winds make them more suitable for urban environments.	- *Lower efficiency*: VAWTs are generally less efficient than HAWTs, especially in large-scale power generation. - *Mechanical complexity*: VAWT designs can be more complex, leading to potential reliability issues and higher production costs.

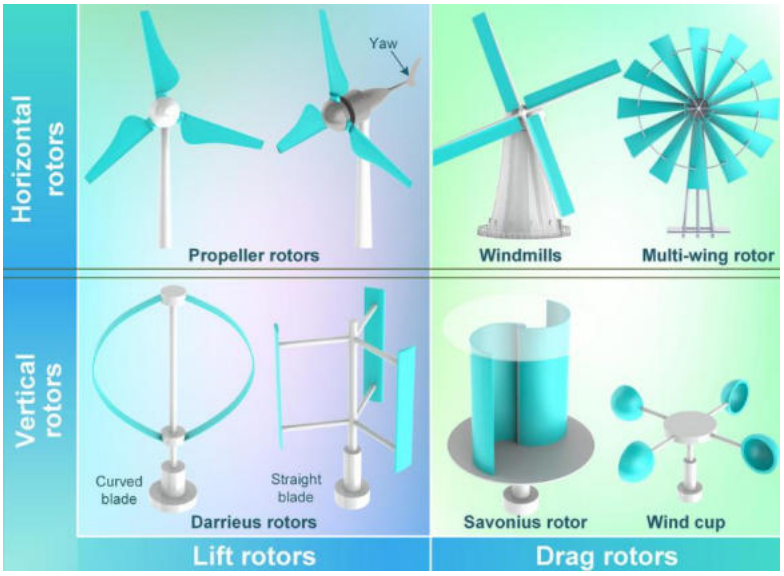

Fig. 3 – Wind turbines types (*Wang et al., 2023*)

A distinct subcategory within wind energy systems is small wind turbines, typically intended for domestic or small commercial applications. These systems are often horizontal-axis designs, though vertical-axis models are also used where spatial or wind conditions favor them. Small turbines are installed on rooftops or in open areas to provide localized power generation.

Table 3

Advantages and disadvantages of Small Wind Turbines (*Probst et al., 2011*)

Advantages	Disadvantages
- *Energy independence*: They allow homeowners or small businesses to generate their electricity and reduce grid dependency.	- *Limited power generation*: small turbines may not generate enough electricity to meet the power needs of larger buildings or multiple homes.
- *Cost-effective for small installations*: For smaller energy needs, these turbines are more cost-effective than large-scale installations.	- *Wind dependence*: These turbines are highly dependent on local wind conditions, which can be variable.

This introduction provides an overview of the principles, configurations, and applications of wind turbines, setting the stage for deeper exploration into their design optimization. In particular, as interest grows in sustainable urban energy systems, vertical-axis wind turbines are attracting renewed attention due to their adaptability and compact footprint. The following sections will focus on modeling and enhancing the performance of such turbines, with a particular emphasis on computational approaches and design refinement.

SPECIFICITY OF WIND TURBINES. WIND TURBINE TECHNOLOGIES

Wind energy has emerged as one of the most popular and rapidly growing renewable energy sources worldwide. Concerns about climate change and the environmental impact of fossil fuels have fueled the need for sustainable alternative resources. Wind turbines stand out from other renewable energy sources due to their efficiency, scalability, and environmental reasons (*Savino et al., 2017*). This section investigates wind turbine technology, focusing on their many varieties, the concepts behind their operation, their advantages, and current technical developments. Wind turbines are divided into two categories: horizontal axis wind turbines (HAWTs) and vertical axis wind turbines (VAWTs) (*Paraschivoiu et al., 2018*). Both types convert the kinetic energy of the wind into mechanical energy that is then used to create electricity. However, their design, application, and efficiency vary greatly.

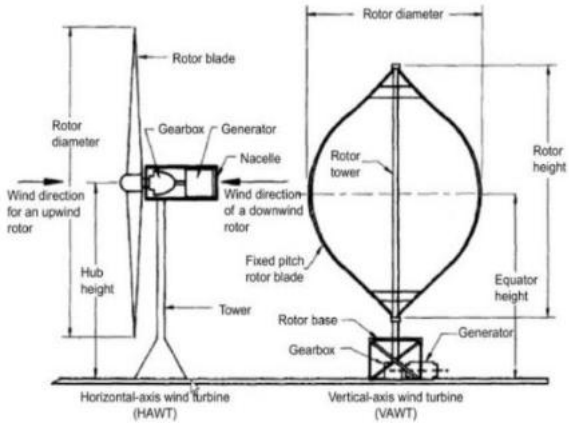

Fig. 4 - The Basics of HAWT and VAWT Configurations (*Ismail et al., 2021*)

Horizontal axis wind turbines are the most common and commonly used in large-scale commercial wind farms. These turbines have their blades attached to a horizontal shaft, and the entire turbine is aligned with the direction of the wind. HAWTs are often considered the most efficient form of wind turbine due to their aerodynamic design (*Sedaghat et al., 2014*). They generally have three blades that are designed to capture the most wind energy. HAWT blades rotate along a horizontal axis and can generate huge amounts of power, making them suitable for use in areas with regular wind speeds, such as coastal or offshore areas. On the other hand, vertical axis wind turbine blades rotate around a vertical axis that is perpendicular to the ground (*Chaudhary et al., 2014*). VAWTs are suitable for areas with irregular or turbulent wind patterns because, unlike HAWTs, they do not require orientation into the wind. Because they can be positioned closer to the ground, VAWTs offer advantages in terms of maintenance, although they are often smaller and less efficient than horizontal ones (*Xisto et al., 2016*). In addition, VAWTs are often quieter and have a smaller aesthetic impact, which may increase their acceptability in residential and urban environments (*Kumar et al., 2018*).

The essential concept behind wind turbines is the transfer of kinetic energy from the wind into mechanical energy, which is then converted into electrical energy by the generator (*Wang et al., 2018*). The operation of a wind turbine can be divided into several parts (*Li et al., 2011*). The first is wind capture, in which wind turbines use enormous blades to capture the kinetic energy of the wind. When wind blows over the blades, it generates lift and drag forces, causing them to rotate (*Schaffarczyk et al., 2017*). This rotational motion powers the turbine generator. The rotating blades are attached to a shaft, which is connected to a gearbox. The gearbox increases the rotational speed of the shaft to reach the speed required by the generator. The mechanical energy is transmitted to the generator and converted into electrical energy (*Keung et al., 2008*).

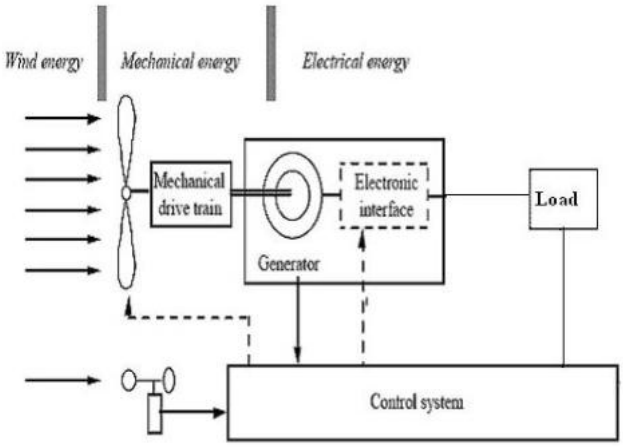

Fig. 5 - Wind energy conversion scheme (*Rambabu et al., 2012*)

The generator, which normally consists of a rotor and a stator, works on the concept of electromagnetic induction. The shaft rotates, causing the rotor to rotate inside the stator, generating energy. The electricity produced is then sent through wires to the grid or to a local power system. Modern wind turbines are equipped with advanced control systems that improve their performance (*Balat et al., 2009*). These systems use wind speed, direction, and other environmental parameters to determine the turbine's orientation, blade pitch, and energy output. This increases efficiency and reduces damage in adverse weather conditions. Due to their many advantages, wind turbines are becoming an increasingly important part of the world's transition to renewable energy. Unlike fossil fuels, wind energy does not emit greenhouse gases or air pollutants while it is operating. Since wind turbines have a low environmental impact, they are a crucial tool in the fight against climate change and reducing the carbon footprint (*Pryor et al., 2010*). In addition, wind energy has become one of the most affordable sources of renewable energy in recent decades due to the huge reduction in costs. The design, materials, and manufacturing methods of wind turbines have improved, making wind energy more competitive with traditional sources such as nuclear, coal, and gas (*Abbasi et al., 2017*).

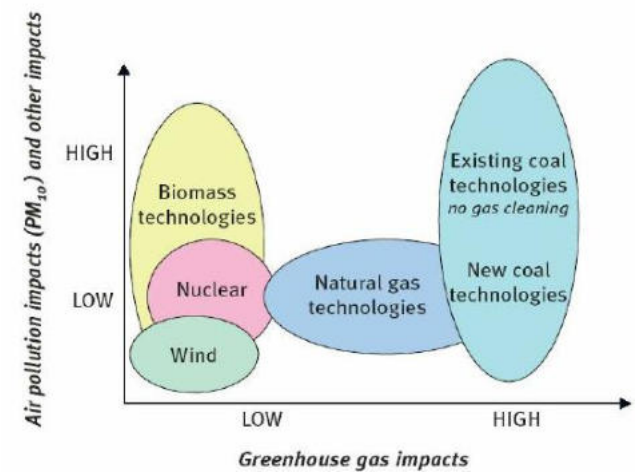

Fig.6 - Comparison of energy sources
(Van Kuik et al., 2008)

Fig.7 - Decreasing the cost of renewable energy
(*https://www.statista.com/chart/26085/price-per-megawatt-hour-of-electricity-by-source/*)

By investing in wind energy, nations can reduce their dependence on imported fossil fuels, improving their economic stability and energy security.

Producing wind energy locally can help the renewable energy industry create jobs and reduce dependence on international energy markets. Around the world, the wind energy sector has generated millions of jobs in production, installation, operation, and maintenance (*Aldieri et al., 2017*). The need for skilled personnel in a variety of disciplines, including engineering, logistics, and research, is growing with the demand for wind turbines.

In recent years, significant technological developments have taken place in the operation and design of wind turbines. Thanks to these advances, wind energy is now more economical, reliable, and efficient (*Kaldellis et al., 2011*). Some contemporary wind turbines have rotor diameters of over 200 meters, demonstrating the significant increase in wind turbine size. Since offshore wind farms have a lot of space and wind resources, these larger turbines are of great help there (*Bilgili et al., 2022*).

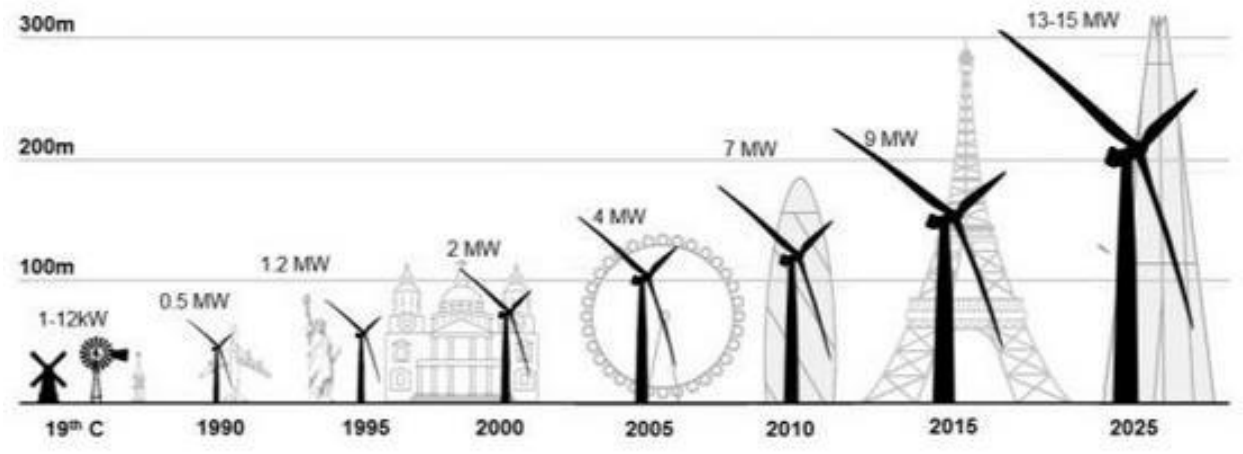

Fig. 8 - Evolution of wind turbine size (*Pisanò et al., 2019*)

Floating wind turbines are an innovative technology that allows wind turbines to be installed in deeper oceans, where conventional fixed-bottom turbines are impractical. These turbines are fixed to the seabed by floating platforms and can be erected in places with strong and persistent winds, far from shore. Floating wind technology has the potential to open up vast new areas for wind energy generation.

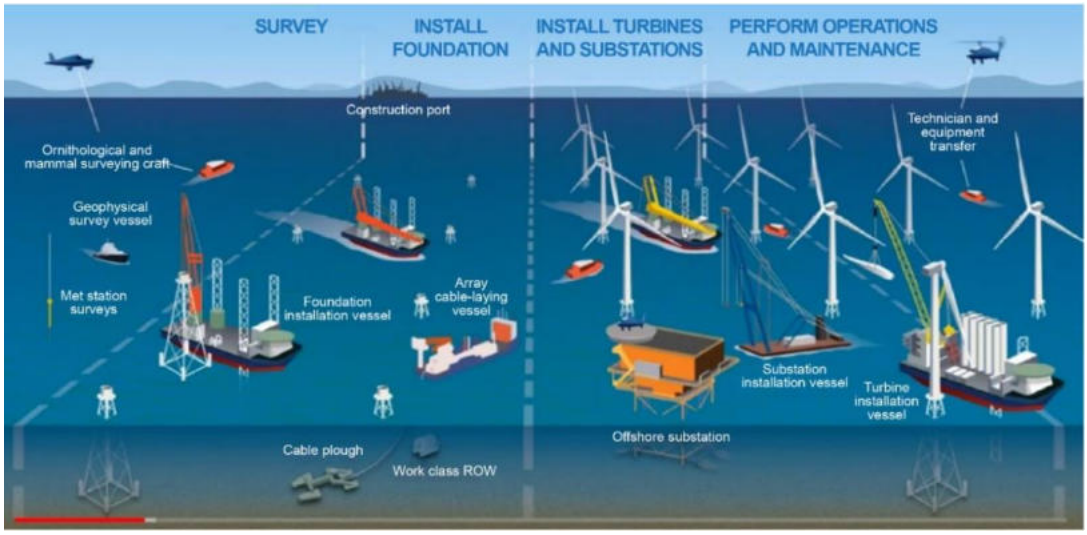

Fig. 9 - Offshore wind turbine installation (*Ryu et al., 2022*)

Because wind power is intermittent, its production is dependent on the availability of wind. However, more efficient integration of wind power into the electricity grid is possible with the development of smart grid technology. Energy storage devices, sophisticated forecasting methods, and wind power can all be used by smart grids to control the fluctuation of wind power and provide a constant and reliable source of energy (*Abbey et al., 2008*).

To increase efficiency, the design of turbine blades has changed dramatically. More wind energy can be captured at lower speeds due to the aerodynamic efficiency, reduced length, and weight of modern blades. Innovative features such as fins, which reduce drag and improve performance, are also included in some blades (*Chehouri et al., 2015*).

In addition to size increases and floating offshore installations, recent breakthroughs in materials science have had a substantial impact on wind turbine performance. The adoption of carbon fiber-reinforced polymers (CFRPs) and other advanced composites has led to lighter yet stronger blades, improving aerodynamic efficiency and durability while reducing maintenance needs (*Sun et al., 2025*). These materials also contribute to the feasibility of longer blades without compromising structural integrity.

Additive manufacturing (3D printing) is beginning to revolutionize turbine component production. It allows for complex, custom geometries that were previously unfeasible and enables localized manufacturing, reducing costs and transportation emissions (*Sivamani et al., 2020*).

Another major breakthrough is the integration of artificial intelligence (AI) and machine learning algorithms in wind turbine control systems. These smart controllers optimize blade pitch, yaw, and even predict maintenance needs based on real-time environmental data and turbine health metrics (*Al Noman et al., 2022*). Predictive maintenance, enabled by AI-driven condition monitoring, significantly reduces downtime and increases turbine lifespan.

Modular turbine designs are also emerging as a way to reduce installation complexity and allow for easier transportation, especially in remote or urban environments (*GU et al., 2021*). In offshore installations, autonomous robotic systems are being developed for turbine inspection, repair, and cleaning, reducing the need for human intervention in harsh marine conditions.

Looking ahead, several trends are poised to define the next generation of wind energy technology:

- *hybrid renewable systems*: Future wind turbines will increasingly be integrated into hybrid energy systems, combining wind with solar, hydrogen production, or battery storage. These systems enhance grid stability and ensure continuous energy supply during low-wind periods (*Mohamed*, 2023).

- *vertical axis wind turbine farm optimization*: As urban and distributed generation grows, VAWTs may see renewed attention. New research into aerodynamic interaction in VAWT arrays is improving their efficiency when placed in close proximity, enabling more compact and urban-friendly wind farms (*Barnes et al., 2019*).

- *bio-inspired blade design*: Nature-inspired designs—like humpback whale tubercles or bird wings—are being mimicked to reduce drag, increase lift, and enhance performance in turbulent wind conditions (*Hassan et al., 2023*).

- *dynamic blade morphing*: Research into smart materials such as shape-memory alloys and piezoelectrics is paving the way for turbine blades that adapt in real time to changing wind conditions, optimizing power capture (*Baghdadi et al., 2020*).

- *end-of-life and recycling innovations*: With sustainability at the forefront, the development of fully recyclable turbine blades and circular economy strategies for decommissioned components will become increasingly important (*Kouloumpis et al., 2020*).

- *high-altitude wind energy* (HAWE): Technologies such as airborne wind turbines (e.g., tethered drones or kites) are being explored to capture stronger, steadier winds at higher altitudes, potentially revolutionizing onshore energy production (*Breban et al., 2020*).

In a short period of time, wind turbine technology has advanced significantly, becoming a major force in the global energy transition due to advances in design, operation, and efficiency. With increasing accessibility and scalability, wind energy could contribute significantly to global energy supply.

Even so, ongoing developments in infrastructure and technology are helping to eliminate obstacles such as intermittency and grid integration. Wind turbines will be essential for reducing dependence on fossil fuels, preventing climate change, and building a sustainable energy future as the globe continues to embrace renewable energy.

WORKING PROCESS OF VERTICAL AXIS WIND TURBINES - COMPARATIVE ANALYSIS OF SAVONIUS AND DARIEUS TURBINES

Wind energy has become one of the most promising renewable energy sources in the modern world as sustainable ways are sought to meet energy demands. The vertical axis wind turbine (VAWT) is a special and often overlooked option among the different types of wind turbines. The VAWT is much more versatile than the horizontal axis wind turbine, which is more popular due to its design, which allows it to harness wind energy from any direction, especially in regions with irregular wind patterns (*Ashwill et al., 2012*).

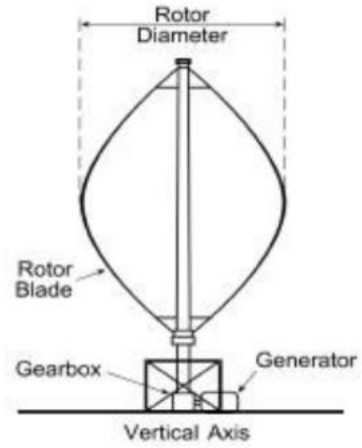

Fig. 10 - VAWT (*Salem, 2016*)

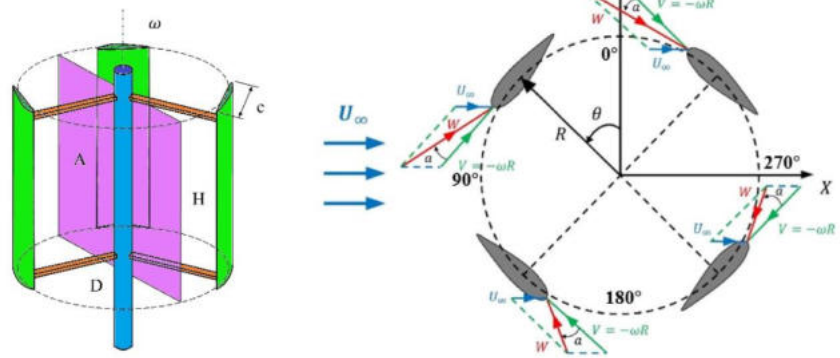

Fig. 11 - Force distribution on a VAWT (*Abbasi et al., 2024*)

The moment the wind hits the blades of a VAWT is when the action begins. The design of a VAWT ensures that it can capture wind energy regardless of the direction of the wind, unlike conventional turbines that must be pointed into the wind. This feature makes a VAWT an excellent option for urban settings where airflow can be disrupted by buildings or other obstacles, and wind flows are erratic.

VAWTs differ fundamentally in their construction in that their blades rotate along a vertical axis instead of a horizontal one. The shape of these blades varies depending on the type of turbine. Similar to the wings of an airplane, the blades in some designs are designed as curved sails that provide lift. In others, the blades are designed to produce drag, much like a cup or spoon that catches the wind. These two types are called Darrieus and Savonius turbines, respectively.

The entire process from wind to electricity is a smooth, uninterrupted cycle. An environmentally friendly alternative to conventional energy sources such as coal or natural gas, the energy produced by VAWTs is clean and renewable. One benefit of this system is that VAWTs are more suitable for residential and urban environments, as they are quieter and less invasive than their horizontal equivalents. Furthermore, compared to traditional turbines, which often have parts located at high altitudes, the VAWT design ensures that its mechanical components are easily accessible, making maintenance simpler and less expensive (*Abdolahifar et al., 2024*).

VAWTs have many disadvantages, despite their benefits. Their lower efficiency compared to HAWTs is one of their main disadvantages, especially in regions with regular wind patterns. In addition, the durability of the blades can occasionally be affected by mechanical stresses caused by the rotational forces acting on them. To increase the turbine's performance and longevity, experts are still working to improve the design by using stronger materials and improving the aerodynamics of the blades (*Kragten, 2024*).

An important feature that makes the VAWT unique among turbine designs is its ability to capture wind from all directions. A rotating mechanism, which orients the turbine towards the wind, is not required for VAWTs, unlike HAWTs, which must be orientated towards the wind. This ensures that the turbine will continue to operate efficiently in settings where wind direction changes frequently (*Lee et al., 2018*).

The small size of the VAWT offers an additional benefit. The turbine is an excellent option for cities with limited space, as it can be located in smaller areas and can operate well in stormy or low-wind conditions. Whether installed on a rooftop or incorporated into the architecture of a building, the VAWT is a discreet yet efficient source of renewable energy. Furthermore, by reducing dependence on fossil fuels, VAWTs contribute to a sustainable future (*Bashir et al., 2021*). Finding sustainable, reliable, and scalable

energy solutions is more crucial than ever as cities expand and populations grow. With its practical and environmentally beneficial energy solution, VAWTs have great potential in this field. Although still in development, VAWTs have already shown promise in small-scale applications, and research is still ongoing to increase their effectiveness and design. VAWTs could become increasingly widespread in urban energy networks as engineers strive to maximize turbine performance, providing a creative response to the problems associated with contemporary energy use (*Aresti et al., 2013*).

The vertical axis wind turbine is an interesting and efficient way to capture wind energy. VAWTs have enormous potential for the future of renewable energy due to their small size, ease of maintenance, and ability to capture wind from any direction. Although there are still issues, mainly with sustainability and efficiency, these are being addressed by ongoing technological developments. With the introduction of clean, renewable energy in cities and small-scale applications around the globe, VAWTs may become increasingly significant in the coming years as we move towards a more sustainable energy future (*Kavade et al., 2017*).

Fig. 12 - Applications of VAWT in urban environments (*Tasneem et al., 2020*)

The type of wind turbine known as vertical axis wind turbines (VAWTs) has attracted interest in both research and real-world applications. Two well-known types of VAWTs, among the many designs, are the Savonius and Darrieus turbines. The efficiency, adaptability for specific applications, operating processes, and design complexity of these two categories vary greatly. Based on their operating principles, benefits, disadvantages, and applicability to different applications and climatic situations, they can be compared (*Abid et al., 2015*).

Among the vertical axis wind turbines, the Savonius turbine is one of the most basic designs. Two or more semi-cylindrical blades arranged in an “S” shape and fixed on a vertical axis usually make up its rotor. For strength and longevity, these blades are often composed of metal or composite materials. A Savonius turbine operates on the basis of drag forces. The curved blades rotate when the wind hits them due to wind pressure. Due to the configuration of the blades, the turbine always rotates because one side of the rotor experiences a greater drag force than the other (*Akwa et al., 2012*).

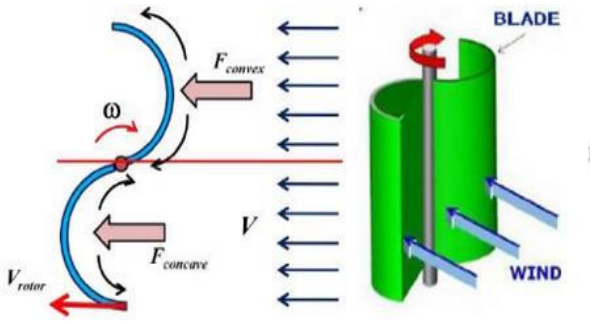

Fig. 13 - Diagram of a Savonius VAWT (*Khandagale et al., 2017*)

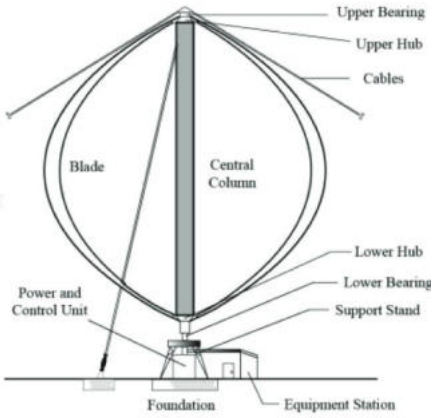

Fig. 14 - Diagram of a Darrieus VAWT *(Li, 2019)*

Often called an “egg beater” because of its unusual design, the Darrieus turbine has vertical blades that are usually curved and mounted on a vertical shaft. Like an airplane wing, the blades are often shaped with aerodynamic profiles to increase lift forces. The Darrieus turbine works on the basis of aerodynamic lift, which produces rotational motion by varying the air pressure on the opposing surfaces of each blade (*Tjiu et*

al., 2015). The lift force works in a direction that causes the turbine to rotate when the wind blows over the blades. Since the Darrieus turbine cannot start rotating at low wind speeds without external help, it often requires a starting mechanism. It is well known that the Savonius turbine is not as efficient as other types of wind turbines. The main reason for this is that it uses drag forces, which are less efficient than lift-based methods. The efficiency of the Savonius turbine is typically between 10% and 20%, depending on environmental conditions and design differences. However, it has the particular benefit of being able to start rotating at low wind speeds, making it suitable for locations with frequent low wind speeds (*Menet et al., 2004*). The Savonius turbine is also frequently used in settings such as cities or smaller wind farms, where reliability and robustness are more important than efficiency. Compared to the Savonius turbine, the Darrieus turbine often offers higher efficiency. Unlike the Savonius design, which uses drag forces, it uses lift forces, which are more efficient. Depending on the system configuration, wind speed, and blade design, the efficiency of the Darrieus turbine can range from 25% to 45% (*Zereg et al., 2024*). However, in low-wind areas, the Darrieus turbine is less successful because it requires higher wind speeds to start spinning. Large-scale wind power generation is feasible due to its high efficiency and ability to generate more electricity in steady wind.

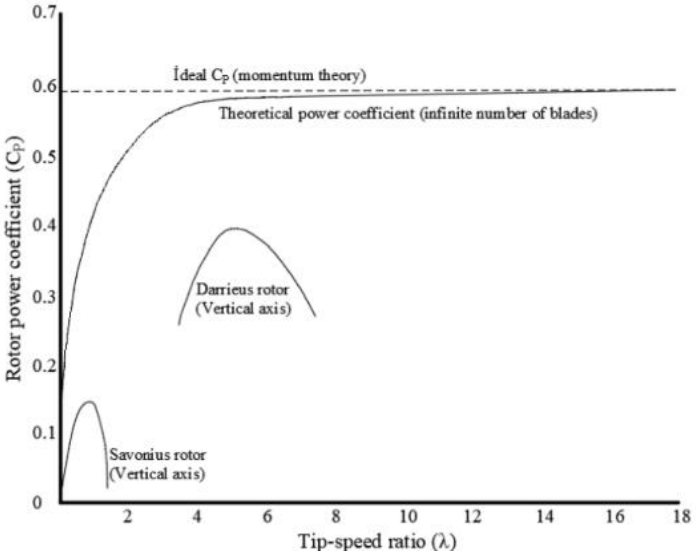

Fig. 15 - Efficiency comparison between Savonius and Darrieus VAWTs (*Muratoğlu et al. , 2019*)

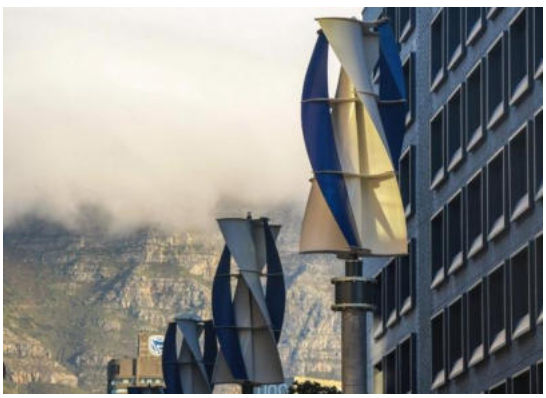
Table 4

Advantages and disadvantages of the Savonius turbine(*Shende et al., 2022*)



Advantages	Disadvantages
- *Low wind speed*: One of the most significant advantages of the Savonius turbine is its ability to start operating at low wind speeds. This makes it ideal for areas where wind conditions are inconsistent or low. - *Simple design*: The Savonius turbine has a relatively simple design and is easy to manufacture, making it cost-effective. This simplicity also leads to easier maintenance and repairs. - *Durability*: Savonius turbines are known for their durability and can withstand high winds and turbulent conditions, making them suitable for harsh environments. - *Vertical axis*: The vertical axis design allows the turbine to operate regardless of wind direction, making it more versatile in environments where wind direction is variable.	- *Low efficiency*: Due to its dependence on drag forces, the Savonius turbine has a relatively low efficiency compared to lift-based designs. This limits its power generation capacity. - *Limited power output*: The design of the Savonius turbine typically results in a lower power output compared to other wind turbines, making it unsuitable for large-scale power generation. - *Noise*: Savonius turbines tend to produce more noise compared to Darrieus turbines, which can be a negative factor in residential or urban areas.

Table 5

Advantages and disadvantages of the Darrieus turbine (*Paraschivoiu et al., 2002*)

Advantages	Disadvantages
- *High efficiency*: the Darrieus turbine operates on aerodynamic lift, which is more efficient than the drag-based operation of the Savonius turbine. This leads to a higher power generation potential. - *Higher power output*: Due to its more efficient operation, the Darrieus turbine can generate much more power than the Savonius turbine, making it more suitable for large-scale applications. - *Compact design*: Although larger than the Savonius turbine, the Darrieus turbine can still be compact in terms of footprint, making it suitable for urban and offshore installations where space is limited. - *Less noise*: the Darrieus turbine typically produces less noise than Savonius turbines, making it more suitable for residential or urban environments.	- *High wind speed*: One of the main disadvantages of the Darrieus turbine is that it requires higher wind speeds to start rotating, making it less efficient in low-wind regions. - *Complex design*: The Darrieus turbine is more complex to manufacture and often requires additional components, such as a starting mechanism, making it more expensive to install. - *Structural challenges*: Darrieus turbines can suffer mechanical stresses due to high loads on the blades, which can lead to fatigue over time, leading to maintenance challenges.

In low-power, small-scale applications where efficiency is not the main concern, the Savonius turbine is frequently used. In cities with irregular wind conditions, the Savonius turbine is frequently used due to its low wind speed. Due to its design, it can work well in places with complicated wind patterns. For off-grid installations or as additional energy sources for homes, farms (*Glasberg et al., 2024*), or industrial sites, the Savonius turbine is perfect. The Savonius turbine is suitable for applications such as water pumping, where constant rotation at low speed is required, due to its robustness and simplicity.

(*https://greenoteka.eu*)

Fig. 16 - Savonius in an urban environment

The higher efficiency and power output of the Darrieus turbine make it more suitable for large-scale applications. In utility-scale wind farms that require a lot of power, the Darrieus turbine is frequently used. When wind conditions are consistent, it can produce more electricity and is more efficient than smaller turbines. For offshore sites, where wind speeds are often higher and more reliable, the Darrieus turbine is perfect due to its robust design and increased power output. To summarize, both Savonius and Darrieus wind turbines have various benefits and uses due to their design, efficiency, and operating circumstances. The Savonius turbine works well in low-wind environments, providing a low-cost and long-lasting solution for small-scale applications, while the Darrieus turbine has higher efficiency and power, making it more suitable for large-scale wind power generation in areas with more consistent wind conditions. Each turbine has a place in the renewable energy landscape, and the decision to choose between them is largely determined by individual energy requirements, environmental circumstances, and available space.

Hybrid vertical axis wind turbines (VAWTs), which integrate Savonius and Darrieus rotor designs, aim to capitalize on the advantages of both configurations—namely, the high starting torque of the drag-based Savonius turbine and the superior aerodynamic efficiency of the lift-based Darrieus rotor (*Hosseini et al., 2019*). This combination enhances self-starting capabilities while maintaining favorable power output at higher wind speeds, making hybrid models particularly attractive for small-scale and urban wind energy applications. The synergy between the two mechanisms contributes to improved rotational stability, smoother power generation across varying wind conditions, and better overall performance compared to standalone designs. Researchers have explored a variety of geometric configurations—such as blade overlap, angular positioning, and rotor placement—to optimize the interaction between the components. Numerical and experimental investigations have demonstrated that these hybrid systems offer a balanced compromise between torque generation and power coefficient, addressing key limitations inherent to each individual turbine type.

SYNTHESIS OF EXPERIMENTAL RESEARCH ON WIND TURBINES AND THEIR WORKING PROCESS

As a clean and sustainable alternative to fossil fuels, wind energy has emerged as a key source of renewable energy in the fight against climate change (Barthelmie et al., 2021). Wind turbines have emerged as a key component of this energy shift, transforming wind energy from kinetic to mechanical and ultimately electrical forms. However, extensive experimental research is needed to ensure that these turbines are efficient, reliable, and capable of operating in a variety of situations. Testing a turbine involves more than just determining how efficiently it produces energy; it also involves evaluating its performance, robustness, and safety in a range of real-world scenarios (He et al., 2022).

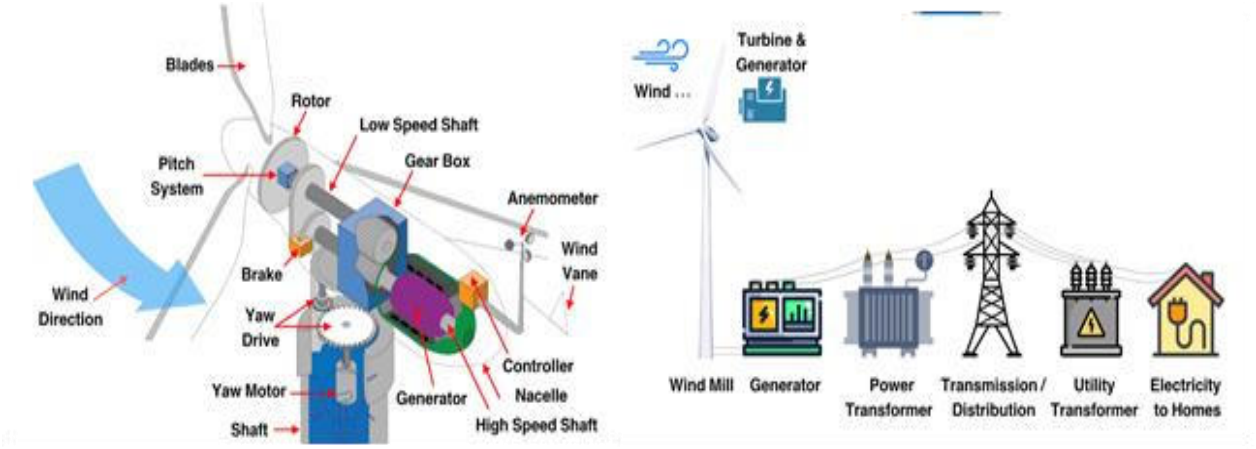

Fig. 17 - Wind turbine diagram
(*https://www.electricaltechnology.org/2021/08/wind-power-plant.html.*)

The fundamentals of wind turbine mechanics need to be understood before getting into the finer points of experimental testing. The parts of a conventional wind turbine include a tower, nacelle, generator, rotor, and blades. The blades rotate as the wind passes over them. A generator is turned by this rotational motion, and the mechanical energy is converted into electrical energy. Wind speed, the turbine operating under different conditions, and the design of the blades are some of the variables that affect the efficiency of this energy conversion (*Elizondo et al., 2009*). Testing these turbines in controlled, real-world settings is necessary to maximize performance and reliability.

To ensure that wind turbines meet the required performance and safety criteria, experimental testing is essential. These tests are primarily designed to evaluate the turbine's ability to generate electricity under a range of wind conditions (*Gaunt et al., 2012*). By monitoring the turbine's response to mechanical loads and severe weather conditions, engineers also aim to assess the structural integrity of the machine. This facilitates the identification of potential defects, predicts the turbine's durability, and ensures its safe operation. In addition, experimental testing helps improve turbine designs by improving overall efficiency and reliability through refinement of materials, control systems, and aerodynamic characteristics (*Bottasso et al., 2014*).

Key elements, including energy production, efficiency, and reliability under varying wind speed and climate conditions, can be measured by engineers through testing. Testing can identify a turbine's power curve, for example, which shows the relationship between wind speed and energy production. This curve helps optimize the turbine design and provides insights into its operating limits (*Carrillo et al., 2013*).

Laboratory testing, field testing, and accelerated life testing are the three main testing approaches that can be used to analyze the complex process of wind turbine testing (*Bastankhah et al., 2017*). Each of them contributes in a different way to the evaluation of different turbine performance factors. Laboratory tests usually focus on specific parts of the wind turbine, such as the generator, nacelle, and blades. The aerodynamic characteristics of the blades are investigated in wind tunnels, and additional tests are conducted to evaluate mechanical performance, stress resistance, and material durability in simulated environments. Before the turbine is assembled and placed in the field, the intention is to understand how each component functions.

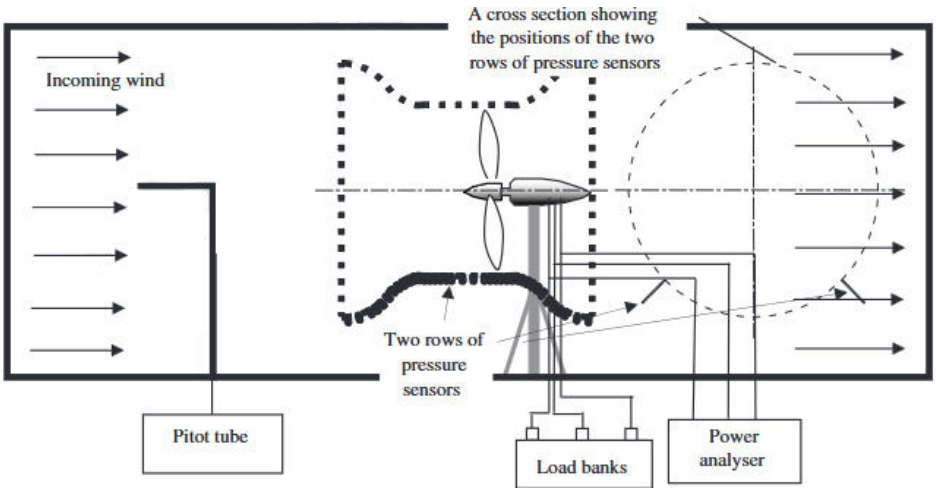

Fig. 18 - Wind turbine testing diagram in wind tunnel (*Agha et al., 2018*)

As an alternative to laboratory testing, field testing involves putting turbines in realistic settings to evaluate how well they perform in wind conditions. Measuring energy production at different wind speeds, evaluating turbine performance under varying wind load conditions, and monitoring long-term performance are common examples of such tests. Field testing allows engineers to see how turbines respond to variables that are difficult to replicate in a laboratory, including turbulence, humidity, and temperature changes.

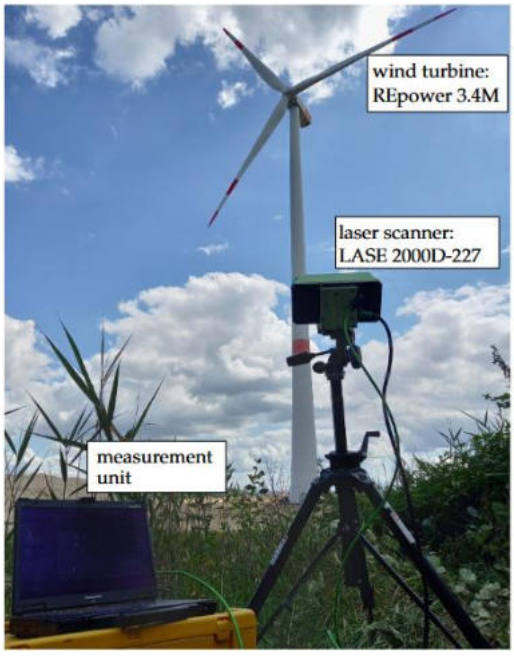

Fig. 19 - Field testing setup (*Helming et al., 2021*)

The data must be examined thoroughly after it has been collected. Key performance parameters such as the power curve, efficiency, and capacity factor are of particular interest to engineers. While efficiency shows how much of the wind energy is converted into electricity, the power curve allows engineers to see how much power a turbine produces at different wind speeds. Engineers can assess the overall performance of the turbine by analyzing the capacity factor, which shows how efficiently the turbine generates energy relative to its maximum potential.

It is also essential to test for noise and vibration. The structural integrity of the turbine can be compromised by excessive vibration or noise, which could lead to mechanical failure or environmental problems in populated areas. Engineers can improve turbine designs to minimize noise and wear by monitoring these variables during experimental testing (*Shinagam et al., 2020*).

Wind turbine testing presents certain challenges. The instability of the wind itself is the main challenge. Because wind direction, speed, and turbulence are so variable, it is difficult to reproduce constant conditions in both laboratory and field experiments. Wind is rarely as predictable as one would like, and conditions in the field can vary rapidly, even though wind tunnels provide controlled environments for some studies. Although engineers frequently use sophisticated forecasting models to predict wind patterns, unpredictability is still a persistent problem.

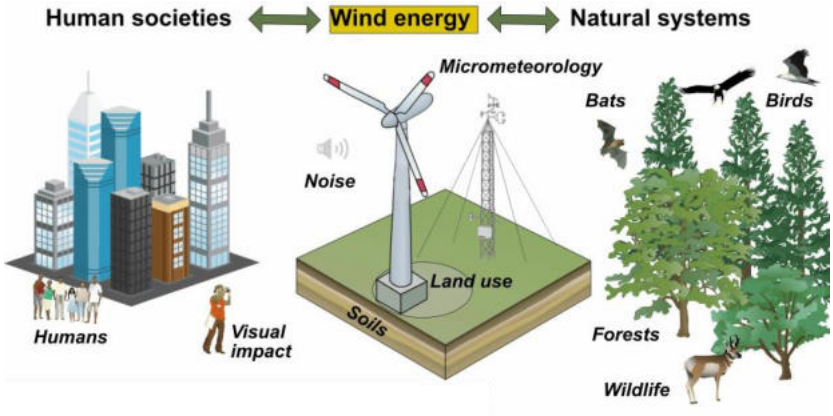

Fig. 20 - Testing challenges and environmental factors (*Sander et al., 2024*)

There are also logistical issues, especially with outdoor tests. Turbines are often located in remote areas, far from maintenance teams or test facilities. The testing procedure could be further complicated by the high cost of installation, maintenance, and transportation. In addition, wind turbines are heavy and bulky, making them difficult to move and install, especially in hilly or offshore wind farms (*Vis et al., 2016*). Another important factor is safety. Field tests can be dangerous for personnel, especially when carried out in adverse weather. Therefore, strict safety procedures must be followed to ensure that people are protected during the testing procedure (*Jin et al., 2016*). Potential risks such as strong winds, electrical failures, or even structural failure of a turbine component during testing must be considered by engineers.

The results of experimental tests have significant ramifications for the future of wind energy and turbine design. Engineers have gained important knowledge through testing, which has led to notable increases in turbine cost-effectiveness, efficiency, and reliability. Modern turbines now have higher energy conversion efficiencies, for example, due to advances in materials science, control systems, and blade design. In addition, superior testing techniques have produced turbines that are more resilient to harsh weather conditions (*Sun et al., 2022*), such as the hot, dry climate of desert regions or the icy winds of the North Sea.

SYNTHESIS OF EXPERIMENTAL RESEARCH ON THE WORKING PROCESS OF SAVONIUS TURBINES

The interest in wind energy has increased significantly due to the search for renewable and sustainable energy sources. Among the types of wind turbines, the Savonius wind turbine (SWT), a vertical axis wind turbine (VAWT), stands out for its ease of use, efficiency in low wind conditions, and low production costs (*Zemamou et al., 2017*). Aerodynamic drag forces drive the turbine, making it perfect for small-scale energy production. However, a large number of experimental tests are required to exploit its potential fully and maximize its performance (*Akwa et al., 2012*).

The original form of the Savonius wind turbine, created in the 1920s by the Finnish engineer Sigurd Savonius, consists of two or more vertically positioned curved blades (*Zoucha et al., 2023*). The drag force generated by the wind hitting the blades of a Savonius turbine allows it to harness wind energy, unlike horizontal-axis wind turbines. The blades are typically spoon-shaped, with one side facing the wind to "catch" it and the other side acting as a drag force to rotate the turbine (*Gall et al., 2023*). Wind energy is converted into mechanical energy as the blades rotate about a vertical axis as a result of the wind interacting with them. Because the Savonius turbine relies on drag forces rather than lift, it is often less efficient than horizontal-axis turbines, while still being successful at low wind speeds (*Dewan et al., 2021*). However, the turbine's simple design and ability to operate in irregular and fluctuating wind conditions make it a desirable choice for small-scale energy applications, especially in off-grid, domestic, or urban environments.

To better understand and improve the performance of Savonius wind turbines, experimental testing is essential. The complexity of real-world wind conditions and turbine performance cannot be fully captured by theoretical models and simulations, although they can provide some insight (*Wenehenubun et al., 2015*). Researchers can evaluate elements such as power output, efficiency, and the impact of environmental conditions through physical tests, which improve design and operation methods. Real-world information about the turbine's power output, efficiency under different wind conditions, and the impact of turbulence and mechanical wear are all provided through testing. Engineers can improve turbine performance and make it more reliable and efficient for specific applications by adjusting important design parameters through experimental testing, such as rotor height, number of blades, and blade curvature (*Zhou et al., 2013*). To determine whether the turbine is suitable for practical use, researchers conduct long-term experiments in a variety of climatic situations to evaluate its longevity and mechanical durability. The best economical and efficient design for a given situation can be found by comparing several turbine designs, combinations, and materials through experimental testing (*Shamsuddin et al., 2022*).

Savonius wind turbines can be experimentally tested in several ways, each designed to evaluate a specific facet of the turbine's performance. Wind tunnel testing, field testing, and computational fluid dynamics (CFD) simulations are the most commonly used techniques (*Ferrari et al., 2017*).

By carefully adjusting wind direction, speed, and turbulence in a controlled wind tunnel, researchers can evaluate how a turbine responds to particular circumstances. Wind tunnel testing is useful for determining power coefficients, evaluating aerodynamic forces acting on blades, and fine-tuning turbine shape (*Ross et al., 2011*). Although wind tunnel testing provides controlled settings and repeatability, it cannot accurately capture the complexity of environmental circumstances seen in the real world.

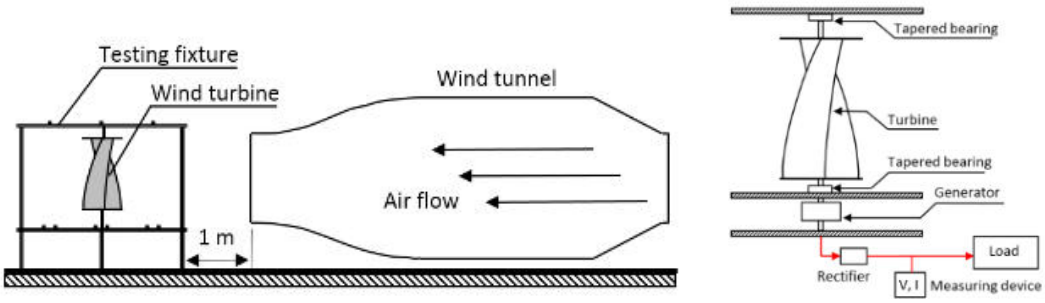

Fig. 21 - Wind tunnel setup for testing Savonius wind turbine
(*Zakaria et al., 2019*)

To track the performance of Savonius turbines over time, field testing involves placing them in real-world outdoor environments. Field tests provide information about the turbine's performance in a variety of wind conditions, including turbulence, gusts, and changing wind directions, unlike wind tunnel experiments. The turbine's behavior in different climates, reliability, and long-term performance are all evaluated through field tests.

A useful technique for simulating wind flow around turbine blades and predicting aerodynamic performance is computational fluid dynamics simulations. In addition to helping researchers refine design features, including blade shape, size, and length, these models provide information about the distribution of aerodynamic forces, drag, and lift (*Dobrev et al., 2011*). Although CFD can help improve the design before physical testing, it may not be able to account for all environmental factors that influence turbine performance.

Turbine output and mechanical load must be measured during field and wind tunnel testing to determine efficiency. Researchers can measure the turbine's rotational speed and torque using instruments such as dynamometers and torque sensors. In addition to providing information to evaluate the turbine's overall performance and energy production, these measurements allow the calculation of the power coefficient (Cp) (*Kadam et al., 2013*).

Several experimental investigations have provided useful information on the performance of Savonius wind turbines. Key findings from these investigations include blade configuration, blade curvature, rotor height, power coefficient, and efficiency.

The number of blades in a Savonius turbine has a large influence on its performance. While two-blade variants are popular due to their simplicity, three- or four-blade turbines offer better torque and stability at low wind speeds. However, this may increase drag and decrease the turbine's efficiency. According to experimental results, the appropriate number of blades is determined by the intended use, with fewer blades being more efficient in higher wind speeds and more blades providing greater efficiency at lower speeds (*Chaichana et al., 2019*).

The curvature of the turbine blades is another crucial component that affects its aerodynamic performance. Blades with steeper curvatures create more drag, which can increase the rotational speed but can also cause mechanical stress, leading to increased wear rates. Blades with shallower curvatures, on the other hand, generate less drag but may be less efficient in transferring wind energy into rotational motion (*Chan et al., 2018*). Experimental investigations suggest that moderate curvature is usually the most effective for balancing drag and performance; however, modifications may be necessary depending on the circumstances and turbine size.

The height of the turbine rotor, or the distance between the center of rotation and the tip of the blades, is also important in influencing performance. Taller rotors can gather wind from a wider region, increasing the power generation capacity. However, increasing the rotor height can increase the complexity and expense of the turbine, with performance gains decreasing beyond a certain point. The rotor height should be adjusted based on the anticipated wind conditions and the unique power requirements of the application, according to tests (*Tahani et al., 2017*).

The power coefficient (C_p) is a useful indicator of the efficiency of a wind turbine. Experimental tests have indicated that the C_p of Savonius turbines typically ranges between 0.2 and 0.3, which is lower than that of horizontal axis wind turbines. However, experimental investigations have shown that by carefully optimizing the design, including changes in blade shape, spacing, and rotor height, it is feasible to increase the power coefficient and improve overall efficiency (*Gad et al., 2014*).

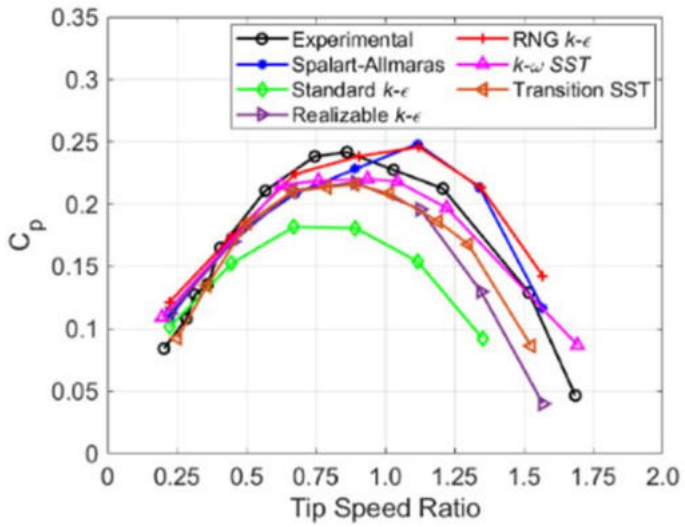

Fig. 22 - Power coefficient (Cp) vs. tip speed ratio (TSR) (*Dewan et al., 2023*)

The Savonius wind turbine is a viable alternative for sustainable energy generation, especially in low to very high wind conditions, where conventional wind turbines have great difficulty operating. Experimentation has provided vital information on its performance characteristics, including blade geometry, rotor height, and energy efficiency. This information can be applied to improve turbine designs, making them more efficient and reliable for real-world applications (*Roy et al., 2017).*

SYNTHESIS OF EXPERIMENTAL RESEARCH ON THE WORKING PROCESS OF DARRIEUS TURBINES

Wind energy, previously considered an alternative energy source, is rapidly becoming a cornerstone of global efforts to reduce dependence on fossil fuels. Wind turbines have played a major role in the renewable energy revolution, and among the various designs investigated, the Darrieus wind turbine stands out for its novel approach to capturing wind energy. Unlike standard horizontal-axis wind turbines (HAWTs), which operate on a horizontal axis, the Darrieus turbine has a vertical axis that allows it to capture wind from any direction (*Du et al., 2019*). While offering fascinating benefits in some situations, the Darrieus turbine faces a number of obstacles that have required substantial experimental study to increase its performance, efficiency, and practicality.

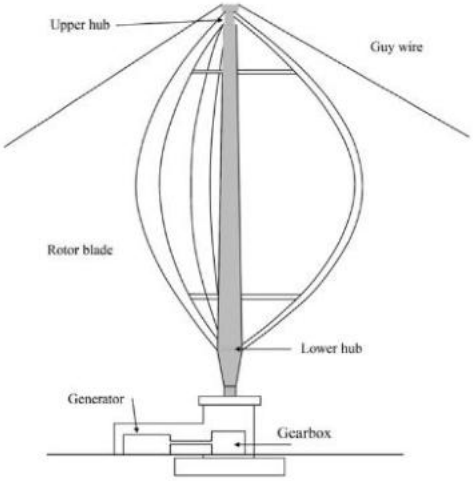

Fig. 23 - Power coefficient (Cp) vs. tip speed ratio (TSR) (*Tasneem et al., 2020*)

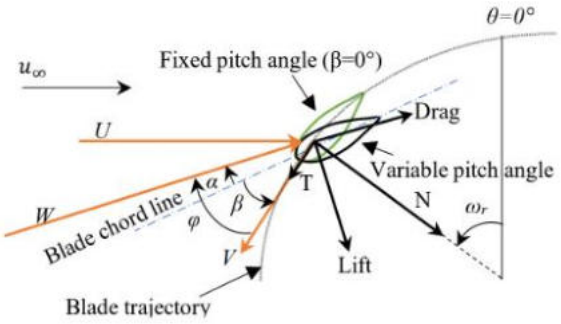

Fig. 24 - Aerodynamic forces on the blade of a Darrieus turbine (*Abdalrahman et al., 2021*)

The Darrieus wind turbine, invented by French engineer Georges Darrieus in the 1920s, is notable for its characteristic curved blades connected to a central vertical shaft. This design sets it apart from conventional turbines. One of the main benefits of the Darrieus turbine is its ability to collect wind from any direction, avoiding the need for a turning mechanism, which is necessary for horizontal-axis turbines to cope with wind (*Malael et al., 2021; Castelli et al., 2011*). While this may seem like a significant benefit, the turbine has long struggled with efficiency, starting torque, stability in varying wind conditions, and structural durability. Experimental research has become critical in an attempt to optimize its design and overcome these obstacles. Much of the initial research on Darrieus turbines has focused on understanding their aerodynamic characteristics. Scaled-down versions of Darrieus turbines are being tested in wind tunnels under controlled wind conditions, and the results provide valuable insight into how many aspects influence turbine performance (*Bedon et al., 2015*). One of the most important findings from these studies is the link between blade shape and efficiency. Curvature, aspect ratio (the ratio of blade length to blade width), and number of blades all play an important role in determining how much energy a wind turbine can generate. Researchers have found that blades with a higher aspect ratio are more efficient at converting wind energy into mechanical power, but their design must be balanced with concerns about structural integrity. The blade profile, whether flat or curved, also influences the lift-to-drag ratio, which is a significant component of turbine efficiency (*Mohamed et al., 2019*).

However, one of the major problems faced by Darrieus turbines is the difficulty of starting. Unlike horizontal-axis turbines, which can start rotating with a light breeze, the Darrieus turbine frequently fails to overcome its inertia when wind speed is low. Early experiments identified this “starting problem” as a significant drawback (*Asr et al., 2016*). In response, various solutions have been sought, some of which have been tested both in the laboratory and in the real world. One way is to include a small starter motor or Savonius rotor in the base of the Darrieus turbine. The Savonius rotor works as a traction-based device, providing the initial torque needed to start the system. In initial experiments, this hybrid technique has produced encouraging results, with the Savonius rotor providing enough torque to start the Darrieus turbine even in low wind conditions (*Chegini et al., 2023*).

The design of Darrieus turbines is further complicated by a phenomenon known as “stall.”. When the wind exceeds the ideal range for turbine operation, lift decreases. Due to the enormous working forces,

turbine efficiency can drop drastically, and in the worst cases, the blades can be damaged (*Fujisawa et al., 2001*). One of the main objectives of experimental research has been to overcome this obstacle. To maximize performance, several experimental setups have investigated the possibilities of active control systems, such as variable pitch blades, which change the angle of attack in real time. Dynamic stall control, which uses sophisticated control algorithms to modify the torque or blade angles in response to changing wind conditions, has been the subject of several investigations. Research into the use of these technologies on a large scale is still ongoing, despite their enormous potential.

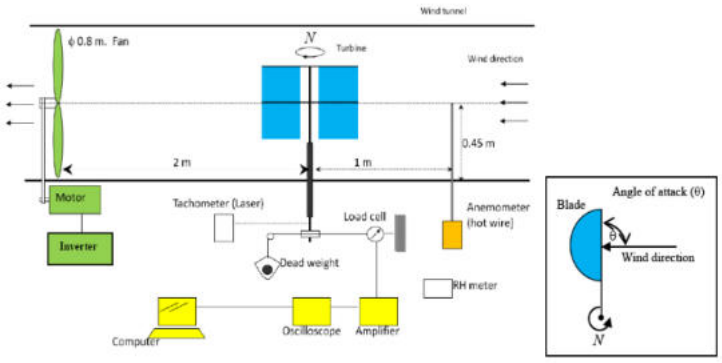

Fig. 25 - Darrieus type wind turbine test setup in the wind tunnel (*Chaitep et al., 2011*)

A crucial method for assessing the practicality of Darrieus turbines has been field testing, despite these difficulties. Turbines are exposed to the unpredictability of real wind conditions during field tests, unlike wind tunnel tests, which provide a controlled environment. In particular, the behavior of the turbine in turbulent wind conditions is one of the performance patterns that is often revealed by the results of these tests (Ferroudji et al., 2016). The vertical axis design of Darrieus turbines makes them particularly vulnerable to vibrations, which over time can cause structural damage. These vibrations can lead to fatigue, reduced efficiency, and, in some cases, failure. They are created by the oscillations of the blades as they move through the wind. Consequently, much of the experimental research in this field has focused on reducing these vibrations through the use of damping devices, including tuned mass dampers, which reduce the oscillations of the turbine blade. The use of materials with better mechanical properties and lighter weight for turbine blades has improved mechanical stability and provided pertinent information on materials science (Olivera et al., 2024).

Fig. 26 - Combination of Darrieus and Savonius wind turbines
(*https://www.windsystemsmag.com/news/first-vertical-axis-wind-turbine-awarded-certification/*)

Along with these experimental methods, computational fluid dynamics (CFD) simulations have emerged as a powerful tool for understanding Darrieus turbine airflow (*Malael et al., 2024*). To reproduce how air moves over the turbine blades, CFD simulations require complex mathematical models. These models provide researchers with a deep understanding of the aerodynamic forces acting on the turbine, allowing them to identify inefficient or turbulent airflow regions. In a wind farm configuration, CFD has been particularly useful in understanding the dynamics of Darrieus turbines, or the turbulent air left behind the

moving blades, and how these flows can affect the operation of neighboring turbines (*Dumitrescu et al., 2015*). CFD has played a key role in guiding experimental research and optimizing turbine configurations by modeling various design changes, such as changing the geometry of the blades or changing the distance between the blades. Increasing the turbine's power coefficient, which measures how well the turbine can convert wind energy into mechanical energy, is one of the main goals of all this research. A wind turbine can only capture 59.3% of the wind's kinetic energy, according to a theoretical restriction called the Betz limit (*Huleihil et al., 2012*). Experimental studies have shown that improvements in blade design and the mitigation of energy losses from friction and turbulence can bring the efficiency of Darrieus turbines closer to their potential limits, even though they frequently operate below this theoretical maximum. According to some research, the power coefficient of the Darrieus turbine could significantly outperform conventional designs and reach values Cp of up to 0.4 or 0.5 with an ideal design. The figure below illustrates turbine efficiency and ideal operating range using a power coefficient versus tip speed ratio (TSR) graph.

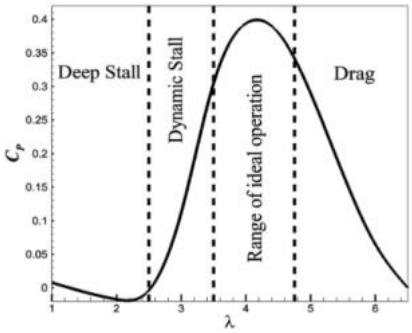

Fig. 27 - Darrieus rotor performance CP versus blade tip speed ratio (*Sagharichi et al., 2016*)

Despite the progress, many obstacles still need to be overcome before Darrieus turbines can be considered a viable alternative for large-scale wind power generation. Field testing, for example, is an expensive and time-consuming operation, with findings often affected by local wind conditions, which are difficult to recreate in controlled environments. Furthermore, while the use of modern materials such as carbon fiber composites holds great potential to increase turbine strength and reduce weight, these materials come at a high cost that must be justified by the long-term performance and longevity of the turbine.

CONCLUSIONS

Vertical Axis Wind Turbines (VAWTs) have been thoroughly examined in this review, with a focus on experimental studies and current developments in their efficiency, performance, and design. Although large-scale wind energy generation is dominated by Horizontal Axis Wind Turbines (HAWTs), VAWTs offer a special opportunity due to their space efficiency and versatility, especially in urban, low-wind, and agricultural areas.

Numerous important areas where VAWT technology is developing, including turbine configuration, blade design, and aerodynamic performance enhancements, have been brought to light by the examination of experimental investigations. Despite their potential, these developments are frequently hampered by issues with cost-effectiveness, noise reduction, and structural integrity—all of which are crucial for the broad use of VAWTs.

Addressing these challenges through innovative engineering solutions and advancements in materials science could significantly enhance the viability of VAWTs. As the demand for renewable energy sources continues to grow, ongoing research and development will be essential in overcoming these obstacles and unlocking the full potential of vertical axis wind turbines.

These issues must be resolved in future advancements, with an emphasis on scalability and integration into various contexts. To ensure that VAWTs can compete with conventional wind turbines and make a significant contribution to the generation of renewable energy, it will be essential to optimize their designs for durability, reduce operating costs, and increase their energy efficiency.

To sum up, VAWTs have a lot of promise as an alternative energy source, especially in areas where conventional wind turbine designs might not be as successful. Unlocking their full potential requires ongoing experimental study in addition to technological and material advancements. VAWTs

may become more important in the shift to decentralized and sustainable energy systems for homes, companies, and the agricultural sector if current constraints are addressed.

This could lead to greater adoption and integration of VAWTs into various environments, ultimately contributing to a more resilient and sustainable energy landscape. As research continues to evolve, innovative designs and applications may emerge that further enhance the viability of vertical axis wind turbines in the renewable energy market.

Keywords: *livestock manure, screw extrusion, solid-liquid separation, parameter optimization*

ABSTRACT

Solid-liquid separation is essential for utilizing livestock and poultry manure, impacting greenhouse gas emissions and pollution control. This study aimed to address the high water content and low efficiency issues in screw extrusion solid-liquid separation technology. A screw separator was designed, and a Box-Behnken test scheme was used to optimize parameters with dairy manure as the test object. The study identified extender length, screw rotation speed, and counterweight mass as the influencing factors, with extrudate water content and solids extraction rate as evaluation indices. A quadratic regression model was established to describe the relationships between the influencing factors and evaluation indices. Optimal parameters were determined as: extender length=10 cm, screw rotation speed=55 r/min, and counterweight mass=34.73 kg. The predicted extrudate water content was 65.44 %, and solids extraction rate was 2.39 m³/h. Validation tests showed an average extrudate water content of 67.71 % and solids extraction rate of 2.10 m³/h, with relative errors of 3.3 % and 9.6 % respectively. The model's reliability was confirmed, providing a reference for designing livestock and poultry manure screw extrusion separators.

摘要

固液分离是畜禽粪便资源化利用的关键共性环节，对控制温室气体排放和环境污染治理具有重要意义。针对螺旋挤压固液分离技术存在的挤出物含水率偏高、处理效率较低的问题，本研究设计了一种螺旋挤压脱水装置，以奶牛粪为试验对象，采用 Box-Benhnken 试验方案开展了参数优化研究。以延长器长度、螺杆转速、配重重量为影响因素，以挤出物含水率和固形物提取率为考核指标，建立了影响因素与考核指标之间的二次回归模型。通过多目标优化函数，确定一组最佳参数组合为：延长器长度=10cm，螺杆转速=55r/min，配重重量=34.73kg，此时挤出物含水率预测值为 65.44%，固形物提取效率预测值为 2.39m³/h。验证试验结果表明，在最优参数组合下，挤出物含水率均值为 67.71%，与预测值相对误差为 3.3%。固形物提取效率均值为 2.10 m³/h，与预测值的相对误差为 9.6%。两个考核指标的实测值与理论预测值均＜10%，表明建立的二次回归模型可靠，可用于参数优化。研究结果可为畜禽粪污螺旋挤压分离机的设计提供参考。

INTRODUCTION

Livestock and poultry manure is one of the most important factors leading to ecological damage and environmental pollution, and is also the second largest source of greenhouse gas emissions from farms *(Aguirre-Villegas et al., 2017)*. For several consecutive years, the Chinese government has been introducing new policies with the aim of increasing the resource utilization of livestock and poultry manure. Solid-liquid separation (compression dewatering) machines are among the core equipment for livestock and poultry manure management and resource utilization, representing a current research hotspot and priority area *(Camilleri-Rumbau et al., 2021; Wu et al., 2021; Zhang et al., 2022)*.

[1] *Weisong Zhao, Ph. D. Assistant Researcher; Qimin Gao, Assistant Researcher; Binxing Xu, Assistant Researcher; Chunsong Guan, Ph. D. Associate Researcher; Biao MA, Associate Researcher; Yan GONG, Researcher.*

After dewatering, dry solids and low impurity filtrate are obtained, which facilitates subsequent management, disposal and field utilization, and reduces the cost of manure treatment *(Husfeldt et al., 2012; Zhang et al., 2009; Zhou et al., 2023)*. In addition, solid-liquid separation has great potential to contribute to the realization of the "two-carbon" goal. Studies have shown that the use of solid-liquid separation can reduce greenhouse gas emissions from farms by up to 38% *(Aguirre-Villegas et al., 2014; Aguirre-Villegas et al., 2019)*. However, the solid-liquid separation technology for livestock and poultry manure in China is relatively weak. The inability to achieve high quality and high efficiency solid-liquid separation seriously restricts the subsequent links to carry out, and is the bottleneck of livestock and poultry manure resource utilization *(Hjorth et al., 2011)*.

Currently, livestock and poultry manure solid–liquid separation technologies mainly include three types: centrifugal, filter-press, and screening. Among them, screw extrusion separation technology, which features low energy consumption and lower investment costs, is the most widely used *(Anlauf, 2007)*. However, there is a trade-off between processing efficiency and the water content of the extrudate, improving one performance indicator often leads to a decline in the other. Therefore, the screw extrusion solid-liquid separator still requires optimization, with the goal of achieving the best possible balance between these two performance parameters.

Currently, the separation technology of solid-liquid mixtures of livestock and poultry manure is receiving attention and research applications from many scholars both in China and abroad *(Jiang et al., 2016; Luo et al., 2020)*. The study done by *Burton et al. (*2007*)* emphasized the key role of solid-liquid separation in livestock and poultry manure treatment, pointing out that the mechanical separation means can effectively remove about 80% of the dry matter components of manure. *Moller et al (2000)*, on the other hand, revealed that the dry matter concentration (TS) of raw materials has a significant effect on the treatment capacity of screw solid-liquid separation equipment. Concentration (TS) has a significant effect on the processing capacity of screw solid-liquid separation equipment. *Shi Huixian et al. (2014)* explored the relationship between TS and apparent viscosity of swine manure and found that swine manure exhibited pseudoplastic fluid properties and followed a power rate equation.

Popovic et al., (2014) investigated the effect of additives, such as biochar, on the separation performance of a screw extruder, and the results showed that the addition of biochar to swine manure could improve the separation efficiency by 2% to 3%. *Apachanov et al*. *(2016)* modeled the material movement inside the screw extruder, and pointed out that the "dead zone" of the material inside the screw and the rotation around the center of the axis are the main factors leading to the decrease of separation efficiency and the increase of energy consumption.

Guan Zhengjun et al. (2011) optimized the process parameters of a screw press separator by taking the TS of separated solids as the main evaluation index. *Shen Jiangtao et al. (2014)* designed a broken screw extrusion separator. *Zhao Weisong et al. (2017)* and *Zhu et al., (2017)* optimized the design of a broken-tooth screw extrusion separator and carried out structural optimization and simulation studies to achieve better progress.

The influence of many factors on separator performance has been explored in previous studies *(Hjorth et al., 2011; Husfeldt et al., 2012).* Examples include material properties of the manure, structural parameters of the screw (e.g., pitch, screw length, interrupted distance, etc.), and kinematic parameters (e.g., screw rotation speed) *(Zhao et al., 2017)*. However, there are more influencing factors on the operation of screw extrusion separator, and the influence law of the factors and the interaction of the factors on the performance of solid-liquid separation still needs to be studied in depth. In particular, the structural parameters at the solid outlet, the lack of research on the effects of extrudate water content and solid extraction rate, restricts the further optimization of the design of the screw extrusion separator.

For this reason, this study designs a screw separator and investigates the effects of extender length, screw rotation speed, and counterweight mass on the device's dewatering performance. It analyzes the influence of each factor on the evaluation indices and determines the optimal parameter combination. The goal is to provide theoretical support for the design and optimization of screw extrusion dewatering machines.

MATERIALS AND METHODS

Test materials

The cow manure used in the experiment was from a dairy farm in Haimen City, Jiangsu Province, and the TS of the cow manure was 10.11% at the time of the experiment. The experiment was conducted in August 2022.

Test equipment

Self-developed livestock and poultry manure screw extrusion dewatering device (Nanjing Agricultural Mechanization Research Institute of the Ministry of Agriculture and Rural Development), SKFG-01 dryer electric constant temperature blower drying box (Shanghai Jiecheng Experimental Instrument Co., Ltd.), SAMPO DT2234A tachymeter (Shenzhen Xinbao Science and Technology Instrument Research and Development Center), NL50-8 sewage slurry pump (Shanghai Sunshine Pump Manufacturing Co., Ltd.), QJB3 /8 sludge mixer (Jiangsu Ru Ke Environmental Protection Equipment Co., Ltd.), SECURA612-1CN electronic balance (Suzhou Sainz Instruments Co., Ltd.).

Machine structure and working principle

Livestock and poultry manure screw separator mainly consists of three-phase motor, reducer, screen, screw, extender, head and other parts, of which the screw is one of the key components of the extrusion separator, used to complete the process of conveying materials, extrusion dewatering and discharging, etc. Self-designed screw is divided into the feeding section, extruding section, discharging section, and adopts a double-screw design. The outer diameter of the screw is 260 mm and the diameter of the screw shaft is 120 mm.

Test method

The water content of extrudate characterizes the wet and dry separation effect of manure, which has a significant impact on the subsequent utilization, and is an index of the performance of wet and dry separator. Separation efficiency reflects the volume of manure that can be processed by the machine per unit of time, and is the main basis for the matching relationship between the scale of farming and the number of machines. Therefore, the water content of the extrudate and the processing efficiency were selected as the objective function. The results of existing studies have shown that the rotational speed of the screw and the outlet resistance are important factors affecting the water content of the extrudate and the separation efficiency. The previous pre-test study shows that the extender length has a greater impact on the wet and dry separation performance: when the extender is shorter, the discharge speed is faster, but the water content is high. When the extender is longer, the discharge speed is slower, but the water content is lower. Therefore, based on the existing results and pre-test results, the initial ranges of the three influencing factors, screw rotation speed, outlet resistance and extender length, were determined, where the outlet resistance is usually measured by the counterweight mass. A three-factor, three-level response surface test design methodology was used with 17 sets of tests, which included five zeros. Based on the Box-Behnken design principle, the response surface test was carried out on the three factors of screw rotation speed, counterweight mass and extender length with extrudate water content and separation efficiency as the evaluation indices, and the test factors and levels are shown in Table 1.

Table 1

Factors and levels of response surface test

Level	Extender Length *a* [mm]	Screw rotation speed *b* [r·min^{-1}]	Counterweight mass *c* [kg]
-1	5	25	20
0	10	40	30
1	15	55	40

The indices were determined by the following methods: separation efficiency was calculated by the volume of cow dung treated per unit time, and water content was calculated by the standard drying method. Before the test, the cow dung was placed in the liquid storage tank, the stirring pump worked continuously to ensure good uniformity of the material in the tank, the timing started when the machine was running stably, and stopped after 30 min of operation, and the separated solids and liquids were collected to be weighed and measured, and the test was repeated three times. Design-Expert 8.0.6 software was used to perform quadratic polynomial regression analysis on the test data for separation efficiency and water content of the extrudate, and response surface analysis was used to study the correlation and interaction effects of the factors.

RESULTS AND ANALYSIS

Test results

The test results and 2 response values are shown in Table 2. In the test, the livestock and poultry manure screw extrusion dewatering device can successfully complete the extrusion dewatering operation, and within the range of the selected parameters, the solids extraction rate varies from 1.78 to 2.63 m³/h, and the water content of extrudate varies from 53.54% to 74.49%.

Table 2

Experiment design and response values

std	run	Extender length *a*	Screw rotation speed *b*	Counter weight mass *c*	Moisture content of dried fecal solids after separation y_1 [%]	Efficiency of dried manure extraction y_2 [m³·h^{-1}]

Regression modeling and significance test

According to the sample data in Table 2, multiple regression fitting analysis was carried out using Design-Expert software to establish the quadratic polynomial response surface regression models of y_1 and y_2 on extender length *a*, screw rotation speed *b* and counterweight mass *c* as shown in Eqs. (1) and (2), and the regression equations were subjected to analysis of variance (ANOVA), and the results are shown in Table 3.

$$y_1=68.17-8.58a-1.24b-1.60c-0.15ab+0.23ac-0.69bc-3.66a^2-0.35b^2-0.27c^2 \quad (1)$$

$$y_2=2.33-0.29a+0.09b+0.06c+0.08ab-0.08ac+0.03bc-0.02a^2-0.04b^2-0.09c^2 \quad (2)$$

where, y_1 is moisture content of dried fecal solids after separation, %; y_2 is efficiency of dried manure extraction, m³·h^{-1}; *a* is extender length; *b* is screw rotation speed; *c* is efficiency of dried manure extraction.

Table 3

Variance analysis

Index	Source	Sum of Squares	df	Mean Square	*F*-value	*P*-value

	a^2	0.002	1	0.002	0.55	0.484
	b^2	0.008	1	0.008	2.32	0.172
	c^2	0.035	1	0.035	10.09	0.016*
	Residual	0.024	7	0.003		
	Lack of Fit	0.018	3	0.006	3.44	0.132
	Pure Error	0.007	4	0.002		
	Cor Total	0.865	16			

*Note: P＜0.01 (highly significant,**); P＜0.05 (significant, *).*

Based on the results of the analysis in Table 3, it can be seen that the *P*-values of the regression equations y_1 and y_2 are less than 0.01, which indicates that the response surface model is highly significant. The *P*-value of the misfit term of the model is greater than 0.05 (y_1=0.784, y_2=0.132), and the non-significant misfit term indicates that the model matches the data to a high degree. y_1 and y_2's coefficient of determination, R^2, are 0.98 and 0.97, respectively, which indicates that the two models can explain more than 97% of the evaluation indices. Based on the above results, it can be seen that the model can adequately describe the 2 response variables of extrudate water content and treatment efficiency, and the prediction of the response surface model is accurate and can be used to optimize the parameters of the screw.

In order to optimize the regression equation, the independent variables that have less influence on the response variables need to be eliminated, and the influence of each parameter on the regression model equation can be reflected by the *P* value.

In the extrudate water content model y_1, the effects of 2 items, a and a^2, were highly significant (P < 0.01); the effects of 2 items, b and c, were significant (P < 0.05); and the effects of the remaining 5 items, ab, ac, bc, b^2 and c^2, were not significant (P > 0.05).

In the dry matter extraction rate model y_2, the effects of a and b^2 terms were highly significant (P < 0.01); c, ab, ac, and c^2, 4 terms were significant (P < 0.05); and the remaining bc, a^2, and b^2 3 terms were insignificant (P > 0.05).

The optimized model was obtained after removing the insignificant terms, as shown in Eq.(3) and Eq.(4).

The significance test *P*-values of the optimized models y_1 and y_2 are both less than 0.01 respectively, indicating that the models are highly significant. None of the misfit terms are significant, indicating a good match between the data and the model. The optimized model is more concise and precise, and can be used for prediction and analysis of actual production.

$$y_1=67.9-8.58a-1.24b-1.60c-3.7a^2 \quad (3)$$

$$y_2=2.3-0.2862a+0.085b+0.0562c+0.075ab-0.0825ac-0.0949c^2 \quad (4)$$

Effect analysis of the influence of each factor on the response value

The influence magnitude of each factor on the evaluation index was determined through the analysis of variance (ANOVA) results in Table 3. The influence of each factor on the water content of the extrudate is in the following order from the largest to the smallest: $a > c > b$. It indicates that among the three factors, the extender length (a) has the greatest influence on the water content of the extrudate, the counterweight mass are the second largest (c), and the screw rotational speed (b) has the smallest influence. This finding is in line with the previous findings that the effects of b and c on y_1 are consistent with the findings of literature (*Zhao et al., 2017*). It was also found that the effect of extender length (a) on y_1 was highly significant over the effect of factors b and c. This finding was missing in the previous study.

The effect of each factor on solids extraction rate was ranked in descending order: $a > b > c$. This indicates that among the three factors, extender length (a) had the greatest effect on solids extraction rate, followed by screw rotational speed (b), and counterweight mass (c) had the least effect. This conclusion indicates that the extender length is an important factor affecting the operational performance of the screw extruder separator, and is the key influence factor of the two evaluation indices of extrudate water content and solids extraction rate. The length of the extender can be adjusted to seek a balance between the two indices of extrudate water content and solids extraction rate to maximize the performance of the separator design.

Interaction analysis of influence factors

Response surface analysis was utilized to examine the effects of factors a, b, and c on the 2 response values of extrudate water content and solids extraction rate, with the goal of determining whether there is an optimal combination of factors when extrudate water content is minimized and solids extraction rate is maximized.

The response surface curves of the interacting factors on extrudate water content are shown in Figure 2, with each response surface plot representing the interaction between the other 2 independent variables when one factor is at the center level.

As can be seen in Fig. 2a, y_1 increases with decreasing a, exhibiting a more pronounced change, and y_1 decreases with increasing b, showing a smaller effect.

The shape of the response surface in Fig. 2b is basically the same as that in Fig. 2a, i.e., c decreases and y_1 increases by a small amount.

From Fig. 2c, it can be seen that y_1 increases as either b or c decreases, and the surface change trend is overall flatter.

From Figure 2d, it can be seen that y_2 increases as a decreases, with a larger change, and y_2 increases as b increases.

From Fig.2e, it can be seen that y_2 increases with the decrease of a, and y_2 shows *a* trend of first increase and then decrease with the increase of *c*, and there is a maximum value.

Similarly, in Fig. 2f, y_2 shows *a* trend of change with the increase of c, and there is a maximum value. The change rule of the response surface is consistent with the analysis results in Table 3.

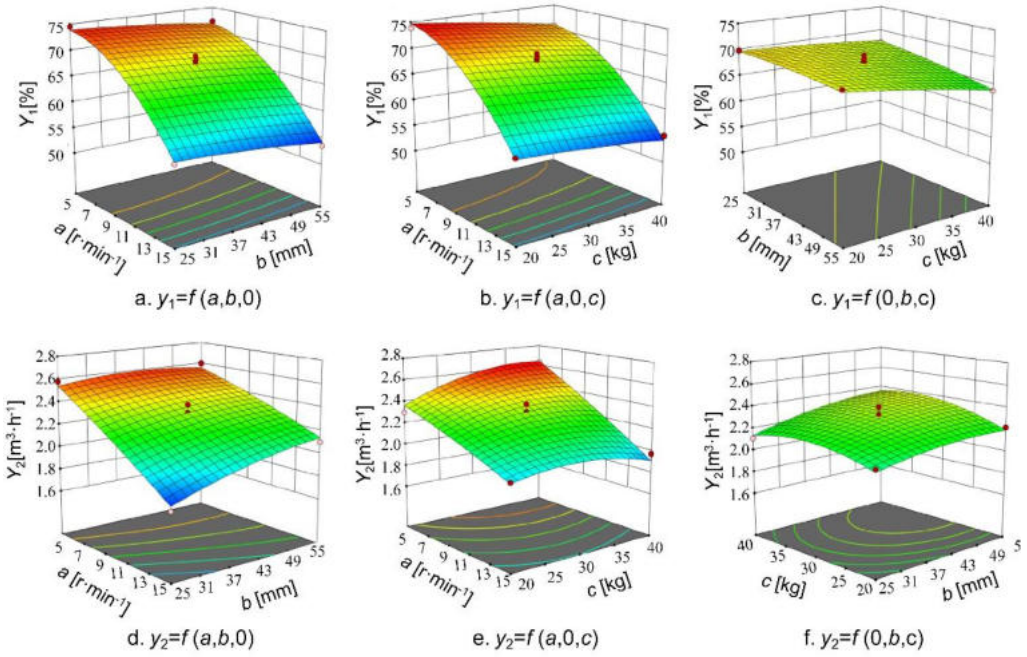

Fig. 2 - Effect of interaction factors on response indicators

Parameter optimization and validation tests

Parameter optimization

In order to realize the optimal operating effect, the solids extraction rate is maximized by ensuring that the water content of the extrudate meets the process requirements for fermentation and other procedures (≤70%). According to the response surface analysis, it can be seen that: to improve the solids extraction rate, it is necessary to reduce the extender length and increase the screw rotation speed. To reduce the water content of extrudate, it is necessary to increase the extender length, increase the screw rotation speed and increase the counterweight mass. The influence of each factor on the water content of the extrudate and the solid extraction rate is more complex, therefore, multi-objective optimization is used to seek the optimal combination of parameters to meet the objectives.

In the livestock and poultry manure fermentation and composting process, the water content of extrudate <70% is more appropriate. In the actual operational requirements, the larger the solids extraction rate is, the higher the efficiency is. Therefore, with y_1 <70% and at the same time y_1 maximum as the objective, Design-Expert software was used to optimize the solution of each parameter. Establish the parameter optimization mathematical model, set the solution objective and constraints as shown in equation (5).

$$\begin{cases} max y_2(a,b,c) \\ 60\% \le y_1(a,b,c) \le 70\% \\ s.t. \begin{cases} 5 \le a \le 15 \\ 25 \le b \le 55 \\ 20 \le c \le 40 \end{cases} \end{cases} \quad (5)$$

According to the solution results, one of the optimal parameter combinations is selected: a=10 cm, b=55 r/min, c=34.73 kg, at this time, the theoretical value of extrudate water content y_1=65.44%, and the theoretical value of solids extraction rate y_2=2.39 m³/h.

Experimental verification

In order to verify the accuracy of the obtained model prediction results, a validation test was carried out. Five replicate tests were conducted with parameter combinations (*a*=10 cm, *b*=55 r/min, *c*=34.73 kg) and the results are shown in Table 4.

Table 4

Validation test results

No.	y_1 [%]	y_2 [$m^3 \cdot h^{-1}$]
1	69.72	1.89
2	68.26	2.51
3	67.78	2.36
4	62.93	1.99
5	69.88	2.06
Average	67.71	2.16
Relative error/%	2.82	0.34

In the validation test, the mean value of water content of the extrudate was 67.71% with a relative error of 3.3% from the theoretical prediction (65.44%). The mean value of solids extraction rate was 2.10 m³/h, and the relative error to the theoretical prediction (2.39 m³/h) was 9.6%. The measured and theoretically predicted values of the two evaluation indices are <10%, indicating that the model is reliable and can be used for parameter optimization. The test site is shown in Figure 3.

Fig. 3 - Tests Scenarios

CONCLUSION AND DISCUSSION

The Box-Behnken central combination test method was used to study the influence law of three factors (extender length, screw rotation speed, counterweight mass) on two evaluation indices (water content of extrudate, solids extraction rate), and the optimization model of the influence factors and evaluation indices was established. The model and optimization results were verified through tests, and the results showed that the model and optimization results were accurate and reliable.

The test results show that the order of significance of the influence of each factor on the water content of extrudate is extender length (*a*), counterweight mass (*c*), screw rotation speed (*b*) in descending order of significance. The order of significance of the effect of each factor on solids extraction rate was in descending order of significance: extender length (*a*), screw rotation speed (*b*), counterweight mass (*c*). In this study, extender length was found to be one of the most critical factors affecting the working performance of the screw extruder separator. This factor has a highly significant effect on both extrudate water content and solids extraction rate. As the extender length increases, the water content of the extrudate decreases, but the solids extraction efficiency also declines. In order to obtain the optimal parameter combinations, a multi-objective optimization function was established, and one of the optimal parameter combinations was obtained as: *a*=10 cm, *b*=55 r/min, *c*=34.73 kg. Under the optimal parameter combinations, the mean value of extrudate water content was 67.71% and the mean value of solids extraction rate was 2.10 m³/h in the validation test.

ACKNOWLEDGEMENTS

We thank all colleagues for their advice and support during this study. This work was supported by the Jiangsu Province Agricultural Science and Technology Independent Innovation Fund Project (project number: CX(22)3093), and the Key Research and Development program of Hebei Province (Grant No.20327313D).

ABSTRACT

Saffron is a high-value crop that requires low growing temperatures and cannot be cultivated in equatorial climates. To address this limitation, an IoT-based Intelligent Saffron Management System (IISMS) is proposed to simulate suitable growing conditions for saffron cultivation in equatorial regions. The IISMS remotely monitors key environmental parameters, and the collected data is displayed via a mobile APP over a Wi-Fi network. The cooling system is automatically activated when the temperature exceeds 10 °C, which is the critical threshold required during the flowering phase. Similarly, the irrigation system is triggered when soil moisture drops below 70%. By providing responsive and automated crop management, the IISMS optimizes growth conditions and improves yield quality. Experimental results showed that saffron cultivated under the IISMS was healthier, taller, exhibited more green shoots, and was generally stronger compared to saffron grown under standard room conditions in Malaysia.

摘要

藏红花是一种高价值作物，需要较低的生长温度，而赤道气候无法种植。本文提出了一种基于物联网的智能藏红花管理系统(IISMS)，用于模拟赤道国家适宜藏红花的生长条件。IISMS远程监控生长条件，并通过Wi-Fi 网络将数据显示在移动应用程序中。如果温度高于10°C，则会启动冷却系统。10°C 被设定为阈值，藏红花在开花期间需要10°C的低温。当土壤湿度低于规定的70% 阈值时开始灌溉。IISMS提供响应式藏红花作物管理，优化生长条件并提高产量质量。与马来西亚室温下未采用 IISMS种植的藏红花相比，在 IISMS下种植的藏红花更健康、更高大、绿芽更多、更强壮。

INTRODUCTION

Saffron is one of the world's most expensive crops due to its rarity, labor-intensive harvesting process, and nutritional and medicinal benefits. It is native to Southwest Asia and is primarily cultivated in the Mediterranean region, including countries such as Iran, Greece, and Turkey (*Cardone et al., 2020*). Successful saffron cultivation depends on mild weather and moderate rainfall, with optimal temperatures of 23–25°C in September. Flowering of the bulbs requires mild conditions as well, with daytime temperatures around 17°C and nighttime temperatures near 10°C (*Mehmeti et al., 2024*). Saffron is a high-value crop with notable nutritional and medicinal properties. It is highly favored in the market due to its broad applications in healthcare products, pharmaceuticals, and the food industry (*Dalir et al., 2025*). The primary active compound in saffron is crocin, which is responsible for its distinctive color and aroma. Crocin also exhibits significant pharmacological effects (*Malik et al., 2024*). As a result, saffron has increasingly become a key player in the global market for premium agricultural products, with demand rising steadily each year. However, the growing demand and high market value of saffron are placing pressure on production, and current efficiency levels have not kept pace with the rapid increase in demand.

A key challenge for saffron cultivation expansion is the need for more information about optimal growing conditions. Factors like temperature, humidity, light intensity, and pH are essential for saffron growth and development. It is important to monitor these critical parameters such as moisture level, pH value, light intensity, and environmental humidity *(Narayana et al., 2024)*. Continuous observation and accurate monitoring of these variables are essential to growing saffron in the best possible conditions.

Nevertheless, the growth and production features of saffron have very high demands on such environmental conditions as temperature, humidity, light, soil moisture and so forth. This slight negligence might harm the saffron growth cycle and yield quality. Conventional planting methods still depend on manual monitoring and adjustment of the environmental conditions. These methods are costly and time-consuming, whilst becoming obsolete with climate change and environmental fluctuations. Such suboptimal approaches of management not only hamper the increase in yields but also raise the cost of production, making it hard to achieve complete economic returns for saffron production.

Temperature is one of the essential factors of the entire growing cycle of saffron. A low temperature of around 10°C is needed for saffron to start the flowering process *(Pirasteh-Anosheh et al., 2023)*. The temperature for flower formation is between 23°C to 27°C. However, the yield of the saffron will drop when the temperature is more than 30°C. It can be concluded that maintaining a suitable temperature is the key to achieving high yields in saffron cultivation.

The second important factor for saffron cultivation is humidity, particularly during the flowering and bulb stages. A study suggested that maintaining humidity at around 65.7% can significantly enhance flower production *(Iqbal et al., 2024)*. However, humidity levels become difficult to manage when rainfall is unpredictable. Controlling humidity is essential for optimizing both the quality and yield of saffron. Uncontrolled humidity levels can negatively affect plant health and reduce overall yield.

The growth and development of saffron are significantly influenced by light. According to research, the yield and quality of saffron can be significantly influenced by properly adjusting the lighting. The red-to-blue light ratio of 3:2 with a photosynthetic photon flux density of 200 $\mu molm^{-2}s^{-1}$ has been found to enhance stigma yield and improve nutritional content *(Kang et al., 2022)*. However, while high light intensity can promote photosynthesis and leaf growth, it may also reduce both the quantity and quality of saffron stigmas (*Zhou et al., 2022*). These findings suggest that optimizing both the light spectrum and intensity is essential for improving saffron output and quality.

Saffron is highly sensitive to soil pH, which significantly affects microbial activity, nutrient availability, and overall plant health. Soil pH, which ranges from 0 to 14, indicates the acidity or alkalinity of the soil. Values below 7.0 signify acidic conditions, while those above 7.0 indicate alkalinity. Most crops thrive in a pH range of 6.0 to 7.5, which supports optimal root development and nutrient absorption. Saffron performs best in neutral to slightly acidic soils, with an ideal pH range of 6.0 to 8.0 *(Kumar et al., 2022)*. This pH range ensures the availability of essential nutrients such as nitrogen, phosphorus, potassium, and various micronutrients, supporting the healthy development of saffron bulbs and sprouts.

Numerous projects were carried out to collect and analyze environmental data in order to enhance agricultural yield and productivity. One such initiative proposed a portable system that monitors air humidity, temperature, and soil moisture using sensors, with the collected data used to control irrigation for vegetable crops *(Penchalaiah et al., 2021)*. Sensor networks have also been employed in precision agriculture to optimize crop yields and resource efficiency *(Sanjeevi et al., 2020)*. A real-time remote management and monitoring system was introduced for greenhouses, utilizing wireless networks to track plant conditions *(Bersani et al., 2022)*. The Internet of Things (IoT) was used to monitor 14 environmental parameters in order to increase the crop yield *(Aditya et al., 2024)*. Another IoT-based system was designed to capture and analyze environmental variables such as humidity, indoor and outdoor temperature, soil moisture, and carbon dioxide concentration in tomato plantations *(Ge et al., 2022)*. Additionally, a prototype equipped with Bayesian predictive networks was proposed to respond to sensor feedback on plant growth metrics, water levels, pH, light intensity, and humidity *(Kocian et al., 2020)*. All collected data and prototype operations were stored in the cloud, highlighting the potential of IoT technologies in advancing sustainable agriculture.

Intelligent and automated planting management strategies are urgently needed to enhance the yield of saffron plantations. IoT technology presents promising opportunities to address this challenge. The integration of IoT with agriculture has greatly advanced precision farming practices by improving crop monitoring and resource management *(Dhanaraju et al., 2022; Haziq et al., 2022; Leao, 2024; Lokman et al., 2024)*. Furthermore, IoT has demonstrated strong potential in regulating microclimate conditions to enhance crop yield and quality *(Pangave et al., 2023)*. An intelligent planting system equipped with IoT sensors and automated control mechanisms can continuously collect environmental data such as temperature and humidity. This enables real-time monitoring and precise regulation of the saffron growing environment, optimizing conditions for plant development. As a result, such systems not only improve crop yield and quality with high efficiency but also provide a scientific foundation for data-driven saffron cultivation.

Existing research has yet to propose a smart and reliable IoT system specifically tailored for saffron cultivation. Due to the unique environmental requirements of saffron, conditions that are particularly difficult to achieve in equatorial regions, there is an urgent need for a dedicated IoT-based intelligent management system. To address this gap, the IoT-Enabled Smart Saffron Management System (IISMS) is proposed. This system is designed to monitor and control four critical environmental parameters essential for saffron growth: temperature, humidity, light intensity, and soil pH.

MATERIALS AND METHODS

The proposed IISMS provided a real-time monitoring and intelligent control of the saffron planting environment to meet the strict requirements of saffron for temperature, humidity, light and soil moisture. The architecture of the IISMS system is shown in Figure 1. IISMS consists of four main systems, i.e., 1) a lighting system, 2) an irrigation system, 3) a cooling system, and 4) a soil monitoring system. The lighting system supplies the artificial light source through LED. A water pump is equipped in the automatic irrigation system. A semiconductor cooling module is installed to control the temperature. A monitoring system is used to monitor the soil's parameters. The IISMS provides real-time monitoring and automated management of saffron growth environments.

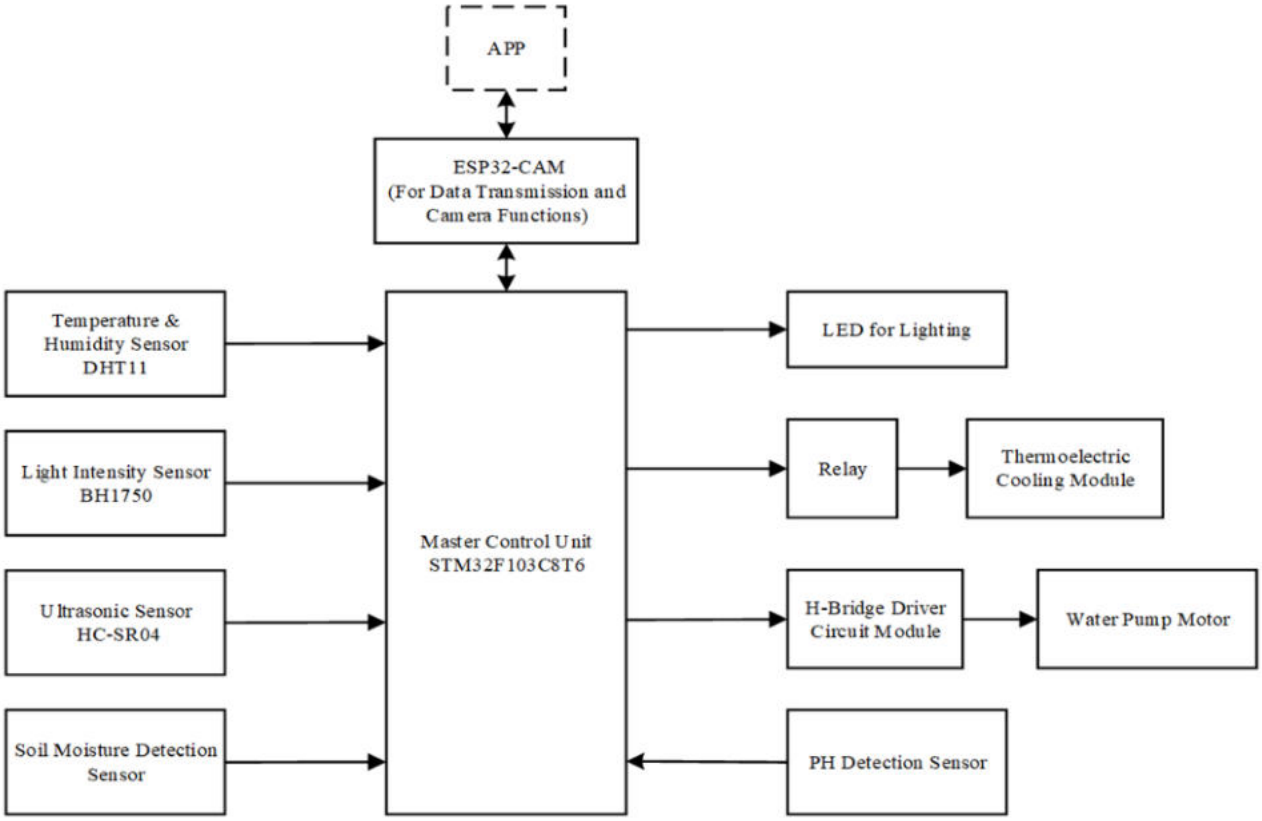

Fig. 1 – The System Architecture of IISMS

The STM32 (STM32F103C8T6) microcontroller is the core controller of IISMS. The STM32 microcontroller is used to control and process the data collected. It is responsible for reading different sensors and controlling the actuators based on a pre-configured threshold so that saffron in its growing environment finds a suitable environment. The STM32 microcontroller offers a wide range of input/output (I/O) interfaces, enabling efficient integration and operation of various sensors and actuator modules. It serves as the central controller of the system, coordinating all sensors and actuators to perform data acquisition, logical processing, and control output. With its high performance, low power consumption, and rich peripheral interfaces, the STM32 is well-suited to meet the system's requirements for handling multiple sensor inputs and controlling multiple actuators simultaneously.

IISMS used a BH1750 light sensor (Figure 2) to measure the light intensity of the environment and provide the system with reliable light data, thereby assisting in automated light control. BH1750 is a light sensor that has I2C communication to output the digital value of ambient light intensity and this will reduce the

overhead in data processing. It has high sensitivity and stability. It can give accurate measurement results under different light conditions, which is very suitable for monitoring the saffron growth environment. When the system detects that ambient light intensity drops below the predefined threshold, the IISMS sends a high-level signal to the General Purpose Input/Output (GPIO) to activate the LED fill light. This ensures that saffron plants receive adequate illumination under low-light conditions, supporting healthy growth. Once the light conditions return to normal, the system deactivates the LED light. The LED light operates at a voltage of 3.3 V. The design of the lighting system is simple and the power consumption is low. The LED has a long service life and low power consumption, which is suitable for long-term continuous operation to meet the needs of plant growth.

The soil moisture sensor was used to track the soil moisture level instantly (Figure 3). The sensor is used to measure the moisture content in the soil where saffron is cultivated. It detects the level of dryness or wetness, allowing the system to automatically regulate irrigation based on real-time soil moisture data. The output of the sensor is an analog signal, which is connected to the analog-to-digital interface of the STM32 to achieve real-time measurement of soil moisture. The sensor module was equipped with a potentiometer, and the user can configure the threshold by adjusting the potentiometer to adapt to different soil moisture requirements. The system automatically starts the water pump for irrigation when soil moisture is less than the threshold value to keep humidity conditions in the range.

The pH detection sensor (Figure 4) was used to measure the pH value of the soil. Accurate monitoring of the pH value is essential for the healthy growth of saffron, so this sensor module is used to measure the pH value of the soil in real time. The sensor transmits data to the main control unit through serial communication. The pH sensor will measure the pH of the soil and give the user the health status of the soil to ensure that the soil is well-suited for saffron growing.

The DHT11 temperature and humidity sensor (Figure 5) was used to obtain the current environmental temperature and humidity data, which provides the basic information for temperature–humidity control. The DHT11 sensor can provide relatively stable temperature and humidity data. The sensor uses a single bus protocol for data transmission and can read data by occupying a GPIO pin of the microcontroller.

The IISMS automatically activates the semiconductor cooling system, LED lights, and water pumps based on predefined thresholds to regulate temperature, supplement light, and provide irrigation. The ESP32-CAM module collects and transmits real-time images and environmental data to a mobile. The APP (Figure 6) provided users with a data display to monitor the saffron growth. Users can remotely view the key parameters such as temperature and humidity, light intensity, soil moisture and pH value of the environment through the APP.

Fig. 2 – BH1750 light sensor

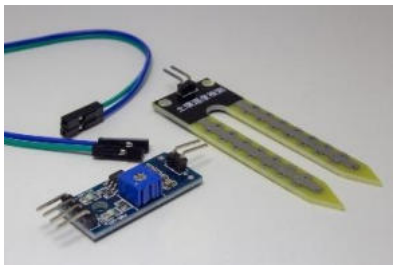

Fig. 3 – Soil moisture sensor

Fig. 4 – PH sensor

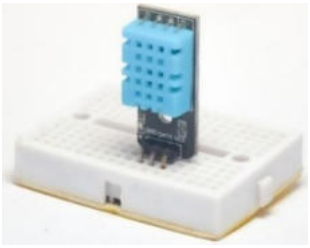

Fig. 5 – DHT11 temperature and humidity sensor

Fig. 6 – The mobile APP of the IISMS

A relay was used to control the semiconductor cooling module shown in Figure 7. It began to cool down the temperature as soon as the thermostat detected that the temperature was above the threshold value. A HC-SR04 ultrasonic sensor was used to measure saffron growth height and provide data support for crop growth monitoring. The system can monitor the height changes from time to time to record and indicate saffron growth for subsequent planting management and data analysis.

The system used the AMS1117-3.3 voltage regulator chip to step down the input voltage to a stable 3.3V ensuring reliable operation of the STM32 microcontroller. To minimize power supply noise and stabilize the output voltage, decoupling capacitors of 100 µF and 10 µF were connected at the input of the voltage regulator circuit. These capacitors effectively filtered out voltage fluctuations and contributed to a smooth and consistent power supply.

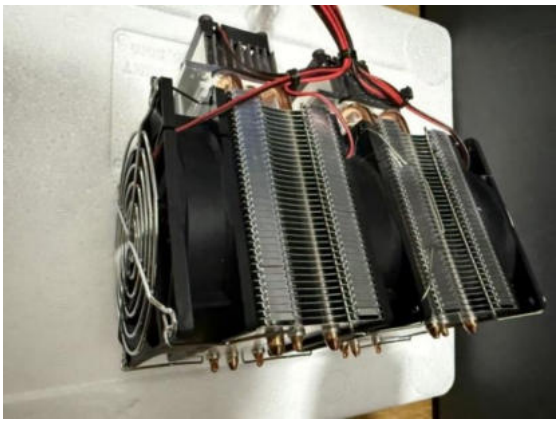

Fig. 7 – The cooling module used in IISMS

The proposed IISMS provides a customized solution designed to simulate optimal environmental conditions for saffron cultivation. Threshold values for key parameters were carefully selected based on the physiological requirements of the saffron plant. The soil moisture threshold was set at 70%, representing the ideal hydration level to support bulb development and flowering while avoiding waterlogging. The temperature threshold was set at 10°C, a critical value for initiating the flowering phase of saffron.

An extensive experiment was carried out to evaluate the performance of IISMS. The experiment was conducted indoors using two pots of saffron plants. Saffron was planted in both pots under identical initial conditions and cultivated in parallel. One pot was cultivated using the IISMS inside a styrofoam box, which actively monitored and regulated environmental parameters. The other pot served as a control and was grown under standard indoor, air-conditioned room conditions with an artificial light source in Malaysia. A general-purpose fertilizer was used in this experiment. IISMS was exposed to varying environmental conditions to test its responsiveness and accuracy. The LED fill light was triggered when ambient light intensity dropped below the predefined threshold, and deactivated once normal lighting conditions were restored. Similarly, the cooling module was activated when the temperature exceeded 10°C. The irrigation system was programmed to initiate when soil moisture fell below 70%, which is the optimal level for saffron bulb development without risking overwatering. The experiment was carried out with the styrofoam box closed to control a low temperature, and the LED light was turned on to provide a light source. The experiment was conducted over a one-week period, during which environmental data and plant responses were continuously recorded. The results were presented in the next section.

RESULTS

The extensive experimental test was carried out through the testbed shown in Figure 8.

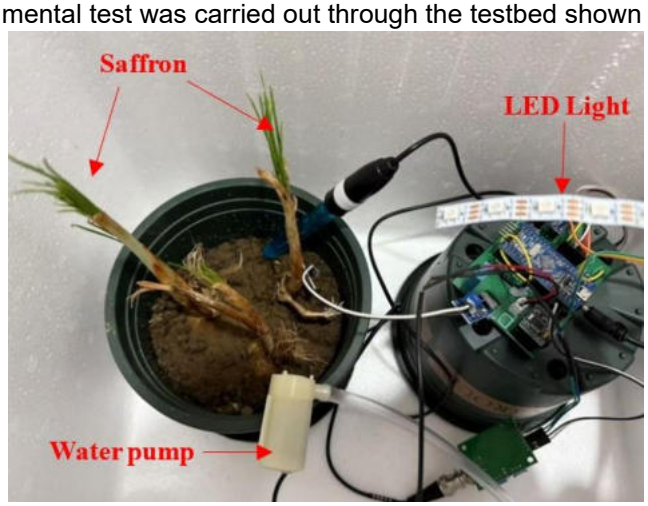

Fig. 8 - The System Architecture of IISMS

The testbed was designed for small-scale saffron cultivation. The saffron plant was cultivated in a pot filled with soil. An automated water pump was connected to the pot to ensure consistent irrigation, while an LED light strip was installed above the plant to provide artificial lighting, simulating optimal sunlight conditions. The LED light was turned on for 8 hours daily, since the experiment was conducted inside a closed Styrofoam box. The IISMS was activated at the beginning of the experiment to monitor and regulate environmental parameters.

Figure 9 illustrates the soil moisture level of the testbed. Initially, the moisture level started at around 60%. The IISMS detected a drop in soil moisture, and the irrigation system was activated, maintaining the moisture level at approximately 70% over the following hour. The moisture level reached around 100% by day 2 due to the excess water that was supplied to the saffron plant, resulting in a high moisture percentage. After this peak, the moisture level dropped and stabilized around the 70% reference line. The result showed that IISMS effectively maintained the target soil moisture level throughout the remainder of the observation period.

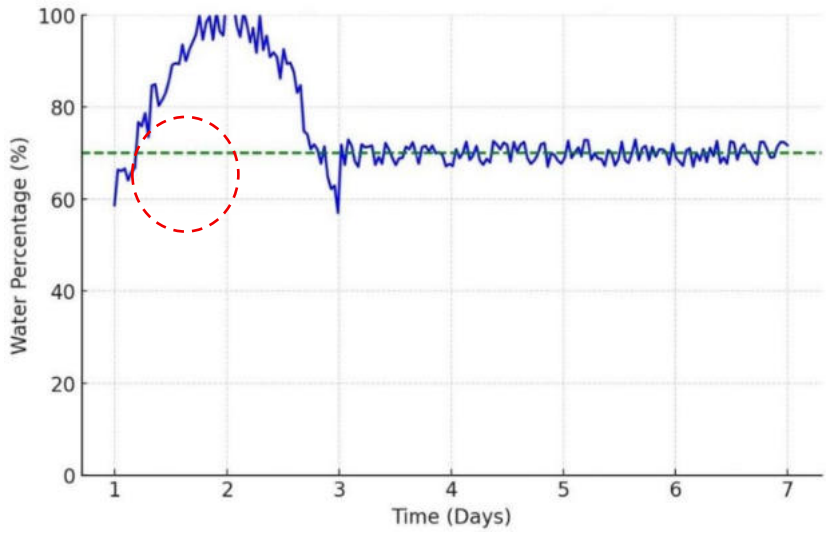

Fig. 9 – The soil moisture levels measured over a week

Figure 10 illustrates the variation in temperature over 7 hours. The temperature initially remained high at around 35°C but dropped sharply to approximately 10°C after 2.5 hours, as a result of the IISMS activating the cooling system. The temperature stabilized with minor fluctuations for the remainder of the 7-hour observation period. The IISMS was designed to automatically activate the cooling module when the temperature exceeded the preset threshold of 10°C and to deactivate it once the temperature returned to the threshold. The temperature remained stable at 10°C over a period of 7 days. However, the graph was presented over a 7-hour timespan to highlight the initial temperature changes during the early stage of the experiment. This shows the effectiveness of the IISMS in regulating temperature and provides the desired temperature level for saffron cultivation.

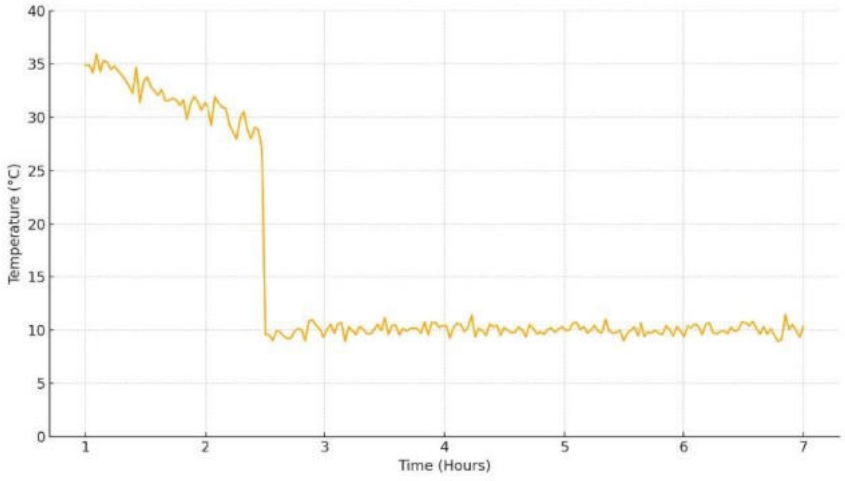

Fig. 10 – The temperature values measured over a week

Figure 11 illustrates the change in pH value over 7 days. The pH level started at approximately 7.2 and gradually declined to around 6.6 by Day 7. An annotation on the graph noted that the pH value dropped by 0.6 over the week. The pH dropped from 7.05 to 6.6 over the week, and several peaks were observed in the collected data. These fluctuations were primarily caused by the uneven distribution of fertilizers through the irrigation system's water flow. This pattern demonstrated that soil pH was directly influenced by soil fertility and irrigation practices, highlighting the importance of consistent monitoring and controlled nutrient delivery to maintain optimal growing conditions.

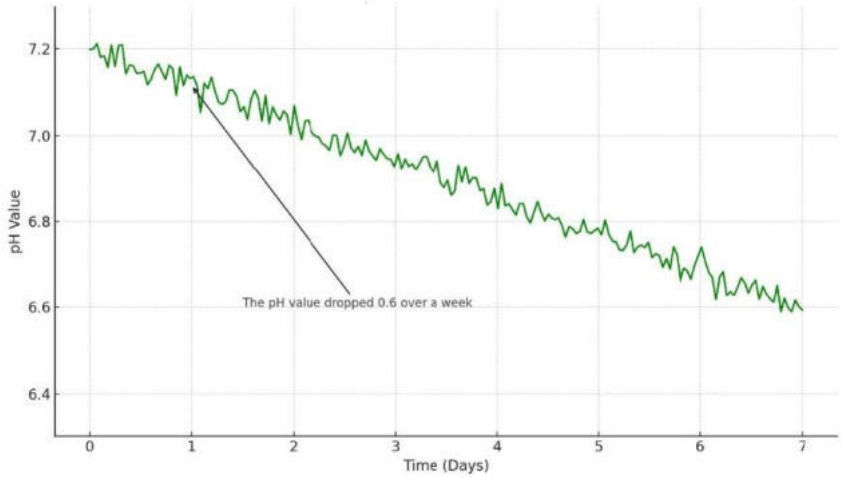

Fig. 11 – The pH values obtained over a week

Figure 12 shows two pots of saffron planted in parallel, one pot was planted with the IISMS, and the other was grown under standard indoor conditions. As shown in Figure 12, the saffron grown with the IISMS appeared healthier, taller, with more green shoots and stronger compared to the saffron cultivated without IISMS under room conditions, with fewer and less vigorous shoots. This indicated that the IISMS successfully simulated suitable growing conditions for saffron in Malaysia.

Fig. 12 – The growing conditions of saffron plants with and without IISMS

CONCLUSIONS

The proposed IISMS successfully simulates optimal growing conditions for saffron, demonstrating high accuracy and stability in environmental monitoring. All sensors performed reliably under varying environmental conditions, delivering accurate data that supports the system's automatic control functions. The IISMS effectively monitors key environmental parameters, such as temperature, humidity, light intensity, and soil pH,

in real time and automatically adjusts these conditions to promote healthy saffron development. Additionally, it enables users to remotely access environmental data and respond promptly to abnormal conditions. However, some areas for improvement were identified. The DHT11 temperature and humidity sensor exhibited a delayed response during rapid environmental changes, which affected the real-time accuracy of the readings. Despite this limitation, the IISMS performed well across environmental monitoring, automatic adjustment, and remote control functionalities, validating its feasibility and potential for agricultural applications. Future improvements could include integrating solar energy to offset the high power consumption of the cooling system. Moreover, deploying the IISMS in greenhouse environments would allow assessment of its performance in managing larger-scale cultivation. The system's adaptability also suggests potential for application in other crop management scenarios, enhancing its flexibility and scalability for broader agricultural use.

Keywords: *Yanhusuo, discrete element, simulation parameter, calibration, stacking angle.*

ABSTRACT

To address the lack of contact parameters for yanhusuo during the mechanization process, its basic physical and contact parameters were derived through both theoretical calculations and practical measurements. Utilizing 3D scanning technology, a 3D model of yanhusuo was obtained. A discrete element model was then established using an automatic filling method. The key factors influencing the stacking angle of yanhusuo were identified using Plackett-Burman tests. The optimal ranges for these factors were determined through the steepest ascent experiment, and a quadratic regression model for the stacking angle was developed using response surface methodology (RSM) based on a rotational orthogonal experimental design. The optimized parameters - a restitution coefficient of 0.481, static friction coefficient of 0.508, and rolling friction coefficient of 0.029 - yielded a stacking angle of 21.23°. Experimental validation showed a relative error of just 0.86% between the simulation and physical tests. These results demonstrate that the discrete element model and calibrated parameters closely replicate real-world conditions, providing valuable insights for the mechanical design of yanhusuo planting and harvesting equipment.

摘要

针对延胡索机械化过程中延胡索接触参数缺乏的问题，通过理论计算和实际测量，推导了延胡索的基本物理参数和接触参数。利用 3D 扫描技术，获得延胡索的 3D 模型。采用自动填充法建立延胡索离散元模型。通过 Plackett-Burman 试验确定了影响延胡索堆积角的重要因素。通过最陡上升试验确定了这些重要因素的最佳范围，并通过旋转正交实验设计的响应面法（RSM）建立了与这些因素相关的堆积角的二次回归模型。优化后的参数—恢复系数为 0.481、静摩擦系数为 0.508、滚动摩擦系数为 0.029——产生的堆叠角为 21.23°。实验验证显示模拟与实际测试之间的相对误差为 0.86%。这些结果表明，离散元模型和校准参数密切复制了现实条件，为延胡索种植和收获的机械设计提供了宝贵的见解。

INTRODUCTION

Corydalis yanhusuo, a plant belonging to the Papaveraceae family and the Corydalis genus, is a traditional Chinese medicinal herb *(Chen et al., 2013; Ping et al., 2019*) that grows in loose, moist soils such as sandy or semi-sandy land. It typically has a flattened spherical shape, with a diameter ranging from 6 to 25 mm. *The yanhusuo* contains over 30 alkaloids, including tetrahydropalmatine and protopine, and exhibits significant pharmacological effects such as pain relief, sedation, and antiarrhythmic properties. As a result, *yanhusuo* hold considerable medicinal value *(Gu et al., 2020; Zhang et al., 2018*). In recent years, the increasing demand for *yanhusuo* due to its expanding applications in the pharmaceutical industry has led to a rise in its cultivation benefits. However, the seeding and harvesting of *yanhusuo* largely depend on manual labor, which presents challenges such as low efficiency and high costs. As an emerging economic crop, *yanhusuo* suffers from underdeveloped mechanization, and the lack of research in this field severely restricts the growth of the *yanhusuo* industry. Therefore, the mechanization of *yanhusuo* cultivation, from sowing to harvesting, is an urgent need. The accurate and objective collection of the mechanical parameters of *yanhusuo* is a prerequisite for developing specialized mechanized equipment.

Discrete Element Method (DEM) model and parameter calibration (*Ahmad et al., 2020; Horabik and Molenda, 2016; Mousaviraad and Tekeste, 2024; Ur Rehman et al., 2022*) are pivotal components in the simulation research of agricultural machinery. *Zhang et al., (2024),* developed a DEM model for red flowers, employing the Hertz-Mindlin (no slip) contact model to conduct packing angle tests and determine the optimal parameter set through orthogonal testing.

Chen et al., (2018), introduced a model approach for individual corn seeds and seed combinations, based on a classification of seed shapes, and validated their method through piling tests and "self-flow screening" tests. *Sun et al., (2022),* utilized the multi-sphere method to create wheat seed models consisting of 13, 17, 25, and 33 spheres. The accuracy and applicability of these models were verified through stacking angle simulations and physical tests. However, the *yanhusuo* exhibits a complex shape, and no DEM studies related to the *yanhusuo* have been reported, resulting in a lack of reference material. Therefore, the DEM model and parameters calibration for *yanhusuo* are critical for advancing simulation studies on this plant.

This study presents the determination of the fundamental physical and contact parameters for *yanhusuo* through theoretical analysis and empirical measurement tests. A multi-sphere bonded DEM model (*Guo et al., 2020; Ucgul et al., 2014, 2018; Wang et al., 2022; Xu B. et al., 2021; Xu T. et al., 2018*) for *yanhusuo* was established using the auto-filling method. The Plackett-Burman design and steepest ascent tests were employed to identify the significant factors affecting the packing angle of *yanhusuo* and their respective ranges. The optimal parameter combination was determined through an orthogonal rotation combination test. The reliability of the DEM model and contact parameters *(Katinas et al., 2019; Li et al., 2024; Poppa et al., 2024; Zhuang et al., 2023*) for the *yanhusuo* was further validated through test verification. The results provide fundamental parameters for simulating the mechanized seeding and harvesting of *yanhusuo*, offering a reference for the calibration of similar crops.

MATERIALS AND METHODS

Determination of basic physical parameters

The y*anhusuo* variety examined in this study is ZheHu No.1. The five-point sampling method was employed to collect a sample of *yanhusuo*, and its fundamental physical parameters were measured. A total of 50 *yanhusuo* were randomly selected and divided into five groups. Using an electronic balance with a precision of 0.01 g, the total mass of each group was measured and recorded. A graduated cylinder with a precision of 0.1 mL was filled with 98% ethanol to ensure complete submersion of the y*anhusuo* samples. The volume of each group was calculated by determining the difference between the initial and final readings of the graduated cylinder. Subsequently, the density of the *yanhusuo* was determined using the density formula, yielding a value of 1.085 g/cm³.

The moisture content of the *yanhusuo* is one of its fundamental parameters. In this study, an OHAUS MB23 rapid moisture analyzer was used to measure the moisture content of *yanhusuo*. The samples were divided into five groups for individual measurements, resulting in an average moisture content of 61.27%.

Poisson's ratio is the ratio of lateral strain to axial strain when a material is subjected to uniaxial compression (*Zhao et al., 2024*). It is a crucial mechanical characteristic parameter of *yanhusuo*. In this test, the compression deformation of *yanhusuo* was tested by Texture Analyzer. The Poisson's ratio of *yanhusuo* was calculated by measuring the deformation in the lateral (horizontal) and vertical (height) directions before and after loading, as shown in Figure 1.

Fig. 1- Compression test of *yanhusuo*

Before the test, the length and height of the *yanhusuo* were measured. At the start of tests, the *yanhusuo* was placed on the platform of Texture Analyzer. The compression head was manually adjusted to ensure its plane made contact with the upper surface of the *yanhusuo*. The experimental parameters were set with a loading rate of 0.5 mm/s and a loading duration of 3 seconds. After the test, the length and thickness of the

yanhusuo were measured again. The tests were repeated five times, and the average value was taken. The Poisson's ratio of the *yanhusuo* was calculated to be 0.49 using Eq.(1).

$$\lambda = \frac{\Delta L / L}{\Delta H / H} \quad (1)$$

where:

λ – Poisson's ratio;

ΔL – the absolute deformation in the direction of the length of the *yanhusuo*, mm;

L – the original length of the *yanhusuo*, mm;

ΔT – the absolute deformation in the direction of the height of the *yanhusuo*, mm;

T – the original length in the direction of the height of the *yanhusuo*, mm.

Young's modulus (*Khatchatourian et al., 2014; Shi et al., 2024*) is one of the mechanical characteristic parameters of the *yanhusuo*. In this study, Young's modulus of the *yanhusuo* was determined through compression testing by Texture Analyzer. The resulting compression force-displacement curve was obtained using the post-processing module of the computer software, as depicted in Figure 2.

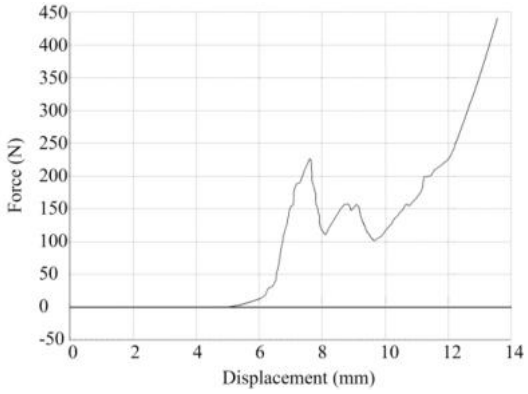

Fig. 2 - Load-displacement curve

The tests were repeated 5 times, the average value was calculated, and the Young's modulus of *yanhusuo* was calculated from Eq. (2) as *E* = 5.93 MPa

$$E = \left(\frac{\sigma}{A}\right) / v \quad (2)$$

where: E is the Young's modulus of the *yanhusuo*, [Pa]; σ is the maximum compressive stress, [kN]; A is the contact area of the compression head with the *yanhusuo* is 1.58 mm^2; v is the line strain.

Determination of contact parameters

Determination of the restitution coefficient

The restitution coefficient between the *yanhusuo* and steel plate was determined using a free-fall test (*Xu Bing et al., 2022)*. Before testing, the grid paper was positioned vertically on a horizontal surface, as illustrated in Figure 3. The *yanhusuo* sample was clamped at a height of H = 200 mm and released to fall freely. Upon impact with the steel plate, the rebound motion was captured using a high-speed camera system. The rebound height (h) was measured with the aid of graph paper and a ruler. This procedure was repeated ten times, and the average value was calculated.

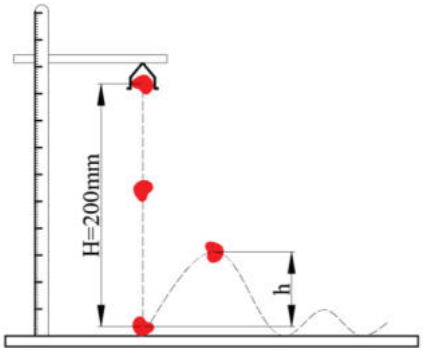

Fig. 3 - Schematic diagram of the test used to measure the restitution coefficient

The restitution coefficient can be calculated using the following formula:

$$e = \frac{v_4 - v_3}{v_2 - v_1} \quad (3)$$

$$v_4 = \sqrt{2gh} \quad (4)$$

$$v_2 = \sqrt{2gH} \quad (5)$$

where: e is the restitution coefficient between the *yanhusuo* and the colliding material; v_1 is the velocity of the colliding material before the collision, [mm·s^{-1}]; v_2 is the velocity of the y*anhusuo* before the collision, [mm·s^{-1}]; v_3 is the velocity of the colliding material after the collision, [mm·s^{-1}], v_4 is the velocity of the *yanhusuo* after the collision, [mm·s^{-1}]; H is the height from which the object is dropped before free fall, [mm]; h is the rebound height, [mm]; g is the gravity acceleration, [m·s^{-2}].

The measured restitution coefficient between *the yanhusuo* and the steel plate was 0.531.

Determination of the static friction coefficient

In this study, the inclined plane method was employed to measure the static friction coefficient between the *yanhusuo* and steel plate, as shown in Figure 4. By the hand-cranked mechanism, the angle of the inclined plane was gradually increased at a constant rate. The angle at which the tuber began to slide downward was recorded.

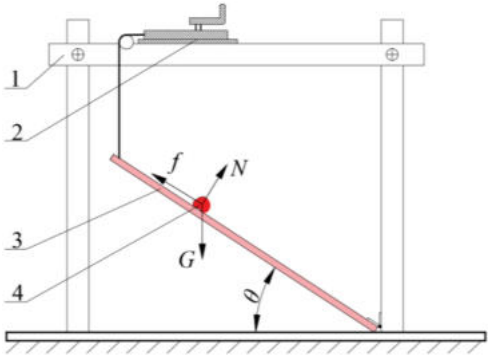

Fig. 4 - Static friction coefficient measurement test schematic

1. Rack; 2. Adjusting screws; 3. Inclined plane; 4. Yanhusuo.

Ten sets of tests were conducted for *yanhusuo* with steel plates, and the average values were calculated.

The formula for calculating the static friction coefficient is as follows:

$$f = G\sin\theta \quad (6)$$

$$F_N = G\cos\theta \quad (7)$$

$$\mu = \frac{F_N}{f} \quad (8)$$

where: f is the frictional force acting on *the yanhusuo*, [N]; G is the gravitational force on the *yanhusuo*, [N]; F_N is the support force acting on the *yanhusuo*, [N]; μ is the static friction coefficient; θ is the angle between the inclined plane and the horizontal surface, [°].

The average inclination angles for the *yanhusuo* tests with steel plate were substituted into Eq. (8) to calculate the static friction coefficients. The resulting static friction coefficient between *the yanhusuo* and the steel plate was 0.493.

Determination of rolling friction coefficient

The rolling friction refers to the resistance encountered when one object rolls on the surface of another without slipping, or when there is a tendency for rolling. It occurs as the contact surfaces of the two objects are compressed, resulting in deformation, which in turn generates a hindrance to the rolling motion. This study employs the bevel rolling method to measure the rolling friction coefficients between *the yanhusuo* and steel plate. As shown in Figure 5, where the angle between the inclined and horizontal planes is 30°. *The yanhusuo* was placed at a distance of L = 35 mm and allowed to roll freely with an initial velocity of 0 m/s until it came to a stop. The horizontal rolling distance(S) was subsequently measured. A total of 10 trials were conducted for each material.

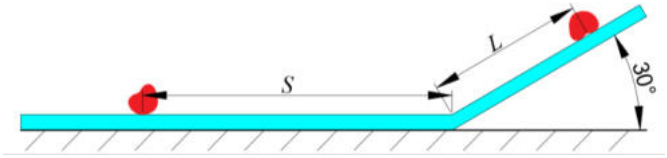

Fig. 5 - Schematic diagram of the method used to measure the rolling friction

The formula for calculating the rolling friction coefficient is as follows:

$$\mu' = \frac{GL\sin\beta}{G(L\cos\beta + S)} \tag{9}$$

where: G is the gravitational force on the *yanhusuo*, [N]; β is the angle of inclination of the inclined plane, [°]; S is the distance by the *yanhusuo* while rolling on a flat surface, [mm]; L is the distance by *the yanhusuo* while rolling on an inclined plane, [mm]; μ' is the rolling friction coefficient of *the yanhusuo* and the steel plate.

The rolling distance between *the yanhusuo* and the steel plate is 122.1 mm. Substituting these values into Eq. (9), the rolling friction coefficient between *the yanhusuo* and the steel plate is calculated to be 0.115.

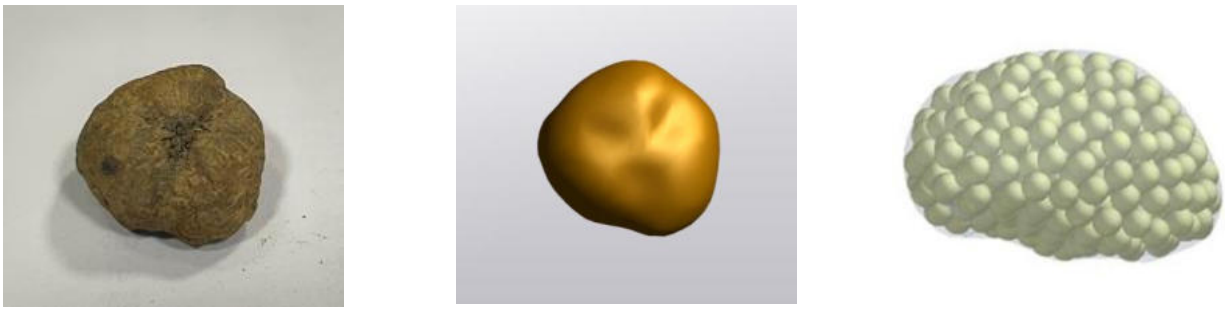
The test for determining the stacking angle of *Yanhusuo*

In this study, data was initially obtained using the funnel method, followed by verification through the draw plate method. In the funnel method stacking test, the funnel, the base plate, and the baffle plate are all made of steel. The funnel has a height of 260 mm, a bottom diameter of 80 mm, and a top diameter of 240 mm. The funnel is positioned 150 mm above the base plate, with its discharge opening covered by the baffle plate. A total of 1000 *yanhusuo* are placed inside the funnel. The baffle plate is quickly removed, allowing *yanhusuo* to fall freely onto the base plate and accumulate. The test is shown in Figure 6.

Fig. 6 - Funnel method stacking test

1. Funnel; 2. Baffle plate; 3. Base plate; 4. Yanhusuo.

After photographing stacked *yanhusuo*, MATLAB image processing techniques are applied. Through binarization, edge detection is performed to extract the edge contour curve. A linear fit is then conducted to obtain the equation of the line, from which the stacking angle is calculated, as shown in Figure 7.



(a) Original image (b) Edge extraction and fitted image

Fig. 7 – *Yanhusuo* stacking angle

A total of 10 tests were conducted, with the slope values taken from both the left and right sides for each group. The final average value obtained was 21.05°.

Discrete element method modeling and simulation

The complex shape of *the yanhusuo* was addressed in this study by using 3D scanning imaging technology to capture their external contour models. The 3D contour models of *the yanhusuo* were exported in STL format. These files were imported into EDEM software, where a multi-sphere bonded particle model was applied, and the particle auto-fill method was used to construct the discrete element model of the *yanhusuo*, as illustrated in Figure 8.

(a) *Yanhusuo* (b) Physical model © Discrete Element Model

Fig. 8 – *Yanhusuo* and discrete element model

The contact model between *the yanhusuo*, as well as between *the yanhusuo* and equipment components, was based on the Hertz-Mindlin contact theory. The material in contact with the *yanhusuo* is stainless steel, with the relevant parameters presented in Table 1.

Table 1

Simulation test parameters

Parameters	Numerical value
The Poisson's ratio of the y*anhusuo*	0.49
The density of the y*anhusuo,* [kg·m^{-3}]	1085
The Young's modulus of the *yanhusuo*, [Pa]	5.93×10^{6}
The Poisson's ratio of the steel	0.289
The density of the steel, [kg·m^{-3}]	7850
The Young's modulus of the steel, [Pa]	2.1×10^{11}

Parameter optimization for discrete element simulation

Plackett – Burman test

Plackett-Burman design was employed to screen for parameters that have a significant effect on the stacking angle. In the DEM simulation of y*anhusuo*, 8 parameters were selected as variable factors. The Plackett-Burman tested design was conducted using Design-Expert 13.0 software. A Plackett-Burman table with *N* = 12 was employed, with the stacking angle of *yanhusuo* as the response value. Each variable was set at two levels: high (+1) and low (-1). Table 2. provides an overview of the factors and levels used in the simulation.

Table 2

Plackett-Burman test measurement range table

Symbols	Test parameters	Low level (-1)	Hight level (+1)
A	Poisson's ratio of *the yanhusuo*	0.29	0.69
B	Young's modulus of the yanhusuo, [Mpa]	3.0×10^{6}	3.0×10^{7}
C	The collision recovery factor of *yanhusuo*	0.25	0.65
D	The coefficient of static friction of *yanhusuo*	0.35	0.75
E	The rolling friction coefficient of *yanhusuo*	0.005	0.045
F	*Yanhusuo*–steel plate collision recovery factor	0.3	0.8
G	*Yanhusuo*–steel plate coefficient of static friction	0.1	0.7
H	*Yanhusuo*–steel plate rolling friction coefficient	0.01	0.07

The steepest climb test

Based on the results of the Plackett-Burman test, significant factors were identified. Subsequently, the steepest ascent method was employed to quickly approach the optimal range of these significant factors.

Central composite design with quadratic orthogonal rotations

Based on the optimal factor level ranges identified through the steepest climb test, significant factors were selected for a central composite design with quadratic orthogonal rotations. Using the test results, a response surface model was fitted to derive the regression equation, which was then used to predict the optimal combination of simulation parameters for the *yanhusuo* that closely matches the actual stacking angle.

RESULTS AND DISCUSSION

Results of Plackett – Burman test

The results and analysis of variance for the Plackett-Burman test are presented in Tables 3 and 4. The results indicate that the restitution coefficient of *yanhusuo*, the static friction coefficient of *yanhusuo*, and the rolling friction coefficient of *yanhusuo* significantly influence the stacking angle, while other factors exhibit no significant effect. Therefore, the three significant factors identified above were selected for the steepest ascent tests.

Results of the steepest climb test

The design and results of the steepest climb test are shown in Table 5. The combination from group 3 yielded the smallest relative error in the stacking angle, with a value of only 1.08%. Therefore, Group 3 is selected as the zero level, and the optimal range of factor levels lies between group 2 and group 4.

Table 5

Scheme and results of the steepest climbing test

No.	Test factors			Result

Using Design-Expert 13.0, the data in Table 6. was subjected to fitting analysis. The resulting regression equation for the relative error of the stacking angle, considering the collision restitution coefficient between *yanhusuo* (C), the static friction coefficient between *yanhusuo* (D), and the rolling friction coefficient between *yanhusuo* (E), is as follows:

$$Y = 1.36 + 0.6013C + 0.8228D - 3.31E + 1.55CD - 2.94CE - 1.15DE + 1.81C^2 + 0.9572D^2 + 2.90E^2 \quad (10)$$

The analysis of variance (ANOVA) for the regression equation is shown in Table 7. The coefficient of determination R^2 of the regression equation is 0.9713, indicating a high reliability of the model. The factors influencing the relative error of the stacking angle, in descending order of impact, are the rolling friction coefficient E, the static friction coefficient D, and the collision restitution coefficient C.

Table 7

Parameter optimization

Based on the test results and the derived regression equation, the optimization function in Design-Expert 13.0 was used to minimize the relative error. The software was employed to search for the optimal combination of significant factors that yields the smallest relative error.

The objective function and constraints are as follows:

$$\begin{cases} \min Y(C,D,E) \\ \begin{cases} 0.282 \le C \le 0.618 \\ 0.382 \le D \le 0.718 \\ 0.008 \le E \le 0.042 \end{cases} \end{cases} \quad (11)$$

The optimized collision restitution coefficient between *yanhusuo* is 0.481, the static friction coefficient is 0.508, and the rolling friction coefficient is 0.029, with a relative error of the stacking angle of 0.804%. These parameters were input into the EDEM software, where 10 accumulation simulation trials were conducted. The average stacking angle obtained was 21.23°, with a relative error of only 0.86%. This indicates that the optimized parameter combination is highly reliable and can be used for subsequent DEM simulation tests.

Experimental validation

To further validate the authenticity of the *yanhusuo* discrete element simulation parameters, the board removal method was used for verification. A cuboid made of stainless steel was selected for the test. The dimensions of the cuboid are 150 mm in length, 150 mm in width, and 300 mm in height. A total of 1000 *yanhusuo* were placed inside. The baffle plate was quickly removed, allowing the *yanhusuo* to freely accumulate. The stacking angle was obtained using MATLAB image processing. Simultaneously, the corresponding DEM simulation was conducted. The test setup is shown in Figure 9.

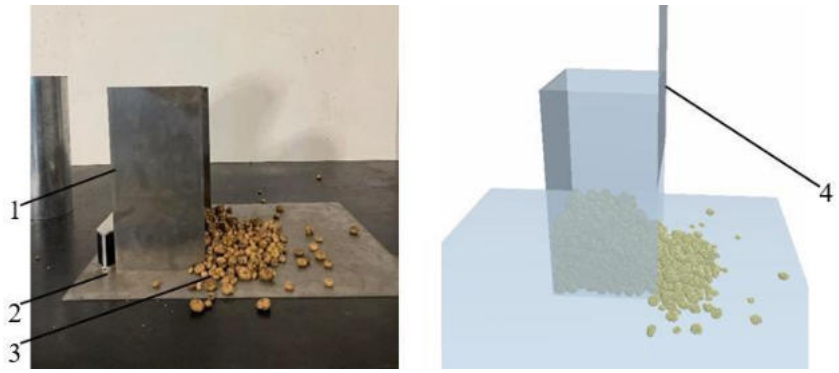

Fig. 9 - Measurement of *Yanhusuo* stacking angle by extraction plate method

1. Empty box of cuboids; 2. Base plate; 3. Yanhusuo; 4. Baffle plate.

Both types of tests were conducted for 10 trials each, and the average values were taken. The results are shown in Table 8.

Table 8

Actual and simulation test results of stacking angle by *Yanhusuo* draw plate method

No.	Actual test slope	Actual stacking angle / °	Simulation test slope	Simulation stacking angle / °
1	0.382	20.92	0.428	23.17
2	0.397	21.65	0.321	17.80
3	0.474	25.36	0.472	25.27
4	0.418	22.70	0.410	22.29
5	0.373	20.46	0.392	21.41
6	0.369	20.26	0.369	20.26
7	0.403	21.95	0.415	22.54
8	0.422	22.90	0.431	23.32
9	0.425	23.00	0.398	21.70
10	0.511	27.06	0.422	22.88
Average	**0.410**	**22.25**	**0.399**	**22.06**

The relative error between the actual measured stacking angle and the simulated value is 0.96%, indicating that the calibrated and optimized *yanhusuo* discrete element parameters can be reliably used for subsequent DEM simulations.

CONCLUSIONS

1. This study focuses on "Zhehu No. 1" as the research subject and conducts physical testing to determine the basic physical parameters of *yanhusuo*, including its density, moisture content, Young's modulus, and Poisson's ratio. Furthermore, the contact parameters between *yanhusuo* and steel plate were determined, including the restitution coefficient, static friction coefficient, and rolling friction coefficient.

2. The physical parameters of *yanhusuo* were selected as the simulation test parameters. Significant factors affecting the stacking angle were identified through the Plackett-Burman test, and the optimal range for these significant factors was further determined through the steepest ascent tests. Subsequently, a second-order orthogonal rotating combination test was conducted, with the minimization of the relative error in the stacking angle as the optimization objective, resulting in the optimal combination of simulation parameters.

3. The optimal parameter combination for *yanhusuo* was determined through calibration: a restitution coefficient of 0.481, a static friction coefficient of 0.508, and a rolling friction coefficient of 0.029. Verification tests showed that the relative error between the simulation and test tests was only 0.86%.

Keywords: *fresh corn harvester, grain collection box, high-level unloading of grain, electro hydraulic control, low loss*

ABSTRACT
In response to the problems of low unloading height, small collection box capacity, and high ear damage rate during grain collection in the fresh corn combine harvester, a large collection box with buffering and shock absorption mechanism and high unloading height was designed based on the 4YX-6 fresh corn combine harvester, which is a fully hydraulic driven fresh corn combine harvester. The device mainly consists of a box body, a buffering and shock-absorbing mechanism, a grain unloading extension mechanism, an electro-hydraulic system, etc. According to the agronomic requirements for fresh corn cultivation, the volume of the grain collection box is designed to be 10 m³. According to the height range of the grain receiving truck during the harvest of fresh corn, the unloading stroke height of the grain collection box is designed to be 2.9 m~4.4 m. To achieve synchronization of lifting and flipping actions during high-level unloading, a synchronous series hydraulic system is designed. Conduct force analysis on the drop of fruit ears to the bottom of the grain collection box and design a buffering and shock-absorbing mechanism. The designed grain collection box was installed on the 4YX-6 fresh corn combine harvester for field experiments, with ear damage rate and unloading time as performance indicators. The results showed that the ear damage rate ranged from 0.5% to 0.8%, the unloading time was from74 s to 126 s, and there were no safety issues such as deformation or tilting of the device during operation. The ear damage rate met the standards, and the working performance was stable, meeting the operational requirements.

摘要
针对鲜食玉米联合收获机卸粮高度低、集粮箱容积小、集粮时果穗损伤率高的问题，基于4YX-6型鲜食玉米联合收获机设计了具备缓冲减震机构、可高位卸粮的全液压驱动鲜食玉米联合收获机大型集粮箱。该装置主要由箱体、缓冲减震机构、卸粮延长机构、电液系统等组成。根据鲜食玉米种植的农艺技术要求，将集粮箱容积设计为10 m³。根据鲜食玉米收获期间接粮车的厢体高度范围，将集粮箱卸粮行程高度设计为2.9 m ~ 4.4 m，为实现高位卸粮时升举、翻转动作的同步性，设计了同步串联式液压系统。对果穗掉落到集粮箱底部时进行受力分析，设计缓冲减震机构。将设计的集粮箱安装在4YX-6型鲜食玉米联合收获机上进行田间试验，以果穗破损率和卸粮时间为性能指标，结果表明：果穗损伤率范围在0.5% ~ 0.8%，卸粮时间在74 s~126 s，作业过程中装置未出现形变、倾斜等安全性问题，果穗损伤率符合标准，工作性能稳定，满足作业要求。

INTRODUCTION
Fresh corn, including sweet corn and glutinous corn, refers to a type of corn that can be processed and consumed after harvesting or directly harvested for consumption (*Zhou et al., 2020; Zhao et al., 2011; Li et al., 2019*). Due to its delicious taste, sweet and glutinous texture, and high nutritional value that are beneficial to the human body, it has attracted increasing attention, and therefore its planting area has been increasing year by year (*Chen et al., 2023; Zhu et al., 2012; Zhang et al., 2023*). At present, the annual planting area of fresh corn in China has reached 1.67 million hectares, and the annual market consumption has reached 75 billion ears. China has become the world's largest producer and consumer of fresh corn. Against the backdrop of the current promotion of green and high-quality development strategies, the Ministry of Agriculture and Rural Affairs has also issued a notice stating that the area of fresh corn should remain stable at over 20 million acres (*Islam et al., 2021; Geng et al., 2023*).

For fresh corn, its harvest period is relatively short. After reaching the picking conditions, it should be picked and sent to the production line for processing as soon as possible. If the optimal picking time is exceeded, it will cause the aging of fresh corn, which not only affects the quality and taste of fresh corn, but also leads to nutrient loss, affects the processing flow, and ultimately affects sales, causing property losses and a series of other problems.

At present, technical personnel have conducted extensive research on the issue of grain collection boxes in combine harvesters. Scholar analyzed and summarized various structures of ear boxes, such as side flip and back flip, and analyzed the structural characteristics and operational advantages and disadvantages of different styles of ear boxes (*Zhou, 2013*). Scholars from Heilongjiang academy of agricultural machinery engineering sciences analyzed a loss reduction and diversion device was designed for the problem of ear damage caused by impact of fresh corn entering the grain collection box, effectively reducing the ear damage rate (*Zhang et al., 2025*). Scholars from Modern Agricultural Equipment Co. Ltd. analyzed optimization of the support structure for the ear box of the corn harvester for seed production has been carried out, improving the stress strength of the ear box (*Liu et al., 2017*). Foreign scholars often use DEM methods to design grain tanks and study the motion and mechanical characteristics of grains in the silo, providing assistance for the design of harvesting machinery grain tanks (*González-Montellano et al., 2012; Ma et al., 2022; Balevičius et al., 2011*). In response to issues such as large capacity grain tanks and high position unloading, major foreign companies have designed corresponding products to reduce the number of unloading times and improve operational efficiency (*Fu, 2020; Yan, 2016*). Existing research has mainly focused on the design of grain collection boxes for ordinary grain corn. Although the volume and unloading height have been improved, the effect of the improvement is not significant for fresh corn combine harvesters, and the damage caused by the collision between fresh corn ears and the box body has not been considered.

In response to the above challenges, this article presents the design of a large grain collection box for a fully hydraulic-driven fresh corn combine harvester, based on the 4YX-6 model. The collection box features a buffering and shock-absorbing mechanism and is capable of high-position unloading. The design includes the external structure, functional components, and dimensional specifications of the grain collection box, tailored to meet the unloading method and operational requirements. Field performance tests were conducted to evaluate the effectiveness and reliability of the proposed design.

MATERIALS AND METHODS

Whole machine structure and working principle

This article focuses on the design of a large grain collection box for the 4YX-6 fresh corn combine harvester, with a side flip unloading method. The main external structure of the host of the 4YX-6 fresh corn combine harvester is shown in Fig. 1.

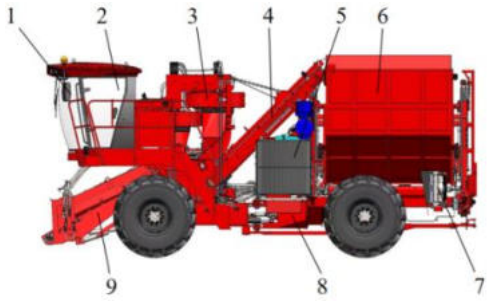

Fig. 1 – 4YX-6 Fresh corn harvester

1. Electrical system; 2. Driving cab; 3. Fan; 4. Elevator; 5. Powertrain; 6. Grain collection box; 7. Hydraulic system; 8. Chassis; 9. Bridge elevator

The main technical parameters are shown in Table 1.

Table 1

Main Technical Parameters

Technical parameter	Numerical value
Overall dimensions (length x width x height) / (mm×mm×mm)	11280×3390×3840
Number of working rows	6
Row spacing/mm	700/400
Working width/mm	3300
Fuel tank capacity/L	460

Technical parameter	Numerical value
Hydraulic oil tank capacity/L	205
Wheelbase/mm	4180
Track width/mm	2920
Rated power/kW	194
Grain collection box capacity/m^3	10

Structure and working principle of grain collection box

The grain collection box is mainly composed of a box body, a box body bracket, a buffering and shock-absorbing mechanism, a grain unloading extension mechanism, a hydraulic system, etc. Fresh corn ears are transported via an elevator and enter the bottom of the grain collection box. When the grain collection reaches a certain level, it can be unloaded at a high position either at the center or head of the cornfield. The box body is connected to the bracket through a hydraulic cylinder. The bracket itself is securely fixed to the chassis of the harvester. The overall structure of the grain collection box is illustrated in Fig. 2.

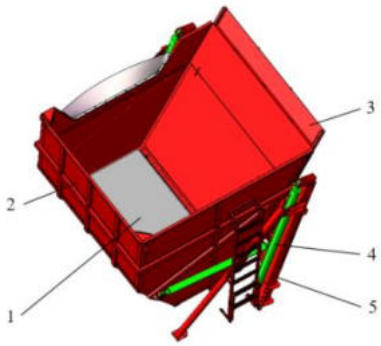

Fig. 2 – Structure of grain container

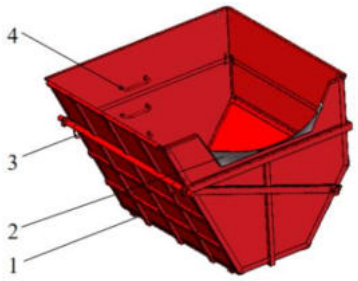
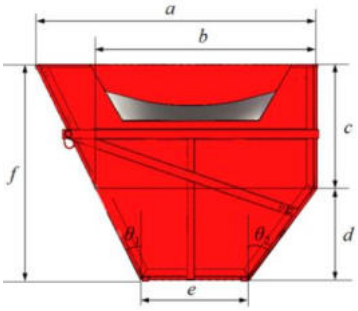


1. Buffer and shock absorber mechanism; 2. Box; 3. Unloading extension mechanism; 4. Hydraulic cylinder; 5. Anti-nose-dive leg

Fresh corn has a higher moisture content at harvest and is more prone to damage compared to grain corn. Therefore, a buffer and shock absorber mechanism is installed on the bottom plate of the grain collection box to reduce the probability of damage caused by rigid collision between fresh corn and the bottom plate. To increase the unloading distance between the harvester and the grain receiving truck, an unloading extension mechanism is designed. To achieve stable and fast lifting and flipping of the grain collection box when unloading to the high-level grain receiving truck, a hydraulic compensation directional valve is developed, and a synchronous series hydraulic system with adjustable lifting and flipping speeds is designed.



Box design

Due to the short optimal harvesting period of 2-3 days for fresh corn after maturity, the harvesting efficiency should be improved. If the volume of the grain collection box is small, it will increase the number of grain unloading times and reduce the harvesting efficiency. To reduce the frequency of unloading grain and lower transportation costs, large trailers are often parked on the ground and directly loaded onto the trailers from the harvester. According to the agricultural technology requirements for fresh corn cultivation, the planting method in Northeast China is mostly large ridges and double rows, with a ridge width of 1100 mm and a plant spacing of 250 mm to 280 mm (*Cui et al., 2024*). The length of a single ridge is usually around 500 meters. Taking a 6-row fresh corn harvester as an example, one round trip of the grain collection box can store about 24000 ears of fresh corn.

Using the variety Wannuo 2000 fresh corn as the research object, the drainage method was used to measure the volume of a single ear (*Tang, 2024*). Taking the average of multiple experiments, the volume of a single ear was found to be 0.0003 m^3. After calculation, it was found that the volume of an ear harvested in one round trip was 7.2 m^3. Due to the irregular arrangement of fruit clusters in the grain box and the large gaps between them, the total volume needs to exceed 7.2 m^3. In actual harvesting operations, the grain collection box cannot be filled to the brim, otherwise it will fall and lose. Therefore, in order to leave sufficient space, the volume of the grain collection box is set to 10 m^3. The box structure is shown in Fig.3 (a).

(a) Axonometric drawing

(b) Front view of the box

1-Reinforcement board; 2-Rubber baffle; 3-Unloading and flipping axis; 4-ladder

Fig. 3 – Box structure

Figure 3(b) shows the structural dimensions from the front view of the grain collection box. The left slope in the figure represents the unloading side. To prevent tipping or sliding of fresh corn after the box is lifted to its highest position, the slope angle should exceed the natural rolling angle of fresh corn. Therefore, θ1 is designed at 25°. Additionally, due to the installation of a cooling fan at the lower right section of the box, the opposite slope angle (θ2) is set at 35°, and the distance d is designed at 0.93 mm to accommodate and avoid interference with the fan's position. The chassis of the 4YX-6 fresh corn combine harvester is designed with a 1.0 m distance and a 2.5 m length between the two support beams that hold the grain collection box. Accordingly, the width (e) of the grain collection box is set to 1.1 m, and the length in the front–rear direction (l) is set to 2.5 m to match the chassis structure. In field operations, grain is often unloaded into small trucks with guardrails typically around 2.5 meters high. To improve unloading efficiency, the design adopts a method that allows unloading without lifting. Considering the chassis height, the box height (f) is designed to be 2.2 meters. Based on geometric and structural calculations, the value of c is determined to be 1.27 meters. The remaining dimensions, a and b, can be calculated using Equations (1) and (2):

$$a = f\tan\theta_1 + dan\theta_2 + e \quad (1)$$

$$b = d\tan\theta_1 + dan\theta_2 + e \quad (2)$$

The calculation shows that a is 2.77 m and b is 1.8 m. The volume of the box is:

$$V = \left[\frac{(b+e)d}{2} + \frac{(a+b)c}{2}\right]l \quad (3)$$

By inputting the relevant data into the above equation, the volume can be obtained as 10.625 m^3. To increase the ability of the box to resist deformation, all steel plate materials are selected as Q345B, and reinforcing ribs are used around the ear box for reinforcement.

Design of Unloading Extension Mechanism

During the unloading process, the distance between the harvester and the grain receiving truck needs to be maintained within the range of 0.3 m to 0.4 m, which requires accurate control of their relative positions to achieve the goal of unloading all grain into the grain receiving truck. However, when the two are very close, it is easy to cause scratches and safety hazards during unloading. When the two are far apart, it is easy to cause the grain to not be accurately dumped onto the receiving truck during unloading, resulting in waste. Therefore, it takes a long time to adjust the relative position of the two, greatly reducing the efficiency of the operation. Therefore, a retractable unloading extension mechanism is installed on the unloading outlet side of the grain collection box through a connecting plate. During harvesting, the opening of the box is facing upwards, and the moving extension plate slides in a fixed slide through a pulley under the action of gravity, naturally contracting to an unexpanded state without blocking the opening of the box or exceeding its own height. When it is necessary to dump grain, the box flips over, and the moving extension plate slides out naturally under the action of gravity. The moving extension plate can be limited in travel by a locking slider. A limit plate can be optionally installed in the fixed slide, which is divided into two gears and can be selectively installed according to different operating conditions to adjust the travel of the slide. The unloading extension mechanism is shown in Fig.4.

The dimensions of the mobile extension plate designed here are 2500 mm in length and 600 mm in width. Due to the locking slider, the actual extendable stroke is 400 mm, which can achieve unloading of grain within a distance of 0.7 m between the harvester and the grain receiving vehicle. The unloading distance is greatly increased, avoiding repeated adjustment of vehicle distance, accelerating unloading efficiency, and reducing safety hazards.

Dynamic analysis of fruit ear

The harvest period of fresh corn is during the milk or wax ripening stage, when the grain moisture content is very high at around 65%, which can easily cause serious damage during rigid impact (*Zhang et al., 2019; Gao et al., 2024*). The corn ears are thrown out by the elevator and then dropped into the box in an inclined manner, resulting in a height difference between the ears and the bottom plate of the box. Due to the steel plate material of the box, the fruit clusters that enter the box at the beginning of harvesting will directly fall onto the bottom plate of the box, causing severe collision between the clusters and the steel plate, resulting in significant damage and loss. When the bottom plate is covered with a layer of fruit clusters, elastic collisions between clusters will occur inside the box, reducing or eliminating damage. To solve this problem, a buffering and shock-absorbing mechanism is installed on the bottom plate of the box, so that the initially entering fruit clusters come into elastic contact with the box to reduce damage.

Study on the mechanical properties of fresh corn

Fresh corn has a high moisture content and crisp grain texture. To provide reference for the design of buffering and shock-absorbing mechanisms, the mechanical properties of fresh corn ears during harvesting were studied. The variety Wannuo 2000 was used for the experiment of fresh corn ears, and 10 ears of fresh corn were randomly picked from the experimental field for measurement. The compressive strength and elastic modulus of the ear during harvest are important parameter indicators. This article used the RGT series desktop universal testing machine (speed accuracy ± 0.5%, load accuracy ± 0.5%) to measure 10 fruit ears (*Zhao et al., 2022*). Compression tests were conducted on the front, middle, and tail sections of the fruit ears, and the results were averaged. When the grain underwent significant deformation to the point of bleeding, it was considered damaged. The experimental process is shown in Fig.5.

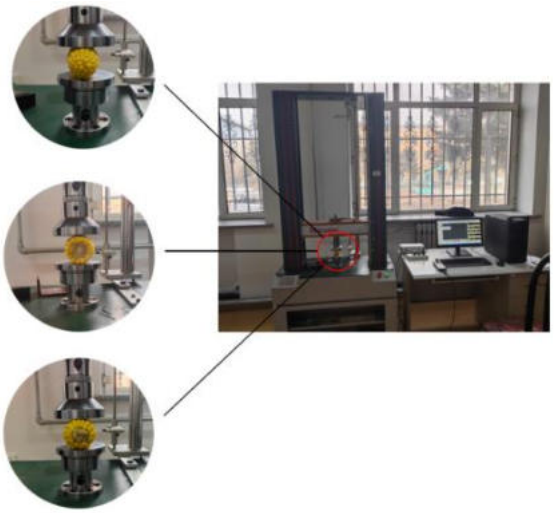

Fig. 5 – Mechanical measurement test

Statistical analysis was conducted on 10 fruit ears, with an average compressive strength of 8.16×10^4Pa, an average elastic modulus of 0.82 MPa, and a Poisson's ratio of 0.35.

Dynamics analysis of corn ear

Fresh corn was thrown out of the conveyor belt and entered the grain collection box in a diagonal motion. The dynamic analysis of the movement process of the ear is shown in Fig.6.

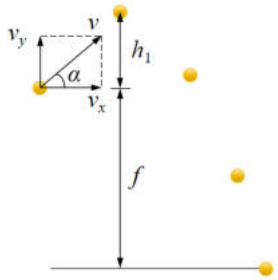

Fig. 6 – Movement process of the fruit ear

The movement of fruit ears in the air is divided into two stages: ascending and descending. Analyzing the movement stages of fruit ears includes:

$$\begin{cases} v_x = v\cos\alpha \\ v_y = v\sin\alpha \\ h_1 = v_y^2/(2g) \\ h = h_1 + f \end{cases} \quad (4)$$

where:

v—represents the initial velocity at which the ear leaves the conveyor belt, m/s;

V_x—horizontal velocity of the fruit ear, m/s;

V_y—vertical velocity of the fruit ear, m/s;

α—the angle between the initial velocity of the fruit ear and the horizontal direction, (°);

H_1—the distance at which the ear rises to the highest point, m;

G—gravitational acceleration, taken as 9.8 m/s^2;

H—the distance between the fruit ear being thrown to the highest point and falling onto the bottom plate of the grain collection box, m;

The speed range of the conveyor belt was 300-350 r/min, and the installation angle between the conveyor belt and the horizontal ground α was 45°. This article takes the middle value of the speed as calculate based on 325 r/min, with an initial velocity v of 3.4 m/s. By substituting the data into the above equation, h can be obtained as 2.5 m.

When the corn ear came into collision contact with the bottom plate, its contact stress was calculated to evaluate the impact force (*Wei, 2023*).

$$\begin{cases} \sigma_c = \dfrac{F_j}{A_c} \\ A_c = 0.8973h + 112.2 \end{cases} \quad (5)$$

where:

σ_c —represents the contact stress between the ear and the bottom plate during collision, Pa;

F_j—the contact force between the ear and the bottom plate during collision, N;

A_c—contact area at the time of collision, mm^2;

The previous analysis showed that h was 2.5 m, and the calculated contact area at the time of collision was 2355.45 mm^2.

According to the contact mechanics calculation formula, the load and compressive deformation at the point of contact between the corn ear and the steel plate were analyzed to evaluate the mechanical response during impact.

$$\begin{cases} F_j = \dfrac{4}{3} E^* \sqrt{R^*}\, \delta^{\frac{3}{2}} \\ \dfrac{1}{E^*} = \dfrac{1-\mu_1^2}{E_1} + \dfrac{1-\mu_2^2}{E_2} \\ R^* = \dfrac{1}{R_1} + \dfrac{1}{R_2} \\ \delta = \left(C\sigma \dfrac{\pi\sqrt{R^*}}{2E^*} \right)^2 \\ C = \min\left(1.295e^{0.763\mu_1}, 1.295e^{0.763\mu 2}\right) \end{cases} \quad (6)$$

According to the above formula:

$$F_j = \frac{(\pi C\sigma)^3}{6} \left(\frac{E^*}{R^*} \right)^2 \quad (7)$$

where: E^*—Comprehensive modulus of elasticity, MPa;

R^*—Compressing equivalent radius, m;

δ—The compression deformation amount when the ear undergoes deformation, mm;

μ_1—Poisson's ratio of fruit ear;

μ_2—Poisson's ratio of steel plate;

E_1—Elastic modulus of fruit ear, MPa;

E_2—Elastic modulus of steel plate, MPa;

R_1—Vertical radius of collision between fruit clusters and steel plates, mm;

R_2—The radius of the steel plate when in contact, mm;

C—Stress coefficient, take the smaller value;

σ—Yield stress of fruit ear, taken as 0.27 MPa.

The previous experiment has measured the elastic modulus of the fruit ear to be 0.82 MPa and the Poisson's ratio to be 0.35. According to the Mechanical Design Manual, the elastic modulus of the steel plate is 2.1 × 10^5 MPa and the Poisson's ratio is 0.3. By measuring the external dimensions of the ear, the diameters of the top, middle, and tail of the ear were measured separately, and the average diameter was 40 mm, which was used as the vertical radius when the ear collided with the steel plate. Since the steel plate is located at the bottom of the grain collection box as a plane, its radius can be considered infinite.

By substituting the relevant data into equations (6) and (7), the contact force between the ear and the bottom plate during collision was 294.95 N. As mentioned earlier, the contact area between the ear and the bottom plate during collision was 2355.45 mm^2. Combining equation (5), the contact stress between the ear and the bottom plate was 12.8 × 10^4 Pa. In the section on mechanical properties of the ear, the average compressive strength of the ear was measured to be 8.16 × 10^4 Pa, which means that the contact stress between the ear and the bottom plate was greater than the compressive strength of the ear. Therefore, when the ear was thrown out of the conveyor belt and came into contact with the steel plate, it was damaged.

Design of buffer and shock absorption mechanism

The buffering and shock-absorbing mechanism is installed on the bottom plate of the grain collection box and is required to bear the majority of the load from the accumulated corn ears. When the box is full, the mechanism must remain structurally intact and capable of restoring to its original state after unloading. To ensure its reliability, it is essential to calculate the maximum pressure the buffering and shock-absorbing mechanism can withstand. For this purpose, the front view of the grain collection box was simplified, as shown in Figure 7, and a force analysis was conducted based on this model.

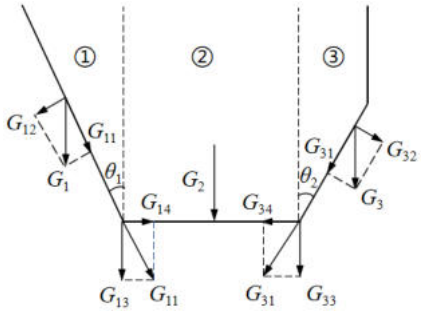

Fig. 7 – Force analysis of the box body

According to the structure of the box, the box is divided into three areas ①, ②, and ③ for separate force analysis. The first regional analysis is:

$$\begin{cases} G_{11} = G_1 \cos\theta_1 \\ G_{12} = G_1 \sin\theta_1 \\ G_{13} = G_{11} \cos\theta_1 \\ G_{14} = G_{11} \sin\theta_1 \end{cases} \quad (8)$$

where: G_1—total gravity of fruit ears in the first region, N;

G_{11}— component of G_1 along the inclined plane, N;

G_{12}— component of G_1 perpendicular to the inclined plane, N;

G_{13}—G_{11} vertical bottom plate force, N;

G_{14}—G_{11} component force along the bottom plate, N.

For Region ②, the entire gravitational force G_2 of the fruit ears acts directly and vertically on the bottom plate.

The third regional analysis is:

$$\begin{cases} G_{31} = G_3 \cos\theta_2 \\ G_{32} = G_3 \sin\theta_2 \\ G_{33} = G_{31} \cos\theta_2 \\ G_{34} = G_{31} \sin\theta_2 \end{cases} \quad (9)$$

where: G_3—total gravity of fruit clusters in the third region, N;

G_{31}—G_3 component force along the inclined plane, N;

G_{32}—the force component of G_3 vertical inclined plane, N;

G_{33}—G_{31} vertical bottom plate force, N;

G_{34}—G_{31} component force along the bottom plate, N.

From the above analysis, it can be seen that the total gravity of the fruit clusters inside the box does not act entirely on the bottom plate, but is partially shared by the inclined surfaces on both sides, reducing the pressure that the air cushion needs to bear. In section 2.1, it was calculated that a 6-row fresh corn combine harvester can harvest 24000 ears of fresh corn in one round trip. The average weight of a single ear was 290 g measured in the field, and the total weight was 6960 kg with a total gravity of 68208 N. The cross-sectional area ratio of the three regions is the ear gravity ratio, and the area of the three regions is calculated as:

$$\begin{cases} S_1 = \dfrac{f^2 \tan\theta_1}{2} \\ S_2 = ef \\ S_3 = \dfrac{(c+f)d \tan\theta_2}{2} \end{cases} \quad (10)$$

where: S_1 - the cross-sectional area of the region ①, m²;

S_2 - the cross-sectional area of the region ②, m²;

S_3 - the cross-sectional area of the region ③, m²;

Enter data to obtain S_1: S_2: S_3 =G_1: G_2: G_3 =1.13:2.42:1.13. Calculate G_1, G_2, and G_3 as 16469N, 35270N, and 16469N, respectively. The total pressure on the bottom plate of the box, G_z, is:

$$G_Z = G_{13} + G_2 + G_{33} \quad (11)$$

Combining equations (8), (9), and (11), the total pressure exerted on the bottom plate is 59684 N.

The area S_d of the bottom plate of the box is:

$$S_d = el \quad (12)$$

The calculated area of the bottom plate is 2.75 m^2.

Combining equations (11) and (12), it can be concluded that the pressure exerted on the bottom plate is 21.7 kPa. Therefore, the designed shock absorber pad should have a compressive strength greater than 21.7 kPa and a load capacity greater than 6.9 t. There are very few products that can achieve such a large load capacity and restore elasticity after compression in this area, and the price is expensive. The actual production and application costs are high. Therefore, this article designs a buffering and shock-absorbing mechanism with a simple structure and low cost. The schematic diagram of the buffer and shock absorber mechanism is shown in Fig.8.

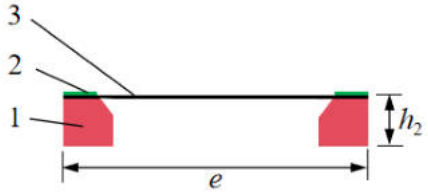

Fig. 8 – Schematic diagram of buffer and shock absorber mechanism

1.Heel; 2.Splint; 3.High elasticity rubber

High elasticity rubber is fixed by pads and clamps, with the pads fixed to the bottom plate of the box. To reduce stress concentration caused by downward bending of the rubber, a 20 mm chamfer is designed on the inside of the pads. Due to the thin thickness of the rubber sheet, which is much smaller than its length and width, and the linear elastic deformation of the rubber, a certain horizontal pre tension T is applied to the rubber sheet during clamping to ensure sufficient buffering deformation space between the rubber and the bottom plate of the box. The pre tension taken in this article is 500 N.

When the ear falls onto the rubber plate, the calculation condition is based on the ear falling into the middle of the rubber plate. The deformation of the rubber sheet can be regarded as the result of the combined action of pre tension and intermediate pressure. To calculate the deformation of the rubber sheet:

$$\begin{cases} \delta_1 = \dfrac{PL^3}{192D} \cdot \dfrac{1}{1+\dfrac{TL^2}{12D}} \\ D = \dfrac{E_3 H^3}{12\left(1-\gamma^2\right)} \end{cases} \quad (13)$$

Where: δ_1—Rubber deformation amount, mm;

P—Contact force between fruit ear and bottom plate collision, N;

L—Rubber sheet length, taken as 2.5 m;

D—Rubber sheet bending stiffness;

E_3—Rubber elastic modulus, 4×10^6 Pa;

H—Rubber sheet thickness, m;

γ—Rubber Poisson's ratio, taken as 0.47.

This article takes a rubber sheet thickness of 10 mm. The deformation obtained by inputting the data into the above equation is 0.09 m. In order to provide sufficient buffer space when the ear comes into contact with the rubber, the height h_2 of the cushion block is designed to be 100 mm. As the number of fruit clusters in the box gradually increases, the high elasticity rubber deforms and comes into contact with the bottom plate. After unloading the grain, the rubber rebounds and continues to play a buffering role.

Design of hydraulic system

The grain collection box is connected to the plunger pump oil supply system through hydraulic fittings and joints. The hydraulic system circuit is shown in Fig.9, mainly including hydraulic compensating directional valves, hydraulic cylinders, overflow valves, and other auxiliary components. When the system is in operation, the inlet P and outlet T are respectively connected to the oil supply system and oil tank of the pump body. When solenoid valves 3 and 4 are powered on, they can respectively achieve the lifting function of the grain collection box, and when solenoid valves 1 and 2 are powered on, they can respectively achieve the flipping function of the grain collection box. The overflow valve regulates the system pressure and protects the hydraulic circuit from overpressure conditions.

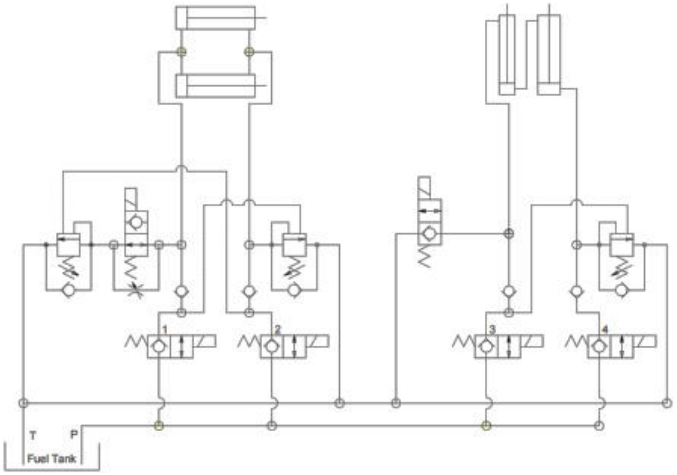

Fig. 9 – Hydraulic circuit of grain collection box

The grain box bracket for installing the lifting oil cylinder moves through a slide. Due to the uneven distribution of the weight of the fruit clusters in the grain box, the load on the grain box is the highest during lifting. If the lifting speed of the two oil cylinders is not the same, it will cause the grain box to tilt. In mild cases, the grain box will be stuck and unable to move, and in severe cases, the grain box frame will deform, causing safety issues. To ensure stable lifting, the two hydraulic cylinders must operate in synchronization. Therefore, the lifting oil cylinder design uses synchronous series oil cylinders, which should ensure that the effective working area of the two series oil cylinders is equal. Due to leakage in the series circuit during actual operation, a hydraulic compensation type reversing valve is designed in the circuit to replenish oil to the system. When the oil cylinder is in a constant power state during the lifting process, it can stop at any position within the stroke range at any time. When the oil cylinder is in a stationary state, the system is in a constant pressure state. The maximum working pressure of the oil source system is 16 MPa, and the maximum load-bearing ear weight calculated earlier is 68208 N. The theoretical thrust of the hydraulic cylinder can be calculated using the following formula:

$$F_u = \eta \frac{\pi}{4} D_0^{\,2} P_1 \qquad (15)$$

where: F_u—Theoretical thrust of the hydraulic cylinder, N;

η— Mechanical efficiency, taken as 0.85;

D_0— Diameter of the main piston in the synchronized hydraulic cylinder, mm;

P_1— Working oil pressure, Pa.

Select the hydraulic cylinder based on the above analysis. Refer to the product manual and select the HSG type hydraulic cylinder for engineering use. The synchronous main oil cylinder uses a hydraulic cylinder with a piston diameter of 140 mm and a piston rod diameter of 70 mm. Based on the above formula, the maximum pressure can reach 209249 N, which is greater than the total weight of the ears and grain collection box when fully loaded, meeting the lifting requirements. Due to the fact that the effective working area of the two series connected oil cylinders should be equal, that is, the cross-sectional area of the main cylinder with a rod chamber is equal to the cross-sectional area of the auxiliary cylinder without a rod chamber, when selecting, the piston rod diameter of the auxiliary cylinder and the main cylinder should be kept consistent. After calculation, the piston diameter of the auxiliary cylinder is 121.2 mm.

The flipping cylinder has relatively low synchronization requirements during flipping operations, so parallel cylinders are selected for flipping cylinders. During the operation, the box rotates around the flipping axis under the extension of the reverse oil cylinder. The force analysis of the reverse oil cylinder operation process is shown in Fig.10. In the figure, O_1 is the support point of the flipping cylinder, simplifying the fruit clusters inside the box into particle O_2, O_3 is the hinge point of the flipping axis when the box is flipped, and O_4 is the hinge point of the flipping cylinder. O_1O_3 is the direction of the connection between the support point of the flipping cylinder and the hinge point of the flipping shaft, O_1O_4 is the length direction of the flipping cylinder, O_2O_3 is the direction of the connection between the grain particle and the hinge point of the flipping shaft, and O_3O_4 is the direction of the connection between the hinge point of the flipping cylinder and the hinge point of the flipping shaft.

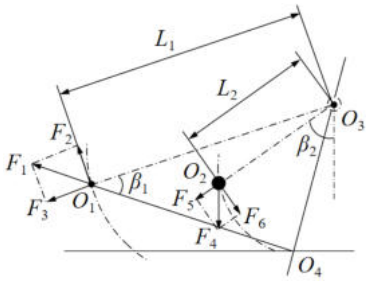

Fig. 10 – Force analysis of flipping cylinder operation

To achieve the flipping of the box, it is necessary to meet the following requirements:

$$\begin{cases} F_2 L_1 > F_6 L_2 \\ F_2 = F_1 \sin \beta_1 \\ F_6 = F_4 \sin \beta_2 \end{cases} \quad (16)$$

where: F_1—The force exerted by the flipping cylinder, N;

F_3—The force component of F_1 in the O_1O_4 direction, N;

F_2—F_1 component perpendicular to O_1O_4 direction, N;

F_4—Total gravity of box and ear, N;

F_5—Force component of F_4 in the direction of O_2O_3, N;

F_6—F_4 component perpendicular to O_2O_3 direction, N;

β_1—Angle between O_1O_3 and O_1O_4, (°);

B_2—The angle between O_2O_3 and the vertical direction, (°);

During the unloading reversal process, the maximum hydraulic cylinder pressure is required when the box is about to flip, so this state is analyzed. According to the installation structure of the grain collection box, the length of L_1 is 2381 mm and β_1 is 25 °. To obtain the length of L_2, the position of the center of mass needs to be obtained. In the 3D software SolidWorks 2020, 6960 kg of mass is added to the inside of the box according to the shape of the box, and material properties are added to each component of the grain collection box. After calculation, the box mass is 800 kg, β_2 is 81 °, and the length of L_2 is 1412 mm. Combining equation (16), it can be concluded that F_1 should meet the minimum requirement of 60686 N. Therefore, the HSG type hydraulic cylinder with a piston diameter of 80 mm and a piston rod diameter of 40 mm is selected for the flipping cylinder.

Design of electronic control system

All functions of the grain collection box are operated inside the cab, and the buttons use a reset switch. The control system mainly includes power supply, handle, controller, solenoid valve, etc. To streamline the system structure, a hydraulic compensating directional valve has been developed, with all solenoid valves concentrated on top. The lifting and flipping functions are controlled by solenoid valves to control the oil cylinder. To achieve rapid unloading of grain, a speed regulating valve is added to the flipping circuit of the grain collection box. Fast flipping can be selected according to the actual harvest situation. When the grain collection box is not fully loaded and the load is close to half, fast flipping unloading can be selected to reduce unloading time and improve operational efficiency. The control logic is shown in Fig.11.

RESULTS

Field performance test

The experiment was conducted in September 2024 at the 47th parallel farm in Yi'an County, Qiqihar City, using the 4YX-6 fresh corn combine harvester. The fresh corn variety planted on the experimental plot was Wannuo 2000. At the time of the experiment, the fresh corn was in the milk ripening stage, which met the harvesting conditions for fresh corn. The planting mode adopted a large ridge double row, with a ridge length of 500 m, a ridge spacing of 1.1 m, and a plant spacing of 0.25 m.

The basic parameters of the fruit ear were measured using random sampling method, and the results are shown in Table 2.

Table 2

Determination of Basic Parameters of Ears

Parameter	Average value
Ear length/mm	173
Large end diameter of fruit ear/mm	46
Grain quality/g	291
Moisture content/%	69

The measurement was conducted based on the ear damage rate and unloading time as experimental indicators, and the GB/T 21961-2008 Corn Harvesting Machinery Test Method (*Wang, 2023*) was used as the ear damage evaluation standard. The field experiment site is shown in Fig.12.

(a) Small grain truck unloading grain

(b) Large grain trucks unloading grain

Fig. 12 – Field unloading experiment

When conducting ear damage statistics, the main consideration is the ears in direct contact with the bottom of the box. Therefore, during the experiment, the harvester advances ten meters each time and stops immediately after harvesting ten meters to conduct damage statistics on the ears in the grain collection box. The experiment is repeated five times, and the damage rate ranges from 0.5% to 0.8%, which meets the operational requirements.

There are two main types of grain receiving vehicles used in field operations, namely small grain receiving vehicles pulled by high-powered tractors (low-level unloading) and large heavy-duty trucks (high-level unloading). During the experiment, unloading tests were conducted on both types of grain receiving vehicles. The experiment is conducted when the grain collection box is empty (without fruit ears) and full (harvested by the harvester back and forth once), and the entire process time from the start of lifting the grain collection box to the end of unloading and returning to its original position is taken as the unloading time. To obtain an accurate range of unloading time, various situations were used to calculate the unloading time, and the unloading time was found to be between 74 s and 126 s. The correspondence between operating status and unloading time is shown in Table 3.

Table 3

Operating Status and Unloading Time

Work status	Time/s
Empty load low position quick flipping unloading of grain	74
Empty high position quick flipping unloading of grain	113
Fully load low position normal flipping unloading of grain	86
Full load high position normal flipping unloading of grain	126

The whole machine did not experience any safety issues such as tilting, overturning, or cracking of the frame during operation, and both the harvester and the grain receiving truck can unload grain within a range of 0.7 meters, with an unloading height of 2.9 meters to 4.4 meters. The operation is stable and safe.

CONCLUSIONS

(1) A large grain collection box suitable for fresh corn harvesting was developed to address key issues in existing combine harvesters, including low unloading height, limited grain box capacity, and a high damage rate to corn ears during collection. The box volume was designed to be 10 m³, based on agronomic requirements and harvesting operation needs. To extend the unloading reach between the harvester and grain-receiving trucks, a grain unloading extension mechanism was incorporated. Additionally, dynamic analysis of the unloading process was performed, leading to the design of a buffering and shock-absorbing mechanism to reduce ear damage during impact.

(2) To improve the convenience of unloading grain, an electro-hydraulic control system was designed. It can achieve synchronization of hydraulic mechanism operation and has fast flipping function, reducing unloading time.

(3) Field experiments revealed that the damage rate of corn ears resulting from direct contact with the bottom of the grain collection box ranged between 0.5% and 0.8%. Statistical analysis of unloading time under various working conditions showed that the unloading height ranged from 2.9 m to 4.4 m, while the unloading time ranged from 74 s to 126 s. The test results meet relevant standards and satisfy operational requirements, demonstrating the effectiveness and reliability of the proposed design.

Keywords: *combine harvester, threshing cylinder, motor drive, dynamic parameter identification, real time speed adjustment, adaptive control*

ABSTRACT

In response to the speed control requirements of the threshing cylinder in combine harvesters, this paper analyzes the working condition characteristics of the threshing cylinder and establishes a dynamic model. A mathematical model for the electrically driven threshing cylinder is established, and an adaptive speed control strategy is proposed based on the identification of moment of inertia. Experimental results indicate that, the control accuracy and robustness of the system are enhanced. During the start-up process, the overshoot in speed and convergence time are reduced by 11.1% and 31.3%, respectively; when fluctuations occur in the feed rate of the threshing cylinder, the maximum speed fluctuation and adjustment time are reduced by 55% and 33.3%, respectively; when the moisture content of crops changes, the shortest convergence time and maximum fluctuation amplitude of the threshing cylinder's speed are reduced by 57.7% and 18.8%, respectively. This research provides theoretical support and practical foundation for the intelligent control of electrically driven combine harvesters, demonstrating considerable application value.

摘要

针对联合收割机中脱粒滚筒的转速控制需求，本文分析了脱粒滚筒的工况特征并建立了动力学模型，构建了电驱动脱粒滚筒的数学模型，提出了一种基于转动惯量辨识的电驱动脱粒滚筒转速自适应控制策略。实验结果表明，系统的控制精度和鲁棒性得到增强。启动过程中的转速超调量和收敛时间分别减少了11.1%和31.3%；作物喂入量发生波动时，最大转速波动和调整时间分别减少了55%和33.3%；当作物的含水率变化时，脱粒滚筒的转速最短收敛时间和最大波动幅度分别减少了57.7%和18.8%。本研究为电驱动联合收割机的智能化控制提供了理论支持和实践基础，具备良好的应用价值。

INTRODUCTION

Under the dual challenges of skyrocketing global food demand and climate change, combine harvesters hold a central position in modern agricultural systems. Due to the seasonal nature and high labor intensity of the crop harvesting process, there is an urgent demand for combine harvesters that are efficient in production, provide good operational quality, are easy and comfortable to control, and possess intelligent features *(Liu et al., 2024; Ou et al., 2024)*.

The main working components of the combine harvester include header, threshing cylinder, separation and cleaning device and grain unloading auger. Among them, the threshing cylinder is one of the core components, with the main function of separating the grains from the rice heads. Threshing cylinder not only largely determines the threshing quality and production efficiency but also significantly impacts the subsequent processes of separation and cleaning in the combined harvester *(Wang et al., 2023; Tang et al., 2022; Yang et al., 2018; Miu et al., 2007)*. Traditional combine harvesters rely on mechanical transmission systems to transfer engine power to various working components, which limits the speed adjustment range and overload capacity. As a result, it is challenging for the speed of these working components to be adjusted in real-time according to fluctuations in the feed rate of the harvester. This can lead to issues such as significant crop losses due to carryover and clogging of the threshing cylinder, which in turn reduces the crop cleaning rate and overall production efficiency. Therefore, enhancing the dynamic responsiveness and overload capacity of the threshing cylinder's speed adjustment is crucial for improving the harvesting quality and efficiency of combine harvesters.

In response to issues such as the narrow adjustment range of the threshing cylinder speed of the combine harvester, high threshing loss rate, and frequent clogging, some scholars have conducted related research. The research on the operation quality and efficiency of the threshing cylinder of the combine harvester primarily focuses on improving the quality and efficiency of the threshing process through mechanical structural design and the collaborative optimization of operational parameters *(Ivan et al., 2015; Cristea et al., 2023; Vlădut et al., 2023)*. *Vlădut et al., (2022),* proposed a mathematical model describing the axial flow characteristics during the threshing and separation processes of the threshing cylinder. *Wang et al., (2022),* addressed the issue of clogging in the threshing cylinder by designing a telescopic rod tooth-ribbed rod roller type threshing device. This design improves the flow of crops through the synergistic operation of the internal structures. *Zewdie et al., (2024),* explored the performance of bean threshers, using different cylinder speeds, concave apertures, feed rates, and moisture levels as variables. They obtained relatively ideal operating parameters for the threshing cylinder, which improved threshing efficiency and reduced grain loss rates. In addition, research on the threshing cylinder mainly focuses on exploring the interactions between threshing quality, operating parameters, and mechanical structure, aiming for structural optimization design *(Wang et al., 2021; Song et al., 2022; Li et al., 2023; Gong et al., 2024; Tang et al., 2024)*. *Abdeen et al., (2025),* improved the operational parameters and structure of the rice threshing device, reducing costs and power consumption, and significantly enhancing the overall efficiency of the threshing cylinder. *Gou et al., (2025),* introduced the structural design and advancements in intelligent technology applications of the combine harvester's threshing device. However, the drawbacks of multi-stage mechanical transmission systems still exist, such as long transmission routes and low transmission efficiency, which restrict the independent control capacity for adjusting the speed of various operating components as needed. Additionally, the working environment of combine harvesters is complex, with issues such as crop lodging and uneven moisture content, leading to high harvesting loss rates and poor cleanliness.

With the global climate change and the increasing awareness of environmental protection, the rapid development of new energy technologies has become a key driver for the green transformation and upgrading of industries. This provides impetus and ideas for promoting the intelligent development of new energy agricultural equipment. The integration of smart technologies with new energy sources can enhance operational efficiency, reduce emissions, and optimize resource use in agricultural practices, ultimately contributing to sustainable farming and improved productivity *(Liu et al., 2024)*. However, research on electrically driven combine harvesters is still in the preliminary exploration stage *(Jiang, 2015; Han, 2017; Hou, 2020)*, and there is a notable lack of information regarding the electric drive research of core components like the threshing cylinder. This gap indicates a significant opportunity for further study and innovation in this area. Developing electric drive systems for the threshing cylinder could enhance efficiency, reduce fuel consumption, and support the overall shift toward sustainable agricultural practices. Addressing this research gap could lead to advancements in the performance and adaptability of electric combine harvesters in various working conditions.

In summary, this paper addresses the speed requirements of the threshing cylinder during the operation of combine harvesters and aims to improve the system's control accuracy and responsiveness, thereby enhancing harvesting quality and efficiency. Considering that the threshing cylinder is a special component with large inertia affected by its shape, size, and structure, a self-disturbance control method for the threshing cylinder's speed in rice and wheat combine harvesters based on moment of inertia identification is proposed. This research analyzes the working principle and operational needs of the threshing cylinder, develops a dynamic model for it, and establishes a torque equation. By directly driving the threshing cylinder with a Permanent Magnet Synchronous Motor (PMSM), the advantages of quick dynamic response, superior speed control, and strong overload capacity of the motor are utilized. This approach resolves issues related to fixed transmission ratios and the inability to individually control the threshing cylinder's speed. Furthermore, by combining the PMSM's motion model, the operational characteristics of the electrically driven threshing cylinder is analyzed. This allows the combine harvester to maintain the threshing cylinder's speed within optimal ranges under different working conditions, ultimately reducing threshing losses and improving operational efficiency and quality. The study supports the advancement of combine harvesters from automation to intelligent operation.

MATERIALS AND METHODS

Analysis of operating requirements for electrically driven threshing cylinder

This paper is based on the 4LZ-6.0ME tracked combine harvester from World Agricultural Machinery Co., Ltd. (Zhenjiang, Jiangsu Province, China). A schematic diagram of the motor-driven threshing cylinder is shown in Figure 1. In the diagram, T_e represents the electromagnetic torque of the PMSM, while $T_L+B\omega_m$ denotes the load torque on the threshing cylinder and external friction resistance. The PMSM drives the threshing cylinder to generate the rotational angular velocity ω_m. This setup illustrates the relationship between the motor's output and the load conditions on the threshing cylinder, emphasizing the importance of effectively managing these parameters to enhance operational performance.

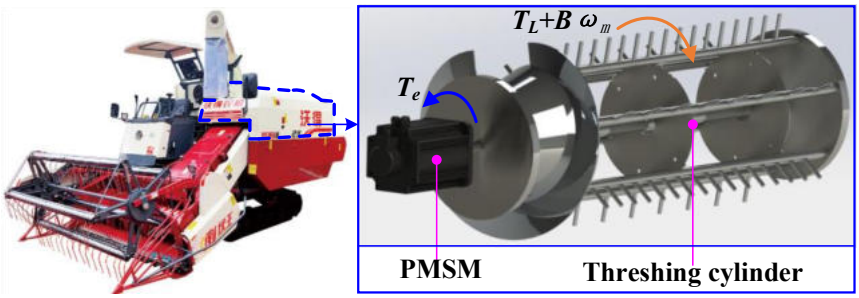

Fig. 1 - Schematic diagram of electrically driven threshing cylinder

The PMSM structure of this paper is shown in Figure 2 and its structural parameters are shown in Table 1 *(Xiang et al., 2024; Xiang et al., 2024)*:

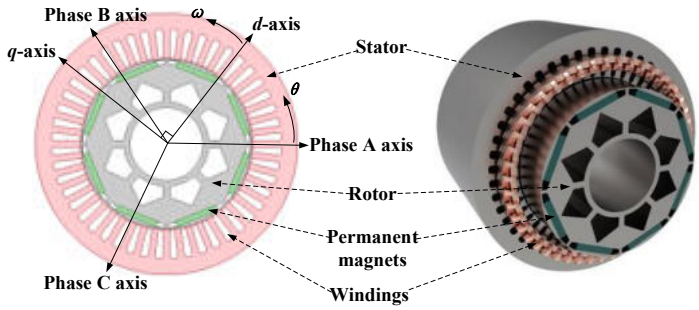

Fig. 2 - Structure diagram of PMSM (Permanent Magnet Synchronous Motor)

Table 1

Parameters of PMSM

Parameter	Value	Unit
Rated voltage	600	V
Rated power	11	kW
Rated speed	1500	rpm
Rated torque	70	Nm
Stator outer diameter	248	mm
Rotor outer diameter	160	mm
Rotor axial length	131	mm
Number of rotor poles	8	/

Relationship between threshing cylinder speed and threshing performance

There are many factors that influence the threshing quality of combine harvesters, including cylinder speed, feed rate, concave clearance, crop properties, field conditions, and the structural design of the cylinder. Among these, the rotational speed of the threshing cylinder is one of the key parameters affecting threshing performance, as the strength of the impact, brushing, and rubbing actions on the crops primarily depends on this speed *(Da, 2021)*. As shown in Figure 3, the relationship between the threshing cylinder speed and various performance indicators indicates that at lower speeds, the impact force is weakened, leading to reduced cleaning and separation rates, which in turn lowers production efficiency. Conversely, as the threshing speed increases, the brushing and rubbing actions become more pronounced, improving both the cleaning rate and

operational efficiency *(Han, 2017)*. However, excessively high speeds can lead to increased damage to the grains and straw, as well as higher power consumption *(Qu et al., 2018)*. Additionally, the timing of crop harvesting and the moisture content of the crops impose certain requirements on the cylinder speed. When threshing wetter crops, it is advisable to increase the cylinder speed to enhance separation rates. Conversely, for drier crops, the cylinder speed should be reduced to ensure the integrity of the grains and minimize breakage *(Jiang, 2015)*.

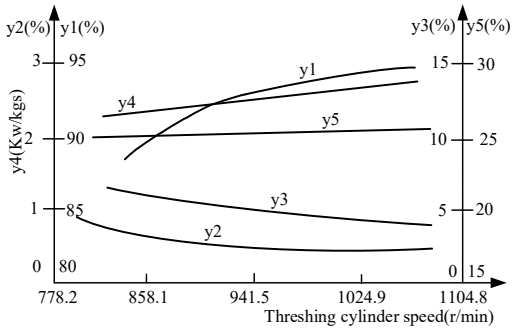

Fig. 3 - Relationship curves between threshing cylinder speed and various performance indicators
y1 – separation rate; y2– unthreshed rate; y3 – entrainment loss rate; y4 – unit power consumption; y5 – trash content

In summary, it is essential to determine the most suitable threshing speed range for the threshing cylinder based on its real-time operational conditions. Additionally, the threshing speed should be adjustable according to factors such as the crop feed rate and growth status. By maintaining the cylinder speed within this optimal range, the harvesting quality and efficiency of the combine harvester can be significantly improved. This adaptive control approach not only enhances overall performance but also ensures better handling of varying crop conditions during operation.

Performance requirements of permanent magnet driven motors for threshing operations

For the electrically driven threshing cylinder, the performance requirements of the drive motor are shown in Figure 4. The performance requirements that the motor must meet include: (1) The motor should have a robust overload capability, able to output 2-3 times the peak torque for short durations. This is essential for overcoming the large inertia loads of the threshing cylinder, enabling acceleration and stable operation while maintaining the required rubbing intensity to reduce crop impurity and loss rates. (2) A higher torque-to-inertia ratio enhances the acceleration performance of the threshing cylinder. This ratio is critical for achieving quick response times during operation. (3) The motor should offer a broad range of speed adjustments to meet the threshing speed requirements for various crop types and operating conditions, thereby further reducing production costs. (4) The driving motor should operate efficiently across a wide range to accommodate random fluctuations in operational load, which helps increase the duration of effective operation for the electric drive system.

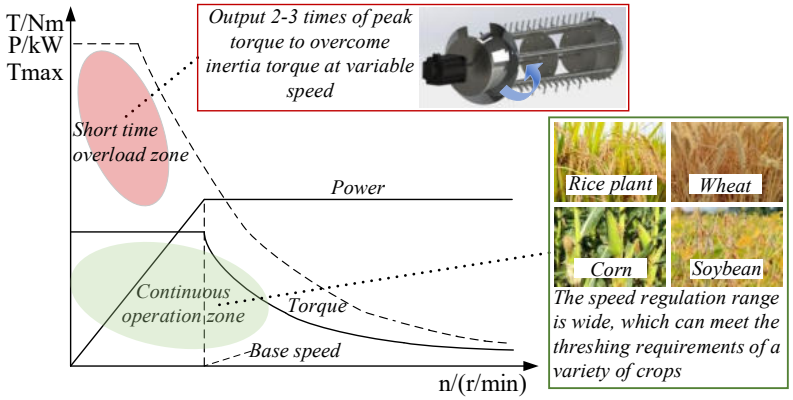

Fig. 4 - Performance output requirements of driving motor

By meeting these performance criteria, the electric motor can significantly enhance the operational efficiency and effectiveness of the electrically driven threshing cylinder in combine harvesters.

Mathematical model of electrically driven threshing cylinder

Mathematical model of PMSM

According to Figure 2, the mathematical model of PMSM in d-q axis system is established. The stator voltage equation for PMSM in the d-q coordinate system is as follows (eq. 1) *(Fu et al., 2024; Zhang et al., 2025)*:

$$\begin{cases} u_d = R_s i_d + L_d \frac{di_d}{dt} - \omega_e L_q i_q \\ u_q = R_s i_q + L_q \frac{di_q}{dt} + \omega_e (L_d i_d + \psi_f) \end{cases} \quad (1)$$

The electromagnetic torque equation is as follows (eq. 2) *(Fu et al., 2024; Zhang et al., 2025)*:

$$T_e = \frac{3}{2} P_n [\psi_f + (L_d - L_q) i_d] i_q \quad (2)$$

The mechanical motion equation is as follows (eq. 3) *(Fu et al., 2024; Zhang et al., 2025)*:

$$T_e = J \frac{d\omega_m}{dt} + B\omega_m + T_L \quad (3)$$

where: u_d, u_q = the stator voltage direct and cross-axis components [V]; i_d, i_q = the stator current direct and cross-axis components [A]; R = the stator winding resistance [Ω]; P = the number of pole pairs; ω_m = the mechanical angular velocity [rad/s]; L_d, L_q = the stator d, q axis inductance [H]; L_s = the stator inductance [H]; ψ_f = the magnetic chain of permanent magnets [Wb]; J = the rotational moment of inertia [kg·m²]; T_e = the electromagnetic torque [N·m]; T_L = the load torque [N·m]; B = the viscous friction factor.

Mathematical model of threshing cylinder

When the combine harvester starts operation, the active torque required to drive the threshing cylinder rotor shaft mainly includes the torque M_k required to overcome its own idle running, the torque M_g to overcome its own moment of inertia to generate angular acceleration, and the torque M_w (working torque) that pushes the crop to overcome the resistance movement and make it gain acceleration *(Zhang et al., 2001)*. The force analysis is shown in Figure 5.

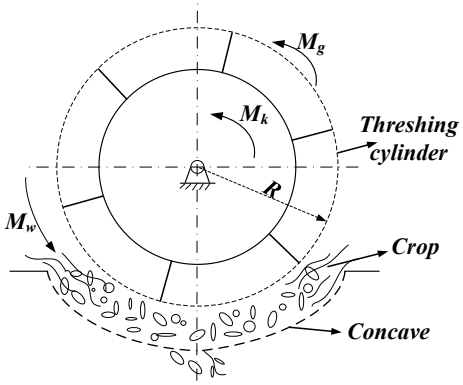

Fig. 5 - Force analysis diagram of threshing cylinder

M_k –idle running load torque of threshing cylinder, [N·m]; M_g – the inertia moment of threshing cylinder, [N·m]; M_w –the working torque of threshing cylinder, [N·m]

(1) Idle running load torque

The threshing cylinder has to overcome mechanical friction resistance and wind resistance during idle running, and according to Golikovich's cylinder theory *(Zhao,1984)*, the total idle running resistance torque is:

$$M_k = A + B\omega^2 \quad (4)$$

where: ω = the angular velocity of the cylinder[rad/s]; A = the torque generated by mechanical friction, taken as 0.004; B = the cylinder wind force torque coefficient, taken as 0.64 × 10-6.

(2) Moment of inertia of threshing cylinder

$$M_g = J \frac{d\omega}{dt} \quad (5)$$

where: J = moment of inertia of the threshing cylinder [kg·m²].

(3) Working torque of threshing cylinder

The working torque of the threshing cylinder includes the torque required to accelerate the movement of the crops and the torque needed to overcome the friction between the crops and the cover plate, concave plate, and spike teeth during the movement. The research shows that *(Zhang et al., 2000)*, the tangential speed of crops at the threshing cylinder outlet is 1/2~1/5 of the linear speed of the cylinder rotation. The crop outlet speed ratio λ is introduced, which is defined as the ratio of the velocity of the stalks being ejected at the discharge opening to the rotational linear velocity, helps to analyze the process. The crop movement speed at the feeding inlet of the threshing cylinder is significantly lower than the average movement speed within the cylinder, so it can be neglected. Assuming that the crop flows continuously through the threshing cylinder without crop breakage or clogging, the amount of crop fed in at time Δt is essentially equal to the amount of crop flowing out. Neglecting the axial speed of motion of the stem draft output, the amount of change in the kinetic energy of crop in the threshing cylinder in time Δt is given as follows *(Zhang et al.,1999)*:

$$E_v = \frac{1}{2} q \Delta t \frac{\lambda+\Delta}{1+\Delta} R^2 \omega^2 \tag{6}$$

where: q = feed rate [kg/s]; λ = crop outlet speed ratio; Δ = grass-to-grain ratio; R = the effective radius of the spike teeth on cylinder [m].

Therefore, the torque required by the threshing cylinder to propel the crop in accelerated motion is:

$$M_v = \frac{1}{2} q \frac{\lambda+\Delta}{1+\Delta} R^2 \omega \tag{7}$$

Research has shown that the torque required to accelerate the crop always accounts for a certain proportion of the total working torque. Therefore, Golikovich introduced the friction coefficient f to represent the proportional relationship between the working resistance and the total working torque *(Kanavetsky,1983)*, as shown in equation (8):

$$M_w = \frac{M_v}{1-f} \tag{8}$$

where: f = the friction coefficient of threshing cylinder.

Combining equations (4), (5) and (8), the torque equation for the threshing cylinder can be obtained as shown in equation (9):

$$M_T = M_g + M_k + M_w = J \frac{d\omega}{dt} + (A + B\omega^2) + \frac{qR^2\omega(\Delta+\lambda)}{2(1-f)(\Delta+1)} \tag{9}$$

Combining equations (2), (3) and (9), the mathematical model of motor-driven threshing cylinder can be obtained as shown in equation (10):

$$\frac{3}{2} P_n i_q \left[\psi_f + (L_d - L_q) i_d\right] = J \frac{d\omega}{dt} + (A + B\omega^2) + \frac{qR^2\omega(\Delta+\lambda)}{2(1-f)(\Delta+1)} \tag{10}$$

Control strategy for electrically driven threshing cylinder

When the rotating shaft of the PMSM is coupled to the threshing cylinder, the moment of inertia of the motor consists of the moment of inertia of the motor rotor and the moment of inertia of the threshing cylinder. The fluctuation of crop feed rate makes the load of threshing cylinder produce random disturbances, which causes the change of moment of inertia, and the required torque of threshing cylinder is positively correlated with its own moment of inertia, when the moment of inertia of the threshing cylinder increases, the required torque of the cylinder increases accordingly, and vice versa *(Liu, 2013; Li, 2023)*. Therefore, the online identification strategy of moment of inertia is introduced to enhance the control accuracy and stability of the system.

The control system block diagram of the electrically driven threshing cylinder is shown in Figure 6, including speed control loop, current control loop, coordinate transformation and moment of inertia identification module.

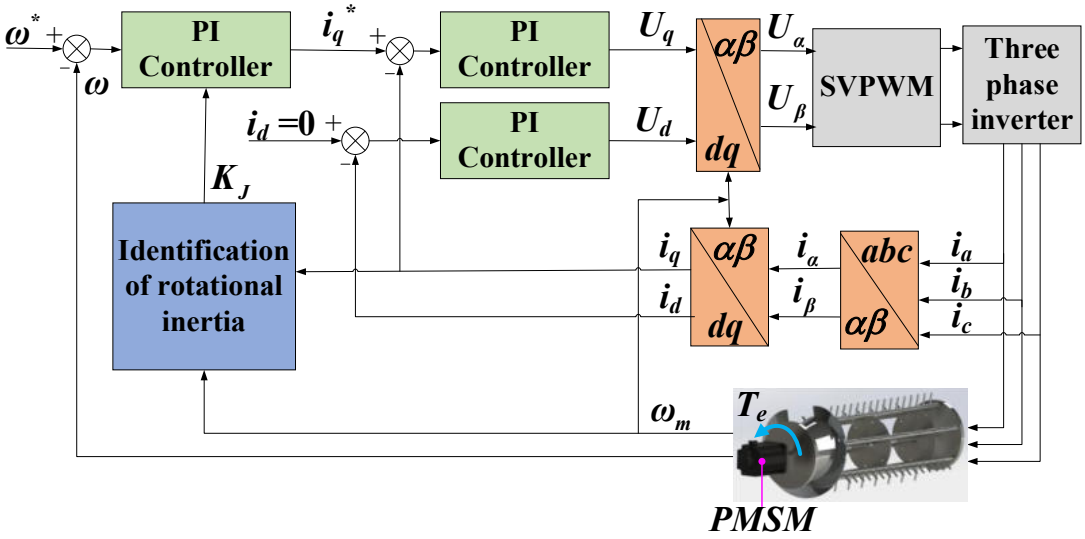

Fig. 6 - Control block diagram of electrically driven threshing cylinder

Identification of moment of inertia of electrically driven threshing cylinder system

Identification of moment of inertia of motor rotor

When the motor is undergoing acceleration or deceleration, the direction of the electromagnetic torque and the load is not fixed. Ignoring the motor's damping coefficient, let $\alpha=d\omega_m/dt$, then the mechanical motion equation of the motor can be expressed as:

(a) Acceleration process:

$$J\alpha_1 = T_e - T_L = K_T I_q - T_L \tag{11}$$

(b) Deceleration process:

$$J\alpha_2 = T_e + T_L = -(K_T I_q + T_L) \tag{12}$$

where: K_T = torque coefficient; I_q = q-axis current of motor(A).

In order to accurately identify the moment of inertia, it is necessary to take into account the effect of the load torque, and the load is equated as follows:

(a) Equation of motion for acceleration process:

$$K_T I_q = J\alpha_1 + T_L \triangleq J_{Acc}\alpha_1 \tag{13}$$

Then the equivalent moment of inertia during acceleration process is shown in equation (14):

$$J_{Acc} \triangleq J + \frac{T_L}{\alpha_1} \tag{14}$$

(b) Equation of motion for deceleration process:

$$K_T I_q = J\alpha_2 - T_L \triangleq J_{Dec}\alpha_2 \tag{15}$$

Then the equivalent moment of inertia during deceleration process is shown in equation (16):

$$J_{Dec} \triangleq J - \frac{T_L}{\alpha_2} \tag{16}$$

This leads to the estimation equation for the moment of inertia of the motor rotor as shown in equation (17):

$$\hat{J} = \frac{J_{Acc}+J_{Dec}}{2} = J + \frac{1}{2}\left(\frac{T_L}{\alpha_1} - \frac{T_L}{\alpha_2}\right) \approx J \tag{17}$$

The identification process of motor rotor moment of inertia is shown in Figure 7:

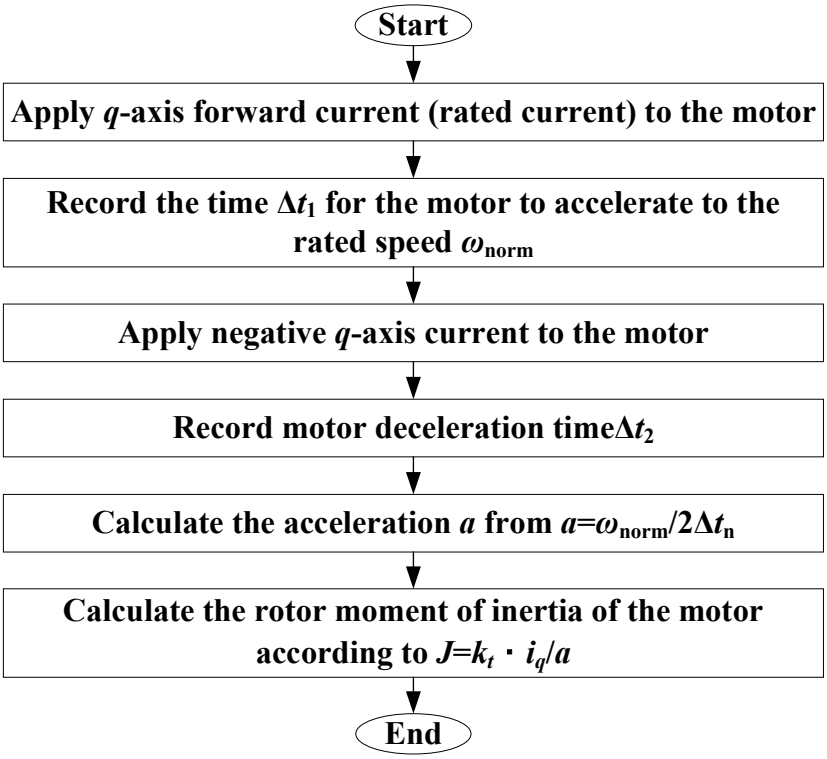

Fig. 7 - Flowchart for identification of motor rotor moment of inertia

Identification of moment of inertia of threshing cylinder

The moment of inertia identification of the threshing cylinder is implemented using the recursive least squares method with a forgetting factor *(He, 2020)*. The dynamic equations of the servo system are shown in equations (18) - (20):

$$T_m = JA_m \tag{18}$$

$$T_m = T_e - T_d - T_f \tag{19}$$

$$A_m = \frac{d\omega_m}{dt} \tag{20}$$

The performance index function equation (21) is constructed using T_m and A_m as input observations and the threshing cylinder moment of inertia J as the estimated quantity:

$$y = [T_m - JA_m]^2 \tag{21}$$

The criterion function is shown in equation (22):

$$V_N(k) = \frac{1}{N}\sum_{i=1}^{N}\left[T_m(k) - \hat{J}(k)A_m\right]^2 \tag{22}$$

The moment of inertia identification algorithm of the threshing cylinder is constructed based on the recursive least squares theory *(Song, 2019)*, as shown in equation (23):

$$\begin{cases} \hat{J}(k) = \hat{J}(k-1) + L(k)\left[T_m(k) - \hat{J}(k-1)A_m(k)\right] \\ L(k) = \frac{P(k-1)A_m(k)}{1+A_m^2(k)P(k-1)} \\ P(k) = [1 - L(k)A_m(k)]P(k-1) \end{cases} \tag{23}$$

Based on equation (23), the least squares identification algorithm with the addition of a forgetting factor λ is shown in equation (24):

$$\begin{cases} \hat{J}(k) = \hat{J}(k-1) + L(k)\left[T_m(k) - \hat{J}(k-1)A_m(k)\right] \\ L(k) = \frac{P(k-1)A_m(k)}{\lambda+A_m^2(k)P(k-1)} \\ P(k) = [1 - L(k)A_m(k)]P(k-1)\lambda^{-1} \end{cases} \tag{24}$$

where: T_m = the torque for accelerating or decelerating the rotational inertia of the threshing cylinder [N·m]; T_e = the motor output torque [N·m]; T_d = the disturbance torque of threshing cylinder [N·m]; T_f = friction torque [N·m]; A_m = the motor acceleration [r/s^2]; J = the moment of inertia of threshing cylinder [kg·m^2].

The moment of inertia identification process for the threshing cylinder is illustrated in Figure 8.

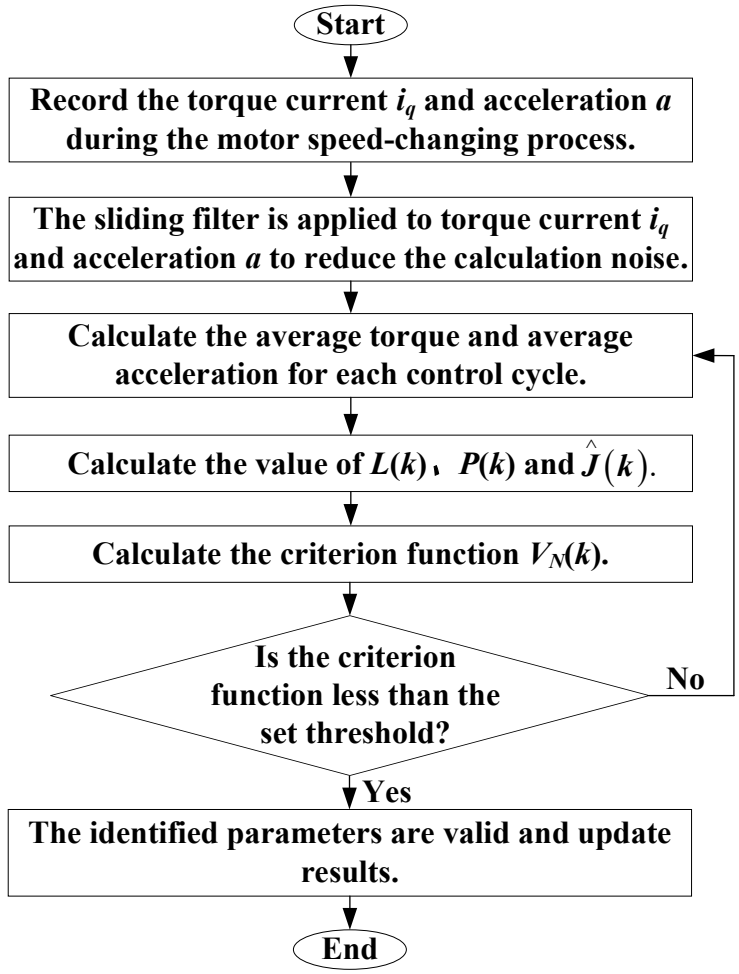

Fig. 8 - Flowchart for the identification of the moment of inertia of the threshing cylinder

Self-tuning of speed loop parameters in electrically driven threshing cylinder control system

The purpose of moment of inertia identification is to make real-time adjustments to the speed loop parameters based on changes in inertia, optimizing the conversion structure of the speed loop, and improving the responsiveness of speed conversion. The speed loop control block diagram is shown in Figure 9.

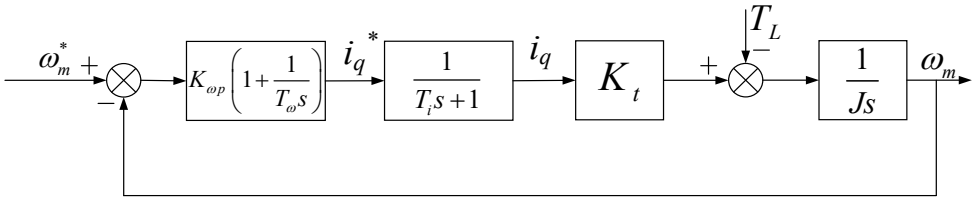

Fig. 9 - Speed loop control block diagram

In Figure 9, ω^*_m is the given speed; $K_{\omega p}$ is the proportional coefficient of the speed loop; T_ω is the integral time constant of the speed loop; T_i is the equivalent time constant of the current loop.

Based on the control block diagram in Figure 9, the open-loop transfer function of the system is derived as Equation (25):

$$G(s) = K_{\omega p}\left(1+\frac{1}{T_\omega s}\right)\left(\frac{1}{T_i s+1}\right)\frac{K_t}{Js} \tag{25}$$

The speed loop is a typical type II system *(Zhu et al., 2023)*, and the relationships of the system parameters are shown in equations (26) and (27):

$$T_\omega = hT_i \tag{26}$$

$$K = \frac{h+1}{2h}\cdot\frac{J}{T_i K_t} \tag{27}$$

where: K = the open-loop gain; h = the intermediate frequency bandwidth, according to the performance index of the system, take h = 5.

The calculation process of the PI parameters in the speed loop is shown in equations (28) and (29):

$$K_{\omega p} = \frac{J(h+1)}{2hT_i K_t} = \frac{J(h+1)R_s}{3hLp_n\psi_f} \tag{28}$$

$$K_{\omega i} = \frac{J(h+1)}{2h^2T_i^2 K_t} = \frac{J(h+1)R_s^2}{3h^2L^2p_n\psi_f} \tag{29}$$

where: $K_{\omega i}$ = Integral coefficient of speed loop.

When the motor drives the threshing cylinder, the total moment of inertia J is shown in equation (30):

$$J = J_0 + J_L \tag{30}$$

where: J_0 = the moment of inertia of motor rotor [kg·m²]; J_L = the moment of inertia of threshing cylinder [kg·m²].

The ratio of the moment of inertia of the threshing cylinder to the motor rotor is defined as the load inertia ratio K_J, the expression of which is shown in equation (31):

$$K_J = \frac{J_L}{J_0} \tag{31}$$

According to equations (28), (29) and (31), the PI parameters can be transformed as shown in equations (32) and (33):

$$K_{\omega p} = \frac{(K_J+1)J_0(h+1)}{2hT_i K_t} = \frac{(K_J+1)J_0}{3hLp} \tag{32}$$

$$K_{\omega i} = \frac{(K_J+1)J_0(h+1)}{2h^2T_i^2 K_t} = \frac{(K_J+1)J_0(h+1)R_s^2}{3h^2L^2p_n\psi_f} \tag{33}$$

By substituting the identified inertia ratio K_J into equations (32) and (33), the PI parameters of the speed loop are continuously revised, achieving the self-tuning capability of the PI parameters for the electrically driven threshing cylinder control system.

Experimental equipment

In this paper, based on the $dSPACE1007$ platform, a control system equivalent simulation test bench for an electrically driven threshing cylinder is constructed, as shown in Figure 10.

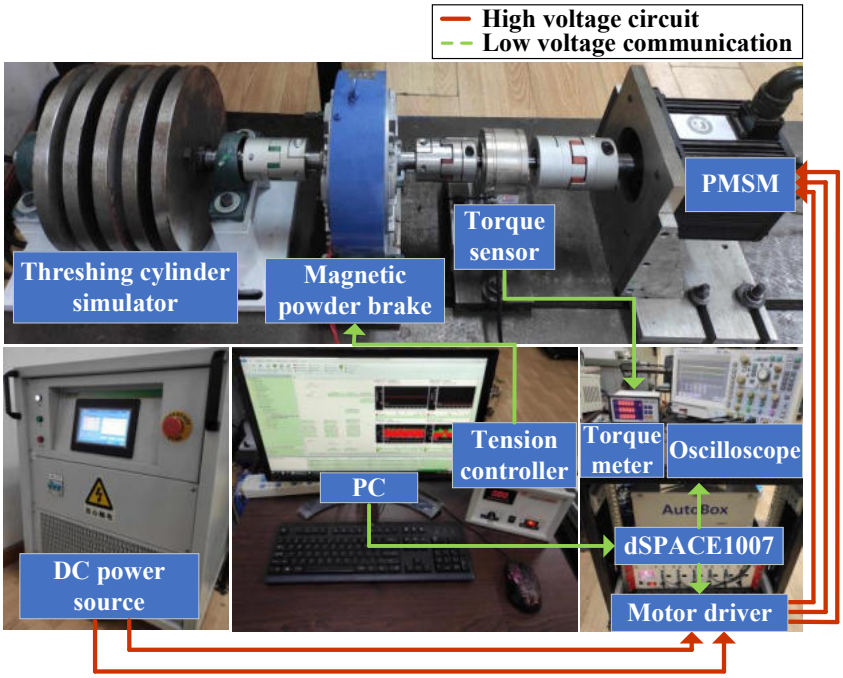

Fig. 10 - Equivalent simulation test bench for electrically driven threshing cylinder

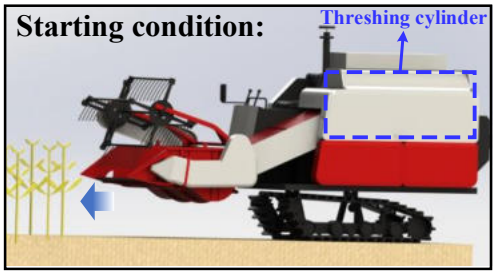
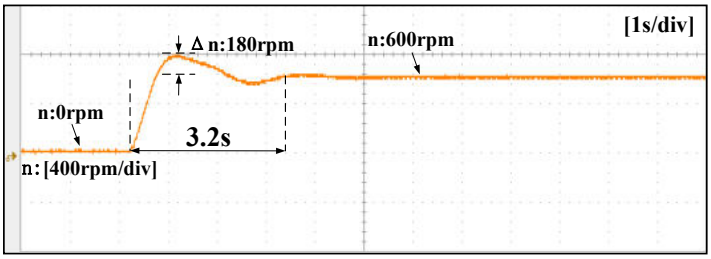
Among them, the threshing cylinder simulator is used to simulate the threshing cylinder of the combine harvester, and the magnetic powder brake is used to simulate the load disturbance of the threshing cylinder caused by the crop feed rate of the combine harvester during the field operation. According to the field operation environment and operational requirements of combine harvester, three experimental conditions are designed to compare control effects and verify the superiority of the proposed algorithm.

RESULTS ANALYSIS AND DISCUSSION

Condition 1:

As shown in Figure 11, the threshing cylinder is considered a large inertia component due to its size, shape, structure and other factors, and the required torque is positively correlated with its own moment of inertia. Therefore, at the beginning of the harvesting operation the resistance of the threshing cylinder is larger, resulting in a higher starting current, which can lead to overshoot in the speed and a slower response time of the control system. Thus, it is necessary to enhance the responsiveness and robustness of the control system.





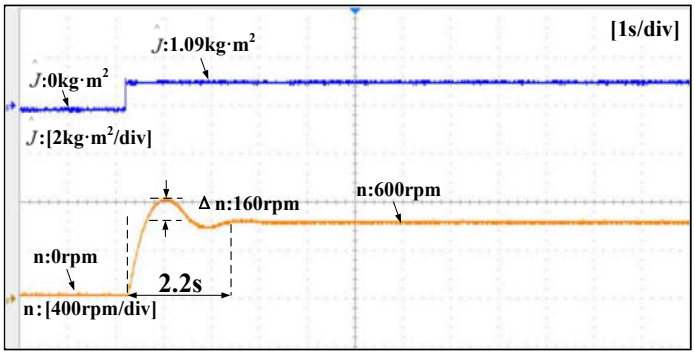


Fig. 11 - Starting condition of the threshing cylinder in the combine harvester

As shown in Figure 12, the start-up performance of the electrically driven threshing cylinder is compared with that of the traditional PI control method and the moment of inertia identification control method based on this paper, in which the sum of the moment of inertia of the motor and the threshing cylinder simulator is J=1.09 kg·m^2, and the target speed is 600 r/min.

It can be found that, in the start-up process of the electrically driven threshing cylinder, when the speed reaches the target speed, the value of the moment of inertia identified by the system in Figure 12(b) reaches the actual moment of inertia value, demonstrating high accuracy and good steady-state performance. After adaptive adjustment of the parameters of the speed loop, the start-up speed overshoot is 160 r/min, and the convergence time of speed oscillation is 2.2 s, which is 11.1% and 31.3% shorter than that of the speed overshoot amount of 180 r/min and the convergence time of 3.2 s in Figure 12(a), respectively.

(a) Traditional PI control method

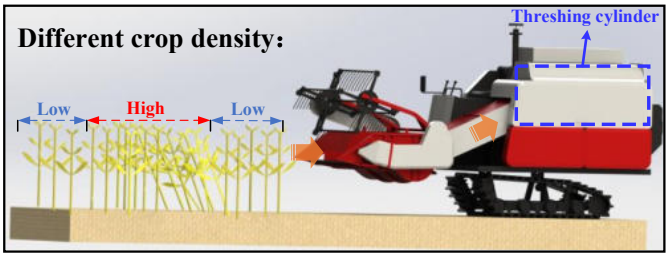
(b) Control method based on moment of inertia identification

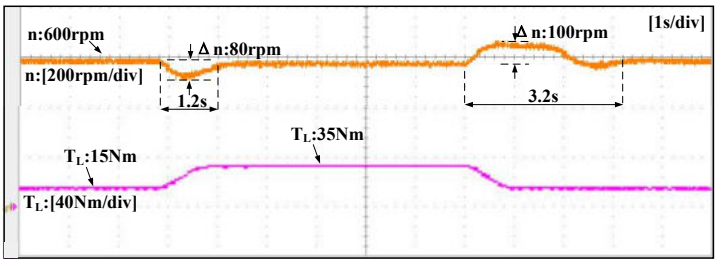
Fig. 12 - Comparison of start-up performance of electric drive system

The electrically driven threshing cylinder control method based on moment of inertia identification can effectively reduce the speed inertial shock and oscillation of the system during start-up process, which can effectively mitigate wear and tear on combine harvester.

Condition 2:

As shown in Figure 13, during harvesting operations, the combine harvester may encounter adverse weather conditions such as strong winds and heavy rain, which can cause crops to lodge. Additionally, the natural growth density of the crops may fluctuate, and the forward speed of the combine harvester can also vary due to factors like ground conditions and driver operating habits. These various external factors can lead to fluctuations in the feed rate of the combine harvester. Therefore, it is essential to enhance the stability of the threshing cylinder's speed to ensure a smooth operation process and improve the quality of threshing.





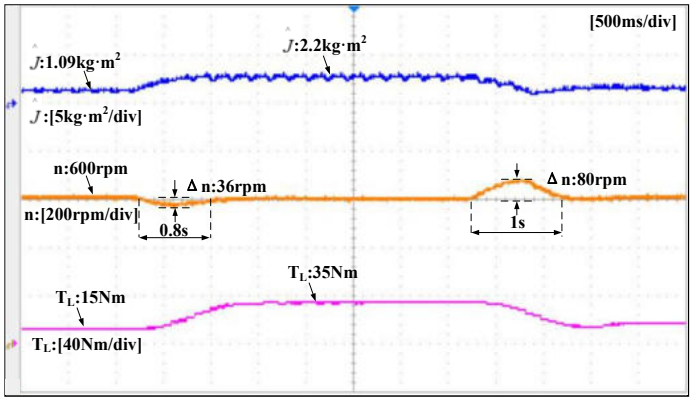


Fig. 13 - Fluctuation condition of feed rate to the threshing cylinder in combine harvester

The experimental results of the feed rate fluctuation tests for the two control strategies are given in Figure 14. In the feed rate fluctuation test, the electrically driven threshing cylinder runs at the rated speed of 600 r/min, the feed rate load changes abruptly from 15 Nm to 35 Nm, and then the load changes abruptly to 15 Nm after the speed stabilizes. As can be seen in Figure 14(b), when the feed rate load changes abruptly, the system can identify the actual value of moment of inertia and track the actual value, which has a better dynamic performance. The value of moment of inertia is fed back to the controller for real-time updating, and after self-tuning of the PI values of the speed loop, the maximum drop in speed and the maximum overshoot are 36 r/min and 80 r/min respectively, which are 55% and 20% less than those of 80 r/min and 100 r/min in Figure 14(a), and the dynamic adjustment time in Figure 14(b) during the process of abrupt increase and decrease of feed load are shortened by 33.3% and 68.8% respectively, indicating an enhanced disturbance rejection capability of the control system for the electrically driven threshing cylinder.

(a) Traditional PI control method

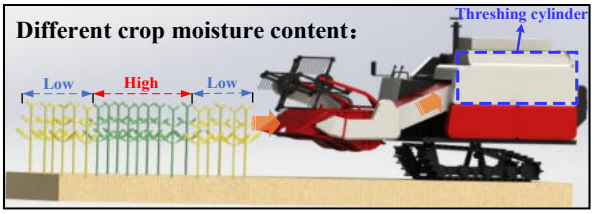
(b) Control method based on moment of inertia identification

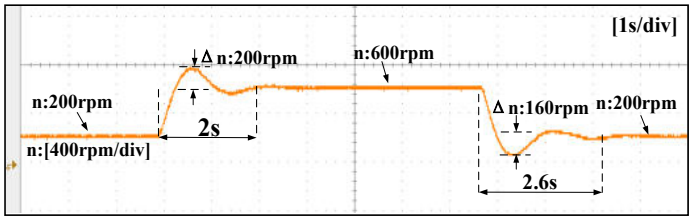
Fig. 14 - Comparison of load sudden change experiment

The moment of inertia identification-based speed control method significantly enhances the load disturbance rejection performance of the electrically driven threshing cylinder, improving the system's robustness. This results in a smoother and more seamless threshing process for the crops, thereby further increasing the processing efficiency and the quality of threshing.

Condition 3:

As shown in Figure 15, during harvesting operations, the moisture content of crops in the same field can fluctuate due to external environmental influences. Therefore, the speed of the threshing cylinder needs to be adjusted in real-time. When the moisture content of the crops increases, the speed of the threshing cylinder should be appropriately increased; conversely, when the moisture content decreases, the speed should be appropriately reduced.





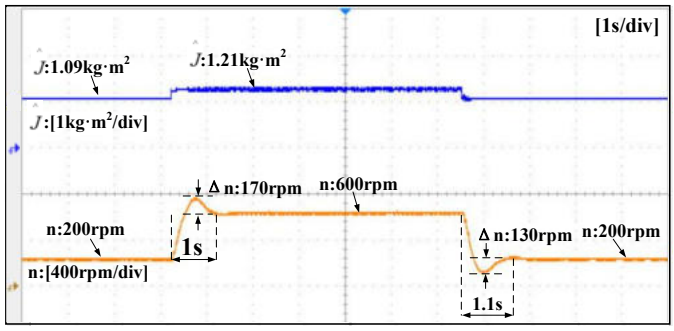


Fig. 15 - Fluctuating condition of crop moisture content

In order to verify the dynamic performance of the strategy proposed in this paper in the speed regulation process, the results of the comparison of the variable speed performance of the two control methods are given in Figure 16. In the experiment, the speed of the electrically driven threshing cylinder is increased from 200 r/min to 600 r/min, and then decreased back to 200 r/min after the speed stabilizes.

It can be seen that the system in Figure 16(b) can identify the actual value of moment of inertia during the speed change process and can track the actual value faster; the speed adjustment time during acceleration is 1 s, and the overshoot of the speed of the threshing cylinder is 170 r/min, which is 50% shorter and 15% smaller than the 2 s convergence time and 200 r/min speed overshoot of the traditional PI control strategy in Figure 16(a); the speed convergence time and the overshoot of the speed in Figure 16(b) are 57.7% shorter and 18.8% smaller, respectively, compared to Figure 16(a) during the speed deceleration process.

(a) Traditional PI control method

(b) Control method based on moment of inertia identification

Fig. 16 - Comparison of speed variation experiment

The speed control method based on moment of inertia identification effectively improves the speed regulation responsiveness and stability of the threshing cylinder in the combine harvester. For different types of crops or varying growth stages of the same crop, the adaptability of the threshing cylinder's speed is enhanced, which helps reduce harvesting losses and improve the crop's cleaning rate, further enhancing the quality of the harvest.

CONCLUSIONS

This paper studies the electrically driven speed control system for the threshing cylinder of a combine harvester during field operation, based on the working condition requirements. A dynamic model of the threshing cylinder is established, and a mathematical model of the electrically driven for the threshing cylinder is constructed by combining the motor motion model and characteristics of a permanent magnet synchronous motor. A load variation control strategy based on rotational inertia identification is proposed to meet the demands of multiple working points at different speeds under various operating conditions.

The experimental results indicate that during the startup process of the threshing cylinder, the control method based on rotational inertia identification reduces the overshoot and convergence time of the rotational speed by 11.1% and 31.3% respectively, compared to the traditional PI control method, effectively lowering the system's inertial impact and oscillation.

When there are fluctuations in the crop feed rate of the combine harvester, the control method based on rotational inertia identification decreases the speed drop and overshoot by 55% and 20%, respectively, while the dynamic adjustment time is shortened by 33.3% and 68.8%, enhancing the system’s disturbance resistance. Additionally, under varying crop moisture content conditions, the convergence times of acceleration and deceleration during speed adjustments are reduced by 50% and 57.7%, while the overshoot of the rotational speed decreases by 15% and 18.8%. These improvements enhance the responsiveness and stability of the threshing cylinder speed regulation. This system can effectively adapt to the dynamic power demands of modern agriculture, providing a theoretical basis for the development of intelligent agricultural equipment.

Based on this study, follow-up research will focus on conducting collaborative research between the threshing cylinder and other working modules to explore the optimal speed matching ratios between the modules, thereby improving the overall operational efficiency of combine harvester. In addition, the research will also aim to further reduce energy consumption through advanced energy management strategies, achieving greater economic efficiency and environmental friendliness. Furthermore, the research will involve manufacturing a prototype for field experiments to further verify the superiority of the electric drive operating system.

ABSTRACT
This study investigates the nonlinear stability of flat-elliptical greenhouse skeletons under wind loads, accounting for initial imperfections. A finite element model was developed in ABAQUS, with nonlinear buckling analysis conducted via the arc-length method. Eigenvalue buckling analysis identified imperfection modes, and the impact of imperfection amplitudes on bearing capacity was assessed. Results showed that increasing imperfection amplitude decreased the ultimate bearing capacity, with a 461.2 N·m² capacity at L/300, and 520.26 N·m² at L/800. Initial imperfections notably influenced yield stages. This study demonstrates that considering initial imperfections provides a more accurate assessment of the skeleton's stability under extreme loads.

摘要
本研究研究探讨了在风荷载作用下，考虑初始缺陷的平面椭圆形温室骨架的非线性稳定性。通过 ABAQUS 建立了有限元模型，并采用弧长法进行非线性屈曲分析。特征值屈曲分析用于识别缺陷模式，并评估缺陷幅度对承载力的影响。研究结果表明，随着缺陷幅度的增加，最终承载力下降，在 L/300 情况下承载力为 461.2 N·m²，而在 L/800 情况下为 520.26 N·m²。初始缺陷显著影响了屈服阶段。研究表明，考虑初始缺陷能够更准确地评估骨架在极端荷载下的稳定性。

INTRODUCTION
In modern agriculture, greenhouses are essential for maintaining stable crop growth, particularly in regions with harsh or fluctuating climates. They offer controlled environments that improve yield and quality. The structural skeleton, as the main load-bearing system, is critical to a greenhouse's longevity, stability, and safety. Thus, investigating its mechanical behavior under complex loads holds significant theoretical and practical value.

Historically, bamboo served as the primary structural material until the 1950s, but its susceptibility to corrosion and degradation limited its durability. In the 1980s, hybrid structures combining bamboo and steel emerged to improve strength, yet corrosion at the interface remained problematic. With advancements in steel production and reduced costs in the 21st century, steel—particularly galvanized steel pipes with high corrosion resistance and load-bearing capacity—became the dominant material, markedly enhancing greenhouse performance and lifespan. Plastic greenhouses with different skeleton types as shown in Fig. 1.

Steel structures, favored for their high strength and stiffness, resist external loads like wind and snow effectively while minimizing deformation. However, initial imperfections in steel components can compromise stability, often causing local or global buckling prior to reaching ultimate strength. These imperfections—defined by their location, shape, and evolution—are critical factors influencing failure modes. Nonlinear buckling analysis offers a more accurate evaluation of these effects, especially under complex or extreme load conditions. Cylindrical lattice shells, akin to greenhouse frames, have been extensively studied. For instance, Liu (2016) and Gu (2019) analyzed stochastic initial imperfections and their impact on buckling under various loads. Their findings underscore the necessity of including imperfections in structural analyses to ensure safety and performance reliability. Traditional analyses often assume ideal, defect-free models. Studies by *Ren (2019), Jiang (2021)*, and others employed finite element and time-domain methods to analyze stress and vibration responses in idealized skeletons. However, such simplifications may underestimate structural vulnerability under severe loads like heavy snow or strong winds, leading to significant instability and deformation.

Given the nonlinear nature of the loads acting on greenhouses, initial imperfections can exacerbate the risk of buckling and instability, affecting the long-term performance of the structure. Therefore, nonlinear buckling analysis of greenhouse skeletons, considering initial imperfections, is essential for a more accurate assessment of structural behavior under real-world loading conditions. Moreover, such analysis can reveal the impact of initial imperfection on the stability of the structure under extreme loads or adverse environmental conditions *(Cai, 2015; Zeng, 2024)*. While several studies have incorporated initial imperfections in the stability analysis of greenhouse skeletons, including the work by *Yu (2007) and Bao (2023)*, who performed nonlinear buckling analysis of arch-roof and Venlo-type greenhouses, there remains a gap in the research on the nonlinear buckling behavior of greenhouse skeletons under full dynamic wind loads. The specific mechanisms of structural instability in these conditions are not yet fully understood.

This study aims to fill this gap by assessing the stability of greenhouse structures under full dynamic wind load, highlighting potential instability risks induced by local buckling, and ultimately improving structural safety margins. The findings of this research will provide valuable theoretical support for the design, construction, and long-term operation of greenhouse structures, ensuring their safety and performance under extreme loading conditions.

MATERIALS AND METHODS

Analysis process

According to the code for design of steel structures *(GB50017-2017)* and the technical specification for space skeleton structures *(JGJ 7—2010)*, the impact of initial geometric imperfections, specifically the installation deviations from the intended curved surface shape, must be considered in the full-process analysis of lattice shell structures (skeletons). The distribution of initial geometric imperfections is typically represented by the lowest-order buckling mode of the structure, with the maximum value of the imperfection taken as 1/300 of the span of the lattice shell.

Based on these specifications, the following steps were taken to perform the nonlinear buckling analysis of the greenhouse skeleton structure:

(1) Finite Element Model Creation and Verification: A detailed finite element model of the greenhouse skeleton was established and verified to ensure its accuracy in simulating the structural behavior.

(2) Eigenvalue Buckling Analysis: A characteristic eigenvalue buckling analysis was conducted on the skeleton structure to determine the lowest-order buckling mode of the system.

(3) Simulation of Initial Geometric Imperfections: The distribution pattern of the initial geometric imperfections was simulated using the lowest-order eigenmode. The maximum value of the imperfections was set as 1/300 of the span of the greenhouse skeleton, as per the relevant design codes.

(4) Nonlinear Stability Analysis: A nonlinear stability analysis was performed using the arc-length method. The load-displacement curves and stability coefficients of the structure under different initial imperfections were compared to explore the influence of these imperfections on the stability of the structure.

Finite element model

In this study, a finite element model of a plastic greenhouse skeleton with 50 elliptical pipes was established using ABAQUS. The dimensional schematic of the skeleton is shown in Fig. 2.

As shown in Fig. 2, the structural span $L=10$ m; the structural height $H=3.6$ m; the rafter spacing $d=1$m.

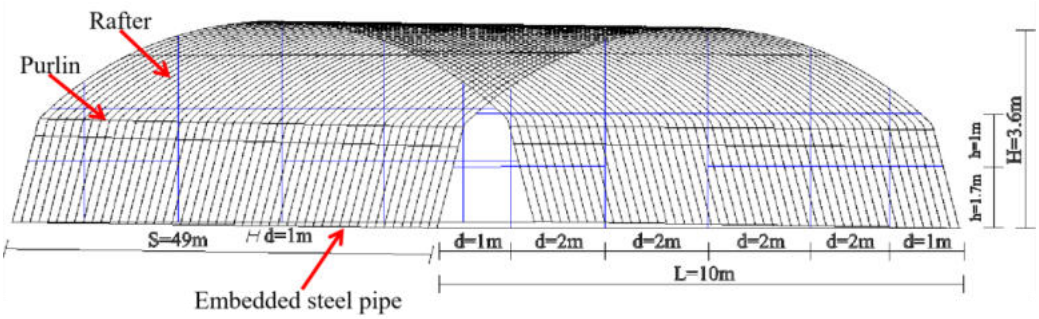

Fig. 2 – The dimensional schematic of the flat-elliptical pipe plastic greenhouse's skeleton

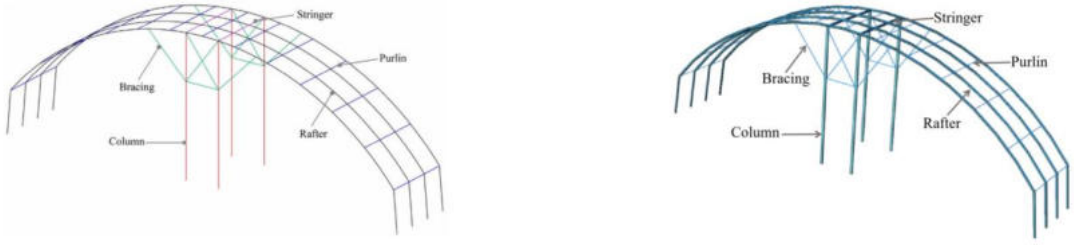
The material property parameters of the rafter, embedded steel pipe, and purlin are shown in Table 1.

Table 1

Material parameter of steel pipe



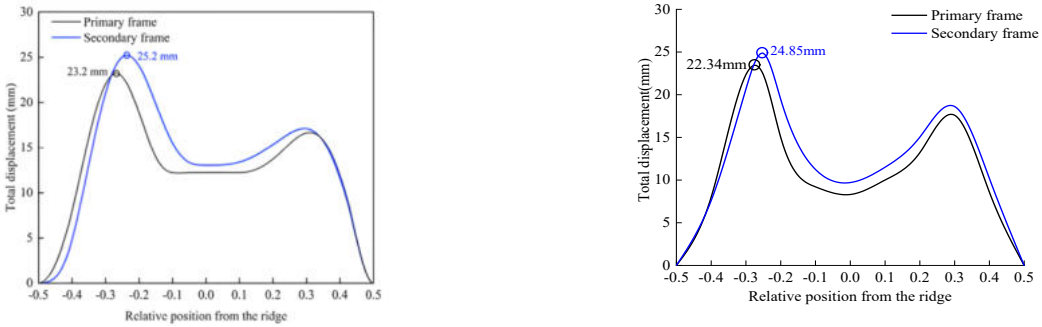
Material	*b*×*h* or *R* (mm)	*t* (mm)	ρ (kg/m³)	f_y (MPa)	λ	E (MPa)
Rafter	30×60	2	7.85	235	0.28	2.1×10^5
Embedded steel pipe	30×80	2	7.85	235	0.28	2.1×10^5
Purlin	ϕ 20	2	7.85	235	0.28	2.1×10^5

where: *b* is the width of section; *h* is the depth of section; *t* is thickness of section; *ρ* is density; f_y is the yield strength of steel; *λ* is Poisson ratio of steel; *E* is elasticity modulus of steel.

The C3D8R eight-node linear hexahedral element was selected to simulate the elliptical pipe greenhouse skeleton. The rafter was meshed according to its dimensions, with an approximate overall size set to 0.2, and each rafter was discretized into 2,380 elements. In actual engineering, the rafters and purlins are connected by clips, while the connections between the skeleton and the embedded steel pipe are welded. To improve computational efficiency, the connections between the rafters, purlins, and the embedded steel pipe were simplified to binding connections. This study applies full constraints between the two ends of the skeleton and the embedded steel pipe, restricting translational and rotational movements in all directions. For the other skeletons, hinged connections are used between the rafter and the embedded steel pipe.

Validation of the accuracy of the modeling method

Wang (2023) conducted a numerical analysis of a large-span pipe skeleton structure plastic greenhouse under the combined effects of dead load, wind load, live load, and crop load. Figure 3(a) shows the schematic diagram of the greenhouse skeleton model from the literature, while Figure 3(b) shows the finite element model established using the ABAQUS software in this study.



a) Literature ***b) Present***

Fig. 3 – Comparison of the structural diagrams of the greenhouse

To verify the accuracy of the modeling method, the validation model established in this study has the same material properties, skeleton dimensions, and boundary conditions as those in the original literature. All components are made of Q235 steel, with a yield strength of 235 MPa, Young's modulus of 206 GPa, Poisson's ratio of 0.3, and a density of 7850 kg/m³. The material is modeled using an ideal elastic-plastic constitutive relation. The rafter has a cross-section of a flat elliptical hollow pipe ($w\times h\times t=90\text{mm}\times40\text{mm}\times3\text{mm}$), while the columns have a rectangular hollow pipe cross-section ($w\times h\times t=90\text{mm}\times40\text{mm}\times3\text{mm}$).

The stringer also has a rectangular hollow pipe cross-section, with the same dimensions as the columns. The bracing has a circular hollow pipe cross-section ($d \times t = 32\text{mm} \times 2\text{mm}$), and the purlins have a circular hollow pipe cross-section as well ($d \times t = 25\text{mm} \times 1.5\text{mm}$). The bottom of the rafters and columns are set as fixed ends, restricting all degrees of freedom in all directions. The rafters and columns are connected with binding connections, and the connections between the bracing and the columns, rafters, and purlins are modeled as hinged.

In the literature, the greenhouse skeleton was modeled and analyzed using ANSYS software. In this study, the greenhouse skeleton was modeled and analyzed using the C3D8R solid element in ABAQUS finite element software. To verify the accuracy of the modeling method, displacement data at various points of the 1st and 2nd skeletons were extracted. The displacement data for the 1st and 2nd skeletons at each point are shown in Fig. 4.

a) Literature result *b) Present result*

Fig. 4 – Comparison of the total displacement distribution curves

As shown in Fig. 10, the displacement variation trend calculated using the modeling method in this study is in good agreement with the displacement variation trend from the literature. In the literature, the maximum displacement of the 1st skeleton is 23.2 mm, while the modeling method in this study yields a maximum displacement of 22.34 MPa, with a relative error of 3.7%. For the 2nd skeleton, the maximum displacement in the literature is 25.2 mm, while the maximum displacement calculated in this study is 24.85 MPa, with a relative error of 1.38%. The results fall within a reasonable error range, indicating that the finite element modeling method used in this study is reliable.

Wind loads calculation

This study primarily investigates the nonlinear behavior of the steel skeleton under wind loads. Therefore, the structural load combination mainly consists of dead loads and wind loads. For simplicity, in the subsequent eigenvalue buckling analysis, the critical buckling load of the structure is determined by applying the dead and wind loads in the form of concentrated forces at each point of the skeleton, as shown in Fig. 5.

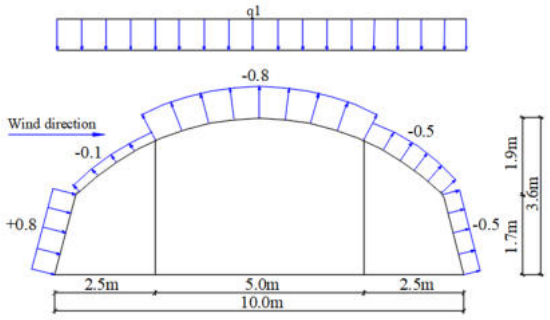


Fig. 5 – Shape coefficient on the flat-elliptical pipe skeleton plastic greenhouse

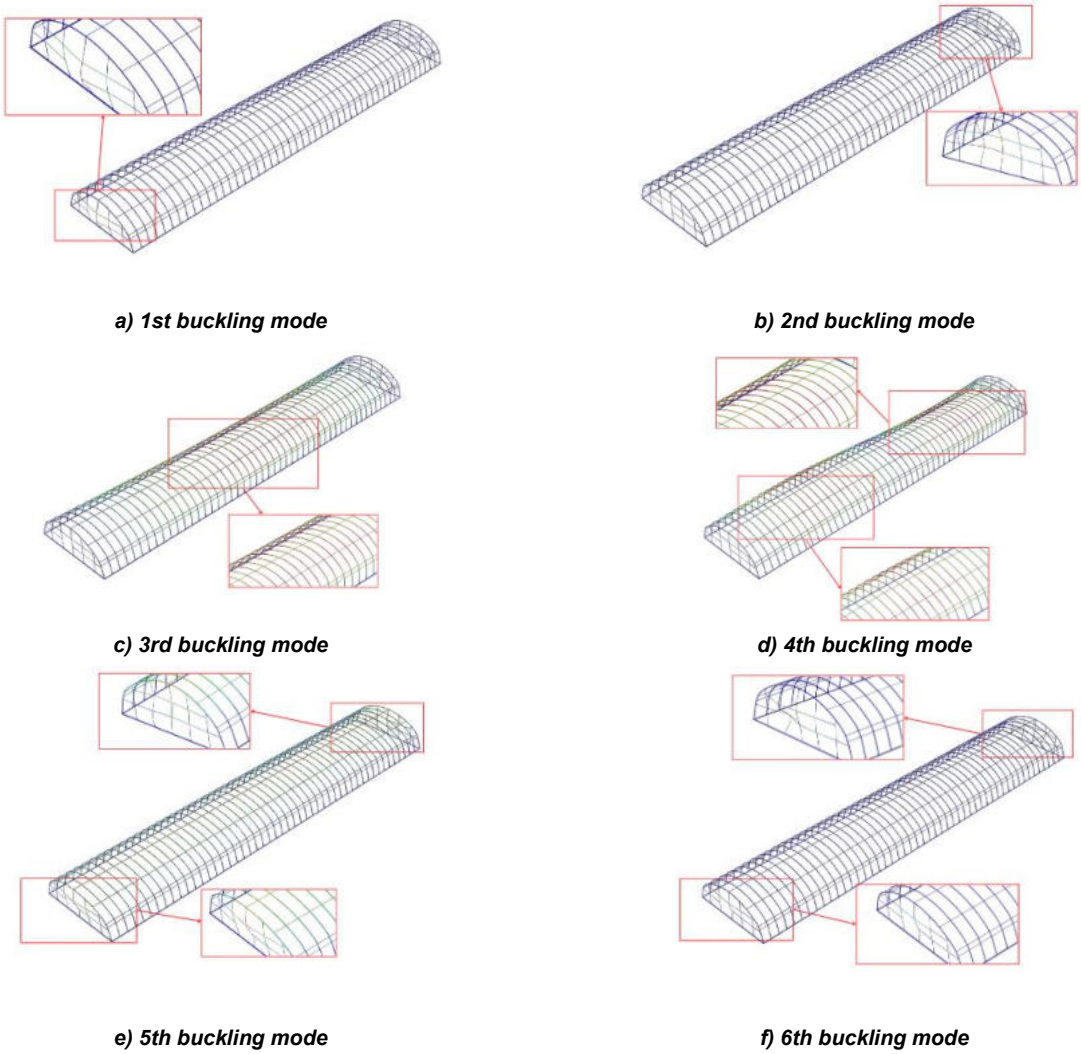
The plastic greenhouse studied in this study is located in Jiamusi City, Heilongjiang Province, China. According to the Chinese standard *GB/T51183-2016 (MOHUED, 2016),* the design service life of a plastic greenhouse is 10 years. Based on this code, the basic wind pressure in Jiamusi is 0.38 kN/m², which corresponds to the instantaneous wind speed with a duration of 3 seconds. On the other hand, according to the *Chinese standard GB/T50009-2012 (MOHUED, 2012),* the basic wind pressure in Jiamusi is 0.65 kN/m², which is based on the 10-minute average wind speed for a 50-year return period. The ratio of the 10-year return period wind pressure to the 50-year return period wind pressure is 0.734, thus the basic wind pressure for a 10-year return period with a 10-minute duration is 0.65 × 0.734 = 0.477 kN/m². After comparing the results from both codes, the basic wind pressure of 0.477 kN/m² was adopted in this study.

RESULTS AND DISCUSSION

Eigenvalue buckling analysis



First, the linear buckling analysis of the greenhouse skeleton structure was conducted using the finite element software ABAQUS, yielding the buckling modes and eigenvalues of the structure. Since initial imperfections are inevitably present in real structures, eigenvalue buckling analysis often overestimates the stability and load-bearing capacity of the structure. However, the linear buckling analysis provides an upper limit load value and initial imperfection distribution, serving as a basis for nonlinear buckling analysis.

The governing equation for eigenvalue buckling analysis is:

$$\left(\left[K_E\right]+\lambda\left[K_\sigma\right]\right)U=0 \tag{1}$$

where: $[K_E]$ is the elastic stiffness matrix of the structure; $[K_\sigma]$ is the geometric stiffness matrix of the structure; λ is the buckling factor, which is the eigenvalue, and U is the eigenvector matrix corresponding to each buckling factor, representing the buckling mode.

The eigenvalue buckling analysis of the greenhouse skeleton was conducted using ABAQUS finite element software under the action of dead load and wind load. The first 6 buckling modes and corresponding eigenvalues of the greenhouse skeleton are shown in Figure 6 and Table 2. To better visualize the buckling modes of the skeleton, the displacement has been amplified by a factor of 500 for easier observation.

a) 1st buckling mode *b) 2nd buckling mode*

c) 3rd buckling mode *d) 4th buckling mode*

e) 5th buckling mode *f) 6th buckling mode*

Fig. 6 – The first 6 buckling modes of the skeleton structure

As shown in Figure 6, the first 2 modes of instability of the greenhouse skeleton structure occur in the sidewall areas. This is because, when the skeleton is considered as a whole, the skeletons on the sidewalls are weaker regions, causing the sidewall skeletons to experience instability first. The 3rd mode of instability exhibits an overall wave-like buckling, with the largest displacement observed near the central skeleton, where the structure bulges outward toward one side. The 4th mode of instability also shows wave-like buckling, but

the overall instability manifests as the skeletons near the two ends bulging outward in opposite directions. The 5th mode of instability is characterized by strip-like buckling, with localized instability occurring in the sidewall areas. The 6th mode, compared to the 5th, lacks the overall strip-like instability, and the instability is concentrated in the skeletons at both ends of the sidewalls.

Table 2

First 6 eigenvalues of the structure

Mode order	1st	2nd	3rd	4th	5th	6th
Eigenvalue	-25.1	-33.31	-35.43	-39.6	-41	-48.48

Nonlinear buckling analysis

According to the Technical specification for space frame structures *(JGJ 7—2010)*, the stability of the grid shell can be calculated using the finite element method considering geometric nonlinearity (i.e., load-displacement full process analysis). In the analysis, material behavior can be assumed to be elastic or elastic-plastic. In this study, both geometric and material nonlinearities are considered in the nonlinear buckling analysis of the structure. The first-order buckling mode of the skeleton structure is introduced as an initial imperfection into the greenhouse skeleton model, and a load-displacement full process analysis is performed. The iteration equation is as follows:

$$\left[K_t\right]\Delta U^{(i)} = F_{t+\Delta t} - N_{t+\Delta t}^{(i-1)} \tag{2}$$

where, $[K_t]$ is the tangent stiffness matrix of the structure at the current time step, $\Delta U^{(i)}$ is the iterative increment of the displacement at the current time step; $F_{t+\Delta t}$ and $N_{t+\Delta t}^{(i-1)}$ represent the external nodal load vector and the corresponding internal force vector of the structural members at the current time step, respectively.

For solving the above equation, various equilibrium path tracking methods can be used, such as the displacement increment method, load increment method, work increment method, residual energy method, and arc-length method. In this study, the Modified Riks method, commonly used for nonlinear buckling analysis in ABAQUS, is employed for solving. The constraint equation for the Modified Riks method is as follows:

$$(\Delta\bar{u})^T(\Delta\bar{u}) + \psi(\Delta\lambda)^2 = (\Delta l)^2 \tag{3}$$

where, ψ=1 represents the arc length increment for each iteration. An initial arc length must be specified, and during the calculation process, the arc length Δl is adjusted according to the specific problem to ensure both computational efficiency and accuracy.

In addition, during the loading process, the original geometry and shape of the structure will change due to the applied loads, causing the overall stiffness matrix to vary. Therefore, the linear equilibrium equation cannot effectively represent the behavior of the structure in the nonlinear process.

The linear equilibrium equation of the structure can be expressed as:

$$\left[K\right]u = F \tag{4}$$

where, $[K]$ is the overall stiffness matrix of the structure; u is the displacement vector of the structure; and F represents the external loads, which, for buckling problems, are typically the loads modified by the buckling load factor.

The updated overall stiffness matrix $[K]$ is commonly represented by the tangent stiffness matrix $[K_t]$, which is equivalent to the slope of the load-displacement curve. This type of nonlinear situation falls under the category of geometric nonlinearity. The tangent stiffness matrix is often used in the calculation of the equilibrium path to achieve rapid convergence. Its calculation is given by the following equation:

$$\left[K_t\right] = \left[K\right] + \left[K_\sigma\right] + \left[K_L\right] \tag{5}$$

where, $[K_t]$ is the tangent stiffness matrix of the structure at the current time step; $[K_L]$ is the initial displacement matrix.

In the absence of initial imperfections, the critical buckling load P_{cr} can be calculated using the Euler's buckling formula:

$$P_{cr} = \frac{\pi^2 EI}{L^2} \tag{6}$$

where, P_{cr} is the critical buckling load in the absence of imperfections; E is the Young's modulus; I is the moment of inertia of the cross-section; and L is the span of the structure.

The modified formula after introducing initial imperfections is as follows:

$$P_{cr}(\delta) = P_{cr}(1-\frac{\delta}{L}) \tag{7}$$

where, $P_{cr}(\delta)$ is the critical buckling load after introducing imperfections; δ is the initial imperfection amplitude.

The buckling analysis formula considering initial displacement imperfections, geometric nonlinearity, material nonlinearity, and the modified critical buckling load can be written as follows:

$$\left[K + K_{\sigma} + K_{L}\right]u + P_{cr}(1-\frac{\delta}{L})u = F \tag{8}$$

Nonlinear buckling analysis with initial imperfections was performed on the flat elliptical pipe greenhouse skeleton using the Riks method in ABAQUS finite element software. The load-displacement curves at the top of the middle rafter under different initial imperfections are shown in Fig.7.

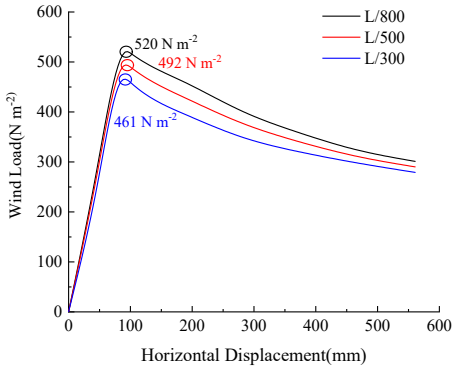


Fig. 7 – Load-displacement curves at the top of the middle rafter

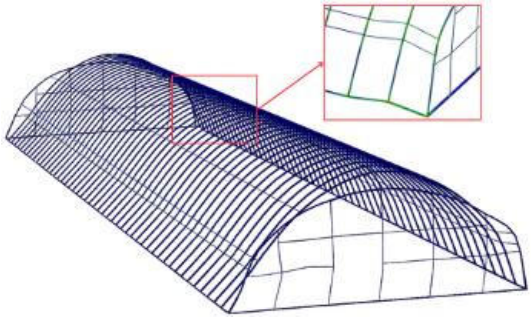
As shown in Figure 7, when the load is small, the displacement increases in a linear trend. According to the technical specification for space frame structures *(JGJ 7—2010)* the first critical load value obtained from the full process analysis of the structure is taken as the ultimate load-bearing capacity of the structure. Therefore, when the maximum initial geometric imperfection amplitude is L/300, the ultimate bearing capacity is 461.2 N·m²; when the maximum initial geometric imperfection amplitude is L/500, the ultimate bearing capacity is 492.22 N·m²; and when the maximum initial geometric imperfection amplitude is L/800, the ultimate bearing capacity is 520.26 N·m². This shows that the ultimate bearing capacity of the structure decreases with the increase in the maximum initial geometric imperfection amplitude. This result is consistent with the conclusions previously drawn by *Xie and Chen (2015)*.

Comparison analysis of overall and local buckling of the skeleton

To investigate whether the post-buckling behavior of the structure meets the safety design requirements for steel structures, stress–displacement curves at various positions of the deformed skeleton were extracted. This analysis aims to clarify the impact of structural buckling on the stress distribution of individual members and to identify the most vulnerable positions within the skeleton. The displacement diagram of the skeleton structure, obtained through nonlinear buckling analysis, is presented in Fig. 8.



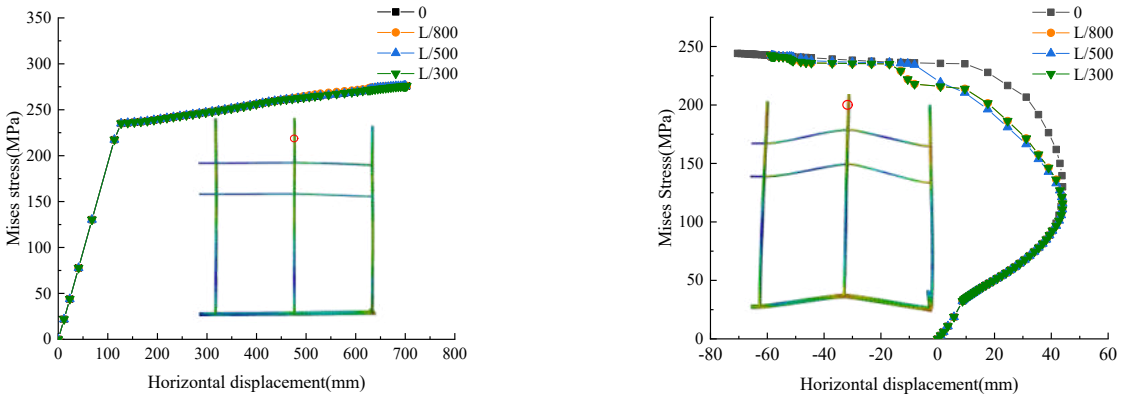


Fig. 8 – Displacement diagram of the skeleton structure

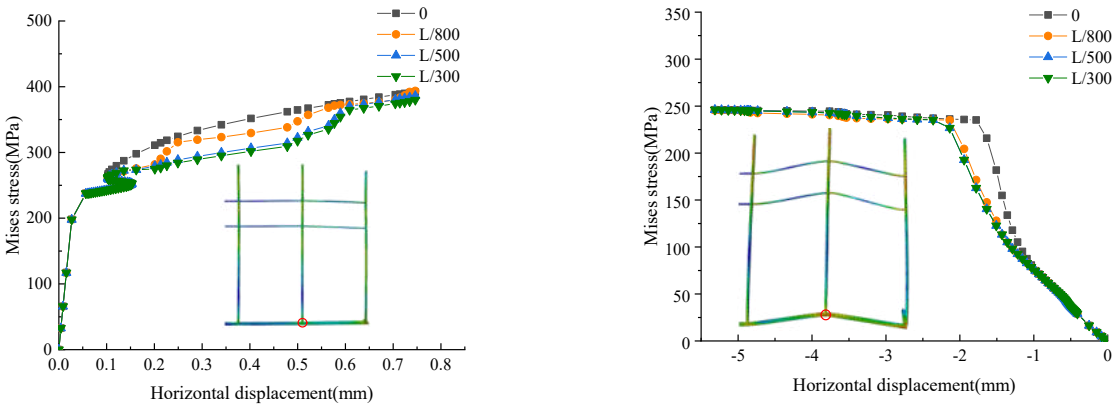
As shown in Fig. 8, the structure experiences significant overall buckling on the windward side, primarily manifesting as an overall strip-like instability. Meanwhile, on the leeward side, localized buckling deformation occurs at the end regions, primarily characterized by the arching of the steel pipes at the base, which induces deformation in both the skeleton and purlins. Therefore, this study will focus on analyzing the stress–displacement behavior of the components at both the localized buckling and overall buckling regions.

Stress analysis of rafter

The rafter, as the primary load-bearing components of the greenhouse skeleton, play a crucial role in supporting the structure under wind loads. Since wind loads primarily induce horizontal displacement in the structure, this study focuses on the variation of stress and horizontal displacement during the stress analysis. The Mises stress–horizontal displacement curves for the most unfavorable position of the rafter during the overall buckling and the local buckling of the structure were extracted and are shown in Fig. 9.

a) overall buckling *b) local buckling*

Fig. 9 – Most unfavorable position of Mises stress–horizontal displacement curves for rafter



As shown in Figure 9(a), when the horizontal displacement ranges from 0 mm to 150 mm, all curves exhibit a similar linear trend, indicating that initial imperfections have minimal impact on the structure's linear elastic behavior. During this stage, stress increases steadily, with a near-linear relationship between displacement and stress. As the displacement increases further, the structure enters the yielding stage, where the rate of stress growth slows. No significant differences are observed between curves with varying initial imperfections during this stage. From 200 mm to 700 mm horizontal displacement, the curves under different initial imperfection conditions stabilize, with minimal difference observed between the curves with and without initial imperfections (L/800, L/500, L/300). This suggests that, during overall buckling, initial imperfections have a relatively limited effect on the yield strength of the rafters, particularly in the linear-elastic stage.

In contrast, Figure 9(b) illustrates that the impact of initial imperfections becomes significant after local buckling. In the 0 mm to 40 mm displacement range, all curves show a near-linear increase, but as displacement reaches 40 mm, the curves diverge sharply. Samples with no initial imperfections show the highest yield stress, while increasing initial imperfections (L/800, L/500, L/300) cause the yield point to occur earlier and the yield strength to decrease. This indicates that initial imperfections considerably weaken the structure's resistance to yielding.

From 10 mm to -10 mm displacement, the gap between the curves narrows after reaching the yield point. In the range from -10 mm to -70 mm, the stress increase becomes more gradual, and the curve for the structure without initial imperfections exhibits a longer plateau, indicating greater plastic deformation capacity and higher ultimate load-bearing capacity.

Stress analysis of embedded steel pipe

The Mises stress–horizontal displacement curves at the most unfavorable position of the embedded steel pipe during the overall buckling and the local buckling of the structure were extracted and are shown in Fig. 10.

a) overall buckling *b) local buckling*

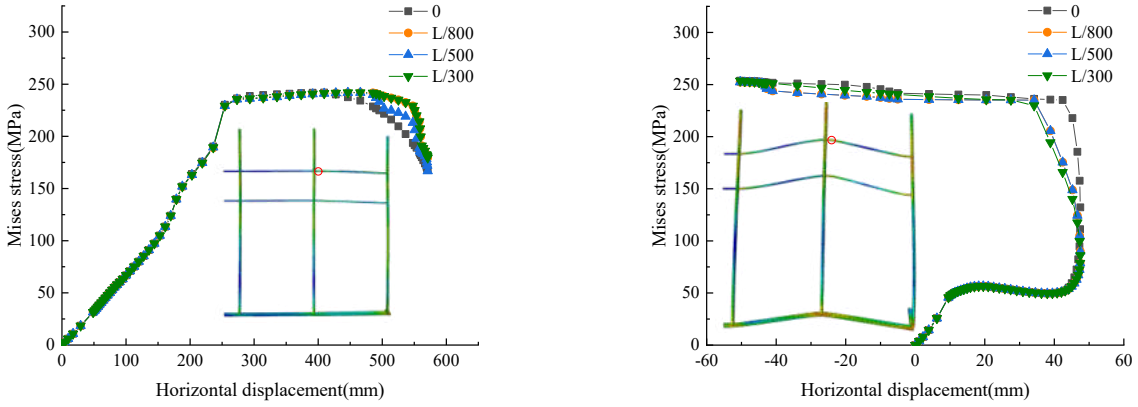


Fig. 10 – Most unfavorable position of Mises stress–horizontal displacement curves for embedded steel pipe

Figure 10(a) illustrates that within 0 mm to 0.06 mm of horizontal displacement, the curves exhibit a nearly identical linear trend, suggesting minimal impact of initial imperfections on the linear elastic behavior of the embedded steel pipe. Stress increases linearly, indicating stable elastic deformation. However, as the displacement progresses beyond 0.06 mm, the curves enter the yielding stage, where stress growth slows down. Between 0.1 mm and 0.6 mm displacement, the curves deviate from the linear relationship, displaying non-linearity. Notably, as initial imperfections increase, the curve flattens, reflecting a decrease in plastic deformation capacity and overall bearing capacity. This indicates that initial imperfections significantly weaken the yield strength and stability during overall buckling.

As shown in Fig. 10(b), from 0 mm to -1 mm displacement, the curves show a similar linear trend, again suggesting minimal impact of initial imperfections in the early stage. As displacement increases from -1 mm to -2 mm, the curves exhibit a nonlinear increase. The yield point varies significantly depending on initial imperfections, with structures without imperfections showing the steepest slope. From -2 mm to -5 mm displacement, the curves deviate further, entering the yield stage. The rate of stress increase slows, and significant differences emerge: without initial imperfections, the structure maintains higher yield strength and bearing capacity. However, with increasing initial imperfections (L/800, L/500, L/300), the yield point shifts earlier, and yield strength decreases, particularly under L/300 imperfections, highlighting the substantial reduction in load-bearing capacity.

Stress analysis of purlin

The Mises stress-horizontal displacement curves at the most unfavorable position of the purlin during the overall buckling and the local buckling of the structure were extracted and are shown in Fig. 11

a) overall buckling *b) local buckling*

Fig. 11 – Most unfavorable position of Mises stress–horizontal displacement curves for purlin

As shown in Fig. 11(a), within the 0 mm to 100 mm horizontal displacement range, stress increases linearly, reflecting elastic deformation of the purlin. Initial imperfections have minimal impact during this phase. From 100 mm to 250 mm displacement, the curves show slight nonlinearity, with negligible differences between initial imperfection conditions, suggesting limited influence on the elastic behavior. As displacement reaches 250 mm to 450 mm, the purlin enters the yielding stage, characterized by a deceleration in stress increase. Curves for different initial imperfections level off, indicating stable plastic deformation. From 450 mm to 575 mm, stress sharply decreases as the purlin enters the necking stage. Notably, the curve without initial imperfections has a steeper slope, reflecting a weaker load-bearing capacity during the necking phase compared to those with initial imperfections (L/800, L/500, L/300).

Figure 11(b) reveals that the impact of initial imperfections becomes more significant after local buckling. In the 0 mm to 10 mm range, stress increases linearly, with minimal variation across curves. From 10 mm to 20 mm, the slope of the curves decreases, and from 20 mm to 50 mm, stress initially decreases before rising again. At 50 mm displacement, the curve without initial imperfections exhibits the steepest slope, indicating higher stiffness. The slope decreases with increasing imperfection size (L/800, L/500, L/300), highlighting a more pronounced effect of initial imperfections during the elastic stage of the purlin.

In summary, initial imperfections have a significantly different impact on the overall buckling and local buckling of the structure. In the case of overall buckling, initial imperfections have a relatively small effect on the rafters, embedded steel pipes, and purlins, especially during the elastic deformation stages, where the change in yield strength is minimal. However, as the horizontal displacement increases, the negative effects of the initial imperfections become more pronounced, primarily as the structure enters the yield and plastic stages. The yield point occurs earlier, and the yield strength significantly decreases, indicating a weakened ability to resist yielding.

CONCLUSIONS

In this study, an FEM model of the elliptical pipe greenhouse skeleton was established using ABAQUS software. The consistent imperfection method was employed to simulate the initial imperfections of the greenhouse skeleton, and the arc-length method was used to conduct nonlinear buckling analysis of the skeleton. The ultimate bearing capacity of the skeleton under different initial imperfection conditions was obtained. Stress analysis of various structural components at both overall and local buckling regions was performed. The following conclusions were drawn:

(1) The impact of initial imperfections on the rafters, embedded steel pipes, and purlins at the overall buckling positions is primarily concentrated in the yielding and plastic deformation stages. In contrast, the influence of initial imperfections at the local buckling positons on the rafters, embedded steel pipes, and purlins is not limited to the yielding and plastic stages; it also manifests significantly during the elastic stage. This results in a reduction in the structural stiffness and a decrease in the bearing capacity of the skeleton.

(2) When considering only the impact of initial imperfections, with the initial imperfection amplitude being L/300, the maximum displacement of the skeleton is approximately 1.33 times that of the skeleton without initial imperfections. Similarly, the maximum stress of the skeleton is approximately 1.11 times that of the skeleton without initial imperfections.

From the results of this study, it is evident that initial imperfections have a significant impact on the loading behavior of the greenhouse skeleton. After considering the effects of initial imperfections, both the displacement and stress of the skeleton increase significantly. Therefore, it is recommended that the design of such structures take into account the adverse effects of initial imperfections in order to enhance the structure's ability to resist wind loads.

ABSTRACT

Crop straw is a key feed raw material processed by straw mills, but traditional mills have been hindered bulky structures, high power consumption, and low productivity. Previous research has primarily focused on optimizing the hammer structure, often overlooking the baffle, despite its considerable weight and lack of specific design applications. This study addresses that gap by optimizing the baffle design of the HQ-800 straw mill, simplifying it using a double-baffle framework. The force analysis considered gravity, hammer centrifugal force, shaft centrifugal force, main shaft torque, and material impact. Deformation and stress nephograms revealed that the area between the hammer shaft holes required structural improvement. Two optimization schemes - flat and curved - were compared. The curved design reduced maximum deformation to 29.007 μm, compared to 52.009 μm for the flat design, making it the preferred approach. Key parameters, including cutting circle diameter, center distance, and baffle thickness, were optimized using a three-factor, three-level orthogonal test, resulting in preliminary values of 200 mm, 250 mm, and 12.5 mm, respectively. Subsequent Box–Behnken testing refined these parameters to optimal values: 209 mm, 256 mm, and 12 mm. Under these conditions, the straw mill achieved a productivity of 1673 kg/h and a power consumption of 10.42 kWh/t. Compared to the unoptimized design, the optimized mill reduced volume by 44.46%, increased productivity by 5.89%, and lowered power consumption by 14.10%, fully meeting the design objectives.

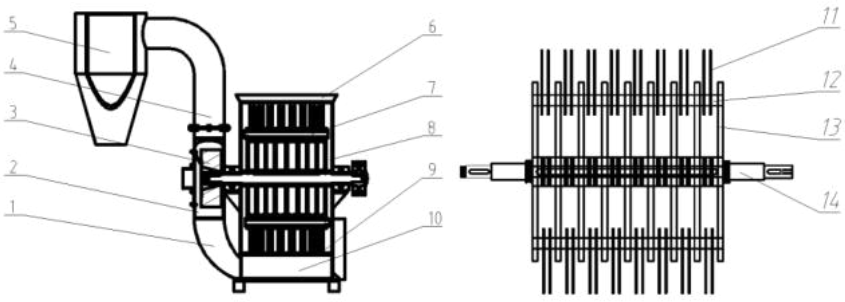
摘要

农作物秸秆经粉碎机加工是饲料重要来源，传统粉碎机隔板结构不合理致能耗高、效率低。本文以 HQ-800 型粉碎机隔板为对象，简化模型后进行受力与有限元分析，确定锤轴孔间区域为优化位置，对比方案选弧面优化。通过三因素三水平正交试验得初步参数：切割圆直径 200 mm、圆心距 250 mm、隔板厚度 12.5 mm。Box-Benhnken 试验验证最佳参数为 209 mm、256 mm、12 mm 时，生产率 1673 kg/h，吨料电耗 10.42 kW·h/t，体积减 44.46%，效率提 5.89%，能耗降 14.10%，试验结果满足设计要求，为粉碎机结构优化提供理论支撑。

INTRODUCTION

Feed is the material basis for the development of animal husbandry, providing essential nutrition for herbivorous livestock such as cattle and sheep, and ensuring the high-quality, high-yield and efficient development of animal husbandry. However, the supply of feed raw materials is insufficient, and there has been a long-term reliance on imports *(Zhang et al., 2021; Zartha et al., 2021)*. Crop straw, as one of the feed raw materials, can alleviate the shortage of feed supply if utilized efficiently. Crop straw can be processed into feed through the straw mill, but traditional straw mills have several issues, including a bulky structure, high power consumption and low productivity *(Cao et al., 2021; Cotabarren et al., 2020; Thomas et al., 2018)*. The baffle is the key component in the crushing mechanism of the straw mill, responsible for guiding the straw through the straw mill and ensuring it is effectively crushed and processed. The weight of the baffle typically accounts for more than 50% of the total weight of the crushing mechanism. Therefore, it is necessary to optimize the baffle structure to reduce weight, reduce power consumption and improve productivity.

In recent years, both domestic and international scholars have conducted extensive research on the structural optimization and performance enhancement of crushing-related machinery. *Li et al., (2024),* optimized the process parameters of feed crushing using a back-propagation neural network combined with particle swarm optimization, identifying optimal parameters that significantly improved pulverizer performance.



Ismail et al., (2022), analyzed the synergistic effects of classifier blade lengths and opening angles in coal pulverizers using CFD technology, revealing the classification mechanism by examining the coupling between flow field characteristics and particle movement trajectories. *Kshirsagar et al., (2014),* used finite element analysis software to analyze the stress and deformation of the main components of an automation can/plastic bottle crusher machine, ensuring the stability of the machine. These studies mainly used simulation and machine tests to optimize the structure, and their approaches are worth learning from. However, due to different objects of study, the relevant results cannot be directly applied to straw mill. *Wang et al., (2023),* designed a new type of biomimetic hammer with beaver incisors as biomimetic prototype, and used response surface method to optimize the structural parameters of biomimetic hammer, which showed improved performance compared to conventional hammers. *Zhang et al., (2024),* designed a field returning machine with a biomimetic serrated grinding knife with good straw crushing performance, and when used in combination with traditional crushing knife, it significantly increased the crushing efficiency of the entire machine. *Yancey et al., (2013),* optimized the shape parameters of the mill's hammer, enhancing the crushing performance of the machine. The straw mill is mainly hammer-type, the current optimization focus is mostly on hammers. However, the baffle in the crushing mechanism has a larger weight proportion and is in greater need of optimization. *Ruan et al., (2014),* analyzed the baffle force under both no-material and material conditions of the hammer mill, and verified its strength using simulation software, with results meeting the requirements. *Zhang et al., (2019),* performed topological optimization on the baffle structure with a 50% material removal rate, and used finite element analysis software to conduct static and modal analysis on the optimized structure, obtaining a lightweight baffle that meets strength and stiffness requirements. Overall, research on baffle structural parameter optimization is currently limited, and the few existing studies mainly focus on simulation and verification of specified dimensions, without combining gradual optimization and machine tests in actual working scenarios, lacking a systematic optimization scheme.

In this study, the HQ-800 straw mill was selected as the research subject, with a specific focus on baffle design. Aiming to achieve weight reduction, energy efficiency, and productivity enhancement, the model was simplified, and a comprehensive force analysis was conducted. The structural parameters of the baffle were optimized using finite element simulation, and the proposed improvements were rigorously validated through experimental testing. This research not only provides a strong theoretical foundation but also offers practical guidance for the optimized design of straw mills, contributing to the advancement of agricultural machinery engineering.

MATERIALS AND METHODS

Machine structure

The HQ-800 straw mill is composed of a motor, an air conveying system, a crushing system, and other components (see Figure 1a). The air conveying system includes a lower conveying pipeline, an upper conveying pipeline, an air pump, and a pump chamber. The crushing system, which is central to the machine's operation, consists of a crushing chamber, an advanced crushing mechanism, and a screen. The crushing mechanism comprises a main shaft, 9 baffles, 32 hammer shafts, and 64 hammers (see Figure 1b). The baffles are fixed to the main shaft at specific intervals, providing essential structural support. Each baffle is securely connected to four hammer shafts, and each hammer shaft supports two hammers, which are hinged to allow swinging at a certain angle. This configuration enables efficient impact and pulverization of straw into finer particles.

Working principle

The crushing system is equipped with a feed port, through which crop straws are introduced into the crushing chamber. When the motor is activated, it drives the main shaft via belt transmission. The main shaft then rotates the baffle, which in turn sets the hammers on the hammer shaft into motion. These rotating hammers work in conjunction with the screen to crush the crop straws into feed particles, which subsequently fall into the material bin. Simultaneously, the motor also drives the air pump through the main shaft of the crushing mechanism. The air pump generates air pressure that transports the feed particles from the material bin through both the lower and upper conveying pipelines, ultimately delivering them to the discharge port for packaging. The main technical parameters of the HQ-800 straw mill are listed in Table 1.

Table 1

Main technical parameters

Parameter	Unit	Value
Power	kW	55
Voltage	V	380
Machine size (length×width×heigh)	mm×mm×mm	1800×1500×2000
Maximum speed of main shaft	rpm	2800
Diameter of main shaft	mm	80
Number of hammers	/	64
Feed particle size	mm	2

Design of baffle model

Although the crushing mechanism consists of numerous components, many along the main shaft are highly repetitive. Therefore, two adjacent baffles were selected as the focus of the research and analysis. This section includes four hammer shafts and eight hammers. The simplified baffle model is illustrated in Figure 2.

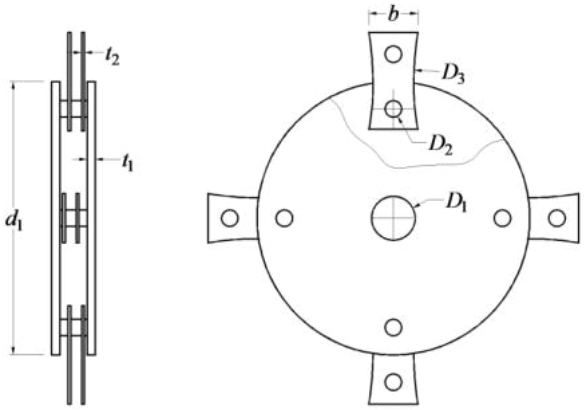

Fig. 2 - Schematic of baffle model

The baffle parameters are as follows: baffle diameter d_1=500 mm, baffle thickness t_1=15 mm, diameter of the main shaft hole D_1=80 mm, and diameter of the hammer shaft hole D_2=30 mm. The hammer features a cambered structure with the following specifications: cambered surface diameter D_3=550 mm, hammer width b=90 mm, and hammer thickness t_2=5 mm.

Force analysis of baffle model

The force analysis of baffle model can be categorized into two types: operation without material and operation with material. In the absence of material, the forces acting on the baffle model primarily consist of the gravity of the baffle model, the friction between the hammer and the hammer shaft, the centrifugal force of the hammer on the hammer shaft, and the torque transmitted by the main shaft *(Liu et al., 2011; Li et al., 2012; Ruan et al., 2014)*. However, when material is present, the impact force of the material on the hammer is added, and the torque transmitted by the main shaft will also change due to the altered load. This results in a more complex force situation for the baffle model, which more accurately reflects the actual operating conditions of the machine. Therefore, the force analysis of the baffle model in the presence of material will be detailed below.

The force analysis diagram of the baffle model is depicted in Figure 3.

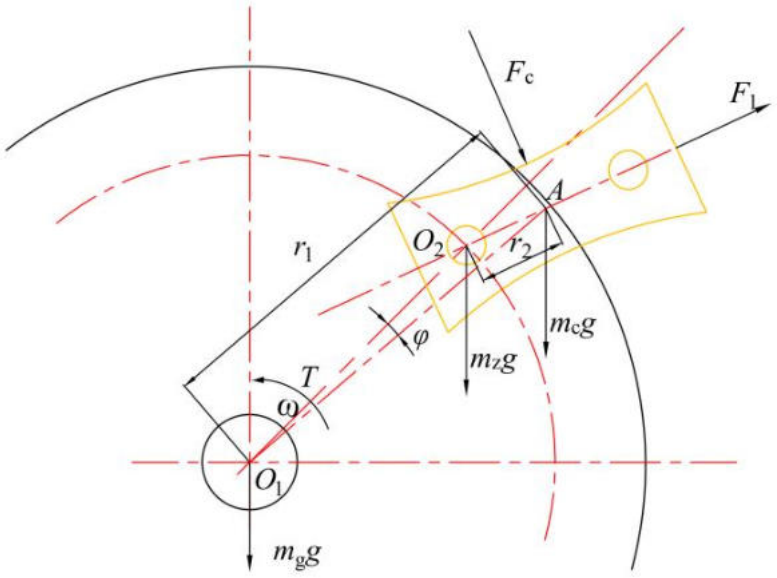

Fig. 3 - Force analysis diagram of baffle model

During the operation of the straw mill, the hammers experience a critical deflection angle $\varphi \approx 3^{\circ}$ relative to the center of the hammer holes *(Ruan et al., 2014)*.

The total weight of the baffle model is the sum of the weights of all its components, and is calculated using Equation (1).

$$G_z = 2m_g g + 4m_z g + 8m_c g \quad (1)$$

where: G_z - total weight of baffle model, [N]; m_g - baffle mass, [kg]; m_z - hammer shaft mass, [kg]; m_c - hammer mass, [kg].

The torque on each baffle is calculated using the following Equations (2) and (3).

$$T_1 = T/9 \quad (2)$$

$$T = 9550 \times \frac{P}{n} \quad (3)$$

where: T_1 - torque on each baffle, [N·m]; T - main shaft torque, [N·m]; n - main shaft rotation speed, [rpm]; P - crushing system power, [kW].

The crushing system power P=20 kW, the main shaft rotation speed n=2000 rpm. It is calculated that the main shaft torque T=95.5 N·m, and the torque on each baffle T_1=10.6 N·m.

Each hammer shaft experiences centrifugal force generated by a hammer, which can be calculated using Equation (4).

$$F_l = m_c \omega^2 r_2 \quad (4)$$

where: F_l - centrifugal force generated by each hammer, [N]; ω - angular velocity of the main shaft, [rad/s]; r_2 - distance from O_2 (the center of the hammer shaft hole) to A (the center of mass of the hammer), [mm].

Under operating conditions with material loaded, the main shaft rotation speed is n=2000 rpm, the hammer mass is m_c =0.16 kg, and the distance from O_2 to A is r_2=50 mm. Based on these values, the angular velocity of the main shaft is calculated as ω=209.33 rad/s, and the centrifugal force generated by each hammer is F_l=350.55 N. Since each hammer shaft is hinged to two hammers, the total centrifugal force acting in one direction of the baffle model is 701.10N.

The hammer experiences the maximum impact force from the material *(Wang et al., 2009)*, and this force is calculated using Equations (5) and (6).

$$F_c = \frac{m_w}{t}(v_c - v_1) \quad (5)$$

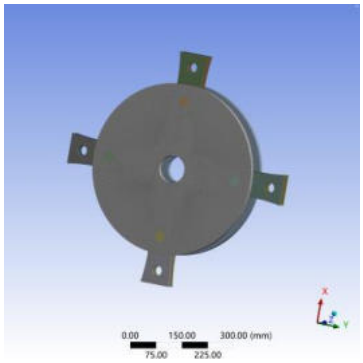
$$v_c = \omega r_1 \quad (6)$$

where F_c - maximum impact force exerted by the material on the hammer, [N]; m_w - maximum mass of material carried by a hammer, [kg]; v_c - peripheral velocity of the hammer during impact, [m/s]; v_l - minimum peripheral velocity of the material during impact, [m/s]; t - minimum collision time [s]; r_1 - distance from O_1 (the center of the main shaft hole) to A (the center of mass of the hammer), [mm].

Under maximum feed conditions, the maximum mass of the material carried by a hammer is m_w=0.1 kg, the distance from O_1 to A is r_1=247 mm, and the peripheral velocity of the hammer is v_c=51.70 m/s. During the feeding process, the material accelerates from an initial state of rest to match the hammer's motion, with its peripheral velocity gradually increasing. Therefore, the minimum peripheral velocity of the material is v_1=0m/s. The collision time typically ranges from 1×10^{-3} to 4×10^{-3} seconds; for this analysis, the minimum collision time is taken as t=1×10^{-3} s. It is calculated that the maximum impact force is F_c=5170 N.

Model settings of simulation test

Simulation testing is a widely used method in structural optimization design, employing techniques such as static analysis, dynamic analysis, and fluid mechanics to evaluate the physical behavior of the designed structure *(Wu et al., 2023; Wang et al., 2024)*. In this study, the 3D model was imported into ANSYS Workbench. The materials were assigned as follows: Q235 for the baffle and hammer shafts, and 65Mn for the hammers. A Body-Ground Revolute constraint was applied to the virtual main shaft, while a Body-Body Revolute constraint was used between the hammer and hammer shaft. The mesh size was set to 5 mm. The resulting mesh, shown in Figure 4, consists of 488,740 nodes and 99,252 elements, with an average mesh quality of 91.87%.



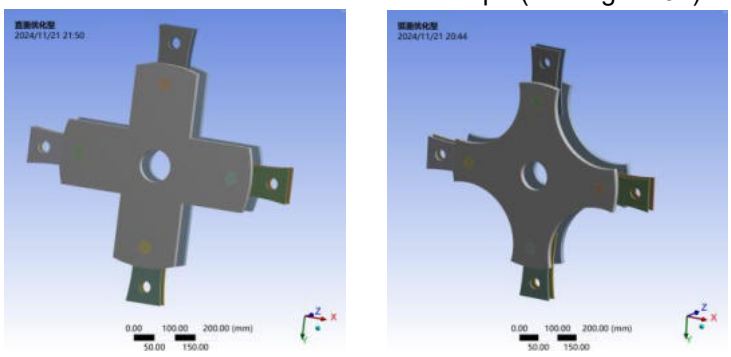


Fig. 4 - Schematic of grid model

Optimization method of baffle structure

As shown in Figure 5, the baffle structure can be optimized using either flat-surface removal or curved-surface removal. Two models are proposed, each removing the same volume of material, while maintaining the original installation configuration of the baffle, hammer shaft, and hammers. In the first model, the baffle corners are removed in a sector shape, resulting in a "cross"-shaped remaining structure (see Figure 5a). In the second model, the baffle corners are removed in an oval shape (see Figure 5b).

(a) *(b)*

Fig. 5 - Schematics of optimized contrastive baffle model

(a)Flat-optimized baffle model; (b)Curved-optimized baffle model

Simulation parameter optimization of baffle structure

During the operation of the straw mill, the maximum deformation of the components in the crushing mechanism affects the efficiency of the machine. *Xu et al., (2021),* conducted a study on the maximum deformation of key components in the crushing mechanism. Combining this with the team's prior analysis and tests, it was found that when the maximum deformation of the baffle reaches 35 μm, the efficiency of the machine significantly decreases, and malfunctions are more likely to occur. Referring to the unoptimized baffle model, the maximum deformation is 27.803 μm. It is recommended that the simulation analysis reference index should not exceed 5% of this value, and the smaller the maximum deformation, the better.

Combining the topological optimization study of the baffle by *Zhang et al., (2019),* the curved-optimized scheme can cut the four corners of the baffle along a curve, but it is necessary to avoid the hammer shaft hole and maintain a certain distance from the main shaft hole. Considering that the parameters of a variable-curvature curve are numerous and have minimal impact on the optimization results, four equal-diameter circular arcs are used to trim the edges of the baffle. The optimization parameters of the curved-optimized baffle are shown in Figure 6, where the main shaft hole is located at the center of the baffle, and the four hammer shaft holes are located at the edges of the baffle, the center distance *L* between the center of the baffle and the center of the cutting circle, and the cutting circle diameter *D*, together affect the amount of baffle removal. In addition, the baffle thickness *t* also has a significant impact. Therefore, the main optimization parameters of the baffle include the cutting circle diameter, the center distance, the baffle thickness, the diameter of the main shaft hole, and the diameter of the hammer shaft hole.

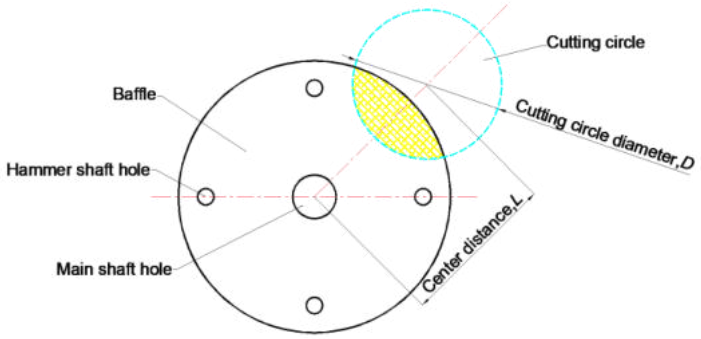

Fig. 6 - Optimization parameters of curved-optimized baffle

In accordance with the assembly requirements of the crushing mechanism, the baffle's main shaft hole and hammer shaft holes are precisely fitted with the main shaft and hammer shafts, respectively. In the early lightweight design of the main shaft and hammer shafts, their dimensions have already been optimized to the minimum. Increasing the diameters of the main shaft hole and hammer shaft holes could reduce the mass of the baffle but would also increase the mass of the main shaft and hammer shafts, thereby negatively impacting the overall performance of the crushing mechanism. Therefore, the optimization analysis of the baffle only considers three factors: the cutting circle diameter, the center distance, and the baffle thickness. The evaluation indexes are selected as the maximum deformation and the volume reduction ratio. The maximum deformation is the greatest deformation of the baffle caused by the force when it is in operation with material, while the volume reduction ratio is calculated as (The volume of the unoptimized baffle - The volume of the optimized baffle for each test group) / The volume of the unoptimized baffle. The volume reduction ratio reflects the optimization rate of the baffle structure for each test group. Considering the structural characteristics of the baffle, the table of test factors is presented in Table 2. The orthogonal test method with three factors and three levels is adopted *(Wang et al., 2017; Li et al., 2024)*, and the simulation results are shown in Figure 9.

Table 2

Table of test factors

Number	Factors		
	Cutting circle diameter A, (mm)	**Center distance B,(mm)**	**Baffle thickness C,(mm)**
1	150	200	10
2	200	250	12.5
3	250	300	15

Field test standard

The tests are conducted in accordance with the standards GB/T 6971-2007 "Test Method for Feed Mills" and NY/T 1554-2007 "Technical Specification of Quality Evaluation for Feed Grinder"

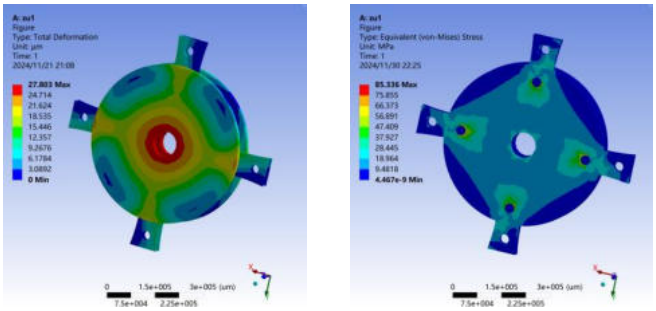
These standards clearly specify the evaluation indexes for the performance of straw mill, which include productivity, power consumption, feed particle size, feed temperature rise, motor load, noise, and dust concentration. Based on the results of the previous tests, it was found that the optimized baffle structure primarily affects the first two performance evaluation indexes.

The feed production per unit time of the straw mill is termed the productivity, and is calculated using Equation (7).

$$E = \frac{M}{t_1} \tag{7}$$

where: E - productivity, [kg/h]; M - feed production during test time, [kg]; t_1 - test time, [h].

The energy consumption required for the straw mill to produce each ton of feed is termed the power consumption, and is calculated using Equation (8).



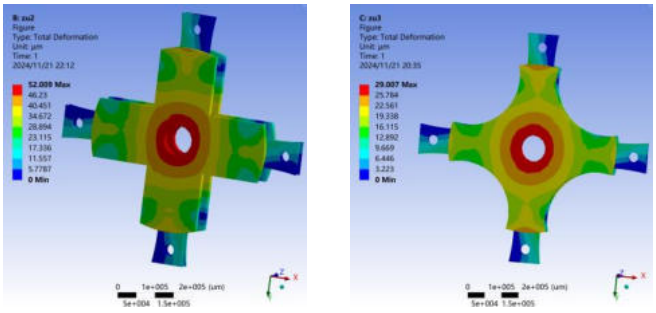
$$W = \frac{W_n}{M/1000} \tag{8}$$

where: W- power consumption, [kWh/t]; W_n - energy consumption during test time, [kW·h].

RESULTS

Simulation results

As shown in Figure 7a, the maximum deformation was mainly concentrated around the main shaft hole and the hammer shaft holes, with the maximum deformation being 27.803 μm. There were some positions between the hammer shaft holes of the baffle where the deformation was relatively low, which could be considered for optimization and removal. Figure 7b showed that the positions of the stress concentration were consistent with the positions of the deformation. Therefore, the positions between the hammer shaft holes of the baffle could be optimized and removed.

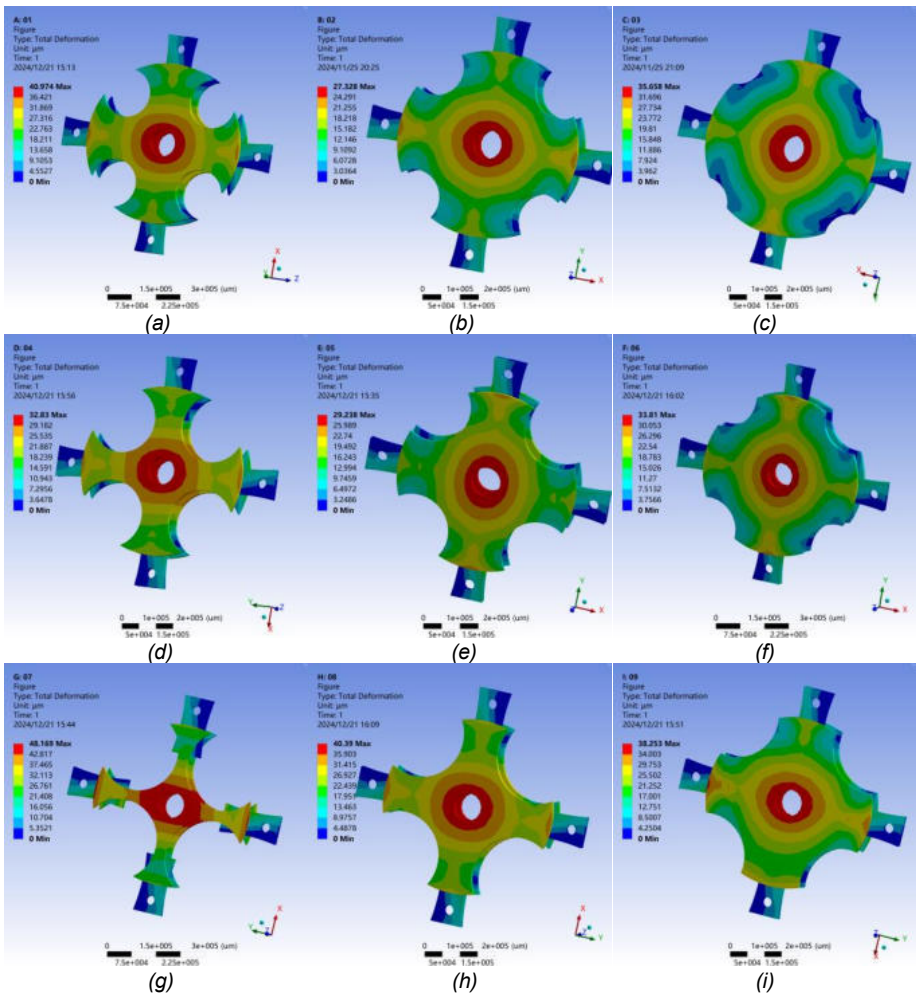


(a) (b)

Fig. 7 - Total deformation and stress nephogram of baffle model

(a)Total deformation nephogram; (b)Stress nephogram

As shown in Figure 8a, the flat-optimized scheme reduced the baffle volume, but the contour transition was poor, leading to stress concentrations close to the main shaft center. The maximum deformation was concentrated at the main shaft hole and the hammer shaft holes, with the maximum deformation reaching 52.009 μm. In Figure 8b, the curved-optimized scheme offered a more coordinated contour, also significantly reduced the baffle volume, and was less likely to produce noticeable stress concentrations. The maximum deformation was 29.007 μm, with a small increase in deformation. Therefore, the curved-optimized scheme could ensure a significant reduction in baffle volume while maintaining a small increase in deformation.



(a) (b)

Fig. 8 - Contrastive nephogram of total deformation

(a) Flat-optimized baffle model; (b) Curved-optimized baffle model

As shown in Figure 9, the distribution trend of the maximum deformation across the nine sets of curved-optimized baffles aligned well with the structural optimization logic. The highest deformation was concentrated around the main shaft hole and hammer shaft holes, while smaller deformations appeared near the material removal regions. The simulation results were consistent with the force analysis outcomes. Although the amount of material removed increased, the maximum deformation did not exhibit a strictly linear growth. This indicates that the relationship among the three influencing factors and the maximum deformation is complex and requires further analysis.

Analysis of simulation results

The test scheme and results are presented in Table 3. Through range analysis, the factors influencing the maximum deformation of the baffle were identified as the cutting circle diameter, the center distance, and the baffle thickness. The optimal combination of these factors was found to be $A_2B_2C_2$, corresponding to a cutting circle diameter of 200 mm, a center distance of 250 mm, and a baffle thickness of 12.5 mm. Comparison of the volume reduction ratios revealed that the maximum deformation was not directly proportional to the volume reduction, indicating that the volume reduction ratio should be used as a secondary evaluation index. Variance analysis was conducted to test the significance of the impact of each factor on the maximum deformation, as shown in Table 4. The results confirmed that the cutting circle diameter, the center distance, and the baffle thickness have a significant effect on the maximum deformation, validating the rationality of the orthogonal test.

Field test scheme and results

The test site was a corn planting test field, and the test machine was the HQ-800 straw mill. The test material was corn straw, with a length of approximately 400 mm and a moisture content controlled between 12% and 18%. The material contained no other impurities. The main shaft speed of the test machine was set at 2000 rpm, and each test lasted 20 minutes. The test was repeated three times, and the average value was taken.

Based on the simulation analysis results, further verification of the effects of cutting circle diameter, center distance, and baffle thickness on the performance of the straw mill was conducted through machine tests. The coding of test factors is presented in Table 5. The performance evaluation indicators for the straw mill are productivity and power consumption.

Table 5

Coding of test factors

Level	Factors		
	Cutting circle diameter A, (mm)	Center distance B,(mm)	Baffle thickness C,(mm)
-1	150	200	10
0	200	250	12.5
1	250	300	15

The completely randomized test design was developed by coding the cutting circle diameter, center distance and baffle thickness as test factors *(Wen et al., 2023; Zhang et al., 2022).* The test scheme and results are presented in Table 6.

Table 6

Test scheme and results

Test number	Factors			Productivity E, (kg·h^{-1})	Power consumption W, (kWh·t^{-1})

17	0	0	0	1673	10.41

The Box-Behnken Design (BBD) module in Design-Expert software was utilized to analyze the test data. The outcomes of this analysis are detailed in Tables 7 and 8. The regression model expressing the relationship between the productivity, the power consumption, and the encoded values is provided below:

$$E=1673.20+18.38A+11.13B-13.50C-1.5AB-1.75AC+1.25BC-53.85A^2-43.35B^2-28.10C^2 \quad (8)$$

$$W=10.35-0.089A-0.026B-0.060C+0.140AB+0.313AC+0.053BC+0.554A^2+0.384B^2+0.322C^2 \quad (9)$$

The regression models for productivity and power consumption were found to be extremely significant ($P < 0.01$). The P values for the lack of fit were 0.6558 and 0.2163, respectively, both of which were non-significant ($P > 0.1$), indicating a high degree of model fit. As shown in Table 7, the cutting circle diameter, center distance, and baffle thickness had extremely significant effects on productivity, with the cutting circle diameter having the greatest impact, followed by baffle thickness and then center distance. Table 8 indicates that the cutting circle diameter had an extremely significant effect on power consumption, while the center distance had a significant effect and the baffle thickness had a non-significant effect. The order of influence was cutting circle diameter, center distance, and baffle thickness. The determination coefficients (R^2) for the regression models of productivity and power consumption were 0.9957 and 0.9743, respectively, indicating excellent model fit. The adjusted determination coefficients (Adjusted R^2) were 0.9902 and 0.9413, respectively, which are close to the R^2 values, suggesting strong correlations. These results confirm the validity and reliability of the test design and analysis.

Analysis of field test results

To further analyze the effects of each factor on productivity and power consumption, two-factor response surfaces were generated using Design-Expert software. The response surface for productivity of baffle thickness and cutting circle diameter is shown in Figure 10a. As the cutting circle diameter increases from 150 mm to 250 mm, the baffle volume decreases, and productivity first increases steadily and then gradually decreases. This is because, when the cutting circle diameter is small, increasing its size results in more material being removed from the baffle, reducing the mass of the crushing mechanism. With constant input power, the straw mill can then allocate more energy to the actual crushing of straw, thereby increasing productivity. However, once the cutting circle diameter reaches a certain value, further increases in size lead to a decrease in the baffle's stiffness and other mechanical properties, which reduces the straw mill performance and thus productivity. As the baffle thickness increases from 10 mm to 15 mm, the baffle volume increases, and productivity first increases and then decreases. Response surface for power consumption of center distance and cutting circle diameter is shown in Figure 10b. As the cutting circle diameter increases from 150 mm to 250 mm, the baffle volume decreases, and power consumption first decreases and then increases. Similarly, as the center distance increases from 200 mm to 300 mm, the baffle volume increases, and power consumption first decreases and then increases.

(a) *(b)*

Fig. 10 - Response surface for productivity and power consumption

(a) Response surface for productivity of baffle thickness and cutting circle diameter;
(b) Response surface for power consumption of center distance and cutting circle diameter

Based on the test data and as shown in Figure 10, the optimal productivity of 1677.105 kg/h and power consumption of 10.352 kW·h/t were achieved when the cutting circle diameter was 208.638 mm, the center distance was 256.123 mm, and the baffle thickness was 11.892 mm. These values closely aligned with the simulation results. Considering the manufacturing characteristics for the baffle, the dimensions were rounded to the nearest whole numbers, resulting in a final optimized cutting circle diameter of 209 mm, a center distance of 256 mm, and a baffle thickness of 12 mm. The baffle with the final optimized dimensions was tested on the machine, with each test repeated three times to obtain the average values. The test results were then compared to those of the unoptimized baffle, as shown in Table 9.

Table 9

Contrastive analysis of before and after optimization

Baffle Structure	Baffle volume (mm^3)	Maximum deformation (μm)	Productivity ($kg \cdot h^{-1}$)	Power consumption ($kWh \cdot t^{-1}$)
Unoptimized	2827433	27.803	1580	12.13
Finally optimized	1570436	28.525	1673	10.42
Rate of change(%)	-44.46	+2.60	+5.89	-14.10

As shown in Table 9, the finally optimized baffle volume was significantly reduced, while the maximum deformation slightly increased but remained within the allowable range. Productivity slightly improved, and power consumption was notably reduced. These results indicate that the optimization logic for the baffle structure is rational and the optimization effect is satisfactory.

CONCLUSIONS

Based on the domestic and international status quo analysis of straw mill, the baffle was identified as the target for optimization. A simplified double-baffle model was established. Through force analysis of the baffle model under material conditions, the force parameters of the baffle model were obtained, including the gravity of the baffle model, the impact force of the material on the hammer, the centrifugal force of the hammer, and the torque transmitted by the main shaft.

Finite element analysis software was used to simulate the baffle model. Based on the total deformation and equivalent stress nephogram, it was determined that the positions between the hammer shaft holes on the baffle could be optimized. Comparing the flat-optimized and curved-optimized schemes, it was found that under the same volume removal conditions, the curved-optimized baffle resulted in a smaller increase in maximum deformation and allowed for greater volume optimization.

Further finite element analysis tests were conducted, with the cutting circle diameter, center distance, and baffle thickness as the three factors in an orthogonal test design, and the maximum deformation as the evaluation index. The preliminary optimized dimensions of the baffle were determined to be a cutting circle diameter of 200 mm, a center distance of 250 mm, and a baffle thickness of 12.5 mm.

The machine tests were conducted using the Box-Behnken test design method. Productivity and power consumption were used as evaluation indexes. Considering the manufacturing characteristics of the baffle structure, the optimal combination was found to be a cutting circle diameter of 209 mm, a center distance of 256 mm, and a baffle thickness of 12 mm. The finally optimized baffle achieved a productivity of 1673 kg/h and a power consumption of 10.42 kWh/t. Compared to the unoptimized baffle, the finally optimized baffle volume was reduced by 44.46%, productivity increased by 5.89%, and power consumption decreased by 14.10%, demonstrating a significant improvement in overall performance.

Keywords: *DEM, Soil-lifting plate, Straw buried, Mixed*

ABSTRACT
This study developed a lift-type winged chisel plow-straw-soil interaction model, and its validity was confirmed through multiple experimental indicators obtained from both soil bin tests and simulation experiments. The Discrete Element Method (DEM) was employed to analyze soil disturbance behavior and straw incorporation performance. Results showed that the plow tip of the lift-type winged chisel plow effectively sheared, loosened, and fractured the plow pan soil, while the soil-lifting plate pushed and turned the soil, promoting thorough mixing of straw and soil. Compared to traditional designs, the addition of wings increased the working width, and the soil-lifting plate significantly enhanced the frequency of straw–soil disturbance and soil fragmentation - resulting in a mixing rate of 42.98% and a uniformity rate of 92%.

摘要
本研究建立了抬土式带翼凿式犁-秸秆-土壤相互作用模型，通过土槽实验和仿真实验中的多试验指标（秸秆的正向和侧向位移、牵引力、秸-土混埋率）证明了模型的合理性。采用 DEM 研究其对土壤的扰动行为和秸秆的混埋行为。结果表明：抬土式带翼凿式犁的铲尖剪切、松动、破碎犁底层土壤；抬土板推移、翻动、混合秸秆-土壤。相比于传统的凿式犁相比，铲翼提升了作业宽度，同时抬土板增加了其对秸秆-土壤的扰动次数和土壤的破碎程度，混埋率提高到 42.98%，秸-土混合均匀度提高到 92%。

INTRODUCTION
Surface residue cover helps retain soil moisture and enhance soil fertility (*Reicosky & Saxton, 2007; Jacobs et al., 2022*). However, excessive residue density can negatively affect seeding quality and hinder seedling growth, becoming a key limiting factor for crop yield (*Wu & Chen, 2024; Li et al., 2022*). Therefore, evaluating the effectiveness of residue displacement and incorporation is essential for assessing the operational performance of tillage tools (*Hobbs et al., 2008*). Traditional tillage methods, such as rotary tillage for full straw incorporation (*Zhou et al., 2020; Zhu et al., 2023*), bury most of the straw in the soil. While effective in incorporation, these methods disturb the original soil profile, expose moist soil to the surface, and leave minimal residue cover - leading to increased soil erosion and runoff (*Wu & Chen, 2024*). In contrast, the winged chisel plow used for partial straw incorporation has proven effective in both straw incorporation and soil loosening (*Salar et al., 2021*). This implement mixes a portion of the straw residue into the soil to improve soil organic matter content while retaining some surface residue to minimize moisture loss. However, its performance can be limited by uneven soil aggregate fragmentation and inconsistent straw-soil mixing.

The winged chisel plow not only breaks through the limitations of the soil tillage layer system but also incorporates part of the straw into the soil, achieving straw incorporation and surface coverage operations (*Zhang et al., 2022*). *Xia, (2018),* demonstrated that the winged chisel plow could break through the constraints of the tillage layer and plow pan, achieving more uniform soil fragmentation and improving soil permeability. However, this study did not explore the effectiveness of straw incorporation (straw-soil mixing mechanism) in conjunction with its operation.

[1] *Juanjuan Wu, Lecturer Ph.D. Eng; Xianliang Wang, Assoc. Prof. Ph.D. Eng; Kun Chen, M.S. Stud. Eng.*

Wang, (2018), investigated the effects of the winged chisel plow on soil disturbance behavior, suggesting that soil fragmentation at different depths, real-time displacement, and velocity changes of particles at key positions are important indicators for evaluating its operational performance. *Zeng et al., (2020),* studied the effects of different types of chisel plows on straw-soil disturbance and straw burial rate. However, they did not examine the degree of soil aggregate fragmentation after disturbance, nor did they relate this to the degree of straw-soil mixing. These studies primarily focused on soil fragmentation, soil disturbance, and straw-soil mixing rates, without considering the uniformity of straw-soil mixing after incorporation. In contrast, the straw-soil mixing mechanism during the operation of the winged chisel plow is more complex. Investigating the mechanism of incorporation and mixing is a prerequisite for designing and optimizing high-performance winged chisel plows. Building on the foundation of incorporation and return-to-field technology, this study proposes adding a soil-lifting plate to the rear of the winged chisel plow (*Wang., 2021*). This addition aims to improve soil loosening and fragmentation effects and enhance the uniformity of straw-soil mixing during partial straw incorporation.

This incorporation mechanism involves mixing a portion of the straw into the soil while leaving the rest on the surface to improve soil structure, reduce soil erosion, and lower runoff risks (*Salar et al., 2021*). However, accurately and intuitively representing the operational mechanism of the lift-type winged chisel plow remains a challenge.

The discrete element method (DEM) offers unique advantages in analyzing the interactions between agricultural machinery components, straw, and soil. It provides data on the forces and motions of soil and straw under specific machinery structures and operational conditions from a microscopic perspective (*Barr et al., 2018; Sadek et al., 2021*). By building precise models, DEM overcomes the limitations of two-dimensional measurements. During the simulation of straw-soil operations, it reveals the complex coupled mechanisms of factors such as straw morphology distribution and soil aggregate interactions. Additionally, it enables precise capture and quantification of the dynamic changes in the uniformity of straw-soil mixing (*Liu et al., 2023a&b*), addressing the limitations of single-point practical observations that fail to present the mixing effects. DEM also comprehensively represents the three-dimensional spatial characteristics of the straw-soil mixing process (*Zeng et al., 2020*), providing theoretical support and technical guidance for the study of the lift-type winged chisel plow.

In summary, the objectives of this study are to establish a discrete element model of the interaction among the lift-type winged chisel plow - straw - soil, reveal the mechanisms of straw-soil disturbance and incorporation by the soil-lifting plate from a microscopic perspective during the incorporation operation, and quantify the changes in straw burial rate and the uniformity of straw-soil mixing under the influence of the soil-lifting plate, so as to provide a theoretical basis for the research and evaluation of straw incorporation tools and operational performance.

MATERIALS AND METHODS

Measurement of Straw and Soil Basic Parameters

(1) Measurement of Straw and Soil Properties

Soil samples were taken from a no-tillage seeding experimental field in Xilu Village, Zhangdian District, Zibo City, Shandong Province (36°87′~36°88′ N, 117°98′~119°99′ E). The soil samples were weighed on an electronic balance (model FA2104B), and the average soil sample density was calculated to be 241 kg/m³. The soil moisture content was determined using the drying method according to the "Standard for the Determination of Soil Dry Matter and Moisture by Weight" (Standard No.: HJ 613-2011), yielding a moisture content of 21.37% (on a dry weight basis).

Prior to selecting straw samples, corn plants (Zhongbang 1088 corn, commonly grown in northern China) were screened to ensure they were disease-free. Using a sampling knife, whole corn stalks were cut at a height of 50 mm above the ground. According to the methods outlined in GB/T 14699.1-2005 (Feed Sampling) and GB/T 6435-2014 (Determination of Moisture and Other Volatile Substances in Feed), the straw moisture content and density were measured to be 16.59% and 1450 kg/m³, respectively.

The soil shear strength was measured using the ZJ-type strain-controlled direct shear apparatus from Nanjing Soil Instrument Factory, under a vertical load pressure of 50 kPa. The shear force was obtained by combining the mechanical dial readings with the stress ring correction coefficient (C = 1.531 kPa/0.01 mm). Shear tests were conducted on soil samples from three different depths, and the values collected from each point were averaged. The measured internal friction angle of the test soil was 21.93°, and the Poisson's ratio was calculated as 0.38 using Equation 1.

$$\tau = c + p\,tan\,\varphi \quad (1)$$

where: τ is Stress (N); c is Soil cohesion (N); p is Vertical pressure (N); φ is Internal friction angle of the soil (°).

(2) Measurement of the straw-soil mixture repose angle

The repose angle of the soil and straw mixture was measured physically. Since this study does not involve radial and axial damage to the straw, only the physical parameters related to the straw skin were calibrated. The repose angle of the straw-soil mixture was measured as 38.415° using an intelligent powder characteristics tester (model BT-1001).

(3) Measurement of Material Friction Between Agricultural Machinery Components, Straw, and Soil Using an Inclined Plane Test

The static and dynamic friction coefficients between the straw-soil-steel plate are determined using the inclined plane method. The static and dynamic friction coefficients between the two materials are calculated using Equations 2 and 3, respectively.

$$f_s = \tan\theta \quad (2)$$

where:

f_s is the static friction coefficient; θ is the angle between the wooden board and the horizontal plane (°).

$$f_d = \frac{L_1 \sin\theta + L_2}{L_1 \cos\theta} \quad (3)$$

where:

f_d is the rolling friction coefficient; θ is the angle between the wooden board and the horizontal plane (°); L_1 is the sliding distance along the inclined plane (cm); L_2 is the horizontal sliding distance (cm).

The experiment was repeated 10 times, and the average values were calculated. The static and dynamic friction coefficients were measured for the following material pairs: soil-soil, straw-soil, soil-steel plate, straw-straw, and straw-steel plate.

Establishment of the Straw-Soil Simulation Model

The soil particles were defined as uniform spherical particles with a radius of 5 mm, and the Hertz-Mindlin with Bonding contact model was selected. During the operation of the lift-type winged chisel plow, the effect on the straw was primarily spatial displacement, with negligible deformation of the straw. Therefore, the straw was treated as a rigid body. The corn straw was modelled as an assembly of uniform particles with a radius of 10 mm. The mechanical interaction model between the straw, soil, and the lift-type winged chisel plow was set to the Hertz-Mindlin (no-slip) contact model to facilitate the analysis of the interactions between the implement, straw, and soil.

Establishment and Validation of the Lift-Type Winged Chisel Plow-Straw-Soil Model

The soil and straw model parameters were defined based on the calibrated values. Particle positions were randomly generated, resulting in a total of 234,250 soil particles and 709,181 bonding keys used to simulate cohesive interactions among the soil particles. The soil bin dimensions were set to 2000 × 1000 × 300 mm. Considering the actual working depth of the implement and the variation between the cultivated layer and the plow pan, the soil profile was divided into two layers: a cultivated layer and a plow bottom layer. To simulate field straw coverage, 1,200 straw pieces were randomly distributed on the soil surface, corresponding to a surface coverage density of 0.5 kg/m². The geometric model of the lift-type winged chisel plow was created using SolidWorks 2022, exported in STEP format, and imported into EDEM 2022 for simulation. The material used was 65Mn steel.

Simulation experiment of the motion state measurement of the lift-type winged chisel plow-straw-soil interaction

In the simulation experiments, the motion states of the soil and straw are monitored by tracking the positions of 12 soil tracers and 5 straw tracers. The soil cutting force (traction force, vertical force, and lateral force) is the sum of the contact forces between the soil particles and the machine in the corresponding directions.

In the center direction of the chisel plow operation, starting from the surface, four particles are sequentially marked at intervals of 50 mm downwards, labeled as J12, J22, J32, and J42. Then, 8 additional particles are marked 100 mm to the left and right of these four particles, labeled as J11, J21, J31, J41, J13, J23, J33, and J43, as shown in Figure 1.

At the same time, straw tracer 3 is placed at the center of the chisel plow's working area, with tracers 1, 2, 4, and 5 placed in parallel on either side of straw tracer 3 at a 40 mm interval. The soil displacement in the forward, lateral, and vertical directions is calculated by the changes in the coordinates of the soil tracers, while the forward and lateral shifts of the straw are calculated by the changes in the coordinates of the straw tracers in the forward direction.

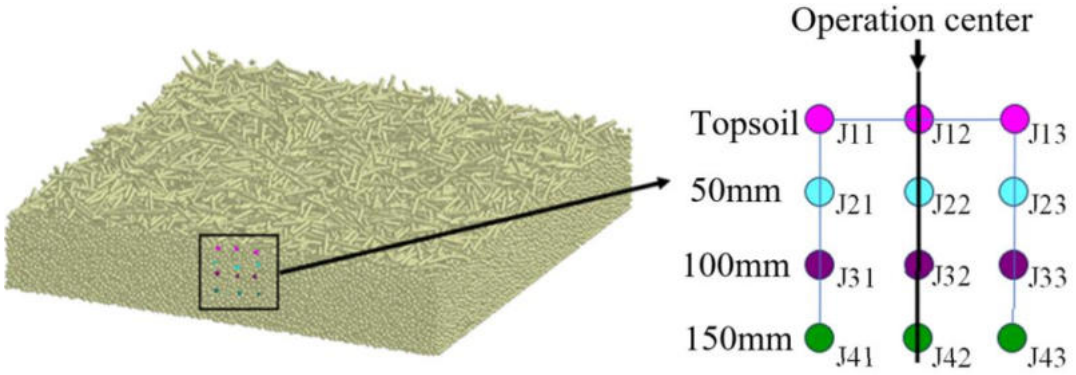

Fig. 1 - Marking the Position of Particles

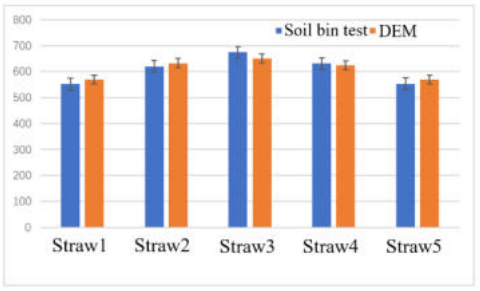
Comparison of working performance between the lift-type winged chisel plow and the standard chisel plow

The experiment was conducted in the digital soil bin at the Agricultural Machinery Equipment Greenhouse of Shandong University of Technology. The soil in the bin was loam (72% sand, 15% silt, and 13% clay). Before each test, the soil was tilled using a 1 GKN-125 rotary tiller (tillage depth 120-160 mm), and then compacted using the soil bin vehicle. Soil samples were randomly taken from 10 different locations in the soil bin using a ring knife, with sampling depths of 5 mm, 10 mm, and 15 mm. The soil samples were dried in an oven at 105°C for 24 hours to measure soil moisture content. The average moisture content and average bulk density of the soil were measured as 17.6% (dry basis) and 1.36 g/cm³, respectively, according to ASABE Standards (2015).

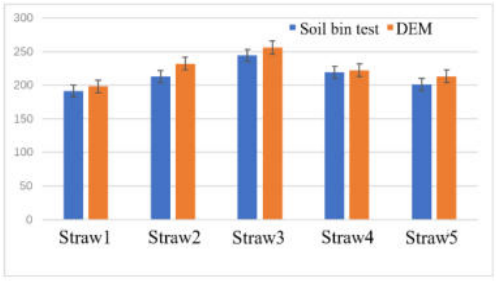
RESULTS

Contact Model Parameter Results and Validation



Within the parameter range set for the simulation test, the optimization module in Design Expert 12 software was used to optimize the regression equation for the repose angle, with the measured repose angle of 38.415° from the actual experiment as the target value. Several solutions obtained were validated through discrete element simulations to find the solution that most closely matched the actual repose angle. The optimal solution was chosen based on the simulation results.

The optimized parameters are as follows: soil-soil static friction coefficient of 0.57, soil-soil rolling friction coefficient of 0.18, and straw-soil dynamic friction coefficient of 0.12. The model parameters were set to these optimal values in EDEM 2022 software, while other parameters were taken as the average values measured in the actual experiment. The simulation was repeated five times, with the average measured repose angle being 39.49°, resulting in a relative error of 3.29% when compared to the actual experimental repose angle, thus validating the accuracy of the discrete element model.

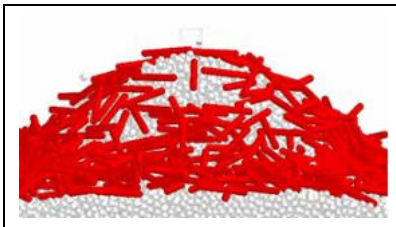


Validation Results of the Lift-Type Winged Chisel Plow-Straw-Soil Interaction Model

The forward and lateral displacements of straw, traction force, and straw burial rate from both the soil bin experiment and the simulation experiment were compared, with relative error used to assess consistency.

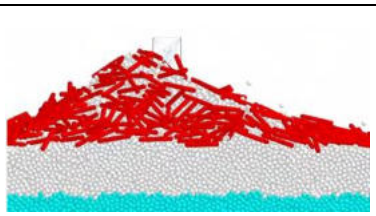
The forward and lateral displacements of the five marked straw pieces from both the soil bin experiment and the simulation experiment were plotted as bar charts, as shown in Figure 2. From the figure, it can be observed that straw 3, located at the center of the machine's operation, has the largest displacement. The further the straw is from the center position, the smaller its displacement. The overall trend of straw displacement is consistent with the simulation results. The forward displacement error of the straw ranges from 1.67% to 5.45%, and the lateral displacement error ranges from 0.52% to 6.84%.

(a)



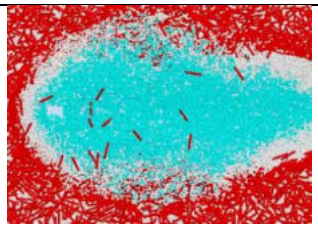
(b)

Fig. 2 - Comparison between simulation and actual experiment. (a) Horizontal displacement (b) Positive displacement



The average straw burial rates in the soil bin experiment and the simulation experiment were 84.37% and 78.3%, respectively, with a straw burial rate error ranging from 2.54% to 6.37%. The average traction force of the machine during stable operation in the soil bin experiment and the simulation experiment were 1603.24 N and 1498.77 N, respectively, with a machine traction resistance error ranging from 5.29% to 12.60%. All indicator errors are within the permissible range of model errors (*Ucgul et al., 2017*), and the variation trends in the experimental data are consistent with the simulation results. The soil bin experiment verified the accuracy of the discrete element simulation and the feasibility of discrete element modeling for field trials.

Analysis of the Performance of the Lift-Type Winged Chisel Plow in Simulation Experiments



The lift-type winged chisel plow is equipped with a soil-lifting plate on the winged part of the chisel plow. By comparing the working performance of the two plows, the role of the soil-lifting plate in the operation of the machine can be analyzed more intuitively. Figures 3 and 4 show the disturbance trajectories of soil and straw in the X (horizontal), Y (longitudinal), and Z (vertical) directions at the same moment, with color processing applied to the straw and soil (red for straw, white for tilled soil, green for plow bottom soil), enhancing the contrast. Compared to the Winged Chisel Plow with less burial effect, the lift-type winged chisel plow has a wider working width and less straw residue on the soil surface (Figures 3c and 4c). It also demonstrates better soil turnover (Plow bottom soil eversion, Figure 3b and 4b), surface straw burial, and straw-soil mixing effects. In summary, the soil-lifting plate can increase the working width of the winged chisel plow (51.5%) and improve the efficiency of straw mixing (69.3%).

Analysis of Straw-Soil Micro-Disturbance Process at Different Moments

To understand the disturbance state of soil at different positions below the surface as the lift-type winged chisel plow moves forward, the Clipping function in the post-processing module of EDEM software is used to create a cross-sectional view of the soil model along the longitudinal centerline of the lift-type winged chisel

plow. Four moments are selected for the cross-section: when the plow has not yet entered the soil (0.02 s), when it has fully entered the soil (0.22 s), during the deep loosening process (0.42 s), and during the soil ejection process (0.62 s), as shown in Figure 5.

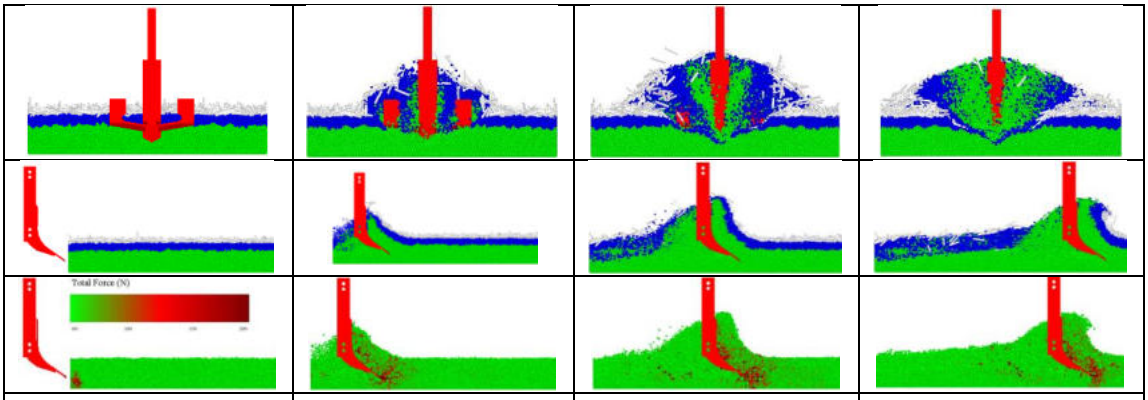

Fig. 5 - Disturbance of soil-lifting plow with wing chisel at different times
(a) 0.02 s (b) 0.22 s (c) 0.42 s (d) 0.62 s

Micro-disturbance Analysis of Straw-Soil at Different Positions

In order to explore the working range of the lift-type winged chisel plow and understand the soil disturbance state at different positions and depths, the role of each component in mixing and burying the straw was clarified. The longitudinal and transverse cross-sections of the soil at intermediate moments during the stable working process of the lift-type winged chisel plow were obtained. Based on the width of the chisel wing and the horizontal distance from the chisel tip to the chisel wing, the distances between the longitudinal and transverse cross-sections were set to 80 mm and 50 mm, respectively. Figure 6 shows the cross-sections in each direction at intermediate moments.

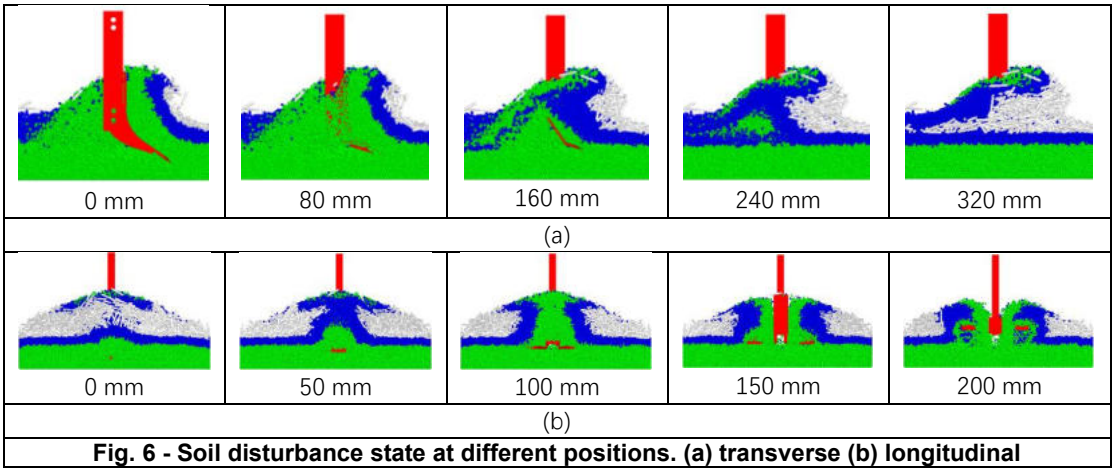

Fig. 6 - Soil disturbance state at different positions. (a) transverse (b) longitudinal

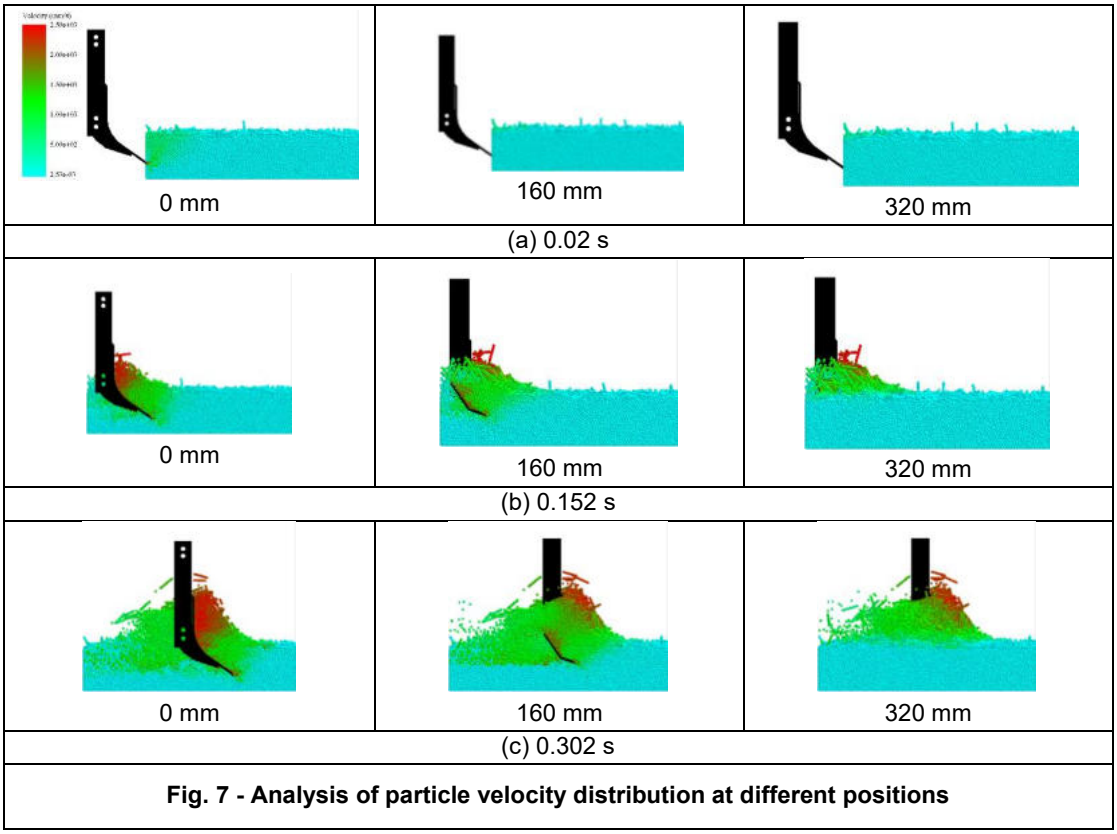
As shown in Figure 6(a), the disturbance of the plow bottom layer by the lift-type winged chisel plow gradually decreases as the horizontal longitudinal distance increases. Comparing the positions at 0 mm and 160 mm, the disturbance of the plow bottom layer by the chisel wing is relatively small. Due to the effect of the lifting plate, the straw-soil mixture in front of the chisel wing undergoes a turning action, and secondary disturbance is caused to the straw-soil mixture overturned by the lifting plate. From the changes in the number of straws before and after the positions at 240 mm and 320 mm in Figure 6(a), it can be seen that the working width on one side of the tool is about 300 mm, with the total working width of the tool being 600 mm. Within the horizontal width range of 300 mm from the center, there is very little straw.

Figure 6(b) illustrates that the lift-type winged chisel plow effectively turns and displaces the soil in the plow bottom layer, loosening the compacted soil by pushing it to both sides. The chisel tip initially cuts through the bottom layer soil, while the lifting plate lifts it through a turning motion. At transverse positions of 150 mm and 200 mm, the chisel wings notably expand the working width of the implement. Additionally, the lifting plate introduces secondary disturbances to both soil and straw particles (Figure 6a & 6b), thereby enhancing soil loosening, increasing fragmentation, and improving the uniformity of the straw-soil mixture following incorporation.

Straw-soil motion state analysis

To analyze the effect of the lift-type winged chisel plow on the overall motion behavior of the straw-soil mixture during operation, longitudinal cross-sections were taken at three key positions: the longitudinal center of the chisel plow (0 mm), the midpoint of the winged blade (160 mm), and the edge of the winged blade (320 mm). Three time points were selected for analysis: the moment the chisel tip enters the soil (0.02 s), the point at which the entire lift-type winged chisel plow is fully engaged in the soil (0.152 s), and the midpoint of the working stroke (0.302 s). A comparative analysis of the straw-soil motion velocity and distribution patterns at different times and cross-sectional positions was conducted, as shown in Figure 7.



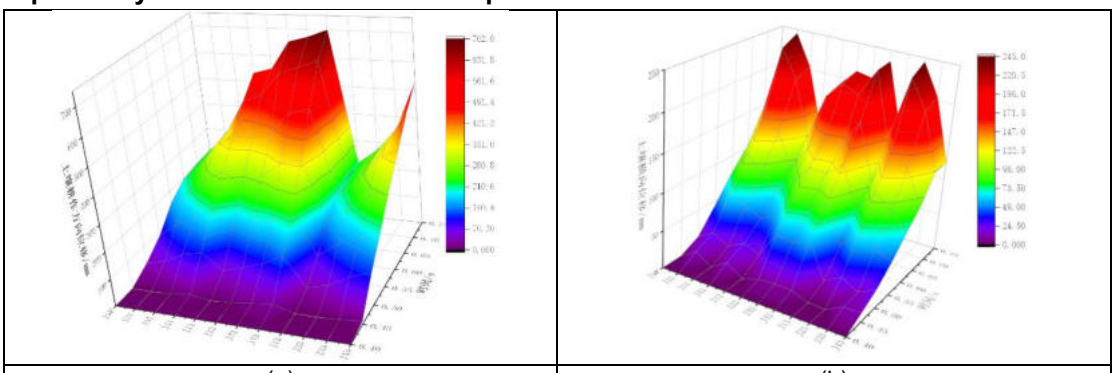


Fig. 7 - Analysis of particle velocity distribution at different positions

After the chisel tip enters the soil (Figure 7a), the subsoil begins to move upward due to the extrusion effect generated by the chisel tip. Simultaneously, the straw on the soil surface above the chisel tip begins to shift. However, because the pushing force of the chisel tip is limited, it produces minimal disturbance in the soil at the wing and wing-edge positions. When the wing enters the soil (Figure 7b), significant surface soil movement is observed at the horizontal center position (0 mm). This is attributed to the combined action of the lifting plate's pushing force and the extrusion pressure from the underlying soil. The highest movement velocities of both straw and soil occur in the region near the lifting plate of the lift-type winged chisel plow.

At the wing position, 160 mm from the horizontal center, the soil adjacent to the wing exhibits higher velocity. The maximum soil velocity curve closely aligns with the contour of the wing's lifting plate, indicating that this region is directly influenced by the wing structure. At this stage, the surface straw located above also begins to move under the combined action of the wing and lifting plate. By 0.302 s, the lifting plate actively flips the straw and soil through its plowing action. The highest movement velocities of both soil and straw are observed in front of the lifting plate. In these regions, particularly around the wing and lifting plate, the surface straw also gains significant velocity due to tool-induced disturbance. Meanwhile, the ridged soil lifted above the surface gradually collapses and backfills into the furrow under the influence of gravity.

Analysis of the velocity distribution across different positions reveals that the region in front of the lifting plate experiences the most intense disturbance. The maximum velocity contours of the soil particles correspond closely with the shape of the lifting plate and wing of the lift-type winged chisel plow. This demonstrates that the wing notably enhances disturbance in the cultivated soil layer and surface straw, contributing to improved mixing and loosening performance.

Microscopic Analysis of Soil Disturbance Displacement

(a) (b)

Fig. 8 - Soil displacement analysis Soil tillage.
(a) vertical displacement; (b) horizontal displacement

In the working direction (Figure 8a), the soil particles located beneath the lift-type winged chisel plow's lifting plate (J12, J22, J32, J42) exhibit relatively larger displacements. Among them, the bottommost soil particle at the center of the tool (J42) shows the greatest displacement in the working direction, while the soil particles near the wing blades and the lifting plate exhibit relatively smaller displacements. The soil particle directly beneath the lifting plate (J41) displays the smallest displacement. In the horizontal direction (Figure 8b), the soil particles directly beneath the lifting plate (J41, J43) exhibit minimal horizontal movement. In comparison, the remaining soil particles show relatively consistent horizontal displacement magnitudes. The soil particles located at the center of the lifting plate and the chisel tip (J21, J42, J23) experience the largest displacements. Considering the combined horizontal and working-direction displacements of soil particles, it can be observed that J41 and J43 are not directly influenced by the tool. Instead, the movement of particles in their vicinity is indirectly caused by the compressive forces among soil particles. At this point, the wing blades are positioned above a soil depth of 150 mm, and the lifting plate exhibits a greater disturbance effect on the cultivated soil layer. For soil particles located at the center of the lifting plate and chisel tip, the displacement increases with depth. This is due to the overturning action of the lifting plate, which flips the bottom-layer soil to a higher position, resulting in a longer forward movement duration. Conversely, the soil particles near the wing blades and the lifting plate are flipped to a lower height due to the height limitations imposed by the lifting plate. As a result, these particles experience a shorter forward movement duration and smaller displacements in the working direction.

In summary, the lift-type winged chisel plow exhibits the greatest disturbance within the cultivated soil layer. The addition of wing blades and the lifting plate effectively expands the disturbance range within this layer, although the direct force exerted by the wing blades on the plow pan is relatively limited. The chisel tip is capable of disturbing deeper soil layers, and a lower installation height of the wing blades increases the effectiveness of disturbance at depth. However, this also results in greater resistance, leading to increased energy consumption and reduced soil-loosening efficiency. The lifting plate of the lift-type winged chisel plow plays a critical role in achieving effective straw-soil mixing. However, its height significantly influences the displacement of the soil in front of it. During tillage operations, an insufficient lifting height may limit the upward movement of the soil above the lifting plate, impairing the burial of surface straw. This can ultimately reduce the effectiveness of straw-soil mixing achieved by the implement.

Performance Comparison of Soil Bin Tests

To investigate the effects of the winged blade and lifting plate on implement performance, soil bin tests were conducted to compare the straw burial rate (R), working width (W), straw burial depth (H), and straw-soil mixing uniformity (E) between the conventional chisel plow and the lift-type winged chisel plow. The lift-type winged chisel plow, with its wing blades and soil-lifting plate, demonstrated superior straw burial performance.

As shown in Table 1, compared to the conventional chisel plow, the lift-type winged chisel plow increased the burial rate to 42.98%, working width to 81.33 cm, and straw-soil mixing uniformity to 92%. The experimental results indicate that the lift-type winged chisel plow meets the quality standards for straw burial treatment as specified in DB21/T 3590-2022: Technical Specifications for Mechanized Operations of Corn Straw Incorporation into Soil. Comparing the actual working performance of the two implements, the lift-type winged chisel plow demonstrated superior loosening and crushing of the soil, as well as better uniformity of straw-soil mixing after incorporation.

Table 1

Soil bin test results

Category	R / %	W / cm	H / cm	E / %
Lift-type winged chisel plow	42.98	81.33	16.1	92
Ordinary chisel plow	13.2	39.47	17.2	61

CONCLUSIONS

This study investigated the motion characteristics of straw and soil during the operation of the lift-type winged chisel plow, as well as its effect on the micro-disturbance of the straw-soil mixture. A discrete element interaction model of the lift-type winged chisel plow, straw, and soil was established to explore the mechanism of straw-soil disturbance caused by the implement. The accuracy of this interaction model was validated through soil bin tests, and the working performance of the conventional chisel plow and the lift-type winged chisel plow was compared. The main conclusions are as follows:

1. The optimal combination of contact parameters for the straw-soil mixture was determined to be: a soil-soil static friction coefficient of 0.57, a soil-soil rolling friction coefficient of 0.18, and a soil-straw dynamic friction coefficient of 0.12. Under this parameter combination, the relative error between the simulated and experimental repose angles was 3.29%.

2. From a micro-scale perspective, the motion states of straw and soil at different time intervals and locations, as well as their influence on straw-soil micro-disturbance, were analyzed. The height of the soil-lifting plate was identified as the primary factor affecting soil fragmentation and straw burial efficiency.

3. The lift-type winged chisel plow shears and loosens the subsoil with its chisel tip, while the soil-lifting plate pushes, overturns, and mixes the straw and soil. Compared to the conventional chisel plow, the wing blades increased the working width, while the soil-lifting plate enhanced the frequency of straw-soil disturbance. The burial rate was improved to 42.98%, and the straw-soil mixing uniformity increased to 92%.

Keywords: *wheat bran, vibration mill, impact-blocking effect, powder particle size, grinding media diameter, damping coefficient*

ABSTRACT
During the vibration crushing of wheat bran, an impact-blocking effect occurred between the grinding media and wheat bran powder. Experimental results showed that the impact depth exhibited quadratic relationship with respect to particle size, while the acceleration and damping coefficients followed the order: fine powder > coarse powder > uncrushed bran > micro powder. Increasing the diameter of the grinding media enhanced the impact depth by 81.10% for uncrushed bran and by 40.41% for coarse powder, but reduced acceleration by 45.35% and 29.56%, respectively. Damping coefficients positively correlated with grinding media diameter but negatively with cylinder diameter. Material layer thickness demonstrated threshold-dependent bidirectional regulation, peaking at 40 mm, with maximum damping difference rates of 20.40% for uncrushed bran and 17.67% for coarse powder. Drop height linearly influenced the impact depth, while showing cubic relationships with both acceleration and damping. Both parameters were minimized at 500 mm. Sensitivity analysis identified grinding media diameter as the primary factor affecting damping coefficients, revealing the sensitivity hierarchy: grinding media diameter > drop height > material layer thickness > cylinder diameter. This study provided a theoretical foundation and experimental support for optimizing the vibration superfine crushing efficiency of wheat bran.

摘要
在振动粉碎小麦麸皮时，磨介与粉体间存在冲击阻滞效应。实验表明，冲击深度与粉体粒度呈二次非线性关系，加速度、阻尼系数大小顺序为：细粉 > 粗粉 > 未粉碎麸皮 > 微粉。增加磨介直径可使未粉碎麸皮和粗粉的冲击深度分别增加 81.10% 和 40.41%，加速度降低 45.35% 和 29.56%。阻尼系数与磨介直径正相关，与圆筒直径负相关。料层厚度对各参数有双向调控作用，临界厚度为 40mm。下落高度与冲击深度线性相关，与加速度、阻尼呈三次非线性关系，500mm 时二者取极小值。灵敏度分析显示，磨介直径是影响阻尼系数的主因，灵敏度顺序为：磨介直径 > 落差高度 > 料层厚度 > 筒体直径。该研究为优化小麦麸皮振动超微粉碎效能提供依据。

INTRODUCTION
Wheat bran is rich in essential nutrients such as protein, dietary fiber, vitamins, and minerals. Its superfine powder has shown significant application potential in the development of functional foods, pharmaceutical excipients, and biochemical research (*Praveenet et al., 2023; Zheng et al., 2022; Ying et al., 2022*). However, the high lignocellulose content in its structural layers poses a major challenge for conventional grain crushing equipment, which often fails to achieve the required superfine particle size (<25 μm) (*Hemery et al., 2011*). Vibration mills, leveraging comprehensive crushing actions including impact, shearing, extrusion, and friction, have emerged as a promising solution for wheat bran superfine crushing (*He et al., 2018; Rajaonarivony et al., 2021*). During the vibration process, wheat bran particles in the grinding cylinder are subjected to continuous crushing forces from grinding media, while imposing a blocking effect that hinders media movement, reduces collision velocity, and consumes energy (*Bulgakov et al., 2018*).

[1]Min Cheng, Lecturer Ph.D.Eng.; [1]Haocong Meng, M.Stud.Eng.; [1]Guangbo Xiang, Lecturer M.S.Eng.; [2]Shihao Zhou, M.Stud.Eng.; [1]Mingxu Wang, Prof. Ph. D. Eng; [1]Baoguo Liu, Prof. Ph. D. Eng.

This bidirectional impact-blocking interaction directly influences grinding media dynamics and energy transmission, thus determining the overall crushing efficiency.

Current research on vibration mills focuses on grinding media dynamics, crushing process optimization, and media-material interaction mechanisms. High-speed cameras and the discrete element method (DEM) have been applied to analyze media dynamics. The former confirmed three motion forms of spherical media: impact, total rotation, and self-rotation, while DEM studies on non-spherical media remain limited. *Yokoyama et al. (1996)* simulated 2D media motion, analyzing collision characteristics and grinding rate. *Lee et al. (2010)* established an impact model for media-material grinding, and *Yang et al. (2015, 2016)* studied media flow dynamics under different vibration conditions.

In the optimization of vibration crushing process efficiency, DEM and experimental research methods are typically employed to investigate the effects of vibration characteristics, grinding media properties, filling rate, crushing time, and other factors on the crushing efficiency mechanism of vibration mills. *Li et al. (2015)* discovered that grinding media size correlates with power density, achieving a 42% increase in griseofulvin dissolution through process optimization. *Yang et al. (2016)* demonstrated that medium-frequency and large-amplitude operation of double-mass vibration mills optimizes super hard particle crushing, refining diamond to a median particle size (D_{50}) of 0.26 μm. *Bogdanov et al. (2019)* proposed a poly-harmonic vibration mill with adjustable multi-parameters to enhance crushing efficiency. *Qian et al. (2023)* revealed that amplitude-frequency coupling dominates particle crushing, developing a model that reduced calcium carbonate crushing energy consumption by 29.2%. *Haddad (2020)* identified rotating mass as a key factor, determining optimal conditions (1500 rpm, 16 mm media, 222 g rotating mass) for minimal grinding time. *Yildirim et al. (2025)* recently achieved the multi-objective optimization of the dry grinding of hydrated lime in a vertical vibratory mill, producing powders with a D_{50} of 6.26 μm and a specific surface area of 2.71 m²/g.

Concerning the interaction between grinding media and materials and the grinding mechanism, it primarily reveals the formation process of impact, compression, shear, friction, and other mechanisms through which grinding media in the grinding cylinder act on the crushed material, as well as their influence on the crushing effect. *Frolov et al. (2017)* found ceramic media had 30-50% lower wear than steel, with cylindrical shapes reducing contamination. *Cheng et al. (2019, 2021)* showed particle size affects crushing mechanisms (impact extrusion for large particles, impact shearing for small) and media properties (density, size, shape) influence yield by up to 70.07%. *Tomach (2024)* reported a grinding time that was 22.5% shorter with 15 mm media than with 12 mm media. Notably, research on materials' reverse influence on media dynamics remains scarce, with most studies relying on indirect evidence via particle size or moisture comparisons.

To investigate the impact-blocking effect between the grinding media and wheat bran in the vibration crushing process, this study constructed a grinding media-wheat bran powder impact test platform. Wheat bran powder with different particle sizes was used to simulate various stages of wheat bran crushing, material layer thickness simulated the bran filling amount, drop height simulated the impact velocity of the grinding media, and grinding media diameter and cylinder diameter directly represented the geometrical dimensions of the grinding media and the cylinder. Using impact depth, average acceleration, and damping coefficient as key indicators, this study systematically investigated the effects of wheat bran particle size, grinding media diameter (8–16 mm), cylinder diameter (60–180 mm), layer thickness (20–60 mm), and drop height (400–800 mm) on the impact-blocking effect. On this basis, a sensitivity analysis was conducted to rank the influence of factors on damping coefficients. The study aims to provide both theoretical foundations and practical guidance for optimizing vibration mill efficiency in wheat bran superfine crushing.

MATERIALS AND METHODS

Preparation of wheat bran powder samples

The raw material of wheat bran was Zhengmai 379, produced in 2024 and purchased from Zhengzhou Jinyuan Flour Mill. During the experiment, materials passing through a 5 mesh sieve and retained by a 20 mesh sieve were taken as wheat bran samples, with an adjusted moisture content of approximately 10.65%. To simulate the different crushing stages of wheat bran in a vibration mill, the samples were pre-crushed in a vibration mill prior to the experiment. The crushed samples were then sieved and classified, yielding four types of powder: uncrushed bran (d_A > 900 μm), coarse powder (280 μm < d_A < 900 μm), fine powder (74 μm < d_A < 280 μm) and micro powder (d_A < 74 μm). Their morphologies are shown in Fig. 1.

a. Uncrushed bran b. Coarse powder c. Fine powder d. Micro powder

Fig. 1 - Wheat bran powder samples

Experimental principle and platform

To investigate the impact-blocking effect between grinding media balls and wheat bran powder during vibration crushing, a test platform for the impact mechanical properties of wheat bran powder was constructed based on the free–fall principle, as shown in Fig. 2. This experimental platform mainly consists of a height-adjustable support, an electromagnet capable of adsorbing the grinding media balls, and a plexiglass cylinder filled with wheat bran powder (*Seguin et al., 2008*).

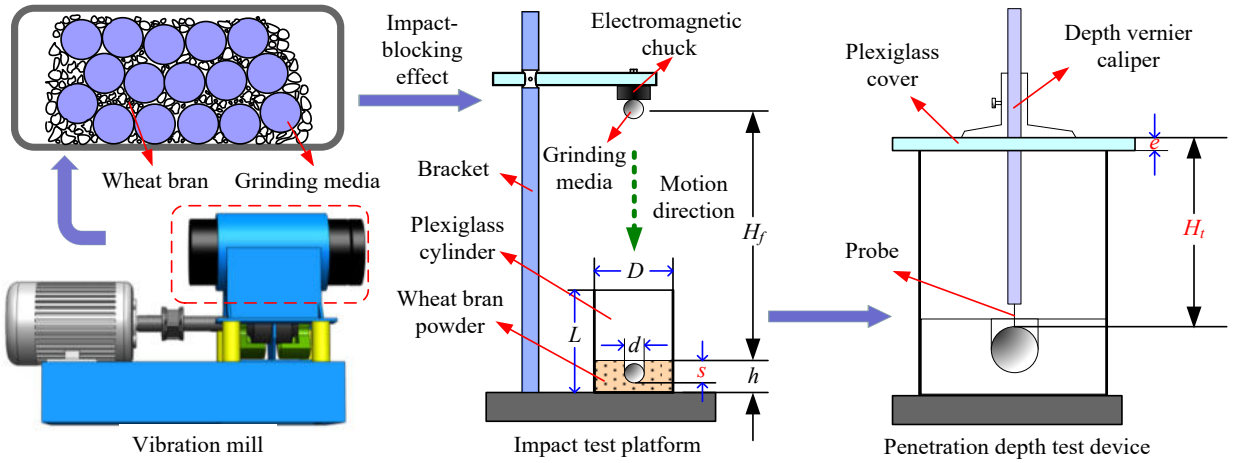

Fig. 2 - Grinding media-wheat bran powder impact test platform

d - grinding ball diameter; D - cylinder diameter; e - plexiglass cover plate thickness; h - material layer thickness; H_f - grinding ball height from material surface; H_t - distance between depth gauge base and probe; L - cylinder height; s - grinding ball impact depth in bran powder

During the experiment, the height of the grinding media is first adjusted, then the grinding media is aligned with the center of the cylinder and the power supply to the electromagnet is disconnected. At this point, the grinding media will continuously accelerate under the effect of gravity until it contacts the surface of the bran powder and starts to decelerate, and finally stops at a certain depth due to the resistance of the bran powder. To measure the impact depth of the grinding media, a probe is installed at the bottom of the depth gauge, and a glass cover plate is installed at the top, forming a gauge that allows direct read of the impact depth of the grinding media ball. After the experiment, first gently brush away the bran powder above the grinding media; then, touch the probe of the depth gauge to the upper surface of the grinding ball and read the distance H_t between the depth gauge's measuring base and the probe. Finally, the impact depth of the grinding ball s as it penetrates into the bran powder can be calculated using the mathematical relationship among the cylinder height L, grinding ball diameter d, and plexiglass cover plate thickness e.

Experimental scheme

Numerous impact test studies on powder or granular materials have shown that factors such as the particle size of the powder or granules, the size of the impacting object, the cylinder diameter, the material layer thickness, and the drop height (or impact velocity) can all affect the impact mechanical properties (*Ji et al., 2012, 2016; Wang and Ji, 2018*). To explore the impact-blocking effect between the grinding media balls and the wheat bran powder, the bran powder particle size, grinding media ball diameter, cylinder diameter, material layer thickness, and drop height were selected as experimental conditions. A series of tests were conducted to investigate the effect of grinding media balls on wheat bran powder.

The objectives were to simulate different crushing stages of wheat bran by using powders with different particle sizes, to simulate the boundary effect of the grinding cylinder by using cylinders with different diameters, to simulate the filling rate of bran by using material layers with different thicknesses, and to simulate the impact velocity of the grinding media balls by using different drop heights.

During the experiment, one experimental condition was selected as the variable, while the other four were kept constant. The specific experimental design is shown in Table 1. To improve the reliability of the results, each group of experiments was repeated at least 10 times. To reduce experimental errors, unreasonable test data such as extreme values were excluded. To eliminate the impact of the cylinder's boundary effect, the cylinder diameter was required to be more than 5 times the grinding media ball diameter (*Ji et al., 2012*). As shown in Table 1, the diameters of the media balls and cylinders meet this requirement. The masses of the grinding media balls with different diameters listed in Table 1 were 2.14 g, 4.17 g, 7.23 g, 11.45 g, and 17.06 g, respectively.

Table 1

Experimental scheme

Experimental factors	Variable experimental conditions					Constant experimental conditions			
	NO.1	NO.2	NO.3	NO.4	NO.5	Grinding media diameter [mm]	Cylinder diameter [mm]	Material layer thickness [mm]	Drop height [mm]
Powder particle size [μm]	5-20	20-60	60-200	<200	—	10	90	30	500
Grinding media diameter [mm]	8	10	12	14	16	—	90	30	500
Cylinder diameter [mm]	60	90	120	150	180	12	—	30	500
Material layer thickness [mm]	20	30	40	50	60	10	90	—	500
Drop height [mm]	400	500	600	700	800	10	90	40	—

Experimental evaluation indicators

To simulate and analyze the impact-blocking effect between the grinding media ball and the bran powder in the grinding cylinder of the vibration mill, the impact depth of the grinding media ball in the bran powder, the average acceleration of the grinding media ball after being blocked by the bran powder, and the average damping coefficient were selected as evaluation indicators.

According to Fig. 2, the impact depth of the grinding media ball can be obtained as:

$$s = H_t + h + d - e - L \tag{1}$$

Assuming that the grinding media ball undergoes uniform deceleration while impacting through the wheat bran powder, its average acceleration can be calculated from Fig. 2 as:

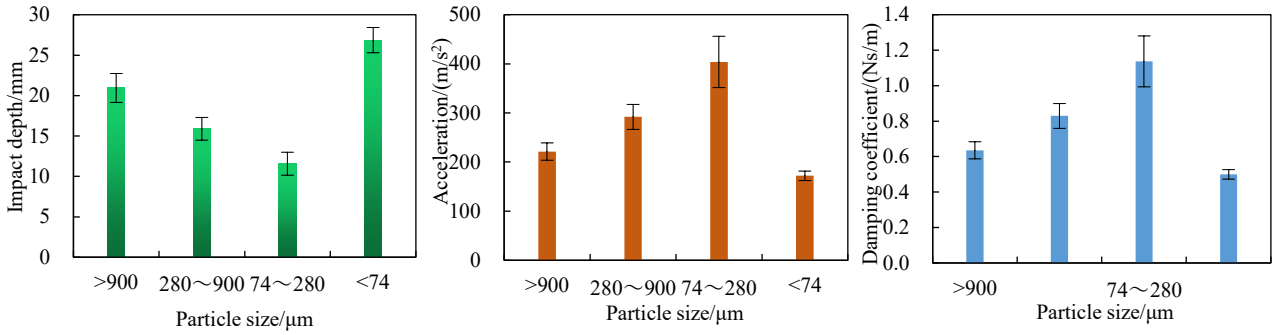
$$a = \frac{gH_f}{H_t + h + d - e - L} \tag{2}$$

Where: a is the average acceleration, m/s^2; g is the gravitational acceleration, 9.8 m/s^2.

By neglecting the elastic compression effect of the grinding media ball on the wheat bran powder during the impact process and the frictional energy consumption between the powder particles, the average damping coefficient of the bran powder acting on the grinding media ball is derived as:

$$c = m\sqrt{2gH_f}\left(\frac{1}{H_f} + \frac{1}{H_t + h + d - e - L}\right) \tag{3}$$

Where: c is the average damping coefficient, Ns/m. During the experiment, H_f, h, d, e, and L are known parameters. By measuring H_t with a depth gauge and substituting it into Eqs. (1), (2), and (3) respectively, the specific values of evaluation indicators s, a, and c can be determined.



RESULTS

Influence of powder particle size on the blocking effect of wheat bran powder

Fig. 3 shows the variations in the impact depth, acceleration, and damping coefficient when grinding media balls impact four types of wheat bran powders respectively. Under the same impact conditions, as depicted in Fig. 3 (a), the impact depth exhibits a quadratic nonlinear trend of first decreasing and then increasing with decreasing powder particle size.

The average acceleration of the grinding media balls and the damping coefficient of the wheat bran powder both demonstrate a quadratic nonlinear pattern: they first increase and then decrease. This pattern is exactly opposite to the trend of the impact depth, as shown in Fig. 3 (b) and Fig. 3 (c).

When the bran powder particle size is relatively large, the inter-particle voids are large, and the powder fluidity is good. When the grinding media balls penetrate, the resistance mainly originates from the frictional force between the particles and the grinding media surface. At this point, the resistance is relatively small, leading to a large impact depth. When the powder particle size is moderate, the inter-particle voids decrease, and powder fluidity diminishes. During media ball penetration, the particle collision frequency increases, as does the resistance to particle rearrangement. Here, the resistance reaches a maximum, and the impact depth attains a minimum. When the powder particle size is relatively small, the inter-particle voids further decrease, and the powder fluidity significantly declines. During grinding media ball penetration, the inter-particle collision resistance decreases, and the particles become more flowable. The resistance instead decreases, causing the impact depth to increase. In the field of particle damping and vibration reduction, studies have shown that for a specific type of damping particles, an optimal particle size typically exists, at which the particle-generated damping is the maximized (*Shinde and Pathak, 2016*; *Kumbhar, 2021*).

a. Impact depth b. Average acceleration c. Damping coefficient

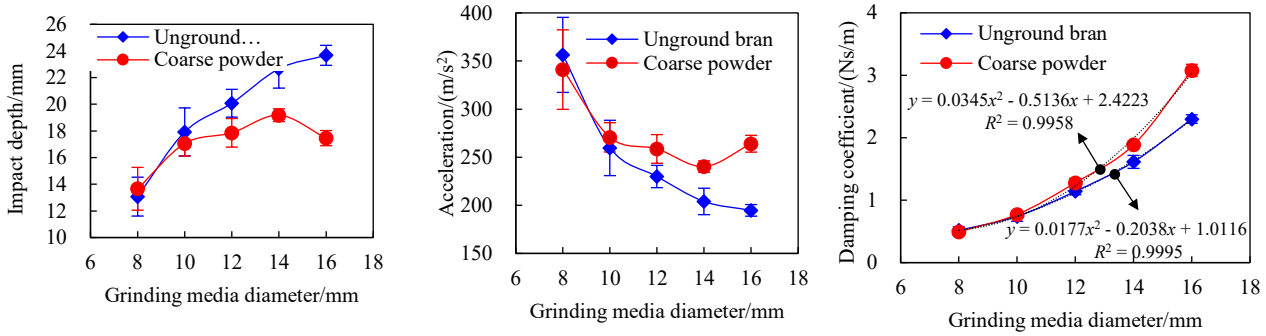


Fig. 3 - Impact mechanical property parameters of wheat bran powders with different particle sizes

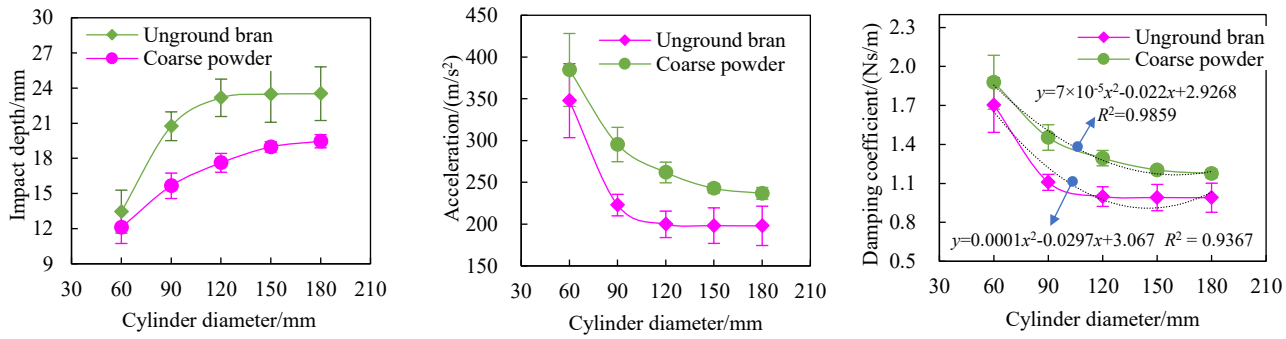
As shown in Fig. 3, the impact depth of the grinding media ball in the fine powder is the smallest, measuring 11.57 mm, and that in the micro powder is the largest, reaching 26.86 mm. The difference rate between the maximum and minimum impact depths is 132.15%, while the difference rates for the acceleration and damping coefficient are 134.79% and 127.53% respectively. This indicates that the bran powder particle size significantly influences the blocking effect on the grinding media ball. Given that the impact depth in the fine powder is minimal and the damping coefficient is maximal, the grinding media ball encounters the greatest resistance when penetrating the fine powder, whereas penetration into the micro powder is the easiest. This implies that crushing the fine powder into micro powder is relatively difficult. It further reveals that during different stages of vibration crushing, the crushing difficulty of wheat bran particles varies, as do the required crushing force and energy consumption. To avoid the mutation region between fine powder and micro powder and ensure test result reliability, this study selects uncrushed bran and coarse powder as the impacted materials to further investigate the effects of grinding media diameter, drop height, material layer thickness, and cylinder diameter on their blocking effect.

Influence of grinding media diameter on the blocking effect of wheat bran powder

According to Fig. 4(a), as the impact depth of the grinding media ball generally increases as its diameter increases. This is because, at the same drop height, a larger media ball diameter corresponds to higher gravitational potential energy, thereby increasing its impact kinetic energy gradually. It is also observed that the impact depth in uncrushed bran is typically greater than that in coarse powder, consistent with the results in Section 3.1. Notably, when the grinding media ball diameter is 8 mm, its impact depth in coarse powder exceeds that in uncrushed bran. This can be explained by the better fluidity of coarse powder, which facilitates the penetration of the small grinding media ball. Conversely, when the grinding media ball diameter is 16 mm, the impact depth in coarse powder decreases. This may be due to the larger grinding media ball encountering changes in structural support or inter-particle friction within the coarse powder, leading to reduced impact depth (*Ye et al., 2015*).

As shown in Fig. 4(b), the variation trend of acceleration during the grinding media ball impacts and penetration into the two types of bran powder is completely opposite to that of the impact depth. According to Fig. 4(c), the damping coefficients for the two types of wheat bran powder increase with the grinding media ball diameter, and the damping from the coarse powder exceeds that from the uncrushed bran. This is because a larger grinding media ball diameter increases the contact area between the grinding media surface and the bran powder, thereby enhancing the frictional force between the wheat bran powder particles and the grinding media surface. As the grinding media ball diameter increases, the damping coefficient of the coarse powder rises more rapidly, widening the gap between the damping coefficients of the two types of bran powder. This can be attributed to the voids and mobility of the coarse powder particles. Based on the fitted expressions in Fig. 4(c), when the grinding media diameter exceeds 9.25 mm, the coarse powder exhibits higher sensitivity than the uncrushed bran, meaning its damping coefficient is more susceptible to changes in the grinding media diameter. Therefore, to optimize the vibration crushing efficiency of wheat bran, the grinding media diameter should be rationally selected based on the results of wheat bran vibration crushing tests (*Cheng et al., 2021*).



a. Impact depth b. Average acceleration c. Damping coefficient

Fig. 4 - Influence of grinding media diameter on the blocking effect of wheat bran powder

Influence of cylinder diameter on the blocking effect of wheat bran powder

As shown in Fig. 5(a), the impact depth of the grinding media in uncrushed bran is consistently greater than that in coarse powder, in line with the results in Section 3.1. As the cylinder diameter increases, the impact depth of the grinding media in the two types of bran powders increases and gradually stabilizes, following an approximate quadratic nonlinear trend. In other words, the boundary effect of the grinding cylinder on the impact depth of the grinding media diminishes as the cylinder diameter increases. This is because a small cylinder diameter imposes higher resistance to bran diffusion in all directions, leading to a larger proportion of frictional energy consumption between bran powder particles and the cylinder wall during impact (*Seguin, 2023*). Conversely, a larger cylinder diameter results in lower diffusion resistance, and the proportion of frictional energy consumption between particles and the cylinder wall is small and tends to be stabilize. As shown in Fig. 5(b) and Fig. 5(c), the average acceleration and damping coefficient exhibit identical variation trends, which are opposite to that of the impact depth of the grinding media. Both parameters decrease with increasing cylinder diameter and eventually reach a stable state.

a. Impact depth b. Average acceleration c. Damping coefficient

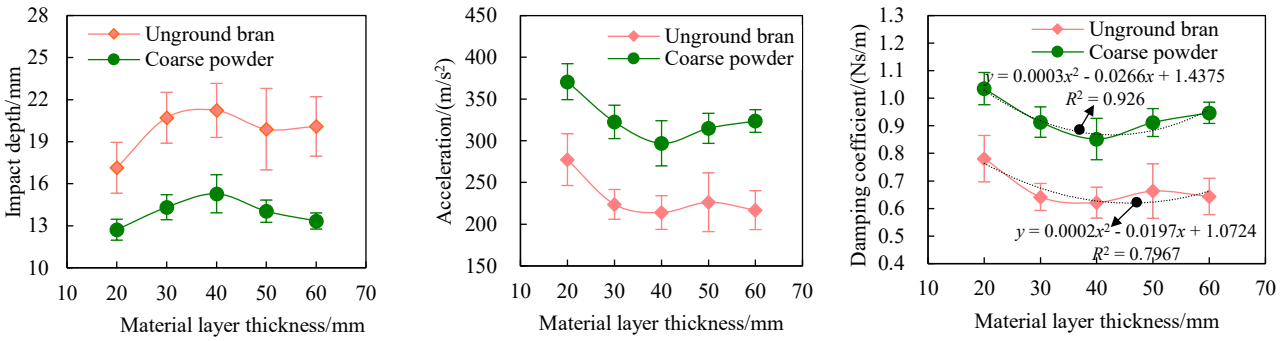


Fig. 5 - Influence of cylinder diameter on the blocking effect of wheat bran powder

As shown in Fig. 5(c), when the cylinder diameter exceeds 114.46 mm, the uncrushed bran exhibits higher sensitivity than the coarse powder. When the cylinder diameter surpasses 145.12 mm and 160.35 mm respectively, the slopes of the functional relationships for the damping coefficients of uncrushed bran and coarse powder become zero, and the damping coefficients stabilize, indicating the disappearance of the cylinder's boundary effect. In conclusion, the critical cylinder diameters for the two types of bran differ, with the coarse powder having a larger critical diameter than the uncrushed bran. This discrepancy may primarily arise because the coarse powder has a higher density than the uncrushed bran, enabling a more stable energy transfer path that allows the impact wave from the grinding media ball to propagate further. As demonstrated above, the ratios of cylinder diameter to grinding media diameter for the two types of bran powders are 9.54 and 12.09 respectively. This indicates that the cylinder's boundary effect is influenced by both the powder type and its particle size (*Ji et al., 2012*).

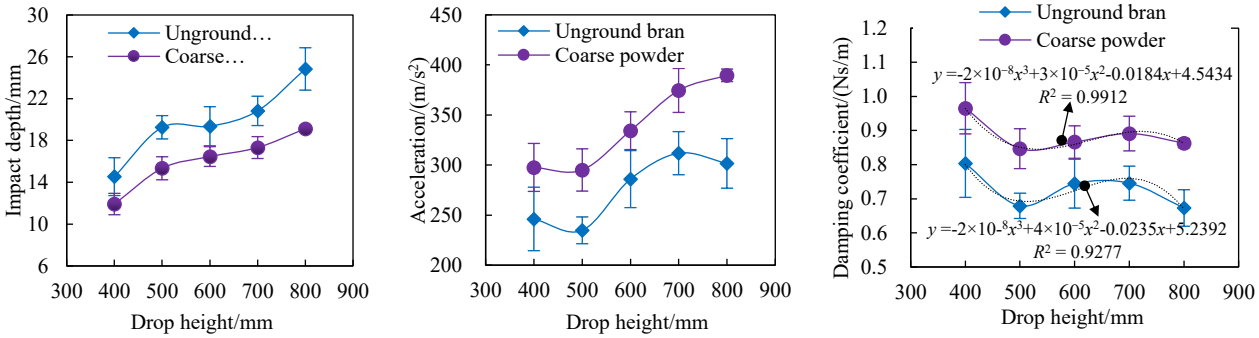
Influence of material layer thickness on the blocking effect of wheat bran powder

As depicted in Fig. 6(a), with the increase in thickness of the two types of wheat bran powder layers in the cylinder, the impact depths of the grinding media both display a trend of first increasing, then decreasing, and finally stabilizing. This can be attributed to the fact that when the material layer thickness exceeds an optimal threshold, its elastic effect intensifies, absorbing the impact energy of the grinding media. *Tomach (2024)* and *Seguin (2023)* have also pointed out that for particles with different shapes, the critical material layer thickness varies, and the damping rate exhibits a pattern of increasing first, then decreasing, and eventually stabilizing with increasing thickness—findings that align well with the results of this study. When the material layer thickness reaches a critical value of 40 mm, the impact depths of the grinding media in both bran powders attain their maxima. The ratio of material layer thickness to the grinding media diameter at this point is 4:1. Additionally, it is observed that the impact depth of the grinding media in uncrushed bran is consistently greater than that in coarse powder, in line with the results presented in Section 3.1. The difference rates between the maximum and minimum impact depths for uncrushed bran and coarse powder are 23.86% and 20.13%, respectively. This indicates that material layer thickness has a significant effect on the impact depths of the two types of wheat bran powders. The maximum difference rate in impact depth between the two types of bran powders is 33.60%, with the minimum rate at 25.79%, further highlighting the substantial influence of powder particle size on the blocking effect of wheat bran powder.

As shown in Fig. 6(b) and Fig. 6(c), the variation trends of the average acceleration and damping coefficient of the grinding media are consistent and opposite to that of the impact depth. The average acceleration and damping coefficient for the coarse powder are consistently higher than those for the uncrushed bran. When the ratio of material layer thickness to grinding media diameter is 4:1, the damping coefficient reaches its minimum. The difference rates between the maximum and minimum damping coefficients of uncrushed bran and coarse powder are 25.63% and 21.47%, respectively.

a. Impact depth b. Average acceleration c. Damping coefficient

Fig. 6 - Influence of material layer thickness on the blocking effect of wheat bran powder



As shown in Fig. 6(c), when the material layer thickness is between 26.1 mm to 45.8 mm, the uncrushed bran demonstrates higher sensitivity than the coarse powder. During this range, variations in material layer thickness more significantly influence the damping coefficient of the uncrushed bran. For thicknesses of 20–26.1 mm and 45.8–60 mm, the coarse powder exhibits greater sensitivity, indicating it is more responsive to thickness changes. In wheat bran vibration crushing, the material layer thickness correlates positively with the bran filling amount. The higher the filling, the thicker the material layer that the grinding media need to penetrate.

When the thickness reaches the critical value, the damping coefficient of the bran powder is minimized, optimally facilitating the penetration of the grinding media. Thus, to improve wheat bran crushing efficiency, the bran powder filling amount should be rationally determined through experimental analysis.

Influence of drop height on the blocking effect of wheat bran powder

As shown in Fig. 7(a), the impact depth increases overall with the drop height of the grinding media (*Seguin et al., 2008*). Within a certain error margin, the relationship between drop height and initial impact velocity can be considered approximately linear. Thus, drop height can be regarded as equivalent to the initial impact velocity of the grinding media. This is consistent with the conclusion that "under identical conditions, the greater the initial impact velocity of an object, the deeper its impact depth"(*Ye et al., 2016*). The impact depth of the grinding media in uncrushed bran exceeds that in coarse powder, in line with the results in Section 3.1.

As shown in Fig. 7(b), owing to varying initial impact velocities, the average acceleration of the grinding media during their impact and penetration into wheat bran powder shows a cubic nonlinear trend: decreasing first, then increasing, and then decreasing again. The average acceleration of the coarse powder remains higher than that of the uncrushed bran. According to Fig. 7(c), the damping coefficient reaches a local minimum at a grinding media drop height of 500 mm. From the impact velocity perspective, it is not that the higher the impact velocity, the more favorable the penetration of grinding media into bran powder; instead, there exists a locally optimal impact velocity. The difference rates between the maximum and minimum damping coefficients of the uncrushed bran and the coarse powder are 19.41% and 13.98%, respectively; those for impact depths are 70.84% and 60.40%, respectively; and the coefficients of variation for accelerations are 32.83% and 32.04%, respectively. As shown above, the uncrushed bran exhibits higher difference rates in impact depth, acceleration, and damping coefficient than the coarse powder. The order of influence of drop height on the three parameters is: impact depth > acceleration > damping coefficient.

a. Impact depth b. Average acceleration c. Damping coefficient

Fig. 7 - Influence of drop height of the grinding media ball on the blocking effect of wheat bran powder

As shown in Fig. 7(c), when the drop height is between 429 mm and 656 mm, the uncrushed bran demonstrates higher sensitivity than the coarse powder. Within this range, variations in drop height more significantly influence the damping coefficient of the uncrushed bran. For drop heights of 400–429 mm and 656–800 mm, the coarse powder exhibits greater sensitivity, indicating it is more responsive to drop height changes. In conclusion, the performance parameters of the vibration mill, such as rotational speed and amplitude, should be rationally selected within a defined range to bring the grinding media's impact velocity close to the optimal state. This approach reduces the damping coefficient between the grinding media and bran powder, enabling more energy to be converted into crushing energy.

Sensitivity analysis of the damping coefficient of wheat bran powder

Given that the dimensions and value intervals of the experimental factors (e.g., the grinding media diameter, material layer thickness, drop height, and cylinder diameter) vary, the sensitivities of the damping coefficients for uncrushed bran and coarse powder with respect to these influencing factors are not comparable. Thus, dimensionless normalization of these factors is necessary.

Considering the non-negativity of the factors' value intervals, the following equation for dimensionless normalization can be used.

$$X_i = (x_i - \min\ x_i)/(\max\ x_i - \min\ x_i) \quad (4)$$

where:

X_i is the i-th dimensionless value, with $X_i \in (0, 1)$; x_i is the i-th dimensional value.

By using Eq. (4) to perform dimensionless normalization on the above influencing factors, the dimensionless fitting expressions for the damping coefficients of uncrushed bran and coarse powder with respect to these factors can be derived, as shown in Table 2.

According to Table 2, the dimensionless sensitivity distribution curves for the damping coefficients of the two types of wheat bran powders can be derived, as illustrated in Fig. 8.

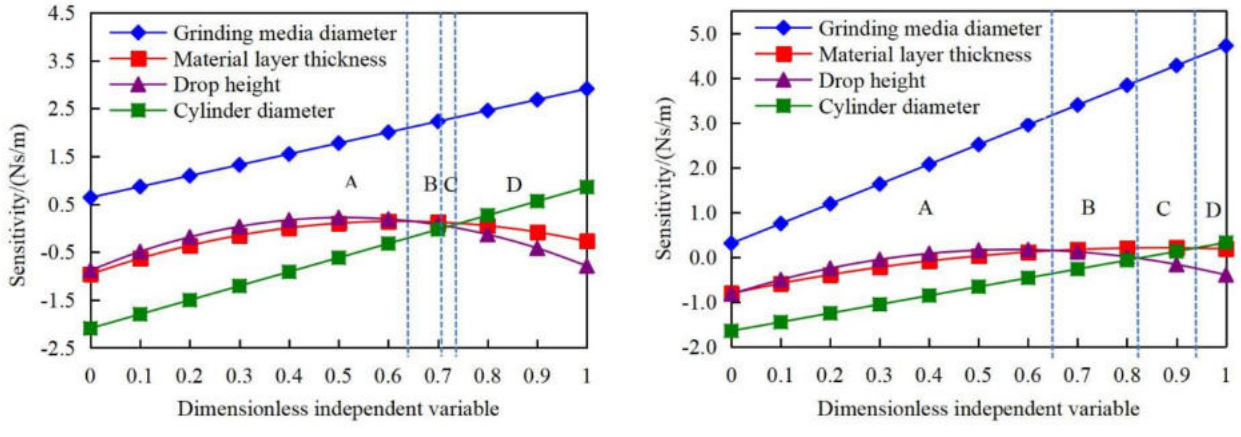


Fig. 8 shows that the sensitivity distribution laws of the damping coefficients of the two types of bran powders are very similar. This indicates that the test results have relatively high reliability. For both types of wheat bran powders, the grinding media diameter is consistently the most sensitive factor for changes in the damping coefficient, exceeding the drop height, material layer thickness, and grinding cylinder diameter.

Table 2

Dimensionless fitting expressions of damping coefficients of two types of wheat bran powders

Powder type	Uncrushed bran	Coarse powder
Grinding media diameter	Y=1.1354X^2+0.6402X+0.5164 (R^2=0.9995)	Y=2.2072X^2+0.306X+0.5211 (R^2=0.9958)
Cylinder diameter	Y=1.4754X^2-2.0933X+1.6515 (R^2=0.9367)	Y=0.986X^2-1.6491X+1.8558 (R^2=0.9859)
Drop height	Y=-1.4062X^3+2.1542X^2-0.8787X+0.8002 (R^2=0.9277)	Y=-1.0171X^3+1.7386X^2-0.8236X+0.9641 (R^2=0.9912)
Material layer thickness	Y=-0.9577X^3+1.7805X^2-0.96X+0.7818 (R^2=0.9962)	Y=-0.451X^3+1733X^2-0.8101X+1.0379 (R^2=0.9658)

For uncrushed bran and coarse powder, when 0 < X < 0.65 or 0 < X < 0.68 (Region A), the sensitivity ranking is: grinding media diameter > drop height > material layer thickness > cylinder diameter; when 0.65 < X < 0.72 or 0.68 < X < 0.82 (Region B), the sensitivity ranking is: grinding media diameter > material layer thickness > drop height > cylinder diameter; when 0.72 < X < 0.74 or 0.82 < X < 0.94 (Region C), the sensitivity ranking is: grinding media diameter > material layer thickness > cylinder diameter > drop height; when X > 0.74 or X > 0.94 (Region D), the sensitivity ranking is: grinding media diameter > cylinder diameter > material layer thickness > drop height.

a. Uncrushed bran b. Coarse powder

Fig. 8 - Dimensionless sensitivity of damping coefficient of wheat bran powder

Thus, when regulating the vibration crushing effect of wheat bran, the grinding media diameter should be adjusted preferentially. Subsequently, the performance parameters of the vibration mill and powder filling amount can be optimized. In practice, the size or capacity of the grinding cylinder is typically non-adjustable, which aligns with previous research conclusions (*Haddad, 2020; Cheng et al., 2021*).

CONCLUSIONS

This paper constructed an impact test platform for grinding media-wheat bran powder to simulate the impact-blocking effect, with impact depth, average acceleration, and damping coefficient serving as evaluation indicators. The effects of powder particle size, grinding media diameter, cylinder diameter, material layer thickness, and drop height were investigated, leading to the following conclusions:

(1) Under identical impact conditions, as wheat bran powder particle size decreases, impact depth demonstrates a quadratic nonlinear trend of decreasing first and then increasing, whereas average acceleration and damping coefficient change in the opposite direction. Particle size exerts a significant influence on the impact-blocking effect, with maximum-minimum difference rates of the three indicators reaching 132.15%, 134.79%, and 127.53%, respectively. The order of acceleration and damping coefficient is: fine powder > coarse powder > uncrushed bran > micro powder.

(2) An increase in media or cylinder diameter results in an increase in impact depth, but a decrease in acceleration. The damping coefficient exhibits a quadratic nonlinear relationship with both diameters: it increases with grinding media diameter (accompanied by growing differences) and decreases with cylinder diameter, stabilizing at critical diameters of 145.12 mm (uncrushed bran) and 160.35 mm (coarse powder). This finding helps to select the grinding media diameter and cylinder diameter based on the powder type or crushing stage.

(3) With the increase in material layer thickness, impact depth first increases then decreases, while acceleration and damping coefficients first decrease and then increase, stabilizing at a critical thickness of 40 mm (4:1 ratio to grinding media diameter). Impact depth increases monotonically with drop height, whereas acceleration and damping coefficients follow a cubic nonlinear pattern, reaching minima at 500 mm. Drop height has the most significant influence on impact depth, followed by average acceleration and damping coefficient. This finding facilitates the determination of the cylinder's material filling amount based on the critical warning value of layer thickness.

(4) Uncrushed bran and coarse powder show consistent dimensionless sensitivity distributions for damping coefficients, with grinding media diameter being the most sensitive factor, outperforming drop height, material layer thickness, and cylinder diameter. This finding contributes to the development of sensitivity weight-based control algorithms for multi-parameter coupled control of vibration crushing.

This study revealed the impact-blocking mechanism in wheat bran vibration crushing by simulating different stages and parameters of the crushing process. The results contribute to the understanding of the vibration mill's crushing mechanism and provide insights for optimizing its efficiency.

ABSTRACT
Precision rice broadcasting technology plays a significant role in the mechanization of planting and yield enhancement, with seed friction and mechanical properties being critical factors in seeder design. In this study, experiments were conducted to evaluate the frictional and mechanical properties of different rice seed varieties. The results showed that higher seed moisture content led to reduced flowability and lower mechanical strength. When rice seeds underwent chitting treatment, their viability remained above 90% under external loads not exceeding 20 N or cutting lengths within 1.5 mm. This study provides a theoretical foundation and data support for the design and optimization of direct-seeding machinery, contributing to the advancement of rice direct-seeding technology and equipment.

摘要
水稻精准直播技术对种植机械化和产量提升意义重大，种子摩擦与力学特性是排种器设计的关键。因此，本研究对不同稻种的摩擦与力学特性进行实验。结果表明，种子含水率越高，流动性越差，力学强度越低。当种子处于露白处理后，外部载荷不超过 20 N 或切除长度不超过 1.5 mm 时，种子存活率均在 90%以上。本研究为水稻直播排种器设计优化提供了理论依据和数据支持，推动了水稻直播技术及装备发展。

INTRODUCTION
Rice, the staple food for over half of the global population, is critical for global food security *(Liberatore et al., 2025; Shang et al., 2024; Zhang et al., 2018*). However, traditional rice transplanting methods have become increasingly impractical due to rising labor costs and shifting rural demographics *(He et al., 2024; Qian et al., 2024*). In response, rice direct seeding technology has gained widespread adoption valued for its labor-saving, cost-effective, and high-efficiency characteristics (*Li et al., 2023a; Li et al., 2023b*). This approach involves mechanized direct seeding, eliminating the labor-intensive and resource-consuming aspects of traditional transplanting. Nevertheless, the precision of direct seeding remains constrained by the performance of seeders, which directly impacts seeding uniformity, seedling establishment rates, and overall field management costs *(Li et al., 2022; Liu et al., 2023*).

Accurate determination of seed mechanical and frictional characteristics is essential for developing theoretical models and defining simulation boundary conditions in seeder design *(Gao et al., 2022; He et al., 2022; Xing et al., 2018*). While traditional empirical trial-and-error approaches have been largely replaced by numerical simulations - such as those based on the Discrete Element Method (DEM) and Computational Fluid Dynamics (CFD) - the accuracy and completeness of material property parameters remain critical to simulation reliability. Previous studies have primarily focused on specific rice seed varieties or single physical states *(Dun et al., 2022; Wang et al., 2022a)*. Domestic researchers have conducted a series of studies on the characteristic parameters of rice seeds. The results indicated significant differences in the frictional and mechanical characteristic parameters among rice seeds of different varieties and types.

Currently, research methods are primarily focused on parameter calibration within EDEM software or rely on referencing and extending previous findings. However, existing studies still face limitations in both the scope of research objects and methodological innovation. Most research has concentrated on single rice varieties or seeds in the dry state *(Dong et al., 2022; Wang et al., 2022b)*. However, China's vast rice-growing regions span multiple climatic zones and involve diverse direct seeding practices - such as dry seeding, wet seeding, and film mulching - alongside a wide variety of rice types (including conventional, hybrid, and water-saving drought-resistant varieties). This complexity poses significant challenges to the applicability of existing parameter systems. In particular, the contact model parameters used in DEM simulations for rice seeds vary considerably depending on the seed's physical state. Relying on empirical or generalized parameters may result in design deviations in critical seeder components, ultimately reducing seeding efficiency and performance. Current methods for determining the mechanical and frictional properties of rice seeds are often limited to single varieties or seed states, and there is a lack of systematic studies encompassing multiple varieties and treatment conditions. Furthermore, the standardization of parameter acquisition methods remains inadequate, leading to poor data comparability across studies *(Li et al., 2021; Xing et al., 2021; Xing et al., 2020*).

To address these challenges, this study innovatively developed a multidimensional parameter determination system. The system encompassed seven conventional and three hybrid rice varieties, representing the primary direct-seeded rice types cultivated across China's major rice-growing regions *(Baral et al., 2021; Shun et al., 2020; Tang et al., 2021*). It simultaneously evaluated seeds in dry, soaked, and chitted states, and analyzed the effects of moisture content gradients on the mechanical and frictional properties of the seeds. This comprehensive approach enabled the establishment of accurate methods for determining the physical properties of rice seeds, offering strong theoretical and data support for the design and optimization of rice direct-seeding machinery. The findings lay a solid foundation for future theoretical modeling and virtual simulation studies, and ultimately contribute to the advancement of rice direct-seeding technology, improved mechanization, and enhanced national food security.

MATERIALS AND METHODS

Experimental Materials

This study selected 7 conventional rice varieties (Suigeng 27, Longjing 31, Nangeng 9108, Huanghuazhan, Xiangzaoxian 45, Longken 2021, Nongken 58) and 3 hybrid rice varieties (Jingliangyouhuazhan, Jingliangyou 534, Longliangyouhuazhan) as experimental materials based on dimensions such as planting areas, promotion areas, and farmer preferences. For ease of data compilation, the 10 different rice varieties were represented as M_i, where M_1 represented Suigeng 27, M_2 represented Longjing 31, M_3 represented Nangeng 9108, M_4 represented Huanghuazhan, M_5 represented Xiangzaoxian 45, $M6$ represented Longken 2021, M_7 represented Nongken 58, M_8 represented Jingliangyouhuazhan, M_9 represented Jingliangyou 534, and M_{10} represented Longliangyouhuazhan. Different states of rice varieties were represented as G_i, where G_1 represented untreated and G_2 represented treated with exposure.

Experimental Methods

The friction and mechanical properties of rice seeds could serve as a basis for analyzing the complex motion mechanisms such as friction and rolling between the seed population inside the seeder and between seeds and working components. This effectively revealed the operational mechanisms for precise seeding in rice precision hole direct seeding seeders.

Static Friction Coefficient

The static friction coefficient was crucial for assessing a material's scattering performance. In this study, the inclined plane method was utilized to measure the static friction coefficient of rice seeds. The procedure involved placing the material on an inclined plane in contact with the rice seeds and gradually tilting it until sliding occurred. High-speed photography captured the angle between the inclined and horizontal planes at the onset of sliding. The tangent of this angle represented the static friction coefficient. Measurements were conducted using a custom-built device, depicted in Figure 1.

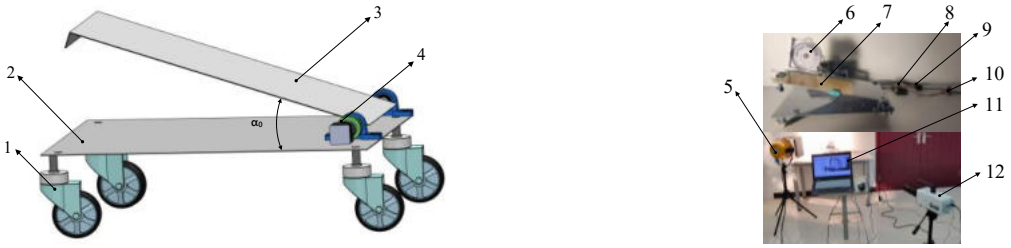

Fig.1 - Static friction coefficient measuring device

(1) Supporting Wheel; (2) Base Plate; (3) Inclined Plane; (4) Drive Motor; (5) Supplementary Lighting Device; (6) Angle Measurement Instrument; (7) Contact Material; (8) Microcontroller; (9) Start-Stop Button; (10) Speed Controller; (11) Computer Terminal; (12) High-Speed Photography Device

Different contact materials could be installed on the inclined plane, and when rice seeds came into contact with different materials, simply placing the respective material on the inclined plane was sufficient. During measurement, 100 grains of each of 10 randomly selected rice varieties in different states were placed on different contact materials on the inclined plane. The start-stop button was then activated to slowly raise the inclined plane. The computer terminal recorded the angles between different rice varieties in different states and different contact materials, providing a theoretical basis for subsequent simulation and theoretical analysis studies. The formula for calculating the static friction coefficient was shown in Equation 1.

$$\mu_1 = \tan \alpha_0 \tag{1}$$

where: μ_1 is the static friction coefficient, and α_0 is the angle between the contact surface and the horizontal plane (°).

Coefficient of Dynamic Friction

When the rice seeds moved on the inclined plane at different angles of inclination α_0, the experiment involved capturing the coordinates (x_{n-1}, y_{n-1}), (x_n, y_n), and (x_{n+1}, y_{n+1}) corresponding to frames $n-1$, n, and $n+1$ using a high-speed photography device, with each frame interval was t_0, as illustrated in Figure 2.

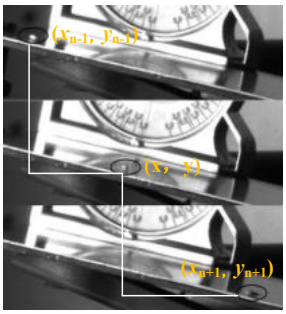

Fig. Error! No text of specified style in document. **- Rice seed coordinate point measurement**

Based on the coordinates measured for the rice seeds, the instantaneous velocity v_0 of the rice seeds at frame n could be calculated. The formula for calculating the instantaneous velocity v_0 was shown in Equation 2.

$$v_0 = \frac{\sqrt{(x_n - x_{n-1})^2 + (y_n - y_{n-1})^2} + \sqrt{(x_{n+1} - x_n)^2 + (y_{n+1} - y_n)^2}}{2t_0} \tag{2}$$

By measuring the instantaneous velocity of the rice seeds at time point n, it was possible to further calculate the rice seeds' instantaneous kinetic energy at that moment. Simultaneously, by using the specific coordinates of the rice seeds at time point n, the total distance traveled by the rice seeds along the inclined plane since the release could be determined. Based on this distance, it was then possible to estimate the proportion of energy loss due to frictional forces during the movement of the rice seeds on the inclined plane to the total energy. The formula for calculating this proportion was shown in Equation 3.

$$C_0 = \frac{W_f}{U_0} = \frac{k_0 mg \cos \alpha_0 \cdot L_0}{mgL_0 \sin \alpha_0} = k_0 \cot \alpha_0 \tag{3}$$

where:

C_0 represents the proportion of lost energy to total energy; W_f denotes the work done by frictional force, (J); U_0 stands for gravitational potential energy, (J); k_0 represents the coefficient of dynamic friction; m is the mass of the grains, (g); g is the acceleration due to gravity, (m/s²); L_0 is the travel distance of the rice seeds on the inclined plane, (m).

From Equation 3, it could be observed that the proportion of lost energy to total energy was linearly related to the cotangent of the angle, with the coefficient of dynamic friction as the correlation factor. Therefore, by varying the angle α_0 between the inclined plane and the horizontal plane, it was possible to calculate the proportion of different lost energy to total energy. Subsequently, by performing a linear regression, the relationship between C_0 and $\cot\alpha_0$ could be fitted, with the slope of the fitted line represented the coefficient of dynamic friction.

Elastic Modulus

The experiment utilized a TMS food physical performance analyzer from FTC, as shown in Figure 3, to evaluate the elastic modulus, shear modulus, and Poisson's ratio of rice seeds. The sensor had a measurement range of 0–2000 N, with an accuracy of 0.015% and a data acquisition frequency of 10 Hz. To reduce the risk of cracking in white rice seeds during testing, the samples were prepared by trimming their axial ends. The height, width, and thickness of each sample were measured to calculate the cross-sectional area. The elastic modulus is a critical parameter that reflects the seeds' resistance to deformation under external forces. This mechanical property is essential for evaluating seed stability within seeders and their capacity to withstand pressure and impact during handling and movement in direct-seeding equipment.

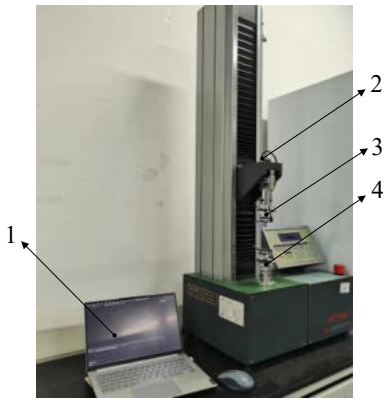

Fig. 3 - Mechanical properties test instrument

(1) Data Acquisition Device; (2) Sensor; (3) Compression Probe; (4) Baseplate

In the compression experiments, the elastic modulus of rice seeds was determined as the ratio of stress to strain. When a force was applied to a sample with a known cross-sectional area and initial length, the sample underwent deformation. Within the elastic range, stress was defined as the applied force per unit area, while strain was defined as the deformation per unit length. By measuring these two parameters, the elastic modulus was calculated according to Equation (4).

$$\begin{cases} E_1 = \frac{\sigma_0}{\varepsilon_0} \\ \sigma_0 = \frac{F_0}{A_0} \\ \varepsilon_0 = \frac{\Delta L_1}{L_1} \end{cases} \quad (4)$$

where:

E_1 is the elastic modulus of the rice seed, (MPa); σ_0 is the stress acting on the rice seed, (MPa); ε_0 is the strain of the rice seed; F_0 is the force applied axially to the rice seed, (N); A_0 is the cross-sectional area of the rice seed, in square meters (m^2); $\triangle L_1$ is the length of the cross-section, (m); and L_1 is the deformation of the cross-section, (m).

To measure the elastic modulus of rice seeds, 10 grains were randomly selected from various samples and the moisture content for the white rice treatment group was adjusted. During the compression test, the compression probe was configured to move at 20 mm/min, with a test speed of 1 mm/min and a return speed of 50 mm/min. The maximum testing distance was set to 60% of the specimen's length.

Shear Modulus

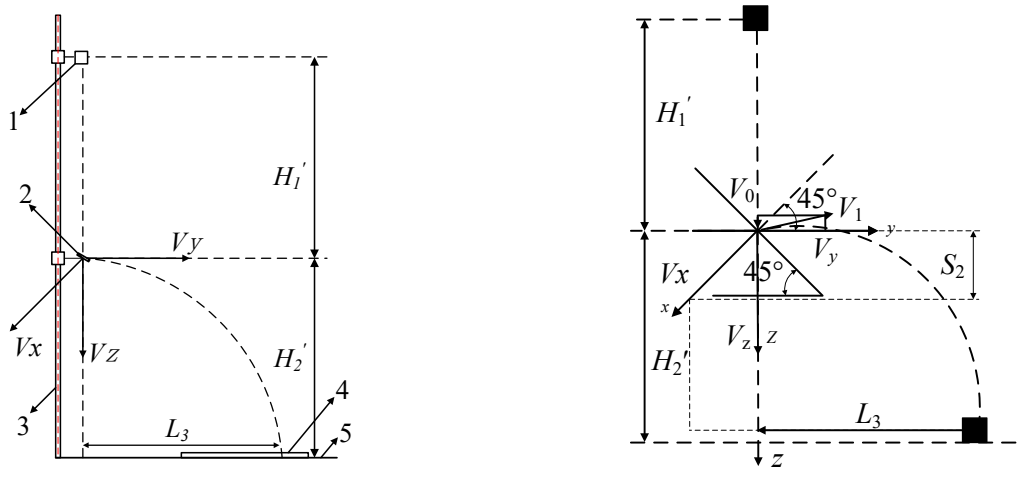
The preparation of test samples and the experimental procedure followed the same methodology used for measuring the elastic modulus, with calculations provided in Equation (5). Prior to the experiment, the following parameters were configured: the probe's moving speed was set to 20 mm/min, the test speed to 1 mm/min, and the initial pressure to 0.1 N. The maximum testing distance was set to 120% of the specimen's original length, and during the return phase, the return speed was adjusted to 50 mm/min.

$$\begin{cases} E_2 = \frac{\tau_0}{\zeta_0} \\ \tau_0 = \frac{F_1}{A_1} \\ \zeta_0 = \frac{\Delta L_2}{L_2} \end{cases} \quad (5)$$

where:

E_2 is the shear modulus of the rice seed, (MPa); τ_0 is the shear stress acting on the rice seed, (MPa); ζ_0 is the shear strain of the rice seed; F_1 is the force applied to the cross-section of the rice seed, (N); A_1 is the area on which the force is applied on the upper surface of the rice seed, (m²); $\triangle L_2$ is the distance moved on the upper surface, (m); and L_2 is the deformation of the upper surface, (m).

Coefficient of Restitution



A coefficient of restitution of 1, 0, and less than 1 respectively indicated that the collision of particles was perfectly elastic, perfectly inelastic, and partially inelastic. This signifies that particles could fully recover to their original state, particles could not recover to their original state, and there was energy loss in particles after collision. The calculation formula for the coefficient of restitution is shown in Equation 6.

$$e^2 = \frac{E_3}{E_4} \quad (6)$$

where:

e is the coefficient of restitution; E_3 is the energy after the collision, measured in joules, (J); and E_4 is the energy before the collision, (J).

Using the energy physics definition of the coefficient of restitution, a measurement model was established as depicted in Figure 4.

(a) **(b)**

Fig. 4 - Measurement principle of collision recovery coefficient

(1) Seed Drop Point; (2) Inclined Plane (45°); (3) Support Stand; (4) Coordinate Collection Plate; (5) Support Plate; (a) Measurement Principle; (b) Velocity Decomposition

In this model, a seed underwent free fall from a fixed height with an initial velocity of zero. Upon colliding with the contact material, the seed's velocity was decomposed into the x, y, and z axes. The collision height was set to a constant value. Due to the seed's geometric shape and instantaneous friction during the collision, it experienced displacement along the x and y axes post-collision. High-speed photography captured the entire sequence from collision to landing on the collection plate. By varying the contact test plate, the coefficient of restitution between the rice seed and different contact materials under various conditions could be determined.

One hundred rice seeds were individually dropped from the seeding point with zero initial velocity. During the descent, the seeds first encountered a 45° inclined plate, and then followed a projectile motion to land on the coordinate collection plate. To prevent the seeds from sliding on the coordinate collection plate, a layer of oil was applied to its surface. When the test rice seeds fell onto the coordinate collection plate at the bottom, the coordinate points of each experimental sample were statistically analyzed. Based on this, IBM SPSS software was used to post-process the data of each variety to determine the center coordinates of the seeds and calculate the distance from the center point to the origin. The distance from the center point to the origin satisfies the Pythagorean theorem with the horizontal and tangential deviations of the seeds. During the experiment, a high-speed camera was used to measure the average time taken for the seeds to collide and fall. The formula for calculating the coefficient of restitution is shown in Equation 7.

$$e = \sqrt{\frac{E_3}{E_4}} = \sqrt{\frac{V_x^2+V_y^2+V_z^2}{2gH_1}} = \sqrt{\frac{S_2^2+L_3^2+\left(H_2-\frac{1}{2}gT_1{}^2\right)^2}{2gH_1T_1{}^2}} = \sqrt{\frac{D_1^2+\left(H_2-\frac{1}{2}gT_1{}^2\right)^2}{2gH_1T_1{}^2}} \quad (7)$$

where:

V_x is the velocity component along the x-axis of the rice seed after collision, (m/s); V_y is the velocity component along the y-axis of the rice seed after collision, (m/s); V_z is the velocity component along the z-axis of the rice seed after collision, (m/s); g is the acceleration due to gravity for the rice seed, (9.8 m/s²); S_2 is the tangential deviation distance of the rice seed's motion after collision, (m); L_3 is the horizontal deviation distance of the rice seed's motion after collision, (m); D_1 is the distance from the center to the origin, (m); and T_1 is the average time taken for the rice seed to fall after collision, (s).

External Load and Survival Characteristics

Initially, 10 rice seed varieties under different conditions were selected, with each variety divided into 3 groups of 50 seeds. The moisture content for the white exposure treatment group was adjusted accordingly. Seeds that met sowing criteria were secured in a prone position on the base of a mechanical testing instrument. A rigid probe head served as the flat probe, descended at 2 mm/min and applied a load started from 0 N, increased by 5 N per test group along the seed embryo's thickness. Afterwards, samples were placed in planting pots within a controlled environment at 20°C to 25°C with appropriate lighting, as shown in Figure 5.

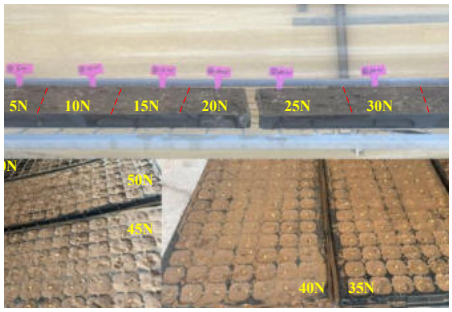


Fig. 5 - External static load and survival test

The non-white exposure group was watered twice daily to ensure thorough soil saturation. After germination and stabilization, the growth continuation percentage post-load was calculated for each sample group, based on consistent data over three consecutive days.

Cutting and Seedling Characteristics

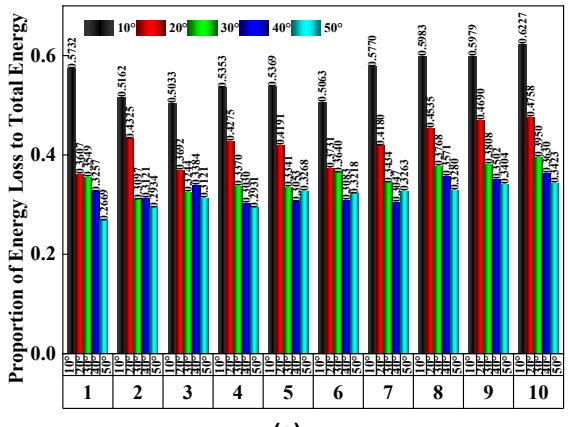
Ten different varieties of rice seeds in different conditions were selected for this study. Specifically, three groups of each variety, with 50 rice seeds in each group, were chosen as experimental samples. The moisture content of the rice seeds in the white exposure treatment group was adjusted accordingly. Each group of experimental samples has the rice seeds cut along the embryonic axis, with the embryo length being approximately 3 mm. Therefore, the difference in embryo length cut each time is 0.5 mm. The rice seeds after cutting were then used for sowing experiments to evaluate their ability to continue surviving based on their germination status. The experimental process and methods were the same as those in the External Load and Survival Characteristics test. By analyzing the experimental data, the relationship between cutting length and survival rate was determined.

RESULTS AND ANALYSIS

Experiment Results and Analysis of Static Friction Coefficient

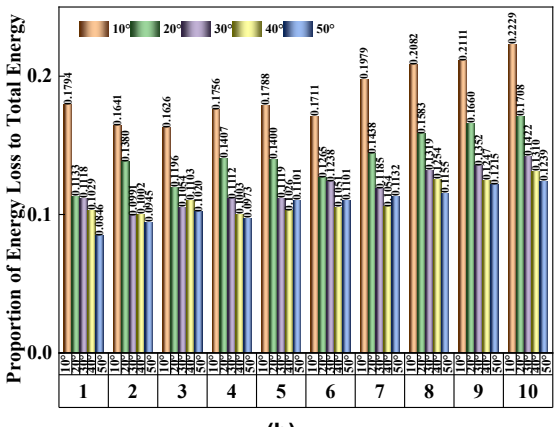
ABS resin was chosen as a contact material and various materials were affixed to an inclined surface on a custom static friction coefficient measurement device. Seed boards were created by attaching rice seeds to resin boards, simulating seed-to-seed contact. A brush board was made by attaching brush material to resin boards to simulate seed-to-brush contact, reflecting common seeding device configurations. This setup enabled separate measurement of static friction coefficients between rice seeds, and between seeds and ABS plastic or brush materials. High-speed photography captured the angle at which the inclined surface was gradually raised. These angle values were substituted into a formula to calculate the static friction coefficients. The experimental results were detailed in Table 1.

Table 1



Static friction coefficient test results

Experiment Rice Seeds	Contact Materials			Experiment Rice Seeds	Contact Materials		
	Rice Seeds	ABS	Brushes		Rice Seeds	ABS	Brushes
G_1-M_1	0.36	0.28	0.32	G_2-M_1	0.54	0.42	0.46
G_1-M_2	0.39	0.30	0.34	G_2-M_2	0.64	0.48	0.52
G_1-M_3	0.41	0.29	0.33	G_2-M_3	0.61	0.46	0.50
G_1-M_4	0.36	0.23	0.26	G_2-M_4	0.52	0.37	0.41
G_1-M_5	0.31	0.20	0.24	G_2-M_5	0.54	0.39	0.42
G_1-M_6	0.34	0.23	0.26	G_2-M_6	0.59	0.45	0.49
G_1-M_7	0.37	0.25	0.29	G_2-M_7	0.55	0.40	0.44
G_1-M_8	0.33	0.22	0.25	G_2-M_8	0.59	0.43	0.48
G_1-M_9	0.37	0.23	0.27	G_2-M_9	0.63	0.47	0.51
G_1-M_{10}	0.35	0.21	0.25	G_2-M_{10}	0.61	0.44	0.48



The analysis indicated that the rice seed variety had minimal impact on the static friction coefficient, while the moisture content had a significant effect. For dry seeds, the static friction coefficients between seeds, between seeds and ABS plastic, and between seeds and a brush were in the ranges of 0.31 to 0.41, 0.20 to 0.30, and 0.24 to 0.34, respectively. After chitting treatment, these values increased to 0.52–0.64, 0.37–0.48, and 0.41–0.52, respectively. This is because the increased moisture enhanced the adhesion forces, thereby raised the static friction coefficient and reduced the flowability. Further analysis reveals that at the same moisture level, the friction between rice seeds was higher than that between seeds and ABS plastic, suggesting that the surface of rice seeds was rougher and that the flowability on the ABS plastic surface was better.

Experiment Results and Analysis of Dynamic Friction Coefficient

Rice seeds were placed at a certain height on an inclined plane with a certain angle to the horizontal plane and were initially at rest before sliding along the incline. By analyzing high-speed photography videos, the coordinates of the seeds in each frame could be obtained, with the experimental data extracted a time interval of 0.001 s between two frames. The experiment involved selecting five incline angles ranged from 10° to 50°, with 10 seeds of each variety tested for each angle and the average value taken. The experimental results were shown in Figure 6.

(a)

(b)

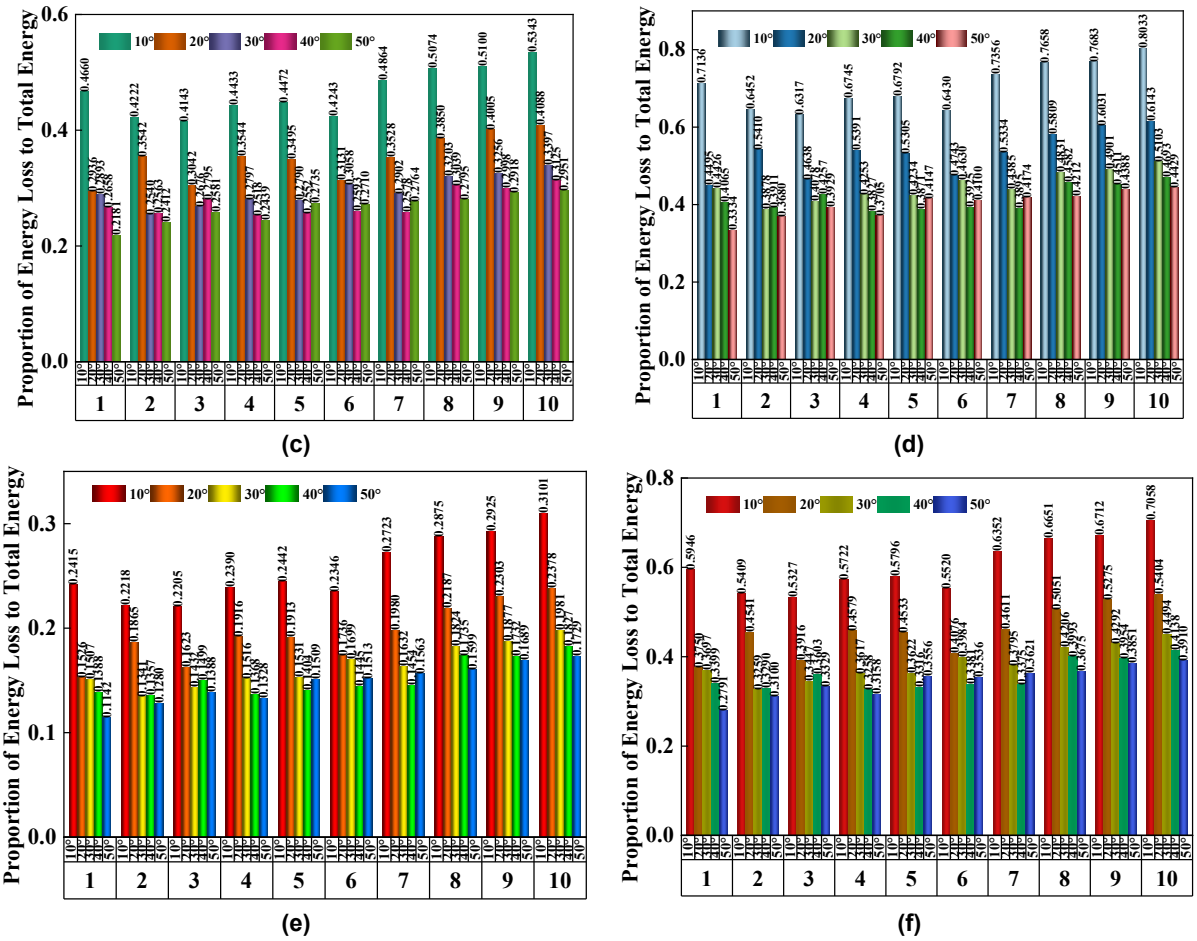


Fig. 6 - Dynamic friction coefficient test results

(a) G_1 Rice Variety - G_1 Rice Variety (b) G_1 Rice Variety - ABS Material (c) G_1 Rice Variety - Bristle Brush
(d) G_2 Rice Variety - G_2 Rice Variety (e) G_2 Rice Variety - ABS Material (f) G_2 Rice Variety - Bristle Brush

The results indicated that whitening treatment increased the energy loss proportion in rice varieties, suggested greater energy dissipation on the contact surface and a higher friction coefficient. As the angle increased, energy loss proportion decreased due to the conversion of gravitational potential energy into kinetic energy and frictional heat, with shorter incline travel time reducing energy loss. Among different conditions, energy loss was greatest between rice varieties, followed by rice varieties with bristle brushes, and lowest with ABS materials, highlighting better flowability on ABS. Linear fitting of the energy loss proportion (C_0) against cot α_0 for each contact material yielded the dynamic friction coefficients k_0, as shown in Table 2.

Table 2

Coefficient of dynamic friction between different kinds of rice and different materials

Experiment Rice Seeds	Materials			Experiment Rice Seeds	Materials		
	Rice Seeds	ABS	Brushes		Rice Seeds	ABS	Brushes
G_1-M_1	0.0601	0.0181	0.0427	G_2-M_1	0.0724	0.0242	0.0601
G_1-M_2	0.0494	0.0151	0.0391	G_2-M_2	0.0599	0.0203	0.0499
G_1-M_3	0.0411	0.0124	0.0321	G_2-M_3	0.0490	0.0168	0.0411
G_1-M_4	0.0547	0.0167	0.0472	G_2-M_4	0.0648	0.0227	0.0547
G_1-M_5	0.0515	0.0158	0.0398	G_2-M_5	0.0607	0.0215	0.0515
G_1-M_6	0.0426	0.0131	0.0329	G_2-M_6	0.0501	0.0179	0.0426
G_1-M_7	0.0615	0.0191	0.0472	G_2-M_7	0.0716	0.0262	0.0615
G_1-M_8	0.0613	0.0193	0.0496	G_2-M_8	0.0709	0.0263	0.0612
G_1-M_9	0.0611	0.0192	0.0466	G_2-M_9	0.0703	0.0264	0.0611
G_1-M_{10}	0.0657	0.0207	0.0499	G_2-M_{10}	0.0751	0.0286	0.0657

The results showed that in dry conditions, the average dynamic friction coefficients were 0.0411 to 0.0657 between rice varieties, 0.0124 to 0.0207 with ABS, and 0.0321 to 0.0499 with bristle brushes. After whitening treatment, these coefficients increased to 0.0490 to 0.0751, 0.0168 to 0.0286, and 0.0411 to 0.0657, respectively. Higher moisture content elevates these coefficients, reducing flowability. The order of dynamic friction coefficients, from highest to lowest, was: rice seeds, bristle brushes, and ABS material. This indicates that rice seeds flow most easily over ABS surfaces, but exhibit greater resistance when interacting with other seeds. These findings provide important insights for future structural design considerations.

Elastic Modulus

After each sample test, the pressure versus displacement curve was exported using software compatible with the testing machine. Stable data before the yield point was selected, and stress and strain values were calculated to determine the elastic modulus, as shown in Table 3. Differences in the elastic modulus were observed at varying moisture contents. As moisture content increased, the elastic modulus decreased, as higher moisture reduced cohesion between seeds, leading to decreased stiffness. In dry conditions, the elastic modulus ranged from 365.27 to 418.19 MPa, while chitting treatment reduced it to 180.92 to 209.15 MPa.

Table 3

Elastic modulus test results

Experiment Rice Seeds	Elastic Modulus/MPa	Experiment Rice Seeds	Elastic Modulus/MPa
G_1-M_1	365.27	G_2-M_1	206.37
G_1-M_2	371.96	G_2-M_2	194.12
G_1-M_3	379.60	G_2-M_3	200.35
G_1-M_4	377.72	G_2-M_4	209.15
G_1-M_5	388.63	G_2-M_5	192.56
G_1-M_6	398.74	G_2-M_6	183.01
G_1-M_7	376.26	G_2-M_7	204.54
G_1-M_8	410.45	G_2-M_8	184.49
G_1-M_9	407.03	G_2-M_9	180.92
G_1-M_{10}	418.19	G_2-M_{10}	184.70

Shear Modulus

During the shear modulus testing process, the same experimental method as the elastic modulus was used to process the data of the samples to obtain the shear modulus of the samples, and the test results were shown in Table 4. The analysis of the results revealed that there were differences in the shear modulus of rice seeds at different moisture contents. With an increase in moisture content of each rice seed, the shear modulus of the test sample showed a decreasing trend. When rice seeds are in dry condition, the shear modulus ranged from 137.38 to 151.88 MPa. When rice seeds underwent chitting treatment, the shear modulus ranged from 74.08 to 82.45 MPa.

Table 4

Shear modulus test results

Experiment Rice Seeds	Shear Modulus/MPa	Experiment Rice Seeds	Shear Modulus/MPa
G_1-M_1	137.38	G_2-M_1	81.58
G_1-M_2	139.27	G_2-M_2	77.69
G_1-M_3	141.51	G_2-M_3	79.76
G_1-M_4	140.89	G_2-M_4	82.45

Impact Restitution Coefficient Test Results and Analysis

The test results for the impact restitution coefficient, as outlined in Table 5, indicated a positive correlation between the moisture content of rice seeds and their deformation upon collision.

Higher moisture content resulted in increased deformation, led to greater energy loss during impact, thus reduced the normal separation velocity and subsequently the impact restitution coefficient. In dry conditions, the impact restitution coefficient ranged from 0.412 to 0.471 between rice seeds, 0.438 to 0.501 between rice seeds and ABS material, and 0.454 to 0.519 between rice seeds and brush. After chitting treatment, these values decreased to 0.351 to 0.408, 0.357 to 0.414, and 0.396 to 0.460, respectively. The coefficients were ranked from highest to lowest as follows: rice seeds and brush, rice seeds and rice seeds, and rice seeds and ABS material, across both states of the rice seeds.

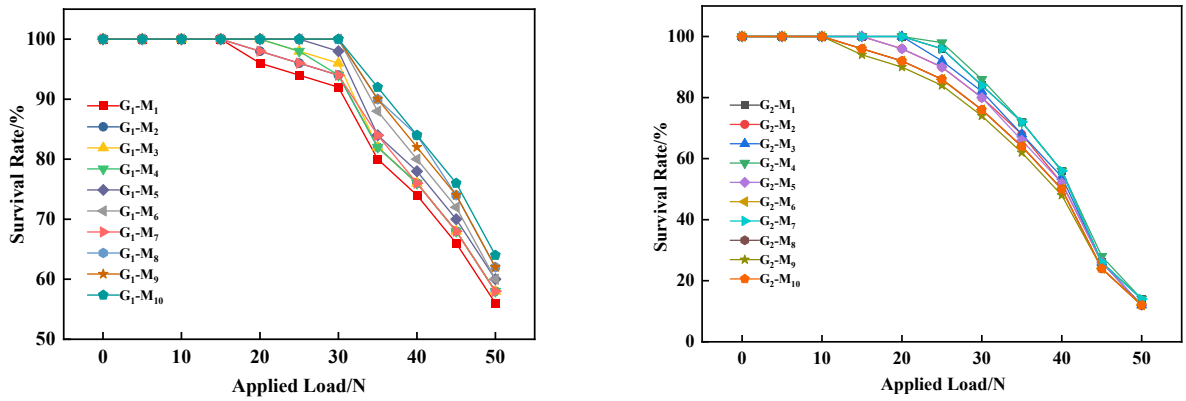

Table 5

Experimental results of collision recovery coefficient

Experiment Rice Seeds	Impact Contact Materials			Experiment Rice Seeds	Impact Contact Materials

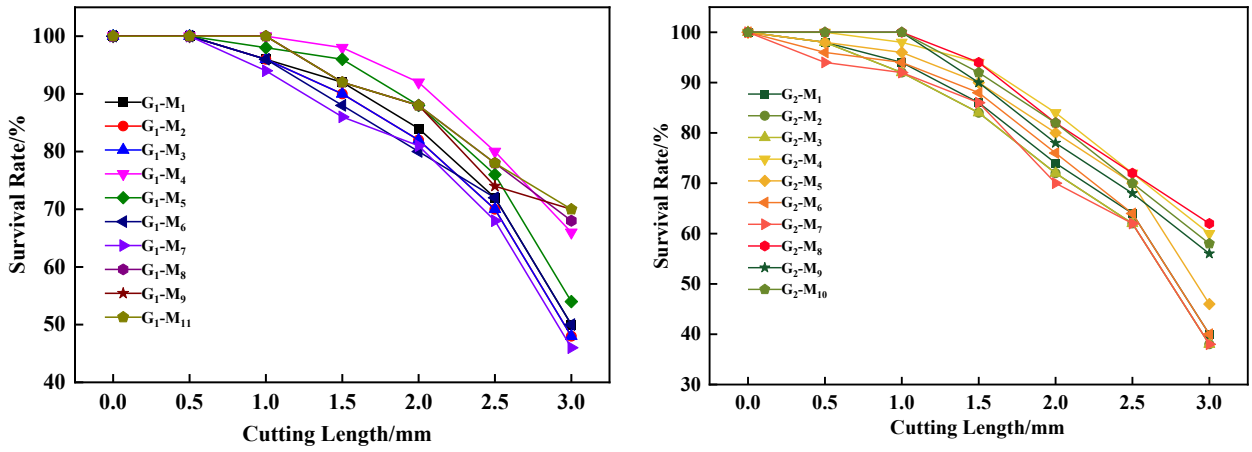
External Load and Survival Characteristics Test Results and Analysis

After the external load and survival characteristics test method, static loads ranged from 0N to 50N were applied to the test samples. The resulting data was used to plot a load-survival rate curve, as shown in Fig. 7.

(a) (b)

Fig. 7 - Survival rate and applied load curve of rice seeds



(a) Dry Rice Seeds (b) Chitting Treatment

Analysis revealed a decline in the survival rate of rice seeds with increased static load. For the same type of seeds, higher moisture content correlated with a reduced ability to withstand static loads, making them more susceptible to breakage. In dry conditions, survival rates ranged from 62% to 100%, but rapidly dropped below 90% when loads exceeded 35N. For seeds undergoing chitting treatment, survival rates ranged from 12% to 100%, with a noticeable declined when loads exceeded 20N, and a rapid dropped below 90% beyond 25N. Further analysis indicated that excessive static loads compromised seed survival by rupturing the surface membrane, disrupting moisture regulation, and impairing germination and growth. The data showed that external loads up to 20N did not significantly impact germination, with survival rates remaining above 92%. These findings suggest that, during direct seeding, rice seeds can withstand certain levels of external load without compromising viability.

Cutting and Seedling Characteristics

Using the experimental method for cutting and seedling characteristics, cuts were made along the embryo axis of rice seeds at lengths from 0 mm to 3 mm. A relationship curve between cutting length and survival rate was plotted, as shown in Figure 8.

The results indicated that survival rates decreased with increased cutting length, underscored the critical impact of embryo damage on seed survival. In dry conditions, survival rates ranged from 48% to 100%, with a rapid decline beyond 1.5 mm. For seeds undergoing chitting treatment, survival rates ranged from 38% to 100%, with a noticeable drop below 90% when the cutting depth exceeded 1.0 mm. Further analysis showed that seeds with larger three-axis dimensions exhibited slightly higher survival rates under the same cutting length. Additionally, higher moisture content enabled seeds to maintain survival rates above 90% when cutting lengths did not exceed 1.5 mm. These findings suggest that during direct seeding, minor damage to seeds does not significantly impact survival, provided that the cutting depth remains within these thresholds.

CONCLUSIONS

The study's methodology and results offered a robust theoretical foundation and data support for optimizing planter design, constructing theoretical models for various processes, and conducting virtual simulations. The main conclusions were as follows.

For untreated rice seeds, static friction coefficients with seeds, ABS plastic, and bristle plates ranged from 0.31-0.41, 0.20-0.30, and 0.24-0.34, respectively, with dynamic coefficients at 0.0411-0.0657, 0.0124-0.0207, and 0.0321-0.0499. Post-chitting, static coefficients increased to 0.52-0.64, 0.37-0.48, and 0.41-0.52, with dynamic coefficients at 0.0490-0.0751, 0.0168-0.0286, and 0.0411-0.0657.

For untreated seeds, the restitution coefficients with seeds, ABS plastic, and bristle plates were 0.412-0.471, 0.438-0.501, and 0.454-0.519. After chitting, these stabilized at 0.351-0.408, 0.357-0.414, and 0.396-0.460, respectively. Untreated seeds showed an elastic modulus of 365.27-418.19 MPa, shear modulus of 137.38-151.88 MPa. Chitting reduced these values to 180.92-209.15 MPa, 74.08-82.45 MPa.

Under dry conditions, maintaining an external load below 20 N and a cutting length under 1.5 mm ensured seed survival rates above 90%. While this study provided a comprehensive analysis of the frictional and mechanical properties of rice seeds, it did not include calibration experiments for key parameters, which represents a noted limitation of the research.

ACKNOWLEDGEMENT

We are grateful to the Henan Provincial Science and Technology Attack Project/Henan Nanyang Municipal Science and Technology Attack Project for its financial support under grant number 252102111175/2024KJGG0102. We also extend special thanks to the National Engineering Research Center for Agricultural Intelligent Equipment for its contributions to this research.

Keywords: *rice straw; adjustable wrapping machine; straw bale; tensile film*

ABSTRACT

China annually produces over 210 million tons of rice straw; however, its utilization as feed remains low due to the scarcity of supporting equipment. In feed production, wrapping straw bales with plastic film is crucial for accelerating degradation. Given the diverse types of straw balers, a variety of wrapping machines are required. This study presents the design of an adjustable wrapping machine capable of handling straw bales with diameters ranging from 400 to 1200 mm and lengths between 500 - 1000 mm. Wrapping time, coefficient of variation, and elongation rate were selected as key evaluation indicators. Experimental results demonstrate that all performance metrics comply with industry standards for straw bale machinery, indicating the machine's practical feasibility and reliability in agricultural applications.

摘要

中国水稻秸秆年产量在 2.1 亿吨以上，但饲料化利用率仍然很低，其原因是缺少配套的装备，饲料化生产需要利用塑料膜包裹稻草捆以加速降解。由于秸秆打包机类型较多，故此需要不同型号的包膜机与之相匹配。本工作设计了一种可调包装机，可实现直径 400~1200mm、长度 500~1000mm 的稻草捆进包膜处理。选取缠绕时间、变异系数和伸长率作为评价指标，通过包膜检验包膜效果。结果表明，各项指标均达到了秸秆包捆机械的行业标准。

INTRODUCTION

China boasts a colossal crop straw yield, with annual production reaching 800 million tons—equivalent to 30% of the global total, ranking first worldwide (*Tian, 2020; Cong et al., 2021; Zhang et al., 2021*). Among this, rice straw contributes 210 million tons yearly, accounting for approximately one - fourth of China's total crop straw resources *(Li et al., 2020; Lu et al., 2021; Liu, 2024*). However, current utilization methods (Fig. 1) remain inefficient. Burning straw for heat or char production results in low calorific value and causes environmental pollution. Returning straw to the soil offers limited economic benefits and increases the risk of pests. Industrial applications, such as the production of low-quality paper and rope, are hindered by high costs associated with collection, transportation, and labor (*Wang et al., 2017; Huo et al., 2019; Feng et al., 2021; Cong et al., 2019*). In contrast, feed utilization has emerged as a promising solution, offering economic benefits without causing environmental harm.

Nevertheless, raw rice straw is unpalatable and nutritionally inadequate for livestock, necessitating degradation and fermentation before being used as feed. Transforming rice straw into feed not only optimizes resource utilization (*Liu, 2021; Huo et al., 2022; Gu et al., 2017*) but also alleviates forage shortages, thereby benefiting animal husbandry.

In the rice straw feed production process, key steps include bundling, spraying decay agents, wrapping bales with plastic film, and fermenting. These treatments reduce crude fiber content while increasing protein and soluble sugar levels, thus boosting livestock feeding rates.

Liyan Wu, Prof. Ph.D. Eng.; Huchao Tan, Na Zhang, Hengyi Wei, Zhenyu Wang, M.S. Stud. Eng.; Chunhua Ban, engineer; Cuihong Liu Prof. Ph.D. Eng.

Commercially available wrapping machines struggle to accommodate straw bales of diverse sizes (with diameters ranging from 500 to 1200 mm and lengths from 500 to 1000 mm). In response, this study developed an adjustable wrapping machine compatible with various balers. Following tests and analysis of the mechanical properties of wrapping plastic films, the machine's structure was designed, and subsequent wrapping tests were conducted. Key parameters—including wrapping time, variation coefficient, and film elongation rate—were evaluated. These findings not only significantly enhance rice straw feed production efficiency but also provide valuable insights for the design of wrapping machinery for other crops and grasses.

MATERIALS AND METHODS

Prior to designing the adjustable rice straw wrapping machine, a study on the mechanical characteristics of the tensile film was conducted. The test results will provide basic data for the subsequent determination of motion parameters, rotational speed, and the overall structural design of the machine.

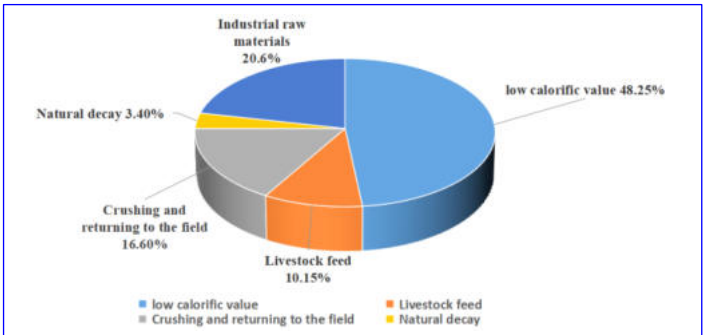

Fig. 1 - Different utilization of rice straw

Materials and Instruments

Tensile film: Antioxidant silage tensile film (thickness: 0.025 mm; width: 250 mm; material: linear low-density polyethylene (LLDPE)), produced by Shandong Xinlian Heavy Industry Agriculture and Animal Husbandry Machinery Company.

Test instrument: Universal material tensile testing machine. The sensor has a measuring range of 2 mN–2 kN with an accuracy of ±1% or better. The loading speed is adjustable within the range of 0.01–500 mm/min.

Methods

The operation process includes 5 steps: sample preparation, length and width determination, calibration, testing, and data processing. A quadratic orthogonal rotation combination test scheme was adopted, with tensile film length (X_1), width (X_2), and loading speed (X_3) set as the test factors. According to the test requirements, the levels of the test factors are represented by the coded values -1.628, -1, 0, 1, and 1.628. The corresponding relationship between the coded values and actual values of the test scheme is shown in Table 1.

Table 1

Factor level coding

Levels	Factors		
	Length X_1/(mm)	Stretch film width X_2/(mm)	Loading speed X_3/ (mm/min)
-1.682	70	18	60
-1	100	23	75
0	150	30	100
1	200	37	125
1.682	230	42	140

In accordance with the national standards "Determination of Tensile Properties of Plastic Films" (GB/T 13022-91) and "Test Conditions for Films and Sheets in the Determination of Plastic Tensile Properties" (GB/T 1040-2006), the maximum tensile force (Y1) and elongation at break (Y2) were designated as the test indicators. Tensile film samples were cut neatly, as illustrated in Fig. 2.

Y1, the maximum force at which the film breaks.

ε_t, elongation rate calculated by Equation (1).

$$\varepsilon_t = \frac{L - L_0}{L_0} \times 100\% \quad (1)$$

where:

L_0—original length of the tensile film, [mm];

L—length after breaking, [mm].

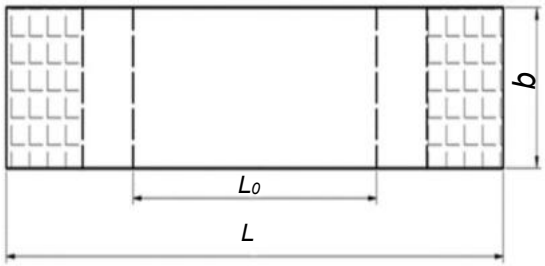

Fig. 2 - Tensile test device

RESULTS AND ANALYSIS

Establishment of tensile film model

Using Design-Expert 12.0 software, an analysis of the test factors and indicators was conducted to determine the influence of each factor. The test scheme and corresponding results are presented in Table 2.

Table 2

Test scheme and results

Test number	Test factors			Test indicators	
	Mold length X1 / (mm)	Film width X2 / (mm)	Loading speed X3 / (mm/s)	Maximum breaking force Y1 / (N)	Elongation rate Y2 / (%)
1	-1	-1	-1	16.2	262.7
2	1	-1	-1	12.6	212.1
3	-1	1	-1	21.1	283.4

22	0	0	0	10.3	235.9
23	0	0	0	9.9	227.4

Establishment of regression model of the maximum breaking force

The regression equation composed of primary, quadratic and interaction terms are obtained, equation (2). This regression equation expressed the relationship of the maximum breaking force Y1 and the three factors, the film length X1, width X2, and the loading speed of X3.

$$\hat{Y_1} = 10.78 - 1.53X_1 + 3.13X_2 - 0.97X_3 + 0.66X_1X_3 + 0.79X_2X_3 = 1.88{X_1}^2 + 1.92{X_2}^2 \quad (2)$$

The significance of the regression equation was tested using ANOVA, and the results are presented in Table 3.

Table 3

Variance analysis of experiment results Y_1

Variance source	Square sum	Degrees of freedom	Mean square	F-value	P-value
Mold	301.84	9	33.54	47.30	< 0.0001**
X_1	31.94	1	31.94	50.45	< 0.0001**
X_2	133.53	1	133.53	188.33	< 0.0001**
X^3	12.93	1	12.93	18.23	0.0009**
X_1X_2	0.15	1	0.15	0.21	0.6518
X_1X_3	3.51	1	3.51	4.95	0.0444*
X_2X_3	4.96	1	4.96	7.00	0.0202*
X_1^2	56.18	1	56.18	79.24	< 0.0001**
X_2^2	58.32	1	58.32	82.25	< 0.0001**
X_3^2	1.33	1	1.33	1.68	0.1939
Residual	9.22	13	0.71		
Lost proposal	6.30	5	1.26	3.45	0.0869
Error term	2.92	8	0.36		
Aggregate	311.06	22			

Note: * * Most significant level (p <0.01); * significant level (p <0.05).

As showed in Table 3, the established model is highly significant ($P < 0.0001$), the P-values of the three factors X_1, X_2, X_3 are less than 0.05, indicate that each factor exerts a significant effect on the maximum breaking force. The lack-of-fit term (P=0.0869)>0.05) is non-significant, demonstrating that the model has a high degree of reliability. The order of influence of the three factors on the maximum breaking force is $X_2>X_1>X_3$. i.e., tensile film width> tensile film length > loading speed. Specifically:

The linear terms X_1, X_2 and X_3 have highly significant effects on the results ($P < 0.01$).

The interaction terms X_1X_3 and X_2X_3 exert significant effects ($p < 0.05$), while the interaction term X_1X_2 has a non-significant effect ($p > 0.05$).

The quadratic terms X_1^2 and X_2^2 show highly significant effects ($p < 0.01$), whereas the quadratic term X_3^2 has a non-significant effect ($p > 0.05$).

Establishment of regression model of the elongation rate

Through fitting the test results using Design-Expert 12.0 software, a regression equation incorporating linear terms, quadratic terms, and interaction terms was derived, as shown in Equation (3). This regression equation characterizes the relationship between the elongation (Y_2) and the three factors: tensile film length (X_1), width (X_2), and loading speed (X_3).

$$\hat{Y_2} = 238.08 - 19.52X_1 + 11.47X_2 - 10.70X_3 + 6.94X_1X_2 + 7.79X_2X_3 + 5.71{X_3}^2 \quad (3)$$

This regression equation is tested with ANOVA, and the results are shown in Table 4.

Table 4

Variance analysis of Y_2

Variance source	Square sum	Degrees of freedom	Mean square	F-value	P-Value
Mold	10121.78	9	1124.64	18.93	< 0.0001**
X_1	5201.47	1	5201.47	78.67	< 0.0001**
X_2	1796.81	1	1796.81	27.17	0.0010**
X_3	1563.72	1	1563.72	23.65	0.0003**
X_1X_2	385.03	1	385.03	5.82	0.0313*
X_1X_3	114.76	1	114.76	1.74	0.2104
X_2X_3	485.16	1	485.16	7.34	0.0179*
X_1^2	154.65	1	154.65	2.34	0.1501
X_2^2	110.11	1	110.11	1.64	0.8900
X_3^2	522.79	1	522.79	7.91	0.0147*
Residual	859.58	13	66.12		
Lost proposal	586.66	5	117.37	3.44	0.0590
Error term	272.72	8	34.09		
Aggregate	11080.08	22			

Note: * * Most significant level (p <0.01); * significant level (p <0.05).

As can be seen from Table 4, the established model is significant ($P < 0.0001$), the P-value of the three factors X1, X2, X3 are all less than 0.05, indicating that the three factors have a significant impact on the elongation. The lack of fit term (P(0.059)>0.05) is not significant, which suggests that the model has a high degree of reliability. The order of influence of the three factors on the elongation Y2 is X1 > X2 > X3, i.e., the film length X1 > width X2 > loading speed X3. Specifically:

The linear terms (primary terms) X1, X2, and X3 all have a highly significant effect on the results (P < 0.01).

The interaction terms X1X2 and X2X3 have a significant effect (P < 0.05), while the interaction term X1X3 has no significant effect (P > 0.05).

The quadratic term (secondary term) X3 has a significant effect on the results (P < 0.05), whereas the quadratic terms X1 and X2 have no significant effect (P > 0.05).

Overall structure of the machine

The adjustable wrapping machine is designed for wrapping rice straw bales of varying sizes, consisting primarily of a frame, an adjustable roller mechanism, a rocker mechanism, a film-supplying mechanism, a lifting mechanism, and a transmission system. The adjustable roller, rocker mechanism, and transmission system are all motor-driven.

The adjustable roller mechanism is mainly composed of two rollers and a circulating reciprocating drive device, where the latter consists of a stepper motor, left- and right-hand screws, rails, and sliding blocks. This mechanism is capable of lifting straw bales with diameters ranging from 500 to 1200 mm. The transmission system drives the rollers to rotate the straw bale.

The rocker mechanism comprises a rocker arm, a frame, and a gear motor. The overall structure of the adjustable straw bale wrapping machine is illustrated in Fig. 3.

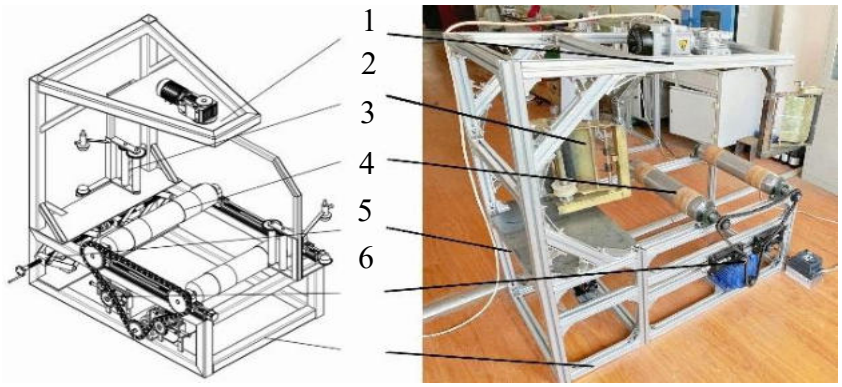

Fig. 3 - The overall structure of the machine

1- Rocker mechanism; 2-Film supplying mechanism; 3-Adjustable roller mechanism; 4-Lifting mechanism; 5-Chain tensioning mechanism; 6-Frame

Working principle

Before operation, the distance between the two rollers is adjusted to an appropriate position by moving the sliding blocks according to the size of the straw bale. The straw bale is then placed on the supporting rollers. Via the lifting mechanism, the symmetrical center plane of the film-feeding mechanism is aligned with the center plane of the straw bale. Subsequently, the tensile film is threaded through the film-feeding rollers, preparing for the wrapping process.

During operation, the sprocket motor is activated to rotate the rollers, which in turn drives the straw bale to rotate around its axis. Simultaneously, the rocker mechanism is initiated, carrying the film-supplying mechanism to revolve around the straw bale. The tensile film is fed through the film-supplying rollers and exits with a certain degree of tension and elongation. Through the combined rotation of the straw bale and the rocker arm, the plastic film is wrapped around the bale.

In the wrapping process, the film-supplying mechanism and the straw bale rotate simultaneously, with their respective rotation planes perpendicular to each other. For each full rotation of the film, the straw bale rotates by a corresponding angle. When the tensile film completes its second rotation, it overlaps with the first rotation by a certain extent; this rotation continues until the wrapping process is finished.

For each batch of straw bales of the same size, the roller spacing and height only need to be adjusted once to meet operational requirements. The overall design of the machine complies with the standard DB21/T 3527-2021, featuring simple operation, a compact structure, and low noise. Relevant parameters of the machine are listed in Table 5.

Table 5

Main parameters of the whole machine

Name	Parametric
Mass / kg	380
Sizes / mm	1580×1140×1780
Drive method	Electric powered
Round bale size (Diameter×Length)	Φ500×500~Φ1200×1000
Number of film layers/layer	≧2
Operating efficiency/(pack/h)	50
Bunching rate /%	≧99

Theoretical analysis of the wrapping process

Force analysis of the wrapping process

During the wrapping process, the straw bale is subjected to several forces: its own gravity G, the tension from the tensile film F_{pull}, the normal support forces from the two rollers $F1$, $F2$, and the frictional forces between the rollers and the bale surface f_1, f_2 (*Li et al.,2018*), as illustrated in Fig.4.

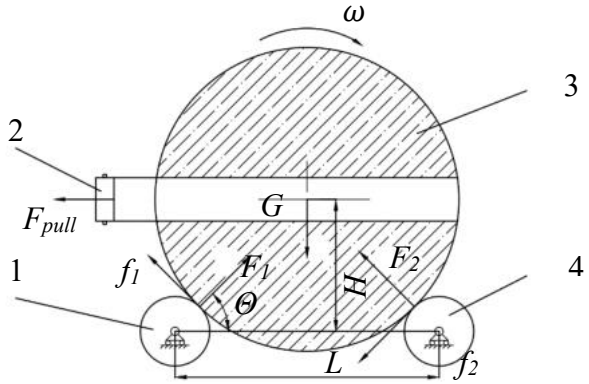

Fig. 4 - Stress analysis diagram of straw bale

1-Left roller; 2-Film roller; 3-Straw bale; 4-Right roller

The tensile force of the film significantly affects the quality and stability of the wrapping effect. Excessive tensile force can easily cause the straw bale to become unbalanced and roll. In such cases, the normal support force of the right roller becomes zero, and the frictional force between the right roller and the straw bale also vanishes. It is therefore necessary to analyze the forces acting on the bale in this critical state, as expressed in Equation (4) below:

$$F_{pull}L_1 = F_1\frac{L_1}{2}cos\,\theta - f_1\frac{L_1}{2}sin\,\theta \tag{4}$$

In Fig.4:

$$G = F_1\,sin\,\theta \tag{5}$$

$$f_1 = \mu F_1 \tag{6}$$

where:

F_{pull}— The pulling force exerted by the film on the straw bale, [N];

G— Gravity, [N];

F_1—The normal support force of the left roller, [N];

f_1—The friction between the left roller and the straw bale, [N];

L_1—The length of the straw bale, [mm];

μ—The coefficient of friction between the left roller and the straw bale;

θ—The angle between F_1 and the horizontal direction, [°].

From the above equation, it can be seen that in the process of wrapping, the F_{pull} should satisfy the following equation (7):

$$F_{pull} \le \frac{G}{2}(cot\theta - \mu) \tag{7}$$

Furthermore, based on equations from (4) to (6), the F_{pull} is related to the gravity of the bale, the friction coefficient between the bale and the rollers, and the angle between the support force and the horizontal line. For the maximum bale size is selected, its weight is approximately 72 kg. When the angle is 45°, the straw bale rotates most smoothly on the roller. With a friction coefficient of 0.78, the calculated F_{pull} value is 79.2N. Therefore, to ensure the smooth rotation of the straw bale during the wrapping process, the tensile force exerted by the film on the bale should be less than 79.2 N.

Determination of the speed ratio (i)

The overlap rate directly affects the quality of wrapping, fermentation efficiency, storage duration, and compactness of straw bales. Theoretically, more wrapping layers improve fermentation outcomes (*Zhang et al., 2017*), but in practical production, 2 layers of tensile film are sufficient to ensure effective fermentation. In this experiment, wrapping tests with 2, 4, and 6 layers of film were conducted to analyze film elongation performance and wrapping efficiency.

The overlap rate must be set reasonably: an excessively low rate results in poor sealing, which can easily lead to fermentation failure; while an excessively high rate, although ensuring good sealing, may cause film waste and significantly reduce efficiency. In this study, the film overlap rate was set at 50%, meaning each cycle of film covers half of the area wrapped in the previous cycle (*Zhang et al., 2019; Wang et al., 2024*). A schematic diagram of the overlap effect is shown in Fig. 5.

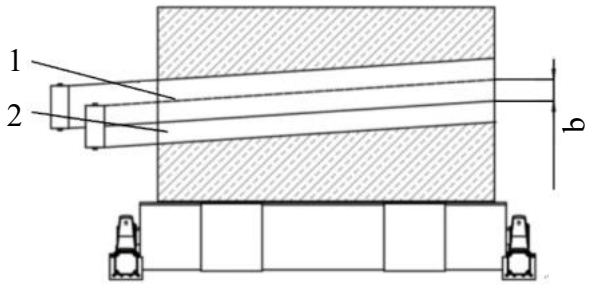

Fig. 5 - Overlapping diagram of straw bale

1 - First film; 2 - Second film

The overlap coefficient M of the tensile film can be calculated by Equation (8):

$$M = \left(\frac{b_1 - b}{b_1}\right) \times 100\% \tag{8}$$

And the following equations:

$$b = \omega r t \tag{9}$$

$$\omega = \frac{2\pi n_1}{60} \tag{10}$$

$$t = \frac{60}{n_2} \tag{11}$$

where:

M—Overlap coefficient of the tensile film, 50 %;

b_1—Width of the tensile film, 250 mm;

b—Staggered distance between two adjacent films, [mm];

ω—Angular speed of the roller, [rad/s];

r—Roller radius, 80 mm;

t—Time for the rocker to rotate around the bale, [s];

n_1—Roller speed, [r/min];

n_2—Rotational speed of the rocker, [r/min].

By substituting Equations (9) ~ (11) into Equation (8), M can be calculated using Equation (12).

$$M = \left(1 - \frac{2n_1}{n_2}\right) \times 100\% \tag{12}$$

Wrapping efficiency is determined by the roller speed and rocker speed. When the overlap rate (M) is 50%, the calculated speed ratio between the roller and the rocker arm (n_1/n_2) is approximately 0.25, which provides a basis for the design of the transmission mechanism.

DESIGN OF THE KEY COMPONENTS OF THE WHOLE MACHINE

Design of the adjustable roller mechanism

The adjustable roller mechanism, as illustrated in Fig. 6, mainly consists of two rollers, a stepper motor, a guideway, a sliding plate, a coupling, left- and right-hand threaded rods, and a limit block. During the wrapping process, the straw bale is placed on the two rollers, and the adjustable roller mechanism allows for the placement of straw bales with different diameters. In this study, the distance between the two rollers can be adjusted within the range of 466 mm to 960 mm to accommodate straw bales of varying sizes.

The two rollers are fixed to the ends of the sliding plates via bearing blocks. While the rollers drive the straw bale to rotate, the stepper motor drives the threaded rods to rotate, enabling the symmetrical movement of the sliding blocks.

1 - Roller; 2 - Reciprocating drive; 3 - Guideway 4 - Slider; 5 - Left and right rotating screws; 6 - Rolling bearing; 7 - Limit switch; 8 - Stepper motor

Design of the film supply mechanism

The film supply mechanism is mounted on the rocker arm (*Yang et al., 2020; Zhao et al., 2024*), consisting of upper and lower support rollers, two film supply rollers, a supply frame, a torsion spring, a film baffle, a sprocket, and a film roll. Its structure is illustrated in Fig. 7. The film is secured between the upper and lower support rollers, with the two film supply rollers positioned on the supply frame. The two film supply rollers are driven by a sprocket, which pulls the tensile film from the film roll.

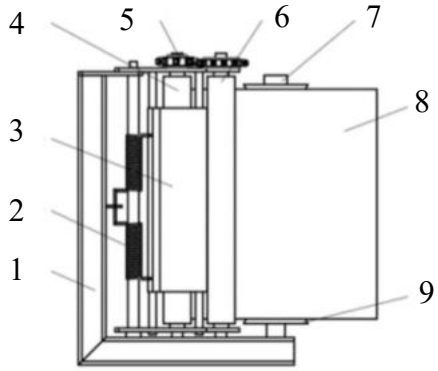

Fig. 7 - Schematic diagram of the film supplying mechanism
1 - Frame; 2 - Torsion spring; 3 - Baffle 4 - Supply rollers 5 - Sprocket; 6 - Supply rollers; 7 - Upper supporting roller; 8 - Film; 9 - Lower supporting roller

Rocker arm mechanism design

The rocker mechanism is primarily responsible for supporting the rocker arm and motor, while driving the rocker arm and film-supplying mechanism to rotate around the straw bale. Composed of a rocker arm, support frame, motor, and fixing plate (as shown in Fig. 8), the mechanism features a rocker motor connected to the middle of the rocker arm. The lower part of the rocker arm is positioned facing the adjustable roller mechanism, with its rotation center aligned with the symmetric central plane of the adjustable roller mechanism. This design prevents eccentricity.

PERFORMANCE TEST OF ADJUSTABLE RICE STRAW ROUND BALE WRAPPING MACHINE

Materials: Three sizes of rice straw bundles (400×400 mm, 500×500 mm, 600×600 mm) with good compaction were used in the test. All bundles were well compacted, free from protrusions or sharp edges, and had an average moisture content of 55%. Tensile film: The wrapping film used was linear low-density polyethylene (LLDPE) with a thickness of 0.025 mm and a width of 250 mm. It was supplied by Shandong Xinlian Heavy Industry Agriculture and Animal Husbandry Machinery Co., Ltd.

Methods: In accordance with the standards DB21/T 3527–2021 and NY/T 3121–2017, straw bales were divided into three groups by size (400×400 mm, 500×500 mm, 600×600 mm). Wrapping tests with 2, 4, and 6 layers of film were conducted for each group, with the following evaluation indicators:

Wrapping time

Defined as the time required to wrap a single straw bale. Five replicate tests were performed, and the average value was calculated.

Coefficient of variation of layers

For each bale size, 5 bales were randomly selected. At 5 randomly chosen positions on each bale, the tensile film was cut along the circumferential direction, and the average number of film layers at these 5 positions was recorded.

Elongation rate

Marker holes were punched in the middle of the film roll, with tracers inserted into the holes as reference marks. After wrapping, the positions of these marker holes were identified on the bale surface, and the distance between two adjacent holes was measured as L. The elongation rate (ε_t) was then calculated using Equation (13):

$$\varepsilon_t = \frac{L - L_0}{L_0} \times 100\% \quad (13)$$

where:

L is the distance between two marking holes after wrapping operation, and L_0 is actually the circumference of the film roll.

The rocking arm mechanism speed was set to 35 r/min, as referenced by *Yang, (2016)*. Based on the transmission ratio between the roller and the rocker arm (i = 0.25), the corresponding roller speed was calculated to be 8.75 r/min. The spacing between the two rollers was adjusted according to the size of the straw bale: 353 mm for 400×400 mm bales, 424 mm for 500×500 mm bales, and 495 mm for 600×600 mm bales.

RESULTS AND ANALYSIS

Wrapping time

The test results are presented in Table 6. Wrapping time varies depending on the specifications of the straw bales:

For 400×400 mm bales, the average wrapping times for 2, 4, and 6 layers were 18.6 s, 32.4 s, and 44.8 s, respectively.

For 500×500 mm bales, the average wrapping times for 2, 4, and 6 layers were 20.4 s, 33.6 s, and 45.2 s, respectively.

For 600×600 mm bales, the average wrapping times for 2, 4, and 6 layers were 21.4 s, 34.4 s, and 46.4 s, respectively.

All results meet the industry standards for straw bale wrapping machinery.

Table 6

Wrapping time of straw bales with different sizes

Number of wrapping layer	400×400 mm wrapping time /s					
	1	2	3	4	5	Average value
2	18	19	18	19	19	18.6
4	33	32	33	32	32	32.4
6	44	44	46	45	45	44.8
Number of wrapping layer	**500×500 mm wrapping time /s**					
	1	2	3	4	5	Average value
2	19	21	20	21	21	20.4
4	33	33	34	33	35	33.6
6	45	45	46	45	45	45.2
Number of wrapping layer	**600×600 mm wrapping time /s**					
	1	2	3	4	5	Average value
2	21	21	21	22	22	21.4
4	34	35	34	34	35	34.4
6	46	47	47	46	46	46.4

Coefficient of variation of layers

Fifteen groups of tests were conducted, with forty-five points randomly selected to record the number of film layers. The results are presented in Table 7. All 15 groups showed a film overlap rate exceeding 50%, and the number of layers at each point was calculated using Equation (14).

$$C = \frac{C_1 + C_2 + C_3 + \cdots C_{45}}{45} = \sum_{i}^{45} C_i/45 \tag{14}$$

where:

C—Average value of layers.

C_i—$C_1 \cdots C_{45}$ Number of layers at each point.

The coefficient of variation is calculated using Equation (15).

$$X = \frac{S}{C} \times 100\% \tag{15}$$

where: S is the standard deviation calculated by Equation (16).

$$S = \sqrt{\frac{\sum_i^{45}(C_i - C)^2}{45 - 1}} \tag{16}$$

After calculation, the coefficients of variation for the uniformity of the wrapping film were found to be 8.70% (400×400 mm), 11.20% (500×500 mm), and 10.70% (600×600 mm), respectively. All these values are below the 15% threshold specified in the industry standards for straw bale wrapping machinery.

Table 7

Number of wrapping film pickup points for different straw bale sizes and layer counts

Straw bale specifications	Straw bale number	2-layer film pickup point number					4-layer film pickup point number					6-layer film pickup point number				
		1	2	3	4	5	1	2	3	4	5	1	2	3	4	5
400×400mm Straw bale	1	2	2	2	2	2	4	4	4	4	4	6	6	6	6	6
	2	2	2	2	2	2	4	3	4	4	4	7	6	6	6	6

	5	2	2	2	2	2	4	4	4	4	4	6	6	6	6	6

Straw bale specifications	Straw bale number	2-layer film pickup point number					4-layer film pickup point number					6-layer film pickup point number				
		1	2	3	4	5	1	2	3	4	5	1	2	3	4	5
600×600mm Straw bale	1	2	2	2	2	2	4	4	5	4	4	6	6	7	6	6
	2	2	2	3	2	2	4	4	4	4	4	6	6	6	6	6
	3	2	2	2	2	2	4	4	5	4	4	6	6	6	7	6
	4	2	2	3	2	2	4	4	4	4	4	6	6	6	6	6
	5	2	2	2	2	2	4	4	4	4	4	6	6	6	6	6

Elongation rate ε_t

Five wrapped bales of each size were randomly selected, and the elongation rate (ε_t) was calculated using Equation (13). The final result was approximately 59%, with a 2.4% deviation from the design requirements. This elongation rate meets the industry standard, and detailed results are presented in Table 8.

Table 8

Elongation rate

Measured parameter	Elongation of 5 tested wrapping bales - 400×400mm					
	1	2	3	4	5	Average value
L_0(mm）	315.8	312.6	310.1	307.4	304.3	310.04

CONCLUSIONS

In the entire process of rice straw forage production, straw bales require wrapping, but the supporting machinery cannot adapt to bales of different sizes. To address this issue, this study designed a rice straw bale wrapping machine with adjustable rollers to accommodate various bale sizes, laying a foundation for improving the production efficiency of straw forage. The main conclusions are as follows:

(1) The mechanical properties of stretch films were studied. Film length, width, and loading speed were selected as test factors, with maximum tensile force and elongation rate as evaluation indicators. The results indicate that in actual wrapping operations, using shorter film lengths, lower loading speeds, and wider film widths can not only enhance the tensile strength of the film but also increase its elongation, thereby improving wrapping effectiveness.

(2) The overall structural scheme of the adjustable straw bale wrapping machine was designed. Based on theoretical analysis of the wrapping process, the tension applied to straw bales should be less than 79.2 N. A speed ratio of 0.25 between the roller and the rocker arm ensures a 50% wrapping overlap rate, achieving optimal wrapping results.

(3) Key components including the adjustable roller mechanism, film feeding mechanism, and rocker mechanism were designed. The spacing between the two rollers can be adjusted within the range of 466–960 mm, enabling the wrapping of bales with sizes ranging from 400 to 1200 mm.

(4) Performance testing of the adjustable straw bale wrapping machine was completed, with the rocker speed set at 35 r/min. The average wrapping times for 2, 4, and 6 layers of different-sized bales were measured. The film overlap rate reached 50%, with coefficients of variation for film uniformity at 8.70%, 11.20%, and 10.70% respectively, and the total average elongation rate of the stretch film was 59%. All indicators meet the design standards.

ABSTRACT

The solar greenhouse is the main agricultural facility in northern China, providing a suitable environment for cultivating vegetables and flowers during the winter season. However, during the months of March and April, adjustments to the indoor temperature in northern Chinese solar greenhouses are necessary through the manipulation of upper and lower air vents. To investigate the impact of varying ventilation speeds on the thermal conditions within a solar greenhouse, Computational Fluid Dynamics (CFD) simulations were employed. The study assessed four different ventilation speeds on the air, soil, and wall temperatures within the greenhouse, assuming the absence of crops and disregarding humidity levels. The results showed that a wind speed of 0.5 m/s effectively reduced air temperature but had little effect on soil and wall temperatures; at wind speeds of 1.0 m/s and 1.5 m/s, the differences in air, soil, and wall temperatures inside the greenhouse were small. Considering economic benefits and crop growth conditions comprehensively, a wind speed of 1.0 m/s was identified as the optimal choice. This study provides data support and a theoretical basis for ventilation design in solar greenhouses.

摘要

日光温室是中国北方主要的农业设施，可为越冬期的蔬菜和花卉种植提供适宜环境。但是在中国北方 3 月和 4 月份需要通过开启上下风口调控室内温度。为研究不同通风风速对日光温室内热环境变化影响，本文通过 CFD 模拟，在假定温室内无作物和忽略湿度工况下，设置 0 m/s、0.5 m/s、1.0 m/s、1.5 m/s 四种风速，研究其对温室内空气、土壤和墙体温度的影响。结果表明，0.5 m/s 风速可有效降低空气温度，但对土壤和墙体温度影响较小；1.0 m/s 和 1.5 m/s 风速下，温室内空气、土壤和墙体温度差异较小。综合考虑经济效益与作物生长环境等因素，1.0 m/s 风速为最佳选择。该研究为日光温室通风设计提供了数据支撑和理论依据。

INTRODUCTION

Solar energy, as the best green and renewable energy source, is one of the effective ways to address energy shortages and environmental pollution through its maximum utilization (*Liu W. et al., 2018*). Agriculture, the most traditional industry utilizing solar energy, includes the Chinese solar greenhouse (CSG), a unique horticultural facility in northern China with thermal insulation walls on three sides and a plastic film on the south side, enabling off-season cultivation during the northern winter (*Liu X. A. et al., 2022*). However, current CSGs still suffer from excessively high daytime temperatures, leading to pest and disease outbreaks and reduced crop yields. Therefore, it is urgent to study the temperature and humidity in the crop area of CSGs to control the temperature within the range suitable for crop growth (*Zhang Q. Y. et al., 2023*).

Given the issue of high daytime temperatures in solar greenhouses causing pest damage and crop yield reduction, domestic scholars have made notable achievements in researching the thermal environment and optimizing ventilation in these greenhouses.

Lu L., (2022), designed and developed a ventilation control system for solar greenhouses, achieving automated regulation combined with sensor data and enhancing the intelligent level of the greenhouse environment. *Yang Y. Q. et al., (2024),* investigated the impact of different natural ventilation methods on the performance of solar greenhouses in desert areas, pointing out that rational ventilation design can effectively improve the greenhouse microclimate and promote crop growth.

Zhao G. M., (2024), focused on the impact of different natural ventilation methods on the environment of solar greenhouses and tomato growth. The experimental results indicated that the ventilation method directly affects the distribution of temperature and humidity in the greenhouse and the physiological state of crops.

With the development of Computational Fluid Dynamics (CFD) technology, many scholars have used CFD numerical simulation to study greenhouse ventilation. Several studies have investigated the indoor thermal conditions of solar greenhouses using Computational Fluid Dynamics (CFD) (*Baglivo et al., 2020; Dhiman et al., 2019; Kim et al., 2021; Wei et al., 2022*). The outcomes of these simulations offer valuable insights for optimizing the thermal regulation within solar greenhouse environments.

Wei D.D., (2022), systematically studied the numerical simulation of the thermal environment and ventilation characteristics of solar greenhouses, emphasizing the impact of wind speed and ventilation methods on the temperature field in the greenhouse.

Wu X.Y., (2022), conducted research on the structural optimization of energy-saving solar greenhouses based on CFD thermal environment simulation, proposing several structural improvement measures. *Zhao Z., (2022)*, studied the summer cooling effect of a new type of connected solar greenhouses, verifying the practical value of CFD simulation in greenhouse design. *Jing W. In summary, foreign scholars mainly focus on Venlo-type glass greenhouses and plastic greenhouses. This paper simulates the changes in indoor temperature and humidity fields in solar greenhouses under different ventilation types and speeds. The simulation provides references for natural ventilation control, making the greenhouse environment more suitable for crop growth, reducing pests and diseases, and improving economic benefits.

MATERIALS AND METHODS

The construction and meshing of the solar greenhouse geometric model

Computational Fluid Dynamics (CFD) integrates mathematical models, fluid mechanics, and computer science to numerically simulate fluid flow, efficiently and intuitively solving complex fluid problems. It allows in-depth analysis of air flow and heat transfer in greenhouses. By simulating the impact of different wind speeds on the thermal environment of solar greenhouses, it reveals air flow patterns and temperature distribution changes. This provides a scientific basis for greenhouse ventilation design, energy-saving control, and crop growth environment optimization, holding significant theoretical and practical value.

A three-dimensional geometric model of a common solar greenhouse in Hulun Buir City, Inner Mongolia was constructed. The greenhouse faces south, with a span of 12 meters, a ridge height of 5 meters, a north wall height of 4.8 meters, and an east-west length of 100 meters. The north wall and the east-west gable are trapezoidal, with a base width of 8 meters and a top width of 2 meters. Solid Works software was used for 1:1 three-dimensional modeling, as shown in Figure 1.

In Computational Fluid Dynamics (CFD) simulation, fluent meshing aims to construct an accurate mathematical model. Mesh size and quality directly affect computational accuracy. For the solar greenhouse model, only the wall surface involving heat transfer needs to be refined. The 3D model uses structured, unstructured, and hybrid meshes.

Considering boundary refinement and accuracy, a hybrid mesh was chosen. The mesh size was set to 500 mm, with a total of 156,775 cells. Grid quality was determined using the grid metric, with values closer to 1 indicating better quality. The meshing and corresponding quality are illustrated in Figures 2 and 3.

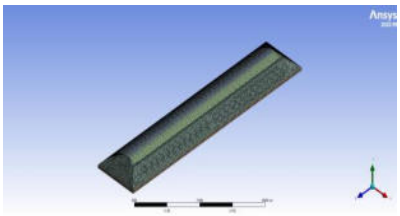

Fig. 2 - Mesh Division

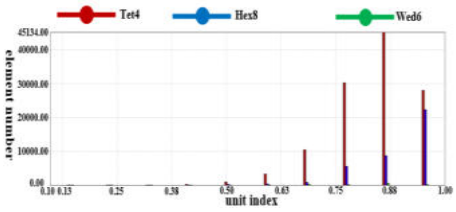

Fig. 3 - Grid Quality

The establishment of CFD numerical model

Model assumptions

The temperature change in a solar greenhouse is a dynamic and complex process, influenced by various factors including greenhouse structure, outdoor climate, crop growth, and ventilation. To reduce analysis time and enhance accuracy, the CFD numerical model of greenhouse temperature was simplified as follows:

(1) The solar greenhouse is in a completely closed state except for the upper and lower vents;

(2) The influence of humidity on the temperature of the solar greenhouse was not considered;

(3) The material parameters of each part did not change with the change of temperature.

The basic control equation of CFD

CFD is based on the conservation laws of mass, momentum, and energy for heat and mass transfer in fluids. The mass conservation equation describes the relationship between fluid motion and mass distribution. The momentum conservation equation links the rate of change of fluid momentum to external forces. The energy conservation equation is crucial in solar greenhouses, embodying the first law of thermodynamics and describing the conservation of total energy during fluid flow. Temperature changes and fluid motion interact to maintain energy balance.

Turbulence model and Radiation model

To better simulate the complex fluid flow and illumination environment inside the solar greenhouse and handle radiation heat transfer, this study selected the standard k-ε model, the DO radiation model, and the solar radiation model.

The solar radiation calculator sets the solar orientation, radiation intensity, and material thermal radiation parameters. The solar greenhouse is at 49°21′N, 119°25′E in the East 8 time zone. Solar radiation data from March 1, 2025 (sunny day) was used for simulation. Starting at 8:00, the coordinate axis was set with the X-axis positive to the north, the Z-axis positive to the east, the sunshine coefficient at 1, and illumination parameters configured using the solar calculator.

Setting of material parameters

Solar greenhouse experience temperature differences due to solar radiation during the day, causing minor changes in air density. The Boussinesq approximation, which treats air density as constant, simplifies the solution of fluid mechanics equations. The thermal properties of the greenhouse enclosure materials are shown in table 1.

Boundary conditions and initial conditions

The setting of boundary condition parameters has a great influence on the numerical simulation. According to the experimental data, the boundary conditions and initial conditions are determined as follows:

(1) Setting of boundary conditions. The boundary conditions mainly include the setting of the boundary of the front and rear roofs, the east and west gables, the north wall and the soil of the solar greenhouse. The interface between the various parts is set to the coupling wall. From 8:00 a.m. to 15:00 p.m., the south roof was provided with a transparent plastic film.

(2) The setting of initial conditions. The exterior surface of the wall was set as a convective boundary condition with a heat transfer coefficient of 10; the south roof was set as a mixed (convective + radiative) boundary condition with a heat transfer coefficient of 15; the back roof was set as a convective boundary condition with a heat transfer coefficient of 5; the soil around was set as adiabatic. The experimental measurement data on March 6, 2025 were selected for model construction. The initial temperatures near the south, middle and wall of the greenhouse were 15.2°C, 16.8°C and 18°C, respectively. The outdoor temperature was applied to the outer surface of the greenhouse envelope. In addition, the initial values of the inner surface temperature of the north wall, soil and rear roof were 19°C, 20°C and 15°C, respectively.

(3) The upper and lower tuyeres were opened at the same time. The lower tuyere, measuring 100 m in length and 1 m in width, was located at the base of the southern shed film. In contrast, the upper tuyere, also 100 m long and 1 m wide, was positioned at the top of the shed film, approximately 1 m horizontally from the north wall and 5 m above the ground. The upper tuyere was set as the pressure outlet condition. The wind speed of the lower tuyere was set to 0m/s, 0.5m/s, 1m/s, and 1.5m/s. The effects of different wind speeds on air temperature, soil temperature, and wall temperature at different positions in the solar greenhouse were explored.

Solve the setting of control parameters

In this simulation, the relaxation factors were set as follows: pressure at 0.3, density, body force, turbulent viscosity, and energy at 1, k and ε at 0.8, and momentum at 0.7. The convergence criteria were set at 1×10^{-3} for continuity, momentum, k, and ε equations, and at 1×10^{-6} for energy and radiation equations. These settings ensured high-precision results suitable for engineering applications.

Table 1

Material thermal property parameters of the solar greenhouse envelope

Parameters	PE	Wall	Soil	backward slope
Densities [kg/m³]	950	2000	1600	70
Specific heat capacity [J/[kg·K]]	1600	1050	1050	1880
Thermal conductivity[W/[m·K]]	0.34	0.8	0.75	0.04
Absorption coefficient	0.15	0.88	0.88	0.1
Scattering coefficient	0	0.12	0.12	0
Index of refraction	1.72	1.92	1.92	1.72

RESULTS AND DISCUSSION

In this research, CFD simulation was used to analyze the effects of four different wind speeds on the temperatures of air, soil, and walls inside a solar greenhouse across horizontal, vertical, and longitudinal dimensions. The coordinate origin was at the greenhouse's south bottom corner, with the y-axis extending upward and the x-axis pointing north.

Influence of different ventilation rates on indoor air temperature

Influence of different ventilation rates on indoor air temperature along the horizontal direction

To investigate the impact of different wind speeds at the ventilation openings on air temperature at various horizontal positions in a solar greenhouse, a cross-sectional analysis along the north-south direction at the midspan in the east-west direction was conducted. Temperature variation curves at four different locations (Y=1200 mm, X=3000 mm, X=5000 mm, X=7000 mm, X=9000 mm) were selected for data analysis.

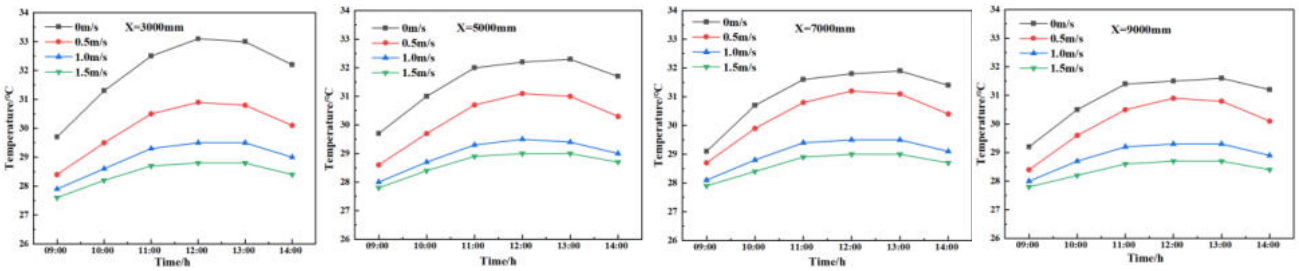

Fig. 4 - Influence of different wind speeds on indoor air temperature at various horizontal locations

As shown in Figure 4, under different wind speeds, the temperature at all horizontal measurement points increased rapidly from 9:00 to 11:00, stabilized from 11:00 to 13:00, and then decreased. Higher wind speeds led to lower temperatures, with the most evident differences at 13:00. At X=3000 mm, X=5000 mm, X=7000 mm, and X=9000 mm, the temperature differences between 0.5 m/s and 0 m/s wind speeds were 2.2°C, 1.3°C, 0.8°C, and 0.8°C, respectively. The differences between 1.0 m/s and 0.5 m/s were 1.4°C, 1.6°C, 1.6°C, and 1.5°C, respectively. The differences between 1.5 m/s and 1.0 m/s were 0.7°C, 0.4°C, 0.5°C, and 0.6°C, respectively.

It was concluded that Ventilation significantly reduces air temperature, with greater cooling effects at locations farther from the north wall. At 0.5 m/s, the cooling effect was more significant at X=3000 mm; at 1.0 m/s, it was more pronounced at X=5000 mm, X=7000 mm, and X=9000 mm.

Influence of various ventilation rates on indoor air temperature in the vertical direction

To investigate the influence of different wind speeds at the ventilation openings on air temperature at various vertical locations in a solar greenhouse, a cross-sectional analysis along the north-south direction at the midspan in the east-west direction was conducted. Temperature variation curves at four different locations (X=6000 mm, Y=1000 mm, Y=2000 mm, Y=3000 mm, Y=4000 mm) were selected for data analysis.

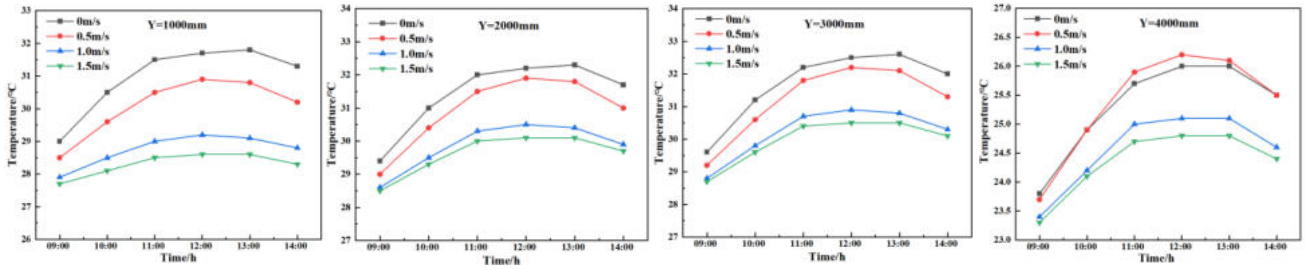

Fig. 5 - Influence of different wind speeds on air temperature at various vertical locations

As shown in Figure 5, under different wind speeds, the temperature trends at all vertical measurement points were consistent: rapid increase from 9:00 to 12:00, stabilization from 12:00 to 13:00, and gradual decrease after 13:00. Higher wind speeds led to lower temperatures. The temperature data at 0.5 m/s for the measurement point at Y=4000 mm, located directly beneath the greenhouse film and influenced by unique convective effects, were excluded from the analysis. At 13:00, when temperature differences were most pronounced, the differences at Y=1000 mm, Y=2000 mm, and Y=3000 mm were 1.0°C, 0.5°C, and 0.5°C between 0.5 m/s and 0 m/s; 1.7°C, 1.4°C, and 1.3°C between 1.0 m/s and 0.5 m/s; and 0.6°C, 0.3°C, and 0.3°C between 1.5 m/s and 1.0 m/s.

It was concluded that ventilation significantly reduced air temperature at different vertical locations, with the effect diminishing as the Y value increased. A wind speed of 0.5 m/s had a more pronounced impact on the measurement point at Y=1000 mm.

Influence of different ventilation rates on indoor air temperature along the longitudinal direction

To investigate the influence of different wind speeds at the ventilation openings on air temperature at various longitudinal locations in a solar greenhouse, temperature variation curves at four different locations (X=7000 mm, Y=1200 mm, Z=20440 mm, Z=32940 mm, Z=45440 mm, and Z=70440 mm) were analyzed.

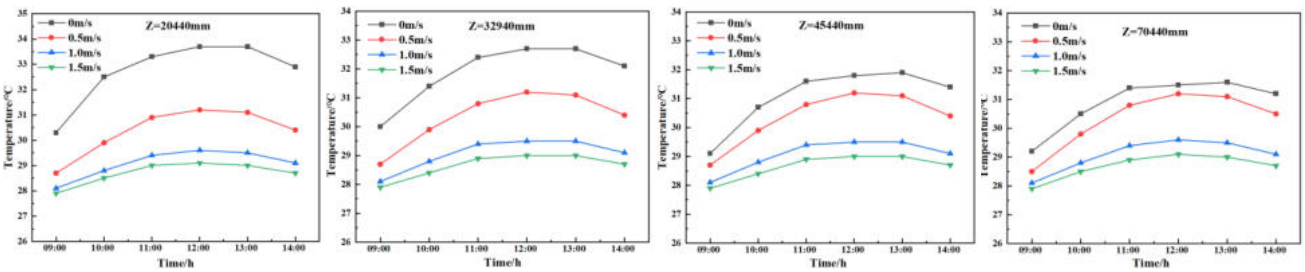

Fig. 6 - Influence of different wind speeds on air temperature at various longitudinal locations

As shown in Figure 6, under different wind speeds, the temperature trends at all longitudinal measurement points were consistent: rapid increase from 9:00 to 12:00, stabilization from 12:00 to 13:00, and gradual decrease after 13:00. The maximum temperature increases at the same measurement point varied significantly under different wind speeds: 3.5°C at 0 m/s, 2.7°C at 0.5 m/s, 1.4°C at 1.0 m/s, and 1.2°C at 1.5 m/s. This indicates that higher wind speeds result in smaller temperature increases and overall lower temperatures. At 13:00, temperature differences were most pronounced. At measurement points Z=20440 mm, Z=32940 mm, Z=45440 mm, and Z=70440 mm, the temperature differences between 0.5 m/s and 0 m/s were 2.6°C, 1.6°C, 0.8°C, and 0.5°C, respectively. The differences between 1.0 m/s and 0.5 m/s were all 1.6°C, and between 1.5 m/s and 1.0 m/s were all 0.5°C.

It was concluded that Ventilation significantly reduced air temperature at different longitudinal locations, with the effect diminishing from west to east. A wind speed of 0.5 m/s had a more pronounced impact at Z=20440 mm. Overall, ventilation effectively reduced air temperature, with 0.5 m/s and 1.0 m/s wind speeds having more pronounced cooling effects. However, considering the smaller influence range of 0.5 m/s compared to 1.0 m/s, and taking into account multiple factors such as economic benefits and crop growth environment, a wind speed of 1.0 m/s was determined to be a more optimal choice for ventilation.

Influence of different ventilation rates on soil temperature

Influence of different ventilation rates on soil temperature along the horizontal direction

To investigate the influence of different wind speeds at the ventilation openings on soil temperature at various horizontal locations in a solar greenhouse, a cross-sectional analysis along the north-south direction at the midspan in the east-west direction was carried out. As documented in reference (*Cheng W. W. et al., 2024*), soil temperature at a depth of 50 mm from the ground surface is considerably influenced by air temperature. Thus, soil temperatures at a depth of 50 mm at locations X=3000 mm, X=5000 mm, X=7000 mm, and X=9000 mm were analyzed.

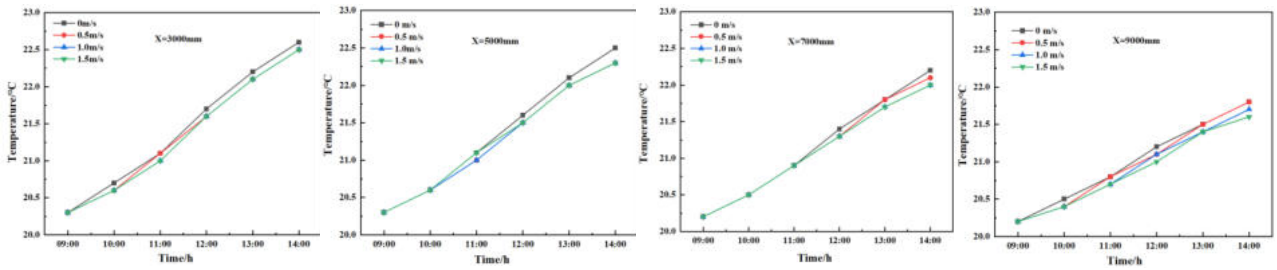

Fig. 7 - Influence of different wind speeds on soil temperature at various horizontal locations

As shown in Figure 7, from 9:00 to 14:00, the soil temperature at each location increased. Ventilation significantly affected soil temperature at different horizontal positions. After the ventilation openings were opened at 9:00, the soil temperatures at X=3000 mm and X=9000 mm changed rapidly, with clear temperature differences appearing soon after; the soil temperatures at X=5000 mm and X=7000 mm changed more slowly. Under various wind speeds, the soil temperature differences at each location grew over time, with maximum differences of 0.1°C, 0.2°C, 0.2°C, and 0.2°C, respectively.

At X=3000 mm and X=5000 mm, soil temperatures showed no significant variation under wind speeds of 0.5 m/s, 1.0 m/s, and 1.5 m/s, and were significantly lower than those at 0 m/s. At X=7000 mm and X=9000 mm, soil temperature decreased with increasing wind speed. The differences in soil temperature under wind speeds of 1.0 m/s and 1.5 m/s were minor, with maximum differences of 0°C and 0.1°C, respectively.

Influence of different ventilation rates on soil temperature along the vertical direction

To investigate the impact of different wind speeds at the ventilation openings on soil temperature at various vertical locations in a solar greenhouse, a cross-sectional analysis along the north-south direction at the midspan in the east-west direction was conducted. Soil temperature variation curves at four different depths (50 mm, 200 mm, 350 mm, and 500 mm) at X=7000 mm were analyzed.

As shown in Figure 8, from 9:00 to 14:00, the soil temperature at each location increased progressively over time. Specifically, the rate of increase was faster from 9:00 to 11:00 and slower from 13:00 to 14:00.

After the ventilation openings were activated at 9:00, noticeable temperature differences at all locations under different wind speeds emerged by 11:00. The response rate was slower under a wind speed of 0.5 m/s compared to those under 1.0 m/s and 1.5 m/s.

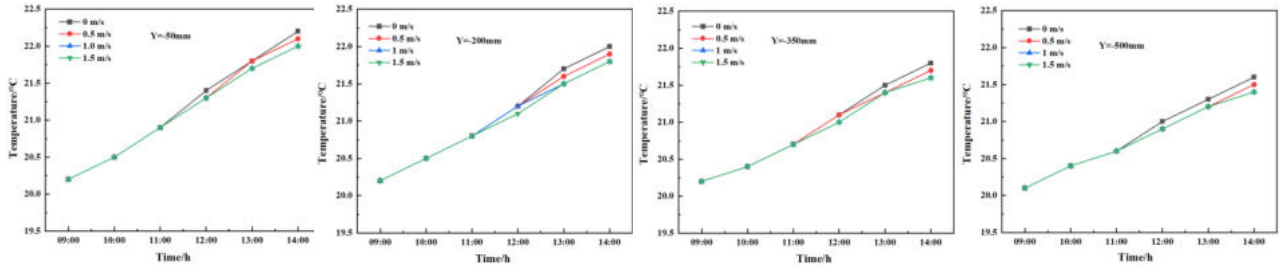

Fig. 8 - Influence of different wind speeds on soil temperature at various vertical locations

At depths of 50 mm, 200 mm, 350 mm, and 500 mm from the ground surface, opening the ventilation openings effectively reduced soil temperature. Under wind speeds of 1.0 m/s and 1.5 m/s, soil temperatures were similar and lower than at 0.5 m/s, with a maximum difference of 0.2°C.

Influence of different ventilation rates on soil temperature along the longitudinal direction

To investigate the impact of different wind speeds at the ventilation openings on soil temperature at various longitudinal locations in a solar greenhouse, temperature variation curves at four different locations (X=7000 mm, depth of 50 mm, Z=20440 mm, Z=32940 mm, Z=45440 mm, and Z=57940 mm) were analyzed.

As shown in Figure 9, from 9:00 to 14:00, the soil temperature at each location increased over time. Ventilation had a significant impact on soil temperature at different longitudinal positions. After the ventilation openings were activated, noticeable temperature differences emerged at Z=20440 mm and Z=32940 mm. For Z=45440 mm and Z=57940 mm, significant temperature differences appeared after 11:00. The soil temperature differences at each location under various wind speeds gradually widened over time, with the maximum differences reaching 0.3°C, 0.3°C, 0.2°C, and 0.1°C, respectively.

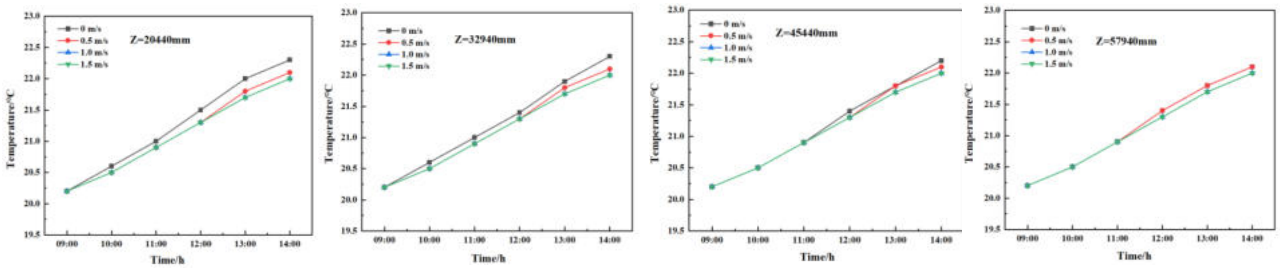

Fig. 9 - Influence of different wind speeds on soil temperature at various longitudinal locations

At locations Z=20440 mm, Z=45440 mm, and Z=32940 mm, At Z=20440 mm, Z=45440 mm, and Z=32940 mm, soil temperature was not affected by wind speeds of 0.5 m/s, 1.0 m/s, and 1.5 m/s during 9:00-12:00. From 12:00 to 14:00, soil temperatures under 1.0 m/s and 1.5 m/s were the same but significantly higher than those under 0.5 m/s, with a maximum difference of 0.1°C. At Z=57940 mm, during 9:00-14:00, 0.5 m/s had no effect on soil temperature, matching that under 0 m/s. Soil temperatures under 1.0 m/s and 1.5 m/s were the same and significantly lower than that under 0.5 m/s, with a maximum difference of 0.1°C.

In summary, ventilation effectively reduced soil temperature. Wind speeds of 1.0 m/s and 1.5 m/s achieved more pronounced cooling effects on soil temperature. However, given that the impact of these two wind speeds on soil temperature was relatively close, and considering economic benefits and the crop growth environment, a wind speed of 1.0 m/s was selected for ventilation.

Influence of different ventilation rates on wall temperature

Influence of different ventilation rates on wall temperature along the horizontal direction

To investigate the impact of different wind speeds on the horizontal variation of wall temperature in the greenhouse, a cross-sectional analysis along the north-south direction at the midspan of the east-west direction of the north wall was conducted. Temperature variation curves at four locations (L=300 mm, L=600 mm, L=900 mm, and L=1200 mm) from the inner side of the north wall were analyzed.

As shown in Figure 10, from 9:00 to 14:00, the wall temperature at locations L=300 mm, L=600 mm, L=900 mm, and L=1200 mm increased progressively over time. Different wind speeds had an impact on wall temperature at different horizontal positions. Specifically, at locations L=300 mm and L=600 mm, noticeable temperature differences emerged after 11:00. At locations L=900 mm and L=1200 mm, the temperature differences were consistent from 9:00 to 12:00 but began to change after 12:00. The wall temperature differences at each location under various wind speeds gradually widened over time, with the maximum differences reaching 0.2°C, 0.1°C, 0.1°C, and 0.1°C, respectively.

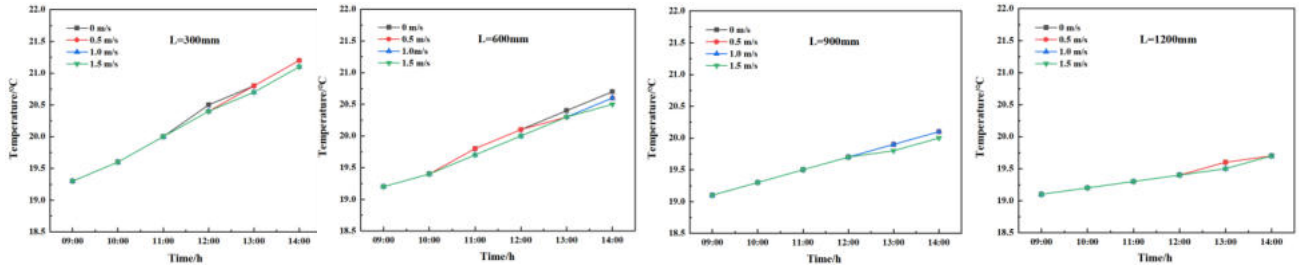

Fig. 10 - Influence of different wind speeds on wall temperature at various horizontal locations

At L=300 mm and L=600 mm, a 0.5 m/s wind speed had little impact on wall temperature, while 1.0 m/s and 1.5 m/s wind speeds effectively reduced it, with minimal differences (max 0°C and 0.1°C, respectively). At L=900 mm, 0.5 m/s and 1.0 m/s had no effect, but 1.5 m/s significantly lowered wall temperature. At L=1200 mm, all wind speeds had almost no impact.

Influence of different ventilation rates on wall temperature along the vertical direction

To study the impact of different wind speeds on the vertical variation of wall temperature in the greenhouse, a cross-sectional analysis along the north-south direction at the midspan of the north wall was conducted, analyzing temperature variation curves at four locations (Y=1000 mm, Y=1500 mm, Y=2000 mm, and Y=2500 mm) 200 mm from the inner side of the north wall.

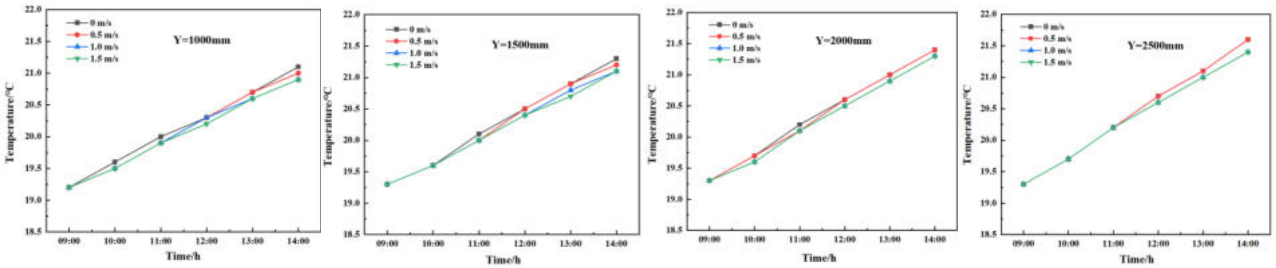

Fig. 11 - Influence of different wind speeds on wall temperature at various vertical locations

As shown in Figure 11, from 9:00 to 14:00, the wall temperature at various vertical locations increased over time. Different wind speeds had varying impacts on wall temperature. At Y=1000 mm and Y=1500 mm, the impact of wind speed showed synchronicity, with temperature differences gradually increasing over time. Differences were minimal from 9:00 to 11:00 but became more pronounced after 11:00. At Y=2000 mm, the impact was slower, with stable differences from 9:00 to 11:00 and changes beginning after 12:00. At Y=2500 mm, the impact was most delayed, with minimal differences from 9:00 to 12:00 and increasing differences after 12:00. The maximum temperature differences at each location under various wind speeds were 0.2°C, 0.2°C, 0.2°C, and 0.2°C, respectively.

At Y=1000 mm, Y=1500 mm, Y=2000 mm, and Y=2500 mm, wind speeds of 1.0 m/s and 1.5 m/s effectively reduced wall temperature with minimal differences between them. At Y=1000 mm and Y=1500 mm, 0.5 m/s had a smaller impact, while at Y=2000 mm and Y=2500 mm, 0.5 m/s had almost no effect.

Influence of different ventilation rates on wall temperature along the longitudinal direction

To investigate the impact of different wind speeds on the longitudinal variation of wall temperature in the greenhouse, temperature variation curves at four different locations (X=10900 mm, Y=1875 mm, Z=20440 mm, Z=32940 mm, Z=45440 mm, and Z=70440 mm) were analyzed.

As shown in Figure 12, from 9:00 to 14:00, the wall temperature at Z=20440 mm, Z=32940 mm, Z=45440 mm, and Z=70440 mm increased. The impact of different wind speeds varied. At Z=20440 mm, the wind speed effect was delayed, with differences increasing after 11:00. At Z=32940 mm, wind speeds of 0.5 m/s, 1.0 m/s, and 1.5 m/s reduced wall temperature after 11:00. At Z=45440 mm and Z=70440 mm, the wind speed impact was synchronized, with differences increasing after 11:00, and wind speeds of 1.0 m/s and 1.5 m/s having a pronounced cooling effect. The wall temperature differences at each location gradually increased over time, with maximum differences of 0.4°C, 0.2°C, 0.2°C, and 0.1°C, respectively.

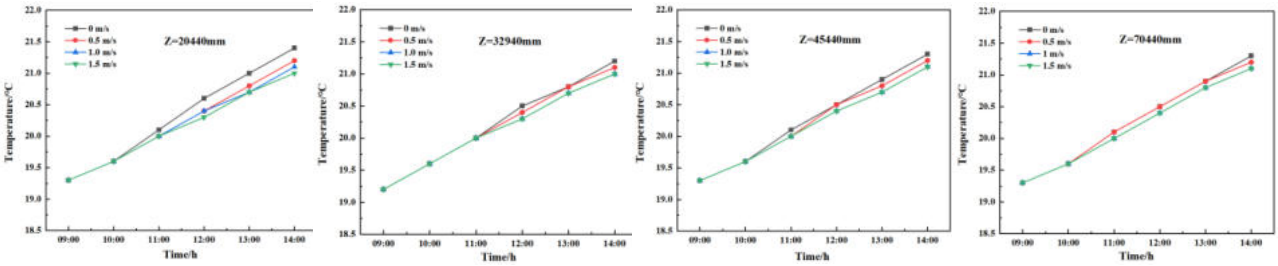

Fig. 12 - Influence of different wind speeds on wall temperature at various longitudinal locations

At a wind speed of 0.5 m/s, the impact on wall temperature was greatest at location Z=20440 mm and smaller at locations Z=32940 mm, Z=45440 mm, and Z=70440 mm. At location Z=20440 mm, the difference in wall temperature between wind speeds of 1.0 m/s and 1.5 m/s was minimal, at 0.1°C. At locations Z=32940 mm, Z=45440 mm, and Z=70440 mm, there were no significant differences in wall temperature between wind speeds of 1.0 m/s and 1.5 m/s.

The study found that greenhouse wall temperature rose over time, with varying impacts of wind speed by location. Horizontally, impact decreased with distance from the north wall. Vertically, higher positions showed more lag. Longitudinally, greater distance from the midspan increased lag. Wind speeds of 1.0 m/s and 1.5 m/s had stronger cooling effects than 0.5 m/s, with 1.5 m/s being more effective later on.

CONCLUSIONS

Through CFD simulation of the solar greenhouse, the impact of different ventilation rates on the indoor air, soil, and wall temperatures within the solar greenhouse was investigated. The conclusions are as follows:

(1) Between 9:00 and 14:00, indoor air temperature initially increased rapidly, stabilized, and eventually decreased. Concurrently, soil and wall temperatures gradually increased over time. Additionally, wind speed inversely correlated with temperature, with higher speeds corresponding to lower temperatures.

(2) A wind speed of 0.5 m/s exerts minimal influence on indoor air temperature, soil temperature, and the temperature of the north wall. In contrast, wind speeds of 1.0 m/s and 1.5 m/s have a pronounced impact on these parameters. The magnitude of variation in indoor temperature, soil temperature, and north wall temperature was greater with an increase in wind speed from 0.5 m/s to 1.0 m/s compared to an increase from 1. m/s to 1.5 m/s.

In summary, a wind speed of 0.5 m/s effectively reduced indoor air temperature but had a minimal impact on soil and wall temperatures. The differences in temperature for indoor air, soil, and walls were relatively small under wind speeds of 1.0 m/s and 1.5 m/s.

Keywords: *energy, hydrodistillation, nutmeg leaves, ohmic heating*

ABSTRACT
The objectives of the study were: to determine the ratio of electrical voltage and volume to the hydrodistillation rate, conductivity, energy, and yield. The method used is hydrodistillation of nutmeg leaves according to the treatment. The treatment of voltage and water volume were 3 levels each. Observations included voltage, current, temperature, and yield. The results showed that the hydrodistillation rate, electrical conductivity, energy, and oil nutmeg leaves yield were influenced by electrical voltage and solvent volume. The maximum oil yield was 1.07% at a voltage of 50 Vac and 750 ml of water.

ABSTRAK
Tujuan penelitian adalah: mengetahui rasio tegangan listrik dan volume terhadap laju hidrodistilasi, konduktivitas, energi, dan rendemen. Metode yang digunakan adalah melakukan hidrodistilasi daun pala sesuai perlakuan. Perlakuan tegangan dan volume air masing-masing 3 level. Pengamatan meliputi tegangan, arus, suhu, dan rendemen. Hasil penelitian menunjukkan bahwa laju hidrodistilasi, konduktivitas listrik, energi, dan rendemen minyak daun pala dipengaruhi oleh tegangan listrik dan volume pelarut. Rendemen minyak maksimum sebesar 1,07% pada tegangan 50 Vac dan air 750 ml.

INTRODUCTION
Distillation is one of the methods used to extract distillates in the form of oil or other materials contained in certain materials. Distillation is the process of heating a liquid or solid until it turns into steam, which is channeled into a separate vessel, then condensed with a cooler. In distillation, a mixture of substances is boiled so that it evaporates, and this steam is cooled back into liquid form. Substances that have a lower boiling point will evaporate first.

The distillation method includes physical operations that involve heat transfer and mass transfer. There are 2 types of distillation methods, i.e., the dry distillation method and the wet distillation method. The dry distillation method is carried out without using water, while wet distillation uses water. There are 3 types of water distillation methods, i.e., the material is boiled in water in one vessel, the material is steamed using water vapor in one vessel, and the material is steamed with water vapor in a separate vessel. Each of the three methods has advantages and disadvantages for the results and quality of the distillate produced. These three methods are commonly used to extract materials from plants containing essential oils.

Plants that produce essential oils include cloves, nutmeg, patchouli, and so on. Essential oils have a selling value and are among Indonesia's leading export commodities. According to the latest report from the Ministry of Industry, Indonesia's essential oil production in 2020 reached around 8,500 tons. From 2017 to 2020, an increase in the value of essential oil exports was recorded, with a total value of essential oil exports from January to September 2021 reaching USD 185 million (*Mukhtarom*, *2024*). Nutmeg is a plant that produces essential oils. Indonesia is the largest producer of nutmeg in the world, i.e., between 70% and 75% *(Balai Komoditi Industry, Deptan, 2009*). Essential oil from nutmeg plants can be obtained from fruit, mace, and nutmeg leaves. The highest oil content is obtained from fruit and mace, while nutmeg leaves have a low content. The yield of essential oil from 1 kg of fresh nutmeg leaves is 0.4% (*Damayanti, 2017*). Although the content of nutmeg leaf oil is small, if the amount is large, it will still provide economic value.

The extraction of nutmeg leaf essential oil by craftsmen/farmers is done by distilling a mixture of steam and water. Steaming the leaves in a closed vessel produces a mixture of water vapor, which is then routed into a cooling pipe for condensation. The condensation results in a liquid consisting of water and nutmeg leaf oil. The energy used for steaming nutmeg leaves comes from firewood. The use of firewood for the distillation process is not environmentally friendly because it can pollute the environment due to the smoke from burning firewood.

Currently, many researchers are developing environmentally friendly distillation and extraction methods. One distillation method is using ohmic heating. Ohmic heating is a heating process that occurs due to alternating electric current in a liquid that has conductivity. Ohmic heating (OH) is a volumetric heating technique that emerged as an alternative to conventional heating by utilizing alternating electric current to heat the product (*Sain et al., 2024; Talha et al., 2024*). Heat will be generated in the liquid due to the collision of particles in the liquid. Heating in this way is environmentally friendly because it does not produce smoke and other hazardous materials. Research utilizing ohmic heating for extraction includes the extraction of phytochemical component products from potatoes (*Pereira et al., 2016*), the extraction of essential oils of aromatic plants (*Gavahian et al., 2020*), the extraction of olive leaves (*Safarzadeh et al., 2022*), the effectiveness of ohmic heating technology for the extraction of phenolic compounds from red beet roots (*Cabas and Icier, 2021*), grape pomace (*Ferreira-Santos et al., 2024*), the extraction of phenolic content and antioxidant activity of cocoa bean skin (*Sánchez et al., 2023*), and the phenolic extraction of avocado leaves (*Gumustepe et al., 2023*).

The conditions for heating in ohmic heating are the presence of electrical voltage and liquid materials that have conductivity values. The mixture of water and nutmeg leaves has a conductivity value, so if given an electric voltage, it will be able to flow an electric current. The electric current flowing in the mixture of water and nutmeg leaves will generate heat. The heat will increase the temperature of the mixture of water and nutmeg leaves until it reaches boiling point (100°C). The water vapor formed contains a mixture of water and oil; if condensed, it will produce separate water and oil. The use of ohmic heating for nutmeg leaf extraction can be done using the water distillation or hydrodistillation method. Hydrodistillation is done by boiling essential plant materials and water in one vessel. The success of ohmic heating is influenced by many factors such as electrical conductivity, field strength, particle size, concentration, ionic concentration, and electrodes (*Kaur & Singh, 2016*).

The electrode in ohmic heating is a connection between a solid-state conductor (i.e., the current feeder) and a liquid-state conductor (i.e., the heating medium) (*Samaranayake & Sastry, 2005*). There are several types of electrodes used for heating using ohmic heating, i.e., aluminum (*Uemura et al., 1994*), carbon (*Getchell, 1935*), glassy carbon, titanium (*Amatore et al., 1998*), platinum (*Tzedakis et al., 1999*), rhodium (*Palaniappan & Sastry, 1991*), stainless steel (*Assiry et al., 2003*), and platinized titanium (*Stirling, 1987*). Based on the description above, the author is interested in knowing the amount of electrical energy needed in the process of hydrodistillation of nutmeg leaves using ohmic heating. The use of different electrical voltages and electrode areas will affect the energy and also the time for the distillation process of nutmeg leaves. The objectives of this study are (a) to determine the effect of voltage and water volume on the hydrodistillation rate, (b) to determine the effect of voltage and water volume on electrical conductivity, (c) to determine the effect of voltage and water volume on hydrodistillation energy consumption, and (d) to determine the effect of voltage and water volume on the yield of nutmeg leaf oil.

MATERIALS AND METHODS

Materials

The ohmic heating hydrodistillation equipment used consists of an outer pan made of aluminum and an inner pan made of stainless steel. The outer pan functions as a protector. The inner pan is a treatment room as a heating place. There are 2 inner pans, i.e., the one located on the edge with an open position with a height of 106 mm and a diameter of 182 mm. This pan functions as a place for materials and water for the boiling process as well as a neutral electrode. The second pan with an open position with a diameter of 88 mm and a height of 82 mm is located in the middle and functions as a phase electrode (fig. 1). Other equipment needed is a 1000 W step-up/down transformer, ampere meter, volt meter, measuring cup, analytical balance, camera, and stopwatch. The material used is dried nutmeg leaves. The treatments carried out were 3 voltage levels, i.e., 50 Vac, 75 Vac, and 100 Vac, and 3 levels of water volume treatment, i.e., 750 ml, 1000 ml, and 1250 ml.

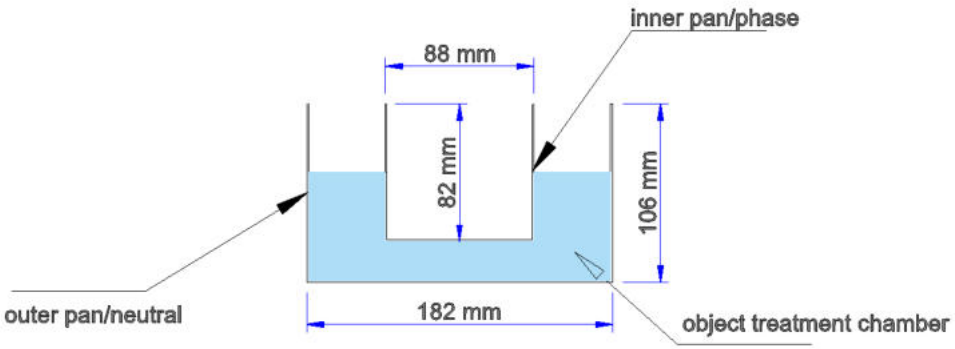

Fig. 1 - Treatment chamber scheme

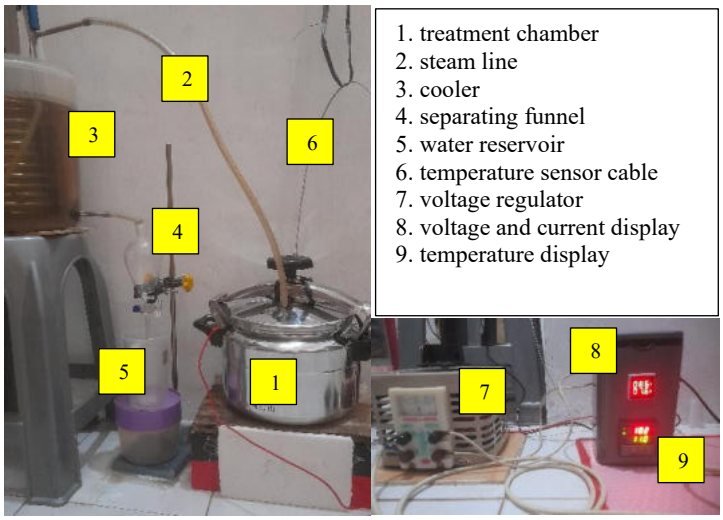

Fig. 2 - Ohmic heating device

Research stages

1. Designing and assembling the 1.3 liter ohmic heating hydrodistillation device (fig. 2)

2. Testing the ohmic heating hydrodistillation device by (a) Weighing 100 g of dried nutmeg leaves and cutting them into several parts. (b) Inserting the cut dried leaves into the treatment chamber and adding distilled water according to the treatment. (c) Closing the treatment chamber and flowing alternating current with the voltage according to the treatment. (d) Turning on the switch so that the hydrodistillation process takes place. (e) Recording the temperature, voltage, and electric current during ohmic heating hydrodistillation. (f) Collecting oil and water from the hydrodistillation process. (g) Separating the water and nutmeg leaf oil using a separating funnel. (h) Weighing the nutmeg leaf oil. (i) Conducting ohmic heating hydrodistillation of nutmeg leaves with different voltages and ratios of water and nutmeg leaves. (j) Repeating the steps above according to the treatment, and each is repeated 3 times.

3. Conduct observations on changes in voltage, changes in electric current, changes in temperature, oil yield, and oil characteristics according to SNI.

4. Process data and present it in the form of tables and graphs.

5. Electrical conductivity (σ) is calculated using the following equation (*Assiry et al., 2003; Zell et al., 2009; Salengke et al., 2007*).

$$\sigma = \frac{L}{A} x \frac{I}{V}$$

where:

σ = Electrical conductivity (S/m);
L = distance between electrodes (m);
A = area of the material to be heated (m^2);
I = electric current (Amperes);
V = Electric voltage (Volts).

RESULTS

Voltage

The requirement for heating in ohmic heating hydrodistillation is the presence of electric voltage flowing in the liquid to be heated. The liquid must have a conductivity value; if the conductivity approaches zero, then the electric current does not flow and will not generate heat. The mixture of water and nutmeg leaves has a conductivity value, so if given an electric voltage, it will be able to flow an electric current. The electric current flowing in the mixture of water and nutmeg leaves will generate heat. One of the factors that affects the success of the hydrodistillation process is electric voltage. In this study, 3 voltage levels were used, i.e., 50 Vac, 75 Vac, and 100 Vac. The volume of water used was 3 levels, i.e., 750 ml, 1000 ml, and 1250 ml. The results of the study on the treatment of electric voltage and water volume are presented in Fig. 3 and Fig 4.

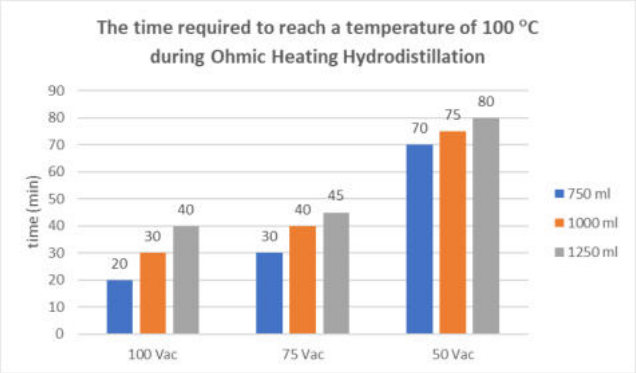

Fig. 3 - Time required to reach a temperature of 100°C

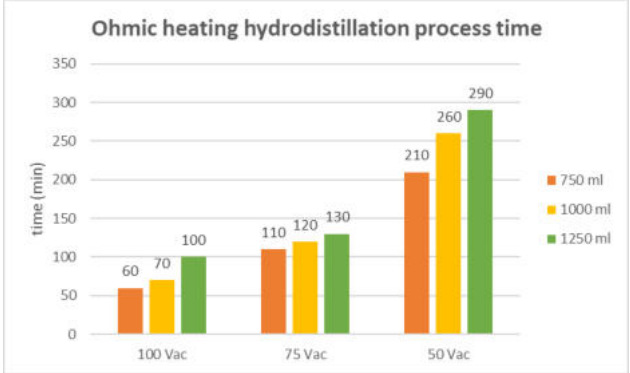

Fig. 4 - Time required for ohmic heating Hydro distillation process

Based on Fig. 3, it can be seen that the magnitude of the voltage affects the heating of the mixture of nutmeg leaves and water. At a voltage of 100 Vac, the heating time to reach a temperature of 100°C requires a shorter time compared to a voltage of 75 Vac and a voltage of 50 Vac. At the same water volume of 750 ml, the time required to reach a temperature of 100°C at a voltage of 100 Vac is 20 minutes; at a voltage of 75 Vac, it takes 30 minutes; and at a voltage of 50 Vac, it takes 70 minutes. At a water volume of 1000 ml, with a voltage of 100 Vac, it takes 30 minutes to reach a temperature of 100°C, while at a voltage of 75 Vac, it takes 40 minutes, and at a voltage of 50 Vac, it takes 75 minutes. At a larger water volume of 1250 ml, the time to reach a temperature of 100°C at a voltage of 100 Vac is 40 minutes, while at a voltage of 75 Vac it is 45 minutes, and at a voltage of 50 Vac it is 80 minutes. The higher the voltage, the faster the time to reach the boiling point of the liquid.

From Fig. 3, it can be seen that at the same voltage, the time required for ohmic heating hydrodistillation process is influenced by the volume of water used. The greater the volume of water used, the longer the time to reach the boiling point. The fastest time to boil a mixture of water and nutmeg leaves is at a volume of 750 ml, followed by 1000 ml, and the longest is 1250 ml. The higher the volume of water, the heating rate will decrease. The heating process using ohmic heating is influenced by many factors such as electrical conductivity, field strength, particle size, concentration, ionic concentration, and electrodes (*Kaur & Singh, 2016*).

Based on Figure 4, it can be seen that at the same voltage, the hydrodistillation process is influenced by the voltage and water used. The higher the voltage and the less volume of water used, the shorter the hydrodistillation process will be. This is like using a voltage of 100 Vac with 750 Watts; the hydrodistillation process takes 60 minutes. At a low voltage of 50 Vac with a water volume of 1250 ml, the longest time is required during the hydrodistillation process, which is 290 minutes. At a higher voltage of 100 Vac, the heat generation process is faster, while at a lower voltage of 50 Vac, the heating process is slow.

Electrical conductivity

Electrical conductivity (σ) is a measure of a material in accommodating the movement of an electric charge, i.e., the ratio of current density to electric field strength. The unit of electrical conductivity is Siemens per meter (S/m) (*Assiry et al., 2003; Salengke & Sastry, 2007; Zell et al., 2009*). Electrical conductivity is the ability of a material to conduct heat and electricity. Electrical conductivity works based on the physical

movement of electrons and the transfer of energy between electrons. The existence of electrical conductivity is very necessary in ohmic heating. The requirement for the heating process in ohmic heating, in addition to the presence of electric voltage, is that the liquid must have a conductivity value. The electrical conductivity value is influenced by the content of conductive materials in the liquid, such as acid, base, salt, or materials containing electrolytes such as silver, copper, gold, aluminum, zinc, nickel, and brass.

The measurement of the initial electrical conductivity value of a mixture of distilled water and nutmeg leaves before the hydrodistillation process using ohmic heating averaged 34 µS/cm. Pure water has a conductivity close to zero because it contains little electrolyte (*Asgarpanah & Kazemivash, 2012*). The addition of nutmeg leaves to pure water can increase the conductivity value even though the value is relatively small. The electrical conductivity value of the mixture of water and nutmeg leaves during the hydrodistillation process varies depending on the volume of water, voltage, and temperature. The results of the calculation of the electrical conductivity value during the hydrodistillation process of nutmeg leaves using ohmic heating on the same water volume are presented in Fig. 5–Fig. 7.

In general, at the start of heating, the electrical conductivity of the same volume of water is low, but it increases with process time. Each voltage's electrical conductivity has a maximum value, which decreases over time. The higher the voltage, the faster it reaches its maximum conductivity value. The magnitude of conductivity during the ohmic heating hydrodistillation process at the same volume of water is affected by the magnitude of voltage.

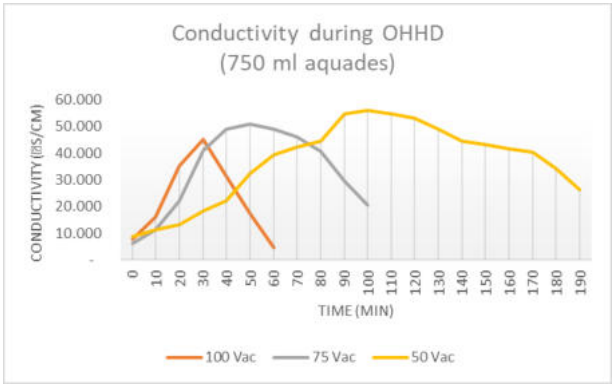

Fig. 5 - Conductivity during OHHD (750 ml of distilled water)

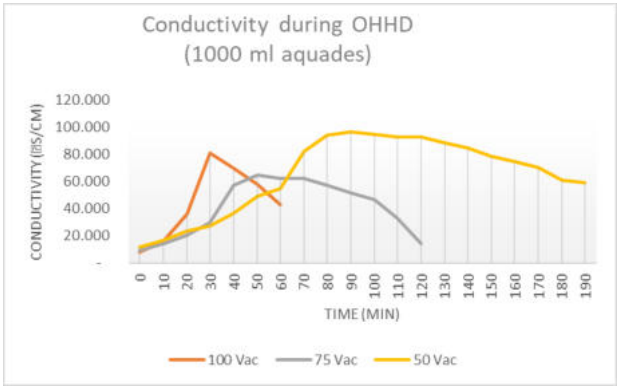

Fig. 6 - Conductivity during OHHD (1000 ml of distilled water)

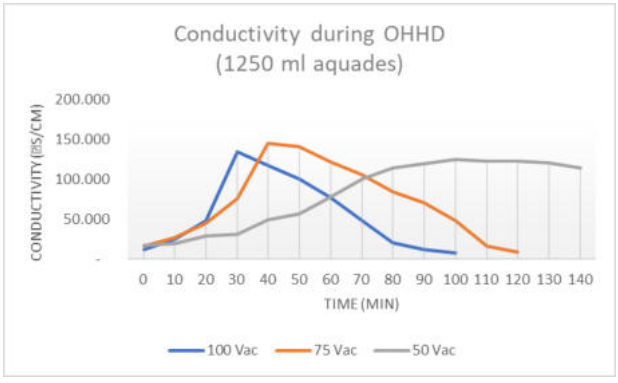

Fig. 7 - Conductivity during OHHD (1250 ml of distilled water)

Electrode area

Electrode area in ohmic heating are important components for heat to occur. Without electrodes, there will be no heating. The electrodes used in ohmic heating are selected from materials that do not change properties (corrosive) due to electricity flowing and do not dissolve in the heated solution. In this study, stainless steel was used as the electrode because it has corrosion-resistant properties (*Assiry et al., 2003*).

The electrodes used are a pair of parallel plates in the form of a cylinder/tube. The inner and outer electrodes have different areas. The cavity between the two electrodes functions as a place for agricultural materials that are given heating treatment or a hydrodistillation chamber. The outer electrode (neutral) has a tube cover area of 592.2 cm² with a tube base area of 253.2 cm², while the inner electrode (phase) has a tube

cover area of 227.1 cm² and a base area of 61.1 cm². The area of the outer electrode (blanket and base) is 845.4 cm², and the area of the inner electrode (blanket and base) is 288.2 cm². When given different treatments of adding water and nutmeg leaves, the electrode plates immersed in water are also different. The difference in the water that is immersed causes a difference in the contact area of the electrode or a difference in the electrode area. Table 1 presents the relationship between water volume and electrode surface area.

Table 1

Electrode area

water volume (ml)	water level (cm)	outer electrode area (cm^2)	inner electrode area (cm^2)	average electrode area (cm^2)
750	*3,9*	*473,1*	*105,4*	*289,3*
1000	*5,1*	*540,8*	*138,6*	*339,7*
1250	*6,7*	*631,0*	*182,9*	*407,0*
full	*10,5*	*845,4*	*288,2*	*566,8*

The electrode area, or the area of contact between the object and the electrode, also affects the success of ohmic heating hydrodistillation. The electrode area will affect the value of electrical conductivity. The results of the calculation of the electrical conductivity value during the nutmeg leaf hydrodistillation process using ohmic heating at the same electrical voltage are presented in figures 8, 9, and 10. Based on the figure, in general, at the same voltage, the conductivity value is influenced by the volume of water used. The greater the volume of water used, the greater the conductivity value.

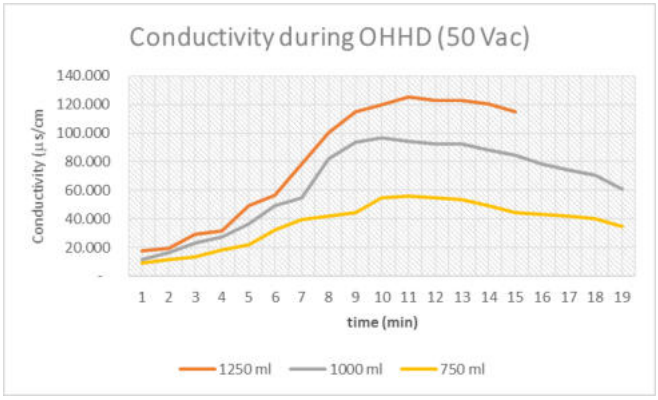

Fig. 8 - Conductivity during OHHD (Voltage 50 Vac)

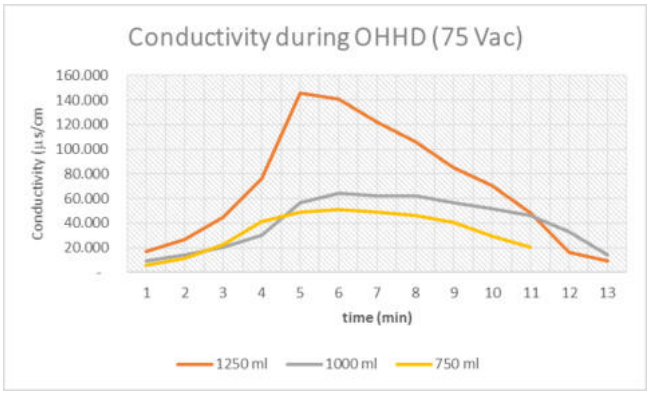

Fig. 9 - Conductivity during OHHD (Voltage 75 Vac)

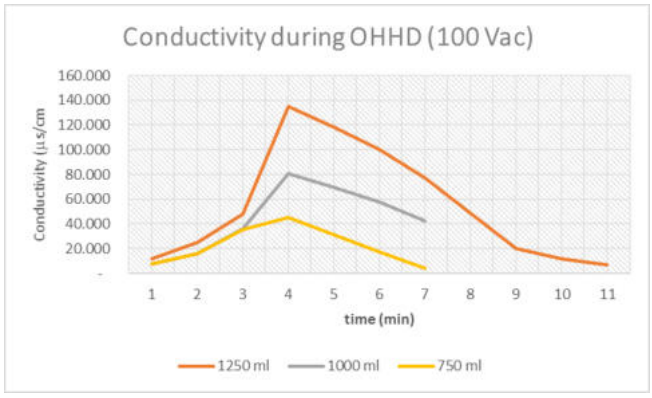

Fig. 10 - Conductivity during OHHD (Voltage 100 Vac)

The greater the volume of water used, the higher the water level in the treatment chamber. The higher the water level in the treatment chamber, the greater the surface area of the electrode. So, at the same voltage, the wider the electrode surface, the greater the electrical conductivity value. Electrical conductivity in the ohmic heating hydrodistillation process is influenced by the distance between electrodes, surface area, electric current, and electric voltage (*Zell et al., 2009*).

During the ohmic heating hydrodistillation process, energy is required from electricity. The electric current is converted into heat energy to boil the mixture of water and nutmeg leaves. In ohmic heating hydrodistillation, heating occurs due to the electric current in the mixture of water and nutmeg leaves. The heating rate is influenced by the amount of voltage and the volume of water used. In this study, 3 different voltage levels were used, i.e., 50 Vac, 75 Vac, and 100 Vac, and 3 levels of water volume that affect the duration of the heating process. Both factors will affect the amount of energy required during the ohmic heating hydrodistillation process. The amount of energy during ohmic heating hydrodistillation is as shown in Fig. 11 and Fig. 12.

The amount of hydrodistillation energy varies from each water volume treatment and voltage treatment. Figure 11 shows that the energy consumption pattern for a water volume of 1250 ml and a water volume of 1000 ml gives the same results. At the same water volume, the higher the voltage, the greater the energy required during the process.

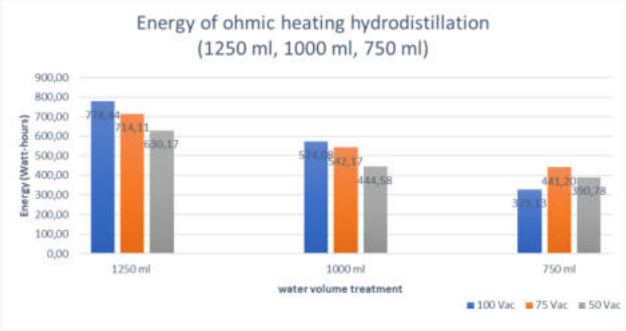

Fig. 11 – Energy of OHHD at 1250 ml, 1000 ml, and 750 ml

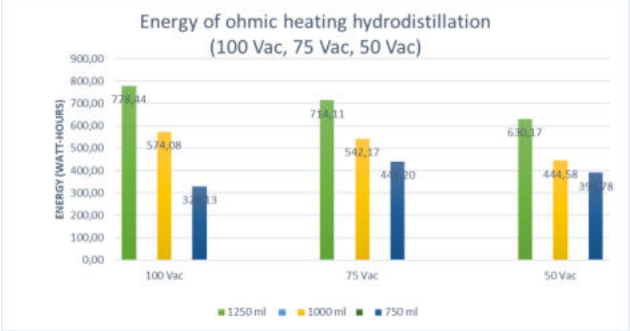

Fig. 12 – Energy of OHHD at 100 Vac, 75 Vac, and 50 Vac

A different pattern occurs in a water volume of 750 ml, i.e., at a voltage of 100 Vac, the energy produced during the process is smaller than the energy at a voltage of 75 Vac and 50 Vac. This is influenced by the duration of the hydrodistillation process. At a voltage of 100 Vac, the time required for the ohmic heating hydrodistillation process is only 50 minutes, while for voltages of 75 Vac and 50 Vac, it is greater, i.e., 100 minutes and 190 minutes. In the combination of 100 Vac voltage and 750 Vac water, the water evaporates faster so that the electric current stops because there is no water.

Ohmic heating hydrodistillation energy at the same voltage is shown in Fig. 12. Based on the figure, it can be seen that the energy required from each voltage has the same pattern. At a voltage of 100 Vac, the energy required for a water volume of 1250 ml is greater than for a water volume of 100 ml and a water volume of 750 ml. At voltages of 75 Vac and 50 Vac, the pattern is the same as at a voltage of 100 Vac. At the same voltage, energy consumption is influenced by the amount of water. The greater the volume of water, the greater the energy required to boil the mixture of water and nutmeg leaves.

Oil yield

The results of laboratory analysis indicated that the resulting oil had a refractive index of 1.4776 and an optical rotation of -4.834. The results of GC (gas chromatography) analysis indicated that nutmeg leaf oil had 25 compounds (Fig. 13). The content of nutmeg leaf oil includes main compounds such as Sabinene compounds (19.07%), α-pinene (18.04%), 4-terpineol (11.83%), limonene (8.32%), and β-pinene (7.92%) (*Asgarpanah & Kazemivash, 2012*). According to the measurement of mass spectrometry (MS), the myristicin concentration was 4.80% (SNI min 10%). SNI 06-2388-2006, pertaining to nutmeg oil derived from nutmeg seed distillation, serves as the standard reference for nutmeg oil. Since there is no SNI for nutmeg leaf oil used as a reference, some test results, like optical rotation and myristicin content, do not meet the SNI.

Oil yield is an extract of nutmeg leaves oil produced from the hydrodistillation process using ohmic heating. The resulting nutmeg leaves oil has a pale yellow color (Fig.14). The highest oil yield that could be extracted in this research was 1.07% when 50 Vac voltage and 750 ml of water or a nutmeg leaf to water ratio of 1:0.75 was combined, while the lowest yield of 0.38% was obtained when 75 Vac voltage and 1250 ml of water were combined (Fig. 15). The production of nutmeg leaf oil in ohmic heating hydrodistillation is influenced by the electric voltage and water volume. Ohmic heating not only produces a heating effect but also causes the cell walls of the leaves to permeate. The rate of diffusion through the cell wall, the extraction yield, and the reaction process can all be accelerated by increasing cell wall permeabilization (*Sofi'i & Arifin, 2022*).

Results of laboratory tests on the content of nutmeg leaf oil using the Soxhlet method chemical solvent gave a yield of 1.49%, while according to *BSN (2006)*, the oil content of nutmeg leaves is no more than 1.7%. If the hydrodistillation method using ohmic heating with a water solvent is compared to the Soxhlet method with an n-hexane solvent, it shows that the ohmic heating hydrodistillation method has an oil extraction efficiency of 1.07% divided by 1.49% or 71.8%.

Fig. 14 – Nutmeg leaves oil

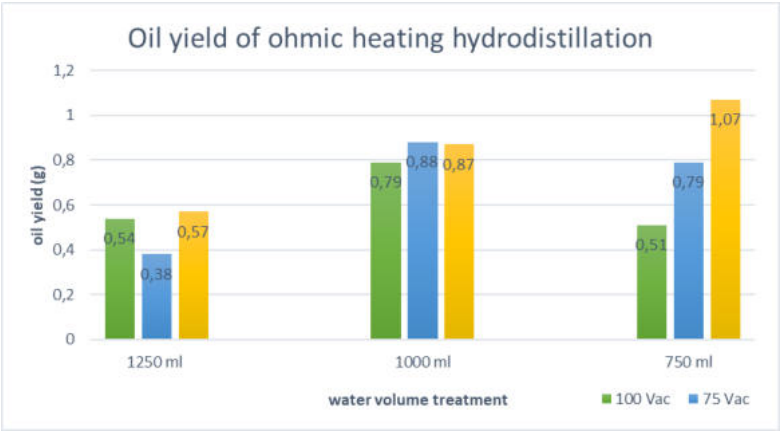

Fig. 15 - Nutmeg leaves oil yield

CONCLUSIONS

The higher the voltage, the faster the time to reach the boiling point of the liquid. The higher the volume of water, the lower the heating rate. The duration of the hydrodistillation process is influenced by the voltage and water used. The electrical conductivity value of the mixture of water and nutmeg leaves during the hydrodistillation process varies depending on the volume of water, voltage, electrode surface area, and temperature. At the same volume of water, the higher the voltage, the greater the energy required during the process. The greater the volume of water, the greater the energy required to boiling the mixture of water and nutmeg leaves. In ohmic heating hydrodistillation, the magnitude of the electric voltage and the volume of water used affect the yield of nutmeg leaf oil. The maximum oil yield that can be extracted is 1.07% at a combination of 50 Vac voltage and 750 ml of water, while the lowest yield is 0.38% at a combination of 75 Vac voltage and 1250 ml of water.

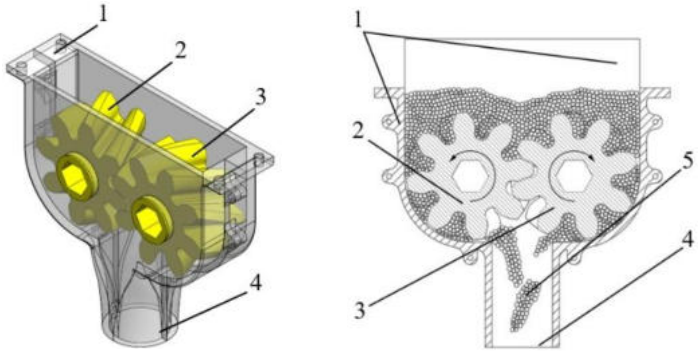
ABSTRACT
Based on the agronomic characteristics of pineapple fertilization and the challenges posed by moist fertilizer particle adhesion, an interactive gear fertilizer discharger was developed. This device utilizes a pair of continuously meshing, counter-rotating gears to achieve centralized and interactive mixing of fertilizer. Through theoretical analysis, the fertilizer discharge volume and maximum operating speed of the discharger were determined. In the experimental design, the pressure angle and helix angle of the fertilizer wheel were selected as test factors, while the coefficient of fluctuation in fertilizer uniformity served as the test index. A single-factor test was conducted to analyze the influence of each factor on the index and to determine the appropriate range of values. Subsequently, a quadratic general rotary combination design was used to optimize the fertilizer wheel parameters. The results indicated that both the pressure angle and helix angle had a significant effect on the coefficient of fluctuation of fertilizer uniformity (P<0.01). The lowest fluctuation coefficient, 11.82%, was achieved when both angles were set to 30°. A simulation verification test yielded a result of 11.92%, with a relative error of 0.85% compared to the theoretical value. Bench tests conducted under optimal parameters showed a relative error of 2.77% between the experimental and simulated values. Furthermore, the average error between the measured fertilizer discharge flow rate and the theoretical value under varying speeds was 3.75%. No fertilizer adhesion was observed on the surface of the discharge wheel, demonstrating that the system enables fine regulation of fertilizer output while effectively mitigating fertilizer adhesion.

摘要
根据菠萝施肥的农艺特性以及潮湿肥料颗粒粘连问题，设计了一种交互式防粘齿轮排肥器，其采用一对持续啮合反向挤压旋转的齿轮实现肥料的对中交互混排。通过理论分析确定交互式齿轮排肥器的理论排肥量与最大转速，利用 EDEM 软件对排肥过程进行仿真模拟。以排肥轮的压力角和螺旋角为试验因素，以排肥均匀性波动系数为试验指标，通过单因素试验分析试验因素对试验指标的影响，并确定试验因素的范围。通过二次通用旋转组合设计试验优化出排肥轮的最优参数。试验结果表明：排肥轮压力角和螺旋角对排肥均匀性变异系数均有极显著影响（P＜0.01），当排肥轮压力角和螺旋角均为 30°时，排肥均匀性变异系数最小为 11.82%。仿真验证试验结果为 11.92%，相对误差为 0.85%，最优参数下台架试验结果表明：试验值与仿真值的相对误差为 2.77%，排肥流量可通过排肥轮转速线性调节。其结果表明：在排肥转速流量曲线下排肥流量与理论值平均误差为 3.75%，排肥轮表面并无粘结肥料，实现对排肥量的精量调控且有效降低其肥料对排肥轮的粘连作用。

INTRODUCTION
The proper use of fertilizers plays a crucial role in the growth of pineapples in terms of fruit quality and yield. Unreasonable fertilization methods will not only damage crops and reduce their production but also cause some problems, such as the waste of resources, environmental pollution, and land degradation. Studies have shown that compared with unreasonable fertilization methods, precision fertilization can better alleviate the above problems under the premise of meeting the needs of crop growth, which is of great significance for the sustainable development of agriculture *(Chen et al., 2015; Li et al., 2008; Du et al., 2020)*.

At present, the widely used fertilizer discharger in the market is the external grooved wheel type fertilizer discharger, which has high requirements for the physical properties of fertilizers. Still, the effect is good when discharging and applying dry granular fertilizers, and poor when discharging and applying moist granular fertilizers and powdered fertilizers *(Lv et al., 2013; Liu et al., 2021)*. Mechanical fertilizer application can effectively reduce the labor intensity of fruit farmers, improve the efficiency and quality of fertilizer application, and reduce the cost of agricultural production.



The fertilizer discharger is the key component of the fertilization device, and its performance will directly affect the fertilization effect. If the uniformity of the fertilizer discharger is very low, it will not only reduce the fertilizer utilization rate, and affect the quality and yield of crops, but also make it difficult to achieve precision fertilization *(Tai et al., 2020; Su et al., 2015)*. Relevant experts and scholars have done a lot of research on improving the uniformity of fertilizer discharge and realizing precision fertilization. *Wang et al., (2017),* analyzed the effects of the working length of the outer groove wheel, the rotational speed of the fertilizer shaft, and the opening angle of the fertilizer tongue on the amount of fertilizer and the uniformity of fertilizer discharge. *Dun et al., (2018),* analyzed the influence of the structural parameters of the fertilizer tongue of the outer groove wheel fertilizer discharger on the uniformity of fertilizer discharge by discrete element method. *Zhu et al., (2018),* analyzed the influence of the groove wheel radius, the number of grooves, the effective working length and the shape of the groove section on the uniformity of fertilizer discharge. *Yao et al., (2020),* realized precision fertilization by adjusting the motor speed to control the amount of fertilizer. *Zuo et al., (2016),* developed a precise fertilizer control system, which can adjust the amount of fertilizer in real time according to the operation speed of the machine. *Yu et al., (2020),* designed a double-gear type fertilizer discharger, whose tooth ridge and tooth groove continuously alternating operation even fertilizer effect has been significantly improved, but its uniformity still has room for improvement. The research of experts and scholars in discrete element simulation and precision fertilization has played an important supporting role in this study.

In this study, an interactive gear fertilizer distributor was designed based on the principle of fertilizer alignment and interactive mixing. Through theoretical analysis, the theoretical fertilizer discharge amount and maximum speed of the fertilizer discharger are determined, and the fertilizer discharge process is simulated by discrete element simulation technology. The test range was determined by single factor test, and the influence of different factors on the coefficient of variation of fertilizer uniformity was analyzed by quadratic general rotary combination design test, and the structural parameters of the interactive gear fertilizer distributor were optimized when the coefficient of variation of fertilizer uniformity was the lowest. The interactive gear fertilizer distributor prototype with optimal parameters was made by 3D printing technology. The simulation value and theoretical value were verified by bench test, and the relationship between fertilizer discharge flow and fertilizer discharge wheel speed was analyzed by controlling the rotational speed of fertilizer discharge wheel through motor controller. Based on the speed-flow relationship curve of the fertilizer wheel, an electronically controlled fertilizer discharge controller was developed and its working performance was tested in order to improve the uniformity of fertilizer discharge and achieve precise control of fertilizer discharge.

MATERIALS AND METHODS

The Structure and Working Principle of The Whole Machine

The three-dimensional model and sectional working diagram of the interactive gear fertilizer discharger are shown in Fig.1. The device consists of a left-handed fertilizer discharge gear, a right-handed fertilizer discharge gear, a fertilizer discharge box, and a fertilizer outlet.

a) *b)*

Fig. 1 - Interactive gear fertilizer apparatus schematic diagram

a) Three-dimensional model diagram; b) The schematic diagram of section work

1. Fertilizer box; 2. Left-handed fertilizer gear; 3. Right-handed fertilizer gear; 4. Outlet; 5. Fertilize

When working, the drive motor drives the left-handed fertilizer gear to rotate counterclockwise. The right-handed fertilizer gear rotates clockwise through the gear meshing, and the rotation of the fertilizer gear drives the fertilizer movement. The fertilizer is confined in the fertilizer space formed by the tooth grooves and the fertilizer box. It moves downward along the contour of the fertilizer box until the tooth grooves rotate to the top of the fertilizer outlet. The fertilizer is discharged alternately to fall into the fertilizer outlet by gravity, which ensures the continuity of fertilizer discharge and realizes the uniformity of fertilizer discharge.

Fig. 2 illustrates the anti-sticking mechanism during the fertilizer discharge process. Moisture in the fertilizer can cause particles to stick to the gear surface. As the gears rotate and mesh in the interaction zone, the clinging material is subjected to rolling and squeezing forces between adjacent teeth. This mechanical contact helps dislodge the adhered fertilizer, causing it to fall into the discharge area. The use of diagonally arranged gear teeth increases the meshing duration and overlap, improving the cleaning effect and enhancing anti-adhesion performance.

1. Interaction zone; 2. Fertilizer discharge zone.

Theoretical Fertilizer Discharge and Maximum Speed

The interactive gear fertilizer discharger alternately discharges fertilizer through continuous meshing and reverse rotation of a pair of gears. The volume of a single discharge fertilizer is determined by the size of the fertilizer space formed by the tooth groove and the fertilizer discharge box. Therefore, calculating the volume of the tooth groove of the fertilizer discharge gear is of great significance for studying the theoretical fertilizer discharge and maximum speed of the fertilizer discharger. The fertilizer discharge gear model is shown in Fig. 3.

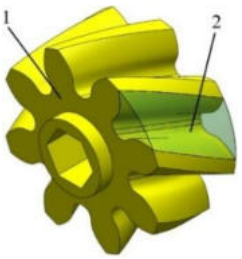

Fig. 3 - Fertilization gear model

1.Fertilizer gear; 2. Fertilizer space.

According to the existing research *(Hu et al., 2016)*, the area of a single tooth groove of the fertilizer gear is calculated using the following equations:

$$s_c = \frac{s_a - s}{z} \tag{1}$$

$$s_a = \frac{\pi d_a^2}{4} \tag{2}$$

$$da = mz + 2h_a^* m \tag{3}$$

$$s = \frac{\pi d^2}{4} \tag{4}$$

$$d = mz \tag{5}$$

where: s_c is the area of the single tooth groove of the fertilizer gear, [mm^2]; s_a is the top circle area of fertilizer gear, [mm^2]; s is the pitch circle area of the fertilizer gear, [mm^2]; d_a is the top circle diameter of fertilizer gear, [mm]; d is the pitch circle diameter of the fertilizer gear, [mm]; h_a* is the top height coefficient of fertilizer gear; z is the number of teeth; m is the modulus, [mm].

The total mass of the fertilizer discharged by the fertilizer discharger is calculated as follows:

$$M = \rho\gamma V \tag{6}$$

where:

$$V = \frac{s_c bntz \times 10^{-4}}{3} \tag{7}$$

where: M is total mass of discharged fertilizer, [g]; P is the bulk density of fertilizer, [g/cm^3]; γ is fertilizer filling coefficient; V is total volume of discharged fertilizer, [cm^3]; b is tooth width of fertilizer gear, [mm]; n is the rotational speed of the fertilizer gear, [r/min]; t is the operating time of the fertilizer discharger.

According to the combined formula (5) ~ (7), the total mass of the fertilizer discharged by the fertilizer discharger is:

$$M = \frac{\rho\gamma bnt\pi\left[m^2\left(z+2h_a^*\right)^2-\left(mz\right)^2\right]\times 10^{-4}}{12} \tag{8}$$

The fertilizer gear is a standard cylindrical gear. The tooth width is set to 30 mm, the number of teeth is 8, the modulus is 6 mm, the addendum height coefficient is 1, the fertilizer bulk density is 0.9 g/cm^3, and the filling coefficient is 0.7. The maximum moving speed of the fertilizer applicator is 7 km/h. Based on the design of the crop ridge spacing of 65 cm, it can be calculated that in order to meet the fertilization requirements of 750 kg/hm^2, the maximum theoretical speed required for the fertilizer distributor is 147.484 r/min *(Dun et al., 2019; Liang et al., 2023; Sun et al., 2019)*.

Discrete Element Simulation Test

Establish Fertilizer Particle Model

The water content of urea particles on the market is usually less than 0.5%, the surface adhesion is small, more than 0.5% will significantly increase the inter-particle hydrogen bonding, so that the adhesion increases, and most of them are spherical. Therefore, urea is selected as the test material for discrete element simulation *(Wen et al., 2020; Yuan et al., 2018; Michele et al., 2015)*. 80 urea particles produced by Anhui Red Sifang Fertilizer Co. Ltd. were randomly selected to measure the triaxial length and mass. The average radius of urea particles was 1.11 mm and the density was 1158 kg/m^3. Therefore, the spherical particles with a particle radius of 1.11 mm are selected as the particle model of discrete element simulation.

Setting Simulation Parameters

Hertz-Mindlin (no slip) in EDEM software was selected as the contact model between fertilizer and fertilizer, fertilizer and fertilizer wheel, shell *(Marcinkiewicz et al., 2019)*, and the parameters were set as shown in Table 1 by consulting literature *(Dun et al., 2020)*.

Table 1

Discrete element simulation parameters

Item	Particle Property	Numerical Value
Fertilizers	Poisson's Ratio	0.25
	Shear modulus/Pa	2.8×10^7
	Density/kg·m^{-3}	1158
Fertilizers unit	Poisson's Ratio	0.43
	Shear modulus/Pa	1.3×10^7
	Density/kg·m^{-3}	1240
Fertilizers - Fertilizers	Restitution coefficient	0.11
	Static friction coefficient	0.30
	Rolling friction coefficient	0.10
Fertilizers - Fertilizers wheel shell	Restitution coefficient	0.41
	Static friction coefficient	0.32
	Rolling friction coefficient	0.18

Discrete Element Model of Fertilizer Distributor

SolidWorks 2020 is used to design the structure of the interactive gear fertilizer discharger and establish the three-dimensional model. The specific steps are as follows: The Maidi three-dimensional design tool set is used to generate the fertilizer wheel model with different pressure angles and helix angles, and the model of the fertilizer discharger is completed according to the fertilizer wheel model. Simplify the fertilizer model, save it as a .stl file, and import it into the discrete element simulation software EDEM, and set the fertilizer and model parameters according to Table 1.

Independent particle factories were created above the two rows of fertilizer wheels, separated by a diaphragm in the middle, and the same fertilizer parameters were used to generate particles. The total number of particles generated in both factories was 10,000, and the generation rate was 10,000/s. Then, a fertilizer collection plate will be set up below the fertilizer discharger. To facilitate the observation of the interaction of fertilizer particles and their distribution on the fertilizer collection plate, the rotational speed of the fertilizer wheel was set to 60 r/min, and the movement speed of the fertilizer collection plate was 1 m/s. The simulation step size was 4.89×10^{-6} s, the data recording time interval was 0.01 s, and the total simulation time was 2.6 s. The simulation process is shown in Fig. 4.

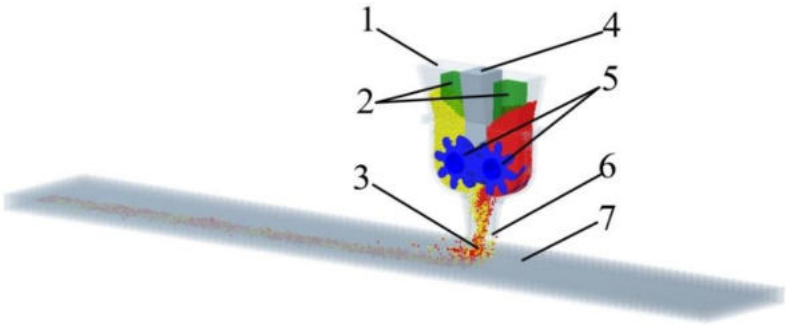

Fig. 4 - Simulation process

1. Fertilizer discharge zone; 2. Particle factory; 3. Fertilizer; 4. Diaphragm; 5. Fertilizer wheel; 6. Fertilizer outlet; 7. Fertilizer collection plate.

Evaluation of Fertilizer Performance

The timing diagram is used to show the process of fertilizer discharge in order to observe the mixing process of fertilizer particles, as shown in Fig. 4. The fertilizer quality monitoring area was established, and the quality data of yellow particles, red particles and total particles in the monitoring area were collected and the particle quality change curve was made by Origin software. The change process of two kinds of fertilizer particles and total particle quality can be seen more intuitively, as shown in Fig. 5.

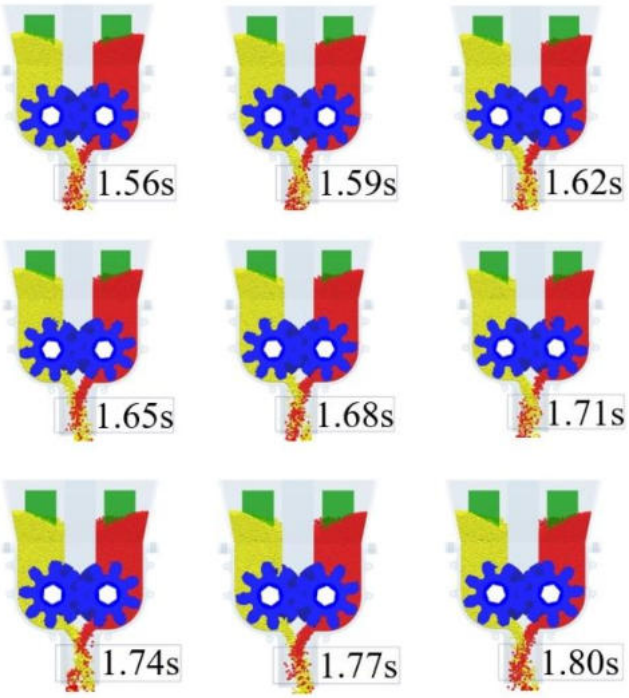

Fig. 5 - Time sequence diagram of fertilizer discharge process

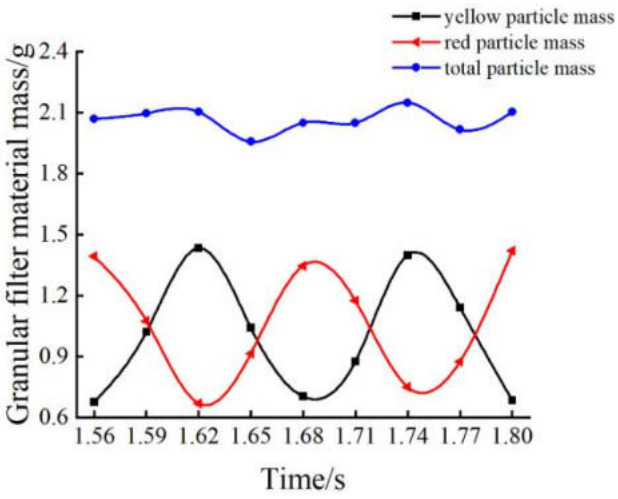

Fig. 6 - Particle mass change diagram

It can be seen from Fig. 5 and Fig. 6 that yellow particles and red particles are alternately discharged and mixed with each other under the action of the fertilizer wheel. The mass of yellow particles and red particles fluctuates with time. When the mass of yellow particles is the most, the mass of red particles is the least. When the mass of yellow particles increases, the mass of red particles decreases, and vice versa. This way of fertilizer discharge can ensure the uninterrupted discharge of fertilizer and ensure the uniformity of fertilizer discharge.

In order to accurately evaluate the uniformity of the interactive gear fertilizer distributor, the grid method was used to count the fertilizer quality on the fertilizer collection plate *(Yang et al., 2020)*, as shown in Fig.7.

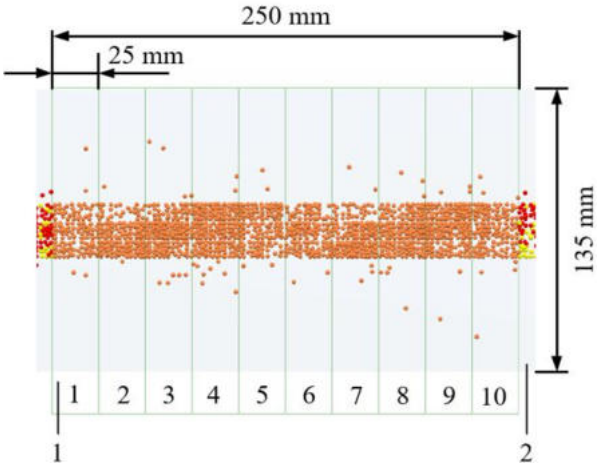

Fig. 7 - Grid division diagram

1. Uniformity test area; 2. Fertilizer collection plate.

The fertilizer is alternately discharged by the left-handed fertilizer gear and the right-handed fertilizer gear, and presents a periodic distribution on the fertilizer collection plate. According to the rotational speed of the fertilizer wheel and the moving speed of the fertilizer collection plate, the moving distance of the fertilizer collection plate is 125 mm for each cycle of fertilizer discharge. Therefore, the length of the monitoring area is set to 250 mm, and the monitoring area is divided into 10 parts by grid and numbered from 1 to 10, and the fertilizer quality in each grid is counted respectively. The smaller the coefficient of variation of the uniformity of the fertilizer is, the better the uniformity of the fertilizer is. Therefore, the coefficient of variation of the uniformity of the fertilizer is used as the evaluation index of the fertilizer performance of the fertilizer discharger. The average value, standard deviation and coefficient of variation of fertilizer quality in the monitoring area were calculated by formulas (9) ~ (11).

$$\overline{m} = \frac{\sum_{i=1}^{10} m_i}{n} (i = 1,2,\ldots,10) \tag{9}$$

$$s = \sqrt{\frac{\sum^{10}(m_i - \overline{m})^2}{n-1}} (i = 1,2,\ldots,10) \quad (10)$$

$$\sigma = \frac{s}{m} \times 100\% \quad (11)$$

where: $\overline{m}$ is Average quality of fertilizers in the monitoring area, [g]; m_i is the total mass of fertilizer in the i grid, [g]; n is the number of grids, n = 10; s is the standard deviation of fertilizer quality in monitoring area, [g]; σ is Coefficient of variation of fertilizer uniformity in monitoring area.

Relationship Between Pressure Angle of Fertilizer Discharge Wheel and Uniformity of Fertilizer Discharge

The size of the pressure angle of the fertilizer discharge wheel will affect the size and shape of the fertilizer space *(Liu et al., 2020)*, which in turn will affect the time interval between two adjacent slots discharging fertilizer, the falling speed of fertilizer and other factors during the fertilizer discharge process.

According to the design principle of the involute gear, the pressure angle of the fertilizer discharge wheel is selected as 5°, 10°, 15°, 20°, 25°, 30° *(Chen et al., 2008; Song et al., 2016)*. During the single-factor comparative test of the pressure angle of the fertilizer discharge wheel and the uniformity of fertilizer discharge, the helix angle of the fertilizer discharge wheel was uniformly 0°. The variation coefficient of fertilizer discharge uniformity of fertilizer discharge wheels with different pressure angles is shown in Fig. 8 below.

The variation coefficient of fertilizer discharge uniformity decreases with the increase of pressure angle of fertilizer discharge wheels. When the pressure angle of the fertilizer discharge wheel is 30°, the coefficient of variation of the uniformity of fertilizer discharge is the smallest, indicating that when the pressure angle of the fertilizer discharge wheel is 30°, the distribution of fertilizer on the collecting plate is the most uniform, and the fertilizer discharge performance is the best.

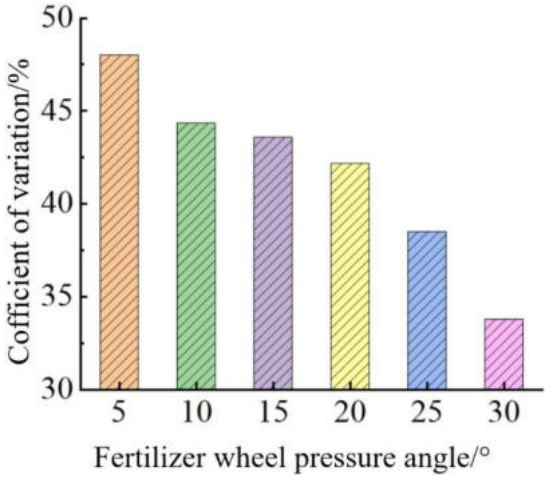

Fig. 8 - The relationship between the pressure angle of fertilizer wheel and the coefficient of variation of fertilizer uniformity

The Relationship Between the Helix Angle of The Fertilizer Discharge Wheel and The Uniformity of Fertilizer Discharge

The size of the helix angle will also affect the size and shape of the fertilizer space. Compared with the spur gear, the helical gear with the same tooth groove has a longer longitudinal length during the falling process, and the fertilizer is more evenly distributed on the collecting plate. When two adjacent tooth slots of the helical fertilizer discharge gear overlap in the axial direction, the fertilizer in the previous slot may not be fully discharged before the next slot begins releasing fertilizer. This overlapping discharge process ensures a continuous and uninterrupted flow, thereby improving the uniformity and effectiveness of fertilizer application.

According to the design principles of helical gears, the helix angle of the fertilizer discharge wheel was selected as 0°, 5°, 10°, 15°, 20°, 25°, and 30°. In the single-factor comparative experiment evaluating the effect of helix angle on the uniformity of fertilizer discharge, the pressure angle was fixed at 20°. The coefficient of variation in fertilizer discharge uniformity for wheels with different helix angles is presented in Figure 9.

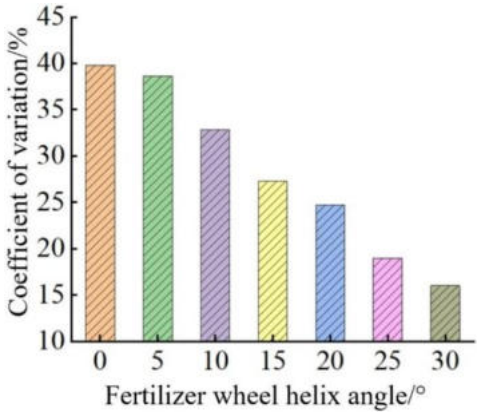

Fig. 9 - Relationship between the helix angle of the fertilizer discharge wheel and the coefficient of variation of fertilizer discharge uniformity

The coefficient of variation in fertilizer discharge uniformity decreased with increasing helix angle of the fertilizer discharge wheels. When the helix angle reached 30°, the variation coefficient was at its lowest, indicating the most uniform distribution of fertilizer on the collecting plate. This suggests that a 30° helix angle provides the optimal discharge performance and the highest uniformity in fertilizer application.

RESULTS

RESPONSE SURFACE EXPERIMENT

Test Design

Based on the results of the single-factor experiments, it was observed that the coefficient of variation in fertilizer discharge uniformity decreases with increasing pressure angle and helix angle of the fertilizer discharge wheel. By analyzing the effects of different pressure angles and helix angles of the fertilizer discharge wheel on the fertilizer distribution performance of interactive anti-adhesion gears, the structural parameters of the fertilizer discharge wheel are optimized. A secondary general rotational combination test method was selected to analyze the effects of the pressure angle and helix angle of the fertilizer discharge wheel on fertilizer uniformity. The coefficient of variation of fertilizer uniformity was used as the evaluation criterion. Based on the results of single-factor simulation tests, the pressure angle range of the fertilizer discharge wheel was selected as 5° ~ 30°, and the helix angle range was selected as 0° ~ 30°. The coded levels of the experimental factors are shown in Table 2, where X_1 and X_2 are the factor code values for the pressure angle and helix angle, respectively.

Table 2

Test factor coding table

Coding	Test Factor	
	Fertilizer Wheel Pressure Angle X_1 / [°]	Fertilizer Wheel Helix Angle X_2 / [°]
1.414	30.00	30.00
1	26.34	25.61
0	17.50	15.00
-1	8.66	4.39
-1.414	5.00	0.00

Test Results and Analysis of Variance

Taking the pressure angle X_1 and the helix angle X_2 of the fertilizer discharge wheel were selected as test factors, and the coefficient of variation σ of the fertilizer discharge uniformity was used as the evaluation index. Using Design-Expert software a regression analysis was conducted on the experimental data to determine the relationship between discharge uniformity and the two factors. In addition, an analysis of variance (ANOVA) was performed to assess the statistical significance of the regression model (*Dun et al., 2024*). The test scheme and corresponding results are presented in Table 3, while the ANOVA results are shown in Table 4.

Table 3

Test scheme and results table

Serial number	Test Factor		σ [%]
	Pressure Angle X_1 / [°]	Helix Angle X_2 / [°]	
1	17.50	0.00	41.47
2	8.66	4.39	41.74
3	17.50	15.00	27.75
4	30.00	15.00	25.17
5	17.50	15.00	31.13
6	17.50	30.00	13.40
7	17.50	15.00	28.41
8	17.50	15.00	30.72
9	5.00	15.00	32.61
10	8.66	25.61	19.65
11	17.50	15.00	27.40
12	26.34	4.39	35.46
13	26.34	25.61	17.08

Table 4

Significance analysis of test parameters

Source	Sum of squares	Degree of freedom	Mean square	F number	P value
Model	857.58	5	171.52	95.58	0.0001**
X_1	46.91	1	46.91	26.14	0.0014*
X_2	803.34	1	803.34	447.68	0.0001**
X_1X_2	3.44	1	3.44	1.92	0.2087
X_1^2	1.781×10^{-3}	1	1.781×10^{-3}	9.924×10^{-4}	0.9757
X_2^2	3.85	1	3.85	2.14	0.1866
Residual	12.56	7	1.79		
Lack of fit	0.63	3	0.21	0.070	0.9728
Pure error	11.93	4	2.98		
Sum	870.15	12			

*Note: ** indicates highly significant effect (p<0.01), * indicates significant effect (0.01<p<0.05).*

From the analysis of variance in Table 4, it can be seen that the significance test of the model is F=95.58, P<0.0001, and the coefficient of determination R^2=0.9856. This indicates that the regression model is extremely significant, and the test result of the lack of fit item is not significant (P>0.05). This also indicates that the regression model fit well within the experimental range. At the same time, X_1 and X_2 have a very significant effect on the variation coefficient of fertilizer uniformity (P<0.01), and the remaining items have no significant effect (P>0.05). Remove the coefficients of insignificant factors from the regression equation. The finally regression equation of the fertilizer uniformity coefficient model is:

$$\sigma = 49.1 - 0.42X_1 - 0.92X_2 \quad (12)$$

Influence of Experimental Factors on Indicators

The influence of the pressure angle and helix angle of the fertilizer discharge wheel on the uniformity of fertilizer discharge is shown in Fig. 10. It can be seen from the response surface plot in Figure 9 that when the helix angle is 0° and 30°, the coefficient of variation decreases with the increase of the pressure angle, and when the helix angle is 30°, the coefficient of variation is generally lower. When the pressure angle is 5° and 30°, the coefficient of variation decreases with the increase of the helix angle, and when the pressure angle is 30°, the coefficient of variation is generally lower. At the same time, it can be seen that the variation trend of the coefficient of variation with the change of pressure angle is relatively gentle, this is because the influence of pressure angle on the coefficient of variation is smaller than that of the helix angle. Overall, the trend of change is consistent with the results of the single-factor test and analysis of variance. After optimization, it can be obtained that the pressure angle and helix angle of the fertilizer discharge wheel corresponding to the minimum coefficient of variation are both 30°, and the minimum coefficient of variation is 11.82%.

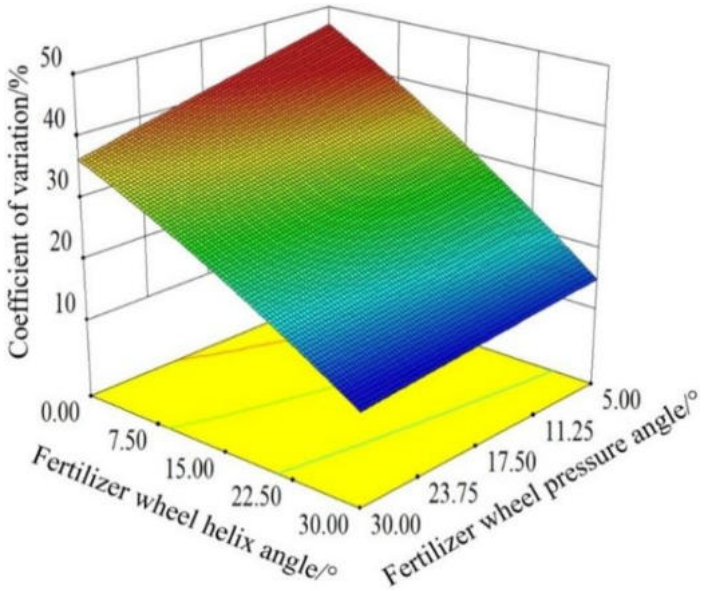

Fig. 10 - Response Surface Plot

In the discrete element simulation software EDEM, a discrete element simulation test was carried out on the model of the optimized interactive gear fertilizer discharger. The test measured that the coefficient of variation of the fertilizer uniformity of the optimized interactive gear fertilizer discharger was 11.92%, The relative error with the theoretical value is 0.85%, which proves the accuracy and validity of the theoretical value.

Bench Experiment and Results

In order to verify the correctness of the simulated value and the theoretical value, the uniformity of the fertilizer discharge of the interactive gear fertilizer was tested through a bench test, and the relationship between the speed of the fertilizer discharge wheel and the flow rate was analyzed by controlling the speed of the fertilizer discharge wheel. D printing technology was used to make an interactive gear fertilizer prototype with optimal parameters, and urea produced by China Salt Anhui Hongsifang Fertilizer Co. Ltd. was selected as the test material.

Verification Test

The width of each fertilizer collection box used in the bench test was 20 mm. To facilitate the calculation of the coefficient of variation for fertilizer discharge uniformity, the monitoring area was divided using 10 fertilizer collection boxes. The conveyor belt speed was set to 0.5 m/s, and the rotational speed of the fertilizer discharge wheel was set to 60 r/min. The test was repeated three times, and the average value was taken as the final result, as shown in Figure 11. The test results showed that the coefficient of variation for fertilizer discharge uniformity of the interactive gear fertilizer discharger was 12.25%, with a relative error of 2.77% compared to the simulation value. The discrepancy is attributed to the fact that the urea particles used in the test were not perfect spheres. However, since the relative error was less than 5%, it is considered within an acceptable range, thus validating the accuracy of the simulation model.

Fertilizer Discharge Flow Rate Test

According to the theoretical calculation of the limit speed of the fertilizer discharge wheel, the rotational speed was set to 30 r/min, 60 r/min, 90 r/min, 120 r/min, and 150 r/min, and five groups of experiments were conducted. During testing, the conveyor belt was turned on and maintained at a constant speed of 0.5 m/s. The motor controller was used to adjust the fertilizer discharge wheel to each specified speed. Once the system reached stable operation at each speed, 10 fertilizer collection boxes were used to collect fertilizer discharged from the outlet. The fertilizer discharge flow rate was then calculated based on the time required for all 10 boxes to fill. Each experiment was repeated three times, and the average value was recorded as the final result. The relationship between fertilizer discharge flow rate and the rotational speed of the fertilizer discharge wheel was analyzed using linear fitting in Origin software. The fitting results showed a strong linear correlation, with the regression equation $y=0.74x+1.39$. This indicates that the fertilizer flow rate can be linearly adjusted by controlling the rotational speed of the fertilizer discharge wheel.

1. Fertilizer wheel; 2. Lithium battery; 3. Motor controller; 4. Drive motor; 5. Fertilizer box; 6. Test frame; 7. Interactive gear fertilizer; 8. Urea granules; 9. Fertilizer collection box.

Five speeds were randomly selected within the range of 30 r/min to 140 r/min, and the fertilizer discharge controller was used to set the fertilizer discharger to the corresponding speeds for testing. The fertilizer discharge flow rate test was conducted at each speed, repeated three times, and the average value was taken as the final result. The measured values were then compared with the corresponding preset target values. The test results are shown in Figure 12. From the results, it can be seen that the mean deviation between the measured discharge flow rate and the preset value is 3.75%, indicating that the system is capable of achieving precise control of the fertilizer discharge amount.

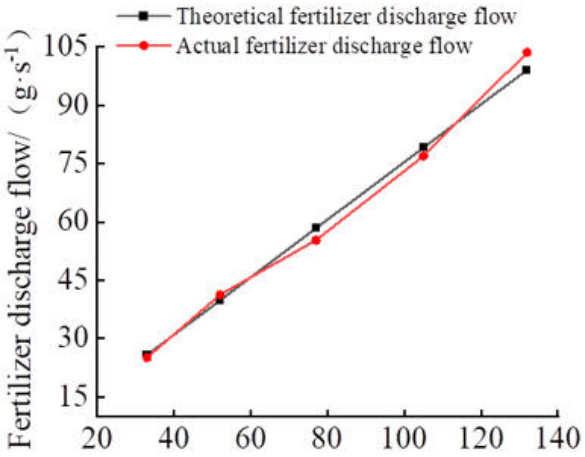

Fig. 12 - Test result diagram

Anti-Adhesion Verification Test

To simulate real working conditions, urea particles were moistened with water to increase adhesion. The Double-Gear Fertilizer Discharger *(Dun et al., 2019)* was used as a reference. Both the reference discharger and the Interactive Anti-Stick Fertilizer Discharger were tested at a fertilizer discharge wheel speed of 30 r/min. Each test was repeated five times, and the surfaces of the fertilizer discharge wheels were inspected after operation. The results showed that in the Double-Gear Fertilizer Discharger, fertilizer adhesion was clearly observed on the surface and in the grooves of the discharge wheel. Sticking traces were particularly evident at the bottom of the gear grooves, as shown in Figure 13a. In contrast, the Interactive Anti-Stick Fertilizer Discharger exhibited no obvious fertilizer adhesion during or after operation. Upon removal, the gear surfaces showed no significant sticking traces, as seen in Figure 13b. These results suggest that the Interactive Anti-Stick design effectively reduces fertilizer adhesion. Its mechanism allows residual fertilizer on the wheel to be dislodged during gear meshing, where compression between meshing teeth helps detach moist fertilizer particles. Compared to the conventional double-gear design, the anti-sticking performance is significantly improved.

The 3D model was saved in IGS format and imported into EDEM software. Hertz-Mindlin (no slip) in EDEM was selected as the contact model between granular fertilizer and granular fertilizer, caking fertilizer and caking fertilizer, granular fertilizer and caking fertilizer, granular fertilizer and fertilizer discharge device, and caking fertilizer and fertilizer discharge device. The fertilizer discharge device was modeled using PLA (polylactic acid) as the material. The detailed material and contact parameters used in the simulation are provided in Table 2.

CONCLUSIONS

（1）Based on the agronomic fertilization requirements of pineapple orchards, an interactive gear fertilizer discharger was designed using the principle of fertilizer centering and interactive mixed discharge. The system utilizes a pair of continuously meshing, counter-rotating gears to alternately discharge fertilizer. A single-factor experiment and a response surface experiment were conducted using the pressure angle and helix angle as experimental factors, with the coefficient of variation of fertilizer discharge uniformity as the evaluation index. The structural parameters of the fertilizer discharger were optimized, and bench tests were performed to verify the results and analyze the relationship between the fertilizer discharge wheel speed and the fertilizer discharge flow rate.

（2）The results of the single-factor and response surface experiments indicate that both the pressure angle and helix angle of the fertilizer discharge wheel have a highly significant effect on the coefficient of variation of fertilizer discharge uniformity. The coefficient of variation decreases as the pressure angle and helix angle increase. When both angles are set to 30°, the minimum variation coefficient of fertilizer discharge uniformity is achieved at 11.82%.

（3）The bench test results show that the relative error between the theoretical, simulated, and experimental values is 2.77%, confirming the model's accuracy. Additionally, the fertilizer discharge flow rate can be linearly adjusted by changing the rotation speed of the fertilizer discharge wheel. The fitted linear relationship is described by the equation y=0.74x+1.39. Under the optimal parameter combination, the average deviation between the actual and preset fertilizer discharge flow rates is 3.75%, indicating a high level of precision and stable performance.

（4）A comparison of fertilizer adhesion on the gear surfaces under identical working conditions demonstrated that the interactive anti-adhesive fertilizer discharge wheel significantly reduces adhesion compared to the conventional double gear-type fertilizer discharger. This verifies the feasibility and effectiveness of the anti-adhesion design, effectively enhancing the anti-stick performance of the fertilizer discharge wheel surface.

（5）Therefore, the interactive anti-stick gear fertilizer discharger developed in this study is well-suited for fertilizer application in pineapple orchards. It effectively enhances the accuracy of fertilizer application, improves the stability of fertilizer discharge, and increases the utilization efficiency of fertilizer, ultimately contributing to higher yield and improved fruit quality. Additionally, the system offers environmental benefits by reducing fertilizer waste. These findings provide a valuable reference for the design and development of fertilizer application machinery for pineapple orchards and other orchard-based fertilization systems.

Keywords: *Camellia oleifera, vibration harvest, High-speed photography, Mechanical vibration*

ABSTRACT
This study employed high-speed photography to reproduce the vibration behavior of Camellia oleifera fruit and flower buds. Vibration energy was transmitted through the branches to break the balance of the Camellia oleifera branch system, causing the fruit and flower buds to exhibit anisotropic chaotic swings. Post-processing of images showed that the fruit detachment force ranged from 4.57 to 11.85 N, and the flower bud detachment force ranged from 0.68 to 3.24 N. At a vibration frequency of 12.98 Hz, the vibration amplitude did not have a significant effect on the detachment force of fruit and flower buds. The detachment time of Camellia oleifera fruit and flower buds decreased with the increase of vibration amplitude or excitation frequency. Through fitting and analysis of the collected data, the Fourier fitting curves and functions of the motion acceleration of oil-tea fruit and flower buds were obtained, with R^2 values of 0.83996 and 0.73718, respectively.

摘要
通过高速摄影还原了油茶果实与花苞振动行为，振动能量经枝干传递打破枝条系统平衡，使其呈各向异性混沌摆动。后处理影像显示，果实脱落力4.57~11.85N、花苞0.68~3.24N，12.98Hz振动下幅值对脱落力影响不明显，脱落时间随幅值或频率增加而减少。经数据拟合得果实、花苞运动加速度傅里叶拟合曲线及函数，R^2分别为0.83996、0.73718。

INTRODUCTION
Camellia oleifera, a tree species lacking a distinct main trunk, is well-suited for mechanical harvesting of its fruits using canopy vibrators *(Du et al., 2024; Wu et al., 2022; Zhang et al., 2020)*. Compared to manual picking, mechanical harvesting equipment significantly reduces production costs. Mechanical vibration devices apply excitatory forces to fruit trees, inducing synchronized vibration of fruits through branch movement. When the inertial force of a fruit exceeds the binding force between the fruit and its stalk, the fruit detaches *(Freitas Grupioni et al., 2020; Juan et al., 2020; Zhou et al., 2022)*.

Current research on fruit abscission faces a key limitation: most studies rely on physical experiments and theoretical models *(Tombesi et al., 2017; Wu et al., 2020a; Brondino et al., 2021)*, primarily measuring static detachment forces between fruits and stalks. Dynamic analysis of real-time abscission forces under forced vibration remains scarce. While some researchers use physical sensors (e.g., accelerometers) to monitor target motion during tree vibration—requiring sensor placement on fruits or branches to measure acceleration responses under excitation *(Castro-Garcia et al., 2017; Niu et al., 2022; Yuan, 2022; Wu et al., 2020b)*—others have detected through trunk/fruit sensors that fruit drop frequency correlates with vibrator frequency, with resultant acceleration values dependent on fruit-vibrator system interactions *(Torregrosa et al., 2014; Juan et al., 2020; Sargent et al., 2020)*. Though these sensor-based methods efficiently capture motion response patterns, they inherently alter the physical properties of the original branch-fruit system. The added mass and mechanical interference from sensors introduce uncertainties into experimental results.

Enlong Zhao, Ph.D. Stud. Eng; JinHui Zhao, Engineer, M.S. Eng; Tengfei Zhuang, engineer Ph.D. Eng.;
Lijing Liu, Researcher, Ph.D. Eng.; HaiHua Wu, Researcher, Ph.D. Eng.; Yanwei Yuan, Researcher, Ph.D. Eng.

Non-contact measurement technologies offer a solution to these limitations. High-speed photography (HSP) and image processing *(Torregrosa et al., 2014; Xu et al., 2019)* enable precise, contact-free reconstruction of fruit motion during forced vibration. By recording the instantaneous process of fruit-stalk separation with HSP and analyzing key parameters (displacement, velocity, acceleration) via post-processing software, researchers can characterize dynamic behaviors of fruits under vibration and deepen mechanistic understanding of abscission.

This study employs high-speed photography to capture dynamic changes in Camellia oleifera fruits and flower buds during vibration, documenting their abscission timing and modes. Through video data processing, movement trajectories are quantified and vibration-responsive characteristics are analyzed, providing a theoretical basis for optimizing vibrator-based harvesting equipment parameters.

MATERIALS AND METHODS

This study utilized dwarf *Camellia oleifera* trees cultivated in Hunan Province, China, with "Xianglin" fruit varieties as the experimental material. The experiments were conducted in November 2024, corresponding to the mature and optimal harvest period of the "Xianglin 210" cultivar. Branches bearing both fruits and flower buds were excised from the trees and transported to the laboratory for vibration testing.

Excitation device

In the mechanical picking process, regardless of the excitation method employed, vibration energy is transmitted from the branches to the fruits. When the inertial force of the fruits reaches the binding force, the Camellia oleifera fruits will fall off. The experimental test uses a crank - connecting rod - slider mechanism as the vibration energy source (as shown in Figure 1). The vibration frequency of the excitation device can be continuously adjusted within the range of 0 – 30 Hz, and the excitation amplitude values are available in size specifications of 10 mm, 20 mm, 50 mm, and 100 mm. The excitation device is fixed on the small lifting platform to adjust the height of the excitation position. At the same time, a specific clamping mechanism is designed at the end of the slider. Theoretically, the acceleration of the excitation device can be obtained through the following formula:

$$a = \frac{dv}{dt} = -\omega^2 R \sin\left(\omega t + \varphi\right) \tag{1}$$

The maximum absolute value in this case:

$$Abs\left(a_{\max}\right) = \omega^2 R = \left(2\pi f\right)^2 R \tag{2}$$

where: t — time, [s];
R — the length of the crank, [m];
ω — the angular velocity, [rad/s];
f — the frequency, [Hz];
φ — the phase, [rad];
v — the linear velocity, [m/s];
a — the acceleration, [m/s^2].

The theoretical values of the parameters at different amplitudes and frequencies are compared with the results of video analysis.

Image acquisition and analysis

The images were captured using a high-speed industrial camera (resolution: 1920(H)×1080(V); 2.0 megapixels; Model: L-PRI 1000; Exposure time: 2 μs/frame rate; AOS Technologies AG), along with a computer, Phantom control software, and data analysis and processing software.

Data analysis and processing software was employed to analyze the motion states of Camellia oleifera fruits and buds. Using the center of the target fruit or bud as the origin, the position of the tracked fruit or bud was collected every 0.02 seconds. The acceleration of fruits and buds during the forced vibration of Camellia oleifera branches was calculated using the following acceleration formula:

$$a = \frac{v}{t} = \frac{x}{t^2} \tag{3}$$

where:

a — the acceleration, [m/s^2];

v — the velocity, [m/s];

t — the interval between two adjacent photos, which is 0.02 s;

x — the relative displacement of the fruit in the two pictures, [m].

By measuring the quality of the fruit and bud, you can know the size of the inertia force when the fruit and bud fall off. The inertia force when falling off is:

$$\begin{cases} F_g = m_g a_g \\ F_h = m_h a_h \end{cases} \tag{4}$$

where: F_g — the inertial force when the fruit falls off, [N];

F_h — the inertial force when the bud falls off, [N];

m_g — fruit mass, [kg];

m_h — bud mass, [kg];

a_g — the acceleration of fruit shedding, [m/s^2];

a_h — the acceleration when the bud falls off, [m/s^2].

Test

The slider's end is fixed to the Camellia oleifera stem, with the fixed point located 100 mm away from the fixture (Fig. 1).

Fig. 1 - Vibration test device

During the test, the excitation amplitude is regulated by altering the connecting rod's position on the crank, while the excitation frequency is adjusted by using a frequency modulator to control the motor speed. In each test run, after setting the excitation frequency and amplitude, the clamp is used to secure Camellia oleifera branches under laboratory conditions. Specifically, the branch samples are clamped onto the fixture to ensure they form a specific angle with the vibration platform, simulating the natural growth posture of branches on the tree. Subsequently, the motor is activated, and a high-speed camera records the motion response of Camellia oleifera fruits under forced vibration.

RESULTS AND DISCUSSION

Vibration exciter movement analysis

According to the method given, the video in high-speed photography is analyzed frame by frame and the actual acceleration is calculated. Comparing these accelerations with the theoretical calculations results in very close values (Tab.1). The maximum relative error between the theoretical value and the actual value of the output acceleration of the exciter is 1.84%, and the parameter combination at this time is the excitation frequency of 2.05 Hz and the amplitude of 10 mm. It shows that the moving image acquired by high-speed photography base is reliable after post-processing.

Table 1

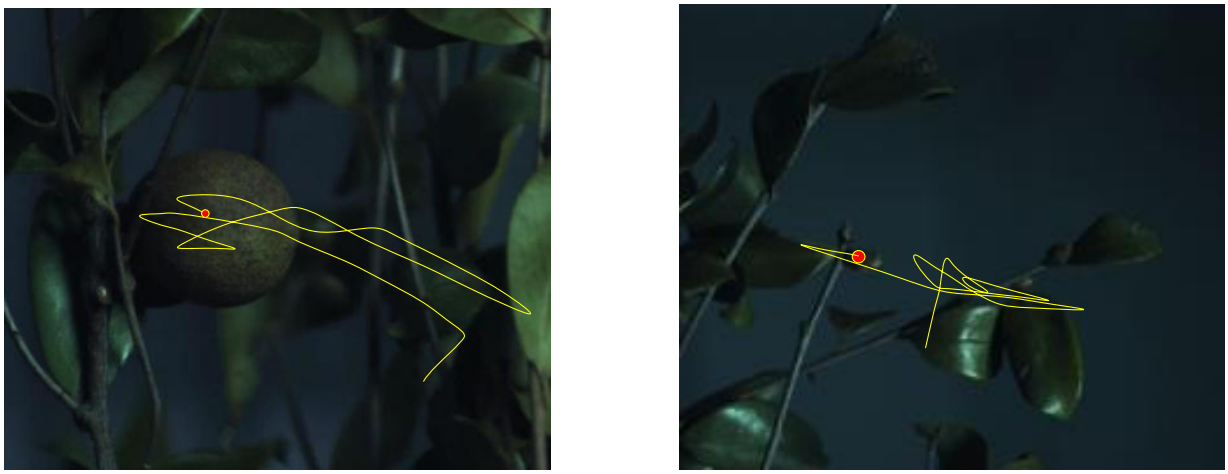
Vibration transfer efficiency with different parameters

Amplitude [mm]	Frequency [Hz]	Vibration exciter output acceleration [m/s^2]		error [%]
		Theoretical value	Actual value	
10	2.05	1.66	1.63	1.84
20	7.52	44.61	44.35	0.59
50	12.98	332.23	333.52	0.39

Impact analysis of vibration parameters

Through analysis of the high-speed video, the shedding force of Camellia oleifera fruit was found to range from 4.57N to 11.85N, while that of buds ranged from 0.68N to 3.24N. These values are significantly lower than the binding force measured via static testing of Camellia oleifera fruit *(Wang et al., 2024)*. This phenomenon can be attributed to the following: during static measurement of the fruit-stalk binding force, the fruit was pulled vertically along the stalk. In contrast, high-speed photography revealed that during vibration, the fruit-stalk exhibited a certain swing angle relative to the branch — indicating that the shedding force of the fruit-stalk varies with different angles of application.

Table 2



Effects of vibration parameters on fruit and bud shedding of *Camellia oleifera*

Amplitude [mm]	Frequency [Hz]	Fruit			Bud		
		Mean shedding force [N]	Mean shedding time [s]	Swing period	Mean shedding force [N]	Mean shedding time [s]	Swing period

50	12.98	7.38	1.27	5	1.92	2.54	4
100	2.05	11.85	1.24	5	0.93	2.57	5
100	7.51	8.54	1.08	4	0.75	1.78	4
100	12.98	7.64	0.69	5	1.88	0.83	4

The table also indicates that at low frequency (2.05 Hz), increasing the vibration amplitude from 20 mm to 50 mm results in only a 0.2 N difference in fruit shedding force and a 0.11 N difference in bud shedding force, whereas increasing the amplitude from 50 mm to 100 mm causes fruit shedding force to rise from 6.58 N to 11.85 N and bud shedding force to decrease from 2.26 N to 0.93 N; at high frequency (12.98 Hz), the effect of vibration amplitude on the shedding force of both fruits and buds is negligible.

The shedding time of Camellia oleifera fruits and buds is inversely related to excitation parameters, decreasing as either vibration amplitude or frequency increases, with the rate of change in fruit vibration shedding time being lower when increasing from low frequency (2.05 Hz) to medium frequency (7.52 Hz) than when transitioning from medium frequency (7.52 Hz) to high frequency (12.98 Hz), while the opposite pattern is observed for buds, where the change rate is higher during the low-to-medium frequency increase than during the medium-to-high frequency increase.

Movement rules of Camellia oleifera fruit and bud

(a) Fruit movement path *(b) Locus of bud movement*

Fig. 2 - Motion state of *Camellia oleifera* fruit under forced vibration

Under the condition that Camellia oleifera fruits and buds move within the same plane, high-speed video was used to capture the approximate trajectories of fruits (Fig. 3a) and buds (Fig. 3b) under vibration excitation with a vibration amplitude of 50 mm and a frequency of 7.52 Hz. Vibrational energy is transferred to the fruits and buds through the branches, disrupting the overall system balance and causing the fruits and buds to exhibit anisotropic random and disordered mixed oscillation behavior *(Hoshyarmanesh et al., 2017; San et al., 2018)*.

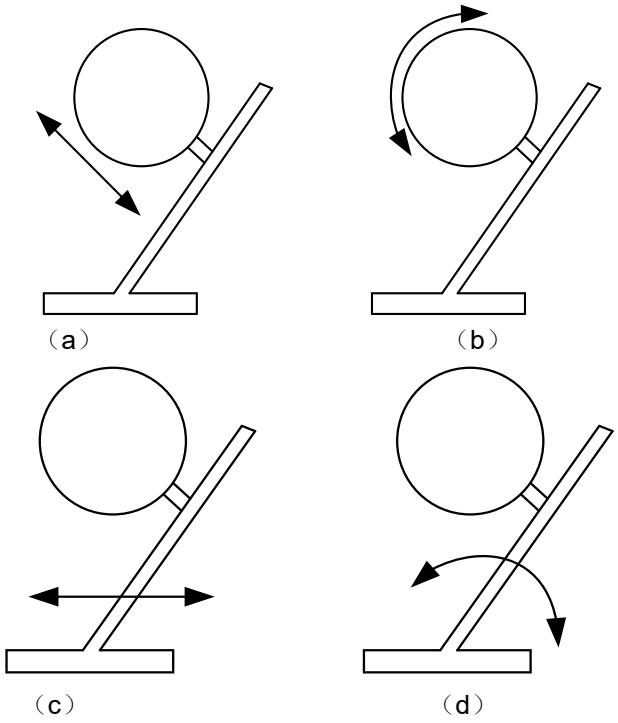

Fig. 3 - Motion decomposition

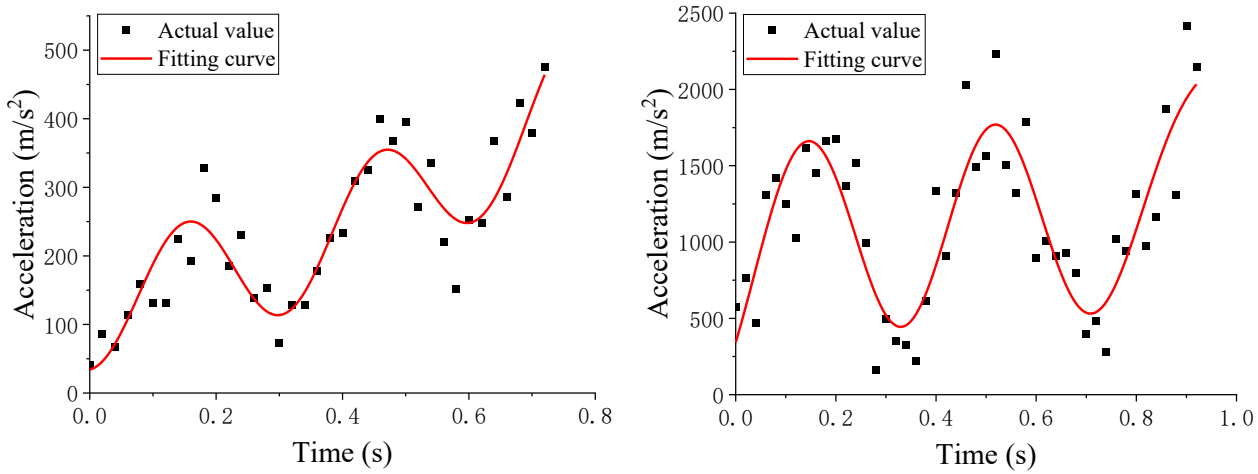

(a) Parallel stalk movement of fruit; (b) The fruit moves around the stalk; (c) The fruit and the branch move together; (d) The fruit and the branch move together around the excitation point.

Trajectories of Camellia oleifera Fruit and Buds Under 7.52 Hz Excitation (Fig. 2). Under 7.52 Hz excitation, Camellia oleifera fruits and buds exhibit dynamic oscillatory behavior: they first accelerate and swing in the direction of the applied force, then rapidly reverse direction. The entire branch-fruit and branch-bud system undergoes periodic oscillations around the excitation origin. Notably, the fruit and its supporting branch show significant positional displacement, characterized by wobbling of the fruit and torsional movement of the branch. Observation points on the structures demonstrate altered relative positions, with marked fruits displaying obvious deflection. This complex motion can be attributed to the combined behaviors illustrated in Figure 3, consistent with similar findings in prior studies *(Cao et al., 2023; Hoshyarmanesh et al., 2017; San et al., 2018; Wang et al., 2024)*.

As shown in Figure 4, the movement trajectories of fruits and buds do not reciprocate along a straight line within the same period, indicating relative motion (e.g., swinging or twisting) between fruits and branches during vibration. Under identical vibration conditions, fruits exhibit significantly greater motion responses (i.e., displacement) than buds. The movement of fruits and buds is also influenced by neighboring fruits and branches in an unpredictable manner, leading to frequent changes in their trajectories due to potential collisions. Quantitative analysis of these trajectories represents a promising direction for future research.

Motion curve fitting

When the camellia fruit and flower bud acquire sufficient inertial force, that is, when the critical value of the binding force between the fruit stem and the branch is exceeded, the camellia fruit or flower bud will fall off. Through the analysis of the movement images and data of the target camellia fruit and flower bud captured by the high-speed camera, the sample will be taken every 0.02 s, as shown in Figure 4 of the acceleration and time relative to the origin point.

(a) fruit (b) bud

Fig. 4 - Vibration shedding process

From the beginning of vibration to the shedding acceleration, *Camellia oleifera* fruit experienced three stages: 0 to 0.3 s, 0.3 to 0.58 s and 0.58 to 0.72 s. The first stage period of *Camellia oleifera* fruit was 0.3 s, and the peak acceleration occurred at 0.18 s (328.24 m/s^2). The period of the second stage is 0.28 s, and the peak acceleration occurs at 0.46 s and is 400.18 m/s^2. The fruit of *Camellia oleifera* fell off before reaching the complete cycle in the third stage. The vibration shedding time was 0.72 s and the shedding acceleration was 475.38 m/s^2. Fourier fitting was performed on the acceleration of *Camellia oleifera* fruit. The R2 of the fitting curve was 0.83996, and the equation of the fitting curve was as follows:

$$a_g = 208.52 + 1612.57\sin(0.59t) - 85.14\cos(0.002t) - 383.53\sin(1.87t) - 89.25\cos(20.52t) \quad (5)$$

There were 3 stages from the initial vibration to the shedding acceleration: 0 to 0.36 s, 0.36 to 0.74 s and 0.74 to 0.92 s. In the first stage, the movement period was 0.36 s, and the peak acceleration occurred at 0.2 s (1676.63 m/s^2). The period of the second stage is 0.38 s, and the peak acceleration occurs at 0.52 s, which is 2232.17 m/s^2. The buds of *Camellia oleifera* fell off before reaching the complete cycle in the third stage.

The vibration shedding time was 0.92 s, and the shedding acceleration was 2147.4 m/s^2. Fourier fitting was performed on the acceleration of *Camellia oleifera* bud. The R2 of the fitting curve was 0.73718, and the equation of the fitting curve was as follows:

$$a_h = -780.29 + 39212.57\sin(0.11t) + 1375.24\cos(3.45t) + 471.89\sin(14.61t) - 252.91\cos(18.72t) \quad (6)$$

CONCLUSIONS

In this paper, the motion of *Camellia oleifera* fruit and bud was observed by image acquisition technology, and the motion behavior of *Camellia oleifera* fruit and bud under different vibration parameters was analyzed in detail. By using mathematical model to study the characteristics of *Camellia oleifera* branches, and using high-speed photography technology to measure and analyze the dynamic characteristics of *Camellia oleifera* fruits and buds, the following conclusions are drawn:

- The maximum relative error between the theoretical value and the actual value of the output acceleration of the exciter is 1.84%; The fruit shedding force of *Camellia oleifera* ranged from 4.57 N to 11.85 N, and the bud shedding force ranged from 0.68 to 3.24 N.
- Under high frequency (12.98 Hz) vibration, the change of vibration amplitude has no obvious effect on the shedding force of fruit and bud. The shedding time of *Camellia oleifera* fruit and bud decreased with the increase of vibration amplitude or excitation frequency.
- The vibrational energy is transferred to the fruit and bud through the branches, the balance of the whole system is broken, and the fruit and bud show anisotropic random and disorderly chaotic oscillation behavior;
- Using the collected data for fitting analysis, the Fourier fitting curve and your sum function of the motion acceleration of *Camellia oleifera* fruit and the bud were obtained, with R2 of 0.83996 and 0.73718, respectively.

***Keywords**: Combine harvester, threshing drum, electric drive, torque compensation*

ABSTRACT

In response to the issues faced by conventional combine harvesters' threshing drums, such as the difficulty in maintaining stable speed due to load fluctuations and torque disturbances, as well as the limited speed adjustment range to adapt to changes in crop varieties and properties, this study proposes a novel dual power source threshing drum (DPSTD). By incorporating a power coupling device and a motor into the existing mechanical structure, the DPSTD utilizes the flexible speed and torque output capabilities of the motor to achieve a wide speed adjustment range and enhance its resistance to interference. A robust model predictive control strategy is designed based on finite time disturbance observer (FTDO) to compensate for torque under load fluctuations. Simulation results demonstrate that the DPSTD can achieve rapid and accurate speed regulation. Moreover, under torque disturbances and load mutations, the DPSTD with the torque compensation control strategy, can reduce the speed error by 73.90%. This significantly improves the speed tracking performance of the threshing drum, exhibiting good anti-interference capabilities. Finally, the superiority of the DPSTD is validated through bench tests, confirming its effectiveness and feasibility and providing new insights for control research on threshing drums.

摘要

针对传统联合收获机脱粒滚筒面对负载波动和扭矩干扰时难以稳速影响作业效果，以及调速范围小难以适应作物品种和属性的变化等问题，本文基于并联式混合动力技术提出了一种新型双动力源脱粒滚筒 (DPSTD)，通过在原有的机械驱动结构上加入动力耦合装置和电机，利用电机灵活的转速和转矩输出功能实现脱粒滚筒的大范围调速并提高抗干扰能力。本文对 DPSTD 各部件进行数学建模，并设计了基于有限时间干扰观测器 (FTDO) 的电机鲁棒模型预测控制策略，以实现 DPSTD 在负载波动和干扰下的扭矩补偿，进一步对 DPSTD 的调速和稳速性能进行研究，仿真结果表明，DPSTD 可以快速精准地进行转速调节，并且在存在扭矩干扰和负载突变的情况下，采用扭矩补偿的控制策略的 DPSTD 可以将脱粒滚筒的转速误差均方根值降低 73.90%，最大转速误差降低 76.18%，冲击度均方根值降低 33.51%，最大冲击度降低 73.18%。可明显改善模式切换平顺性和脱粒滚筒转速跟踪效果，具备较好的抗干扰能力。最后台架试验进一步验证了 DPSTD 的调速和稳速性能，证明了其有效性和可行性，为联合收获机脱粒滚筒控制研究提供了新思路。

INTRODUCTION

The combine harvester is one of the widely used core agricultural machinery in agricultural production *(Sun et al., 2018)*. With the development of agricultural automation technology, there is an increasing demand for automatic control of combine harvesters *(Chen et al., 2017; Shojaei, 2021)*. The threshing drum has always been considered a core component of the combine harvester and has been extensively studied *(Vlădut et al., 2022; Zhang et al., 2024; Hou et al., 2023; Li et al., 2023)*.

Zhihao Zhu, Student; Xiaoyu Chai, Lecture; Lizhang Xu, Research fellow; Li Quan, Professor; Chaochun Yuan, Professor; En Lu, Associate professor; Shuofeng Weng, Student; Shichao Tian, Student; Guangqiao Cao, Research fellow

Resistance to interference and speed control are important research directions in the control of threshing drums, and they are of significant importance for enhancing the overall functionality and operational performance of the machine *(Olaye et al., 2016; Sudajan et al., 2002; Alizadeh and Khodabakhshipour 2010). Zhang et al (2011)* designed a robust control method for the threshing drum speed in a combine harvester, with the travel speed and feeding rate of the harvester as control variables and the drum speed as the controlled variable. The effectiveness of this method was verified through simulations and experiments. *Qin et al (2009)* proposed a mathematical model for the walking, harvesting, and threshing system of a combine harvester, which can effectively simulate the actual working process of the harvester. *Zhang et al (2023)* designed a control system based on active disturbance rejection and dynamic matrix modeling. This approach achieved real-time control of the drum speed and compensation of the control delay.

However, due to the limitations of the mechanical structure in conventional combine harvesters, the control of the threshing drum speed is typically achieved indirectly through the vehicle speed and feeding rate. This approach suffers from drawbacks such as low speed control accuracy, time delays, reduced operational efficiency, and the inability to adjust the speed according to changes in crop varieties and properties. In recent years, the research and application of electrification technology in agricultural machinery are becoming increasingly widespread *(Khatawkar et al., 2019; Scolaro et al., 2021; Mocera, & Somà, 2022; Zhu et al., 2023)*. Electric motors offer advantages such as fast response, high driving efficiency, and a wide range of speed and torque outputs. These advantages can effectively enhance the flexibility and efficiency of agricultural equipment. *Yang et al (2022)* conducted an electrification transformation of the reaping and threshing components of a combine harvester and designed a control system for the motors. Furthermore, they tested the system's speed tracking and anti-clogging functionalities in wheat harvesting experiments, and the results indicated that the system exhibited favorable practicality. *Sahoo & Raheman (2020)* developed a pure electric small rice harvester driven by two DC motors. Field test results showed that the product has high operational efficiency and endurance, and can effectively reduce environmental pollution and harvesting costs. *Wang et al (2020)* electrified the reaping part of a combine harvester, conducted finite element simulation on its mechanical structure, and designed a control method for the motor. Field test results showed that the modified harvester can automatically adjust its reaping speed according to the travelling speed, thereby improving the operational performance.

The purpose of this article is to improve the anti-interference capability of the threshing drum and broaden its speed range to adapt to the harvesting requirements of various crops using electric drive technology. However, considering that the threshing drum is the most power-demanding component in a combine harvester, relying solely on electric motor drive would require the installation of high-power motors and a high-power supply system, resulting in higher costs. Therefore, this article retains the original mechanical transmission components and proposes a novel dual power source threshing drum that combines an electric motor with a power coupling device. The power coupling device diverts power from both the motor and the engine, allowing the threshing drum to achieve a wide speed range. By incorporating an additional smaller electric motor. Additionally, the torque compensation provided by the electric motor enhances the threshing drum's anti-interference capability, enabling stable and high-quality operation.

In this study, a dual power source threshing drum (DPSTD) is proposed and an electric motor robust model predictive control system based on disturbance observer is designed. Furthermore, the speed control and torque compensation functions of the DPSTD are validated through simulation and bench test.

MATERIALS AND METHODS

Architecture of the DPSTD

The specific structure of the newly designed DPSTD for a combine harvester, as depicted in Fig.1, incorporates a power coupling device with a planetary gear set to distribute the power from both the engine and the motor. The power coupling device comprises a reducer, a sun gear, an outer planetary carrier, and an inner planetary carrier. The central shaft of the primary gear of the reducer serves as Input 1 of the power coupling device (connected to the motor), while the secondary gear of the reducer is coaxially integrated with the sun gear. The inner planetary carrier has an outer gear ring and an inner gear ring, the outer gear ring meshes with the outer planetary carrier, the inner gear ring meshes with the sun gear, the central axis is the input 2 of the power coupling device (connected to the engine source power output shaft), and the central axis of the outer planetary carrier is the output end of the power coupling device (connected to the threshing drum). The motor power is transmitted through the reduction set, resulting in torque amplification, and then delivered to the sun gear. Simultaneously, the engine power is transmitted to the inner planetary carrier.

As the inner planetary carrier engages with both the sun gear and the outer planetary carrier, the engine power and the motor power are combined and transmitted through the outer planetary carrier to drive the threshing drum. The speed of the engine source power output shaft remains relatively stable during operation. By adjusting the motor speed, the speed regulation function of the threshing drum is achieved to adapt to different harvesting conditions.

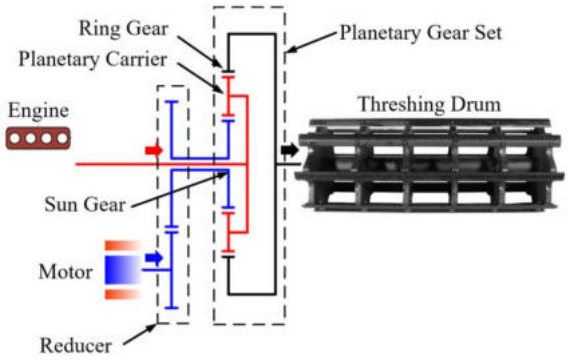

Fig. 1 - Structure of the DPSTD

The DPSTD has three power modes: hybrid mode, conventional mode, charging mode, and reversal mode, as shown in Fig. 2. In the hybrid mode, the threshing drum is driven by the engine and the motor. This mode is used when the engine's allocated power to the threshing drum during the harvesting process is lower than the instantaneous power required for threshing or when the preset mechanical speed of the threshing drum does not match the actual required speed. In the conventional mode, the threshing drum is solely driven by the engine. This mode is used when the power provided by the engine to the threshing drum meets the operational load requirements, and the preset speed of the threshing drum satisfies the harvesting needs of the current crop. In reversal mode, the threshing drum is driven by the motor to rotate in the opposite direction. This mode is used for special working conditions where the drum is overloaded and causes blockage.

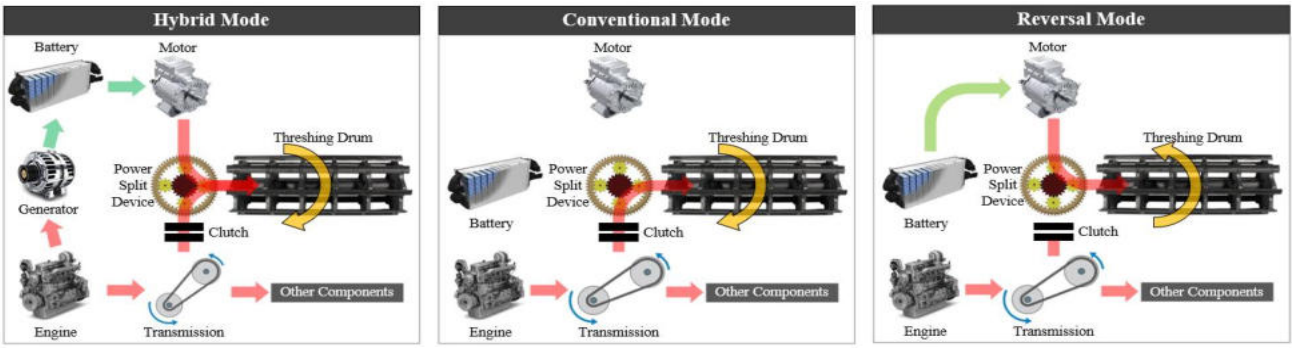

Fig. 2 - Three power mode of the DPSTD

DPSTD model

Dynamic model of the threshing drum

The active torque required by the threshing drum mainly includes the torque required for the idling of the drum itself, the torque to push the grain to overcome the resistance movement, the torque to overcome the angular acceleration generated by the rotational inertia of the drum itself, and the torque to push the grain to obtain acceleration. The total driving torque of threshing drum is

$$T_{TD} = A + B\omega_{TD}^{\ 2} + \frac{qR_{TD}^{\ 2}\omega_{TD}}{2(1-f_r)}\frac{\lambda+\Delta}{1+\Delta} + J_{TD}\dot{\omega}_{TD}$$

$$q = \rho v H \tag{1}$$

where ω_{TD} is the angular velocity of the drum, A is the torque to overcome mechanical friction, B is the air friction coefficient, q is the harvest quantity, ρ is the crop density, v is the travelling speed of the harvester, H is the cutting range, R_{TD} is the operating radius of threshing drum, Δ is the grass-grain ratio, f_r is the friction coefficient, J_{TD} is the rotational inertia of the threshing drum.

Model of the power coupling device

According to Fig.1, the power coupling device in the DPSTD consists of a reducer and a single-row planetary gear mechanism. The corresponding components are connected to the power output shaft of the engine, the motor, and the threshing drum, respectively, which closely relate the system's power transmission to the speed-torque characteristics of the power coupling device.

The output speed of the power coupling device can be expressed as:

$$\omega_{out} = \frac{(1+k)\omega_e - \omega_m / i_r}{k} \tag{2}$$

The output torque of the power coupling device can be expressed as:

$$T_{out} = -(\frac{T_m}{i_r \eta_r} + T_e) \tag{3}$$

where ω_e and ω_m are the speed of engine power output shaft and motor, T_e and T_m are the torque of engine power output shaft and motor, i_r is the gear ratio of the reducer, η_r is the efficiency of the reducer, and k is the ratio of the number of teeth on the outer planetary gear to the number of teeth on the sun gear.

It can be seen that the speed and torque of the threshing drum can be adjusted by adjusting the output speed and torque of the motor.

Torque coordination control of the DPSTD

As described previously regarding the DPSTD's three modes, its hybrid mode offers speed control and stability—features not found in conventional threshing drums—effectively enhancing the combine harvester's performance and versatility. Therefore, the torque coordination control of the DPSTD motor in hybrid mode is a key issue addressed in this study. During the operation of the harvester, complex and varying terrains, as well as uncertainties in crop attributes, will generate random and time-varying disturbances. These disturbances are transmitted through the powertrain, resulting in torque impacts and interferences on the threshing drum, which in turn affect the operational performance. Therefore, it is crucial to pay special attention to disturbance estimation and compensation under such conditions during the operation of DPSTD. Designing reliable control strategies is necessary to mitigate the performance fluctuations caused by torque disturbances. The key issues of torque coordination control in DPSTD operation in hybrid mode can be summarized in the following two aspects:

(1) A high-performance controller needs to be designed to accurately regulate the motor speed during the drum speed adjustment process, ensuring that the threshing drum operates at the desired speed and improving operational performance.

(2) To address unpredictable disturbances caused by varying terrains and crop attributes, it is necessary to design corresponding disturbance observers to estimate the disturbances and uncertainties, and then perform compensation control.

Based on the analysis of the hybrid mode of DPSTD mentioned above, a torque coordination control strategy for dual power sources is proposed. The strategy structure is illustrated in Fig. 3.

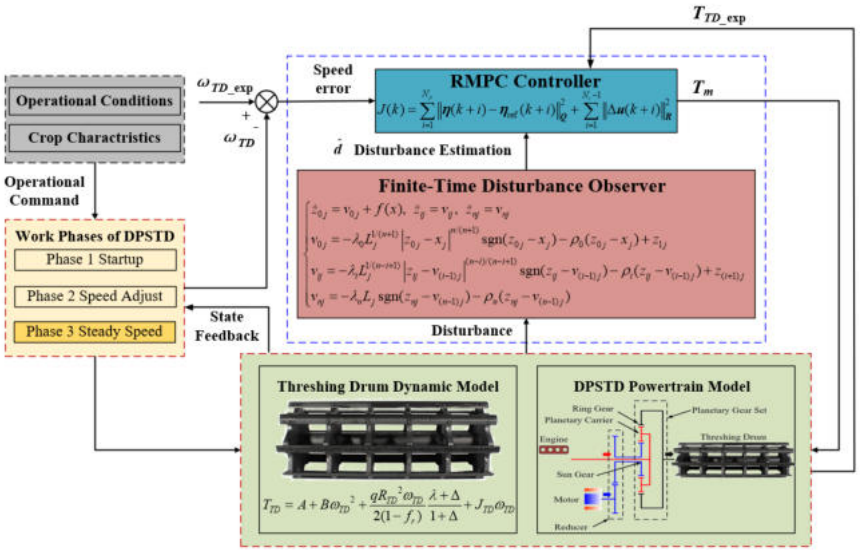

Fig. 3 - Control strategy structure of DPSTD

During the harvesting operation, the operator first sends instructions to the system according to the operating conditions and crop properties to determine the working stage and expected rotation speed of the threshing drum. The expected rotation speed of the threshing drum can be expressed as *(Li et al., 2009):*

$$\omega_{TD_\exp} = \frac{60\sqrt{\frac{2R_{\max}}{m}}}{\pi D(1+\varepsilon)\cos\beta} \tag{4}$$

where $R_{\max}$ is the maximum work required to detach the grains from the spike, m is the mass of the grain, β is the angle between the axial direction of the grain and the direction of the axial movement of the threshing teeth, ε is the restitution coefficient during the impact between the grain and the threshing teeth, and D is the diameter of the threshing drum.

During harvesting operations, the engine power is generally kept relatively constant. Therefore, at the desired speed of the threshing drum, the target output speed of the motor is:

$$\omega_{m_\text{tgt}} = i_r[(1+k)\omega_e - k\omega_{TD_\exp}] \tag{5}$$

The preliminary target output torque of motor without considering disturbances is:

$$T_{m_\text{tgt}} = -(T_e + T_{TD_\exp})i_r\eta_r \tag{6}$$

where $T_{TD_\exp}$ is the theoretical torque required by the threshing drum at the desired speed.

Based on this, in order to further achieve precise torque coordination control of the motor, a Robust Model Predictive Control (RMPC) controller is designed to regulate the motor torque. Furthermore, a Finite-Time Disturbance Observer (FTDO) is introduced to estimate the torque disturbances that exist during the harvesting process.

Design of the RMPC controller

Defining the speed of threshing drum and the speed of engine power output shaft as the state variables, motor output torque as the control variables, and the load fluctuation of threshing drum and the resistance torque of engine source as the disturbance variables, the dynamics equation of the threshing system can be written as the following state space equation:

$$\begin{cases} \dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{u} + \boldsymbol{C} + \boldsymbol{\Gamma}\boldsymbol{d} \\ \boldsymbol{y} = \boldsymbol{D}\boldsymbol{x} \end{cases} \tag{7}$$

where the state variables $\boldsymbol{x} = \left[\omega_{TD}, \omega_{TD}^{\ 2}, \omega_e\right]^T$, $\boldsymbol{u}$ is the control variables, the disturbance variables $\boldsymbol{d} = \left[d_1, d_2\right]^T$,

$$\boldsymbol{A} = \begin{bmatrix} -\frac{qR_{TD}^{\ 2}}{2J_{TD}(1-f_r)}\frac{\lambda+\Delta}{1+\Delta} & -\frac{B}{J_{TD}} & 0 \\ 2 & 0 & 0 \\ 0 & 0 & -\frac{c_e}{J_e} \end{bmatrix}, \boldsymbol{B} = \left[\frac{1}{J_{TD}i_r\eta_r}, 0, 0\right]^T, \boldsymbol{C} = \left[\frac{T_{TD}-A}{J_{TD}}, 0, \frac{T_e}{J_e}\right]^T, \boldsymbol{\Gamma} = \begin{bmatrix} \frac{1}{J_{TD}} & 0 \\ 0 & \frac{1}{J_e} \end{bmatrix}, \boldsymbol{D} = \left[1, 0, 0\right]^T,$$

c_e is the damping of the engine power output shaft, J_e is the rotational inertia of the engine power output shaft.

The forward Euler method is used to discretize the above state space equation, and the corresponding discretization form can be expressed as:

$$\begin{cases} \boldsymbol{x}(k+1) = \boldsymbol{A}_k\boldsymbol{x}(k) + \boldsymbol{B}_k\boldsymbol{u}(k) + \boldsymbol{C} + \boldsymbol{\Gamma}_k\boldsymbol{d}(k) \\ \boldsymbol{y}(k+1) = \boldsymbol{D}\boldsymbol{x}(k) \end{cases} \tag{8}$$

where $\boldsymbol{A}_k(T_s) = \boldsymbol{I} + T_s\boldsymbol{A}$, $\boldsymbol{B}_k(T_s) = T_s\boldsymbol{B}$, $\boldsymbol{\Gamma}_k(T_s) = T_s\boldsymbol{\Gamma}$.

A new model prediction equation is established according to the above formula, which is expressed as:

$$\xi(k) = \left[\boldsymbol{x}(k),\ \boldsymbol{u}(k-1)\right]^T \tag{9}$$

Then the system state space equation in incremental form can be written as:

$$\begin{cases} \xi(k+1) = \tilde{\boldsymbol{A}}_k\xi(k) + \tilde{\boldsymbol{B}}_k\boldsymbol{u}(k) + \tilde{\boldsymbol{\Gamma}}_k\boldsymbol{d}(k) + \boldsymbol{C} \\ \boldsymbol{\eta}(k) = \tilde{\boldsymbol{D}}\xi(k) \end{cases} \tag{10}$$

where $\tilde{\boldsymbol{A}}_k = \begin{bmatrix} \boldsymbol{A}_k & \boldsymbol{B}_k \\ 0_{m\times n} & \boldsymbol{I}_{m\times n} \end{bmatrix}$, $\tilde{\boldsymbol{B}}_k = \begin{bmatrix} \boldsymbol{B}_k \\ \boldsymbol{I}_{m\times n} \end{bmatrix}$, $\tilde{\boldsymbol{\Gamma}}_k = \begin{bmatrix} \boldsymbol{\Gamma}_k \\ \boldsymbol{I}_{m\times m} \end{bmatrix}$, $\tilde{\boldsymbol{D}} = [\boldsymbol{D} \quad 0 \quad 0]$, $\boldsymbol{\eta}(k)$ is the output variable, m is the dimension of the control variable, and n is the dimension of the state variable.

If the current time of the system is k, the prediction time domain is N_p, and the control time domain is N_c, and $N_c \le N_p$, then the system output vector at N_p step and the control increment vector at N_c step can be expressed as:

$$\begin{aligned} \boldsymbol{Y}(k) &= [\boldsymbol{\eta}(k+1\,|\,k), \boldsymbol{\eta}(k+2\,|\,k), \cdots, \boldsymbol{\eta}(k+N_p\,|\,k)] \\ \Delta\boldsymbol{u}(k) &= [\Delta\boldsymbol{u}(k), \Delta\boldsymbol{u}(k+1), \cdots, \Delta\boldsymbol{u}(k+N_c)-1] \end{aligned} \tag{11}$$

The output of the system at step N_p can be calculated by the prediction equation in the following form:

$$\boldsymbol{Y}(k) = \boldsymbol{S}_{\xi}\boldsymbol{\xi}(k) + \boldsymbol{S}_u\Delta\boldsymbol{u}(k) + \boldsymbol{S}_{\omega}\Delta\boldsymbol{d}(k) \tag{12}$$

where $\boldsymbol{S}_{\xi} = \begin{bmatrix} \tilde{C}_{dk}\tilde{A}_{dk} \\ \tilde{C}_{dk}\tilde{A}_{dk}^2 \\ \vdots \\ \tilde{C}_{dk}\tilde{A}_{dk}^{N_c} \\ \vdots \\ \tilde{C}_{dk}\tilde{A}_{dk}^{N_p} \end{bmatrix}$, $\boldsymbol{S}_{\omega} = \begin{bmatrix} \tilde{C}_{dk}\tilde{\Gamma}_{dk} \\ \tilde{C}_{dk}\tilde{\Gamma}_{dk}^2 \\ \vdots \\ \tilde{C}_{dk}\tilde{\Gamma}_{dk}^{N_c} \\ \vdots \\ \tilde{C}_{dk}\tilde{\Gamma}_{dk}^{N_p} \end{bmatrix}$, $\boldsymbol{S}_u = \begin{bmatrix} \tilde{C}_{dk}\tilde{B}_{dk} & 0 & 0 & \cdots & 0 \\ \tilde{C}_{dk}\tilde{A}_{dk}\tilde{B}_{dk} & \tilde{C}_{dk}\tilde{B}_{dk} & 0 & \cdots & 0 \\ \cdots & \cdots & \vdots & \ddots & \vdots \\ \tilde{C}_{dk}\tilde{A}_{dk}^{N_c-1}\tilde{B}_{dk} & \tilde{C}_{dk}\tilde{A}_{dk}^{N_c-2}\tilde{B}_{dk} & \cdots & \cdots & \tilde{C}_{dk}\tilde{B}_{dk} \\ \tilde{C}_{dk}\tilde{A}_{dk}^{N_c}\tilde{B}_{dk} & \tilde{C}_{dk}\tilde{A}_{dk}^{N_c-1}\tilde{B}_{dk} & \cdots & \cdots & \tilde{C}_{dk}\tilde{A}_{dk}\tilde{B}_{dk} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \tilde{C}_{dk}\tilde{A}_{dk}^{N_p-1}\tilde{B}_{dk} & \tilde{C}_{dk}\tilde{A}_{dk}^{N_p-2}\tilde{B}_{dk} & \cdots & \cdots & \tilde{C}_{dk}\tilde{A}_{dk}^{N_p-N_c-1}\tilde{B}_{dk} \end{bmatrix}$

According to the prediction equation, the reference vector of the system can be expressed as:

$$\boldsymbol{\eta}_{\text{ref}}(k) = [\boldsymbol{\eta}_{\text{ref}}(k+1\,|\,k), \boldsymbol{\eta}_{\text{ref}}(k+2\,|\,k), \cdots, \boldsymbol{\eta}_{\text{ref}}(k+N_p\,|\,k)] \tag{13}$$

Therefore, the system objective function with quadratic form corresponding to the RMPC controller can be expressed as:

$$J(k) = \sum_{i=1}^{N_p} \|\boldsymbol{\eta}(k+i) - \boldsymbol{\eta}_{\text{ref}}(k+i)\|_{\boldsymbol{Q}}^2 + \sum_{i=1}^{N_c-1} \|\Delta\boldsymbol{u}(k+i)\|_{\boldsymbol{R}}^2 \tag{14}$$

where $\boldsymbol{\eta}_{\text{ref}}$ is the reference vector of system, $\boldsymbol{Q}$ and $\boldsymbol{R}$ are the weight coefficient matrix of output and control of system respectively.

The objective function reflects the tracking error and control quantity. It can be transformed into a standard quadratic form, which is easy to solve, so as to minimize the tracking error and control increment.

According to the output of system, the reference vector of system can be written as:

$$\boldsymbol{\eta}_{\text{ref}} = [\omega_{TD_\text{ref}}] \tag{15}$$

The weight coefficient matrix of output and control quantity of system is:

$$\begin{cases} \boldsymbol{Q} = diag([w_{\omega_{TD}}]) \\ \boldsymbol{R} = diag([w_{T_m}]) \end{cases} \tag{16}$$

The deviation within the prediction range is defined as:

$$\boldsymbol{E}(k) = \boldsymbol{S}_{\xi}\boldsymbol{\xi}(k) - \boldsymbol{\eta}_{\text{ref}}(k+1) \tag{17}$$

The objective function of the system can be transformed into a standard quadratic form and expressed as:

$$J(\Delta\boldsymbol{U}(k)) = \begin{bmatrix} \Delta\boldsymbol{U}(k) \\ \varepsilon \end{bmatrix}^{\text{T}} \boldsymbol{H} \begin{bmatrix} \Delta\boldsymbol{U}(k) \\ \varepsilon \end{bmatrix} + \boldsymbol{G} \begin{bmatrix} \Delta\boldsymbol{U}(k) \\ \varepsilon \end{bmatrix} \tag{18}$$

where $\boldsymbol{H} = \begin{bmatrix} \boldsymbol{S}_u^{\text{T}}\boldsymbol{Q}'\boldsymbol{S}_u + \boldsymbol{R} & 0 \\ 0 & \rho \end{bmatrix}$, $\boldsymbol{G} = [2\boldsymbol{E}(k)^{\text{T}}\boldsymbol{Q}'\boldsymbol{S}_u \quad 0]$.

The constraints of system state, control quantity and output variable are respectively defined as:

$$\begin{cases} \Delta\boldsymbol{U}_{\min} \le \Delta\boldsymbol{U} \le \Delta\boldsymbol{U}_{\max} \\ \boldsymbol{U}_{\min} \le A\Delta\boldsymbol{U} + \boldsymbol{U} \le \boldsymbol{U}_{\max} \\ \boldsymbol{Y}_{\min} - \varepsilon \le \boldsymbol{S}_{\xi}\boldsymbol{\xi}(k) + \boldsymbol{S}_u\Delta\boldsymbol{U}(k) \le \boldsymbol{Y}_{\max} + \varepsilon \end{cases} \tag{19}$$

where $\Delta\boldsymbol{U}$ is the increment of control quantity.

By solving the quadratic programming problem in each control domain, a series of increments of control input in the control domain can be calculated:

$$\Delta \boldsymbol{U}^* = \left[\Delta \boldsymbol{u}^*(k), \Delta \boldsymbol{u}^*(k+1), \Delta \boldsymbol{u}^*(k+2), \cdots, \Delta \boldsymbol{u}^*(k+N_c-1)\right]^{\mathrm{T}} \tag{20}$$

Therefore, the control input of motor torque can be calculated by the following formula:

$$\boldsymbol{u}(k) = \boldsymbol{u}(k-1) + \Delta \boldsymbol{U}^* \tag{21}$$

Design of the FTDO

The FTDO is further introduced to estimate the disturbance variables. For the system with the form of Eq. (7), the system disturbance satisfies the following conditions: the disturbance term d_i is *n*-order continuously differentiable (where *n* represents the system order), and its *j*-order derivative is bounded and satisfies $\left|d_i^{(j)}\right| \le L_i$, where $L_i > 0$, $i = 1, \cdots, n$, and $j = 0, 1, \cdots, n$.

The FTDO to be designed has the following standard forms:

$$\begin{cases} \dot{z}_{0j} = v_{0j} + f(x) \\ \dot{z}_{ij} = v_{ij} \\ \dot{z}_{nj} = v_{nj} \\ v_{0j} = -\lambda_0 L_j^{1/(n+1)} \left|z_{0j} - x_j\right|^{n/(n+1)} \operatorname{sgn}(z_{0j} - x_j) - \rho_0 (z_{0j} - x_j) + z_{1j} \\ v_{ij} = -\lambda_i L_j^{1/(n-i+1)} \left|z_{ij} - v_{(i-1)j}\right|^{(n-i)/(n-i+1)} \operatorname{sgn}(z_{ij} - v_{(i-1)j}) - \rho_i (z_{ij} - v_{(i-1)j}) + z_{(i+1)j} \\ v_{nj} = -\lambda_n L_j \operatorname{sgn}(z_{nj} - v_{(n-1)j}) - \rho_n (z_{nj} - v_{(n-1)j}) \end{cases} \tag{22}$$

where $\lambda_0, \cdots, \lambda_n$ and $\rho_0, \cdots, \rho_n$ are the pending coefficients of the FTDO respectively. z_{0j} is the estimated value of the state variable. $z_{1j}, \cdots, z_{nj}$ are the estimated values of the disturbance quantity $d_j^{(0)}, \cdots, d_j^{(n-1)}$ respectively. $i = 1, \cdots, n-1$, $j = 1, \cdots, n$, and $f(x)$ corresponds to the equation of state shown in Eq. (7).

When $j = 1$ and $j = 2$ respectively, the torque disturbance can be estimated by the following FTDO equation respectively:

$$\begin{cases} \dot{z}_{01} = v_{01} + f(x_1) \\ \dot{z}_{11} = v_{11} \\ \dot{z}_{21} = v_{21} \\ v_{01} = -\lambda_0 L_1^{1/3} \left|z_{01} - x_1\right|^{2/3} \operatorname{sgn}(z_{01} - x_1) - \rho_0 (z_{01} - x_1) + z_{11} \\ v_{11} = -\lambda_1 L_1^{1/2} \left|z_{11} - v_{01}\right|^{1/2} \operatorname{sgn}(z_{11} - v_{01}) - \rho_1 (z_{11} - v_{01}) + z_{21} \\ v_{21} = -\lambda_2 L_1 \operatorname{sgn}(z_{21} - v_{11}) - \rho_2 (z_{21} - v_{11}) \end{cases} \quad \begin{cases} \dot{z}_{02} = v_{02} + f(x_3) \\ \dot{z}_{12} = v_{12} \\ \dot{z}_{22} = v_{22} \\ v_{02} = -\lambda_0 L_2^{1/3} \left|z_{02} - x_2\right|^{2/3} \operatorname{sgn}(z_{02} - x_2) - \rho_0 (z_{02} - x_2) + z_{12} \\ v_{12} = -\lambda_1 L_2^{1/2} \left|z_{12} - v_{02}\right|^{1/2} \operatorname{sgn}(z_{12} - v_{02}) - \rho_1 (z_{12} - v_{02}) + z_{22} \\ v_{22} = -\lambda_2 L_2 \operatorname{sgn}(z_{22} - v_{12}) - \rho_2 (z_{22} - v_{12}) \end{cases} \tag{23}$$

where: z_{01} and z_{02} are the estimated values of the state quantity ω_{TD} and ω_e respectively. z_{11} and z_{12} are the estimated values of disturbance d_1 and d_2 respectively. z_{21} and z_{22} are the estimated values of $\dot{d}_1$ and $\dot{d}_2$ respectively.

To further analyze the stability and convergence of the proposed FTDO, the above estimation errors are defined as:

$$\sigma_{0j} = \frac{z_{0j} - x_j}{L_j}, \sigma_{1j} = \frac{z_{1j} - d_j}{L_j}, \cdots, \sigma_{nj} = \frac{z_{nj} - d_j^{(n-1)}}{L_j} \tag{24}$$

From Eq. (9), the differential form of Eq. (24) can be obtained as follows:

$$\dot{\sigma}_{0j} = -\lambda_0 \left|L_j \sigma_{0j}\right|^{n/(n+1)} \operatorname{sgn}(\sigma_{0j}) - \rho_0 \sigma_{0j} + \sigma_{1j} \tag{25}$$

Similarly:

$$\dot{\sigma}_{1j} = \frac{1}{L_j}\left(-\lambda_1 L_j^{1/(n+1)} \left|z_{1j} - v_{0j}\right|^{(n-1)/n} \operatorname{sgn}(z_{1j} - v_{0j}) - \rho_1 (z_{1j} - v_{0j})\right) + \sigma_{2j} \tag{26}$$

It can be seen that:

$$z_{1j} - v_{0j} = \lambda_0 L_j \left|\sigma_{0j}\right|^{n/(n+1)} \operatorname{sgn}(\sigma_{0j}) + \rho_0 (L_j \sigma_{0j}) = L_j (\sigma_{1j} - \dot{\sigma}_{0j}) \tag{27}$$

Then, substituting Eq. (27) into Eq. (26) yields:

$$\dot{\sigma}_{1j} = -\lambda_1 \left|\sigma_{1j} - \dot{\sigma}_{0j}\right|^{(n-1)/n} \operatorname{sgn}(\sigma_{1j} - \dot{\sigma}_{0j}) - \rho_1 (\sigma_{1j} - \dot{\sigma}_{0j}) + \sigma_{2j} \tag{28}$$

Similarly, for i = 2, …, n-1, it follows that:

$$\dot{\sigma}_{ij} = -\lambda_i \left|\sigma_{ij} - \dot{\sigma}_{(i-1)j}\right|^{(n-i)/(n-i+1)} \operatorname{sgn}(\sigma_{ij} - \dot{\sigma}_{(i-1)j}) - \rho_i (\sigma_{ij} - \dot{\sigma}_{(i-1)j}) + \sigma_{(i+1)j} \tag{29}$$

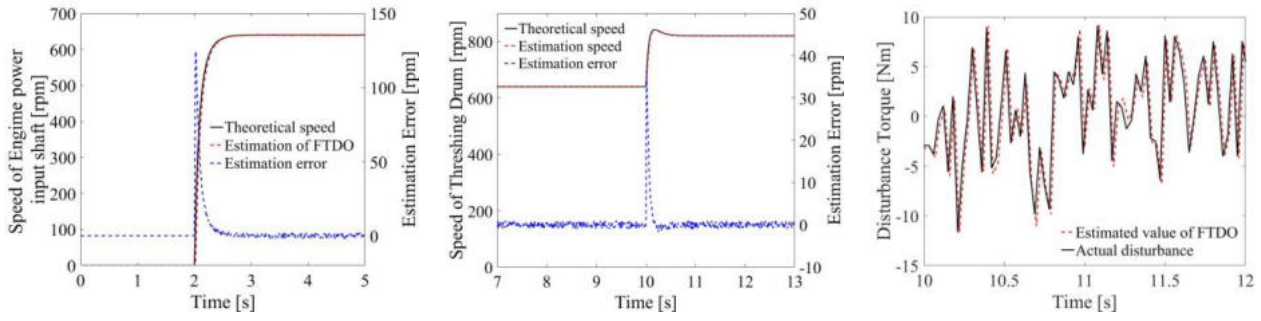
$$\dot{\sigma}_{nj} = -\lambda_n \operatorname{sgn}(\sigma_{nj} - \dot{\sigma}_{(n-1)j}) - \rho_n (\sigma_{nj} - \dot{\sigma}_{(n-1)j}) + \frac{1}{L_j} d_j^n \tag{30}$$

Therefore, the estimation error of the FTDO can be expressed as follows:

$$\begin{aligned}
&\dot{\sigma}_{0j} = -\lambda_0 \left|\sigma_{0j}\right|^{n/(n+1)} \operatorname{sgn}(\sigma_{0j}) - \rho_0 (\sigma_{0j}) + \sigma_{1j} \\
&\vdots \\
&\dot{\sigma}_{(n-1)j} = -\lambda_{n-1} \left|\sigma_{(n-1)j} - \dot{\sigma}_{(n-2)j}\right|^{1/2} \operatorname{sgn}(\sigma_{(n-1)j} - \dot{\sigma}_{(n-2)j}) - \rho_{n-1} (\sigma_{(n-1)j} - \dot{\sigma}_{(n-2)j}) + \sigma_{nj} \\
&\dot{\sigma}_{nj} = -\lambda_n \operatorname{sgn}(\sigma_{nj} - \dot{\sigma}_{(n-1)j}) - \rho_n (\sigma_{nj} - \dot{\sigma}_{(n-1)j}) + \frac{1}{L_j} d_j^n
\end{aligned} \tag{31}$$

According to the relevant research conclusions *(Nguyen et al, 2021)*, it can be seen that the system (31) is stable in finite time, indicating that the estimation error of the FTDO can converge to zero in finite time.

Then the compensation torque of motor is:



$$\boldsymbol{u} = T_{m_\mathrm{com}} = -i_r \eta_r (z_{21} + z_{22}) \tag{32}$$

RESULTS AND DISCUSSION

The previous section focused on the control methods of the designed DPSTD in hybrid mode, specifically addressing the regulation of drum speed for combined harvester operation, as well as its resistance to disturbance and overload. To explore the effectiveness of the DPSTD's structure and control methods proposed in this paper, a simulation model of the DPSTD was further developed using the MATLAB/Simulink platform. The simulation includes the performance evaluation of the designed FTDO, speed control functions of the DPSTD, as well as a comparison of the proposed control method's effectiveness in suppressing disturbances and load fluctuations with and without disturbance compensation.

Verification of the FTDO performance

Assuming that the combine harvester experiences a random disturbance torque from the engine power source during the harvesting process, characterized by Gaussian white noise with a sampling time of 0.01, a variance of 30, and a mean of 0. This disturbance torque is applied to the actual output torque of the DPSTD engine power input shaft. The results of the state estimation and the disturbance estimation of the FTDO during the operation of the DPSTD are shown in Fig. 4.

(a) (b) (c)

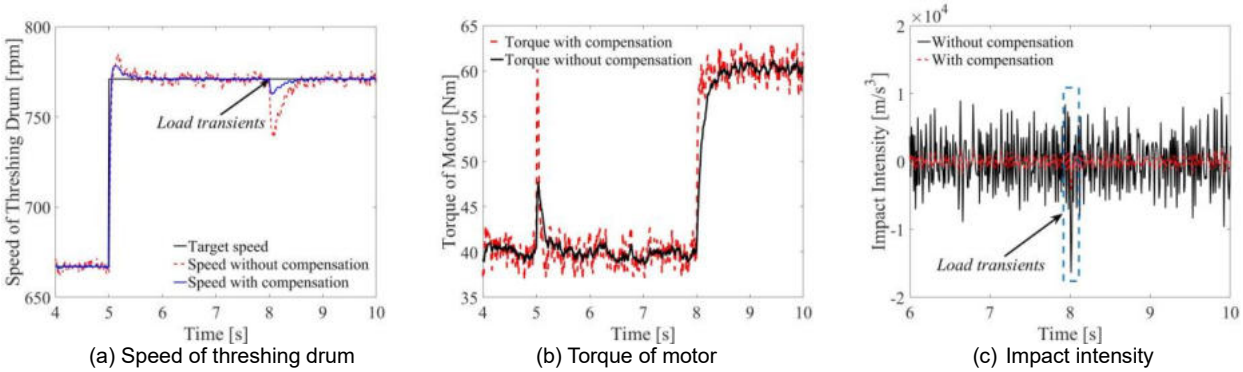


Fig. 4 -The result of the FDTO estimation

(a) State estimation (speed of engine power input shaft); (b) State estimation (speed of threshing drum); (c) disturbance estimation

Fig. 4(a) and Fig. 4(b) show the variations of the two state variables of the speed of engine power input shaft and threshing drum obtained by the FTDO during the estimation of random disturbance. The engine startup process begins at approximately 2.0 s, while the speed adjustment process of the threshing drum starts at 10.0 s. It can be observed that the FTDO accurately estimates the speed of engine power input shaft and the threshing drum with small estimation errors and convergence stability within a finite time. Fig. 4(c) represents the estimated disturbance torque obtained by the FTDO, which exhibits the same trend with the actual values and demonstrates good estimation accuracy.

Simulation of torque dynamic compensation control of the DPSTD

A control simulation analysis of the DPSTD torque compensation control was performed to test its anti-interference and overload resistance capabilities. Assume that the target speed of the DPSTD is from 660 rpm to 770 rpm, and there is a random disturbance torque during the operation. Additionally, a step change in load of 20 Nm occurs at the 8th second. Fig. 5 compares the effects of the DPSTD with torque compensation control based on FTDO and without compensation control under the influence of torque disturbances and load transients.

(a) Speed of threshing drum (b) Torque of motor (c) Impact intensity

Fig. 5 - Comparison of torque compensation control

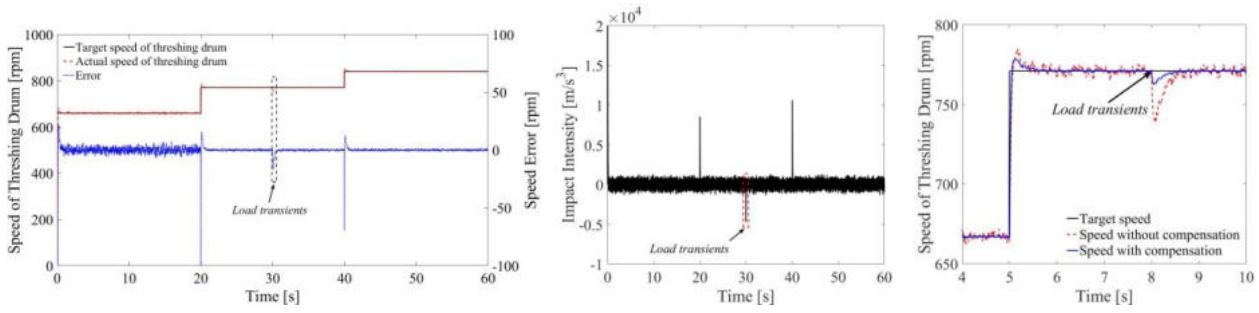
From Fig. 5(a) and Fig. 5(b), it can be observed that when the DPSTD does not employ any interference compensation control strategy, the torque disturbances significantly deteriorate the smoothness of the threshing drum speed tracking. Additionally, these disturbances are not detected by the upper-level controller, and the torque command to the motor continues to be issued by the basic torque controller. However, when employing the FTDO interference compensation control strategy, the current disturbance signal value can be estimated, and subsequently, the output torque of the motor is recalculated, which greatly reduces the impact of the DPSTD, improves the stability of speed tracking, and enhances the quality of mode switching.

Furthermore, according to the simulation results of load transients starting at the 8th seconds in Fig. 5(c), when there is no torque compensation control, the output load transients greatly deteriorate the operation quality of the DPSTD, causing an impact with an amplitude of $1.64 \cdot 10^4$ m/s^3, and the speed tracking shows obvious oscillation. However, the torque compensation control based on FTDO accurately estimates the load changes and coordinates the output torque of the motor, effectively limiting the impact within the range of [$-0.45 \cdot 10^4$ m/s^3, $0.45 \cdot 10^4$ m/s^3]. It also reduces the speed oscillations, achieving a smoother speed tracking. Table 1 presents a comparison of the effects with and without torque compensation control. It can be observed that the control strategy with compensation significantly reduces the impact and speed errors of DPSTD. The root mean square (RMS) value of speed errors is decreased by 73.90%, the maximum speed error id decreased by 76.18%, the RMS value of impact is decreased by 33.51%, and the maximum impact is reduced by 73.18%. In conclusion, the designed torque compensation control strategy based on FTDO can significantly improve the smoothness of mode switching and the speed tracking of the threshing drum, making the DPSTD has a strong anti-interference capability.

Table 1

Comparison of control effects based on two strategies

Control strategy	RMS of speed error (rpm)	Maximum speed error (rpm)	RMS of impact intensity (m/s^3)	Maximum impact intensity (m/s^3)
Without compensation	32.64	31.32	1.94×10^3	1.64×10^4
With compensation	8.52	7.46	1.29×10^3	0.43×10^4



Bench test

In order to verify the feasibility of the structure and control strategy of the DPSTD, a bench test is carried out based on a testing platform. It should be noted that due to the limitations of the experimental equipment, the engine test cannot be realized but considering that the purpose of the test is to verify the effectiveness of the control strategy in the presence of torque disturbances from the engine source, the motor can be used to simulate this part of the torque disturbance. Fig. 6 is the schematic diagram of testing platform for the DPSTD, which is mainly composed of a multi-functional power coupling device (with two built-in motors), two electric dynamometers (corresponding to the left and right driving semi-axis respectively), a testing platform controller and related auxiliary equipment. The functionality of reading the status parameters of the power coupling device, load simulation of the electric dynamometers, and parameter settings and status monitoring of the upper computer can be achieved through CAN bus communication. The multi-functional power coupling device can be used to simulate the power coupling device in the DPSTD, while one of its built-in motors emulating the engine source power, while the other one acts as the driving motor in the DPSTD. Additionally, the electric dynamometers are used to simulate the load input.

Fig. 6 - The testing platform

The designed observer and controller are integrated into the motor controller application layer of the testing platform, enabling the application of the designed control strategy. Fig.7 presents the bench test results of the DPSTD applying the torque compensation control strategy during mode switching, speed regulation, and when subjected to load transients.

(a) (b) (c)

Fig. 7 - The results of bench test

(a) Speed of threshing drum; (b) Impact intensity; (c) Torque of motor and engine power input shaft

It can be observed from Fig. 7(a) that in the bench test, the actual speed of the threshing drum is closely aligned with the target speed, with only significant errors occurring during demand speed transients. This is attributed to the controller response and communication delays in the experiment. However, the error duration is short and will not significantly affect the performance. Hence, the errors generated in this case can be disregarded. Additionally, in the conventional mode where the motor is not engaged, the speed error is noticeably higher compared to the hybrid mode. This observation demonstrates that the DPSTD employing motor disturbance compensation control can effectively improve speed tracking accuracy. Fig. 7(b) shows that compared to the simulation results with compensation control, the bench test exhibits higher impact intensity but remains within 1.1×10^4 m/s^3. During load transients, the impact intensity is slightly higher than the simulation results, but the overall effect is still satisfactory.

It can be seen from Fig. 7(c) that the driving motor can promptly start and engage during mode switching, accomplishing the speed regulation function of the DPSTD. Simultaneously, effective torque compensation can be achieved to mitigate disturbances and load transients, reducing speed oscillations and minimizing torque shocks in the transmission system.

To sum up, compared with the closed simulation environment, the bench test results are different from the simulation results due to the differences in equipment parameters, motor performance, communication and control time delay and other factors, but still achieved satisfactory outcomes. The test verifies that the designed DPSTD possesses sensitive and versatile speed regulation capabilities, enhancing the versatility of the combine harvester. Additionally, the proposed motor control method realizes disturbance identification and compensation control, improving the DPSTD's anti-interference ability during operation, thereby ensuring stable operational performance. Consequently, the superiority of the DPSTD's threshing system over that of conventional combine harvesters is demonstrated.

CONCLUSIONS

Based on a parallel hybrid system, this study proposes a dual power source threshing drum that can be driven by both an engine and an electric motor. A RMPC controller is designed for the motor control, and FTDO are incorporated to enhance the control performance. The study further explores the performance of the DPSTD, including its speed regulation capability and disturbance rejection ability. Finally, a bench test is conducted to validate the effectiveness and superiority of the DPSTD. According to the findings above, the following conclusions were reached:

(1) Compared to conventional threshing drums, the DPSTD driven by engine and motor can use the large-scale speed regulation function of motor to realize the adjustable speed of threshing drum in hybrid mode, and has fast dynamic response, allowing for quick parameter adjustments according to the harvesting requirements of different crops, enabling versatile applications.

(2) The RMPC controller for motor based on the FTDO can accurately estimate the disturbance torque and operating load during operation, enabling fast and precise torque compensation. Simulation results show that, in the presence of torque disturbances and load transients, the control strategy with torque compensation reduces the RMPC value of speed error by 73.90%, the maximum speed error by 76.18%, the RMPC value of impact intensity by 33.51%, and the maximum impact intensity by 73.18% compared to the control strategy without compensation. This approach significantly improves smoothness of mode switching and speed tracking performance of the threshing drum, demonstrating excellent anti-interference ability.

(3) The bench test demonstrates that the designed DPSTD with torque compensation can effectively perform speed adjustment and exhibits anti-interference ability. The test results are similar to the simulation results, which proves the rationality and effectiveness of the designed DPSTD in terms of its structure and control strategy, and provides a novel and valuable reference for the research on the speed control of threshing drum of combine harvester.

ABSTRACT
The article addresses the development of foundational principles for improving the quality of plant product preservation. The application of the proposed technologies enables a reduction in nutrient losses in raw plant materials during storage. This assertion is supported by the results of both theoretical and experimental studies on the physical and mechanical properties of plant materials, as well as on the energy, operational, and technological performance of the equipment, including its structural design parameters and modes of operation. The use of the proposed technology enhances nutrient preservation by preventing cell structure damage and preserving plant juices, while also minimizing internal voids and reducing the amount of free air within the compacted monolith. Consequently, this leads to a decrease in the cost of dietary components. The implementation of the proposed technological process in haylage production significantly reduces nutrient losses during storage. Furthermore, using plant raw materials stored with this method results in lower milk production costs compared to traditional storage techniques.

АННОТАЦИЯ
Статья посвящена разработке основ повышения качества хранения растительной продукции. Применение предложенных технологий позволит снизить потери питательных веществ в растительном сырье в процессе его хранения. Достоверность такого утверждения подтверждаются результатами теоретических и экспериментальных исследований физико-механических свойств растительного сырья, энергетических, эксплуатационных и технологических показателей агрегата, его схемы, конструктивных параметров и режимов работы. Использование предложенной технологии улучшает сохранность питательных веществ, благодаря отсутствию повреждений клеточной структуры и сохранности внутриклеточного сока, снижением свободного пространства между стеблями, что соответственно уменьшает объем воздушной массы в уплотненном монолите. Предложенная технология обеспечивает снижение стоимости компонентов рациона. Применение предложенной технологической линии при заготовке сенажа обеспечивает снижение потерь питательных веществ в процессе консервирования растительного сырья. При использовании растительного сырья, заложенного по предложенной технологии, себестоимость молока снижается в сравнении с существующими вариантами.

INTRODUCTION
Much attention has been paid to plant raw materials research since ancient times. Compaction of straw materials as an alternative fuel can be considered as the first attempts. The devices for stem materials compaction have been used since the end of the 9th century. Approximately the same time, there were the first attempts to provide a scientific substantiation for this process. Yet more detailed studies of stem materials compaction were started in the early twentieth century.

The first mechanisms for fuel briquettes production were peat briquette presses of the stamp type. But they were not adapted to the pressing of plant raw materials. Therefore, it was necessary to conduct physical and mechanical research as well as technological properties of materials to be pressed. All of the above was necessary for defining the design and technological parameters and modes of operation of the press equipment.

Great contribution to the study of vegetable raw materials compaction problems was made by the scientists *Goryachkin,(1965), Gutyar, (1936), Pustigin, (1948)* and others and no plant materials (*Olaleye et. al., 2020; Vanhoorne et al., 2020; Orisaleye and Ojolo, 2019 and others*).

Special press briquetting machines for stem materials were the results of their work for stem materials. As the result of stem materials compaction research, having been conducted by many authors, various dependences of the material density *ρ* and the degree of its compression on the applied force *P* were set. However, despite all the efforts, researchers did not come a single opinion as for the regularities of the process of hay and straw materials pressing.

On the bases of data obtained, many equations have been proposed that relate the pressure to the deformation or density of the pressed material. Some scientists believe that the relationship between the pressing pressure and the density of the material in the chamber can be expressed by a power function, in the form $P = C\rho S$, while other researchers (*Pustigin M., 1948, Osobov V., 1963, Dolgov I., 1971*) consider that the dependence should have an exponential dependence in the form $P = AeB\rho$. Whereas *Dolgov I. (1971)* was certain that the relationship between pressing pressure and density will change its physical meaning when the humidity of the pressing materials changes, namely at humidity up to 15.6%, the dependence will be gradual, while with increasing humidity more than 18% the dependence will already be exponential. We should also not forget about the supporters of Hooke's law, such as *Goryachkin V., (1965)* and *Gutyar* E., *(1936).*

For example, *Goryachkin V., (1965),* proposed the dependence of the axial pressure on the movement of the piston.

$$p = p_{max}(1 - \frac{x^2}{S^2}) \quad (1)$$

where:

p, p_{max} - respectively, the current and maximum pressure on the piston, [Pa];

x, S - respectively, the path and stroke of the piston, [m].

Pustygin M., (1948), noticed that in the presence of nodes availability, leaves and stems with different orientation there is no direct fracture of the stems, and the process takes place along with the flattening. As a result, the compaction process proceeds smoothly and evenly. The materials to be pressed have only physical, mechanical and technological properties that affect the compaction process. That is why many researchers have sought to identify these properties and identify their impact on the process. For example, *Gutyar E., (1936),* in the proposed dependences took into account the modulus of elasticity of the first kind and the Poisson's ratio. Such researchers as *Perezhogin M., (1963),* and *Khrapach E., (1956),* took into account the moisture content of the fodder as well as the rate material of deformation.

THEORETICAL BACKGROUND

At the present stage, it is no longer a secret that the preservation of feed should first avoid contact of the feed mass with the air. It is achieved in a various way, such as filling storage containers with inert gases, compacting the feed mass, compacting near the shelter storage or containers with airtight films or laying in polymer sleeves, and so on. But the most widespread ones are the processes of compaction of the feed mass, where due to the direct compression of freely placed particles there is the displacement of air from the feed mass. *Khvorostyanov, (1980), Semenikhin, (1998),* and others have already dealt with these issues. However, these issues could not be finally resolved. Theories of fodder mass compaction as well as theories of porosity, stacking, etc. were offered. However, the issue remains topical due to excessive nutrient losses (about 15%) during storage. Therefore, the relevance of this topic remains and needs further development. *Khvorostyanov, (1980),* was engaged in the processes of self-compaction of fodder masses in small storages. He most systematically considered the physical and mechanical properties of silage. Academician Muller R., (*Muller, 1963*) put forward some empirical formulas for soils of normal humidity, which, with certain assumptions, can be applied to silage monoliths. According to them, the normal vertical pressure p_z will be equal:

For containers with rectangular cross section:

$$p_z = 9.81\rho_{cp}\frac{1}{2}\sqrt{\frac{\pi si}{2\Psi(i+1)}}\cos\left(\sqrt{\frac{1}{s}}\cdot\frac{2x}{a}\right)\cos\left(\sqrt{\frac{1}{s}}\cdot\frac{2y}{b}\right)\Phi\left[\frac{2z}{a}\sqrt{\frac{\Psi(i+1)}{si}}\right] \quad (2)$$

For containers with round section:

$$p_z = 9.81\rho_{cp}\frac{1}{2}\sqrt{\frac{\pi si}{2\Psi(i+1)}}\cos\left(\sqrt{\frac{2}{s}}\cdot\frac{r}{R}\right)\Phi\left[\frac{2}{R}\sqrt{\frac{2\Psi}{s}}\right] \quad (3)$$

where:

ρ_{cp} - average mass density, [kg/m^3];

a, b - length and width of a rectangular container, [m];

i - the ratio b/a;

R - the radius of the round container, [m];

s - the coefficient that characterizes the smoothness of the tank walls;

Ψ - coefficient of lateral pressure;

Φ (a) - is the Laplace function;

$$u = \frac{r}{R}\sqrt{\frac{2\Psi}{s}}$$

x, y, z, r - coordinates of the point for which the pressure is being determined, [m].

The optimal from the positions of providing the highest normal vertical pressure p_z are containers with a round cross section, which are already followed by containers with a square cross section because they have a smaller perimeter with the same cross-sectional area. Moreover, in all cases, containers with large cross-sectional areas have advantages over containers with small cross-sections, and containers with large heights have advantages over smaller ones.

Many authors in making their hypotheses use the provisions of Hooke's law on the deformation of elastic-plastic materials, namely:

$$Hn\frac{d\varepsilon}{dt} + E\varepsilon - \sigma - n\frac{d\sigma}{dt} = 0 \quad (4)$$

where:

E, H - long and instantaneous modulus of elasticity, [Pa];

σ, ε - stress and relative deformation, [Pa];

$n = \mu / E$ - relaxation time, [s];

μ - viscosity, [Pa*s].

Semenikhin A., (1998), studied the compaction processes of forage material by tractors, specifically how the forage mass is compacted in the track or inter-track area of the tractor. He derived the following equation, which expresses the magnitude of the relative deformation in the horizontal plane: (5), where L is the track width or wheelbase of the traction vehicle, and l_0 is a parameter of the laying body.

$$\varepsilon_H = \frac{2l_0}{(L-2l_0)} \quad (5)$$

where:

ε_H is the amount of relative deformation in the horizontal plane;

L is the width or wheelbase of the energy source;

l_0 – is a parameter of the laying body.

In the work of *Semenikhin, (1998)*, it was proposed to continue the above theory through the use of echelon loading of the feed mass when stacked in storage. As a result, they offer optimal conditions for the implementation of the proposed method of compaction, which requires maintaining the required level of the monolith surface, and setting the required geometric size of the deformation. To maintain a zero balance of voids and compaction along the stroke of the rammer, and to ensure that the monolith remains in a position aligned with the path of the support element, it is necessary to implement a combined scheme with geodetic levels placed along the direction of movement. Additionally, several studies have examined the effects of periodic loading in similar contexts.

For example, *Gurinenko, (2007)*, in her work, in addition to examining the impact of heavy mobile equipment, also addresses the problem of particle placement within the feed mass monolith during compaction and proposes three placement schemes.

The process of distributing silage mass within the storage volume is accompanied by periodic loading from caterpillars or wheels over a gradually increasing layer. This layer consists of particles with finite size, geometric shape, and varying orientations. At the points of loading, specifically under the tracks of the rammer, these particles form discrete aggregates that respond differently to the rammer's deformation. These include both relaxing and non-relaxing deformation centers, which are not structurally connected. In such conditions, the feed mass does not form a unified structure; its mechanical strength is governed by frictional interactions, which are influenced by the height and size of the particles. As the layer's height increases, the number of elementary aggregates also increases, while the distances between them decrease only slightly. This results in the silage mass simulating imperfections of the original discrete particles and gradually integrating the mechanical behavior of these disconnected aggregates. Eventually, the mass transitions to a new boundary condition level, where elementary structures begin to interconnect.

At this stage, the structure becomes dominated by horizontally oriented particles. When the layer height reaches approximately 0.8 m to more than 1 m, its surface begins to exhibit load-bearing capacity, characterized by shear strength (τ) and compressive strength (σ) due to cross-dense packing, while retaining the elastic-viscous behavior of its constituent components. Thus, it can be concluded that before compaction, the feed mass behaves as an elastic-viscous body composed of numerous aggregates distributed throughout its volume.

The particles possess defined dimensions and can migrate toward areas of lower density and between layers. Under the influence of periodic loading, the feed mass undergoes changes in both its physical-mechanical and rheological properties, gradually approaching the upper density limit and minimum porosity characteristic of a compacted monolith. This study is based on the dynamic behavior of multicomponent media, considering variations in their damping properties and their capacity to absorb mechanical energy during compaction.

The mechanics of elastic-viscous media of plant origin are characterized by properties such as stress relaxation, viscosity, and creep, which are not functionally dependent on porosity and density. This distinction highlights the relevance of the present work. Considering all the above, it can be concluded that significant efforts have been made to reduce porosity - an important factor in minimizing feed contact with air. However, there is still a lack of sufficient technological solutions to effectively eliminate voids and prevent the formation of empty layers within the feed mass. Therefore, it is deemed necessary to enhance the theoretical foundations of the feed mass compaction process and to continue research in this critical area.

MATERIALS AND METHODS

Based on the results of laboratory research having been conducted by *Milko, (2020, 2019), Maraldi et al., (2016), Lisowski et al., (2020), Kaliyan et al, (2013), Cabrales et al, (2020), Siyal et al., (2021)*, an experimental and production prototype of equipment for plant material compaction was developed (Fig. 1).

The system consists of a frame *1* equipped with a feeder *2* and a twin-screw compactor *3*, all integrated into a single technological unit. All actuators are powered by adjustable electric drives, which are automatically controlled and can also be manually operated via a centralized control panel. The technological process for compacting vegetable raw materials is as follows: the material is first delivered by the feeder *2* into the twin-screw compactor *3*, where the screws - arranged in layers - separate and structure the incoming particles. The mass is then directed toward the diffuser, where it undergoes a twisting motion. This twisted mass is subsequently fed through the diffuser, where it is compacted (Fig. 2).

In the present research, the following equipment was used: RN-50SHVP-1 scale, electronic scales, laboratory quadrant scales VLK-500-M, sampling bags, a box for volume determination, caliper, engineering ruler, and a type S 0.2 stopwatch. Scales for measurements up to 500 kg. Additional measuring instruments included: dial scales РН–10Ц13У (TU 25.06.575–70), laboratory technical quadrant scales VLTK-500, pointer tachometer PM-10R (GOST 21339), mechanical stopwatch SOPpr-2a-3-000 "Agate" 4282 (GOST 5072-79), metal ruler 0–500 mm (GOST 427-75), tape measure P2 (GOST 7502-80), vernier caliper ShTs 0–150 (GOST 166-80), camera, metal container (V = 0.15 m^3), and a measured set K-50 (GOST 8711 and GOST 8476).

1 – frame; 2 – feeder; 3 - twin-screw compactor.

Fig. 2 - Compaction of the twisted mass as it passes through the diffuser

The measuring stand was equipped with a Danfoss VLT Micro FC51 frequency converter integrated with the MCT-10 software suite (Fig. 3). Using the mathematical theory of experimental design, the dependencies of quantitative, qualitative, and energy performance of the preservative dispenser and the twin-screw compactor on the studied factors were also determined. The corresponding regression equations were based on three factors.

The research on a twin-screw compactor for vegetable raw materials was conducted by analyzing the influence of design parameters, operating conditions, and material properties. Specifically, the study focused on the ratio of the inlet height to the screw diameter, screw rotation speed, and the initial mass density of the material. Both active and passive experimentation methods were employed - active variation of selected factors was combined with passive observation of others. The screw speed and the inlet height-to-screw diameter ratio were varied according to a three-level, three-factor experimental design matrix. The initial mass density was based on values obtained during previous compaction cycles. The variation range for the inlet height-to-screw diameter ratio was 1.27 to 1.95, with an average value of 1.6, representing a 20.6% variation. Screw rotation speeds ranged from 21 to 125 rpm, giving a variation interval of 72 rpm or 71.2%, indicating a wide experimental scope for both parameters. The initial mass density of haylage varied from 150 to 555 kg/m³. To optimize the design and operational parameters of the twin-screw compactor, a full second-order factorial design matrix with three levels and three factors was applied.

RESULTS AND DISCUSSION

During the experiment, screws with the required pitch and diameter were installed on the twin-screw compactor for vegetable raw materials, and the screw rotation speed was adjusted accordingly. The pre-compaction press parameters were then set, including the loading window height coefficient and the piston speed, to achieve the desired density at the entrance of the twin-screw compactor. Next, the hopper of the pre-compaction press was loaded with vegetable raw materials. The electric motor reducers of both the twin-screw compactor and the pre-compaction press were activated, and the compaction cycle was initiated. Throughout the process, energy consumption and the productivity of filling the polymer storage unit were recorded. These values reflect all stages of the material handling process: loading, compaction, and storage. To prevent air infiltration during storage, it is necessary to hermetically seal or tightly pack the polymer storage unit after filling. The variation levels of the independent factors - screw speed n (1/s), window height coefficient k (the ratio of the feed window height to the screw diameter), and the pre-compacted mass density ρ (kg/m³) - along with their combinations, were organized according to a three-level, full-factorial second-order experimental design and are presented in Table 1.

Table 1

Variation levels of factors for investigating the twin-screw compactor for plant raw materials

№	Factor level					
	Coded			Decoded		
	X_1	X_2	X_3	Screw speed	Window height coefficient	Pre-compacted mass density
				[1/s]	-	[kg/m³]
1	-1	-1	-1	25	1.25	320
2	1	-1	-1	125	1.25	320
3	-1	1	-1	25	1.95	320
4	1	1	-1	125	1.95	320
5	-1	-1	1	25	1.25	720
6	1	-1	1	125	1.25	720
7	-1	1	1	25	1.95	720
8	1	1	1	125	1.95	720
9	-1	0	0	25	1.6	520
10	1	0	0	125	1.6	520
11	0	-1	0	75	1.25	520
12	0	1	0	75	1.95	520
13	0	0	-1	75	1.6	320
14	0	0	1	75	1.6	720

Experimental data and studies for performance (Q), power consumption (N), energy consumption (E), and output density (R), based on the factor combinations presented in Table 1, are summarized in Table 2.

Table 2

Results of hay compaction studies

№	Screw speed	Window height ratio	Input density	Productivity	Power	Energy consumption	Output density

According to the data presented in correlation Table 3, which is based on the experimental results in Table 2, a statistically significant ($p < \alpha$) moderate correlation (as per Chaddock's scale) is observed between productivity, power, and output mass density with the screw rotation speed during the compaction of haylage and heap material. Notably, the correlations for output mass density are negative.

Productivity, energy consumption, and power also show statistically significant correlations with the window height coefficient, but only when considering the input density. Among these, power demonstrates a correlation strength ranging from moderate to relatively high across all analyzed indicators.

Table 3

Correlation table for haylage compaction estimation

Indicator	Productivity	Power	Energy consumption	Output density R
Haylage				
Screw speed	.3780	.8020	-.1982	-.3654
	p=.014	p=.000	p=.208	p=.017
Window height ratio	.4299	-.2706	-.5806	.1763
	p=.004	p=.083	p=.000	p=.264
Input density	.2962	.4118	.0057	.0348
	p=.057	p=.007	p=.971	p=.827

The results of the preliminary evaluation of the experimental data for determining the values of productivity, power, and energy consumption - using Student's *t*-test, the range of the truncated sample, and Cochran's test at a significance level of α = 0.05 - are presented in Table 4.

Table 4

Preliminary evaluation results of experimental data using statistical criteria

Name of the criterion	The value of the criterion	Criterion			
		Productivity	Power	Energy consumption	Output density
Haylage					
Student's *t*-test	Maximum value	1.061	1.061	1.135	1.066
	Critical value	4.303			
Truncated sample range k	Maximum value	0.602	0.602	0.805	0.612
	Critical value	3.157			
Cochran's test G	Estimated value	0.438	0.146	0.298	0.124
	Critical value	0.570			

Table 4 shows the preliminary evaluation of experimental data for productivity, power, energy consumption, and output density. Statistical assessments were carried out using Student's *t*-test, the range of the truncated sample (*k*), and Cochran's *G* test at a significance level of α = 0.05 are given in Table 4.

Table 5

Regression equation indicators for the dependent variable – performance of the two-screw compactor

Indicator	Decoded regression coefficient	Standard error of the regression coefficient	Student's actual criterion	Significance Level
Haylage				
Free term	1634.059	171.534	9.526	0.001
Screw speed	0.738	0.688	1.072	0.344
Window height ratio	-1487.907	217.063	-6.855	0.002
Input density	-2.382	0.239	-9.950	0.001
Speed of rotation × Window ratio	-2.984	0.259	-11.533	$3.228 \cdot 10^{-4}$
Speed of rotation × Input density	-0.006	$4.528 \cdot 10^{-4}$	-13.096	$1.963 \cdot 10^{-4}$
Window ratio × Input density	1.420	0.065	21.957	$2.546 \cdot 10^{-5}$
Square of screw speed	0.057	0.003	17.533	$6.214 \cdot 10^{-5}$
Square of window height ratio	378.571	66.640	5.681	0.005
Square of input density	0.001	0.000	3.966	0.017

As a result of processing the extended matrix of experimental data - including pairwise interactions of independent factors and their squared terms, based on Table 1 - Table 5 presents the decoded regression coefficients and their statistical evaluation for haylage compaction. The regression model was established using Statistica software.

CONCLUSIONS

Analyzing the response surface of energy consumption during plant material compaction - based on the screw speed of the two-screw compactor, the window height coefficient, and the input density - it is observed that optimizing compaction parameters for maximum productivity also allows achieving the desired output density. Specifically, when the screw rotational speed is set at 40-45 rpm, the window height coefficient is around 1.8, and the input density is approximately 350–370 kg/m^3, the output density of the compacted heap reaches 600 - 700 kg/m^3 under the same equipment settings.

Based on the conducted research, the following compaction parameters for vegetable raw materials are recommended. For haylage compaction: window height coefficient: k = 1.6; input density ρ = 620 kg/m^3; screw rotation speed n = 100 rpm. For heap compaction: window height coefficient k = 1.8; input density: ρ = 420 kg/m^3; screw rotation speed: n = 100 rpm

ACKNOWLEDGEMENT

The research was carried out within the framework of the scientific topic: "FRRS-2023-0019 Improving the efficiency of grain production through the introduction of modern processing methods in the conditions of the MSU Food Safety Research and Production Center."

ABSTRACT
This study used eXtreme Gradient Boosting (XGBoost) to predict the drying behavior of Boesenbergia rotunda (L.) under hot air and ultrasonic vibration. A dataset of 73 samples with temperature, time, and vibration as inputs was used. The model achieved high accuracy with R^2 = 0.99 and RMSE = 8.71 on test data. SHAP analysis revealed that ultrasonic vibration improved moisture reduction, especially during longer drying times. These results demonstrate the effectiveness of combining XGBoost and SHAP for understanding and optimizing complex drying processes in food and agricultural engineering.

บทคัดย่อ
งานวิจัยนี้ใช้เทคนิค XGBoost เพื่อพยากรณ์พฤติกรรมการอบแห้งของกระชายขาว (Boesenbergia rotunda (L.)) ด้วยลมร้อนร่วมกับคลื่นการสั่นสะเทือนความถี่สูง โดยใช้ชุดข้อมูลจำนวน 73 ตัวอย่างที่มีอุณหภูมิ เวลา และการสั่นสะเทือนเป็นตัวแปรนำเข้า โมเดลสามารถทำนายได้อย่างแม่นยำ โดยมีค่า R^2 เท่ากับ 0.99 และ RMSE เท่ากับ 8.71 จากข้อมูลทดสอบ การวิเคราะห์ด้วย SHAP แสดงให้เห็นว่าคลื่นเสียงช่วยลดความชื้นได้ดีขึ้นเมื่อใช้กับเวลาการอบแห้งที่นาน ผลลัพธ์นี้ชี้ให้เห็นถึงศักยภาพของการผสาน XGBoost กับ SHAP ในการเพิ่มประสิทธิภาพกระบวนการอบแห้งสำหรับงานด้านวิศวกรรมอาหารและเกษตร

INTRODUCTION
White fingerroot, also known as Chinese ginger, is an important medicinal herb primarily found in Southeast Asia (*Larsen, 1996; Taheri et al., 2022*). Its significance stems from both its culinary uses and its medicinal properties, making it highly valued in traditional medicine and modern pharmaceutical research. White fingerroot contains important nutrients, including vitamins, minerals, and antioxidants (*Trakoontivakorn et al., 2001; San et al., 2022*). Drying is an important step in processing herbs to enable them to be stored for a longer period and effectively retain their medicinal value (*Orphanides et al., 2016; Thamkaew et al., 2021*).

Ultrasonic vibration drying is an innovative drying technique that uses high-frequency sound waves to enhance the removal of moisture from various materials, including food, herbs, and industrial products (*Musielak et al., 2016*). This method leverages mechanical vibrations, typically at frequencies between 20 kHz-1 GHz, to break the bonds between water molecules and the material, allowing for faster and more efficient evaporation compared to conventional drying methods (*Yao, 2016; Cheeke, 2012*). In ultrasonic vibration drying, a transducer generates high-frequency sound waves that are transmitted into the material being dried. These waves cause rapid, microscopic vibrations in the material and the surrounding moisture. These vibrations break up water droplets and reduce the surface tension, enabling moisture to evaporate more easily. The process is highly efficient because the mechanical energy from the vibrations increases the rate of moisture transfer without requiring high heat (*Kahraman et al, 2021; García-Pérez et al., 2023; Thanompongchart et al., 2022*).

Patipat Thanompongchart, Asst. Prof.; Pakamon Pintana, Lecturer; Tossapon Katongtung, PhD student; James C. Moran, Assoc. Prof.; Nakorn Tippayawong, Prof.

The use of ultrasonic vibration for drying offers several significant advantages. Firstly, it enables faster drying times as the ultrasonic waves substantially accelerate the evaporation process. This method also consumes less energy because it operates at lower temperature compared to traditional drying techniques. Additionally, minimal temperature exposure is a key benefit, making it ideal for preserving sensitive materials such as herbs and food, which can otherwise lose essential nutrients, flavor, or texture due to excessive heat. Furthermore, ultrasonic vibrations promote uniform moisture evaporation, ensuring improved quality and consistency by preventing issues like over-drying or uneven results. Lastly, this drying method is environmentally friendly, as it is non-invasive and sustainable, relying neither on chemicals nor high temperatures, which makes it an eco-friendlier option *(Musielak et al., 2016; Gallego-Juarez et al., 1999).* However, ultrasonic vibration still poses a problem of high heat accumulation at the vibrator, resulting in a short lifespan. This technology is especially beneficial in industries where preserving the quality of sensitive materials is essential, such as food, herbs, and pharmaceuticals. Its ability to enhance moisture removal without high heat positions ultrasonic vibration drying as a modern, sustainable solution to traditional drying challenges (*Mujumdar, 2004; 2006*).

Machine learning (ML) can improve the industry by enabling more accurate predictions of drying behavior, thus optimizing efficiency, quality, and resource management. By analyzing large datasets generated during the drying process, ML models can uncover patterns and relationships between key variables like temperature, humidity, airflow, and material properties. These models, including regression models, neural networks, and support vector machines are trained to predict drying kinetics and outcomes (*Martynenko and Misra, 2020; Taur et al., 2019; Đaković et al., 2023*). ML models identify how these factors interact to influence the drying rate and moisture ratio (*Çetin, 2022*). Once trained, the model can accurately predict the behavior of agricultural products under given drying conditions (*Tagnamas et al., 2023*), offering insights into optimizing the process for better energy efficiency, faster drying, and improved product quality (*Soares et al., 2013*). Moreover, ML algorithms estimate product yields, optimal conditions, and variables or affect operational efficiency in others applications (*Katongtung et al., 2022; 2024a; 2024b; Kittichotsatsawat et al., 2023*).

The novelty of this work lies in the fact that an ML algorithm is applied to estimate the drying of white fingerroot with conventional hot air dryer combined with an ultrasonic vibration system. The objective of this study is to develop a predictive model for the drying behavior of *Boesenbergia rotunda* (L.) using hot air combined with ultrasonic vibration. The eXtreme Gradient Boosting (XGBoost) algorithm was employed to optimize and analyze the drying process with the goals of minimizing material waste, enhancing product consistency, and increasing overall processing efficiency. The findings emphasize the importance of dataset expansion in mitigating overfitting and improving the model's generalization capability, in line with prior studies (*Chamorro et al., 2026*). A larger and more diverse dataset enables the model to capture fundamental patterns more effectively, thereby increasing the accuracy and robustness of predictions in both experimental validation and practical applications.

MATERIALS AND METHODS

Experimental setup and procedure

The experimental dryer is a modified hot air oven integrated with an ultrasonic vibration system, as illustrated in Fig. 1(a). Positioned centrally beneath the product trays inside the dryer is an ultrasonic vibration unit operating at a frequency of 40 kHz, 60 W (Piezoelectric) with 1 unit set per tray. The dryer accommodates two tiers of product trays. To prolong the operational life and durability of the ultrasonic system, an air-cooling system is installed via ducts beneath the trays in Fig. 1(b). The system is programmed to operate in cycles of 1 min on and 5 min off.

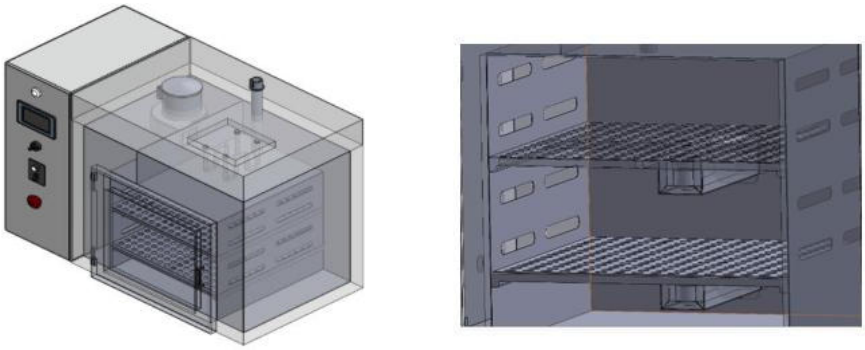

Fig. 1 – (a) Hot air dryer integrated with an ultrasonic vibration system and (b) installation of the ultrasonic vibration system underneath product trays

The dryer's heating system uses electric heaters and a fan to ensure uniform airflow and efficient moisture extraction through the top vent. White fingerroot (*Boesenbergia rotunda* (L.)) was prepared for drying by washing and cutting it longitudinally into pieces generally less than 1 cm thick and approximately 10 cm long. The pieces were arranged on mesh trays at 1.5 kg per tray, with a maximum spacing of 8 ± 1 cm. Two trays were used for each drying run. Each condition was tested in triplicate. Drying experiments were conducted at temperatures of 50 °C, 60 °C, and 70 °C using a combined method involving hot air and ultrasonic vibration. The dried white fingerroot was weighed every hour during the drying process. Afterward, samples were further dried in a hot air oven at 103 °C for 72 hours to determine dry matter content based on AOAC (1995) standards. The final moisture content was then calculated. According to *Rungsardthong, (2002),* the moisture content of dried white fingerroot suitable for storage should not exceed 7% on a wet basis.

Data analysis

In physics-based modeling, the drying process is analyzed through theoretical models derived from mathematical reasoning. This section establishes a boundary value problem by incorporating the governing equations of transport phenomena, along with relevant assumptions, initial conditions, and boundary conditions (*Akter et al., 2022*). The moisture content of the drying material decreases as it absorbs thermal energy, along with the sensible heat present in the surrounding air. During the drying process, the amount of thermal energy absorbed by the material corresponds to the latent heat required for the evaporation of its moisture (*Wengang et al., 2024*).

Determination of humidity on a wet basis is the ratio of the weight of water in a material to the material weight, calculated as:

$$M_w = \frac{(w - d)}{w} \times 100 \quad (1)$$

where:

M_w is moisture content wet basis (%), w is initial weight of the material (kg) and d is weight of dry material (kg). The initial moisture content of the white fingerroot was 93 ± 1.5% wb and the final value was lower than 7% wb.

The drying water evaporation rate is the amount of water that evaporates during the drying process per unit of time. It can be calculated by:

$$\dot{M}_w = \frac{M_w}{t} \quad (2)$$

where:

$\dot{M}_w$ is water evaporation rate ($kg_{(water)}$/h), M_w is evaporated water mass ($kg_{(water)}$) and *t* is time (h).

Machine learning model and evaluation

In this study, an ML model was developed to predict average moisture content using XGBoost, a widely used and highly efficient algorithm (*Katongtung et al., 2022; 2024a; 2024b*). XGBoost is a machine learning algorithm that builds multiple decision trees in an iterative fashion to solve both regression and classification problems. It is an implementation of gradient boosting that is optimized for performance and speed. Gradient boosting is a technique where weak learners, typically decision trees, are trained sequentially with each new tree attempting to correct the errors made by the previous ones. XGBoost has become widely used because of its ability to handle large datasets and its robustness across a variety of tasks, including structured/tabular data problems, where it often outperforms other models. It is also popular in many Kaggle competitions due to its competitive accuracy.

The high efficiency of XGBoost is derived from several key factors. One of the most important is regularization, as it incorporates both L1 (Lasso) and L2 (Ridge) techniques to prevent overfitting, allowing the model to generalize well on unseen data. XGBoost also benefits from parallel processing, enabling parallel tree construction, which reduces computational time and significantly improves training efficiency. Additionally, XGBoost is equipped with built-in mechanisms to handle missing data, a critical feature when working with real-world datasets. Its sparsity-aware learning optimizes performance when dealing with high-dimensional datasets that often contain many zero-valued features. Moreover, the algorithm includes automatic pruning of trees, helping to avoid unnecessary complexity, reduce model size, and enhance interpretability.

XGBoost is an ensemble learning method that implements gradient boosting using decision trees. The algorithm builds the model in an additive, stage-wise manner by iteratively fitting new trees to the residuals (errors) of previous predictions. The goal is to minimize a regularized objective function, which is composed of two main components (*Noh et al., 2024*):

(a) Loss function (L): This measures the difference between the predicted values and the actual values. For a given dataset with n examples, the loss is typically represented as:

$$L(\theta) = \sum_{i=1}^{n} l(y_i, \hat{y}_i) \quad (3)$$

where:

l is a differentiable loss function, y_i are the true values, and $\hat{y}_i$ are the predicted values.

(b) Regularization term (Ω): This term penalizes the complexity of the model to prevent overfitting. For decision trees, complexity might be measured in terms of the number of leaves and the magnitude of leaf weights. The regularization term for a tree model *f* can be written as:

$$\Omega(\boldsymbol{f}) = \boldsymbol{\gamma}\mathbf{T} + \frac{1}{2}\boldsymbol{\lambda}\sum_{j=1}^{T}\boldsymbol{w_j^2} \quad (4)$$

where:

$\mathbf{T}$ is the number of leaves in the tree, w_j is the weight of the j leaf, γ is a parameter controlling the penalty for additional leaves, and λ is the L2 regularization term on leaf weights.

The combined objective function that XGBoost aims to minimize is:

$$obj = \sum_{i=1}^{n} l(y_i, \hat{y}_i^{(t)}) + \sum_{k=1}^{t} \Omega(f_k) \quad (5)$$

where:

$\hat{y}_i^{(t)}$ is the prediction for the i^{th} instance at the t iteration, and f_k represents the k decision tree. At each iteration, the model updates its prediction by adding the output of a new tree f_t

$$\hat{y}_i^{(t)} = \hat{y}_i^{(t-1)} + f_t(x_i) \quad (6)$$

The new tree f_t is chosen by approximating the loss function using a second-order Taylor expansion and then optimizing the objective with respect to the structure and leaf weights of the tree. This results in an efficient, scalable algorithm that is capable of handling large datasets and complex models. XGBoost's effectiveness lies in its ability to balance model complexity with predictive accuracy through this rigorous mathematical framework, making it a popular choice for various machine learning tasks.

The dataset comprised 73 data points, with three input features (temperature, time and vibration), and one target output (average moisture), presenting a significant challenge in ML model development due to the limited number of data points and features. Despite these limitations, the model's performance was assessed using the coefficient of determination (R^2) and root mean square error (RMSE). Furthermore, the relationship between the input features and the target output was analyzed using Shapley values, providing a detailed explanation of the contribution of each variable to the model's predictions. Shapley values are used in machine learning to analyze the relationship between input features and the target output by quantifying each feature's contribution to the model's predictions. They provide a fair and consistent method to attribute the influence of each variable, offering detailed explanations of how each feature affects the prediction. Shapley values enable both local interpretability for individual predictions and global insights into overall model behavior. This approach ensures transparency in understanding the model's decision-making, helping to identify which variables drive outcomes and to what extent. The distribution of data used in this study is shown in Fig. 2. Shapley values originate from cooperative game theory and provide a fair distribution of a total payoff among players based on their individual contributions. Mathematically, consider a set *N* of players (or features) and a value function $v: 2^N \rightarrow \mathbb{R}$ that assigns a real number to every subset S⊆ N.

The Shapley value $\emptyset_i$ for player ii is defined as:

$$\emptyset_i(v) = \sum_{S \subseteq N \setminus \{i\}} \frac{|S|!(|N|-|S|-1)!}{|N|!} [v(S \cup \{i\}) - v(s)] \quad (7)$$

where:

N is the set of all players (or features), S is any subset of players not including ii, |S| is the number of players in S, |N| is the total number of players, $v(s)$ is the value (or payoff) of the subset S, and $v(S \cup \{i\}) - v(s)$ represents the marginal contribution of player ii to the subset S.

The fraction:

$$\frac{|S|!\,(|N|-|S|-1)!}{|N|!}$$

represents the probability of S occurring as the set of players preceding ii in a random ordering of N. In machine learning, Shapley values are used to attribute the contribution of each feature to the prediction made by a model, offering a robust and theoretically justified method for model interpretation.

The trained models were assessed using various performance metrics, such as the R^2 score and RMSE. These metrics were defined as follows: Eqs. (8)-(9) (*Katongtung et al., 2022; 2024a; 2024b*).

$$R^2 = 1 - \frac{\sum(y_i - \hat{y}_i)^2}{\sum(y_i - \bar{y}_i)^2} \tag{8}$$

$$RMSE = \sqrt{\frac{\sum_{i=1}^{N}(y_i - \hat{y}_i)^2}{N}} \tag{9}$$

where:

y_i is represents the actual value, $\hat{y}_i$ is represents the predicted value, $\bar{y}_i$ is represents the mean value of the *i-th* data point, and *N* is the total number of data points.

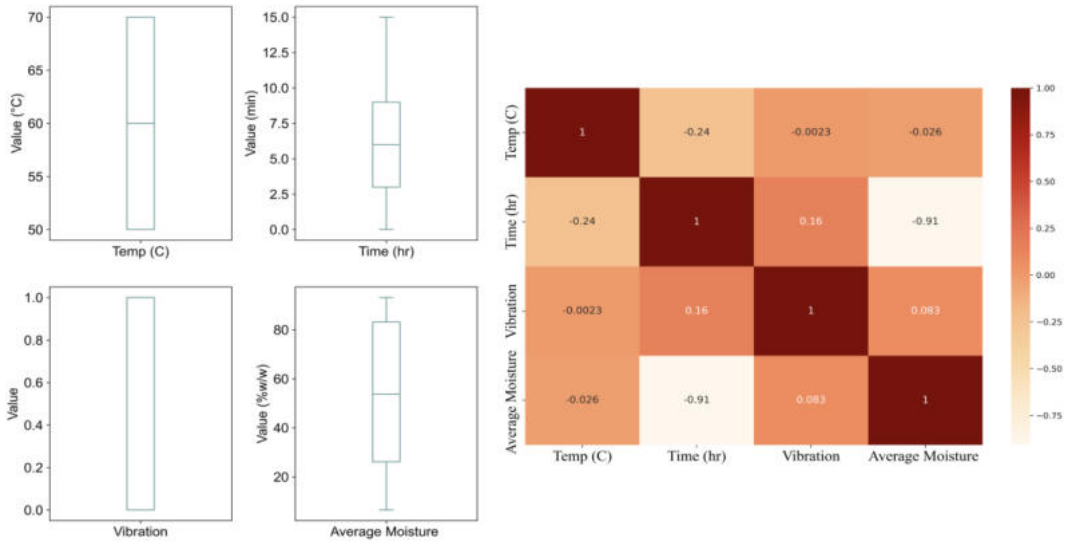

Fig. 2 – Box plot and heat map of the data set

In this study, cross-validation was not employed due to the limited size of the dataset, which comprised only 73 data points. Applying cross-validation under such conditions may lead to excessively fragmented training and validation subsets, potentially resulting in unstable performance estimates and diminished model generalizability. Therefore, a simple train–test split (75% training, 25% testing) was adopted to retain enough data for both model training and performance evaluation. To address potential overfitting, multiple regularization strategies were implemented during model development. These included early stopping, which halts training once performance on a validation set ceases to improve, as well as the tuning of regularization parameters such as lambda (L2 regularization), alpha (L1 regularization), and gamma (minimum loss reduction required to make a further partition). These techniques effectively constrained model complexity and contributed to enhanced generalization on unseen data. The incorporation of these regularization and validation strategies strengthens the reliability and transparency of the predictive modeling approach, particularly when working with limited datasets.

RESULTS AND DISCUSSION

Water evaporation rate

From the experiment, the water evaporation rate when using hot air drying combined with an ultrasonic vibration system is higher than conventional drying methods under all conditions. The maximum value was achieved at a drying temperature of 70°C, reaching 0.313±0.016 $kg_{(water)}$/h.

A 25% increase in performance was observed compared to the conventional hot air drying process. Additionally, a linear regression analysis was conducted based on experimental data, as illustrated in Fig. 3.

The results of this study showed that increasing ultrasonic vibration for drying significantly reduced drying time, which is consistent with previous research on pineapple drying (*Thanompongchart et al., 2022*). The dried white fingerroot exhibited superior quality in terms of its physical properties and active compound content, particularly when dried at a temperature of 60°C.

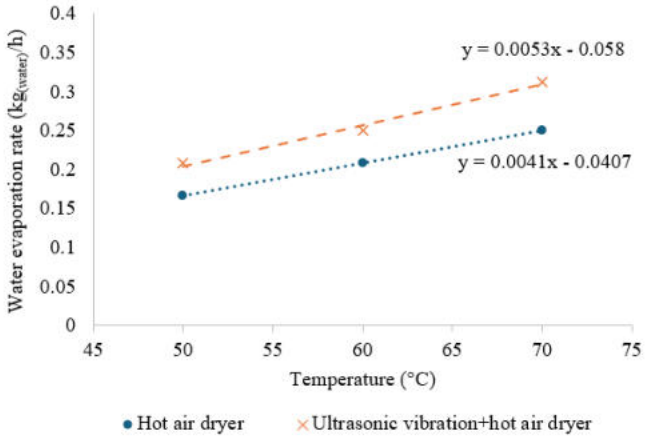

Fig. 3 – Water evaporation rate during drying of white fingerroot

ML model accuracy

In machine learning, a dataset is often split into two key sections: one for training and another for testing. The training portion is used to help the model recognize patterns and relationships in the data. As the model learns, it fine-tunes its internal parameters to improve its predictions or classifications. After training, the test set, which remains unseen by the model during training, is used to assess how well the model performs. This helps provide a fair evaluation of its ability to generalize to new data, offering insights into its overall accuracy and effectiveness. In this study, the dataset was divided into 75% training data and 25% test data to evaluate the performance of the ML model.

Fig. 4 presents the accuracy graph for the average moisture content prediction of the ML model, using both training and test data.

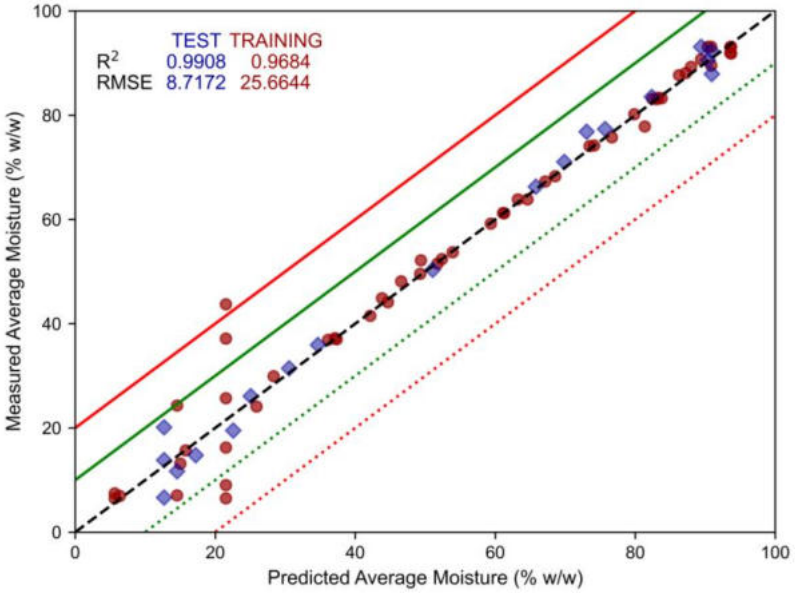

Fig. 4 – Distribution and accuracy of training and test data

The red line indicates the 20% error range, while the green line marks the 10% error range. The model demonstrated high prediction accuracy, with an R^2 value of 0.9908 and an RMSE of 8.7171. However, due to the relatively small dataset, the training data yielded an R^2 value of 0.9684 and an RMSE of 25.6644, which was a bit lower than the test prediction accuracy. This suggests that increasing the dataset size would reduce overfitting and enhance the reliability of the ML model.

In ML, overfitting occurs when a model learns not only the underlying patterns in the training data but also noise and random fluctuations that do not generalize to new, unseen data. As a result, the model performs well on the training dataset but fails to generalize, leading to poor performance on test or real-world data providing more examples for the machine learning model to learn from. When the dataset is small, the model is more likely to memorize specific details rather than learning general patterns, which leads to overfitting. With a larger dataset, the model is exposed to a wider variety of examples and variations, making it harder for the model to memorize individual points, encouraging it to generalize instead.

Increasing the size of a dataset offers several important advantages. Firstly, it helps reduce overfitting by providing more diversity in the data, allowing the model to distinguish between noise and true patterns. With a larger and more representative dataset, the model can capture generalizable trends instead of focusing on anomalies specific to the training set. Secondly, it improves generalization, meaning the model becomes better at making accurate predictions on unseen data. This ensures that the model performs well not just on the training data but also in real-world scenarios. Thirdly, increasing the dataset size enhances the reliability of the model, making it more robust and dependable by learning from a broader and more diverse set of examples. As a result, the model is less likely to make erroneous predictions, leading to more trustworthy and consistent outcomes. Lastly, a larger dataset helps reduce the variance in predictions, making the model less sensitive to small changes in the training data and resulting in more stable and reliable predictions.

Fig. 5 illustrates the use of Shapley values to explain the impact of individual variables on the model's predictions. The analysis reveals that drying time is the most significant factor, followed by vibration and temperature. The color of the SHAP summary plot further indicates whether the effect is positive or negative. In this study, it was found that longer drying times negatively affect average moisture content, whereas shorter drying times have a positive effect. Longer drying times can negatively affect the average moisture content of a material due to uneven moisture removal, with some areas drying too much while others retain moisture. This unevenness, combined with the potential for moisture reabsorption over time, increases the overall average moisture content. In contrast, shorter drying times promote more efficient and uniform moisture removal, reducing the chances of reabsorption and preventing over-drying in certain sections. Reduced drying time without raising temperature effectively minimizes color changes, decreases undesirable texture attributes (hardness, cohesiveness, gumminess, chewiness), and preserves bioactive compounds (*Yitayew and Fenta, 2021*).

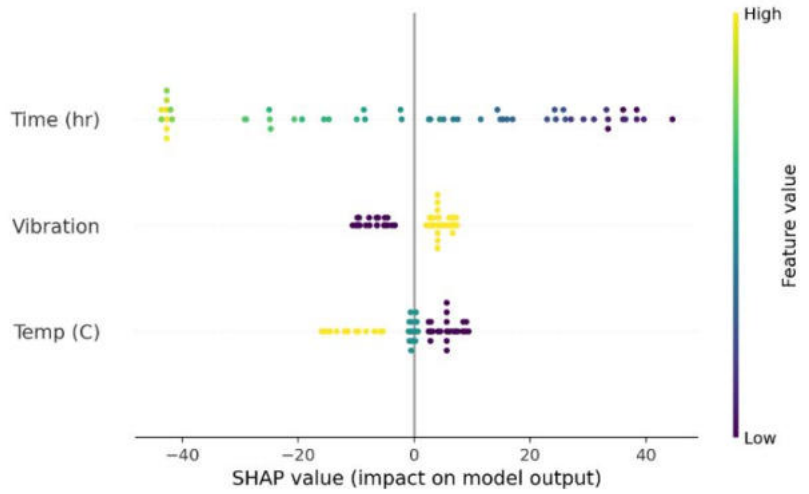

Fig. 5 – SHAP summary plot

Similarly, the vibration variable positively affects average moisture content during the drying process by enhancing moisture movement within the material, allowing water molecules to migrate more easily to the surface for evaporation. It improves airflow around the material, facilitating better interaction between the moist material and the drying medium, which helps carry away evaporated moisture more effectively. Additionally, vibration promotes uniform drying, ensuring no parts of the material dry excessively while others remain wet. It also reduces surface tension, making it easier for moisture to escape, and minimizes heat stress by distributing heat evenly. Together, these factors contribute to a more efficient and effective drying process, leading to a lower average moisture content (*Yang et al., 2024*).

The temperature variable influences average moisture content similarly to drying time, with higher temperatures negatively impacting moisture levels while lower temperatures have a positive effect. High temperatures can lead to rapid surface evaporation, causing the outer layers of a material to dry too quickly and potentially trapping moisture in the inner layers, a phenomenon known as "case hardening." This uneven drying not only increases average moisture content but can also degrade the quality of sensitive materials, such as food, by stripping away essential nutrients and flavors. In contrast, lower temperatures promote gradual and even moisture removal, reducing the likelihood of trapping moisture and preventing reabsorption from the environment. This controlled drying process helps maintain the quality of the material while effectively lowering average moisture content, leading to better overall results (*Mougang et al., 2024*).

Moreover, Fig. 6 showcases SHAP dependence plots, which help visualize how specific variables influence the average moisture content of a material. Fig. 6(a) focuses on the relationship between temperature and drying time. At a low temperature of 50°C, extending the drying time tends to have a positive effect on reducing average moisture content, meaning that longer drying periods at this temperature help remove more moisture. When the temperature is raised to a medium level of 60°C, the effect of drying time becomes minimal; in this range, increasing the drying time does not significantly change the average moisture content. Finally, at a high temperature of 70°C, shorter drying times become more beneficial for reducing average moisture content, suggesting that quick drying at this temperature effectively removes moisture without causing detrimental effects. Fig. 6(b) examines how vibration interacts with drying time. It shows that introducing vibration during the drying process has a more pronounced positive effect on average moisture content when the drying times are longer. This means that the benefits of using vibration in the drying process are more noticeable over extended periods, helping to enhance moisture removal compared to shorter drying times, where the effect is less significant.

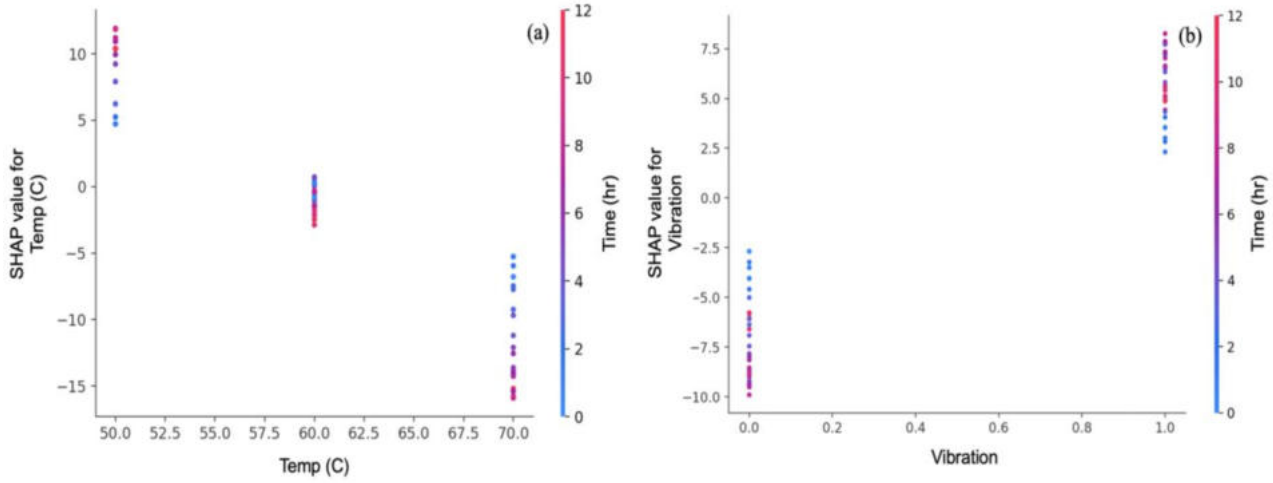

Fig. 6 – SHAP independence plot: (a) temperature and time; (b) vibration and time

Table 1 shows the prediction results from the ML model compared to experimental data at 50, 60, and 70°C, using combined hot air and ultrasonic vibration methods, based on a random selection of 10 runs. The results indicate that the ML model predictions closely align with the experimental values, with the smallest difference being 0.09 and the largest difference being 1.15. Overall, the predicted values demonstrate strong agreement with the experimental data, suggesting that the ML model is well-suited for predicting the average moisture content in the drying process. However, this ML approach may be effective under hot air drying combined with an ultrasonic vibration system. Further research may be required to develop and validate its applicability for other drying methods.

Table 1

ML average moisture content prediction results compared with experimental results

Run	ML (average moisture content)	Experimental (average moisture content)	Difference
1	79.87	80.19	0.32
2	5.62	6.48	0.86
3	63.22	63.85	0.63
4	90.36	90.59	0.23
5	12.67	13.82	1.15
6	43.80	44.89	1.09
7	73.47	74.09	0.62

Run	ML (average moisture content)	Experimental (average moisture content)	Difference
8	44.65	44.12	0.53
9	82.44	83.14	0.7
10	15.77	15.68	0.09

CONCLUSIONS

This study developed a predictive machine learning model based on the XGBoost algorithm to estimate the average moisture content during the drying of *Boesenbergia rotunda* (L.). The drying process employed a hybrid technique combining hot air and ultrasonic vibration. A dataset comprising 73 samples with three input features, temperature, drying time, and vibration amplitude was utilized. The dataset was divided into training and testing sets at a 75:25 ratio, yielding a high predictive performance with an R^2 of 0.9908 and RMSE of 8.7171 on the test set.

SHAP analysis was conducted to interpret model behavior, revealing that drying time was the most influential variable, followed by vibration amplitude and temperature. The findings indicate that shorter drying durations and moderate temperatures contribute to more uniform and efficient moisture removal, while ultrasonic vibration enhances internal moisture migration and airflow dynamics. Comparison between model predictions and experimental results at 50, 60, and 70 °C demonstrated strong agreement, confirming the model's robustness. However, the relatively small dataset may introduce limitations such as overfitting. Therefore, future work should focus on expanding the dataset to improve generalization capability and reliability. While the model has shown promising results under the hot air–ultrasound drying system, further investigations are recommended to assess its applicability across different drying techniques and material types.

ABSTRACT
To address the issue of height disparity between the output device of the tray placement machine and the seedbed in stacked-tray germination under enclosed conditions - which can lead to vibration and displacement when trays are placed - a slide-type output device with a buffering function equal to the height difference was designed to ensure gentle placement of seedling trays. A three-factor, five-level quadratic orthogonal rotational combination test was conducted using Adams software for simulation analysis. The test factors included the horizontal inclination angle of the tilting frame, the horizontal inclination angle of the sliding plate, and the speed of the seedling tray pusher. Evaluation indices included the qualification rate of tray spacing, the qualification rate of alignment, and the efficiency of tray placement. Test results were analyzed using Design Expert 13 software, and multi-objective parameter optimization was performed. The optimal parameter combination was determined as follows: a tilting frame inclination angle of 15°, a sliding plate inclination angle of 18°, and a tray pusher speed of 0.16 m/s. Field trials conducted to validate these parameters resulted in a 96.11% qualification rate for tray spacing, a 95.89% alignment qualification rate, and a tray placement efficiency of 714 trays per hour - within 1% of the theoretical optimal value. These findings provide a theoretical foundation for the smooth and efficient operation of automatic seedling tray placement machines.

摘要
针对叠盘暗室育秧模式下摆盘机因出盘装置与苗床之间存在高度落差，导致秧盘着床时易产生震动位移的问题，设计了一种具有落差缓冲能力的滑板式出盘装置，实现秧盘的平稳摆放。通过 Adams 软件仿真分析，以倾斜架水平倾角、出盘滑板水平倾角、推盘推杆速度为试验因素，秧盘间距合格率、排齐率、摆盘效率为试验指标，进行三因素五水平二次正交旋转组合试验。应用 Design Expert 13 软件对试验结果进行分析并进行多目标参数组合优化，确定仿真最佳参数组合为：倾斜架水平倾角 15°，出盘滑板水平倾角 18°、推盘推杆速度 0.16m/s，并通过田间试验验证得到秧盘间距合格率 96.11%，排齐率 95.89%，摆盘效率 714 盘/h，与理论优化值误差小于 1%。研究结果为摆盘机平稳摆盘提供理论基础。

INTRODUCTION
Rice is one of the most important grain crops in China, with total output ranking first in the world. Heilongjiang Province is the main rice-growing region in China, with an annual rice output that continues to rank first in the country (*Yan et al., 2023; Li et al., 2024*). As Heilongjiang Province (*Xue et al., 2024*) is a high latitude cold region prone to cold damage at low temperatures when sowing in spring, relying on constant temperature stacked seedling tray darkroom rice seedling cultivation can improve the quality of rice seedlings and shorten the rice-planting cycle (*Li et al., 2021*). However, manual seedling tray placement is labor-intensive, so using a seedling tray placement machine reduces labor requirements and intensity (*Cheng et al., 2025; Li et al., 2020*).

The existing seedling tray placement devices can be divided into two types according to the seedling tray-out mode *(Pan et al., 2024; Li et al., 2018; Yang et al., 2023)*. One type uses a seedling tray placement machine with a fixed truss to move to the designated position. The storage frame servo controls the seedling tray's movement status. When the servo opens, the lowest seedling tray falls into the seedling bed under its own gravity to achieve orderly seedling tray placement. The other type uses a seedling tray placement machine with a conveyor to transport the seedling tray to the seedling tray-out device. Finally, a pushing device throws the seedling tray into the seedbed. In the latter case, the seedling tray is transported to the discharge device by a tractor via a conveyor belt, and is then thrown into the seedbed by a pushing device. Regardless of how the seedling tray is discharged, due to the height difference between the seedling tray device and the seedbed, the seedling tray will vibrate and displace when landing on the bed. This results in the seedling tray not being placed neatly and can even cause the phenomenon of 'overlap'. This not only wastes the seedbed, but also makes it easy for weeds to grow in the cracks of the seedling tray. This makes it difficult for the subsequent disking operation (*Yan et al., 2024*).

Currently, many scholars at home and abroad have conducted research on rice seedling devices. For example, the precision automated production line from Dutch company *Visser (2016)* is equipped with a special device for rice seedling cultivation that can accommodate seedling trays of various sizes and has a production efficiency of 1250 trays per hour. However, such equipment is relatively expensive to purchase, and the automated production lines developed in Europe and the United States are mainly aimed at vegetable and flower cultivation, so they have not yet been widely used in China (*Luo et al., 2019*). For example, indoor rice seedling cultivation equipment developed by companies such as *Kubota (2024)* and *Yanmar (2024)* is highly integrated, achieving a high degree of automation in factory-based seedling cultivation. Its precision tray feeding mechanism has a complex structure and an operating efficiency of over 1000 trays per hour *(Iseki et al., 2024)*. The degree of automation is higher and it can realize the automatic placement of seedling trays. However, these models are expensive and have high installation and commissioning requirements, making them difficult to implement in China's agricultural production. In China, an earlier hand-pushed, trackless seedling tray placement device has a lower degree of automation and needs to be controlled manually, but because of its simple structure and ease of operation, it is widely used for small-scale household seedling tray placement operations (*Lv et al., 2018*).

Zhang Xiuhua et al., (*2018*), developed an articulated automatic placement machine for vegetable seedling hole trays, featuring a high degree of automation. However, the robotic program costs were too high for large-scale rice seedling tray placement. *Xie Lianshuang et al.,* (*2015*), developed a machine for potting rice seedlings, which uses a motorized rod propulsion device on a conveyor belt to place seedling trays in greenhouses. *Xia Xudong et al.,* (*2021*), designed a double cam-controlled seedling tray placement trolley, which moves along a truss to the designated area and automatically arranges the trays by separating them using a dual-cam mechanism.

This paper aims to address the above challenges by investigating an automatic seedling tray placement machine for multi-row rigid rice seedling trays. To ensure smooth tray placement without vibration or spacing gaps, the machine is equipped with a slide-type tray output mechanism featuring a fall-buffering design. One end of the slide naturally aligns with the seedbed under its own weight, enabling stable and gap-free placement of seedling trays.

MATERIALS AND METHODS

Overall structure and working principle

The automatic seedling tray placement machine for multi-row rigid rice seedling trays primarily consists of a conveyor belt, a transverse conveying device, a frame, a tray discharge mechanism, a mobility system, a height adjustment unit, a battery, and a PLC control system, as shown in Fig. 1. The frame serves as the core structural support of the entire machine and mainly includes a tilting frame, tray positioning guides, and other components. The transverse conveying device comprises a transverse pushing mechanism, a longitudinal pushing mechanism, an overturning frame, a linear push rod mechanism, and other parts. The machine is operated via a PLC control system, which coordinates the working sequence of each mechanism to achieve efficient tray conveying and placement. It moves along a fixed track to ensure stable transportation of trays, while the frame height is adjustable to accommodate different operational environments. The performance indicators of the automatic seedling tray placement machine for multi-row rigid rice seedling trays are presented in Table 1.

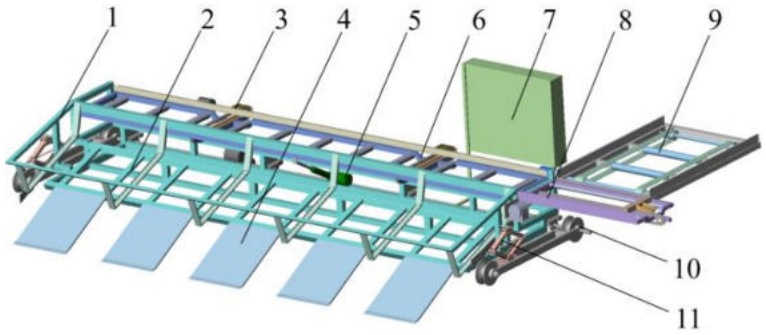

Fig. 1 – Automatic seedling tray placement machine for multi-row rigid rice seedling trays

1. Frame; 2. Tilting frame; 3. Longitudinal pushing mechanism; 4. Output device; 5. Linear pusher mechanism; 6. Flip frame; 7. PLC control box; 8. Transverse pushing mechanism; 9. Conveyor belt; 10. Mobility device; 11. Height adjustment device.

Table 1

Main technical parameters

Parameter	Number
Machine size / (length x width x height) / (mm×mm×mm)	4000×2100×950
Supporting power / W	1200
The working width is wide / mm	3000
Overall machine quality / kg	350
Number of cycles in operation / unit	5
Seedling tray size / (length x width x height) / (mm×mm×mm)	600×300×30

The working process of the automatic seedling tray placement machine for multi-row rigid rice seedling trays is illustrated in Fig. 2. First, the conveyor belt delivers seedling trays to the placement machine. The transverse pushing mechanism then transfers the trays to the flip frame. When five seedling trays are in position, the conveyor belt halts, and the linear pusher mechanism contracts, causing the flip frame to rotate to a specific angle and dock with the tilting frame. Next, the linear pusher mechanism stops, and the longitudinal pushing mechanism gently pushes the five trays down onto the seedbed. Simultaneously, the entire tray placement machine moves forward along the working direction, completing one placement cycle. Afterward, each mechanism returns to its initial position, and the process is ready to repeat.

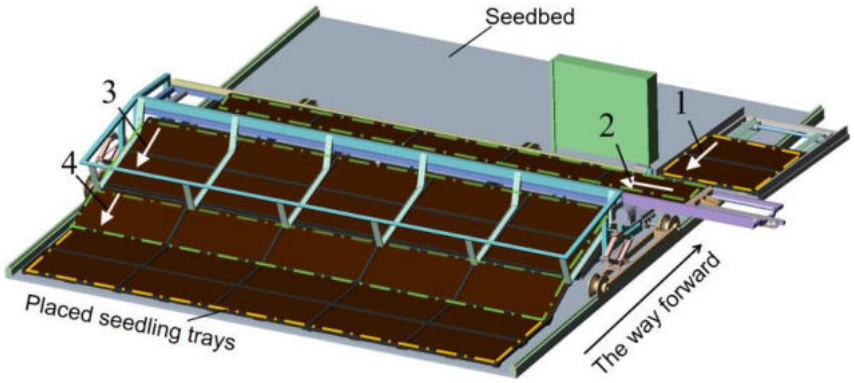

Fig. 2 – Workflow diagram of the seedling tray placement machine

1. Tray supply process; 2. Transverse conveying process; 3. Longitudinal conveying process; 4. Tray placement process.

Transverse conveying device

The transverse conveying device is an important component that affects the working efficiency of the tray placement machine and ensures the smooth transfer of seedling trays. It is primarily composed of a transverse pusher, transmission chain, push-type seedling tray pusher, flip frame, conveyor rollers, longitudinal push motor, linear pusher, and other auxiliary components. The structural diagram of the transverse conveying device is shown in Fig. 3.

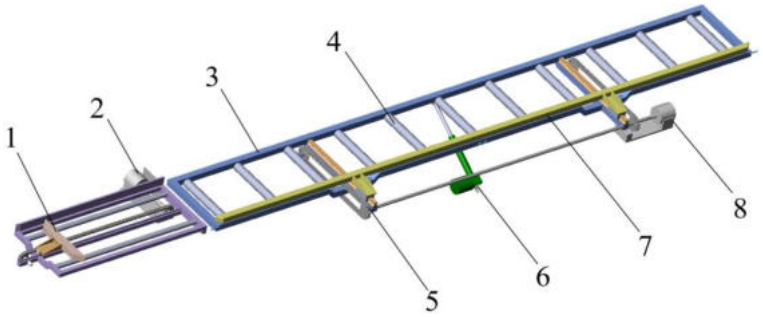

Fig. 3 – Transverse conveying device

1. Transverse pusher; 2. Transverse pusher motor; 3. Flip frame; 4. Conveyor roller; 5. Transmission chain; 6. Linear pusher motor; 7. Seedling tray pusher; 8. Longitudinal pusher motor.

The transverse pusher motor drives the transverse pusher in a continuous reciprocating motion. Once five seedling trays are pushed onto the flip frame, the linear pusher motor begins to contract, causing the flip frame to rotate around its axis to a predetermined angle. The linear pusher mechanism stops contracting once the flip frame is fully docked with the tilting frame. Subsequently, the seedling tray pusher pushes out a row of five trays simultaneously. The operating speeds of both the transverse pusher and the seedling tray pusher can be adjusted by regulating their respective motor speeds to accommodate different working requirements.

Tilting frame structure design

The horizontal inclination angle of the tilting frame directly influences the smooth movement of rice seedling trays during the discharge process. If the inclination angle is too small, the trays experience greater frictional resistance, which can lead to discharge blockages. Conversely, if the inclination angle is too large, the trays may slide uncontrollably due to gravity acting along the surface of the tilting frame, negatively affecting the placement accuracy. To analyze the forces acting on the rice seedling tray during its movement along the tilting frame, a right-angle coordinate system is established: the direction along the tilting frame is defined as the positive x-axis, and the direction perpendicular and upward from the tilting frame is defined as the positive y-axis. The force analysis of the seedling tray under these conditions is illustrated in Fig. 4.

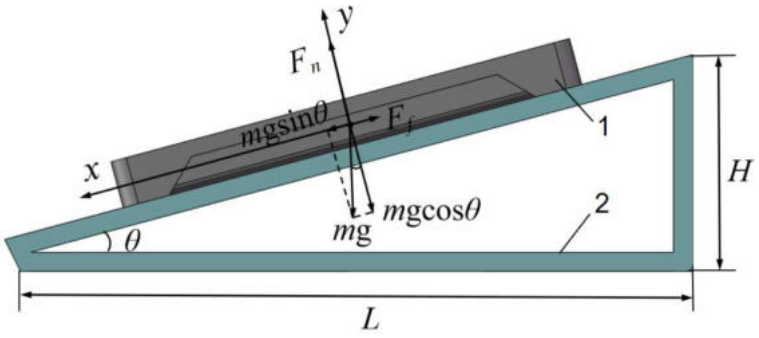

Fig. 4 – Force analysis diagram of the seedling tray

1. Rice seedling tray; 2. Tilting frame.

As can be seen from the Fig. 4, the conditions for the seedling tray to remain smooth on the tilting frame without producing the relative sliding phenomenon are as follows:

$$F_f - mg\sin\theta \geq 0 \tag{1}$$

The following equation is derived from the friction formula:

$$F_f = \mu_1 F_n = \mu_1 mg\cos\theta \tag{2}$$

where: μ_1 is friction coefficient between the seedling tray and the inclined frame; m is quality of seedling tray, (kg); F_n is the support force of the inclined frame on the seedling tray, (N); F_f is the friction between the seedling tray and the inclined frame, (N); θ is horizontal inclination of the tilting frame, (°).

Substituting formula (1) into formula (2) results in:

$$\theta \leq \arctan \mu_1 \tag{3}$$

The coefficient of friction between the seedling tray and the tilting frame was determined to be approximately 0.4 based on the material properties (*Yi et al., 2023*). The maximum horizontal inclination angle θ of the tilting frame was calculated to be 21.8° using the following formula:

$$\tan \theta = \frac{H}{L} \tag{4}$$

where:

H - height of the tilting frame, (m); L - horizontal distance between the inclined supports, (m).

Due to the low height of the edge of the rice-planting shed, the overall height of the machine must be reduced. To accommodate this constraint and to make the structure of the tray placement machine more compact, the horizontal inclination angle of the tilting frame is set between 10° and 20°, and the height H is set to 0.2 m. Once the inclination angle is determined, the horizontal distance L can be calculated using formula (4).

Design of the output device

(1) Overall structure

One of the key performance indicators of the seedling tray placement machine is whether the trays are arranged neatly on the seedbed. To address the issue of vibration and displacement of seedling trays caused by the height difference between the output device and the seedbed - which often results in misaligned trays - a slide-type output device with buffering capability was developed. The device is composed of five sliding plates, each connected to the tilting frame via bolts. Under the action of gravity, the sliding plates naturally conform to the surface of the seedbed, ensuring stable and accurate tray placement without vibration or gaps. The structural diagram of the seedling tray output device is shown in Fig. 5.

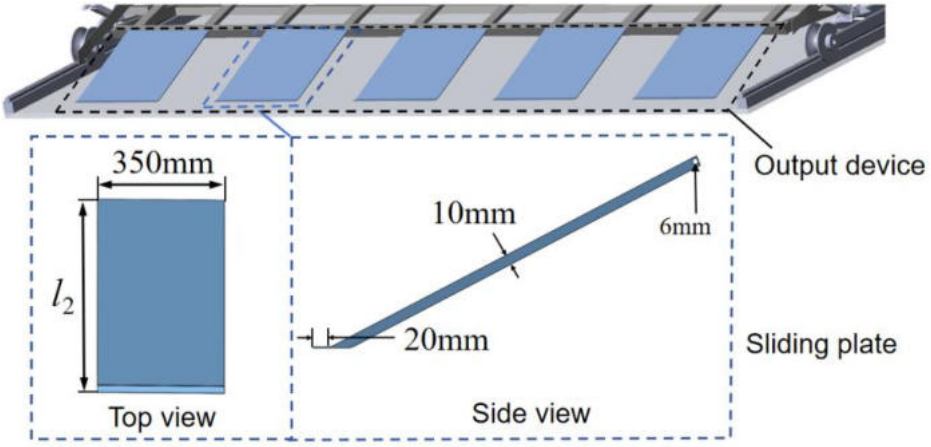

Fig. 5 – Structure of the seedling tray output device

(2) Mechanical analysis of the seedling tray placement process

During the placement of seedling trays, the angular difference between the tilting frame and the discharge sliding plate is considered in the theoretical analysis to prevent tray jamming. A right-angle coordinate system is established, where the downward direction along the tilting frame is defined as the positive x-axis, and the upward direction perpendicular to the tilting frame is defined as the positive y-axis, as illustrated in Fig. 6.

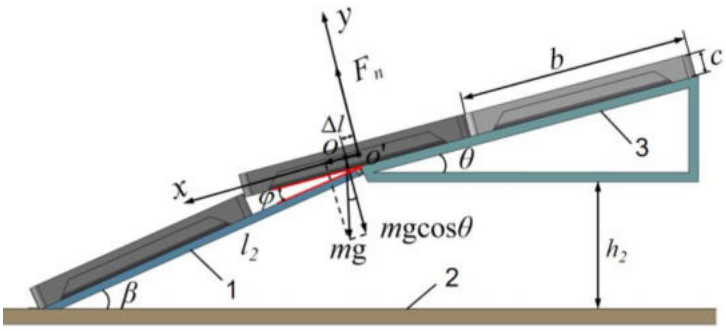

Fig. 6 – Mechanical analysis of the seedling tray placement process

1. Sliding plate; 2. Seedbed; 3. Titling frame.

As illustrated in Fig. 6, the angular difference between the tilting frame and the sliding plate is clearly shown, along with its relationship to the horizontal inclination angle of the sliding plate and the inclination angle of the tilting frame. This angular difference is expressed as:

$$\varphi = \beta - \theta \tag{5}$$

When the angular difference is large, the rear edge of the seedling tray may ride up over the front edge of the tray in front of it, causing a "hitching" phenomenon. This interference negatively impacts the proper arrangement of trays and can hinder subsequent seedling growth. In the theoretical analysis, counterclockwise rotation of the seedling tray around its center of mass is defined as positive, while clockwise rotation is defined as negative.

Define the center of mass of the seedling tray as point O, and the point of applied force as O`. Let $e$ represent the distance between the center of mass O and the force point O`. Before reaching the critical state, the force point O` coincides with the center of mass O, thus e=0. The moment equation under this condition is given by:

$$M = -mg\cos\theta \times \Delta l = 0 \tag{6}$$

After reaching the critical state, e>o. At this time:

$$M = -mg\cos\theta \times \Delta l + F_n \times 0 < 0 \tag{7}$$

where: M is torque on the seedling tray, (N·m).

In this state, the seedling tray will begin to rotate counterclockwise under the action of gravity. Simultaneously, the angle difference between the sliding plate and the tilting frame will gradually decrease. When e = 0, φ reaches its maximum value. To prevent the occurrence of the interference phenomenon at the tray outlet stage, the angle difference between the sliding plate and the tilting frame must satisfy the following condition:

$$\varphi \leq \arcsin\frac{2c}{b} \tag{8}$$

where: b is the width of the seedling tray, (mm); c is height of the seedling tray, (mm).

Based on the dimensions of the seedling tray, the width b is 300 mm, and the height c is 30 mm. When these values are substituted into formulas (7) and (8), the horizontal inclination angle β of the seedling tray sliding plate is calculated to be less than 21.53°.

Furthermore, as illustrated in Fig. 8, a direct correlation is evident between the height of the tilting frame above the ground and the length of the sliding plate.

$$h_2 = l_2\sin\beta \tag{9}$$

where: h_2 is the height of the tilting frame above the ground, (mm); l_2 is the length of sliding plate, (mm).

To avoid interference between the seedling tray machine and the seedbed, the tilting frame is set 100 mm above the ground. Once the sliding plate's horizontal inclination has been determined, its length can be calculated using formula (9).

(3) Speed analysis of seedling tray placement process

The placement of seedling trays is influenced not only by the angle at which they land on the seedbed, but also by their relative speed at the moment of landing. To ensure smooth discharge and neat placement of the trays, it is necessary to analyze the discharge speed of the seedling tray. This speed primarily depends on two factors: the traveling speed of the tray placement machine and the pushing speed of the seedling tray pusher.

To investigate this relationship, a right-angle coordinate system is established, as shown in Fig.7, where the positive x-axis corresponds to the forward motion of the machine (locomotive direction), and the positive y-axis is defined as the direction perpendicular and upward relative to the seedbed. A theoretical analysis of the placement process is then performed based on this coordinate system.

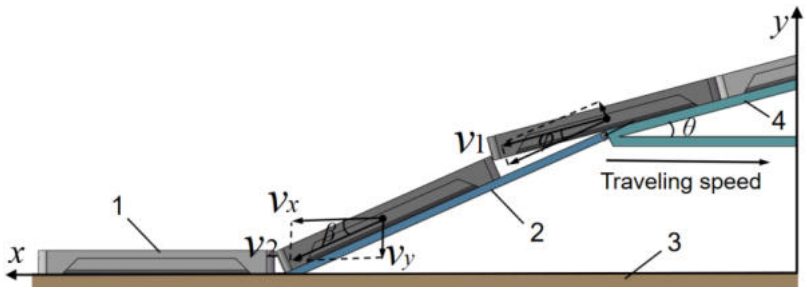

Fig. 7 – Speed analysis of seedling tray placement process
1. Placed seedling trays; 2. Sliding plate; 3. Seedbed; 4. Titling frame.

In this study, the focus is on the relationship between the pusher speed (which corresponds to the motion of the seedling trays along the tilting frame), the tray movement speed, and the relative speed of the trays along the X-axis on the sliding plate. The relationship among these three velocities is given by the following system:

$$\begin{cases} v_1 \cos\varphi = v_2 \\ v_2 \cos\beta = v_x \end{cases} \quad (10)$$

By combining these two equations, it results:

$$v_x = v_1 \cos\varphi \cos\beta \quad (11)$$

The speed of the seedling tray relative to the ground is then given by:

$$v_3 = v_0 + v_x \quad (12)$$

where:

v_0 - machine travel speed, (m/s); v_1 - speed of the pusher, (m/s); v_2 - speed of the seedling tray along the tilting frame, (m/s); v_x - relative velocity of the seedling tray along the x-axis, (m/s); v_3 - velocity of the seedling tray relative to the ground, (m/s).

When the velocity of the rice seedling tray relative to the ground $v_3 > 0$, the pusher speed exceeds the traveling speed of the tray placement machine. In this case, the seedling tray will land with excess forward motion and may overlap or press against the previously placed tray, causing tray displacement and compromising the placement quality. Conversely, when $v_3 < 0$, the pusher speed is less than the machine's travel speed. As a result, the seedling tray lands more slowly, leading to an increased gap between trays, which also affects the overall placement uniformity. Therefore, the most stable and precise placement occurs when $v_3 = 0$, meaning the seedling tray's velocity relative to the ground is zero at the moment of landing. Under this condition, the relationship between the travel speed of the tray placement machine and the pusher speed satisfies the following equation:

$$v_0 = -v_1 \cos\varphi \cos\beta \quad (13)$$

Simulation test

To evaluate the performance of the seedling tray placement machine and determine the optimal parameter values for each influencing factor, the tray discharge process was simulated and analyzed using ADAMS kinematic simulation software.

(1) Simulation parameter determination

During the simulation, the seedling tray comes into contact with other trays, the tray placement mechanism, and the seedbed. Therefore, the contact and material parameters - including those related to seedbed soil and tray materials - were determined with reference to relevant literature (*Che et al., 2023; Yi et al., 2024; Ma et al., 2025*), as summarized in Table 2.

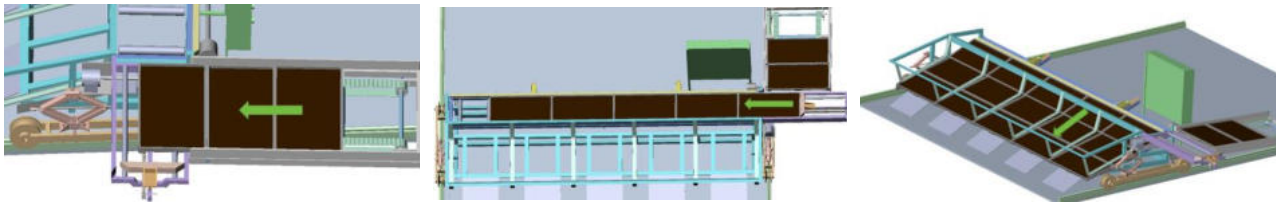

Table 2

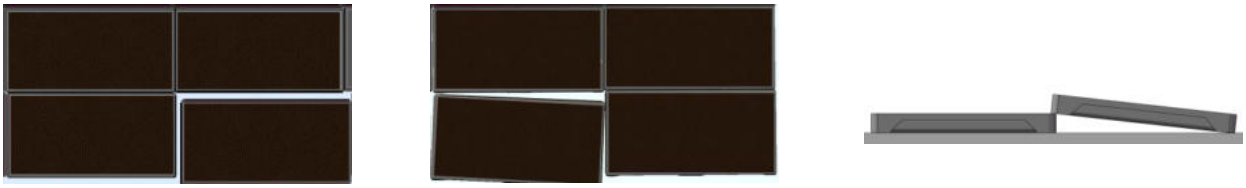
Soil parameters of the seedling bed and the contact parameters of each material

Type of interacting material	Parameter	Numerical value
Seedling tray - Seedling tray	Coefficient of restitution	0.3
	Static friction coefficient	0.114
	Kinetic friction coefficient	0.1
Seedling tray - Tray placement machine	Coefficient of restitution	0.5
	Static friction coefficient	0.4
	Kinetic friction coefficient	0.03
Seedling tray - Seedbed	Coefficient of restitution	0.4
	Static friction coefficient	0.8
	Kinetic friction coefficient	0.2
Tray placement machine - Seedbed	Coefficient of restitution	0.6
	Static friction coefficient	0.6
	Kinetic friction coefficient	0.05
Nursery soil	Density（kg/m^3）	1189
	Poisson ratio	0.4
	Shear modulus (Pa)	1e+08

(2) Simulation modelling



To facilitate simulation and computation, the 3D model of the seedling tray placement machine was simplified using SolidWorks and imported into ADAMS simulation software. The material properties of each component and the contact parameters between interacting parts were defined prior to assigning the driving conditions for the simulation. Although the soil inside the seedling trays is relatively viscous, it does not significantly impact the simulation results. Therefore, only the weight of the seedling tray was considered in the model. The simulation process is illustrated in Fig. 8.

(a) Seedling tray supply process (b) Transverse conveying process (c) Seedling tray placement process

Fig. 8 – Simulation process of seedling tray placement machine

To improve the accuracy and convenience of identifying unqualified seedling tray placements, visual observations can be made during the simulation to detect trays exhibiting clear signs of 'slip' (Fig. 9(a)), 'deflection' (Fig. 9(b)), or 'overlap' (Fig. 9(c)). These phenomena indicate improper placement. Following this, the post-processing module is used to plot the velocity-displacement curves of the center of mass of the seedling trays at different time points. By analyzing these curves, the placement quality of each tray can be evaluated to determine whether it meets the qualification criteria.

（a）The "slip" phenomenon （b）The "deflection" phenomenon （c）The "overlap" phenomenon

Fig. 9 – Unqualified rice seedling tray placement

(3) Evaluation indicators

According to the standardized rice planting operation regulations of Heilongjiang Province, the agronomic requirements for rice seedling tray placement are as follows: seedling trays must be placed horizontally and vertically aligned, starting from the end of the preparatory area. The first row of seedling trays serves as the reference benchmark. For subsequent trays, the horizontal misalignment with respect to the corresponding tray in the first row must not exceed 10 mm (±0.5 mm). The spacing between two adjacent seedling trays must be ≤ 5 mm (±0.5 mm). In addition, there must be no visible overlap between trays. The agronomic placement requirements for rice seedling trays are illustrated in Fig. 10.

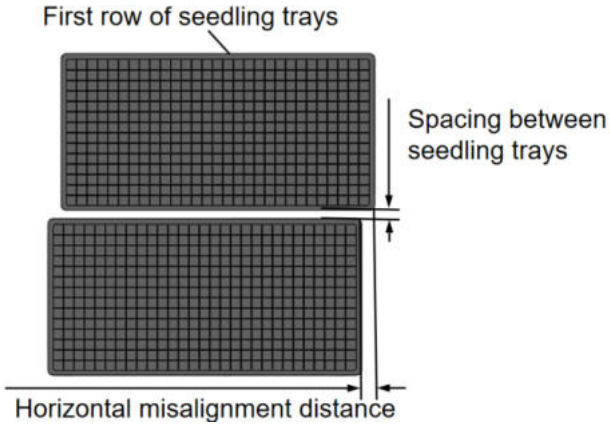


Fig. 10 – Rice seedling tray placement requirements

The qualification rate of seedling tray spacing refers to the percentage of seedling trays for which the spacing between two adjacent seedling trays is ≤5 mm (±0.5mm) and for which the 'overlap seedling trays' phenomenon (i.e. where the spacing between seedling trays is≥0) does not occur.

$$Y_1 = \frac{N_1}{N} \times 100\% \tag{14}$$

where:

Y_1 is the qualification rate of seedling tray spacing, (%); N is the total number of seedling trays placed, (unit); N_1 is number of eligible seedling trays in stock, (unit).

The qualification rate of alignment is defined as the percentage of seedling trays with a lateral misalignment distance of ≤10 mm (±0.5mm) from the corresponding seedling trays in the first row. This is calculated by using the first row of seedling trays as the reference and then determining the percentage of seedling trays with this misalignment.

$$Y_2 = \frac{N_2}{N} \times 100\% \tag{15}$$

where: Y_2 is the qualification rate of alignment, (%); N_2 is the number of seedling trays with qualifying lateral misalignment distance, (unit).

The efficiency of seedling tray placement is calculated by timing and counting the time taken to place 60 seedling trays. This time is then converted and rounded up using the following formula:

$$Y_3 = \frac{60}{t} \times 3600 \tag{16}$$

where: Y_3 is seedling tray efficiency, (trays/h); t is the time taken to successfully place 60 seedling trays, (s).

(4) Experimental method design

In order to further investigate the influence of each working parameter on the effect of seedling tray placement, the following three-factor, five-level quadratic regression orthogonal rotational combination test was carried out. According to the theoretical analysis in the early stage, the tilting frame horizontal inclination angle was set at 10~18°, the horizontal inclination angle of sliding plate at 14~22°, and the pushing speed of the seedling tray pusher at 0.10~0.22m/s. As a result, regression equations and optimization models between the test factors and the evaluation indexes were established. The coded values of the experimental factors are presented in Table 3, where X1, X2 and X3 represent the coded forms of each factor.

Table 3

Test factors coding

Coding	Factor		
	Horizontal inclination angle of tilting frame. X_1 (°)	Horizontal inclination angle of sliding tray X_2 / (°)	Pushing speed of the seedling tray pusher X_3 / (m/s)
1.682	18	22	0.22
1	16.38(16)	20.38(20)	0.1957(0.20)
0	14	18	0.16
-1	11.62(12)	15.622(16)	0.1243(0.12)
-1.682	10	14	0.10

Field validation test

To verify the optimal working parameters of the seedling tray placement machine, a field experiment was conducted at the '895 Farms' Rice Ecological Planting Base in Heilongjiang Province. The primary instruments used in the test included electronic scales, a 5-meter tape measure, and vernier calipers. The experimental trays were rigid rice seedling trays. Before the test, the pusher speed was calibrated by adjusting the motor speed, while the horizontal inclination angles of both the tilting frame and the sliding plate were adjusted to their target values using the height adjustment device. All three parameters - the horizontal inclination of the tilting frame, the horizontal inclination of the sliding plate, and the pusher speed - were set to their optimized values. To minimize experimental error, the five-point sampling method was adopted. Five positions were selected for group testing, with three repeated trials conducted at each position. The average of each group was calculated to validate the results. The experimental site is shown in Fig. 11.

Fig. 11 – Field test of the seedling tray placement machine

RESULTS AND ANALYSIS

Analysis of simulation test results

A number of simulation experiments were carried out, and the experimental results are shown in Table 4.

Table 4

Test results

Number	Factor			Performance indicators

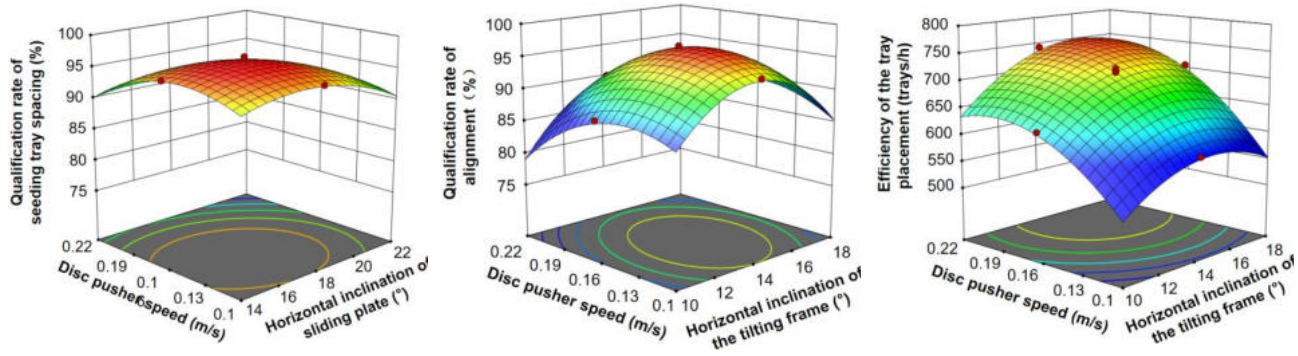
Note: '*' denotes a significant difference (P < 0.05), while '**' denotes a highly significant difference (P < 0.01). The same applies below.

The experimental data were analyzed using Design Expert 13 software to perform analysis of variance (ANOVA), allowing identification of the factors with the most significant influence. Based on this, regression equations between the performance indicators and the coded factor values were established.

$$\begin{cases} Y_1 = 96.18 + 0.41X_1 - 1.33X_2 - 1.63X_3 + 0.90X_1X_3 - 0.63X_2X_3 - 2.36X_1^2 - 0.98X_2^2 - 1.38X_3^2 \\ Y_2 = 96.24 + 0.97X_1 - 0.54X_2 - 1.36X_3 + 0.42X_1X_3 - 2.38X_1^2 - 1.89X_2^2 - 1.69X_3^2 \\ Y_3 = 716.19 + 13.14X_1 + 11.28X_2 + 60.16X_3 - 5.00X_1X_3 - 18.13X_1^2 - 9.64X_2^2 - 11.06X_3^2 \end{cases} \quad (17)$$



Response surface analysis

To analyze the relationship between the test indexes and the factors more intuitively, the response surface of the factors' interaction with the test indexes was obtained using Design-Expert 13 software, as shown in Fig. 12.

Fig. 12(a) illustrates the effects of the horizontal inclination angle of the sliding plate and the pusher speed on the passing rate of rice seedling tray spacing. Overall, the passing rate remains relatively stable and consistently high. However, as both the horizontal inclination angle and the pusher speed increase, the passing rate gradually declines. This trend can be attributed to the influence of the tilt angle on the tray's orientation during landing and the pusher speed on its vertical velocity. Both factors affect the placement accuracy and alignment of the seedling trays, leading to decreased spacing uniformity and thus a lower passing rate.

Fig. 12(b) shows the influence of the horizontal inclination angle of the tilting frame and the pusher speed on the alignment qualification rate of the seedling trays. When the pusher speed is held constant, increasing the tilting frame inclination angle initially improves the alignment qualification rate, but further increases lead to a decline. In contrast, when the tilting frame inclination is fixed, increasing the pusher speed results in a continuous decrease in the alignment qualification rate. This indicates that pusher speed has a more significant effect on alignment accuracy compared to the tilting frame angle.

Fig. 12(c) illustrates the effects of the horizontal inclination angle of the tilting frame and the pusher speed on the tray placement efficiency. As both the inclination angle and pusher speed increase, the efficiency of the tray placement process also improves. Among the two factors, the pusher speed has a more pronounced influence on overall efficiency. In general, high placement efficiency is observed when the pusher speed is within the range of 0.16~0.22 m/s and the horizontal inclination angle is between 12° and 18°.

（a）X_1=0 （b）X_2=0 （c）X_2=0

Fig. 12 – Response surface of the interaction effect of test factors on the qualified rate of seedling tray spacing

Optimization of parameter combinations

To obtain the optimal parameter combination of the tray placement machine, the multi-objective parameter optimization algorithm in Design Expert 13 software was used to optimize the experimental design, establish a parametric mathematical model, and combine the boundary conditions of the experimental factors, thereby improving the overall operational quality of the machine. The objective function is:

$$\begin{cases} \max y_1(X_1,\ X_2,\ X_3) \\ \max y_2(X_1,\ X_2,\ X_3) \\ \max y_3(X_1,\ X_2,\ X_3) \\ \text{s.t.} \begin{cases} -1.682 \le X_1 \le 1.682 \\ -1.682 \le X_2 \le 1.682 \\ -1.682 \le X_3 \le 1.682 \end{cases} \end{cases} \tag{18}$$

Using the multi-objective parameter optimization module in Design-Expert 13 software to analyze and solve the objective function, the optimal operating parameters for the seedling tray placement machine were determined. Optimal performance is achieved when the horizontal inclination angle of the tilting frame is 15°, the horizontal inclination angle of the sliding plate is 18°, and the pushing speed of the seedling tray pusher is 0.16 m/s. Under these conditions, the qualification rate for tray spacing reaches 96.25%, the qualification rate for alignment is 96.16%, and the tray placement efficiency is 722 seedling trays per hour.

Field test results

To verify the optimal parameter combination of the seedling tray placement machine, multiple field validation tests were conducted, and the results were processed and analyzed. The machine was tested under the optimized conditions: a horizontal inclination angle of the tilting frame set to 15°, a horizontal inclination angle of the sliding plate set to 18°, and a pusher speed of 0.16 m/s. Under these conditions, the average qualification rate for tray spacing was 96.11%, the alignment qualification rate was 95.89%, and the tray placement efficiency reached 714 trays per hour. The mean error between the simulation and field results was less than 1%, indicating that the optimization model is reliable. A comparison of the simulation results and field test results is provided in Table 6.

Table 6

Comparison test results

Type	Qualification rate of seedling tray spacing Y_1/(%)	Qualification rate of alignment Y_2/(%)	Efficiency of seedling tray placement Y_3/(trays/h)
simulation test	96.25	96.16	722
field test	96.11	95.89	714

CONCLUSIONS

1) To address the problem of height disparity between the output device of the tray placement machine and the seedbed in the enclosed stacked-tray seedling cultivation mode, which leads to vibration and displacement of the seedling trays during landing, an output device with buffering capability was designed. This structure ensures that the seedling trays are placed smoothly and accurately, improving overall placement quality.

2) Field validation tests showed that under the optimized operating parameters - 15° horizontal inclination angle of the tilting frame, 18° horizontal inclination angle of the sliding plate, and 0.16 m/s pusher speed - the qualification rate for tray spacing was 96.11%, the alignment qualification rate was 95.89%, and the tray placement efficiency reached 714 trays per hour. These results are largely consistent with the simulation predictions, confirming the reliability of the optimization model.

3) The developed automatic seedling tray placement machine for multi-row rigid rice seedling trays is controlled via a PLC system, which enables fully automated tray conveying and placement. The system ensures high efficiency and standardized operation, while the precise alignment of trays minimizes greenhouse space waste and reduces production costs for farmers.

Keywords: *YOLOv11n, Automatic detection, Dry direct-seeded rice, DSConv, FASFFHead*

ABSTRACT

Identifying dry-direct seeded rice seedlings provides valuable information for field management. To address the challenges of seedling detection in cold-region dry-direct seeded rice fields, this study proposes an enhanced YOLOv11n-DF model. Key innovations include: 1) integrating DSConv into the C3k2 module to optimize phenotypic feature extraction, and 2) employing the FASFF strategy to improve scale invariance in the convolutional head. Experimental results show that the improved model achieves an mAP50 of 96%, with high recall, precision, and a processing speed of 251.5 FPS, outperforming the original YOLOv11n by 5 percentage points in mAP50, and surpassing YOLOv7–YOLOv10 in detection accuracy. The proposed algorithm effectively addresses challenges such as seedling occlusion and non-uniform distribution, offering a robust solution for automated seedling monitoring in precision agriculture.

摘要

识别旱直播秧苗，可为田间管理提供一定苗情信息。本研究为应对寒地旱直播稻田的幼苗检测难度大的问题，提出改进 YOLOv11n-DF 方法。该方法引入了两个关键创新：1）DSConv 引入 C3k2 模块以优化水稻表型特征提取，2）利用 FASFF 策略优化卷积头增强模型特征尺度不变性。实验结果表明，改进后模型的 mAP50、召回率（R）、检测精度（P）分别为 87.12%、77.07%和 84.11%，处理速度为 49.5 FPS，mAP50 较改进前 YOLOv11n 提高 4.28 个百分点，在检测精度方面超过了同类目标检测网络（YOLOv7~10）。该算法有效地处理了旱直播秧苗相互遮挡和非均匀分布挑战，为精准农业应用中的自动秧苗监测提供了新的解决方案。

INTRODUCTION

Dry-direct seeding is a rice cultivation method that replaces traditional transplanting with direct mechanical seeding. This planting approach - often referred to as dry-direct seeding - offers advantages such as water conservation, labor savings, and greater planting efficiency (*Li et al., 2023*). As a major production area for high-quality rice, Heilongjiang Province adopted dry-direct seeding technology in response to labor shortages and the development of drought-tolerant rice varieties (*Liu et al., 2022*). However, the emergence rate of dry-direct seeded rice is highly sensitive to climatic conditions, particularly in the cold regions of Northeast China, often resulting in uneven or unstable seedling emergence, which impairs rational dense planting (*Li et al., 2024*). Accurate identification and counting of seedlings provides a scientific basis for evaluating planting density, which reflects both sowing quality and varietal performance. Notably, the accuracy of seedling identification directly impacts the reliability of seedling counting (*Liu et al., 2024*).

The traditional rice seedling emergence number counting is determined manually, which is time-consuming, costly and difficult to implement (*Zhu et al., 2024*). In the past decade of research, machine vision technology has been gradually applied to the field of agricultural engineering, which greatly improves the reliability of agricultural information acquisition and provides a new solution idea for the detection of dry-direct seeded rice seedlings. For example, *Lu et al. (2021)* proposed the use of the TasselNetv3 segmentation network to achieve accurate rice plant counting. Similarly, *Takaho et al. (2022)* employed the Super Green Index (SGI) algorithm to predict seedling growth.

Interference from occlusion and background noise can affect image segmentation techniques. In addition, target detection is an important method of acquiring agricultural information. *Yi et al.* (*2022*) used a peak detection-based algorithm to count sunflower and soybean seedlings. *Rojas et al.* (*2022*) used a principal component analysis combined with an SVM detection algorithm to detect weeds. This type of hand-designed algorithm has strong specificity for target detection and better performance on tidy crops with obvious characteristics. Along with the introduction of deep learning methods for target detection, the way of agricultural information acquisition has become more diversified. Velumani et al. proposed the density statistics of maize seedlings by Faster R-CNN. *Shen et al.* (*2024*) utilized the improved YOLOv8 algorithm to achieve the detection of pod pepper. *Qiu D.F.* (*2024*) realized the detection of locust targets by improving the YOLOv7. improvement to achieve locust target detection. The single-stage target detection algorithm in deep learning networks directly realizes the simultaneous regression of target localization and classification through the end-to-end network architecture, and compared with the two-stage target detection algorithm, it discards the candidate region generation, reduces the computational redundancy and maintains a better detection accuracy at the same time.

Currently, there is limited research on target detection in complex scenarios such as dry-direct seeded rice seedlings, which are characterized by high planting density, complex backgrounds, and severe mutual occlusion. For instance, *Huang et al. (2024)* and *Li et al. (2023)* optimized YOLOv5 for the plant counting of oilseed rape seedlings, achieving improved detection accuracy. Although studies targeting this specific type of context-aware object detection remain scarce, such research is crucial for advancing precision agriculture.

In summary, while deep learning-based target detection algorithms demonstrate strong adaptability in agricultural applications, their detection accuracy remains limited when applied to dry-direct seeded seedlings, which often exhibit multi-scale morphological features and densely distributed, non-uniform row patterns. To address this issue, this paper proposes an improved YOLOv11n-based method tailored for the dry strip sowing environment. The approach enhances the feature extraction capabilities of the backbone network and improves the model's ability to capture deep, multi-scale features of densely distributed seedlings, thereby achieving more accurate detection of dry-direct seeded rice plants.

MATERIALS AND METHODS

Data Acquisition and Pre-processing

Image data was acquired on 18 June 2024 at the Jian Sanjiang Qixing Farm in Jiamusi City, Heilongjiang Province, China. Acquisition took place between 08:00 and 11:00 under clear weather conditions. Figure 1 shows the image acquisition device and the acquisition route diagram. The DJI Mavic 3T UAV was used at a height of 3 m and a speed of 1 m/s, in accordance with the planned route, to acquire images at an orthographic angle. The original image was filtered to remove some of the edges of the paddy field images and 640×640 pixel images were randomly extracted from different areas of the image, totaling 1489.

Fig. 1- Image acquisition equipment and range

The rice variety under study is "Magic Rice 119", which was planted according to the pattern of alternating wide and narrow row spacing (300 mm/200 mm). Field management followed the "dry sowing and water pipe" cultivation technique, in which the paddy field is irrigated after the four-leaf stage of rice growth. To accurately capture the morphological characteristics of dry-direct seeded rice seedlings and avoid the influence of water reflections on plant feature extraction, images were collected during the pre-irrigation stage. This standardized image acquisition process provides a reliable data foundation for subsequent rice phenotyping.

(a) Rice field environment (b) Background Straw (c) Post-irrigation environment

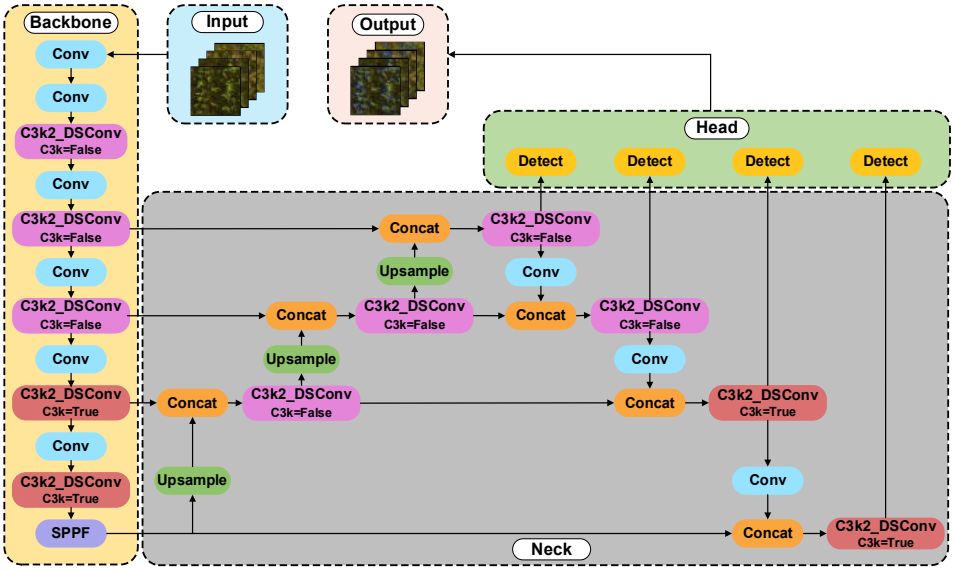
Fig. 2- Live streaming of dry rice paddy environment

Data set construction

Adobe Lightroom was used to preprocess 1489 of the images: adjusting contrast, exposure and saturation to enhance the distinction between straw and seedlings, and combining sharpening and noise reduction to highlight the details of the plants and reduce background noise, resulting in a darker background and more distinctive morphological features of the seedlings, which facilitated the algorithm's extraction of plant features. Mixed preprocessing and original images are used to enhance the adaptability of the model, and 90504 “rice” target frames are labeled by Labelimg. Finally, the independent training set, validation set and test set are divided according to the ratio of 8:1:1, which ensures the reliability of model training and testing while guaranteeing the richness of data.

Model selection and construction

The heterogeneity of plant morphology, the narrow, linear structure of rice leaves, and the low contrast between dark green moss and light green leaves on wet soil surfaces make classical target detection algorithms highly susceptible to lighting and background interference, hindering the effective capture of seedling features. Furthermore, due to the nature of strip sowing and variable soil moisture, seedling distribution is often non-uniform, exhibiting both aggregated bands and random sparsity. This complexity requires the detection model to possess both robust feature extraction capabilities and the ability to adapt to irregular spatial distributions.



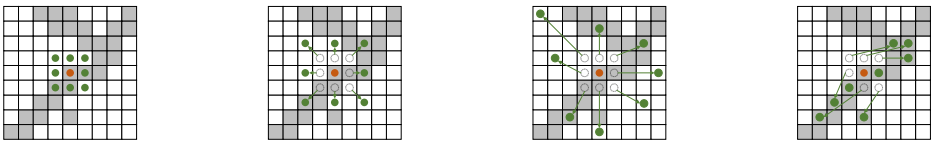


Fig. 3- YOLOv11n-DF model structure diagram

The YOLO model, with the advantage of single-phase detection architecture, exhibits excellent detection performance in the complex environment. Among them, YOLOv11 embeds multi-attention through the C2PSA mechanism, which strengthens the feature fusion ability and can cope with the scale changes and background interference in the large field environment (*He et al., 2025*). The YOLOv11 algorithm provides five different depth models, YOLOv11n, YOLOv11s, YOLOv11m, YOLOv11l, and YOLOv11x, in order to cope with different detection scenarios. It is important to note that the number of floating-point computations and parameters increases with the increase of the model depth. Among them, the model depth of YOLOv11n is the shallowest, which requires the least number of floating-point computational parameters to maintain better accuracy, while the training cycle is shorter than other models (*Wang et al.,2025*). This is consistent with the application scenario of high-efficiency real-time dry-direct seeded rice detection. Therefore, this paper selects the YOLOv11n algorithm for optimizing the detection algorithm for dry-direct seeded rice.

In this study, the C3k2 module in the YOLOv11n network was optimized by integrating DSConv convolution, and the original Detect head was replaced with the FASFFHead to improve the model's consistency in handling seedling phenotypic feature scales. The structure of the improved YOLOv11n-DF algorithm is shown in Fig. 3.

DSConv convolution

The leaves of the dry-direct seeded rice seedlings sown in strips, exhibit distinct narrow and slender morphological characteristics at the four-leaf stage, forming interlocking bands that provide mutual shading. The convolutional layer, a critical component in shallow phenotypic feature extraction, has a direct impact on the model's ability to assess target features. As illustrated in Fig. 4, which compares different convolution strategies, the standard convolutional kernel extracts local features with spatial invariance using a fixed receptive field, based on local connections, weight sharing, and hierarchical abstraction. However, the stacked structure with globally shared weights struggles to adapt to the irregular morphology of seedlings. Therefore, employing structure-adaptive convolution is essential for achieving accurate detection.

(a) Conv (b) Dilated Conv (c) Deformable Conv (d) DSConv

Fig. 4 - Comparison of different convolution strategies

Dynamic serpentine convolution focuses on slender and meandering local structures by adaptively adjusting the offsets of sampling paths, which enhances the model's ability to capture features of elongated structures (*Qi et al., 2023*). These characteristics make DSConv significantly more effective than the rigid grid sampling used in traditional convolutional kernels for extracting features from non-rigid and non-linear structures in complex scenes (*Zhang et al., 2024*). To address the challenge of capturing the narrow, elongated structures of dry-direct seeded rice seedlings, this study introduces DSConv into the C3k2 module. This integration takes into account the distributional characteristics of dry-direct seeded seedlings and enhances the geometric perception of convolutions by dynamically adjusting the sampling paths of convolution kernels, allowing them to continuously extend along thin, curved leaf structures. A lightweight subnetwork is used to predict incremental offsets at each sampling point, with each point's position determined by the cumulative offset from the previous point. This design ensures a smooth and continuous sampling path and prevents perceptual drift - a common issue in traditional deformable convolution caused by independent offset predictions.

The incremental offset of each sampling point is calculated as follows:

$$\delta \mathrm{p}_k = f_{\mathrm{offset}}(\mathrm{X};\mathrm{p}_0,\mathrm{p}_k) \tag{1}$$

where f_{offset} is the offset prediction network; X is the input feature map; p_0 denotes the coordinates of the center position of the current convolution kernel; p_k represents the coordinates of the kth sampling point; along the x-axis.

Since the offset values may be floating-point numbers, sampling at non-integer coordinates becomes necessary. To address this, bilinear interpolation is employed to compute the pixel values at these non-integer positions, ensuring smooth and continuous feature extraction. The interpolation is performed using the following formula:

$$\mathrm{X}(\mathrm{p}_0+\mathrm{p}_k+\Delta\mathrm{p}_k)=\sum B(q,\mathrm{p}_0+\mathrm{p}_k+\Delta\mathrm{p}_k)\cdot \mathrm{X}(q) \tag{2}$$

where B is a bilinear interpolation kernel decomposed into one-dimensional interpolations along the x and y directions; $\mathrm{p}_k+\Delta\mathrm{p}_k$ is the dynamically adjusted coordinate of the kth sampling point; q refers to the four surrounding integer-coordinate neighbors.

During the image acquisition process, the morphology of field-grown seedlings exhibits significant heterogeneity. To enhance the model's generalization capability for seedling detection, a multi-feature fusion approach is proposed. This involves extracting feature maps $f^l(K_x)$, $f^l(K_y)$ along the x-axis and y-axis, respectively, at the lth layer, using multi-morphology convolutional kernel templates generated by DSConv. The goal is to capture the shallow morphological features of the seedlings and to efficiently cluster key features, thereby improving detection robustness across varying seedling shapes.

During the target detection process, the model often fails to capture the shallow structural features of seedlings due to mutual occlusion among the leaves of dry-direct seeded rice. To reduce detection inaccuracies caused by disrupted seedling targets and to preserve the overall linear structure of the seedlings as much as possible, a topological continuity constraint loss is introduced into DSConv. This is achieved by calculating the bi-directional Hausdorff distance between the persistence maps of the predicted and ground truth labels, as defined by the following equation:

$$d_H^*(P_O, P_L) = \max(\max_{u \in P_O} \min_{v \in P_L} \|u - v\|, \max_{v \in P_L} \min_{u \in P_O} \|v - u\| \quad (3)$$

where P_O is the persistence map of the prediction, recording the birth and death times of topological features; P_L is the persistence map of the ground truth labels used for comparison with P_O; d^*_H represents the bi-directional Hausdorff distance, which quantitatively measures the topological discrepancy between P_O and P_L.

Serpentine convolution has been proven effective in extracting fine and narrow structural features of seedling leaves. Additionally, the C3k2 module has been optimized to enhance the model's perception of seedling features through four key mechanisms: chained accumulation of dynamic offsets, bilinear interpolation of fractional coordinates, a multi-view feature fusion strategy and a topological continuity constraint loss.

Multi-scale detection head

Seedling scale diversity in field environments leads to inconsistent seedling features in feature maps, affecting single-stage target detectors. The paper proposes a FASFFHead for the head network as a four-head detection mechanism based on an adaptive spatial feature fusion design to maintain feature scale consistency in the seedling detection model (*Liu et al., 2019*).

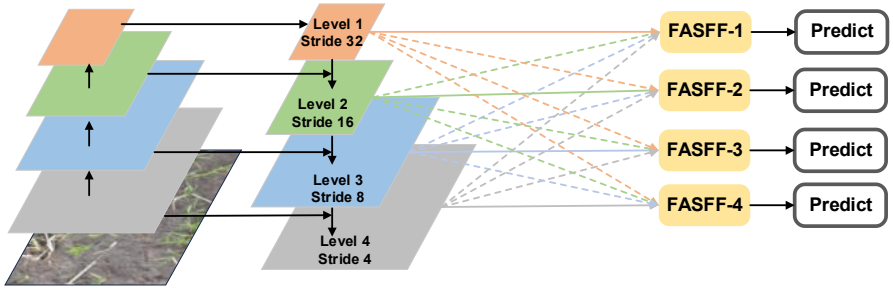

Fig. 5 - Schematic diagram of FASFF

The FASFFHead model adopts an improved feature fusion mechanism based on ASFF and introduces an additional small-scale target detection layer to the original 3-layer ASFF architecture, resulting in a 4-layer FASFF feature fusion framework (*Li et al., 2023*). This enhancement improves the algorithm's ability to capture and integrate features of small seedlings, enabling cross-scale information fusion through dynamic optimization of multi-layer feature strategies. As shown in Fig. 5, the working principle diagram of the FASFF mechanism illustrates how Level 1 through Level 4 (represented by different colors) correspond to varying spatial resolutions in the feature pyramid, each encoding seedling features at different scales. The labels FASFF-1, FASFF-2, FASFF-3, and FASFF-4 denote the fusion operations applied at each respective level, enabling layer-wise feature fusion across different resolutions.

To balance seedling feature representation, information retention, and computational efficiency, the FASFF method introduces a unified hierarchical structure for feature fusion. The core mechanism, Feature Aggregation and Selection (FAS), aims to standardize the resolution of feature maps from different hierarchical levels. For low-resolution seedling features, the number of channels is first compressed to match the target hierarchy using 1×1 convolution, followed by bilinear interpolation for up-sampling, thereby enhancing spatial resolution. In contrast, for high-resolution features, the resolution is first reduced via max pooling, and then 3×3 convolution is applied to achieve effective down-sampling.

Building on this foundation, a learnable spatial attention weight matrix is constructed. Through a parameterized weight learning module, the model dynamically learns the spatial contribution of features at each level, enabling adaptive aggregation of shallow features across multiple layers in the spatial dimension. This mechanism also preserves the local responses of features sensitive to different target scales, while effectively suppressing cross-level semantic conflicts and filtering out interfering information during feature fusion.

To address the scale inconsistency inherent in single-stage detection algorithms, FASFF enhances scale invariance by introducing an adaptive spatial feature fusion strategy. This approach improves the consistency across different feature scales by learning to suppress conflicting features. As a result, the model can flexibly determine which feature layers contribute most significantly to final predictions, depending on the contextual information at each specific location and scale.

RESULTS

Experimental Environment

The hardware equipment platform in this experiment includes: CPU Intel Core I7-13700KF, RAM 32GB, GPU Nvidia GeForce RTX 4070TI Super 16G; the software platform includes: 64-bit Windows 10 operating system and deployed Cuda11.8, Cudnn11.x with Python 3.11, using Pytorch 2.0.1 depth learning framework, PyCharm2023.3.5 editor for network model training. The relevant hyper-parameters were set: the number of epochs was 400, the batch size was 16, the optimizer was selected as SGD, and the initial learning rate was set to 0.02 in order to improve the convergence rate.

Evaluation index

In order to verify the applicability of the improved model for dry-direct seeded rice seedling detection, this study selects key performance indicators for multi-dimensional evaluation: in terms of detection accuracy, Precision - *P,* Recall - *R* and mAP50 are used as the core indicators; for the model complexity and model volume, the floating point operations (GFLOPs) and model Size are selected for quantitative analysis, and the detection speed of the model is evaluated using the detection speed (FPS). By comparing the experiments with mainstream target detection algorithms, the proposed method is comprehensively verified to see if the enhancement effect of the proposed method in model accuracy meets the expectation.

Model Performance Analysis

The training set of dry-direct seeded rice seedlings was used to train the improved model. The results showed that the YOLOv11n-DF model achieved an mAP50 of 87.12%, precision (*P*) of 84.11%, and recall (*R*) of 77.07%. Compared with the pre-improvement baseline, the mean average precision (mAP50) increased by 4.28 percentage points. Additionally, the model size remained compact at 12.7 MB, supporting efficient deployment.

The loss function curve, shown in Fig. 6, illustrates that both training loss and validation loss decrease rapidly and in synchronization during the first 50 epochs. After approximately 300 epochs, both curves converge in parallel, indicating that the model has reached a Pareto optimal state. Throughout the training process, the two models exhibit similar trends, and no significant fluctuations are observed in the validation loss. The final convergence difference between training and validation loss remains below 2%. The YOLOv11n-DF model, designed specifically for dry-direct seeding detection, does not exhibit overfitting or underfitting. Furthermore, it demonstrates strong memory retention and excellent generalization performance.

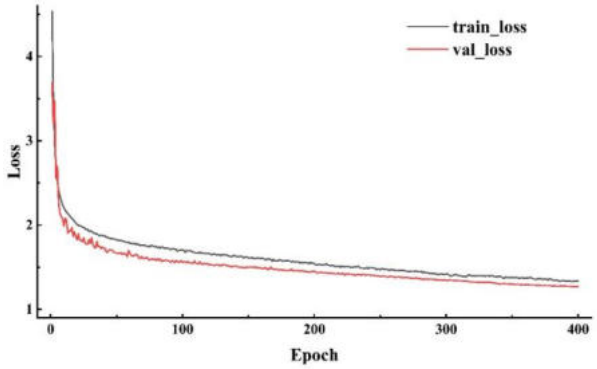

Fig. 6 - Loss function curve

As shown in Fig. 7, the detection results for both pre-processed and unpreprocessed images across different scenes are compared before and after the model improvement. The improved YOLOv11n-DF algorithm demonstrates a significantly enhanced ability to accurately detect dry-direct seeded rice seedlings in both types of images. Compared to the pre-improvement version, the improved model can more effectively identify individual seedlings, reduce redundant detections, and accurately focus on small targets - particularly in sparsely populated regions. These results highlight the enhanced robustness and adaptability of the improved algorithm under various image conditions.

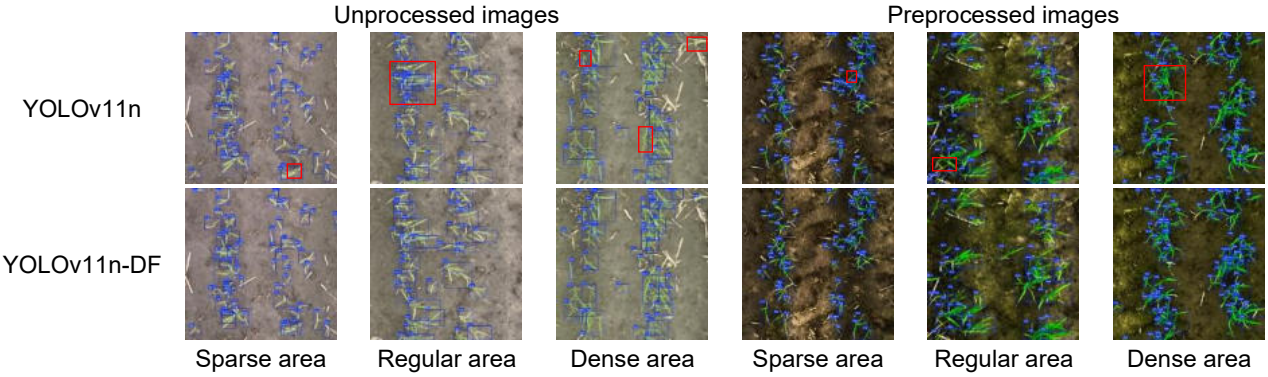

Fig. 7 - Sample images for image detection in different scenarios

Ablation experiments

To evaluate the effectiveness of the model improvements, ablation experiments were conducted based on the YOLOv11n baseline. The results demonstrated that both incorporating the DSConv mechanism into the C3k2 module and replacing the original detection head with the FASFFHead independently enhanced the model's ability to detect dry-direct seeded rice seedlings. In particular, the FASFFHead yielded a notable improvement in mAP50, although the addition of multiple detection heads also led to a corresponding increase in GFLOPs. Further module combination experiments confirmed the good compatibility of the improved components. Integrating both DSConv and FASFFHead significantly increased GFLOPs due to the multi-head structure, but this trade-off was justified by the sustained accuracy gains. The experimental findings indicate that the proposed improvements form a two-tier optimization architecture: DSConv enhances the backbone's ability to extract linear structural and distributional features of seedlings, while the four-head FASFFHead improves multi-scale detection performance. The final YOLOv11n-DF model achieves an mAP50 of 87.12%, representing a 4.28% increase over the baseline, with only a 13% increase in computational cost, thus meeting the expected performance improvements.

Table 1

Results of ablation experiment

YOLOv11n	DSConv	FASFFHead	mAP	Precious	Recall	FPS	GFLOPs	Size (M)
√	-	-	82.84%	80.62%	74.35%	**273.4**	**6.3**	**5.3**
√	√	-	84.62%	82.55%	74.63%	168.7	6.5	5.6
√	-	√	85.13%	83.20%	75.10%	154.7	7.1	11.8
√	√	√	**87.12%**	**84.11%**	**77.07%**	49.5	7.3	12.7

Note: The bolded data in the table represents the maximum value of the same group

Comparison of detection results across models

To more clearly highlight the performance differences in dry-direct seeded rice seedling detection, a comparative experiment was conducted between the improved YOLOv11n-DF model and several mainstream YOLO-based architectures. These comparisons provide a comprehensive evaluation of the model's effectiveness in handling the challenges of dry-direct seeded rice seedling detection. The detailed performance metrics and detection results are presented in Table 2.

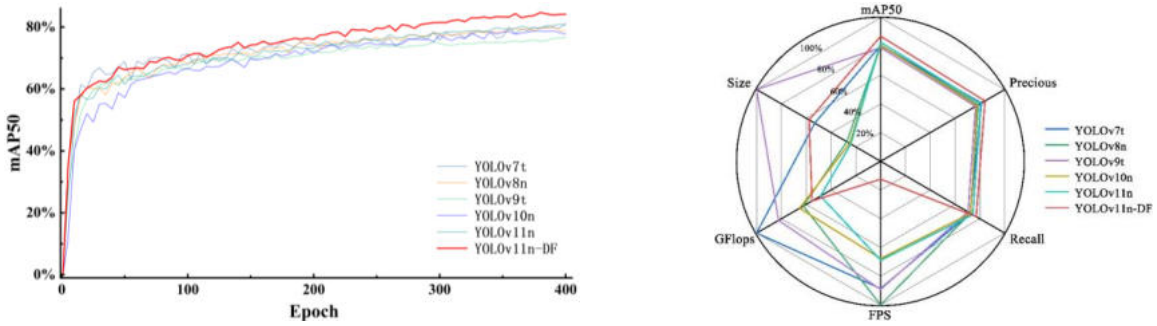

Table 2

Comparison of detection results by model

Models	mAP	Precious	Recall	FPS	GFLOPs	Size (M)
YOLOv7t	80.70%	81.25%	72.13%	351.6	13	11.7
YOLOv8n	80.91%	78.61%	72.22%	**396.8**	8.1	6
YOLOv9t	79.17%	76.49%	70.42%	354.3	10.7	22
YOLOv10n	80.83%	77.68%	72.53%	268.6	8.5	5.5
YOLOv11n	82.84%	80.62%	74.35%	273.4	**6.3**	**5.3**
YOLOv11n-DF	**87.12%**	**84.11%**	**77.07%**	49.5	7.2	12.7

Note: The bolded data in the table represents the maximum value of the same group

Fig. 8(a) shows the change curves of the mAP50 of different models with the number of training rounds. As the number of training rounds increases, the mAP50 of each model shows a general growth trend, and all models achieve basic convergence after about 300 epochs, with only small fluctuations. Among them, the pre-improved YOLOv11n model has a slower curve growth after 200 epochs, but still has some growth, and shows better learning ability in the detection of dry-direct seeding of rice seedlings. The improved YOLOv11n-DF grows second after the YOLOv7t model in the first 100 epochs, and the mAP does not fluctuate significantly in the training epoch, and still maintains a steady growth after 100 epochs, compared with the YOLOv11t model. After 300 epochs, the mAP50 stabilizes without significant growth, reaching a basic convergence.

(a) mAP50 comparison curve chart (b) Model performance radar chart

Fig. 8 - Comparative experimental results

To visually compare the performance differences among the models, radar charts based on normalized results were generated, as shown in Fig. 8(b). The improved YOLOv11n-DS network demonstrates clear advantages in terms of mAP50, *P*, and *R*, aligning with the intended improvement objectives. These results confirm that the YOLOv11n-DS network, which integrates enhanced feature extraction in the backbone and a multi-head detection strategy, outperforms similar object detection models in the task of dry-direct seeded rice seedling detection.

Visual Analysis

The visual analysis of the model can break through the limitations of the “black-box” model in the deep network. Heat map localization analysis can quantify the intensity with which the model focuses on the target region, verify whether the improved model suppresses noise and strengthens the target region of seedling plants, and assess the interpretability of the improved YOLOv11-DF model for seedling detection.

As shown in Fig. 9, Grad-CAM was used to visualize and analyze six detection scenarios. After integrating DSConv into the C3k2 module of the backbone network, the model exhibited a stronger focus on the banded distribution of dry-direct seeded rice seedlings, particularly in denser regions, compared to more sparse or scattered areas. The visualization shows that the model can effectively identify target regions in both preprocessed and original images, demonstrating enhanced generalization ability. Furthermore, the model’s attention is more concentrated on the seedling distribution in preprocessed images, suggesting that image preprocessing aids in the extraction of phenotypic features. Overall, the improved C3k2 module with DSConv significantly enhances the network’s ability to capture the structural and morphological characteristics of dry-direct seeded rice seedlings, especially those arranged in regular banded patterns.

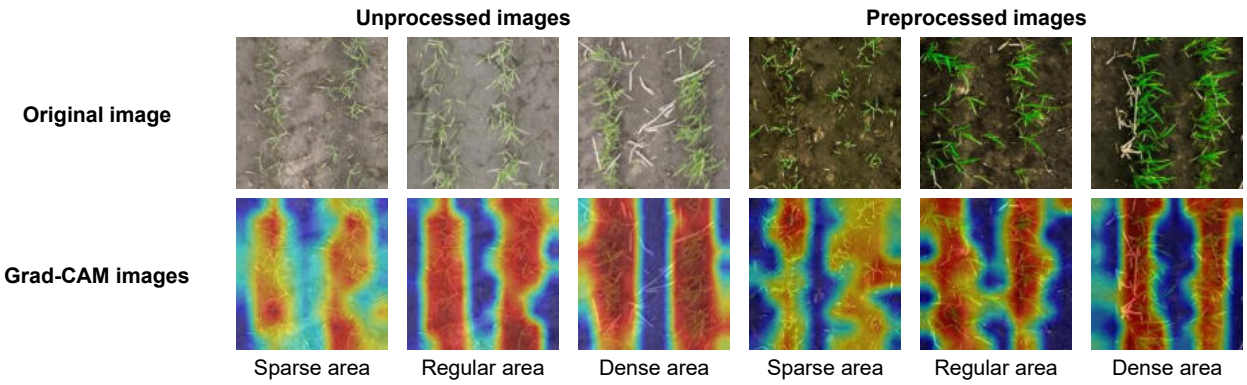

Fig. 9 - Grad-CAM visualization of detection scenarios

CONCLUSIONS

This study proposes an individual seedling detection algorithm based on an enhanced YOLOv11n network, aimed at addressing the challenges posed by the heterogeneous morphology and uneven distribution of dry-direct seeded rice. The following section outlines the results of this method:

(1) Use YOLOv11n to create a target algorithm that captures the visual traits of dry-direct seeded rice. The DSConv depthwise separable convolutional optimization C3k2 module strengthens the linear extraction of seedlings' traits, while a FASFF-based adaptive feature fusion mechanism improves the detection head's structure to better capture the multi-scale traits of seedlings.

(2) Use comparison and ablation experiments to verify the effectiveness of model improvement. The YOLOv11n-DF model's accuracy and recall reached 84.11% and 77.07%, respectively. Its mAP50 was 87.12%, showing better detection performance than the original model and mainstream algorithms. This model accurately detected multiscale seedlings in complex field environments.

(3) The interpretability of the model improvement is analyzed using visualization tools. DSConv improves the detection of linear phenotypic features of seedlings by the C3k2 module and focuses on seedlings with banded distributions. The four-detector-head architecture of FASFFHead mitigates the inconsistency in the scale of the fused multiscale features through dynamic weight allocation. The model improvement meets the design expectation, and YOLOv11n-DF has better generalization and interpretation.

(4) In summary, the improved model can accurately detect dry-direct seeded rice seedlings. Subsequent research could reduce the model's complexity using a pruning technique to meet video detection requirements in field management.

ACKNOWLEDGEMENT

This research, entitled "Research on a detection algorithm for dry-direct seeded rice based on YOLOv11n-DF", was funded by the National Natural Science Foundation of China Youth Fund Program (32201655).

ABSTRACT

In the conditions of intensively developing digital technologies, agriculture is also an active environment for their application. The article demonstrates some of the capabilities of the intelligent Scanfield-5S system and the integrated DSC - "Digital Soil Cube" for assessing the condition of the soil. The DSC method uses non-contact measurement of electrical conductivity (ECa) up to 0.4m depth in the soil. The study was usually conducted after harvest and before agricultural operations for the next crop. All collected ECa data are georeferenced. An adaptive soil sampling scheme was applied, which is specific for a given field. The number of sampling sites was determined after applying a graph-analytical method. A high confidence probability (over 80%) was obtained from the ECa data, which is a confirmation of the suitability of the method. Analyses were performed for bulk density (BD), relative humidity (dW), clay content (Clay), organic matter (OM) and activated carbon (C_(act.)) in the soil. The presented results characterize the soil as homogeneous with relatively good biological indicators (OM and C_(act.)). The adaptive soil sampling scheme and the obtained regression models for the soil parameters are specific to the studied field. The regression models for the observed parameters are linear and are presented through spatial resolution maps. The Scanfield-5S system provides solutions such as variable rate maps (VRA), soil carbon prediction, and overall soil health assessment. The digital soil model created using the DSC method is specific to the field under study, but has the potential for universality.

РЕЗЮМЕ

В условията на интензивно развиващи се цифрови технологии селското стопанство също е активна среда за тяхното приложение. Статията демонстрира част от възможностите на интелигентната система Scanfield-5S и интегрирания DSC – „Digital Soil Cube" за оценка на състоянието на почвата. DSC методът използва безконтактно измерване на електрическата проводимост (ECa) до 0,4 m дълбочина в почвата. Проучването обикновено се провежда след прибиране на реколтата и преди земеделските операции за следващата реколта. Всички събрани данни от ECa са георeферирани. Приложена е адаптивна схема за вземане на почвени проби, която е специфична за дадено поле. Броят на пробовземните места е определен след прилагане на графо-аналитичен метод. От данните на ECa е получена висока степен на доверие (над 80%), което е потвърждение за пригодността на метода. Извършени са анализи за обемна плътност (BD), относителна влажност (dW), съдържание на глина (Clay), органична материя (OM) и активен въглен (C_(act.)) в почвата. Представените резултати характеризират почвата като хомогенна със сравнително добри биологични показатели (OM и C_(акт.)). Адаптивната схема за вземане на почвени проби и получените регресионни модели за почвените параметри са специфични за изследваното поле. Регресионните модели за наблюдаваните параметри са линейни и са представени чрез карти с пространствена разделителна способност. Системата Scanfield-5S предоставя решения като карти с променлива скорост (VRA), прогнозиране на въглерода в почвата и цялостна оценка на здравето на почвата. Цифровият модел на почвата, създаден по метода DSC, е специфичен за изследваното поле, но има потенциал за универсалност.

INTRODUCTION

With the rapid development of digital technologies, agriculture has become a key area for their application. These technologies provide solutions that enable agriculture to strike a balance between protecting natural resources and meeting the growing demand for high-quality food and industrial raw materials, all while ensuring sound management decisions at various levels of government.

The basis of the predominant part of digital technologies in agriculture is the use of mathematical models proven by science and practice, describing separately or in combination various physical, mechanical, biological and other processes occurring during the cultivation of agricultural crops. In this way, technologies in agriculture can acquire adaptive, can become adaptive and even proactive - capable of responding promptly to changing conditions and adjusting the expected outcomes accordingly. The sustainability of such technologies largely depends on maintaining a constant connection with the environment in which they are implemented. By developing adequate mathematical models, it is possible to predict and adapt processes and phenomena manifested at a later stage as a result of changes in the factors influencing the object of impact.

Advances in understanding plant growth and development, as well as improvements in instrumentation, lead to better analysis and interpretation methods.

In the past and even today, many farms treat the entire cultivated area as a uniform unit—irrigating the whole field when it's time to water, or applying the same fertilizer rate across the entire area when needed. In reality, however, the needs of different parts of the field vary due to soil heterogeneity.

Acquiring, analyzing and applying accurate information through analytics is essential for making the right decisions. Soil testing is an important tool related to the application of technologies for growing crop plants. The adequacy of soil analysis largely depends on the methodology's ability to determine the non-uniform nature of the soil in a given field.

The basis of the existing methods for soil analysis is the classical methodology with its three main stages, which include:

Stage 1. Building the soil sampling – the surveyed field is divided into modular units (plots) of certain sizes, with the number and locations for drilling marked along a pre-defined trajectory. Generally, the "W-scheme" is suitable for most plot shapes and sizes, but "Z-scheme" or "X-scheme" also apply. Thus, one soil sample should be formed from each modular unit, obtained after mixing the samples from the drilling sites. The goal in drawing up a drilling scheme is to capture the soil diversity in the surveyed field. The number of drilling sites in a modular unit varies from 10 to 40, and the size of a modular unit from 0.5 ha to 10-12 ha (*FAO soil bulletin 18; https://sites.google.com/site/poushkarov/home/vzemane-na-pocveni-probi; The LaMotte soil handbook*);

Stage 2. Soil sampling – it is done either manually or mechanically using special tools that extract samples from soil layers with a depth of 0-30 cm; 30-60 cm and 60-90 cm, according to the purpose of the surveyed field and the goals of the analysis;

Stage 3. Laboratory analysis – soil samples collected from the field are subjected to laboratory tests according to established procedures and standards (*Benton, 2001*). The analysis of the results compares the reported with the reference values of the observed indicators and on this basis a generalized assessment of the soil condition is formed and relevant recommendations can be prepared.

A mandatory requirement for the classic method is soil sampling, and the reliability of the results depends on the sampling density (*https://bds-bg.org/bg/project/show/bds:proj:109684*). This determines the representativeness of the soil material collected. Due to the complexity of ensuring the representativeness of soil samples in Stage 1 of the conventional method, modern specific developments such as global navigation satellite system (GNSS), global positioning system (GPS), geographic information systems (GIS) are being used. According to a set algorithm, these systems can divide the field into modular units of a certain shape and size, which forms a network of drilling points on the field. The network density, resp. the density of sounding points is set by the size of the modular unit.

Conventional soil analysis methods typically rely on a set of samples to ensure representativeness and reliability of the analysis results. These samples are often combined into a composite sample, the analyses of which are assigned to the soil in the entire field. This makes their application difficult in modern digital technologies.

In the sense of the digital transformation in agriculture, classical soil analysis cannot provide a high enough degree of precision. It also takes a lot of time and resources, which is why farmers often neglect it.

The idea of the DSC method is related to digitalization of soil analysis. A key point in it is the replacement of the soil sample from the so-called "Digital soil cube" which, by means of mathematical models, provides timely information on the condition of the soil.

To develop the method, a cybernetic approach known from science is applied. The approach is based on the principle of the black box, according to which any object can be studied and managed only by its reactions caused by one or other external influences, without knowing the processes and phenomena that take place inside the object (*Mitkov, 2011; Mitkov and Bratoev, 2023*). The application of this approach is also related to the use of probabilistic statistical methods (*Kardashevski and Mitkov, 1977; Mitkov, 2011; Mitkov and Minkov, 1989, 1993; Mitkov and Bratoev, 2023*), in which the reactions shown by the object are viewed as a random event, a random variable or a random process. At the so-called poorly organized systems (objects) including soil, these methods are a means of obtaining objective information. The DSC methodology uses the elements of mathematical statistics, correlation analysis, dispersion analysis and regression analysis (*Kardashevski and Mitkov, 1977; Mitkov, 2011; Mitkov and Bratoev, 2023*).

The reactions of the object (the soil) and the external influences are considered as random quantities that describe a given feature (property) of the general population (the soil in the entire field). A given property of the soil is seen as a reaction of the soil, and the soil itself as an object with an external influence. The entire soil survey process is passive in terms of the statistical data collected (*Kardashevski and Mitkov, 1977; Mitkov, 2011; Mitkov and Bratoev, 2023*). The methodology for implementing the DSC is distinguished by a dynamic functional scheme. In its entirety, this functional scheme consists of five stages that must be followed to obtain the final digital soil model. Once created, the digital soil model allows the functional scheme to be reduced to two stages - the first and the last, and the soil analysis itself takes on a proactive nature.

Stage 1. Measurement of the electrical conductivity of the soil - one of the significant measurements that can be used as an indicator of soil fertility and digitized is its electrical conductivity (*Corwin et al.,1996, 2005; Drommerhausen et al. 1995; Greenhouse et al.,1983; Hanson et al., 1997; Kitchen et al., 1999*). Soil electrical conductivity (ECa) is a measurement that correlates with soil properties that affect crop productivity. Such properties include soil texture, cation exchange capacity (CEC), organic matter, salinity, nutrient availability, etc. The nature of the current flow in soil has been described in detail in numerous studies (*Corwin et al.,1999; Ellsbury et al., 1999; Fitterman et al., 1986; Halvorson et al., 1976; Rhoades et al., 1990, 1991, 1992, 1999*). Some studies have reported the effects of soil salinity, CEC, water content, and bulk density on ECa (*Bohn et al.,1979; Bratoev et al., 2020; Corwin et al.,2005; Hanson et al., 1997; Slavich et al., 1990*). Others have analyzed the effects of clay, organic matter, soil temperature, texture, and cation availability (*Brevik et al., 2002; Cook et al., 1992; Corwin, 1996; Corwin et al.,1999; Drommerhausen et al., 1995; Stroh et al., 2001; Triantafilis et al., 2001*). ECa measurements should be interpreted with these factors in mind. Studies have shown that the optimal ECa values for fertile soils should be in the range of 110 – 570 mS/m (*Cook et al., 1992; Triantafilis et al., 2001*). The level of soil moisture and the nutrients dissolved in it play a decisive role in the measured ECa in the soil. In order to use it as an indicator of soil health and therefore to make informed decisions, it is necessary to understand the relationship of ECa with soil properties. The complex nature of the relationships between individual soil parameters is also transferred to their relationship with ECa (*Bohn et al., 1979; Brevik et al., 2002; McDaniel et al., 2014*). Such complex relationships are difficult to describe with traditional functional mathematical relationships. By measuring the ECa, the information contained in the soil about its main characteristics is recorded as a numerical series that provides an opportunity to describe the complex interrelationships. In the DSC method, non-contact measurement of ECa is used, based on the principle of electromagnetic induction. Soil ECa screening is performed for 100% of the surveyed field area, with the location of each record being marked with geographic coordinates.

Stage 2. Building the soil sampling - the collected data on ECa of the soil in the surveyed field are subjected to statistical processing. The aim is to identify areas of the field in which the ECa can be assumed to be the same from a statistical point of view. In general, zones with strong, medium and weak electrical conductivity of the soil are formed, but in detail the number of zones depends on the observed soil diversity in the field. Statistical processing consists of determining the estimates of numerical characteristics and testing statistical hypotheses. The information from the received assessments is used to find the so-called the maximum relative error, which is accepted in the DSC method, should not exceed 10%. Such an error value determines the number of soil samples that must be taken from an area in order to guarantee the results obtained at a 95% confidence level. By performing a statistical hypothesis test for equality of a series of means it can be

determined at how many zones within the field the hypothesis will be rejected. Thus, zones will be formed on the field, which will be significantly different from each other by the measured ECa of the soil in them.
The outlines of each of the zones are determined by the geographic coordinates of the individual records during the scan. The field locations where soil samples will be taken are also set with their geographic coordinates, their location being adjusted to avoid autocorrelation with respect to ECa.

Stage 3. Soil sampling - it is carried out either manually or mechanically using special tools that extract samples from four soil layers with a depth of 0.2 m; 0.4 m; 0.7 m and 1.0 m, according to the purpose of the surveyed field and the goals of the analysis. Each soil sample is marked with its geographic coordinates and recorded ECa value.

Stage 4. Laboratory analyses - the soil samples collected from the field are subjected to laboratory tests according to established procedures and standards (*Benton, 2001*). The obtained results of the laboratory analyses are used in the next stage to compile mathematical models.

Stage 5. Creating digital soil models - a digital soil model is a collection of separate regression models expressing the relationship between a given soil parameter and the measured soil ECa. To obtain a specific regression model, the ECa data at the drilling (sampling) site and the results obtained from the laboratory analysis for the selected soil indicator are used. With these data, a regression analysis is carried out to quantitatively describe the relationship between the soil parameter and ECa. The statistical analysis of the obtained regression models shows that the change of the soil index can be described by ECa and the obtained regression model. Another aspect of the statistical analysis is determining the adequacy of the model, which in the case of individual digital models is confirmed by Fisher's criterion (*Kardashevski and Mitkov, 1977; Mitkov, 2011; Mitkov and Minkov, 1989; ; Mitkov and Minkov, 1993; Mitkov and Bratoev, 2023*). This gives reason to assume that the error of the model does not exceed the error of the experimental data. By including a given regression model to the coordinates of the field, georeferenced data is obtained, with which the values of the observed soil indicator in the given field can be presented visually (through spatial resolution maps) or digitally.

MATERIALS AND METHODS

The digital nature of the DSC method allows it to be integrated with other modern digital technologies. Such a digital technology is the Scanfield-5S system, which offers innovative services and solutions for agriculture. The Scanfield-5S system platform is built on several main pillars of a digital nature: 3D scanner, Data processing and analyses.

3D scanner – a patented scanner is used for non-contact measurement of soil electrical conductivity (*https://geoprospectors.com/en/*). Raw data from the ECa scanner is converted into information on several baseline metrics: soil zones, depth to compaction, relative soil moisture and tillage maps. The scanner mounts directly on a vehicle, which can be a tractor, ATV, pickup truck, or similar field vehicle. The sensor can be used on any soil, even when it is covered with vegetation. There is also no restriction on minimum or maximum soil moisture content. The scanner works on the principle of electromagnetic induction. A magnetic field is induced through a transmission coil (Fig. 1). Four receiving coils then measure electrical conductivity at four cumulative depths, up to 1.0 m. The device also permanently records spatial information. No contact with the ground is required to obtain soil electrical conductivity data, making it suitable for scanning dry soils. The data is collected and can be processed in real time to be immediately used on the tractor (for example for managing agricultural equipment).

Data processing - raw data is processed with filters and sophisticated algorithms to produce a series of files. Some of these files can be used directly from the agricultural machine's ISOBUS terminal for further use. With the filtered data, spatial resolution maps of the observed indicators are prepared. From the spatial resolution maps for the soil zones, the locations of the soil sampling sites are determined.

Analysis – physical soil samples are sent to a soil analysis laboratory. The obtained results are processed and analyzed using specialized software and the DSC method, after which the data are transformed into soil maps. The soil maps are spatial resolution maps for each soil parameter for which a digital model was obtained using the DSC method. Each map is made by specialized software. The data from the maps can also be transformed into a tabular form. The detail in the soil map can be changed according to the needs of the user.

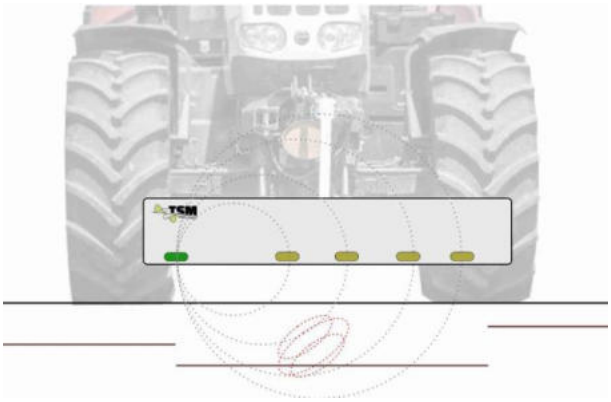

Fig. 1 - Top Soil Mapper (Geoprospectors GmbH)

1) Description of the study site

The studied field is located in the territory of the village of Boychinovtsi, Montana region in Bulgaria. The soil in this field is loam (*Gyurov and Artinova, 2001*). The field has an area of 207.7 ha, on which cereals and cereal crops are grown. The research was conducted after the wheat harvest. Up to the time of the study, no soil treatments were carried out.

2) Soil condition

In order to assess the soil condition, the following steps were taken: (a) ECa measurement across the field, (b) formation of markers for soil sampling, (c) analysis of soil properties, and (d) compilation of georeferenced spatial resolution maps for visual presentation of results.

a) ECa measurement across the field

The measurement of the ECa was carried out on 01.09.2023 with a mobile electromagnetic scanner TSM (Top Soil Mapper) of Geoprospectors GmbH. Successively, the measurements were taken about 1 m apart, collecting almost 20000 soil ECa data in four layers at the depth of 0.2 m; 0.4 m; 0.7 m and 1.0 m. All collected data are georeferenced with a GLONASS system (GNSS) receiver.

b) Formation of markers for soil sampling

Using the ECa data and the methodology of the Scanfield-5S system, six characteristic zones were formed within the field (Fig. 2). The resulting zones are distinguished by the average ECa in them, covering a different proportion of the field area, and in general characterize the spatial variability in ECa of the whole field. The marker in a given zone provides a statistical representation of the most frequently measured ECa in the zone. The location of the marker is georeferenced and a soil sample should be taken from it.

The soil samples were taken on the ECa measurement day (September 1, 2023). Soil cores were taken consecutively from the top two soil layers with a depth of 0.2 m to a depth of 0.4 m. Extraction of soil cores from the soil was carried out with a Royal Eijkelkamp hand probe. Duplicate soil samples were taken within each zone to ascertain variability at the zonal level. A total of 12 markers (stars on Fig. 4) were formed, from which a total of 24 soil samples were taken (12 from both soil layers).

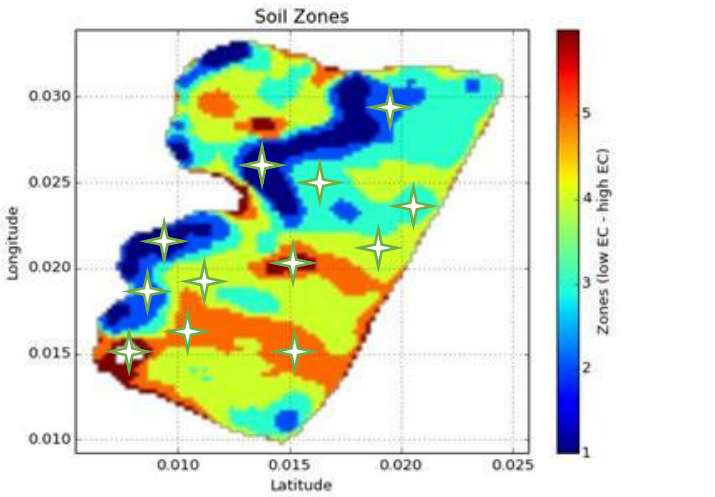

Fig. 2 - Zones and field markers (from TSM Client Cloud & Scanfield-5S) *

*Note: * full field coordinates not presented*

c) Analysis of soil properties

Relative humidity dW, bulk density BD and clay content were analyzed for the 24 soil samples from soil physical properties, and organic matter OM and active carbon $C_{act.}$ in the soil were analyzed as biological indicators. The choice on these indicators is dictated by the fact that the physical and biological properties of the soil are often not a focus when performing soil analyses. Validated methods were used to analyze these indicators (*Trendafilov and Popova, 2007; Moebius-Clune et al., 2017*). The relative humidity is expressed as a percentage of the maximum field moisture content of the soil, the value of which is 31.5%. Statistical processing was performed with TIBCO's "Statistica" software product.

d) Compilation of georeferenced spatial resolution maps for visual presentation of results

All spatial data for the ECa, as well as those from soil analyses, are entered into the Scanfield-5S system. Georeferenced spatial resolution maps are created for each of the observed soil indicators, for which a digital model was obtained using the DSC method. The data from the maps can also be transformed into a tabular form. The detail in the soil map can be changed according to the needs of the user.

RESULTS

After statistical processing of the ECa values measured by TSM for the soil layer with a depth of 0.2 m, an overall average value $\overline{ECa}_{20cm} = 27.95\ mS/m$ and a coefficient of variation $V_{20cm} = 14.9\ \%$ are obtained. For the layer with a depth of 0.4 m, these estimates are respectively $\overline{ECa}_{40cm} = 34.71\ mS/m$ and $V_{40cm} = 15.4\ \%$.

All data for ECa_{20cm} and ECa_{40cm} are divided into six groups (classes), which are a prerequisite for the formation of georeferenced areas in the field. The number of classes was determined after applying a graph-analytical method (*Mitkov and Bratoev, 2023*). Its result shows that over 80 % is the confidence probability that the average value obtained from the six groups does not differ by more than 10 % from the ECa average for the corresponding layer, i.e., $\overline{ECa}_{20cm}$ and $\overline{ECa}_{40cm}$. The high confidence probability justifies the spatial variation of the ECa to be represented by six georeferenced zones along the field.

After grouping the data for ECa_{20cm}, the average coefficient of variation in individual groups is $\bar{V}_{20cm} = 5.3\%$. For the groups of data referring to ECa_{40cm}, the average coefficient of variation is obtained $\bar{V}_{40cm} = 5.4\%$. The nearly identical values of the two coefficients of variation, along with the previously mentioned graph-analytical method, indicate that two measurements within a group or field zone are sufficient to guarantee 90% accuracy of the ECa group average. This confirms the necessity of collecting duplicate soil samples in each zone.

This is how the 12 markers for this field are formed, and their locations are determined by the georeferenced data associated with the most common ECa in a given group. The number and locations of markers, i.e., the soil sampling scheme depends on the spatial variability of soil ECa in the field being studied. Therefore, such a soil sampling scheme is adaptive in nature. The need to change existing soil sampling schemes when using the ECa is noted in research by D.L. Corwin and S.M. Lesch (*Corwin et al., 2005*).

From the correlation matrix (Table 1) it can be seen that ECa_{20cm} stands out as the most influential and most powerful indicator. As expected, this indicator has the strongest linear correlation with ECa_{40cm} ($\hat{r} = 0.94$), which is positive. The correlation of ECa_{20cm} are significant and with the other indicators, such as with BD_{20cm}, it is negative - $\hat{r} = -0.74$. A negative correlation is also observed between ECa_{40cm} and BD_{40cm} - $\hat{r} = -0.61$. Therefore, in areas of the field where the observed ECa decreases, the bulk density BD of the soil in these areas is expected to increase. An increase in soil stiffness is likely to occur as BD increases, but this was not included in this study.

A similar but positive correlation of ECa_{20cm} is observed with $Clay_{20cm}$ and the included biological indicators - OM_{20cm} and $C_{act.20cm}$, respectively $\hat{r} = 0.7$; $\hat{r} = 0.77$ and $\hat{r} = 0.74$. The correlation of the indicators OM_{40cm} and $C_{act.40cm}$ with ECa_{40cm} is also significant ($\hat{r} = 0.6$; $\hat{r} = 0.74$). The absence of a significant correlation of ECa_{40cm} with $Clay_{40cm}$ ($\hat{r} = 0.4$) as well as with dW_{40cm} ($\hat{r} = 0.51$) may be due to unforeseen circumstances, since sees that they are highly correlated with the conductivity ECa_{20cm}.

The significant correlation of ECa_{20cm} and ECa_{40cm} with biological indicators (OM_{20cm}, $C_{act.20cm}$, OM_{40cm} and $C_{act.40cm}$) makes the measurement of soil ECa a suitable tool for determining the amounts of organic carbon (OC) in the soil.

Table 1

Correlation matrix- Marked correlations are significant at p <0.05. N=12

Variable	Means	Std.Dev.	ECa_{20cm} (mS/m)	ECa_{40cm} (mS/m)
ECa_{20cm} (mS/m)	26.49	8.21	1.00	0.94
ECa_{40cm} (mS/m)	29.40	8.19	0.94	1.00
BD_{20cm} (t/m^3)	1.30	0.39	-0.74	-0.66
BD_{40cm} (t/m^3)	1.17	0.33	-0.62	-0.61
dW_{20cm} (%)	38.30	10.79	0.58	0.59
dW_{40cm} (%)	50.70	14.67	0.58	0.51
$Clay_{20cm}$ (%)	28.28	4.03	0.70	0.68
$Clay_{40cm}$ (%)	29.03	4.34	0.62	0.40
OM_{20cm} (%)	3.39	0.28	0.77	0.89
OM_{40cm} (%)	2.66	0.83	0.76	0.60
$C_{act.20cm}$ (mg/kg)	527.23	110.00	0.74	0.65
$C_{act.40cm}$ (mg/kg)	430.11	124.15	0.72	0.74

Tables 2 and 3 show the basic statistics characterizing the observed soil properties in the 0.2 m and 0.4 m depth layers, respectively. The average values of the properties show that the soil in the studied field has good levels of the observed indicators. The higher values of the coefficient of variation (Coef. Var.) for ECa_{20cm} and ECa_{40cm} compared to $V_{20cm} = 14.9\%$ and$V_{40cm} = 15.4\,\%$ is the result of the 12 measurements being counted as individual rather than group data. Taking into account the grouping of the data for the measured ECa_{20cm} and ECa_{40cm} in the entire field, the obtained values of the corresponding coefficient of variation differ by less than 5% from the total V_{20cm} and V_{40cm} (*Kardashevski and Mitkov, 1977*). A similar result can be expected regarding the variation in the other indicators in the tables. At values of coefficient of variation around and below 30 %, it can be assumed that the spatial variability of the given indicator obeys the normal distribution (*Kardashevski and Mitkov, 1977*). The higher BD values in the upper soil layer (0.2 m) are probably the result of the movement of agricultural machines during the harvest and the lower relative humidity in it.

Table 2

The spatial variation of the observed soil indicators is represented by spatial resolution maps shown in Figures 3 and 4. Each of the maps was obtained using the Scanfield-5S system methodology. The maps combine information on the values of the observed parameter and the georeferencing of this information within the studied field. The different color representation of the field sections is integrated into a legend explaining what notional mean values are expected from the presented metric in the respective sections.

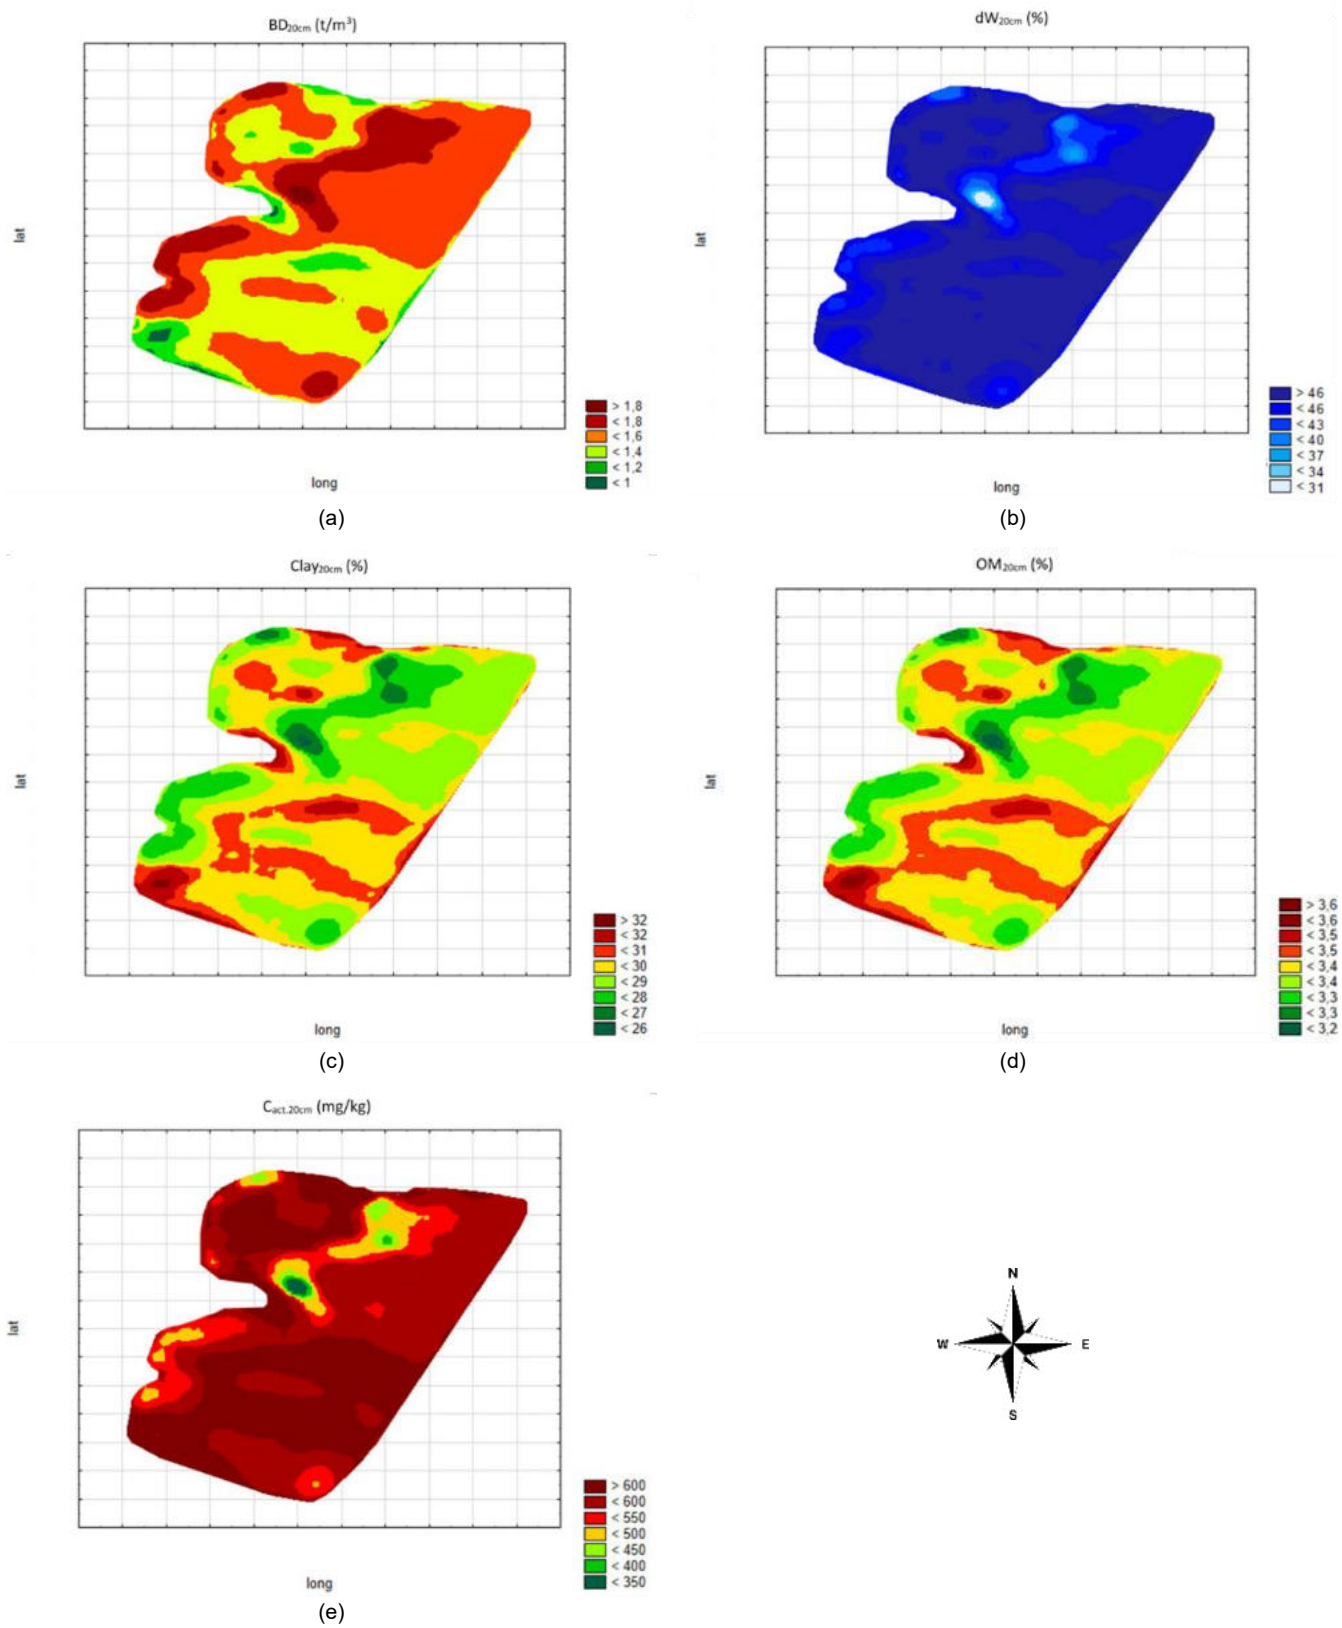

Fig. 3 - Spatial resolution maps of soil properties in the layer with a depth of 0.2 m:
(a) - bulk density (BD); (b) - relative humidity (dW); (c) - clay content (Clay);
.(d) - organic matter (OM); (e) - activated carbon ($C_{act.}$)

The presented spatial models of the observed properties of the soil are quantitatively related to the spatial variation of its ECa in the two layers - ECa_{20cm} and ECa_{40cm}. The analysis of the spatial resolution maps from Fig. 3 shows that 72 % of the field area is occupied by sections in which the volume density of the soil (BD_{20cm}) has a value falling within the confidence interval for the general average value. Similar results are also observed for the other indicators of this soil layer, and for active carbon ($C_{act.20cm}$) the relative share of

these areas reaches 90 %. These results mean that the soil in the topsoil is consolidated around some good levels of its indicators. Slightly lower relative humidity values (dW_{20cm}) are an expected result around the harvest period. The obtained levels of the biological indicators (OM_{20cm} and $C_{act.20cm}$) testify to a fairly good activity of microorganisms in the soil.

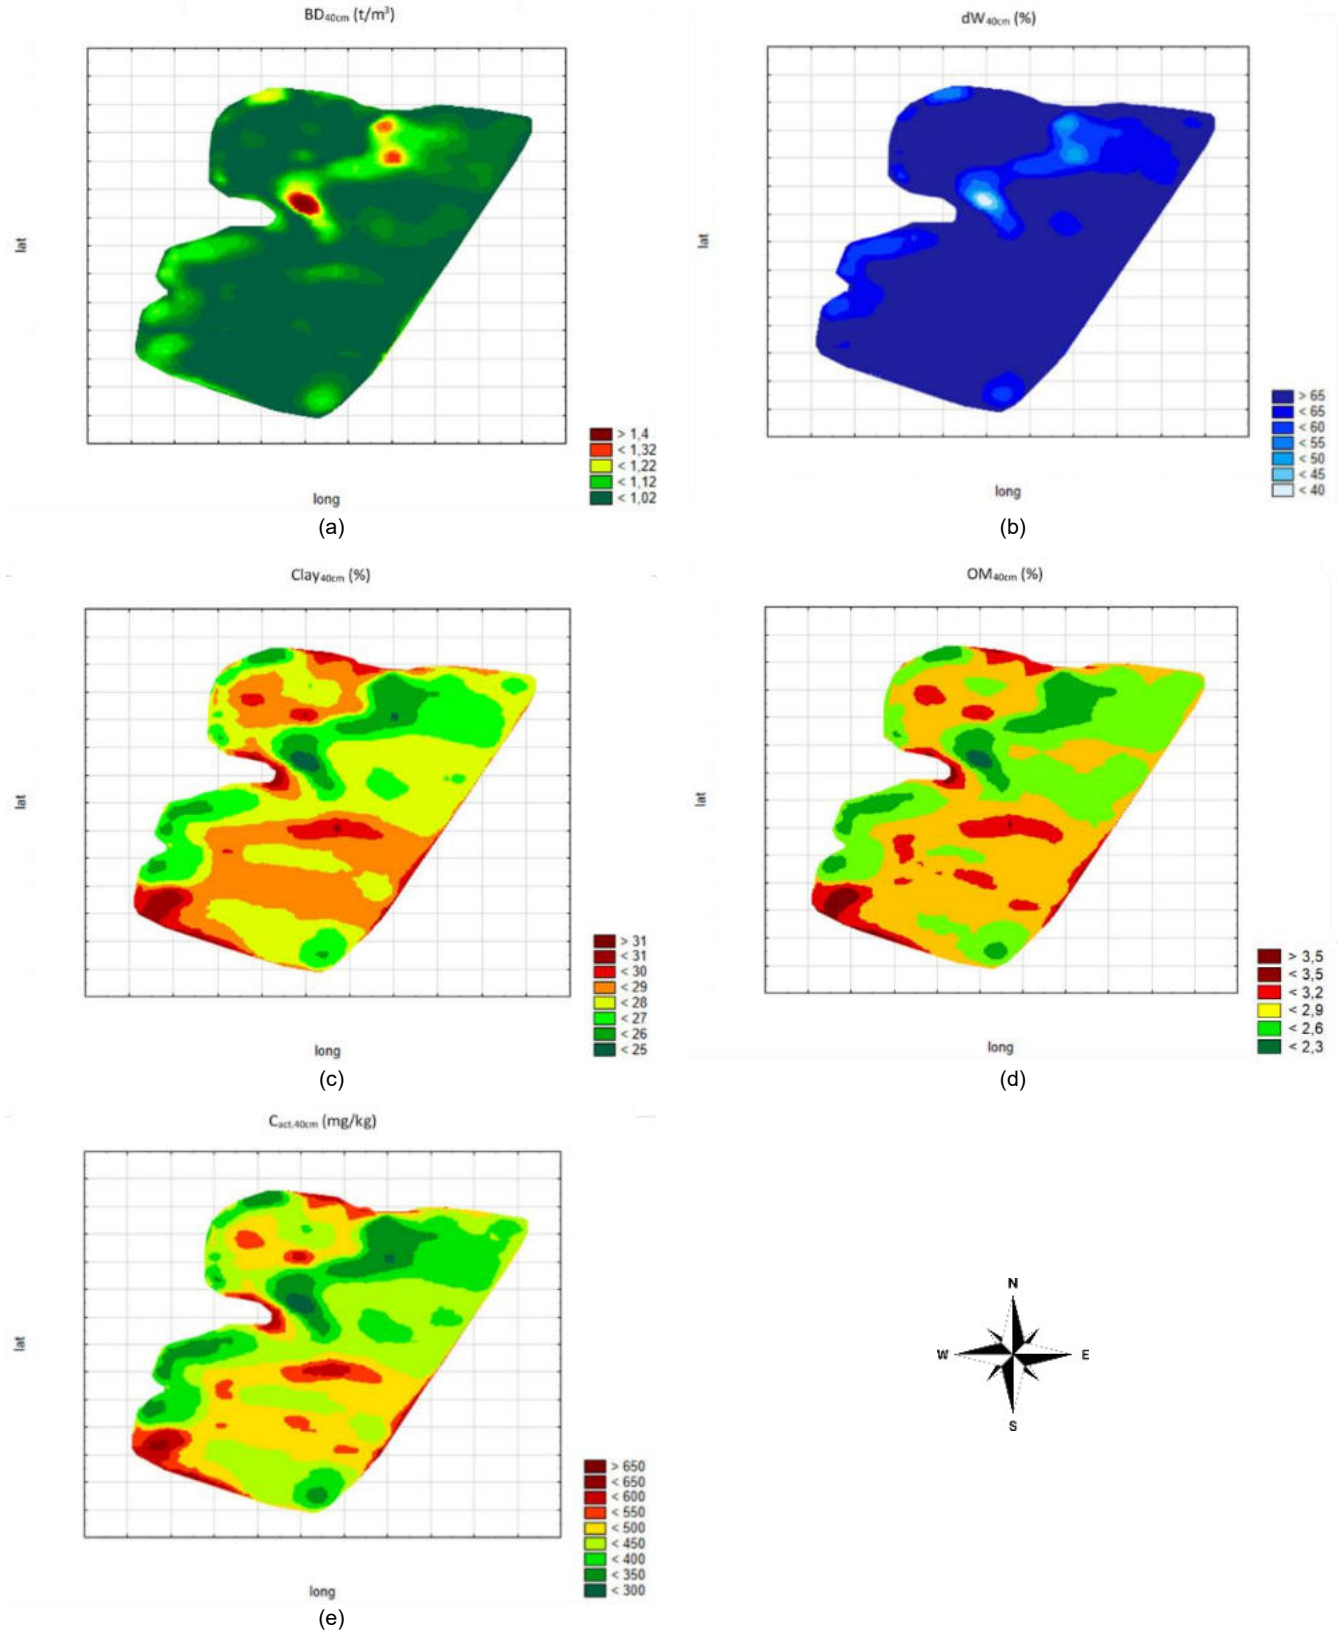

Fig. 4 - Spatial resolution maps of soil properties in the layer with a depth of 0.4 m
(a) - bulk density (BD); (b) - relative humidity (dW); (c) - clay content (Clay);
(d) - organic matter (OM); (e) - activated carbon ($C_{act.}$)

A similar analysis can be made for the spatial resolution maps from the deeper soil layer - 0.4 m (fig. 4). Here, the predominant part (81 %) of the soil has a bulk density $BD_{40cm} < 1.02\ t/m^3$, which suggests the appearance of a positive (left) asymmetry in the normal and distribution. An asymmetry in the normal distribution is also assumed for the relative humidity, but here it should be negative (right), since for 83 % of the layer area, the relative humidity is $dW_{40cm} > 60$ %. The average levels of biological indicators (OM_{40cm} and $C_{act.40cm}$) in this layer are lower than the previous layer (0.2 m), but still remain good.

Together, the two sets of spatial resolution maps outline that the soil in the surveyed field has a deep (up to 0.4 m) and thick humus horizon and has good levels of bulk density ($\sim 1.3\ t/m^3$). This implies that such technologies are applied in the cultivation of crops that ensure sustainability of the resources in the soil of that field.

CONCLUSIONS

The presented DSC method offers the possibility of digitalization of soil analysis, the key point of which is the use of information on soil electrical conductivity (ECa) and its relationship with soil properties through mathematical models. The DSC application methodology is distinguished by a dynamic functional scheme that provides timely information on the state of the soil. The creation of a digital soil model allows traditional soil analysis to become proactive. The adaptive soil sampling scheme used can be designed only after the spatial variability of ECa in the soil of the entire field has been measured. As the spatial variation of ECa increases, the number of places from which soil samples need to be taken also increases. It can be said that soil heterogeneity is a leading factor in the preparation of the sampling scheme. In conventional soil analysis methods, its heterogeneity is based on external signs in the field and a large number of samples, which vary depending on the standard used.

The five observed indicators: bulk density (BD_{20cm}, BD_{40cm}), relative humidity (dW_{20cm}, dW_{40cm}), clay content ($Clay_{20cm}, Clay_{40cm}$), organic matter (OM_{20cm}, OM_{40cm}) and active carbon ($C_{act.20cm}, C_{act.40cm}$) have a significant correlation with ECa, which is confirmed by the results in Table 2. The application of the DSC method is an opportunity for a reliable and adequate presentation of the change in these indicators for 100% of the field area.

The created spatial resolution maps are a convenient tool for visualizing and evaluating the condition of the soil in a given field. It was found that the spatial variability of ECa in the upper two layers of the soil is about 15 %, which is sufficient reason to consider this soil as sufficiently homogeneous. This is also confirmed by the results in the spatial resolution maps, where from 72-90 % of the field area is occupied by soil, whose indicators have values close to the average for the entire field. The levels of biological indicators are quite good for a soil that is engaged in agricultural production and the soil can be considered healthy and the applied agricultural practices sustainable.

The integrated solution of the intelligent Scanfield-5S system provides a practical tool for soil assessment when soil properties are related to ECa. The application of mathematical models requires the use of both precise measuring instruments and methods that determine individual soil parameters with the smallest possible error. The presented soil analysis solution demonstrates a way to digitally transform the most important resource in agriculture - soil. The Scanfield-5S system can provide farmers with reliable solutions tailored to their needs and applicable to modern technologies. One such solution is the creation of a variable rate application (VRA) maps. Such a map can be used for sowing, fertilizing with liquid or solid fertilizers, watering and other agricultural operations that are advisable to be carried out with a high degree of precision. Another potential option is the issuance of carbon certificates that would allow farmers to declare the amount of carbon accumulated in their fields. In addition to the direct benefits of carbon certificates, farmers will have information on how much their farming practices contribute to improving soil health.

Another proven option for determining soil health is to compare its experimental indicators with its corresponding reference indicators using the Harrington function. The minimum difference between the obtained functions is an indicator of soil health, i.e. it tends to its natural state.

The digital soil model created by the DSC method is specific to the studied field, but has the potential for universality.

ABSTRACT

Aiming at the problems that corn planters are prone to in sandy loam soil conditions, such as uneven soil covering thickness and seed position deviation, which affect the sowing quality, an innovative disk-type soil covering device based on the bionic shape of the claw legs of sand crabs has been optimized and designed. In this study, the contour features of the pincers of sand crabs were extracted using MATLAB software and applied to the tooth profile design of the soil cover plate, aiming to improve their operational performance in sandy loam soil. This study analyzed the operation mechanism of the bionic soil covering device based on the characteristics of sandy loam soil and determined the key parameters affecting the soil covering effect, including the installation deflection angle, installation inclination angle and the distance between the openings at the back of the soil covering tray. Taking the qualified rate of soil cover thickness and the standard deviation of seed lateral displacement as evaluation indicators, and with the help of EDEM discrete element simulation technology, the interaction model of sandy loam - seed - bionic soil cover device was constructed, and the single-factor and Box-Behnken response surface experimental designs were systematically carried out. Through simulation analysis and optimization, the optimal parameter combination of the soil covering device suitable for sandy loam soil was determined as follows: installation deflection angle 21.3°, installation inclination angle 20.1°, and the opening spacing behind the soil covering tray 100.0 mm. It has laid a foundation for the research on improving the uniformity of soil covering and the straightness of seed rows in the soil covering device of sandy loam soil seeders.

摘要

针对沙壤土条件下玉米播种机覆土易出现覆土厚度不均、种子位置偏移等影响播种质量的问题，创新性地优化设计了一种基于沙蟹螯足齿形仿生的盘式覆土装置。本研究利用 MATLAB 软件提取了沙蟹螯足的轮廓特征，将其应用于覆土盘齿形设计，旨在提升其在沙壤土中的作业性能。本研究基于沙壤土特性分析了仿生覆土装置的作业机理，确定了影响覆土效果的关键参数，包括安装偏角、安装倾角和覆土盘后方开口间距。以覆土厚度合格率和种子横向位移标准差作为评价指标，借助 EDEM 离散元仿真技术，构建了沙壤土-种子-仿生覆土装置的互作模型，系统开展了单因素与 Box-Behnken 响应面试验设计。通过仿真分析与优化，确定了适用于沙壤土的覆土装置最优参数组合为：安装偏角 21.3°、安装倾角 20.1°、覆土盘后方开口间距 100.0mm。为研究改善沙壤土播种机覆土装置的覆土均匀性与种行直线度奠定了基础。

INTRODUCTION

Sandy loam is an important type of agricultural soil due to its good air and water permeability *(Wang et al., 2025; Deng et al., 2025).* However, its loose texture and low cohesion characteristics can easily cause problems such as uneven soil cover thickness and seed positioning deviation in mechanical sowing and soil covering operations, seriously affecting the germination rate of sowing and the uniformity of crop growth *(Wang et al., 2025; Luo et al., 2025).* Traditional soil covering devices often face challenges such as difficult soil flow control, large disturbance and poor soil covering stability in sandy loam soil, making it difficult to meet the requirements of high-quality sowing. Therefore, optimizing the soil covering device plays a significant role in improving the uniformity of seed soil covering under sandy loam conditions.

In recent years, researchers at home and abroad have conducted extensive studies on soil covering devices on various seeders. The basic structural forms of the soil covering device mainly include three types:

the eight-shaped plate soil covering device, the double disc soil covering device and the extrusion type soil covering and pressing wheel *(Feng et al., 2025; Wu et al., 2024; Liu et al., 2023; Geng et al., 2022; Zhang et al., 2024., Guo, 2019).* Researchers have also conducted research and analysis on the soil covering performance. Lu Qi et al. first constructed a discrete element model of the interaction among soil, seeds and soil covering devices, breaking through the limitations of the traditional "soil-machine" binary simulation and laying the foundation for the parameter optimization of soil covering devices *(Lu et al., 2024).* Liu Fang et al. designed an arc-shaped double-toothed disc soil covering device in response to the fact that traditional scraper or disc soil covering devices are prone to causing fluctuations in soil covering thickness, resulting in exposed seeds or overly deep soil covering, which improved the uniformity of sowing *(Liu et al., 2024).* Inspired by the digging feet of the Oriental mole cricket, Zhang *Zhijun et al. (2018)* designed a bionic soil-breaking disc soil-covering device by measuring key parameters of the insect's toe claws to enhance the soil-breaking performance of a soybean planter. In order to improve the uniformity of seed distribution and the consistency of soil covering thickness, Li Liyan designed a new type of soil covering device with separate discs placed at the front and back. This enables the soil covering volume of two sets of discs to be the same as that of a traditional set of discs, avoiding the drawback of excessive soil covering volume at one time causing significant displacement of seeds *(Li et al., 2017).*

Inspired by the efficient ability of sand crab claws to manipulate sandy soil, this study designed a disc-type soil covering device based on the bionic shape of its teeth. The contour features of the claw legs of sand crabs were digitally extracted using MATLAB and applied to the tooth shape design to enhance the adaptability to sandy loam soil and operational performance. By analyzing the operation mechanism of the device, it was determined that the installation inclination angle, deflection angle and the distance between the rear openings were the key adjustable parameters. To optimize performance, taking the qualified rate of soil cover thickness and the difference in seed lateral displacement as indicators, an interaction model of sandy loam - seed - device was established using EDEM *(Lu et al., 2023)*, and based on this, single-factor and Box-Behnken response surface tests were carried out to seek the optimal parameter combination to improve the uniformity of soil cover and the accuracy of seed positioning.

MATERIALS AND METHODS

The working principle of the soil covering device

The operation process of the soil covering device (Fig.1) consists of three stages: soil insertion, stabilization operation and soil removal. The device is inserted into the soil at an angle, and its deflection angle drives the toothed cutting edge to push the soil laterally, guiding the soil to converge towards the center line to evenly cover the seed furrows. The thickness of the soil cover is dynamically controlled based on the principle of volume conservation through the deflection angle (to regulate the amount of soil pushed) and the spacing of the rear openings (to regulate the concentration of the soil cover). This process of "tangential soil insertion - directional soil transportation - precise soil covering" adapts to the fluidity of sandy loam soil and builds a stable seed bed for seeds.

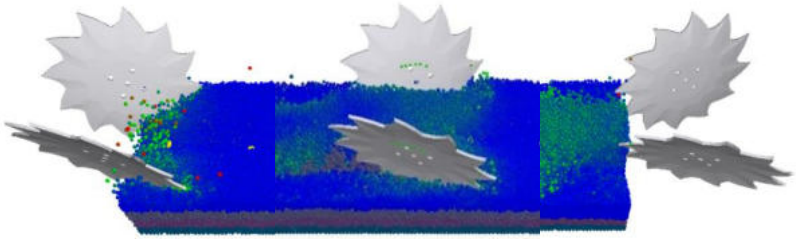

Fig. 1 - Working process of the soil covering device

a) Soil insertion stage; b) Stable operation stage; c) Excavation stage

Tooth profile design of the soil covering device

When the soil covering device is in operation, it mainly achieves soil covering by pushing the soil laterally. However, while its tooth shape pushes away the soil, it is prone to exert lateral forces on the soil and seeds, causing the seeds to shift and thereby disrupting the uniformity of soil coverage and the straightness of the seed rows. To effectively inhibit the lateral sliding of seeds, this study adopted bionics principles and drew on the tooth shape of the claw legs of sand crabs to optimize the design of the soil covering device.

The contour curve of the claw teeth of the sand crab was extracted using MATLAB software, as shown in Fig. 2a. Some of the curves were fitted through MATLAB software, and the fitting process is shown in Fig.2b.

The extracted data coordinates of the outer contour points are imported into the MATLAB curve fitting machine, with the X-axis and Y-axis representing the horizontal and vertical coordinates of the contour points respectively, with the unit being mm. The outer contour curve was fitted using an eighth-degree polynomial function, as shown in Equation (1):

$$y = -1.714x^8 + 2.659x^7 + 8.724x^6 - 13.98x^5 - 12.96x^4 + 25.88x^3 - 6.283x^2 - 17.39x + 756.8 (R^2 = 0.9957) \quad (1)$$

The coefficient of determination $R^2 > 0.99$, indicates that the fitted curve closely matches the actual biometric contour, demonstrating a high level of fitting accuracy.

Studies have shown that the number of notches on the grass-pulling wheel and the notch disc typically ranges from 8 to 15 *(Liu et al., 2024).* Although the uniformity of soil cover is high when the number of teeth is greater than 15, it also leads to increased forward resistance and wear. If the number of teeth is less than 10, uneven soil covering will cause the seed furrows to collapse. Therefore, 12 teeth were selected, and the spacing between the teeth can effectively inhibit the flow of sandy loam soil.

Diameter design of the soil covering device

Using the fitted equation as a reference, a bionic soil covering device was modeled in SolidWorks 3D software. As the device falls under the category of disc rakes, its key design parameters were calculated based on empirical formulas commonly used for shallow tillage disc rakes *(Lu et al., 2024; Liu et al., 2024)*. The structural schematic of the device is shown in Figure 3.

a) ***b)***

Fig. 3 - Schematic diagram of the soil covering device structure

a) Structural parameters of the soil covering device; b) Three-dimensional modeling of the soil covering device

$$D = kH \quad (2)$$

where: D is the diameter of the bionic soil covering device, [mm]; k is diameter to depth ratio coefficient; H is maximum designed depth of penetration into the ground, [mm].

The sowing depth of corn is generally 30 to 50 mm. The soil in this study is sandy loam with poor water retention. Therefore, the sowing depth was taken as 50 mm, and the maximum depth of penetration was 60 mm. The k value of the disc is generally taken as 4 to 6 *(Liu., 2025)*. Thus, the diameter of the bionic soil covering device is ≤ 360 mm.

Considering that sandy loam soil has loose particles, low viscosity and is prone to being scattered during soil covering operations, the diameter should be designed to avoid splashing of sandy loam soil. The formula is:

$$D \geq \frac{v^2}{g tan\varphi} \quad (3)$$

where: v is the operating speed of the seeder, taken as 0.8 to 1.4 m/s; g is acceleration due to gravity, taken as 9.8 m/s; φ is the angle of repose in sandy loam soil, taken as 28° to 32°.

After calculation, it can be found that the critical diameter of the bionic soil covering device for avoiding sandy loam soil splashing is ≥ 346 mm, and the final selected diameter is 360 mm.

Thickness design of the soil covering device

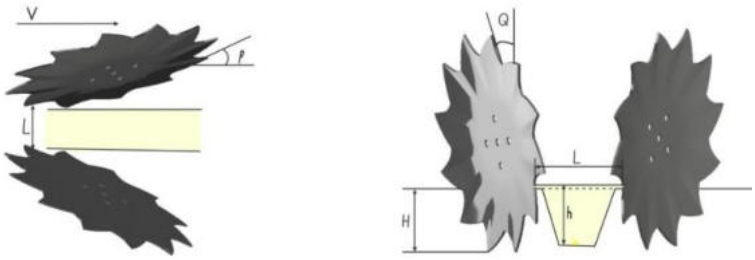
The selection of the thickness of the bionic soil covering device is related to the depth of the device's penetration into the soil and the size of the working load *(Bai., 2019)*. It was calculated by the empirical formula: $b = (0.008 \sim 0.012)D$

The thickness b of the bionic soil covering device was calculated to range between 2.88 and 4.32 mm. Given that sandy loam contains a high proportion of hard, abrasive sand particles, excessive wear at the device's edge can lead to failure. Additionally, a thinner and lighter disc lacks sufficient rigidity, which may increase vibration and negatively impact soil covering uniformity. Therefore, a thickness of b=4 mm was selected for this study.

Design of other structural parameters of the soil covering device

In sandy loam soil, the spherical radius R is the key to regulating the stability and resistance of flow diversion. Reducing the spherical radius R can enhance the directional restraint of the soil, but the frictional resistance increases significantly. Although increasing the spherical radius R reduces resistance, it weakens the accuracy of flow guidance. The design experience formula is:

$$R = \frac{D}{2\sin\phi} \tag{4}$$



where: ϕ is spherical center angle, taken as 21 to 27 degrees, [°].

After calculation, 396≤R≤502, and finally R=450 mm was selected.

Under the condition of ensuring the strength of the cutting edge and allowing the manufacturing process, the cutting edge angle should be taken as small as possible to reduce the resistance of cutting soil. The common range of cutting edge angles is 14°30' to 22° *(Chinese Academy of Agricultural Mechanization Sciences., 2007)*, so α is taken as 15°.

Analysis of the Relationship between Installation Parameters and Soil Cover Volume

Based on the principle of volume conservation per unit time, the volume of soil pushed by the soil covering device ≈ the volume of soil covering. The parameter ranges of the installation deflection angle *P*, installation inclination angle *Q* and the distance *L* of the rear opening of the bionic soil covering device were calculated, as shown in Fig. 4

a) ***b)***

Fig. 4 - Schematic diagram of the relationship between the bionic soil covering device and the soil in the seed furrow

$$h \times L \times v = A_d v$$

$$A_d = k \times D \times H \times \sin P \times \cos Q$$

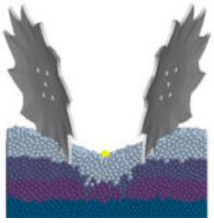
$$h = \frac{25920 \times \sin P \times \cos Q}{L} \geq 50 \tag{5}$$

where: h is requirements for soil cover thickness, h≥50 mm; v is the forward speed of the seeder, v =1.4 m/s; k is soil displacement efficiency coefficient of the soil covering device, k=1.2; A_d is the cross-sectional area of the soil pushed by the soil covering device; L is rear opening spacing, [mm]; D is diameter of the soil covering device, D=360 mm; H is the depth of the soil covering device's penetration into the soil, H=60 mm; Q is installation inclination angle, [°]; P is installation bias angle, [°].

After calculation, it can be determined that the rear opening spacing of the bionic soil covering device is 90 mm <L< 125 mm, the installation inclination angle is 15°< Q < 30°, and the installation deflection angle is 17°< P <30°. Due to the high fluidity of sandy loam soil, to avoid uneven soil cover caused by excessive soil dumping, the lower limit of the deflection angle was extended to 10°.

Establishment based on the EDEM simulation model

Based on the research on the qualified rate of soil covering thickness and the standard deviation of lateral displacement of the bionic soil covering device, solid modeling was carried out using SolidWorks 3D software and imported into EDEM in step format to establish a corn seed model and a soil trough model with a length, width and height of 1500×300×180 mm. Considering the soil characteristics of sandy loam, the Hertz-Mindlin (no slip) model in EDEM software was adopted as the contact model *(Hao et al., 2020)*. The simulation model of the sandy loam - seed - bionic soil covering device established is shown in Fig. 5.



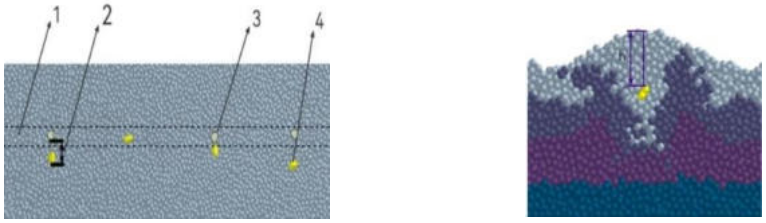


Fig. 5 - Simulation model establishment of soil-seed-soil covering device

The corn seeds are located in the middle of the seed trench, evenly distributed with a total of 8 seeds. Given the small sample size and relatively large error, the number of seeds per replicate was increased to eight. Seeds were sown in the same row for ten consecutive replicates, resulting in a total of eighty seeds. As shown in Fig. 6a, the horizontal offset of the actual position of a single seed after soil covering operation relative to its position before soil covering in the direction perpendicular to the sowing advance is called the lateral displacement S. By statistically analyzing the lateral displacement of the seeds, the standard deviation of the lateral displacement of the seeds was calculated to represent the straightness of the seed rows. The thickness of the soil cover above 80 seeds was measured using the Ruler tool in the post-processing of EDEM, as shown in Figure 6b. A thickness of 40 mm < soil cover thickness h<60 mm is considered qualified, Pass rate $\eta = \frac{\sum_{i=1}^{N} I(h_i)}{N} \times 100\%$ .The basic parameters of discrete element simulation obtained through literature are shown in Table 1 *(Lin et al., 2022; Wang et al., 2017)*.

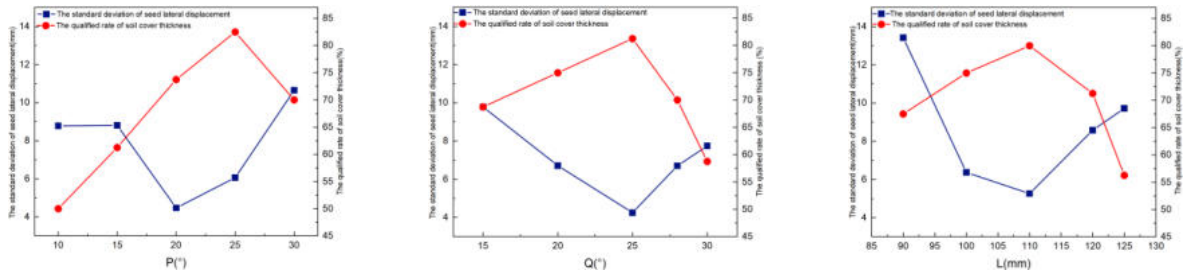
Table 1

Basic parameters of discrete element simulation model

Parameters	Numerical value
Soil density [kg·m^{-3}]	1.39
Soil Poisson's ratio	0.4
Soil shear modulus [Pa]	1.09e+07
Steel density [kg·m^{-3}]	7.85
Steel Poisson's ratio	0.26
Steel shear modulus [Pa]	8.0e+10
Soil - soil recovery coefficient	0.15
Soil-soil static friction coefficient	0.27
Soil-soil kinetic friction coefficient	0.70
Soil-steel plate recovery coefficient	0.50
Soil-steel plate static friction coefficient	0.75
Soil-steel plate kinetic friction coefficient	0.15



Single-factor trial

Based on the structural design and working principle analysis of the bionic soil covering device, the structural parameters that affect the performance of soil covering operations, namely the installation deflection angle P, installation inclination angle Q, and rear opening spacing L, were selected as the test factors. The influence of each factor on the soil covering thickness and the standard deviation of the seed lateral displacement was analyzed. According to the actual operation of the seeder, the forward speed of the equipment was set at 1.4 m/s. The levels of the single-factor test are shown in Table 2, and the test results are presented in Fig. 7.

Table 2

Single-factor test factor levels for the operation effect of the soil covering device

level	installation deflection angle [°]	installation inclination angle [°]	opening spacing behind the soil covering tray [mm]

4	25	28	120
5	30	30	125

a) *b)* *c)*

Fig. 7 - Results of the single-factor simulation test

To ensure the uniformity of soil covering and the straightness of seed rows, a larger amount of soil covering and a smaller standard deviation of seed lateral displacement are required. As shown in Fig. 7a, the pass rate of soil cover thickness is the highest when the deflection angle is 25°. When the deflection angle is less than 15°, the pass rate is low due to insufficient soil throwing. If the deflection angle is greater than 25°, it will decrease due to excessive scattering and insufficient soil covering at the center. The standard deviation of the lateral displacement of the seeds is the lowest when it is 20°, because the soil reflux path is the optimal. If the deviation angle is too large or too small, the seeds will shift sideways due to the imbalance of soil flow direction. After comprehensive consideration, the recommended installation deflection angle ranges from 15° to 25°.

As shown in Fig. 7b, the qualified rate of soil cover thickness increases slowly with the increase of inclination angle, reaching the peak at 25°. When the inclination angle is less than 20°, the qualified rate is low due to the formation of soil ridges on both sides of the seed furrows and insufficient soil covering in the center. The inclination angle greater than 28° drops due to soil being flung out of the seed furrows and insufficient backfilling. The standard deviation of the lateral displacement of the seeds changes gently between 15° and 25°, and increases significantly between 25° and 30° (if the inclination angle is too high, the soil cover is roughly insufficient, and the seeds exposed on the surface are affected by vibration, resulting in a sudden increase in displacement). To ensure the qualified rate of soil covering and the straightness of the seed rows, the installation inclination angle should be selected between 20° and 28°.

As shown in Fig. 7c, the qualified rate of soil cover thickness increases with the subsequent opening spacing, reaching a maximum at 110 mm. When the spacing is less than 100 mm, the narrow and congested passage leads to discontinuous soil coverage, resulting in a low pass rate. Conversely, if the spacing exceeds 120 mm, the qualified rate decreases due to poor soil concentration and insufficient coverage on both sides of the seed trench. The standard deviation of the lateral displacement of the seeds is the lowest when it is 110 mm (uniform soil coverage ensures balanced force on the seeds). To ensure the stability and continuous uniform soil coverage of the seeds, the spacing of the rear openings should be selected as 100 mm to 110 mm.

RESULTS

Box-Behnken Design Simulation Tests

Based on the single-factor test, taking the installation deflection angle P, inclination angle Q, and rear opening spacing L as factors, and the qualified rate of soil cover thickness and the standard deviation of seed lateral displacement as indicators, a three-factor and three-level Box-Behnken test was conducted to explore the relationship between the key factors and the indicators. The codes of the experimental factors are shown in Table 3, and the protocols and results are presented in Table 4.

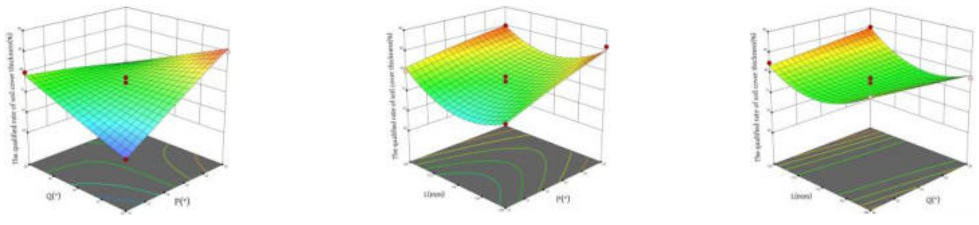
As can be seen from Table 4, when the installation deflection angle P=25°, the installation inclination angle Q=24°, and the rear opening spacing L=100 mm, the minimum standard deviation of the seed lateral displacement is 2.13 mm, and the maximum qualified rate of the soil cover thickness is 86%.The results of the analysis of variance (see Tables 5 and 6) indicate that the installation deflection angle P, inclination angle Q, and rear opening spacing L have extremely significant effects on the standard deviation *(Z)* of the seed lateral displacement and the qualification rate *(F)* of the soil cover thickness, and the regression equations of Z, F with P, Q, and L have been established. Based on the analysis of the influence of the interaction of P, Q and on Z and F by Design-Expert, the response surfaces are shown in Fig. 8 and 9.



$$Z = +3.89 - 0.5237P - 0.2800Q + 0.7938L + 1.38PQ + 0.5350PL - 0.8225QL - 0.3720P^2 + 0.9805Q^2 + 0.2730L^2 \quad (6)$$

$$F = +77.50 + 3.25P + 1.12L - 5.31PQ - 1.19PL + 1.56QL - 0.3438P^2 + 0.0313Q^2 + 4.66L^2 \quad (7)$$

a) *b)* *c)*

Fig. 8 - Response surface illustrating the interaction effects of various factors on the standard deviation of seed lateral displacement

a) *b)* *c)*

Fig. 9 - Response surface illustrating the interaction effects of various factors on the qualification rate of soil cover thickness

Experiments show that P, Q and L all affect Z and F. To obtain the optimal parameters of the device, the Design-Expert optimization module was utilized for optimization.

The objective function and constraint conditions are: $\begin{cases} min\, Z\,(P,Q,L) \\ max\, F\,(P,Q,L) \\ 20^\circ \le P \le 25^\circ \\ 20^\circ \le Q \le 28^\circ \\ 100\text{mm} \le L \le 120\text{mm} \end{cases}$

The optimal parameter combination that satisfies the constraint conditions was obtained as follows: when the installation deflection angle is 21.3°, the installation inclination angle is 20.1°, and the installation spacing is 100.0 mm, the standard deviation of the seed lateral displacement is 3.1 mm, and the qualified rate of the soil cover thickness is 85.0%.

CONCLUSIONS

1. Considering the characteristics of sandy loam soil and soil covering requirements, a bionic soil covering device was optimized. Using MATLAB, the claw profile of the sand crab was fitted ($R^2 > 0.99$) to realize continuous operations of "tangential soil entry–directional transport–precise covering," which enhanced soil adaptability while ensuring uniform covering thickness and the straightness of the seed rows.

2. Theoretical analysis defined the test factor ranges, and single-factor simulations via the discrete element method were conducted. Installation deflection angle *(P)*, inclination angle *(Q)*, and rear opening spacing *(L)* were selected as variables, while the standard deviation of seed lateral displacement *(Z)* and soil covering qualification rate *(F)* served as evaluation indices. A regression model between *(P, Q, L)* and *(Z, F)* was developed using Box-Behnken design. The optimal parameter set was determined as P = 21.3°, Q = 20.1°, and L = 100.0 mm.

ABSTRACT

This study used SolidWorks to create a chili harvester model, 3ds Max to create planting terrain and chili plant models, and developed a virtual simulation platform for chili harvesting experiments based on Unity 3D. Finally, the feasibility of the virtual simulation platform was confirmed through human-machinery interaction effects and virtual simulation harvest experiments, which can provide reliable training and research data, solve the drawbacks of on-site training and testing, and contribute to the sustainable development of China's chili industry.

摘要

本研究应用 SolidWorks 创建辣椒收获机模型，应用 3ds Max 创建种植地形和辣椒植物模型，以及基于 Unity 3D 开发了一款的辣椒收获实验虚拟仿真平台。最后，通过人机交互效果和虚拟仿真收获实验证实了该虚拟仿真平台的可行性，能够提供可靠的训练和研究数据，解决了场地培训、试验的弊端，有助于中国辣椒产业的可持续化发展。

INTRODUCTION

China has been an agrarian society since ancient times, with a continuous history of farming and animal husbandry spanning over ten millennia. Throughout the extended period of traditional agricultural economy, ancestors created a splendid farming civilization through their diligence and wisdom *(Peng et al., 2011)*. Against the backdrop of China's comprehensive rural revitalization and accelerated modernization of agriculture and rural areas, it is of significant practical importance to provide mechanical harvesting training for agricultural engineering students and new-era professional farmers. By conducting harvest training experiments on crops, it can cultivate students' passion for agriculture, enhance the skills of new-era professional farmers, and accelerate the translation of agricultural machinery R&D achievements into field applications *(Liu et al., 2023)*.

However, field experiments for pepper harvesting face limitations such as seasonal constraints, farming cycles, and weather dependencies, resulting in prolonged timelines and high costs. To address these challenges, this study developed a virtual simulation platform for pepper harvesting experiments based on Virtual Reality (VR) technology.

In recent years, with the rapid advancement of computer and information technologies, virtual reality (VR) technology has emerged as a powerful tool grounded in computational systems. Leveraging its immersion, interactivity, and simulation capabilities, VR has been successfully implemented across diverse domains such as industry, agriculture, medicine, military, and education. The progress in VR has further facilitated the digitization and visualization of operational processes, offering innovative solutions to challenges in experimental training and practical applications *(Seth et al., 2011)*.

Both domestic and international researchers have conducted numerous explorations in utilizing VR technology to showcase cultural heritage and disseminate traditional culture.

For instance: *Zhang et al. (2011)* from Beijing Forestry University employed VR technology to design and implement a virtual landscape of the Northern Song Dynasty imperial gardens; *Liu et al.(2010)* from Northwest University reconstructed a 3D digital model of the Small Wild Goose Pagoda from the Tang Dynasty by acquiring point cloud data; *Chen Yan et al. (2019)*, *Wang Jianxiang et al. (2022)* developed a virtual simulation platform for mechanized corn harvesting based on Unity 3D respectively, conducting harvest simulation experiments under various conditions such as different operating speeds and plant densities. *Liu et al. (2014)* established a virtual testing platform for sprinkler irrigation vehicles using Unity 3D and *Li et al. (2017)* created a virtual demonstration platform for ancient Chinese farming scenes based on Unity 3D. Other similar research has been conducted by *Cheng et al. (2018),* who studied the performance of combined forest harvesters through a Unity 3D-based virtual training system; *Lü et al. (2015)* developed a virtual fruit tree pruning platform using Unity 3D and *Cheng et al. (2018)* designed a virtual exhibition platform for agricultural culture based on Unity 3D.

The aforementioned studies demonstrate that numerous scholars and experts in China have conducted extensive research on virtual reality technology. Developing virtual simulation platforms based on virtual reality technology can effectively demonstrate operational processes, showcase cultural and product features, and exhibit market potential. Among these, Unity 3D, as an engine for virtual reality system development, can create high-quality 3D virtual simulation environments with immersive experiences. By using the C# scripting language to develop control programs, it enables interactive behaviors between objects, revealing the principles of their interactions *(Yan et al., 2013; Liu et al., 2014).* This provides valuable references for the related research in this paper.

Although numerous researchers have developed virtual simulation platforms using VR technology, no existing studies have specifically addressed interactive virtual simulation for pepper harvesting operations. As the world's leading producer and consumer of peppers, with cultivation widespread across China's agricultural regions, peppers represent both a nutritionally valuable vegetable containing unique bioactive compounds and a significant cash crop for natural pigment extraction *(Zhang et al., 2021; Du et al., 2023)*. Given this agricultural importance, the present study establishes pepper as the target crop for developing an interactive virtual simulation platform of mechanized harvesting processes using Unity 3D. This innovative platform will not only simulate the complete mechanized harvesting workflow but also enable comprehensive performance evaluation of pepper harvesting machinery *(Wang et al., 2024)*.

MATERIALS AND METHODS

Structure of pepper harvesters

The pepper harvester consists of several key components: a picking device, conveying mechanism, cleaning and separation mechanism, collection bin, chassis, power transmission system, and hydraulic control system. Fig. 1 illustrates the schematic diagram of a typical pepper harvester structure. The key components are numerically labeled as follows: *1*. spring-tooth drum picking device, *2*. operator control cabin, *3*. primary conveying system, *4*. operator seat, *5*. engine and power transmission assembly, *6*. cleaning and re-picking device, *7*. secondary conveying system, *8*. auto-discharging collection bin, *9*. crawler-type traveling mechanism, *10*. belt pulley assembly, *11*. sprocket-chain transmission set.

Among these components, the picking device serves as the most critical part of the pepper harvester, as shown in Fig. 2. The key components are numerically labeled as follows: *1.* steel frame, *2.* upper cover plate; *3.* shield cover plate; *4.* left side plate; *5.* driving shaft; *6.* imitate terrain roller; *.7* left divider; *8.* spring finger cylinder; *9*. roller for bending branches; *10*. right divider. It performs dual functions of combing and conveying peppers, directly determining the machine's overall harvesting efficiency and quality *(Song et al., 2024)*.

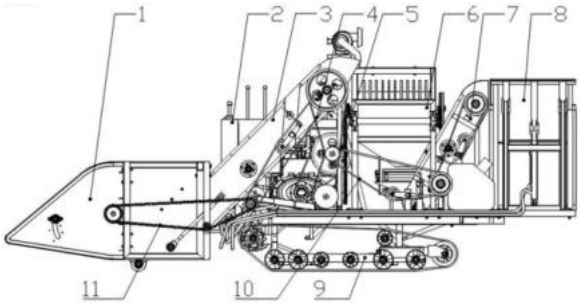

Fig. 1 - Schematic diagram of pepper harvester structure

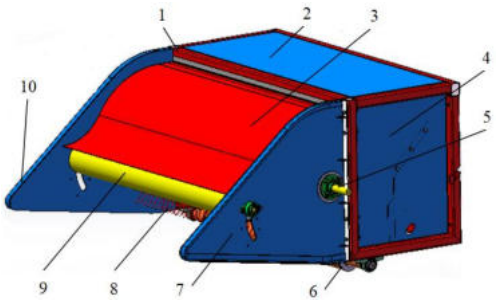

Fig. 2 - Structure model of pepper picking device

Working principle of pepper harvesting

During field harvesting operation, the pepper harvester advances forward with its picking device. The terrain-following wheels maintain continuous ground contact, providing stable support for the picking assembly. The pressure roller first bends the taller pepper plants to an optimal harvesting angle for spring-tooth drum picking. The spring-tooth drum rotates clockwise at 180-220 rpm, with the flexible teeth executing a combined action of impact detachment, frictional removal, and combing collection. Then, the peppers picked attain an initial velocity, and the subsequent trajectory controlled by its gravity acceleration, aerodynamic resistance, and the guide baffle's surface geometry. Then, the chili peppers enter the primary conveyor along the rotating path of the drum for next process under the interaction of multiple factors *(Du et al., 2024; Zhou et al., 2024)*. Fig. 3 schematically illustrates this dynamic harvesting process.

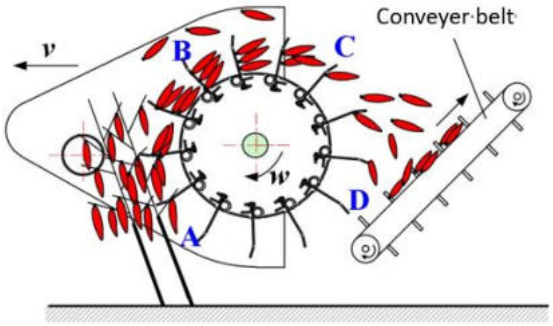

Fig. 3 - Schematic diagram of spring-tooth drum pepper picking mechanism

Development logic of virtual simulation platform

The virtual simulation platform for mechanized pepper harvesting was developed using Unity 3D within a Client-Server (C/S) architectural framework. As shown in Fig. 4, the system implements a structured five-layer architecture consisting of model layer, data layer, service layer, development layer, application layer. This hierarchical architecture offers several technical advantages: modular system design enabling component-based development, clear functional decoupling between layers, scalable infrastructure for future capability expansion, distributed computing support through C/S architecture.

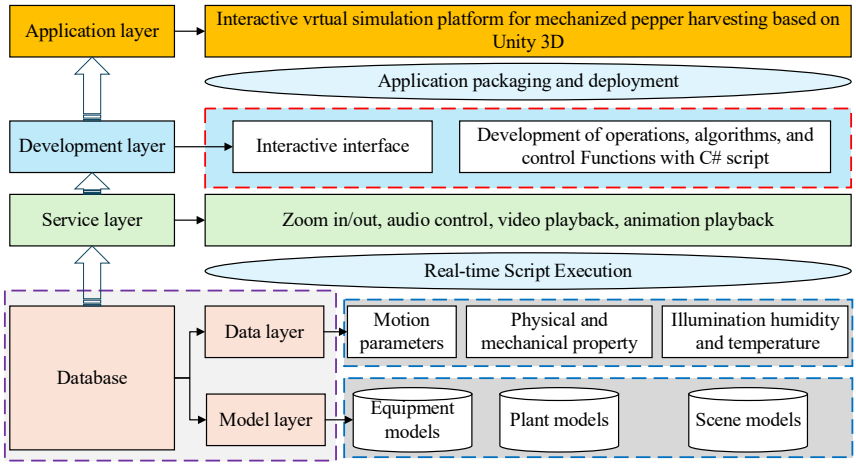

Fig. 4 - Hierarchical structure diagram for development of the virtual harvest simulation platform

The model layer provides basic resources for the virtual harvest simulation system, including virtual models of chili harvesters, chili plant models and environment models designed by 3D modeling software such as SolidWorks and 3D Max *(Xiang et al., 2014)*. Data layer is used to manage agricultural datasets and operational parameters. The service layer is used to make real-time calls to the model library and database, enhancing the performance of the simulation system, such as configuring animation playback, interface zooming in and out, background sound, etc.

The development layer is located between the service layer and the application layer, and is the central hub of the system, including control programs edited in C # language, statistical algorithms for harvesting chili peppers, view stitching algorithms, and other script files, as well as human-machinery interaction interfaces. The data collected by the application layer can be sent to the service layer, and the data feedback from the service layer can be sent to the application layer for display.

The application layer is located at the outermost layer of the entire system, which packages the various modules of the system logically and hierarchically before publishing the application program, thus forming a set of application programs with functions such as interface display, human-machinery interaction, and data input.

Structural framework of the virtual simulation platform

Based on the working principles of pepper harvesters and the development logic of virtual simulation platforms, the structural framework of the mechanized pepper harvesting virtual simulation platform is shown in Fig. 5. The virtual simulation platform consists of six core modules, which are interface & perspective observer, pepper harvester model manager, pepper plant models manager, environment observer, models base, and database.

Interface & perspective observer is used to provide user interaction and multi-angle visualization by setting the camera follows mode. Pepper harvester model manager is used to provide configurable component models for harvesters, such as picking device model, material conveying mechanism model, walking mechanism model, and steering system model. Pepper plant model manager is used to provide chili plant virtual model and planting patterns. The harvesting operation environment model includes sunlight, sky, fields, trees, buildings, etc. Model base stores 3D component models. The database is used to store various characteristics and motion parameters of chili harvesters, harvest data, as well as various parameters of chili plants.

In addition, to achieve an interactive virtual simulation platform for mechanized harvesting of chili peppers, rigid body properties and physical collision functions should be added to the virtual models, and script files should be edited using C # language in the Unity 3D development environment.

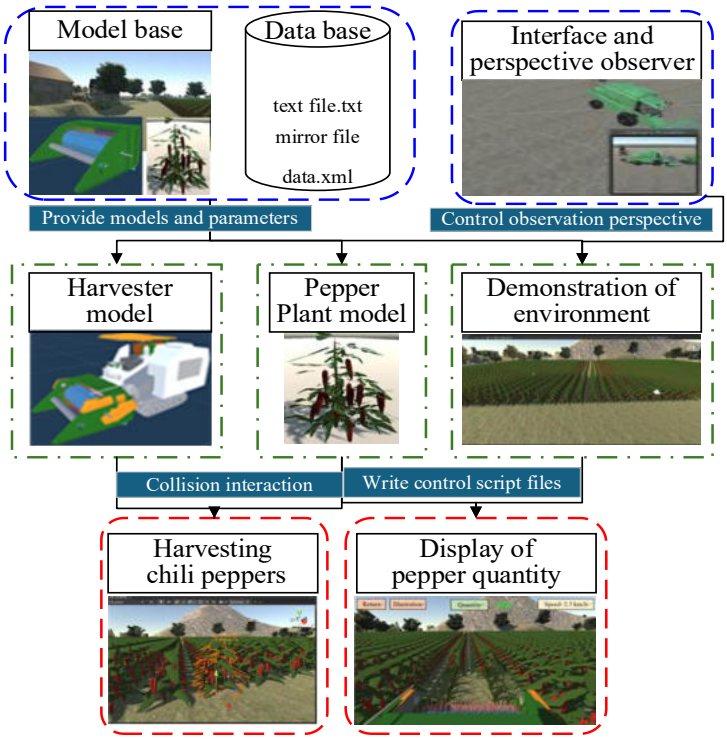

Fig. 5 - System architecture diagram of chili harvesting virtual simulation platform

Technical process of virtual simulation platform development

Development of the virtual simulation platform follows the relevant technical development flowchart, as illustrated in Fig. 6. Firstly, collect relevant data of the pepper harvester, pepper plants, and virtual harvesting scene, create 3D models using SolidWorks and 3D Max, followed by optimization, rendering, and unit/size format conversion; Secondly, import the constructed models into Unity 3D software for editing, and create a virtual farm scene using the Terrain component in Unity 3D software. Once again, design rigid body components and collider components for the constructed models to enable physical interactions, and add sound and animation playback, write application programs, and implement the relevant functions and harvesting tasks of the virtual harvester. Finally, generate the application software and conduct relevant virtual simulation experiments.

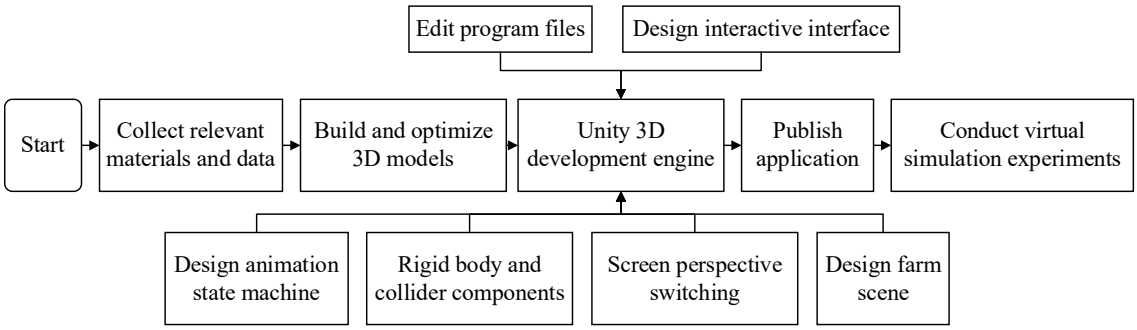

Fig. 6 - Relevant technical development flowchart

Development of virtual simulation platform

Under the structural framework of the interactive virtual simulation platform, adhere to the technical workflow for virtual simulation platform development to develop 3D virtual models for each component, design the UI interactive interface, integrate attribute components, and design control strategies and corresponding programs, thereby realizing the interactive functions of the virtual simulation platform and achieving the simulation effect of chili pepper mechanized harvesting.

Virtual model of chili harvester

Taking a certain chili pepper harvester as a reference, a three-dimensional model of the pepper harvester was established using SolidWorks, the key components include picking device, material conveying mechanism, cleaning and separation mechanism, aggregate box, walking mechanism, and hydraulic control system, as illustrated in Fig. 7. Among them, the picking device is the core harvesting component for pepper, consisting of spring teeth and roller. The 3D model was then imported into 3D Max for texture rendering and optimization before being exported in .fbx format for compatibility with the simulation platform.

Virtual model of pepper plants

A three-dimensional model of peppers and pepper plant was established based on relevant parameters of chili peppers, as shown in Fig. 8. To optimize performance and reduce computational load, the model underwent texture mapping and rendering in 3D Max, then exported as an .fbx file for importing into Unity 3D.

Construction of terrain model

The virtual farm terrain was constructed using Unity 3D's built-in Terrain Toolkit, enabling realistic topographical features such as elevation variations, soil textures, and crop row layouts. Key parameters (e.g., field size, slope gradient) were calibrated to match real-world harvesting conditions, as shown in Fig. 9.

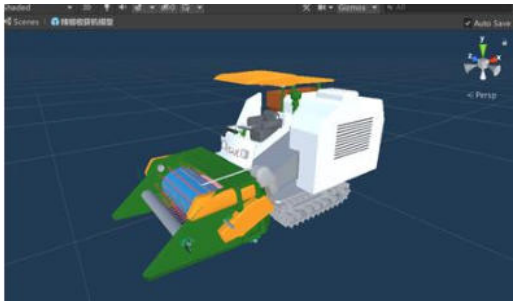

Fig. 7 - Virtual model of pepper harvester

Fig. 8 - Pepper plant model

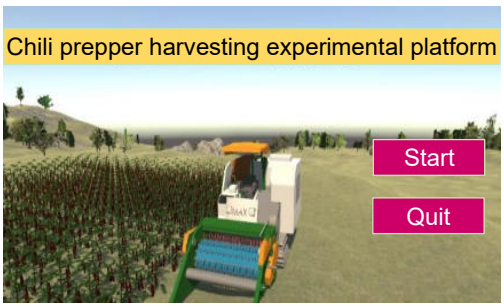

Fig. 9 - Terrain model

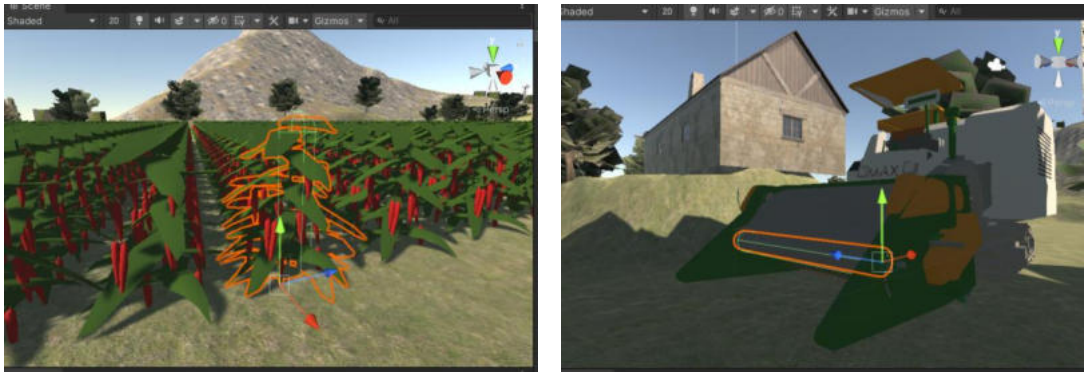

Configuration of rigid body and collider properties

To accurately simulate the physical interactions between the chili pepper harvester and pepper plants within the virtual environment, rigid body and collider components were assigned to both models. This implementation ensures the pepper harvester and pepper plant models adhere to Newtonian motion laws, enabling authentic collision responses (e.g., plant displacement during harvesting), *(Wu et al., 2018)*.

There are six types of colliders provided by Unity 3D software to simulate physical interactions: Box Collider, Sphere Collider, Capsule Collider, Wheel Collider, Terrain Collider, and Mesh Collider. Each type of collider is strategically implemented based on its unique characteristics. Box Collider is applied to the harvester body for optimal performance due to its simple geometry, low computational overhead, and fast processing speed. Mesh Collider is utilized for high-precision collision detection, matching the complex geometry of the cutting surface with accurate mesh representation.

Wheel Collider is implemented for realistic wheel physics, featuring integrated collision detection, physical parameters, and a slip-based tire friction model. Terrain Collider is assigned to the field plot to provide ground physical properties and support all 3D models within the scene, to avoid model penetration (e.g., harvester falling through terrain) *(Wang et al., 2022)*. Capsule Collider is custom-fitted to both the chili pepper plant model and toothed roller model to enable accurate collision detection during harvesting operations, as shown in Figures 10 (a) and 10 (b).

This script executes the picking action when the toothed roller interacts with chili peppers, ensuring realistic harvesting behavior.

Animation state machine

An animation state machine is a control system designed to manage the sequential or conditional transitions between discrete animation states of a character or object. By partitioning complex animation sequences into modular, action-specific segments (e.g., "idle," "walk," "attack"), it enables dynamic state transitions triggered by in-timeline events, user inputs, or programmatic logic. Widely adopted in game development and interactive applications, this system streamlines animation control by defining states (distinct animation phases) and transition rules (conditions for switching between states), ensuring efficient, scalable, and maintainable animation pipelines.

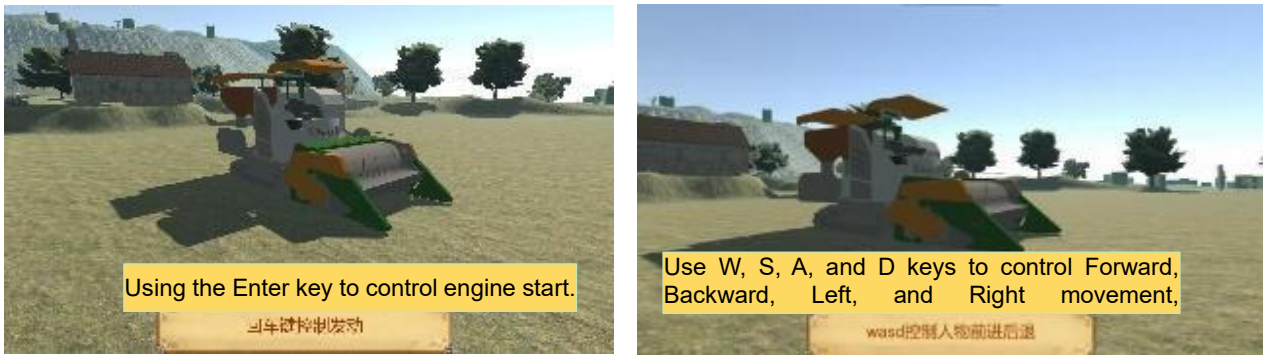
The process of mechanized harvesting of chili peppers includes multiple animation states such as users getting on a harvester, starting the engine, adjusting the height of the cutting table, adjusting the operating speed, controlling the movement of the harvester, and picking chili peppers. Therefore, the animation can be controlled and serialized using the functions of the animation state machine, achieving modular editing and improving the maintainability and reusability of the control code.

The design process of an animation state machine is as follows: Firstly, complete the entire animation process of operating the chili harvester using 3D Max software, and focus on the start and end frames of each animation segment for each operating state. Then, group the "*.fbx*" format files according to their animation states and divide them into animation segments. Drag and drop the divided animation clips to the already created state machine to assign attributes and create animation transition lines. Write relevant code programs to drive trigger functions on the timeline, so as to enable an animation to be called at a certain time node and complete the transformation of the animation.

First-person navigation and view control

To enhance user immersion and experience, a first-person navigation system has been applied in the virtual environment. The first-person navigation system enables users to freely explore the scene and control their viewing perspective through intuitive keyboard and mouse inputs. Create script files within the character controller to manage movement and viewpoint rotation. Implementation details include configuring appropriate motion parameters (such as speed, gravity, etc.), using the W/S keys to control forward and backward movement, A/D keys to control left and right steering, and Q/E keys to control vertical movement (up/down). Right-click and drag to activate 'View Control' for adjusting the camera's rotation and orientation.

This implementation provides users with an intuitive and immersive navigation experience while maintaining optimal performance within the virtual environment. The system can be easily modified to accommodate different movement styles or control schemes as needed.



Design and implementation of UI Interface

A human-computer interaction system was designed through the graphical user interface (GUI) in Unity3D, utilizing the built-in UI system for optimal functionality and user experience. In order to ensure the user experience of the UI interface, the creation of UI components, button configuration, visual design parameters, interactive functions, and other aspects need to be carefully designed. The implementation process included the creation of a hierarchical UI structure consisting of a main control panel, function-specific submenus, and a status display area. Each button was configured with multi-state visual settings, event listeners for click actions, associated sound effects, and tooltip information for hover events. Interaction handling was implemented using Unity's EventTrigger component, custom C# scripts for complex interactions, and animation controllers to provide smooth transitions.

RESULTS

Human- harvester interaction operation effect

Upon logging into the PC-based virtual simulation platform, users can engage in practical simulation operation training. When a user is outside the chili pepper harvester, the W, S, A, and D keys on the keyboard enable control of the user's movements, supporting forward, backward, left, and right turns. Upon reaching the proximity of the virtual chili pepper harvester model and pressing the F key (designated as the "boarding" action), the user enters the harvester's cab. At this point, the control target shifts to the harvester itself, transitioning to a first-person perspective for direct operation of the pepper harvester model. Then, the engine can be started by pressing the "Enter" key on the keyboard, accompanied by a realistic "rumbling" startup sound (Fig.11 a). Following engine ignition, movement control - forward, backward, left, and right-is enabled via the W, S, A, and D keys, delivering an immersive operational experience that closely mimics real-world harvester work (Fig.11 b).

a) b)

Fig. 11 - Control of the motion state of the virtual pepper harvester

a) Engine start; b) Harvester movement: forward, backward, left/right steering

The virtual simulation results demonstrate that the mechanized pepper harvesting simulation platform effectively supports human-machine interaction, confirming the feasibility of the proposed design.

Demonstration and analysis of the effect of pepper harvest experiment

Within the UI interactive interface, clicking the "Experiment" button activates the chili harvesting experiment module. From a first-person perspective, users perform pre-operation preparations such as adjusting the picking device height above the ground and shifting gears. Once the harvester is started, users can switch to a third-person perspective to observe the machine's working process in the field. Movement control (forward/backward/left/right) is managed via the W, S, A, and D keys on the keyboard. When the spring teeth on the picking device make contact with chili plants, the fruits are harvested while the plant stems remain intact on the ground. Meanwhile, the graphical user interface (GUI) dynamically displays real-time statistics of harvested chili fruits. Figure 12 illustrates the pre- and post-harvest scenarios of chili plants, visually demonstrating the efficiency of the picking process.

a) b) c)

Fig. 12 - The state before and after harvesting chili peppers

a) Before harvest; b) Choose walking speed; c) After harvest

A comprehensive series of virtual harvesting simulation experiments were conducted to evaluate system functionality and operational validity under varying operating speeds and drum rotation speeds. These virtual harvesting simulation experiments validated that the virtual simulation platform for mechanized pepper harvesting can execute harvesting experiments according to preset parameters and align with actual harvesting principles. These results confirm the platform's effectiveness as both a training tool and a research platform for optimization pepper harvesting.

CONCLUSIONS

This study successfully developed a virtual simulation platform for mechanized chili pepper harvesting based on Unity 3D. During the simulation platform development phase, detailed 3D models of chili harvesters, chili plants, and their operational environments were constructed. Functional control script files were programmed using C# to enable human-machine interaction simulations and virtual harvesting experiments under diverse conditions.

Experimental results validated the rationality of the design of virtual simulation platform and the correctness of the code governing overall machine movement. In addition, trainees provided feedback that the platform helps them carefully observe the harvesting process, understand the working principle of the harvester, and gain an immersive operating experience, thus confirming that the platform authentically simulates real-world field harvesting operations.

Although this research has achieved phased milestones, several limitations require further improvement. For instance, future work will focus on developing a flexible stem model with elastic properties to better simulate the stress dynamics during the picking process. Additionally, enhancing interaction rules through behavioral reasoning will improve the realism of virtual harvester-chili plant interactions, enabling more lifelike simulations of plant and fruit motion. Furthermore, conducting multi-factor, multi-level orthogonal experiments under varied conditions will help analyze the impacts of key parameters (e.g., operational speed, drum rotation) on harvest loss rate, net harvest rate, and damage rate. These advancements will provide critical references for optimizing harvester design and manufacturing processes.

ABSTRACT
An accurate method for determining palm fruit maturity is needed by the palm oil industry to increase productivity and quality of crude palm oil. This study developed a portable instrument based on the AS7265x sensor (410–940 nm) to determine oil palm maturity accurately. Reflectance from 270 oil palm fruits at various maturity were measured, pre-processed, and classified into three maturity levels using PCA. PCA with SNV pre-treatment explained 97% of the variance. Classification was validated using SVM, RF, and KNN, with KNN achieving 100% accuracy. The instrument with SNV-PCA-KNN method has the potential to be used for oil palm fruit maturity classification.

ABSTRAK
Metode penentuan tingkat kematangan buah kelapa sawit dibutuhkan oleh industri sawit untuk meningkatkan produktivitas dan mutu minyak sawit kasar. Penelitian ini mengembangkan sebuah instrumen portabel berdasarkan sensor AS7265x (410-940 nm) untuk menentukan kematangan kelapa sawit. Reflektansi dari 270 buah kelapa sawit dengan beragam kematangan diukur, dilakukan pra-pengolahan, dan diklasifikasikan ke dalam tiga tingkat kematangan dengan menggunakan analisis komponen utama (PCA). PCA dengan pra-perlakuan SNV menjelaskan 97% dari varians. Klasifikasi divalidasi menggunakan SVM, RF, dan KNN, dengan KNN mencapai akurasi 100%. Instrumen dengan metoda SNV-PCA-KNN berpotensi diterapkan untuk klasifikasi kematangan buah kelapa sawit.

.

INTRODUCTION

Palm oil (*Elaeis guineensis*) is a major commodity crop, with global demand for palm oil continuing to increase due to its versatility and economic value. Timely and accurate harvesting is essential to maximize oil yield and quality *(Junior & Suharjito, 2023)*. Conventionally, harvesting is based on the maturity level of the fruit, which is determined by changes in fruit color and the detachment of fruit from the bunch. Manual classification is greatly affected by environmental factors like inconsistent lighting, rain, and shading, leading to misjudgments (*Mansour et al., 2022*). This time-consuming process relies on manual labor, limiting scalability and consistency in large plantations. Consequently, operational efficiency declines, which can negatively impact oil extraction rates (OER), resulting in lower yields, higher free fatty acid (FFA) content, reduced oil quality, and increased waste from suboptimal fruit (*Malyala, 2024*). These challenges highlight the limitations of manual methods for precise and large-scale harvesting especially in large plantations where variability in fruit maturity is high.

Recent studies have explored non-destructive to tackle the shortcomings of visual maturity assessment approaches such as image processing *(Saifullah et al., 2023),* electrical properties (Chin-Hashim et al., 2022), and near infrared (NIR)(Suci et al., 2024) *Budiastra et al., 2024*). Spectroscopy technologies have attracted growing interest due to their rapid detection capabilities and ability to simultaneously measure multiple constituents of oil palm fruit. Although these methods are promising, many rely on complex instrumentation and are limited in portability and field applicability, primarily due to the high costs of the necessary hardware and software.

Yunisa Tri SUCI, PhD.Stud.Agr. Eng; I Wayan Budiastra, Prof. Dr.Agr.Eng; Y Aris Purwanto,Prof.Dr.Agr.Eng; Slamet Widodo Assoc. Prof. Dr.Agr.Eng

Multichannel spectral sensors, particularly the AS7265x which covers the visible to near-infrared range (410–940 nm), offer a compact and cost-effective alternative for real-time spectral data acquisition. Despite its potential, the application of the AS7265x sensor in oil palm maturity classification remains underexplored. This sensor measures the absorption and reflection of light at particular wavelengths using various materials, including oil palm fruits. This sensor can provide precise information on the oil palm fruit's maturity by recognizing its spectral "fingerprints".

Researchers have used machine learning techniques and spectroscopic sensors to classify various agricultural products. A portable and low-cost spectrometric system using an AS7265x sensor and custom microcontroller was successfully used to classify coffee roasting levels using the Random Forest model *(Sagita et al., 2024)*, and to accurately determine the maturity of 'Ataulfo' mangoes *(Cano et al., 2024)*. Moreover, the integration of multichannel spectral sensors with machine learning models especially for on-site classification tasks has not been fully investigated in oil palm research. Prior work has focused on lab-based data acquisition or single-wavelength approaches, which do not reflect the complexities of dynamic outdoor environments. This study proposes an innovative solution by developing a portable, non-destructive instrument based on the AS7265x sensor, capable of real-time spectral acquisition, and coupling it with dimensionality reduction (PCA) and machine learning classifiers (SVM, RF, KNN) has the potential to be used for accurate maturity classification of oil palm fruitlets. The integration of spectral sensing and data-driven classification supports the advancement of precision agriculture, where timely and site-specific harvesting decisions are crucial for optimizing productivity and quality of crude palm oil. This approach not only addresses the limitations of existing manual and laboratory methods, but also contributes a novel, field-deployable solution that integrates multispectral sensing. This study aims to develop a portable instrument based on an AS7265X multichannel sensor and test its performance equipped with several machine learning algorithms for classifying the maturity level of oil palm fruits non-destructively.

MATERIALS AND METHODS

Portable instrument design based on multichannel spectral sensors

A portable instrument using multichannel sensors was developed to classify palm fruit maturity. The multichannel sensor used to build the palm oil detection system is the AS7265x sensor (9) of Austria Micro System, Styria, Austria. The sensor is explicitly composed of three TRIAD AS726x sensors, AS72651 (visible), AS72652 (UV) and AS72653 (IR) that detect absorbance at 18 wavelengths (410, 435, 460, 485, 510, 535, 560, 585, 610, 645, 680, 705, 730, 760, 810, 860, 900 and 940 nm). By default, UV LED emissions are recorded at six wavelengths from 410 to 535 nm, visible LED reflectance from 560 to 705 nm, and IR reflectance from 730 to 940 nm. This sensor allows for customizable LED configurations and data collection, enabling additional spectral data features. In this study, UV LED reflectance was also measured at 560 to 705 nm, known as fluorescence. This multispectral data acquisition sensor operates based on the principle of an optical reflective sensor. It features a light-emitting diode (LED) that emits light towards the palm kernel, which acts as the illuminated object. The light reflects off the palm oil fruit and is captured by a photodetector as the receiving sensor. The chemical composition of the oil palm influences the reflected light signal, resulting in a light wavelength signal that contains information about the chemical content of the palm fruit. The optoelectronic sensor then processes this information.

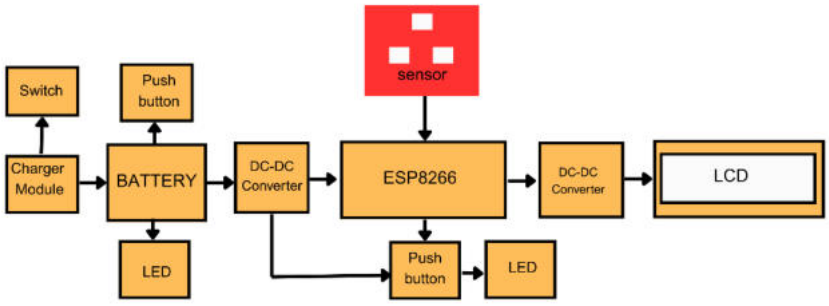

Fig. 1 - Component schematic of UV VIS NIR multichannel sensor acquisition equipment

The AS7265x multichannel sensor is connected to the ESP8266 via a jumper cable with resistors and integrated with a power supply (battery) for stable power supply. The electronic circuits are designed to be embedded in the PCB so that the connection of each component is stable. The data acquisition results will be sent to the cloud via Wi-Fi on the ESP8266 connected to a Wi-Fi router.

Data recorded in the form of date, time, and 24 channel spectrum data with symbols A, B, C, D, E, F, G, H, I, J, K, L, F1, F2, F3, F4, F5, and F6 sequentially.

The software used to control the microcontroller during data acquisition from the AS7265x sensor is Arduino IDE. The measurement results will be transferred in Microsoft Excel format, processed and analyzed using Unscrambler X for Principal component analysis (PCA), and classified using a machine learning algorithm. The component schematic of the portable instrument is summarized in Figure 1.

Sample preparation and spectra acquisition

The palm fruits used in the study were Tenera variety palm fruits from Cikabayan Plantation at IPB University, Bogor, Indonesia. The fruits were classified into 10 levels of harvesting age from young to old, starting at week 12 to 24 weeks of age, where at the age of 12 to 16 weeks, fruit collection was carried out once a week. The fruitless samples were taken from fresh fruit bunches from 3 different trees. A total of 9 fruits were taken from the center and apical parts of the FFBs, so the total number of loose fruit samples used was 270.

Spectra acquisition procedure is shown in Figure 2. The fruitlet was placed on a sample holder. A light beam from an LED exposed the fruitlet sample. Light reflected from the sample was captured by a photodetector with a 410-940 nm wavelength. The reflectance of the sample was measured by an instrument three times with different positions. The data acquisition results were sent to the cloud via Wi-Fi on the ESP8266 connected to a Wi-Fi router. The data spectral is recorded and stored in the cloud as date, time, and 24-channel spectrum data, which is then downloaded for further analysis.

Classification of palm fruit maturity with machine learning

In this research, data from the AS7262X sensor is evaluated using PCA and machine-learning algorithms to classify oil palms according to their maturity level. This research utilizes three widely recognized machine-learning algorithms. RF, SVM, and KNN. The classification of oil palm fruit maturity, which includes 10 maturity levels, involves several stages: pre-treatment of spectroscopic data, dimensionality reduction using PCA, classification with machine learning models, and performance evaluation.

Pre-treatment of spectroscopic data

Raw reflectance data were pre-processed using three techniques: normalization, Standard Normal Variate (SNV), and Savitzky–Golay derivative filtering. These methods were applied to enhance signal quality, reduce noise, and correct for baseline shifts and light scattering effects, which are common in spectral data collected under field conditions. Spectral measurements obtained from multichannel sensors often exhibit variations caused by illumination changes, surface reflections, and environmental noise. The selected preprocessing techniques mitigate these issues by leveling the baseline, reducing scattering effects, and emphasizing subtle spectral features associated with chemical changes during fruit ripening. This preprocessing step is essential to improve feature differentiation and enhance the performance of subsequent classification models.

Principal component analysis (PCA)

After pre-processing, PCA was performed to reduce high-dimensional spectral data into uncorrelated variables (principal components) that capture significant variance related to fruit maturity. It aids in data compression and reveals clustering patterns among the 10 ripeness levels. Typically, the principal components explain 80% to 95% of the dataset's variability (*Michael et al., 2025*). PCA is effective for dimensionality reduction and identifying natural patterns in maturity data, serving as a foundation for advanced classification.

Classification using Machine Learning

To evaluate the effectiveness of the reduced features from PCA, three supervised machine learning algorithms SVM, RF, and KNN were implemented. These models were trained on the PCA-transformed data to classify the fruitlets into three consolidated maturity levels, which were derived from the original ten stages based on their PCA groupings. Based on the cluster pattern from PCA and referring to previous studies *(Eya'a et al., 2023)* the classification was consolidated into three maturity levels: unripe, ripe, and overripe. These categories are not only more physiologically representative but also more industrially relevant and applicable to support harvesting decisions. With this approach, the classification becomes more stable and accurate for application in portable sensor based non-destructive systems in the field. The machine learning classification process was conducted using Google Colab with Python 3.11.13 and the Scikit-learn package version 1.3.0. A total of 270 spectral samples from oil palm fruitlets were used, initially processed through group labelling into three maturity classes (unripe, ripe, overripe), followed by standardization to ensure uniform feature contribution, significant for distance-based algorithms such as KNN and SVM and class balancing to prevent bias toward dominant classes. The dataset was split into 70% training and 30% testing using stratified sampling to maintain class proportions and improve generalizability. Three classification models (SVM, RF, KNN) were trained on the training data, with hyperparameter optimization performed using GridSearchCV. This method conducts an exhaustive search over specified parameter grids via cross-validation to prevent overfitting and ensure optimal model configuration. Each model was then calibrated and validated on the test set and evaluated based on accuracy, precision, recall, and F1-score using both classification reports and confusion matrices. The final performance evaluation enabled the selection of the best-performing model by comparing all metrics, with the optimal model and its tuned parameters retained for potential deployment and future analysis.

Performance metric

Classification metrics are crucial for evaluating the efficacy of models and directing advancements. They offer a way to assess how well a classification algorithm performs and give insight into how effectively a model is differentiating between classes. Metrics for evaluating classification models include accuracy, precision, recall, and F1 score *(Arifuddin et al., 2024).*

RESULTS

Characteristics of UV-VIS-NIR Spectra

The original spectra of oil palm fruit at various harvesting maturities within the UV-VIS-NIR wavelength range, obtained using a multichannel sensor, are illustrated in Figure 3.

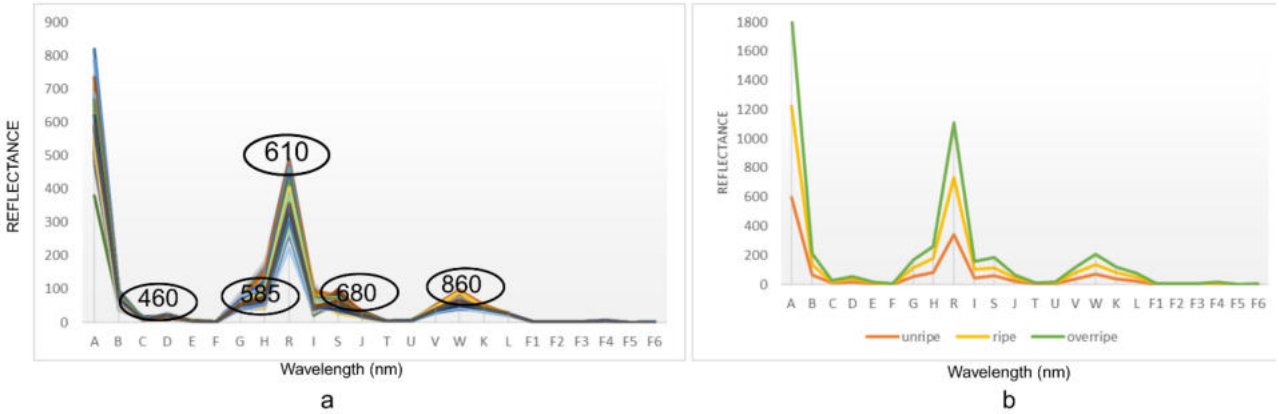

Fig. 3 - Spectrum of oil palm fruits at different harvesting ages

a. Original spectrum b. averaged spectrum

The resulting spectra exhibit peaks and waveforms indicative of the absorption of chemical bonds by UV-VIS-NIR wavelengths. Prominent peaks are observed at wavelengths such as 460, 585, 610, 680, and 860 nm. Peaks within the UV-VIS region correspond to pigments in the fruit, including chlorophyll, carotenoids, xanthophylls, anthocyanins, and other phenolic compounds. As reflected in these pigments, fruit color is a critical quality attribute closely associated with the fruit's functional properties and developmental stages.
