While no mobile applications currently exist for MATAG variety detection using spectral signatures, this section presents a conceptual application framework for how such applications could be developed and implemented. Farmers should choose a smartphone with a high-resolution camera capable of taking good pictures. Some smartphones have multi-spectral sensors, but basic smartphones can also be used using apps developed for MATAG variety identification and spectral analysis. The apps use algorithms to evaluate spectral data and associate it with several MATAG species. Plantix and Cropio are two applications for crop monitoring that can be connected with MATAG variety detection. To ensure accurate spectral analysis, images must be captured under consistent lighting conditions. The smartphone will improve the image quality by adjusting brightness, contrast, and reducing noise. It will also extract spectral information from the images, then transmit the results to a server for further assessment. This outcome includes examining the light reflected by the MATAG trees in various electromagnetic spectrum wavelengths, including red, green, blue, and near-infrared. The server detects the unique MATAG variety via spectral signature analysis. The selected variety is then reported back to the farmer via mobile apps, giving them correct information about the trees.

Creating an online database via smartphone from the processed images of spectral signatures for MATAG requires continuous monitoring of the plantation. The database should have a list of MATAG varieties

that can be used to identify specific characteristics as either the true-to-type or off-type seedlings, on an image. Therefore, MATAG classification demands images from various seedling ages to harvesting stages, as well as dates that coincide with crop growth stages. Aerial images should adjust the spectral resolution to fit the spectral signatures in the database. Other metadata, such as instrument characteristics, date of acquisition, vegetation biophysical parameters, soil characteristics, and other significant data, can also be displayed in this database.

The camera attached to a smartphone can be used to obtain imagery data for MATAG trees collected on the ground and varying levels of canopy decline, and stored in the database. With that, developers have created a smartphone attachment and application for simple spectroscopy. It uses a camera and a small spectrometer to collect the spectral data in MATAG trees. Farmers can identify with the MATAG variety using all the processing links to the server, including image preprocessing, transformation, and clustering (*Nesarajan et al., 2020*). The additional information includes the specific date and time, percentage of cloud cover, temperature, humidity, species homogeneity, the health of MATAG, size of the surveyed area, illumination and viewing setting, device calibration, and instrument settings that can be inserted into the smartphone.

Therefore, a spectrum library must be created to store MATAG variety data, identify different disease severity levels across a large area, and provide users with an action plan for crop management. The spectral library also contains normatively measured and processed background situation parameters for the specified MATAG species. The five components of the spectral library system include a knowledge database, a measured spectral library, an auxiliary library, spectral analysis, and an end-user application demonstration. Certain information, i.e., background knowledge on pest and disease species, could be identified in a knowledge database. Then, all of the calculated spectra of different species could be saved in the measured spectral library, and the auxiliary library can store several of the ancillary data of the species measured. The spectra gathered in the spectral analysis could be pre-analysed to verify the accuracy of the library before end-users use it in practical tasks. Fig. 6 presents an example of the data model of the spectral library system of MATAG.

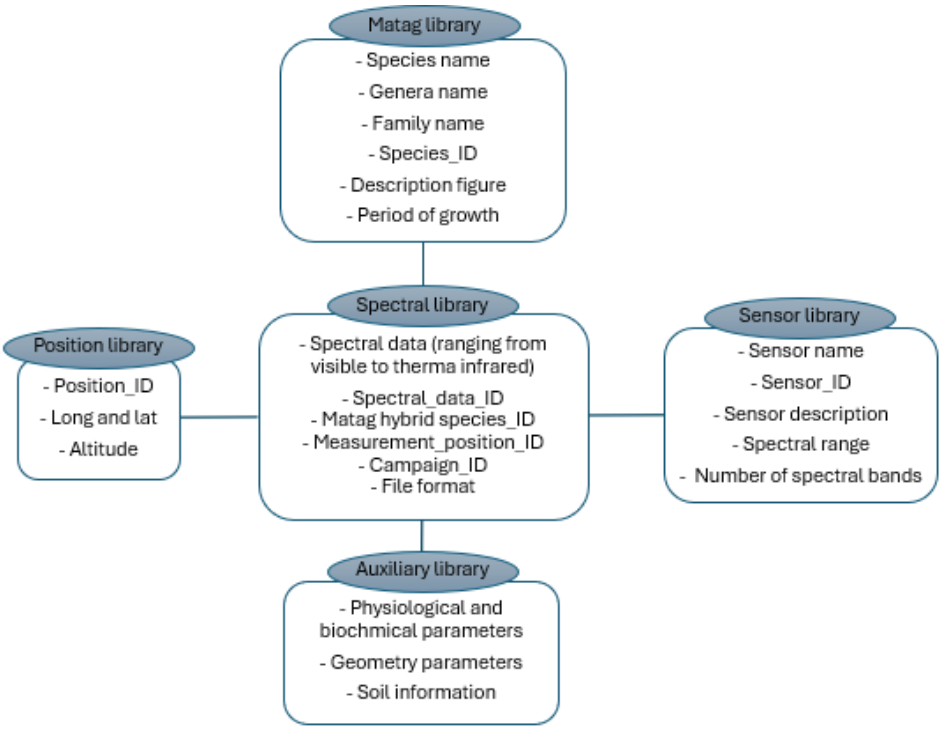

Fig. 6 - The data model of the Spectral Library System of MATAG variety detection

The spectral signature graph can be stored in a multifunctional database, such as mobile applications, enabling easy access by consumers and researchers (*Rossel et al., 2016*). The spectral signature was displayed as a reflectance graph for each MATAG variety identification. Creating a spectral library for MATAG in crop fields using the proposed mobile apps is an excellent technique to record spectral signatures for future reference.

5.5. Proposed System Architecture of IoT-Enhanced Smartphone Platform for MATAG Detection

The proposed platform describes IoT sensors as the primary spectral data collectors, with smartphones functioning as user interfaces and local processing units. Such an approach will integrate the smartphone accessibility with the precision of dedicated spectral sensors. The proposed mobile app design consists of two parts: system architecture (back-end) and menu design (graphical user interface), as illustrated in Table 2. The system architecture consists of three layers: presentation, logic, and data. The presentation layer allows users to view and interact with the app. The flow should be intuitive, with every menu having a specific objective. The logic layer serves as an API for farmers to obtain data from the database layer and send requests to the presentation layer. The data are then transmitted to the presentation layer. The data layer is the core of the proposed mobile application, where all data will be stored and retrieved. Each request for information in the presentation layer passes through the logic layer and then to the data layer before being displayed to the user in the presentation layer. Fig. 7 demonstrates the theoretical basis for creating a spectral signature graph to detect the MATAG variety that uses smartphones.

Table 2

List of main menus of the proposed mobile applications

Menu	Details Information
Location	Research site, crop-field area, and total number of plots used in the study
Planting schedule	Schedule of planting activities
UAV images	Spectral images
Field problems	Images showing field conditions and observed problems
Pest and disease	MATAG pest and disease categories, their spectral-signature graphs, and recommended control measures
Weather forecast	Weather conditions and forecasts for the field site
Yield	Quantity of harvested produce
Report	A function that allows farmers to prepare and submit reports on various MATAG characteristics

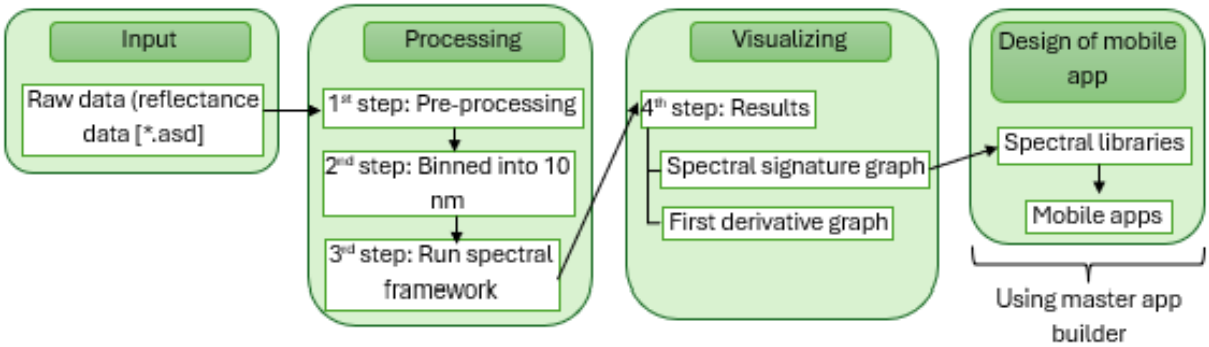

Fig. 7 - Theoretical framework for generating the spectral signature graph for detecting the MATAG variety using a smartphone

The spectral imaging module can be placed either on an aerial platform like a UAV or a stationary platform like a high pole, which keeps collecting data at regular intervals, which are determined by the type of MATAG and its characteristics. In the spectral imaging module, the data is sent directly to the cloud (*Inamdar et al., 2021*). Following the use of image-to-map geometric rectification techniques to coincide the image data with the actual map coordinates, the image is preprocessed before the spectral response is extracted from it. The processing involves applying suitable smoothing filters to the image to remove any outliers or incorrect data.

The next step involves the use of the Internet of Things (IoT), which enables the storage of farm data over the cloud to be utilised for data analytics and pattern recognition. Fig. 8 shows the overall system. The data that were obtained from the seedlings is collected and transmitted by the sensor nodes. These data are given to the Sink node, which transforms them into IP packets that can be transmitted to the cloud. The spectral Image Module captures the spectral image and sends it to the cloud on its own. The cloud then processes the data before being sent to the user. The cloud platform is accessible to farmers, who can access the dataset and its output (*Esther et al., 2019*).

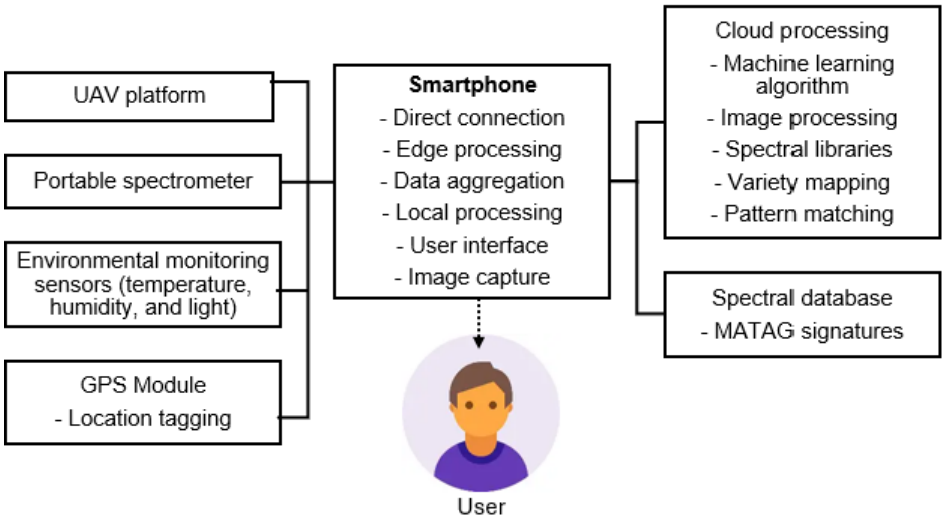

Fig. 8 - IoT-Enhanced Smartphone Platform

The spectral response of an image is then extracted. The sensor module's sensitivity to various wavelengths of optical radiation is determined by its spectral response. Therefore, the farmer can obtain information about the MATAG variety based on the number of different wavelengths. For example, the necessary parameters are estimated using the NDVI value as a standard. Data collected from the sensor node will be buried in the ground through the sink node stored in the cloud alongside the processed data. The data from these two sources are compared and processed per the MATAG's needs and the parameters estimated from the data collected (*Mohanty et al., 2022*). A proposed procedure for the development of intelligent MATAG coconut seedling identification using spectral signature analysis is presented in Fig. 9.

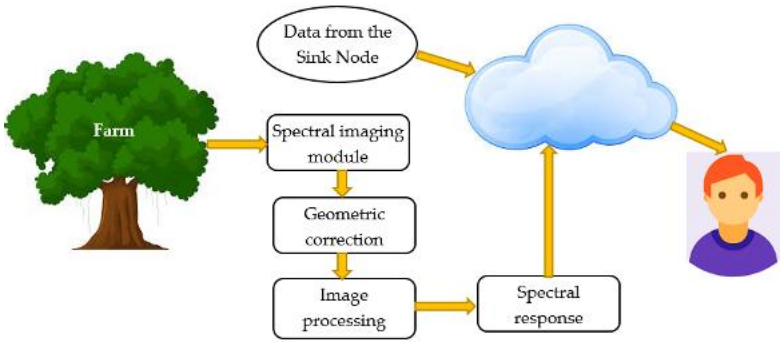

Fig. 9 - Spectral imaging with IoT

Finally, the future MATAG detection apps can provide a health assessment based on the spectral signature analysis based on healthy, stressed, or diseased categories that can improve interpretation and decision making. The app may provide recommendations for interventions, such as fertiliser application, pest control measures, or watering schedules. Regular monitoring and data collection are essential. The app can be used periodically to capture new data and update the health status of the MATAG trees. In short, tools will be involved in developing apps that involve the smartphone with a camera and GPS (to capture images and geotagging), mobile applications (software that performs spectral analysis), cloud services (to store data and perform complex computations), and machine learning models (to analyse spectral data and predict health conditions).

As a summary, the integrated workflow begins with UAV-mounted sensors collecting canopy-scale reflectance data, complemented by IoT devices monitoring soil and environmental parameters. In the meantime, smartphones are used by farmers to capture close-up seedling images. All data streams are integrated via a centralised platform, where analysis is performed, and the processed results are then returned to the farmer's smartphone for decision-making. Each technology complements the others to ensure continuous monitoring from planting to maturity.

6. CASE STUDIES AND TESTIMONIALS FROM FARMERS ON HOW SMARTPHONE HAVE REVOLUTIONISED CROP MONITORING PRACTICES

Three case studies reported the application of spectral signature analysis for coconut variety detection and monitoring using smartphones, which could be applied to MATAG studies in the future. First, an article published in the Journal of Agricultural Technology monitors health and detects diseases in coconut palms using spectral signature analysis. The researchers built a mobile app that uses a smartphone camera to capture images of coconut leaves. The app processes the images to extract spectral signatures, mainly focusing on specific wavelengths that relate to chlorophyll content and other indicators of plant health. Data collected by the app is analysed to determine stress indicators, including nutrient deficiencies or the presence of pests and diseases (*Singh et al., 2021*).

Second, an article published in the International Journal of Remote Sensing predicts the yield of coconut trees using spectral data collected. The researchers developed a mobile app to capture images of the coconut canopy. The app used machine learning algorithms to analyse the spectral data and predict crop production. Normalised Difference Vegetation Index (NDVI) was used to assess the health and productivity of the trees. The mobile app provided accurate yield predictions with a high association between predicted and actual yields (*Hebbar et al., 2022*).

Third, an article published in the Plantation Management Journal improves plantation management practices by monitoring coconut tree growth and health using spectral data. The app collected spectral data from the leaves and processed it to provide insights into the overall health of the plantation. Parameters such as leaf area index (LAI) and chlorophyll content were generated from the spectral signatures. Farmers reported improved management practices, such as optimised irrigation and fertilisation, based on the data provided from the app (*Samarakoon et al., 2025*).

However, none of the above studies detect the MATAG variety or even crop species based on the spectral signature analysis using a smartphone. Hence, this review mentions an app that found the weed species, which could be adopted for the identification of MATAG species in the future. For example, *Roslin et al. (2021)* generated a spectral signature graph of weeds and created a mobile app for spectral signature analysis of weeds. Using Master AppsBuilder, all spectral signatures were saved in a spectral database and illustrated on smartphones. Fig. 10 displays the website's main menu, which includes a list of applications, while Fig. 11 provides the content of menus, images, description, the control technique, and a spectral signature graph of MATAG. The main menu consists of information, spectral signatures, and recommendations for weed control. Users can download the mobile app on their devices. Besides the case study, this study also identified the testimonials from farmers on crop monitoring practices that were extracted from Google search, as shown in Fig. 12.

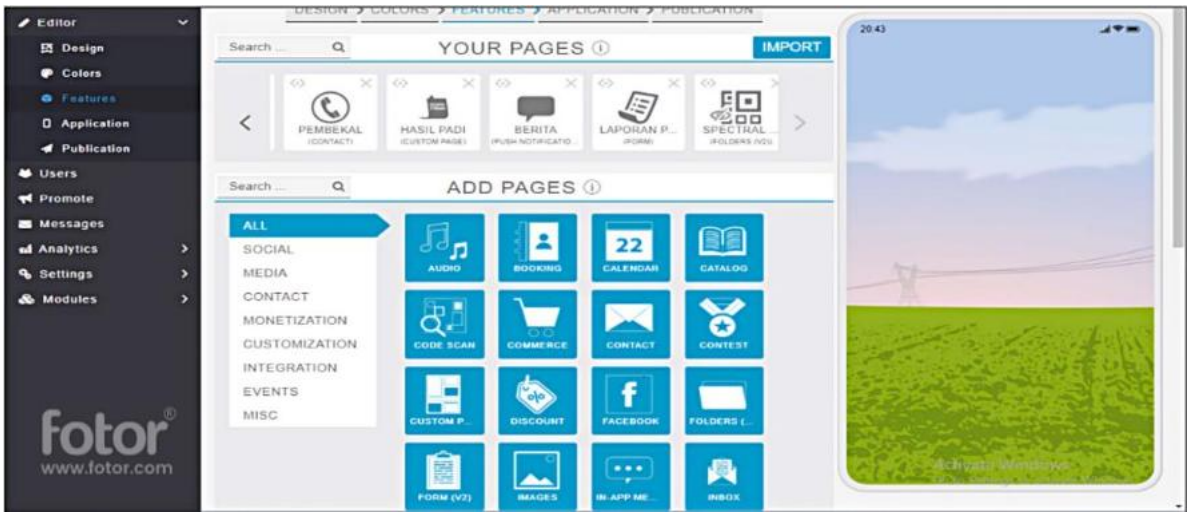

Fig. 10 - The application Editor tool and Feature menu in the MasterAppBuilder Application. (PEMBEKAL: SUPPLIER, HASIL PADI: RICE YIELD, BERITA: NEWS, LAPORAN: FORM)

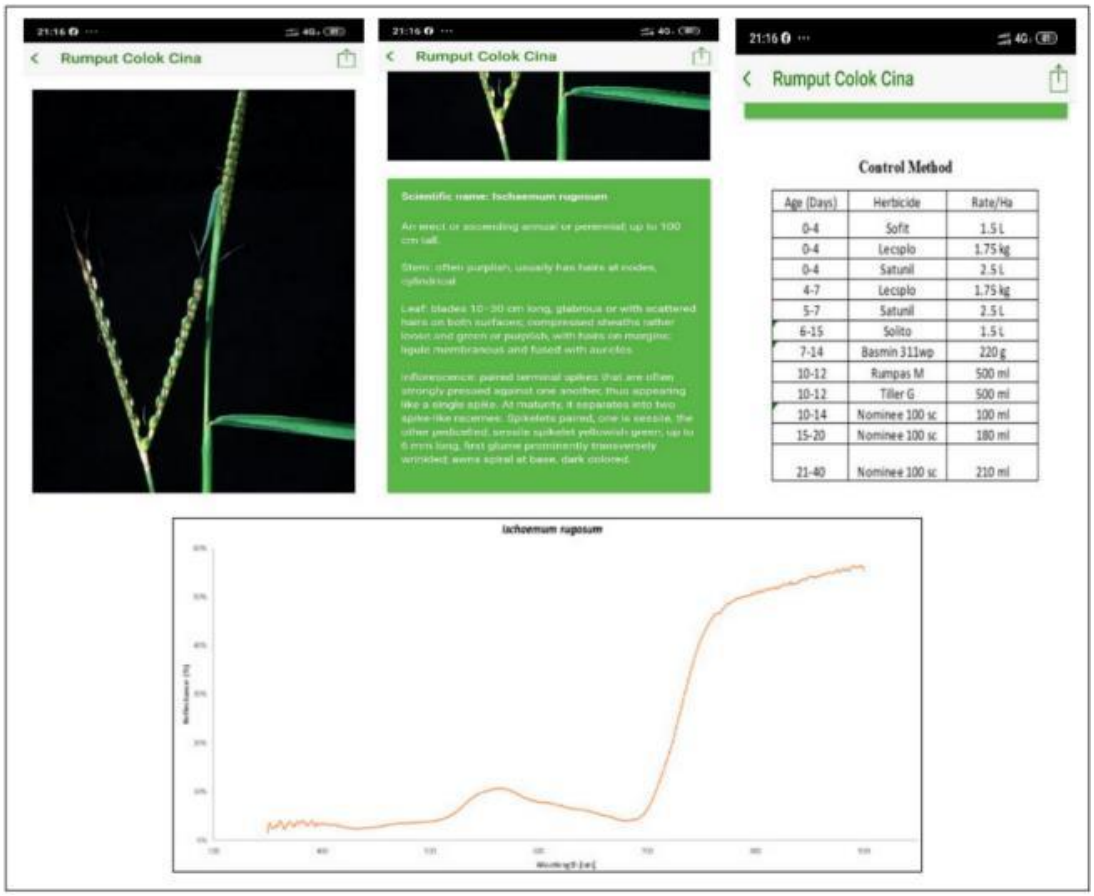

Fig. 11 - The content of menus, pictures, description, control method, and spectral signature graph of MATAG

7. POTENTIAL BENEFIT OF USING SMARTPHONE DEVICES TO THE AGRICULTURAL INDUSTRY

This section presents potential benefits and future perspectives for integrating smartphone-based spectral signatures into MATAG detection rather than established conclusions. While smartphones and spectral technologies show promise for MATAG identification, further field validation and multi-location trials are required before widespread adoption. Studies suggest that using smartphones for crop monitoring may have potential advantages for farm management. First, farmers can use a smartphone to identify early signs of crop stress, nutrient deficiencies, and disease outbreaks through real-time image-based monitoring, enabling timely and site-specific interventions (*Nyakuri et al., 2025*). This feature enables earlier mitigation measures to be implemented, lowering the chance of crop loss while increasing yield. Early intervention also saves resources through preventing expensive chemical treatments. Second, smartphones could help farmers to effectively monitor soil moisture levels, allowing them to change irrigation schedules based on crop needs. This feature assures that crops get enough moisture without wasting water, lowering water costs. Previous research demonstrates that images captured by smartphone sensors (under controlled lighting) can predict soil moisture with moderate accuracy (i.e., MAE = 0.35, RMSE = 0.15, $R^2 \approx 0.60$), confirming the feasibility of image-based soil moisture estimation (Riaz Hasib Hossain and Ashad Kabir, 2023). Third, farmers who have access to precise data on soil moisture, meteorological, and crop growth patterns can maximise resource allocation, including water, fertilisers, and pesticides (*Mansoor et al., 2025*). It ends up with a minimised environmental impact.

Fourth, farmers can use data-driven insights and practical alternatives to reduce risks, increase productivity, and improve overall farm management. This informed decision-making aspect eliminates the need for expensive trial-and-error procedures (*Mishra and Mishra, 2024*). Fifth, smartphones automate data gathering and analysis, reducing the need for human record-keeping and data entry. This characteristic not only saves time but also reduces the possibility of errors or anomalies in the handling of data (*Payero et al., 2021*). Farmers can concentrate more on their main farming tasks, leading to improved operational efficiency. Sixth, online monitoring using sensors might decrease agricultural maintenance expenditures. Such monitoring is crucial for small and medium-sized farms, where resources are limited. It can cut maintenance costs by up to 30% by enabling online monitoring via sensors. Real-time data on crop status improves production efficiency and resource utilisation (*Aarif et al., 2025*). Seventh, a smartphone should be compatible with existing farm management systems and interface with other farm-related devices. This compatibility implies seamless exchange of data while reducing the need for extra hardware or software investments (*Choudhary et al., 2025*).

Eighth, a smartphone may automate tasks including data collection and processing, freeing up staff for other important farming tasks. This automation lessens labour expenses and improves overall efficiency (*Mumuni and Mumuni, 2025*). Ninth, smartphone use imagines recognition technology to detect pests and diseases that potentially impact crops. Farmers can immediately identify and solve these problems, avoiding the need for costly chemical treatments and related expenditures. Tenth, smartphones allow farmers to precisely monitor soil moisture levels, ensuring that crops receive enough moisture without wasting water resources. IoT-based soil moisture monitoring systems integrated with smartphone alerts enabled real-time irrigation decisions, resulting in up to 30% water savings compared to conventional methods (*Dong et al., 2024*). Eleventh, a smartphone can help farmers optimise their energy consumption by providing real-time data. This optimisation facilitates them to regulate their energy use patterns, lowering energy expenses and environmental impact (*Ahmed and Shakoor, 2025*).

Twelfth, smartphones automate collection and analysis, reducing the need for human record-keeping and data entry. Such automation lowers labour expenses involved with data management, allowing farmers to concentrate on primary farming activities (*Resti et al., 2024*). Thirteenth, smartphones automate data administration, which reduces the probability of errors or discrepancies. This feature indicates that the data is correct and reliable, which reduces the need for costly adjustments (*Kumar, 2024*). Fourteenth, smartphones offer farmers data-driven insights and useful guidance, allowing them to improve their operations. Such a feature leads to increased agricultural yields and greater farm profitability. The global market for smart agriculture is predicted to expand from $12.4 billion in 2020 to $34.1 billion by 2026, indicating the enormous economic potential of implementing these technologies (*Techspian, 2024*). Farmers can use these economic benefits to reduce crop monitoring and management costs, resulting in enhanced efficiency and profitability. Overall, smartphones offer an effective and accessible platform for integrating spectral data into MATAG identification. However, successful adoption will depend on addressing technological limitations, farmer training, and validation in diverse environments.

8. CHALLENGES IN DETECTING THE MATAG VARIETY USING A SMARTPHONE

There are a few challenges in developing future MATAG detection apps for detecting MATAG using spectral signature analysis. The processing capacity, i.e., the operating time of mobile apps, is one of the main challenges. There is also a need to transfer the data to be processed to a remote server. Besides, some locations may not have an Internet connection, which loses its ability the operation time and could cause a delay because it can only be used when there is access to the Internet. When facing a weak Internet connection, the user needs to bring the apps to other nearby locations to ensure that the device is connected to the Internet, which is inefficient in practice (*Mendes et al., 2020*).

Another limitation is the size of the smartphone's screen. The small size of smartphones could result in changing geometric relationships between the user's face and the phone screen and low-resolution frontal cameras. Instead of purchasing a computer that has a bigger screen size, farmers should be able to use their smartphone simply. Although almost all smartphones today have sizable screens, there are some with smaller screens; hence features of the applications must be designed to be user-friendly across screen sizes.

Smartphone keyboards have much smaller buttons or touch spaces than standard desktop or PC keyboards. Therefore, incorrect touches could frequently happen. In addition, when using a capacitive touchscreen interface, there is a problem with dirt on the screen that is caused by fingerprints and finger sweat. Therefore, touch interfaces cannot be used as smartphone interfaces are not disabled-friendly or it is less functional when both hands are carrying something or doing some activities. Moreover, such mobile devices have an integrated camera as the default configuration.

There is also another issue that needs to be considered when developing apps for smartphones. The problem is the skill of the manpower to use the device, such as farmers. They primarily work in the field, are elderly, and do not particularly adapt to such technology. As a result, the future MATAG detection apps must be as simple, intuitive, and handy to use in their daily farming activities (*Abdullahi et al., 2021*). Consequently, user behaviour in using smartphones differs across community backgrounds. For instance, rural farmers in low-income countries may be restricted by low literacy and a lack of exposure to device interfaces. Therefore, they require highly intuitive interfaces, in which using too much text as an interface may be incomprehensible or difficult to use.

Other constraints were the high cost of buying smartphones, maintenance, lack of encouragement, and usage awareness. As a result, some farmers prefer to use the conventional method, which results in low participation of farmers. Moreover, it is not that easy to insert and update the information into the apps (*Abdullahi et al., 2021*). Therefore, smartphone application developers must solve this limitation by creating an interface design that is handy for multiple users.

9. FUTURE RESEARCH OPPORTUNITIES OF MATAG VARIETY DETECTION USING A SMARTPHONE

Many apps are being used in the public domain in the agricultural field, and not just by licensed users. However, most farmers who use these applications have little or no knowledge of the device attributes. Therefore, the future MATAG detection apps need to be designed in a simple way and be efficient to use promptly. However, as a new generation of farmers gains proficiency in using these apps, this issue will be addressed over time.

More apps that involve IoT in their farming practices are being developed, but users will only need a little IT knowledge to use the device. In addition, the developer will design criteria and usability standards so that the apps must consider work tools rather than just applications for enthusiasts or entertainment. It is also projected that software that currently operates on smartphones will progressively shift to larger devices such as tablets, tab, and iPads.

To increase smartphone processing capabilities, apps are likely to use deep learning, machine learning, or artificial intelligence techniques on the smartphone. This approach avoids the inability to use apps in remote areas where Internet access may be unavailable or limited. Instead, the apps are expected to be able to be used offline and then transfer data to a remote server that will be accessible via various devices.

Future developments in smartphone spectral signature technology are anticipated to focus on both hardware and software advancements. Developing equipment with image sensors capable of acquiring wavelengths outside of the visible spectrum is also anticipated to open up new alternatives for this type of application. Smartphones equipped with cameras capable of capturing the spectrum in the near-infrared and infrared zones will allow the implementation of vegetative vigour determination applications, such as creating spectral signature graphs of the MATAG variety in coconut nurseries.

More precise detection of physiological and varietal variations will be made possible by developments in smartphone cameras, such as the incorporation of multispectral and hyperspectral sensors or the use of

affordable clip-on spectrometers. Smartphones with powerful processors will be able to conduct on-device spectral analysis without exclusively depending on desktop or lab computers.

The combination of cloud computing and artificial intelligence will be equally significant. Real-time data analysis is feasible with AI algorithms implemented through mobile applications, providing farmers with fast decision support. It will also be essential to create open, standardised spectral libraries for coconut varieties so that farmers and researchers may access reliable reference data. Participatory collection of data, in which farmers help create extensive spectral repositories, could be used to develop these databases.

Smartphones will probably serve as hubs in larger digital agriculture ecosystems in the future, connecting cloud platforms, IoT field sensors, and UAV-based imaging. This integration will facilitate yield forecast, crop health monitoring, and MATAG hybrid identification. Future studies must focus on user accessibility, cost, and training in addition to policy assistance to promote digital agriculture solutions in coconut-producing countries to ensure successful adoption.

10. CONCLUSIONS

This article reviewed the potential of integrating smartphones with spectral signature analysis for detecting the MATAG hybrid. Key topics discussed consist of the morphological challenges of identifying MATAG varieties, the utilisation of spectral reflectance data and derivative analysis, the role of spectral signature libraries, and the comparison of smartphone-based methods with traditional approaches. The spectral signature graph was displayed as a reference to detect various species of MATAG more efficiently. The review emphasises that spectral libraries generated in mobile applications, when combined with external sensors and spectral databases attached to the smartphone, could provide a promising and affordable platform for intelligent MATAG seedling identification. Future research should focus on field validation, farmer adoption strategies, and the development of user-friendly applications tailored to plantation conditions.

11. ACKNOWLEDGEMENT

The authors delegate our thanks to the Department of Agriculture, Jorak (Johor) and Lekir (Perak) for providing the sample of MATAG species in this project and the Ministry of Higher Education, Malaysia under the Long-term Research Grant Scheme (LRGS) for the program titled “Precision Management of Coconut Nursery for Production of High Quality Seedlings”- LRGS/1/2020/UPM/01/2 (Vote No: 5545202) for the funding.

Keywords: *deep learning, citrus, target recognition, depth camera*

ABSTRACT
Target recognition and localization of picking robots are very important in orchard environments. This paper analyzed the You Only Look Once version 8 normal (YOLOv8n) method in deep learning for citrus picking robots, introduced FasterNet, efficient multi-scale attention (EMA) mechanism, and Wise Intersection over Union (WIoU) loss function, developed an improved YOLOv8n method, and collected a citrus fruit dataset to analyze the recognition and positioning effects of the proposed methods. The selected FasterNet, EMA, and WIoU were all superior to the other types compared, and the improved YOLOv8n method achieved an accuracy of 0.893, a recall rate of 0.894, and a mean average percentage (mAP) of 0.895 for citrus recognition, outperforming other recognition methods. In terms of citrus localization, the average errors on X, Y, and Z axes were 3.56 mm, 3.54 mm, and 4.74 mm, respectively. The findings demonstrate the reliability of the proposed model, and it can be applied to actual citrus picking robots.

摘要
在果园环境下，采摘机器人的目标识别与定位十分重要。本文针对柑橘采摘机器人，分析了深度学习中的 YOLOv8n 方法，引入 FasterNet、EMA 注意力机制以及 WIoU 损失函数，设计了一种改进 YOLOv8n，并采集柑橘果实数据集，对所提方法的识别和定位效果进行了分析。结果发现，所选择的 FasterNet、EMA 以及 WIoU 均优于所比较的其他类型，改进 YOLOv8n 在柑橘识别上获得了 0.893 的准确率、0.894 的召回率和 0.895 的 mAP，优于其他识别方法。在柑橘定位上，在 、Y、Z 上的平均误差分别为 3.56mm、3.54mm 和 4. 4mm。结果证明了所提方法的可靠性，可以在实际的柑橘采摘机器人中进行应用。

INTRODUCTION
With the advancement of technologies such as intelligent control and mechanized equipment, the agricultural industry has also undergone tremendous changes. In the fruit industry, due to the limitations of planting patterns and terrain conditions, the degree of mechanization in orchards is still relatively low. Especially in fruit picking, as the seasonal intensity is high and the picking environment is complex, the labor cost is constantly rising. The high labor cost poses a huge challenge to the development of the fruit industry. The research, development, and application of intelligent picking equipment have become an important aspect of the development of the forest and fruit industry. The picking robot is a type of robot used to complete the picking of fruits and vegetables (*Wang et al., 2024*), and it is an important part of the current research on agricultural intelligence. The machine vision system is the perceptual core of a picking robot, and its target recognition accuracy, real-time inference speed, and three-dimensional positioning accuracy can directly affect the picking success rate and operation stability of the robot. In recent years, deep learning provides new technologies for visual perception in complex agricultural environments with its excellent feature extraction and autonomous learning abilities. *Chen et al.* (*2025*) designed a method for target recognition of agricultural picking robots in low-light conditions using template matching, achieving a maximum recognition accuracy of 98.56%, which enables efficient picking in low-light conditions. *Rong et al.* (*2024*) designed a tomato-picking robot system, and field trials showed that the robot had a harvesting success rate of over 50% and an average harvesting cycle of 24 seconds. *Zhao* (*2024*) developed a You Only Look Once version 5 (YOLOv5)-RACF algorithm for the problem of automatic apple picking, with an average detection accuracy of 98.748% and a time of 0.13 seconds to calculate the diameter of one apple. *Zhu et al.* (*2025*) designed an improved You Only Look Once version 7 (YOLOv7) network for the detection of Agaricus bisporus, and the experiment found that the acquisition success rate of this method was 80%, which could achieve automated acquisition.

Matache et al. (2026) designed a greenhouse tomato harvesting system that uses a hybrid vision framework that integrates convolutional neural networks (CNNs) and watershed-based segmentation to detect and position fruits. This system achieved a fruit detection precision of 96.9%. Citrus is a kind of fruit with high yield and demand at present. In the research of citrus-picking robots, *Lin et al.* (*2019*) designed an algorithm based on red-green-blue-depth (RGB-D) image analysis to detect and localize citrus. They conducted experiments on a dataset of 506 RGB-D images and found that the proposed algorithm was robust, with an F1 score of 0.9197. *Yin et al.* (*2023*) proposed an integrated citrus-harvesting robot solution, which adopted a multi-sensor-based fused simultaneous localization and mapping algorithm to achieve positioning and navigation for the orchard robot. Its overall success rate was 87.2%, and the average picking time was 10.9 seconds per fruit. *Zhang et al.* (*2025*) selected YOLOv5 for citrus object detection and achieved an accuracy of 92.3%, a recall of 79.1%, and a mean average percentage (mAP) of 88.5%, which verifies that this network is capable of handling detection tasks in real environments. *Hou et al.* (*2024*) combined a convolutional block attention module (CBAM) with the backbone network of a Mask region-based convolutional neural network (R-CNN). They found that the mean absolute error and relative error of citrus picking point localization was 8.63 mm and 2.76%, respectively, providing a valid solution for the accurate detection and localization of citrus picking points for harvesting robots.

In the current research, the main deficiencies are as follows. Firstly, most of the existing high-precision algorithms rely on deep and heavy network structures, which have a large number of parameters and high computational requirements, resulting in high hardware deployment costs and making it difficult to meet the real-time operation requirements of picking robots. Secondly, the training and performance verification of most models rely on small-scale and single-scene datasets, leading to insufficient robustness. Thirdly, most existing models have problems such as insufficient feature extraction, weak ability to recognize difficult samples, and low boundary regression accuracy, which limit the practical application of citrus picking robots. In response to the above research status and deficiencies, this paper aimed at high precision and strong robustness and took You Only Look Once version 8 normal (YOLOv8n), which has few parameters and is suitable for embedded devices, as the basic model for design. The effectiveness of the proposed method was verified through training with multi-scene datasets and laboratory positioning experiments, providing theoretical support for the design and application of citrus picking robots.

MATERIALS AND METHODS

Citrus identification model based on YOLOv8

In actual orchards, the robot first needs to accurately identify the target fruit, a process usually accomplished using object detection techniques. Conventional object detection techniques-including R-CNN and its improved variant, Faster R-CNN-have a slower detection speed and are not suitable for citrus picking tasks that require rapid object detection. CNNs are a typical method in deep learning and have shown excellent performance in visual information processing (*Shao et al., 2023*). You Only Look Once (YOLO) is a CNN-based object detection method that can classify and locate images through a single neural network and perform object detection better and faster. Currently, the YOLO series of methods have good applications in many fields such as pedestrian detection and equipment fault identification.

You Only Look Once version 8 (YOLOv) is one of the highly flexible and scalable models in the YOLO series and has been utilized in various domains such as medicine and agriculture (*Jraba et al., 2025*). Among them, YOLOv8n has the characteristics of fewer parameters and smaller size, which is more suitable for resource-constrained environments and has higher real-time performance. Therefore, this paper selected YOLOv8n to develop a citrus recognition model. The main current flaws of YOLOv8n are as follows.

(1) Convolutional mapping operations in the backbone network result in a large computational load for the model;

(2) The influence of overlapping citrus fruits and light intensity in the orchard environment results in the loss of target feature information, and more attention should be paid to key target areas;

(3) The original loss function may cause significant deviations in scenarios such as occlusion, density, and light variations.

Therefore, in order to achieve better results in citrus recognition and enhance the picking performance of robots, improvements need to be made based on the YOLOv8n.

Citrus recognition model based on YOLOv8n

The backbone network of YOLOv8n was improved by introducing FasterNet to reduce computational complexity. FasterNet is a model based on partial convolution (PConv). PConv refers to performing the convolution operation only on some channels of the input feature map while keeping the remaining channels unaltered, thereby reducing the computational load without compromising feature expression ability.

The FasterNet module is shown in Figure 1.

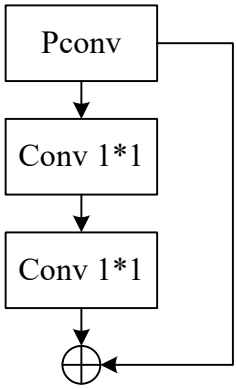

Fig. 1 - FasterNet module

The bottleneck module in the C2f module in the YOLOvn8 backbone network is substituted by the FasterNet module, thereby reducing the computational burden of the model while maintaining high feature expression ability.

By introducing the attention mechanism, the model can focus on information more relevant to citrus recognition among the numerous input information, thereby improving the performance of citrus recognition. Efficient multi-scale attention (EMA) is a mechanism that does not require dimensionality reduction, which significantly reduces computational costs while effectively preserving the integrity of feature channel information. Integrating it into citrus recognition models can enable the models to achieve better performance. The main structure of EMA is shown in Figure 2. EMA is combined with the C2f module to strengthen the model's capability to extract citrus features.

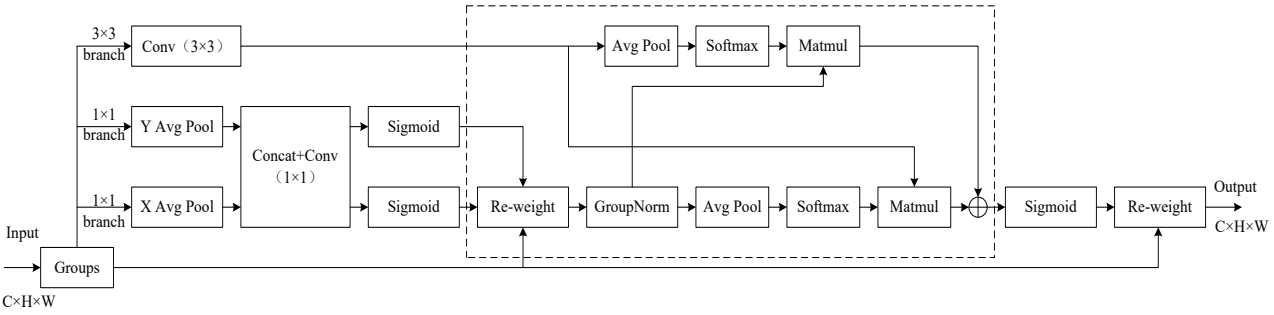

Fig. 2 - EMA mechanism

Finally, Wise Intersection Over Union (WIoU) replaces the Complete Intersection over Union loss (CIoU) function in the original YOLOv8n model.

$WIoU$ is defined as:

$$WIoU=\frac{\sum_{i=1}^{n} w_i IoU(b_i,g_i)}{\sum_{i=1}^{n} w_i} \quad (1)$$

where:

n denotes the number of ground-truth boxes, b_i is the coordinates of the i-th ground-truth box, and g_i is the coordinates of the ground-truth annotation box of the i-th object.

Combining the above three parts, the structure of the improved YOLOv8n is presented in Figure 3.

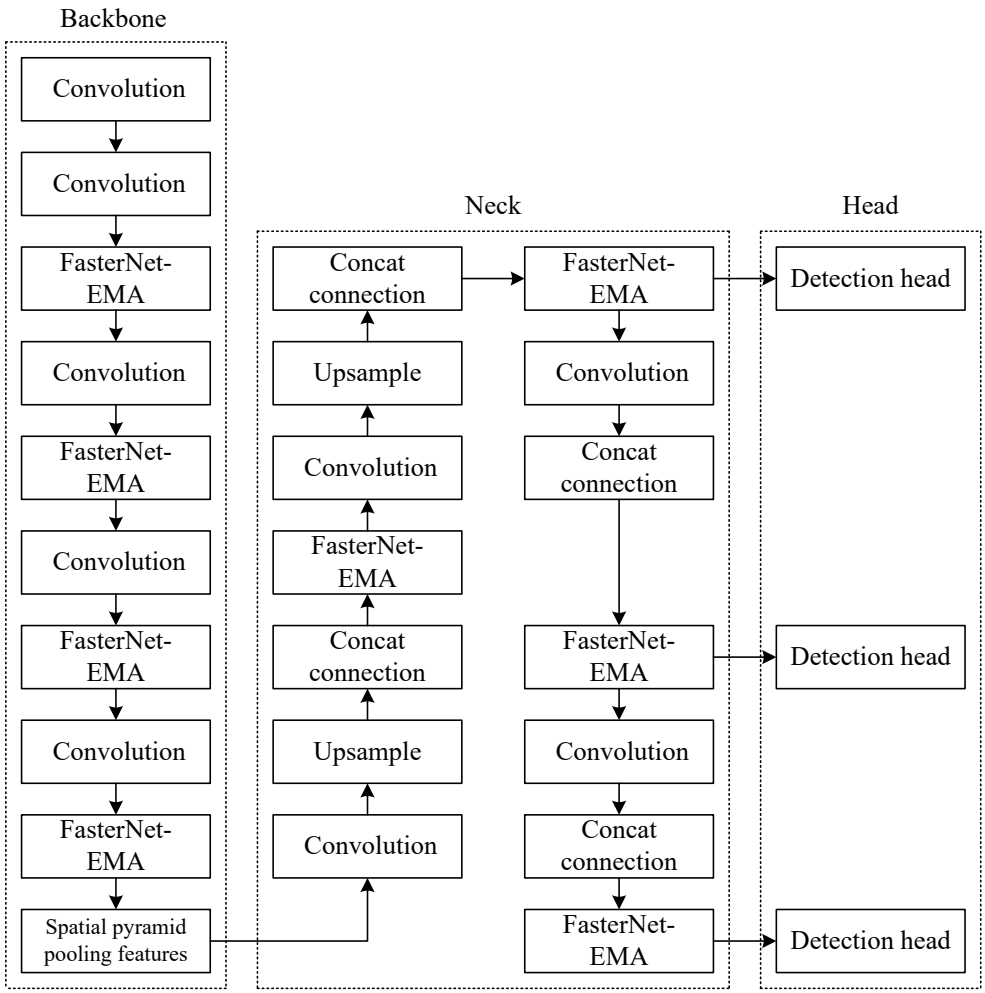

Fig. 3 - The structure of the improved YOLOv8n

Citrus positioning model

During the visual positioning process of the picking robot, a series of coordinate transformations are required to achieve three-dimensional positioning of the recognized fruit. The improved YOLOv8n outputs the rectangular detection box of a citrus target, extracts the pixel coordinates (u, v) of the center point of the box, and then obtains the relationship between the world coordinate system and the pixel coordinate system through coordinate transformation.

First, it is the conversion from the world coordinate system (X_W, Y_W, Z_W) to the camera coordinate system (X_C, Y_C, Z_C):

$$\begin{bmatrix} X_C \\ Y_C \\ Z_C \\ 1 \end{bmatrix} = \begin{bmatrix} R_{3\times3} & t_{3\times1} \\ 0 & 1 \end{bmatrix} \begin{bmatrix} X_W \\ Y_W \\ Z_W \\ 1 \end{bmatrix} \tag{2}$$

where R refers to a rotation matrix and t is a translation vector.

Then, (X_C, Y_C, Z_C) is converted to the image coordinate system (x, y):

$$\begin{cases} x = \frac{f}{Z_C} x_c \\ y = \frac{f}{Z_C} y_c \end{cases} \tag{3}$$

Ignoring image distortion, point P in the pixel coordinate system is (u, v), and the correspondence with (x, y) is:

$$\begin{cases} u = \frac{x}{dx} + u_0 \\ v = \frac{y}{dy} + v_0 \end{cases} \tag{4}$$

where (u_0, v_0) is the projection coordinate of the optical center in the image coordinate system, dx and dy are scaling factors.

When shooting, this article used the Astra Pro depth camera with parameters shown in Table 1.

Table 1

1Astra Pro depth camera parameters

	Parameter
Depth range	0.6-8 m
Relative accuracy	1 m ± 3 mm
Resolution	19,220 × 1,080
Frame rate	30 frames per second
Support operating system	Android/Windows/Linux

For the calibration method, the currently widely used Zhang Dingyou calibration method (*Zhang, 2000*) was used, and Table 2 presents the results of camera calibration.

Table 2

Results of camera calibration

	Calibration result
Internal parameter matrix	$\begin{bmatrix} 784.1254 & 0 & 0 \\ -0.1524 & 784.5524 & 0 \\ 947.5268 & 486.2145 & 1 \end{bmatrix}$
Radial distortion matrix	$[0.1325 \quad 0.4425 \quad -1.0547]$
Tangential distortion matrix	$[0.0063 \quad -0.0026]$

Laboratory experiment

In a laboratory environment, the measurement accuracy of the localization method proposed in this paper for citrus fruits was verified. A depth camera was fixed on the camera support, and a simulated citrus tree model was used to mimic the canopy structure of a real citrus tree. Several citrus fruits were randomly placed on the tree to simulate the picking scenario in an orchard. The laboratory lighting was kept stable to avoid the interference of external light changes. An aurora rangefinder was employed to detect the actual depth values of the fruits, and a spirit level was used to measure the actual coordinates of the fruits. Figure 4 shows the experimental setup.

Fig. 4 - Localization experiment

RESULTS

Dataset establishment

A dataset of citrus fruits was collected in an actual orchard environment to simulate the harvesting scenario of a picking robot. Images were taken in scenarios such as overlapping, dense, and occluded under different environments like front light, backlight, sunny days, and cloudy days. The distance between the camera and the outer edge of the canopy layer was 0.5-1.5 m, depending on the size of the fruit tree, and ultimately 1,186 images were taken. The dataset was divided into training, validation, and testing subsets (80%, 10%, and 10%).

The collected citrus fruit images were labeled using GitHub open-source labeling tool LabelImg (*Du et al., 2024*) to obtain xml format files, and Mosaic data augmentation technique was employed to expand the dataset, yielding a training set of 2,846 images, a validation set of 356 images, and a test set of 356 images.

Experimental setup

The experimental environment and software configurations are presented in Table 3.

Table 3

Experimental environment and software configurations

	Version
Central processing unit	Intel (R) Core i5-13500HX@4.70GHz
Graphics processing unit	RTX4060
Deep learning framework	PyTorch 1.8.1
Python	Python 3.10
Compute Unified Device Architecture (CUDA)	CUDA 11.3

During training, the stochastic gradient descent (SGD) optimizer was used, the epoch was set to 300, the initial learning rate was set to 0.01, the number of weight decay times was 0.005, and the batch size was 32.

Analysis of citrus recognition results

In the improved YOLOv8n model, FasterNet replaced the original backbone network. The recognition results of FastNet and several other models after replacing the YOLOv8n backbone network were compared (Table 4).

Table 4

Comparison of various backbone networks

	Accuracy	Recall	mAP@0.5-0.95
Original bottleneck	0.863	0.847	0.872
efficientViT *(Mu et al., 2025)*	0.871	0.853	0.875
MobileNetV4 *(Qin et al., 2017)*	0.868	0.836	0.874
HGNetV2 *(Deng et al., 2025)*	0.864	0.851	0.876
FasterNet	0.874	0.857	0.884

According to Table 4, when using FasterNet, the accuracy was 0.874, showing an increase of 1.27% compared to the original bottleneck, the recall rate was 0.857, showing an increase of 1.18%, and the mAP was 0.884, showing an increase of 1.37%. Among the comparisons with other models, FasterNet still performed the best. The results suggest that FasterNet's improvements to YOLOv8n is effective.

The recognition effects of various attention mechanisms were compared.

Table 5

Comparison of various attention mechanisms

	Accuracy	Recall	mAP@0.5-0.95
None	0.863	0.847	0.872
SENet (*Du et al., 2025*)	0.874	0.843	0.874
Convolutional Block Attention Module (CBAM)	0.872	0.845	0.875
EMA	0.876	0.855	0.881

According to Table 5, the performance of the model was enhanced to varying degrees after introducing the attention mechanism to YOLOv8n. Specifically, it was found that compared with SENet and CBAM, EMA was the best choice. Compared with the original YOLOv8n, accuracy was enhanced by 1.51%, recall rate by 0.94%, and mAP by 1.03%. The simultaneous improvement in accuracy and recall rate was achieved, suggesting the best performance in citrus recognition. The finding demonstrates the reliability of combining EMA with YOLOv8n.

The recognition outcomes of various loss functions were compared.

Table 6

Comparison of various loss functions

	Accuracy	Recall	mAP@0.5-0.95
CIoU	0.863	0.847	0.872
Distance Intersection over Union (DIoU) (*Huo et al., 2023*)	0.867	0.851	0.875
Efficient Intersection over Union (EIoU) (*Kumar & Dhanalakshmi, 2024*)	0.862	0.845	0.873
WIoU	0.871	0.849	0.882

According to Table 6, the recognition effect of the CIoU used in the original YOLOv8n was relatively poor. WIoU achieved a 0.93% enhancement in accuracy, a 0.24% enhancement in recall rate, and a 1.15% enhancement in mAP compared to CIoU, indicating that using WIoU as the loss function in YOLOv8n can achieve better citrus recognition results.

Finally, the improved YOLOv8n model was compared with some of the current popular deep learning-based detection methods.

Table 7

Comparison of various detection methods

	Accuracy	Recall	mAP@0.5-0.95
Faster R-CNN	0.836	0.826	0.846
YOLOv5n	0.851	0.843	0.867
YOLOv8n	0.863	0.847	0.872
Improved YOLOv8n	0.893	0.894	0.895

According to Table 7, Faster R-CNN performed poorly in citrus recognition, with a mAP as low as 0.846, indicating poor usability of the method in citrus recognition. The comparison between YOLOv5n and YOLOv8n showed that the recognition effect of YOLOv8n was better, demonstrating the reliability of the improvement to YOLOv8n. Finally, the improved YOLOv8n model achieved a mAP of 0.895 for citrus recognition, which can satisfy the recognition needs of the robot.

Analysis of citrus localization results

A total of ten sets of coordinate samples were counted, and the actual coordinates and positioning coordinates of citrus fruits were compared.

According to Table 8, the average errors in the X, Y, and Z directions for citrus positioning were 3.56 mm, 3.54 mm, and 4.74 mm respectively, indicating a relatively small overall positioning error. These errors may come from camera calibration errors and system hardware errors. But overall, the average error of the positioning results was within 5 mm, which can satisfy the positioning needs of robots in the actual citrus orchard environment.

Table 8

Analysis of citrus location results

	Actual coordinates/mm	Positioning coordinates/mm	Error value/mm
1	(352.18, 214.37, 1526.42)	(348.57, 217.94, 1522.11)	(3.61, 3.57, 4.31)
2	(487.62, 189.25, 1468.37)	(491.18, 185.73, 1463.89)	(3.56, 3.52, 4.48)
3	(296.73, 256.48, 1583.65)	(300.24, 252.95, 1578.84)	(3.51, 3.53, 4.81)
4	(415.89, 172.64, 1427.83)	(412.37, 176.28, 1423.26)	(3.52, 3.64, 4.57)
5	(371.52, 238.76, 1542.19)	(367.98, 242.33, 1537.92)	(3.54, 3.57, 4.27)
6	(523.47, 165.38, 1396.24)	(519.89, 168.92, 1391.73)	(3.58, 3.54, 4.51)
7	(284.35, 269.52, 1624.78)	(287.93, 265.96, 1620.07)	(3.58, 3.56, 4.71)
8	(438.71, 157.93, 1375.46)	(442.32, 154.46, 1371.18)	(3.61, 3.47, 4.28)
9	(309.64, 247.25, 1563.82)	(306.07, 250.78, 1559.33)	(3.57, 3.53, 4.49)
10	(466.28, 181.37, 1448.59)	(469.83, 177.86, 1444.28)	(3.55, 3.51, 4.31)

2

CONCLUSIONS

In this study, an optimized YOLOv8n model was developed for the recognition and localization of citrus fruits by citrus-picking robots. Through the analysis of a series of performance indicators, it was found that after replacing YOLOv8n backbone network with FasterNet, the recognition accuracy and FPS were improved. This indicates that the design of partial convolutions effectively reduces the memory access cost while maintaining the feature expression ability. In the comparison of attention mechanisms, EMA did not adopt the dimensionality reduction operation, which avoided the loss caused by channel information compression. Meanwhile, its parallel multi-scale structure fully utilized the parallel computing power of the GPU, hardly increasing parameter quantity and the computational burden. The comparison of loss functions demonstrated that WIoU exhibited good accuracy and mAP. This may be because WIoU assigns dynamic weights to samples of different qualities, forcing the model to focus more on the boundary regression of low-quality samples, such as those with severe occlusion and overlap, during training. According to the outcomes of the indoor positioning experiment, the positioning error of the proposed method for citrus fruits was within 5 mm.

Although the research has achieved certain results, there are two limitations.

(1) Dataset scale: The collected data is limited to a single orchard. The generalization ability of the model in more extensive scenarios (different production areas, fruit maturity levels, and tree shapes) needs to be verified.

(2) Lack of actual picking experiments: The positioning experiments were performed in a simulated laboratory environment, using model trees and artificially arranged citrus fruits. The picking situation in a real orchard environment was not involved.

Based on the limitations, future research will expand the dataset by collecting image data of different varieties, at different maturity stages, and under different weather conditions in multiple citrus-producing areas to construct a larger-scale and more representative citrus fruit dataset, build a complete prototype system of citrus picking robots to conduct end-to-end picking experiments in actual orchards, and study the task allocation and path planning methods for multiple picking robots in large-scale citrus orchards to achieve intelligent and clustered harvesting management of orchards.

In summary, the citrus recognition and localization method based on the improved YOLOv8n performs excellently in terms of recognition accuracy, inference speed, and positioning error, providing effective technical support for citrus picking robots. Although there are certain limitations in aspects such as the dataset scale, this study verifies the basic feasibility and advantages of the method.

ABSTRACT
This study presents a particle-scale coupled CFD–DEM numerical approach for elucidating aerodynamic sorting mechanisms and optimizing process parameters. Non-spherical particle models were developed to represent the geometric and physical differences between shells and seed-bearing particles. The Stokes number, which characterizes the balance between aerodynamic drag and particle inertia, was identified as the primary determinant of sorting performance. Under the optimized conditions, a primary airflow velocity of 8.4 m/s, a secondary airflow velocity of 7.85 m/s, and a feed mass flow rate of 80 g/s, the system achieved a shell purity of 95.3% and a recovery rate of 58.2% when processing feedstock with an initial shell content of 5%. The results further revealed an inherent trade-off between purity and recovery. These findings provide a theoretical and numerical basis for the design and optimization of aerodynamic sorting equipment.

摘要
本研究提出了一种基于颗粒尺度的 CFD-DEM 耦合数值模拟方法，旨在阐明气动分选机制并优化工艺参数。建立了非球体模型，以表征果壳与种子团聚体之间的几何和物理差异。研究发现，表征气动阻力与惯性平衡的斯托克斯数是分选性能的核心决定因素。在最优条件下（主气流速度 8.4 m/s，副气流速度 7.85 m/s，进料速率 80 g/s），以初始纯度为 5%的原料为进料，可获得 95.3%的壳体纯度和 58.2%的回收率。研究揭示了纯度与回收率之间固有的权衡关系，为分选设备的设计与优化提供了理论和数据支持。

INTRODUCTION
Zanthoxylum bungeanum serves as a vital spice and economic crop in China, celebrated for its unique pungent and numbing flavor, which primarily derives from the volatile oils and alkyl amides found in its pericarp *(Shi et al., 2025)*. Post-harvest processing typically results in a mixture of hollow shells and seed-bearing particles after threshing. Given the significant differences in flavor profiles, economic value, and suitability for downstream processing between the shells and seed-bearing particles, efficient separation is essential for improving product purity and market value *(Mutinda et al., 2023)*. Conventional sieving methods are ineffective due to the overlapping size and density ranges of these components. However, the distinct shapes and aerodynamic properties of the shells and seed-bearing particles offer a promising opportunity for separation through airflow classification, a precise sorting technique well-suited for this fine separation task *(Stepanenko et al., 2022).*

Aerodynamic sorting is a clean, efficient technology widely used for cleaning and grading agricultural materials. Its effectiveness depends on the interaction between material properties (size, shape, density, terminal velocity) and airflow parameters *(Zhu et al., 2021).* Particle shape significantly influences aerodynamic behavior; non-spherical particles behave differently from spherical ones *(Ulusoy et al., 2023). Zanthoxylum bungeanum* shells and seed-bearing particles are typical non-spherical granules. Their separation involves complex gas-solid interactions that traditional empirical design methods fail to adequately explain at the particle scale. In recent years, coupled CFD–DEM has become a robust tool for investigating complex multiphase flows. DEM effectively captures the geometry, contact mechanics, and motion of non-spherical particles *(Ma et al., 2022).*

Representative applications include: safflower petal cleaning, where high-fidelity shape models visualized trajectory separation driven by mass and aerodynamic differences *(Hu et al., 2021)*; sunflower seed shell-kernel separation, optimizing air channel parameters *(Guan et al., 2025);* rice cleaning, using multi-sphere models to study airflow velocity and inclination angle effects on impurity and loss rates *(Ma et al., 2020)*.

Accurate CFD–DEM simulations rely on precise particle models and contact parameters. Foundational studies have established the fundamental physical properties of *Zanthoxylum bungeanum* particles and their contact parameters with common engineering materials via experiments and calibration *(Wang et al., 2023; Zhang et al., 2022)*, providing a reliable particle-scale mechanical basis. For non-spherical particles, the parametric function method offers a flexible, efficient approach to construct complex non-convex geometries, especially suitable for biological particles with concave features *(Zhao et al., 2021)*. Despite advancements, systematic CFD–DEM studies on the motion, separation dynamics, and mechanisms of *Zanthoxylum bungeanum* shell-seed mixtures in tailored airflow fields remain lacking. To address this gap, the present study employs parametric proxy models based on superquadric surfaces *(Xu et al., 2025)* to capture critical geometric differences between shells and seed-bearing particles. High-fidelity discrete–element simulations are achieved by three-dimensional modeling in SolidWorks and subsequently importing them into rocky DEM software.

MATERIAL AND METHODS

GOVERNING EQUATIONS AND NUMERICAL METHODOLOGY

In the simulation herein, air was simply modelled as an incompressible ideal gas *(Xiao et al., 2022)*. The overall initial conditions of the system assumed homogeneous air distribution, neglecting other secondary factors such as dust generation, particle shrinkage, and chemical reactions. The gas phase was treated as a single continuous medium, with its flow governed by the continuity and momentum equations solved within a standard Eulerian framework. Momentum exchange between the gas and solid phases was incorporated through appropriate interphase momentum exchange terms *(Wu et al., 2025)*. Utilizing the widely adopted fluent-rocky coupled strategy, this model employed the Eulerian multiphase model in commercial fluent to resolve gas flow, while simultaneously the Discrete Element Method (DEM) in rocky was used to track the motion of individual particles. This robust integrated approach facilitated a high-fidelity coupled simulation of the gas-solid two-phase system.

The mass conservation equation is expressed as:

$$\frac{\partial}{\partial t}\left(\rho_g \theta_g\right) + \nabla \cdot \left(\rho_g \theta_g u_g\right) = 0 \tag{1}$$

where: u_g is the fluid velocity vector, m/s; ρ_g is the gas-phase density, kg/m^3; θ_g is the gas phase volume fraction, %.

The momentum conservation equation is:

$$\frac{\partial}{\partial t}\left(\rho_g \theta_g u_g\right) + \nabla \cdot \left(\rho_g \theta_g u_g u_g\right) = -\nabla P + \nabla \cdot \left(\theta_g \tau_g\right) + \rho_g \theta_g g + M \tag{2}$$

where: P is the static pressure, Pa; τ_g is the gas-phase viscous stress tensor, Pa; g is the gravitational acceleration vector, m/s²; M is the gas-solid interphase momentum exchange rate per unit volume, N/m³.

For a Newtonian fluid, the viscous stress tensor can be expressed as:

$$\tau_g = \mu_g \left[\nabla u_g + \left(\nabla u_g\right)^T\right] - \frac{2}{3}\mu_g \left(\nabla \cdot u_g\right) I \tag{3}$$

where: u_g is the gas dynamic viscosity.

The interphase momentum exchange rate is given by the following equation:

$$M = -\frac{1}{V_{cell}} \sum_{l=1}^{n} F_{d,l} \tag{4}$$

where: $F_{d,l}$ is the drag force acting on particle i, N; V_{cell} is the computational cell volume, m^3.

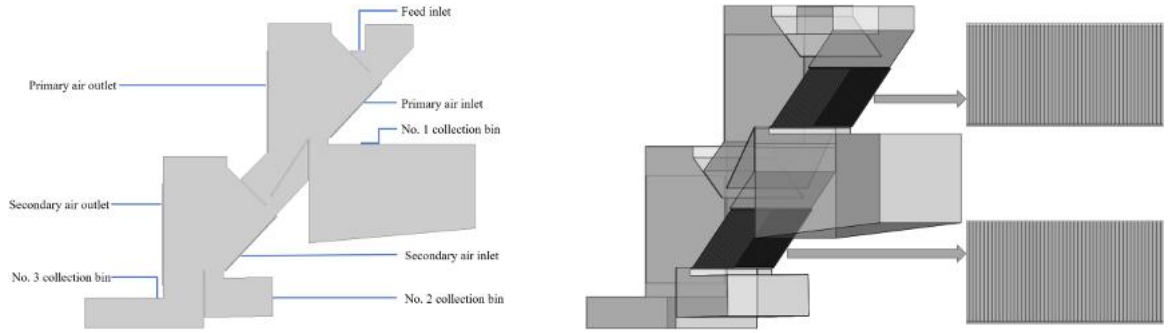
In multiphase flow systems, the motion of the particulate phase can be described using a probability distribution function in conjunction with the Liouville equation *(Domínguez-Vázquez et al., 2024)*. For the particulate phase of *Zanthoxylum bungeanum*, a distribution function $f\left(x, u_p, p_p, V_p, t\right)$ is defined, where x, u_p, p_p, V_p and t represent the particle's spatial position, velocity vector, density, volume, and time. This function fully defines the probabilistic distribution state of the particles in phase space, and the system is closed by solving the following Liouville equation:

$$\frac{\partial f}{\partial t} + \nabla_x \cdot (f u_p) + \nabla_{u_p} \cdot (f a_p) = 0 \quad (5)$$

where: a_p is the particle acceleration, m/s², determined by the net force acting on the particle according to Newton's second law.

In the simulation, air enters the chamber and penetrates the porous particle layer. Confined by walls and outlet geometry, fully developed turbulence forms. Due to short inlet–outlet distance and narrow flow gaps, a complex flow structure with recirculation and vortices emerges *(Echendu et al., 2011)*. To simulate this turbulence, the Realizable k-ε model *(Gong et al., 2025)* is used to close the Reynolds-averaged Navier-Stokes equations. This model computes turbulent viscosity by solving transport equations for turbulent kinetic energy (k) and dissipation rate (ε).

$$\mu_t = \rho_g C_\mu \frac{\kappa^2}{\epsilon} \quad (6)$$



where: C_μ is no longer a constant. The empirical constants in the model take the following standard values: $C_{1\epsilon}$=1.44, C_2=1.9, σ_k=1.0, σ_ϵ=1.2.

SIMULATION SETUP

Computational Model and Parameter Specification

To investigate the motion patterns of particles during air-classification, a model of the classification apparatus measuring 397 mm in length, 110 mm in width and 309 mm in height was constructed; the apparatus is equipped with one feed inlet, two air inlets, two air outlets, three collection chambers and two classification stages (Fig. 1a). The two air inlets, with a combined length of 110 mm and a width of 76 mm, are inclined at an angle of 46.7° relative to the horizontal plane. They consist of a series of slotted inlets, each 2 mm wide and spaced 0.1 mm apart (Fig. 1b). They are made of the same material as the apparatus casing, and the width of the inlets is smaller than that of the *Zanthoxylum bungeanum* grains.

During the sorting process, the particles fall under the influence of gravity along a deflector plate inclined at an angle of 45° to the horizontal. The first stage performs preliminary separation, increasing the shell proportion entering the second stage. After first-stage separation, most seed-bearing particles and a few shells enter Collection Bin 1. The remaining mixture proceeds to the second stage for fine sorting. Ultimately, Collection Bin 3 yields predominantly shells, while Bin 2 contains a mixture.

(a) general schematic diagram *(b) close-up*

Fig. 1 - Schematic of the sorting device model

ANSYS Fluent was used to establish a continuous-phase flow field; *Zanthoxylum bungeanum* particles were generated using the 3D modelling software SolidWorks and imported into Rocky for DEM simulation. In the numerical simulation, the continuous-phase CFD calculations were performed on a 12th-generation Intel® Core™ i5-12490F processor with 16 GB of system memory. The discrete-phase DEM calculations were performed on an NVIDIA GeForce RTX 4060 graphics card with 8 GB of dedicated GDDR6 video memory. The CFD simulation for the gas phase took approximately 10 minutes, using the 'Automatic' time-step method, a time scaling factor of 0.1, and 200 iterations; the DEM simulation for the solid phase took approximately 74 hours, with a simulation duration of 4 s, with a time interval of 0.01 s. Since the volume fraction of the particulate phase is 0.068%, constituting a dilute gas-solid two-phase flow, and given the simulation time constraints, the gas-phase separation process was simulated using the Fluent-Rocky unidirectional coupling method *(Guan et al., 2025; Luo et al., 2020)*. The gas-phase governing equations are discretized by the finite volume method with the SIMPLE algorithm and second-order upwind scheme, and the realizable k-ε model is used for turbulence closure. For the discrete particle phase, the soft-sphere contact model is applied to calculate inter-particle and particle-wall contact forces, and particle kinematics are updated by an explicit time integration scheme in the Lagrangian framework.

The coefficient of restitution, coefficient of static friction and coefficient of rolling friction between *Zanthoxylum bungeanum* particles are 0.378, 0.56 and 0.0143, respectively. As the rolling coefficient of friction between *Zanthoxylum bungeanum* particles and galvanized steel sheet is relatively low (0.168) *(Zhang et al., 2022)*, this material was selected for the device walls. In this simulation, the density of the *Zanthoxylum bungeanum* was set at 997 kg/m³, with a Poisson's coefficient of 0.168 and a Young's modulus of 1.568×10^7 Pa *(Wang et al., 2023)*. The density of galvanized steel was 7,850 kg/m³, with a Poisson's coefficient of 0.3 and a Young's modulus of 206 GPa *(Gu et al., 2024)*.

Rationale and Parameterization of Particle Geometry Simplification

This study investigates the sorting process of *Zanthoxylum bungeanum* shells and seed-bearing particles. The total feed mass is 50 g, and the initial shell mass fraction is 5%. The material enters via the feed inlet at the top of the apparatus, with a total mass flow rate of 50 g/s to 120 g/s; the feed falls freely without any initial velocity. Air enters through two air inlets at a velocity of 6.85 m/s to 8.85 m/s, which corresponds to a volumetric flow rate of 206.16 m³/h to 266.35 m³/h. In the coupled CFD–DEM simulations, physics-oriented proxy models are used to balance computational efficiency and fidelity *(Ma et al., 2022)*.

Geometry is simplified based on dominant aerodynamic sorting mechanisms to capture the separation of shells from seed-bearing particles. Despite similar density, shells and seed-bearing particles behave differently due to geometry-induced forces. In transverse flow, trajectory reflects the Stokes number (drag vs. inertia), set by the volume-to-mass ratio linking geometry to dynamics *(Zhao et al., 2024)*. Based on mechanistic analysis, the volume-to-mass ratio is identified as the dominant parameter controlling shell–seed separation. To capture this difference in the model, two critical geometric features are abstracted: (1) the hollow, thin-walled shell structure, which causes the mass difference; (2) the aperture size, which affects the maximum projected area and thus the drag coefficient. Guided by this analysis, parametric proxy models are established *(Michaelides et al., 2023)*: pepper shells are modeled as hollow, thin-walled structures with large apertures to achieve a high volume-to-mass ratio; seed-bearing particles are modeled as composite structures with small apertures and internal spherical seed fillings to obtain a low volume-to-mass ratio. Geometric parameters are determined via sensitivity analysis from a preliminary study to maximize the difference in dynamic behavior.

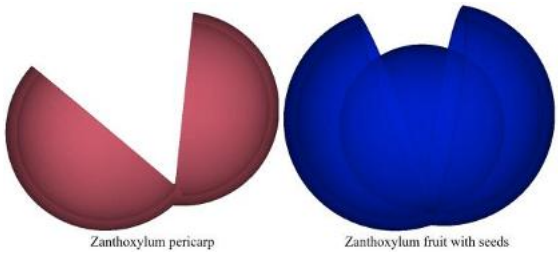


Fig. 2 - Geometric models of the particles

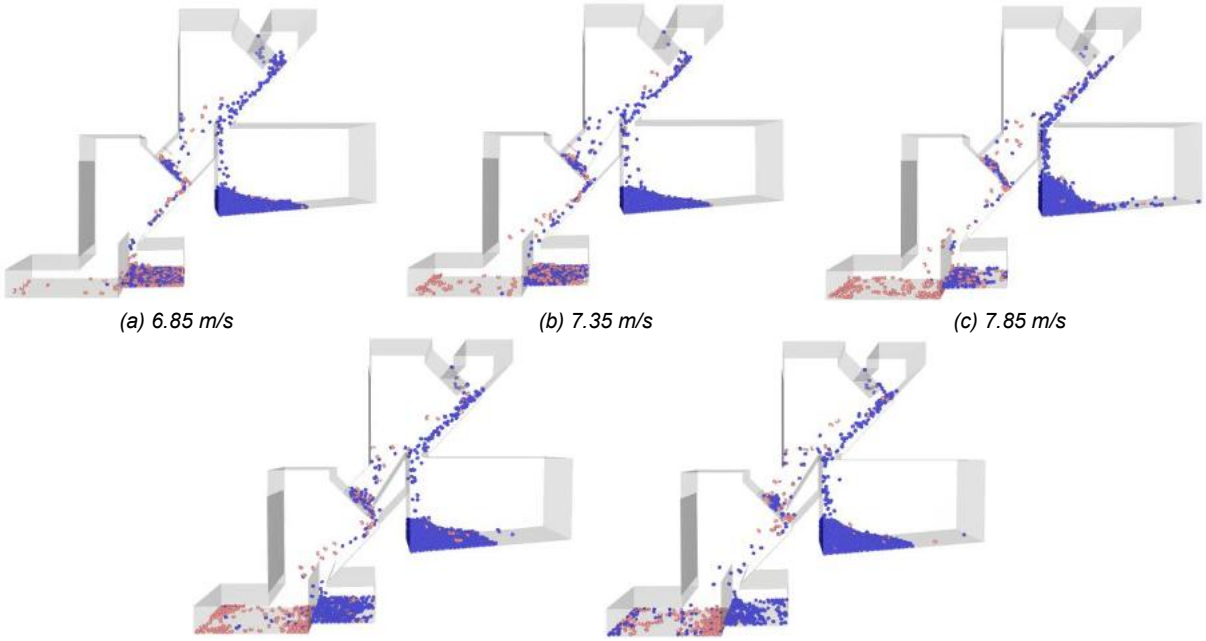
RESULTS AND DISCUSSION

Particle Distribution and Separation Mechanism

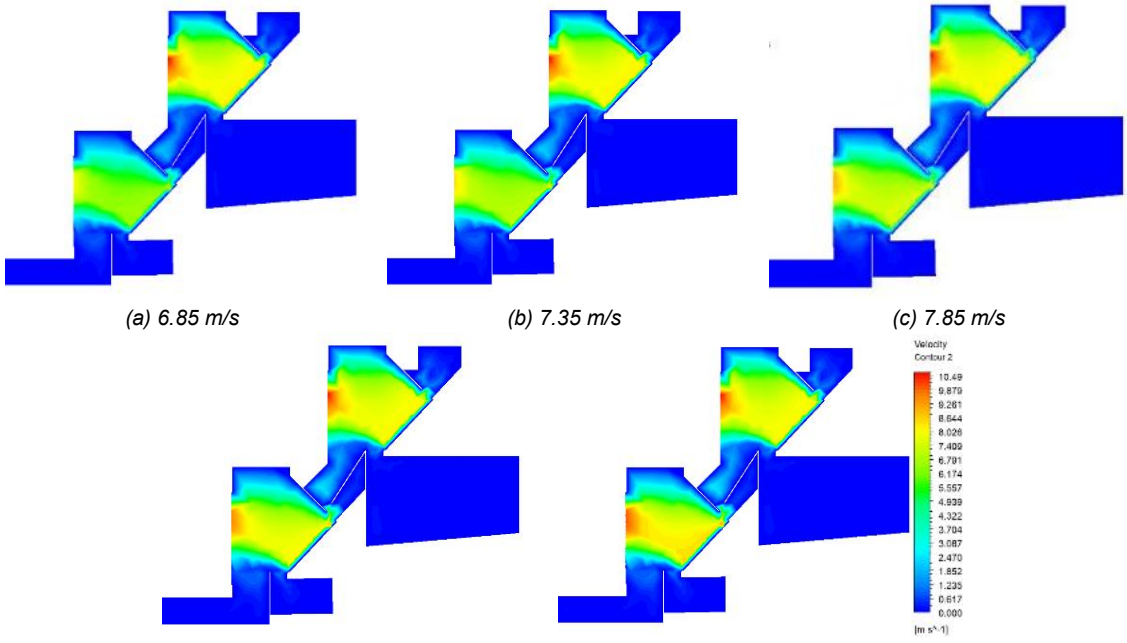


Recovery and purity are in conflict *(Lundin et al., 2024)*; for *Zanthoxylum bungeanum*, high purity is demanded. We thus maximize shell recovery in Bin 3 at >90% purity, acknowledging that relaxing purity boosts yield. To separate shells from seed-bearing particles, simulations employed distinct particle sizes/shapes *(Li et al., 2024)*. Despite similar density, volume/mass differences cause distinct free-fall behaviors. In airflow, particles experience gravity, drag, and inertia. Shells have a high volume-to-mass ratio and are easily entrained; seed-bearing particles have a low ratio, leading to stronger sedimentation and shorter migration *(Zhou et al., 2023)*. Adjusting airflow velocity amplifies this ratio's effect on trajectories, achieving separation. CFD–DEM validation clarifies sorting physics, enabling rational parameter selection over empirical optimization.

Effect of Secondary Airflow Velocity on Sorting Performance

Secondary airflow velocity was a key parameter governing both the flow-field characteristics and separation performance within the second-stage classification zone. By analyzing the flow-field contour maps (Fig. 4) and particle-distribution patterns (Fig. 3) at different airflow velocities, the underlying separation mechanism was clarified.

At low velocities (6.85–7.35 m/s), the low-velocity regions (cool colors) was uniform with a gentle gradient and lacks a high-speed core, indicating insufficient kinetic energy to penetrate the particle bed. At the optimal velocity (7.85 m/s), a stable, well-defined high-speed pathway formed without recirculation or vortices, concentrating flow energy along the separation path for highly selective sorting. At higher velocities (8.35–8.85 m/s), the flow became chaotic, with localized high-speed patches and recirculation vortices, where excess



kinetic energy caused instability, dissipation, and flow separation. At low velocities, insufficient drag yielded high Stk; particle motion was inertia-dominated. Shells were not conveyed to Bin 3, causing low recovery; seed-bearing particles settled normally. Bin 3 purity remained acceptable, but the efficiency was poor. At the optimal velocity (7.85 m/s), drag and inertia were balanced: shells were carried into Bin 3, while seed-bearing particles settled into Bin 1, achieving separation. At high velocities, excessive drag caused an “over-bearing” effect, entraining seed-bearing particles into Bin 3 and reducing its purity to 52.5%. The Stokes number difference between the two particle types diminished; their dynamic responses converge, and separation selectivity was lost. Thus, secondary airflow velocity governed particle trajectories via the Stokes number by modulating flow-field structure and gas-solid momentum transfer.

(d) 8.35 m/s *(e) 8.85 m/s*

Fig. 4 - Contour of secondary airflow velocity

As shown in Fig. 5, with increasing secondary airflow velocity, shell purity in Bin 3 first rose then declined (with a sharper drop at high speeds), while purity in Bin 2 decreased continuously. Although excessively low airflow velocity helped prevent heavier seed-bearing particles from entering Bin 3, it also reduced the overall inflow of pepper shells, resulting in low shell purity in this bin.

Notably, seed-bearing particles had a larger mass and settling velocity, and even a small amount of their potential contamination could markedly reduce the purity of pepper shells. Notably, Bin 2 purity remained below 30%, whereas Bin 3 consistently exceeded 50%, confirming effective enrichment by the secondary airflow stream. At an airflow velocity of 7.35 m/s, the shell purity in Bin 3 reached a maximum of 96.6%, whereas the recovery rate was only 25.7% (Fig. 6). When the airflow velocity increased to 7.85 m/s, purity decreased slightly to 91.8%, while recovery increased substantially to 59.7%. These results clearly demonstrate the inherent trade-off between purity and recovery, indicating that system optimization must balance these competing objectives. The findings are consistent with the fundamental principles of aerodynamic classification and provide previously unavailable particle-scale mechanistic insights into the separation behavior of *Zanthoxylum bungeanum*. The validated CFD–DEM framework therefore offers a robust tool for the rational design and optimization of sorting equipment for similarly complex agricultural materials.

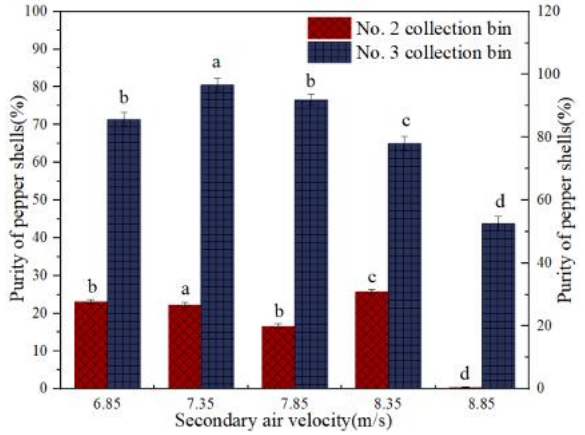

Fig. 5 - Purity of Pepper Shells in Different Collection Bins

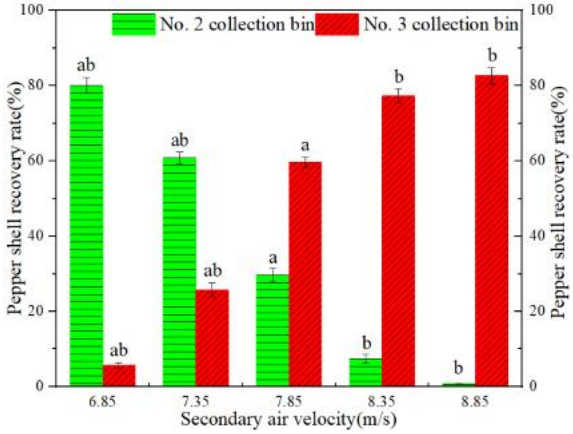

Fig. 6 - Recovery Rate of Pepper Shells in Different Collection Bins

As shown in Fig. 6, Bin 2 achieved the highest shell recovery at an airflow velocity of 6.85 m/s, reaching 80.1%, although shell purity remained below 25%. At 8.85 m/s, shell recovery in Bin 3 increased to 82.7%; however, the entrainment of seed-bearing particles reduced shell purity to a minimum of 52.5%. These results indicate that increasing airflow velocity enhances shell recovery but may simultaneously reduce product purity because of greater carryover of non-target particles. Figs. 5 and 6 further quantify the effect of secondary airflow velocity. Increasing the velocity from 7.35 to 7.85 m/s reduced shell purity in Bin 3 from 96.6% to 91.8%, while markedly increasing recovery from 25.7% to 59.7%, resulting in a more favorable overall separation performance at 7.85 m/s. This behavior can be interpreted in terms of Stokes number (Stk) optimization *(Farooq et al., 2023)*. At 7.85 m/s, Stk for the shells was much less than 1, indicating fluid-dominated motion, whereas Stk for the seed-bearing particles was close to or greater than 1, indicating inertia-dominated motion. Maximizing the difference in Stk between the two particle groups therefore promotes efficient aerodynamic separation.

At an airflow velocity of 8.85 m/s, shell recovery increased to 82.7%, whereas purity decreased sharply to 52.5%. This indicates that excessive airflow velocity reduces the difference in Stokes number between the two particle groups, thereby weakening separation selectivity. Accordingly, 7.85 m/s was identified as the optimal velocity for balancing recovery and purity. Under this condition, Bin 3 achieved a shell recovery of 59.7% and a purity of 91.8%. Aerodynamic drag enabled highly selective separation while minimizing the carryover of seed-bearing particles. The less-than-maximum recovery may be attributed to shells with aerodynamic characteristics close to the separation threshold, as well as particle losses caused by interparticle collisions and unfavorable initial positions. These limitations could be addressed in future studies through multistage cascade separation or improved flow-field uniformity.

By achieving a purity of 91.8% and a recovery of 59.7%, the separation of *Zanthoxylum bungeanum* shells from seed-bearing particles was successfully accomplished, despite their similar physical properties. This result outperforms traditional sieving processes (which are prone to blockages and are inefficient), demonstrating the feasibility and superiority of aerodynamic sorting in this application. The CFD–DEM framework elucidates the mechanisms at the particle scale and provides a predictive tool for optimizing the sorting of other complex agricultural products. A limitation of this study is its focus on single-stage optimization; future research could explore dynamic control or multi-stage integration to further enhance the upper limits of purity and recovery.

Effect of Primary Airflow Velocity on Sorting Performance

The primary airflow provides the initial momentum and performs pre-classification for the entire sorting process. With the secondary airflow velocity fixed at the optimal 7.85 m/s, the influence of the primary airflow velocity was systematically investigated. As shown in Fig. 7, increasing the primary airflow velocity led to a gradual decrease in the purity of pepper shells collected in Bin 3. The underlying cause of this trend can be attributed to a chain reaction in the dynamics: an excessively high primary velocity imparts substantial horizontal initial kinetic energy to the particles, reducing their effective residence time in the first-stage classification zone. The resulting high-energy, high-concentration particle stream then enters the stabilized flow field of the secondary classification zone, where it substantially increases the frequency of interparticle collisions. These interactions promote dynamic agglomeration and ultimately impair separation performance. Therefore, the objective of primary-airflow optimization is not to maximize preliminary separation, but rather to deliver a uniformly distributed feed with moderate kinetic energy to the secondary stage. This is an essential prerequisite for effective fine classification. Unlike studies that evaluate airflow parameters independently, the present analysis reveals the coupling between successive classification stages and highlights the importance of coordinated parameter optimization for overall system performance.

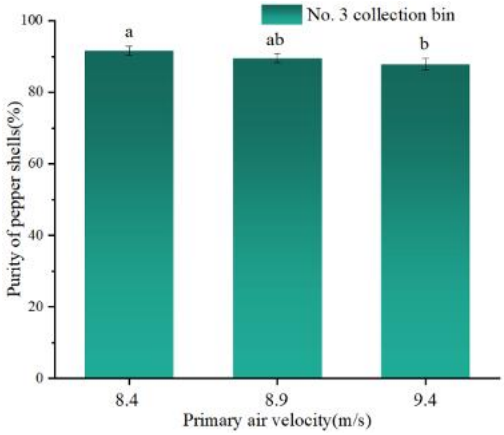

Fig. 7 - Purity of Pepper Shells in Collection Bin 3

Effect of Feed Mass Flow Rate on Sorting Efficiency

Under the optimal airflow conditions, the feed mass flow rate exhibited a trade-off between processing capacity and separation performance. As the feed mass flow rate increased from 64 to 80 g/s (Figs. 8 and 9), shell purity in Bin 3 increased from 91.8% to 95.3%, while recovery decreased slightly from 59.7% to 58.2%. This behavior may be attributed to the higher solid-to-gas ratio at the increased feed rate.

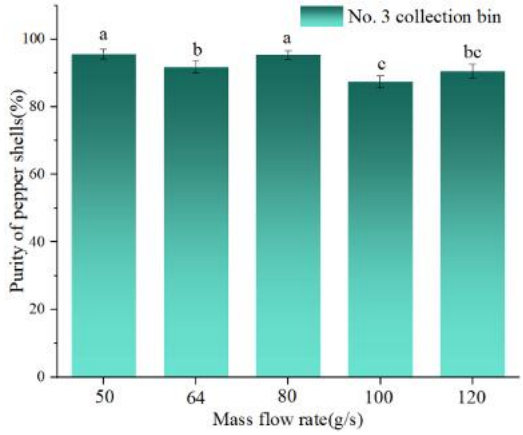

Fig. 8 - Purity of Pepper Shells in Collection Bin 3

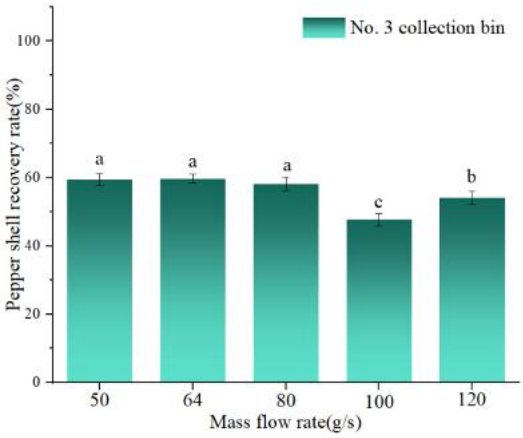

Fig. 9 - Recovery Rate of Pepper Shells in Collection Bin 3

The greater particle concentration intensified interparticle interactions and reduced the average aerodynamic drag acting on individual particles. The consistently high purity observed over the tested range indicates that the fundamental separation mechanism remained effective. Increasing the feed mass flow rate to 80 g/s produced a 25% increase in throughput with only a minor reduction in recovery, representing a

favorable engineering compromise. Considering purity, recovery, and processing capacity together, 80 g/s was identified as the optimal feed mass flow rate, yielding a shell purity of 95.3%, a recovery of 58.2%, and the highest throughput tested. In practical applications, overall system performance is more important than maximizing any single indicator. The recovery of 58.2%, achieved without compromising shell purity, represents a balanced and practically relevant operating condition for potential industrial scale-up. These findings demonstrate the value of multi-objective optimization over isolated parameter adjustment and provide a transferable approach for designing sorting systems for similarly complex agricultural materials.

Effect of Feedstock Shell Purity on Sorting Performance

Under the optimal operating conditions—a primary airflow velocity of 8.4 m/s, a secondary airflow velocity of 7.85 m/s, and a feed mass flow rate of 80 g/s—increasing the shell content of the feedstock from 5% to 80% progressively increased shell purity in Collection Bin 3 from 95.3% to 99.5% (Fig. 10). This strong positive relationship demonstrates the substantial influence of particle composition on separation selectivity.

The increase in Bin 3 purity may be explained by changes in the internal particle-flow structure. At a low feedstock shell content of 5%, the target shell fraction is dispersed within a dense background of seed-bearing particles. Although the aerodynamic drag acting on individual shells may be sufficient for separation, frequent collisions with the more abundant seed-bearing particles disturb shell trajectories, preventing some shells from reaching Bin 3 and limiting purity to 95.3%. At higher feedstock shell contents of 60–80%, the particle stream becomes shell-dominated. This collective flow structure may reduce random particle motion, strengthen momentum coupling among shells, and promote more coherent migration of the particle cloud toward Bin 3. Consequently, shell purity approaches 99.5%.

However, increasing the feedstock shell content from 5% to 80% reduced shell recovery in Bin 3 from 58.2% to 49.2% (Fig. 11), revealing an inherent trade-off between purity and recovery. For applications requiring extremely high product purity, a feedstock shell content of at least 60% may be selected, yielding up to 99.5% purity while accepting a recovery of approximately 49.2%. By contrast, when higher recovery is prioritized, a feedstock shell content of 5% provides approximately 95.3% purity and 58.2% recovery. These relationships provide a basis for selecting operating conditions according to different production objectives.

CONCLUSIONS

This study elucidated the fundamental mechanism governing the aerodynamic separation of *Zanthoxylum bungeanum* shells from seed-bearing particles. The results demonstrated that separation is primarily controlled by the balance between aerodynamic drag and particle inertia, as characterized by the Stokes number. The substantial difference in Stk between the two particle types, arising from their distinct volume-to-mass ratios and aerodynamic responses, enabled effective segregation.

Systematic parameter analysis showed that the secondary airflow velocity was the most influential factor affecting separation selectivity. At 7.85 m/s, the secondary airflow established a stable flow field in which aerodynamic drag and particle inertia were favorably balanced. The primary airflow mainly conditioned and distributed the incoming particle stream, whereas an excessively high primary airflow velocity disrupted secondary classification. A feed mass flow rate of 80 g/s provided a favorable compromise between throughput and separation performance.

Under the optimized operating conditions of a primary airflow velocity of 8.4 m/s, a secondary airflow velocity of 7.85 m/s, and a feed mass flow rate of 80 g/s, the device processed feedstock containing 5% shells and produced a shell fraction in Collection Bin 3 with a purity of 95.3% and a recovery rate of 58.2%. These results validated the proposed aerodynamic separation mechanism. The study also quantified the inherent trade-off between purity and recovery, thereby providing practical guidance for selecting operating conditions according to different downstream requirements.

Feedstock composition strongly influenced the internal particle-flow regime. Feedstock with a high shell content promoted a shell-dominated flow structure and enhanced collective particle migration toward Collection Bin 3, resulting in shell purities exceeding 99%. However, this improvement was accompanied by a lower recovery rate, indicating that feedstock composition should be considered in the design of upstream pre-sorting processes.

The integrated framework combining physics-based proxy modeling with CFD–DEM simulation successfully reproduced the aerodynamic separation of a non-spherical, multicomponent particle mixture. By linking particle-scale mechanics with system-scale separation performance, the framework provides a reliable basis for the design and optimization of sorting equipment for similarly complex agricultural materials.

ABSTRACT
Automatic transplanting of plug seedlings is critical for improving agricultural efficiency. However, existing systems often suffer from functional fragmentation and use rigid end-effectors prone to damaging seedlings. This study presents a fully integrated automatic transplanting system that uniquely combines multi-tray storage and conveying, precise step-moving, manipulator-based picking and placing with a novel flexible end-effector, and automatic tray collection. In experiments using pepper seedlings, conducted over repeated trials (n=5) with 576 seedlings per trial, the integrated system achieved a picking success rate of 93.24% and a damage rate of 1.43%, with a maximum conveying positioning deviation of 1.79 mm. Compared with previously reported transplanting systems, the proposed system achieves a superior success rate while delivering a substantially lower seedling damage rate. This research provides a practical, highly integrated solution for small-to-medium scale nurseries.

摘要
全自动穴盘苗移栽对于提高农业效率至关重要。然而，现有系统常存在功能碎片化问题，且使用易损伤幼苗的刚性末端执行器。本研究提出了一种全自动移栽系统，创新地集成了多盘存储与输送、精确步进定位、基于机械手的移栽（配备新型柔性末端执行器）以及空盘自动收集。在以辣椒幼苗为对象的重复试验中（n=5，每次 576 株），该集成系统的取苗成功率达 93.24%，损伤率为 1.43%，最大输送定位偏差为 1.79 mm。与已有文献报道的移栽系统相比，本系统在达到更优异的取苗成功率的同时，实现了更低的幼苗损伤率。本研究提供了一种实用、高度集成的解决方案，适用于中小型苗圃。

INTRODUCTION
Seedling transplanting techniques are extensively used in the cultivation of major crops such as vegetables and rapeseed in China *(Liu et al., 2023)*. Compared with direct seeding, transplanting can shorten the field growth period of crops, enhance their resistance to natural disasters, and significantly increase yield per unit area *(Sharma and Khar, 2022)*. As labor shortages and rising costs become more pronounced, the development of efficient and reliable automatic transplanting machines is crucial *(Yang et al., 2020)*.

Currently, seedling transplanting in China still predominantly relies on semi-automatic transplanters *(Han et al., 2019; Jin et al., 2021)*. Their operational efficiency and quality are limited by the speed of manual seedling picking, resulting in low productivity, operator fatigue, and inconsistent plant spacing *(Wen et al., 2021; Zhang et al., 2024)*. To overcome these bottlenecks, developing fully automatic transplanting mechanisms has become a key research focus *(Khadatkar et al., 2021; Liu et al., 2022)*.

In European and American countries, fully automatic transplanters have reached an advanced level, such as the FUTURA from Ferrari and the GR-2700 from Visser *(Shao et al., 2021)*. However, such machines are typically large, costly, and designed for standardized trays, making them difficult to adapt to the small-to-medium scale and diversified operation modes in China *(Tian et al., 2022)*.

Chinese researchers have focused on the core seedling picking device, developing various technical approaches. *Shang et al. (2026)* developed an automatic seedling picking and placing manipulator for tobacco

Chao He, Ph.D. Eng.; Tian Jiao, Ph.D. Eng.; Tie Ye, Ph.D. Agr.; Mingyuan Wei, Ph.D. Eng.; Wanrui Song, Ph.D. Agr.

seedling transplanting machines, and conducted kinematics analysis and optimization. While their study did not address the integration of the manipulator with upstream seedling feeding and downstream tray handling, leaving the overall workflow discontinuous. *Jin et al. (2018)* designed a single-row automatic transplanting device for tomato plug seedlings, although the device demonstrated feasibility, the use of rigid picking fingers caused noticeable damage to seedling roots during clamping.

Han et al. (2023) developed a simplified automatic transplanting device equipped with a multi-needle gripper. However, the multi-needle design exerted concentrated stress on the substrate surface, leading to local breakage of the soil plug in approximately 2.69% of the seedlings tested. *Ye et al. (2020)* proposed a rotary seedling pick-up mechanism that improved picking speed, yet the rotating motion generated considerable inertial forces that compromised positioning accuracy at higher operating speeds. *Zhou et al. (2024)* combined pneumatic and mechanical technologies to design a dual-row seedling pick-up transplanter, but the complex pneumatic circuit and multiple actuators increased system cost and maintenance complexity.

In terms of functional integration, *Zhao et al. (2022)* designed a multi-functional transplanting system integrating sorting, transplanting, and replanting. Despite its innovative integration, the system relied on a vision module that significantly increased processing time, reducing overall throughput. *Zhu et al. (2025)* put forward automated equipment for vegetable seedling transplanting, which enables intermittent seedling feeding, precise seedling picking and rapid seedling planting. Nevertheless, their system still employed rigid end-effectors without passive compliance, and the upstream/downstream tray logistics were not fully automated.

A critical review of the existing literature indicates that several key challenges and research gaps persist. Firstly, most seedling pick-up mechanisms utilize rigid fingers that can damage the root system *(Bai et al., 2022)*. This issue is particularly acute in the designs of *Jin et al. (2018)*, *Han et al. (2023)*, and *Zhu et al. (2025)*, where concentrated clamping forces directly injured seedlings. Secondly, mechanisms with multiple simultaneously operating end-effectors can generate significant inertial impact, affecting precision and stability, as observed in the rotary mechanism of *Ye et al. (2020)* and the pneumatic system of *Zhou et al. (2024)*. Thirdly, and most critically, at the system level, existing research often focuses narrowly on picking and placing, neglecting upstream processes of tray storage and conveying, and downstream empty tray collection. This functional fragmentation limits overall automation and operational continuity.

To address these challenges, the present study puts forward the following innovations: (1) A novel flexible end-effector with a passive compliance mechanism is developed, integrating a spring-buffering and hinge-sliding composite structure that effectively decouples actuation force from clamping force, thereby reducing clamping impact and minimizing seedling injury. (2) An integrated automatic transplanting system is established, combining multi-tray storage and conveying, step-by-step positioning, manipulator-based picking and placing, and automatic tray collection. Our integrated design achieves a continuous and fully automated process from full-tray input to empty-tray stacking, eliminating intermediate manual interventions.

The overarching objective of this study is to provide a practical, highly integrated, and low-damage automatic transplanting solution suitable for small-to-medium scale nurseries in China. Through the integrated design and flexible end-effector, this research offers a feasible technical pathway for automated plug seedling transplanting, and serves as an important reference for developing next-generation automatic transplanting equipment.

MATERIALS AND METHODS

Overall Design of the Integrated Automatic Transplanting System

The automatic transplanting system consists of a frame, plug trays, a multi-tray storage and conveying unit, a tray step-moving unit, a seedling picking and placing unit, and a tray collecting unit (Fig. 1). The key technical specifications of the developed automatic transplanting system are summarized in Table 1.

The system workflow is as follows: eight 72-cell plug trays (cell center distance 42 mm) are placed on the storage unit. A geared motor drives them vertically to the picking station. An electric push rod pushes the tray onto the step-moving unit, which uses a dual-axis linear module to move the tray step by step (42 mm each time) along an S-shaped path. After the tray step-moving unit completes precise tray positioning, a cam in the seedling picking and placing unit ejects the seedling from the tray. Subsequently, a manipulator equipped with the flexible end-effector completes the seedling picking, lifting, transferring, and releasing operations. When all seedlings in one tray are transplanted, the empty tray is pushed to the collection unit, where it is lifted by cams and supported by electric push rods for stacking. Simultaneously, the multi-tray storage and conveying unit pushes the next tray filled with seedlings onto the step-moving unit, allowing the seedling picking and placing unit to begin a new transplanting cycle, achieving continuous operation.

Table 1

Key technical specifications of the integrated automatic transplanting system

Parameter	Value / Specification
Overall dimensions (L × W × H)	2140 × 705 × 1265 mm
Total weight	273 kg
Total installed power	approximately 1.0 kW
Power supply	220V AC
Manipulator X/Y repeatability	±0.03 mm
Manipulator Z repeatability	±0.2 mm
Minimum motion cycle	0.8 s
Maximum operating speed	approximately 600 mm/s
Rated load (at min. cycle)	200 g
Transplanting efficiency	60 plants/min/row

Design of the Seedling Picking and Placing Unit

The seedling picking and placing unit mainly consists of a manipulator device and a seedling ejection device. The ejecting device pushes the seedling out of the tray, and the manipulator device then picks, transports, and releases the ejected seedling.

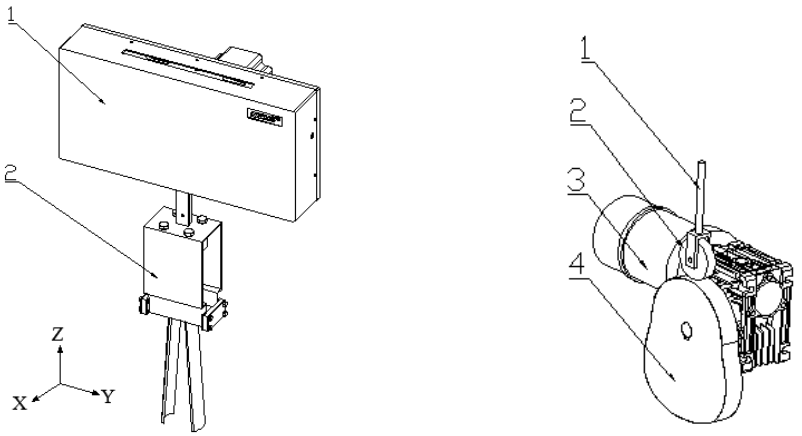

Fig. 2 - Seedling picking and placing unit

(a) Manipulator device

1 - Manipulator controller; 2 - Flexible end-effector

(b) The seedling ejection device

1 - Ejector rod; 2 - Roller; 3 - Geared motor; 4 - Cam

The manipulator device is primarily composed of a manipulator controller and a flexible end-effector (Fig. 2a). The flexible end-effector, which can perform clamping and splaying motions, is mainly responsible for seedling picking and releasing. The manipulator controller drives the flexible end-effector to lift, translate, and lower, thereby transporting the seedling.

The seedling ejection device mainly consists of a geared motor, a cam, an ejector rod, and a roller (Fig. 2b). When the geared motor is not working, the cam's near-dwell section contacts the roller. When the geared motor runs, the cam enters the lift phase, causing the roller to raise the ejector rod, which pushes the seedling out through the ventilation hole at the bottom of the tray cell. As the manipulator device picks the seedling, the geared motor continues to rotate, and then the ejector rod descends back to its initial position, waiting to eject the next seedling.

The complete picking and placing sequence (descending → gripping → lifting → releasing) is illustrated in Fig. 3. In process (a), the manipulator moves to the initial picking position while the end-effector remains open and the ejector rod stays in its lower position. In process (b), the ejecting motor rotates the cam, driving the ejector rod upward to push the seedling out of the tray cell. In process (c), the end-effector closes to grasp the ejected seedling. In process (d), the manipulator lifts the end-effector and moves rightward; simultaneously, the ejecting motor continues rotating, causing the cam to retract the ejector pin back to its initial lower position. In process (e), upon reaching the rightmost limit, the manipulator descends to its lowest position. In process (f), the end-effector opens, allowing the seedling to fall under gravity into the planter for soil insertion. After process (f), the seedling tray shifts one cell to the left, and the manipulator returns the end-effector to the initial position (a) to repeat the cycle.

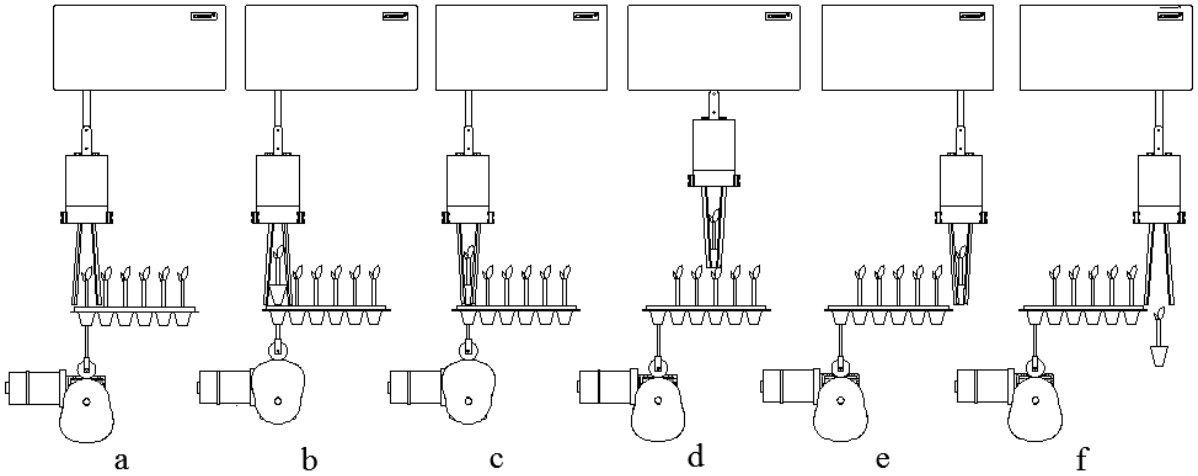

Fig. 3 - The process of picking and placing seedlings

Flexible End-Effector Design

The flexible end-effector developed in this study is of the finger-clamp type, specifically designed to pick the soil plug of the seedling, with an emphasis on flexibility. Recognizing that rigid fingers could potentially damage the delicate substrate, a spring buffer mechanism was integrated into the mechanical structure to significantly reduce the clamping impact on the soil plug, thereby minimizing the risk of root damage. The overall structure of this flexible end-effector is illustrated in Fig. 4.

The finger material was 20# stainless steel with a density of 7.85 g/cm^3, while the cone block was made of aluminum alloy (density 2.70 g/cm^3) to reduce inertial mass. The coefficient of friction between the steel fingers and the seedling substrate was taken as μ = 0.6, based on design calculations for reliable gripping. Both the tension springs and buffer springs were fabricated from stainless steel with a shear modulus of 71000 MPa.

The working principle of this flexible end-effector is as follows: When the electric cylinder piston extends, the cone block moves downward. As the cone block descends, the bearings following its inclined surfaces cause the fingers to rotate inward around their hinge points, transitioning from an open to a clamped position. When the fingers contact and pick the soil plug of the seedling, any excessive clamping force is absorbed by the buffer springs through lateral displacement of the hinges within their supports. This spring-based design effectively decouples the actuation force from the clamping force, allowing the fingers to prevent damage to the root system, and fit variations in plug size and shape.

To substantiate the force-decoupling effect, a mechanical model was established. The clamping force F_c is governed by the buffer spring preload F_0 and its compression x_s:

$$F_c = F_0 + k_s \cdot x_s \quad (1)$$

where K_s = 2.5 N/mm is the total spring stiffness. The springs are preloaded to F_0 = 20 N/mm, and the maximum hinge displacement is limited by a mechanical slot to x_s = 6 mm, yielding a maximum clamping force of:

$$F_{c,\max} = 20 + 2.5 \times 6 = 35\text{N} \quad (2)$$

This value is deliberately designed to remain below the substrate's allowable limit. Preliminary unconfined compression tests on seedling plugs (n=10) determined a compressive strength of 0.12MPa. With an effective finger-plug contact area of 400 mm^2, the maximum permissible clamping force is:

$$F_{\text{allow}} = 0.12 \times 400 = 48\text{N} \quad (3)$$

Thus, $F_{c,\max}$ = 35 N < 48 N, confirming that the spring-buffering mechanism effectively prevents over-clamping. Without this buffering, direct actuation would produce a theoretical clamping force of approximately 68 N (calculated from the cone block geometry with α=15°), which would exceed the substrate tolerance and cause damage. This quantitative analysis validates that the design decouples actuation force from clamping force, ensuring reliable gripping with minimal seedling injury.

Seedling Ejection Device Design

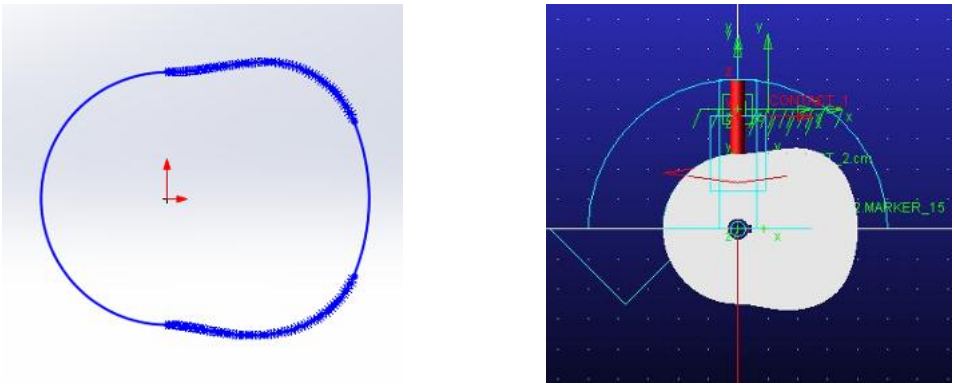
The seedling ejection device employs a disk cam with a roller follower and an ejector rod (Fig. 2b). Its function is to push the plug seedling out of the tray cell through the bottom ventilation hole. Based on the seedling height and tray structure, the ejector rod stroke was set to 30 mm, which pushes the soil plug (plug height ≈ 40 mm) upward sufficiently for the end-effector fingers to grip its lower portion. The cam base circle radius (30 mm) was chosen to fit the available under-tray space while maintaining a pressure angle below 30° for smooth force transmission, as verified by ADAMS simulation (Fig. 6). The cam rotational speed (30 r/min) was synchronized with the 1.0 s manipulator cycle to ensure continuous workflow without idle waiting, and matches the tray conveying motor speed for simplified control. To ensure smooth movement with minimal impact, the lift phase was designed using a constant acceleration-deceleration motion, while the return phase adopted simple harmonic motion (cosine acceleration), achieving zero velocity at start and end points to avoid rigid impact.

With the cam rotation center as the origin, a polar coordinate system was established. The relationship between the ejector rod displacement s and the cam rotation angle δ was determined in segments (lift phase: $0 \le \delta \le \pi/2$; upper dwell: $\pi/2 \le \delta \le \pi$; return phase: $\pi \le \delta \le 3\pi/2$; lower dwell: $3\pi/2 \le \delta \le 2\pi$). Substituting the displacement expressions for each segment into the cam profile equations (4) and (5), the coordinates (x and y) of points on the theoretical cam profile were yielded:

$$x = (s_0 + s)\sin\delta + e\cos\delta \quad (4)$$

$$y = (s_0 + s)\cos\delta - e\sin\delta \quad (5)$$

where s is the ejector rod displacement, mm; δ is the cam rotation angle, °; e is the offset distance, mm; and $s_0 = \sqrt{r_0^2 - e^2}$. Since the designed cam mechanism is an in-line type, e = 0 and $s_0 = r_0$.



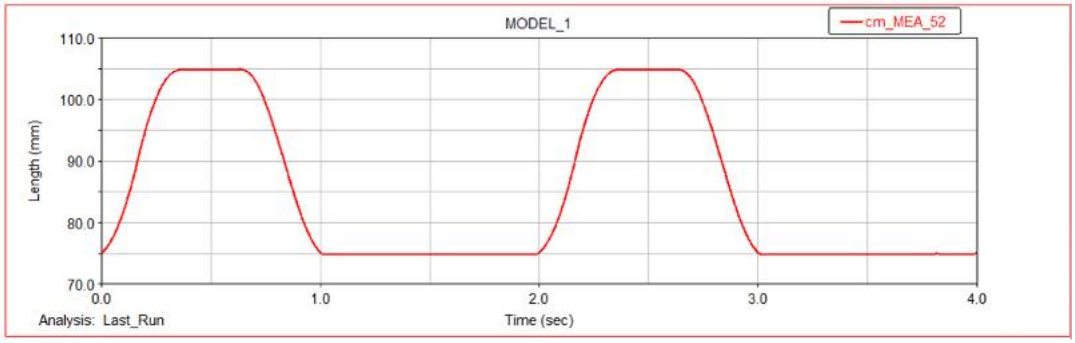


Fig. 5 - Cam design

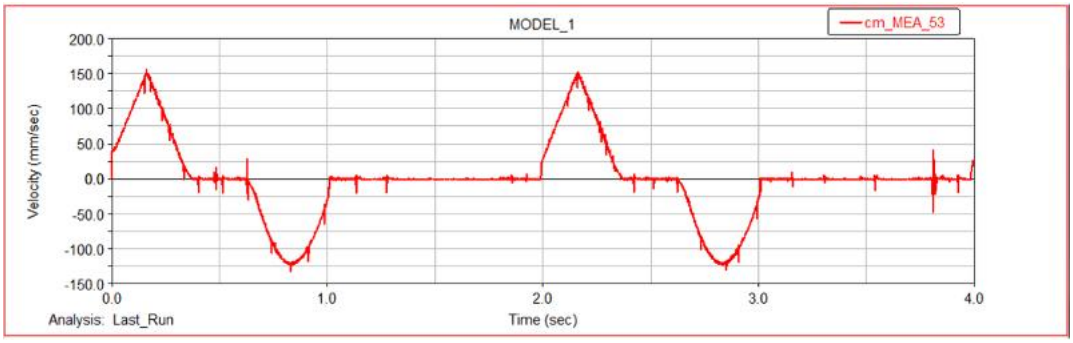

(a) Cam profile curve **(b) ADAMS simulation model**

A program was written in MATLAB software to calculate the coordinates at 1° intervals. The coordinate data were imported into SolidWorks software to generate the cam profile curve (Fig. 5a) and create a three-dimensional model of the cam.

To verify the rationality of the cam profile, the model was imported into ADAMS/View for motion simulation (Fig. 5b). A revolute joint was established between the cam and ground, and a translational joint between the ejector rod and ground. Contact forces were defined, and a driver with a rotational speed of 30 r/min was applied. Simulation results (Fig. 6) show that the displacement curve is smooth and the velocity curve is continuous without abrupt changes, confirming that the cam design meets the requirements for seedling ejection with smooth motion and no rigid impact.

(a) Displacement curve

(b) Velocity curve

Fig. 6 - Simulation results

Design of the Tray Step-Moving and Collecting Units

The tray step-moving unit (Fig.7) consists of a pallet and a dual-axis linear module that moves the tray in step increments of 42 mm (due to tray cell center distance 42 mm) with a positioning repeatability of ±0.05 mm. The tray collecting unit (Fig.8) uses a dual-cam mechanism and electric push rods to automatically stack empty trays. The cam profile was optimized to ensure the tray is lifted horizontally, following the same design methodology used for the seedling ejection device cam.

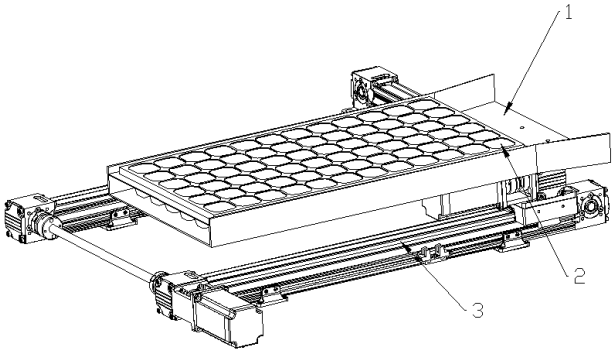

Fig. 7 - Structure of the tray step-moving unit

Control System Design

The control system is built around a Delta DVP40ES200T Programmable Logic Controller (PLC). It controls three stepper motors (manipulator, X-axis, Y-axis), three geared motors (tray conveying, seedling ejecting, tray lifting), and nine relays (for electric push rods). The system operates in manual and automatic modes. In automatic mode, the PLC coordinates sequential actions for initialization, tray conveying and positioning, the seedling picking cycle (including step positioning, ejection, picking, transport, release, and return), and empty tray collection.

Experimental Design

Following the design methodology described above, a prototype of the integrated automatic transplanting system was developed, as shown in Fig. 9. To verify the performance of the developed system, pepper seedlings cultivated in 72-cell plug trays were used as test material (Fig. 10). The pepper seedlings had an average plant height of 150 mm, individual plant weight ranging from 20 to 50 g, and a substrate moisture content of 55%-60%.

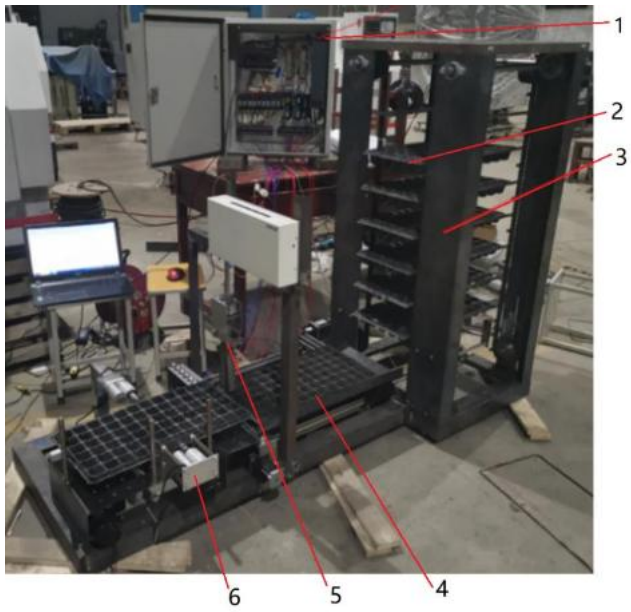

Fig. 9 - Prototype of the developed automatic transplanting system

1 - Control system; 2 - Plug tray; 3 - Multi-tray storage and conveying unit; 4 - Tray step-moving unit; 5 - Seedling picking and placing unit; 6 - Tray collecting unit

The experiments were conducted in three parts:

(1) Tray conveying accuracy test: Eight full plug trays were sequentially pushed from the storage unit to the step-moving unit. The deviation between the center of tray cell and the corresponding hole center on the pallet was measured, and the maximum and average deviation values were recorded.

(2) Standalone seedling-picking performance test: To evaluate the picking reliability of the flexible end-effector itself and eliminate potential interference from the ejecting device, seedlings were manually pre-positioned at the picking point in this test. The PLC independently controlled the manipulator and flexible end-effector to complete the full action cycle of descending, picking, lifting, translating, and releasing. Each group consisted of 72 seedlings, and the test was repeated five times. The numbers of damaged seedlings N_d, missed seedlings N_m, and successfully picked seedlings N_s were recorded.

(3) Integrated seedling-picking system performance test: The system was operated automatically at a transplanting rate of 60 plants per minute per row, corresponding to a manipulator motion cycle of 1 s (determined through preliminary debugging to ensure smooth operation). Each group consisted of 8 trays (72 seedlings per tray), and the test was repeated five times. The same indicators as above were recorded.

The seedling picking success rate S_s, damage rate S_d, and miss rate S_m were calculated using the following formulas:

$$S_s = \frac{N_s}{N_0} \times 100\% \quad (6)$$

$$S_d = \frac{N_d}{N_0} \times 100\% \quad (7)$$

$$S_m = \frac{N_m}{N_0} \times 100\% \quad (8)$$

where N_0 is the total number of seedlings, N_s is the number of successfully picked seedlings, N_d is the number of damaged seedlings, and N_m is the number of missed seedlings.

Fig. 10 - Pepper seedlings used in the experiment

Statistical Analysis

All experiments were conducted with five independent replications for each test condition. Data are presented as mean ± standard deviation (SD). To compare the seedling picking performance between standalone control and integrated system conditions, an independent-samples t-test was performed using SPSS software (version 22.0). The null hypothesis (H_0) was that there is no significant difference in the performance indicators (success rate, damage rate, and miss rate) between the two test conditions, while the alternative hypothesis (H_1) was that a significant difference exists. A two-sided *p*-value < 0.05 was considered statistically significant. In addition, 95% confidence intervals (CIs) for the mean differences between the two conditions were calculated to quantify the magnitude of the observed effects.

RESULTS

Tray Conveying Accuracy

The results of tray conveying accuracy are shown in Table 2. The deviations for the eight trays ranged from 1.12 mm to 1.79 mm, with an average deviation of 1.60 mm (SD = 0.24 mm, n = 8) and a maximum deviation of 1.79 mm. These deviations were primarily caused by vibrations during the conveying process.

Since the design tolerance for the holes on the pallet bottom was 2 mm, the maximum observed deviation of 1.79 mm remained within this tolerance. Therefore, the conveying accuracy meets the positioning requirements for seedling picking.

Table 2

Accuracy of tray conveying to the step-moving unit

Tray No.	Deviation (mm)	Maximum Deviation (mm)	Average Deviation (mm)
1	1.65	1.79	1.60 ± 0.24
2	1.63		
3	1.76		
4	1.79		
5	1.12		
6	1.39		
7	1.79		
8	1.70		

Seedling Picking Performance

(1) Standalone Control Test

Under standalone control of the manipulator device, without considering the influence of the ejecting device, the seedling picking performance indicators are shown in Table 3. The average success rate of seedling picking was 97.14%, with an average damage rate of 1.21% and an average miss rate of 1.65%. The low damage rate indicates the flexible end-effector verified reliable performance. Fig. 11 showed that the flexible end-effector securely holds the substrate without causing visible damage to the soil plug or root system, demonstrating the effectiveness of the spring-buffered finger-clamp mechanism.

Fig. 11 - Multi-angle photographs of the flexible end-effector gripping the seedling soil plug

Table 3

Seedling picking performance under separate control

Test Group	Success Rate S_s (%)	Damage Rate S_d (%)	Miss Rate S_m (%)
1	97.65	0.93	1.42
2	96.73	1.38	1.89
3	97.21	1.56	1.23
4	97.13	0.78	2.13
5	96.98	1.40	1.58
Mean ± SD	97.14 ± 0.35	1.21 ± 0.32	1.65 ± 0.35

(2) Integrated System Test

The seedling picking performance of the fully automated transplanting system is shown in Table 4. The average success rate of seedling picking was 93.24%, with an average damage rate of 1.43% and an average miss rate of 5.33%. Compared with the standalone control test, the damage rate showed no significant change, but the miss rate increased substantially, leading to a decrease in the success rate.

Observations during the experiment revealed that the primary cause of the increased miss rate was the clearance between the ejector rod and its linear bearing. The ejector rod was fitted with a linear bearing with a radial clearance of approximately 0.02 mm (standard fit tolerance). Under dynamic operation, this clearance caused a lateral deflection at the rod tip of approximately 1–3 mm, corresponding to an angular deviation of 1.5°–2.5° from the vertical axis. This deviation occasionally tilted the seedlings as they were pushed out of the tray cells, causing the flexible end-effector to miss the target and resulting in the increased miss rate.

Table 4

Seedling picking performance of the integrated system

Test Group	Success Rate S_s (%)	Damage Rate S_d (%)	Miss Rate S_m (%)
1	93.34	1.24	5.45
2	93.44	1.67	4.89
3	93.31	0.93	5.76
4	93.02	1.85	5.10
5	93.09	1.46	5.45
Mean ± SD	93.24 ± 0.18	1.43 ± 0.37	5.33 ± 0.33

Transplanting Efficiency

The transplanting efficiency was primarily influenced by the manipulator device in the seedling picking and placing unit. The movement speed of the manipulator was controlled by adjusting the input pulse frequency of its stepper motor via the PLC. Through repeated debugging trials (n = 5), it was determined that a manipulator motion cycle of 1.0 s (SD = 0.05 s) yielded the smoothest operation of the flexible end-effector, corresponding to a transplanting efficiency of 60 plants per minute per row. To further increase the efficiency, a high-speed manipulator with a shorter motion cycle would be required.

Tray Collection Performance

Observation of the tray collecting unit showed that the empty trays were stacked neatly according to the design requirements, as illustrated in Fig. 12. This confirms the reliability of the collection unit design.

Fig. 12 - Successfully collected empty trays

Discussion

Statistical comparison between the standalone control and integrated system tests revealed no significant difference in damage rate (1.21 ± 0.32% vs. 1.43 ± 0.37%; mean difference = 0.22 percentage points; 95% CI: -0.29 to 0.73; independent-samples t-test, *t* = 1.02, *p* = 0.34 > 0.05), indicating that the flexible end-effector maintained consistent clamping performance even when integrated with the ejection and conveying units. The 95% confidence interval contains zero, which further confirms the lack of statistical significance and supports the null hypothesis that the damage rate does not differ between the two conditions. However, the miss rate increased significantly in the integrated system (1.65 ± 0.35% vs. 5.33 ± 0.33%; mean difference = 3.68 percentage points; 95% CI: 2.86 to 4.50; *t* = 16.78, *p* < 0.001), which was the primary cause of the reduced overall success rate (97.14 ± 0.35% vs. 93.24 ± 0.18%; mean difference = 3.90 percentage points; 95% CI: 3.50 to 4.30; *t* = 22.04, *p* < 0.001). The confidence intervals for both miss rate and success rate do not contain zero, providing strong evidence against the null hypothesis. These statistically significant differences confirm that the ejection device, rather than the end-effector itself, was the limiting factor in system performance.

Compared with existing technologies, the main advantage of this study lies in the integration of multiple functions into a complete system, reducing manual intervention and improving operational continuity. The experimental results demonstrate that the developed automatic transplanting system performs reliably. Under standalone control, the flexible end-effector achieved a seedling picking success rate of 97.14%, which is higher than the 92.59% reported by *Jin et al. (2018)* and comparable to the 96.3% reported by *Ye et al. (2020)*. The seedling damage rate of 1.21% is lower than the 2.69% reported by *Han et al. (2023)* and 1.59% reported by *Zhou et al. (2024)*. The lower damage rate observed in this study can be attributed to the spring buffer mechanism incorporated into the finger-clamp design, which effectively reduces impact forces during clamping and accommodates variations in plug size and shape.

The transplanting efficiency of 60 plants per minute per row is higher than the 40 plants/min reported by *Han et al. (2018)* and the 48 plants/min achieved by *Jin et al. (2018)*, while it is lower than that of advanced international machines such as the Ferrari FUTURA *(Shao et al., 2021)*. Selecting a manipulator with a shorter motion cycle or increasing the number of end-effectors operating in parallel could improve efficiency, but may also increase mechanical complexity and cost. For small-to-medium scale nurseries in China, cost-effectiveness and adaptability may be more critical than achieving maximum possible speed. Tray conveying accuracy, with a maximum deviation of 1.79 mm, remained within the 2 mm design tolerance, comparable to results reported by *Yue et al. (2024)* and *Zhou et al. (2024)*.

Despite these promising results, several limitations of the present study should be acknowledged. First, the experiments were conducted exclusively with pepper seedlings, and the system's adaptability to other crop species (e.g., tomato, eggplant, or tobacco) with different plug sizes remains untested. Second, the transplanting efficiency of 60 plants/min/row, while outperforming several domestic counterparts, is lower than that of advanced international machines. Third, the clearance-induced wobble of the ejector rod (0.02 mm radial clearance resulting in approximately 1–3 mm tip deflection) remains a weak point of the current design. Fourth, all performance evaluations were conducted under relatively ideal laboratory conditions; the system's reliability under real field conditions have yet to be verified.

CONCLUSIONS

This study developed an automatic transplanting system for plug seedlings, integrating multi-tray storage and conveying, step-by-step positioning, manipulator-based picking and placing, and automatic empty tray collection. Through theoretical analysis, simulation optimization, and prototype experiments, the following conclusions were drawn:

(1) The system achieves fully automated operation from tray input to empty tray stacking, addressing functional fragmentation and reducing manual intervention.

(2) A finger-type flexible end-effector with a spring buffer mechanism was designed. Under standalone control, it achieved a picking success rate of 97.14% and a damage rate of 1.21%.

(3) Experiments with pepper seedlings showed that the integrated system achieved a success rate of 93.24% with a damage rate of 1.43%; tray conveying accuracy had a maximum deviation of 1.79 mm; and the tray collecting unit successfully stacked empty trays. The results demonstrate the feasibility of low-damage, fully automated transplanting for small-to-medium nurseries.

(4) Future work will focus on three aspects: (i) evaluating the system's adaptability to other crop species to broaden its applicability; (ii) refining the ejection mechanism by replacing linear bearings with precision guide rails to reduce wobble; (iii) integrating machine vision for seedling quality detection and exploring high-speed manipulators to further improve system performance; and (iv) evaluating the system's reliability and stability under actual field conditions, including uneven terrain and varying environmental factors.

ABSTRACT
In the process of agricultural intelligence, precise detection of plant organs serves as the foundation for core tasks such as crop phenotyping analysis and yield prediction. However, in complex field environments, small targets such as citrus flowers and shoots face challenges including scale variation, background interference, and dense occlusion, which severely impact detection accuracy. This study improves the YOLOv10 model by introducing the BAM (Bottleneck Attention Module) attention mechanism and GIoU (Generalized Intersection over Union) loss function, constructing a YOLOv10s-BAM-GIoU model suitable for citrus flower, fruit, and shoot recognition. The BAM attention mechanism enhances the model's feature extraction capability for small target organs under complex backgrounds through parallel channel and spatial attention branches; the GIoU loss function improves the localization accuracy of densely occluded targets by optimizing the geometric alignment between predicted and ground-truth boxes. Validation experiments were conducted on a self-constructed dataset. The experimental results show that the improved YOLOv10s achieves significant advantages in comprehensive detection accuracy, with an mAP50 of 89.1%, representing an improvement of 2.9%~9.5% over the original YOLOv10s and other comparative models. In fine-grained category detection, the model achieves mAP50 of 91.2%, 83.6%, and 92.5% for shoots, flowers, and fruits, respectively. Furthermore, while maintaining high detection accuracy, the model achieves a detection speed of 23.6 ms per frame, meeting real-time detection requirements. The research results demonstrate that the improved YOLOv10s model integrating the BAM attention mechanism and GIoU loss function achieves an optimal balance between accuracy and speed in citrus organ detection tasks, providing a preferred solution for field real-time detection systems.

摘要
在农业智能化进程中，植物器官精准检测是作物表型分析、产量预测等核心任务的基础。然而，田间复杂环境下柑橘花、梢等小目标存在尺度多变、背景干扰及密集遮挡等问题，严重影响检测精度。本研究基于 YOLOv10 模型，通过引入 BAM 注意力机制和 GIoU 损失函数对其进行改进，构建了适用于柑橘花果梢识别的 YOLOv10s-BAM-GIoU 模型。其中，BAM 注意力机制通过通道与空间的并行注意力分支，增强模型对复杂背景下小目标器官的特征提取能力；GIoU 损失函数则通过优化预测框与真实框的几何对齐，提升模型对密集遮挡目标的定位精度。在本研究自建数据集上进行验证，实验结果显示，改进后的 YOLOv10s 在综合检测精度上展现显著优势，其 mAP50 达到 89.1%，较原始 YOLOv10s 及其他对比模型提升 2.9%~9.5%。在细分类别检测中，该模型对梢（shoot）、花（flower）、果实（fruit）的 mAP50 分别达到 91.2%、83.6%、92.5%。此外，模型在保持较高检测精度的同时，检测速度达到 23.6ms/帧，满足实时检测需求。研究结果表明，融合 BAM 注意力机制与 GIoU 损失函数的改进 YOLOv10s 模型在柑橘器官检测任务中实现了精度与速度的最佳平衡，为田间实时检测系统提供了优选方案。

INTRODUCTION
The citrus industry is a vital component of agricultural economy. However, traditional cultivation management relies on manual experience, making it difficult to precisely regulate the proportion of flowers and fruits, leading to significant yield fluctuations and inconsistent fruit quality. Accurate identification of the number of flowers, fruits, and shoots is a prerequisite for implementing precision management measures such as flower and fruit thinning and scientific pruning.

Nevertheless, citrus flowers, fruits, and shoots share similar morphology and color and are often distributed in clusters. Traditional manual counting methods are inefficient and highly subjective, failing to meet the refined requirements of modern smart agriculture. The precise recognition of citrus flowers, fruits, and shoots enables scientific regulation of flower and fruit loads, thereby enhancing citrus quality and promoting the digital transformation of the industry.

Addressing the challenges of refined recognition that traditional methods struggle to solve, researchers have conducted extensive studies based on deep learning technologies in recent years, achieving significant progress. Huang et al. proposed ORD-YOLO, an enhanced YOLOv8-based model for citrus maturity detection. The key innovations of their approach include the incorporation of ODConv for robust feature extraction, RepGFPN for multi-scale feature fusion, and a Dynamic Head for adaptive key feature perception (*Huang et al., 2025*).

Lin et al. enhanced YOLOv5s by incorporating CBAM and Contextual Transformer modules into its backbone network and substituting GIoU with SIoU as the loss function. These modifications improved the average recognition accuracy for citrus fruits by 3.51% compared to the original algorithm (*Lin et al., 2023*).

For accurate assessment of citrus fruit ripeness (unripe and fully ripe), *Ünal et al.* proposed a lightweight deep learning model featuring an optimized YOLO12n-Seg backbone. By embedding a GhostConv module into the neck to minimize parameter overhead and applying a Global Attention Mechanism (GAM) to enhance feature discrimination, the model effectively reduces background clutter while maintaining high detection fidelity (*Ünal and Eceoğlu, 2025*). To accurately and immediately recognize mature citrus, *Xu et al.* proposed a novel method based on the Otsu adaptive threshold method and on the improved random ring method (*Xu et al., 2020*).

Lyu et al. achieved precise detection of green citrus fruits in natural scenes by proposing the YOLO-GC model incorporating GhostNet and GAM attention mechanisms, achieving a model mAP of 97.8%, yet missed detections occurred in densely overlapped fruit areas (*Lyu et al., 2024*).

El Akrouchi et al. broke whole-tree high-resolution images of small green citrus fruits into smaller patches to capture finer details, and employed a model combining Multiscale Vision Transformer version 2 (MViTv2) with Cascade Mask R-CNN for fruit detection (*El Akrouchi et al., 2025*).

Xiao et al. achieved high-precision citrus recognition in orchard environments by proposing the AC-YOLO model with a self-attention mechanism, attaining an average precision of 97.27%, though recognition performance for severely occluded fruits remained suboptimal (*Xiao et al., 2024*). A yield prediction scheme was proposed by *Qin et al*., which employs both Faster R-CNN and SSD to detect citrus fruits on the tree and subsequently computes fruit size based on the short diameter measurement (*Qin et al., 2021*).

Subeesh et al. used unmanned aerial vehicles (UAVs) to capture images of citrus fruits, and employed multiple deep learning algorithms such as YOLOv7 to detect two categories of fruits, "harvest-ready" and "unripe," from canopy images, thereby enabling orchard yield estimation (*Subeesh et al., 2024*). Based on the mask regional convolutional neural network (Mask R-CNN) and a branch segment merging algorithm, an integrated system was developed to simultaneously detect and measure citrus fruits and branches (*Yang et al., 2020*).

Qiu et al. achieved automatic segmentation and phenotypic quantification of citrus floral organs by independently developing the CF-ASPM model, enabling fine segmentation of seven organ types including petals, styles, and ovaries (*Qiu et al., 2025*). To estimate citrus flower quantities in natural orchards, *Lu et al.* proposed a lightweight recognition model based on an improved YOLOv4 architecture. To reduce model complexity, they employed MobileNetV3 as the backbone feature extractor and incorporated depthwise separable convolutions to accelerate inference (*Lu et al. 2021*).

Li et al. achieved citrus fruit-stem segmentation and precise picking point localization by improving the YOLOv8n-seg model and integrating the CBAM attention mechanism, attaining fruit-stem segmentation accuracy of 97.12%, though generalizability across different varieties remains unverified (*Li et al., 2025*). *Liu et al.* enhanced the YOLOv5s model with the BiFormer attention mechanism to achieve precise detection of citrus spring shoots, identifying 14-4 days before full bloom as the optimal phenological detection window, with a model mAP of 89.6% (*Liu et al., 2025*).

Yin et al. achieved intelligent recognition of citrus shoot growth by improving the YOLOX-Nano algorithm with multi-attention mechanisms, attaining a model mAP of 88.07% and successfully deploying it on mobile terminals, though detection accuracy for fine targets at the germination stage still requires improvement (*Yin et al., 2022*).

In summary, current research on citrus flower, fruit, and shoot recognition has achieved significant progress in technical methodologies. Improved YOLO series models combined with attention mechanisms have effectively enhanced recognition accuracy in complex scenes, research targets have expanded from single organs to multi-phenological dynamic monitoring, and model lightweighting has laid the foundation for real-time orchard applications. However, existing research still faces the following critical challenges. First, current research on citrus target detection predominantly focuses on a single category, such as detecting fruits, flowers, or shoots separately, while comprehensive methods that simultaneously encompass all three categories remain scarce. Second, the adaptability of existing models to complex environments, which are characterized by drastic illumination changes and severe occlusion, still requires further improvement. Third, the lack of standardized datasets hinders horizontal comparison among different studies and impedes the reproducibility verification of research results.

To address the aforementioned limitations, this study performs a targeted expansion of the existing citrus dataset on the PaddlePaddle platform, with particular emphasis on enhancing sample coverage under drastic illumination changes and severe occlusion. Furthermore, a multi-target detection model is constructed to simultaneously encompass three categories: fruits, flowers, and shoots. Specifically, this model introduces the BAM attention mechanism into the neck network of YOLOv10 to enhance feature extraction capability for small-target objects under complex backgrounds, while replacing the original CIoU loss function with the GIoU loss function to improve localization accuracy for densely occluded targets by optimizing geometric alignment between predicted and ground-truth boxes. This improvement scheme aims to enhance the model's simultaneous detection capability for flowers, fruits, and shoots in complex orchard environments through synergistic optimization of feature representation and localization loss, while improving its adaptability to challenging scenarios such as illumination variations and occlusion interference. Furthermore, by constructing a standardized dataset covering multiple phenological stages and varieties, this research provides a foundation for horizontal comparison and reproducibility verification in subsequent studies, thereby promoting the development of citrus organ detection technology toward practical and standardized applications.

MATERIALS AND METHODS

Image dataset

The recognition of citrus flowers, fruits, and shoots is of great significance for cultivation monitoring and yield estimation. The generalization ability and stability of the model heavily rely on citrus datasets covering different growth periods, lighting conditions, and occlusion scenarios. To ensure the effective application of the model under actual agricultural production conditions, the citrus dataset should include images of varying sizes and resolutions, as well as diverse scenarios such as overlap, complex backgrounds, and varying lighting conditions. This study adopts the following combined dataset:

Public dataset: A citrus flower, fruit, and shoot dataset provided by the PaddlePaddle platform, consisting of 420 JPG format images with a resolution of 608×608 pixels. The dataset includes annotation files in YOLO format, covering images from different growth stages that closely resemble real orchard scenes.

Self-constructed dataset: A citrus flower, fruit, and shoot dataset constructed through field photography using a commercial smartphone with a 64MP autofocus camera. This dataset comprises 380 JPG format images with a resolution of 640×640 pixels, encompassing citrus flowers, fruits, and shoots under various lighting conditions, occlusion, overlap, and different levels of background complexity. Sample images are shown in Figure 1.

a. Front lighting b. Back lighting c. Overlap d. Branch occlusion

Fig. 1 - Sample images from the dataset

To simulate the photometric and geometric distortions commonly observed in field operations, data augmentation techniques were applied to the dataset, including horizontal flipping, rotation, cropping, and brightness transformation. Ultimately, the number of sample images was increased to 1,000. The effect of data augmentation is shown in Figure 2.

a. Original image b. Mirror flip c. Rotation d. Cropping e. Brightness

Fig. 2 - Results of data augmentation

To ensure scientific training and testing of the model, the dataset consisting of 1,000 images was divided into training set and test set at a ratio of 8:2. To maintain an equal number of categories in both the training set and test set, stratified sampling was adopted. The number of labels for citrus flowers, fruits, and shoots in the dataset was statistically analyzed, and the label composition is shown in Table 1.

Table 1

Dataset Composition

Type	Data set	Flower	Fruit	Shoot
Train set	800	1813	1929	1351
Test set	200	465	483	338
Sum	1000	2278	2412	1689

Field Deployment and On-site Validation Pipeline

The proposed model was deployed on a handheld mobile terminal integrated with a monocular RGB camera, simulating a real-time in-field detection scenario. The system was calibrated under varying natural illumination conditions between 9:00 AM and 4:00 PM to cover extreme backlighting and shading conditions across different growth stages of citrus. Validation was conducted in a commercial citrus orchard located in Shanxi Juxin Modern Agricultural Demonstration Park. To ensure diversity, samples (fruits, flowers, and shoots) were collected from peripheral (outer canopy) and inner canopy layers, as well as from low-hanging and upper branches, to represent the occlusion complexity in real harvesting environments. Images were captured at a resolution of 1920 × 1080 with a fixed working distance of 0.5 m to 1.5 m. A total of 200 images were collected, consisting of 52 images of flowers, 57 images of fruits, and 99 images of shoots. Due to the difficulty of manual labeling in dynamic outdoor backgrounds, a pre-labeling correction strategy was adopted: initial bounding boxes were generated by the model and then manually corrected by three expert agronomists using LabelImg to establish the high-confidence ground truth for the validation set.

Improved YOLOv10 Model

YOLOv10 is a new generation real-time object detection model proposed by the research team at Tsinghua University in 2024 (*Wang et al., 2024*). Building upon the classic "backbone-neck-head" three-stage architecture inherited from the YOLO series, it achieves breakthroughs in detection performance and computational efficiency through two core innovations.

First, YOLOv10 proposes a consistent dual label assignment strategy, deploying both a one-to-many head (providing rich supervision signals) and a one-to-one head (simulating inference output) during training, while retaining only the latter during inference.

This fundamentally eliminates the reliance on non-maximum suppression (NMS) post-processing, significantly reducing inference latency and simplifying the deployment process. Second, it systematically optimizes the architecture from both efficiency and accuracy perspectives. In terms of efficiency, it adopts lightweight classification heads, spatially-channel decoupled downsampling, and rank-guided module design to reduce computational redundancy. In terms of accuracy, it introduces large-kernel depthwise convolutions in deeper stages to expand the receptive field, and designs a partial self-attention mechanism to enhance global feature representation capability at minimal computational cost. Based on these designs, YOLOv10 achieves industry-leading detection performance while significantly reducing inference latency and computational overhead. The network structure is shown in Figure 3.

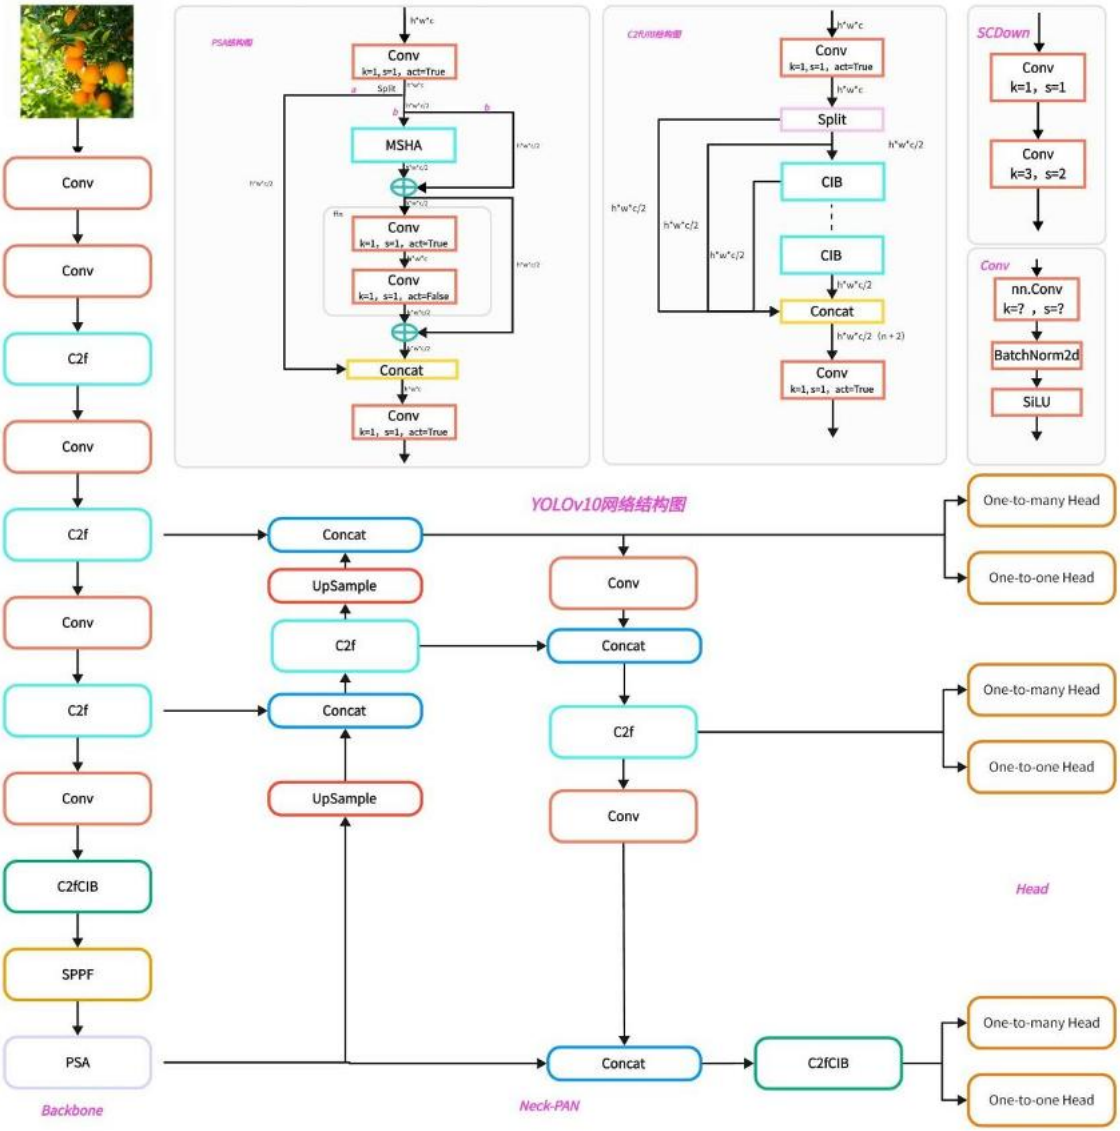

Fig. 3 - Structure of the YOLOv10 network

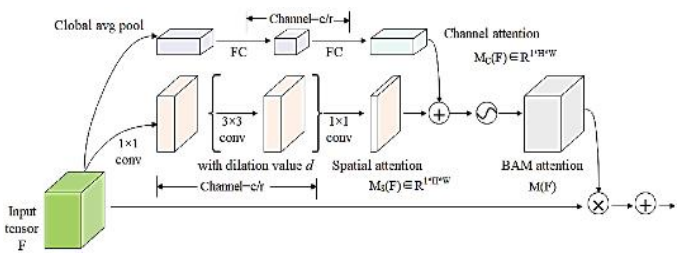

Fig. 4 - BAM Calculation mode

In this paper, the BAM (Bottleneck Attention Module) attention mechanism is incorporated into the neck network of the YOLOv10 model. BAM is an attention mechanism that combines both spatial and channel dimensions(*Park et al., 2020*). For a given feature map, this module processes it through channel attention and spatial attention branches separately to generate a 3D attention map. The specific workflow and structure are illustrated in Figure 4.

The BAM attention module can be integrated with any convolutional neural network, inferring attention maps along both spatial and channel dimensions to generate a 3D attention map that emphasizes important elements. This module combines two attention branches to reduce computational cost and parameter count, while employing residual learning to facilitate gradient flow.

In object detection tasks, IoU is used to measure the overlap between the predicted and ground truth box. Generalized Intersection over Union (GIoU) (*Rezatofighi et al., 2019*) is a loss calculation method for bounding boxes prediction derived from IoU that is scale-invariant. Compared with IoU Loss optimization part is: adding the influence of non-overlapping regions (in the prediction bounding box and the ground truth box there is no overlap part can also reflect the distance between the two boxes), can better measure to the degree of overlap, has a faster convergence speed. The formula is shown below:

$$GIoU = IoU - \frac{A^c - u}{A^c} \tag{1}$$

$$L_{GIoU} = 1 - GIoU \tag{2}$$

As can be seen from the formula, the final result of calculating GIoU Loss is returned as 1-GIoU. Since the value of 1-GIoU is in the range of [0,2] and has a certain “distance” property, i.e., the larger the overlap area between the predicted bounding box and ground truth box, the smaller the loss, and vice versa, the larger it is; and it can avoid the influence of the target shape size and more accurately reflect the interrelationships of the boxes, and possesses scale invariance.

Evaluation metrics

To evaluate the effectiveness of the proposed method, this experiment selects evaluation metrics from multiple dimensions. For model performance evaluation, precision (P), recall (R), mean average precision at IoU threshold 0.5 (mAP50), mean average precision averaged over IoU thresholds ranging from 0.5 to 0.95 with a step size of 0.05 (mAP50-95), and the harmonic mean of precision and recall (F1-score) are adopted. For performance efficiency evaluation, floating point operations (FLOPs), number of parameters (Parameters), and weight model memory size (weights size) are included. The specific formulas for each metric are as follows:

$$\text{Presicion} = \frac{\text{TP}}{\text{TP}+\text{FP}} \tag{3}$$

$$\text{Recall} = \frac{\text{TP}}{\text{TP}+\text{FN}} \tag{4}$$

$$\text{Accuracy} = \frac{\text{TP}+\text{TN}}{\text{TP}+\text{FP}+\text{TN}+\text{FN}} \tag{5}$$

$$\text{F1-score} = \frac{2 \bullet \text{Presicion} \bullet \text{Recall}}{\text{Presicion}+\text{Recall}} \tag{6}$$

In the formulas, TP (True Positive) represents the number of correctly predicted targets (both prediction and ground truth are positive), FP (False Positive) represents the number of incorrectly predicted targets (ground truth is negative but prediction is positive), TN (True Negative) represents the number of non-target regions correctly detected as non-targets (both prediction and ground truth are negative), and FN (False Negative) represents the number of missed targets (ground truth is positive but prediction is negative). The F1-score is the harmonic mean of precision and recall.

RESULTS

To comprehensively compare the performance of YOLOv10 models in citrus flower, fruit, and shoot detection, this study selected four models—YOLOv5s (*Jocher et al., 2021*), YOLOv7s (*Wang et al., 2023*), YOLOv8s (*Jocher et al., 2023*), and YOLOv10s—along with the improved YOLOv10s model for comparative experiments. Each model was trained and evaluated on the same dataset with identical training parameters, ensuring the comparability of test results. The baseline detection performance of each model is presented in Table 2.

Table 2

Comparison of Efficiency Performance Among Different Models

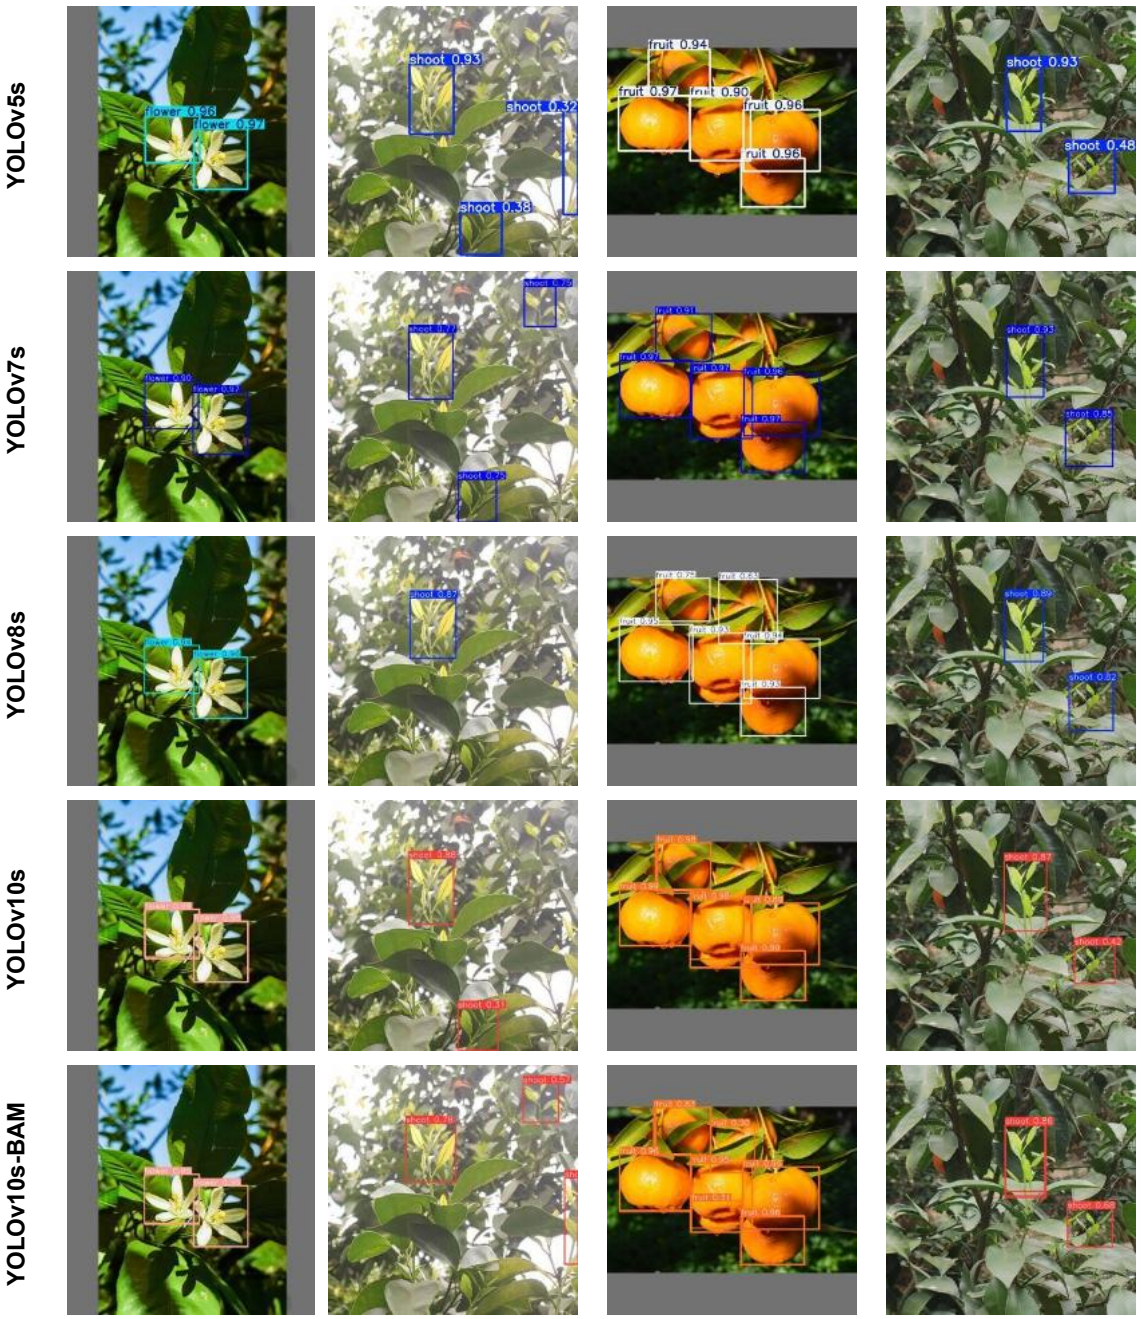
model	Params/M	FLOPs/G	VRAM/MB	F1-Score
YOLOv5s	7.0	15.8	159	0.797
YOLOv7s	13.0	33.1	180	0.831
YOLOv8s	11.1	28.4	145	0.793
YOLOv10s	8.0	24.5	127	0.814
YOLOv10s-BAM	8.2	25.2	127	0.827
YOLOv10s-BAM-GIoU	8.2	25.8	127	0.842

To comprehensively evaluate the effectiveness of the improvement strategy, this study conducted a quantitative comparative analysis of the detection performance of different models. In terms of model complexity, the original YOLOv10s has 8.0M parameters, 24.5G FLOPs, and 127MB VRAM usage, while the improved YOLOv10s-BAM-GIoU model has 8.2M parameters, 25.8G FLOPs, and maintains 127MB VRAM usage, indicating that the introduction of the BAM attention mechanism and GIoU loss function brings only minimal computational overhead without imposing additional burden on VRAM usage. In terms of detection accuracy, the original YOLOv10s achieves an F1-score of 0.814, outperforming YOLOv5s (0.797) and YOLOv8s (0.793), but lower than YOLOv7s (0.831). After introducing the BAM attention mechanism, the F1-score of YOLOv10s-BAM increases to 0.827. With the further integration of the GIoU loss function, the F1-score of YOLOv10s-BAM-GIoU reaches 0.842, representing a 2.8 percentage point improvement over the original YOLOv10s and a 1.1 percentage point improvement over YOLOv7s, achieving the optimal performance among all compared models. These results demonstrate that the BAM attention mechanism effectively enhances the model's feature extraction capability for small target organs under complex backgrounds, while the GIoU loss function improves the localization accuracy of densely occluded targets by optimizing the geometric alignment between predicted and ground-truth boxes. The synergistic effect of these two improvements enables the YOLOv10s-BAM-GIoU model to achieve significant detection accuracy gains with minimal computational overhead, validating the effectiveness and superiority of the proposed improvement strategy in complex agricultural scenarios.

To comprehensively evaluate the effectiveness of the proposed improvement strategy, comparative experiments were conducted on six models using a self-constructed citrus flower, fruit, and shoot dataset, with mAP@0.5, mAP@0.5-0.95, and per-class average precision as evaluation metrics. The comparison results of accuracy metrics are shown in Table 3.

Table 3

Comparison of Accuracy Performance Among Different Models



Model	mAP@0.5	mAP@0.5-0.95	Flower	Fruit	Shoot
YOLOv5s	0.831	0.521	0.806	0.782	0.904
YOLOv7s	0.862	0.541	0.864	0.81	0.912
YOLOv8s	0.842	0.539	0.839	0.779	0.909
YOLOv10s	0.796	0.483	0.810	0.724	0.853
YOLOv10s-BAM	0.854	0.539	0.849	0.804	0.908
YOLOv10s-BAM-GIoU	0.891	0.576	0.912	0.836	0.925

The original YOLOv10s achieved mAP@0.5 of 79.6% and mAP@0.5-0.95 of 48.3%, underperforming compared to YOLOv5s (83.1%/52.1%) and YOLOv7s (86.2%/54.1%), likely due to its lightweight design limiting feature capture capability for small targets in complex agricultural scenes. After introducing the BAM attention mechanism, YOLOv10s-BAM achieved mAP@0.5 of 85.4% (a 5.8 percentage point improvement) and mAP@0.5-0.95 of 53.9% (a 5.6 percentage point improvement), demonstrating that the BAM module enhances feature extraction for small target organs under complex backgrounds through parallel channel-spatial attention. With the further integration of the GIoU loss function, YOLOv10s-BAM-GIoU achieved optimal performance among all compared models, with mAP@0.5 reaching 89.1% (a 3.7 percentage point improvement over YOLOv10s-BAM) and mAP@0.5-0.95 reaching 57.6% (a 3.7 percentage point improvement). Compared to the original YOLOv10s, mAP@0.5 improved by 9.5 percentage points and mAP@0.5-0.95 by 9.3 percentage points; compared to the baseline optimal model YOLOv7s, improvements of 2.9 and 3.5 percentage points were achieved, respectively.

In terms of per-class detection accuracy, the original YOLOv10s achieved 81.0%, 72.4%, and 85.3% for flowers, fruits, and shoots, respectively, with relatively lower accuracy for fruits possibly due to dense overlap and similar color to the background. After introducing the BAM attention mechanism, detection accuracy for the three categories improved to 84.9%, 80.4%, and 90.8%, respectively.

With the further integration of the GIoU loss function, YOLOv10s-BAM-GIoU achieved 91.2%, 83.6%, and 92.5% for flowers, fruits, and shoots, representing improvements of 10.2, 11.2, and 7.2 percentage points over the original YOLOv10s, and 4.8, 2.6, and 1.3 percentage points over YOLOv7s, respectively. Notably, the most significant improvements were observed for small targets (flowers and fruits), validating the effectiveness of the proposed improvement strategy for small target recognition in complex scenes. These results demonstrate that while the original YOLOv10s has certain limitations in complex agricultural scenarios, the introduction of the BAM attention mechanism and GIoU loss function effectively compensates for these shortcomings. The synergistic effect of BAM enhancing feature representation for small target organs and GIoU optimizing localization accuracy enables YOLOv10s-BAM-GIoU to achieve significant detection performance improvements with minimal increases in parameters and computational overhead, validating the effectiveness and superiority of the proposed improvement strategy for citrus flower, fruit, and shoot recognition tasks.

To validate the effectiveness of the proposed model in complex environments, the six models in this study were visualized under front-lighting, back-lighting, occlusion, and background interference conditions respectively. The comparison results are show in Figure 5.

front-lighting back-lighting occlusion background interference

Fig. 5 - Visualization of model recognition results under different scenes

In the comprehensive detection task of citrus flower, fruit, and shoot recognition, the detection performance of each model under different lighting and occlusion conditions showed significant differences. Under front-lighting conditions, YOLOv5s, YOLOv7s, YOLOv8s, YOLOv10s, YOLOv10s-BAM, and YOLOv10s-BAM-GIoU all demonstrated good detection performance, accurately identifying various citrus organs. Under back-lighting conditions, although YOLOv5s, YOLOv8s, and YOLOv10s could capture citrus shoots at image edges, they exhibited varying degrees of missed detection for small targets; YOLOv7s and YOLOv10s-BAM-GIoU showed stronger small-target recognition capabilities, though missed detections still occurred for targets at image boundaries.

Detection results under occlusion conditions further revealed performance differences among the models. For scenarios with partial leaf occlusion and large-area fruit occlusion, YOLOv5s, YOLOv7s, and YOLOv10s all exhibited varying degrees of missed detection; YOLOv8s performed poorly only under large-area occlusion; YOLOv10s-BAM detected all targets, but annotation completeness required improvement; YOLOv10s-BAM-GIoU performed optimally under occlusion scenarios, achieving the highest detection rate and better annotation accuracy. Under complex background interference conditions, all models demonstrated relatively stable detection performance.

To evaluate model applicability under real agricultural conditions, YOLOv10s and YOLOv10s-BAM-GIoU were validated using 200 unaugmented images from Shanxi Juxin Park, covering backlighting, occlusion, fruit overlap, and tiny shoots without augmentation. The results are presented in Table 4.

Table 4

Validation Results of YOLOv10s and YOLOv10s-BAM-GIoU on The Field Dataset

Model	mAP@0.5	mAP@0.5-0.95	Flower	Fruit	Shoot
YOLOv10s	0.790	0.498	0.741	0.883	0.746
YOLOv10s-BAM-GIoU	0.812	0.519	0.771	0.907	0.757

The proposed YOLOv10s-BAM-GIoU achieves a mAP@0.5 of 81.2% on the challenging field dataset, representing a 2.2% absolute improvement over the standard YOLOv10s (79.0%). Moreover, the proposed model demonstrates its most substantial improvement over YOLOv10s on the "Flower" category (a 3.0 percentage points improvement, from 74.1% to 77.1%), followed by "Fruit" (a 2.4 percentage points improvement) and "Shoot" (a 1.1 percentage points improvement). These enhancements confirm that the integration of the BAM attention mechanism and GIoU loss function effectively mitigates environmental disturbances, particularly in scenarios with complex backgrounds and variable illumination. An unexpected yet insightful finding from the field validation is the superior detection performance for ''Fruit'' (AP = 90.7%) compared to ''Flower'' (77.1%) and ''Shoot'' (75.7%). This contrasts with the common assumption that fruits, being larger and more prone to occlusion, would exhibit the greatest performance degradation. This phenomenon is attributed to two principal factors: (i) the spherical shape and distinctive orange coloration of citrus fruits generate strong contrast against the green foliage background, facilitating robust feature extraction even under variable illumination; and (ii) the field validation images predominantly captured fruits at mid-to-late developmental phases with prominent visual saliency, whereas flowers and shoots presented comparatively greater scale- and color-ambiguity challenges. These findings underscore the importance of category-specific optimization in agricultural vision systems, particularly for enhancing small-target and low-contrast detection.

Comprehensive test results indicate that YOLOv10s-BAM-GIoU achieved the highest detection accuracy and annotation completeness under the most challenging back-lighting and occlusion scenarios. This model not only accurately identifies small targets but also possesses robust capabilities for handling occluded targets, demonstrating its advanced nature in complex agricultural production scenarios.

In conclusion, YOLOv10s-BAM-GIoU can be considered the optimal choice for citrus flower, fruit, and shoot recognition tasks, particularly suitable for complex environmental scenarios commonly encountered in agricultural production.

CONCLUSIONS

This study proposed an improved YOLOv10s model incorporating the BAM attention mechanism and GIoU loss function for the accurate recognition of citrus flowers, fruits, and shoots in complex orchard environments. The experimental results demonstrate that the proposed YOLOv10s-BAM-GIoU model achieves superior detection performance, with an mAP50 of 89.1%, representing improvements of 2.9%~9.5% over the original YOLOv10s and other comparative models. In fine-grained category detection, the model attains mAP50 of 91.2%, 83.6%, and 92.5% for shoots, flowers, and fruits, respectively. The BAM attention mechanism enhances feature extraction capability for small target organs under complex backgrounds through parallel channel-spatial attention branches, while the GIoU loss function improves localization accuracy for densely occluded targets by optimizing geometric alignment between predicted and ground-truth boxes. The synergistic effect of these two improvements enables significant detection accuracy gains with minimal computational overhead, as evidenced by the model's parameter count of 8.2M, computational load of 25.8G FLOPs, and detection speed of 23.6 ms per frame, meeting real-time detection requirements for agricultural applications.

The comparative analysis of six models under varying environmental conditions further validates the robustness and practical applicability of the proposed approach. Under challenging scenarios such as back-lighting and severe occlusion, YOLOv10s-BAM-GIoU consistently outperformed other models, achieving the highest detection rates and annotation accuracy. While YOLOv5s, YOLOv7s, YOLOv8s, and the original YOLOv10s exhibited varying degrees of missed detections for small targets and occluded objects, the improved model demonstrated reliable performance in detecting targets at image boundaries, handling partial and large-area occlusion, and maintaining accuracy under complex background interference. These results confirm that the integration of attention mechanisms and optimized loss functions effectively addresses the key challenges in agricultural target detection, including scale variation, background clutter, and dense occlusion, thereby providing a robust solution for real-world orchard monitoring applications.

The field validation results confirm the model's robustness under realistic orchard conditions, achieving a mAP@0.5 of 81.2% with consistent improvements over the baseline YOLOv10s across all categories, with gains of 3.0 percentage points for "Flower", 2.4 percentage points for "Fruit", and 1.1 percentage points for "Shoot". Notably, an unexpected finding emerged: "Fruit" achieved the highest detection accuracy (AP = 90.7%), substantially surpassing "Flower" (77.1%) and "Shoot" (75.7%). The superior performance of "Fruit" is likely attributable to its higher visual saliency in field images, offering valuable insights for the design of practical agricultural vision systems.

In conclusion, this research contributes to the advancement of precision agriculture by presenting an efficient and accurate deep learning model for citrus organ detection. The YOLOv10s-BAM-GIoU model achieves an optimal balance between detection accuracy and computational efficiency, making it suitable for deployment in field real-time detection systems. The findings highlight the importance of synergistic architectural improvements—combining attention mechanisms for enhanced feature representation with optimized loss functions for precise localization—in addressing the specific challenges of agricultural computer vision tasks. Although the accuracy is somewhat reduced due to the field environment, the system still demonstrates sufficient robustness in specific scenarios, providing a practical reference for the subsequent intelligent management of citrus orchards. Future work could focus on expanding the dataset to include more diverse citrus varieties and growing regions, further optimizing the model for edge device deployment, and extending the approach to other fruit crops and phenological stages. Additionally, integrating the detection system with automated agricultural equipment for precision management practices such as targeted spraying, thinning, and harvesting could realize the full potential of this technology in smart agriculture applications.

ABSTRACT

To address the high labour intensity, low operating efficiency, and safety risks associated with loading and unloading flue-cured tobacco leaves in bulk-curing barns, a tobacco-clip loading and unloading device suitable for the confined barn environment was developed. The device integrates a powered platform, a two-stage scissor-lift mechanism, and an online weighing and conveying system. Mechanical modeling and finite element analysis were conducted to verify the structural strength and overturning stability of the lifting mechanism under a rated load of 350 kg and a maximum lifting height of 3 m. The resulting overturning stability coefficient was approximately 2.9. Within an inclination range of 0°–25°, the mass-measurement error of the conveying system did not exceed 0.40%. Field performance tests showed that the maximum conveying rate reached one tobacco clip every 2.7 s. The loading time for a single bulk-curing barn was reduced from 4 h to 1.5 h, while the required labour force decreased from four workers to two. Overall operating efficiency increased by 4.33 times, and the mean time between failures met the requirements for continuous operation during the tobacco-curing season. The developed device enables efficient, low-cost, and reliable loading and unloading of flue-cured tobacco leaves and provides technical support for improving the quality and efficiency of flue-cured tobacco production.

摘要

针对密集烤房烟叶装卸作业中存在的劳动强度大、作业效率低、安全隐患突出等问题，研究设计了一种适配密集烤房环境的烤房烟夹装卸装置。该装置集成了动力平台、二级剪叉式升降机构、在线称重输送系统，以适应烤房狭小空间。通过力学建模与有限元分析，验证了升降装置在额定载荷 350 kg、最大升降高度 3 m 条件下的结构强度与抗倾覆稳定性，抗倾覆系数 K≈2.9；输送系统在 0°–25°倾斜范围内的质量检测误差率不超过 0.40%；现场性能测试表明，装置单夹运输时间最短为 2.7 s，每烤房装烟时间由人工的 4 小时缩短至 1.5 小时，用工由 4 人减少至 2 人，作业效率提升了 4.33 倍，平均无故障运行时间满足烤烟季连续作业要求。该装置实现了烟叶装卸的高效低成本与高可靠性，为烤烟生产的提质增效提供了技术支撑。

INTRODUCTION

China is one of the world's major producers of flue-cured tobacco, and most of the crop is now cured in bulk-curing barns *(Liu, 2024)*. Over the past two decades, field operations from transplanting to stalk removal have become increasingly mechanized; however, tobacco loading and unloading are still performed manually. High labour costs, heavy workloads, and a low level of operational standardization remain the main challenges at this stage. Together, these constraints have hindered the tobacco industry's transition toward more efficient, large-scale, and intensive production.

Curing quality depends on two things: how the fans and heat exchangers hold airflow, temperature and humidity, and how the sticks are stacked on the racks (*Liang et al., 2014*). The heat side has moved faster. Ge et al. optimised a tobacco-drying heat pump that recovers waste heat from a nearby data centre, cutting the primary energy input while keeping drying temperatures within target (*Ge et al., 2024*). Wang et al. took a related route, integrating dehumidification into an air-source heat pump and reporting an average COP of 2.85 across a full curing cycle (*Wang et al., 2025*).

Both gains assume that the sticks are already stacked evenly and that the load per rack is known. Neither condition can be checked by the barn operator in the field today.

Zhang built a toppling-rotary rig that swings sticks from a horizontal frame onto the vertical racks (*Zhang, 2023*), and Jiao followed with an inclination stage that lets the loaded rack tilt into position (*Jiao, 2025*). *Lin et al*. and *Ai et al*. took a different route, using a side-mounted chain to hoist the sticks along the barn wall, which gives a smaller footprint and lower peak power (*Ai et al., 2025; Lin et al., 2021*). What none of these prototypes offers is a lift geometry sized to the door and rack layout of a Chinese curing barn, or an on-line record of the weight loaded onto each rack.

Guo et al. reported a mast-lift loading machine for dense curing barns, raising sticks to 1.3–3.6 m and tilting them by 0–32° through staggered linear modules; field trials returned a loading success rate above 90% at 2.89–4.60 times the throughput of manual work (*Guo et al., 2026*). However, this prototype does not record the weight loaded onto each rack, nor is it sized as a station platform placed at the barn door. These are the two functions that determine whether uneven rack loading can be detected before firing begins.

Islam et al. used a bond-graph model to predict the dynamic response of a scissor lift under load (*Islam et al., 2014*). Their study did not extend to static structural strength or anti-tipping stability under an off-centre agricultural payload. These are the conditions a barn-door platform must survive when a fully loaded rack is lifted to 3 m. For on-line weighing during the handling cycle, *Cveticanin, (2003),* proposed a walking-speed model that keeps the weighing error low while the payload moves on a horizontal belt. The accuracy of that approach on a tilted belt has not been reported. The present work addresses both gaps: FEA-based static and anti-tipping verification and belt-scale calibration over a 0°-25° tilt range.

This study designs and tests a loading and unloading device for cured tobacco, sized to the operating conditions inside a dense curing barn. The working environment and the load requirements were analysed first, and the overall layout of the power platform, the two-stage scissor lift, the conveying system and the control unit was drawn up on that basis. The strength and stability of the key parts were then checked by mechanical calculations and finite element analysis. A prototype was built and taken to a working barn, where its efficiency, safety and reliability were measured. The goal is a compact and easy-to-operate machine that lowers the physical load on operators, raises loading throughput, and supports the mechanisation and large-scale operation of tobacco curing.

MATERIALS AND METHODS

Overall structural design of the loading and unloading device for tobacco clips

The loading and unloading device for tobacco clips comprises a power platform, lifting device, conveying system, and control system. The power platform includes a power system and walking mechanism (*Li and Kang, 2020*). The walking mechanism adopts a four-wheel-drive design and is driven by an electrically remote-controlled chassis. The lifting device is a core component of the system. It uses a compact and highly load-resistant two-stage scissor-type lifting mechanism, which is driven by a hydraulic system to adapt to the maximum height of the tobacco rack in the curing barn. The conveying platform adopts a chain roller-driven conveyor belt structure with an adjustable inclination to improve conveying efficiency. The control system integrates weighing sensors, speed sensors, and proximity switches to achieve automatic control. The overall structure of the device is shown in Figure 1, and the main parameters are listed in Table 1.

Number of operators	2

Design of the Lifting Device

Overall design of the lifting device

As the core component of the device, the lifting mechanism directly determines the efficiency and safety of the loading and unloading process. The scissor mechanism is the core component of the lifting device, and its design parameters affect the lifting performance (*Paramasivam et al., 2021*). *Huy et al. (2022)* used the MARCOS multi-criteria decision-making method to optimise the choice of scissor mechanism. Following their approach, and taking the working conditions and design requirements into account, a two-stage scissor mechanism was adopted here.

The structure is illustrated in Figure 2.

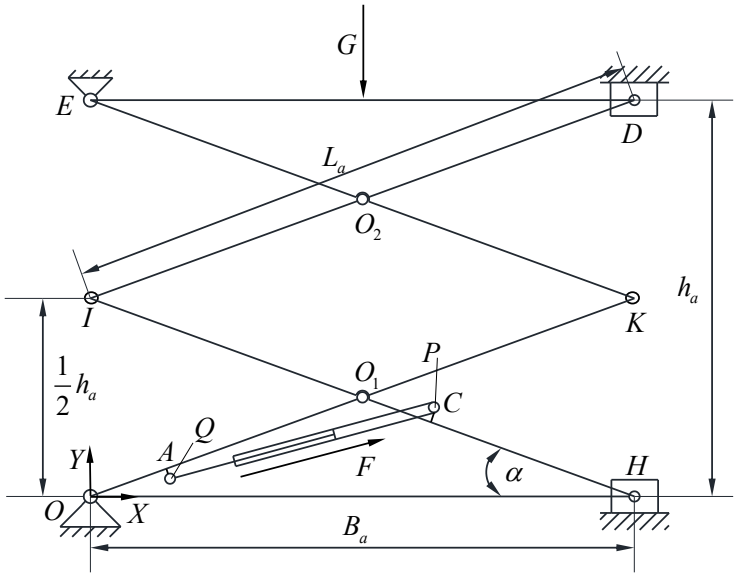

Fig. 2 - Schematic of the scissor-lift mechanism

As shown in Figure 2, O is the origin of the lifting structure coordinate system, DE is the worktable, AC is the lifting hydraulic cylinder, and B_a is the distance between O and H. EK, KO, DI, and IH are the scissor arms; L_a is the length of the scissor arm; O_1O, O_1H, O_1K, O_1I, O_2I, O_2K, O_2D, and O_2E have the same length; P and Q are the connection points between the upper and lower ends of the lifting hydraulic cylinder and scissor arms; O is the hinge point between the scissor arm and frame; E is the hinge point between the scissor arm and worktable; O_1 and O_2 are the hinge points of the two scissor arms; h_a is the lifting height of the worktable; G is the total weight of the worktable and load; α is the angle between the scissor arm and horizontal plane; and F is the thrust of the lifting hydraulic cylinder (*Yu, 2021*).

Optimisation of the hydraulic cylinder therefore focused on three factors: the maximum load, the stroke, and the movement speed. The force conditions of the scissors-lifting mechanism during the lifting process are illustrated in Figure 3.

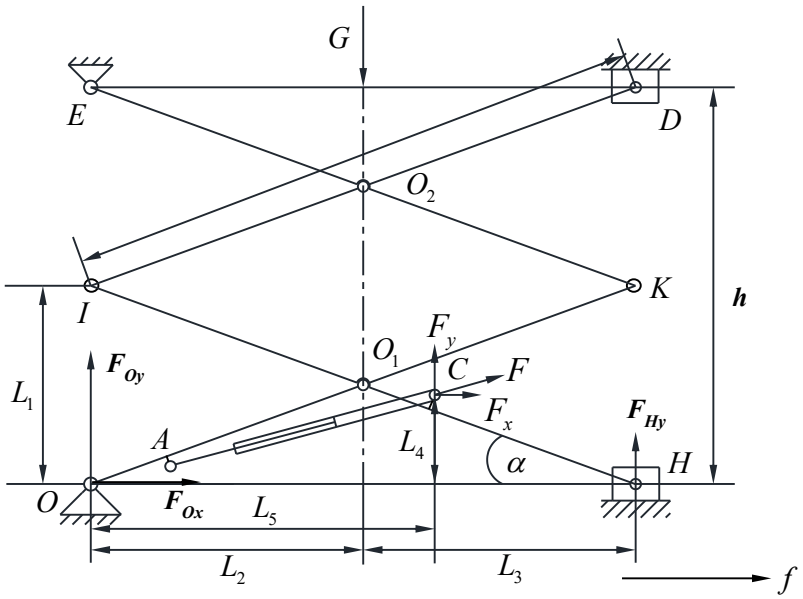

Fig. 3 - Force analysis of the scissor-lift mechanism

As shown in Figure 3, F_{Ox} and F_{Oy} are the horizontal and vertical restraining forces of the fixed hinge support O point on the mechanism, respectively; F_x and F_y are the horizontal and vertical components of the hydraulic cylinder thrust F, respectively; F_{Hy} is the vertical supporting force of the sliding hinge support H on the mechanism; f is the sliding friction force generated between the sliding hinge support H and the guide rail; L_1 is the vertical distance from the fixed hinge support O point to the hinge point I; L_2 is the horizontal distance from the fixed hinge support O point to the symmetry centre line of the mechanism; L_3 is the horizontal distance from the sliding hinge support H to the symmetry centre line of the mechanism; L_4 is the vertical distance from the force point C of the hydraulic cylinder to OH; and L_5 is the horizontal distance from the fixed hinge support O point to the force point C of the hydraulic cylinder. According to Figure 3, the equilibrium equation is listed as follows:

$$F_x = F\cos\alpha \tag{1}$$

$$F_y = F\sin\alpha \tag{2}$$

$$F_{O_x} + F_x + f = 0 \tag{3}$$

$$F_{O_y} + F_{H_y} + F_y - G = 0 \tag{4}$$

$$f = F_{H_y} \times \mu \tag{5}$$

At point O, list the torque equilibrium equation

$$G \cdot L_2 + F_{H_y} \cdot (L_2 + L_1) + F_x \cdot L_4 + F_y \cdot L_5 = 0 \tag{6}$$

It is assumed that the hydraulic cylinder drives the scissor-lifting mechanism at a constant speed under the thrust force. The vertical height at which the centre of mass rises per unit time is h, the vertical distances moved by the two ends of the hydraulic cylinder are h_1 and h_2, and the distance moved at point H is s. According to the law of conservation of energy:

$$F \cdot h_1 + F_1 \cdot h_2 = G \cdot h + f \cdot s \tag{7}$$

$$F + F_1 = 0 \tag{8}$$

From Eq. (7) and (8),

$$F = \frac{G \cdot h + f \cdot s}{h_1 - h_2} \tag{9}$$

The above analysis determines the quantitative relationship between the thrust, external load, and frictional resistance of the hydraulic cylinder and the vertical displacement of the hydraulic cylinder. This inclined-cylinder layout gives good space use, a reliable structure and a compact arrangement, and was

therefore adopted (*Liu, 2022*).

The lifting device is composed of a scissor arm assembly, hydraulic cylinders, guiding mechanism, platform frame, and limit switches, and can achieve safe and reliable lifting. Considering the working conditions of the tobacco rack in the curing barn with a height of 3.6 m, the maximum lifting height of the device was determined to be 3 m. When the machine is fully lowered, the height is 0.5 m, which meets the requirements for free movement within the curing barn. A dedicated wireless remote control (Fonda electronic power unit) provides precise control of chassis movement. The structure of the lifting device is shown in Figure 4, and the design parameters are listed in Table 2.

Design of the Hydraulic System for the lifting device

The stability of the hydraulic system is a key guarantee for the safe operation of aerial work platforms (*Liu et al., 2020*). The hydraulic system adopts a stroke-segmental speed-regulating hydraulic cylinder (Luo, 2022). The non-hydraulic end of the cylinder is equipped with two independent oil ports, and the distance between the two oil ports matches the length of the piston-sealing section. This design provides a structural basis for the regulation of segmental speed. The basic configuration of the circuit is illustrated in Figure 5.

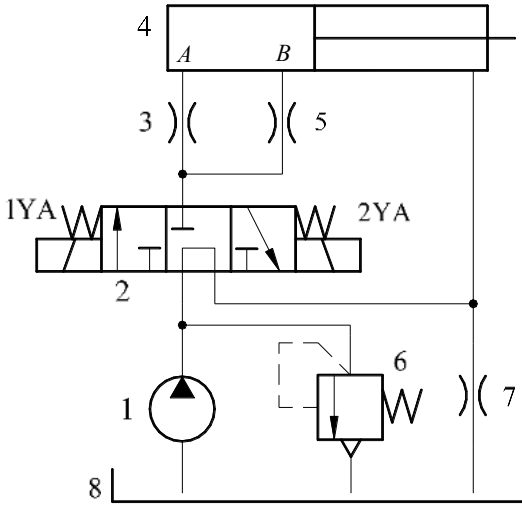

Fig. 5 - Schematic of the basic hydraulic system

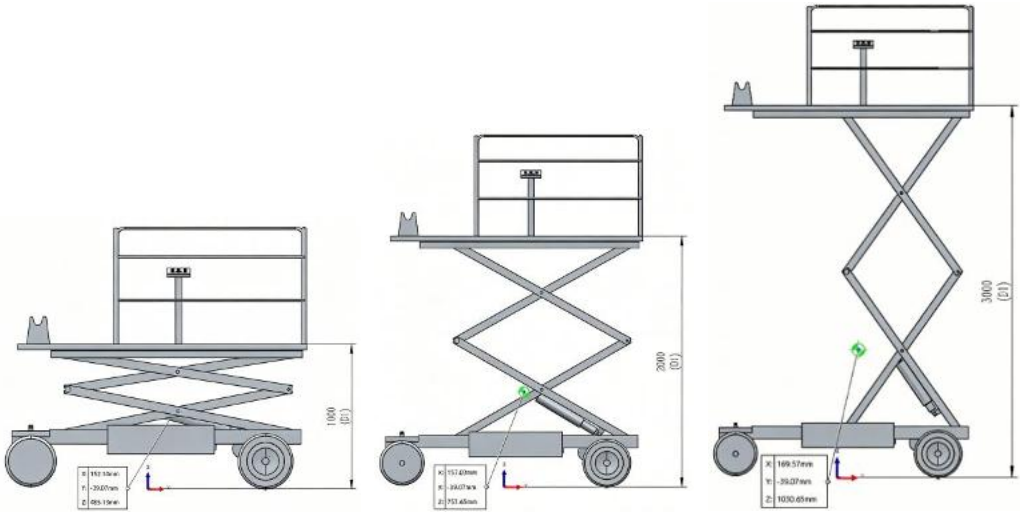

(1) hydraulic pump; (2) 3-position 3-way solenoid-operated directional control valve; (3) throttle valve; (4) hydraulic cylinder; (5) flow-control valve; (6) pressure-relief valve; (7) return-line throttle valve; (8) hydraulic oil tank

During the lifting stage of the workbench, after 1YA is energised, the hydraulic pump starts to operate, and the main directional control valve switches to the left position. The high-pressure oil is sent to the left chamber of the hydraulic cylinder through throttle valve 3, and the piston rod is moved to the right. When the piston is between points A and B, the piston rod moves at a lower velocity. After the piston rod passes point B, it accelerates and reduces the lifting time of the work platform.

During the descent stage of the work platform, when the 2YA is energised, the main reversing valve switches to the right position. Under the influence of the self-weight of the scissor mechanism, the hydraulic cylinder gradually retracts. The oil in the non-hydraulic cylinder chamber flows synchronously through throttle valves 3 and 5 in both directions and exits the chamber. The scissor-lifting platform then descends rapidly to the ground. When the piston moves to the left and passes point B, the movement speed of the hydraulic cylinder decreases. The scissor-lifting platform then falls back to the initial position at a lower speed, reducing the impact and ensuring smooth descent (*Yu et al., 2021*).

Analysis of the force on the lifting device

The centre of gravity of the lifting device directly determines the stability of the lifting process. Inside the narrow space of a curing barn, precise calculation and verification are needed to make sure the machine does not tip over under static or overload conditions. This analysis centres on a two-stage scissor-lift device. A Cartesian coordinate system was set up in SolidWorks. The plane containing the bottom of the scissor mechanism was taken as the reference plane, and the centre of that bottom as the origin. The centre of gravity coordinate points were obtained within the 1-3 m lifting range, as shown in Figure 6.

(a) Height 1000 mm *(b) Height 2000 mm* *(c) Height 3000 mm*

Fig. 6 - Point sampling process diagram

Based on the centre of gravity coordinate points, the overturning and restoring moments of the device were calculated and analysed. According to the rated load of 350 kg, the load force F = 350 × 9.8 = 3430 N. The mass of the device itself is 1046.494 kg, and its gravity G = 1046.494 × 9.8 = 10255.6412 N. The dimensions of the lifting platform are 2000 mm × 1000 mm, and the maximum lifting height is 3 m. At the maximum height, the Z-axis coordinate of the weight of the device was 1030.65 mm. The overturning moment calculation formula is shown in Eq. (10), and the restoring moment formula is presented in Eq. (11).

$$M_r = F \cdot h \tag{10}$$

where M_r is the overturning moment [N·m]; F is the load force [N]; and h is the centre of gravity height [m].

$$M_o = G \cdot d \tag{11}$$

where M_o is the restoring moment [N·m]; G is the gravity of the device [N]; and d is half the platform length.

The overturning moments at different elevations were calculated, and the results are shown in Figure 7.

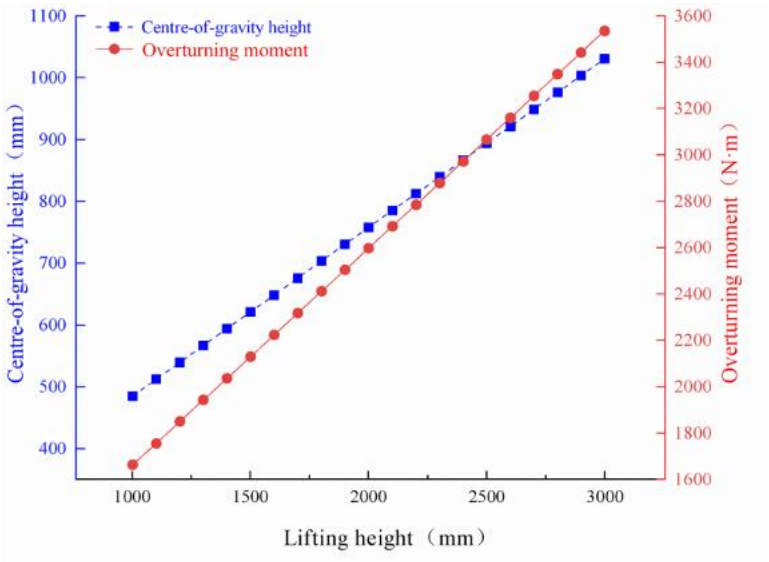

Fig. 7 - Variation in centre-of-gravity height and overturning moment with lifting height

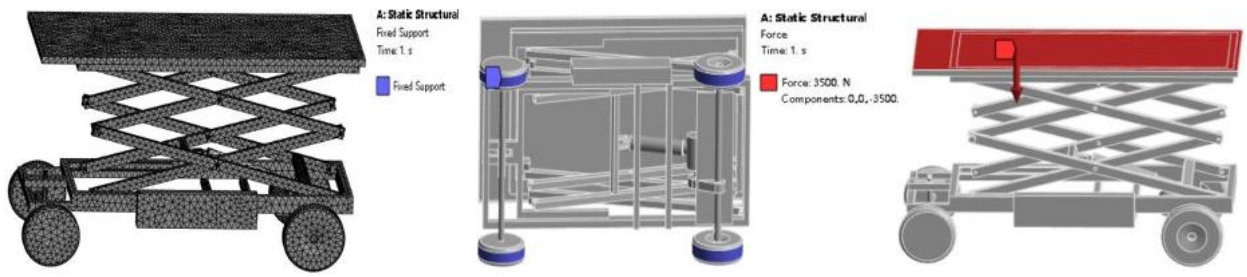
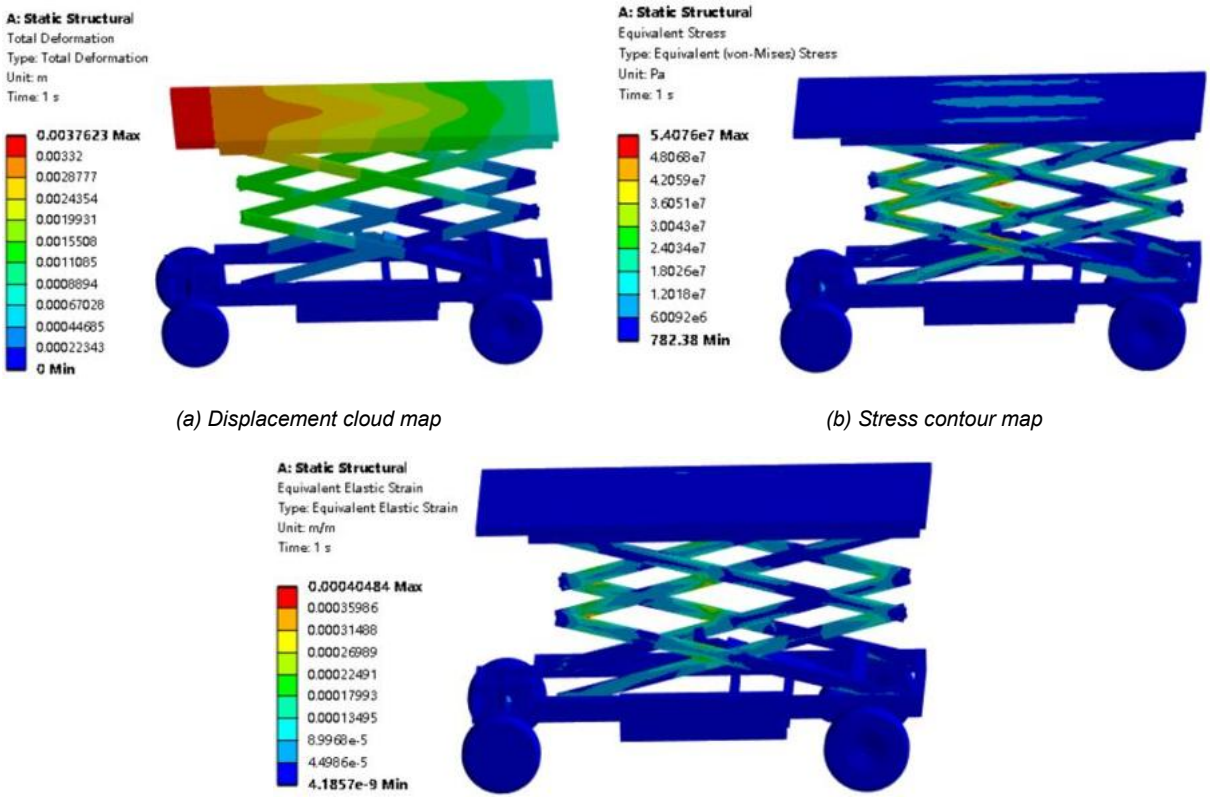


To further verify the overturning resistance capability of the device, the overturning coefficient K was introduced as an evaluation parameter. The overturning coefficient K must be determined. According to industry standards, K should be ≥ 1.5. The overturning moment at the highest point M_r = 3430 × 1.03065 = 3535.1295 N·m, and the restoring moment M_o = 10255.6412 × 1 = 10255.6412 N·m. The overturning coefficient is calculated using Eq. (12).

$$K = \frac{M_O}{M_r} = \frac{10255.6412}{3535.1295} \approx 2.9 \tag{12}$$

The results show that under the working condition of a maximum lifting height of 3 m and a rated load of 350 kg, the restoring coefficient K is approximately 2.9, which is higher than the safety limit value of 1.5 stipulated by the industry standards. This proves that the stability of the lifting device meets the design requirements set by industry standards (*Pan et al., 2017*).

Analysis of the Load-bearing Capacity of the Lifting Device



Finite element analysis is used to verify the structural strength and stiffness of scissor mechanisms. *Dengiz et al.* obtained key parameters such as the stress distribution, deformation, and safety factor of the scissor mechanism through a SolidWorks simulation (*Dengiz et al., 2018*). Ugwuoke et al. analysed the mechanical responses of each connection point of a scissor platform using CAD simulation (*Ugwuoke and Olushola, 2023*). In this study, ANSYS Workbench was used to conduct a static analysis of the lifting device, and in accordance with the usage requirement of the platform to carry out work by two people, to ensure a sufficient safety margin, a uniformly distributed load of approximately 350 kg was applied on the working platform, which is equivalent to the load condition of four adults. A process diagram is shown in Figure 8.

(a) Mesh generation *(b) Application of constraints* *(c) Application of the load*

Fig. 8 – Finite element analysis procedure

The finite element analysis results for the lifting device are presented in Figure 9.

(a) Displacement cloud map *(b) Stress contour map*

(c) Strain map

Fig. 9 - Lifting device stress contour plot

Figure 9 shows the displacement, stress distribution, and equivalent elastic strain of the lifting device under the rated load condition. The displacement distribution indicates that the platform frame has the maximum vertical downward displacement at the leftmost position, with a value of 3.7623 mm. This displacement is within the allowable engineering range and does not affect the normal operation of the equipment. The stress distribution shows that the stress concentration of the scissor mechanism mainly occurs at the movable hinge, with a maximum stress value of 54.076 MPa, which is less than the yield strength of the material and meets the strength requirements (*Shang et al., 2024; Zhao et al., 2022*). The finite element analysis results show that the scissor mechanism has good structural performance under the rated load, which is consistent with previous research results (*Bembenek et al., 2026; Ogbemhe et al., 2024*).

RESULTS

Design and Testing of Conveying Device

Overall Design of the Conveying Device

The conveying device is the core component of the tobacco clip loading and unloading system in a curing barn. It adopts a wear-resistant and anti-slip rubber conveyor belt, a high-strength and lightweight truss steel structure, an elastic adjustment device with a monitoring function (*Li, 2025*), and a control system with monitoring capabilities (*Ming and Qin, 2026*). Through the rotation of the rollers, the tobacco clips are directly borne and moved, achieving the continuous and automated conveying of the tobacco clips (*Tian, 2020*). The structural form of the conveying device is shown in Figure 10, and the design parameters are listed in Table 3.

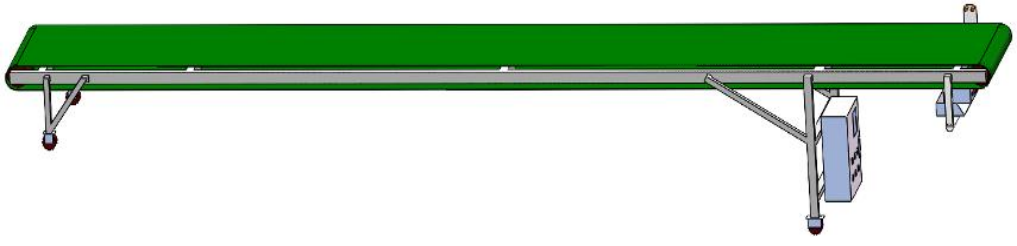


Fig. 10 - Conveyor structure

Table 3

Design parameters of the conveying device

Parameter	Value
Conveyor-belt width [mm]	920
Conveyor-belt length [mm]	7000
Conveying speed [m/min]	22
Maximum load capacity [kg]	150

Quality of Conveying Device - Correlation Test of Inclination Angle

The conveying device is prone to exhibit various tilt postures during actual operation in a curing barn. The tilt angle directly affects the quality detection accuracy and measurement stability of the belt scale. To quantify the correlation between the angle and detection quality and to optimise the system calibration parameters to ensure the reliability of the weighing data throughout the entire process, it is necessary to conduct a test on the correlation between the quality of the conveying device and tilt angle. The on-line weighing of the conveyor belt used the PSD-X3U model of the PUSHTON high-precision weighing sensor with a range of 50 kg, as shown in Figure 11.

Fig. 11 - High-precision weighing sensor

The test was conducted on the loading and unloading devices in the curing barn. The angle adjustment component and lifting device were used to achieve inclination angle regulation with an accuracy of ±0.5°. Four standard weights (5, 10, 15, and 20 kg) were used for the test. The independent variable of the test was the inclination angle of the conveyor belt, with six gradients set at 0° (horizontal reference group), 5°, 10°, 15°, 20°, and 25°, covering the travel range of the lifting device. The dependent variables were the detected mass values and detection error rates of the belt scale. The control variables included the standard weights of the conveyor belt, and running speed of the conveyor belt to ensure the reliability of the results.

Before the test, the conveyor belt was set to a 0° horizontal position and the belt scale was calibrated. The detection error should be within ±1% in the horizontal state. During the formal test, the target angle was adjusted and stabilised for 3 min. Different specifications of standard weights were placed steadily at the centre of the conveyor belt, and the conveyor belt was then started. The data were recorded after the weights completely passed through the detection zone. Each combination of angle and weight was tested three times and reset to avoid cumulative errors. The relationship between the conveyor belt inclination angle and the error rate of quality detection is shown in Figure 12.

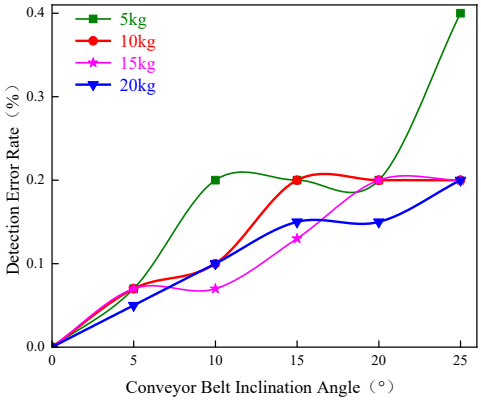

Fig. 12 - Relationship between conveyor belt inclination angle and detection error rate for different standard weights

The detection error rate rose with the belt inclination, showing a positive correlation. Under the horizontal reference state of 0°, the detection error rate for each standard weight was 0.00%. This verified the accuracy of the equipment calibration before the test and complied with the design specifications. As the inclination angle increased from 5° to 25°, the detection error rate for each standard weight gradually increased. Among them, the error rate of the 5 kg standard weight reached a maximum value of 0.40% at 25°, and the error rates of the other weights were controlled within 0.20%.

Design of the Device Control System

Considering the environment of the curing barn and the requirements of tobacco leaf handling operations, this control system features a high-precision measurement accuracy of 0.2 level, customisable interfaces, and MODBUS bus expansion. It adopts incremental digital PID control and can adapt to complex operating conditions. The automatic lifting control is set by the touchscreen to the target height and combined with limit switches to achieve deceleration when approaching the target height, ensuring stable and reliable operation. The control panel is shown in Figure 13.

(a) Control system front panel *(b) The rear panel of the control system*

Fig. 13 - The control panel

The setting of the key parameters of the control system directly determines the measurement accuracy and the control performance. The specific configuration of each parameter is as follows: the belt speed is 22 m/min, the length of the weighing section is 1 m, the speed measurement specification is 1000 P/m, the PID proportional coefficient is 8.0%, the integration time is 0.5 s, the control cycle is 50 ms, the rated load capacity of the system is 350 kg, the overload protection threshold is 110% of the rated load capacity, the belt speed deviation threshold is ±20% of the set value, the MODBUS address can be set within the range of 1 to 255, the baud rate supports 2400, 4800, 9600, and 19200 bps options, the data bit is 8 bits, the stop bit is 1 bit, and the check bit supports no check, odd check, and even check modes.

Loading and unloading measurement control is the core function of this system, which includes two processes: loading and unloading tobacco. During loading, the tobacco clip is placed on the conveyor belt, which is then started. The controller calculates the instantaneous flow rate in real time from the weight and speed sensors. When the clip reaches the end and triggers the proximity switch, the conveyor belt stops. After manual mounting and resetting, the next cycle is initiated. After the curing process is completed, the conveyor belt runs in reverse during unloading, and the measurement system accumulates the weight of the unloaded tobacco. To improve the control accuracy and response speed and reduce the adjustment fluctuations, the system adopts an incremental PID algorithm for closed-loop control. The error calculation and output correction are completed according to the PID control algorithm formula, as shown in Eq. (13).

$$\Delta u(k) = K_P\left[e(k) - e(k-1)\right] + K_i \cdot e(k) + K_d\left[e(k) - 2e(k-1) + e(k-2)\right] \quad (13)$$

where $\Delta u(k)$ is the increment of the kth output, K_P is the proportional coefficient, K_i is the integration coefficient, K_d is the differential coefficient, and $e(k)$ is the kth deviation.

The corresponding PID parameter adjustment strategy, adapted from established tuning rules (*Zhou, 2026*), is as follows: when adjusting the proportional coefficient (K_P), increasing K_P can enhance the system

response speed, but it may lead to overshoot if it is too large; when adjusting the integral coefficient (K_i), increasing K_i can reduce the steady-state error, but it may cause integral saturation if it is too large; when adjusting the derivative coefficient (K_d), increasing K_d can improve the system dynamic characteristics and suppress overshoot.

System calibration is crucial for ensuring measurement accuracy. Zero-point calibration is used to eliminate the drift. After the load is stable, the system automatically collects and saves the zero-point value. It must be calibrated before the first use and is usually performed once a week. Range calibration is accomplished using standard weights at 50–80% of the full range to correct the coefficient. It is calibrated before the first use and is typically performed once a month. It should be recalibrated after the key components are replaced.

Overall Performance Test

Tobacco Loading and Unloading Test

The device was manufactured, assembled and commissioned according to the above design, as shown in Figure 14. The test site was the dense curing barn of the Pingdingshan Modern Tobacco Agricultural Science Park in Li Kou Town, Jia County, Henan. The curing barn was 8 m long, 3 m wide, and 4.5 m high, which meets the general standards for dense-curing barns in China. The number of layers of the tobacco racks inside the curing barn was three, with a spacing of 1.2 m per layer, and the average length and width of the test tobacco clips were 1.5 m and 0.2 m, respectively.

Fig. 14 - Photograph of the Curing Oven Tobacco Clip Loading and Unloading Device

The basic performance tests included load capacity and positioning accuracy tests. The load test was conducted by applying 200, 300, and 350 kg loads to the lifting platforms. Under each load condition, the platform was raised to a height of 3 m and maintained for 10 min to observe any sinking or deformation of the platform. Simultaneously, 100 kg and 150 kg loads were applied to the conveying device to check whether the conveyor belt slipped or had an abnormal speed. The positioning test involved raising the platform to heights of 1, 2, and 3 m, as illustrated in Figure 15.

Fig. 15 - Experimental process

The test results show that this device can stably and efficiently complete operations such as lifting and lowering tobacco leaves, transportation, and loading into curing racks. It can adapt well to the curing barn environment and significantly improve operational efficiency.

Loading and Unloading Efficiency Test

To test the efficiency of the device for loading and unloading, a comparative test was conducted using a traditional manual method. The loading and unloading operations were performed separately in the same dense tobacco curing barn, and the operation time, number of workers, efficiency, and labour cost were recorded. The results showed that it took four hours and four workers to manually load tobacco into each curing barn. After adopting the tobacco curing barn tobacco clip loading and unloading device, the loading time for each curing barn was reduced to 1.5 h, and only two workers were needed to operate it. The comparison results indicated that the operation time was shortened from 4 h to 1.5 h, saving 62.5%; the number of workers was reduced from 4 to 2, and the labour cost decreased by 50%. The overall efficiency increased by 4.33 times.

CONCLUSIONS

This study addresses the problems in China's tobacco curing process, such as the reliance on manual operations for loading and unloading of tobacco leaves in curing barns, high labour intensity, low efficiency, and significant safety hazards. The design, analysis, manufacturing, and test verification of a loading and unloading device for tobacco leaves in curing barns were completed, and a technical solution suitable for dense curing barns was developed. The main conclusions are as follows:

(1) The device integrates a four-wheel-drive power platform, a two-stage scissor-type lifting mechanism, an on-line weighing and conveying system, and an incremental-PID control loop into a single barn-door station. The rated load is 350 kg and the lifting range is 0.5–3 m, meeting the requirements for loading tobacco in dense curing barns.

(2) A method combining mechanical modelling with finite element analysis provided a scientific basis for design verification of the scissor mechanism. Under the rated load, the maximum deformation was 3.7623 mm and the maximum stress was 54.076 MPa, both within the strength and stiffness limits. At the 3 m maximum lift and 350 kg rated load, the restoring coefficient K was approximately 2.9, well above the industry safety limit of 1.5.

(3) The conveying device adopted a truss-type steel structure with a rubber conveyor belt. Weighing tests over the 0°–25° inclination range gave a maximum error rate of ≤ 0.40 %, clarifying the influence of belt inclination on weighing accuracy and ensuring accurate weight detection across the full operating angle.

Field trials showed that the shortest transportation time per clip was 2.7 s, the loading time per curing barn was reduced from 4 h under manual operation to 1.5 h, and the number of operators was decreased from four to two, giving a 4.33-fold gain in overall efficiency. The fault-free working time met the requirements for continuous operation during the tobacco-curing season. Compared with manual loading, the device lowers labour intensity and improves the consistency of the loading and unloading process. Compared with hand loading, the device reduces manual intervention, lowers the physical demand on operators, removes the variability of hand loading, and improves the accuracy and stability of the loading and unloading process.

The main scientific contributions of this work are threefold. First, it presents a barn-door station platform that integrates power transfer, scissor lifting and on-line belt weighing into a single mobile unit, moving the loading task from inside the barn to a controlled workstation at the barn door. Second, it provides a quantitative restoring envelope for a two-stage scissor lift under an off-centre agricultural payload, with an restoring coefficient of K ≈ 2.9 at a lifting height of 3 m and a rated load of 350 kg. Third, it reports a measured error envelope of ≤ 0.40 % for on-line belt weighing across the 0°–25° tilt range, filling the gap in tilt-dependent weighing accuracy for agricultural conveyors. Together, these results supply reusable design data for the mechanised loading stage of dense-curing barns.

The field trial covered a single curing season, one site and one tobacco variety. Multi-region and multi-variety trials will be undertaken to verify adaptability across leaf moisture levels and barn geometries. The belt-scale weighing was validated only within a 0°-25° tilt range and under uniform loading. The model will be extended to wider tilt angles, higher loading rates and non-uniform leaf distribution. Integration with machine-vision leaf grading and IoT-based curing monitoring will also be explored to enable closed-loop optimisation of the curing chain.

Keywords: *Plasma Agriculture; Dielectric Barrier Discharge; Surface Modification; Electrical Conductivity; Dosage Effect*

ABSTRACT
To overcome the problems of low germination rate and irregular emergence caused by dense surface structure, poor water permeability, and dormancy of forage seeds, this study screened the optimal plasma generation mode suitable for continuous treatment of forage seeds under atmospheric pressure and evaluated its efficacy and mechanism. Through a comparative analysis of the uniformity and stability of corona, spark, gliding arc, and dielectric barrier discharge (DBD), the results showed that DBD can generate large-area, low-temperature, and uniform plasma in atmospheric air. Taking Leymus chinensis seeds as the research object, the effects of different treatment voltages (0–16 kV) on the glume microstructure and the electrical conductivity of the leachate were investigated. Scanning electron microscopy (SEM) observations indicated that DBD treatment with appropriate parameters caused significant etching on the seed glume surface, forming micropores and fissures, and removing impurities. The electrical conductivity measurements further revealed a "dosage effect": moderate voltage helped maintain the integrity of the membrane system, whereas excessive voltage led to severe damage to the glume and leakage of intracellular contents. The study confirmed that atmospheric pressure DBD plasma, through physical etching and surface modification, can effectively improve the water absorption channels and physiological activity of Leymus chinensis seeds, and an optimal parameter window exists. These findings provide a technical basis for the development of continuous plasma seed treatment equipment.

摘要
为克服牧草种子因表面结构致密、透水性差及休眠特性导致的萌发率低、出苗不齐等问题，本研究筛选适用于常压条件下牧草种子连续处理的最佳等离子体发生方式，并评估其效能与作用机制。通过对比电晕、火花、滑动电弧及介质阻挡放电（DBD）的均匀性与稳定性，结果显示，DBD 可在常压空气中产生大面积、低温、均匀等离子体。以羊草种子为对象，探究不同电压（0–16 ）处理对其颖壳微观结构及浸提液电导率的影响。扫描电镜观察表明，适宜参数的 DBD 处理可使种子颖壳表面产生显著刻蚀，形成微孔与裂隙，并清除杂质；电导率测定结果进一步揭示了"剂量效应"：中低电压有助于维持膜系统完整性，过高电压则导致颖壳过度损伤及内含物外渗。研究证实，常压 DBD 等离子体通过物理刻蚀与表面改性，可有效改善羊草种子的吸水通道与生理活性，且存在最优处理参数窗口。研究结果为开发连续式等离子体种子处理装备提供了技术依据。

INTRODUCTION
Superior forage seeds constitute the material basis for ecological restoration, pasture management, and urban greening (*Fekete et al., 2024*). However, a substantial number of dominant grass species are characterized by inherent physiological defects, such as hard and dense seed coats, poor water and air permeability, and deep dormancy. These characteristics inevitably lead to slow germination, irregular seedling emergence, and low seedling rates under natural conditions, thereby severely restricting their efficient utilization (*Harrison et al., 2025*). Although traditional physical or chemical treatment methods—such as mechanical scarification, concentrated sulfuric acid treatment, and hormone soaking—have demonstrated certain efficacy, they are associated with significant drawbacks.

These include uneven treatment, potential damage to the embryonic body, chemical residue pollution, and difficulties in scaling up. Consequently, these conventional approaches fail to fundamentally meet the new requirements for high efficiency, safety, and environmental protection demanded by modern green agriculture and ecological construction.

In recent years, various physical pre-sowing treatments have been explored to overcome seed dormancy and improve germination. For instance, pulsed electric fields (*Evrendilek et al., 2021*; *Hou et al., 2023*; *Song et al., 2025*) and electromagnetic treatment (*Ganeva et al., 2015; Pentoś et al., 2024*) have been reported to enhance seed germination and stress tolerance by affecting membrane potential and ion transport. However, these methods primarily rely on electric or magnetic forces without altering the seed coat's physical structure or surface chemistry. As a modern physical agricultural high-technology, low-temperature plasma has been introduced within the rapidly developing field of Plasma Agriculture, offering distinct advantages (*Waskow et al., 2021*; *Hui et al., 2025*). Research indicates that reactive species and ultraviolet radiation from plasma can etch seed coats, enhance hydrophilicity, and induce biostimulation (*Attri et al., 2023*; *Benabderrahim et al., 2025*). Various plasma technologies have been applied to seed treatment: corona discharge on alfalfa seeds reduced contact angle and increased water absorption (*Xu et al., 2021*); cold plasma jet on oat seeds improved germination under salt stress (*Zhang et al., 2024*); transient spark discharge restored germination of fungus-infected wheat seeds (*Doshi et al., 2024*); gliding arc discharge inactivated pathogens on Astragalus seeds while increasing germination rate (*Liu et al., 2021*).

Despite these confirmations, a systematic comparison of different atmospheric plasma generation modes for forage seed treatment is still lacking. Most studies focus on single technologies without evaluating their uniformity, continuity, and suitability for large-scale, continuous seed processing. Therefore, the research gap addressed by this paper is the need to identify the optimal plasma generation mode for continuous, non-damaging treatment of forage seeds under atmospheric pressure.

To address this gap, this study provides a side-by-side comparison of corona, spark, gliding arc, and DBD for seed treatment, identifies DBD as the preferred mode for continuous processing, and systematically evaluates the dosage effect on seed coat microstructure and membrane integrity, thereby establishing a technical basis for equipment development. Accordingly, the core hypothesis is that under atmospheric pressure, DBD plasma represents the optimal technical route for overcoming the inherent defects of grass seeds and achieving efficient continuous treatment.

MATERIALS AND METHODS

1 Comparative Experiment on Atmospheric Pressure Plasma Generation Modes

Based on the different configurations of electrodes, gas discharge generates plasma in various forms. Common discharge modes include corona discharge, spark discharge, glow discharge, Dielectric Barrier Discharge (DBD), and gliding arc discharge (*Wang et al., 2025*). To screen for an atmospheric pressure plasma generation mode suitable for continuous seed treatment, experimental test benches corresponding to each discharge principle were established. The experiments were conducted under ambient temperature and pressure conditions using seeds as the treatment object. By directly observing the discharge phenomena and seed status, the plasma generation modes were qualitatively evaluated from the perspectives of discharge uniformity and continuity, the stability of the discharge state upon seed introduction, thermal effects within the discharge region, and the risk of physical damage to the seeds (*Mazandarani et al., 2020*).

2 Evaluation Experiment of Plasma Treatment on Seed Performance

Upon determining the optimal atmospheric pressure plasma generation mode, an integrated plasma forage seed treatment prototype was developed based on the experimental setup to verify the feasibility of continuous treatment. Wild *Leymus chinensis* seeds, a typical gramineous forage, were selected as the experimental material and processed using this prototype.

2.1 Experimental Design for Plasma Seed Treatment

The DBD device used a plate-to-plate electrode configuration with a quartz glass dielectric barrier. The discharge gap was fixed at 6 mm, and the dimensions of each electrode plate were 150 mm × 150 mm. The power supply (CTP-2000K) operated at an AC frequency of 1–100 kHz (adjustable) and provided an output voltage from 0 to 30 kV.

Six discharge voltage levels were applied: 0 (control), 3, 6, 10, 13, and 16 kV. These values were selected to cover a wide range from weak to intense discharge, based on the adjustable capability of the power supply and preliminary observations of discharge stability. A fixed treatment time of 20 s was chosen for voltage effect tests, as suggested by preliminary experiments and prior work (*Tang et al., 2017*).

2.2 Assessment of Plasma Seed Treatment Performance

(1) Scanning Electron Microscopy (SEM) Test

To systematically elucidate the plasma seed treatment mechanism, specifically the physical etching and surface modification effects of DBD plasma on the seed coat of *Leymus chinensis*, high-resolution morphological observations were conducted using a scanning electron microscope (SU3500, Hitachi High-Tech Corporation). Samples were taken from untreated seeds and seeds treated with plasma at different voltages (3, 6, 10, 13, and 16 kV). The seeds were positioned at various orientations on the sample stage to facilitate the observation of different morphological features. For *Leymus chinensis* seeds, observations were required for the central protrusion, depressions, and edge bristles. The smooth surfaces and awns were observed at magnifications of 300x and 500x, respectively. The changes in surface particles, cracks, gaps, pores, and impurity contaminants on the seed coat were focused on and recorded to visualize the structural alterations under different discharge voltages.

(2) Electrical Conductivity Test

Electrical conductivity measurement was utilized to analyze the ion permeability of the seed leachate. Seeds treated at different voltages (0, 3, 6, 10, 13, and 16 kV) were divided into groups, with 40 seeds per group, and placed in beakers containing 50 mL of deionized water to ensure complete immersion. At a room temperature of 25°C, the electrical conductivity of the leachate was measured every 2 hours using a conductivity meter for a continuous duration of 24 hours. The experimental group was repeated 5 times to obtain the average value. By comparing the variation trends of conductivity over time among different treatment groups, the influence of plasma treatment on seed coat membrane permeability and the leakage of endogenous substances was analyzed, thereby revealing the potential dosage effect.

RESULTS AND DISCUSSION

1 Screening Results and Analysis of Plasma Generation Modes

The mode of plasma generation constitutes the core of the design for the seed pre-sowing treatment device, as the characteristics of plasma generated by different gas discharge forms and their effects on seeds vary significantly. Therefore, based on the fundamental principles of various gas discharges, corresponding test benches were designed. By positioning seeds within different forms of electric fields and regulating voltage and current parameters, the differences in discharge phenomena before and after the addition of seeds were systematically compared. The focus was placed on the uniformity and continuity of the discharge under atmospheric pressure, as well as its adaptability to seeds, to screen out the plasma generation mode most suitable for batch and continuous seed treatment in plasma agriculture.

1.1 Gliding Arc Discharge Seed Treatment

Based on the principle of gliding arc discharge, a seed treatment test bench was designed (Fig. 1). The apparatus primarily consists of a radio frequency (RF) power supply, a voltage regulator, an oscilloscope, a fan, electrodes, and a seed treatment section. The discharge component is composed of two high-voltage metal plate electrodes with a phase difference of 180°, mounted on an aluminum alloy frame. A fan is installed directly above the electrodes, while the seed treatment chamber is positioned directly below, with a discharge voltage range of 0–50 kV.

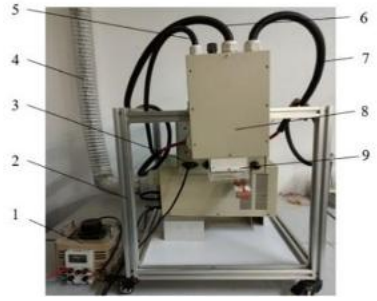

Fig. 1 - Gliding arc discharge seed treatment test bench

1. Voltage regulator; 2. Frame; 3. Discharge power supply; 4. Exhaust pipe; 5. Fan power cable; 6. High-voltage cable A; 7. High-voltage cable B; 8. Fan and electrode; 9. Seed treatment chamber

Observations of the discharge phenomena were conducted by placing different types of seeds in the gliding arc electric field and adjusting the discharge voltage via the regulator. The complete process from generation to extinction of the gliding arc was demonstrated: upon activating the power supply and fan, the gas between the electrodes was broken down, forming an initial arc (Fig. 2a).

Driven by the airflow generated by the fan, the arc moved along the electrode towards the other end and gradually elongated (Fig. 2b and c). When the supplied energy was insufficient to maintain arc propagation and compensate for thermal diffusion losses, the arc was extinguished and subsequently regenerated at the electrode throat, thereby entering the next discharge cycle (Fig. 2d). The discharge process after the addition of alfalfa seeds is shown in Fig. 3. The results indicated that due to the limited action area of the arc and the susceptibility of small-sized seeds to dispersion by strong airflow, this method is difficult to implement for the high-efficiency treatment of large batches of small seeds. Additionally, the high local temperature of the arc is prone to causing thermal damage to the structure of the treatment chamber.

Fig. 3 - Phenomenon of gliding arc discharge seed treatment

1.2 Corona Discharge Seed Treatment

Based on the principle of corona discharge, a needle-to-plate corona discharge seed treatment test bench was designed, as illustrated in Fig. 4. The test bench is primarily composed of a radio frequency (RF) power supply, a voltage regulator, and a seed treatment chamber. The discharge component includes a high-voltage electrode and a grounded electrode. Specifically, the high-voltage electrode consists of a needle electrode fabricated from a conductive screw, whereas the grounded electrode is a flat metal plate. The overall frame structure is constructed using aluminum alloy profiles.

The working principle of the corona discharge test apparatus is described as follows: During the experiment, seeds were spread flat on the grounded electrode plate, and the distance between the needle and plate electrodes was adjusted via a lifting knob. The high-voltage and grounded electrodes were connected to the corresponding terminals of the power supply, respectively. By regulating the voltage parameters of the power supply, the corona discharge phenomena and the state of plasma wrapping around the seeds under different voltages were observed, thereby evaluating the applicability of this discharge form for seed treatment.

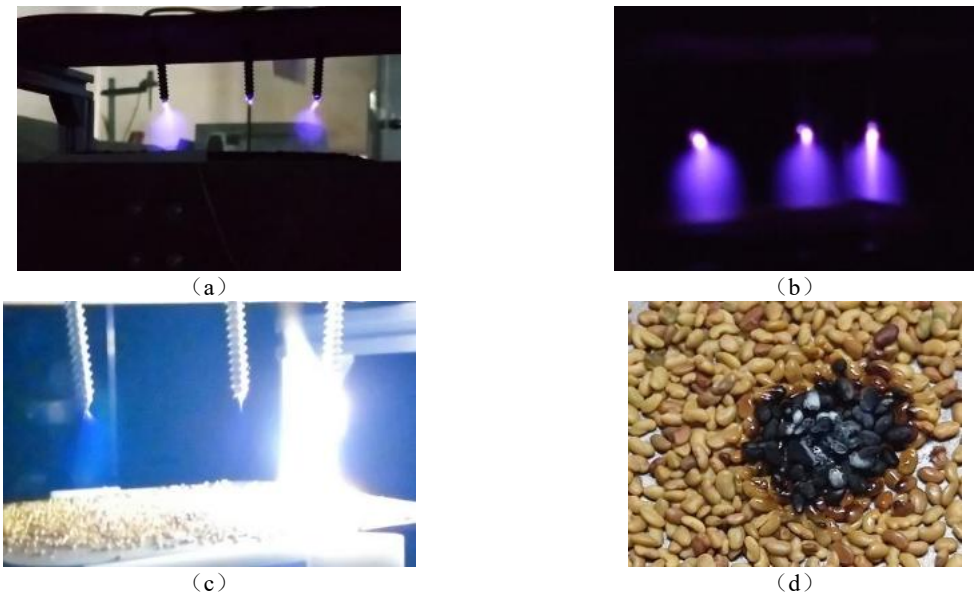

Fig. 4 - Corona discharge seed treatment

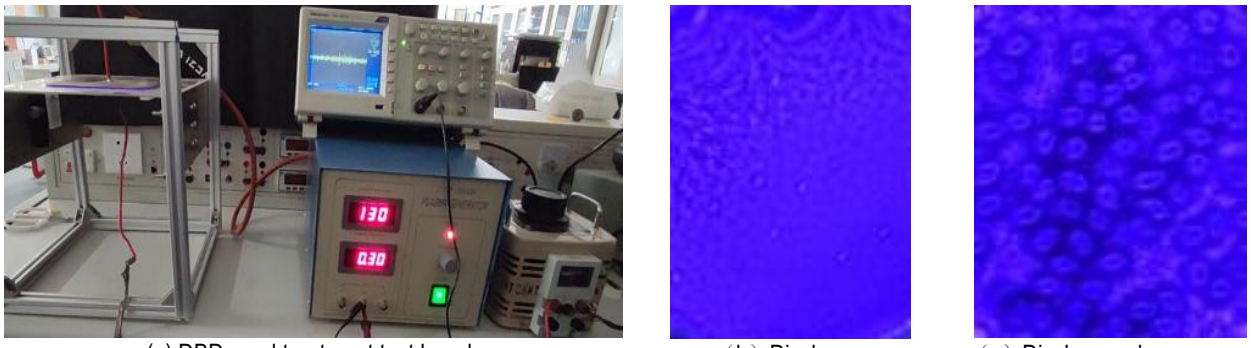
Note: (a), (b), (c) Discharge phenomena with gradually increasing discharge voltage; (d) Treatment effect on the seeds at maximum discharge voltage.

At the initial discharge stage, a glow accompanied by a "hissing" sound appeared around the needle electrode, with the current concentrated locally at the needle tip (Fig. 4a). As the voltage increased, localized discharge and halo phenomena emerged (Fig. 4b). When the voltage was further increased (Fig. 4c), significant damage was observed on the seed surface (Fig. 4d). The experiments demonstrated that the current density in corona discharge is highly concentrated at the needle tip, resulting in uneven charge distribution and poor electric field uniformity. Consequently, achieving a uniform plasma wrapping effect on the seed surface was difficult. Furthermore, this mode is prone to breakdown and high discharge temperatures, easily leading to seed scorching.

1.3 Spark and Glow Discharge

Spark discharge is mechanistically distinct from other forms, characterized by high current requirements and accompanying flashes and cracking sounds in charged regions with high potential differences. Although the voltage between the poles is high during discharge, the power supply is limited; once discharge occurs, the channel resistance drops sharply, causing the voltage to fall and the discharge to interrupt temporarily. This results in an intermittent process. Thus, despite its high intensity, the discontinuity of spark discharge limits its application in continuous seed treatment.



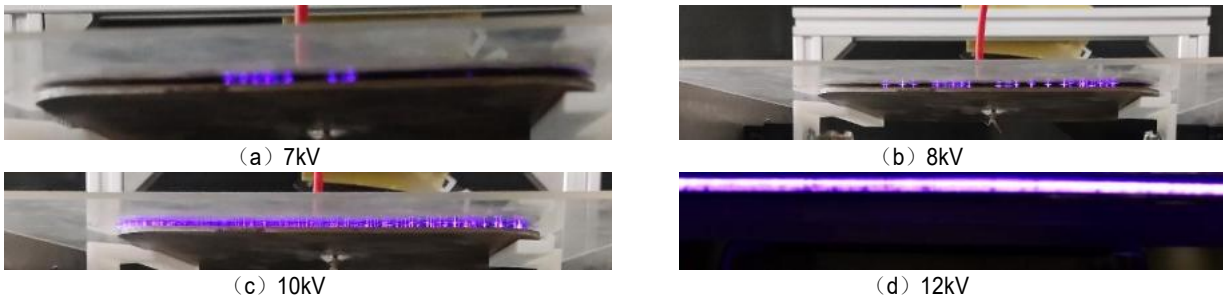
Glow discharge is a self-sustaining discharge phenomenon typically generated under low-pressure conditions (thin gas) and usually requires a sealed environment to maintain the plasma. Currently, this technology is mainly applied in the manufacturing of precision devices. However, in atmospheric, open-type agricultural scenarios, its applicability is limited due to the requirement for vacuum systems and the difficulty in achieving large-volume uniform discharge.

1.4 Dielectric Barrier Discharge (DBD) Seed Treatment

Based on the principle of Dielectric Barrier Discharge (DBD), a plate-to-plate seed treatment test bench was designed to investigate the discharge characteristics under different seed types and voltage parameters, as shown in Fig. 5(a) . The apparatus was primarily composed of a radio frequency (RF) power supply, a voltage regulator, an oscilloscope, and a seed treatment section. The discharge component of the test bench consisted of a high-voltage electrode and a grounded electrode. The dielectric barrier was constructed from quartz glass, while the high-voltage electrode plate was made of metal, and the frame was fabricated from aluminum alloy profiles.

The working principle of the Dielectric Barrier Discharge apparatus is described as follows: The height of the grounded electrode plate was adjusted via a screw rod. Seeds were spread flat on the grounded electrode, which was then elevated to an appropriate height. The high-voltage and grounded electrode plates were connected to the corresponding terminals of the power supply via wires. By regulating the voltage parameters of the power supply, the discharge phenomena of the device were observed and recorded.

Fig. 5 (b) and 5(c) illustrate the significant disparity in discharge phenomena with and without the presence of seeds under identical voltage conditions. It was observed that in the absence of seeds, atmospheric pressure DBD exhibited a filamentary discharge pattern. However, under the same conditions, the introduction of seeds caused the filamentary discharge to transition into a uniform discharge. The seed surfaces were uniformly wrapped by low-temperature plasma streamers, and the luminous intensity above the seeds was significantly higher than that in the interstitial regions. This indicates a dense distribution of low-temperature plasma over the seeds, whereas the regions between adjacent seeds exhibited weak luminescence and a lower plasma density. This phenomenon suggests that the introduction of seeds altered the electric field distribution between the plates and the transport behaviour of charged particles. This is likely due to the dielectric properties of the seed surface enhancing the local electric field, thereby promoting discharge uniformity and stability. Consequently, this result provides a critical basis for achieving continuous and uniform plasma treatment of seeds under atmospheric pressure.



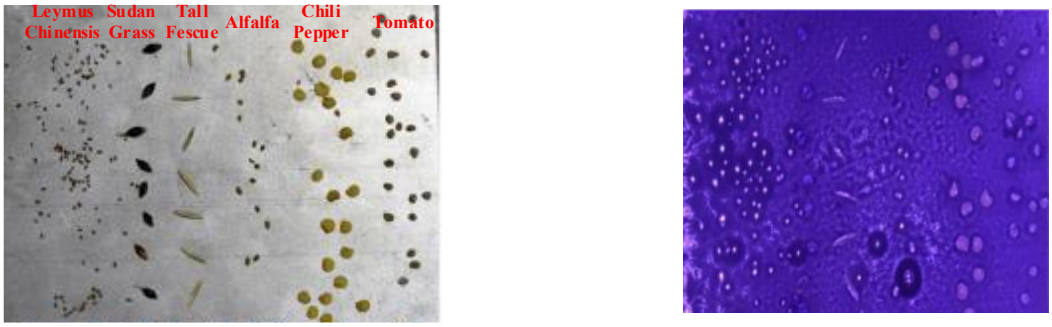
(a) DBD seed treatment test bench

（b）Discharge phenomenon without seeds

（c）Discharge phenomenon with seeds

Fig. 5 Dielectric barrier discharge seed treatment test bench

Medicago sativa (alfalfa) seeds were placed in the discharge test bench, and varying voltages (0–15 kV) were applied, resulting in the discharge phenomena shown in Fig. 6. As the discharge voltage was regulated and increased to 7 kV, discharge initiated at the locations of the seeds. With a further increase in voltage, the discharge intensity enhanced, the discharge area expanded, and discharge occurred in most of the air gap locations. As the voltage continued to rise, a large number of filamentary discharges began to appear in the air gap. When the voltage reached 10 kV, the alfalfa seeds were wrapped in low-temperature plasma. Upon the applied power supply voltage amplitude reaching 12 kV, the interior of the discharge device exhibited a complete and uniform discharge. Through these discharge tests, it was found that with the increase of discharge voltage, the Dielectric Barrier Discharge developed from filamentary discharge to uniform discharge. Under appropriate voltage conditions, DBD achieved uniform discharge, with low-temperature plasma wrapping the seeds, thereby subjecting them to uniform treatment.



（a）7kV （b）8kV

（c）10kV （d）12kV

Fig. 6 - Discharge phenomena of plasma treatment on alfalfa seeds under different voltages

To investigate the influence of seed physical characteristics on the dielectric barrier discharge process, various typical forage and crop seeds—including *Leymus chinensis*, Sudan grass, tall fescue, alfalfa, chili, and tomato—were selected. These were simultaneously placed within the same DBD electric field, and the power supply voltage was regulated within the range of 0–20 kV to systematically observe their discharge behaviour, as shown in Fig. 7. The results indicated distinct differences in the discharge inception voltage for different seeds within the same electric field.

As the voltage gradually increased, the locations occupied by the thicker alfalfa seeds were the first to induce discharge, followed sequentially by chili, tomato, and tall fescue seeds. When the voltage rose to 16 kV, all seeds were uniformly wrapped by plasma, and the electric field achieved complete and uniform discharge coverage. It was experimentally determined that seed thickness is negatively correlated with the required discharge voltage. The mechanism is inferred to be that an increase in seed thickness reduces the equivalent discharge gap between the seed surface and the upper electrode plate. This leads to a reduction in the number of initial electrons in the air gap of that region, which in turn lowers the reverse potential in the area above the seed (*Liu et al., 2023*). Therefore, under the same applied voltage, the actual electric field strength in the air gap surrounding thicker seeds is higher, making it easier to reach the discharge threshold and thereby preferentially inducing plasma discharge (*Judée and Dufour, 2020*). This phenomenon reveals the significant regulatory role of seed geometric characteristics in the DBD process.

(a) Different seed types (b) Seeds fully wrapped by plasma

Fig. 7 – Discharge phenomena of different seed types in an electric field

As discussed in sections 1.1–1.3, the other discharge modes exhibit intrinsic limitations for continuous seed treatment. Corona discharge suffers from localized current concentration at the needle tip, leading to uneven charge distribution and a high risk of seed scorching (Fig. 4a–c).

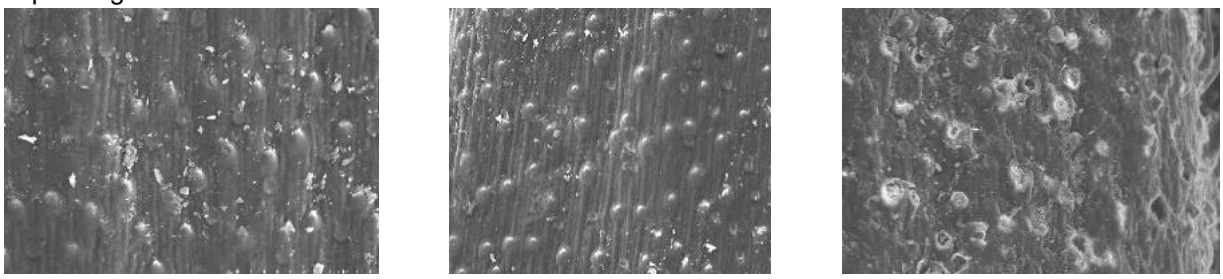
Spark discharge is inherently intermittent due to its rapid breakdown and extinction cycle, making continuous uniform treatment unattainable. Despite reports demonstrating its efficacy in water sterilization and seed germination enhancement — for example, spark dielectric barrier discharge (SDBD) plasma achieved complete inactivation of E. coli and S. aureus after 8 min of treatment, increased coriander seed germination rate from 23.3% to 46.6% after 5 min, and reduced water contact angle from 105.65° to 57.19° owing to surface hydrophilization (*Dhakal et al., 2023*) — the intrinsic intermittency and discontinuity of spark discharge fundamentally preclude its application in continuous, large-scale seed processing. Gliding arc discharge, while capable of generating plasma at atmospheric pressure, produces a high-temperature arc zone that can thermally deform seeds and is further complicated by the tendency of small seeds to be dispersed by the required airflow (Fig. 2a–d, Fig. 3).

Glow discharge, though uniform and low in temperature, typically requires low-pressure (vacuum) conditions, which are impractical for large-scale, open-environment agricultural processing. Although large-volume atmospheric pressure glow discharge has been successfully demonstrated for Moringa oleifera seed treatment, achieving fungal disinfection and enhanced germination at low energy doses (2.46–4.35 mJ), it operates in a pulsed mode and still faces challenges in scaling to continuous seed flow (*Ouf et al., 2022*).

The requirement for precise gap control and the risk of arc transition at higher doses further limit its applicability for continuous, high-throughput processing. In contrast, Dielectric Barrier Discharge (DBD) overcomes all these drawbacks. Under the same atmospheric conditions, DBD generates a large-area, low-temperature, and remarkably uniform plasma. More importantly, the introduction of seeds into the DBD gap does not disrupt the discharge; instead, it promotes the transition from filamentary to uniform discharge (Fig. 5c), with the seeds being evenly wrapped by low-temperature plasma streamers (Fig. 6d, Fig. 7b). This unique behavior, attributed to the dielectric properties of the seed surface enhancing the local electric field (as described in section 1.4), enables continuous, non-thermal, and scalable treatment.

A systematic comparison of all five discharge modes based on experimental observations and literature evidence is provided in Table 1. Therefore, DBD is identified as the preferred discharge mode for developing continuous plasma seed treatment equipment for forage grasses under atmospheric pressure.

Table 1

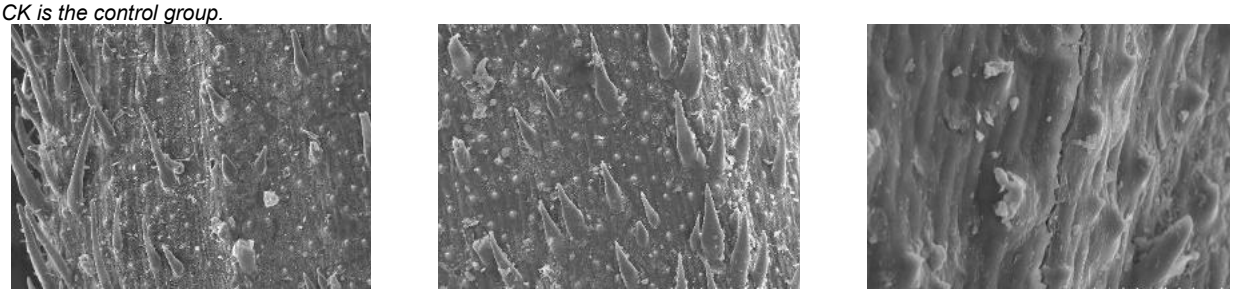


Comparison of different atmospheric pressure plasma generation modes

Discharge Mode	Uniformity & Continuity	Thermal Effect	Seed Damage Risk	Suitability for Continuous Treatment
Corona	Localized at needle tip (Fig. 4a–c)	Local temperature rise	Scorching at high voltage (Fig. 4d)	Low
Spark	Intermittent, flashes/cracking (*Dhakal et al., 2023*)	High (~1754 K)	Not directly observed	Very Low
Gliding Arc	Arc moves, small area (Fig. 2a–d)	High local temperature	Possible thermal deformation (Fig. 3)	Moderate
Glow	Uniform but requires low-pressure/vacuum; pulsed at atm. pressure (*Ouf et al., 2022*)	Low (~310 K)	Low at low doses, harmful at high doses	Low
DBD (This work)	Uniform, stable, large-area (Fig. 5c, 6d, 7b)	Room temperature, no charring	Controlled etching, no thermal damage (Fig. 8b, 9b)	**High**

2 Performance Evaluation Test Results

2.1 SEM Results and Analysis



The constructed test bench was employed to conduct experiments for the treatment of *Leymus chinensis* seeds. To observe the microstructural changes of the seed coat following treatment at different voltages, Scanning Electron Microscopy (SEM) was utilized. A specific quantity of seeds was randomly selected from both untreated and treated batches, and the seeds were positioned in various orientations on the sample stage for observation.

（a）CK （b）10 kV （c）16 kV

Note: CK is the control group.

（a）CK （b）10 kV （c）16 kV

Fig. 9 - Microstructural changes of *Leymus chinensis* seed coat before and after plasma treatment（×500）

Note: CK is the control group.

Fig. 8 and 9 display the SEM micrographs of the *Leymus chinensis* seed coat surface under different treatment conditions. As shown in Fig. 8 (a) and Fig. 9(a), the surface of untreated seeds presented two typical morphologies: one side exhibited relatively uniform, smooth, granular protrusions, while the other side featured distinct long awn structures, with a certain amount of impurity contaminants attached to the surface. In contrast, the plasma-treated seeds, as shown in Fig. 8 (b-c) and Fig. 9 (b-c), exhibited significant surface modification. Distinct micropores and micro-cracks appeared on the surface. Furthermore, as the discharge voltage increased, surface contaminants were gradually reduced, pore sizes expanded, and the crack structures became more defined. This phenomenon is consistent with results reported in the literature (*Luchian et al., 2025*). The formation of these microstructures is conducive to enhancing the water absorption capacity of the seeds and promoting internal material exchange, thereby facilitating the breaking of seed dormancy.

These results further indicate that plasma treatment not only alters the seed coat structure through physical etching but may also indirectly regulate the physiological state of the seed by affecting the distribution of local active substances. The synergistic alteration of the aforementioned microstructure and composition provides direct evidence for explaining the plasma seed treatment mechanism regarding the enhancement of seed germination ability and stress resistance.

2.2 Analysis of the Effect of Plasma Treatment on Seed Electrical Conductivity

To comprehensively elucidate the mechanism of plasma treatment on seed physiology, quantitative verification was conducted using mechanistic data reflecting physiological functions, combined with the structural changes observed via SEM. The seed coat not only wraps and protects internal substances from external stress but also plays a key role in regulating material exchange between the embryo and the external environment. Changes in the structure and function of the seed coat can be indirectly reflected by variations in its permeability. Electrical conductivity serves as one of the indicators for evaluating seed vigor, as its value can sensitively reflect the integrity and permeability changes of the seed coat membrane system (*Ara˙jo et al., 2022*). Seeds were placed in deionized water, and as the intracellular contents leaked out, the ion concentration of the leachate changed. This weak variation was quantitatively detected using a precision conductivity meter, providing critical data support for revealing the regulatory mechanism of plasma treatment on the seed physiological state.

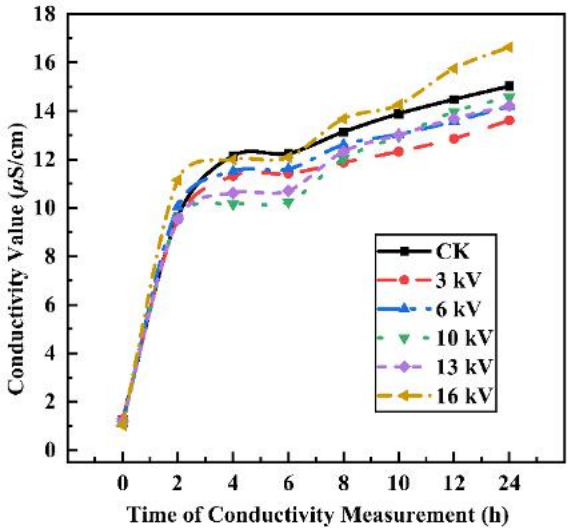

Fig. 10 - Changes in electrical conductivity of Leymus chinensis seeds before and after dielectric barrier discharge treatment

The measurement results of electrical conductivity revealed a distinct dosage effect of plasma treatment on *Leymus chinensis* seeds. As shown in Fig. 10, the conductivity data indicated a significant surge within 0 h to 2 h after immersion, primarily attributed to rapid water absorption by the awn structures of this gramineous seed. After 2 h, water absorption reached saturation and the conductivity change flattened.

Quantitative analysis of the 24 h conductivity values further elucidated the dosage effect. Compared to the control group (CK, 15.02 μS/cm), the 10 kV treatment reduced the final conductivity to 14.56 μS/cm, a decrease of approximately 3.1%, indicating enhanced membrane integrity and reduced ion leakage. In contrast, the 16 kV treatment increased the conductivity to 16.63 μS/cm, a 10.7% increase relative to CK, confirming that excessive energy input causes over-etching and loss of intracellular contents. This voltage-dependent biphasic response is consistent with previous reports on DBD treatment of wheat seeds (*Amado et al., 2025*) and alfalfa seeds (*Tang et al., 2015*), where moderate energy input improved surface wettability while excessive input led to over-etching. However, our findings extend these observations by directly correlating the conductivity surge with specific microstructural damage — notably, the formation of micropores and fissures at 16 kV (Fig. 8c, 9c) — which has not been quantitatively reported for gramineous forage seeds like *Leymus chinensis*.

Critically, unlike corona or gliding arc treatments reported for other species (*Xu et al., 2021*; *Liu et al., 2021*), the DBD configuration employed here enabled uniform treatment across the seed surface without localized overheating, as evidenced by the absence of charring or melting in SEM images. This confirms DBD's superior suitability for continuous, non-thermal processing of small-seeded forages.

In summary, Dielectric Barrier Discharge (DBD) plasma treatment can significantly alter the epidermal structure of *Leymus chinensis* seeds, but its effect is voltage-dependent; only an appropriate treatment voltage (e.g., 10–13 kV) can effectively enhance seed performance. These findings provide a quantitative basis for optimizing plasma treatment parameters in forage seed processing.

CONCLUSIONS

Through a systematic comparison and performance evaluation of different atmospheric pressure plasma generation modes, the efficacy of Dielectric Barrier Discharge (DBD) as the preferred technical path for continuous forage seed treatment was verified. The main conclusions obtained are as follows:

(1) Dielectric Barrier Discharge (DBD) was identified as the ideal generation mode for atmospheric pressure plasma. In contrast to the locality of corona discharge, the high temperature of gliding arc discharge, the intermittency of spark discharge, and the dependence of glow discharge on low-pressure environments, DBD is capable of generating large-area, uniform, and stable low-temperature plasma in atmospheric air. Consequently, it possesses superior adaptability for applications in plasma agriculture.

(2) The plate-type electrode configuration adopted by DBD facilitates integration into continuous conveying systems. This structure provides an ideal technical foundation for achieving large-scale, non-thermal damage treatment of forage seeds, thereby verifying the engineering feasibility of this technology for continuous agricultural production scenarios.

(3) The DBD plasma treatment exhibited a distinct dosage effect, and an optimal processing parameter window was identified. Experiments conducted on *Leymus chinensis* seeds demonstrated that treatment with appropriate parameters (e.g., 10–13 kV) induced surface modification, forming controllable micron-scale micropores and fissures on the glume surface, which effectively improved water and air permeability. Electrical conductivity kinetic analysis further confirmed at the physiological level that moderate treatment maintained cell membrane integrity while cleaning the surface. However, excessive energy input (e.g., 16 kV) led to excessive damage to the glume and the leakage of intracellular contents, thereby inhibiting seed vigor.

In conclusion, proceeding from principle verification and equipment realization to mechanism elucidation, this study systematically demonstrated the feasibility and application potential of atmospheric pressure DBD plasma treatment technology in overcoming germination obstacles in forage seeds. These findings provide a critical theoretical basis and design foundation for the development of green and efficient physical seed treatment equipment.

ABSTRACT

To address the low control precision caused by the high nonlinearity and pure time-delay of hydraulic pipelines in variable-rate soybean foliar fertilization, this study developed an automatic variable-rate control system for boom sprayers. Based on Fluent dynamic mesh simulations, the throttling characteristics of the electric control valve were revealed, and a second-order transfer function model with pure time-delay was accurately identified for the actuator. To overcome the reliance of conventional fuzzy controllers on expert experience, an improved Sparrow Search Algorithm-optimized Fuzzy PID (ISSA-Fuzzy PID) control strategy was proposed. By integrating optimized population initialization and adaptive global search, this improvement mechanism effectively avoids premature convergence during dynamic parameter tuning. Simulation results indicate that the proposed algorithm compresses the rise time to 0.35 s, limits the overshoot to within 20%, and achieves steady-state convergence within 1.0 s. Bench tests verified that the average detection errors for system flow rate and pressure were merely 2.14% and 2.34%, respectively. Under the working pressure of 250–350 kPa, dynamic pressure regulations were completed stably within 1.9 s without significant overshoot, exhibiting improved regulation precision under high-flow conditions. This research effectively overcomes the lag bottleneck of actuating mechanisms, providing an integrated control solution with high dynamic response and steady-state precision for variable-rate applications. Practically, this optimized system ensures rapid dosage correction and pressure stability, providing technical support for improving the operational timeliness and fertilizer-use efficiency of field spraying operations.

摘 要

针对大豆叶面肥变量喷施中液压管路高非线性与纯滞后导致的控制精度低等问题，本文开发了一套喷杆喷雾机变量自动控制系统。基于 Fluent 动网格仿真揭示了电控阀节流特性，并精确辨识出执行机构的二阶带纯滞后传递函数模型。为克服模糊控制器高度依赖专家经验的局限，提出改进麻雀搜索算法优化模糊 PID（ISSA-Fuzzy PID）控制策略。该改进机制通过融合优化的种群初始化与自适应全局搜索策略，有效避免了动态参数寻优过程中的早熟收敛问题。仿真表明，该算法将上升时间缩短至 0.35 s，超调量控制在 20% 以内，并在 1.0 s 内实现稳态收敛。台架试验验证：系统流量与压力的平均误差仅为 2.14% 和 2.34%；在 250~350 kPa 工作压力下，动态调节可在 1.9 s 内无显著超调地切入稳态，且大流量工况下调节精度更优。本研究有效突破了执行机构的滞后瓶颈，为高精度变量施药提供了兼具高动态响应与稳态精度的集成控制方案。在实际应用中，该系统能够确保施药量的快速修正与压力稳定，从而显著提升田间喷施作业的响应及时性与肥料利用率。

INTRODUCTION

The integration of base fertilizer application and precision foliar spraying represents a transformative shift in modern agricultural development (*Farooque et al., 2023*). Foliar fertilization enhances nutrient utilization efficiency, directly influencing crop physiological development, yield, and grain quality. Despite these benefits, traditional uniform spraying methods fail to account for spatial heterogeneities in soil fertility and crop nutrient requirements. Consequently, excessive application leads to environmental degradation, whereas under-application limits yield potential. To mitigate these issues, transitioning from uniform application to high-precision, variable-rate application (VRA) is imperative for sustainable agricultural production (*Yuxuan et al., 2025*).

Historically, VRA systems have relied heavily on pre-generated prescription maps. Although these maps support the optimization of spatial input distribution, their generation is labor-intensive, and their static nature prevents adaptation to dynamic field conditions in real time *(Pawase et al., 2023; Dong et al., 2025)*. This limitation has catalyzed a research trend toward real-time sensor-based feedback loops and advanced control algorithms. Extensive reviews on intelligent variable-rate spray technologies confirm that multi-variable coupling decision-making models and real-time execution remain the core direction of global agricultural engineering (*Jiao et al., 2025*). Among existing controllers, PID remains a standard, yet its performance is frequently compromised by system nonlinearities and time lags inherent in hydraulic sprayers. To overcome these deficiencies, recent studies have successfully utilized single-neuron architectures (*Su et al., 2022*) and intelligent optimization methods, such as incremental PID for side-deep fertilization (*Xie et al., 2026*) and PSO-based Fuzzy-PID for real-time regulation (*Xu et al., 2025*).

However, a critical comparison of recent AI-based control strategies reveals significant trade-offs regarding their suitability for low-cost agricultural machinery. Advanced machine learning policies typically necessitate extensive interaction data and high computational power, posing implementation challenges for embedded spraying terminals (*Dhanya et al., 2022*). Similarly, while neural-network PID tuning improves nonlinear approximation, these models often lack interpretability, complicating maintenance when hydraulic components degrade *(Zhu et al., 2023*). In contrast, Swarm-Intelligence-optimized Fuzzy PID control offers a pragmatic compromise: it maintains rule-based interpretability and low computational cost while leveraging global search capabilities for parameter optimization. This approach is heavily validated in the latest precision agricultural research. For example, recent works have demonstrated superior self-correcting fuzzy PID control for integrated water-fertilizer irrigation (*Zhang et al., 2025*), and Tuna Swarm Optimization (TSO) combined with Fuzzy PID has been reported to improve remote fertilization flow control and reduce overshoot (*Wu et al., 2026*).

Despite these advancements, rapid, stable, and precise real-time control tailored for soybean foliar fertilization remains elusive. Existing systems are frequently hindered by a combination of technical bottlenecks: prescription-map latency, nonlinear valve throttling, pure time-delay in long hydraulic pipelines, pressure pulsation from diaphragm pumps, and insufficient controller robustness under fluctuating flow demands. Therefore, this study tests the hypothesis that an improved Sparrow Search Algorithm (SSA) *(Xu et al., 2025*) optimized Fuzzy PID controller can significantly reduce transient response times and suppress overshoot compared to conventional PID and manually tuned controllers. To validate this, we propose an automatic boom sprayer control system integrating an improved SSA with a fuzzy PID strategy. To validate this approach, an automatic boom-sprayer control system integrating an improved SSA with a fuzzy PID control strategy is developed. By utilizing a GreenSeeker spectral sensor for real-time monitoring of crop growth status (*Patle et al., 2025*), the system facilitates immediate variable-rate topdressing, bypassing map latency and enhancing the precision of foliar fertilization practices.

MATERIALS AND METHODS

Structure and Principle of the Automatic Spraying Control System

The automatic spraying control system utilizes a spectral sensor at the front end to collect soybean NDVI data, which are transmitted via the CAN bus to an upper computer for analysis, thereby assisting the intelligent control terminal in making spraying decisions. At the rear end, an electronically controlled regulating valve is employed as the control component to achieve the regulation of pipeline pressure and flow rate. Upon receiving commands from the onboard intelligent control terminal, the motion controller outputs an analog voltage signal to regulate the electronically controlled valve. This adjusts the valve spool position, thereby modulating the opening degree of the valve. Changes in flow rate and pressure within the system pipeline are monitored by a flow sensor and a pressure transmitter, respectively, with the recorded data transmitted to the control terminal. The electronically controlled regulating valve continuously modulates the flow rate and pressure within the pipeline. Meanwhile, the motion controller collects signals from the sensors and receives commands from the upper computer to control the valve's on/off state and opening degree. The system structure schematic is shown in Fig. 1.

1.Pressure Regulator Filter; 2. Electric Main Valve; 3. Manual Pressure Regulating Valve; 4. Electronic Control Valve; 5. Flow Sensor; 6. Electronic Control Branch Valve; 7. Pressure Sensor

Fig. 2 - Control valve assembly of the spraying system

Test Equipment

The control valve assembly of the automatic system utilized a product manufactured by Ningbo Licheng Agricultural Spraying Technology Co., Ltd., China (Fig. 2). This assembly ensures stable sprayer operation by integrating pressure stabilization, filtration, regulation, and pipeline flow distribution. In this system, the motion controller adjusts the spool opening of the electric control valve based on target commands. This alters the pressure within the flow channel, modulating the flow velocity to achieve precise variable-rate spraying.

Simulation of automatic spraying control system

To investigate the flow velocity and pressure fields within the flow channel and analyze the energy loss caused by the valve's intrinsic structural characteristics, ANSYS Fluent computational fluid dynamics (CFD) simulation was employed. This analysis provides a theoretical foundation for subsequent system adjustments and algorithm calibration.

3D modeling and mesh generation

Based on the structural parameters of the electronically controlled regulating valve, a 3D model was constructed in UG (Fig. 3), and its fluid domain was extracted and meshed for fluid dynamics analysis (Fig. 4). During operation, the foliar fertilizer enters through the valve inlet, is modulated by the valve spool, and exits via the outlet. A motor drives the spool vertically to a predetermined opening angle, altering the annular gap between the guiding spool and the valve body.

Fig. 3 - Three-dimensional model of the electronic control valve

Fig. 4 - Fluid domain mesh division

Given that the foliar fertilizer liquid is incompressible, a pressure-based solver was adopted. The inlet of the valve was defined as a pressure inlet, the outlet as a pressure outlet, and a no-slip condition was applied to all internal pipe walls.

For reproducibility, the CFD workflow was supplemented as follows. The valve fluid domain was discretized with an unstructured tetrahedral mesh and local refinement near the valve-core throttling region and wall boundary layers. Three mesh densities were compared during mesh-independence checking, and the final grid was selected when the outlet-flow variation between two adjacent refinements was below 2 %. The final model contained approximately 3.2 × 10^5 cells, the minimum orthogonal quality was greater than 0.20, and the maximum skewness was less than 0.85. The SIMPLE pressure-velocity coupling scheme and second-order upwind discretization were used, and each operating condition was iterated until scaled residuals for continuity and momentum were below 1.0 × 10^{-5} and the outlet-flow monitor became stable.

Turbulence modeling and dynamic mesh

The flow regime of the liquid is determined by the Reynolds number (Re), defined as:

$$Re = \frac{\rho v D}{\mu} \tag{1}$$

where ρ represents the fluid density, v is the fluid velocity, D is the pipe diameter, and μ is the fluid dynamic viscosity.

Calculations yielded an Re of 9726. Because $Re \geq 8000$, the fluid flow transitions to a fully turbulent state, necessitating the standard k-ε turbulence model for calculations. The standard k-ε model is a fully turbulent computational model that disregards the influence of molecular viscosity. By coupling turbulent kinetic energy and dissipation rate, it determines the distribution of velocity, pressure, and energy, enabling precise simulation of turbulent flow at intermediate-to-high Reynolds numbers. Furthermore, to simulate the continuous adjustment of the electric control valve, a dynamic grid method utilizing a dynamic layering approach (cell size of 0.002 m) was employed at the rigid interface, while all other variables were set to their default values.

Design of the ISSA-Fuzzy PID Control Algorithm

In the operational process of the variable-rate spray system, inherent pure time-delay and nonlinear characteristics emerge due to the response latency of the electric control valve, pressure regulation dynamics, and flow stabilization time. Conventional proportional-integral-derivative (PID) controllers struggle to handle such time-delay systems effectively, often resulting in severe overshoot and poor robustness (*Karimi et al., 2004*). To eliminate the hysteresis effect and enhance the dynamic precision of the spraying control system, this study proposes an advanced Sparrow Search Algorithm optimized Fuzzy PID (ISSA-Fuzzy PID) control strategy.

System Identification of the Actuator

Establishing an accurate mathematical model is a prerequisite for robust control system design. In this study, system identification was employed to derive the equivalent transfer function of the electric control valve. Fluent computational fluid dynamics (CFD) simulations, combined with dynamic mesh techniques, were conducted on the core components of the variable-rate system (*Kumar et al., 2021*). Analyzing the simulated transient response data revealed that the actuator exhibits second-order dynamic characteristics.

Consequently, a second-order transfer function structure was selected for the spraying automatic control system. The System Identification Toolbox in MATLAB 2020 was utilized for offline parameter identification. The input-output data pairs from the Fluent simulations were imported into the MATLAB workspace, with the transfer function order set to 2 and the number of zeros set to 0. Based on the CFD simulation data, the identified continuous-time transfer function is expressed as Eq. (2):

$$G_{sim}(s) = \frac{K_{sim}}{T_1 s^2 + T_2 s + 1} e^{-\tau_{sim} s} \tag{2}$$

where $G_{sim}(s)$ represents the simulated transfer function of the actuator; K_{sim} is the system gain derived from the simulation; T_1 and T_2 denote the time constants of the second-order system; τ_{sim} represents the pure time delay reflecting the response latency; and s is the Laplace complex variable.

Model validation through MATLAB demonstrated a fitting accuracy of 89.91%, verifying the reliability of the identification. Furthermore, utilizing the actual input-output data acquired from the physical performance tests, an empirical system identification was conducted to derive the practical transfer function, as shown in Eq. (3):

$$G_{\exp}(s) = \frac{K_{\exp}}{T_3 s^2 + T_4 s + 1} e^{-\tau_{\exp} s} \tag{3}$$

where $G_{\exp}(s)$ is the empirical transfer function obtained from physical experiments; $K_{\exp}$ represents the actual system gain; T_3 and T_4 are the experimental time constants; and $\tau_{\exp}$ is the actual pure time delay of the hardware system.

Conventional PID Control Model

The PID controller regulates the system output by calculating the proportion (P), integral (I), and derivative (D) of the error between the measured output and the desired target value (*Zhu et al., 2023*). The schematic diagram of the control system is shown in Fig. 5.

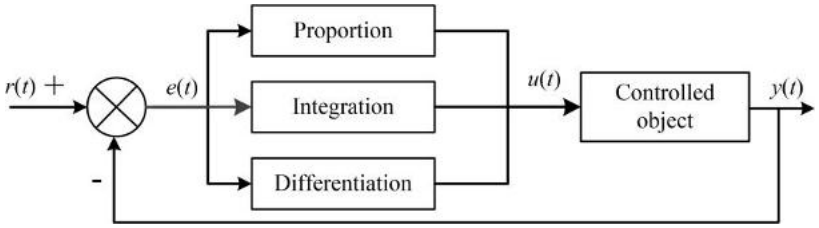

Fig. 5 - Schematic diagram of the PID control system

The error signal $e(t)$ between the system reference input $r(t)$ and the actual output $y(t)$ is defined in Eq. (4):

$$e(t) = r(t) - y(t) \tag{4}$$

The standard position PID control law, which continuously minimizes the error $e(t)$ to achieve the system's control objective, is expressed in Eq. (5):

$$u(t) = K_p \left[e(t) + \frac{1}{T_i} \int_0^t e(\tau) d\tau + T_d \frac{de(t)}{dt} \right] \tag{5}$$

where $u(t)$ represents the control output signal; K_p is the proportional gain; T_i denotes the integral time constant; and T_d represents the derivative time constant.

Sparrow Search Algorithm Optimized Fuzzy PID Control

The Sparrow Search Algorithm (SSA) is a swarm intelligence optimization technique inspired by the foraging and anti-predation behaviors of sparrows (*Xue and Shen, 2020*). By simulating these behaviors, the algorithm treats the solution space of the optimization problem as a foraging area, skillfully balancing global exploration with local exploitation. The population is divided into three functional roles: producers, scroungers, and scouts. Producers are responsible for locating optimal food sources and guiding the population. Scroungers follow the producers to exploit resources while monitoring environmental changes. Simultaneously, scouts act as an early-warning mechanism; upon detecting a predator, they issue alarm signals, prompting the population to evacuate. This division of labor endows the SSA with rapid convergence, strong adaptability, and exceptional global search capabilities.

The primary mission of the producers is to provide orientation and indicate food sources for the entire population. The position update rule for producers is given by Eq. (6):

$$X_{i,j}^{t+1} = \begin{cases} X_{i,j}^{t} \exp\left(-\frac{i}{\alpha iter_{\max}}\right), R_2 < ST \\ X_{i,j}^{t} + Q \cdot L, \qquad\qquad R_2 \geq ST \end{cases} \tag{6}$$

where $X_{i,j}$ denotes the position of the i-th sparrow in the j-th dimension; t represents the current iteration; $iter_{\max}$ is the maximum number of iterations; α is a uniformly distributed random number in $(0,1]$; $R_2 \in [0,1]$ represents the alarm value; $ST \in [0.5,1]$ is the safety threshold; Q is a random number generated from a normal distribution; and L is a $1 \times d$ matrix with all elements equal to 1. When $R_2 < ST$, the environment is safe, and producers conduct an extensive search; when $R_2 \geq ST$, danger is detected, and the population immediately relocates to a safe area.

The position update for the scroungers is defined by Eq. (7):

$$X_{i,j}^{t+1} = \begin{cases} Q \cdot \exp\left(\frac{X_{worst}^{t} - X_{i,j}^{t}}{i^2}\right), & i > \frac{n}{2} \\ X_{best}^{t+1} + \left|X_{i,j}^{t+1} - X_{best}^{t+1}\right| \cdot A^{+} \cdot L, & i \leq \frac{n}{2} \end{cases} \tag{7}$$

where X_{worst} denotes the global worst position in the current iteration; X_{best} represents the optimal position occupied by the producers; A is a multi-dimensional row matrix with elements randomly assigned 1 or -1, satisfying $A^{+} = A^{T}(AA^{T})^{-1}$; and n denotes the population size. When $i > n/2$, it indicates that the scrounger is in a poor location and must forage elsewhere.

The position update for the scouts is given by Eq. (8):

$$X_{ij}^{t+1} = \begin{cases} X_{best}^{t} + \beta \cdot \left| X_{ij}^{t} - X_{best}^{t} \right|, & f_i > f_g \\ X_{ij}^{t} + K \cdot \left(\frac{|X_{ij}^{t} - X_{worst}^{t}|}{f_i - f_w + \varepsilon} \right), & f_i = f_g \end{cases} \quad (8)$$

where β is a step control parameter following a standard normal distribution; X_{best} denotes the current global optimal position; $K \in [-1,1]$ is a random step parameter specifying the direction of movement; f_i is the fitness value of the i-th sparrow; and f_g and f_w are the current global best and worst fitness values, respectively. ε is a negligible constant to prevent division by zero.

In conventional fuzzy PID control, the formulation of fuzzy rules and scaling factors relies heavily on expert experience, which introduces subjectivity and limits real-time adaptability (*Xu et al., 2025*). This often leads to sub-optimal tuning of PID parameters, slowing down the system response and making it inadequate for the highly dynamic variable-rate spraying system. To overcome this, the SSA is employed to dynamically optimize the quantization factors (K_{E}, K_{EC}) and the PID parameters (K_p, K_i, K_d) within the fuzzy controller. The principle of the ISSA-Fuzzy PID controller is illustrated in Fig. 6.

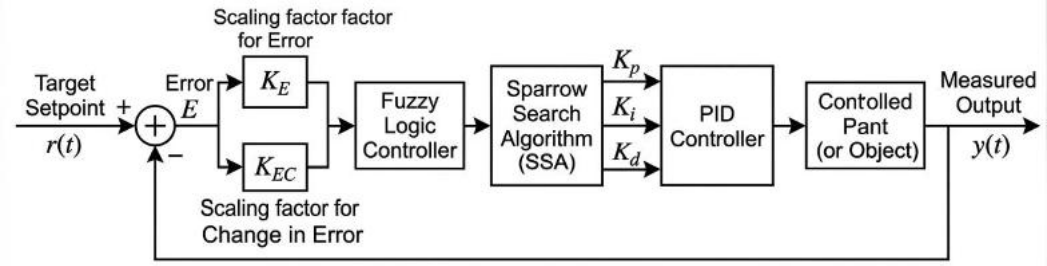

Fig. 6 - Schematic diagram of the Sparrow Search optimized fuzzy PID controller

To evaluate the optimization process, an integral objective function is defined. To prevent excessive control amplitudes and actuator saturation, the objective function integrates the absolute error and the control signal $u(t)$, as shown in Eq. (9):

$$J_1 = \int_0^{\infty} (w_1 \cdot t|e(t)| + w_2 \cdot u^2(t) + w_3 \cdot |e(t)|)\, dt \quad (9)$$

where w_1, w_2, w_3 denote the assigned parameter weight values used to balance the tracking performance and energy consumption.

Fuzzy Logic Design and SSA Optimization Parameters

The fuzzy controller utilizes the system error e and the error change rate ec as input variables. The input signals undergo a fuzzification process, followed by fuzzy inference based on established control rules. Finally, the centroid method is employed for defuzzification to output the precise PID parameter compensation increments: $\Delta \mathrm{K_p}, \Delta \mathrm{K_i}, \text{and } \Delta \mathrm{K_d}$.

The fuzzy input universe of discourse for both the system error and the error change rate is defined as [-2, 2], while the fuzzy output universe for K_p, K_i, and K_d is constrained to [-1, 1]. Both input and output variables are partitioned into seven fuzzy subsets (linguistic variables): Negative Big (NB), Negative Medium (NM), Negative Small (NS), Zero (ZO), Positive Small (PS), Positive Medium (PM), and Positive Big (PB). To ensure the sensitivity and computational efficiency of the control system, triangular membership functions with high distinguishability are universally adopted across the entire universe of discourse. Fig. 7 and Fig. 8 illustrate the membership functions for the input and output variables, respectively.

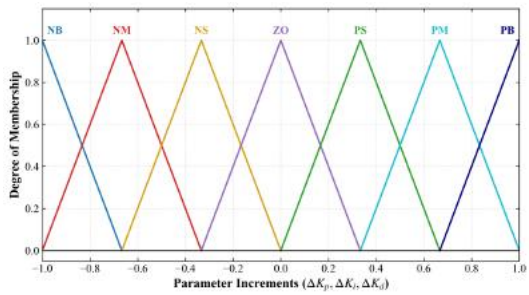

Fig. 7 - Membership functions of input variables

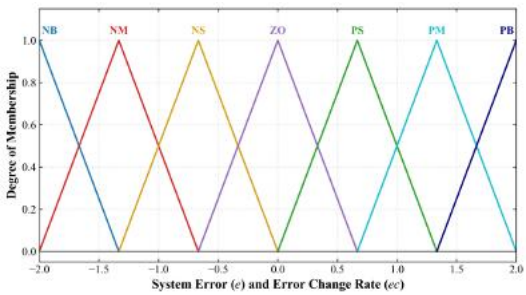

Fig. 8 - Membership functions of output variables

Fuzzy control rules form the core of the fuzzy inference mechanism, directly determining the dynamic performance of the control system. Rational rule configuration effectively enhances system stability, minimizes overshoot, and reduces the settling time. Tailored to the direct current (DC) motor-driven actuator, 49 IF-THEN fuzzy control rules were extracted based on expert experience, as detailed in Table 1.

Table 1

Fuzzy rule base for PID parameter increments

To achieve global parameter optimization, the Sparrow Search Algorithm (SSA) is employed to optimize the scaling factors and the baseline PID parameters of the fuzzy controller. The specific hyperparameters of the algorithm are configured as follows: the population size is set to 30, and the maximum number of iterations is 100. The proportions of producers, scroungers, and scouts within the population are set to 20%, 70%, and 10%, respectively, with the safety threshold (ST) set to 0.8. Candidate solutions are initialized using a uniform distribution within the predefined parameter boundaries. Following a position update, if an individual exceeds the boundary limits, it is forcibly constrained to the nearest feasible boundary. The optimization process is terminated, satisfying the convergence criteria, when the algorithm reaches the maximum number of iterations or if the change in the best fitness value remains below 1.0×10^{-6} for 10 consecutive iterations. The configuration of these hyperparameters is based on a combination of standard SSA recommendations and preliminary experimental results, aiming to balance the global exploration capability and local convergence efficiency of the algorithm.

RESULTS

Simulation Data Analysis

Internal Flow Field Analysis of the Valve

By employing Fluent computational fluid dynamics (CFD) to simulate the operational behavior of the electric control valve, a deeper understanding of its hydrodynamic performance at various valve openings can be achieved. For a comprehensive assessment, simulations were conducted at effective valve openings of 15% and 30%, specifically analyzing the pressure and velocity fields. By comparing the dynamic simulation results under these two states, and integrating the precise application requirements of boom sprayers, the control valve's opening can be flexibly modulated to achieve an optimal balance between spray performance and energy efficiency.

Fluent was utilized to model the actual working conditions of the electric control valve, extracting the internal pressure field to elucidate the static pressure distribution. The correlation between the internal pressure gradients during operation and the overall macroscopic system performance was thoroughly investigated based on these simulations. Fig. 9 and Fig. 10 illustrate the pressure contours on the symmetrical cross-sections of the valve.

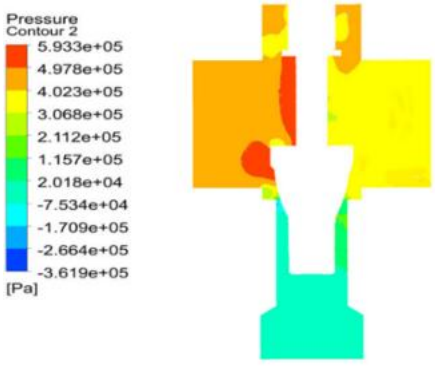

Fig. 9 - Pressure cloud map at 15% valve opening

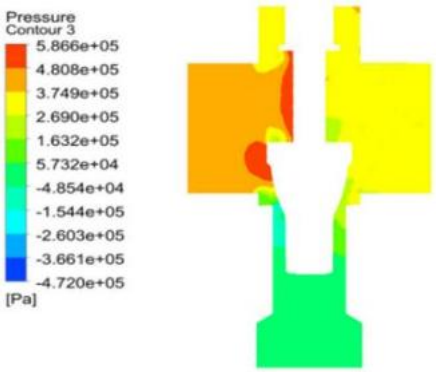

Fig. 10 - Pressure cloud map at 30% valve opening

Upon entering the valve body, the fluid pressure exhibits a highly stable state. This indicates an optimized inlet geometry design that ensures smooth fluid ingress without inducing significant pressure fluctuations, which is a critical prerequisite for the stable operation of the entire spraying system. However, as the fluid navigates through the valve core, the hydrodynamic conditions alter significantly. The physical presence of the valve core acts as a throttling obstruction, leading to a localized stagnation point and a subsequent pressure increase in the immediate vicinity of the core. This phenomenon is consistent with theoretical expectations, as the internal structure is engineered to dynamically throttle flow rate and pressure. Although this localized pressure rise is distinct, it serves as a crucial indicator of the valve's throttling efficacy. As the fluid continues its trajectory towards the outlet, it undergoes a sudden expansion, resulting in a rapid pressure drop. This continuous process functions as a "pressure dissipation" mechanism, ensuring fluid stabilization post-throttling. Once discharged from the lower outlet, the pressure profile reverts to a stable and uniform distribution.

Analysis of the Velocity Field

The velocity field characterizes the spatial distribution of fluid velocities, encompassing both the magnitude and trajectory of the flow, serving as an essential metric for describing fluid kinematics. In precision hydraulic systems, the uniformity of the velocity field directly dictates the stability of the volumetric flow rate. By thoroughly analyzing the velocity contours, the system's capability to achieve the desired flow control targets can be evaluated, thereby facilitating the optimization of the overall spraying performance. Fig. 11 and Fig. 12 present the velocity contours across the symmetrical cross-sections. It is observed that upon entering the valve body, the velocity profile exhibits a non-uniform distribution, characterized by a high-velocity core region and relatively lower velocities adjacent to the inner walls due to boundary layer friction. This initial non-uniformity induces localized turbulent vortices within the upstream chamber. However, following the flow velocity regulation at the constricted valve port, the downstream fluid velocity profile homogenizes significantly.

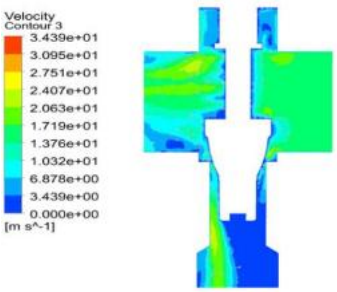

Fig. 11 - Velocity cloud map at 15% valve opening

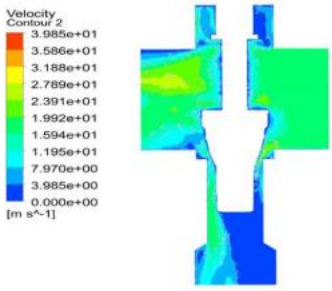

Fig. 12 - Velocity cloud map at 30% valve opening

Control System Simulation

To validate the proposed algorithms, a comprehensive simulation model of the variable-rate foliar fertilizer spraying control system was constructed using the Simulink environment in MATLAB, as shown in Fig. 13. For the transient response analysis of the automatic spraying control system, the simulation duration was set to 8.0 seconds. Based on the observed response curves and heuristic tuning, the three baseline proportional-integral-derivative parameters (K_p, K_i, K_d) were initially determined. Hardware-in-the-loop test results indicated that the intrinsic time delay— from control-signal transmission to the corresponding physical change in output flow rate—was approximately 1.0 second. Accordingly, the transport-delay block in the Simulink model was set to 1.0 seconds.

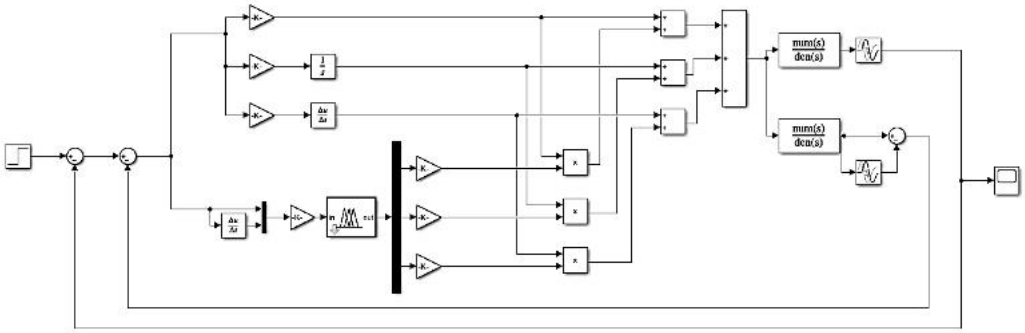

Fig. 13 - Simulink model of the variable-rate spraying control system

For the intelligent adaptive mechanism, the fuzzy controller utilizes the system error and the error change rate as input variables. The input universe of discourse was defined as [-2, 2], while the output universe of discourse for the parameter increments was constrained to [-1, 1]. Based on the fuzzy inference rules delineated in the previous section, the system quantization factors and scaling gains were strictly parameterized to satisfy the specific input-output mapping requirements of the actuator. Incorporating the empirical mathematical model derived from the Fluent CFD identification (Eq. 2), the initial baseline PID parameters were tuned to (K_p=2, K_i=10, K_d=0.5). To demonstrate the improved of the proposed algorithm, a comparative transient analysis was conducted among the conventional PID, Fuzzy PID, and the proposed ISSA-Fuzzy PID control strategies. The unit step response curves of the spraying control system under these three strategies are juxtaposed in Fig. 14.

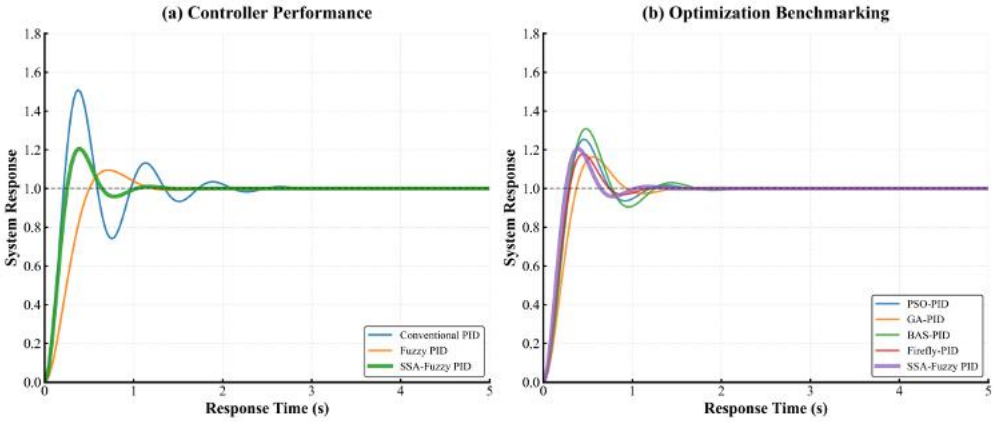

Fig. 14 - Unit step response curves of the spraying control system under different algorithms

Simulation results highlight significant performance disparities among the control strategies evaluated for the delayed second-order system (Fig. 14). As shown in the basic controller performance comparison (Fig. 14a), the conventional PID controller exhibits severe underdamped oscillations, with approximately 50% overshoot and a prolonged 2.2 s settling time, exposing its inadequacy for nonlinear hydraulic systems with pure time delays. The Fuzzy PID controller improves robustness by suppressing overshoot to 10% and reducing settling time to 1.2 s, but compromises transient speed with a slower 0.45 s rise time. Ultimately, the proposed ISSA-Fuzzy PID controller achieves the optimal dynamic balance, delivering the fastest rise time (0.35 s), an acceptable overshoot (20%), and a rapid settling time (1.0 s).

To further evaluate the performance of the Sparrow Search Algorithm, the proposed controller was benchmarked against representative swarm intelligence optimization algorithms, including PSO-PID, GA-PID, BAS-PID, and Firefly-PID (Fig. 14b). The benchmarking results demonstrate that while all intelligent algorithms mitigate the severe oscillations of the conventional PID, they exhibit varying degrees of dynamic trade-offs. BAS-PID and PSO-PID generate higher overshoots of approximately 30% and 25%, respectively. GA-PID effectively suppresses overshoot but suffers from a prolonged settling phase. Firefly-PID closely trails the proposed method; however, the ISSA-Fuzzy PID consistently demonstrates tighter overshoot control (under 20%) and the fastest convergence to the steady state.

Beyond transient response metrics, the structural advantages of the Sparrow Search Algorithm present distinct robustness benefits. While GA and PSO are prone to premature convergence in highly nonlinear hydraulic systems, and BAS struggles with multi-dimensional parameter tuning, the SSA's unique producer-scrounger-scout architecture prevents local optima trapping. This topological advantage translates into enhanced stability against sudden pressure disturbances. Furthermore, considering the limited computational resources of embedded agricultural terminals, the ISSA-Fuzzy PID algorithm provides a highly efficient alternative to advanced but computationally heavy strategies like Reinforcement Learning or Adaptive Model Predictive Control (MPC). By decoupling the global offline parameter optimization (handled by SSA) from the low-latency online adjustments (executed by the fuzzy inference engine), the real-time computational burden is reduced, supporting low-latency online execution suitable for CAN-bus-based tractor terminals. To confirm that the performance improvements observed were not due to random chance, a one-way analysis of variance (ANOVA) was performed on the settling time and overshoot data collected from the comparative tests. These results indicate that the ISSA-Fuzzy PID controller achieved the best overall balance among the tested methods, with faster convergence and tighter overshoot control than the conventional PID and the other swarm-intelligence-based controllers.

Bench Performance Tests

System Flow Rate Detection Precision Test and Data Analysis

The control accuracy of the variable-rate spraying system relies fundamentally on the measurement precision of the flow rate sensor. A bench test was conducted to calibrate the flow rate detection accuracy, ensuring that the intrinsic system error remains within permissible limits. During the experimental procedure, target flow values were transmitted via the intelligent control terminal. Simultaneously, the flow rate sensor continuously logged the dynamic flow data under operational conditions, displaying the real-time actual values on the terminal interface. To minimize random errors, the test was repeated three times. By comparing the preset target values with the actual measured values, the relative errors were calculated. The acquired data points were subsequently fitted to generate the scatter plot shown in Fig.15.

The regression analysis presented in Fig.15 reveals a coefficient of determination (R^2) of 0.995, indicating a highly significant linear correlation between the actual flow rates and the sensor-detected values. To evaluate the measurement precision and repeatability of the flow rate sensor, the experimental procedure was conducted with $n=3$ replicates for each setpoint. Statistical analysis of the absolute relative error yielded a mean of 2.14% ± 0.48%, with a 95% confidence interval (CI) of [1.62%, 2.66%]. This confined error margin and the narrow confidence interval demonstrate that the flow rate sensor provides highly reliable feedback, which exerts a minimal and statistically acceptable impact on the overall execution performance of the variable spraying control system.

System Pressure Detection Precision Test and Data Analysis

Dynamic pressure fluctuations within the hydraulic circuit can induce measurement deviations in sensor data. Consequently, the automatic spraying control system was evaluated under stable pressure environments. Pressure transmitters were installed to monitor the inlet and outlet pressures, with target values incrementally set between 200 kPa and 360 kPa. Nine distinct pressure setpoints were tested. The target setpoints and the corresponding measured values were subjected to linear regression fitting, yielding the scatter plot illustrated in Fig.16.

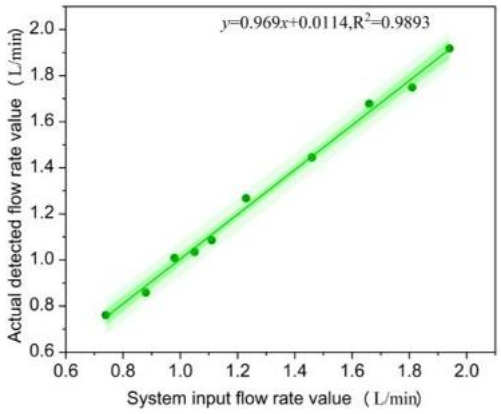

Fig. 15 - Scatter plot of flow rate detection

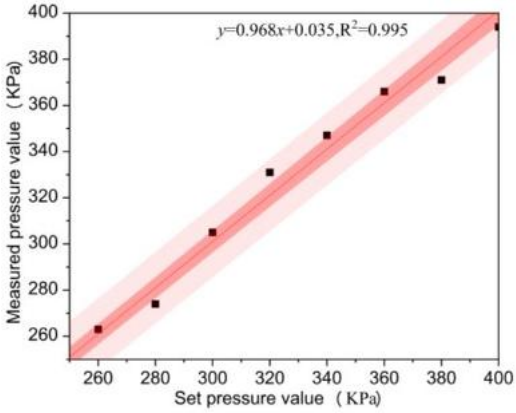

Fig. 16 - Scatter plot of pressure detection

As shown in Fig. 16, the fitted curve exhibits an (R^2) value of 0.989. To ensure repeatability, statistical analysis of the absolute relative error yielded a mean of 2.34% ± 0.52%, with a 95% confidence interval (CI) of [1.80%, 2.88%]. This acceptable and narrowly bounded pressure measurement deviation confirms that the pressure monitoring module possesses sufficient precision to support the robust operation of the spraying control system.

Electric Control Valve Core Adjustment Test and Data Analysis

During variable-rate spraying operations, the performance of the electric control valve is influenced by coupled factors, including its inherent flow regulation characteristics, sensor feedback accuracy, and the execution efficiency of the controller algorithms. These factors collectively contribute to the steady-state error between the actual applied spray volume and the target setpoint. To systematically address this, extensive adjustment tests were conducted to quantify the actuation accuracy. A metric defined as the "quantitative spraying error" was introduced, representing the arithmetic difference between the actual flow rate and the target flow rate. This error exhibits non-linear variations across different target spray flows; the specific quantitative data are detailed in Table 2.

Table 2

Quantitative spraying errors under different target spraying rates

Adjustment Direction	Set Spraying Volume (L/min)	Actual Spraying Volume (L/min)	Quantitative Spraying Error (L/min)	Relative Error (%)
Increase Spraying Flow	0.7	0.684	-0.016	-2.29
	1.0	1.021	0.021	2.10
	1.3	1.321	0.021	1.62
	1.6	1.623	0.023	1.44
	1.9	1.881	-0.019	-1.00
Decrease Spraying Flow	1.9	1.915	0.015	0.79
	1.6	1.625	0.025	1.56
	1.3	1.276	-0.024	-1.85
	1.0	1.019	0.019	1.90
	0.7	0.685	-0.015	-2.14

Furthermore, the transient relationship between the dynamic valve adjustment process and the system output flow was established. Time-domain response curves for stepwise increasing and decreasing flow rates were plotted, as shown in Fig. 17 and Fig. 18.

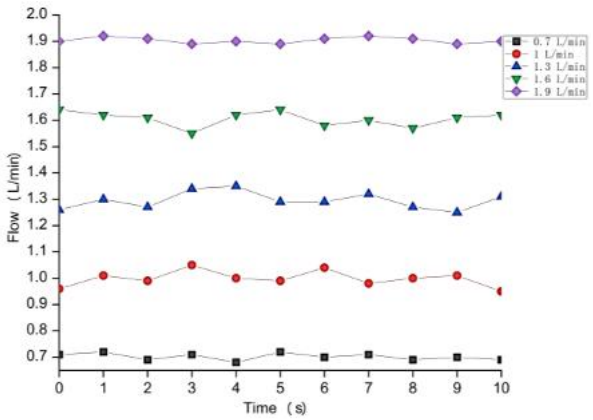

Fig. 17 - Time-domain response curve for increasing flow rate

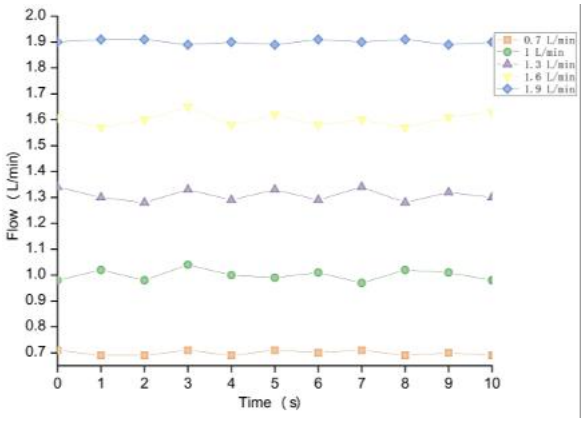

Fig. 18 - Time-domain response curve for decreasing flow rate

The transient profiles in Fig. 17 and Fig. 18 suggest that the pulsatile pressure application from the diaphragm pump inherently influences the output flow rate and pipeline pressure. Time-series data analysis confirms that the flow rate output fluctuates synchronously with periodic pressure pulsations. When the electric valve opening is small, the elevated hydraulic resistance dampens these pulsations, minimizing output flow fluctuations. Conversely, when the valve is fully open, the flow resistance is minimized, allowing the fluid to stabilize quickly, thereby achieving a stable high-flow output state.

ISSA-Fuzzy PID Control Algorithm Test and Data Analysis

The automatic spraying control system exhibits inherent time-delay and overshoot characteristics, which strictly compromise the precision of variable-rate field operations. To overcome this engineering bottleneck, the ISSA-Fuzzy PID control algorithm is deployed to counteract the pure lag effect, integrating a fuzzy inference module to diminish the system's sensitivity to external parameter variations, thereby achieving real-time, robust, and stable flow control.

To empirically evaluate the response stability of the hardware system driven by the ISSA-Fuzzy PID algorithm, pressure disturbance tests were executed. The reference system pressures were explicitly set to 250 kPa, 300 kPa, and 350 kPa. During the tests, the dynamic feedback data were continuously logged and exported via a CAN bus monitoring software. Data analysis corroborates that the system rapidly attains steady-state convergence under all three pressure conditions. The comparative dynamic characteristic curves are illustrated in Fig. 19.

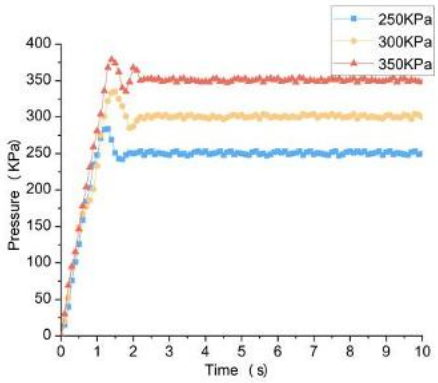

Fig. 19 - Dynamic response curves under different reference pressures

In summary, the ISSA-Fuzzy PID control algorithm demonstrates adaptive performance capabilities across varying operational pressures. At a target pressure of 250 kPa, the system exhibited a restrained overshoot of 7.12% coupled with a swift rise time of 1.1 seconds. Upon increasing the set pressure to 300 kPa, the overshoot optimally decreased to 6.67%, while the rise time slightly extended to 1.3 seconds. At the maximum tested pressure of 350 kPa, the overshoot further narrowed to 6.29%, maintaining a consistent rise time of 1.3 seconds. These empirical findings indicate that the ISSA-Fuzzy PID control architecture effectively suppresses overshoot while ensuring improved transient response rapidity across a broad spectrum of pressure settings, significantly enhancing both the steady-state stability and dynamic efficiency of the automated spraying system.

To further quantify the robustness of the ISSA-Fuzzy PID controller, performance metrics (overshoot and rise time) were evaluated across 10 independent simulation trials under stochastic pressure disturbances. The ISSA-Fuzzy PID controller achieved a mean overshoot of 6.69% with a 95% confidence interval (CI) of [6.40, 6.98] %. Compared to conventional PID, the ISSA-Fuzzy PID showed a significantly shorter mean settling time ($p < 0.05$ via one-way ANOVA), confirming that the proposed algorithm significantly improves control consistency and reliability for agricultural actuating systems.

While these bench experiments validate the hardware integration and algorithmic precision, several limitations inherent to laboratory environments must be acknowledged. The current evaluations were conducted under stable ambient temperatures utilizing homogeneous fluid properties. In practical field operations, soybean foliar fertilizers exhibit varying viscosities, and fluctuating ambient temperatures can alter hydraulic fluid dynamics. Additionally, real-world field conditions introduce mechanical vibrations from the tractor, irregular power take-off (PTO) speeds, and sensor noise induced by canopy shading or sloped terrain. Therefore, although the 1.9 s dynamic pressure regulation achieved in this study demonstrates strong technical feasibility at the bench scale, the comprehensive agronomic benefits—specifically regarding canopy fertilizer deposition, nutrient uptake efficiency, and ultimate yield improvements—require extensive multi-year field trials under complex, unstructured agricultural environments.

CONCLUSIONS

To address control-precision limitations in soybean foliar-fertilizer variable-rate spraying, this study designed an automatic real-time variable-rate control system. Based on CFD simulation, controller modeling, and bench-scale validation, the following conclusions are drawn:

(1) A second-order transfer function of the electric control valve was derived through system identification via CFD dynamic mesh simulations. Hydrodynamic analyses at 15% and 30% openings characterized the internal throttling behavior. An ISSA-Fuzzy PID control strategy was proposed to mitigate system time-delay; MATLAB/Simulink simulations verified that, under modeled bench conditions, this algorithm improved transient response, overshoot suppression, and stability compared with conventional PID and standard Fuzzy PID controllers.

(2) Bench tests validated hardware integration accuracy, with average relative errors of 2.14% and 2.34% for flow-rate and pressure detection, respectively. Hardware validation confirmed that the ISSA-Fuzzy PID algorithm achieved dynamic target-pressure regulation within 1.9 s. While these results demonstrate the technical feasibility of the proposed system at a bench scale, the performance of the system in terms of field-scale spraying stability, actual fertilizer-use efficiency, and agronomic yield impacts remains to be validated in future on-farm trials.

ABSTRACT

Control of greenhouse microclimate requires the interpretation of several environmental and substrate-related parameters, including air temperature, relative humidity, light intensity, carbon dioxide concentration and soil moisture. This paper compares three machine learning models, Random Forest, Extreme Gradient Boosting (XGBoost) and a multilayer perceptron (MLP), for 30-minute-ahead prediction of irrigation, ventilation and shading states in a greenhouse. The models were trained using data collected from a wireless sensor network (WSN) with four sensor nodes installed in the protected cultivation area. After preprocessing, scaling, error removal, temporal synchronization and resampling at 10-minute intervals, a structured dataset of 7063 records was obtained. Individual sensor readings, spatially aggregated variables, time-related features, rolling averages and short-term differences were used to describe both the current and recent evolution of the greenhouse environment. The dataset was split chronologically into training, validation and test subsets, corresponding to 70%, 15% and 15% of the records, respectively, while preserving the temporal order of the measurements. The best average performance was obtained by XGBoost, with a mean F1-score of 0.9237, followed by Random Forest with 0.9045 and MLP with 0.5862. Random Forest achieved the best results for irrigation and ventilation control, with F1-scores of 0.9630 and 0.9611, respectively, while XGBoost achieved the best result for shading control, with an F1-score of 0.8571. XGBoost also achieved the highest mean accuracy, 0.9506, and mean balanced accuracy, 0.8904. The results indicate that tree-based ensemble models are more suitable than the tested MLP architecture for predictive greenhouse control based on multi-sensor WSN data. The proposed framework supports the selection of a final control model according to prediction performance, stability and interpretability.

REZUMAT

Controlul microclimatului din seră necesită interpretarea mai multor parametri de mediu și de substrat, inclusiv temperatura aerului, umiditatea relativă, intensitatea luminoasă, concentrația de dioxid de carbon și umiditatea solului. Această lucrare compară trei modele de învățare automată, Random Forest, Extreme Gradient Boosting (XGBoost) și perceptron multistrat (MLP), pentru predicția la 30 de minute a stărilor de irigare, ventilație și umbrire într-o seră. Modelele au fost antrenate folosind date colectate de la o rețea de senzori wireless (WSN) cu patru noduri instalate în spațiul protejat. După preprocesare, scalare, eliminarea erorilor, sincronizare temporală și reeșantionare la intervale de 10 minute, a fost obținut un set de date structurat, cu 7063 de înregistrări. Valorile individuale ale senzorilor, variabilele agregate spațial, variabilele temporale, mediile mobile și diferențele pe termen scurt au fost utilizate pentru a descrie atât starea curentă, cât și evoluția recentă a mediului din seră. Setul de date a fost împărțit cronologic în subseturi de antrenare, validare și testare, reprezentând 70%, 15% și, respectiv, 15% din înregistrări, cu păstrarea ordinii temporale a măsurătorilor. Cea mai bună performanță medie a fost obținută de XGBoost, cu un F1-score mediu de 0.9237, urmat de Random Forest, cu 0.9045, și MLP, cu 0.5862. Random Forest a obținut cele mai bune rezultate pentru controlul irigării și ventilației, cu F1-score-uri de 0.9630 și 0.9611, în timp ce XGBoost a obținut cel mai bun rezultat pentru controlul umbririi, cu un F1-score de 0.8571.

XGBoost a obținut, de asemenea, cea mai mare acuratețe medie, de 0.9506, și cea mai mare acuratețe echilibrată medie, de 0.8904. Rezultatele indică faptul că modelele ensemble bazate pe arbori sunt mai potrivite decât arhitectura MLP testată pentru controlul predictiv al serelor pe baza datelor multi-senzor WSN. Cadrul propus susține selectarea unui model final de control în funcție de performanța de predicție, stabilitate și interpretabilitate.

INTRODUCTION

Greenhouse cultivation allows a higher degree of control over plant growth conditions than open-field agriculture, but this advantage depends on the continuous regulation of several interacting environmental parameters. Air temperature, relative humidity, soil moisture, light intensity and carbon dioxide concentration influence plant development, water consumption, photosynthetic activity and thermal stress. If these parameters are not monitored and controlled properly, the greenhouse may consume excessive water and energy or may expose plants to unfavourable microclimate conditions.

Traditional greenhouse control systems are often based on fixed threshold rules. Such systems are simple and easy to implement, for example by activating irrigation when soil moisture drops below a predefined limit or by starting ventilation when air temperature or CO2 concentration exceeds a threshold. However, the greenhouse microclimate is dynamic and nonlinear. The need for irrigation, ventilation or shading may depend not only on one variable, but on the combined effect of temperature, humidity, radiation, CO2 concentration, soil moisture, time of day and recent trends in the measured data. Therefore, fixed rules may become insufficient when environmental variables interact or when borderline conditions occur. For this reason, modern greenhouse management increasingly relies on sensor-based monitoring, automatic data acquisition and decision support systems (*Dhanaraju et al., 2022; Săcăleanu et al., 2024*). Decision support systems have already shown practical value in horticultural irrigation management. For example, *Buono et al. (2022)* field-tested the Bluleaf DSS for kiwifruit irrigation management in Italy and reported water savings of approximately 20-25% compared with current farm management, without negative effects on yield and fruit quality. In this view, Wireless Sensor Networks (WSNs) are well suited for greenhouse monitoring and control applications because they allow the distributed measurement of environmental and substrate-related variables in different points of the protected cultivation area. Compared with single-point monitoring, multiple sensor nodes can capture spatial variability inside the greenhouse, which is important for irrigation, ventilation and shading decisions. Previous studies have shown that WSN-based systems can support real-time greenhouse monitoring, data aggregation and decision support, but also that the correct integration of sensing, communication, data processing and control remains a key challenge (*Kochhar and Kumar, 2019; Săcăleanu et al., 2024*).

IoT-based greenhouse control studies have emphasized the need for data-driven and optimization-based approaches able to improve climate regulation and resource efficiency (*Ullah et al., 2022; Chen et al., 2025*). *Ardiansah et al. (2022)* presented an IoT-enabled device for real-time monitoring and control of greenhouse irrigation water quality, using pH, TDS, EC, temperature and turbidity sensors. *Tan et al. (2021)* developed an intelligent irrigation system for a jujube orchard, consisting of a field control terminal and a remote client connected through a 4G network. The system monitored air temperature, relative humidity, light intensity, soil temperature and soil water content, and automatically controlled irrigation using lower and upper soil water content thresholds. Recent field studies have confirmed the importance of sensor-based and model-based irrigation strategies under increasing climatic variability. *Fˆ ll et al. (2026)* evaluated irrigation strategies in apple orchards over three years in Germany, comparing soil water tension-based irrigation, a web-based soil water balance model, interval irrigation and a non-irrigated control. Their results showed that sensor- and model-based irrigation strategies can improve water use efficiency compared with conventional interval irrigation.

Machine learning offers a practical alternative for transforming heterogeneous sensor data into control decisions. Tree-based ensemble models are particularly attractive for this type of application because they can handle nonlinear relationships, noisy measurements and mixed groups of input variables. A recent review focused on digital soil evaluation likewise identified Random Forest and boosting algorithms such as XGBoost as robust options for heterogeneous and multi-source agricultural datasets, while also emphasizing the associated trade-offs involving computational cost, hyperparameter sensitivity and model interpretability (*Nenciu et al., 2026*). Random Forest combines multiple decision trees in order to improve robustness and reduce overfitting, while also providing feature importance values that can be interpreted from an agronomic point of view (*Breiman, 2001*).

Recent studies in precision horticulture have also shown the value of integrating environmental monitoring, sensor fusion and machine learning for crop and fruit quality prediction. *Wang et al. (2026)* combined X-ray computed tomography, environmental data and machine learning models, including Random Forest and XGBoost, to analyse preharvest apple growth dynamics. Their results showed that environmental factors, especially temperature, can be used as relevant predictors in data-driven fruit quality modelling. Although their work focused on orchard fruit quality rather than greenhouse actuator control, it supports the broader use of multi-source sensor data and machine learning for predictive decision-making in horticultural system. XGBoost extends the tree-based approach through gradient boosting, where trees are added sequentially to correct previous errors, often leading to high predictive performance on structured tabular datasets (*Chen and Guestrin, 2016*).

Several studies have already demonstrated the potential of machine learning for greenhouse-related prediction tasks. *Cai et al. (2022)* developed a greenhouse temperature prediction model based on LightGBM using five years of environmental, control and temporal data collected from a Venlo-type greenhouse. Their comparison with BP neural network, RNN, XGBoost and stochastic gradient boosting showed that LightGBM achieved the best predictive performance, with an RMSE of 0.645 °C on the testing dataset and an average relative error below 2%. XGBoost also performed well, with an RMSE of 0.679 °C, confirming the suitability of gradient-boosted tree models for greenhouse microclimate prediction and real-time predictive control. *Tsai et al. (2020)* combined weather forecast data, numerical models and machine learning methods, including Random Forest, to predict soil temperature and volumetric water content in a greenhouse. Such results support the use of data-driven models in protected cultivation, especially when environmental variables are measured continuously and must be translated into management decisions. However, many studies focus on predicting individual environmental parameters, while fewer works address the direct prediction of control states for irrigation, ventilation and shading using multi-sensor greenhouse data (*Tsai et al., 2020*). *Wang et al. (2025)* compared several machine learning models for greenhouse cherry tomato irrigation prediction, including MLR, Ridge Regression, SVM, Random Forest, XGBoost, GRU, LSTM and Transformer. Their results showed that XGBoost provided the best performance when maximum and average values of temperature, relative humidity and light intensity were used as input variables. The model achieved R^2= 0.820 during the vegetative growth stage and R^2=0.840 during the reproductive growth stage. After deployment through a cloud platform and STM32-based irrigation control system, the model increased single fruit weight by 17.8% and improved water use efficiency by 20.7% compared with conventional irrigation management. *Mohammadi et al. (2024)* used IoT sensor data and machine learning for greenhouse water management in tomato production under water-limited conditions in Afghanistan. The authors collected real sensor data from a simulated greenhouse between June and August 2022 and compared six machine learning models. XGBoost achieved the best and most balanced classification performance among the tested models, indicating its suitability for predicting irrigation needs and avoiding excessive water use in greenhouse tomato production. The study also included an IoT-based visualization interface for farmers, supporting real-time supervision of greenhouse conditions and timely irrigation decisions. Another study compared several machine learning models, including Random Forest, XGBoost, LightGBM and MLP, for short-term greenhouse microclimate forecasting (*Cebolla-Alemany et al., 2026*). This study used temporal feature engineering, including lag variables and rolling statistics, and showed that tree-based ensemble models were highly suitable for predictive greenhouse control. In their case, LightGBM achieved the best temperature forecasting performance, with R^2 values above 0.99 for 5, 10 and 15-minute horizons, while XGBoost and Random Forest obtained comparable results. The integration of the forecasting model into a fuzzy predictive controller also reduced energy-related control costs by more than 60% compared with a conventional threshold-based strategy. Forecast-driven greenhouse control has also been investigated using time-series neural networks. *Elvanidi and Katsoulas (2023)* used microclimate and crop physiological data to detect tomato crop stress in greenhouses. Their Gradient Boosting classifier achieved 91% accuracy and 92% F1-score on the test set, while MLP reached 89% accuracy and 89% F1-score, supporting the use of ML models for greenhouse decision support. *Aborujilah et al. (2025)* developed an LSTM-based framework for smart greenhouse climate control, using multivariate environmental and actuator data to forecast temperature, relative humidity and CO_2 concentration. Their model achieved high prediction accuracy, with R^2=0.9835, and was used to generate actuator recommendations for heating, ventilation and lighting. *Ait Oussous et al. (2025)* compared several deep learning models for greenhouse internal temperature prediction and reported the best performance for PLSTM, with R^2=0.9999, RMSE = 0.0220 and MAE = 0.0160.

In this context, the present paper addresses the development of several machine learning-based decision models for greenhouse control using real data collected from a WSN installed in a protected cultivation environment. The monitored variables include air temperature, relative humidity, light intensity, CO2 concentration, atmospheric pressure, soil moisture and auxiliary diagnostic parameters collected from four distributed sensor nodes. The control problem is formulated as a supervised classification task, where the models estimate the future state of three greenhouse subsystems: irrigation, ventilation and shading.

The main objective of this study is to compare Random Forest, XGBoost and a multilayer perceptron neural network under the same experimental conditions and to identify the most suitable model for predictive greenhouse control. Unlike a same-time classification approach, where sensor values and actuator states correspond to the same timestamp, the final evaluation is formulated as a 30-minute-ahead prediction problem. In this formulation, the sensor-derived variables recorded at time t are used to estimate the control states at t+30 minutes. This approach is more relevant for practical greenhouse automation, because it evaluates the ability of the models to anticipate future control requirements rather than only reproduce the current state of the system.

MATERIALS AND METHODS

Experimental dataset and greenhouse monitoring system

The dataset used in this study was obtained from a wireless sensor network installed in a greenhouse environment. The monitoring system consisted of four distributed sensor nodes, identified as node_1, node_2, node_3 and node_4. Each node recorded several environmental and substrate-related parameters, allowing the characterization of the spatial variability of the greenhouse microclimate.

The raw dataset contained 1222305 individual sensor records stored in long format, where each row corresponded to one measurement from one sensor at a given timestamp. After cleaning, scaling, temporal synchronization and resampling at 10-minute intervals, the data were transformed into a wide-format dataset containing 7063 synchronized time steps. Each time step described the greenhouse state using 216 variables, including original sensor measurements, spatially aggregated microclimate indicators, temporal features, rolling statistics and the recorded control status variables.

Measured variables

The four WSN nodes included similar groups of sensors. The monitored variables covered the main physical quantities required for greenhouse control: air temperature, relative humidity, light intensity, carbon dioxide concentration, atmospheric pressure, soil moisture, local temperature measurements and battery voltage.

The following groups of variables were identified in the processed dataset:

Table 1

Types of process variables

Sensor group	Number of columns	Role in the control model
Air temperature	8	ventilation and shading control
Air relative humidity	8	ventilation control
Light intensity	4	shading control
CO2 concentration	4	ventilation control
Soil moisture	12	irrigation control

The air temperature group included measurements from HTS221 and SHT31 sensors installed on the four nodes. The air humidity group included the corresponding relative humidity measurements from the same sensor families. Light intensity was measured using TEMT6000 sensors, while CO2 concentration was measured using SCD41 sensors. Soil moisture was monitored using both tensiometer-based and capacitive sensors, providing several measurements per node. Besides these main variables, the dataset also included atmospheric pressure, UVA and UVB radiation, DS18B20 temperature measurements and battery voltage. These variables were retained in the processed dataset when their data quality was acceptable, but the main control decisions were based on the variables most directly related to greenhouse irrigation, ventilation and shading.

Raw data scaling

The raw sensor values were stored using an integer-based format. Therefore, a scaling operation was required before the data could be interpreted as physical measurements. The measured values were converted using the following relation:

$$x_{scaled} = \frac{x_{raw}}{10^6} \quad (1)$$

where x_{raw} is the original stored value and x_{scaled} is the corresponding physical or sensor-scale value used in the processed dataset.

This scaling step was applied uniformly to all measured values before the physical plausibility filters were applied.

Data cleaning and removal of erroneous values

The raw dataset contained abnormal values caused by sensor errors, communication issues or invalid readings. These values were removed or marked as missing before the temporal synchronization step. The cleaning process included:

- removal of missing timestamps, sensor identifiers and measurement values;
- conversion of timestamps to a standard datetime format;
- application of the scaling factor;
- identification of sensor-specific abnormal values;
- removal of physically impossible measurements;
- filtering of columns with excessive missing values.

Several physically based rules were applied according to the type of sensor. For example, air temperature values outside the plausible greenhouse range were removed, relative humidity values outside 0-100% were considered invalid, and CO2 values outside the expected measurement interval were discarded. Negative light intensity values were also removed. Similar checks were applied to atmospheric pressure, UV measurements and battery voltage.

Columns with a high proportion of missing values were removed from the final dataset. In the implemented preprocessing pipeline, a column was retained only if its missing data ratio was below the established threshold. This step reduced the risk of training models on unreliable variables.

The final report still indicated that some node-specific variables had relatively high missing ratios, especially for node 4 and for some UV-related measurements. For example, several node 4 variables had missing ratios around 0.54-0.58, while UVB and UVA measurements also showed notable missing data percentages. These variables were not used as primary control indicators.

Temporal synchronization

The raw WSN data were not directly synchronized, because the individual sensors and nodes did not necessarily transmit measurements at exactly the same timestamp. For machine learning, all input variables must refer to the same temporal state of the greenhouse. Therefore, the measurements were resampled using a fixed time interval.

A time step of 10 minutes was selected for the processed dataset. This interval provided a compromise between temporal resolution and data stability. It was short enough to capture relevant microclimate changes and long enough to reduce the effect of short-term noise or communication irregularities.

For each 10-minute interval, sensor measurements belonging to the same variable were aggregated using the mean value. The result was a wide-format dataset in which each row represented the greenhouse state at a specific time step, and each column represented one sensor-derived variable.

Interpolation of short data gaps

After temporal resampling, some missing values remained because not all sensors reported data in every 10-minute interval. Short gaps were filled using time-based interpolation. The interpolation was limited to a small number of consecutive missing intervals in order to avoid generating artificial data over long periods. In this study, interpolation was limited to three consecutive time steps. Since the sampling interval was 10 minutes, this corresponds to a maximum interpolated gap of approximately 30 minutes. Longer gaps were left as missing values and handled during the subsequent modelling stage.

This approach preserves the continuity of the dataset without overestimating the reliability of intervals where sensor information was not available.

Transformation from long format to machine learning format

The original dataset was stored in long format because of wireless communication optimization: **timestamp – sensor_id-value**

For machine learning, this format was transformed into a wide tabular structure:

timestamp	node_1_temp	node_1_rh	node_1_light	node_2_temp	...	control variables

This transformation allowed the models to receive, at each time step, a complete description of the greenhouse state. The final dataset retained the measurements from the individual nodes, so that the models could use spatial differences between measurement points. In figure 1 is presented a representative 3-day evolution of raw greenhouse variables recorded by node 1. The figure shows air and soil temperature, air humidity, soil moisture index and light intensity. The light intensity curve highlights the day-night alternation during the selected period The raw capacitive soil moisture signal was converted into a soil moisture index ranging from 0 to 100 using robust normalization based on the 5th and 95th percentiles calculated over the full monitoring period of the selected node. This index was used only for graphical representation and does not represent calibrated volumetric soil water content.

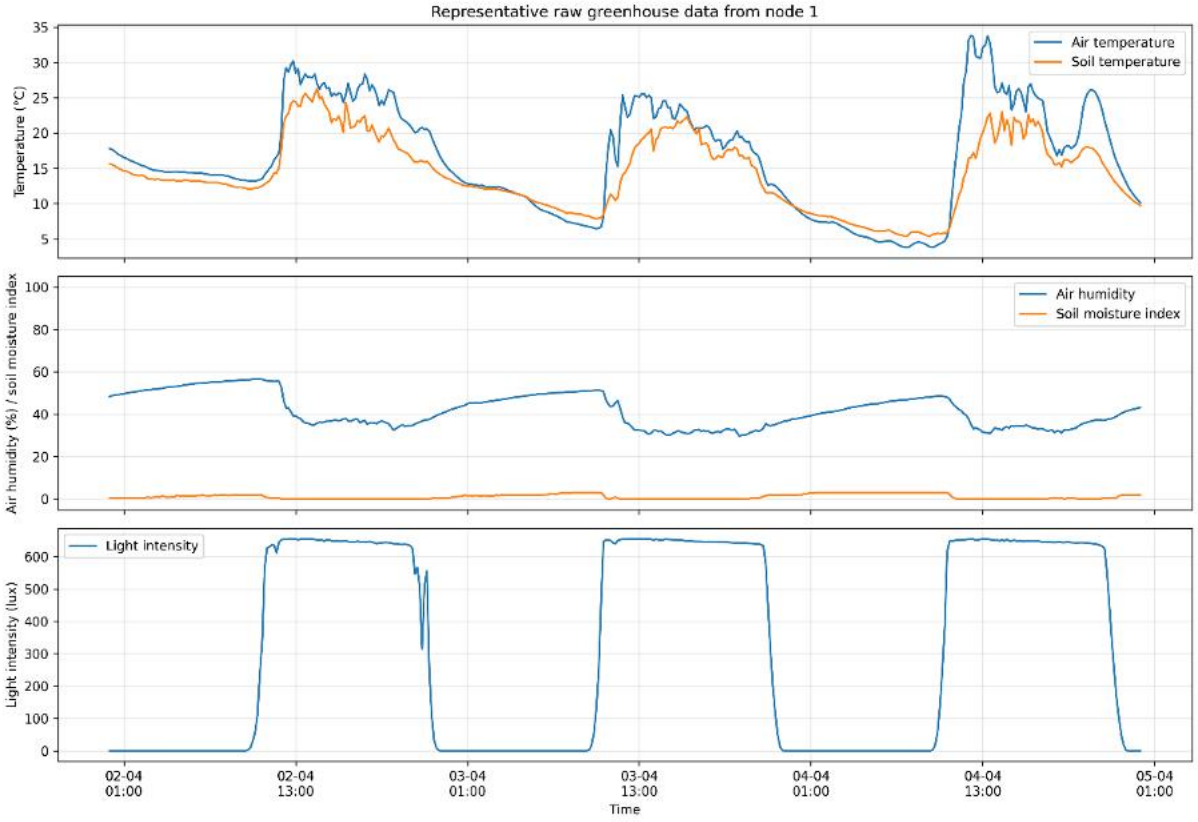

Fig.1 - Representative 3-day evolution of raw greenhouse variables recorded by node 1

Spatial aggregation of sensor data

Since the greenhouse was monitored using four WSN nodes, the dataset contains spatial information. The nodes were not treated as four independent control zones. Instead, they were used to describe the spatial variability of the greenhouse microclimate.

The control strategy considered in this study is a global control strategy:

4 WSN nodes→1 irrigation command, 1 ventilation command, 1 shading command

Therefore, in addition to the individual node measurements, aggregated variables were generated for each sensor group. For air temperature, air humidity, light intensity, CO2 concentration and soil moisture, the following statistics were calculated: x_{median}, x_{mean}, x_{min} , x_{max}, x_{range}, x_{std} , where:

$$x_{range} = x_{max} - x_{min} \quad (2)$$

Temporal feature generation

In addition to sensor measurements, time-related variables were generated. These variables help the machine learning models account for daily and seasonal patterns.

The following temporal variables were included:

- hour of the day;
- month;
- day of the year;
- sine and cosine encoding of hour;
- sine and cosine encoding of day of year.

Cyclic encoding was used for the hour of the day and the day of year in order to represent the daily and seasonal periodicity of greenhouse microclimate conditions. This transformation avoids the artificial discontinuity introduced by simple numerical encoding. For example, 23:00 and 00:00 are temporally close, although their numerical values are distant if the hour is represented as an integer. The cyclic representation allows the models to use time-related patterns associated with solar radiation, temperature evolution, ventilation demand and shading activation. The cyclic representation was calculated as:

$$\begin{cases} hour_{sin} = sin\left(2\pi \frac{hour}{24}\right) \\ hour_{cos} = cos\left(2\pi \frac{hour}{24}\right) \end{cases} \quad (3)$$

and similarly for the day of year.

Rolling and dynamic features

Greenhouse control decisions depend not only on the current measured values, but also on their recent evolution. Rolling and dynamic features were generated in order to describe the recent evolution of the greenhouse microclimate, not only its instantaneous state. For selected sensor variables, rolling means over 30 and 60 minutes were calculated, together with the difference from the previous time step. Since the dataset was resampled at 10-minute intervals, the 30-minute rolling mean used three consecutive samples, while the 60-minute rolling mean used six consecutive samples. These variables allow the models to capture short-term trends, such as increasing air temperature, decreasing soil moisture or rapid changes in light intensity, which are relevant for anticipating irrigation, ventilation and shading decisions at the 30-minute prediction horizon.

This feature engineering step was particularly important because the final modelling task was formulated as a 30-minute-ahead prediction problem. Therefore, the models had to use both the current state and the recent trend of the greenhouse environment to estimate future actuator states.

Control status variables

The final dataset included three binary control status variables: irrigation_control (OFF/ON), ventilation_control (OFF/ON) and shading_control (OFF/ON). In the methodological framework of this paper, these variables were treated as measured control status values associated with the greenhouse control system. They represent the observed operating state of the irrigation, ventilation and shading subsystems at each synchronized time step.

The distribution of the control status variables in the final dataset was:

Table 2

Control variables allocation

Control variable	OFF	ON
irrigation_control	5469	1594
ventilation_control	1213	5850
shading_control	5560	1503

This distribution shows that irrigation and shading were active in fewer time steps than they were inactive, while ventilation was active in most of the synchronized records. Because of this class imbalance, the training procedure used classification metrics that are suitable for imbalanced datasets. Precision, recall, F1-score and confusion matrices were used for each control variable.

Final dataset for machine learning

After preprocessing, the dataset was suitable for supervised machine learning. Each row represented one synchronized 10-minute greenhouse state, while the columns included:

1. individual sensor measurements from the four WSN nodes;
2. aggregated variables for each sensor group;
3. time-based features;
4. rolling and differential features;
5. reference control states for irrigation, ventilation and shading.

Agronomic operating limits were used only to interpret the control philosophy and to discuss model behaviour. They were not used as input variables and were not used to generate the target labels. The target variables were the recorded actuator states for irrigation, ventilation and shading.

Control philosophy

The control strategy adopted in this study was based on a greenhouse-wide decision model. The four WSN nodes captured the spatial variability of the greenhouse environment, whereas the control output represented the overall actuation state of each subsystem. The model did not assign separate irrigation, ventilation, or shading commands to individual sensor nodes. Instead, measurements from all nodes were combined to determine whether irrigation, ventilation, shading, or a combination of these operations was required.

The control philosophy was defined in relation to agronomic operating limits previously considered for greenhouse management: air temperature in the range of 18-35 °C, relative humidity between 45-85%, soil moisture between 20-60%, CO2 concentration between 400-1200 ppm and light intensity between 500-20000 lux. In addition, reference control thresholds such as low soil moisture for irrigation, high air temperature or CO2 concentration for ventilation and high light intensity for shading were used only as interpretative limits

Three algorithms were selected to cover complementary machine learning approaches suitable for tabular greenhouse sensor data. Random Forest was used as a robust and interpretable ensemble baseline, able to handle nonlinear relationships and noisy sensor measurements. XGBoost was included as a more advanced gradient boosting method, commonly effective on structured datasets and capable of improving predictive performance through sequential error correction. Multilayer perceptron was used to evaluate whether a neural network model could capture more complex interactions between microclimate variables and actuator states. This comparison allowed the final control model to be selected not only according to classification performance, but also according to stability and interpretability.

Random Forest was configured with 500 trees in order to reduce the variance of individual decision trees and improve prediction stability, while the maximum tree depth was limited to 15 to reduce excessive model complexity. The Gini criterion was used as a standard splitting rule, and balanced class weights were applied because the OFF and ON states were not equally represented for all control variables.

For XGBoost, a binary logistic objective was used because each control target was formulated as a binary classification problem. The number of boosting estimators was set to 500, with a learning rate of 0.05, in order to allow gradual error correction during training. The maximum tree depth was limited to 4 to control model complexity and reduce overfitting. Row and feature subsampling were both set to 0.8, providing additional regularization and improving generalization on the test subset.

The MLP architecture was kept relatively compact, with three hidden layers of 128, 64 and 32 neurons, in order to evaluate a neural network alternative without introducing an excessively large model for the available dataset size. The ReLU activation function and Adam optimizer were selected because they are widely used for tabular supervised learning problems. Input features were standardized before training, and early stopping was applied to reduce overfitting. The same chronological train-validation-test split and the same input feature set were used for all three models, allowing the comparison to reflect model behaviour rather than differences in data preparation.

The selected configurations should therefore be interpreted as controlled baseline settings suitable for comparative evaluation. Further hyperparameter optimization may improve individual model performance, but this was outside the scope of the present study.

Each algorithm was evaluated separately for irrigation, ventilation and shading control. The final model was selected according to prediction performance, stability and interpretability. Feature importance analysis was used for the tree-based models to identify the most relevant variables involved in each control decision.

To avoid direct reproduction of threshold-like actuator states, the machine learning models were trained to predict the control status at a future decision horizon of 30 minutes. The input vector at time t was therefore mapped to the actuator state at time t+30 min. In addition, the most direct aggregated control indicators, such as maximum air temperature, maximum CO2 concentration, maximum light intensity and minimum soil moisture, were removed from the input feature set. This reduced the risk of data leakage and

provided a more realistic evaluation of the ability of the models to anticipate irrigation, ventilation and shading states from multi-sensor data.

Random Forest, XGBoost and MLP were trained under identical experimental conditions. The same predictive dataset was used for all models, where sensor-derived variables recorded at time t were mapped to actuator states at t+30 minutes. The dataset was split chronologically into training, validation and test subsets, corresponding to 70%, 15% and 15% of the records, respectively. This approach preserved the temporal structure of the greenhouse data and prevented future information from being included in the training phase. The same evaluation metrics were then computed for each model and each control target, allowing a direct comparison of their predictive performance.

Software implementation

The experiments were conducted on a workstation running Windows 10 Pro 64-bit, equipped with an Intel Core i9-9900K processor at 3.60 GHz, 64 GB of RAM and an NVIDIA Quadro P4000 GPU with 8 GB of dedicated memory. All data preprocessing, feature engineering, model training and evaluation were performed using Python 3.9.13. Data handling and numerical operations were carried out using pandas 2.3.3 and NumPy 2.0.2. Data standardization, Random Forest and MLP implementation, and calculation of the evaluation metrics were performed using scikit-learn 1.6.1. The Random Forest and MLP models were executed on the CPU, whereas GPU acceleration was enabled for XGBoost by setting device="cuda" in XGBoost 2.1.4. Matplotlib 3.9.4 was used to generate the graphical representations of the results.

Evaluation metrics

The performance of the machine learning models was evaluated using accuracy, balanced accuracy, precision, recall, F1-score and ROC-AUC. These metrics were selected because the control states of the greenhouse subsystems were not equally distributed between the OFF and ON classes, especially for irrigation and shading. Therefore, the evaluation could not rely only on overall accuracy.

Accuracy represents the proportion of all correctly classified samples. It provides a general indication of model performance, but it can be misleading when one class is much more frequent than the other. For example, if the OFF state is dominant, a model may obtain high accuracy by mostly predicting OFF, while still failing to detect important ON events.

Balanced accuracy was used to provide a more reliable evaluation under class imbalance. Unlike standard accuracy, it considers the classification performance for both classes and gives equal importance to the OFF and ON states. This is important in greenhouse control, because missing an ON command for irrigation, ventilation or shading may have practical consequences even if the overall number of errors is small. Precision indicates how reliable the positive predictions are. In this study, it shows how many of the predicted ON states were actually correct. A high precision value means that the model does not frequently activate a control subsystem when it is not required. This is relevant for reducing unnecessary water use, energy consumption or shading activation.

Recall indicates how well the model detects the actual ON states. It shows whether the model correctly identifies the moments when irrigation, ventilation or shading should be active. A high recall value is important because failing to detect an ON state may lead to water stress, excessive temperature, high humidity, high CO2 concentration or excessive solar radiation inside the greenhouse.

The F1-score combines precision and recall into a single performance indicator. It is especially useful when the dataset is imbalanced, because it reflects both the reliability of ON predictions and the ability to detect actual ON events. For this reason, F1-score was used as one of the main criteria for comparing the models.

ROC-AUC was used to evaluate the ability of each model to distinguish between the OFF and ON classes over different decision thresholds. A high ROC-AUC value indicates that the model assigns higher probabilities to true ON cases than to OFF cases, even before a final classification threshold is applied. This metric is useful for assessing the separability of the two control states.

In this study, the final model selection was based mainly on F1-score, balanced accuracy and recall, rather than accuracy alone. This approach was adopted because the practical objective of the control system is not only to maximize the total number of correct predictions, but also to reliably identify the moments when each actuator should be activated.

RESULTS

An initial same-time classification test was first performed, in which the sensor-derived variables and the actuator states corresponded to the same timestamp. This evaluation produced very high scores, with several F1-

score values close to or equal to 1.00. Although this confirmed that the models could reproduce the observed actuator states from the available sensor data, the results were considered overly optimistic for a practical control application. In such a configuration, the model may learn relationships that are too close to the current control logic, especially when aggregated variables directly related to control decisions are present in the input dataset. Therefore, the final evaluation was reformulated as a predictive task, where the sensor data recorded at time t were used to estimate the actuator states at t+30 minutes. This second configuration was considered more relevant for real greenhouse control, because it evaluates the ability of the models to anticipate future irrigation, ventilation and shading requirements. In addition, the most direct aggregated control indicators, including maximum air temperature, maximum relative humidity, maximum CO2 concentration, maximum light intensity and minimum soil moisture, were removed from the input dataset to reduce the risk of direct threshold reproduction.

Random Forest classifier achieved strong predictive performance for irrigation and ventilation control. For irrigation, the model reached an F1-score of 0.9630, with a precision of 0.9811 and a recall of 0.9455. This indicates that the model was able to detect most future irrigation activation events while keeping false positive predictions low. Ventilation control also showed high performance, with an F1-score of 0.9611 and a recall of 0.9934, showing that most future ventilation ON states were correctly identified. Shading control was more difficult to predict, with an F1-score of 0.7894, mainly due to the lower recall of 0.6772 for the ON class. This suggests that Random Forest was conservative in predicting future shading activation, producing relatively reliable ON predictions but missing some actual shading events.

Table 3

Metrics for Random Forest classifier

Control	Accuracy	Balanced accuracy	Precision	Recall	F1-score	ROC-AUC
Irrigation	0.9962	0.9722	0.9811	0.9455	0.9630	0.9971
Ventilation	0.9311	0.7734	0.9309	0.9934	0.9611	0.9744
Shading	0.9027	0.8315	0.9461	0.6772	0.7894	0.9772

XGBoost classifier achieved high predictive performance on the 30-minute horizon dataset. For irrigation control, the model obtained an F1-score of 0.9533, with high precision and recall. For ventilation, the F1-score was 0.9606, very close to the Random Forest result. The best XGBoost result was obtained for shading control, where the model reached an F1-score of 0.8571, outperforming both Random Forest and MLP. This suggests that XGBoost captured more effectively the nonlinear relationships involved in shading decisions, especially those related to light intensity, temperature evolution and spatial variability within the greenhouse.

Table 4

Metrics for XGBoost classifier

Control	Accuracy	Balanced accuracy	Precision	Recall	F1-score	ROC-AUC
Irrigation	0.9953	0.9631	0.9808	0.9273	0.9533	0.9790
Ventilation	0.9311	0.8123	0.9437	0.9780	0.9606	0.9622
Shading	0.9254	0.8958	0.8843	0.8316	0.8571	0.9789

MLP model showed mixed performance. It achieved acceptable results for ventilation and shading, with F1-scores of 0.9455 and 0.8132, respectively. However, it failed to detect irrigation activation, obtaining an F1-score of 0.0000 for irrigation despite an accuracy of 0.9481. This indicates that the model mainly predicted the majority class for irrigation and did not correctly identify the ON state. The result confirms that accuracy alone is not sufficient for evaluating greenhouse control models when the class distribution is imbalanced. Balanced accuracy, recall and F1-score are more informative for this application.

Table 5

Metrics for MLP classifier

Control	Accuracy	Balanced accuracy	Precision	Recall	F1-score	ROC-AUC
Irrigation	0.9481	0.5000	0.0000	0.0000	0.0000	0.0444
Ventilation	0.9056	0.7836	0.9373	0.9538	0.9455	0.9187
Shading	0.8876	0.8943	0.7358	0.9088	0.8132	0.9480

The comparative evaluation was performed using the predictive dataset, where the sensor-derived variables recorded at time t were used to estimate the irrigation, ventilation and shading states at t+30 minutes.

This formulation provided a more realistic evaluation of the models for greenhouse control, since the objective was to anticipate future actuator states rather than reproduce the current control status. This result does not necessarily indicate that neural networks are unsuitable for greenhouse control in general, but that the tested MLP configuration was not robust enough for the irrigation target under the available dataset size and class distribution.

Table 6

Comparative results for the three investigated classifiers

Model	Accuracy mean	Balanced accuracy mean	Precision mean	Recall mean	F1-score mean	ROC-AUC mean
Random Forest	0.9433	0.8590	0.9527	0.8720	0.9045	0.9829
XGBoost	0.9506	0.8904	0.9363	0.9123	0.9237	0.9734
MLP	0.9138	0.7260	0.5577	0.6209	0.5862	0.6370

The predominance of tree-based ensemble models in the present study agrees with recent greenhouse research. *Mohammadi et al. (2024)* also reported XGBoost as the most balanced classifier for predicting greenhouse irrigation needs, while *Cebolla-Alemany et al. (2026)* found gradient-boosted tree models effective for short-term greenhouse microclimate forecasting. *Elvanidi and Katsoulas (2023)* obtained 91% accuracy and a 0.92 F1-score with Gradient Boosting, compared with 89% for both metrics with MLP, for greenhouse crop-stress detection. In the present study, XGBoost achieved a mean accuracy of 0.9506 and a mean F1-score of 0.9237 across the three actuator targets, whereas the tested MLP reached 0.9138 and 0.5862, respectively. These values should not be interpreted as a direct ranking across studies because the prediction targets, forecast horizons, datasets and validation protocols differ. The specific contribution of the present study is the direct 30-minute-ahead prediction of irrigation, ventilation and shading states from a distributed WSN, using a chronological data split and excluding the most direct aggregated control indicators to reduce data leakage.

To provide a more practical interpretation of the classification results, the predicted and actual actuator states were also compared over five days for a representative interval from the test dataset. The following figures show the 30-minute-ahead predicted states for the recommended model of each subsystem: Random Forest for ventilation, and XGBoost for irrigation and shading. The temporal representation confirms that the models generally followed the actual control transitions, especially for irrigation and ventilation. Shading control showed more deviations, which is consistent with the lower F1-score obtained for this subsystem and indicates that shading activation is more difficult to anticipate from the available sensor-derived variables.

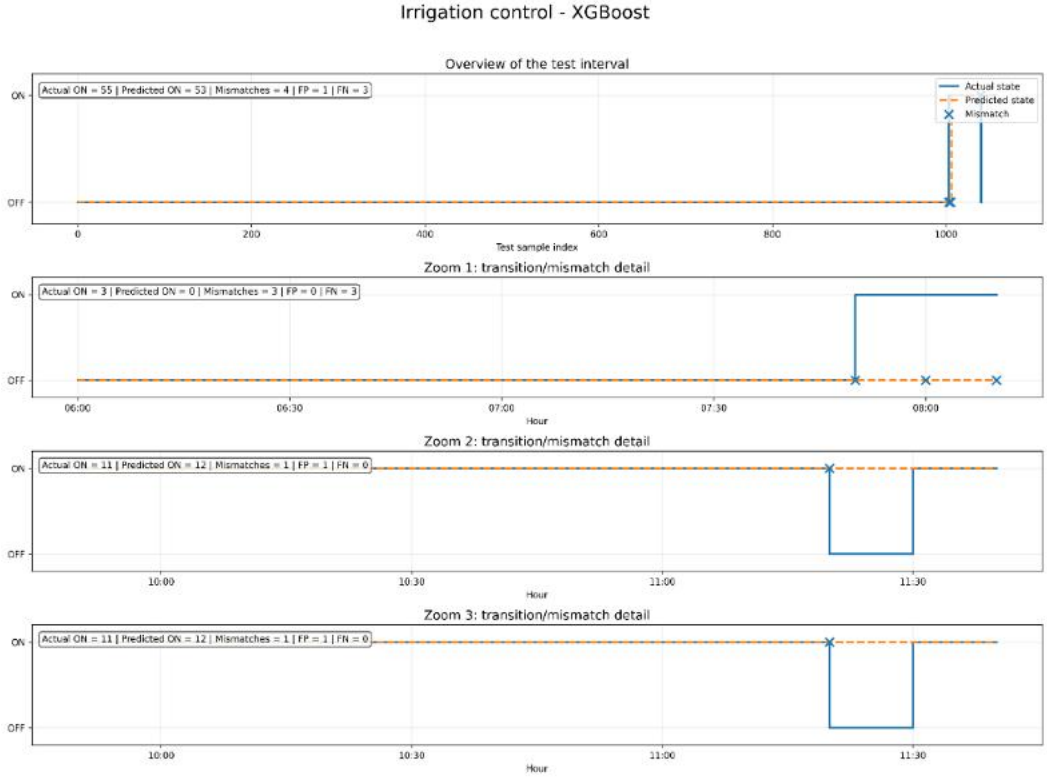

Fig. 2 - Temporal comparison between actual and predicted irrigation control states using the XGBoost model

Because irrigation control events were sparse and concentrated in a limited number of transition periods, a direct full-window visualization was not sufficiently informative. Therefore, the irrigation results were presented using an overview panel together with zoomed transition windows highlighting the agreement between actual and predicted states and the few mismatch cases. The upper panel provides an overview of the test interval, while the lower panels show zoomed details around transition and mismatch events.

For irrigation control, the temporal representation was adapted to the sparse occurrence of ON states. Therefore, an overview of the full test interval was combined with zoomed views around transition and mismatch events. The XGBoost model produced 53 predicted ON states compared with 55 actual ON states, with only four mismatches in the test interval. Most errors occurred near transition moments, indicating that the model captured the dominant irrigation state but remained sensitive to the exact timing of ON/OFF changes.

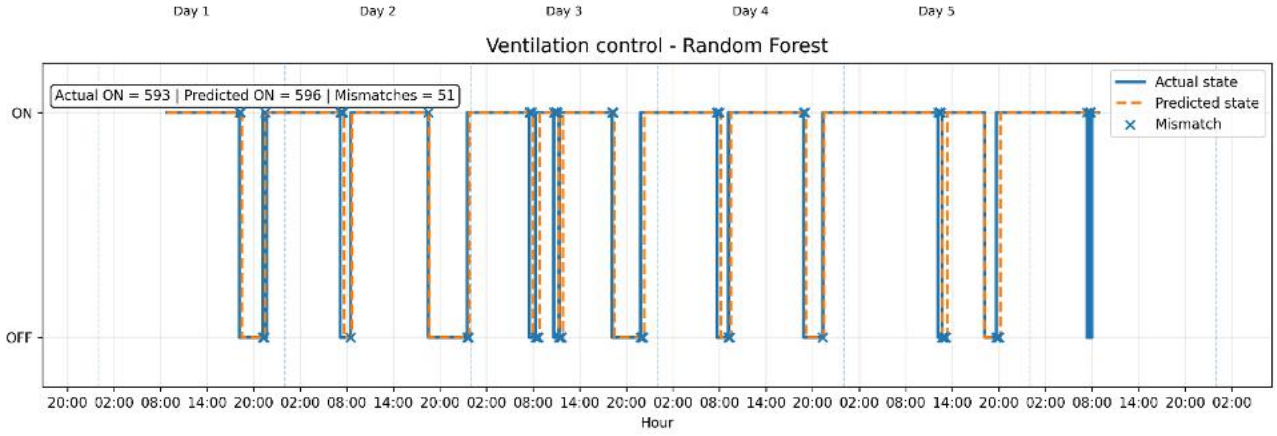

Fig. 3 - Actual and predicted ventilation control states obtained with the Random Forest model over a representative five-day test interval

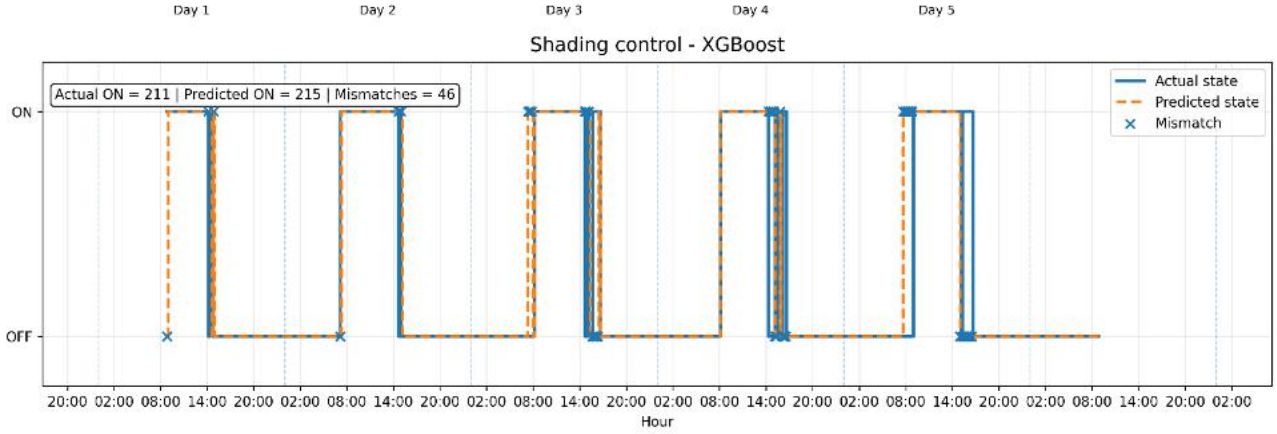

Fig. 4 - Actual and predicted shading control states obtained with the XGBoost model over a representative five-day test interval

The temporal comparison shows that the predicted states generally followed the actual actuator states. Most mismatches occurred close to OFF/ON or ON/OFF transitions, indicating that the main difficulty was not the identification of the dominant control state, but the exact timing of state changes in the 30-minute-ahead prediction task. This behaviour is particularly visible for shading control, where activation depends on rapidly changing light and temperature conditions.

Although Random Forest obtained a slightly higher F1-score for irrigation, XGBoost was retained as the recommended irrigation model because it provided a high and balanced performance and is consistent with the single-model implementation scenario.

Table 7

Recommended classifier for each investigated process

Control	Recommended model	F1-score	Balanced accuracy
Irrigation	XGBoost	0.9533	0.9631
Ventilation	Random Forest	0.9611	0.7734
Shading	XGBoost	0.8571	0.8958

Overall, XGBoost provided the best average predictive performance, while Random Forest offered the best performance for ventilation and remained highly interpretable. For a single-model implementation, XGBoost can be selected due to its highest average F1-score and balanced accuracy. For a subsystem-specific implementation, Random Forest is recommended for irrigation and ventilation control, while XGBoost is recommended for shading control.

CONCLUSIONS

This paper presented a machine learning-based decision model for greenhouse irrigation, ventilation and shading control using multi-sensor data collected from four WSN nodes. The raw dataset was cleaned, scaled, synchronized and transformed into a structured dataset suitable for supervised learning. To obtain a more realistic control formulation, the final evaluation was performed as a 30-minute-ahead prediction task, where sensor-derived variables recorded at time t were used to estimate the future control states at t+30 minutes.

The comparative evaluation showed that tree-based ensemble models were better suited to the processed greenhouse dataset than the tested MLP neural network. Random Forest remains a robust and interpretable alternative, with very strong results for irrigation and ventilation control. XGBoost achieved the highest average predictive performance and the best result for shading control, with an F1-score of 0.8571. The MLP model performed reasonably for ventilation and shading, but failed to detect irrigation activation, confirming that accuracy alone is not sufficient for evaluating imbalanced greenhouse control data.

Future work will first validate the selected model in shadow mode after integration with the actuator nodes, followed by supervised and closed-loop greenhouse trials. These experiments will assess control latency, false activations, missed activation events, robustness to sensor faults and seasonal distribution shifts, as well as the effects of predictive control on water and energy use. Model recalibration across crop cycles and greenhouse operating conditions will also be investigated.

AN EFFICIENT RICE PEST DETECTION METHOD BASED ON YOLOv11N
/
基于 YOLOv11n 的高效水稻害虫检测方法

Keywords: *Rice pest detection, YOLOv11n, Detail-Preserving Contextual Fusion, Multi-cognitive Visual Adapter, Edge-device deployment*

ABSTRACT
Accurate and efficient rice-pest detection is essential for field scouting, early warning and precision control. This study presents a lightweight YOLOv11n-based framework for accurate edge deployment. It integrates a Multi-cognitive Visual Adapter (Mona), a Detail-Preserving Contextual Fusion module (DPCF) and Wise-IoU-based non-maximum suppression (Wise-IoU-NMS). Mona improves multi-scale feature representation with limited overhead; DPCF preserves fine-grained pest details during contextual fusion; and Wise-IoU-NMS stabilizes localization of overlapping and densely distributed targets. On a public dataset of 5,212 images from six near-balanced rice-pest classes, divided 8:1:1 for training, validation and testing, the proposed model achieved 95.4% mAP@50, 94.8% precision and 94.7% recall with 2.65 M parameters and 6.5 GFLOPs. The F1-confidence curve identified 0.476 as the alarm threshold. Deployment on Jetson Nano using ONNX and frame-level logging demonstrated a practical workflow for real-time monitoring and selective spraying.

摘要
水稻害虫的快速、准确检测对于田间巡检、虫情预警和精准防控具有重要意义。本文提出一种面向边缘端高精度部署的轻量化 YOLOv11n 检测框架，融合多认知视觉适配器（Multi-cognitive Visual Adapter, Mona）、细节保留型上下文融合模块（Detail-Preserving Contextual Fusion, DPCF）和基于 Wise-IoU 的非极大值抑制策略（Wise-IoU-NMS）。Mona 以较低开销增强多尺度特征表达，DPCF 在上下文融合中保留细粒度虫体信息，Wise-IoU-NMS 则提高重叠及密集目标的定位稳定性。在包含 5,212 张图像、6 类近均衡水稻害虫并按 8:1:1 划分训练集、验证集和测试集的公开数据集上，所提出模型取得 95.4% 的 mAP@50、94.8% 的精确率和 94.7% 的召回率，参数量为 2.65 M，计算量为 6.5 GFLOPs。F1-confidence 曲线确定 0.476 为报警阈值；基于 ONNX 的 Jetson Nano 部署及逐帧记录验证了该方法用于实时监测和选择性施药的可行流程。

INTRODUCTION

Rice is one of the most important staple crops worldwide, and pest outbreaks during the growing season directly affect yield, grain quality and pesticide-use decisions. Field scouting still relies heavily on visual inspection and manual counting, which are labor-intensive, subjective and difficult to scale across large planting areas. A practical rice-pest detection system therefore needs not only high recognition accuracy, but also real-time inference, stable performance under occlusion and illumination variation, and compatibility with low-power edge devices used in field monitoring or selective spraying.

Deep-learning-based object detection has become an important tool for agricultural pest monitoring. Two-stage detectors such as Faster R-CNN generally provide strong localization ability but require relatively high computational cost, whereas one-stage detectors represented by the YOLO series offer a better accuracy-speed trade-off for real-time applications. Recent studies on rice or field pest identification, including MobileNet-CA-YOLO, AgriPest-YOLO and transformer-based rice-pest detectors, have improved detection accuracy by introducing lightweight backbones, attention mechanisms or multi-scale feature fusion (*Jia et al., 2023; Zhang et al., 2023; Wang et al., 2025*). Complementary international studies have broadened both the sensing scenarios and the task definitions used for rice-pest identification. Hassan et al. combined remote-sensing imagery with a modified YO-CNN to identify major rice pests and demonstrated the potential of wide-area automated scouting *(Hassan et al., 2023)*.

Saufi and Suharjito developed a trap-image CNN for white rice stem borer detection and population counting, but reported that inference still depended on server resources rather than direct processing on the field device *(Saufi and Suharjito, 2024)*. Quach et al. released an expert-reviewed rice-pest dataset assembled from heterogeneous sources, highlighting the importance of data diversity and standardized preprocessing for smart-farming systems *(Quach et al., 2024)*. In parallel, RP-DETR used an end-to-end Transformer architecture to strengthen long-range feature interaction and multi-scale fusion for rice-pest recognition, thereby providing a complementary alternative to convolution-dominated detectors *(Wang et al., 2025)*.

Taken together, these model families address different operational needs. Image-level CNN systems are relatively simple and effective in controlled trap or aerial scenes, but they do not always localize several neighboring pests in a single field image and may require remote-server support *(Hassan et al., 2023; Saufi and Suharjito, 2024)*. Lightweight YOLO detectors generally offer a favorable accuracy-speed balance for edge deployment *(Jia et al., 2023; Zhang et al., 2023; Xiong et al., 2024)*; however, performance remains sensitive to the loss of fine-grained cues during downsampling and to small, dense or overlapping target layouts *(Sunkara and Luo, 2023; Wang et al., 2025)*. Transformer-based detectors capture longer-range dependencies and provide an end-to-end alternative for multi-scale rice-pest detection *(Wang et al., 2025)*. Moreover, headline accuracy values should not be compared directly across studies because pest categories, acquisition platforms, annotation protocols and test sets differ *(Quach et al., 2024; Xiong et al., 2024)*. Collectively, these observations indicate that field-oriented rice-pest detection should be treated as a coupled problem of fine-grained visual representation, reliable localization in dense or occluded scenes, and resource-efficient inference, rather than as an isolated improvement to one network component. Accordingly, the present study develops an integrated lightweight detection framework that coordinates feature representation, multi-scale information interaction and prediction refinement within a unified pipeline. The framework is intended to retain weak boundary and texture cues of very small pests, use broader contextual information to distinguish visually similar categories, reduce missed and duplicate detections in overlapping infestations, and maintain an accuracy-latency balance suitable for edge deployment. Its practical relevance is assessed through class-wise PR/F1 analysis, confidence-threshold selection and Jetson Nano validation at an average inference speed of 36 FPS.

However, several research gaps remain. First, small rice pests are often densely clustered or partially occluded, resulting in increased missed detections and duplicate bounding boxes. Second, many studies focus primarily on benchmark accuracy while providing limited analysis of class-specific errors, confidence-threshold selection, and practical alarm criteria. Third, the deployment performance of improved models on resource-constrained edge devices has often not been sufficiently validated. To address these gaps, this study developed a lightweight YOLOv11n-based detector integrating Mona, DPCF, and Wise-IoU-NMS. The proposed model was evaluated through ablation experiments, cross-model comparisons, class-wise precision–recall and F1-score analyses, and a deployment protocol designed for the Jetson Nano.

MATERIALS AND METHODS

DATA SOURCES AND PREPROCESSING

Because publicly available rice-pest datasets with uniform annotation standards remain limited, this study constructed a rice-pest image dataset from open-source images and expert-reviewed annotations. The dataset contains six target categories: green leafhopper, brown planthopper, rice bug, leaf folder, stem borer and whorl maggot. Representative images from the dataset are shown in Fig. 1.

Fig. 1 - Representative images from the dataset

The dataset used in this study was sourced from publicly available pest images collected from multiple online platforms (Fig. 1).

Before inclusion, the images were manually screened to remove duplicates, irrelevant samples and low-quality records, and the copyright and usage conditions of the source images were checked. Each retained image was annotated with pest category labels and bounding boxes under the guidance of agricultural experts and authoritative entomological references, thereby improving annotation reliability and domain consistency.

A total of 5,212 high-resolution images were collected, covering six rice-pest categories and diverse visual conditions, including occlusion, deformation, complex backgrounds and illumination variation. The dataset was divided into training, validation and test sets at a ratio of 8:1:1, with 4,170, 521 and 521 images, respectively. The six pest categories were arranged in a near-balanced manner: each class contained 868-869 images, corresponding to 16.65-16.67% of the dataset. This distribution reduces class-prior bias and allows the precision, recall and F1-score curves to be interpreted as class-comparable evidence rather than being dominated by one abundant pest category. To improve model generalization and reduce imbalance-related bias, data augmentation was applied, including random rotation, brightness adjustment, horizontal flip, translation, local occlusion and Gaussian noise.

Table 1

Class-wise composition of the rice-pest dataset

Pest class	Chinese name	Total images	Proportion (%)	Train/Val/Test
green-leafhopper	绿叶蝉	869	16.67	695 / 87 / 87
brown-planthopper	褐飞虱	869	16.67	695 / 87 / 87
rice-bug	稻蝽	869	16.67	695 / 87 / 87
leaf-folder	卷叶螟	869	16.67	695 / 87 / 87
stem-borer	螟虫	868	16.65	695 / 87 / 86
whorl-maggot	稻瘿蚊	868	16.65	695 / 86 / 87
Total	-	5,212	100.00	4,170 / 521 / 521

Note: *The dataset was organized as a near-balanced six-class rice-pest dataset. The train/validation/test split follows the 8:1:1 protocol.*

EXPERIMENTAL ENVIRONMENT AND PARAMETER CONFIGURATION

Experimental Environment Configuration

Model training was conducted in Python 3.8 using the PyTorch deep-learning framework. The training workstation ran Ubuntu 22.04.3 with CUDA 12.2 acceleration and used an Intel(R) Core(TM) i5-8300H CPU @ 2.30 GHz and an NVIDIA A100 GPU with 40 GB memory. This environment was used for model development, parameter optimization and benchmark comparison, whereas the edge-device validation was conducted separately on Jetson Nano as described below.

Experimental Parameter Configuration

YOLOv11n was used as the baseline model. All models were trained with an input resolution of 640 x 640 pixels. Stochastic Gradient Descent (SGD) was used for optimization with an initial learning rate of 0.01, momentum of 0.937 and cosine annealing for learning-rate scheduling. The batch size was set to 16 and the maximum number of epochs was 300. The same training and testing configuration was maintained across ablation and comparison experiments to ensure fair evaluation of the proposed modules.

EDGE-DEVICE VALIDATION PROTOCOL

To address the requirement for real-life validation, the final YOLOv11n-Mona-DPCF-Wise-IoU model was prepared for deployment on an NVIDIA Jetson Nano B01 (4 GB). The edge-device workflow included model export to ONNX, graph simplification, TensorRT FP32 engine conversion and local inference on 640 x 640 input frames. The deployment interface integrates image, video and camera-stream input, real-time visualization of bounding boxes and confidence scores, and result logging for subsequent pest occurrence analysis.

In practical use, detections with confidence scores above 0.476, the threshold selected from the F1-confidence curve, are treated as valid pest alarms. Each alarm record includes the pest category, confidence score, bounding-box coordinates and frame information. This design allows the system to support field

scouting, multi-class pest monitoring, pest-density recording and future integration with selective spraying equipment.

ALGORITHM IMPROVEMENT

YOLOv11n Algorithm

This study focuses on YOLOv11n as the baseline detector because of its lightweight structure and real-time potential. The YOLOv11n network consists of four major components: the input layer, backbone, neck feature-fusion network and detection head. The overall network structure is shown in Fig. 2.

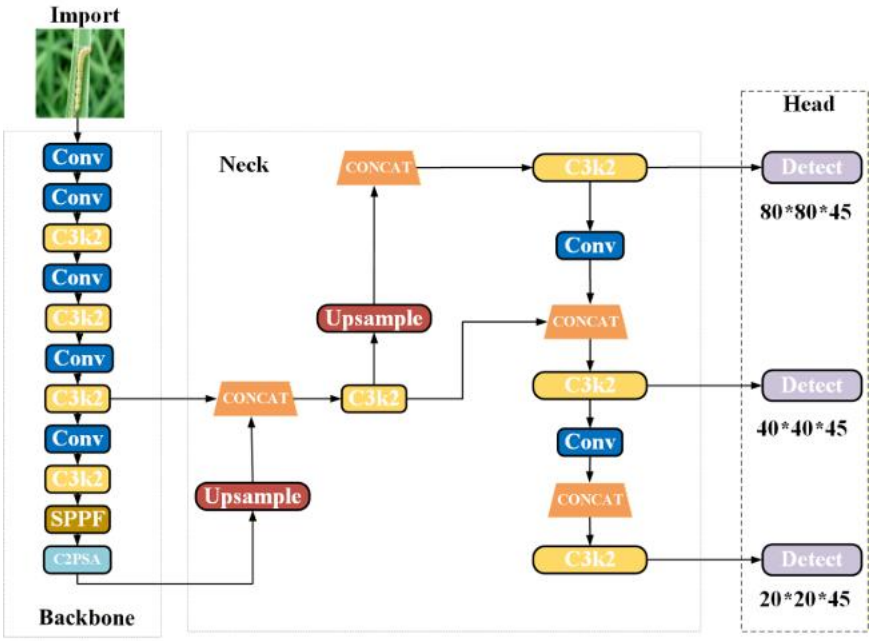

Fig. 2 - Architecture of the YOLOv11n network model

Multi-cognitive Visual Adapter

To address efficient and accurate pest detection under complex visual conditions, Mona (Multi-cognitive Visual Adapter) is introduced as a lightweight feature adaptation module (Fig. 3). Mona is designed to strengthen visual knowledge transfer without substantially increasing trainable parameters. It contains scaled layer normalization and a multi-branch depthwise convolutional filtering module. The scaled LayerNorm uses learnable weights to balance normalized and original features, improving the stability of transferred representations. The convolutional branches use 3 x 3, 5 x 5 and 7 x 7 depthwise kernels to capture pest features at different receptive fields, followed by pointwise convolution and GeLU activation. Residual connections maintain gradient flow and semantic consistency. This design improves fine-grained pest feature representation while preserving the lightweight nature of YOLOv11n.

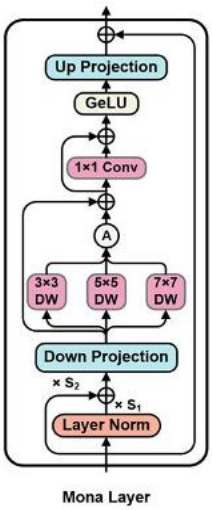

Fig. 3 - Architecture of the Multi-cognitive Visual Adapter

Detail-Preserving Contextual Fusion

To enhance feature fusion for rice-pest detection, the DPCF module is incorporated into the neck architecture (Fig. 4). DPCF addresses the limitations of static fusion schemes such as simple concatenation or summation, which may not sufficiently adapt to multi-scale pests, background interference and partial occlusion. Instead, DPCF performs content-adaptive fusion of hierarchical feature maps, enabling the model to preserve local details while incorporating broader contextual information.

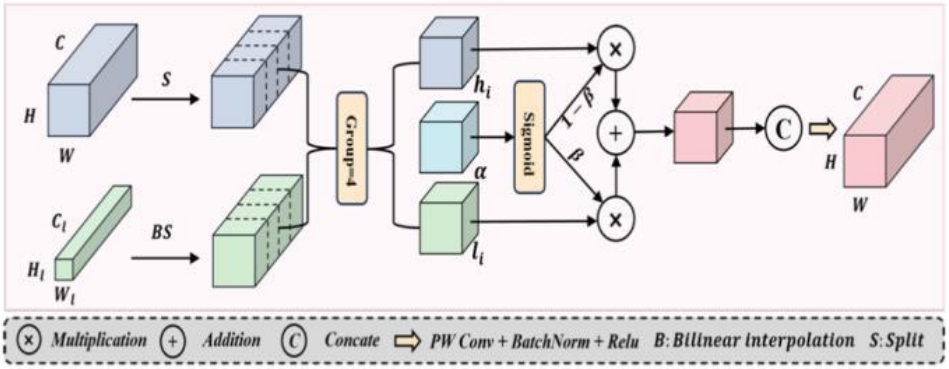

Fig. 4 - Architecture of the Detail-Preserving Contextual Fusion module

Structurally, DPCF is composed of two key components: Depthwise Separable Pyramid Convolution (DSPC) and Channel-wise Dynamic Fusion (CDF). DSPC applies a set of depthwise separable convolutions with multiple receptive fields (3×3, 5×5, 7×7) to enhance contextual representation at each scale. The outputs are then passed through the CDF module, which generates dynamic fusion weights across feature channels using attention mechanisms. These weights allow the model to selectively emphasize semantically relevant features while suppressing noisy or redundant ones. Residual connections are employed to preserve gradient stability and retain original semantic pathways.

Compared to conventional PANet-style feature aggregation, DPCF dynamically learns spatial-semantic relationships, yielding a more adaptive fusion process that is sensitive to local structure and global context. This is particularly advantageous for pest detection, where the targets are often small, densely distributed, and partially occluded. By modeling scale-aware and position-sensitive features, DPCF significantly improves the model's ability to discriminate subtle pest contours from noisy backgrounds.

Wise-IoU-NMS Non-Maximum Suppression Algorithm

The original YOLOv11n adopts conventional non-maximum suppression (NMS). When the Intersection over Union (IoU) between a candidate box and the highest-confidence box exceeds a predefined threshold, the candidate box is removed or heavily suppressed. This strategy may discard valid boxes in overlapping pest scenes and can therefore reduce recall. To alleviate this problem, this study adopts a Wise-IoU-based NMS strategy. The method adjusts suppression weights according to overlap and localization quality, so that boxes are retained or suppressed more adaptively rather than being removed only by a fixed IoU threshold. This improves localization stability for dense and partially occluded pest targets.

In this strategy, M denotes the detection box with the highest confidence score, B_i denotes the i-th candidate box, epsilon denotes the NMS threshold, s_i denotes the classification confidence score and IoU(B_i, M) denotes the overlap between the candidate box and M. The adjusted confidence score is used to determine whether the candidate box should be retained. This design reduces false suppression of valid pest boxes and mitigates duplicate detections caused by multiple high-confidence boxes corresponding to the same target.

For bounding-box regression, h and w denote the height and width of the minimum enclosing box, respectively, while x and y denote the center coordinates of the predicted and ground-truth boxes. The Wise-IoU formulation dynamically adjusts localization weights according to box quality, allowing the model to focus more effectively on difficult samples. The schematic representation is shown in Fig. 5.

Compared with traditional NMS, Wise-IoU-NMS considers overlap, center distance and localization quality jointly. This mechanism is particularly useful for small rice pests that appear close to one another or are partially occluded by leaves and stems. By reducing unnecessary suppression and duplicate alarm boxes, Wise-IoU-NMS improves practical detection reliability in complex field images.

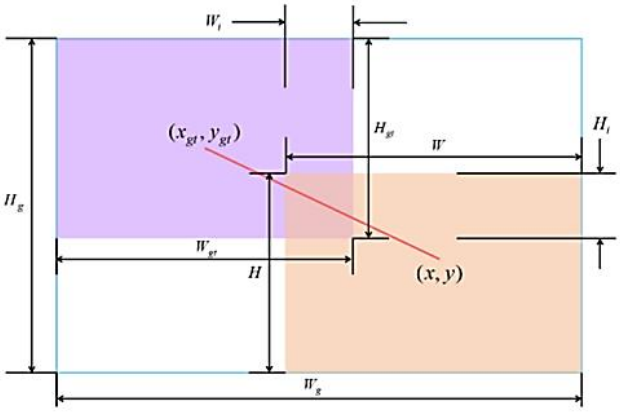

Fig. 5 - The architecture of the Wise-IoU

Overall Improved Network Architecture

This study introduces three key improvements to the YOLOv11n algorithm: Mona for lightweight feature adaptation, DPCF for detail-preserving contextual fusion and Wise-IoU-NMS for refined box suppression. The refined network architecture, denoted as YOLOv11n-Mona-DPCF-Wise-IoU, is depicted in Fig. 6.

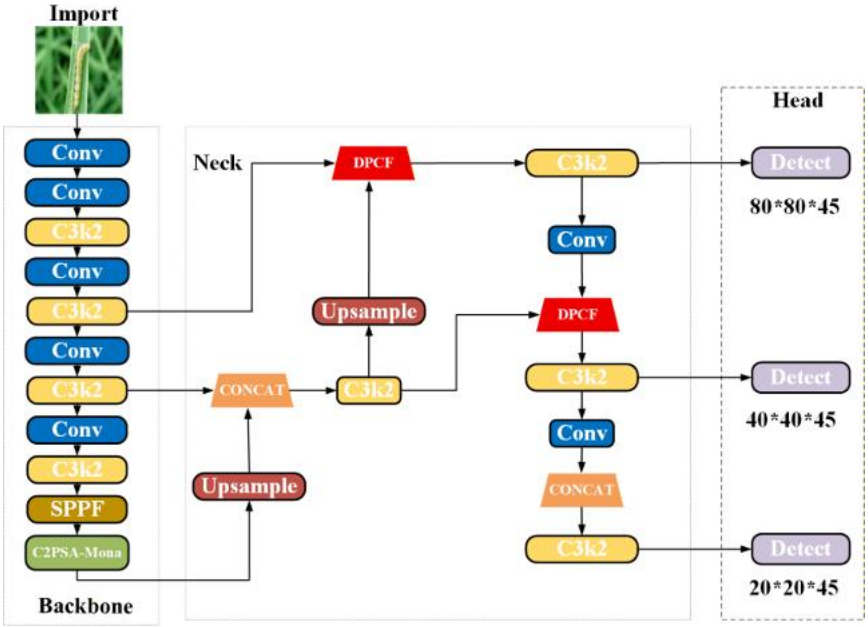

Fig. 6 - Improved YOLOv11n structure

RESULTS

A. Ablation Experiment

To evaluate the contribution of each module to detection accuracy and model complexity, a series of ablation experiments were conducted under identical training and testing conditions. Mona, DPCF and Wise-IoU-NMS were incrementally added to the YOLOv11n baseline. The results on the test set are summarized in Table 2.

Table 2

Ablation results of the proposed model on the test set

Model	Params (M)	GFLOPs	mAP@50
YOLOv11n	2.58	6.3	0.94
YOLOv11n-Mona	2.63	6.4	0.948
YOLOv11n-Mona-DPCF	2.65	6.5	0.952
YOLOv11n-Mona-DPCF-Wise-IoU	2.65	6.5	0.954

The ablation results demonstrate the effectiveness of the proposed components. The baseline YOLOv11n achieved 94.0% mAP@50 with 2.58 M parameters and 6.3 GFLOPs. After introducing Mona, mAP@50 increased to 94.8%, while the parameter count and computational cost only rose slightly to 2.63 M and 6.4 GFLOPs. Adding DPCF further improved mAP@50 to 95.2%, indicating that detail-preserving contextual fusion strengthened multi-scale pest representation. Finally, the complete YOLOv11n-Mona-DPCF-Wise-IoU model achieved the best mAP@50 of 95.4% with 2.65 M parameters and 6.5 GFLOPs. These results show that the proposed modules improve accuracy with limited additional cost, which is important for practical edge deployment.

Figure 7 illustrates the class-wise Precision-Recall (PR) curves of four YOLOv11n variants, corresponding to the baseline and each stage of the proposed incremental enhancements. Subfigure (a) represents the baseline YOLOv11n, which achieved an mAP@0.5 of 0.940. Although the baseline performed well for stem borer (0.979) and whorl maggot (0.974), it showed weaker performance for brown planthopper (0.847), indicating class-specific sensitivity. After Mona was introduced, mAP@0.5 increased to 0.948, with improved precision-recall balance for visually similar pest classes. Incorporating DPCF further improved mAP@0.5 to 0.952 by strengthening multi-scale feature aggregation. The complete YOLOv11n-Mona-DPCF-Wise-IoU model achieved the highest mAP@0.5 of 0.954 and produced more stable PR curves across categories. This confirms that the proposed modules progressively improve class-wise detection reliability, as summarized in Table 2.

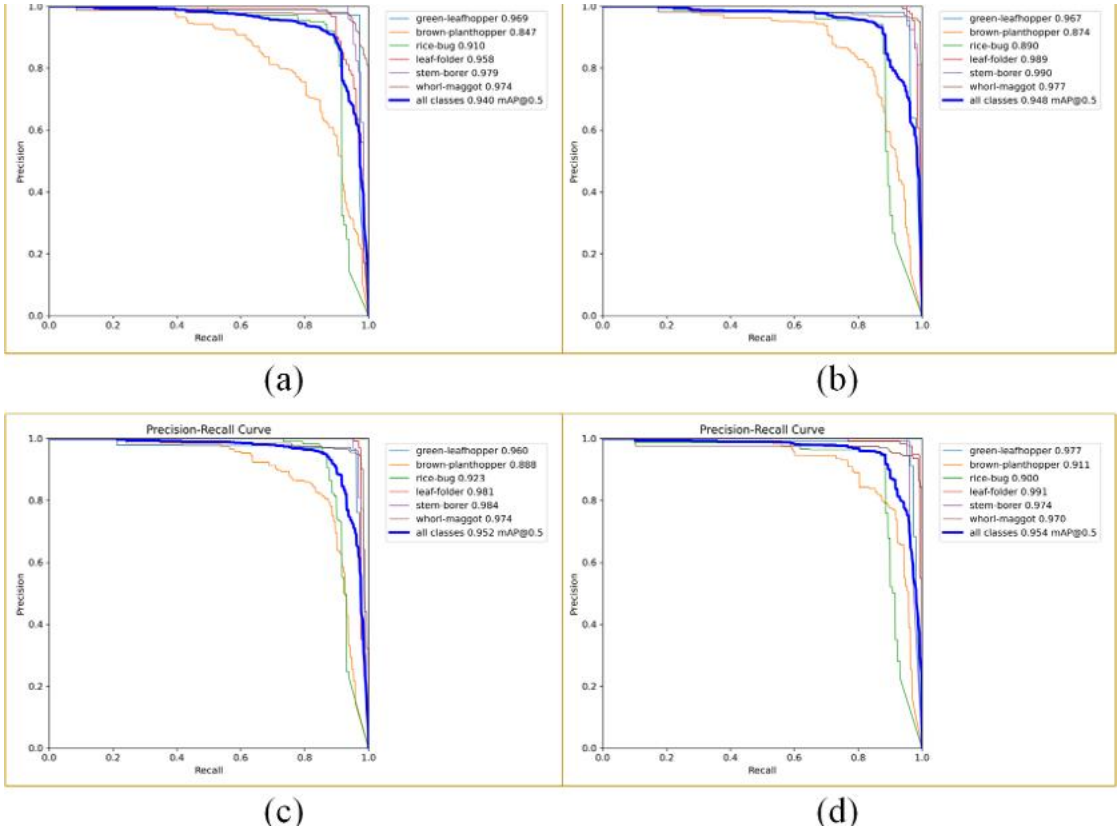

Fig. 7 - Precision-Recall (PR) curves

Figure 8 presents the F1-confidence curves of four sequentially enhanced YOLOv11n models, providing insight into classification robustness and the selection of practical alarm thresholds.

The baseline YOLOv11n reached a peak macro-average F1 score of 0.91 at a confidence threshold of 0.472, but its F1 values were lower for brown planthopper and rice bug, reflecting the difficulty caused by class imbalance and inter-class similarity. After Mona was introduced, the peak F1 score increased to 0.93 at a threshold of 0.437. Adding DPCF further stabilized the curves, with a macro F1 score of 0.93 at 0.452. The complete YOLOv11n-Mona-DPCF-Wise-IoU model maintained the highest F1 score of 0.93 and achieved it at a confidence threshold of 0.476. Therefore, 0.476 was selected as the recommended operating threshold for practical pest alerts in the deployment experiment. Detections with confidence scores above this threshold were treated as valid alarm events, while lower-confidence predictions were retained only for diagnostic review.

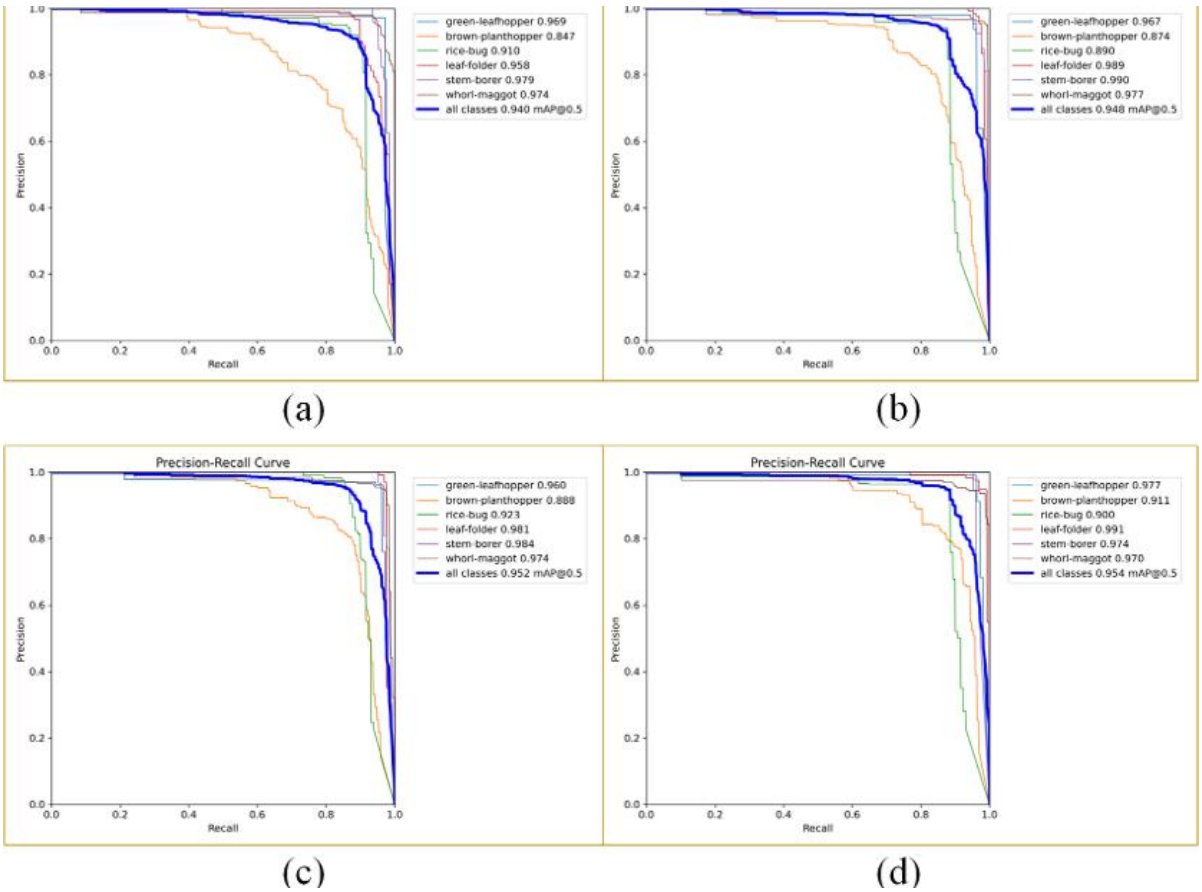

Fig. 8 - F1-Confidence curves

B. Comparative Experiment

To comprehensively evaluate the performance of the enhanced model, this study conducted comparative experiments between the proposed algorithm, YOLOv11n-Mona-DPCF-Wise-IoU, and several other prominent object detection algorithms, including SSD, Faster R-CNN, YOLOv10n, YOLOv12n, TPH-YOLOv5, RT-DETR, and DEIM. The results of these comparative experiments are summarized in Table 3.

Table 3

Comparison results with mainstream object-detection models

Model	Params (M)	GFLOPs	P	R	mAP@50	FPS
SSD	34.3	45.8	0.863	0.807	0.829	78
Faster R-CNN	69.2	217.8	0.894	0.917	0.858	84
YOLOv10n	2.69	8.2	0.911	0.904	0.933	106
YOLOv12n	2.50	5.8	0.931	0.914	0.939	117
TPH-YOLOv5	45.37	260.2	0.928	0.909	0.935	101
RT-DETR	31.99	103.3	0.933	0.921	0.937	95
DEIM	4.0	7.0	0.921	0.916	0.924	105
YOLOv11n	2.58	6.3	0.935	0.925	0.940	112
YOLOv11n-Mona-DPCF-Wise-IoU	2.65	6.5	0.948	0.947	0.954	109

The comparative results in Table 3 show that classical detectors such as SSD and Faster R-CNN obtained lower mAP@50 values of 82.9% and 85.8%, respectively, while requiring higher computational costs. YOLOv10n and YOLOv12n achieved 93.3% and 93.9% mAP@50 with high inference speeds, but their precision and recall were lower than those of the proposed method. The baseline YOLOv11n achieved 94.0% mAP@50 with 2.58 M parameters and 6.3 GFLOPs, demonstrating a strong lightweight baseline for rice-pest detection.

The proposed YOLOv11n-Mona-DPCF-Wise-IoU model achieved the best overall performance, with 95.4% mAP@50, 94.8% precision and 94.7% recall. It retained a compact model size of 2.65 M parameters and 6.5 GFLOPs and maintained high inference speed in the workstation test. Compared with the baseline, the proposed method improved mAP@50 by 1.4 percentage points while adding only 0.07 M parameters and 0.2 GFLOPs. These results indicate that the proposed architecture provides a more favorable balance between accuracy, robustness and computational efficiency than the compared detectors.

Figure 9 shows the mAP@50 convergence curves of the baseline YOLOv11n and the proposed YOLOv11n-Mona-DPCF-Wise-IoU model over 200 training epochs. The improved model converged faster in the early training stage and maintained a stable performance advantage throughout training, ultimately approaching an mAP@50 of 0.954. This indicates that Mona, DPCF and Wise-IoU-NMS not only improve detection accuracy but also enhance training stability.

Figure 10 visually compares the detection performance of YOLOv10n, YOLOv12n, YOLOv11n and the proposed YOLOv11n-Mona-DPCF-Wise-IoU model on three representative pest images. Across the samples, the improved model produced tighter bounding boxes and higher confidence scores.

In the first image, the proposed model localized the pest with a confidence score of 0.84, higher than the compared models (0.71-0.79). In the second image, which contained overlapping pests, the proposed model detected two targets with confidence scores of 0.87 and 0.83, whereas other models missed one target or produced lower-confidence detections. In the third image, which had high brightness and a complex background, the proposed model still detected the target with a confidence score of 0.88. These four valid detections all exceeded the recommended alarm threshold of 0.476, supporting the feasibility of threshold-based pest warning in practical monitoring.

Overall, the results demonstrate that Mona, DPCF and Wise-IoU-NMS improve both localization precision and detection stability, particularly under small-target, occlusion and illumination-challenging conditions. The remaining practical requirement is to verify whether this accuracy-efficiency balance can be maintained on low-power edge hardware; therefore, a Jetson Nano deployment validation was added in the following section.

C. Edge-Device Deployment and Practical Application Validation

To further clarify the engineering application scenario requested by the reviewer, the proposed model was deployed on Jetson Nano for rice-field pest monitoring (Fig. 11). The interface provides functions for opening images, videos and camera streams, starting or stopping detection and saving detection results. During operation, the model identifies six rice-pest categories, namely green leafhopper, brown planthopper, rice bug, leaf folder, stem borer and whorl maggot, and displays the predicted class, confidence score and bounding box in real time.

The deployment result demonstrates that the lightweight YOLOv11n-based model can be transferred from workstation evaluation to an embedded monitoring terminal. In field or greenhouse patrol scenarios, the confidence threshold can be used as an alarm rule: targets above the threshold are recorded as pest occurrences, while repeated frame records can be aggregated to estimate pest density. When connected to a fixed camera, mobile inspection platform or selective sprayer, the system can provide timely multi-class pest warnings and location-aware decision support for precision pest management.

Fig. 11 - Jetson Nano deployment interface of the rice-pest detection system

CONCLUSIONS

This study developed a lightweight rice-pest detector by integrating Mona, DPCF and Wise-IoU-NMS with YOLOv11n. The model achieved 95.4% mAP@50, 94.8% precision and 94.7% recall with 2.65 M parameters and 6.5 GFLOPs. Ablation and comparative experiments confirmed improved accuracy with limited computational overhead, particularly for small, occluded and complex-background targets. The Jetson Nano workflow further demonstrated the feasibility of embedded monitoring and threshold-based alarms. Future work should quantify long-term field robustness and end-to-end latency under varying environmental conditions.

Keywords: *Liquid fertilizer, Precision deep fertilization, Crank-slider injection mechanism, Computational fluid dynamics*

ABSTRACT
To address the limited maneuverability and terrain adaptability of conventional liquid-fertilizer injection equipment in hilly and small-plot farmland, a compact self-propelled injector integrating a narrow-track four-wheel-drive chassis, an angle-adjustable injection unit, and a crank-slider penetration mechanism was developed. Unlike large tractor-mounted or fixed-orientation systems, the proposed machine integrates inter-row movement, posture adjustment, needle penetration, and timed point injection on a lightweight platform. The discharge characteristics of the injection needle were investigated using computational fluid dynamics, and a three-factor, three-level Box–Behnken design was employed to optimize injection duration, inlet pressure, and outlet-hole number, with fertilizer volume per injection as the response. Response surface optimization identified an injection duration of 1 s, an inlet pressure of 0.45 MPa, and six outlet holes as the preferred parameter combination. Field validation yielded a measured fertilizer volume of 675.4 mL per injection, compared with the predicted value of 700 mL, corresponding to a relative difference of 3.51%. The results demonstrate the feasibility of controllable deep point placement under the tested conditions and provide a lightweight equipment solution for liquid-fertilizer application in hilly and small-plot farmland.

摘要
针对传统液肥注射施肥装备在丘陵山区及小地块农田中机动性和地形适应性不足的问题，研制了一种集窄距四轮驱动底盘、角度可调式注射单元和曲柄滑块入土机构于一体的小型自走式液肥注射机。与大型拖拉机悬挂式或固定姿态作业系统相比，该机可在轻量化平台上实现行间行走、姿态调节、施肥针入土及定时定点注肥。采用计算流体动力学方法分析施肥针排液特性，并以单次注肥体积为响应值，开展三因素三水平 Box–Behnken 响应面试验，对注肥时间、入口压力和出液孔数进行优化。响应面优化得到较优参数组合为注肥时间 1 s、入口压力 0.45 MPa 和出液孔数 6 个。田间验证中，单次注肥体积实测值为 675.4 mL，模型预测值为 700 mL，相对误差为 3.51%。结果表明，所研制机具在试验条件下能够实现可控的液肥定点深施，可为丘陵山区及小地块农田液肥机械化施用提供轻量化装备方案。

INTRODUCTION
In agricultural production, fertilizers are mainly applied in solid and liquid forms. Solid fertilizers are widely used, but their slow nutrient release and prolonged crop uptake often result in low utilization efficiency and considerable nutrient loss. In contrast, liquid fertilizers have the advantages of rapid nutrient release, high absorption efficiency and low application cost, making them suitable for crop topdressing *(Zhou et al., 2023)*. However, surface or shallow application of liquid fertilizer is prone to volatilization and nutrient loss, which reduces fertilization efficiency and limits crop yield improvement *(Hu et al., 2016)*. Previous studies have shown that deep point placement of liquid fertilizer can reduce nutrient loss, improve fertilizer use efficiency, mitigate environmental pollution and promote crop yield *(Li et al., 2018)*.

Liquid fertilizer is commonly applied through drip irrigation, foliar spraying and subsurface placement. Among subsurface application methods, band placement and point placement are the two main modes. Deep-placement technology for liquid fertilizer has been investigated relatively early in other countries and various dedicated applicators have been developed to improve application accuracy and fertilizer utilization.

For example, a soil-punching liquid-fertilizer applicator was developed to keep the injection needle vertical during soil penetration and withdrawal, thereby enabling fixed-point injection *(da Silva et al., 2017)*. An injection dosing system for site-specific liquid-fertilizer management was also designed by synchronizing soil punching and liquid-fertilizer injection to improve placement accuracy *(da Silva and Magalhães, 2019)*. In addition, precision injection of dairy sludge in no-till silage corn was reported to improve nutrient uptake under injection placement *(Hunt and Bittman, 2021)*. More recently, a liquid-manure point-injection system was designed and tested under field conditions, showing that subsurface injection could reduce nitrogen losses *(Hesar et al., 2025).*

In China, considerable efforts have also been made to develop liquid-fertilizer deep-placement equipment. The 3SFBQ-500 pneumatic blasting soil-loosening and fertilization machine can achieve fixed-point fertilization at depths of 200–500 mm in orchard hard soil through the coordinated operation of a drilling rod and a fertilizer injection unit *(Xi et al., 2017; Xi, 2018)*. Several liquid-fertilizer point-application devices have been developed, including the 1YJ-140 deep-placement applicator, in which the punching component was driven by a crank-rocker mechanism and the transmission system was improved to enhance operating efficiency *(Wang et al., 2016, 2017, 2018)*. Nevertheless, severe vibration still occurred under high-frequency operating conditions *(Feng et al., 2017; Liu et al., 2016)*. A liquid-fertilizer applicator for maize topdressing was also developed to improve fertilization efficiency and field adaptability by using multiple injection needles and a ground-clearance adjustment mechanism *(Xing, 2019)*.

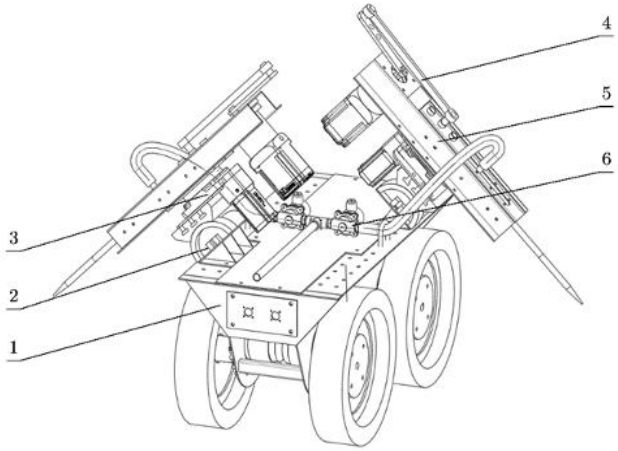
Although substantial progress has been made in quantitative deep placement of liquid fertilizer, existing equipment still has several limitations, including large machine size, inconvenient transport, and poor adaptability to complex terrain. These limitations restrict its application in hilly areas and small plots, where low mass, flexible mobility, posture adjustment, and stable needle penetration are required *(Sun, 2024)*. Moreover, previous studies have focused mainly on tractor-mounted or fixed-orientation systems, whereas integrated solutions that combine terrain adaptation, injection-posture adjustment, and intermittent point application on a lightweight self-propelled platform remain limited.

The main methodological contribution of this study is the integration of CFD-based internal-flow analysis with Box–Behnken response surface optimization to quantify the individual and interactive effects of injection duration, inlet pressure, and outlet-hole number on fertilizer volume per injection. The principal engineering contribution is the integration of a four-wheel-drive narrow-track chassis, a rotary–tilting posture-adjustment platform, and a crank-slider injection mechanism into a compact 45 kg machine. Structural design, mechanical analysis, CFD simulation, parameter optimization, and field validation were combined to evaluate the feasibility of controllable deep point placement in hilly and fragmented farmland.

MATERIALS AND METHODS

Structural design and working principle

The overall structure of the small self-propelled liquid-fertilizer injector is shown in Fig. 1. The machine mainly consists of a narrow-track chassis, an adjustable tilting platform, a rotary adjustment platform, a crank-slider injection mechanism, a guide support mechanism, and a liquid-fertilizer delivery system.



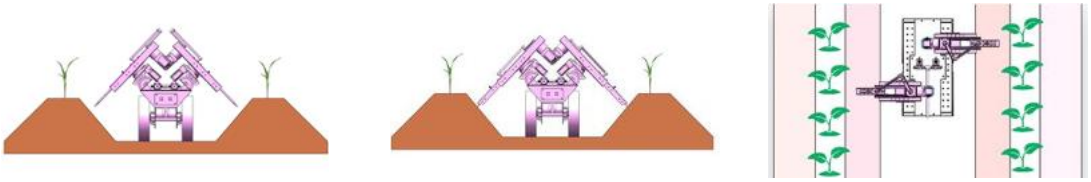


Fig. 1 - Overall structure of the small self-propelled liquid-fertilizer injector

1 - Narrow-track chassis; 2 - Adjustable tilting platform; 3 - Rotary adjustment platform
4 - Crank-slider injection mechanism; 5 - Guide support mechanism; 6 – Liquid-fertilizer delivery system

During operation, the injector is remotely guided into the inter-row space, and the liquid-fertilizer pipeline is connected to the pump. After automatic mode is activated, the machine moves to the preset fertilization position, where the rotary adjustment platform turns through 90 degrees to orient the injection unit perpendicular to the ridge slope (Fig. 2a). The stepper motor then drives the crank-slider mechanism, causing the injection needle to penetrate the soil to the preset depth (Fig. 2b). Once the needle reaches the target position, the solenoid valve opens, and pressurized liquid fertilizer is delivered through the needle into the soil. The needle then retracts, and the machine advances to the next position (Fig. 2c). Repetition of this sequence enables fixed-point deep placement of liquid fertilizer.

Table 1

Main technical parameters of the machine

Item	Technical parameters
Overall dimensions / mm	810 × 430 × 500
Machine mass / kg	45
Narrow-track chassis motor / N·m	0.98
Holding torque of crank drive motor / N·m	80
Driving torque of rotary platform motor / N·m	2.2
Number of injection needles	2
Injection depth / mm	100–200

Design of key components and mechanical analysis

Narrow-track chassis

To improve passability and driving stability on wet, muddy and uneven terrain, the narrow-track chassis was equipped with a four-wheel electric drive system. Compared with a conventional two-wheel-drive configuration, four-wheel drive provides greater traction and improved terrain adaptability, thereby enhancing machine stability under complex field conditions *(Jiang et al., 2025)*. As shown in Fig. 3, the chassis mainly consists of an anti-collision beam, motor reducers, drive motors, a socket plate, triangular inclined plates, waterproof plates, a frame, wheels and flanges.

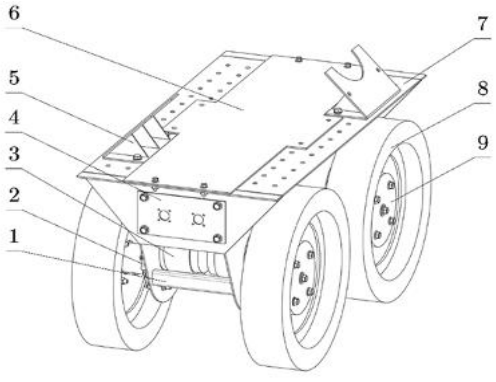

Fig. 3 – Structure of the narrow-track chassis

1 – Anti-collision beam; 2 – Motor reducer; 3 – Drive motor; 4 - Socket plate; 5 – Triangular inclined plate; 6 – Waterproof plate; 7 – Frame; 8 – Wheel; 9 – Flanges

According to China's third national land survey, farmland slopes generally range from 0 to 15 degrees *(People's Daily, 2021)*. Based on the operating conditions of tobacco fields in Guiyang County, Hunan Province, the design slope was set to 10°. The chassis was therefore required to climb a 10-degree slope steadily at 2 km·h^{-1}. A brushed DC motor was selected as the chassis power source, and its principal parameters are listed in Table 2.

Table 2

Main technical parameters of the motor

Item	Parameter
Rated power / kW	0.25
Rated torque / N·m	0.64–0.98
Rated speed / r/min	2400–3700
Maximum speed / r/min	3700
Rated current / A	13.4
Motor efficiency / %	70

Angle-adjustable injection unit

The angle-adjustable injection unit is the core component of the small self-propelled liquid-fertilizer injector, and its structure and operating parameters directly affect injection performance. As shown in Fig. 4, the unit mainly consists of an injection needle, sliding rail, crank-slider mechanism, drive motor, rotary adjustment platform and adjustable tilting platform. Needles with different lengths and diameters can be selected according to crop requirements, while the combined use of the rotary adjustment platform and adjustable tilting platform enables deep placement under different terrain and angular conditions.

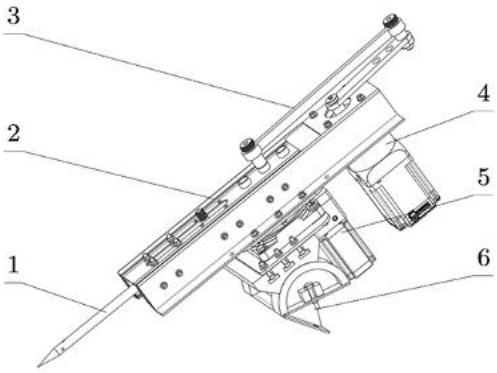

Fig. 4 - Structure of the angle-adjustable injection unit

1 - Injection needle; 2 - Sliding rail; 3 - Crank-slider injection mechanism; 4 - Drive motor; 5 - Rotary adjustment platform; 6 - Adjustable tilting platform

The injection needle directly affects fertilizer discharge through its internal flow channel and outlet geometry, particularly the number and diameter of the outlet holes. The required discharge performance was therefore evaluated through theoretical analysis and CFD simulation to provide a basis for needle design and parameter optimization. For each operating condition, the mean discharge rate of one injection needle was calculated from the injection duration and fertilizer volume as follows:

$$Q_{needle} = \frac{V}{t} \tag{1}$$

where:

Q_{needle} is the mean discharge flow rate of one injection needle (mL/s), V is *the fertilizer volume* delivered during one injection cycle (mL), and t is the injection duration (s).

Under steady-flow conditions, the discharge from each outlet hole is governed mainly by the pressure difference and effective flow area. Therefore, a theoretical discharge relation was established based on the Bernoulli equation as follows:

$$Q = C_d \bullet A \bullet \sqrt{\frac{2\triangle P}{\rho}} \tag{2}$$

where:

Q is the instantaneous flow rate through one outlet hole (m^3/s), C_d is the discharge coefficient, A is the outlet-hole area (m^2), ΔP is pressure difference between the needle inlet and outlets (Pa), and ρ is the density of the liquid fertilizer, taken as 1085 kg/m^3.

To ensure stable soil penetration of the injection needle under field conditions, the soil properties and loading characteristics were analyzed. Soil samples were collected from tobacco fields in Guiyang County, Chenzhou City, Hunan Province, China. Field measurements showed that the soil firmness ranged from 125 to 145 PSI, corresponding to approximately 0.86–1.00 MPa, indicating a relatively compact tillage layer.

During needle penetration, the soil resistance is mainly composed of cohesion, compressive resistance, frictional resistance and adhesion. These components jointly determine the total penetration resistance that must be overcome by the injection needle. Based on the force and failure characteristics of soil during penetration, the resistance model of the injection needle was established as follows *(You et al., 2017)*:

$$P = N + T + C_a + C \tag{3}$$

where: N is the compressive component of soil resistance, T is the frictional component, C_a is the adhesive component and C is the cohesive component of soil resistance.

In Fig. 5, P is the insertion force, which is equal in magnitude to the penetration resistance of the injection needle. N_1, T_1 and Ca_1 represent the normal force, frictional force and tangential adhesion acting on the needle tip, respectively, while N_2, T_2 and Ca_2 are the corresponding forces acting on the needle wall. C is the soil cohesive force.

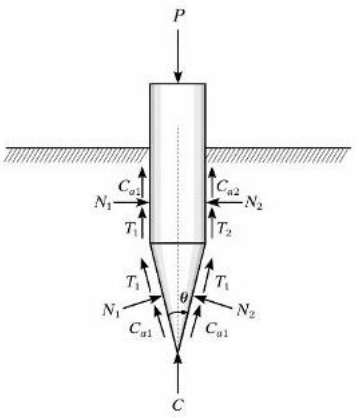

Fig. 5 - Force analysis of the injection needle during soil penetration

The penetration resistance analysis showed that the injection needle must overcome considerable soil resistance during insertion. Therefore, the injection mechanism should provide sufficient driving force while ensuring stable reciprocating motion at the required depth. In this study, an in-line crank-slider mechanism was adopted for the injection unit, as shown in Fig. 6. The mechanism has a simple structure, reliable transmission and good motion stability, and can convert the continuous rotary motion of the motor into the reciprocating linear motion of the injection needle, which is suitable for intermittent liquid-fertilizer deep placement.

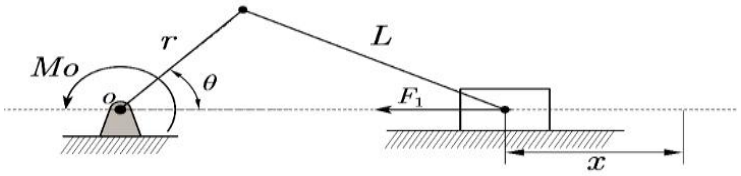

Fig. 6 - Crank-slider injection mechanism

The crank-slider injection mechanism mainly consists of a motor, reducer, crank, connecting rod, slider, and guide rail. According to the agronomic requirements and field operating conditions, the penetration depth of the injection needle was designed as 100–200 mm. To avoid interference between the needle and surface crops or mulch before soil entry, an idle-travel segment was included in the motion path. Therefore, the total slider stroke was designed to be no less than 300 mm, including 100 mm of idle travel and 100–200 mm of effective penetration depth. For the crank-slider mechanism, the slider stroke is determined by the crank radius and can be expressed as follows:

$$S = 2r \tag{4}$$

where: S is the slider stroke (mm) and r is the crank radius (mm).

According to the stroke requirement, the crank radius r was set to 160 mm, corresponding to a theoretical slider stroke of 320 mm. The connecting-rod length L was selected as 315 mm to achieve a compact layout and stable reciprocating motion.

Taking the crank center *O* as the coordinate origin, the horizontal and vertical directions were defined as the x- and y-axes, respectively. During needle penetration, the soil reaction force acting on the slider is transmitted to the crank through the connecting rod, thereby determining the torque requirement of the drive motor. The maximum penetration resistance calculated from the soil resistance model was taken as the design load. Based on the geometric constraints and static equilibrium of the crank-slider mechanism, the relationship among the required crank torque M_0, the penetration resistance F_1 and the connecting rod length L was established as follows:

$$M_0 = F_1 \bullet L \bullet \sin\theta \tag{5}$$

Control system

Due to the limited clearance of narrow ridge furrows and the uneven terrain in hilly areas, inter-row operation requires accurate positioning, stable motion, and safe control. Liquid-fertilizer deep placement also requires coordinated control of vehicle movement, injection-unit posture adjustment, needle penetration, and timed fertilizer injection. Therefore, an electronic control system based on a microcontroller unit (MCU) was developed for the small self-propelled liquid-fertilizer injector. The system forms a control chain comprising command input, signal processing, actuator driving, and status protection. As shown in Fig.7, it mainly consists of a remote controller, signal receiver, main control module, motor drivers, drive motors, solenoid valve, relays, and a 24 V battery.

Wireless remote control was adopted for human–machine interaction. Operator commands were transmitted to the MCU through the signal receiver, and the controller generated output signals according to the selected operating mode and preset logic. The travelling subsystem controlled the drive motors through motor drivers to achieve start–stop, steering, and speed regulation. The injection subsystem controlled the crank-slider drive motor and rotary stepper motor to complete posture adjustment and needle reciprocating motion. During injection, the relay actuated the solenoid valve according to the preset timing sequence, thereby enabling coordinated on–off control of liquid-fertilizer delivery.

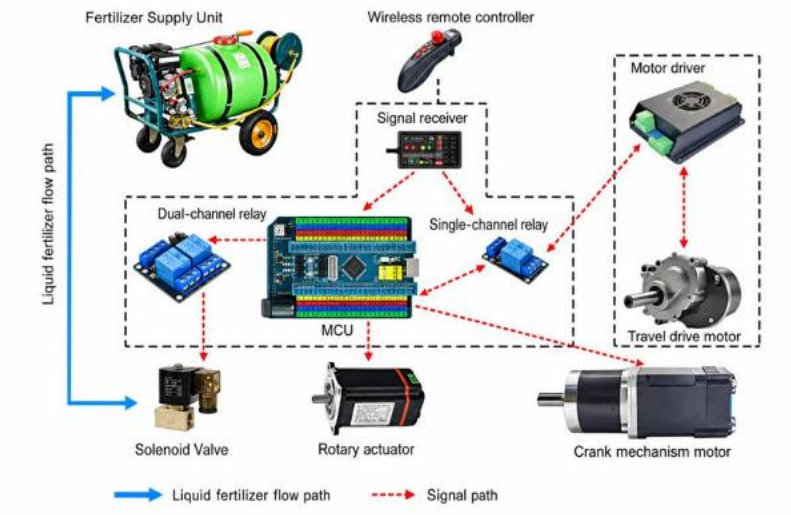

Fig. 7 - Hardware architecture of the control system

CFD simulation analysis of key components

To evaluate the discharge performance of the injection needle and quantify the effects of operating parameters on fertilizer volume per injection, a CFD model was established in ANSYS Fluent 2022 R1 *(Zawawi et al., 2018)*. The steady volumetric flow rate was obtained from the simulated outlet velocity field, and the fertilizer volume corresponding to a specified injection duration was calculated during post-processing using Eq. 7.

The liquid fertilizer was assumed to be an incompressible, single-phase Newtonian fluid uniformly supplied at the needle inlet. The internal flow was treated as steady, and gas–liquid interaction, evaporation, and particle transport were neglected. Under these assumptions, the flow was governed by the Reynolds-averaged continuity and momentum equations for an incompressible fluid.

$$\frac{\partial u}{\partial t}+(u\bullet\nabla)u=-\frac{1}{\rho}\nabla p+v\nabla^2 u \quad (6)$$

As shown in Fig.8, a three-dimensional model of the injection needle was created in SolidWorks 2021 and imported into ANSYS SpaceClaim and DesignModeler for geometry cleanup and internal flow-domain extraction. The computational domain was discretized using polyhedral cells in Fluent Meshing, with local refinement applied at the inlet and outlet-hole regions to resolve the relatively large velocity gradients near these boundaries.

A three-level mesh-independence test was conducted to assess the influence of mesh resolution on the numerical results. The four-outlet injection-needle model was evaluated at an inlet gauge pressure of 0.4 MPa, with all outlets maintained at 1 atm. Global mesh refinement was applied throughout the computational domain, while additional local refinement was imposed at the inlet and outlet regions to better resolve the flow gradients near these boundaries. The total volumetric flow rate through the four outlet holes was selected as the monitoring parameter. Except for the global and local mesh sizes and the resulting cell numbers, the geometry, fluid properties, boundary conditions, turbulence model, numerical schemes, and convergence criteria were kept unchanged. Therefore, differences in the calculated outlet flow rate were attributed solely to mesh refinement.

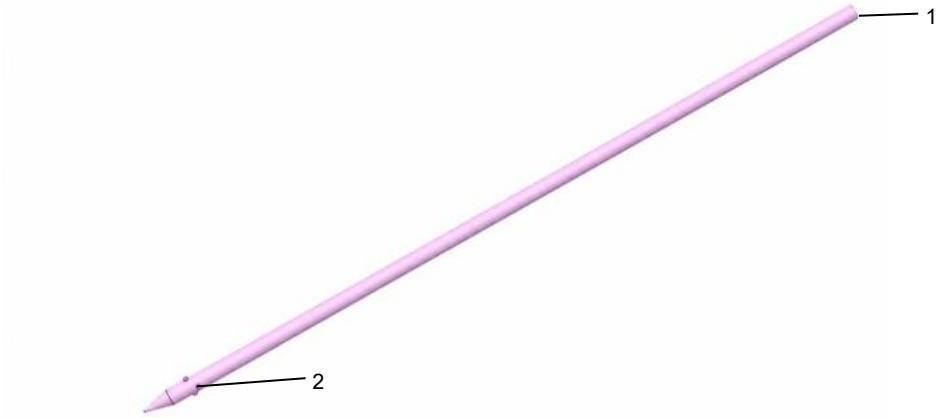

Fig. 8 - Three-dimensional model of the injection-needle flow domain

1 - inlet; 2 - outlet

Table 3

Mesh-independence assessment for the injection-needle internal-flow model

Mesh level	Global mesh size / mm	Local mesh size at the inlet and outlets / mm	Number of cells	Total outlet flow rate / (mL•s^{-1})
Coarse	0.60	0.07	550548	492.36
Medium	0.45	0.05	1565727	520.20
Fine	0.30	0.03	3495430	522.86

The total outlet flow rate increased from 492.36 mL·s-1 for the coarse mesh to 520.20 and 522.86 mL·s^{-1} for the medium and fine meshes, respectively. The relative difference between successive mesh levels decreased from 5.35% for the coarse-to-medium refinement to only 0.51% for the medium-to-fine refinement, demonstrating that further mesh refinement had a negligible influence on the predicted discharge performance. Accordingly, the medium mesh, with a global mesh size of 0.45 mm and a local mesh size of 0.05 mm at the inlet and outlet regions, was selected for subsequent simulations to achieve an appropriate balance between numerical accuracy and computational cost. The selected mesh comprised 1565727 polyhedral cells and 7322916 nodes.

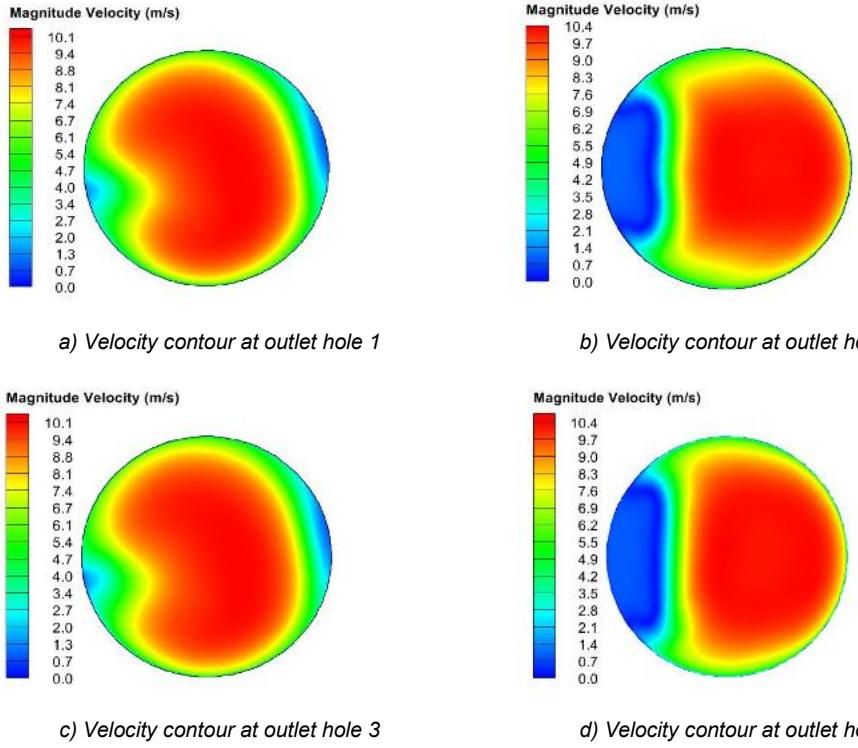
The principal boundary conditions, fluid properties, and numerical settings used in the simulations are summarized in Table 4. In the Fluent post-processing stage, the fluid velocity at the outlet holes was used to calculate the volume as follows:

$$V = Q_v \bullet t = A \bullet v \bullet t \quad (7)$$

where: Q_v is the volumetric flow rate (m^3/s), A is the cross-sectional area through which fluid passes (m^2) and v is the fluid average velocity (m/s).

Table 4

Boundary conditions and numerical settings used in the CFD simulations



Item	Setting
Mesh	Polyhedral cells, global: 0.45 mm, inlet and outlet: 0.05 mm
Solver	Pressure-based, steady-state
Near-wall treatment	Standard wall functions
Turbulence model	Realizable *k-ε*
Pressure–velocity coupling	Coupled algorithm
Boundary conditions	Inlet: 0.2 - 0.6 MPa, outlet: 1 atm, no-slip walls
Fluid properties	ρ=1085 kg/m³, μ=1.05 × 10^{-3} Pa·s *(Zhang et al., 2018)*
Initialization	Standard initialization
Convergence criterion	Scaled residuals < 1 × 10^{-6}

A three-factor, three-level Box–Behnken design was generated using Design-Expert 13. Fertilizer volume per injection (Y_1) was taken as the evaluation index, while injection duration (X_1), injection pressure (X_2), and outlet-hole number (X_3) were selected as experimental factors. The factors and levels are listed in Table 5. In addition, velocity contours at the outlet holes under different working conditions were extracted to characterize the flow-field distribution in the outlet region. As an example, Fig. 9 shows the velocity contours obtained at an inlet pressure of 0.2 MPa with four outlet holes.

Table 5

Factors and levels for Box–Behnken design

Levels	Injection duration X_1 / (s)	Inlet pressure X_2 / (MPa)	Outlet-hole number X_3
-1	1	0.2	4
0	1.5	0.4	5
1	2	0.6	6

16	1.5	0.4	5	848.2
17	1.5	0.2	4	192.3

Design-Expert 13 was used to fit a quadratic polynomial model to Y_1 and perform analysis of variance. Injection duration (X_1), inlet pressure (X_2), and the interactions X_1X_2 and X_2X_3 had highly significant effects on fertilizer volume per injection, while the quadratic term X_2^2 was significant. The remaining terms were not significant, as shown in Table 7.

Table 7

ANOVA results for the fitted regression model of fertilizer volume per injection

Source	Sum of Squares	Df	Mean Square	F-value	*p*-value
Model	2.60E+06	9	2.89E+05	235.18	< 0.0001**

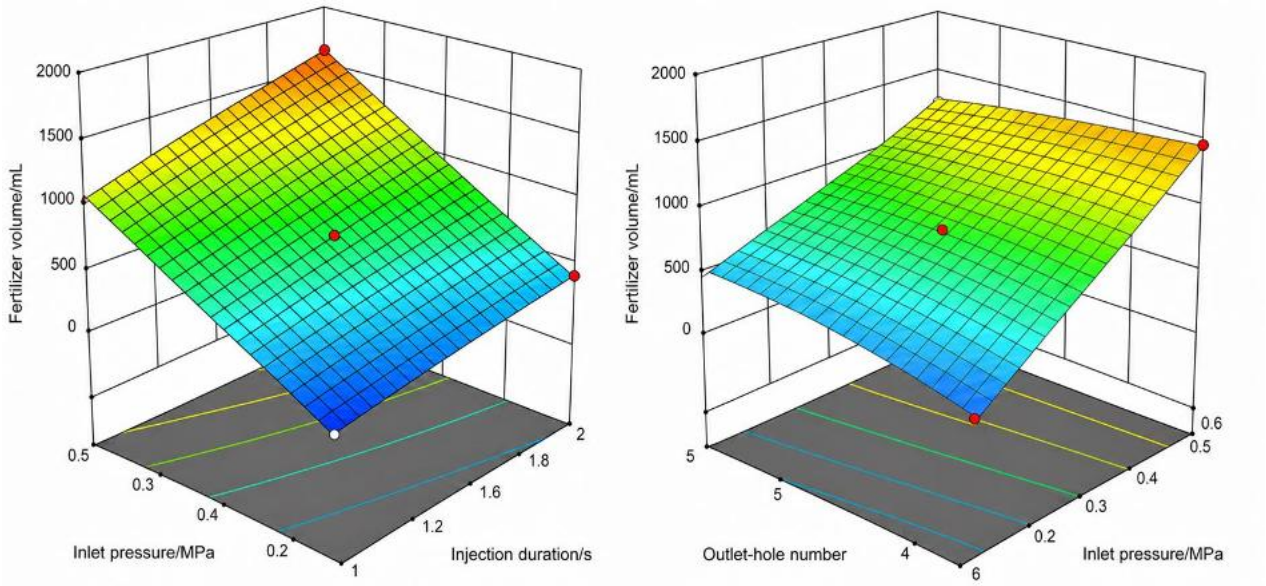
X_1^2	419.37	1	419.37	0.3418	0.5771
X_2^2	7112.46	1	7112.46	5.8	0.0469*
X_3^2	5388.84	1	5388.84	4.39	0.0743
Residual	8588.75	7	1226.96		
Lack of fit	3790.85	3	1263.62	1.05	0.4611
Pure error	4797.91	4	1199.48		
Cor total	2.61E+06	16			

Note: * indicates significance at $p < 0.05$; ** indicates significance at $p < 0.01$.

From the analysis of variance of the regression model, the second-order response regression equation for Y_1 was obtained as follows:

$$Y_1 = 816.18 + 201.19X_1 + 522.87X_2 + 10.01X_3 + 66.95X_1X_2 - 22.13X_1X_3 - 115.2X_2X_3 - 9.98X_1^2 + 41.1X_2^2 - 35.77X_3^2 \quad (8)$$



The model was highly significant, with a p-value below 0.01, an R^2 of 0.9967, an R^2_{adj} of 0.9925 and a CV of 4.30%, indicating an adequate fit for response-surface analysis and parameter optimization.

Response surface analysis

As shown in Table 7, the interaction terms X_1X_2 and X_2X_3 significantly affected fertilizer volume per injection, whereas X_1X_3 was not significant. Because X_2X_3 had the larger F-value, the response-surface analysis focused on the X_1X_2 and X_2X_3 interactions.

Figure 10a shows the interaction between injection duration and inlet pressure at a fixed outlet-hole number. Fertilizer volume per injection increased as both duration and pressure increased. The highest response occurred at the upper levels of both factors, whereas the lowest response occurred at the lower levels.

Figure 10b shows the interaction between inlet pressure and outlet-hole number at a fixed injection duration. Fertilizer volume per injection generally increased with inlet pressure, while the effect of outlet-hole number depended on the pressure level, consistent with the significant X_2X_3 interaction in Table 7.

a) Response surface of the effects of X_1X_2 on Y_1 *b) Response surface of the effects of X_2X_3 on Y_1*

Fig. 10 - Interactive effects of the experimental factors on the evaluation indicator

For tobacco transplanting, the target fertilizer volume per injection was set at 700 mL, while injection duration was minimized to improve operating efficiency. Numerical optimization was performed in Design-Expert 13, with Y_1 set to a target value of 700 mL, X_1 minimized and X_2 and X_3 constrained within their respective design ranges. The resulting preferred parameter combination consisted of an injection duration of 1 s, an inlet pressure of 0.45 MPa, and six outlet holes.

Field test

To evaluate the field feasibility of the optimized parameter combination and compare the measured response with the model prediction, a field validation test was conducted in March 2025 at the Fangyuan Tobacco Research Base in Guiyang County, Chenzhou City, Hunan Province, China. The test object was flue-cured tobacco at the transplanting stage, as shown in Fig. 11. The test was carried out according to GB/T 43908-2024 Water and Fertilizer Integrated Equipment *(SAC/TC 201, 2024)*. During the test, the ambient temperature was 19.2–25.3°C, soil moisture was 24.3%–27.9%, soil pH was 6.05–6.23, and soil firmness was 0.827–0.965 MPa.

One tobacco row was randomly selected for field validation. The plant spacing, ridge-top width, ridge-bottom width, and ridge height were 450, 450, 750, and 300 mm, respectively. The injection direction was perpendicular to the ridge surface, and the injection depth was fixed at 150 mm.

The optimized settings consisted of an injection duration of 1 s, an inlet pressure of 0.45 MPa, and six outlet holes. Five independent injections were performed at spatially separated positions along the selected row. Fertilizer volume per injection was measured using a flowmeter, and the mean value was compared with the model prediction.

Fig. 11 - Field test

The measured fertilizer volume per injection was 675.4 mL, compared with the model prediction of 700 mL, corresponding to a relative error of 3.51%. The agreement between measured and predicted values verified the predictive accuracy of the response surface model under the tested field conditions.

DISCUSSION

Effects of operating parameters and model applicability

The dominant effect of inlet pressure was consistent with the Bernoulli-based discharge relation, according to which the outlet flow rate increases approximately with the square root of the pressure difference. At a given steady volumetric flow rate, fertilizer volume per injection increased approximately linearly with injection duration. Although outlet-hole number alone was not significant within the investigated range, its interaction with inlet pressure was highly significant. Because the diameter of each outlet hole was kept constant, increasing the number of holes increased the total discharge area. However, it also redistributed the internal pressure and altered the local hydraulic losses among the outlets. Therefore, the effect of outlet-hole number cannot be evaluated independently of inlet pressure. This result demonstrates the importance of multi-factor optimization rather than simply selecting the maximum level of each operating parameter.

The relative difference of 3.51% between the predicted and measured fertilizer volumes was probably associated with the response delay of the solenoid valve, transient pressure fluctuations during valve opening and closing, and pressure losses in the pipeline and connectors. These dynamic effects were simplified in the steady-state CFD model. Therefore, the present model provided an acceptable estimate of average discharge under the tested operating condition, but it did not fully characterize the transient start–stop injection process. Future work should incorporate transient CFD analysis and synchronized measurements of pressure and flow rate to improve the description of the dynamic fertilizer-delivery process.

Comparison with previously reported liquid-fertilizer applicators

Previous liquid-fertilizer applicators have mainly focused on soil-punching mechanisms, site-specific fertilizer dosing, injection-trajectory optimization, and subsurface placement under particular cropping systems. The soil-punching system developed by da Silva et al. *(2017)* maintained the injection needle in a nearly vertical orientation to achieve fixed-point application, whereas da Silva and Magalhães *(2019)* synchronized soil punching and fertilizer delivery for site-specific dosing. The mechanisms reported by Wang et al. *(2016, 2017, 2018)* improved punching trajectories and operating efficiency, although vibration remained a concern under high-frequency operation *(Feng et al., 2017; Liu et al., 2016)*. In comparison, the present injector was specifically configured for inter-row operation in hilly and fragmented farmland by integrating a 45 kg narrow-track self-propelled chassis, a rotary–tilting posture-adjustment platform, and a crank-slider injection mechanism.

Table 8

Comparison of the proposed injector with previously reported liquid-fertilizer applicators

Study	Application mode	Primary contribution	Application context
da Silva et al. *(2017)*	Soil punching	Fixed-point placement	Sugarcane fields
da Silva and Magalhães *(2019)*	Site-specific injection	Variable-rate dosing	Site-specific management
Wang et al. *(2016, 2017, 2018)*	Mechanical punching	Trajectory optimization	Mechanized field operation
Zhou et al. *(2023)*	Targeted deep application	Delivery control	Field crop production
Present study	Self-propelled point injection	Posture-adjustable placement	Hilly and small plots

Overall, the comparison shows that the principal distinction of the proposed injector lies in the integration of lightweight self-propelled mobility, posture adjustment, and controllable point injection for hilly and fragmented farmland. Unlike previous studies that mainly emphasized punching trajectories, dosing control, or application performance under specific cropping systems, the present design gives greater consideration to machine maneuverability and injection orientation. However, because the reported systems were evaluated using different crops, operating conditions, and performance indicators, Table 8 provides a qualitative comparison rather than a direct performance ranking.

Limitations and generalizability

Field validation was conducted at a single tobacco research site under a limited range of soil moisture, pH, and penetration resistance. The results therefore demonstrate feasibility under the reported conditions but should not be generalized directly to sandy, highly cohesive, stony, or waterlogged soils. Soil texture, moisture content, bulk density, and compaction may affect needle penetration, liquid distribution in soil, and machine traction. Multi-site experiments covering different soil types, slope gradients, and moisture conditions are required to establish broader applicability. Future studies should also evaluate long-term durability, energy consumption, leakage, operational reliability, and crop-response benefits.

CONCLUSIONS

(1) A lightweight self-propelled liquid-fertilizer injector integrating a four-wheel-drive narrow-track chassis, a rotary–tilting posture-adjustment platform, and a crank-slider injection mechanism was developed for hilly and small-plot farmland. The compact configuration enabled controllable needle penetration and timed point injection while supporting inter-row maneuverability and terrain adaptation.

(2) The combined CFD-based discharge analysis and Box–Behnken response surface optimization quantified the individual and interactive effects of injection duration, inlet pressure, and outlet-hole number on fertilizer volume per injection. Inlet pressure and injection duration were identified as the dominant factors. Field validation under the tested condition showed satisfactory agreement between the predicted and measured fertilizer volumes.

(3) The developed injector provides an engineering reference for lightweight precision deep-placement equipment in fragmented hilly farmland and may support the development of similar systems for tobacco and other row crops. Because validation was limited to one site and one soil condition, further studies should evaluate machine performance under different soil textures, moisture contents, and slope conditions.

ACKNOWLEDGEMENT

This research was funded by the Chenzhou Tobacco Company of Hunan Province under the project Development of a Lightweight Tobacco Ridging Machine for the Nanling Hilly Region (CZYC2022JS05).

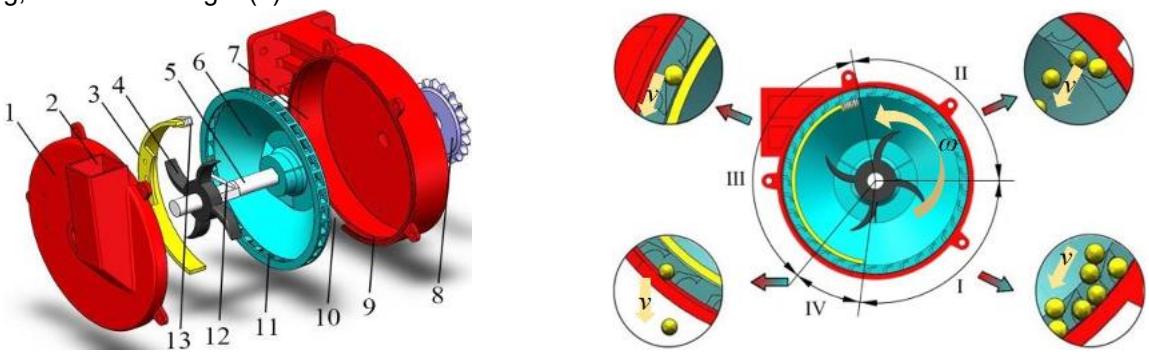
Keywords: *Discrete element, precision metering device, Model, Test, Vibration*

ABSTRACT
To address the deterioration in the seed-metering performance of mechanical seed-metering devices caused by vibration during field operation, a conical deflector-type seed meter was selected as the research object. A vibration-system model of the seed meter under field operating conditions was established, and the principal operating parameters affecting seed-metering performance were determined. The seed-metering process under vibration was then simulated using the discrete element method to investigate changes in the working angle of the seed population and its dynamic characteristics. In addition, vibration bench tests were conducted to evaluate the effects of vibration on seed-metering performance. The main results were as follows: (1) seed-filling efficiency, seed-clearing efficiency, and horizontal seed-throwing displacement were significantly affected by operating speed, vibration acceleration, and vibration frequency; (2) the adverse effect of vibration on seed-metering performance increased with increasing vibration acceleration but decreased with increasing operating speed or vibration frequency; and (3) when the vibration acceleration was below 0.63 g and the vibration frequency exceeded 4.28 Hz, the qualified-seed rate was greater than 95%, and the coefficient of variation of seed spacing was less than 20%. This study clarified the effects of vibration parameters on seed-metering performance and identified appropriate operating ranges, thereby providing theoretical support for the vibration-resistant design and optimization of mechanical seed meters.

ABSTRACT
针对机械式排种器在田间作业过程中易受振动影响导致排种性能下降的问题，选取锥面导流式排种器为研究对象，建立了排种器田间作业振动系统模型，推导出对排种性能产生影响的主要工况参数。运用离散元法对排种器振动工况下工作过程进行仿真试验，研究种群工作角度和动力学特性的变化规律，并通过振动台架试验测试了排种性能受到的影响。结果表明：1）排种器的充、清种效率及水平方向投种位移均受到作业速度、振动加速度和振动频率的显著影响；2）排种性能受到的负面影响随振动加速度的提升而增大，随作业速度和振动频率的提升而减小；3）当振动加速度小于 0.63 ，振动频率大于 4.28H 时，排种器的合格率高于 95%，粒距均匀性变异系数低于 20%。研究阐明了振动参数对排种性能的影响规律及其合理范围，为机械式排种器的抗振设计改进提供了理论支撑。

INTRODUCTION
High-speed precision seeding technology has become the development direction and trend of modern seeding technology due to its outstanding advantages, such as cost-saving, efficiency enhancement, and wide application (*Cujbescu et al., 2021; Emrah et al., 2021; Cay A. et al., 2018; Hijam J.S. et al., 2016*). As one of the carriers to realize high-speed and precision seeding technology, the mechanical precision metering device is still widely used in many countries because of its simple structure, low cost and easy maintenance (*Ibrahim et al., 2022; Shen et al., 2021; Karayel et al., 2022*).

By virtue of its inclined conical surface that guides seeds into the compound holes with reduced orientation requirements and randomness, the conical deflector-type seed-metering device enhances filling efficiency and thus qualifies as a high-speed precision mechanical seed-metering device for soybean planting.



Through the design and optimization of its structure, the optimal structure of the seed-metering device is obtained, and verifies its excellent seed metering performance under the high-speed operation conditions through indoor bench test. Its qualified rate is higher than 97% when the operation speed is 6-12km/h (*Dong, 2021*). At present, studies had shown that the operation of seed-metering device suffers vibrations loads when the planter was working at high speed in the field (*Ku et al., 2021; Muhammad et al., 2021*). In this case, the working performance of the seed-metering device will be seriously affected, which may result in the deterioration of its working quality (*Zhang et al., 2016; Hao et al., 2017*). In order to improve the field operation performance of the planter, it is necessary to further research the influence of vibration on seed-metering device.

However, most studies on seed-metering devices have focused primarily on structural optimization, the effects of structural parameters on seed motion, and seed-metering performance under ideal laboratory conditions *(Chen et al., 2021; Liu et al., 2021; Zhao et al., 2026)*. By contrast, the motion state of seeds and their interaction with the seed-pickup mechanism under high-speed and vibrational operating conditions remain insufficiently understood. Consequently, the effects of vibration on the seed-metering process and performance have not yet been clearly established. Therefore, this study investigates the variation in seed-group motion and seed-metering performance under vibration.

MATERIALS AND METHODS

Conical deflector-type seed-metering device

The conical deflector-type seed-metering device mainly consisted of a seed-metering disc, rotating shaft, deflector, seed baffle, housing, and seed-feed tube, as shown in Fig. 1(a). The seed-metering disc, deflector, and rotating shaft were assembled as an integrated rotating unit driven by an external power source. The operating cycle comprised four stages: I, seed filling; II, seed clearing; III, seed carrying; and IV, seed throwing, as shown in Fig. 1(b).

Vibration-system model of the seed-metering device

During field operation, the planter is subjected primarily to random vertical vibration loads *(Liu, 2016; Huang, 2018)*. Assuming that the excitation caused by tillage-surface unevenness can be represented by a sinusoidal waveform and that the planter remains in continuous contact with the ground during operation, the spring stiffness k and viscous damping coefficient c were treated as linear parameters *(Gao et al., 2021)*. Based on these assumptions, the field vibration model of the seed-metering device was simplified, as shown in Fig.2.

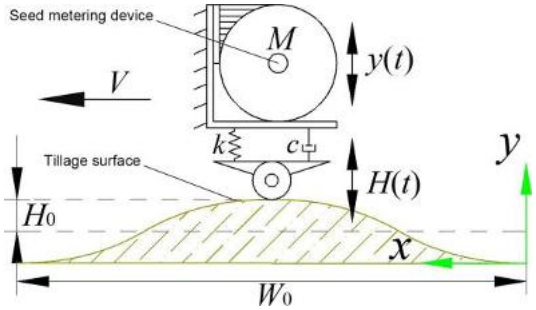

Fig. 2 - Field vibration-system model of the seed-metering device

As shown in Fig.2, the instantaneous displacement excitation in the vertical direction of the planter frame is expressed as follows:

$$H(t)=H_0 \sin \omega_0 t \tag{1}$$

where: ω_0 is the frequency of displacement excitation in the vertical direction (Hz), H_0 is the undulation amplitude of the cross section of the tillage surface compared with the reference plane (m).

Based on Eq. (1) the second derivative can be obtained, the acceleration excitation in the vertical direction of the planter frame is as follows:

$$H''(t) = \left| \frac{d^2 H(t)}{dt^2} \right| = H_0 \omega_0^2 \sin \omega_0 t \tag{2}$$

According to Eq. (2), the dynamic equilibrium equation of the vibration system of the seed-metering device is as follows:

$$M \frac{d^2 y(t)}{dt^2} + c \frac{dy(t)}{dt} + ky = MH_0 \omega_0^2 \sin \omega_0 t^2 \tag{3}$$

where: M is mass of seed metering system (kg).

From Eq. (3), the following expression is obtained:

$$\frac{d^2 y(t)}{dt^2} + 2\zeta \omega_n \frac{dy(t)}{dt} + \omega_n^2 y = \omega_n^2 H_0 \omega_0^2 \sin \omega_0 t \tag{4}$$

where: ω_n is natural frequency of seed metering system (Hz), ζ is the viscous damping ratio of the system.

By solving the steady-state response equation of sinusoidal excitation with frequency ω (4), a specific solution Eq. (5) is obtained, where the amplitude A and phase φ are given by the standard forced vibration amplitude / phase expression.

$$\begin{cases} \omega_0 = 2\pi V / W_0 \\ y(t) = A \sin(\omega_0 t + \varphi_0) \\ A = \dfrac{H_0 \omega_0^2}{\omega_n^2 \sqrt{(1 - \dfrac{\omega_0^2}{\omega_n^2})^2 + (2\zeta \dfrac{\omega_0}{\omega_n})^2}} \\ \varphi_0 = \arctan \dfrac{2\zeta \omega_0 \cdot \omega_n}{\omega_n^2 - \omega_0^2} \end{cases} \tag{5}$$

where: A is system displacement response amplitude (m), and φ_0 is phase difference of system displacement response (rad), V is operating speed of planter (km/h), and W_0 is wavelength of tillage surface section (m).

From Eq. (5):

$$\begin{cases} V_z(t) = \left| \dfrac{dy(t)}{dt} \right| = A\omega_0 \sin(\omega_0 t + \varphi_0) \\ a_z(t) = \left| \dfrac{d^2 y(t)}{dt^2} \right| = A\omega_0^2 \sin(\omega_0 t + \varphi_0) \end{cases} \tag{6}$$

where: $V_z(t)$ is the inertial velocity generated by vibration (m/s), and $a_z(t)$ is the inertial acceleration generated by vibration (m/s^2).

From Eq. (5) and (6), it can be concluded that the seed-metering device was mainly affected by vibration acceleration, vibration frequency and operating speed in the field working environment.

Simulation test

Simulation model and parameter setting

During the vibration process of the seed-metering device, the particle motion characteristics cannot be directly measured. The discrete element method is one of the methods to observe the seed motion characteristics during the vibration process. Therefore, the discrete element method is used in this study. To analyze the influence of vibration condition parameters on different working processes of seed-metering device, a 3D model of seed-metering device was established by using CAD software, and imported into EDEM software for simulation (Fig. 3).

The physical parameters and interaction parameters among the simulation model, the seed model and the material were consistent with the result of the previous research (*Dong, 2021*).

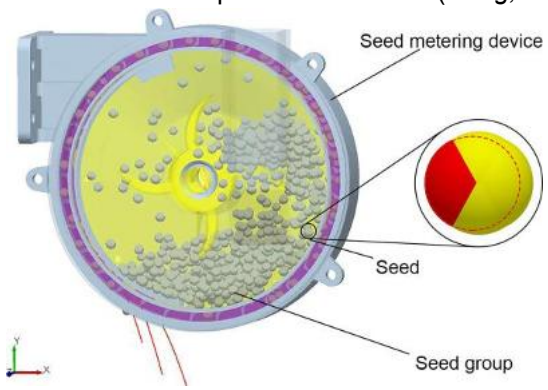

Fig. 3 - Simulation model of seed-metering device

Test method

According to the preliminary experimental results, the simulation was carried out at the speed of 6, 8, 10 and 12km/h (8km/h and above were classified as high-speed operation conditions), and the corresponding rotation speeds were 31.6, 40.8, 50.5, and 60.6r/min, respectively. The parameter value range of acceleration and frequency under vibration conditions were selected (*Wang et al., 2019; Zhang et al., 2016; Liu et al., 2016*). A total of 300 particles were generated in the simulation. The total simulation time was 3 s, and the data were recorded every 0.01 s.

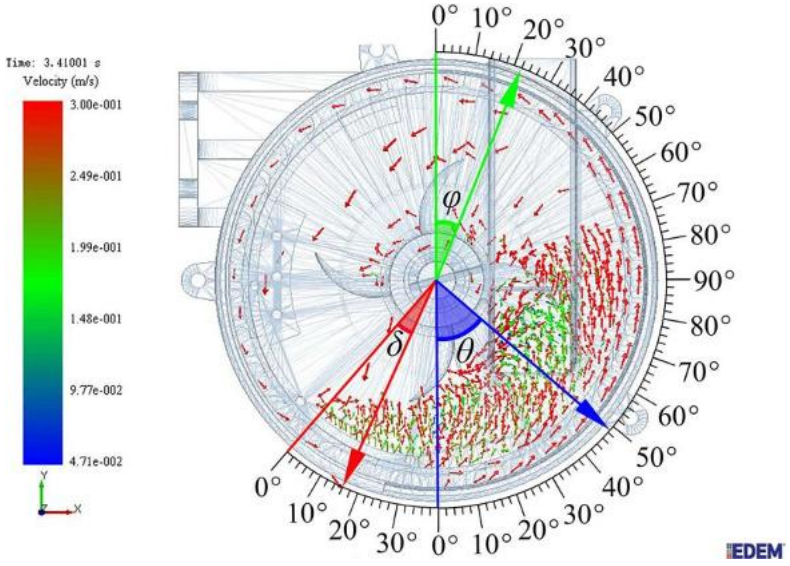
Table 1

Simulation condition parameters

Working parameters	Numerical value	Fixed value
Operating speed [km·h^{-1}]	6; 8; 10; 12	10
Vibration acceleration [*g*]	0.3; 0.5; 0.7; 0.9;1.1	0.7
Vibration frequency [Hz]	3; 5; 7; 9; 11	7

The operating process of the seed-metering device under different vibration conditions was simulated using DEM software, and the velocity vectors of the seed particles were obtained, as shown in Fig.4.

In this study, a smaller seed-filling angle, θ (defined as the angle between the vertical direction and the position at which a seed is about to enter the compound hole) indicated higher seed-filling efficiency. Similarly, a larger seed-clearing angle, φ (defined as the angle between the vertical direction and the position at which the seed to be cleared leaves the compound hole) indicated higher seed-clearing efficiency. A larger seed-throwing angle, δ (defined as the angle between the position at which the seed completely leaves the compound hole and the edge of the seed outlet) indicated a greater horizontal seed-throwing distance.



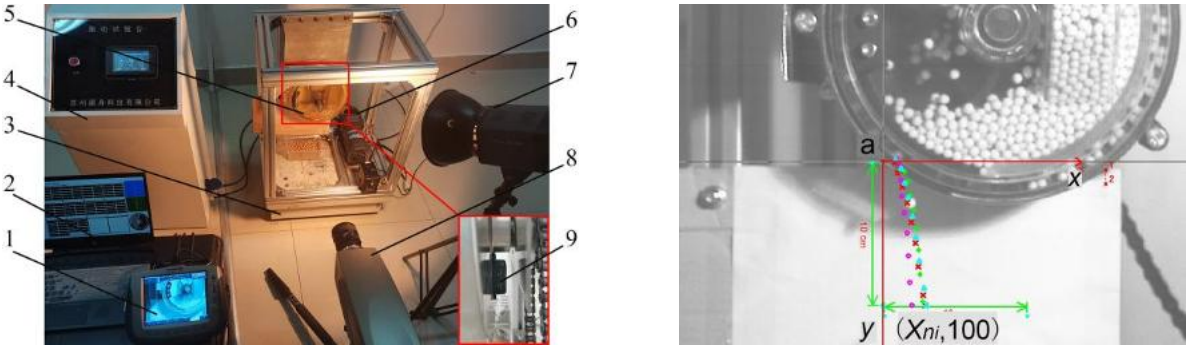


Fig. 4 - Working-angle distributions of seed particles under vibration

Vibration bench test

Test condition

To investigate the effects of vibration conditions on seed-metering performance, a vibration test bench was established in the Agricultural Machinery Laboratory at Northwest A&F University.

The vibration test bench consisted of a conical deflector-type seed-metering device, a mounting frame, a speed-control system, a vibration-excitation system, and an image-acquisition system, as shown in Fig. 5. The speed-control system comprised a 120 W variable-speed motor with an output torque of 8.5 N·m, a planetary gear reducer with a reduction ratio of 1:15, and a motor controller. The vibration-excitation system comprised a variable-frequency electromagnetic vibration table, a vibration-signal controller with a sinusoidal frequency range of 1-2000 Hz, and a vibration sensor equipped with Bluetooth 5.0 wireless transmission, a triaxial acceleration range of ±16 g, a frequency range of 0.2-200 Hz, and an output error not exceeding 1%. The image-acquisition system comprised a high-speed camera (Olympus i-SPEED 3), a computer running i-SPEED Suite software, a spatial grid panel, and a marker pen. Soybean seeds of the cultivar 'Suinong 26' were used in the tests. The thousand-seed mass was 0.21 kg, and the seed density was 1.267 g/cm^3.

Test method

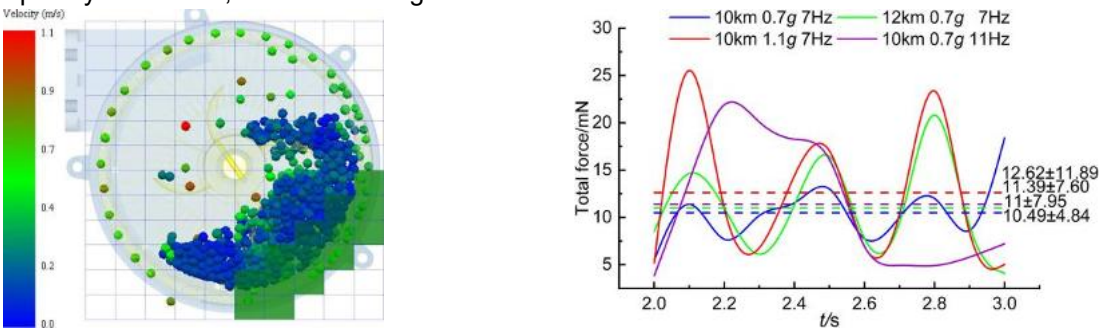
To evaluate the effects of the selected factors on seed-metering performance, a three-factor, three-level Box-Behnken design was employed. The seed-metering performance under different combinations of factor levels was measured using the vibration test bench for the seed-metering device. The factor levels were selected based on the significance of each factor observed in the simulation analysis of the different operating stages of the seed-metering device, as shown in Table 2. Each experimental treatment was repeated three times, and the mean value was used for analysis.

Table 2

Coded levels of the test factors

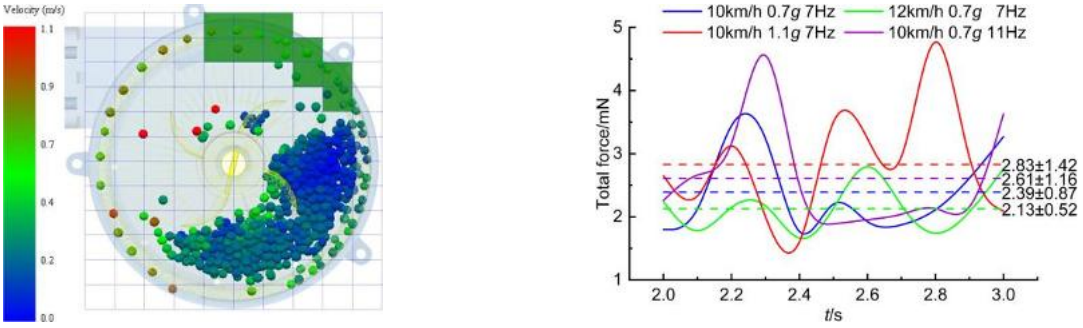
Level	Test factors		
	Rotational speed X1 [r·min^{-1}]	Vibration acceleration [*g*]	Vibration frequency [Hz]
-1	31.6	0.7	6
0	46.1	1.1	9
1	60.6	1.5	12

The response variables were the qualified-seed rate, Y_1, and the coefficient of variation of seed spacing, Y_2, as defined in Eq. (7). In the high-speed image-processing software, point "a" at the seed outlet was set as the coordinate origin, and the theoretical seed-throwing height was set to 100 mm. A seed i was classified as qualified when its spacing, X_i, ranged from 5 to 15 cm. The values of Y_1 and Y_2 were then calculated accordingly *(Shen et al., 2021)*.



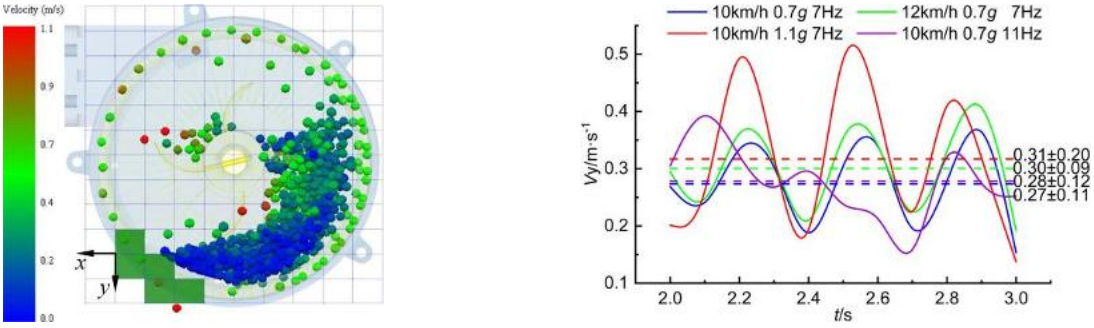
$$\begin{cases} Y_1 = \dfrac{N_1}{N} \times 100\% \\ X_i = X_{Ni} - X_{Ni\text{-}1} + S \\ \bar{X} = \dfrac{1}{N} \sum_{i=1}^{N+1} X_i \\ Y_2 = \dfrac{\sqrt{\dfrac{1}{N} \sum_{i=1}^{N} \left(X_i - \bar{X} \right)^2}}{\bar{X}} \times 100\% \end{cases} \quad (7)$$

where: Y_1 is the qualified-seed rate (%), $\bar{X}$ is the mean seed spacing (mm), Y_2 is the coefficient of variation of seed spacing (%), N_1 is the number of qualified seeds, N is the total number of seeds included in the statistical analysis, X_{Ni} is the abscissa of the i-th recorded seed, $X_{Ni\text{-}1}$ is the abscissa of the preceding recorded seed, S is the theoretical seed spacing, equal to 100 mm, and X_i is seed spacing of qualified seeds (mm).



RESULTS AND DISCUSSION

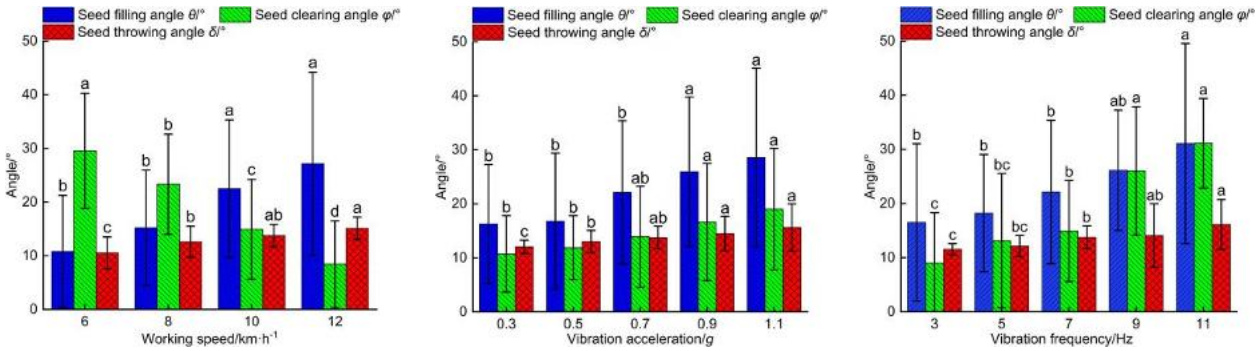
Simulation results



During post-processing of the simulation data, the external forces acting on the seeds in the seed-filling and seed-clearing zones and the downward vertical velocities of the seeds in the seed-throwing zone were statistically analyzed over the 2–3 s interval, as shown in Fig.6. For each simulation run, the seed-filling angle θ, seed-clearing angle φ, and seed-throwing angle δ were recorded from 1 to 5 s at intervals of 0.05 s. At each sampling time, the maximum value of each angle was selected, and the corresponding mean values were subsequently calculated, as shown in Fig.7.

a. Total force acting on the seed group in the seed-filling zone

b. Total force acting on the seed group in the seed-clearing zone



c. Vertical velocity of the seed group in the seed-throwing zone

Fig. 6 - Effects of vibration on seed-group dynamics

As vibration acceleration, vibration frequency, or operating speed increased, the fluctuations in the resultant force acting on the seeds in the seed-filling zone became more pronounced, and the seed-filling zone expanded, as shown in Fig. 6(a). Meanwhile, the mean seed-filling angle, θ, increased, as shown in Fig.7.

Increasing the vibration acceleration or vibration frequency intensified the fluctuations in the resultant force acting on the seeds in the seed-clearing zone and expanded this zone, as shown in Fig. 6(b). Correspondingly, the mean seed-clearing angle, φ, increased, as shown in Fig. 7(b) and (c), indicating improved seed-clearing efficiency. By contrast, increasing the operating speed reduced the force fluctuations and narrowed the seed-clearing zone. The mean value of φ also decreased, as shown in Fig. 7(a), indicating a reduction in seed-clearing efficiency. The vertical seed velocity, Vy, generally increased with operating speed, as shown in Fig. 6(c). The horizontal velocity, Vx, also increased, resulting in a larger mean seed-throwing angle, δ, and greater horizontal seed-throwing displacement, as shown in Fig. 7.

Overall, seed-filling efficiency, seed-clearing efficiency, and horizontal seed-throwing displacement were significantly affected by operating speed, vibration acceleration, and vibration frequency. Increasing any of these three factors reduced seed-filling efficiency and increased horizontal seed-throwing displacement. However, their effects on seed-clearing efficiency differed: increasing vibration acceleration or vibration frequency improved seed-clearing efficiency, whereas increasing operating speed reduced it.

Bench test result

Establishment of regression model

The experimental results presented in Table 3 were subjected to analysis of variance (ANOVA), and the results are summarized in Table 4. As shown in Table 4, the model *P*-values for both Y_1 and Y_2 were less than 0.01, whereas the lack-of-fit *P*-values were greater than 0.05. These results indicate that the regression models were highly significant and that the lack of fit was not significant. The coded regression equations relating Y_1 and Y_2 to the test factors were established as follows:

$$Y_1 = 73.17 + 11.20X_1 - 18.68X_2 + 10.99X_3 + 6.22X_1X_2 - 4.16X_1X_3 + 9.09X_2X_3 - 1.62{X_1}^2 + 4.76{X_2}^2 + 2.49{X_3}^2 \quad (8)$$

$$Y_2 = 24.01 - 3.81X_1 + 6.29X_2 - 1.09X_3 - 4.44X_1X_2 + 3.11X_1X_3 - 0.89X_2X_3 - 0.87{X_1}^2 - 0.19{X_2}^2 + 0.36{X_3}^2 \quad (9)$$

Based on the *F*-values of the individual factors, their effects on both Y_1 and Y_2 were ranked in descending order as follows: vibration acceleration, operating speed, and vibration frequency.

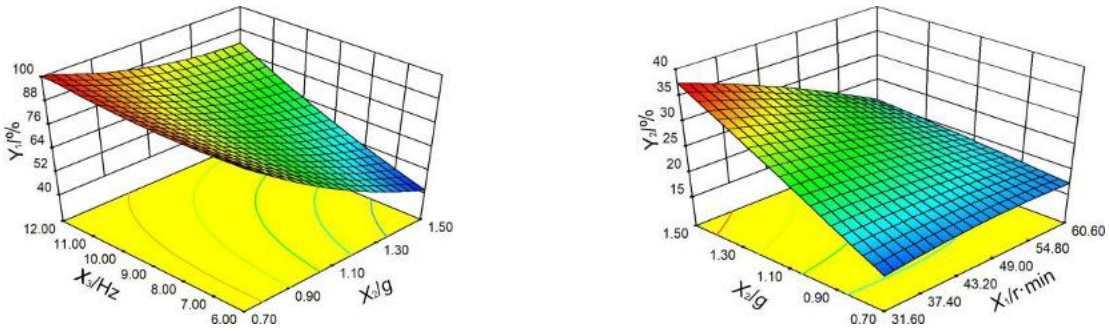
Response surface analysis



Design-Expert software was used to generate response surfaces illustrating the interactions between pairs of factors, as shown in Fig.8. The qualified-seed rate decreased with increasing vibration acceleration, although this decline became less pronounced as rotational speed increased, as shown in Fig.8(a). The qualified-seed rate increased with increasing vibration frequency, but the rate of increase decreased as rotational speed increased, as shown in Fig. 8(b). Similarly, the qualified-seed rate decreased with increasing vibration acceleration, while the magnitude of this decrease was reduced at higher vibration frequencies, as shown in Fig.8(c). The coefficient of variation of seed spacing increased with increasing vibration acceleration, although this increase became less pronounced as rotational speed increased, as shown in Fig.8(d).

a. $Y_1 = f(X_1, X_2, 9)$

b. $Y_1 = f(X_1, 1.1, X_3)$

c. $Y_1=f(46.9, X_2, X_3)$ *d.* $Y_2=f(X_1, X_2, 9)$

Fig. 8 - Response surfaces showing the effects of factor interactions on the response variables

The analysis indicated that increasing vibration acceleration intensified fluctuations in the external forces acting on the seeds and increased radial runout. During seed clearing, these effects promoted premature seed removal and increased variability in the seed-throwing trajectories. By contrast, increasing rotational speed or vibration frequency mitigated these effects.

Accordingly, the adverse effect of vibration on seed-metering performance increased with increasing vibration acceleration but decreased with increasing operating speed or vibration frequency.

To ensure satisfactory seed-metering performance over the tested range of operating speeds, the regression models were subjected to multi-objective optimization using a qualified-seed rate, Y_1, greater than 95% and a coefficient of variation of seed spacing, Y_2, less than 20% as constraints. The objective function is given in Eq. (10):

$$\begin{cases} Y_1(X_1, X_2, X_3) \geq 95\% \\ Y_2(X_1, X_2, X_3) \leq 20\% \\ 31.6\text{r/ min} \leq X_1 \leq 60.6\text{r/ min} \\ \max X_2(X_2 \leq 1.5\text{g}) \\ \min X_3(X_3 \leq 12\text{Hz}) \end{cases} \quad (10)$$

According to Eq. (10), the optimal parameter ranges were X_2<0.63 g and X_3>4.28 Hz. To verify the reliability of the optimization results, validation tests were conducted at rotational speeds (X_1) of 31.6, 46.1, and 60.6 r·min^{-1}. The qualified-seed rate, Y_1, exceeded 98.8%, while the coefficient of variation of seed spacing, Y_2, remained below 17.31%. These results satisfied the optimization objectives.

CONCLUSIONS

This study quantified the relationships between field vibration parameters and the performance of a mechanical conical deflector-type seed-metering device, a device type whose vibration behavior has received limited attention compared with pneumatic and finger-type seed meters. By linking seed-scale DEM simulations with bench-test measurements, the combined effects of vibration acceleration, vibration frequency, and operating speed on the seed-filling, seed-clearing, and seed-throwing processes were determined, and threshold conditions for acceptable seed-metering performance were identified.

1. Seed-filling efficiency, seed-clearing efficiency, and horizontal seed-throwing displacement were significantly affected by operating speed, vibration acceleration, and vibration frequency. Increasing any of these three factors reduced seed-filling efficiency and increased horizontal seed-throwing displacement. Increasing operating speed also reduced seed-clearing efficiency.

2. Based on the *F*-values of the main-effect terms, the effects of the factors on the qualified-seed rate and the coefficient of variation of seed spacing were ranked in descending order as follows: vibration acceleration, operating speed, and vibration frequency. The adverse effect on seed-metering performance increased with increasing vibration acceleration but decreased with increasing operating speed or vibration frequency.

3. Multi-objective optimization showed that when the vibration acceleration was below 0.63 g and the vibration frequency exceeded 4.28 Hz, the qualified-seed rate was greater than 95%, and the coefficient of variation of seed spacing was less than 20%.

Keywords: *solar greenhouse with earthen walls; air temperature; soil temperature; synergy patterns*

ABSTRACT
Chinese solar greenhouses with earthen walls can provide a suitable environment for crop production during winter. In this study, air and soil temperatures inside solar greenhouses in Shanxi Province, China, were monitored from January 1 to March 31, 2024. The results showed that, during nighttime, vertical air-temperature variation among the measurement points was greater than horizontal variation. Zones with approximately equal soil temperatures were also identified among the measurement points. The onset of the increase in weighted mean soil temperature occurred 4 h later than that of the weighted mean air temperature, whereas the onset of the decrease in weighted mean soil temperature occurred 5 h later. These findings provide a data-based foundation for regulating the thermal environment inside Chinese solar greenhouses with earthen walls.

中国土墙日光温室在冬季期间可为作物提供适宜的生长环境,本研究在 2024 年 1 月 1 日-2024 年 3 月 31 日期间对中国山西地区日光温室内空气温度与土壤温度进行测定，其结果显示：在夜间沿测点温度沿竖向的变化速率大于其沿横向的变化速率；土壤测点温度存在近似相等的区域；土壤加权温度升高界点比空气加权温度升高界点滞后 4 个小时，土壤加权温度下降界点比空气加权温度下降界点滞后 5 个小时。该研究可为日光温室内热环境调控提供数据支撑。

INTRODUCTION

Chinese solar greenhouse (CSG) are widely used for winter vegetable production in northern China, where solar energy collection, enclosure insulation and thermal storage help maintain a suitable crop-growing microclimate *(Wang et al., 2026; Sun et al., 2025; Liu et al., 2023)*. Their winter thermal environment is jointly affected by outdoor weather, covering materials, north walls, indoor air, crops and soil. Physical and transient models have shown that greenhouse air temperature is controlled by radiation, convection, conduction, ventilation or infiltration, ground heat exchange and heat storage processes *(Sun et al., 2026; Zhao et al., 2023; Xu et al., 2017; Joudi et al., 2015;)*. Therefore, understanding the internal thermal response of CSG remains important for winter environmental regulation and low-temperature risk management.

Indoor air and soil are two key thermal components with different functions. Air temperature directly affects the canopy-level environment, while soil temperature determines root-zone thermal conditions and influences root activity, water uptake and crop stress. Because greenhouse soil absorbs heat during the daytime and releases part of it during cooling periods, the air-soil temperature relationship is affected by heat storage and thermal inertia. Previous studies have reported significant air-soil temperature correlations *(Chang et al., 2010)* soil-temperature hysteresis under different moisture and fertilizer conditions *(Lin et al., 2010)* and the influence of soil moisture on soil thermal conductivity and heat capacity *(Al-Kayssi et al., 2010)*. Thus, this relationship should be viewed as a dynamic response rather than a simple synchronous correlation.

Kaixiao Cheng, Lecturer M.S.Eng.; Hong Yang, Lecturer M.S.Arc; Weiwei Cheng, Associate Professor. PhD. Eng.

Recent studies have shown that greenhouse soil temperature varies with depth and spatial position: fluctuations generally weaken with depth, peak or valley times may be delayed, and marginal effects or structural asymmetry can produce horizontal differences *(Jiao et al., 2025; Cheng et al., 2024; Cheng et al., 2014)*. Studies on ground thermal storage, soil-wall-air thermal environment and soil heat loss have further emphasized the role of soil in greenhouse heat exchange *(Li et al., 2024; Zhang et al., 2025; Luo et al.,2025)*. Meanwhile, mechanistic, transient and temperature-wave models have described CSG heat transfer processes *(Zhang et al., 2023)* and data-driven models such as LSTM, Attention-LSTM, RF-XGBoost and Transformer-BiLSTM have improved greenhouse air or soil temperature prediction *(Li et al., 2024; Liu et al., 2026; Yu et al., 2025)*. However, most studies still focus on distribution, zoning, heat-loss evaluation or prediction accuracy, with limited explanation of how indoor air temperature fluctuations propagate into multi-depth soil through time lag, phase delay, amplitude attenuation and hysteresis.

Although previous studies provide an important foundation, several issues remain insufficiently addressed. First, the time lag between indoor air temperature changes and soil-temperature responses at different depths is still not clearly quantified. Second, amplitude attenuation, phase delay and thermal hysteresis are often discussed separately or only qualitatively. Third, the effects of spatial position, soil depth, soil moisture and weather condition on air-soil thermal response have not been systematically compared. These gaps limit our understanding of how air temperature waves propagate into greenhouse soil.

In summary, existing research has provided an important foundation for understanding soil temperature distribution, heat transfer processes in greenhouses and temperature forecasting; however, there is still a lack of clear quantification of the patterns of co-variation between indoor air temperature fluctuations and soil temperatures at different depths. In light of the above issues, this paper utilises field-measured air temperature and soil temperature data from solar greenhouses across different spans to analyse the dynamic coupling relationship between indoor air temperature and soil temperature at multiple depths, thereby providing a reference for the analysis of air–soil thermal responses in solar greenhouses and for the management of root-zone temperatures during winter.

Soil temperature, compared with air temperature, exhibited time lags and complexity. Even a difference of just 1°C can have a significant impact on crop growth and development *(Sypka et al., 2016)*. The novelty of this study lies in the quantitative analysis of the thermal lag between indoor air and soil temperatures using multi-point measurements in a Chinese solar greenhouse with earthen walls. The obtained results provide engineering guidance for greenhouse thermal management, energy-saving strategies and intelligent environmental control.

MATERIALS AND METHODS

In this experiment, soil and air temperatures in the greenhouse were measured between 1 January 2024 and 30 March 2024, with measurements taken at 30-minute intervals.

Experimental Greenhouse

This experiment was conducted in the Taigu area of Jinzhong City, Shanxi Province, at 112.50° east longitude and 37.37° north latitude. The experimental greenhouse was a sun-heated structure with earthen walls; the southern side was covered with plastic sheeting, whilst the eastern, western and northern sides consisted of earthen walls. There were 1-metre-wide walkways along the southern and northern edges of the greenhouse, providing access for pedestrians and space for the laying of pipes. The sun-heated greenhouse faced south, with a length of 100 metres, a span of 10 metres and a ridge height of 4.5 metres.

Test Equipment

Indoor and outdoor air temperature: Measurements were taken using the RC-5 USB temperature logger manufactured by Jingchuang Electric Co., Ltd. (as shown in Figure 2.a). The instrument has a measurement range of –30 °C to 70 °C; within the range of –20 °C to 40 °C, the measurement accuracy is ±0.5 °C; outside this range, it is ±1 °C. The data-recording interval was set to 30 min.

Soil temperature and humidity: The Jingchuang GSP-6 was selected as the measuring instrument. The instrument has a temperature measurement range of –40 °C to 85 °C; within the temperature range of –20 °C to +40 °C, the temperature accuracy is ±0.5 °C; for other temperature ranges, the accuracy is ±1.0 °C. Data were recorded at 30-minute intervals.

RESULTS

As January was the coldest month of the year in Taigu, Jinzhong, Shanxi, in order to investigate the patterns of variation in air and soil temperatures during January and their mutual influence, the temperatures recorded at all monitoring stations in January 2024 were averaged on an hourly basis, and the hourly averages for all stations over the month were then calculated.

Variation in air temperature

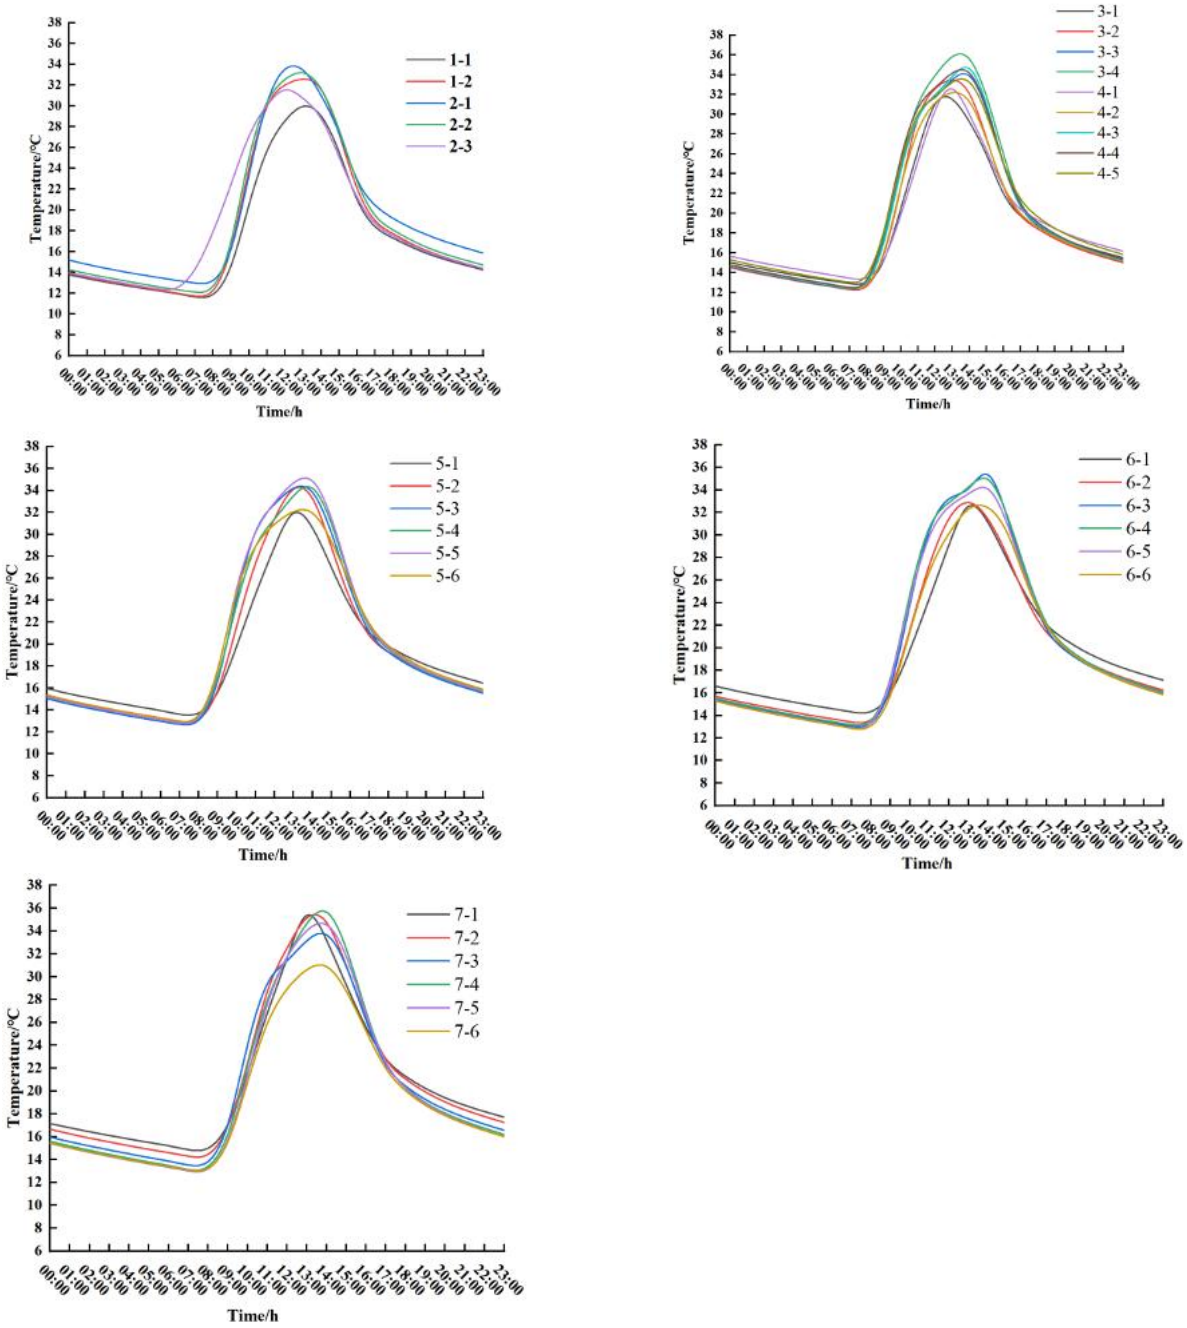

Fig. 3 - Graph of hourly averages at different measurement points in January 2024

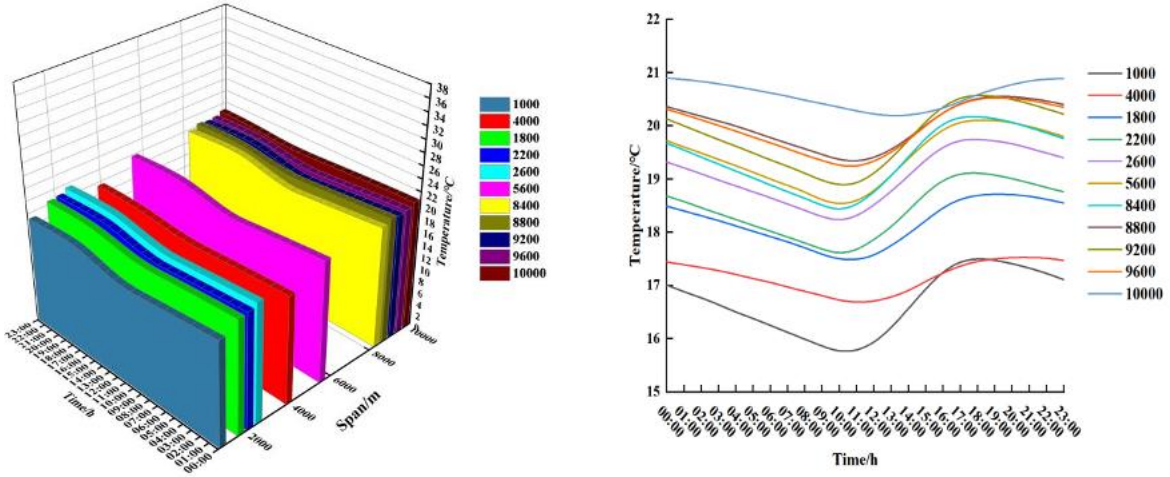
As shown in Table 3, at all measurement points in January, temperatures gradually decreased over time during the night-time periods of 00:00–06:00 and 19:00–23:00, exhibiting a seasonal pattern. The average temperatures at all measurement points in January were above 10 °C; overall, the air temperatures at all measurement points met the requirements for plant growth. An analysis of the coldest days in January revealed that at measurement points 1 and 2—which were furthest from the wall and furthest from the soil, respectively—temperatures fell below 10 °C, with the lowest recorded temperature being 7.9 °C; these conditions still met the air temperature requirements for crop growth.

Between 0:00 and 6:00, temperatures were higher at measurement points closer to the ground. Excluding measurement point No. 1 from each measurement line, the maximum temperature difference among measurement points on the same line was 0.29 °C on measurement line No. 2, with a vertical distance of 600 mm; on measurement line No. 3, the maximum temperature difference was 0.18 °C, with a vertical distance of 1,600 mm; the maximum temperature difference between measurement points on Line 4 was 0.63 °C, with a vertical distance of 2,400 mm; on Line 5, the maximum temperature difference was 0.28 °C, with a vertical distance of 800 mm; on Line 6, the maximum temperature difference was 0.58 °C, with a



vertical distance of 2,400 mm; the maximum temperature difference on measurement line 7 was 1.29 °C, with a vertical distance of 1,600 mm. Therefore, during the period from 00:00 to 06:00, the maximum rate of change in temperature difference across the same span at different heights was 0.81 °C/m, and the minimum rate of change was 0.11 °C/m.

During the period from 0:00 to 6:00, across different spans, the maximum temperature difference at Measurement Point 1 on each transect was 3.37 °C, with a horizontal distance of 9,000 mm; the maximum temperature difference at Measurement Point 2 on each transect was 2.74 °C, with a horizontal distance of 9,000 mm; and the maximum temperature difference at Measurement Point 3 on each transect was 1.99 °C, with a horizontal distance of 8,000 mm; the maximum temperature difference at measurement point 4 on each transect was 0.91 °C, with a horizontal distance of 6,200 mm. Therefore, within the growth height of the crop layer, the maximum rate of variation in temperature difference across the transects was 0.37 °C/m, and the minimum rate was 0.15 °C/m.

Between 06:00 and 18:00, temperatures at each measurement point rose gradually in a curvilinear pattern from 06:00 to 14:00, and fell gradually in a curvilinear pattern from 14:00 to 18:00. Between 06:00 and 14:00, temperatures rose gradually; measurement points near the greenhouse film showed a greater increase in temperature, whilst the peak values at points 6 and 7 were lower than those at the central measurement points due to the obstruction caused by the cotton blankets. Measurement line 1 recorded a maximum temperature rise of 20.26 °C; measurement line 2, 19.71 °C; measurement line 3, 23.6 °C; measurement line 4, 22.84 °C; measurement line 5, 22.48 °C; measurement line 6, 23.35 °C; and measurement line 7, 23.04 °C. Between 14:00 and 18:00, temperatures gradually decreased, with a more pronounced drop observed at measurement points close to the greenhouse film. Measurement line 1 recorded a maximum temperature decrease of 14.55 °C; measurement line 2, 11.7 °C; measurement line 3, 17.38 °C; measurement line 4, 15.86 °C; measurement line 5, 16 °C; measurement line 6, 15.84 °C; and measurement line 7, 16.33 °C.

Consequently, at night, the rate of vertical temperature variation at the measurement points is higher than the rate of horizontal variation; during the daytime, when maintaining the thermal environment in a solar greenhouse, attention should be paid to heat absorption in the morning and heat dissipation in the afternoon. Within the crop growth range, equipment can be used to absorb heat from the greenhouse, thereby maintaining the thermal conditions of the solar greenhouse at night. The pattern of air temperature variation was consistent with the findings of *Cheng et al. (2024)*, with relatively marked vertical variations in temperature.

The pattern of soil temperature variation

a) Figure of soil temperature variation with span and time

b) *Graph of soil temperature over time for different span*

Fig. 4 - Soil temperature at measurement points over time and across different span

As can be seen from Figure 4, the temperatures at each measurement point in the soil gradually decreased over time during the periods from 00:00 to 12:00 and from 18:00 to 23:00, whereas they gradually increased over time during the period from 12:00 to 18:00. During the 00:00–12:00 period, the temperature decreased by 1.09 °C, 0.74 °C, 0.93 °C, 0.82 °C, 0.81 °C, 0.95 °C, 0.92 °C, 0.96 °C, 1.03 °C, 0.98 °C and 0.68°C at measurement points S1 to S11, respectively. During the period from 12:00 to 18:00, the

temperature at the measurement points increased by 1.59 °C, 0.76 °C, 1.14 °C, 1.26 °C, 1.24 °C, 1.34 °C, 1.43 °C, 1.14 °C, 1.48 °C, 1.18 °C and 0.37 °C respectively. During the period from 18:00 to 23:00, the temperature decreased at measurement points 1–11 by 0.4 °C, 0.01 °C, 0.15 °C, 0.36 °C, 0.35 °C, 0.31 °C, 0.42 °C, 0.12 °C, 0.36 °C, 0.16 °C and 0.3 °C respectively. Therefore, during January 2024, excluding the temperature at the measurement point at the base of the north wall (i.e. at y = 10,000 mm), the temperature decreased by approximately 1 °C between 00:00 and 12:00, whilst it increased by approximately 1.2 °C between 12:00 and 18:00, and a decrease of approximately 0.3°C between 18:00 and 23:00; the total temperature rise and fall over the course of the day were thus approximately equal.

At the same time, the temperature at each measurement point gradually increased with the span; compared with the temperature at measurement point S1 at y = 1000 mm, the maximum temperature difference between measurement points S2–S11 and S1 during the period from 00:00 to 12:00 was 0.97 °C , 1.74 °C, 1.94 °C, 2.59 °C, 2.85 °C, 2.83 °C, 3.61 °C, 3.18 °C, 3.5 °C and 4.6 °C; the maximum temperature differences between measurement points S2–S11 and S1 during the period from 12:00 to 18:00 were 0.58 °C, 1.55 °C, 1.90 °C, 2.57 °C, 2.87 °C, 2.86 °C, 3.35 °C, 3.19 °C, 3.3 °C and 3.99 °C; The maximum temperature differences between the S2–S11 measurement points and S1 during the period from 18:00 to 23:00 were 0.36 °C, 1.44 °C, 1.65 °C, 2.29 °C, 2.69 °C, 2.66 °C, 3.29 °C, 3.11 °C, 3.24 °C and 3.78 °C. It can therefore be seen that the temperatures at the soil measurement points are approximately equal. The variations in soil temperature were consistent with those reported in previous studies (*Li et al., 2024; Zhang et al., 2025*). Building on this prior research, the present study defined soil temperature ranges for different span lengths. Further research should be conducted on soil temperatures in solar greenhouses of different structural types and span lengths, in order to investigate the effects of span length and arch height on soil temperature.

The relationship between air temperature and soil temperature

As can be seen from Figure 3 and Figure 4, there was a certain temperature difference between air temperature and soil temperature. Air temperature gradually decreased over time between 18:00 and 06:00 the following day, and between 14:00 and 18:00, whilst it gradually increased between 06:00 and 14:00; soil temperature, on the other hand, gradually decreased with the passage of time between 18:00 and 12:00 the following day, whilst it gradually increased with the passage of time between 12:00 and 18:00. There was a certain discrepancy between the points at which soil temperature and air temperature began to rise. To investigate the relationship between air temperature at the measurement points and soil temperature, coordinate-weighted calculations were performed on the air temperatures from all measurement points in January and on the soil temperatures, and the two temperature series were analysed. The formulas for the coordinate-weighted soil temperature and the coordinate-weighted air temperature were as follows: $T = \frac{\sum T_i x_i y_i}{x_i y_i}$, where T is the weighted temperature, x_i,y_i was the coordinate value, and T_i is the temperature at the i-th measurement point.

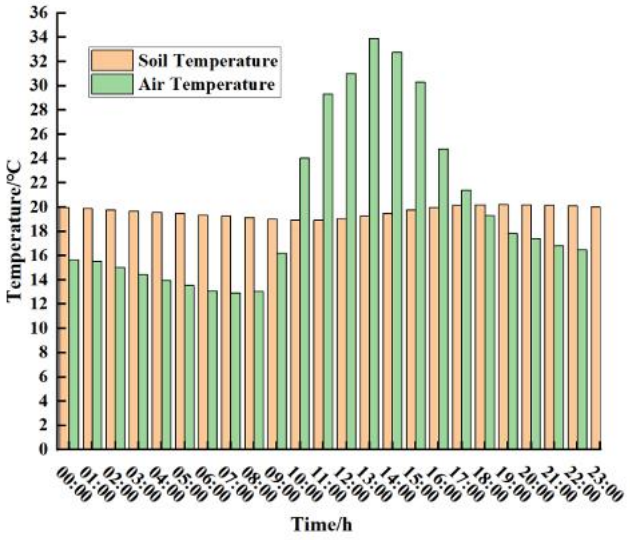


Fig. 5 - Curve of the ratio of air-weighted temperature to soil-weighted temperature in a solar greenhouse at the same time

As can be seen from Figure 5, the soil-weighted temperature gradually decreases between 00:00 and 11:00, whilst the air temperature gradually decreases between 00:00 and 07:00 and gradually increases between 07:00 and 13:00. Between 00:00 and 07:00, the air-weighted temperature was lower than the soil-weighted temperature, with an initial temperature difference of 4.3 °C; at 07:00, the difference between the soil-weighted temperature and the air-weighted temperature was 6.33 °C. At some point between 09:00 and 10:00, the weighted air temperature gradually equalled the weighted soil temperature, and between 10:00 and 14:00, the weighted air temperature was gradually higher than the weighted soil temperature. Between 09:00 and 14:00, the difference between the air-weighted temperature and the soil-weighted temperature gradually increased, reaching a maximum of 14.66 °C at 13:00. Between 14:00 and 19:00, the soil temperature gradually increased while the air temperature gradually decreased; between 17:00 and 18:00, the air-weighted temperature gradually decreased until it equalled the soil-weighted temperature. Consequently, there was a certain lag effect in the transition points for the rise and fall of the air-weighted temperature and the soil-weighted temperature in the solar greenhouse: the transition point for the rise in soil-weighted temperature lagged behind that for the rise in air-weighted temperature by four hours, whilst the transition point for the fall in soil-weighted temperature lagged behind that for the fall in air-weighted temperature by five hours.

At 11:00, the soil temperature only began to rise gradually when the difference between the air-weighted temperature and the soil-weighted temperature was 10.38 °C; at 19:00, the soil temperature only began to fall gradually when the difference between the air-weighted temperature and the soil-weighted temperature was 2.39 °C. Consequently, for the soil-weighted temperature to rise in the morning, there must be a significant difference between the air-weighted temperature and the soil-weighted temperature; similarly, for the soil temperature to fall in the afternoon, there must be a small difference between the air-weighted temperature and the soil-weighted temperature.

Previous studies have examined the factors influencing soil temperature (*Tana et al., 2022*). However, there has been limited research on the lag times and temperature differences between air temperature and soil temperature. This section examines the lag times of air-weighted temperature and soil-weighted temperature in solar greenhouses. The correlation between air-weighted temperature and soil-weighted temperature, as measured by the Spearman coefficient, was low, with an R^2 value of less than 0.1.

CONCLUSIONS

This paper employed experimental equipment to measure air and soil temperatures in a solar greenhouse, and analysed the patterns of variation and interrelationships between air and soil temperatures. The main conclusions were as follows:

(1) During the night, the rate of vertical temperature variation at each measurement point was greater than the rate of horizontal variation; during the daytime, the maintenance of the thermal environment within the solar greenhouse should take into account heat absorption in the morning and heat dissipation in the afternoon; within the crop growth range, equipment can be used to absorb heat from the greenhouse, thereby maintaining the thermal environment of the solar greenhouse at night

(2) Soil temperatures at all measurement points gradually decreased over time between 00:00 and 12:00 and between 18:00 and 23:00, whilst they gradually increased over time between 12:00 and 18:00; there were areas where soil temperatures at the various measurement points were approximately equal.

(3) There was a certain lag effect in the transition points for the rise and fall of the weighted air temperature and weighted soil temperature within the solar greenhouse; the transition point for the rise in weighted soil temperature lagged behind that of the weighted air temperature by 4 hours, whilst the transition point for the fall in weighted soil temperature lagged behind that of the weighted air temperature by 5 hours. Heat can be stored during the day using equipment and thermal storage media to harness the high air temperatures, and then released at night using the same equipment, thereby raising the air temperature in solar greenhouses during winter nights.

ACKOWLEDGEMENT

Keywords: *sustainable agriculture; social media analysis; artificial intelligence; text mining; sentiment analysis; topic modeling*

ABSTRACT

This study aims to investigate how sustainable agriculture is represented in the digital public sphere by examining technology-driven agricultural systems through artificial intelligence–based text analytics. A dataset of 13,354 English posts collected from the X platform during January 2026 was used, with 10,782 posts retained after preprocessing. The methodology integrates text mining, TF-IDF keyword extraction, BERT-based sentiment analysis, and LDA topic modelling. The optimal number of LDA topics was determined using coherence score evaluation to ensure statistical robustness and thematic interpretability. This study integrates text mining, BERT-based sentiment analysis, and LDA topic modelling within a unified artificial intelligence framework to provide a comprehensive analysis of sustainable agriculture discourse on social media. The results show predominantly neutral discourse (65.27%), reflecting informational content, while positive discourse (33.17%) highlights smart farming and innovation. Negative discourse (1.56%) primarily addresses structural challenges. Three dominant themes emerged: climate-oriented sustainability, community-based practices, and technology-driven agriculture, emphasizing the role of digital technologies in shaping sustainable agricultural systems. The findings provide practical insights for policymakers, agricultural stakeholders, and researchers by supporting evidence-based communication strategies and technology-oriented sustainability policies.

ÖZET

Bu çalışma, yapay zekâ tabanlı metin analitiği yöntemlerini kullanarak sürdürülebilir tarımın dijital kamusal alanda nasıl temsil edildiğini ve teknoloji odaklı tarımsal sistemlere ilişkin söylemin temel duygu ve konu yapılarını ortaya koymayı amaçlamaktadır. Ocak 2026 dönemine ait X platformundan 13.354 İngilizce paylaşım toplanmış, ön işleme sonrası 10.782 paylaşım analiz edilmiştir. Yöntemde metin madenciliği, TF-IDF anahtar kelime analizi, BERT tabanlı duygu analizi ve LDA konu modelleme kullanılmıştır. LDA için en uygun konu sayısı, istatistiksel güvenilirlik ve tematik yorumlanabilirlik dikkate alınarak coherence (uyumluluk) skoru yardımıyla belirlenmiştir. Bu çalışma, metin madenciliği, BERT tabanlı duygu analizi ve LDA konu modellemeyi bütünleşik bir yapay zekâ çerçevesinde bir araya getirerek sürdürülebilir tarım söylemine kapsamlı bir bakış sunmaktadır. Bulgular, söylemin ağırlıklı olarak nötr (%65,27) olduğunu, pozitif söylemin (%33,17) akıllı tarım ve inovasyonu vurguladığını göstermektedir. Negatif söylem (%1,56) ise ağırlıklı olarak yapısal sorunlara odaklanmaktadır. Analiz sonucunda üç temel tema belirlenmiştir: iklim odaklı sürdürülebilirlik, topluluk temelli uygulamalar ve teknoloji odaklı tarım. Elde edilen bulgular, sürdürülebilir tarım politikalarının geliştirilmesi, kanıta dayalı dijital iletişim stratejilerinin oluşturulması ve teknoloji odaklı sürdürülebilirlik uygulamalarının desteklenmesi açısından politika yapıcılara, sektör paydaşlarına ve araştırmacılara uygulamaya yönelik katkılar sunmaktadır.

INTRODUCTION

Sustainable agriculture has emerged as a critical framework for addressing the complex and interrelated challenges of global food security, climate change, and natural resource depletion. As agricultural systems are increasingly expected to produce more with fewer inputs, the transition toward sustainability requires not only ecological and economic adjustments but also the integration of innovative technologies and data-driven approaches. In this regard, the transformation of agriculture through digitalization and artificial intelligence has become a defining feature of contemporary agri-food systems.

In recent years, the convergence of sustainability principles with smart farming technologies—such as precision agriculture, artificial intelligence, Internet of Things (IoT), and data analytics—has reshaped the way agricultural production is managed and optimized. These developments align closely with the thematic focus of this special issue, which emphasizes the role of technological innovation in enhancing agricultural sustainability, efficiency, and resilience. Smart agriculture systems enable real-time monitoring, predictive analytics, and optimized resource allocation, thereby contributing to reduced environmental impact and improved productivity.

However, while the technological dimension of sustainable agriculture has been extensively explored, there remains a critical need to understand how these transformations are perceived, communicated, and socially constructed within the digital public sphere. Public discourse plays a vital role in shaping the adoption, legitimacy, and policy direction of sustainable agricultural practices. In this context, social media platforms function as dynamic environments where diverse stakeholders—including farmers, institutions, companies, and individuals—engage in discussions, share knowledge and construct narratives around sustainability and agricultural innovation.

The X platform provides a large-scale, real-time, and user-generated data environment for analyzing public discourse on sustainable agriculture. Unlike traditional data sources, social media data reflect immediate reactions, emerging trends, and multi-actor interactions, making them highly valuable for analyzing the societal dimension of agricultural transformation. Despite this potential, the integration of artificial intelligence–based text analytics into the study of sustainable agriculture discourse remains relatively underdeveloped in the literature.

Addressing this gap, the present study adopts a comprehensive artificial intelligence–based analytical framework to investigate social media discourse on sustainable agriculture. By combining text mining techniques, TF-IDF-based word frequency analysis, BERT-based sentiment analysis, and Latent Dirichlet Allocation (LDA) topic modeling, the study systematically examines large-scale Twitter data to uncover dominant sentiment patterns and thematic structures. This approach not only aligns with the technological orientation of the special issue but also extends it by incorporating the socio-discursive dimension of sustainability.

The contribution of this study is twofold. First, it provides empirical insights into how sustainable agriculture is framed in the digital public sphere, revealing the interplay between technology, sustainability narratives, and stakeholder perceptions. Second, it bridges the gap between artificial intelligence applications and sustainability research by demonstrating how advanced natural language processing methods can be employed to analyze complex, unstructured social media data in the agricultural domain.

LITERATURE REVIEW

Sustainable agriculture has evolved into a comprehensive and multidimensional framework that integrates environmental sustainability, economic viability, and social equity within agricultural systems. Early conceptualizations defined sustainable agriculture as a system capable of maintaining long-term productivity while minimizing environmental degradation and ensuring efficient use of natural resources *(Hobbs et al., 2008; Reganold et al., 1990*). Over time, this perspective has been expanded to include broader ecological and socio-economic dimensions, emphasizing the importance of soil health, biodiversity conservation, and integrated resource management *(Botero-Valencia et al., 2025; Brodt et al., 2011; Kumari et al., 2025; Velten et al., 2015*). Despite these advancements, the practical implementation of sustainable agriculture remains complex, as it requires balancing productivity with environmental protection and socio-economic inclusiveness across diverse regional and institutional contexts.

In recent years, sustainable agriculture has undergone a profound transformation driven by rapid technological advancements. The emergence of artificial intelligence (AI), machine learning, and digital agriculture has redefined traditional farming practices and introduced new opportunities for enhancing

efficiency and sustainability. Studies indicate that AI-based systems can significantly improve decision-making processes, optimize resource allocation, and support climate-resilient agricultural practices *(Rejeb et al., 2025; Xu et al., 2024*). In addition, machine learning applications have been widely adopted in agricultural supply chains, enabling predictive analytics, yield optimization, and risk management (*Anggoro & Sari, 2025*). Bibliometric analyses further confirm that technological innovation has become a central theme in contemporary sustainable agriculture research, reflecting a shift toward data-driven and precision-based farming systems (*Liu & Wan, 2024; Tucciarone et al., 2024*).

However, while existing literature strongly emphasizes the technological dimension of sustainable agriculture, it often adopts a predominantly system-oriented or engineering-focused perspective. These studies typically prioritize efficiency, productivity, and optimization, while paying limited attention to how sustainability is perceived, communicated, and socially constructed by different stakeholders. This indicates a critical gap in literature, as the success of sustainable agriculture depends not only on technological advancement but also on societal acceptance, awareness, and engagement.

Parallel to these technological developments, social media has emerged as a significant platform for information exchange, knowledge dissemination, and stakeholder interaction in agricultural systems. Social media platforms enable farmers, policymakers, institutions, and the public to share information, express opinions, and construct narratives about agricultural practices and sustainability. Studies suggest that social media plays an important role in agricultural development by facilitating knowledge sharing and influencing farmers' decision-making processes (*Chowdhury et al., 2024*). Furthermore, research focusing on precision agriculture highlights that social media discourse reflects both opportunities and challenges associated with digital transformation, including issues related to accessibility, adoption barriers, and institutional constraints (*Sharma et al., 2023*).

Nevertheless, existing studies on social media in agriculture tend to focus primarily on functional or adoption-related aspects rather than examining the discursive and perceptual dimensions of sustainability. In other words, while these studies explore how social media contributes to agricultural development, they do not sufficiently address how sustainable agriculture is framed, interpreted, and communicated within digital discourse. This limitation restricts the understanding of the broader socio-cultural dynamics that shape sustainability narratives in the agricultural domain.

In addition to social media research, computational approaches such as text mining, bibliometric analysis, and topic modeling have gained increasing attention in recent years. These methods allow researchers to analyze large-scale textual datasets and identify underlying patterns, themes, and research trends (*Chiangnangam et al., 2024; Panda & Sinha, 2023*). Topic modeling techniques, particularly Latent Dirichlet Allocation (LDA), have been widely used to uncover latent thematic structures within agricultural and sustainability-related datasets (*Ofori & El-Gayar, 2021*). These approaches provide valuable insights into the evolution of research topics and thematic priorities, contributing to a more systematic understanding of agricultural knowledge production.

However, despite their analytical strengths, most computational studies remain limited in scope, as they often focus on either thematic structures or research trends without incorporating the emotional and perceptual dimensions of discourse. In particular, the integration of advanced sentiment analysis techniques with topic modeling remains underexplored in agricultural research. While sentiment analysis has been applied in various domains to capture user attitudes and emotional responses (*Driscoll & Walker, 2014*), its combined use with topic modeling to analyze agricultural discourse—especially in the context of social media—remains relatively limited.

This gap becomes particularly significant in the context of sustainable agriculture, where public perception, stakeholder attitudes, and narrative framing play a crucial role in shaping policy development, technological adoption, and long-term sustainability outcomes. Understanding not only what is being discussed but also how it is perceived and emotionally framed is essential for developing a comprehensive understanding of agricultural transformation in the digital age.

Although previous studies have investigated sustainable agriculture, social media, or artificial intelligence separately, limited research has integrated text mining, transformer-based sentiment analysis, and topic modelling within a unified analytical framework to examine sustainable agriculture discourse. Consequently, there remains a need for a comprehensive artificial intelligence–based approach capable of simultaneously identifying both the thematic structure and sentiment dynamics of digital sustainability discussions.

Addressing this gap, the present study adopts an integrated analytical framework that combines text mining, TF-IDF-based keyword analysis, BERT-based sentiment analysis, and LDA topic modeling. This approach enables a comprehensive examination of both the thematic and emotional dimensions of sustainable agriculture discourse on social media. Unlike previous studies, which typically focus on isolated analytical dimensions, this research provides a multidimensional and data-driven perspective on how sustainable agriculture is constructed, interpreted, and communicated within the digital public sphere.

The originality of this study lies in integrating text mining, BERT-based sentiment analysis, and LDA topic modelling within a unified artificial intelligence framework to investigate sustainable agriculture discourse on social media. Methodologically, the study demonstrates the applicability of advanced natural language processing techniques to agricultural communication research. Empirically, it provides evidence on how sustainable agriculture is represented, interpreted, and discussed in the digital public sphere, thereby contributing to both artificial intelligence applications and sustainability research.

Based on the identified research gap, this study addresses the following research questions:

RQ1. How is sustainable agriculture represented in social media discourse on the X platform?

RQ2. What are the dominant sentiment patterns associated with sustainable agriculture discourse?

RQ3. What are the major thematic structures underlying sustainable agriculture discussions identified through LDA topic modelling?

Given the exploratory nature of this study and its objective of identifying thematic and sentiment patterns rather than testing causal relationships, no formal research hypotheses were proposed.

MATERIALS AND METHODS

This study utilized a dataset comprising 13,354 English posts exchanged between January 1 and January 31, 2026, to analyze social media discourse on sustainable agriculture. After cleaning the data and preparing the text (removing duplicate content, cleaning URLs and special characters, changing everything to lowercase, removing stop words, and lemmatizing), 10,782 posts were ready for analysis. The study utilized TF-IDF-based word frequency analysis as a text mining technique, employing a pre-trained BERT model for sentiment classification. Additionally, Latent Dirichlet Allocation (LDA) was used for topic modelling to find hidden themes in the conversation about sustainable agriculture. Word clouds, density maps, and keyword co-occurrence networks were used to show the results. The Python programming language was employed for all data processing and analysis tasks.

All analyses were conducted using Python 3.14.6. The main libraries included pandas 3.0.5, NumPy 2.5, NLTK 3.13, scikit-learn 1.9, transformers 5.14.1, gensim 4.4.0, matplotlib 3.11, NetworkX 3.6.1, and WordCloud 1.9.6.

Dataset

The dataset for this study was generated using the keyword 'sustainable agriculture' to examine the contemporary digital discourse surrounding sustainable agriculture. This keyword was selected as it represents the most prevalent and all-encompassing articulation of the concept of sustainable agriculture in the literature, thereby facilitating access to a wide array of content that includes environmental, economic, and social dimensions (*Liu & Wan, 2024; Sharma et al., 2023*). The X platform was selected as the data source due to its widespread use in academic research. It shows real-time public reactions, policy discussions, project announcements, and individual opinions in an open data format (*Driscoll & Walker, 2014; Naskar et al., 2020*). X's official Application Programming Interface (API) infrastructure was utilized to retrieve the data. This approach ensures the scientific reliability of the data in terms of accuracy, integrity, and reproducibility *(Das et al., 2024*).

The data collection process lasts from January 1 to January 31, 2026. This time frame was chosen because it reflects current discourse, minimizes temporal fluctuations by providing a homogeneous single-month period, and allows for the observation of intensive content production on the topic of sustainable agriculture. During the specified time, 13,354 posts were collected. After text preprocessing and cleaning, 10,782 of these posts were used for analysis. In social media–based text mining studies, datasets exceeding ten thousand observations are generally considered sufficient to reliably model thematic structures and sentiment distributions. In this context, the acquired dataset is sufficiently large for statistical and analytical examination of the thematic and sentimental framework of the discourse on sustainable agriculture.

Text Mining

This study employed text mining techniques to facilitate the systematic and quantifiable examination of social media content related to sustainable agriculture. Text mining is an analytical method based on natural language processing (NLP) that tries to find useful patterns, themes, and statistical relationships in unstructured text data (*Lan, 2026*). Because social media data is inconsistent, short, and changes depending on the situation, it needs to be standardized before it can be analyzed (*Zucco et al., 2020*).

In this case, text preprocessing was done first. Text preprocessing was performed to improve data quality and ensure reliable subsequent analyses (*Chai, 2023*). First, duplicate posts were removed to eliminate repeated content. URLs, user mentions, hashtags, punctuation marks, numbers, and other non-textual characters were then removed to reduce noise. Subsequently, all text was converted to lowercase to ensure consistent word representation. Common stop words that did not contribute meaningful semantic information were removed using the NLTK stop-word list (*Mubarak et al., 2023*). Finally, lemmatization was applied to reduce words to their base forms while preserving their semantic meaning. These preprocessing steps reduced the dataset from 13,354 to 10,782 posts, resulting in a cleaner and more consistent corpus for text mining, sentiment analysis, and topic modelling.

Word frequency analysis is one of the most important methods used in text mining. Word frequency refers to the number of occurrences of a term within a dataset. It is used to figure out which ideas are most important in the conversation (*Yeomans et al., 2023*). Nevertheless, raw frequency values may underscore excessively repetitive general concepts, resulting in words with low distinctiveness appearing predominant in the analysis. This study also used the Term Frequency–Inverse Document Frequency (TF-IDF) method for this reason.

TF-IDF is a weighting scheme that quantifies the importance of a term within a document relative to the entire corpus (*Liu et al., 2022*). "Term Frequency (TF)" counts how many times a word shows up in a single document (*Mohammed & Rashid, 2023*), while "Inverse Document Frequency (IDF)" counts how many times the word shows up in all the documents (*Yulita et al., 2023*). The IDF value of a word goes down if it is used a lot in many documents (*Mee et al., 2021*). If it is only used in a few documents, the IDF value goes up. The TF-IDF score, which is the product of these two numbers, helps you find more meaningful keywords by looking at both their local frequency and their global distinctiveness (*Xiao et al., 2024*). Therefore, ideas that are different from each other in the discussion of sustainable agriculture have come to the fore.

Sentiment Analysis

Sentiment analysis is a way to use natural language processing to figure out what someone's attitude and sentimental state (positive, negative, or neutral) is based on text data (*Nandwani & Verma, 2021*). It is commonly employed to methodically categorize users' opinions, expectations, and criticisms based on social media data(*Chakraborty et al., 2020*). This study used a supervised machine learning methodology and employed a pre-trained deep learning model to analyze the sentiment distribution of posts regarding sustainable agriculture.

The pretrained transformer model cardiffnlp/twitter-roberta-base-sentiment-latest, based on the RoBERTa architecture, was used for sentiment classification (*Acheampong et al., 2021*). RoBERTa is an optimized variant of BERT that builds on the Transformer architecture and has demonstrated high performance in sentiment analysis tasks, particularly for short and context-dependent texts such as social media posts *(Pota et al., 2020; Mars, 2022*). Its bidirectional contextual representation enables more accurate interpretation of word meanings by considering both preceding and following contexts, thereby improving classification performance.

The BERT model is trained on big text datasets ahead of time, and it can be fine-tuned to work on a specific task (*Qasim et al., 2022*). The model was used in this study to categorize Twitter texts into positive, negative, and neutral classifications (*Acheampong et al., 2021*). The model breaks the text down into tokens, turning each word into a vector representation. It then learns how words are related to each other through Transformer layers and gives a probabilistic classification output in the last layer *(Rodrawangpai & Daungjaiboon, 2022*). This made it possible to find sentiment orientation in conversations about sustainable agriculture with outstanding accuracy.

Topic Modelling

Topic modelling is a statistical method for analyzing text that tries to find hidden topics in large sets of text (*Vayansky & Kumar, 2020*). This method uses probabilities to model how documents are spread out around certain topic clusters and what words make up each topic (*Churchill & Singh, 2022*). In unstructured datasets with a wide range of content, like social media, topic modelling techniques are a keyway to systematically show the thematic structure (*Laureate et al., 2023*). In this research, topic modelling was used to discern the prevailing themes in the discourse surrounding sustainable agriculture.

In this study, the Latent Dirichlet Allocation (LDA) algorithm was used for topic modelling. The primary reason for selecting LDA is its ability to model texts as encompassing multiple topics, delineating each topic through a distinct word probability distribution (*Li et al., 2024*). Social media texts usually have multidimensional content, LDA's flexible and probabilistic structure makes it a good way to analyze these kinds of data *(Neijzen & Lunter, 2023*). LDA was selected due to its prevalence in social science literature and its capacity to generate interpretable results.

The LDA model posits that each document (in this study, each post) comprises a blend of various topics in designated proportions (*Qiang et al., 2020*). The model works by using two main distributions: (1) the word distribution for each topic and (2) the topic distribution for each document (*Chauhan & Shah, 2021*). The algorithm figures out how likely it is that words belong to certain topics by repeating the process repeatedly (*Churchill & Singh, 2022*). Over time, it finds the most consistent topic-word structures. Therefore, keywords that frequently appear together represent each topic. This has made it possible to systematically and statistically find the main themes of sustainable agriculture conversation.

RESULTS

This part shows the results of the analysis for the dataset that was collected from January 1 to January 31, 2026. After the text pre-processing stage, it was cut down to 10,782 posts. The researchers employed text mining, word frequency analysis, BERT-based sentiment analysis, LDA topic modelling, and diverse data visualization techniques. The Python programming language was employed for all analysis stages. Libraries such as pandas, NLTK, scikit-learn, transformers, gensim, and matplotlib were utilized for data cleaning, natural language processing, modeling, and visualization. The results show, through a comprehensive approach, the themes and sentiment frameworks that shape the conversation about sustainable agriculture on social media. Table 1 shows the framework of sentiment that social media users are using to talk about agriculture.

Table 1

Distribution of sentiment categories in sustainable agriculture discourse on the X platform

Positive	Negative	Neutral
3.576	168	7.038

As presented in Table 1, of the 10,782 posts analyzed, 3,576 (33.17%) were classified as positive, 168 (1.56%) as negative, and 7,038 (65.27%) as neutral. The results suggest that neutral and informative content primarily influences the conversation about sustainable agriculture on social media. The fact that most of the content is neutral shows that the topic is mostly talked about in the context of policy announcements, project sharing, corporate statements, and research-based content.

The fact that 33.17% of posts are positive compared to negative content shows that sustainable agriculture is usually linked to a vision of the future that is hopeful, innovative, and solution orientated. On the other hand, the very low level of negative content (1.56%) shows that criticism is limited but focused on specific implementation problems and structural deficiencies.

These findings indicate that sustainable agriculture doesn't see it as a controversial crisis area but rather as an informative and somewhat positive topic of change and growth.

Qualitative Evaluation of Sample Posts

In this part, a qualitative evaluation was done by picking the three posts with the most likes, reposts, and comments in each sentiment category from the posts that BERT-based sentiment analysis said were positive, negative, or neutral. The goal is to go beyond just looking at the numbers and find out which narrative frameworks, thematic emphasis, and social sensitivities shape the conversation about sustainable agriculture.

The chosen posts exemplify the sentiment category and illustrate the discourse formats that yield the highest visibility and engagement among social media users. In this context, the analysis seeks to elucidate the perceptual and discursive aspects of sustainable agriculture within the digital public sphere with greater depth.

Positive Post Examples

Post 1: "Innovative sustainable farming systems are the future of global food security. Supporting farmers with smart technology will drive real growth and long-term resilience.

This post frames sustainable agriculture as a future-oriented and innovation-driven process, emphasizing the role of smart technologies in enhancing productivity and resilience. The reference to supporting farmers highlights the central role of producers in sustainable transformation.

Post 2: "New agricultural projects are empowering rural communities through sustainable solutions and economic development."

This post presents sustainable agriculture as a multidimensional development tool, linking environmental sustainability with economic growth and rural empowerment. It reflects a project-based and solution-oriented perspective.

Post 3: "Smart agriculture and innovative crop systems are transforming food production for a more sustainable and secure future."

This post emphasizes transformation and modernization, framing sustainable agriculture as a pathway toward a secure and resilient future through technological innovation.

Negative Post Examples

Post 1: "Excessive pesticide use and poor land management are harming sustainable farming efforts."

This post highlights the gap between sustainability discourse and actual practices, emphasizing environmental risks associated with excessive chemical use and poor management.

Post 2: "Small farmers still struggle with limited land and low production despite sustainable farming promises."

This post reflects structural inequalities in agricultural systems, particularly the challenges faced by small-scale farmers in achieving sustainable production.

Post 3: "Food waste and inefficient management systems undermine sustainable agriculture goals."

This post underscores inefficiencies in resource management, indicating that sustainability goals are undermined by waste and systemic limitations.

Neutral Post Examples

Post 1: "National research on sustainable agriculture focuses on food security, rural development and climate resilience."

This post reflects a policy-oriented and research-driven perspective, focusing on food security and climate resilience without evaluative judgment.

Post 2: "Sustainable agriculture initiatives support rural communities and strengthen global food systems."

This post presents sustainable agriculture within an institutional and systems-based framework, emphasizing its role in strengthening global food systems.

Post 3: "Agricultural development strategies address soil health, water management and long-term security."

This post highlights a technical and strategic perspective, focusing on resource management and long-term agricultural planning.

Word Frequency Analysis

This part did a word frequency analysis to find the main ideas that were talked about in the conversation about sustainable agriculture. The analysis process used both raw frequency values and the TF-IDF (Term Frequency–Inverse Document Frequency) method. The primary rationale for selecting TF-IDF is to mitigate the influence of common words that are excessively repetitive yet possess low distinctiveness (e.g., agriculture' or 'sustainable') within the dataset, thereby highlighting more unique and elucidative concepts related to specific sentiment categories or text clusters. This method evaluates both the frequency of terms and their distinctiveness across the corpus. The analysis aims to reveal a more substantial and thematically

cohesive conceptual framework, free from superficial redundancies in the discourse on sustainable agriculture. Table 2 shows the words and frequency distributions that stand out by sentiment category.

Table 2

TF-IDF-based keyword distribution across sentiment categories

Positive	Negative	Neutral
Future	Waste	Agriculture
Innovative	Management	Sustainable
Growth	Small	Development
Project	Less	Security
Systems	Land	Rural
Support	Production	Research
Supporting	Nutrition	National
Solutions	Sustainable farming	World
Technology	Need	Health
Economic	Kerala	Resilience

The results indicate that positive discourse is strongly associated with future-oriented, innovation-driven, and solution-focused narratives. Keywords such as “innovation”, “technology”, and “growth” suggest that sustainable agriculture is framed as a driver of economic development and technological transformation, emphasizing systemic change rather than individual practices.

Negative discourse is primarily associated with structural and operational challenges, including resource inefficiency, inadequate management practices, and constraints faced by small-scale producers. These findings highlight a discrepancy between sustainability narratives and their practical implementation.

Neutral discourse is predominantly informational and institutional, characterized by terms related to policy, research, and development. This indicates that sustainable agriculture is largely framed within a technical and governance-oriented context rather than an evaluative one.

Topic Modelling Analysis

This section employed topic modelling analysis to uncover the underlying thematic structure of the discourse on sustainable agriculture (*Hussain et al., 2026*). The Latent Dirichlet Allocation (LDA) algorithm was used for the topical modelling process. The primary rationale for selecting LDA is its assumption that documents within extensive text datasets may probabilistically pertain to multiple themes, modelling each theme according to the distributions of co-occurring words (*De La Hoz-M et al., 2026*). This is a strong and well-known way to find hidden themes in datasets with multidimensional and mixed content structures, like social media. In addition, LDA makes it easier to analyze social science studies by giving them topical keyword outputs that are easy to understand (*Cheng et al., 2023*).

To identify the optimal topic structure, candidate LDA models with topic numbers ranging from 2 to 10 were evaluated using coherence scores. The corresponding coherence values are presented in Table 3.

Table 3

Coherence scores of candidate LDA models

Number of Topics	Coherence Score
2	0.3462
3	0.4710
4	0.3618
5	0.4526
6	0.4212
7	0.4315
8	0.4403
9	0.3376
10	0.4682

As shown in Table 3, the coherence scores ranged from 0.3376 to 0.4710 across the tested models. The three-topic model achieved the highest coherence score (0.4710), while the ten-topic model produced a very similar value (0.4682). However, qualitative examination indicated that the ten-topic solution generated fragmented and overlapping themes, whereas the three-topic model provided clearer thematic separation and greater interpretability. Models with fewer topics produced overly broad themes, while models with more topics resulted in increasingly fragmented topic structures. Therefore, considering both the quantitative coherence scores and the qualitative interpretability of the extracted topics, the three-topic model was selected for the subsequent analyses.

The findings of the topic modelling analysis are summarized in Table 4, which presents the extracted topics and their corresponding keyword distributions.

Table 4

Identified topics, prevalence, and representative keywords from LDA topic modelling

Topic N	Mean Topic Probability	Prevalence	Topmost co-occurring words
1	0.3900	40.18%	food, farming, systems, 2026, growth, security, innovation, support, farmers, future, development, today, climate, global, health, organic, agricultural, real, new
3	0.3102	30.11%	project, food, pulses, farmers, water, farming, security, innovative, Veera, on Veera, future, soil, communities, irrigation, world, practices, livelihoods, women, day, approach
2	0.2998	29.72%	farmers, farming, development, new, growth, energy, solutions, water, tech, production, land, food, ai, global, climate, farm, 2026, Kenya, soil

The table presents the dominant thematic structures identified through LDA, including topic prevalence and the most representative co-occurring terms.

Topic 1: The Future Vision of Sustainable Agriculture in the Context of Food Security and Climate

The fact that Topic 1 is the most common topic (40.18% of the time, with a mean topic probability of 0.3900) shows that posts about sustainable agriculture are most often about food security and future-orientated change. The words "food", "security", "climate", "global", "health", "organic", "innovation", "farmers", "future", and "development" often appear together. This shows that sustainable agriculture is linked to more than just production efficiency; it is also linked to a larger social agenda that includes healthy eating, fighting the climate crisis, global risks, and organic farming. The focus on "systems" and "innovation" shows that users see agriculture as more than just one thing; they see it as an agriculture-food system. The words "support" and "farmers" together suggest that producers are at the heart of the change. In terms of discourse, this topic sets up a framework that sees sustainable agriculture to build the future and deal with crises. It gives people hope and direction by saying, "Today's problem is tomorrow's solution.

Topic 3: Water, Soil and Community-Based Resilience: Innovative Projects and Sustainable Practices

Topic 3 (Prevalence: 30.11%; Mean Topic Probability: 0.3102) has a narrative that is more focused on projects and applications. Words like "project", "innovative", "practices", and "approach" suggest that sustainable agriculture is being talked about in terms of field applications and projects rather than as an abstract ideal. The three words "water, irrigation, and soil" are the main ideas of this theme. They stress that managing water and keeping soil healthy are important parts of sustainability. Words like "communities", "livelihoods", and "women" show that the conversation isn't just about the technical side of things. It also talks about sustainable agriculture in the context of rural livelihoods, social inclusion, and especially the role of women in agriculture. The language used in this topic supports the ideas of "solution-building" and "transformation". It shows that sustainable agriculture is seen as a practical way to develop that makes communities stronger, gives them more power, and helps them manage their resources better.

Topic 2: Efficient Production with Technology and Artificial Intelligence: Smart Agriculture in the Water-Energy-Food Nexus

Topic 2 (Prevalence: 29.72%; Mean Topic Probability: 0.2998) clearly moves the sustainable agriculture agenda toward technology and digitalization. The words "tech", "solutions", "AI", "energy", and

"production" show that people are talking about sustainability goals through smart farming, AI-supported decision systems, and technology-based solutions. The inclusion of "energy" alongside "water, land, soil" signifies a growing public comprehension of sustainable agriculture through the lens of the water-energy-food (WEF nexus) paradigm, emphasizing the interrelations among resources. Also, the words "Kenya" and "global" show that the conversation has moved beyond being about a local production problem and is now being talked about in a way that compares it to examples from around the world and different country contexts. This topic frames sustainable agriculture as "producing smarter and more resource-efficiently" instead of "producing more". It focuses on the language of efficiency, optimization, and innovation, and it also connects these ideas to climate and food security issues, making technology an "accelerator" of sustainability.

Data visualization

This section employs diverse data visualization techniques to enhance the clarity and interpretability of findings pertaining to discourse on sustainable agriculture. Word clouds, density maps, and keyword co-occurrence networks were used to illustrate the prominent concepts based on sentiment categories and the underlying thematic clustering structures. The visualization process was done with the Python programming language, and the structural relationships of the text mining results were shown in a graph. This method backs up the results of the quantitative analysis and gives us a chance to look at the main ideas and the relational network structure of the sustainable agriculture discourse in a more complete way.

Word cloud analysis

The word cloud was made with the WordCloud library in Python. This library automatically looks at how often words appear in the text and makes images that are proportional to how often they occur *(Trejo, 2025*). The pandas and NLTK libraries were used for data pre-processing, and the matplotlib library was used to organize the graphical output. This combination made it possible to show word density both in numbers and in pictures. Figure 1 shows the positive word cloud, which shows how the ideas in the positive sentiment category are spread out visually.

Fig. 1 - Positive word cloud

The word cloud analysis indicates that positive discourse on sustainable agriculture is dominated by terms related to innovation, productivity, and sustainability. Keywords such as “innovation”, “technology”, and “development” highlight a strong association with future-oriented and solution-driven narratives. In addition, the presence of terms such as “climate”, “water”, and “soil” reflects the integration of environmental sustainability within this positive framing. The prominence of words such as “farmers” and “communities” further suggests a producer-centered and socially inclusive perspective. Overall, the results demonstrate that sustainable agriculture is constructed in positive discourse as a transformative and development-oriented process.

Fig. 2 - Negative word cloud

The negative word cloud highlights that critical discourse is primarily centered on environmental and structural challenges. Terms such as “pesticide”, “waste”, and “management” indicate concerns related to resource inefficiency and unsustainable practices. Additionally, the presence of words associated with climate and resource constraints reflects the perceived risks and limitations in the implementation of sustainable agriculture. Overall, negative discourse emphasizes the gap between sustainability goals and practical challenges.

Fig. 3 - Neutral word cloud

The neutral word cloud reflects an informational and institutional discourse structure, dominated by terms related to policy, research, and development. Keywords such as “agriculture”, “development”, and “research” suggest that sustainable agriculture is primarily discussed within a technical and governance-oriented framework. This indicates that a significant portion of the discourse is descriptive rather than evaluative.

Density visualization

The density visualization was made to show how closely related and clustered concepts are in the discourse of sustainable agriculture (*Dabare et al., 2025*). For this analysis, words that often appeared together were placed on a two-dimensional plane to find areas of conceptual density. This made it possible to see which themes were at the center and which concepts were more strongly connected. This method has given us a more complete view of the main themes and environmental groups in sustainable agriculture conversation.

Figure 4 shows the density map that shows how concepts are grouped based on how similar their meanings are.

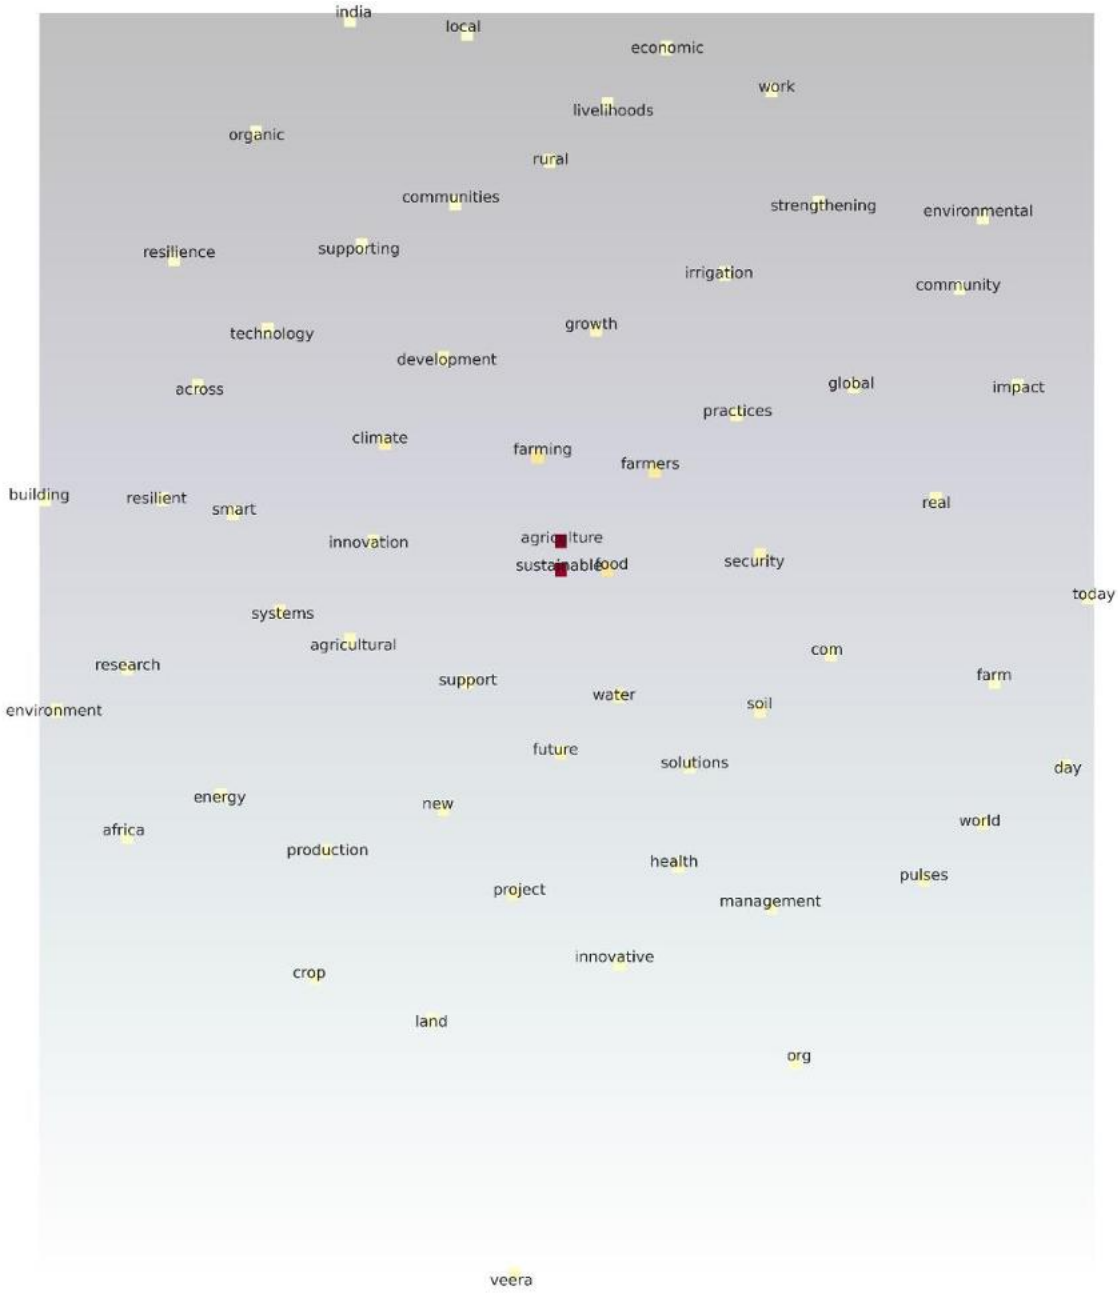

Fig. 4 - Density visualization

The density visualization reveals a clustered conceptual structure centered around key terms such as agriculture, food, and sustainability. This pattern reflects a multi-dimensional discourse shaped by environmental, economic, and social factors.

Keyword Co-occurrence Network

Keyword co-occurrence network analysis was conducted to examine how the concepts used together in the discourse on sustainable agriculture are interconnected. This approach used a node and edge structure to model words that co-occurred in the same post, facilitating an analysis of the connection density between concepts (*Yuan et al., 2022*). In this way, the main ideas that were talked about and the subthemes that went along with them were looked at in a visual network structure (*Yang et al., 2023*). The analysis took place in Python. The word 'co-occurrence matrix' was made first, then the NetworkX library was used to model the network structure, and finally Matplotlib was used to show the results. This method shows not only the ideas that shape the conversation about sustainable agriculture but also how these ideas fit together to make a whole. Figure 5 shows the keyword co-occurrence network, which demonstrates how keywords are related to each other and how the network is structured visually.

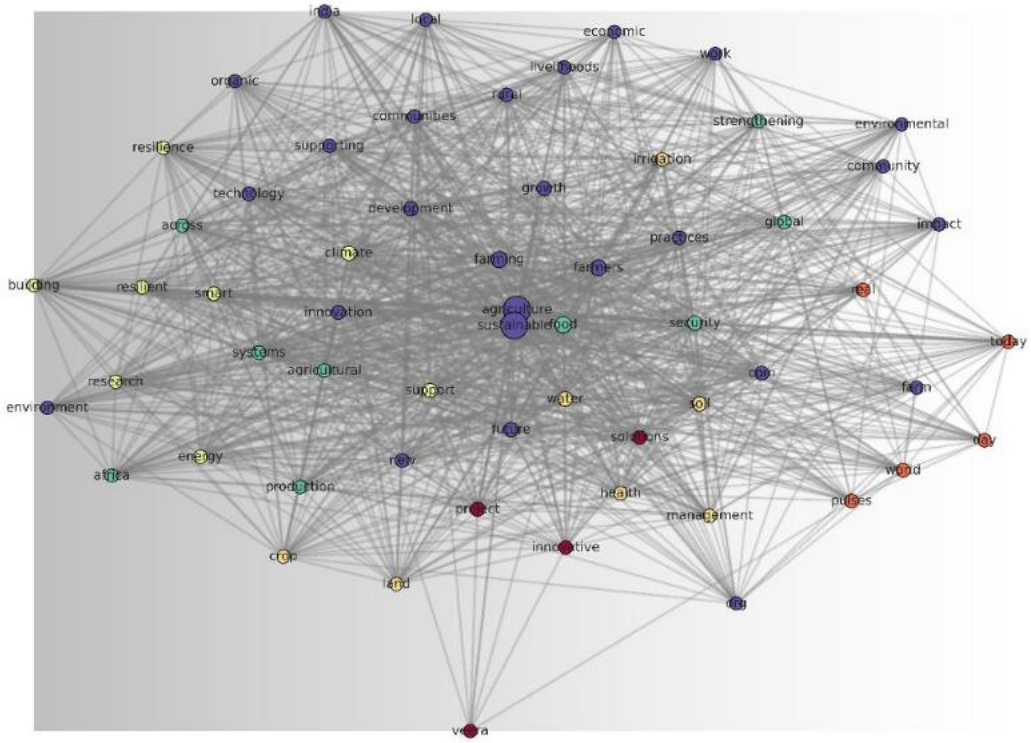

Fig. 5 - Keyword co-occurrence network

The keyword co-occurrence network demonstrates strong interconnections between sustainability, food systems, and technological innovation, indicating a highly integrated and systemic discourse structure.

CONCLUSIONS

This study provides a comprehensive analysis of sustainable agriculture discourse in the digital public sphere by integrating artificial intelligence–based methods with large-scale social media data. The findings reveal that discussions on sustainable agriculture are predominantly neutral and informational, largely shaped by institutional communication, policy-oriented content, and project-based narratives. At the same time, the significant presence of positive sentiment indicates that sustainable agriculture is strongly associated with innovation, technological advancement, and future-oriented development. In contrast, negative discourse remains limited and is primarily related to structural challenges such as resource inefficiency, management limitations, and the constraints faced by small-scale producers.

These findings are consistent with existing literature emphasizing the transformative role of artificial intelligence and digital technologies in sustainable agriculture (*Botero-Valencia et al., 2025; Kumari et al., 2025*). The prominence of themes such as food security, climate resilience, and smart farming aligns with studies highlighting the integration of technological innovation into sustainability frameworks (*Xu et al., 2024*). Furthermore, the dominance of informational discourse supports prior research suggesting that social media functions as both a communication and knowledge dissemination platform in agricultural systems *(Ofori & El-Gayar, 2021; Panda & Sinha, 2023*). However, unlike previous studies that primarily focus on technological applications or bibliometric patterns, this study demonstrates that sustainable agriculture is framed in digital discourse more as a narrative of transformation and opportunity rather than crisis. This shift toward solution-oriented and future-focused narratives represents a notable contribution to literature.

The originality of this study lies in its integration of artificial intelligence–based analytical methods with social media discourse analysis to examine sustainable agriculture from a socio-discursive perspective. By combining text mining, TF-IDF, BERT-based sentiment analysis, and LDA topic modelling, the study provides a multidimensional understanding of both the emotional and thematic structures of digital discourse. This integrative approach extends existing research by bridging the gap between technological innovation and public perception in the context of sustainable agriculture.

Despite these contributions, the study has several limitations. First, the analysis is based solely on data collected from the X platform, which may limit the generalizability of the findings across different digital environments. Second, the dataset was generated using the single keyword "sustainable agriculture," which

may have excluded relevant discussions expressed through alternative keywords or hashtags. Third, only English-language posts were analyzed, limiting the representation of multilingual perspectives on sustainable agriculture. In addition, although standard text preprocessing techniques were applied to improve data quality, these procedures may have removed contextual information and linguistic nuances. Furthermore, despite the use of a pretrained transformer-based sentiment classification model, contextual ambiguity and occasional misclassification may still occur, particularly in short and informal social media posts. Therefore, the findings should be interpreted within the scope of the analyzed dataset and should not be generalized to all online discussions on sustainable agriculture.

Future research can build on this study by incorporating multilingual datasets and cross-platform data sources, including Facebook, Instagram, Reddit, and YouTube, to achieve a more comprehensive understanding of digital agricultural discourse. Longitudinal analyses could also be conducted to examine how perceptions of sustainable agriculture evolve over time. Furthermore, multimodal approaches integrating text, images, and videos may provide richer insights into online discourse. Future studies may also compare alternative topic modelling techniques, such as BERTopic, Non-negative Matrix Factorization (NMF), and Dynamic Topic Models, together with different sentiment analysis models, to further improve the robustness and interpretability of artificial intelligence–based discourse analysis.

This study highlights the importance of integrating artificial intelligence and social media analytics into sustainability research, offering new insights into how agricultural transformation is perceived, constructed, and communicated in the digital age. These findings provide valuable implications for policymakers, practitioners, and researchers, emphasizing the need for inclusive communication strategies, technology-driven solutions, and policy frameworks that address both innovation and structural challenges in sustainable agriculture.

Keywords: *picking manipulator; path planning; Optimized-RRT; grid-number-guided sampling; dynamic sampling region; trajectory smoothing*

ABSTRACT
Irregular branches in agricultural picking environments require rapid collision-free path planning and smooth manipulator motion. This study developed an improved RRT algorithm guided by grid numbering, termed Optimized-RRT, based on a unified indexed-set representation of numbered primary and backup free-grid regions. Within this framework, dynamic region adjustment, target biasing, node occupancy, and local burst expansion jointly guide the search, while greedy pruning and quintic polynomial interpolation are applied to post-process the resulting path. Unlike geometric-region-based methods that generate coordinate samples within an updated sampling window, Optimized-RRT selects a valid grid number from the active set and maps it directly to the corresponding state. Compared with RRT, GB-RRT, and Informed-RRT*, the complete algorithm reduced planning time, the number of iterations, and the final number of path nodes by 40.61%–94.32%, 57.51%–88.66%, and 89.29%–94.59%, respectively, in two-dimensional scenarios, and by 88.95%–98.92%, 79.26%–94.67%, and 67.31%–90.83%, respectively, in three-dimensional scenarios. The reduction in the number of nodes resulted from the combined effects of guided search and path pruning. Manipulator simulations and a demonstration on a single experimental platform confirmed the executability of the generated trajectories under the tested conditions.*

摘要
农业采摘环境中的不规则枝条要求机械臂快速生成无碰撞路径并实现平稳运动。本文提出基于统一索引集合表示的栅格编号引导改进 RRT 算法（Optimized-RRT），将主、备用自由栅格区域表示为可直接寻址的编号集合。在这一表示下，动态区域调整、目标偏置、节点占用和局部突发扩展协同引导搜索，贪心剪枝和五次多项式插值用于所得路径的后处理。不同于在更新后的几何区域中生成坐标样本的方法，Optimized-RRT 从当前活动集合中选择有效栅格编号，并将其直接映射为相应状态。相较于 RRT、B-RRT 和 Informed-RRT，完整算法流程在二维场景中将规划时间、迭代次数和最终路径节点数分别降低 40.61%-94.32%、5.51%-88.66%和 89.29%-94.59%，在三维场景中分别降低 88.95%-98.92%、9.26%-94.6%和 6.31%-90.83%。节点数的降低源于引导搜索与剪枝的共同作用。机械臂仿真和单一平台演示验证了测试条件下轨迹的可执行性。

INTRODUCTION
Labor shortages and the need for consistent harvesting efficiency have accelerated the development of agricultural robots and autonomous fruit- and vegetable-picking systems *(Cheng et al., 2023; Chen et al., 2024)*. In orchards and greenhouses, irregular branches and canopy structures form unstructured obstacles that complicate manipulator motion *(Karim et al., 2025)*. A picking manipulator must therefore generate a collision-free path to the target pose with sufficient planning speed and motion smoothness.

Deterministic graph-search methods such as A* and D* can become computationally demanding as the state dimension and map complexity increase *(Xuan et al., 2025)*, whereas population-based optimization may converge too slowly for online planning *(Zhu and Pan, 2024)*. Sampling-based motion planners avoid exhaustive state-space enumeration and are therefore well suited to complex, high-dimensional planning problems *(Orthey et al., 2024*). In agricultural applications, improved RRT variants have been used for grape-picking manipulators *(Hu et al., 2024)*, adaptive-step planning of tea-picking arms *(Li et al., 2024)*, and RGB-D-assisted Bi-RRT planning for orchard harvesting manipulators *(Liu et al., 2024)*.

These studies establish the application relevance of RRT-based planning, while conventional RRT still remains affected by random exploration, repeated expansion, and non-smooth paths.

Region-restricted and goal-guided sampling methods are the closest prior work to the present study. RRT* established parent reselection and rewiring as a foundation for asymptotically optimal sampling-based planning *(Karaman and Frazzoli, 2011)*, while Informed-RRT* restricts post-solution sampling to an admissible ellipsoidal subset *(Gammell et al., 2014)*. *Feng et al. (2023)* combined map-dependent step size and bias probability with dynamic sampling-region updates, sampling-point optimization, and node reconnection. For manipulators, *Shang et al. (2024)* developed the RRT*-DR algorithm for obstacle-avoidance planning, and *Xiao et al. (2024)* proposed FBi-RRT with heuristic node expansion. *He et al. (2025)* further combined ellipsoidal subset sampling and goal-biased sampling with adaptive step size, node rejection, pruning, and spline smoothing. These representative methods improve efficiency by restricting the geometric sampling domain, biasing expansion toward promising states, optimizing tree connections, or combining these mechanisms.

However, geometric-region restriction and target bias do not by themselves provide a common representation for active-region membership, alternative-region switching, and repeated-cell suppression. A target-biased planner changes how often the goal is selected, but its remaining samples still require a defined sampling domain. Likewise, a dynamically updated geometric window identifies where coordinates may be generated but does not necessarily make the valid free states directly addressable. The remaining engineering need is therefore a representation that coordinates region restriction and sampling control without presenting these established strategies as individually new.

Optimized-RRT addresses this need by representing the free cells of the main and backup regions as disjoint, directly addressable sets of grid numbers. A non-goal sample is obtained by selecting a number from the active set and mapping it directly to the corresponding cell-center state; dynamic restriction is implemented by set intersection, backup-region switching preserves an alternative sampling source, and node occupancy suppresses revisits at the selected grid resolution. Target bias therefore operates within the indexed-set representation rather than replacing region management. This differs from methods that primarily update a continuous sampling window or modify the probability or direction of goal-oriented sampling.

Accordingly, the primary contribution of this study lies in the indexed-set representation and the coordinated search mechanisms that it enables, rather than in the individual application of dynamic region adjustment, target biasing, pruning, or interpolation. The proposed representation supports direct grid-number-to-state mapping generalized to *d*-dimensional spaces and is integrated with local burst expansion, greedy pruning, and quintic polynomial interpolation within a unified search-to-trajectory pipeline for agricultural picking manipulators. The evaluation included repeated 2D and 3D simulations, sensitivity and ablation analyses, manipulator simulations, and a platform-based feasibility demonstration. No new results concerning asymptotic optimality or probabilistic completeness are claimed.

MATERIALS AND METHODS

Kinematic Modeling of the Picking Manipulator

Model of the Picking Manipulator and Modified D–H Parameters

A six-axis collaborative manipulator was used. Its model and modified D–H coordinate system are shown in Fig. 1, and the corresponding parameters are listed in Table 1.

a) *b)*

Fig. 1 – Six-axis collaborative manipulator: (a) manipulator model; (b) modified D–H coordinate system

Table 1

Modified D–H parameters of the manipulator

i	α_{i-1} [°]	a_{i-1} [m]	Joint variable θ_i	d_i [m]
1	0	0	θ_1	0.187
2	90	0	θ_2	0.006
3	0	0.210	θ_3	0
4	-90	0	θ_4	0.2105
5	90	0	θ_5	0
6	-90	0	θ_6	0.1593

Based on the modified D–H convention, the homogeneous transformation matrix from frame i to frame $i-1$ is expressed as:

$$\mathbf{T}_i^{i-1} = \begin{bmatrix} c_{\theta_i} & -s_{\theta_i} & 0 & a_{i-1} \\ s_{\theta_i}c_{\alpha_{i-1}} & c_{\theta_i}c_{\alpha_{i-1}} & -s_{\alpha_{i-1}} & -d_i s_{\alpha_{i-1}} \\ s_{\theta_i}s_{\alpha_{i-1}} & c_{\theta_i}s_{\alpha_{i-1}} & c_{\alpha_{i-1}} & d_i c_{\alpha_{i-1}} \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (1)$$

In Eq. (1), $c_{\theta_i} = \cos\theta_i$ and $s_{\theta_i} = \sin\theta_i$; the same notation applies to α_{i-1}. The end-effector pose relative to the base frame is obtained by successively multiplying the six adjacent-frame transformation matrices:

$$\mathbf{T}_6^0 = \mathbf{T}_1^0\mathbf{T}_2^1\mathbf{T}_3^2\mathbf{T}_4^3\mathbf{T}_5^4\mathbf{T}_6^5 = \prod_{i=1}^{6}\mathbf{T}_i^{i-1} \quad (2)$$

Collision Detection Modeling

For efficient collision checking, manipulator links were approximated by cylinders and irregular obstacles by spherical envelopes *(Jiang L. et al., 2022; Shi et al., 2022; Wang H. et al., 2025)*. As shown in Fig. 2, the link radius, obstacle radius, and an additional safety margin were combined into a conservative collision radius.

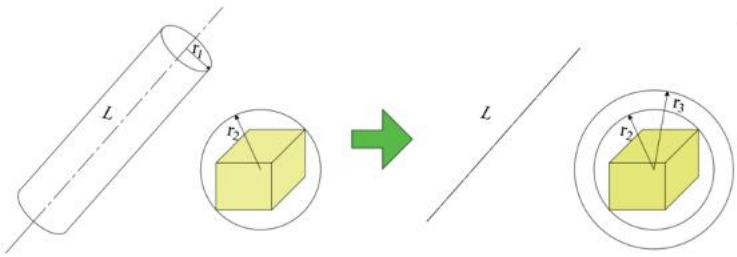

Fig. 2 – Conservative geometric simplification for collision detection

As shown in Fig. 3, each link segment was discretized into N equal subintervals. The point locations, point-to-obstacle distances, conservative collision radius, and collision criterion are defined as:

$$\begin{gathered} \mathbf{P}_i = \mathbf{P}_s + \frac{i}{N}(\mathbf{P}_e - \mathbf{P}_s), \quad i = 0,1,\ldots,N \\ d_i = \|\mathbf{P}_i - \mathbf{C}_o\|_2 = \sqrt{(x_i - x_c)^2 + (y_i - y_c)^2 + (z_i - z_c)^2} \\ r_c = r_l + r_o + \delta_s \\ \min_{0\le i\le N} d_i \le r_c \end{gathered} \quad (3)$$

In Eq. (3), $\mathbf{P}_s$ and $\mathbf{P}_e$ are the start and end points of the link segment, $\mathbf{P}_i$ is its i-th discrete point, and N is the number of equal subintervals. $\mathbf{C}_o = (x_c, y_c, z_c)^{\mathrm{T}}$ is the obstacle-center coordinate, while r_l, r_o, and δ_s denote the link-envelope radius, obstacle-envelope radius, and additional safety margin, respectively.

A collision was identified when the minimum discrete-point distance was not greater than the conservative collision radius. N was selected link-wise to keep adjacent checking points close relative to the conservative envelope. This discrete approximation improves efficiency but does not constitute certified continuous-time clearance; the safety margin represents modeling and localization uncertainty rather than a measured minimum clearance.

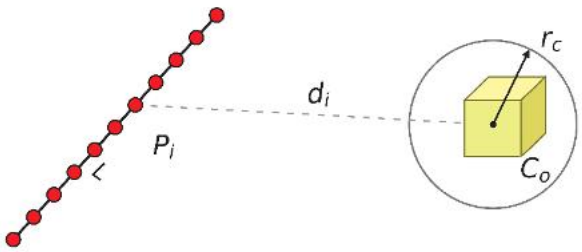

Fig. 3 – Discrete point-to-sphere collision detection along a link segment

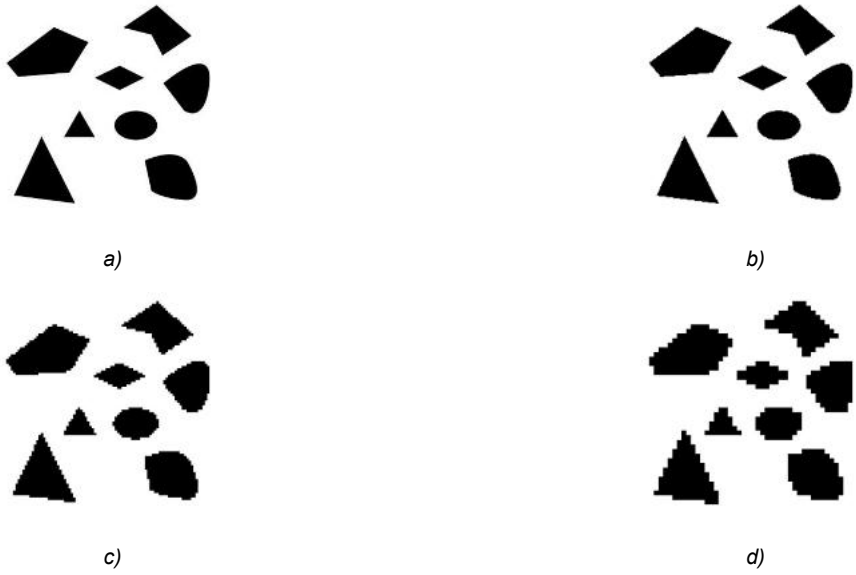
Strategy of the Proposed Optimized-RRT Algorithm

Grid Map Construction

The planning map was discretized into fixed cells. A cell was marked as occupied when it intersected an obstacle; otherwise, it was treated as free. The complete grid set is defined as:

$$\mathcal{C} = \{c_{ij} \mid i = 1,2,\dots,n_r;\ j = 1,2,\dots,n_c\}, \qquad N_g = n_r n_c \tag{4}$$

In Eq. (4), c_{ij} denotes the cell in row i and column j, n_r and n_c are the numbers of rows and columns, and $N_g = n_r n_c$ is the total number of grid cells. The obstacle set is defined as:



$$\mathcal{O} = \{o_k \mid k = 1,2,\dots,N_o\} \tag{5}$$

In Eq. (5), o_k denotes the k-th obstacle and N_o is the total number of obstacles. The occupancy state of each grid cell is described by the Boolean function:

$$\begin{aligned} f(c_{ij}) &= 1, \quad \text{if } \exists\, o_k \in \mathcal{O}:\ \Omega(c_{ij}) \cap \Omega(o_k) \neq \varnothing \\ f(c_{ij}) &= 0, \quad \text{otherwise} \end{aligned} \tag{6}$$

In Eq. (6), $\Omega(c_{ij})$ and $\Omega(o_k)$ denote the physical regions occupied by grid cell c_{ij} and obstacle o_k, respectively. A value of $f(c_{ij}) = 1$ identifies an obstacle cell, whereas $f(c_{ij}) = 0$ identifies a free cell.

Grid resolution controls the trade-off between obstacle-boundary fidelity and computational cost: smaller cells preserve geometry more accurately but increase storage and processing requirements. Fig. 4 compares side lengths of 2, 5, and 10 pixels. The precision retention ratio is the original obstacle area divided by the occupied grid-cell area; lower values indicate greater obstacle expansion after discretization.

a) *b)*

c) *d)*

Fig. 4 – Grid discretization at different resolutions: (a) original image; (b) 2 pixels; (c) 5 pixels; (d) 10 pixels

Table 2

Grid discretization data at different cell sizes

Grid side length [pixels]	Time [s]	Precision retention ratio
2	0.0509	0.97
5	0.0087	0.90
10	0.0027	0.77

As the grid side length increased from 2 to 10 pixels, processing time decreased from 0.0509 to 0.0027 s, while the precision retention ratio decreased from 0.97 to 0.77 (Table 2). The image-based example in Fig. 4 and Table 2 illustrates the general trade-off between grid resolution and processing efficiency. In the subsequent path-planning experiments, a grid side length of 10 mm was adopted as the baseline setting.

Grid-Number-Guided Sampling

Conventional restricted-region sampling defines a geometric domain and then generates coordinates within it; depending on the representation, samples may still fall outside the active free subset or revisit previously explored cells *(Oh et al., 2025; He et al., 2025).* Optimized-RRT instead divides the free workspace into a main sampling region and a backup sampling region (Fig. 5) and represents both regions using disjoint sets of valid grid numbers. The main set concentrates non-goal sampling toward the target, whereas the backup set preserves alternative routes when expansion in the main region becomes inefficient. Target-biased samples are introduced within this set-based region-management framework.

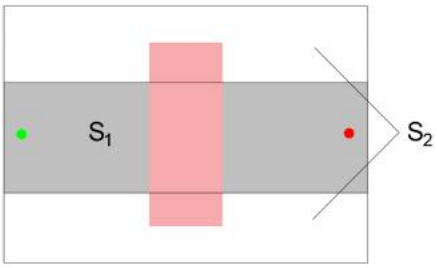


Fig. 5 – Division of the main and backup sampling regions

Each grid cell is assigned a unique number (Fig. 6). Sampling is performed by selecting a number from the active region set and mapping that number to the corresponding cell-center coordinate.

1	8	15	22	29	36	43	50	57	64
2	9	16	23	30	37	44	51	58	65
3	10	17	24	31	38	45	52	59	66
4	11	18	25	32	39	46	53	60	67
5	12	19	26	33	40	47	54	61	68
6	13	20	27	34	41	48	55	62	69
7	14	21	28	35	42	49	56	63	70

Fig. 6 – Grid numbering used for region-guided sampling

Using column-major numbering, each grid cell is assigned a unique number and the free-grid sampling set is defined as:

$$g_{ij} = (j-1)n_r + i, \qquad \mathcal{G}_f = \{g_{ij} \mid f(c_{ij}) = 0\} \tag{7}$$

In Eq. (7), $g_{ij} = (j-1)n_r + i$ is the unique number of the cell in row i and column j, and $\mathcal{G}_f$ contains only free-grid numbers. The main and backup sampling sets are defined as:

$$\begin{gathered} \mathcal{A} = \{g \in \mathcal{G}_f \mid \mathbf{x}(g) \in \Omega_{\text{main}}\} \\ \mathcal{B} = \{g \in \mathcal{G}_f \mid \mathbf{x}(g) \in \Omega_{\text{backup}}\} \\ \mathcal{A} \cup \mathcal{B} = \mathcal{G}_f, \qquad \mathcal{A} \cap \mathcal{B} = \varnothing \end{gathered} \tag{8}$$

In Eq. (8), $\mathbf{x}(g)$ maps grid number g to its cell-center coordinate, while Ω_{main} and Ω_{backup} denote the main and backup spatial regions. The two sets form a disjoint partition of $\mathcal{G}_f$, so direct number selection always produces a sample in the active free-grid region.

The following switching rule determines the active sampling region:

$$\begin{aligned} S_{k+1} &= S_2, \quad S_k = S_1, \quad \frac{N_1^{\text{succ}}}{\max\left(N_1^{\text{fail}}, 1\right)} < T_{\text{eff}} \\ S_{k+1} &= S_1, \quad S_k = S_2, \quad N_2^{\text{succ}} > \text{floor}\left(\frac{L}{10\Delta}\right) \\ S_{k+1} &= S_k \end{aligned} \tag{9}$$

In Eq. (9), S_k is the active region before the k-th switching decision. N_1^{succ} and N_1^{fail} are the numbers of successful and failed node-generation attempts in the main region S_1, respectively. T_{eff} is the region-switching threshold. N_2^{succ} is the number of valid nodes generated in the backup region S_2, L is the start-to-target distance, and Δ is the fixed expansion step.

After each switch, the counters are reset to avoid overly frequent alternation. When the valid-to-invalid expansion ratio in S_1 falls below T_{eff}, sampling is transferred to S_2; after sufficient valid expansion in S_2, the algorithm returns to S_1.

Local Burst Expansion Sampling Strategy

Local burst expansion provides two candidate samples in one iteration. The first is the center of a randomly selected grid; the second is generated within its neighboring-grid region (Fig. 7).

a) b)

Fig. 7 – Local burst expansion: (a) primary grid selection; (b) neighboring-grid sampling region

If the primary candidate fails to generate a valid node, a second candidate is sampled from the neighboring-grid region defined by:

$$\mathcal{R}_{\text{local}} = \{(x, y) \in \Omega_{\text{free}} \mid |x - x_c| \le d,\ |y - y_c| \le d\} \tag{10}$$

In Eq. (10), (x_c, y_c) is the center of the primary grid and d is the neighborhood half-width. For a one-cell neighborhood, d equals the grid side length. The second candidate reduces iterations lost when the first candidate is invalid.

Dynamic Sampling Region Strategy

The active sampling region is dynamically narrowed as the tree approaches the target. When a newly generated node is closer to the target than all existing nodes, its grid number and the target grid number define the updated sampling interval. A narrowly updated region may stagnate near an obstacle (Fig. 8(a)). The interval is therefore expanded on both sides to preserve alternative search directions (Fig. 8(b)).

a) b)

Fig. 8 – Dynamic sampling region: (a) narrowed region; (b) expanded region

The dynamically expanded free-grid interval is defined as:

$$g_{\min} = \max(1, \min(u, v) - fn_r)$$
$$g_{\max} = \min(N_g, \max(u, v) + fn_r) \quad (11)$$
$$\mathcal{G}' = \{g \in \mathcal{G}_f \mid g_{\min} \le g \le g_{\max}\}$$

In Eq. (11), u and v are the grid numbers of the target and the current node closest to the target, respectively; f is the number of columns added on each side; n_r is the number of grid cells per column; and N_g is the total number of grid cells. The operators $\min(u, v)$ and $\max(u, v)$ ensure that the interval remains valid regardless of the numbering direction. The partition sets are then updated as:

$$\mathcal{A}' = \mathcal{A} \cap \mathcal{G}', \qquad \mathcal{B}' = \mathcal{B} \cap \mathcal{G}' \quad (12)$$

Equation (12) intersects the original main and backup sets with the dynamically expanded free-grid set. This preserves the original spatial partition while removing grid numbers outside the active interval.

Extension to Three-Dimensional and Joint Spaces

For a d-dimensional state $\mathbf{q} = (q_1, \ldots, q_d)$, let $q_{k,\min}$ and $q_{k,\max}$ be the bounds of dimension k, h_k its cell width, n_k the number of cells, and $i_k = \lfloor \frac{q_k - q_{k,\min}}{h_k} \rfloor$ its zero-based index. The mixed-radix grid number is $g(\mathbf{q}) = 1 + \sum_{k=1}^{d} i_k \prod_{j=1}^{k-1} n_j$; the inverse state is recovered by integer division and remainder operations followed by cell-center mapping. Equation (7) is the $d = 2$ case; $d = 3$ was used for Cartesian simulation and $d = 6$ for the manipulator configuration space, with joint bounds obtained from the URDF model.

Main and backup sets contain free grid numbers whose centers satisfy the corresponding region definitions, and a local neighborhood satisfies $|i_k - i_{k,c}| \le r_k$ in every dimension. Number/state mapping costs $O(d)$, whereas the potential grid count $\prod_{k=1}^{d} n_k$ grows exponentially with dimension, so memory and behavior depend on resolution. Node occupancy suppresses revisits at cell resolution but may discard distinct configurations within one cell. Accordingly, no probabilistic-completeness or resolution-independent scalability claim is made.

Node occupancy Strategy

Each accepted node marks its grid cell as occupied (Fig. 9). A candidate falling in an occupied cell is discarded, reducing repeated visits and redundant computation.

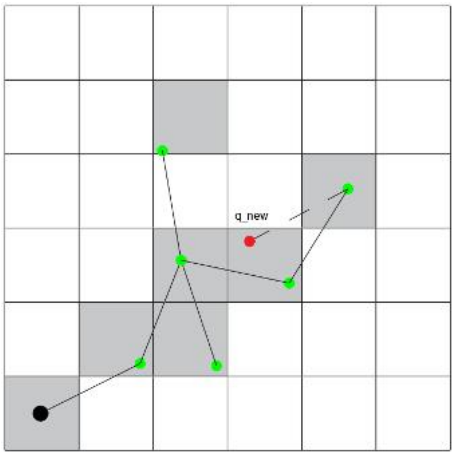

Fig. 9 – Node occupancy strategy

Target-Biased Sampling Strategy

Target-biased sampling improves the directional efficiency of tree expansion. The sampling rule is defined as follows:

$$\mathbf{x}_{\text{sample}} = \mathbf{x}_{\text{goal}}, \quad \xi \le p_g$$
$$\mathbf{x}_{\text{sample}} = \mathbf{x}(g), \quad \xi > p_g, \quad g \sim U(\mathcal{G}_{\text{active}}) \quad (13)$$
$$\xi \sim U(0,1)$$

In Eq. (13), ξ is uniformly distributed over $[0,1]$, p_g is the target-bias probability, $\mathcal{G}_{\text{active}}$ is the currently active grid-number set, and $\mathbf{x}(g)$ maps a selected grid number to its cell-center coordinate.

Greedy Pruning Strategy

The raw path may contain redundant intermediate nodes. Greedy pruning tests direct collision-free connections from the current node to later nodes and removes all bypassed nodes (Fig. 10).

a) b)

Fig. 10 – Greedy pruning: (a) raw path; (b) pruned path

Quintic Polynomial Interpolation for Trajectory Smoothing

A quintic polynomial was applied independently to each joint and each consecutive pruned path segment to obtain continuous joint position, velocity, and acceleration under specified endpoint conditions *(Xu et al., 2023)*:

$$\theta_j^{(s)}(t) = a_{0,j}^{(s)} + a_{1,j}^{(s)}t + a_{2,j}^{(s)}t^2 + a_{3,j}^{(s)}t^3 + a_{4,j}^{(s)}t^4 + a_{5,j}^{(s)}t^5, \quad 0 \le t \le T_s \tag{14}$$

For segment s, the start and end positions are defined by consecutive joint-space waypoints, while the endpoint velocity and acceleration are set to zero. The polynomial coefficients are obtained from:

$$\mathbf{a}_j^{(s)} = \mathbf{M}(T_s)^{-1}\mathbf{b}_j^{(s)}$$

$$\mathbf{M}(T_s) = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 2 & 0 & 0 & 0 \\ 1 & T_s & T_s^2 & T_s^3 & T_s^4 & T_s^5 \\ 0 & 1 & 2T_s & 3T_s^2 & 4T_s^3 & 5T_s^4 \\ 0 & 0 & 2 & 6T_s & 12T_s^2 & 20T_s^3 \end{bmatrix} \tag{15}$$

$$\mathbf{b}_j^{(s)} = \left[\theta_j^{(s)}(0) \quad \dot{\theta}_j^{(s)}(0) \quad \ddot{\theta}_j^{(s)}(0) \quad \theta_j^{(s)}(T_s) \quad \dot{\theta}_j^{(s)}(T_s) \quad \ddot{\theta}_j^{(s)}(T_s)\right]^{\mathrm{T}}$$

In Eq. (15), $\mathbf{a}_j^{(s)} = \left[a_{0,j}^{(s)}, a_{1,j}^{(s)}, \ldots, a_{5,j}^{(s)}\right]^{\mathrm{T}}$ is the coefficient vector for joint j in segment s, T_s is the segment duration, and $\mathbf{b}_j^{(s)}$ contains the prescribed endpoint position, velocity, and acceleration. In this study, the endpoint velocities and accelerations were set to zero.

Quintic interpolation was applied segment by segment after pruning to produce the final executable joint trajectory.

Workflow of Optimized-RRT

Fig. 11 summarizes the complete pipeline: initialization and d-dimensional grid numbering are followed by region-set construction, grid-number sampling, collision and occupation checks, tree extension, region updating, path backtracking, greedy pruning, and quintic interpolation.

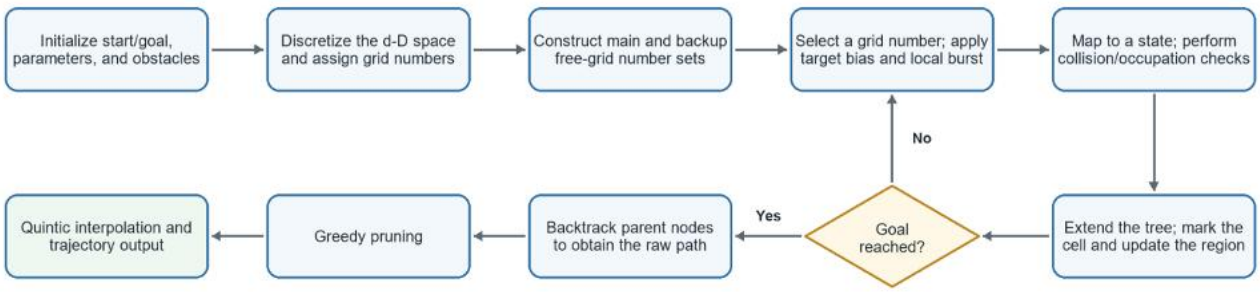

Fig. 11 – Workflow of Optimized-RRT

RESULTS

Simulation Experiments and Analysis of the Algorithm

RRT, goal-biased RRT* (GB-RRT*), Informed-RRT*, and Optimized-RRT were compared as practical time-to-feasible-path planners in 2D, 3D, and manipulator scenarios. Within each scenario, they used the same map, start/target states, obstacle model, collision criterion, computing environment, and expansion settings where applicable. Each implementation retained its own search and rewiring logic and stopped when it returned a feasible path; the comparison therefore concerns the implemented pipelines rather than asymptotic RRT* optimality.

For each algorithm and scenario, 100 independent simulations with random seeds were conducted in MATLAB 2022b on 64-bit Windows 11 Enterprise with an Intel Core i5-13500H processor. The tables report descriptive mean ± standard deviation for planning time, iterations, and path length, and the mean final node count. Greedy pruning was part of the Optimized-RRT pipeline and was not retrofitted to every baseline; consequently, final-node reductions represent the complete pipelines and cannot be attributed solely to sampling. The archived results were aggregate summaries, so no post hoc significance test or success-rate reconstruction was added, and no claim of statistical significance is made.

Two-Dimensional Simulation in a Narrow Agricultural Environment

The basic parameters of the four algorithms were kept consistent in the typical two-dimensional narrow and complex scenario. The simulation map was $1000\ \mathrm{mm} \times 1000\ \mathrm{mm}$, and each grid cell was $10\ \mathrm{mm} \times 10\ \mathrm{mm}$. The start and target points were $(35{,}35)\ \mathrm{mm}$ and $(900{,}900)\ \mathrm{mm}$, respectively, and the fixed expansion step was $\Delta = 20\ \mathrm{mm}$. The target-bias probability of both Optimized-RRT and GB-RRT* was set to $p_g = 0.05$. For Optimized-RRT, the number of expanded columns was $f = 10$, and the region-switching threshold was $T_{\mathrm{eff}} = 0.16$.

Fig. 12 shows the exploration trees and collision-free paths. Green and red circles denote the start and target, black areas denote obstacles, green lines denote the search tree, and the red line denotes the final path. In Fig. 12(d), the area between the blue boundaries is the main sampling region. Across 100 runs, Optimized-RRT reduced mean planning time by 40.61%–94.32%, iterations by 57.51%–88.66%, and final path-node count by 89.29%–94.59% relative to the three baselines (Table 3). Fig. 12 also shows a more concentrated search tree, with fewer repeated expansions near obstacles.

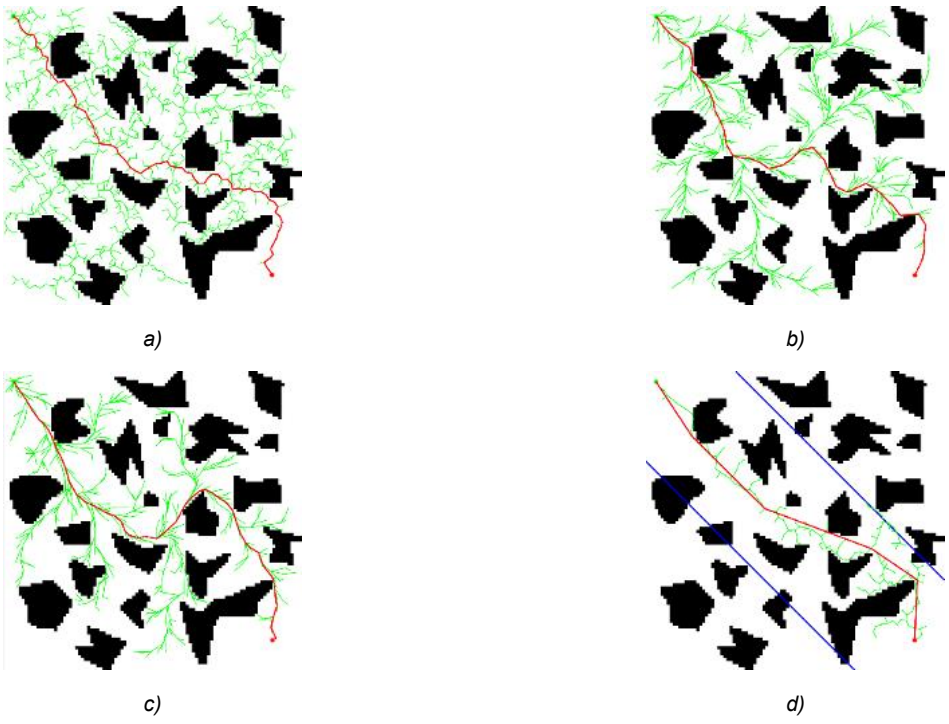

Fig. 12 – Two-dimensional planning results: (a) RRT; (b) GB-RRT*; (c) Informed-RRT*; (d) Optimized-RRT

Table 3

Performance comparison in the two-dimensional scenario (descriptive statistics)

Algorithm	Planning time [s]	Number of iterations	Path length [mm]	Final path nodes
RRT	0.097 ± 0.121	1144.1 ± 641.5	1674.990 ± 89.525	85.04
GB-RRT*	0.049 ± 0.026	662.3 ± 178.0	1448.045 ± 77.170	42.93
Informed-RRT*	0.512 ± 0.654	2480.7 ± 1127.6	1451.024 ± 74.337	43.07
Optimized-RRT	0.029 ± 0.011	281.4 ± 82.0	1291.823 ± 40.641	4.60

Three-Dimensional Simulation

The parameters of the four algorithms were kept consistent in the typical three-dimensional case. The simulation space was $500\,\mathrm{mm} \times 500\,\mathrm{mm} \times 500\,\mathrm{mm}$, and each grid cell was $10\,\mathrm{mm} \times 10\,\mathrm{mm} \times 10\,\mathrm{mm}$. The start and target points were $(10,10,10)\,\mathrm{mm}$ and $(460,460,460)\,\mathrm{mm}$, respectively, and the fixed expansion step was $\Delta = 20\,\mathrm{mm}$. For Optimized-RRT, $f = 10$ and $T_{\mathrm{eff}} = 0.16$.

In the three-dimensional scenario, Optimized-RRT reduced planning time by 88.95%–98.92%, iterations by 79.26%–94.67%, and final path-node count by 67.31%–90.83% relative to the baselines (Table 4). Figs. 13 and 14 show that Optimized-RRT generated a sparser exploration tree and a path with fewer turns. Grid-number-guided sampling concentrated expansion within the active region, while region switching preserved obstacle-bypassing alternatives and pruning simplified the final path.

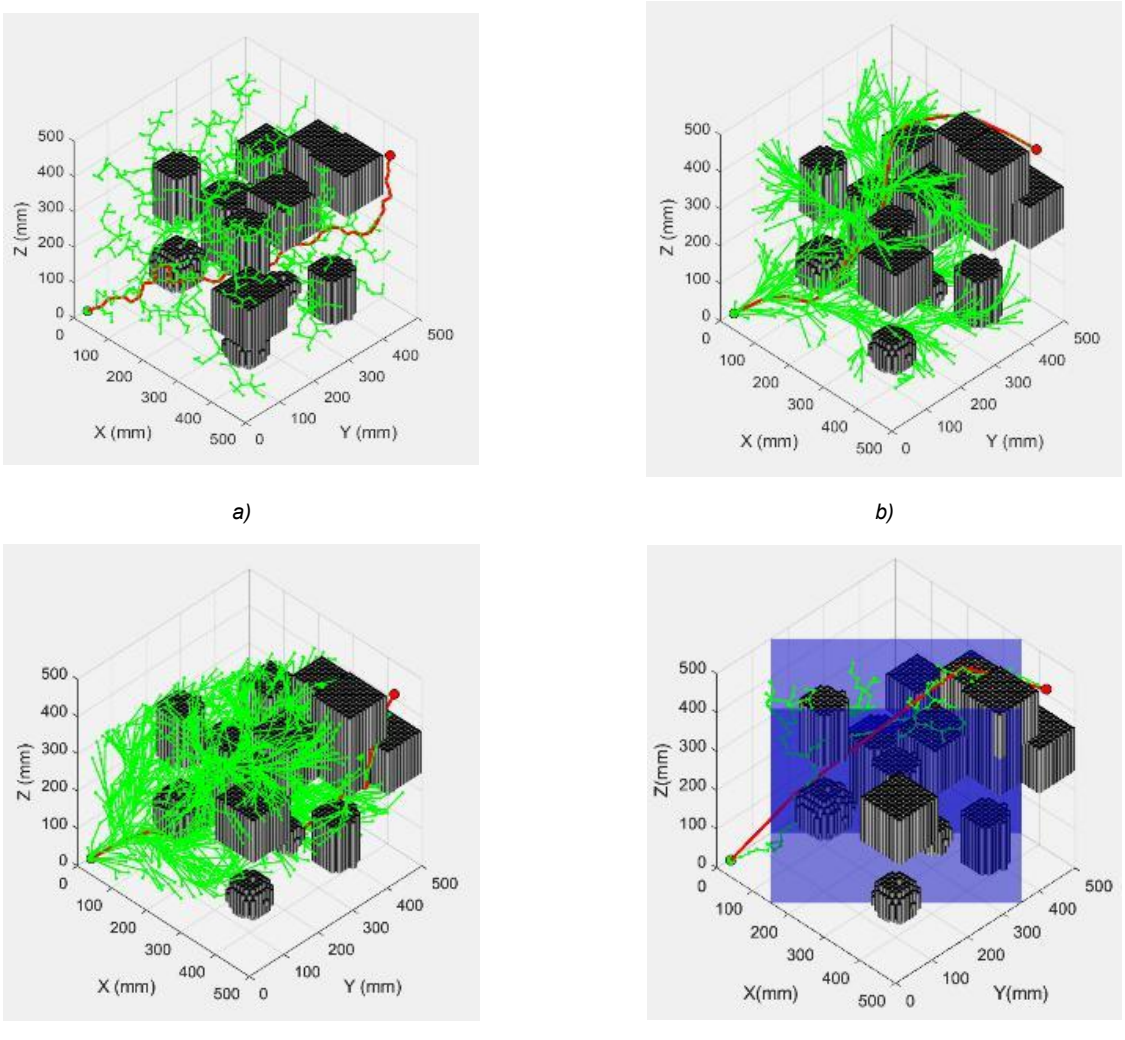

Fig. 13 – Three-dimensional exploration trees: (a) RRT; (b) GB-RRT*; (c) Informed-RRT*; (d) Optimized-RRT

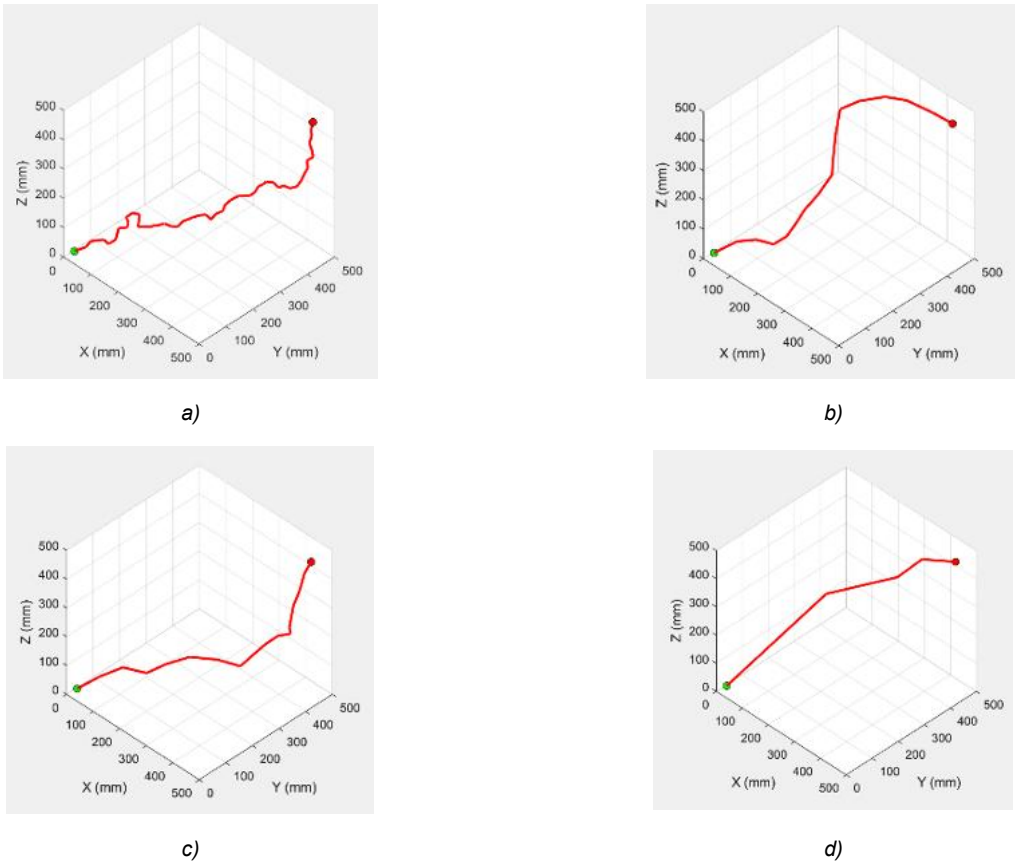

Fig. 14 – Three-dimensional final paths: (a) RRT; (b) GB-RRT*; (c) Informed-RRT*; (d) Optimized-RRT

Table 4

Performance comparison in the three-dimensional scenario (descriptive statistics)

Algorithm	Planning time [s]	Number of iterations	Path length [mm]	Final path nodes
RRT	0.662 ± 0.559	2400.9 ± 931.7	1239.371 ± 93.277	62.89
GB-RRT*	0.376 ± 0.421	1272.1 ± 650.1	932.245 ± 44.793	17.65
Informed-RRT*	3.825 ± 1.824	4948.0 ± 1383.4	947.552 ± 41.742	17.70
Optimized-RRT	0.041 ± 0.017	263.9 ± 81.1	858.918 ± 24.036	5.77

Parameter Sensitivity Analysis

A one-factor-at-a-time sensitivity analysis was conducted in the two-dimensional scenario. Grid side length was set to 5, 10, and 20 mm; expansion step Δ to 10, 20, and 30 mm; target-bias probability p_g to 0.02, 0.05, and 0.10; and region-switching threshold T_{eff} to 0.10, 0.16, and 0.25. Each level used 50 independent simulations with the other parameters fixed at their baseline values.

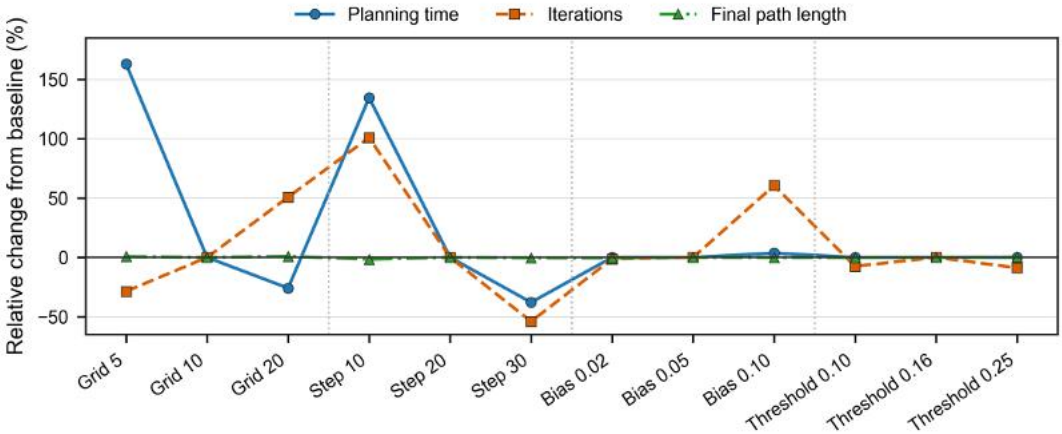

Fig. 15 – Parameter sensitivity analysis relative to the baseline settings

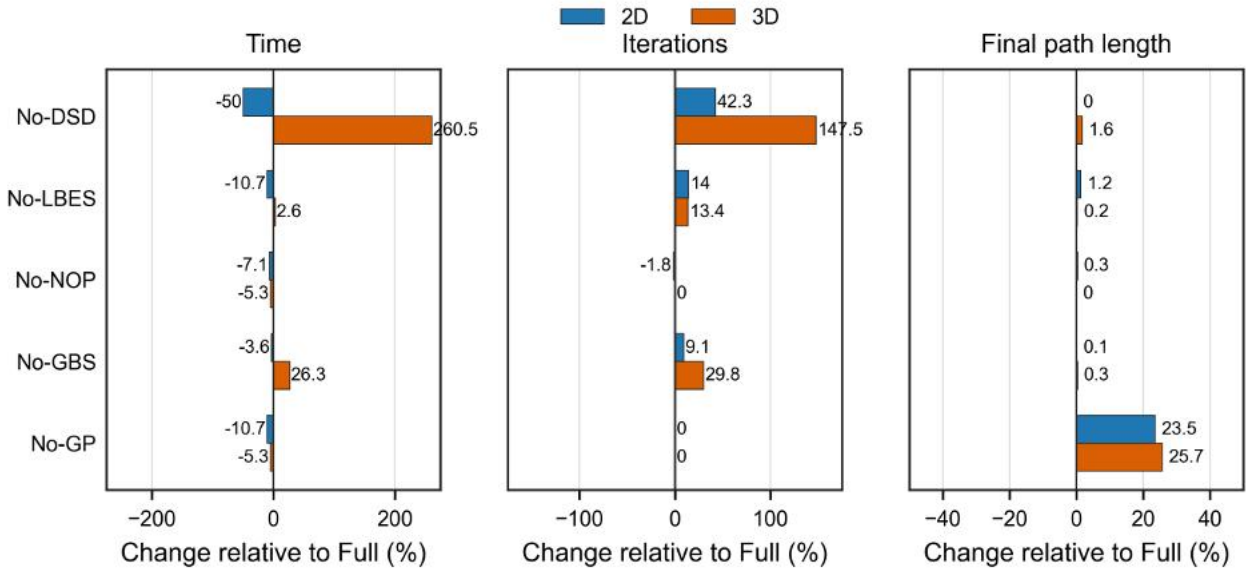
Fig. 15 shows that grid size and step size had the largest effects on planning time and iterations, whereas the final path length varied less. Smaller grids improved representation but increased numbering and search overhead; larger steps reduced expansion count but weakened local adjustment. Target-bias probability and the region-switching threshold had limited influence within the tested ranges. The baseline values—a 10-mm grid, $\Delta = 20\,\mathrm{mm}$, $p_g = 0.05$, and $T_{\mathrm{eff}} = 0.16$—provided a balanced combination of planning efficiency and path quality.

Ablation Experiment on Optimization Strategies

Ablation variants were created by disabling one strategy at a time: dynamic sampling-region adjustment (No-DSD), local burst expansion (No-LBES), node occupancy (No-NOP), target-biased sampling (No-GBS), or greedy pruning (No-GP). All variants used the same map, planning parameters, and random-seed sequence.

Planning time, iterations, original and final path lengths, and original and final node counts were recorded. All variants except No-GP used the same pruning procedure; No-GP retained the raw tree path.

Fig. 16 reports relative changes after each strategy was disabled; positive values indicate increases in time, iterations, or path length. The ablation results show a dimension-dependent trade-off rather than uniform benefit. Removing dynamic region adjustment reduced 2D planning time by approximately 50%, and disabling node occupancy or target bias also produced small 2D time reductions, indicating that set maintenance can outweigh guidance in a simple space. In 3D, dynamic adjustment and target bias produced clearer efficiency benefits, while local burst expansion reduced iterations in both spaces. Greedy pruning dominated final path reduction. Because Fig. 16 contains relative aggregate changes without uncertainty intervals, these effects are interpreted directionally rather than as statistically established module contributions.



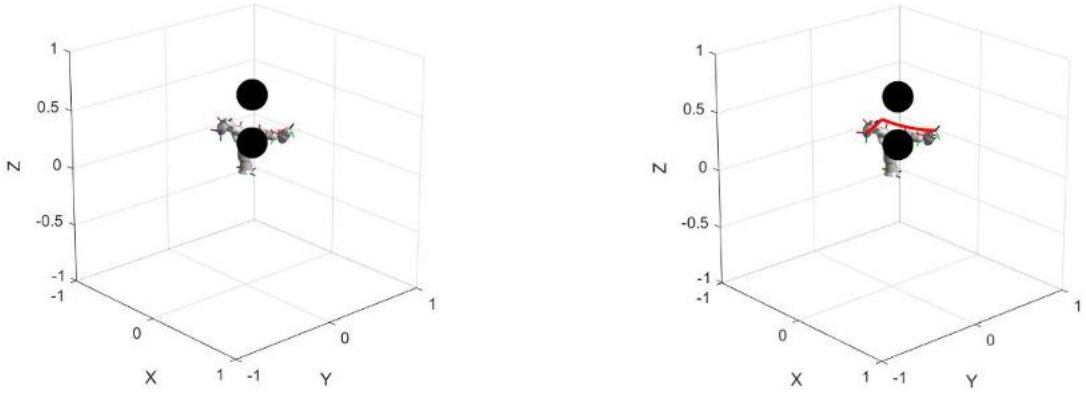


Fig. 16 – Ablation results relative to the complete Optimized-RRT

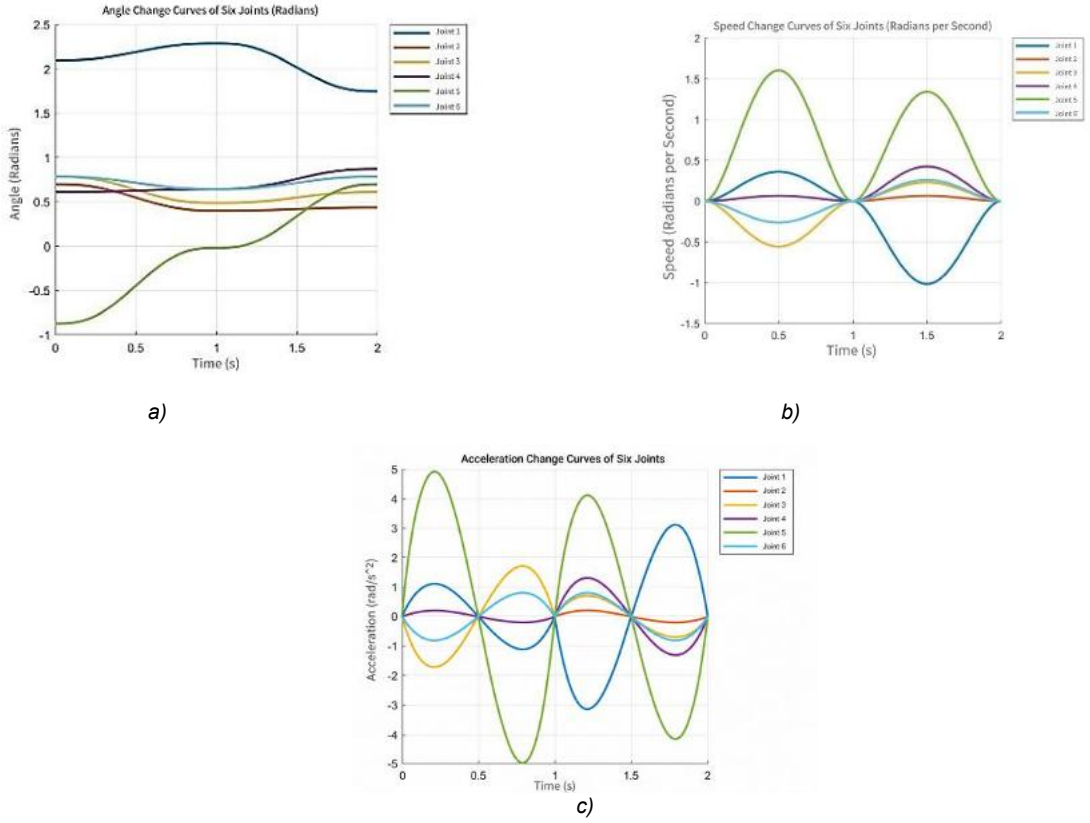
Simulation Experiment on Path Planning for the Picking Manipulator

A MATLAB 2022b manipulator simulation used the URDF model, the initial and target postures shown in Fig. 17, and two spherical obstacles centered at (0.33, −0.23, 0.40) m and (0.33, −0.23, 0.80) m (Fig. 17(a)).



Planning was performed in the six-dimensional joint space using the URDF joint limits and joint-specific grid indices described above. The pruned path was smoothed by quintic interpolation, and the resulting end-effector trajectory is shown in Fig. 17(b).

a) b)

Fig. 17 – Manipulator planning: (a) simulation environment; (b) end-effector trajectory

Fig. 18 shows continuous joint-angle, velocity, and acceleration profiles with the prescribed zero endpoint conditions. These curves demonstrate interpolation continuity, but they were not optimized against measured hardware velocity, acceleration, or jerk limits and should not be interpreted as a time-optimality or actuator-margin assessment.

Real-Platform Feasibility Demonstration in an Agricultural Picking Environment

A single-case feasibility demonstration used a picking platform comprising a six-degree-of-freedom collaborative manipulator, depth camera, flexible end-effector, robot controller, and ROS upper computer; joint commands were transmitted via Gigabit Ethernet. GB-RRT* and Optimized-RRT used the same target, obstacle distribution, and initial posture. Execution time denotes total platform motion/task time rather than isolated planning computation time; joint-space path length and final node count were also recorded. In this arrangement, Optimized-RRT reduced total execution time from 23.1 to 16.5 s (28.57%), joint-space path length from 3.12 to 2.61 rad (16.35%), and final path nodes from 36 to 4 (88.89%) relative to GB-RRT* (Table 5), demonstrating executability and lower path redundancy for this case but not repeatability, statistical superiority, or robustness across greenhouse conditions.

Table 5

Single-case real-platform execution results

Algorithm / optimization rate	Total execution time [s]	Path length [rad]	Final path nodes
GB-RRT*	23.1	3.12	36
Optimized-RRT	16.5	2.61	4
Optimization rate [%]	28.57	16.35	88.89

DISCUSSION AND LIMITATIONS

The indexed-set representation coordinated active-region restriction, backup-region switching, and repeated-cell suppression through a common sampling structure, but the benefits of its component strategies were dimension dependent. Grid-number guidance produced larger 3D gains while incurring 2D bookkeeping overhead. Planning time and iterations reflect sampling, extension, and switching, whereas node and path reductions depend strongly on pruning. Because baseline post-processing differed and only aggregate results were retained, comparisons are pipeline-level and establish neither module-level causality nor statistical significance. The single platform trial demonstrates feasibility, not robustness; discrete checking, uncalibrated clearance, and fixed endpoints limit safety conclusions. Future work should retain run-level data, harmonize post-processing, verify actuator and collision limits, and test varying branch density, occlusion, and localization error.

CONCLUSIONS

Optimized-RRT is built on a unified indexed-set representation of numbered main and backup free-grid regions. Within this representation, dynamic restriction, region switching, node occupancy, target bias, and local burst expansion coordinate the search, while greedy pruning and quintic interpolation post-process the path. In 2D, planning time, iterations, and final nodes decreased by 40.61%-94.32%, 57.51%-88.66%, and 89.29%-94.59%; in 3D, they decreased by 88.95%-98.92%, 79.26%-94.67%, and 67.31%-90.83%. The results support the value of the complete representation-and-processing pipeline rather than demonstrating that every component is uniformly beneficial: guided sampling improved search efficiency, whereas pruning dominated node reduction. Simulation yielded continuous trajectories, and the single platform case reduced total execution time, joint-space path length, and final nodes by 28.57%, 16.35%, and 88.89%, respectively. Repeatability, calibrated clearance, hardware-limit compliance, and robustness to branch density, occlusion, localization error, and fruit-tree geometry require further evaluation.

Keywords: *precision seed metering, mechanical seeding, pneumatic seeding, high-speed seeding, seed filling mechanism, structural optimization*

ABSTRACT

The seed metering device was identified as the core actuating component of precision seeding equipment, directly determining seeding accuracy, seed spacing uniformity, seedling emergence rate, and crop yield. This review systematically examined the technological evolution and research status of mechanical-type and pneumatic-type precision seed metering devices. The identified limitations of mechanical-type devices included low seed filling efficiency, poor seed clearing performance, insufficient operational stability at high speeds, and significant interference from field vibrations. Pneumatic-type devices were found to face technical bottlenecks including difficulties in precision seeding of small-sized seeds, high air pressure loss, poor airtightness, and susceptibility to hole clogging. Recent advances in structural innovation, mechanism analysis, parameter optimization, and performance improvement were summarized. A comparative analysis was conducted on the technical advantages and applicable scenarios of the two mainstream seed metering device types. Future development trends were envisioned towards high-speed and high-efficiency operation, universal adaptability, intelligent monitoring, and low-damage energy saving, providing a reference for the optimal design and technological upgrade of precision seeding equipment.

摘要

排种器是精量播种装备的核心执行部件，其工作性能直接决定播种精度、粒距均匀性、种子出苗率与作物产量。为系统梳理精量排种器技术演进与研究现状，本文针对机械式精量排种器存在的充种效率低、清种效果差、高速作业稳定性不足及田间振动干扰显著等问题，以及气力式精量排种器面临的小籽粒精量播种困难、风压损耗大、气密性与型孔易堵塞等技术瓶颈，分别综述结构创新、机理分析、参数优化与性能提升的最新研究进展；对比分析两类主流排种器的技术优势与适用场景，展望了精量排种器向高速高效、通用适配、智能监测、低损节能方向的发展趋势，为精量播种装备优化设计与技术升级提供了参考。

INTRODUCTION

Precision seeding is a key technology for precision agriculture to save costs, increase efficiency, and ensure uniform seedling emergence. It enables single-grain precision sowing, quantitative positioning, reduced production costs, and significantly improved land utilization and crop yield (*Liao et al., 2025*). As the core functional component of a precision seeder, the seed metering device undertakes the processes of seed storage, seed filling, seed clearing, seed carrying, and seed delivery. Its structural design, working mechanism, and dynamic performance directly affect seeding quality and operational reliability (*Singh et al., 2020*). Precision seed metering devices can be classified into three types based on power source and working principle: mechanical, pneumatic, and electric. Among them, the mechanical and pneumatic types are currently the mainstream applications, while the electric type is still in the experimental and gradual promotion stage (*Ren et al., 2021; Li et al., 2026*). As the present review focuses on the two dominant categories for which sufficient field performance data are available in the published literature, electric-driven seed metering devices were not systematically covered.

---

[2] Jinhui ZHAO, *Senior Engineer*;

As precision agriculture advances toward higher operational speeds and intelligent control, conventional seed metering devices have progressively failed to satisfy modern agronomic demands, particularly in terms of high-speed adaptability, seed versatility, small-seed precision, vibration resistance, and energy efficiency (*Ren et al., 2026; Li et al., 2026*).

Recent system-level syntheses have identified the speed–precision paradox as a coupled phenomenon in which placement accuracy degrades non-linearly beyond architecture-specific thresholds. A three-regime model was proposed: Regime 1 (<10 km/h) where metering-stage singulation quality governs precision; Regime 2 (10–14 km/h) where delivery-stage instabilities are amplified; and Regime 3 (>14 km/h) where vibration, control latency, and soil–machine interactions dominate system-level breakdown (*Hussain et al., 2026*). This framework provides a unified reference for interpreting speed-dependent performance across mechanical and pneumatic architectures.

In recent years, researchers worldwide have conducted extensive studies on seed filling mechanisms, seed clearing and damage prevention, airflow field optimization, vibration suppression, and intelligent detection of seed metering devices, achieving a series of innovative results *(Liu et al., 2026; Li et al., 2026)*. This review was conducted by searching Web of Science, CNKI, and Scopus databases using keywords "precision seed metering", "mechanical seed metering", and "pneumatic seed metering" for publications from 2000 to 2026. A total of 162 papers were initially identified, of which 80 were selected based on relevance to structural design and performance evaluation. For the quantitative comparison tables (Tables 2, 4, and 5), performance ranges were synthesized from the reviewed literature. The reported values represent representative intervals compiled from reported experimental results, reflecting typical operating conditions across multiple studies. These ranges are intended for comparative illustration rather than absolute performance benchmarking. This paper reviews the technical bottlenecks, solutions, and research progress of mechanical and pneumatic precision seed metering devices, clarifies existing problems and breakthrough paths, and discusses future development trends, aiming to provide a theoretical basis and technical reference for the design optimization, performance improvement, and engineering application of precision seed metering devices.

RESEARCH STATUS OF MECHANICAL-TYPE SEED METERING DEVICES

Mechanical-type seed metering devices rely on mechanical structure differentiation and the combination of gravity and mechanical force to complete seed filling, seed clearing, and seed delivery, without the need for air source assistance *(Li et al., 2020)*. They offer advantages such as simple structure, low manufacturing cost, stable operation, and convenient maintenance, and are widely used in small and medium-sized fields and hilly mountainous areas in China.

Research on precision seeding technology in China began in the 1970s. After stages of structural imitation, independent innovation, and performance optimization, mature structures such as disc type (*Li et al., 2022*), wheel-scoop type (*Su et al., 2022*), chain-scoop type (*Zhang et al., 2023; Dun et al., 2022*), indented wheel type (*Lu et al., 2023; Liu et al., 2016*), and finger-clip type (*Wang et al., 2015*) have been developed, which are suitable for sowing corn, soybean, wheat, coarse cereals, and small-seeded cash crops.

Overseas research on precision seeding technology began in the 1940s, with Germany and the United States as representative countries (*Lai et al., 2022*). The focus was on developing highly reliable structures such as the finger-clip type and the inclined disc type, which have significant advantages in high-speed seeding of large-seeded crops (*Barut et al., 2004*). To address the drawbacks of the finger-clip type precision seed metering device, the German company Schmotzer developed an inclined disc type precision seed metering device. This type of metering device is installed obliquely at the bottom of the seed box. Seeds rely on their own gravity to enter the holes laterally to complete seed filling, and then fall into the seed furrow as the disc rotates. This metering device has a simple structure and low seed damage rate. It is suitable for seeds with regular shape and good flowability, and has strong adaptability to round seeds such as soybean and peanut. However, flat seeds have poor flowability and are prone to jamming, leading to miss-seeding. Based on this type of metering device, *Anantachar et al. (2011)* used an artificial neural network to optimize the seeding performance parameters of the inclined disc type metering device, establishing a relationship model among seeding speed, vegetable seed spacing, and seed damage rate. *Yadachi et al. (2013)* investigated the relationship between the continuous seed filling capacity of carrot seeds and the inclined disc angle. Through comparative experimental analysis, they determined that an inclination angle of 50° was most suitable for seeding carrot seeds.

Grewal et al. (2015) studied the seeding performance of an inclined disc onion seeder under different rotational speeds and different numbers of grooves/holes, evaluating the machine using the qualified seeding index, multiple-seeding index, and miss-seeding index, and obtained satisfactory results. *Van Loon et al. (2020)* conducted a cross-continental comparative study of ten mechanical maize seed metering devices from Latin America, Sub-Saharan Africa, and Asia, identifying 20 RPM as the optimal rotational speed across device types and demonstrating that adjustable-hole metering devices consistently outperformed fixed-hole designs in terms of seeding quality and operational flexibility.

Table 1

Mechanical-type precision seed metering devices: types, features and representative crops

(Synthesized from Geng et al., 2016, 2018; Su et al., 2022; Li et al., 2022; Lu et al., 2023; Liu et al., 2016; Wang et al., 2015; Dun et al., 2022)

Type	Main Features	Representative Crops
Disc type	Hole shape determines seed size; hole spacing, together with travel speed, plate rotational speed, transmission ratio, seed bounce, and delivery dynamics, collectively determines plant spacing. Simple structure but limited versatility.	Corn, soybean
Wheel-scoop type	Simple and durable structure, but requires changing the seed scoop to adapt to different seeds.	Sorghum, *Pinellia ternata* (banxia), potato
Indented wheel type	Strong power adaptability but poor seed adaptability. Generally used for seeds with relatively spherical shape and high roundness.	Soybean, rapeseed
Finger-clip type	Relatively stable operational performance, but complex structure and limited versatility.	Corn, *Cyperus esculentus* (tiger nut)

Note: Structural schematic diagrams have been omitted for brevity. For detailed structural illustrations, please refer to the original cited references.

Mechanical-type seed metering devices have the advantages of simple structure, low cost, and reliable operation, but they still suffer from the following problems:

(1) Limited seed filling efficiency: The hole shape must closely match the seed geometry. Under high-speed operation, seed filling is insufficient, leading to an increased miss-seeding rate.

(2) Prominent seed clearing contradiction: Relying on gravity for seed clearing tends to cause multiple-seeding, while relying on rigid components for seed clearing tends to cause seed damage and jamming.

(3) Poor high-speed and vibration resistance: When the operating speed reaches 6 km/h or higher, seed spacing uniformity deteriorates, and field vertical vibration significantly interferes with seeding stability. However, this threshold is device-specific; for example, in a finger-clip type corn seed metering device, seed spacing uniformity was found to deteriorate significantly when operating speed exceeded 6 km/h (*Wang et al., 2019*), whereas newer designs with disturbance-assisted mechanisms have extended this limit substantially.

Rapid seed filling and stable seed delivery

To address the problems of insufficient seed filling and disordered seed delivery under high-speed operation, domestic and overseas scholars have improved performance through structural improvement, mechanical modeling, and parameter optimization. *Huang et al. (2022)* added a guide plate and a lateral double-fixing structure, which shortened the seed delivery path and achieved a qualified seeding rate of >95.27% at operating speeds of 4–14 km/h. *Liu et al. (2016)* proposed an opposed swash plate structure, established a seed filling mechanical model, and determined that the seed filling effect for soybean was optimal at an inclination angle of 20°. *Li et al. (2018)* designed a cone-disc centrifugal pushing structure, which reduced the miss-seeding rate by 2.52% at operating speeds of 7–13 km/h. *Correia et al. (2016)* showed through experiments that moderately increasing the inclination angle of the seed metering device and increasing the working rotational speed could reduce seed accumulation in the chamber and improve the stability of seed filling and seed delivery.

Dong et al. (2025) introduced a posture-adjusting seed metering device for high-speed maize planting, in which seed-filling posture was adjusted and the seed group was fluidized through groove-type structures. EDEM simulation and bench testing demonstrated that the optimized device achieved pass, repeat, and miss rates of 94.8%, 1.3%, and 3.9%, respectively.

Within the speed range of 8–14 km/h, the pass rate consistently exceeded 94%, with repeat rate below 2.1% and miss rate below 3.9%, substantially outperforming devices without posture-adjusting mechanisms.

For rice mechanical seeding, *Zhang et al. (2025)* calibrated DEM contact parameters using a multi-sphere rice model, achieving prediction errors of less than 0.13% for miss-seeding, qualified, and re-seeding rates, demonstrating the effectiveness of DEM-based virtual design for non-spherical seeds. *Zheng et al. (2025)* designed a screw-guided posture-adjusting and filling-promoting precision seed metering device for wheat, establishing a mechanical model of seed posture adjustment under the combined action of spiral guidance and gravity. The device achieved a qualified seeding rate exceeding 90% within a working speed range of 30–70 r/min, providing an effective solution for precision seeding of small-sized cereal seeds.

Poor performance of the seed clearing zone

The seed clearing stage is key to reducing multiple-seeding and minimizing seed damage. *Zhang et al. (2021)* determined through force analysis that the minimum clearance of 1.47 mm in a dual-chamber vertical disc metering device is the critical damage threshold for cotton seeds, with damage occurring when the clearance was less than this threshold, whereas no significant damage was observed above this value under the tested conditions. The study clarified the order of influence of rotational speed, clearance, and installation angle on the damage rate. *Zhang et al. (2014)* replaced the seed guard plate with flexible rubber, reducing the seed damage rate by 0.6%. *Zhou et al. (2018)* established a shear damage model and reduced the breakage rate by constraining the hole length to avoid the shear zone. *Ryu and Kim (1988)* employed methods such as brush clearing and flexible scraping to reduce mechanical damage while ensuring clearing effectiveness.

Effect of vibration on seed metering performance

When a seeder operates in the field, random vibrations are generated due to factors such as soil structure and surface unevenness. Among these, the vertical vibration during forward motion is particularly significant, leading to reduced seeding performance and affecting subsequent crop growth and yield. *Wang et al. (2019)* established a vibration model of a finger-clip type seed metering device and confirmed that vibration has a significant effect on the qualified seeding rate and the coefficient of variation of seed spacing. Vibration experiments were conducted at frequencies of 5–20 Hz and amplitudes of 2–10 mm, based on field measurements from tillage operations. *Li (2022)* combined high-speed photography with trajectory equations to identify the key vibration parameters affecting seed delivery uniformity. *Huang et al. (2021)* revealed the coupled effects of vibration amplitude, frequency, and operating speed on the wheel-scoop type seed metering device, providing a theoretical basis for anti-vibration design. The interaction between vibration and seed metering performance has been further quantified through DEM-based sensitivity analysis. *Zhang et al. (2025)* identified inter-particle static and rolling friction coefficients as the dominant DEM contact parameters affecting rice seed metering, with optimal values of 0.445 and 0.059, respectively. The validation tests confirmed that errors between simulation and bench tests remained below 1.4% for seed number frequency per seeding hole, providing a calibrated modeling approach for evaluating vibration-induced performance degradation.

Table 2

Quantitative comparison of mechanical-type seed metering device performance across key metrics

(Synthesized from Anantachar et al., 2011; Barut and Özmerzi, 2004; Correia et al., 2016; Dong et al., 2025; Dun et al., 2022; Geng et al., 2016, 2018; Grewal et al., 2015; Huang et al., 2021, 2022; Kachman and Smith, 1995; Karayel, 2009; Li et al., 2018, 2020, 2022; Liu et al., 2016; Ryu and Kim, 1988; Su et al., 2022; Van Loon et al., 2020; Wang et al., 2015, 2019; Zhang et al., 2014, 2021, 2025; Zheng et al., 2025; Zhou et al., 2018)

Performance Metric	Disc Type	Wheel-Scoop Type	Indented Wheel Type	Finger-Clip Type
Typical operating speed	4–8 km/h	4–7 km/h	5–9 km/h	6–10 km/h
Qualified index	88–93%	85–90%	90–95%	92–96%
Miss index	3–7%	5–10%	2–5%	2–4%
Multiple index	3–6%	3–8%	2–5%	2–5%
Seed damage rate	0.5–1.5%	0.3–1.0%	0.3–0.8%	0.4–2.0%

Performance Metric	Disc Type	Wheel-Scoop Type	Indented Wheel Type	Finger-Clip Type
Seed adaptability	Poor	Medium	Poor	Medium
Structural complexity	Low	Low	Medium	High
Manufacturing cost	Low	Low	Medium	High

Note: Values represent representative ranges compiled from the cited references based on the authors' synthesis of reported experimental results. The ranges reflect typical operating conditions reported across multiple studies and are intended for comparative illustration rather than absolute performance benchmarking. Specific performance may vary with seed type, rotational speed, operating pressure, and other conditions.

RESEARCH STATUS OF PNEUMATIC-TYPE SEED METERING DEVICES

Pneumatic-type seed metering devices use positive/negative pressure generated by a fan to achieve seed suction, seed carrying, and seed delivery. They have low requirements on seed shape and size, low seed damage rate, high operating speed, and wide adaptability to seed varieties. They are the mainstream configuration for large and medium-sized high-speed precision seeders, and are mainly divided into four categories: air-suction type, air-blowing type, positive/negative pressure combined type, and central pneumatic delivery type.

Bustos-Gaytán et al. (2025) systematically reviewed experimental and numerical simulation approaches for pneumatic seed-metering devices, finding that 86% of studies focused on air-vacuum systems while only 14% addressed air-blowing systems. Numerical tools including CFD, DEM, and coupled CFD–DEM were identified as crucial for optimizing air chamber geometry, seed plate hole shapes, and seed-cleaning device designs. However, fewer studies have focused on seed-cleaning and anti-blocking devices, indicating a research gap.

With the development of mechanical-type seed metering devices, in the 1950s, many overseas scholars combined mechanical structure theory with fluid mechanics to investigate the effects of airflow pressure and direction on the various states of materials within mechanical structures, leading to the invention of pneumatic-type precision seed metering devices. By the 1960s, pneumatic-type precision seed metering devices had begun to be used and promoted, and countries with advanced agricultural systems, such as the United States and Germany, had developed various types of pneumatic seeders. In the 1980s, the new concept of pneumatic precision seeding reached international consensus. After years of development, operating speed and seeding quality have continuously improved, but still cannot meet the ever-increasing agronomic requirements, prompting European and American countries to vigorously develop precision seeding technology, thus leading to the widespread application of pneumatic-type precision seed metering devices. With technological advancement, precision seeding technology has become increasingly mature and is moving towards the direction of precision, high speed, automation, and intelligence, offering advantages such as compact structure and excellent performance (*Karayel, 2009*). Overseas pneumatic-type precision seed metering devices are mainly used for crops such as corn, soybean, and rice, while also serving vegetable seeding. Compared with mechanical-type seed metering devices, pneumatic-type precision seed metering devices have the advantages of less seed damage, wide adaptability, high operating speed, and good seeding performance. They have developed relatively quickly and gradually occupied a mainstream position. At present, pneumatic-type precision seed metering devices are relatively well-developed abroad, but their adaptability to small-sized vegetable seeds still needs improvement.

Table 3

Pneumatic-type precision seed metering devices: types, features and representative crops

(Synthesized from Bustos-Gaytán et al., 2025; Fang et al., 2024; Gao et al., 2022; Guo et al., 2024; Karayel, 2009; Li et al., 2023; Liu et al., 2022; Sun et al., 2025; Wang et al., 2019, 2026; Yan et al., 2017; Yang et al., 2022; Yatskul et al., 2017; Yi et al., 2021; Zha et al., 2024; Zhang et al., 2019)

Type	Main Features	Representative Crops
Air-suction type	Moderate seed adaptability (excellent for large seeds, challenging for seeds <3 mm); high requirements on airtightness; high fan power consumption (depending on system scale and operating pressure); capable of high-speed seeding. Typical negative pressure: 3–6 kPa.	Corn, soybean, vegetables

Type	Main Features	Representative Crops
Air-blowing type	Simple and durable structure; uses positive pressure airflow to assist seed filling and clearing; seed adaptability is improved by adjusting air pressure rather than changing mechanical components. Typical positive pressure: 2–4 kPa.	Sorghum, *Panax notoginseng*
Positive/negative pressure combined type	Generates lower air pressure than the air-suction type; low seed damage rate; good versatility; operating speed ≤8 km/h. Typical negative pressure: 2–4 kPa; positive pressure: 1–2 kPa.	Rapeseed, pak choi
Central pneumatic delivery type	Strong seed adaptability and easy seed filling, suitable for a wide range of crop types including cereals, rapeseed, and other small-to-medium seeds; high miss-seeding index at medium and high speeds requires further optimization.	Cereals, rapeseed, small-to-medium seeds

Note: Structural schematic diagrams have been omitted for brevity. For detailed structural illustrations, please refer to the original cited references.

Pneumatic-type precision seed metering devices are widely used on large and medium-sized seeding equipment in large-scale planting areas due to their low requirements on seed shape and size, good seeding quality, and high operating speed. *Guo et al. (2024)* systematically analysed four key technologies limiting the operational speed improvement of pneumatic seed metering devices: high-speed seed filling technology, stable seed clearing technology, smooth seed delivery control technology, and stable driving technology of the metering device, identifying stable filling, effective clearing, and smooth delivery as the core measures for effectively improving the qualified seeding rate and reducing the coefficient of variation at high speeds. However, they still have some problems:

(1) Multiple-seeding and miss-seeding: High-speed operation leads to airtightness fluctuations, hole clogging, and seed population dragging, resulting in reduced stability *(Zhang et al., 2019)*.

(2) Difficulty in seeding small seeds: Seeds with a particle size of less than 3 mm are light in weight and sensitive to negative pressure, requiring stringent hole geometry and air pressure parameters.

(3) Large air pressure loss: Seal wear and air leakage between chambers lead to increased energy consumption and degradation of metering performance.

Control of multiple-seeding and miss-seeding

To address the problems of multiple-seeding and miss-seeding caused by internal airtightness fluctuations, hole clogging during seed filling and seed clearing, and seed population dragging in pneumatic-type precision seed metering devices during high-speed operation, *Önal et a*l. *(2012)* optimized the airtightness of the air chamber using fluid mechanics and aerodynamics, effectively solving the issue of unstable airflow fields during seed filling for cotton and corn seeds. *Jia et al. (2018)* adopted an air-suction mechanical composite picking mechanism to reduce the interference of sudden negative pressure drops on soybean seeding. *Li et al. (2010)* proposed a seeding frequency method to detect hole clogging in a pneumatic-type precision seed metering device for rapeseed. *Yang (2020)* added grooves and seed disturbing teeth on the suction plate to suppress rapeseed population dragging and reduce miss-seeding. *Wang et al. (2019)* designed a flexible vibrating seed metering belt to achieve high-speed single-seed suction for soybean, and obtained the optimal operating parameters of the metering device through experiments.

Sun et al. (2025) designed a progressive seed-cleaning mechanism for an air-pressure maize precision seed metering device, establishing mechanical models for excess seeds entering the cleaning zone. Through single-factor and multi-factor experiments, the optimal parameter combination was determined as: seed-clearing angle of 0.024°, operating speed of 10 km/h, and positive pressure of 6.0 kPa. Under these conditions, the qualified index reached 98.11%, multiple index 1.44%, and miss index 0.45%. Comparative experiments demonstrated that the device with the seed-cleaning mechanism improved the qualified index by approximately 2.3 percentage points compared to the device without the mechanism. *Wang et al. (2026)* designed and optimized a combined seed cleaning mechanism for an air-suction seed metering device for small-seed crops with multi-seed hill, achieving significantly improved cleaning performance through structural optimization.

Zhang et al. (2019) conducted optimal design and experiments on a double-disc air-suction precision seed metering device with variable hole diameter, demonstrating that the device successfully adapted to six types of vegetable seeds by rotating and combining to produce different hole diameters under negative pressure conditions.

Precision seeding technology for small-sized seeds

For small-sized seeds such as sesame, millet, rapeseed, and vegetables, technologies including negative pressure suction combined with positive pressure seed delivery, variable-diameter holes, and photoelectric detection have been adopted both domestically and internationally. *Yi et a*l. *(2021)* and *Gao et al. (2022)* each designed pneumatic-type precision seed metering devices for millet and rapeseed, respectively, using the principle of negative pressure suction and positive pressure seed delivery. *Li et al. (2018)* proposed a beam-blocking method to detect insufficient filling and hole clogging in pneumatic-type precision seed metering devices, achieving precision seeding detection for white radish, rapeseed, and Shanghai bok choy seeds. *Li (2019)* designed a precision seed metering device capable of rotating and combining to produce different hole diameters under negative pressure conditions, adapting to six types of vegetable seeds. *Liao et al. (2018)* investigated the factors affecting the suction effect of spherical small-sized seeds such as rapeseed and Chinese cabbage, established a critical pressure model for seed suction, and clarified the coupling relationship among thousand-seed weight, hole diameter, and negative pressure.

For rice seeding, *Zha et al. (2024)* developed a branched air-chamber pneumatic seed metering device capable of adjusting seeding quantity from 1–3 to 5–8 seeds per hill by controlling the branched air chamber casing. Bench tests showed optimal qualification rates of 85.81% for 1–3 seeds/hole and 87.27% for 5–8 seeds/hole. *Fang et al. (2024)* integrated image recognition and orientation technology into an air-suction garlic seed metering device, achieving single-seed rates of 95.98%–96.23% under optimized parameters including negative pressure of 11.85–13.21 kPa and rotational speed of 6.85–7.25 r/min. *Zhao et al. (2024)* provided a comprehensive analysis of rice precision direct seeder seed metering devices, identifying the improvement path for air-suction precision: improving seed flowability, stabilizing negative pressure, and adjusting seed posture to enhance singulation accuracy. *Li et al. (2023)* optimized design parameters for a pneumatic hill-drop rapeseed metering device, determining that optimal performance was achieved at hole velocity of 30–70 r/min and negative pressure of –2.5 to –1.5 kPa, with miss-seeding rate consistently below 3%.

Suppression of air pressure loss

The susceptibility to wear of the sealing gasket between the seed plate and the negative pressure chamber of an air-suction type precision seed metering device is the main cause of air pressure loss *Yan et al. (2017)*. *Yan et al. (2017)* and Kverneland AS have both adopted a design where the seed plate and the negative pressure chamber rotate synchronously, thereby reducing sealing gasket wear, decreasing air pressure loss, and ensuring metering performance. On this basis, *Yan et al. (2017)* modified the seed plate into an annular frustum shape, achieving lower air pressure demand and energy consumption compared to Kverneland's design. To address the issue of significant air pressure loss caused by multiple seeding units sharing a common air chamber in air-suction type precision seed metering devices, *Li et al. (2023)* designed an independent grooved airway disc, enabling independent air supply to each row and reducing cross-leakage losses. *Wang et al. (2022)* analysed the mixing device of a central pneumatic delivery type seed metering device and indicated that the greater the amount of seeds being conveyed and the higher the seed-to-airflow ratio, the larger the air pressure loss in the mixing component.

Mechanical-pneumatic hybrid systems

Hao et al. (2026) designed and validated a mechanical-pneumatic hybrid metering device for mixed seeding of forage seeds, combining the simplicity of mechanical seed picking with the conveying capability of pneumatic assistance. The device achieved relative seeding errors of 6.81%–7.49% for mixed forage seed applications, demonstrating the feasibility of hybrid architectures for multi-species seeding operations where seed geometry and physical properties vary significantly among species. *Tang et al. (2023)* designed a high-speed precision seed metering device with air-assisted seed guide (inside-filling air-blowing type), achieving improved seed trajectory stability and placement accuracy through controlled airflow guidance.

Table 4

Quantitative comparison of pneumatic-type seed metering device performance across key metrics

(Synthesized from Bustos-Gaytán et al., 2025; Fang et al., 2024; Gao et al., 2022; Guo et al., 2024; Hussain et al., 2026; Jia et al., 2018; Li et al., 2010, 2023; Liu et al., 2022; Maleki et al., 2006; Önal et al., 2012; Sun et al., 2025; Wang et al., 2019, 2022, 2026; Yan et al., 2017; Yang et al., 2022; Yatskul et al., 2017; Yi et al., 2021; Zha et al., 2024; Zhang et al., 2019)

Performance Metric	Air-Suction Type	Air-Blowing Type	Positive/Negative Pressure Combined Type	Central Pneumatic Delivery Type
Typical operating speed	8–14 km/h	6–10 km/h	≤8 km/h	6–12 km/h
Qualified index	95–98%	90–95%	92–96%	88–93%
Miss index	2–5%	3–7%	2–5%	5–10%
Multiple index	2–5%	3–6%	2–4%	3–8%
Seed damage rate	＜0.5%	＜0.5%	＜0.3%	1–3%
Seed adaptability	Excellent	Good	Good	Excellent
Air pressure loss	High	Medium	Low	High
Fan power consumption	High (depending on system scale and operating pressure)	Medium (2–3 kW/row)	Low (1–2 kW/row)	High

Note: Values represent representative ranges compiled from the cited references based on the authors' synthesis of reported experimental results. The ranges reflect typical operating conditions reported across multiple studies and are intended for comparative illustration rather than absolute performance benchmarking. Specific performance may vary with seed type, rotational speed, operating pressure, and other conditions.

Table 5

Cross-type comparative analysis of mechanical versus pneumatic seed metering devices

(Synthesized from Bustos-Gaytán et al., 2025; Dong et al., 2025; Guo et al., 2024; Hussain et al., 2026; Karayel, 2009; Van Loon et al., 2020; Wang et al., 2019; Yang et al., 2022; Zhang et al., 2019)

Comparison Dimension	Mechanical Type	Pneumatic Type
Maximum stable operating speed	6–10 km/h	8–14 km/h
Qualified index (typical)	85–96%	88–98%
Seed adaptability	Poor–Medium	Good–Excellent
Seed damage rate	0.3–2.0%	<0.5%
Unit energy consumption (relative)	Low (~90 kJ/ha)	High (~6,400 kJ/ha for full pneumatic)
Centrifugal vs. pneumatic power ratio	—	1:71 (centrifugal consumes 1/71 of pneumatic)
Structural complexity	Simple	Complex
Manufacturing cost	Low	High
Operating speed increase trend	Optimized designs reaching 13–14 km/h with >94% qualified index	Clear speed–precision trade-off beyond 14 km/h
Suitable operation scale	Small-to-medium fields, hilly terrain	Large-scale plain farming
Vibration sensitivity	High	Medium
Airtightness requirement	None	Critical

Note: Values represent representative ranges compiled from the cited references based on the authors' synthesis of reported experimental results. The ranges reflect typical operating conditions reported across multiple studies and are intended for comparative illustration rather than absolute performance benchmarking. Specific performance may vary with seed type, rotational speed, operating pressure, and other conditions.

The cross-type comparison presented in Table 5 is intended to illustrate general performance trends and architectural trade-offs rather than to establish precise performance rankings. The reported ranges are compiled from multiple studies with varying experimental conditions. Actual performance comparisons should be interpreted with consideration of operating parameters and test standards.

DEVELOPMENT TRENDS

Mechanism-based and precision-oriented

Deepen the research on the multi-field coupling mechanism of seed–structure–airflow–vibration, and establish a full-cycle dynamic model. Employ simulation tools such as EDEM and CFD to achieve multi-objective optimization of structural and operating parameters. *Bustos-Gaytán et al. (2025)* confirmed that CFD-DEM coupling has become the essential tool for optimizing pneumatic metering components, yet seed-clearing and anti-blocking devices remain understudied. Develop a unified performance evaluation system to enhance the standardization level of seed metering device design, testing, and application. The speed–precision paradox framework provides a quantitative basis for defining architecture-specific performance envelopes and identifying optimal operating windows for different device types.

Lightweight and adaptable

For scenarios such as hilly and mountainous areas and facility agriculture, develop lightweight, miniaturized, and modular seed metering devices to improve adaptability to mountainous regions and small plots. Optimize structural materials and manufacturing processes to reduce cost, extend service life, and simplify maintenance. Promote the integration of mechanical and pneumatic technologies, combining the reliability of mechanical structures with the versatility of pneumatic systems, to form low-cost, high-performance composite seed metering technology. The mechanical-pneumatic hybrid approach demonstrated by *Hao et al. (2026)* offers a promising pathway for multi-species and mixed-seeding applications where seed physical properties vary considerably.

Intelligent and visualized

Integrate machine vision, photoelectric sensing, microcontroller, and virtual instrument technologies to achieve online monitoring of the seeding process, real-time alarming for miss-seeding, clogging, and multiple-seeding, and automatic adjustment of seeding rate. Build a digital twin system for seeding performance to enable visualized simulation and prediction of seed filling, seed clearing, airflow field, and vibration response. *Guo and Zhao* (*2026*) systematically reviewed edge-intelligent precision seeding monitoring and control technologies, identifying photoelectric, fibre-optic, and infrared-based methods as relatively mature in engineering applications. Capacitive, piezoelectric, near-infrared, laser-based, and machine vision methods offer advantages in detection accuracy and information richness, yet face challenges in system complexity, edge-side deployment, and long-term robustness. Future intelligent precision seeding technology was projected to develop toward multi-source heterogeneous information fusion, low-latency closed-loop control, standardized data sharing, and farm-level quality evaluation. Develop fault self-diagnosis and parameter self-optimization systems to enhance the reliability of the entire seeding process.

CONCLUSIONS

This systematic review of mechanical-type and pneumatic-type precision seed metering devices yielded the following synthesized findings.

Mechanical-type seed metering devices, including disc, wheel-scoop, indented wheel, and finger-clip types, offer advantages of simple structure, low manufacturing cost, and high reliability, making them suitable for small-to-medium sized fields and hilly terrain. However, their performance is constrained by architecture-specific thresholds: seed filling efficiency decreases significantly when operating speed exceeds 6–8 km/h, and seed spacing uniformity deteriorates under field vibration. Recent innovations, including disturbance-assisted filling mechanisms, screw-guided posture adjustment, and posture-adjusting metering devices, have extended stable operation to 13 km/h with qualified rates exceeding 94%. Cross-continental comparative testing has demonstrated that adjustable-hole metering devices consistently outperform fixed-hole designs, providing a practical pathway for improving mechanical device versatility.

Pneumatic-type seed metering devices, comprising air-suction, air-blowing, positive/negative pressure combined, and central pneumatic delivery types, demonstrate superior seed adaptability and high-speed capability. Nevertheless, 86% of research has focused on air-suction systems, while seed-cleaning and anti-blocking devices remain understudied. Key challenges include small-seed (<3 mm) precision seeding, air pressure loss from seal wear, and hole clogging at elevated speeds. Recent advances in progressive seed-cleaning mechanisms and branched air-chamber designs have substantially improved performance, with qualified indices exceeding 98% achieved under optimized conditions.

Table 6

Comparative decision framework for selecting seed metering device types

Operating Condition	Recommended Type	Rationale
Speed ≤8 km/h, uniform seed geometry, cost-sensitive	Mechanical	Lower cost, sufficient accuracy, simple maintenance
Speed ≥8 km/h, irregular seed shapes, large-scale	Pneumatic	Higher speed capability, better seed adaptability
Multi-species mixed seeding	Hybrid (mechanical-pneumatic)	Combines picking simplicity with conveying versatility
Small seeds (<3 mm), high precision requirement	Pneumatic with optimized hole/negative pressure	Superior singulation when properly tuned

Quantitative conclusions indicate that pneumatic systems typically achieve qualified indices 5–10 percentage points higher than mechanical types at speeds >8 km/h, at the cost of substantially higher energy consumption. Notably, recent system-level analysis reported that centrifugal metering systems consume approximately 71 times less power than full pneumatic systems under comparable single-row operating conditions. However, this comparison is based on a specific system configuration and operating point; the actual power ratio depends on factors including system scale, operating pressure, number of rows, and seed characteristics. The reported value should be interpreted as an indicative comparison for a reference operating condition rather than a universal constant.

The speed–precision paradox follows a three-stage pattern: Regime 1 (<10 km/h) where metering-stage singulation quality governs precision; Regime 2 (10–14 km/h) where delivery-stage instabilities are amplified; and Regime 3 (>14 km/h) where vibration, control latency, and soil–machine interactions dominate system-level breakdown.

Limitations of this review include: (1) electric-driven seed metering devices were not systematically covered due to limited published field data; (2) quantitative comparative analysis was constrained by inconsistent reporting of performance parameters across studies; and (3) the review primarily focused on English and Chinese language publications, potentially omitting relevant studies in other languages, although English-translated titles were provided for all Chinese references to ensure accessibility. Future research should deepen multi-field coupling mechanisms and integrate mechatronic technologies to promote high-efficiency, adaptive, and intelligent development of precision seed meters for modern agriculture.

ABSTRACT

Furrow opening is a critical operation in the transplantation of Codonopsis pilosula using the seedlings-with-exposed-heads-and-film-covered-bodies (HEBCF) method. The considerable resistance generated during furrow opening results in high power consumption, making resistance reduction an important research objective. Although furrow openers have been widely studied, this study focused on the furrow opener of a self-propelled HEBCF transplanter for C. pilosula. The interaction mechanism between the furrow opener and the soil was investigated through force analysis and the development of models describing soil transport patterns and particle velocities. A discrete element simulation model of the furrow-opening process was established using EDEM to evaluate the effects of the main structural parameters on furrow-opening resistance. A three-factor five-level Box–Behnken response surface experiment was conducted, and regression models for furrow-opening resistance and soil-particle velocity were developed based on the simulation results. The structural parameters were then optimized. The optimal parameter combination consisted of a chisel-tip angle of 65°, a clearance angle of 10°, and an oblique angle of 90°. Under these conditions, furrow-opening resistance was reduced by 30.82%, while the agronomic requirements of a furrow depth of 10 cm and a furrow width of 50 cm were satisfied. These results provide a technical basis for the development and optimization of self-propelled HEBCF transplanters for C. pilosula.

摘要

开种植沟作业为党参露头覆膜移栽流程的关键环节，移栽机在执行开沟作业时会产生较大阻力，进而消耗大量动力，因此减阻开沟技术成为当前研究的首要方向。国内外研究机构针对开沟装置开展了较多研究，本文针对自走式党参露头覆膜移栽机的开沟装置，研究开沟装置与土壤的互作机理，对开沟器进行受力分析，研究土壤运移规律和速度模型；借助 EDEM 软件构建开沟仿真试验模型，全面研究相关因素对开沟阻力的影响，采用 Bo -Behn en 响应曲面法设计三因素五水平的仿真试验，通过开沟性能仿真试验研究，得到开沟阻力模型和土壤颗粒速度模型，进行结构参数优化，最终确定开沟器的铲尖角 65°、隙角 10°和斜切角 90°的最优参数组合，开沟作业阻力降低 30.82%，同时满足党参移栽的开沟深度 10cm、开沟宽度 50cm 的农艺要求，为自走式党参露头覆膜移栽机研发提供支撑。

INTRODUCTION

In recent years, the market for traditional Chinese medicinal herbs has maintained a growth trend, presenting both new challenges and opportunities for the development of the related planting industry *(Wang et al., 2023)*. *Codonopsis pilosula* is one of the major traditional Chinese medicinal herbs in China, known for its effects in tonifying the middle energizer, strengthening qi, invigorating the spleen, and benefiting the lungs, earning it the reputation of "small ginseng" *(Xie et al., 2020; He et al., 2021*).

[1] *Qingxu YU, Ph. D. Assistant Researcher; Ying Lang, Master Candidate; Yan GONG, Researcher.; Xiao Zhang, Assistant Researcher; Hu Jianling, intern researcher; Dehuan Zhou, Associate Researcher;*

The genuine production areas of *Codonopsis pilosula* are mainly distributed in the arid and semi-arid regions of Northwest China. The "*seedlings-with-exposed-heads-and-film-covered-bodies*" (HEBCF) transplanting technique is a high-quality, high-yield, and high-efficiency planting method in these arid areas. It facilitates later field management and mechanized harvesting, thereby promoting the development of full-scale mechanization *(Liu et al., 2023)*. Currently, the HEBCF transplanting process for *Codonopsis pilosula* faces the problem of a "lack of available machinery" and relies entirely on manual transplantation, which is labor-intensive, time-consuming, and incurs high costs for auxiliary workers. With the rapid development of the *Codonopsis pilosula* planting industry, the demand for specialized HEBCF transplanting machines has become increasingly urgent *(Yu et al., 2025)*. Furrow opening is the first step in the *Codonopsis pilosula* transplantation process. The considerable resistance generated during furrow opening results in high power consumption; therefore, reducing furrow-opening resistance is a major research objective. The furrow opener, one of the core components of the transplanting machine, must ensure uniform furrow depth, a neat furrow shape, and minimal soil disturbance. Its performance directly affects seedling placement posture, transplanting uniformity, and plant growth, thereby influencing the yield and quality of the crops *(Chen et al., 1961)*. Currently, there are various types of furrow openers, which can be divided into two major categories: rolling and mobile types *(Li et al., 2020)*. The rolling type includes double-disc, single-disc, axial-rotating, vertical-rotating, and chain types, while the mobile type includes core-spade, sliding knife, and boat types.

Extensive research on furrow-opening devices has been conducted both domestically and internationally, focusing primarily on the resistance reduction design of furrow-opening components, soil-component interactions, and the effects of the physical and mechanical properties of soil on furrow-opening performance *(Aikins et al., 2023)*. The forces exerted by soil on furrow openers mainly include reaction force and frictional force, which are influenced by soil shear strength, cohesion, and internal and external friction angles. Additionally, soil adhesion increases operational resistance and energy consumption. Due to the complexity of soil composition and structural heterogeneity, existing theoretical models are limited and associated calculations remain cumbersome *(Gill et al., 1983)*. To optimize the design of furrow opening components and reduce operational resistance, researchers have employed bionic design, simulation models, and field experiments to investigate the effects of structural and working parameters on soil displacement distance and traction resistance, ultimately optimizing furrow opener design *(Liu et al., 2021; Shmulevich et al., 2007; Wang et al., 2024)*. Domestic scholars have conducted extensive research on furrow openers for medicinal herb transplanters. *Wang et al., (2023),* designed a furrow opener suitable for transplanting Panax notoginseng seedlings based on the agronomic parameters of under-forest cultivation, and performed simulation analysis and experimental validation. *Chen et al., (2023),* designed a moldboard furrow opener suitable for transplanting Astragalus membranaceus. This type of furrow opener features a simple structure, ease of manufacture, and good soil penetration performance. A simulation experiment was conducted using the radius of curvature of the ridge line, the oblique angle, and the clearance angle as experimental factors, with furrow opening resistance and the coefficient of variation of furrow width as evaluation indicators. *Wang et al., (2021),* designed a sharp-angled long-wing furrow opener based on the planting pattern of long-rooted medicinal herbs in the arid regions of Northwest China, aiming to address issues such as soil accumulation and seedling exposure observed in existing medicinal herb transplanters. They simulated the operation process of the furrow opener using EDEM software, and the results demonstrated satisfactory soil covering and backfilling effects. Field experiments indicated that the performance indicators of the furrow opener met the requirements of agricultural industry standards.

Furrow opening is a critical step in the transplanting process of *Codonopsis pilosula*. During operation, the transplanting machine generates substantial resistance, leading to high power consumption. Consequently, resistance reduction technology for furrow opening has become a key research focus. Numerous research institutions worldwide have conducted extensive studies on furrow openers, and domestic scholars have also carried out relevant research on furrow openers for medicinal herb transplanters *(Feng et al., 2025; Wang et al., 2017)*. Research on furrow opening resistance reduction primarily focuses on the resistance reduction design of furrow opening components, the interaction between soil and components, and the influence of soil physical and mechanical properties on furrow opening performance—including reaction forces and friction exerted by soil on the furrow opener, soil shear strength, cohesion, and internal and external friction angles. Additionally, soil adhesion increases operational resistance and power consumption.

Due to the complex composition and structural heterogeneity of soil, existing theoretical models have limitations, and the associated calculations remain relatively complex *(Yu et al., 2009; Pan et al., 2015; Zhang et al., 2024)*. This paper focuses on the furrow opener of a Codonopsis pilosula HEBCF transplanter. It investigates the interaction mechanism between the furrow opener and the soil, analyzes the forces acting on the furrow opener, and examines soil transport patterns and velocity models. Using EDEM software, a simulation test model for furrow opening was developed to comprehensively study the effects of relevant factors on furrow opening resistance. The Box-Behnken response surface method was employed to design a three-factor, five-level simulation experiment. Through the furrow opening performance simulation, a furrow opening resistance model and a soil particle velocity model were obtained, and the structural parameters were optimized. Finally, the optimal combination of chisel tip angle, clearance angle, and oblique angle for the furrow opener was determined.

MATERIALS AND METHODS

Structural design of the furrow opener

Based on the agronomic requirements for HEBCF transplanting of *Codonopsis pilosula*, and considering the topographic characteristics of hilly and mountainous regions in Northwest China as well as the properties of cultivated soils, this study presents the design of a self-propelled HEBCF *Codonopsis pilosula* transplanter. To facilitate turning and maneuverability during transplanting operations, as well as transport and transfer, a diesel powered tracked chassis was selected as the power platform. The machine is equipped with a furrow opener, a directional transplanting device, and a soil covering and film mulching device. It is capable of performing integrated operations, including furrow opening for planting, HEBCF transplanting of *Codonopsis pilosula* seedlings, soil covering, film mulching, and edge covering. The overall structure of the transplanter is schematically shown in Figure 1.

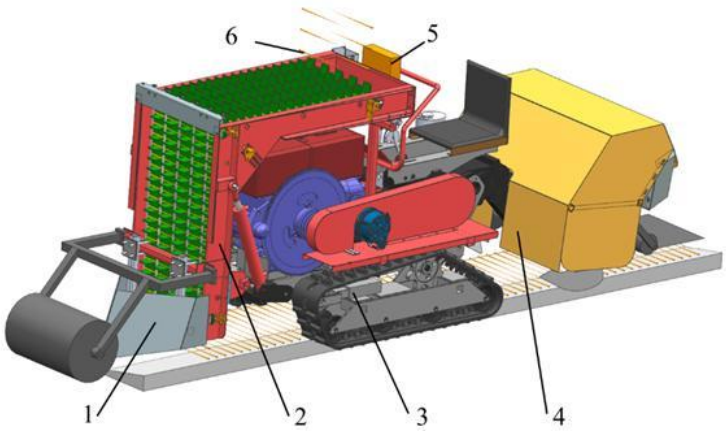

Fig. 1 - Schematic diagram of the overall structure of a transplanter

1. Ditching device, 2. Transplanting device, 3. Tracks chassis; 4. Soil covering and film covering device, 5. Transplanting electronic control system, 6. Codonopsis seedlings

The furrow opener is a key component of the HEBCF *Codonopsis pilosula* transplanting equipment. It is required to form a "V"-shaped planting furrow with a depth of 10–15 cm and a width of approximately 50 cm, with seedlings uniformly placed on one side slope of the furrow. Consistent planting depth and furrow configuration further enhance the survival rate, quality, and yield of *Codonopsis pilosula*. The furrow opener primarily consists of a furrow opener and a support wheel for furrow depth adjustment, as illustrated in Fig. 2.

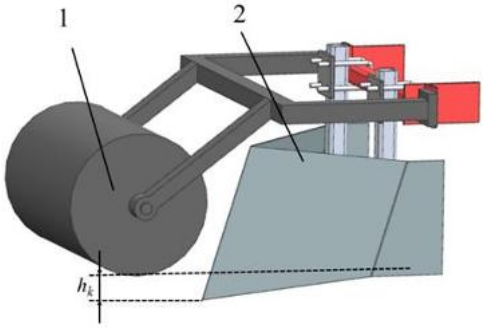

Fig. 2 - Schematic diagram of trenching unit

1. Front support wheel; 2. Furrowing device

By adjusting the mounting height of the furrow opener connecting rod, the relative height between the front support wheel and the furrow opener can be varied, thereby enabling adjustment of the furrow depth h_k. The support wheel ensures uniform furrow depth throughout the operation.

Key structural parameters of the furrow opener

Designed to satisfy agronomic requirements, the furrow opener is shown in Figure 3. Its key structural parameters are opener width (W_k), length(L_k), height (H_k), chisel tip angle (γ), clearance angle (β), and oblique cutting angle (ε). Soil on both sides backflows during trenching, so the opener width must exceed the target furrow width of 50 cm, and (W_k) is set as 52 cm in this study. The dimensions and profile of the opener depend mainly on γ, β and ε, which also affect trenching resistance and furrow cross-section shape. The chisel tip angle γ ranges 45°–75°, penetration clearance angle β is generally below 15°, and oblique cutting angle ε varies 60°–120°.

Soil characteristics of the main Codonopsis pilosula production area

Soil physical properties are a key indicator for mechanical operations and directly influence furrow opening resistance and furrow quality. In this study, soil samples were collected from the *Codonopsis pilosula* genuine producing area in Weiyuan County, Gansu Province. The soil type is sandy loam. Soil compactness was measured using a TYD-2 soil hardness tester, yielding an average value of 231.5 kPa. Measurements were also conducted in cultivated transplanting plots designated for HEBCF transplantation. The transplanting test plots were divided into six sampling areas, with random equal-volume sampling performed in each area. Surface soil samples from a depth of 0–20 cm were collected for testing, and the average moisture content of the soil samples was 16.32%. The soil samples were sieved using a standard sieve, and the proportion of particles larger than 10 mm exceeded 67.6%.

Force analysis of the furrow opener

During operation, the total force F_{Nk} acting on the furrow opener can be decomposed into the lateral force F_X along the X-axis, the forward resistance F_Y along the Y-axis, and the vertical downward force F_Z along the Z-axis. Due to the symmetrical structure of the furrow opener, the lateral forces on the left and right sides along the X-axis cancel each other out. The vertical force along the Z-axis creates a tendency for the furrow opener to penetrate the soil automatically. The power consumption of the furrow opener is primarily influenced by the force along the Y-axis. A schematic diagram of the forces acting on the furrow opener is shown in Fig.4.

During the furrow opening process, a cutting force F_T is generated at the cutting edge. After the soil undergoes shear failure, it slides backward along the furrow opener plate. The soil then exerts a normal load force F_N, tangential adhesion resistance F_S, and sliding friction force F_f on the two side plates. Subsequently, the displaced soil disperses to both sides of the furrow opener under its own gravity, resulting in relative sliding between the soil and the side plates, thereby generating a sliding friction resistance F_{Cf} on the side plates. Additionally, as the furrow opener advances, relative sliding also occurs between its bottom and the ground, causing the ground to exert a sliding friction force F_{Df} on the bottom of the furrow opener.

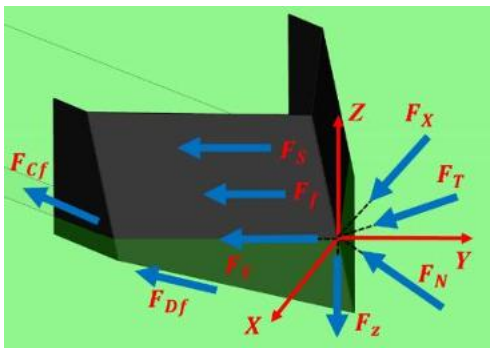

Fig. 4 - Schematic diagram of interaction between furrow opener and soil

Based on the force diagram of the furrow opener shown in Figure 5, the resistance model of the furrow opener can be derived as:

$$\begin{cases} F_X=0 \\ F_Y=F_T \sin(\gamma+\beta)+2F_N \sin(\gamma+\beta)\sin(\varepsilon/2)+2(F_s+F_f)\cos(\varepsilon/2)+2F_{Cf}+F_{Df} \\ F_Z=F_T \cos(\gamma+\beta)+2F_N \cos(\gamma+\beta)+G_k \end{cases} \quad (1)$$

where: G_k— Gravitational force of the furrow opener, N.

The normal load force F_N acting furrow opener plate is expressed as:

$$F_N=K_d S_{XZ} \quad (2)$$

where:

K_d — Resistance coefficient (N/cm²), the value of which is closely related to factors such as the structural parameters of the furrow opener plate, furrow depth, forward speed, self-weight of the furrow opener, and soil properties.

S_{XZ} — Normal cross-sectional area of soil cutting, cm².

The tangential adhesion resistance F_S on the furrow opener plate is given by:

$$F_s=N_n\mu_n+\tau_n \quad (3)$$

where:

N_n — Normal adhesion force on the furrow opener plate, N;

μ_n — Adhesion coefficient, which depends on soil properties and other factors;

τ_n — Tangential adhesion force on the furrow opener plate, N.

The friction force F_f on the furrow opener plate is expressed as:

$$F_f=F_N\mu_m \quad (4)$$

where:

μ_m — Sliding friction coefficient of the furrow opener plate, which depends on soil properties and other factors.

The friction force F_{Cf} on the side plates is given by:

$$F_{Cf}=2S_{YZ}\left(C_a+\frac{1}{2}K_0\rho_t d\tan\varphi+K_0 q\tan\varphi\right) \quad (5)$$

where:

S_{YZ} — Tangential cross-sectional area of soil cutting, cm²;

K_0 — Static earth pressure coefficient, related to soil properties and other factors;

C_a — Soil cohesion coefficient, related to soil properties and other factors;

q — Additional soil load, N;

φ — Soil internal friction angle, °;

ρ_t — Soil density, kg/m³.

The friction force F_{Df} on the bottom surface of the furrow opener is expressed as:

$$F_{Df}=F_Z \cos\beta\,\mu_m \tag{6}$$

Combining Equations (1) through (6), the furrow opening resistance model can be obtained as:

$$\begin{cases} F_X=0 \\ F_Y=F_T \sin(\gamma+\beta)+2K_d S_{XZ} \sin(\gamma+\beta) \sin\ （\varepsilon/2）+2\left(N_n\mu_n+\tau_n+F_N\mu_m\right) \cos\ （\varepsilon/2）+ \\ \&2S_{YZ}\left(C_a+\frac{1}{2}K_0\rho_t d \tan\varphi+K_0 q \tan\varphi\right)+F_Z \cos\beta\,\mu_m \\ F_Z=F_T \cos(\gamma+\beta)+2K_d S_{XZ} \cos(\gamma+\beta)+G_k \end{cases} \tag{7}$$

Analysis of soil particle dynamics

During the HEBCF transplanting operation of *Codonopsis pilosula*, the side plates must prevent premature soil backfilling into the planting furrow, thereby preserving the furrow cross-sectional shape and bottom flatness, and creating a stable and effective space for seedling placement. After the seedlings are deposited, appropriate soil backfilling helps secure the seedling tops to maintain their posture and minimize soil disturbance. Therefore, the length of the furrow opener side plates must be rationally designed, as it significantly influences both the furrow opening quality and the overall effectiveness of subsequent *Codonopsis pilosula* planting. An excessively long side plate increases furrow opening resistance, whereas an insufficiently long side plate leads to premature soil backfilling, resulting in suboptimal planting depth, furrow width, and bottom flatness, thereby compromising furrow opening quality. To further investigate the relevant parameters of the furrow opener side plates, a detailed analysis of soil particle motion characteristics on the furrow opener surface was conducted. Soil particles were assumed to be rigid granular materials that neither deform nor adhere. A specific point on the contact interface between the soil particles and the furrow opener was selected for analysis. A schematic diagram of the forces acting on the soil particles is shown in Figure 5.

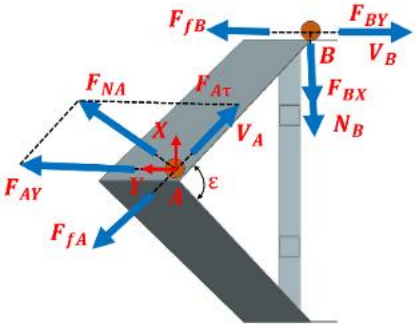

Fig. 5 - Schematic diagram of forces acting on soil particles

Assuming the soil particle is located at point A, it is subjected to a reaction force F_{NA} from the furrow opener plate and a friction force F_{fA}. The reaction force F_{NA} is first decomposed into a component F_{AY} in the forward direction (Y-axis) and a tangential component F_{At} along the furrow opener plate. The force analysis of the particle at point A yields the following equation:

$$\begin{cases} F_{AY}=\dfrac{F_{NA}}{\sin\ （\varepsilon/2）} \\ F_{A\tau}=\dfrac{F_{NA}}{\tan\ （\varepsilon/2）} \\ F_{fA}=F_{NA}\mu_m \\ F_{NA}=M_t g \cos(\gamma+\beta) \end{cases} \tag{8}$$

where:

M_t——mass of soil particles, kg;

g——gravitational acceleration, m/s².

Assuming the initial velocity of the soil particle is zero, if the tangential component F_{AT} of the force acting on the soil particle at point A exceeds the friction force F_{fA}, the soil particle will slide at point A on the furrow opener plate. Its equation of motion can be expressed as:

$$M_t a_A = F_{A\tau} - F_{fA} \tag{9}$$

where:

a_A——acceleration of the soil particles, m/s².

Combining and rearranging Equations (8) and (9) yields:

$$M_t a_A = M_t g \cos(\gamma+\beta)\left(\frac{1}{\tan(\varepsilon/2)} - \mu_m\right) \tag{10}$$

Given that the distance from point A to point B is L_{AB}, the acceleration a_A and velocity V_A of the soil particles during its motion from point A to point B are given by:

$$\begin{cases} a_A = g\cos(\gamma+\beta)\left(\frac{1}{\tan(\varepsilon/2)} - \mu_m\right) \\ V_A = \sqrt{2g\cos(\gamma+\beta)\left(\frac{1}{\tan(\varepsilon/2)} - \mu_m\right)L_{AB}} \end{cases} \tag{11}$$

Soil particles initiate movement from point A and accelerate from rest until they reach point B at the edge of the furrow opener. Subsequently, they collide with the soil at the planting furrow edge, rebound, and continue to move along the side plate. Assuming no energy loss during this process, the interaction between the soil at the furrow edge and the moving soil particles is analyzed. The reaction force exerted by the furrow edge soil on the moving particles can be decomposed into two components in the coordinate system: the force along the X-direction, F_{BX}, and the force along the Y-direction, F_{BY}. In addition, the unmoved soil particles on both sides, characterized by the repose angle α_t, exert a normal load N_B on the moving soil particles, and the side plate exerts a friction force F_{fB} on the particles. As shown in Figure 6, based on the force analysis of the soil particles at point B, the following mechanical model can be derived:

$$\begin{cases} F_{BX} = M_t a_A \sin(\varepsilon/2) \\ F_{BY} = M_t a_A \cos(\varepsilon/2) \\ N_B = M_t g \tan\alpha_t \\ F_{fB} = (N_B + F_{BX})\mu_m \end{cases} \tag{12}$$

The differential equation of motion for the soil particle at point B along the Y-direction is:

$$M\frac{d^2y}{dt^2} = F_{BY} - F_{fB} \tag{13}$$

Combining and rearranging Equations (12) and (13) yields:

$$M_t\frac{d^2y}{dt^2} = M_t a_A \cos(\varepsilon/2) - \left(M_t g\tan\alpha_t + M_t a_A \sin(\varepsilon/2)\right)\mu_m \tag{14}$$

During the soil particle migration process, it is assumed that after moving from point A to point B, the soil particles begin to move along the side plate. Given that the length of the side plate is S, the instantaneous velocity V_B of the soil particles when they detach from the side plate can be derived as:

$$V_B = \sqrt{\left(V_A\cos(\varepsilon/2)\right)^2 + 2\left[a_A\cos(\varepsilon/2) - \left(g\tan\alpha_t + a_A\sin(\varepsilon/2)\right)\mu_m\right]S} \tag{15}$$

EXPERIMENTAL STUDY ON FURROW OPENING PERFORMANCE BASED ON DISCRETE ELEMENT METHOD

Under the condition of maintaining consistent furrow width, furrow depth, and furrow cross-sectional shape, lower furrow opening resistance corresponds to reduced power consumption. The factors directly influencing the resistance of the furrow opener include the chisel tip angle γ, clearance angle β, oblique angle ε, furrow opener width W_k, and furrow opener length L_k, as well as inherent soil properties such as adhesion and density. Among these, the furrow opener width W_k and soil adhesion are considered fixed values and are therefore not treated as experimental factors in this study. The interaction among the chisel tip angle γ, clearance angle β, and oblique angle ε affects the furrow opener length L_k, which directly influences the forward resistance in the Y-direction and the vertical penetration force in the Z-direction. Additionally, it affects the volume of backfilled soil during the furrow opening process, ultimately determining the post-furrowing

cross-sectional shape. Consequently, the chisel tip angle γ, clearance angle β, and oblique angle ε are identified as key parameters and are selected as the main experimental factors.

At a given working depth, the cross-sectional area of furrow opening resistance varies with changes in the chisel tip angle γ, clearance angle β, and oblique angle ε. In this study, the furrow opening resistance per unit area, denoted as P_Y, was adopted as the evaluation index and calculated using the following equation:

$$P_Y = \frac{F_Y}{S_1} \tag{16}$$

where:

F_Y — forward resistance of the ditching tool in the Y direction, N;

S_1 — Cross-sectional area of furrow opening resistance, m².

Simulation test model and experimental scheme for furrow opening

To further investigate the factors influencing furrow opening resistance, a simulation experiment on furrow opening performance was conducted using EDEM software. The soil bin in the simulation measured 1500 mm × 4000 mm × 300 mm. Single spheres were used to simulate soil particles, with a particle radius of 5 mm. The Material Block module was employed to rapidly generate soil particles, and the Hertz–Mindlin (no-slip) contact model was adopted. Extensive research has been conducted by various scholars on the sandy loam soil of Northwest China *(Dai et al., 2019)*. The relevant soil parameters for the simulation test are presented in Table 1. After the soil particles in the simulation soil bin had stabilized, the three-dimensional model of the furrow opener was imported into the simulation model. The furrow opening depth was set to 10 cm, the furrow width to 52 cm, and the forward speed to 0.18 km/h. The furrow opening performance simulation experiment is illustrated in Figure 6. Experimental data on the furrow opening resistance per unit area in the Y-direction (P_Y) were collected from the stable operation zone.

Table 1

Parameters used in the simulation experiments

Material	Parameter	Value
Soil	Poisson's ratio	0.3
	Shear modulus / Pa	5×10^7
	Density (kg·m^{-3})	2600
Steel plate	Poisson's ratio	0.3
	Shear modulus / Pa	7.9×10^{10}
	Density (kg·m^{-3})	7865
Soil-soil	Coefficient of restitution	0.21
	Coefficient of static friction	0.68
	Coefficient of rolling friction	0.27
Soil-steel plate	Coefficient of restitution	0.54
	Coefficient of static friction	0.31
	Coefficient of rolling friction	0.13

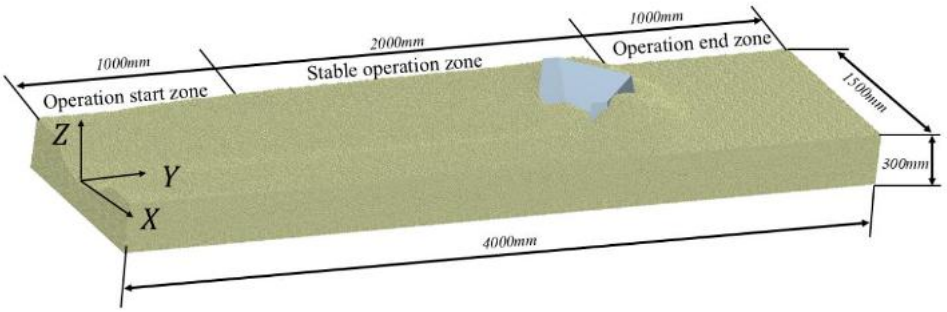

Fig. 6 - Simulation test of furrow opening performance

Through EDEM simulation experiments on furrow opening, the optimal parameter combination for the furrow opener was determined. In this study, the chisel tip angle γ, clearance angle β, and oblique angle ε were selected as experimental factors, while the furrow opening resistance per unit area in the Y-direction (P_Y) was used as evaluation indicators. A three-factor, second-order regression orthogonal rotational combination experiment was conducted to thoroughly investigate the influence of relevant factors on furrow opening performance. The coding of the simulation experiment factors is presented in Table 2, where the coded values correspond to the chisel tip angle γ, clearance angle β, and oblique angle ε, respectively. The design scheme and results of the simulation experiment are shown in Table 3, with the experimental results including the furrow opening resistance per unit area in the Y-direction (P_Y).

RESULTS AND ANALYSIS

Establishment of regression model and significance analysis

Multiple regression analysis was performed on the experimental data presented in Table 4. The regression equations relating the chisel tip angle (γ), clearance angle (β), and oblique angle (ε) to the furrow opening resistance per unit area in the Y-direction (P_Y) was obtained as follows:

$$P_Y=3643.983-52.3\gamma-152.593\beta-12.476\varepsilon+1.151\gamma\beta+0.272\gamma\varepsilon+0.458\beta\varepsilon+0.31\gamma^2+1.773\beta^2+0.036\varepsilon^2 \quad (17)$$

Table 4 presents the significance test results for the regression equations. The p-values for both the P_Y models are less than 0.01, indicating that the goodness of fit is highly significant and that the established models are reliable. The effects of γ, ε, and their interaction γ,ε on P_Y are highly significant ($p< 0.01$), while the effects of other factors on P_Y are not significant.

Table 4

Analysis of variance for the regression model

Source	P_Y - Experimental Results

*Note: * indicates significant effect (P<0.05), ** indicates high significant effect (P<0.01)*

The coefficients of determination (R^2) for the regression equations are 0.9859 and 0.9771, respectively, both close to 1, indicating that the deviations between the predicted values and the actual values are minimal and nearly coincident. This demonstrates that the models accurately capture the relationship between the experimental factors and the response indicators. For the furrow opening resistance per unit area in the Y-direction (P_Y), the predicted R^2 and adjusted R^2 are both 0.9332, with a difference of less than 0.2. This indicates that the model exhibits excellent explanatory and predictive capabilities, and the high consistency between the two suggests that the model is not overfitted.

Figures 7(a) present the residual versus predicted value plots for the furrow opening resistance per unit area in the Y-direction (P_Y), respectively. The residual points for P_Y are randomly distributed with no discernible systematic pattern, indicating that the model fitting does not exhibit significant bias. Additionally, the residuals do not display a funnel-shaped pattern and are randomly scattered within the range of ±3 standard deviations (indicated by the red lines), suggesting the absence of significant outliers. Furthermore, the influence of individual data points on the estimation of model parameters is controllable, which further enhances the reliability of the established models.

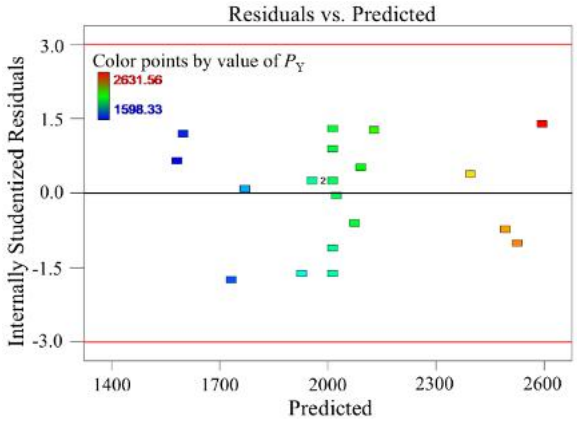

Fig. 7 - Residuals-versus-predicted plot for P_Y

Analysis of Furrowing Resistance per Unit Area in the Y-Direction (P_Y)

Box plots enable a rapid comparison of response distributions across different factor levels, facilitate the identification of outliers and data dispersion characteristics, and assist in evaluating the main effects and potential interactions of factors. To investigate the individual effects of the chisel tip angle (γ), clearance angle (β), and oblique angle (ε) on the furrow opening resistance per unit area in the Y-direction (P_Y), box plots were constructed for each factor against P_Y, as shown in Figure 8.

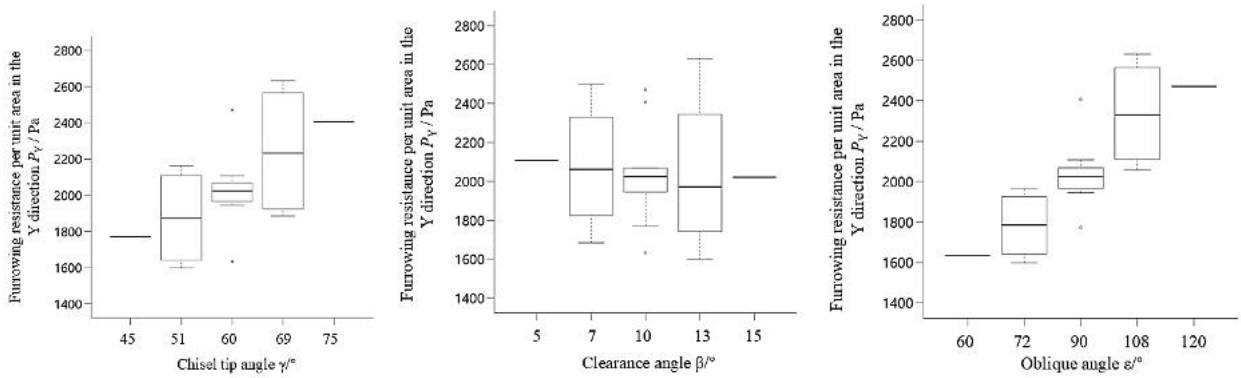

Fig. 8 - Box plot of P_Y

As shown in Figure 8(a), when the chisel tip angle (γ) is at levels −1, 0, and 1, the median values of the furrow opening resistance per unit area in the Y-direction (P_Y) are 1871.88, 2023.67, and 2230.93, respectively. P_Y exhibits a generally rapid increasing trend with increasing γ. At level 1 of γ, the box height is the largest, indicating the highest dispersion of P_Y data, which may lead to greater result variability and reduced data stability. To minimize P_Y, a low level of γ is preferable. As shown in Figure 8(b), when the clearance angle (β) is at levels −1, 0, and 1, the median values of P_Y are 2062.02, 2067.62, and 1971.82, respectively. P_Y initially shows a slight decreasing trend followed by a marginal increase as β increases. An optimal range for minimizing P_Y exists near level 1 of β. However, at level 1 of β, the box height is the largest and the whiskers are longer, indicating high dispersion of P_Y data, necessitating further collaborative optimization analysis considering other factors. As shown in Figure 8(c), when the oblique angle (ε) is at levels −1, 0, and 1, the median values of P_Y are 1785.07, 2023.67, and 2330.15, respectively. P_Y generally exhibits a rapid increasing trend with increasing ε. To minimize P_Y, a low level of ε is preferable.

To further investigate the interactive effects of the chisel tip angle (γ), clearance angle (β), and oblique angle (ε) on the furrow opening resistance per unit area in the Y-direction (P_Y), the influence of factor interactions on P_Y is illustrated in Figure 9.

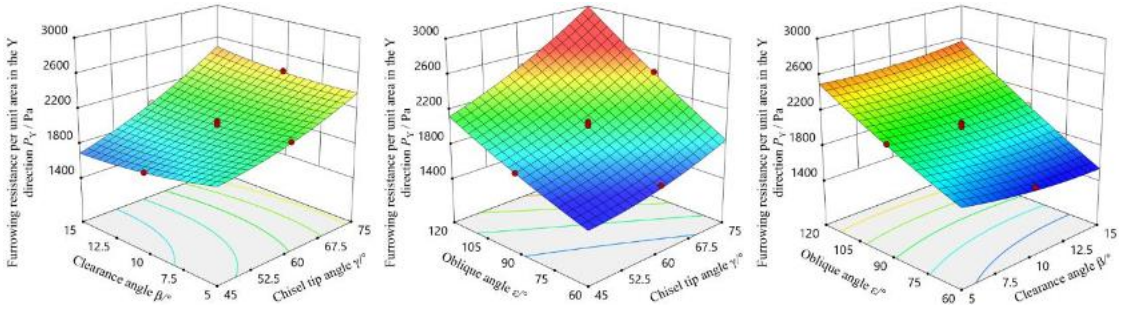

Fig. 9 - The interaction effects of various factors on P_Y

As shown in Figure 9(a), when the chisel tip angle (γ) is small, the furrow opening resistance per unit area in the Y-direction (P_Y) gradually decreases with increasing clearance angle (β); conversely, when γ is large, P_Y gradually increases with increasing β. When β is within the range of 5° to 15°, an increase in γ consistently leads to an increase in P_Y. Therefore, a combination of a smaller γ and a larger β yields a lower P_Y. As shown in Figure 9(b), when the oblique angle (ε) is within the range of 60° to 120°, an increase in γ results in an increase in P_Y. Similarly, when γ is within the range of 45° to 75°, an increase in ε also leads to an increase in P_Y. Both γ and ε exhibit a positive linear relationship with P_Y. Accordingly, a parameter combination of a smaller γ and a smaller ε yields a lower P_Y. As shown in Figure 9(c), when β is within the range of 5° to 15°, an increase in ε consistently leads to an increase in P_Y. When ε is small, P_Y gradually decreases with increasing β; when ε is large, P_Y gradually increases with increasing β. Under these conditions, a combination of a larger β and a smaller ε yields a lower P_Y.

Parameter optimization and simulation performance verification

Based on the established regression models, the influence patterns of the chisel tip angle (γ), clearance angle (β), and oblique angle (ε) on the furrow opening resistance per unit area in the Y-direction (P_Y) was obtained, facilitating an in-depth analysis of the mechanistic effects of these factors on resistance during the furrow opening process. The furrow opening resistance is closely related to γ, β, and ε. In this study, the optimization module of Design-Expert software was employed, with the optimization objectives set as minimizing P_Y, thereby ensuring low and stable furrow opening resistance. A multi-objective optimization mathematical model was established to determine the optimal parameter combination. The objective functions and constraint equations are as follows:

$$\begin{cases} min\ P_Y(\gamma,\ \beta,\ \varepsilon) \\ s.t.\begin{cases} 45 \le \gamma \le 75 \\ 5 \le \beta \le 15 \\ 60 \le \varepsilon \le 120 \end{cases} \end{cases} \tag{19}$$

Multiple sets of optimal parameter combinations were obtained. An increase in the oblique angle (ε) increases furrow opening resistance but also facilitates soil penetration. Considering manufacturability, furrow opener length, and the overall machine layout, the oblique angle ε was selected as 70°, with the optimized chisel tip angle γ = 55° and clearance angle β = 15°. The resistance-reducing furrow opener with the optimal parameter combination is shown in Figure 10. Under these conditions, the furrow opening resistance per unit area in the Y-direction (P_Y) is relatively low, and the penetration force acts in the negative Z-direction, which is conducive to soil penetration during furrow opening operations.

(a) 3D model (b) Physical object

Fig. 10 - Resistance-reducing furrow opener

To further verify the performance of the furrow opener with the optimal parameter combination in actual furrow opening operations, a simulation performance verification was conducted. The furrow opening resistance curve obtained from the simulation test is shown in Figure 11, which illustrates the variation of furrow opening resistance of the optimized furrow opener in the simulated environment, providing an important basis for further in-depth investigation of its performance characteristics. The measured furrow opening resistance in the Y-direction was 500.55 N, the furrow opening resistance per unit area in the Y-direction (P_Y) was 1587.30 Pa. Compared with the initial furrow opener (γ = 65°, β = 10°, ε = 90°), the furrow opening resistance in the Y-direction was reduced by 228.92 N, corresponding to a reduction rate of 30.82%.

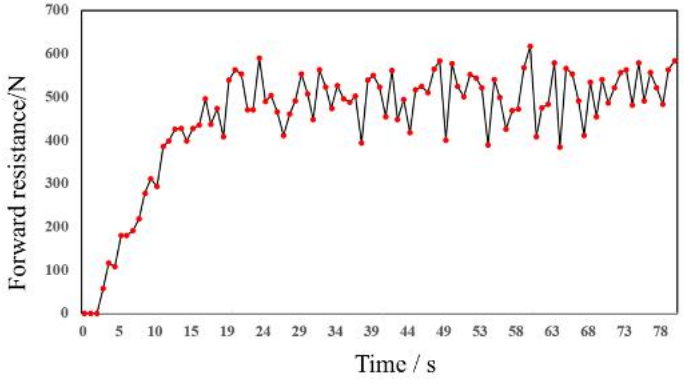

Fig. 11 - Simulation performance test trench resistance curve

Bench test verification of the furrow opener

Verification analysis of furrow opening resistance

A furrow opening resistance verification test was conducted at the research base of Gansu Agricultural University. The soil used in the test was collected from a genuine production area of *Codonopsis pilosula* in Northwest China. The soil moisture content was measured as 15.0% using an LHS16-A halogen moisture meter. Prior to the test, the soil was rotary tilled to simulate the actual transplanting environment. A furrow opener prototype with a chisel tip angle (γ) of 55°, oblique angle (ε) of 70°, clearance angle (β) of 15°, and width (W_k) of 52 cm was mounted on the traction frame of the furrow opener above the soil bin. After each test, the soil in the bin was rotary tilled again, as shown in Figure 12.

Fig. 12 - Bench test for trenching performance

As shown in Figure 13, the results obtained from the EDEM simulation were highly consistent with the actual operation of the furrow opener. The furrow profile predicted by the EDEM simulation closely matched the width, depth, and shape of the planting furrow formed during actual operation. Regarding soil flow direction, the EDEM simulation accurately reproduced the flow path and distribution of soil during the furrow opening process, demonstrating strong agreement with the actual soil flow observed under field conditions. To a considerable extent, the EDEM simulation method reflected the real working conditions of the furrow opener, providing a powerful tool for in-depth investigation of its operating principles and performance characteristics. It enabled the optimization and adjustment of structural and working parameters within a simulated environment and allowed for the prediction of furrow opener performance in advance. Consequently, this approach reduced the number and cost of physical experiments, thereby improving the efficiency and quality of the design and optimization process for the furrow opener.

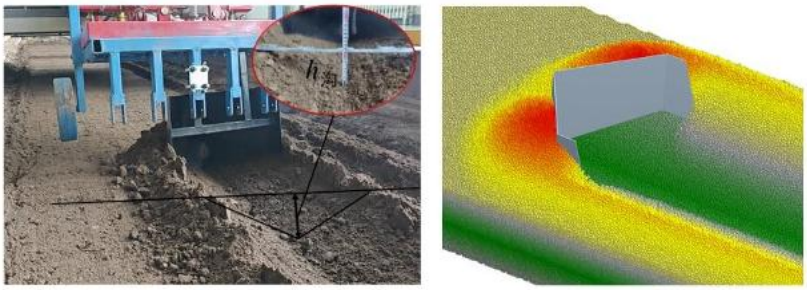

Fig. 13 - Comparative test between simulation and bench trenching operations

The test bench utilized an electric variable-frequency four-wheel-drive soil bin test vehicle as the power source, with the furrow opener attached via a three-point hitch for furrow opening operations. The test bench was equipped with an automated measurement system capable of simultaneously recording forward resistance and vertical resistance, with a data acquisition frequency set to 10 Hz. The operating parameters were consistent with those used in the simulation performance test: the furrow opening depth was set to h_k = 10 cm, the forward speed to 0.18 km/h, and each test run had a length of at least 3 m. The acquired data were processed using a moving average algorithm, and a curve of furrow opening resistance over time was plotted. The furrow opening resistance curve obtained from the bench performance test is shown in Figure 17. As shown in Figure 14, the average forward furrow opening resistance obtained from the bench test was 552.64N, with a relative error of 9.43% compared to the simulation result. Comparison between the simulated and experimental values indicates that the error in forward furrow opening resistance is relatively small, suggesting that the simulation results can reliably reflect the actual forward resistance of the furrow opener.

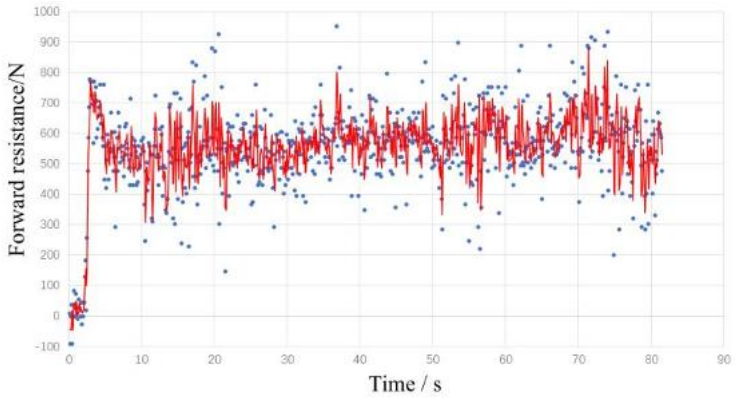

Fig. 14 - Trench resistance curve for bench performance test

CONCLUSIONS AND DISCUSSION

(1) The interaction between the furrow opener and the soil was investigated theoretically to address the high furrow-opening resistance encountered in the sandy loam soils of the main *Codonopsis pilosula* production region. The forces acting on the furrow opener and the soil during furrow opening were analyzed, and a resistance model for the furrow opener was established. The relationships among furrow-opening resistance, the intrinsic properties of the soil, the furrow cross-sectional area, and the structural parameters of the furrow opener were examined. The dynamic behavior of the soil particles during furrow opening was also investigated, and a mathematical model describing the particle velocity at detachment from the side plate was derived. This velocity was related to structural parameters such as the chisel-tip angle. The theoretical analysis indicated that, under fixed soil conditions, the chisel-tip angle, clearance angle, and oblique angle are the principal structural factors affecting furrow-opener performance.

(2) Furrow-opening performance was evaluated through discrete element simulations conducted using EDEM. A three-factor simulation experiment was designed using response surface methodology. Evaluation indicators, including furrow-opening resistance per unit area and penetration force, were defined, and a virtual soil-bin test platform was developed. Multiple regression analysis and analysis of variance were performed on the simulation results, yielding a highly significant regression model for the furrow-opening resistance per unit area in the *Y*-direction, P_Y. Residual analysis and box-plot analysis supported the adequacy and reliability of the model for optimizing the structural parameters of the furrow opener. The results showed that the chisel-tip angle was positively correlated with furrow-opening resistance. The clearance angle exhibited a positive linear relationship with penetration force but had only a limited effect on furrow-opening resistance, whereas the oblique angle significantly affected the evaluated performance indicators.

(3) Multiobjective optimization was conducted to determine the preferred structural parameter combination. An optimization model was established with the objective of minimizing the furrow-opening resistance per unit area in the *Y*-direction, P_Y. The selected optimal combination consisted of an oblique angle of 70°, a chisel-tip angle of 55°, and a clearance angle of 15°. Simulation verification showed that, after optimization, the furrow-opening resistance in the *Y*-direction was 500.55 N and P_Y was 1587.30 Pa, corresponding to a resistance reduction of 30.82%. Bench tests were subsequently conducted to validate the simulation results. The mean forward resistance measured in the bench tests was 552.64 N, resulting in a relative error of 9.43% compared with the simulated value. This level of agreement indicates that the simulation model can provide a useful basis for the structural optimization of resistance-reducing furrow openers for *C. pilosula* transplanting.

ABSTRACT
To address the problems of unstable posture, end crushing, and poor release during conventional press-in sand barrier laying caused by the large diameter, rigid internodes, pronounced nodes, and heterogeneous structure of corn stalks, a smooth composite insertion pin consisting of a front steel pin and a rear sleeve was designed. Based on the structural characteristics of the corn stalk rind, pith, and nodes, a layered discrete element model was established to analyze pith compression, sidewall friction, and local failure during axial insertion. The sleeve contact-segment diameter, steel pin diameter, and sleeve front transition angle were selected as experimental factors, and insertion force stiffness was adopted as the evaluation index. A Box-Behnken response surface design was employed for parameter optimization, followed by internodal validation, finite element analysis, nodal insertion tests, and release tests. The results showed that the sleeve contact-segment diameter had the greatest influence on insertion force stiffness, while the steel pin diameter and transition angle also had significant effects. The regression model exhibited a good fit, and the lack-of-fit was not significant. Considering machining feasibility and structural stability, the optimal structural parameters were a sleeve contact-segment diameter of 5.5 mm, a steel pin diameter of 2.0 mm, and a sleeve front transition angle of 160°, corresponding to a predicted insertion force stiffness of 1.15 N/mm. The validation results agreed well with the model predictions. Although the insertion force increased substantially in the nodal region, the optimized composite insertion pin successfully achieved axial insertion through the nodes and enabled smooth release in both the internodal and nodal regions.

摘要
针对玉米秸秆直径大、节间硬、结节明显及组织非均质导致传统压入式沙障铺设中姿态不稳、端部压溃和脱落不畅等问题，设计了由前端钢针和后部套筒组成的光滑复合插针。基于玉米秸秆表皮、内瓤和结节的结构特征，建立分层复合离散元模型，分析轴向插入过程中的内瓤压缩、侧壁摩擦和局部破坏行为。以套筒接触段直径、钢针直径和套筒前端变径角为试验因素，以插入力刚度为评价指标，开展 Bo －Behn en 响应面优化，并通过普通节间验证、有限元分析、结节插入试验和脱落试验进行验证。结果表明，套筒接触段直径影响最显著，钢针直径和变径角也具有显著影响；模型拟合良好，失拟项不显著。综合考虑加工可行性和结构稳定性，推荐参数分别为 5.5 ㎜、2.0 ㎜ 和 160°，预测插入力刚度约为 1.15 N/㎜。普通节间验证结果表明，实测值与预测值吻合良好；虽然结节处插入力明显增大，但优化后的复合插针仍可完成结节处轴向插入，并能在普通节间和结节位置顺利脱落。

INTRODUCTION
Sand barrier laying is an important engineering measure for desertification control, wind-sand protection and ecological restoration in sandy areas (*Chen et al., 2024*). Its laying quality directly affects near-surface wind-speed reduction, sand-transport flux, surface stability and vegetation recovery. Among different sand-control measures, straw checkerboard sand barriers have been widely used in mobile sandy land, railway and highway protection, and ecological restoration projects because of their accessible materials, simple structure and stable sand-fixing effect. Previous studies have shown that sand barriers improve windbreak and sand-fixation performance by increasing surface roughness, modifying the near-surface airflow structure and weakening aeolian sand transport capacity (*Zhao et al., 2016; Wang et al., 2018; Zhang et al., 2018; Fang et al., 2023; Sun et al., 2024*). Semi-buried sand barriers, plate-type barriers, mesh barriers and porous sand-fixing components have also been developed to improve protective performance.

Their structural size, porosity, arrangement pattern and spacing can significantly affect wind-speed distribution, sediment deposition and sand-blocking efficiency (*Zhao et al., 2016; Wang et al., 2018; Fang et al., 2023; Sun et al., 2024; Xu et al., 2021; Zhang et al., 2021; Wang et al., 2024; Liu et al., 2025*).

With the development of wind-sand control engineering from manual construction towards mechanized, equipment-based and efficient operation, improving the laying quality and working efficiency of sand barriers has become an important research direction in desertification-control equipment (*Qu et al., 2019; Xu et al., 2020; Zhang et al., 2022*).

At present, most sand barrier laying machines have been developed for slender and flexible straw materials, such as wheat straw and reed straw. Conventional laying devices usually use inserting blades, pressing wheels, pressing discs or feeding–guiding mechanisms to press straw into sandy soil, forming sand barrier structures with a certain buried depth and exposed height. Related studies have shown that the mechanism type, feeding mode, pressing depth, working speed and straw feeding uniformity affect the forming quality of sand barriers and the straw mass per unit length (*An et al., 2025; Qi et al., 2025*). However, most existing machines are designed for flexible straw, and their working principle mainly depends on straw bending and overall pressing. For corn stalks with larger diameters, more rigid internodes and pronounced nodes, direct use of the conventional press-in method may easily cause unstable bending, poor posture control, end crushing, local splitting and poor release. Therefore, designing a key end-effector suitable for axial insertion and directional conveying according to the structural characteristics of corn stalks is fundamental for realizing mechanized laying of corn stalk sand barriers.

Corn stalk is a typical heterogeneous biological material consisting of nodes and internodes. Its cross-section includes a dense outer rind, vascular bundles and loose inner pith. Its mechanical properties are strongly affected by loading direction, moisture content, sampling position and stalk posture. Previous studies have shown that the corn stalk rind has relatively high tensile strength and stiffness, whereas the pith is loose and prone to compression, shearing and local failure (*Zhang et al., 2016; Chen and Qu, 2017; Zhang et al., 2020*). In addition, probe geometry, cross-sectional geometry and flexural stiffness affect puncture resistance, failure location and load-bearing capacity of corn stalks (*Robertson et al., 2016; Cook et al., 2020; Stubbs et al., 2022*). These studies provide a basis for understanding the mechanical behavior of corn stalks. Nevertheless, most of them focus on tension, bending, puncture, shearing or lodging, while limited attention has been paid to axial insertion, compression, friction and release of corn stalks during sand barrier laying.

During axial insertion of corn stalks, complex contact interactions occur between the insertion pin and the stalk pith. The front end of the pin first penetrates and compresses the loose pith. Subsequently, the pith is continuously squeezed and sheared. As the insertion depth increases, the contact length between the sidewall of the insertion pin and the pith increases, resulting in increased frictional resistance. When the insertion pin approaches a node, the dense tissue and transverse diaphragm increase local puncture, compression and shear resistance, causing obvious fluctuations or peaks in the insertion force curve. If the insertion pin diameter is too large, pith compression and sidewall friction increase significantly. If the diameter is too small, the supporting and guiding effects of the insertion pin are insufficient, leading to unstable stalk posture. Therefore, the structural parameters of the insertion pin should be optimized by comprehensively considering low-resistance insertion, stable holding and smooth release.

The discrete element method (DEM) can describe the contact, bonding, failure and motion processes of particulate materials, and has been increasingly applied to plant-material modelling, straw crushing, conveying and contact behavior analysis in recent years (*Coetzee, 2017; Zhang et al., 2020*). Meanwhile, response surface methodology is suitable for analyzing coupled effects among multiple factors and establishing regression relationships between structural parameters and performance indicators, and has been applied in the structural parameter optimization of agricultural equipment (*Myers et al., 2016; Montgomery, 2017; An et al., 2025; Qi et al., 2025*).

Based on this, a smooth composite insertion pin consisting of a front steel pin and a rear sleeve was designed for a corn stalk sand barrier laying device. The structural characteristics of corn stalks and the failure mechanism during axial insertion were analyzed, and a layered composite DEM model and an axial force model of the composite insertion pin were established. Then, the sleeve contact-segment diameter, steel pin diameter and sleeve front transition angle were selected as the main factors, and insertion force stiffness was used as the response value for Box-Behnken response surface optimization. Finally, direct internodal insertion validation, finite element analysis, nodal insertion tests and release verification tests were conducted to evaluate the prediction accuracy, structural stability and functional adaptability of the optimized structure.

MATERIALS AND METHODS

STRUCTURAL CHARACTERISTICS OF CORN STALK AND FAILURE MECHANISM DURING AXIAL INSERTION

Structural characteristics of corn stalk

Corn stalks are composed of nodes and internodes. The node is characterized by annular protrusions and contains a transverse diaphragm, with relatively dense tissue, whereas the internode is approximately cylindrical. In the cross-section, the stalk consists of a dense outer rind, vascular bundles and loose pith from the outside to the inside. The vascular bundles gradually become sparser from the outer region toward the center, forming a heterogeneous structure with a dense outer layer and a loose inner core, as shown in Figure 1.

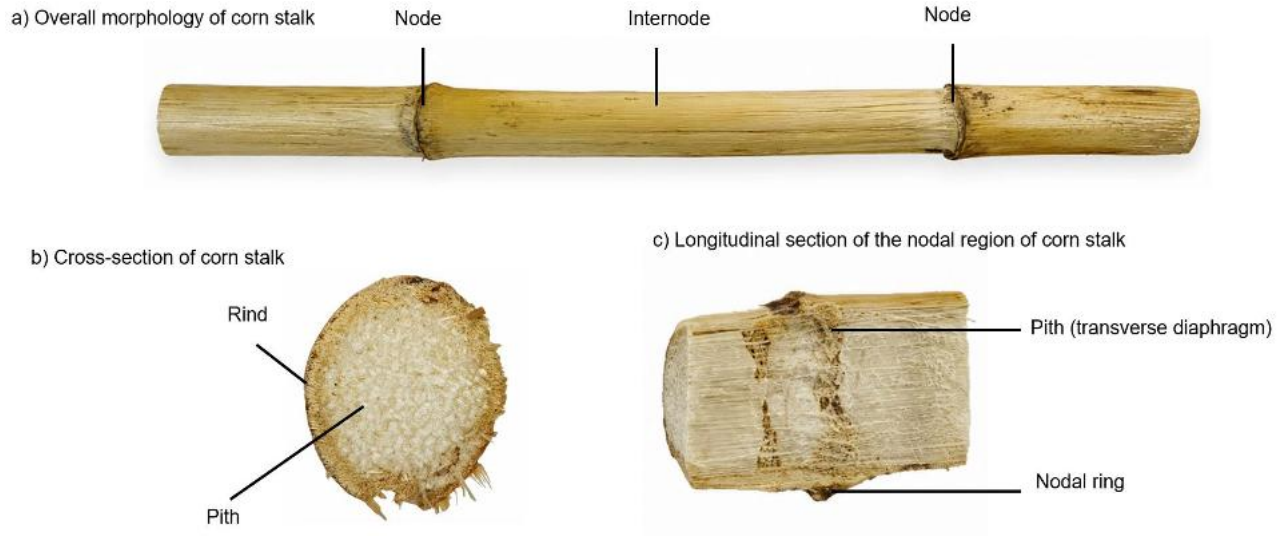

Fig. 1 - Morphological structure and nodal tissue characteristics of corn stalk

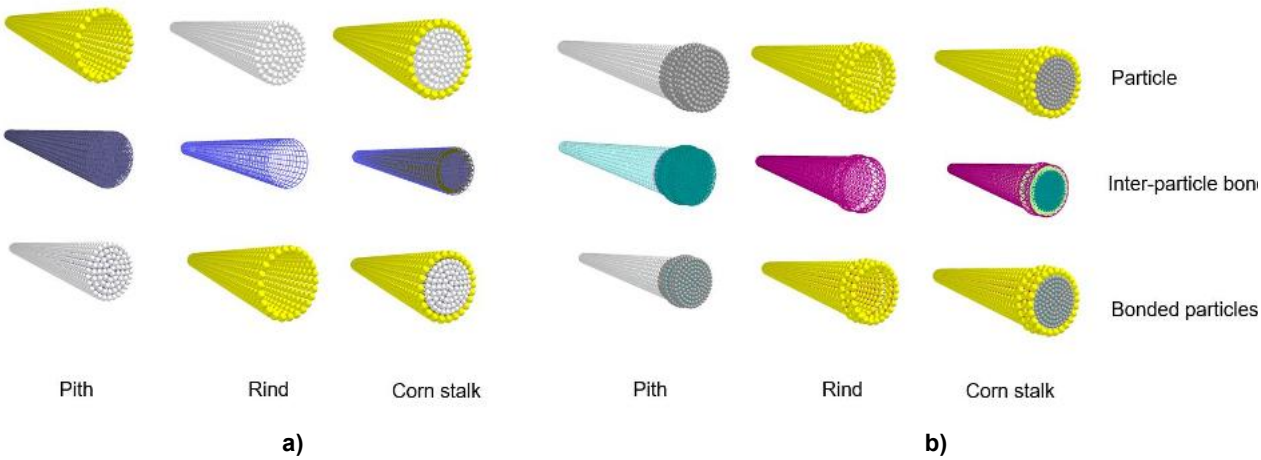
Discrete element representation of the layered structure of corn stalk

According to the structural differences among the rind, pith and nodal tissues, corresponding particle units were constructed and assigned material parameters and inter-particle bonding parameters for different regions, thereby forming a layered composite corn stalk model. The discrete element method (DEM) can describe inter-particle contact force transmission and local failure processes, and has been widely used to simulate the mechanical behavior of agricultural materials (Cundall and Strack, 1979; Tsuji et al., 1992). In recent years, many studies have optimized DEM parameter calibration and particle contact models, improving the simulation accuracy of plant materials (*Zhu et al., 2007*). In addition, DEM parameter calibration methods and model reliability evaluation have been systematically investigated (*Coetzee, 2017*). The model established in this study was used to characterize the structural differences between internodes and nodes, as well as local compression and failure behavior during insertion. The modelling process is shown in Figure 2.



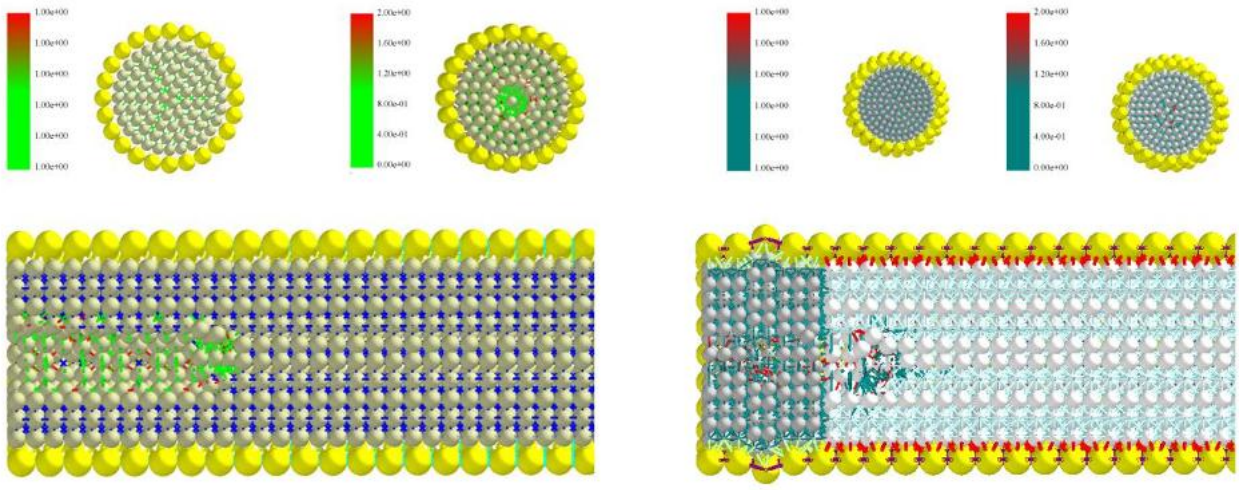


Fig. 2 - Construction process of the corn stalk discrete element model
a) internode model; b) nodal model

Analysis of insertion-induced failure modes

During axial insertion of corn stalks, the main failure modes include end crushing, pith compression, fiber shearing and nodal obstruction. The insertion pin first compresses the loose pith. Subsequently, the pith is continuously squeezed and sheared, while the sidewall friction increases with the contact length. When the pin approaches a node, the dense tissue and transverse diaphragm increase the local puncture and shear resistance, causing fluctuations or peaks in the insertion force curve. A typical process is shown in Figure 3. Therefore, the composite insertion pin should be designed to reduce the front penetration resistance and sleeve frictional resistance, while ensuring bending stability under lateral eccentric loading.

STRUCTURAL DESIGN OF THE INSERTION PIN

Design of the smooth composite insertion pin

The composite insertion pin was designed to realize axial insertion and directional conveying of corn stalks. Its design should ensure low-resistance penetration, stable holding and smooth release. In this study, a structure consisting of a front steel pin and a rear sleeve was adopted. The steel pin was used to penetrate and compress the pith and provide axial support, while the sleeve was used to fix the steel pin and connect it to the conveying mechanism. A gradual diameter transition was arranged between the two parts to reduce abrupt changes in contact resistance and improve the smoothness of load transmission. As shown in Figure 4, the corn stalk was sleeved along the axial direction of the insertion pin under the action of the push block. The thrust of the push block mainly overcame pith compression, local shearing and sidewall friction resistance. In addition, uneven stalk ends and non-uniform internal tissues may cause lateral eccentric loading.

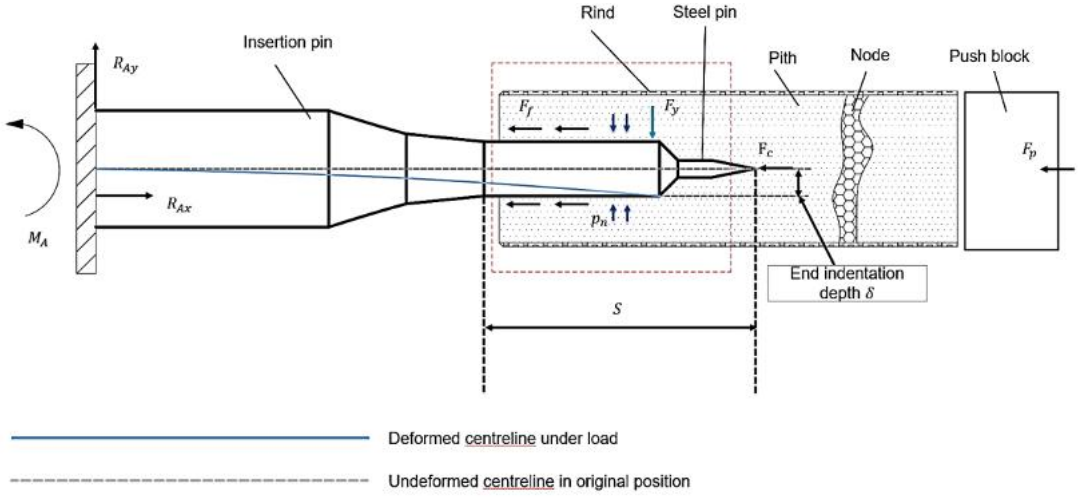

Fig. 4 - Force analysis of the composite insertion pin

In Figure 4, F_p represents the thrust of the push block; F_c represents the resistance caused by compression, squeezing and local shearing of the corn stalk pith; F_f represents the frictional resistance between the sidewall of the insertion pin and the stalk pith; P_n represents the radial normal pressure; and S represents the insertion depth of the stalk. R_{Ay}, R_{Ax}, M_A and F_y denote the vertical reaction force, axial reaction force, bending moment at the fixed end, and lateral force caused by eccentric loading, respectively, which are used to describe the possible non-axial loads during insertion.

Determination of key structural parameters of the composite insertion pin

According to the structural form of the composite insertion pin and the actual insertion process of corn stalks, the main structural parameters included the sleeve contact-segment diameter d_1, steel pin working-segment diameter d_2, sleeve front transition angle α, first transition angle β, second transition angle γ, and actual stalk insertion depth S. The structural annotations are shown in Figure 5.

Among these parameters, d_1 and d_2 jointly affect the compression degree of the stalk pith, sidewall friction and holding stability. When the diameters are small, pith squeezing and friction are reduced, which is beneficial for decreasing the insertion force; however, the supporting effect of the insertion pin on the stalk is also weakened. When the diameters are large, the supporting effect is enhanced, but pith compression and contact friction increase accordingly, resulting in higher thrust of the push block.

The sleeve front transition angle α determines the smoothness of the transition when the sleeve enters the pith, directly affecting contact resistance and sudden changes in thrust. The first transition angle β and second transition angle γ mainly affect the structural transition and load transmission between different diameter sections of the sleeve. The insertion depth S represents the total length of the stalk sleeved onto the composite insertion pin along the axial direction. The parameters and their functions are listed in Table 1.

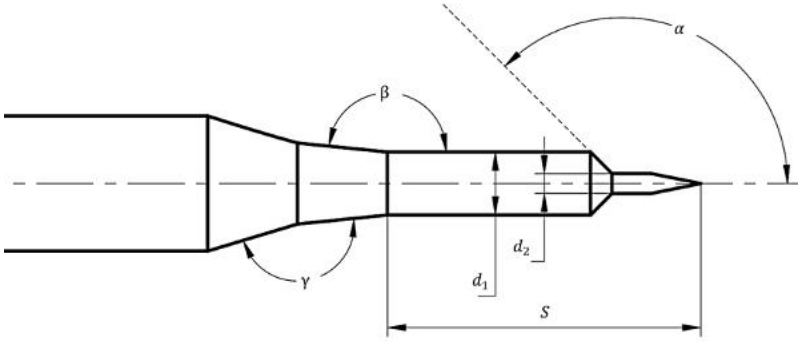

Fig. 5 - Structural parameters of the composite insertion pin

Table 1

Main structural parameters and functions of the composite insertion pin

Parameter	Symbol	Main function
Sleeve contact-segment diameter	d_1	Affects sleeve support stability and sidewall friction resistance
Steel pin working-segment diameter	d_2	Affects penetration resistance, compression resistance and insertion stability
Sleeve front transition angle	α	Affects the contact resistance and thrust fluctuation when the sleeve initially enters the stalk pith
First transition angle	β	Affects load transmission and structural transition at the variable-diameter section
Second transition angle	γ	Affects the structural transition and assembly stability of the rear connecting section
Actual stalk insertion depth	S	Represents the total depth of the stalk sleeved onto the composite insertion pin

Overall force model of the composite insertion pin

Under the action of an external axial load, the corn stalk moved along the axial direction of the insertion pin and was successively sleeved onto the steel pin working segment and the sleeve contact segment. Since the penetration of the steel pin into the stalk pith occurred simultaneously with local pith compression, these two effects were difficult to separate strictly. Therefore, they were collectively regarded as compression resistance. The total axial resistance acting on the composite insertion pin can be expressed by Eq. (1).

$$F_i = F_c + F_f \quad (1)$$

where $\boldsymbol{F_i}$ is the resultant axial force exerted by the stalk on the insertion pin, $\boldsymbol{F_c}$ is the compression resistance, and $\boldsymbol{F_f}$ is the sidewall friction force.

The sidewall friction force is related to the contact state between the insertion pin and the stalk pith and can be simplified by Eq. (2).

$$F_f = \mu p_n A_c \quad (2)$$

where $\boldsymbol{\mu}$ is the equivalent friction coefficient, $\boldsymbol{p_n}$ is the equivalent radial normal pressure, and $\boldsymbol{A_c}$ is the equivalent contact area between the insertion pin and the stalk pith. This equation indicates that increases in the pin diameter and contact length increase the sidewall friction force, thereby increasing the axial resistance during insertion.

During the actual insertion process, lateral force $\boldsymbol{F_y}$ may be generated by uneven stalk ends, non-uniform pith tissue distribution and eccentric loading. In this case, the vertical reaction force at the fixed end can be expressed by Eq. (3).

$$R_{Ay} = F_y \quad (3)$$

The bending moment at the fixed end can be calculated using Eq. (4).

$$M_A = F_i e + F_y l_y \quad (4)$$

where $\boldsymbol{e}$ is the eccentric distance of the resultant axial force relative to the centreline of the insertion pin, and $\boldsymbol{l_y}$ is the distance from the action point of the lateral force to the fixed end. Therefore, although the load mainly acts on the insertion region, its mechanical effect is transmitted to the entire composite insertion pin. The fixed end and the variable-diameter section are the key positions for structural verification.

Analysis of stalk release conditions

After the stalk is sleeved onto the insertion pin, smooth release should be ensured. Since the insertion pin has a smooth structure, the release process mainly needs to overcome the frictional resistance between the sidewall of the insertion pin and the stalk pith. Therefore, the release resistance can be approximated by Eq. (5).

$$F_d \approx F_f \quad (5)$$

To ensure smooth release of the stalk, the condition given in Eq. (6) should be satisfied.

$$F_r > F_d \quad (6)$$

where F_r is the release driving force, and F_d is the release resistance.

Optimization method for structural parameters of the composite insertion pin

To reduce the growth rate of insertion force while considering holding and release performance, the parameters of the composite insertion pin were determined using a procedure of "preliminary tests for range determination–Box-Behnken response surface optimization". Response surface methodology is suitable for analyzing the coupled effects of multiple factors, and the Box-Behnken design can establish a quadratic regression model and evaluate factor significance with fewer tests (*Box and Behnken, 1960; Myers et al., 2016; Montgomery, 2017*). In this study, the sleeve contact-segment diameter $\boldsymbol{d_1}$, steel pin diameter $\boldsymbol{d_2}$, and sleeve front transition angle $\boldsymbol{\alpha}$ were selected as factors, and the insertion force stiffness $\boldsymbol{K_F}$ was used as the response value. The factor levels were first determined through single-factor preliminary tests, and then modelling and optimization were performed using Design-Expert 13.

Insertion force stiffness $\boldsymbol{K_F}$ was selected as the continuous response because it directly characterizes the growth rate of insertion resistance. Holding stability and release performance were treated as functional constraints rather than continuous regression responses. Holding was considered successful when the stalk remained stably sleeved without obvious slipping after insertion, whereas release was considered successful when the stalk was completely detached without jamming, overall end splitting or visible bending of the insertion pin.

PARAMETER OPTIMISATION AND PERFORMANCE VERIFICATION OF THE COMPOSITE INSERTION PIN

Preliminary test design and determination of factor levels

Air-dried corn stalks with an average moisture content of 5.2% and diameters of 20–24 mm were used. Nine preliminary tests and 17 Box–Behnken tests were conducted independently, with a new stalk used in each test. The test system consisted of a screw-driven push block, composite insertion pin, support frame, RP-C30-ST resistive force sensor, voltage-conversion module and data-acquisition unit. The sensor had a nominal range of approximately 0.20–196 N and a sensing-area diameter of 25 mm.

RESULTS

Before testing, the sensor was calibrated, and its output was converted into force according to the calibration relationship. Force and displacement were recorded at 40 Hz during insertion to a depth of 30 mm at a speed of 0.1 m/s. The maximum insertion force $F_{p,max}$ was extracted from each force–displacement curve, and K_F was calculated using Eq. (7).

Table 2

Preliminary test results of structural parameters of the composite insertion pin

Test No.	d_1/mm	d_2/mm	α /(°)	Test purpose	K_F/(N/mm)
1	6	2	155	Centre point	1.17
2	5	2	155	Low level of d_1	1.11
3	7	2	155	High level of d_1	1.66
4	6	1	155	Low level of d_2	1.28
5	6	3	155	High level of d_2	1.50
6	6	2	145	Low level of α	1.57
7	6	2	165	High level of α	1.21
8	6	2	155	Centre point replicate	1.13
9	6	2	155	Centre point replicate	1.18

The preliminary test results showed that the repeated center-point values were 1.17, 1.13 and 1.18 N/mm, indicating good repeatability. As d_1 increased, the insertion force stiffness increased markedly. K_F also showed an increasing trend with the increase in d_2, but the increment was smaller than that caused by d_1. In contrast, K_F decreased as α increased, indicating that a larger transition angle helped reduce the concentrated squeezing of the pith by the front end of the sleeve. These results show that the selected factor levels can be used for the subsequent response surface tests.

Evaluation index of insertion force stiffness

To quantitatively characterize the growth rate of insertion force with displacement, the insertion force stiffness K_F was introduced. Considering that the initial contact stage is strongly affected by uneven stalk ends and local compaction, whereas pith crushing, fiber failure or sudden changes in friction may occur near the peak force, the stable rising interval from $0.1F_{p,max}$ to $0.8F_{p,max}$ was selected for calculating K_F (*Mohsenin, 1986; Bourne, 2002; Rivera et al., 2022*). Accordingly, K_F was calculated using Eq. (7):

$$K_F = \frac{0.8F_{p,\max} - 0.1F_{p,\max}}{s_{0.8} - s_{0.1}} \quad (7)$$

where K_F (N/mm) is the insertion force stiffness; $F_{p,max}$ (N) is the maximum insertion force; and $s_{0.1}$ and $s_{0.8}$ (mm) are the insertion displacements corresponding to $0.1F_{p,max}$ and $0.8F_{p,max}$, respectively.

Response surface test design

A three-factor and three-level response surface test was conducted using the Box-Behnken design in Design-Expert 13, with d_1, d_2 and α selected as the test factors. The insertion depth was fixed at 30 mm, and the push block speed was fixed at 0.1 m/s. The factor levels are listed in Table 3, and the test scheme and results are shown in Table 4.

Table 3

Factors and levels of the response surface test

Factor	Parameter	Low level -1	Centre level 0	High level +1
A	Sleeve contact-segment diameter d_1 / mm	5	6	7
B	Steel pin diameter d_2 / mm	1	2	3
C	Sleeve front transition angle α / °	145	155	165

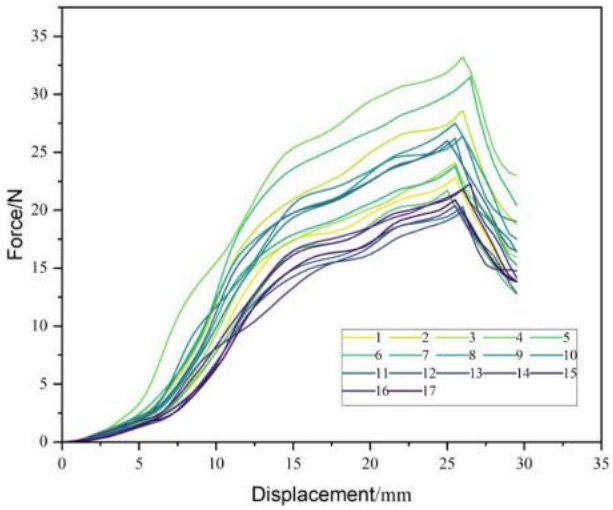

Fig. 6 - Force–displacement curves under different test groups

Table 4

Box-Behnken experimental design and results

Test No	A	B	C	K_F/(N/mm)
1	-1	-1	0	1.34
2	1	-1	0	1.65
3	-1	1	0	1.41
4	1	1	0	1.95
5	-1	0	-1	1.24
6	1	0	-1	1.86
7	-1	0	1	1.41
8	1	0	1	1.51
9	0	-1	-1	1.62
10	0	1	-1	1.55
11	0	-1	1	1.15
12	0	1	1	1.57
13	0	0	0	1.09
14	0	0	0	1.08
15	0	0	0	1.27
16	0	0	0	1.26
17	0	0	0	1.15

Among the 17 test groups, K_F ranged from 1.08 to 1.95 N/mm, indicating that the structural parameters had a significant effect on the growth rate of insertion force. The highest $\boldsymbol{K_F}$ value was 1.95 N/mm in test No. 4 ($\boldsymbol{d_1} = 7$ mm, $\boldsymbol{d_2} = 3$ mm and $\boldsymbol{\alpha} = 155°$). The repeated center-point values ranged from 1.08 to 1.27 N/mm, indicating a relatively small test error. Overall, $\mathbf{K_F}$ was lower near the center region and under some low-level parameter combinations, whereas it increased markedly under high-diameter combinations.

Regression model establishment and analysis of variance

Design-Expert 13 was used to conduct analysis of variance on the insertion force stiffness results, and the quadratic polynomial regression equation was obtained as follows: $\boldsymbol{K_F = 1.17 + 0.1963A + 0.09B - 0.0788C + 0.0575AB - 0.13AC + 0.1225BC + 0.225A^2 + 0.1925B^2 + 0.11C^2}$.

The regression equation shows that the coefficients of the linear terms $\boldsymbol{A}$ and $\boldsymbol{B}$ are positive, indicating that increases in $\boldsymbol{d_1}$ and $\boldsymbol{d_2}$ both increase the insertion force stiffness. The coefficient of $\boldsymbol{C}$ is negative, indicating that an appropriate increase in the transition angle is beneficial for reducing the insertion force stiffness. The quadratic terms $\boldsymbol{A^2}$, $\boldsymbol{B^2}$and $\boldsymbol{C^2}$are all positive, suggesting obvious nonlinear effects of the factors on $\boldsymbol{K_F}$. Therefore, a lower optimization region exists in the response surface.

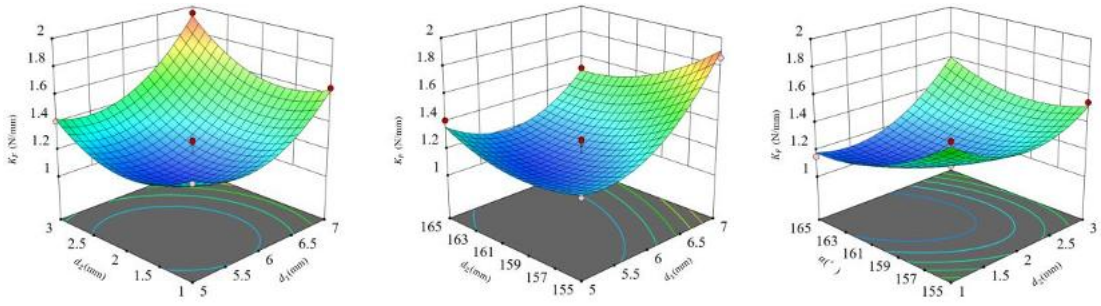

Table 5

Analysis of variance for the regression model

Source	Sum of squares	df	Mean square	F-value	p-value	Significance
Model	1.03	9	0.1142	18.06	0.0005	**
A	0.3081	1	0.3081	48.71	0.0002	**
B	0.0648	1	0.0648	10.25	0.0150	*
C	0.0496	1	0.0496	7.84	0.0265	*
AB	0.0132	1	0.0132	2.09	0.1914	
AC	0.0676	1	0.0676	10.69	0.0137	*
BC	0.0600	1	0.0600	9.49	0.0178	*
A^2	0.2132	1	0.2132	33.70	0.0007	**
B^2	0.1560	1	0.1560	24.67	0.0016	**
C^2	0.0509	1	0.0509	8.05	0.0251	*
Residual	0.0443	7	0.0063			
Lack of fit	0.0113	3	0.0038	0.4556	0.7278	
Pure error	0.0330	4	0.0083			
Total	1.07	16				
R^2	0.9587					
R^2_{Adj}	0.9056					

Note: * indicates significant difference at $\boldsymbol{P} < 0.05$; ** indicates highly significant difference at $\boldsymbol{P} < 0.01$.

The analysis of variance showed that the model was highly significant, with $\boldsymbol{P} = 0.0005 < 0.01$. The lack-of-fit term was not significant ($\boldsymbol{P} = 0.7278 > 0.05$), indicating that the model fitted the test data well. The values of $\boldsymbol{R^2}$ and $\boldsymbol{R^2_{adj}}$ were 0.9587 and 0.9056, respectively, further confirming the good fitting performance of the model. Factor $\boldsymbol{A}$ had a highly significant effect on $\boldsymbol{K_F}$, while factors $\boldsymbol{B}$ and $\boldsymbol{C}$ also had significant effects. This indicates that the sleeve contact-segment diameter had the greatest influence on $\boldsymbol{K_F}$, followed by the steel pin diameter and the sleeve front transition angle. Among the interaction terms, $\boldsymbol{AC}$ and $\boldsymbol{BC}$ were significant.

Parameter optimization and engineering recommended values

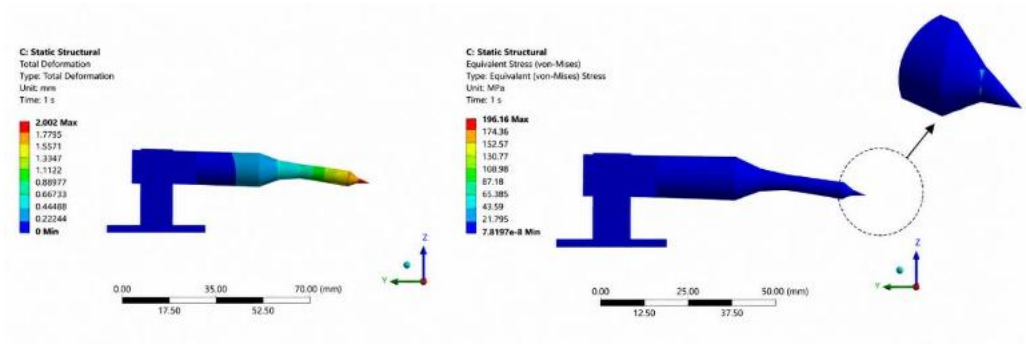
The regression model showed that the theoretical optimal parameter region was approximately $\boldsymbol{d_1} = \boldsymbol{5.70}$ mm, $\boldsymbol{d_2} = \boldsymbol{1.70}$ mm and $\boldsymbol{\alpha} = \boldsymbol{158.5}°$, with a predicted insertion force stiffness of about 1.11 N/mm. Considering practical machining requirements, $\boldsymbol{d_1} = 5.5$ mm, $\boldsymbol{d_2} = 2.0$ mm and $\boldsymbol{\alpha} = 160°$ were finally selected as the engineering recommended parameter combination. Under this combination, the predicted insertion force stiffness was approximately 1.15 N/mm. Its prediction accuracy was subsequently evaluated through internodal insertion tests, whereas nodal insertion and release tests were conducted to assess high-resistance adaptability and functional reliability.

According to the axial force model in Section 3, the insertion force mainly consisted of pith compression resistance and sidewall friction resistance. The steel pin diameter, sleeve contact-segment diameter and sleeve front transition angle affected pith compression, sidewall friction and guided compression, respectively. The response surface results were consistent with the theoretical analysis, indicating that the established model can provide a basis for structural parameter optimization of the composite insertion pin.

It should be noted that the response surface optimization was mainly used to obtain a low-resistance parameter combination under regular axial insertion conditions. Since the nodal region has denser tissue and a transverse diaphragm, stronger local resistance fluctuations occur during insertion. Therefore, nodal insertion was used as a high-resistance adaptability verification of the recommended parameter combination, rather than to evaluate the prediction accuracy of the response surface regression model.

PERFORMANCE VERIFICATION OF THE COMPOSITE INSERTION PIN

Finite element analysis of bending resistance of the composite insertion pin



Static structural analysis was conducted in ANSYS Workbench to evaluate the bending stability of the optimized composite insertion pin. Bonded contacts were defined at the interfaces among the steel pin, steel shaft, PETG sleeve and support. The PETG support base was fixed to represent its frame connection, and a lateral load of 20 N was applied at the pin tip.

Table 6

Mesh convergence results

Element size /mm	Nodes	Elements	Deformation /mm	Average stress /MPa
0.30	1,256,239	730,860	1.9039	1.6589
0.25	1,818,875	1,060,416	2.0224	1.7260
0.20	2,838,580	1,658,786	2.0020	1.7159

The differences between the 0.25 and 0.20 mm meshes were 1.02% for maximum deformation and 0.59% for area-averaged equivalent stress; therefore, the 0.20 mm mesh was adopted. As shown in Figure 8, the maximum deformation was 2.00 mm, while the maximum equivalent stresses of the whole model and PETG sleeve were 196.2 and 36.09 MPa, respectively. Based on yield strengths of 355 MPa for steel and 45 MPa for PETG, the corresponding safety factors were 1.81 and 1.25, indicating that no yielding was predicted under the applied load.

a) **b)**

Fig. 8 - Finite element analysis results of the bending resistance of the composite insertion pin

a) total deformation contour; b) equivalent stress contour

The PETG transition region could be strengthened by increasing the fillet radius and wall thickness, while its mechanical properties could also be improved by optimizing the printing parameters (*Szykiedans et al., 2017; Özen et al., 2021; Tunçel et al., 2024*).

Internodal and nodal insertion verification tests

To directly validate the recommended parameter combination under regular internodal insertion conditions and evaluate its adaptability to the nodal region, five independent internodal and five independent nodal axial insertion tests were conducted. The composite insertion pin with $\boldsymbol{d_1} = 5.5$ mm, $\boldsymbol{d_2} = 2.0$ mm and $\boldsymbol{\alpha} = 160°$ was used. The insertion depth was 30 mm, and the force–displacement curve, maximum insertion force, insertion force stiffness and end failure condition were recorded.

Table 7

Verification test results of axial insertion in the internodal and nodal regions

Test No	Insertion depth /mm	Internodal $F_{p,\max}/N$	Internodal K_F/(N/mm)	Nodal $F_{p,\max}/N$	Nodal K_F/(N/mm)
1	30	39.2	1.12	68.7	2.12
2	30	40.1	1.16	70.1	2.18
3	30	38.7	1.15	71.4	2.25
4	30	41.0	1.19	69.3	2.16
5	30	39.6	1.14	72.0	2.31

a) b) c)

Fig. 9 - Verification tests of axial insertion in the internodal and nodal regions
a) insertion test device and initial state; b) axial insertion process in the internodal region; c) state after insertion in the nodal region

Table 7 and Figure 9 show that the optimized composite insertion pin completed 30 mm axial insertion in all internodal and nodal tests. Under regular internodal insertion, the measured K_F was 1.15 ± 0.03 N/mm, with a relative error of 0.17% from the predicted value of 1.15 N/mm, confirming the prediction accuracy of the response surface model. In the nodal region, $F_{p,\max}$ and K_F increased to 70.3 ± 1.4N and 2.20 ± 0.08 N/mm, respectively, owing to the dense tissue and transverse diaphragm. Nevertheless, no obvious bending of the insertion pin, overall splitting of the stalk or interruption of the insertion process was observed.

Stalk release function verification

To evaluate the holding stability and release performance of the optimized composite insertion pin, repeated release tests were conducted using stalks pre-sleeved in the internodal and nodal regions. The composite insertion pin with $d_1 = 5.5$ mm, $d_2 = 2.0$ mm and $\alpha = 160°$ was used. After being pre-sleeved to a depth of 30 mm, each stalk was axially released by the release mechanism. Holding was considered successful when the stalk remained stably sleeved without visible slipping, whereas release was considered successful when the stalk was completely detached without jamming, overall end splitting or visible bending of the insertion pin. The holding state, release state and possible failure phenomena were recorded.

Fig. 10 - Stalk release verification test results

As shown in Figure 10, stable holding and complete release were achieved in both the internodal and nodal tests. No visible slipping, jamming, overall end splitting, bending of the insertion pin or structural damage was observed. Although the local contact resistance was higher in the nodal region, complete release was still achieved, indicating that the optimized composite insertion pin satisfied the requirements for stable holding and smooth release after axial insertion.

CONCLUSIONS

This study designed and optimized a smooth composite insertion pin consisting of a front steel pin and a rear sleeve to solve the problems of high resistance, obvious force fluctuation near nodes and poor release during axial insertion of corn stalks. The main conclusions are as follows:

(1) A smooth composite insertion pin consisting of a front steel pin and a rear sleeve was designed according to the heterogeneous structural characteristics of corn stalks. The structure enabled axial insertion, stable sleeving and subsequent release while reducing end crushing and overall stalk splitting.

(2) The axial insertion force was mainly composed of pith compression resistance and sidewall friction. The sleeve contact-segment diameter $\boldsymbol{d_1}$, steel pin diameter $\boldsymbol{d_2}$ and sleeve front transition angle $\boldsymbol{\alpha}$ affected sidewall friction, pith compression and guided compression, respectively, providing a theoretical basis for parameter optimization.

(3) The Box–Behnken regression model was highly significant, whereas the lack-of-fit term was not significant, with $\boldsymbol{R^2} = 0.9587$ and $\boldsymbol{R^2_{adj}} = 0.9056$. The sleeve contact-segment diameter had the greatest effect on $\boldsymbol{K_F}$, while the steel pin diameter and transition angle also had significant effects.

(4) Considering response surface optimization, machining feasibility and structural stability, the engineering parameters were determined as $\boldsymbol{d_1} = 5.5$ mm, $\boldsymbol{d_2} = 2.0$ mm and $\boldsymbol{\alpha} = 160°$, with a predicted $\boldsymbol{K_F}$ of approximately 1.15 N/mm. Five internodal validation tests gave a measured $\boldsymbol{K_F}$ of 1.15 ± 0.03 N/mm, with a relative prediction error of 0.17%, indicating good agreement between the measured and predicted results.

(5) Finite element analysis showed that the optimized structure maintained acceptable bending stability under the applied lateral load. In nodal insertion tests, the maximum insertion force increased to approximately 70 N, but no obvious bending, overall stalk splitting or insertion interruption occurred. Holding and release tests further confirmed stable sleeving and complete release in both internodal and nodal regions. However, the present study was limited to laboratory tests over a narrow moisture-content and diameter range, and dynamic impact and fatigue during continuous field operation were not considered. Future work will focus on multi-condition field tests and continuous-operation verification.

ABSTRACT

Conventional deep-burial devices typically employ a split structure consisting of a furrowing shovel and a soil-covering plate. During field operation, vibrations can cause relative displacement between these components, resulting in unstable soil coverage. Such devices may also exhibit structural redundancy, insufficient tillage depth, and high energy consumption. In this study, theoretical analysis and numerical simulation based on mechanical and soil-dynamics models were conducted to elucidate the soil–tool interaction mechanism of a direct-injection winged shovel and determine its key structural parameters. Using an EDEM-based soil–tool interaction model, a single-factor Box–Behnken experimental design was conducted with penetration angle, operating speed, and wing depth as the experimental factors and soil coverage rate and tillage resistance as the response variables. The optimal parameter combination consisted of a shovel-tip penetration angle of 25°, a wing depth of 150 mm, and an operating speed of 1.4 m·s⁻¹. Under these conditions, the direct-injection winged shovel achieved low tillage resistance, a high soil coverage rate, stable operation, and consistent furrow width. Field tests showed that all measured performance indicators met the requirements of the applicable Chinese national standards. The developed shovel exhibited stable and consistent performance during deep straw incorporation, thereby effectively improving operational quality.

摘要

传统深埋部件多采用开沟铲与覆土板分体装配结构，田间作业过程中易受振动发生相对偏移，造成覆土稳定性较差，同时存在结构冗余、耕深不足、作业能耗偏高等问题，为此本文创新设计一体化开沟覆土直注翼铲，单一部件可同步完成开沟、覆土、秸秆深埋、深松复合作业。采用理论分析与数值模拟相结合的方法，通过力学和土壤动力学分析模型，阐明直注翼铲与土壤的相互作用机制，确定直注翼铲主要结构参数。基于 EDEM 土壤耕作仿真模型，采用单因素试验 Box-Behnken 组合试验设计，以入土角、耕作速度、尾翼深度为试验因素，以覆土率、耕作阻力为核心评价指标，结果确定直注翼铲较优参数为铲尖入土角 25°、铲体尾翼深度 150 mm、耕作速度 1.4 m·s-1，该组参数下耕作阻力较小，自动覆土率高，作业稳定性与开沟宽度一致性较好。田间试验结构表明，该直注翼铲各项作业指标均符合国家标准要求，在秸秆还田作业中表现出良好的稳定性与一致性，能够有效提升作业质量。

INTRODUCTION

China is a major agricultural country with extremely abundant crop straw resources, accounting for nearly one-fifth of the global total (*Zhang et al., 2025*). Among them, the production of corn straw ranks first in the country, which is attributed to the continuous development of agricultural mechanization and has now become a necessary support condition for sustainable agricultural development (*Fang et al., 2021; Liu et al., 2025; Awachat et al., 2024; Wang et al., 2023)*. The deep straw incorporation machine buries postharvest crop residues in the subsoil, enabling their efficient incorporation at the required depth. The structural design and operational performance of its furrow-opening and soil-covering components directly affect the quality of straw burial *(Barr et al., 2020; Madhusudan et al., 2024)*.

Most straw incorporation machines currently available in China are designed only to pulverize and scatter straw or apply it as surface mulch, whereas only a limited number of models can incorporate crushed straw deep into the soil *(Shen et al., 2022)*.

This deep-burial device typically employs a split assembly structure comprising a furrowing shovel and a soil covering plate. Due to soil impact and machine vibration, component positions tend to deviate, leading to issues such as uneven soil coverage and insufficient backfilling. The separate connection components introduce structural redundancy, resulting in excessive tillage resistance for the entire unit. Current research lacks an integrated design capable of simultaneously performing furrowing, soil guidance, return flow, and directional soil covering, making it difficult to fundamentally address soil instability caused by positional deviations in the modular assembly (*Aikins et al., 2020*). In contrast, straw incorporation equipment developed in other countries offers greater automation and operational precision, together with compact designs and integrated functions. It can simultaneously perform multiple processes including straw pulverization, soil mixing, and deep burial, offering high operational efficiency and automation*(Lin et al., 2022; Xu et al., 2022)*. Such machine can adapt to various field cultivation needs. However, when applied domestically, these machines face challenges such as high costs, substantial maintenance expenses, and difficulty in adapting to local working conditions.

To address challenges in deep straw incorporation such as unstable soil coverage and high tillage resistance, this study developed a direct-injection wing shovel with the dual functions of furrowing and automatic soil covering, while optimizing its core structure and operational parameters. The effects of key structural parameters, including the penetration angle and tail-wing depth, on soil–tool interactions were analyzed. The physical and mechanical properties of the soil and the requirements for deep straw incorporation were then incorporated into a performance-optimization model. Based on theoretical analysis, an EDEM discrete element simulation was employed to construct a shovel-soil interaction model, identifying the optimal structural and operational parameter combination. Field trials were conducted to validate the shovel's operational efficiency.

MATERIALS AND METHODS

Structure and Working Principle

The deep straw incorporation machine shown in Fig. 1 consists of a three-point hitch frame, chain-drive system, main frame, soil-lifting and covering device, straw-crushing device, flow-guiding device, and transmission system. The machine is mounted on the rear three-point hitch of the tractor, and its transmission system is connected to the tractor power take-off (PTO) shaft through a universal joint *(Cedik et al., 2024)*. During operation, the shovel tip penetrates to a depth of 30 cm below the soil surface. Symmetrically arranged side blades driven by the chain-drive system further crush the preprocessed straw, reducing its particle size. The processed straw is conveyed by airflow through the fan outlet to the flow-guiding device, which collects it and directs it into the feeding tube. The tube then delivers the straw directly into the cavity created by the direct-injection winged shovel as it lifts and displaces the soil. The displaced soil subsequently falls back automatically, covering the accumulated straw at a depth of approximately 30 cm within the subsoil layer. This process enables the concentrated placement and deep incorporation of straw. By promoting straw decomposition and increasing the organic matter returned to the soil, this method can improve soil structure and create favorable conditions for subsequent crop growth.

Design of the direct-injection winged shovel for furrow opening and soil covering

The direct-injection winged shovel shown in Fig. 2 consists of a shovel body, feeding tube, support plate, and soil-guiding rails.

The device delivers crushed straw beneath the cultivated soil layer, while its structural configuration promotes the automatic return of displaced soil, thereby ensuring uniform straw burial and restoration of the soil profile. During operation, the wing-shaped shovel body lifts and displaces the soil, forming a subsurface cavity for deep straw placement. The coordinated design of the feeding tube and shovel body allows the crushed straw to pass smoothly into this cavity. As the shovel advances, the displaced soil falls back over the deposited straw, ensuring deep burial while maintaining a relatively level soil surface and a stable soil profile. The shovel also disrupts the compacted layer beneath the cultivated soil, increasing soil porosity and potentially improving soil aeration, water infiltration, and root development.

Analysis of the Operating Process

The following assumptions were adopted to establish the analytical model: (1) the shovel moves forward at a constant velocity, and acceleration during startup and stopping is neglected; (2) the soil is regarded as a homogeneous elastoplastic medium; (3) stones, crop residues, and other randomly distributed inclusions are excluded; and (4) only the soil stress state under steady-state cutting conditions is considered. Figure 3 illustrates the forces acting on the soil during operation of the direct-injection winged shovel. The soil–tool interaction process is divided into three regions: AB, BC, and BD. In region AB, the soil is primarily subjected to its weight G_1, the friction force f generated by relative motion along the contact surface, and the normal force F_1 exerted by the shovel tip. The weight G_1 acts vertically downward, f acts tangentially to the upper surface of the shovel tip, and F_1 exerted by the shovel tip acts perpendicular to the shovel-tip surface. In region BC, the support plate acts on the soil, which is subjected to its weight G_2 and the contact force F_2 exerted by the plate. This interaction compresses, shears, and fractures the soil, resulting in structural deformation. In region BD, the shovel body interacts with the soil, which is subjected to its weight G_3, the normal force F_3 exerted by the side surface of the shovel body, and the longitudinal compressive force F_4, acting in the direction of travel.

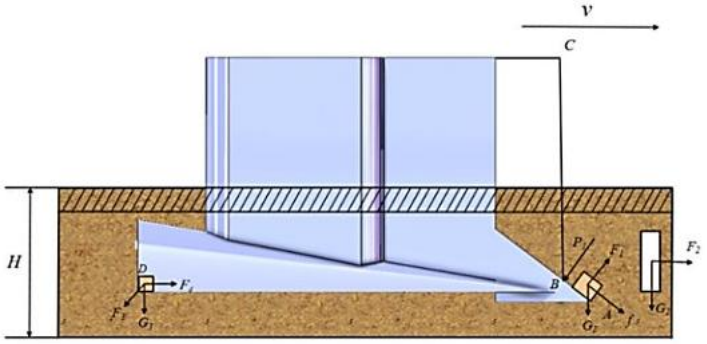

Fig. 3 - Diagram of soil forces

Force analysis during the earth-breaking process

During operation of the direct injection wing shovel, the wedge-shaped soil mass formed ahead of its working area is lifted and subsequently fragmented, preventing soil overturning. As the shovel advances, its blade continuously cuts through the soil while encountering horizontal tillage resistance. The combined traction resistance P generated by the blade tip and handle during soil cutting is calculated as:

$$P = k_1 l_1 + k_2 l_2 \quad (1)$$

In the formula: k_1 and k_2 represent the components of resistance in the direction of movement per unit length; l_1 and l_2 denote the lengths of the blade tip and handle blade, respectively (mm).

Analysis of Soil cutting failure motion

During cultivation, the shovel blades compress the soil, causing shear damage. The horizontal component of the force acting on the shovel blades is the traction resistance T:

$$T = N\sin\alpha + F\cos\alpha = N(\sin\alpha + f\cos\alpha) \quad (2)$$

where N is the normal pressure, F is the friction force of the soil on the shovel tip, and θ is the penetration angle of the direct-injection winged shovel.

The normal stress level of soil is the correlation coefficient of soil. Assuming that the working area of the straight injection wing shovel is A, then the normal pressure N is:

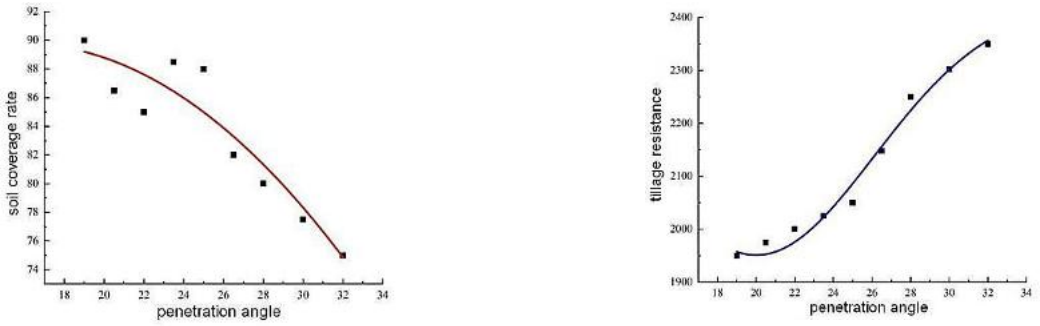
$$N = A \cdot \xi \cdot \delta\Delta t \quad (3)$$

Furthermore:

$$f = tan\,\phi \quad (4)$$

where φ denotes the soil's friction angle.

The traction resistance T is given by:

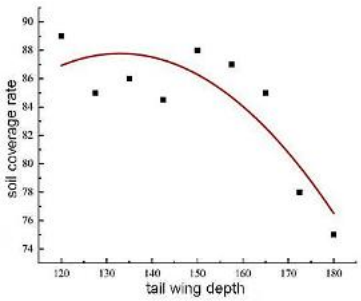


$$T = A \cdot \xi \cdot \delta(sin\,\alpha + f\,cos\,\alpha) = A \cdot \xi \cdot \delta(sin\,\alpha + tan\,\phi\,cos\,\alpha) \quad (5)$$

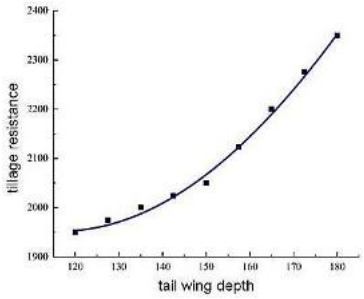
This set of mechanical equations establishes the theoretical relationship among the penetration angle, contact area, and traction resistance, thereby determining the appropriate range for the penetration angle and providing a theoretical basis for selecting factor levels in subsequent Box-Behnken experiments, while establishing an intrinsic connection between the theoretical model and the experimental design.

Structural Optimization

Single-factor experiment



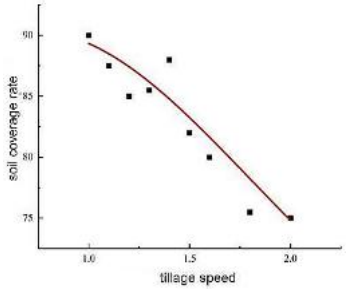
As shown in Figure 4(a), when the penetration angle of the direct-injection wing shovel falls within the range of 19-28°, the soil coverage rate decreases gradually with increasing penetration angle; whereas within the range of 28-32°, the coverage rate exhibits a negative correlation with the penetration angle. Figure 4(b) demonstrates that for penetration angles between 19° and 25°, tillage resistance increases steadily and slowly with increasing angle, while for angles between 25° and 32°, tillage resistance shows an inverse relationship with the penetration angle. Considering the optimization of both soil coverage rate and tillage resistance, an optimal penetration angle range of 22-25° is identified as achieving both significantly improved soil coverage efficiency and effective reduction of tillage resistance.



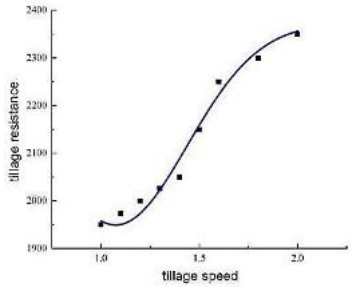
(a) Soil coverage rate at different penetration angles *(b) Tillage resistance at different penetration angles*

Fig. 4 - Effects of shovel tip penetration angle on test indicators

As the depth of the plow body tail wing increases, the soil coverage rate remains generally stable; however, a turning point occurs at a tail wing depth of 150 mm, where the decline rate accelerates significantly. An optimal tail wing depth helps reduce tillage resistance and lower operational energy consumption. Considering the combined effects of tail wing depth on both soil coverage rate and tillage resistance, an ideal range of 120-150 mm is identified, which yields high soil coverage while minimizing tillage resistance.



(a) Soil coverage rate at different tail wing depths



(b) Tillage resistance at different tail wing depths

Fig. 5 - Effects of shovel body tail wing depth on test indicators

The effects of different tillage speeds on soil coverage rate and tillage resistance are illustrated in Figure 6. The experimental results demonstrate that tillage speed significantly influences both coverage rate and tillage resistance. The coverage rate generally decreases with increasing tillage speed, whereas the trend for tillage resistance is opposite. This relationship remains stable within the speed range of 1.2-1.6 m/s. Within this range, an optimal tillage speed can be identified—one that maintains adequate soil coverage by the direct-injection wing shovel while effectively reducing tillage resistance.

(b) Tillage resistance at different tillage speeds

Fig. 6 - Effects of tillage speed on test indicators

Establishment of the simulation model

The direct-injection winged shovel consists of a shovel body, feeding tube, support plate, and soil-guiding rail, as shown in Fig. 3. A 3D model of the shovel was developed in SolidWorks, exported in IGS format, and imported into EDEM. The material properties, contact parameters, and mechanical parameters required for the discrete element method (DEM) simulation were then defined. The parameters used in the simulation are presented in Table 1.

Table 1

Parameter	Numeric value
Poisson's ratio of the direct-injection winged shovel (45 steel)	0.25
Shear modulus of the direct-injection winged shovel (45 steel) (Pa)	8.21×10^{10}
Density of the direct-injection winged shovel (45 steel) (kg·m^{-3})	7900
Shear modulus of the cultivated-layer soil (Pa)	1×10^{6}
Density of the cultivated-layer soil (kg·m^{-3})	1440
Bond stiffness of the cultivated-layer soil (km·m^{-3})	5×10^{7}
Bond strength of the cultivated-layer soil (Pa)	2×10^{4}
Coefficient of friction of the cultivated-layer soil	0.333
Poisson's ratio of the plow-pan soil	0.36
Shear modulus of the plow-pan soil (Pa)	1.1×10^{6}
Density of the plow-pan soil (kg·m^{-3})	1500
Bond stiffness of the plow-pan soil (km·m^{-3})	5×10^{7}
Bond strength of the plow-pan soil (Pa)	3×10^{4}
Coefficient of friction of the plow-pan soil	0.282
Poisson's ratio of the subsoil	0.36
Shear modulus of the subsoil (Pa)	1.2×10^{6}
Density of the subsoil (kg·m^{-3})	1540
Bond stiffness of the subsoil (km·m^{-3})	5×10^{7}
Bond strength of the subsoil (Pa)	4×10^{4}
Coefficient of friction of the subsoil	0.224

The contact model is a fundamental component of the discrete element method (DEM), as it describes the forces and deformations generated by particle–particle and particle–boundary interactions *(Liu et al., 2025)*. Commonly used contact models include Hertz–Mindlin with JKR, the Parallel Bond Model, and Hertz–Mindlin with Bonding. The Hertz–Mindlin with JKR model accounts for adhesive forces at particle contacts but does not explicitly represent the fracture of cemented bonds. The Parallel Bond Model is widely used to simulate the fracture of brittle bonded materials, such as rock, but may require extensive calibration for soil applications. Considering both simulation accuracy and computational efficiency, the Hertz–Mindlin with Bonding model was selected in this study.

By allowing bonds between particles to break when prescribed strength criteria are exceeded, this model can represent soil cracking, shear failure, and the separation and movement of soil layers during tillage. It was therefore considered suitable for simulating the interaction between the direct-injection winged shovel and the soil.

The soil in this experimental area is sandy loam, with the plow pan extending from the surface to a depth of 150 mm. Soil physical analysis reveals that this layer exhibits high porosity and soft texture, primarily composed of granular and columnar soil particles. Below 150 mm lies the shovel subsoil, which shows significantly increased compaction and greater hardness, with soil particles consisting of individual grains and clumps. The core soil layer below 300 mm is classified as the non-plow pan, mainly composed of large-sized kernel-like particles.

For numerical simulations of deep loosening operations, a scaled virtual soil tank was developed with dimensions of 2000 mm × 1200 mm × 450 mm, designed to mitigate boundary effects. Soil parameters were stratified across three layers: 0–150 mm, 150–300 mm, and 300–450 mm, corresponding to the tillage, shovel, and core soil layers, respectively *(Wei et al., 2025)*. A discretized soil particle model was then constructed to balance computational efficiency and the representation of soil structural characteristics, as presented in Fig.7.

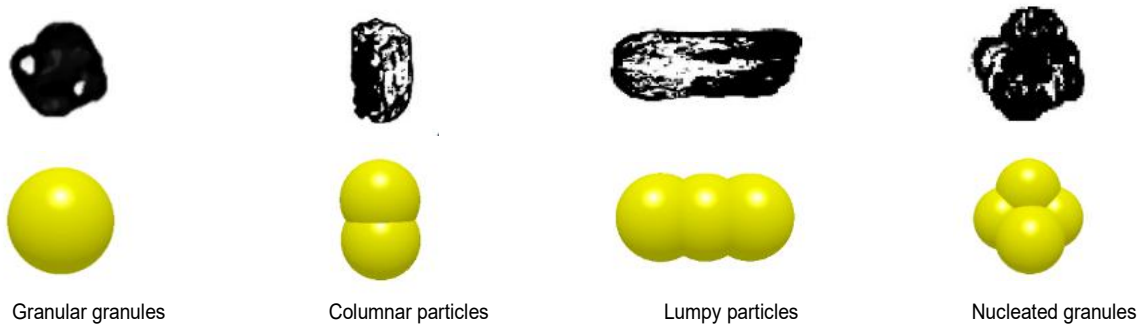

Fig. 7 - Soil particle model

Simulation test analysis

Based on the parameter ranges determined through preliminary single-factor experiments, a Box–Behnken experimental design was developed using Design-Expert 13. The experimental factors and their coded levels are presented in Table 2.

Table 2

Table of factor level coding

Level	Factor		
	Penetration angle *A* / (°)	Tail wing depth *B* / mm	Tillage speed *C* / (m·s^{-1})
-1	22	135	1.2
0	25	150	1.4
1	28	165	1.6

RESULTS

Analysis of variance of the simulation results

A Box–Behnken experimental design was developed using Design-Expert 13, and the simulations were performed according to the resulting design matrix. The design comprised 17 runs, including five replicates at the center point, to estimate experimental error and assess model adequacy. The objective was to determine the effects of three factors—the penetration angle (A), tail-wing depth (B), and operating speed (C)—on the soil coverage rate and tillage resistance of the direct-injection winged shovel. The design matrix and simulation results are presented in Table 3.

Table 3

Experimental design and simulation results

Run	Penetration angle A / [°]	Tail wing depth B / [mm]	Tillage speed C / [min]	Soil coverage rate Y_1 / [%]	Tillage resistance Y_2 / [N]
1	25	150	1.4	88.79	2060.33
2	22	150	1.6	82.43	2073.33

15	25	150	1.4	88.03	2049.33
16	22	150	1.2	80.03	2136.33
17	25	150	1.4	88.43	2099.33

Significance analysis of soil coverage rate Y_1 and tillage resistance Y_2 with direct injection wing shovel

A variance analysis and regression coefficient significance test were performed on the regression model of soil coverage rate Y_1 for direct injection wing shovels, with detailed results presented in Table 4. The regression equation for soil coverage rate Y_1 is as follows:

$$\hat{Y}_1 = 88.29\text{-}1.01A + 1.12B + 0.45C + 0.25AB - AC + 0.5BC - 4.2A^2 - 4.27B^2 - 3.99C^2 \quad (5)$$

A model is considered significant when its F-value reaches 177.94. In this context, a P-value below 0.0500 indicates a statistically significant model term, while a P-value below 0.01 signifies extremely significant. The specific P-values are: A (0.0002), B (0.0001), C (0.0172), AC (0.0018), BC (0.0448), A^2 (0.0001), and B^2 (0.0001). Therefore, terms A, B, C, AC, A^2, B^2, and C^2 are all statistically significant. The out-of-fit term shows an F-value of 2.3 with a P-value of 0.2189, indicating that the out-of-fit term is not significant. This suggests the model fits well and the data is reliable.

Table 4

Analysis of variance of coverage rate

Source of variation	Sum of square	Degree of freedom	Mean square	F value	P value	Significance
Model	269.20	9	29.91	177.94	< 0.000 1	**
A	8.12	1	8.12	48.31	0.0002	**
B	10.12	1	10.12	60.23	0.0001	**
C	1.62	1	1.62	9.64	0.0172	*
AB	0.2500	1	0.2500	1.49	0.2621	
AC	4.00	1	4.00	23.80	0.0018	**
BC	1.0000	1	1.0000	5.95	0.0448	*
A^2	74.44	1	74.44	442.87	< 0.0001	**
B^2	76.94	1	76.94	457.73	< 0.0001	**
AB^2	67.03	1	67.03	398.73	< 0.0001	**
Residual	1.18	7	0.1681			
Lack of Fit	0.7450	3	0.2483	2.30	0.2189	
Pure Error	0.4316	4	0.1079			
Sum	270.37	16				

Note: $p \leq 0.01$ means highly significant (**); $0.01 < p \leq 0.05$ means significant (*); $p > 0.05$ means not significant.

The regression model for tillage resistance Y_2 of direct injection wing shovels was constructed. Through analysis of variance and regression coefficient significance test, the results are shown in Table 5. The regression equation for tillage resistance Y_2 is:

$$\hat{Y}_2 = 2063.13 + 54.93A - 88.78B + 18.5C - 14.87AB + 47.49AC + 27.72BC + 54.19A^2 + 94.67B^2 - 43.7C^2 \quad (6)$$

As shown in Table 5, A, B, and C represent the penetration angle, tail-wing depth, and operating speed, respectively, and tillage resistance is the response variable. The model F-value of 72.86 indicates statistical significance. A P-value below 0.0500 signifies a significant model term, while a P-value below 0.01 denotes extremely significant terms.

Specifically, the P-values for A and B are both <0.0001, C is 0.0135, AC is 0.1046, BC is 0.0103, A^2 is 0.0002, B^2 is <0.0001, and C^2 is 0.0008. Thus, A, B, C, AC, BC, A^2, B^2, and C^2 are significant model terms. The out-of-fit term has an F-value of 0.0566 and a P-value of 0.9799, indicating no significant out-of-fit term, suggesting good model fit and reliable data.

Response surface analysis

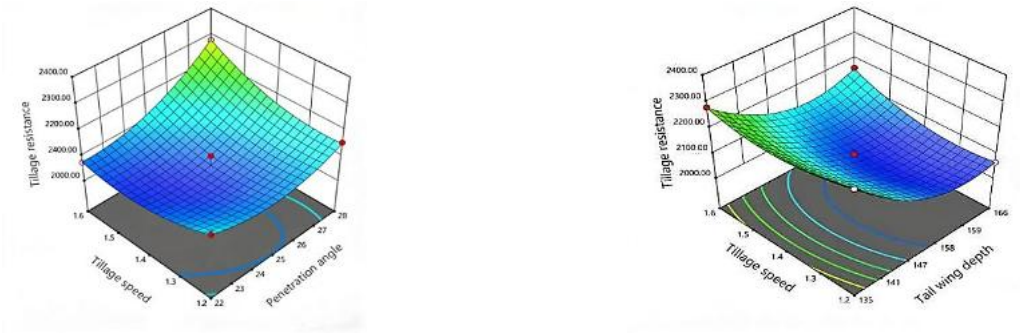
The response surface analysis method was employed to analyze the test data, aiming to investigate the intrinsic relationship between the core performance indicators and key influencing factors of the direct injection wing shovel. Based on the data analysis results, response surface plots of each factor with respect to the soil coverage rate were generated. These plots visually illustrate the specific impact of each influencing factor on the performance evaluation index of the direct injection wing shovel, as well as how these factors interact and jointly influence the evaluation index.

Effects of the experimental factors on soil coverage rate

Response surface analysis was used to evaluate the effects of penetration angle, tail-wing depth, and operating speed on the soil coverage rate of the direct-injection winged shovel. The response surface plots shown in Fig. 8 illustrate the effects of pairs of factors and their interactions on soil coverage rate while the third factor is held at its center level. These plots show the direction and magnitude of the factor effects and reveal how their interactions influence soil coverage performance.

(a) Interaction between penetration angle and tillage speed (b) interaction between tail-wing depth and tillage speed

Fig. 8 - Effects of factor interactions on the soil coverage rate of the direct-injection winged shovel



As shown in Fig. 8(a), under the interactive influence of the penetration angle and the tillage speed, as both the tillage speed and the soil penetration angle increase, the soil coverage rate overall exhibits a trend of first increasing and then decreasing.

The magnitudes of change in the soil coverage rate with respect to the increase and decrease of the tillage speed are approximately equal, and the change pattern is relatively uniform. The soil coverage rate reaches its peak when the tillage speed is approximately 1.5 m·s^{-1}. The overall response surface is convex.

As can be seen from Fig. 8(b), under the interactive influence of the tillage speed and the tail wing depth, the slope of the tangent plane of the response surface first gradually decreases and then becomes steeper, with the tangent slope also first decreasing and then increasing. The influence trends of the two factors are relatively similar, and the soil coverage rate is more significantly affected by the tail wing depth than by the tillage speed.

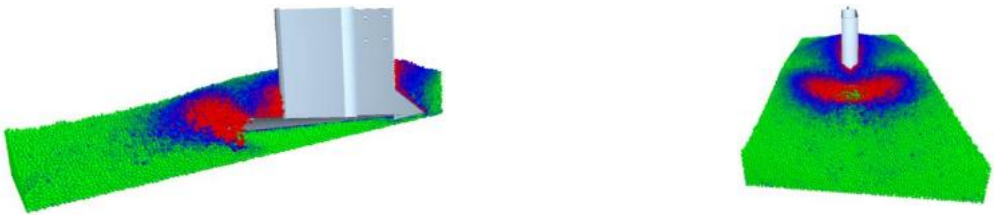
The influence on the tillage resistance of the direct injection wing shovel

Response surface methodology was applied to analyze the experimental data, with a comprehensive investigation into the interactive effects of key influencing factors—penetration angle, tail wing depth and tillage speed—on the tillage resistance, a critical performance index of the direct injection wing shovel. Data analysis further enabled the generation of response surface plots illustrating the relationship between each individual factor and tillage resistance, which are presented in Fig.9.

(a) Interaction between penetration angle and operating speed (b) Interaction between tail-wing depth and operating speed

Fig. 9 - Effects of factor interactions on the tillage resistance of the direct-injection winged shovel

As shown in Fig. 9(a), under the interactive influence of the penetration angle and the tillage speed, the resistance overall exhibits a trend of first decreasing and then increasing as both the tillage speed and the penetration angle increase. When the tillage speed is approximately 1.5 m·s^{-1}, the resistance reaches its minimum value, and the overall response surface is concave.



As can be seen from Fig. 9(b), under the interactive influence of the tillage speed and the tail wing depth, the resistance is significantly more affected by the tail wing depth than by the tillage speed, and this significant influence is completely opposite to the influence on the soil coverage rate.

Simulation Results for Soil Movement

As shown in Fig. 10, when the direct-injection winged shovel is fully engaged with the soil, its tip penetrates the plow pan and loosens the compacted soil layer. As the shovel advances, the shovel tip cuts and lifts the soil, causing soil particles to move upward. The winged shovel body then displaces the lifted soil laterally, creating a furrow. After the shovel passes, the displaced soil falls back into the furrow behind the shovel, thereby completing the furrow-opening and soil-covering process.

(a) Soil movement at 2.2 seconds

(b) Soil movement at 2.8 seconds

Fig. 10 - Soil displacement dynamics during operation of direct injection winged shovel

Field trial

Test conditions

The test equipment comprised a deep straw incorporation machine equipped with the direct-injection winged shovel, a draft-force measurement system, measuring tapes, straightedges, marker poles, and sampling shovels. Field tests were conducted after the autumn harvest to evaluate the operational performance of the shovel and validate the simulation results. Before testing, the dimensions of the designated test plots were measured with a tape measure, and their boundaries were marked with poles in accordance with NY/T 500–2002, *Operating Quality of Straw-Returning Machines*. The selected field was continuous and uniform, with a stated length of more than 1,500 m. The test area was divided into a principal test plot and reserve plots. If abnormal conditions invalidated a test in the principal plot, a comparable reserve plot was used. Field topography and soil conditions were considered when selecting the plots to ensure comparable and representative testing conditions.

Performance Test

The performance evaluation of the direct-injection winged shovel focused on its furrow-opening and soil-covering performance. The selected evaluation indicators were furrow-depth stability, furrow-width consistency, and soil coverage rate.

To measure furrow depth, loose soil was carefully removed from the furrow edges and bottom to expose the original soil surface and furrow bottom. A straightedge was placed across the furrow, and the vertical distance from the straightedge to the furrow bottom was measured as the furrow depth. Before measuring furrow width, naturally collapsed soil was removed. Width measurements were taken at longitudinal positions of 0, 150, and 300 mm, and their mean was calculated as the furrow width. The soil coverage rate was determined within a 100 × 300 mm sampling area. The masses of soil displaced outside the furrow and soil that naturally fell back into the furrow were measured separately. The soil coverage rate was calculated as the mass of soil returned to the furrow divided by the total mass of displaced soil.

As shown in Table 6, the mean furrow depths obtained in five consecutive test runs were 305, 302, 301, 298, and 299 mm, respectively. The furrow-depth stability coefficient exceeded 94% in all runs, indicating that the direct-injection winged shovel maintained consistent operating depth across repeated field tests.

Table 6

Field test results for furrow depth

Parameters		First run	Second run	Third run	Fourth run	Fifth run
Furrow depth	Maximum/mm	308	307	311	306	310
	Minimum/mm	291	297	286	294	297
	Average value/mm	305	302	301	298	299
	Range/mm	17	10	25	12	13
	Stability coefficient	94.75	98.34	94.17	95.48	95.32

To determine the backfilling rate of the direct injection wing shovel, the furrow depth must first be precisely measured *(Bao et al., 2017; Du et al., 2025).* Specifically, soil accumulated both inside and outside the furrow was thoroughly cleared using shovels to ensure the original ground surface and furrow bottom were fully exposed. Next, a straightedge was placed between the furrow walls to measure the vertical height from the furrow bottom to the ground surface.

As shown in Table 7, the average furrow width of the direct injection wing shovel across five consecutive operations was 1008 mm,1004 mm,1005 mm,1003 mm, and 1009 mm, respectively. The maximum deviation in furrow width during each operation never exceeded 20 mm.

Moreover, the furrow-width consistency coefficient exceeded 95% in all five test runs, indicating that the shovel maintained a consistent furrow width. These results demonstrate stable furrow-opening performance over different operating distances.

Table 7

Field test results for furrow width

Parameters		**First run**	**Second run**	**Third run**	**Fourth run**	**Fifth run**
Furrow width	Maximum/mm	1017	1011	1014	1010	1016
	Minimum/mm	1002	995	994	994	998
	Average value/mm	1008	1004	1005	1003	1009
	Range/mm	15	16	20	16	18
	Consistency coefficient	95.39	95.44	96.43	96.32	96.52

Fig. 11 - Operating process of the direct-injection winged shovel during furrow opening and soil covering

During operation, the shovel tip and body penetrate and lift the soil. The displaced soil moves rearward along the shovel body and subsequently falls into the cavity formed behind the shovel. As shown in Fig.11, this cavity provides space for straw placement. After the straw is guided into the cavity, the displaced soil falls back and covers it, thereby completing the deep straw incorporation process. Field tests confirmed that the direct-injection winged shovel performed its intended functions during deep straw incorporation *(Gao et al., 2022)*.

As shown in Table 8, the mean soil coverage rates recorded in five consecutive test runs were 87.45%, 88.05%, 87.55%, 86.75%, and 87.55%, respectively. The small variation among the five mean values indicates that the shovel maintained relatively consistent soil-covering performance across repeated tests.

Table 8

Experimental results of soil coverage rate

Parameters		First run	Second run	Third run	Fourth run	Fifth run
Soil coverage rate	Maximum/mm	88.7	89.3	88.9	92.1	89.4
	Minimum/mm	83.5	85.5	83.2	85.4	83.7
	Average value/mm	87.45	88.05	87.55	86.75	87.55
	Range/%	5.2	4.7	5.7	6.5	5.7

Experimental Comparative Verification

As shown in Table 9, the variation patterns of simulation results and field experiment results are largely consistent, with relative errors for both indicators below 3%, indicating high agreement. The minor discrepancies mainly stem from the following factors: the simulation model simplifies soil as a homogeneous medium, neglecting random variables such as straw residues and local moisture fluctuation; additionally, slight systematic errors exist in soil contact parameter calibration, leading to minor deviations between simulation and measured results. Standard deviation and 95% confidence interval analyses demonstrate that field experiment data exhibit low dispersion and good repeatability, confirming that this discrete element model meets the accuracy requirements for simulation analysis.

Table 9

Evaluating indicator	Experimental Mean value	Simulation mean	Relative error	Standard deviation	Confidence interval
Tillage resistance	2121.00	2063.13	2.73	24.73	[2089.81,2152.19]
Soil coverage rate	87.47	88.29	0.94	0.47	[86.89,88.05]

CONCLUSIONS

To address the insufficient operating depth, limited soil-backfilling capability, and high tillage resistance of conventional furrow-opening and soil-covering components, an integrated direct-injection winged shovel was developed. The effects of its structural and operating parameters on soil coverage and tillage resistance were investigated through theoretical analysis, discrete element simulation, and field testing. The main conclusions are as follows:

(1) The soil properties varied with depth. Moisture content ranged from 15.99% to 22.04%, while bulk density increased from 1.41 to 1.54 g/cm³ from the cultivated layer to the subsoil. The shear strength of the plow pan was 30.43 kPa, which was higher than the 23.30 kPa measured in the cultivated layer. These data provided the basis for designing the direct-injection winged shovel and calibrating the soil model.

(2) EDEM simulation results showed that the direct-injection winged shovel effectively disrupted the plow pan and promoted automatic soil backfilling, with a soil coverage rate of 88.45% and a tillage resistance of 2048.78 N, achieving lower energy consumption than traditional two-step operations.

(3) The optimal parameter combination comprised a shovel-tip penetration angle of 25°, a tail-wing depth of 150 mm, and an operating speed of 1.4 m/s. Under these conditions, the predicted soil coverage rate exceeded 88%, while the tillage resistance remained below 2050 N.

(4) Field tests confirmed that the direct-injection winged shovel performed its intended functions during deep straw incorporation. The reported furrow-depth stability, furrow-width consistency, and soil coverage values were 94.65%, 96.06%, and 87.47%, respectively. The measured performance indicators met the requirements of the applicable Chinese agricultural machinery standard, demonstrating stable furrow opening and soil covering under the tested field conditions.

（5）This study has several limitations. In the discrete element model, each soil layer was treated as a homogeneous medium, and field-scale soil heterogeneity, stones, and crop residues were not represented. These simplifications may have contributed to differences between the simulated and measured results. Moreover, the field tests were conducted only in relatively loose black soil in Northeast China. The performance of the shovel in compacted loess, cohesive paddy soil, and sandy loam therefore remains unknown. Hard soil may accelerate component wear, cohesive soil may adhere to the shovel and obstruct straw delivery, and loose sandy soil may not provide stable soil coverage. In addition, the integrated curved tail-wing structure results in a relatively large overall width, potentially limiting maneuverability in narrow-row fields. Future research should optimize the tail-wing profile to reduce the transverse dimensions, conduct comparative tests in different soil types, and develop a DEM model that accounts for spatial soil heterogeneity. These improvements would enhance simulation accuracy and broaden the applicability of the device.

Keywords: *Discrete element method; Parameter calibration; Notoginseng; laterite soil; JKR contact model*

ABSTRACT

This study calibrated key contact parameters for discrete element simulations of interactions among Panax notoginseng seedlings, lateritic soil, and 65Mn steel to address the lack of systematic multi-media parameter calibration methods. The researchers investigated three core contact interfaces using EDEM software, focusing on JKR surface energy, restitution coefficient, static friction coefficient, and rolling friction coefficient. They employed angle of repose tests, mixture collapse tests, and inclined plane rolling tests, combined with orthogonal design and response surface methodology, to establish correlation models between simulation and physical results. Through analysis of variance and multi-objective optimization, the team identified significant parameters and their optimal combinations for each interface. Validation showed that the optimized model exhibited relative errors below 7.5% across all tests, with prediction accuracy improved by over 30%. Field experiments further confirmed the model's reliability, providing theoretical support for structural optimization of Panax notoginseng transplanters.

摘要

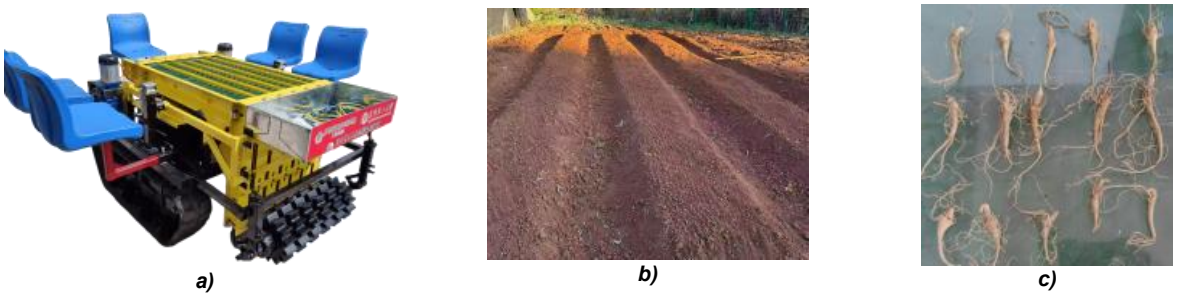
为解决农业机械—红壤—作物相互作用离散元模拟中多介质接触参数缺乏系统标定方法的问题，本研究针对三七种苗—红壤、红壤—红壤、红壤—65Mn 钢三个核心接触界面，采用 EDEM 软件开展了关键接触参数标定优化研究。研究团队以 JKR 表面能、恢复系数、静摩擦系数和滚动摩擦系数为标定参数，采用休止角、混合坍塌、斜面滚动等物理试验，结合正交设计和响应面法，建立了模拟与物理试验的关联模型。通过方差分析和多目标优化，确定了各界面的显著参数及其最优组合。验证表明，优化后模型各项试验相对误差均低于 7.5%，预测精度提高 30% 以上。田间试验进一步证实了模型的可靠性，为三七移栽机结构优化提供了理论支撑。

INTRODUCTION

Panax notoginseng is a rare and valuable medicinal plant endemic to China, primarily cultivated in the southwestern regions including Yunnan, Guangxi, and Guizhou *(Liu et al., 2017; Yang et al., 2019*). Its dried roots and rhizomes have notable therapeutic effects. However, *P. notoginseng* transplantation faces challenges: tender seedlings are easily damaged during mechanical operations, reducing survival rates and yields. The cultivation soil for *P. notoginseng* is a cohesive lateritic soil characterized by poor workability, high moisture content, heavy texture, and high specific resistance (*Shao et al., 2006; Xing et al., 2020*). Such soil causes excessive resistance and severe adhesion, hindering Yunnan's *P. notoginseng* industry and mechanized transplantation development.

Discrete element method (*DEM*) simulation serves as a critical approach for investigating the coupled motion characteristics of the agricultural machinery–soil–seedling system, while accurate and reliable DEM parameters constitute the fundamental basis and prerequisite for studying the interaction characteristics of the agricultural machinery–lateritic soil–*P. notoginseng* system *(Aikins et al., 2021; Zeng et al., 2021*).

[1] *Wei SU, Ph. D. Professor; Qingxu YU, Ph. D. Assistant Researcher; Qinghui LAI, Ph. D. Professor; Yi ZENG, Master Candidate; Congcong LIAO, Master Candidate; Cantong SU, Master Candidate.*



Parameter calibration is a pivotal step in DEM simulations, as its accuracy directly governs the reliability of simulation results. The Johnson-Kendall-Roberts (*JKR*) contact model, capable of precisely characterizing cohesive interactions between particles, has been widely adopted in DEM modeling of cohesive soils. To date, researchers worldwide have conducted systematic studies on seedling–soil contact parameter calibration targeting crops such as corn, potato, and ginseng. *Tian Xinliang et al., (2021*) provided theoretical references for the discrete element simulation of corn straw–soil mixtures in black soil regions. *Xiang Wei et al., (2019*), based on soil accumulation tests, adopted the Hertz-Mindlin with JKR contact model to construct a discrete element simulation model of southern clayey soil. *Li Junwei et al., (2019)*, utilized the Hertz-Mindlin with JKR cohesion contact model in EDEM to calibrate clayey black soil with varying moisture contents in Northeast China, providing references for agricultural machinery operations under different moisture conditions. *Bahrami et al., (2020)*, employed the hysteretic spring–linear cohesion contact model to conduct DEM simulations of plate sinkage tests on cohesive soils with varying moisture contents, elucidating the influence of key parameters on sinkage characteristics. *Adajar et al., (2021)*, performed calibration of the residue–soil friction coefficient and restitution coefficient using the discrete element method, specifically targeting the crop residue–soil contact interface, thereby providing key parameter foundations for modeling soil–crop interactions under straw mulching conditions.

Although substantial progress has been achieved in agricultural DEM parameter calibration, a significant research gap remains regarding the systematic investigation of the distinctive tool–lateritic soil – *P. notoginseng* ternary system. This study focuses on *P. notoginseng* seedlings, southwestern lateritic soil, and 65Mn steel tools, with the primary objective of improving discrete element simulation accuracy. Adopting a methodology that couples physical experiments with simulation modeling, parameter calibration was conducted using three types of tests: angle of repose test, mixture collapse test, and inclined plane rolling test, to acquire fundamental physical data for multiple contact interfaces. A discrete element model was developed using EDEM software, and the JKR contact model was selected to characterize interparticle cohesion and friction behaviors. By integrating orthogonal experimental design with response surface methodology, correlation models between simulation outputs and physical test results were established. Iterative optimization was performed to determine the optimal values of JKR surface energy, coefficient of restitution, coefficient of static friction, and coefficient of rolling friction for all contact interfaces. The reliability of the calibrated model was ultimately validated through experimental verification. The research outcomes provide critical parameter support and theoretical foundations for optimizing the structural design of *P. notoginseng* transplanting machinery and precisely matching operational parameters, while simultaneously establishing a transferable technical framework for DEM parameter calibration in characteristic medicinal plant–regional soil systems.

MATERIALS AND METHODS

Material selection

Lateritic soil samples were collected from the core cultivation area of *P. notoginseng* in Wenshan Prefecture, Yunnan Province, which features typical lateritic soil well-suited for *P. notoginseng* cultivation (*You et al., 2022*). *P. notoginseng* seedling samples were obtained from a cultivation base in Wenshan. In accordance with the DB53/T 055.3-2020 standard for *P. notoginseng* seedlings (*Yunnan Provincial Administration for Market Regulation, 2020*), 30 robust and undamaged first-grade annual seedlings were selected.

Physical test determination of contact parameters

The mechanical behavior and motion characteristics involved in *P. notoginseng* transplantation are governed primarily by the contact parameters for soil–soil, soil–implement, and soil – *P. notoginseng* interactions. Therefore, these contact parameters were initially determined through physical experiments.

The coefficient of restitution (C_R) was determined in this study using the free-fall impact method (*Shi et al., 2020*), as illustrated in Figure 2.

$$C_R = \frac{V_1}{V_0} \tag{1}$$

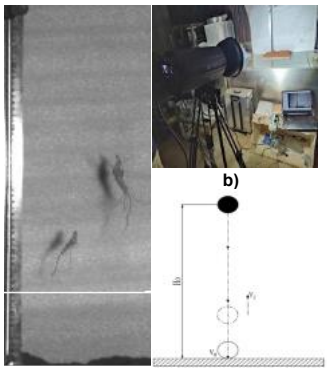

Fig. 2 – Measurement of the coefficient of restitution

a) High-speed photography; b) High-speed photographic setup; c) Schematic diagram of the coefficient of restitution (C_R)

The coefficient of *static friction (S_F)* was determined using the inclined plane method (*Aikins et al., 2021*), as shown in Figure 3.

$$S_F = \frac{F_1}{N_1} = \frac{G_1 \sin\theta_1}{G_1 \cos\theta_1} = \tan\theta_1 \tag{2}$$

where: F_1 is the friction force acting on the material specimen, *N;*

N_1 is the normal support force exerted on the specimen, *N;*

G_1 is the weight of the material specimen, *N;*

θ_1 is the inclination angle at which sliding begins, (°).

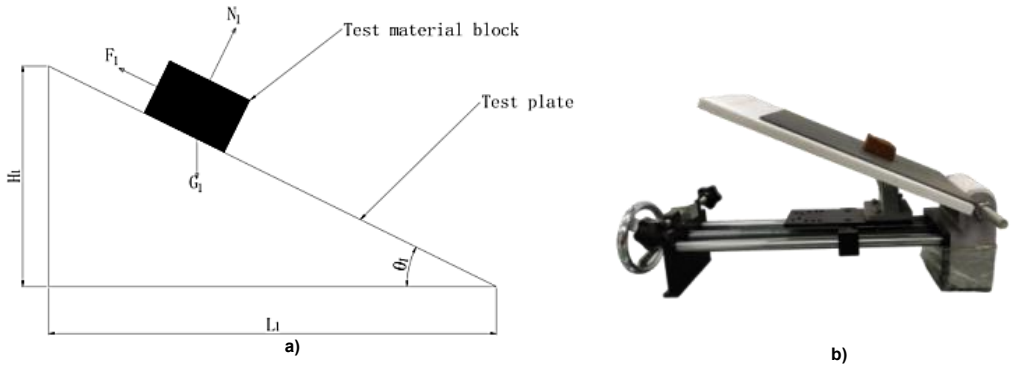

Fig. 3 – Measurement of the coefficient of static friction

a) Principle of static friction coefficient testing; b) Static friction coefficient test bench

The rolling friction coefficient (R_F) was determined using an angle adjustment device based on the principle of energy conservation (*Zhang et al., 2022*), as shown in Figure 4.

$$G_2 H_2 = R_F G_2 (G_2 \cos\theta_2 + L_2) \tag{3}$$

where: G_2 is the weight of the material sphere, *N;*

H_2 is the vertical distance between the material sphere and the horizontal plane, *mm;*

L_2 is the distance traveled by the material sphere along the horizontal plate, *mm.*

θ_2 is the angle between the two test platforms, (°)

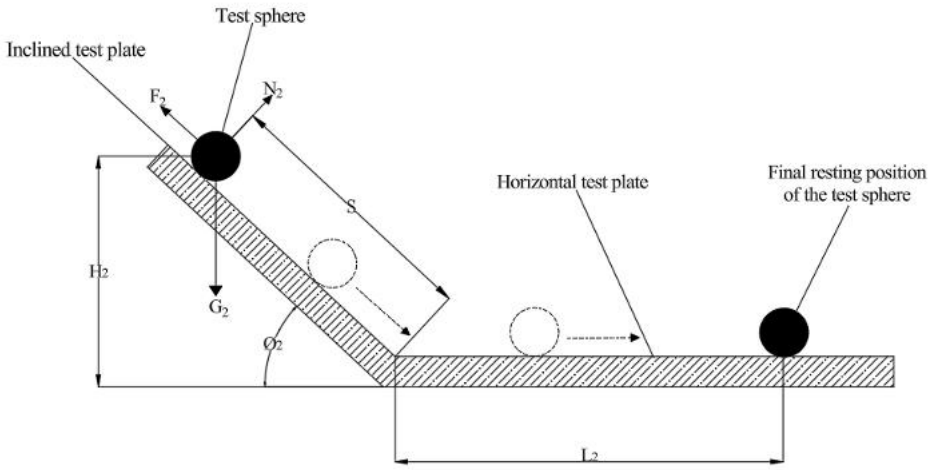

Fig. 4 – Principle of measuring the coefficient of rolling friction

Construction of the Discrete Element Model

Discrete Element Model of Lateritic Soil

Particle size distribution was determined using the standard sieve analysis method. The test equipment consisted of a set of standard sieves (with aperture sizes of 0.15 mm, 0.5 mm, 1 mm, 2 mm, and 3.5 mm) and an electronic balance (accuracy: 0.01 g). Sieve analysis was performed with a consistent shaking duration of 10 minutes. After shaking, the lateritic soil particles retained on each sieve were weighed. The test was repeated three times, with measurements recorded to an accuracy of 0.1 g. The lateritic soil particles after sieving are shown in Figure 5.

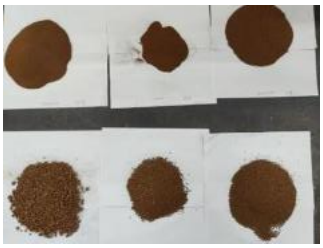

Fig. 5 – Particles after sieving

Based on the fundamental theory of the discrete element method (*DEM*) and the assumption of medium continuity, the macroscopic mechanical behavior of a granular system is essentially governed by the microscopic contact network and interaction forces between particles (*Cundall P.A. et al., 1979*). Through dimensional analysis and similarity principles, an upscaled model can equivalently reproduce macroscopic rheological and mechanical properties while reducing particle count and enhancing simulation feasibility. Currently, there is no unified standard for soil particle modeling based on the discrete element method (*DEM*). Spherical particles with diameters of 4–6 mm are commonly employed in studies (*Hang et al., 2018; Ucgul et al., 2015*). To balance efficiency and authenticity, this study adopts a five-fold coarse-graining technique and generates particles proportionally by mass fraction to ensure consistent particle size distribution. The corresponding mass fraction settings are shown in Table 1.

Table 1

Diameter and Mass Distribution of EDEM-Simulated Red Clay Particles

Actual particle size [mm]	Simulated particle diameter [mm]	Mass fraction [%]
≤0.25	0.625	22.4
0.25-0.5	1.875	11.8
0.5-1	3.250	19.4
1-2	7.500	19.8
2-3	12.500	20.6
≥3	15.000	6.0

Considering both simulation accuracy and modeling efficiency, particles were appropriately scaled up and then consolidated in shape. For particles smaller than 0.5 mm, the default spherical model in EDEM was adopted; for particles ranging from 0.5 mm to 2 mm, a two-ball model in EDEM was employed; and for particles larger than 2 mm, a three-ball model in EDEM was used. The established model is shown in Fig. 6.

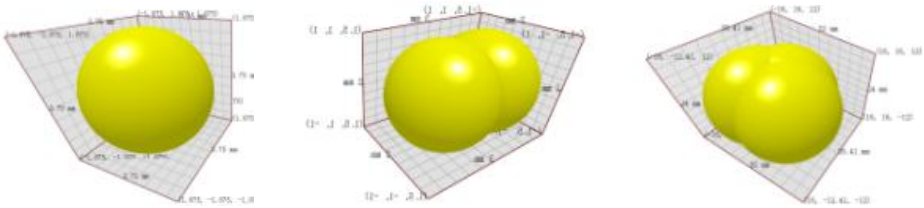

Fig. 6 – Establishment of Simulated Red Clay Particles

Discrete Element Model of Panax notoginseng (DEM)

The key physical parameters of *P. notoginseng* seedlings were determined for construction of the DEM. The morphological structure and principal dimensions of a representative seedling are shown in Fig. 7.

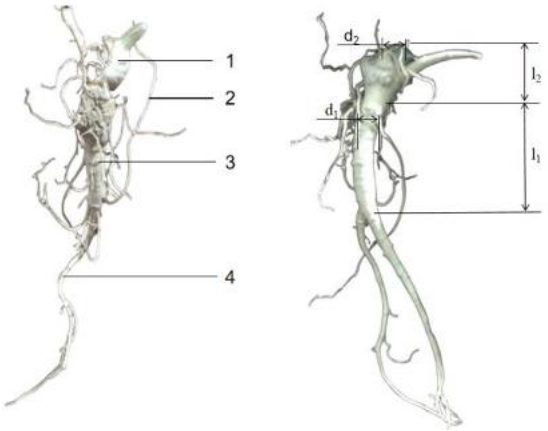

Fig. 7 – *P. notoginseng* seedling

1.dormant bud (rhizome head) 2. lateral root 3. main root 4. fibrous root

Two hundred *P. notoginseng* seedlings were selected for measurement, and their dimensional parameters are presented in Table 2.

Table 2

Dimensional parameters of *P. notoginseng* seedlings

Parameter	Main root length l_1[mm]	Main root diameter d_1[mm]	Dormant bud length l_2[mm]	Dormant bud diameter d_2[mm]
maximum value	26.12	15.68	17.74	8.89
minimum value	17.50	9.08	8.38	4.35
average value	22.42	12.64	13.28	6.15

High-precision point cloud data of *P. notoginseng* seedlings were acquired using the Wiiboox Reeyee 3D scanner, and a digital twin model with realistic topological structure was constructed through reverse engineering technology, overcoming the limitations of traditional contact measurement methods in characterizing the geometric features of complex biological samples (*Tang et al., 2023; Zhao et al., 2023*), as shown in Figure 8.

Fig. 8 – Wiiboox Reeyee 3D scanner

The model was imported into Creo Parametric 2.0, where the biologically characteristic surfaces were mathematically reconstructed by optimizing the control points and imposing surface-continuity constraints. To reduce the computational burden and simulation time, the *P. notoginseng* seedling model was simplified by retaining only the main root structure. The modeling procedure and resulting model are shown in Fig. 9.

Fig. 9 – Modeling process of *P. notoginseng* seedling

Experiment and Simulation

Determination of Simulation Parameters

In the EDEM simulation of interaction processes, the contact parameters include the coefficient of restitution (C_R), coefficient of static friction (S_F), coefficient of rolling friction ($R_{F)}$, and surface energy (S_E) between materials. This study focused on the contact parameters of the implement–lateritic soil – *P. notoginseng* interaction system during transplantation. These parameters included the following: for lateritic soil–lateritic soil, the coefficient of restitution (C_{R1}), static friction coefficient (S_{F1}), rolling friction coefficient (R_{F1}), and surface energy (S_{E1}); for lateritic soil–*P. notoginseng*, the coefficient of restitution (C_{R2}), coefficient of static friction (S_{F2}), coefficient of rolling friction (R_{F2}), and surface energy (S_{E2}); and for lateritic soil–65Mn steel, the coefficient of restitution (C_{R3}), coefficient of static friction (S_{F3}), coefficient of rolling friction (R_{F3}), and surface energy (S_{E3}). The intrinsic parameters and contact parameters were obtained through physical experiments and relevant literature (*Yu et al., 2020; Zhang et al., 2025; Liu et al., 2025*), as listed in Table 3.

Table 3

Ranges of intrinsic material properties and contact parameters

Parameter	Lateritic soil	*P. notoginseng*	65Mn
Density [kg/m^3]	1900	1050	7865
Young's modulus [Pa]	7.8e+06	2.29e+06	7.27e+10
Poisson's Ratio	0.370	0.402	0.35
Coefficient of restitution with lateritic soil	0.06-0.15	0.1-0.5	0.2-0.6
Coefficient of static friction with lateritic soil	0.1-0.6	0.2-0.6	0.1-0.55

Development of Calibration Experiments for the Discrete Element Simulation

Calibration experiments for the lateritic soil–lateritic soil contact parameters were conducted using a Box–Behnken design. The mean natural angle of repose of the lateritic soil, denoted as C_{S1} was selected as the response variable to evaluate the effects and statistical significance of the four factors C_{R1}, S_{F1}, R_{F1}, and S_{E1}. After each simulation, images of the soil pile were captured from the ±*X* and ±*Y* directions, as shown in Figure 10.

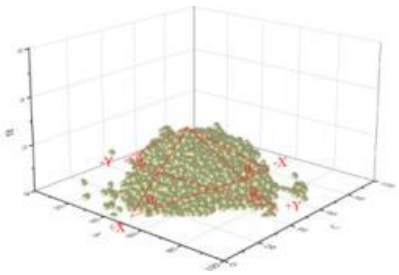

Fig. 10 - Cross-section selection

Calibration simulations for the lateritic soil–*P. notoginseng* contact parameters were conducted using

a Box–Behnken design. The angle of repose of the lateritic soil–*P. notoginseng* mixture, denoted as C_{S2} was selected as the response variable to evaluate the effects and statistical significance of C_{R2}, S_{F2}, R_{F2}, and S_{E2}. As shown in Fig. 11, the mixture was placed in the test container, after which the bottom support plate was withdrawn. Once the material had stabilized, image processing and linear fitting were performed to determine the angle of repose. The mean measured angle was used as the simulation response.

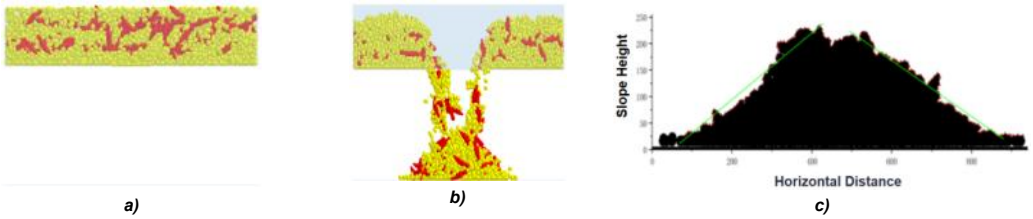

Fig. 11 – Mixture Collapsing Test

a) Laterite-P. notoginseng mixture uniformly distributed; b) Mixture Collapsing; c) Experimental Image Processing

The calibration test for simulation parameters between lateritic soil and 65Mn steel was conducted using an inclined plane simulation with a Box-Behnken design, as shown in Figure 12. A particle factory was set parallel to the inclined plane to generate a 15 mm-diameter soil sphere, which was initialized tangent to the surface with zero initial velocity and allowed to slide naturally, with its sliding distance on the horizontal plane (C_{S3}) recorded as the response value to investigate the effects and significance of the coefficient of restitution (C_{R3}), coefficient of static friction (S_{F3}), coefficient of rolling friction (R_{F3}), and surface energy (S_{E3}).

Results of Box-Behnken Simulation Calibration Experiments

Analysis of variance (*ANOVA*) was performed on the Box-Behnken experimental results for the lateritic soil–lateritic soil contact parameters, as shown in Table 4. After removing the non-significant terms with P > 0.05 from the ANOVA, the final predictive model for the response value under the lateritic soil–lateritic soil contact parameters was obtained as follows:

$$C_{S1} = 39.9 + 1.51R_{F1} + 7.63S_{E1} + 0.475C_{R1}S_{E1} + 2.18S_{F1}S_{E1} + 3.37C_{R1}^2 - 1.08C_{R1}S_{F1} - 0.725R_{F1}S_{E1} - 0.6417S_{F1}^2 - 0.9917R_{F1}^2 + 0.5708S_{E1}^2 \quad (4)$$

Analysis of Simulation Results and Optimal Combination of Contact Parameters

Quadratic multiple regression fitting and analysis of variance (*ANOVA*) were performed on the experimental data of the three contact interfaces using Design-Expert software. The ANOVA results revealed significant interaction effects among the factors, and 3D response surfaces were plotted for the factors with significant interactions, as shown in Figure 13.

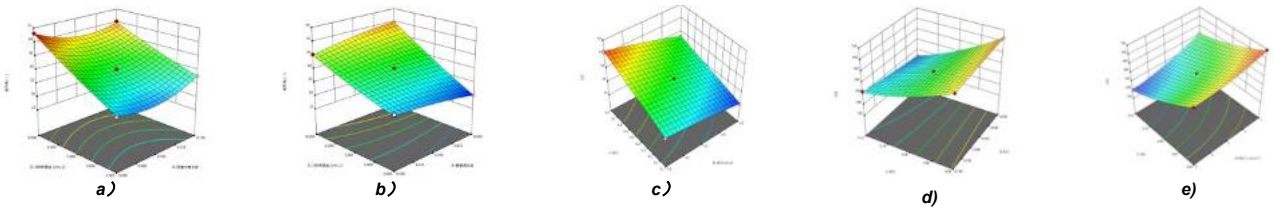

Fig. 13 – 3D response surface of significant factors on C_S

The regression models were solved via Design-Expert optimization, targeting the experimental values: a lateritic soil angle of repose of 41.2°, a mixture collapse angle of 45.2°, and a natural sliding distance of 423 mm. After simulation verification (Figure 14), the parameter combinations closest to the measured data were selected as optimal solutions. For the lateritic soil–lateritic soil interface, the optimal parameters were a rolling friction coefficient of 0.287 and a JKR surface energy of 5.302 J/m², with non-significant factors (static friction coefficient 0.575, coefficient of restitution 0.11) set to average experimental values. For the lateritic soil–*P. notoginseng* interface, the optimal parameters were: coefficient of restitution 0.157, coefficient of static friction 0.482, coefficient of rolling friction 0.124, and JKR surface energy 4.101 J/m². For the lateritic soil–65Mn steel interface, the optimal parameters were a coefficient of static friction of 0.42, a coefficient of rolling friction of 0.09, and a JKR surface energy of 3.806 J/m², with the non-significant coefficient of restitution set to 0.13.

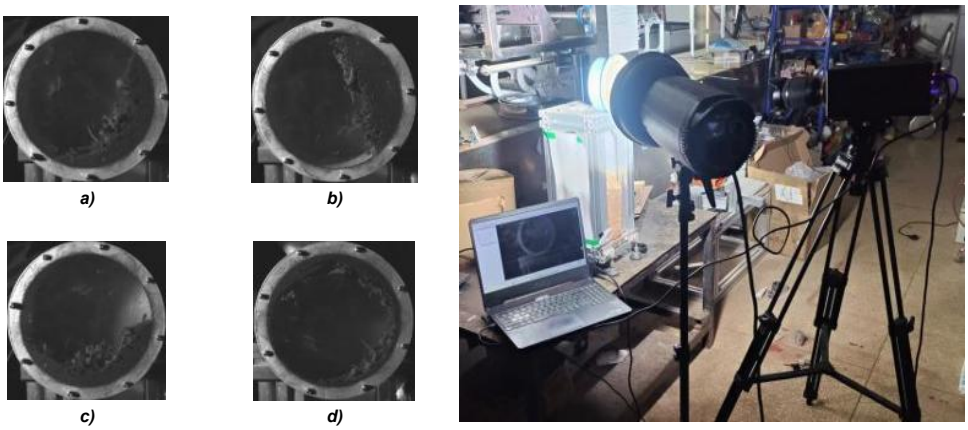
Interactive Simulation Validation

Dynamic Bench-Test Validation

A drum-test simulation based on the discrete element method (DEM) was conducted using EDEM. As shown in Fig. 15, the 65Mn steel drum had a diameter of 300 mm and a height of 80 mm and was uniformly filled with a mixture of *P. notoginseng* and lateritic soil. Three comparative tests were conducted at drum rotational speeds of 60, 90, and 120 r/min, with rotational speed as the only variable. After each simulation, four representative stages were compared: initial material lifting, critical slippage, the first complete circulation cycle, and stable dynamic flow. The analysis included measuring the tangential angle between the material bed and the inner drum wall at the three-quarter lifting position; recording the time from initial lifting to critical slippage; comparing the binarized contours obtained during the first circulation cycle with those from the physical test at the corresponding time point; and measuring the material-distribution length during stable flow to compare it with the stratification observed in the physical tests.



c) d)

Fig. 15 – Four key moments of the mixture

a) initial material lifting; b) critical slippage; c) the first complete accumulation cycle; d) stable dynamic flow

The motion of the materials inside the drum was recorded using a high-speed imaging system, as shown in Fig. 16. The drum dimensions and material properties were consistent with those used in the simulation model.

Tests were conducted at drum rotational speeds of 60, 90, and 120 r/min. Images of the material behavior at four representative stages were captured, and a quantitative comparison between the physical tests and simulation results is presented in Table 12. The relative error in the initial material-lifting angle was 4.33%, the relative error in the time from initial lifting to critical slippage was 4.06%, the contour-overlap rate during the first circulation cycle was 93.3%, and the relative error in the material-distribution length during the stable-flow stage was 2.79%.

Field validation test

A discrete element simulation of the ditching operation was conducted using EDEM, as shown in Fig. 17. The soil bin measured 2.0 m in length, 1.5 m in width, and 0.4 m in height. With the forward speed of the ditching tool as the only variable, three comparative simulations were conducted at 3, 9, and 15 m/min. The simulation used the optimized physical properties of the lateritic soil and the tool–soil contact parameters determined in the preceding study. After each simulation, the top diameter of the ditching hole, *x*, and the hole depth, *y*, were measured consistently.

a) b) c)

Fig. 17 – Ditching Simulation

a) Ditching Simulation; b) Simulation Results and Measurement Principle; c) Soil Mass After Ditching

A field ditching test was conducted using a pitting roller with a length of 842 mm, a shaft diameter of 220 mm, and a tooth height of 50 mm, as shown in Fig. 18.

a) b)

Fig. 18–Results of Field Experiment

a) Field ditching result; b) Field test

The forward speed of the implement was set at three levels: 3, 9, and 15 m/min. After each test, the top diameter of the pit, *x*, and the pit depth, *y*, were measured at five randomly selected locations, and the mean values were calculated. The mean relative errors between the simulated and field-measured values were 3.52% for the pit-top diameter and 4.28% for the pit depth. The comparison between the simulation and physical-test results is presented in Table 7.

Table 7

Comparison of simulation and physical-test results

Operating condition	Evaluation parameter	Simulated result	Measured result	Relative error
Drum speed at 60 r/min; implement speed at 3 m/min.	Initial material-lifting angle [°]	42.8	44.7	4.27%
	Time to critical slippage [ms]	124	128	3.13%
	Material-distribution length during stable flow [mm]	565	550	2.72%
	First complete accumulation stage [mm]	-	-	7.23%
	Pit-top diameter [mm]	36.6	34.3	3.79%
	Pit depth [mm]	41.8	40.2	3.98%
Drum speed at 90 r/min; implement speed at 6 m/min.	Initial material-lifting angle [°]	40.3	42.2	4.50%
	Time to critical slippage [ms]	179	187	4.28%
	Material-distribution length during stable flow [mm]	659	642	2.65%
	First complete accumulation stage	-	-	6.18%
	Pit-top diameter [mm]	36.2	34.5	2.86%
	Pit depth [mm]	40.8	39.2	4.08%
Drum speed at 120 r/min; implement speed at 9 m/min.	Initial material-lifting angle [°]	36.3	37.9	4.22%
	Time to critical slippage [ms]	198	208	4.76%
	Material-distribution length during stable flow [mm]	754	732	3.00%
	First complete accumulation stage	-	-	6.68%
	Pit-top diameter [mm]	34.6	33.3	3.90%
	Pit depth [mm]	38.4	36.6	4.79%

CONCLUSIONS

Three Box-Behnken experiments were conducted to systematically evaluate the relationships between contact parameters and the response variables (C_{S1}, C_{S2}, C_{S3}). The significant factors were identified as follows: R_{F1} and S_{E1} for C_{S1}; S_{F2}, R_{F2}, and S_{E2} for C_{S2}; and R_{F3} and S_{E3} for C_{S3}.

Response surface analysis was then performed using C_{S1}, C_{S2}, and C_{S3} as the response variables to optimize the significant contact parameters associated with each response. The nonsignificant parameters were assigned the mean values obtained from the physical experiments. The optimal parameter combinations were determined as follows: S_{E1}=5.302 J/m², R_{F1}=0.287; S_{E2}=4.101 J/m², S_{F2}=0.482, R_{F2}=0.124; S_{E3}=3.806 J/m², S_{F3}=0.42, R_{F3}=0.09. The corresponding nonsignificant parameters were set to: C_{R1}=0.11, S_{F1}=0.575; C_{R2}=0.157; C_{R3}=0.13.

Comparison of the simulation and physical-test results showed a high degree of agreement under all test conditions, including different drum rotational speeds and implement forward speeds. The relative errors for all evaluated indicators, including pit depth and mixture behavior at four representative stages, were below 7.5%, with a maximum value of 7.23%. This close agreement confirmed the accuracy and reliability of the calibrated parameters used in the discrete element interaction model. The resulting model therefore provides a reliable parameter basis for subsequent simulation and optimization of the operating process of the *P. notoginseng* transplanting machine.

ABSTRACT
To address the impact of changes in dairy cow posture on intelligent body condition scoring, this study proposes a dairy cow body condition scoring model (ME-PointNeXt). Based on PointNeXt, this model incorporates a dynamic graph convolutional module at the global feature level; furthermore, a selective sequence block is added to the encoder's upper layers, improving the SA-FP architecture and enhancing the model's overall understanding of the structure. Using this model to segment the hindquarters of dairy cows, principal component analysis is performed via eigenvalue decomposition of the local neighbourhood covariance matrix. This enables the determination of edge point normal vectors and the calculation of surface curvature, thereby enabling the scoring of the cows' body condition. Experimental results show that the ME-PointNeXt model achieved an overall accuracy, mean precision, mean recall, and mean F1 score of 91.43%, 84.33%, 87.92%, and 90.74%, respectively, on the test set. Compared with PointNeXt, the ME-PointNeXt model achieved improvements of 2.72, 3.65, 4.13, and 4.19 percentage points in overall accuracy, average precision, average recall, and average F1 score, respectively. This study has significantly improved the efficiency of dairy cow body condition scoring, ensuring accuracy whilst reducing the workload, and can provide technical support for non-contact dairy cow body condition scoring.

摘要
为解决奶牛姿态变化对体况智能评分的影响，本研究提出了一种奶牛体况评分模型（ME-PointNeXt）。该模型基于 PointNeXt，在全局特征层加入一个动态图卷积模块；并且在编码器高层中加入一个选择性序列块，改进了 SA-FP 结构，增强整体对结构的理解。利用该模型对奶牛尻部进行分割，通过计算局部邻域协方差矩阵的特征值分解实现主成分分析，进而确定边缘点法向量并计算表面曲率，对奶牛体况进行评分。试验结果表明，ME-PointNeXt 模型在测试集上的总体准确率、平均交互比、平均准确率与平均 F1 分数分别达到 91.43%、84.33%、87.92%和 90.74%。相较于 PointNeXt，ME-PointNeXt 的总体准确率、平均交互比、平均准确率与平均F1 分数分别提升了2.72、3.65、4.13 和4.19 个百分点。本研究显著的提高了奶牛体况的评分效率，在降低工作量的同时保证了精度，可为非接触式奶牛体况评分提供技术支持。

INTRODUCTION
As the scale of dairy cattle farming in China continues to expand *(Zhang et al., 2024)*, the sector is undergoing a transition towards grain-saving and high-efficiency practices, facing significant challenges. Body condition score is a key indicator for assessing animal welfare and herd management; it is closely linked to the health *(Zhao et al., 2025)* and metabolic status *(Sadiq et al., 2017)* of dairy cattle, and provides a reliable basis for formulating feed rations *(Yu et al., 2026).* Body condition scores enable the identification of cows that are either overweight or underweight; formulating rations based on these scores ensures that cows of different body conditions receive appropriate diets. Consequently, body condition assessment is an indispensable part of the dairy farming industry *(Tian et al., 2025)*.

Currently, body condition scoring in dairy cattle is primarily carried out manually; however, due to the subjectivity of human assessment *(Feng et al., 2025)*, the reliability of the results is poor, and the evaluation process is time-consuming and labour-intensive, relying heavily on the assessor's experience *(Huang et al., 2024)*.

Furthermore, the assessment process can induce stress responses in the cattle *(Li et al., 2025)*, making measurement difficult and leading to significant errors *(Fan et al., 2020)*. With the gradual adoption of machine vision and deep learning technologies in the livestock industry *(Qi et al., 2023)*, it is now possible to utilise visual detection techniques to capture conformation characteristics and establish intelligent assessment models linking these to body condition *(Sun et al., 2025)*. Practical evidence indicates that machine vision has already achieved significant success in detecting dairy cow conformation characteristics and behaviour *(Xie et al., 2022)*, offering a new direction for research into dairy cow body condition scoring. *Zhao et al., 2021,* used EfficientNet to identify the structural features of dairy cows and assess their body condition; EfficientNet achieved a recognition accuracy of 73.12% and an average recognition speed of 3.441 s/f, outperforming models such as MobileNet-V2, XceptionNet, and LeNet-5. *Jiang et al., 2025,* incorporated the GSConv module into the YOLOv8s model to enable automatic localisation and detection of the dorsal region of dairy cows, thereby facilitating body condition scoring and individual identification. The improved model achieved accuracy rates of 93.9% and 92.2% for body condition scoring and individual identification, respectively, representing increases of 1.9 and 4.5 percentage points compared to single-task models. *Shi et al., 2023,* proposed a method for body condition scoring in dairy cows based on attention-guided 3D point cloud feature extraction, which incorporates an attention-guidance mechanism into PointNet. This scoring model achieved accuracy rates of 0.49, 0.80, and 0.96 within point deviation ranges of 0, 0.25, and 0.50, respectively, yielding satisfactory estimation results. *Wei et al., 2025,* utilised 3D reconstruction to recreate the spatial morphology of sheep, followed by training a PointNet++ model, achieving relative errors of 3.63%, 1.14%, and 3.57% for chest width, rump height, and body length, respectively. The aforementioned methods all localise the target's entire torso; however, the target's posture and movement can influence the shooting angle, leading to the loss of some key information.

To address the aforementioned issues, this study segments the hindquarters of dairy cows based on 3D point cloud imagery, extracting key regions within a small area to obtain accurate body condition scores. This study proposes the ME-PointNeXt model for dairy cow body condition scoring, which primarily builds upon the PointNeXt model by incorporating a dynamic convolutional module to enhance local edge detection capabilities; simultaneously, selective sequence blocks are introduced at the higher layers of PointNeXt to strengthen the model's global consistency. Finally, the curvature is calculated based on the edge points segmented by the ME-PointNeXt model, and a body condition score is derived.

MATERIALS AND METHODS

Dataset construction

Design of a Contactless Data Collection Device for Cattle

This study developed a non-contact point cloud data acquisition device for dairy cows. From the moment a cow enters the acquisition channel until it exits, the device can capture three-dimensional point cloud data from two different rear angles, thereby enabling intelligent body condition scoring. The system comprises a depth camera (Azure Kinect DK), a power supply, a motion controller, and a measurement channel. To capture depth images of the cow's back and hindquarters, the Arzue Kinect DK depth camera is positioned 2.6 m above the ground and at a 45° downward angle 2.4 m above the ground, respectively. This study employs a single-channel data acquisition design to prevent crowding and congestion of cows within the channel, ensuring that cows maintain a normal standing posture, thereby guaranteeing the validity and reliability of the collected data. The structure of the data acquisition system is shown in Figure 1.

Fig. 1 - Data Acquisition Structure

Test data acquisition

Data collection took place from 25 July to 1 August 2025 at Tibet Nianxiongziji Livestock Co., Ltd. in Zaxi Village, Gadong Town, Bailang County, Shigatse City, Tibet Autonomous Region. The test subjects were Jersey cows with a lactation period of 100 to 300 days. To minimise stress reactions in the cows and their impact on milk yield, data collection commenced after milking. Collection took place between 10:00 and 14:00, and between 15:00 and 19:00. A total of 2,280 point cloud datasets were collected from 104 cows; after removing highly similar datasets, 342 point cloud datasets remained.

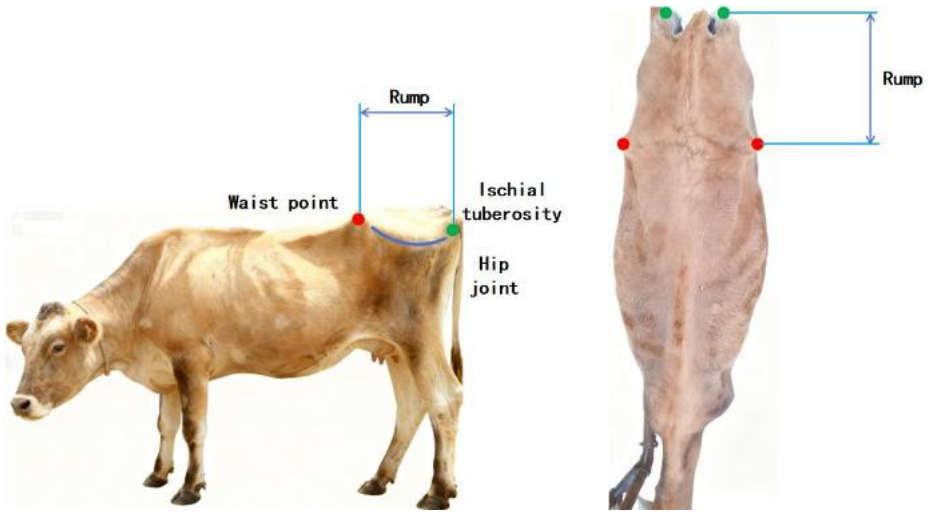
Dataset creation

By comparing the point cloud images captured at the tail root and on the back, it was found that the point cloud image at the tail root contained a significant amount of noise and failed to capture key information in full. Consequently, the point cloud image from the back was ultimately selected as the dataset and divided into training, test and validation sets in a ratio of 8:1:1. The point cloud image at the tail root is shown in Figure 2(a), whilst the point cloud image of the back is shown in Figure 2(b).

(a) (b)

Fig. 2 - Point cloud image of the cow's back and hindquarters

The criteria for assessing a dairy cow's body condition are typically based on body fat reserves. These reserves are primarily evident in the area between the hip bones and the ischial tuberosities, with the rump being the most distinctive feature; the degree of contour variation in this region is useful for assessing the cow's fat reserves and health status. The region of interest is shown in Figure 3.



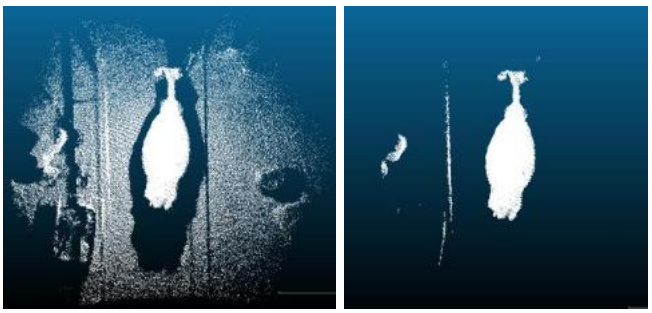


Fig. 3 - Region of interest

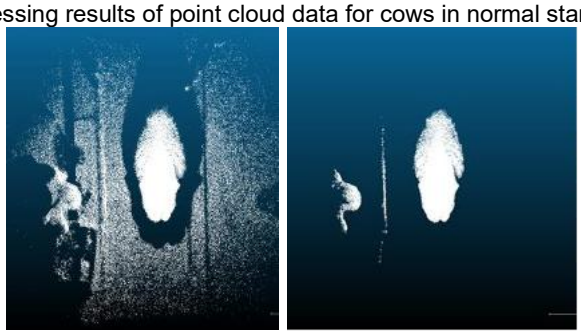
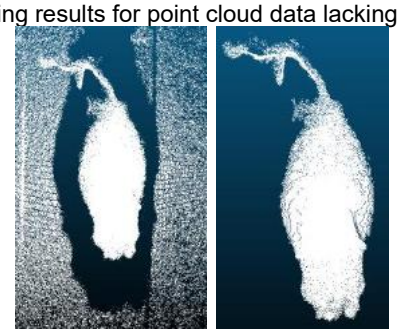


When processing the dataset, CloudCompare was selected to perform radius filtering and statistical filtering as pre-processing steps, followed by manual segmentation and annotation of the filtered dataset. The results of the point cloud data pre-processing are shown in Figure 4.

(1) Statistical filtering. By setting a 30-neighbour radius and a threshold of 1.0 based on the density of the point cloud data, high-frequency noise can be effectively reduced whilst retaining key structural information.



(2) Radius filtering: The radius was set to 15, requiring at least five neighbouring points within the radius. Points where the density within the neighbourhood fell below a specific threshold were treated as outliers and removed. This approach ensures the density of the point cloud after downsampling whilst maximising the retention of the basic features of the cows' hindquarters, and also improves the speed of data processing.

(a) Pre-processing results of point cloud data for cows in normal standing posture

(b) Preprocessing results for point cloud data lacking the cow's head

(c) Pre-processing results of point cloud data from the head of an abnormally standing dairy cow

Fig. 4 - Pre-processing results of point cloud data

Following the removal of duplicates and filtering, manual segmentation and annotation were carried out using CloudCompare. The body part annotated was the rear end of the cow, labelled as “back”; this label is automatically generated once each point cloud image has been annotated. The results of the manual segmentation are shown in Figure 5. To prevent data leakage and overestimation of performance, random noise points were added to the point cloud images during the division of the dataset.

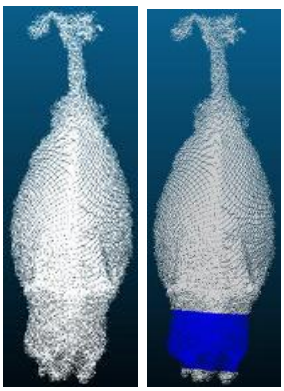


Fig. 5 - Manual segmentation results

Cattle Body Condition Scoring Model

Compared to PointNet, PointNeXt *(Qian et al., 2020)* modifies the training strategy by adopting a hierarchical multi-scale architecture and utilising a feature pyramid, whilst applying local neighbourhood aggregation to the edge features on the cow’s back; this is more conducive to improving the accuracy of the cow’s body condition score. The model applied scaling and rotation enhancements to the data; jittering and randomised data point removal were employed to enhance the model’s generalisation ability.

By introducing slight variations or omissions, the training data was made more diverse, thereby reducing the model's overfitting to data details.

However, due to the model's lack of sensitivity to edge details and its inability to interact with global information, it proved insensitive to information regarding the cows' backs and exhibited low feature utilisation, rendering it incapable of intelligently scoring the cows' body condition. Consequently, a dynamic graph convolutional module *(Wang et al., 2019)* and a sequence block *(Ding et al., 2023)* were incorporated into PointNeXt to enhance edge point perception and global information interaction, ensuring the model could capture structural changes between points and edge features.

ME-PointNeXt

ME-PointNeXt consists of an input head, an encoder, a global feature layer, a decoder and an output head. To address PointNeXt's limited perception of local edge information, a dynamic graph convolutional module is introduced in the global feature layer. By determining the convolutional receptive field through dynamic neighbourhood configuration and constructing geometric convolutional inputs via differential edge features, this enhances the perception of surface curvature changes and boundary details on the cow's hindquarters. The neighbourhood is shifted from geometric proximity to semantic proximity, thereby improving the ability to represent local structures. Furthermore, to mitigate the attenuation and fragmentation of high-level semantic information during multi-level propagation, selective sequence blocks are introduced as global feature interaction modules in the 3rd and 4th Set Abstraction stages following downsampling in the encoder. Relevant selective parameters are generated via point-level linear projection, and state recursion is employed to model long-range dependencies in the sequence dimension, thereby enhancing the global consistency of high-level features in the encoder. The structure of the ME-PointNeXt model is shown in Figure 6.

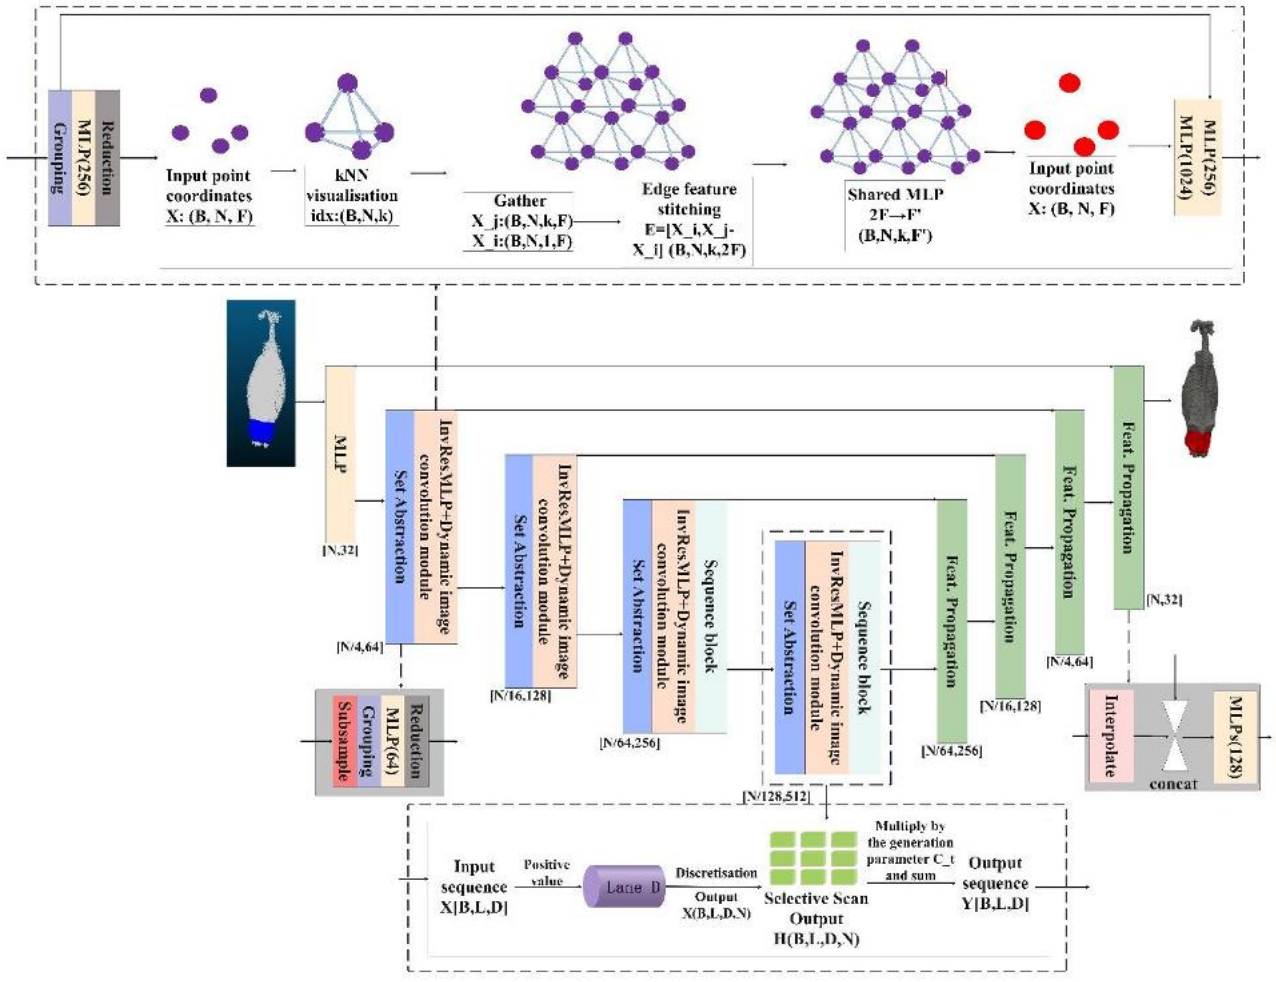

Fig. 6 - ME-PointNeXt Model Architecture

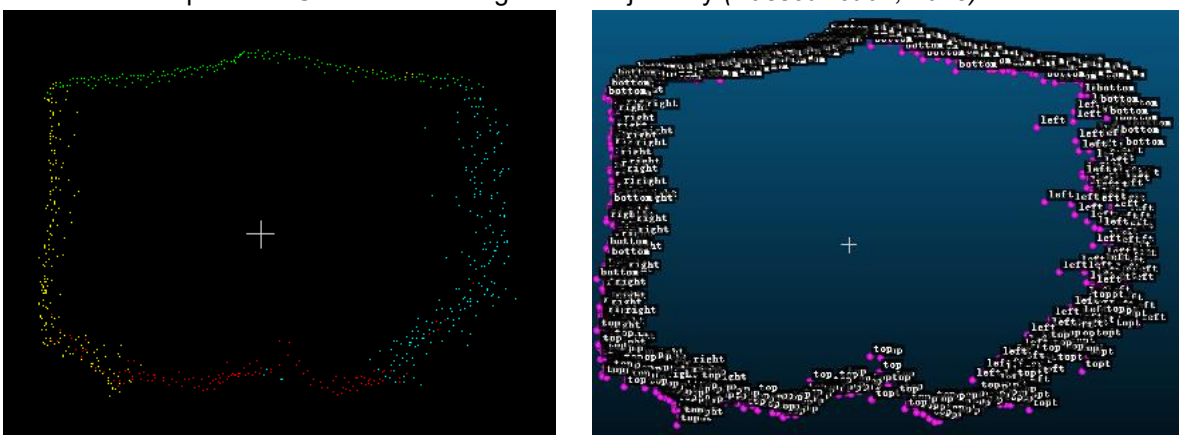
Dynamic image convolution module

To enhance the model's ability to capture global structure and cross-region semantic consistency in the point cloud of a dairy cow's hindquarters, a Dynamic Graph CNN (DGCNN) module has been introduced into the global feature layer of PointNeXt. This module constructs a k-NN dynamic adjacency graph in the feature space to strengthen global semantic representation and robustness. Whilst maintaining the translation invariance of the hindquarters point cloud, the dynamic graph convolutional module effectively mitigates feature instability in the hindquarters region caused by pose variations, sparse sampling or noise interference, thereby improving the consistency of the overall segmentation results and the ability to distinguish boundaries.



Sequence block

To enhance the model's ability to globally fuse point clouds of dairy cows' hindquarters across multiple scales and its adaptability to complex morphological variations, selective sequence blocks are introduced in the third and fourth Set Abstraction layers of PointNeXt. These sequence blocks establish inter-point relationships through projection and employ grouped vector attention to apply weighted groupings to feature channels, thereby facilitating more accurate capture of morphological contours and boundary transition features in the large receptive field stage. The model can strengthen feature interactions and contextual consistency at a higher semantic level, improving robustness against noise, occlusion, and variations in point density, and consequently enhancing the performance of rump segmentation.

Curvature calculation

In this study, a computational programme was developed to perform principal component analysis on edge feature points on the hindquarters of dairy cows. For each point in the point cloud of a dairy cow's rump, the method calculates the three-dimensional covariance matrix of its k nearest neighbours and performs an eigenvalue decomposition using the formula $k = \frac{\lambda 1}{\sum \lambda}$. Through this eigenvalue decomposition, the eigenvector corresponding to the smallest eigenvalue is defined as the surface normal vector of the rump, and the spatial curvature of the rump's edge is calculated. These quantitative geometric features, which are insensitive to changes in posture, provide robust input data for the subsequent development of an objective and efficient body condition scoring model for dairy cows. The body condition score is calculated using the formula $BCS = -15.0 \times K + 3.55$, where *K* represents the spatial curvature of the rump edge points. These quantitative geometric features are unaffected by changes in body posture, providing reliable input data for the subsequent development of an objective and efficient body condition scoring model for dairy cows. Figure 7 illustrates the process of extracting edge points and calculating normal vectors.

Manual scoring involves professional and experienced assessors conducting body condition scoring on the same dairy cows. Whilst the Juan Shan cows are being assessed using the scoring equipment, five assessors also carry out manual body condition scoring on the cows at close range. Where the maximum difference in scores between assessors does not exceed 0.50 points, the arithmetic mean of the individual assessors' scores is taken as the cow's manual reference body condition score; where the maximum difference exceeds 0.50 points, the Juan-Shan cow is re-assessed and the final result is determined through consultation amongst the assessors. For this type of classification analysis, where the category intervals are 0.25 points, the mean is rounded to the nearest 0.25 points. When BCS is treated as a continuous variable, the intraclass correlation coefficient (ICC) can be calculated; when treated as an ordered scale, the weighted Kappa coefficient can be reported. BCS involves a degree of subjectivity *(Vasseur et al., 2013)*.

Fig. 7 - Edge Point Extraction and Normal Vector Calculation

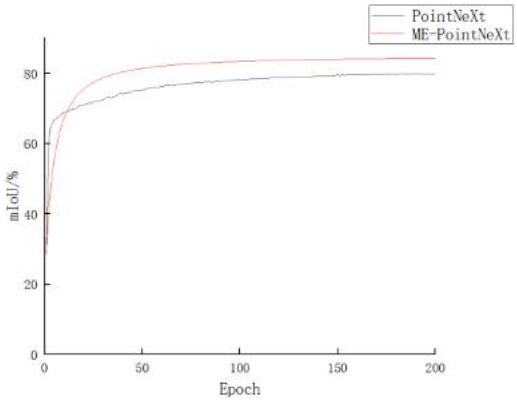
Evaluation criteria

To evaluate the algorithm's performance in segmenting different body parts, this study employed mean Intersection over Union (mIoU), mean Accuracy (mAcc), Overall Accuracy (OA) and mean F1 (mF1) as evaluation metrics. Acc stands for Accuracy, which reflects whether the points predicted by the model for each label fall within the cow's hindquarters; IoU stands for Intersection over Union, which reflects the accuracy of semantic segmentation for each label; after calculating the Intersection over Union (IoU) and accuracy for each label, the mean Intersection over Union (mIoU) and mean Accuracy (mAcc) are obtained; Overall Accuracy (OA) refers to the proportion of correctly predicted samples out of the total number of samples; mF1 refers to the average of the F1 scores across all categories.

RESULTS

In a study examining the contour of a dairy cow's hindquarters, the characteristics of point cloud data were utilised to calculate the average curvature of the hindquarter point cloud, thereby assessing the contour of the hindquarters. A five-point scale is widely used for body condition scoring, with increments of 0.25 points. A score of 1.0 is the lowest, indicating that the cow is excessively thin, whilst a score of 5.0 is the highest, indicating that the cow is excessively fat.

Point cloud segmentation results



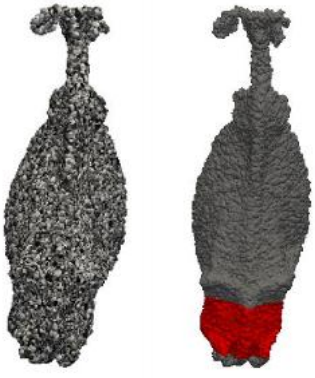


Fig. 8 - Curve depicting the mIoU of the ME-PointNeXt model on the validation set for dorsal segmentation of dairy cows as a function of iteration count

Figure 8 illustrates the trend in the mIoU on the validation set as the number of training iterations increases during the training of the ME-PointNeXt model. In the initial stage, the mIoU increases rapidly with the number of training iterations, indicating that the model is effectively learning the most fundamental and significant patterns from the data. Finally, around 150 iterations, the mIoU levels off and stabilises at approximately 84.33 per cent, suggesting that the model's performance is gradually converging. After 200 iterations, the model converges, and the mIoU on the validation set remains virtually unchanged.

Figure 9 presents a comparison of the model's segmentation results: (a) shows the unlabelled point cloud predicted by the ME-PointNeXt model, and (b) shows the point cloud labelled by the ME-PointNeXt model. The point cloud results demonstrate that incorporating the dynamic convolutional module and selective sequence blocks into PointNeXt enhances the model's ability to extract edge features. The red areas indicate where the rump should be cut. Figure 10 displays the contour map of edge points extracted from the rear of a cow.

(a) (b)

Fig. 9 - Comparison of Model Segmentation Results

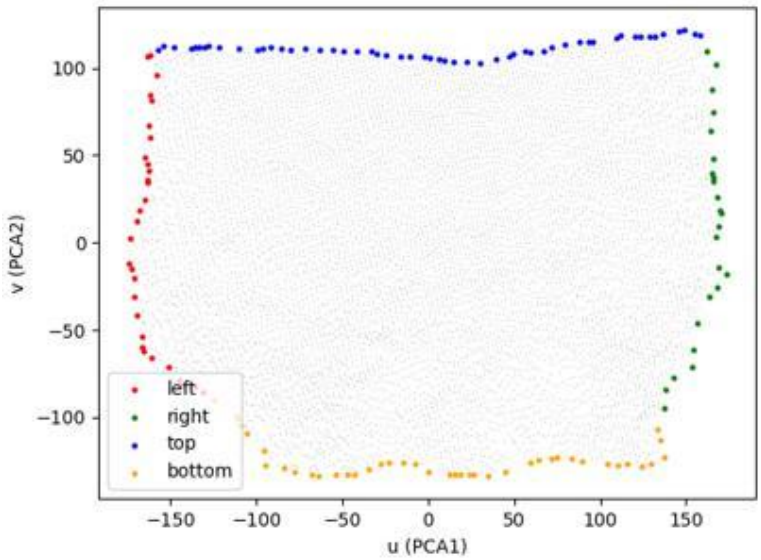

Fig. 10 - Contour diagram extracted from the edge of the cow's hindquarters

A statistical analysis of the segmentation results was conducted using Overall Accuracy (OA), Mean Intersection over Union (mIoU), Mean Accuracy (mAcc), and Mean F1 score as evaluation metrics. The segmentation results for the dorsal region of dairy cows are shown in Table 1.

Table 1

Comparison of partitioning results across test sets for different models

Method	OA/%	mIoU/%	mAcc/%	mF1/%
PointNet	79.65	56.83	69.72	66.49
PointNet++	88.77	80.37	82.83	81.90
PointNeXt	88.71	80.68	83.79	85.55
ME-PointNeXt	91.43	84.33	87.92	89.74

Table 1 presents the quantitative comparison results for PointNet, PointNet++, PointNeXt and ME-PointNeXt on the segmentation task using the test set. As shown in Table 1, because PointNet relies primarily on global feature aggregation, its ability to capture local geometric details and boundaries is limited, resulting in an mIoU of only 56.83%. Following the introduction of hierarchical local neighbourhood modelling, PointNet++ demonstrated a significant improvement in segmentation performance (OA 88.77%, mIoU 80.37%, mF1 81.90%), indicating that local structural features are crucial for this task. Building upon this, PointNeXt further optimises the backbone network and feature extraction methods, achieving further improvements in metrics such as mIoU and mF1 (mIoU 80.68%, mF1 85.55%). In contrast, ME-PointNeXt achieves the best performance across all evaluation metrics, with OA, mIoU, mAcc, and mF1 reaching 91.43%, 84.33%, 87.92%, and 89.74%, respectively. Compared to PointNeXt, ME-PointNeXt's OA, mIoU, mAcc, and mF1 improved by 2.72, 3.65, 4.13, and 4.19 percentage points, respectively, indicating that the proposed improvements effectively enhance the model's ability to recognise key regions and improve prediction consistency, thereby significantly increasing overall segmentation accuracy.

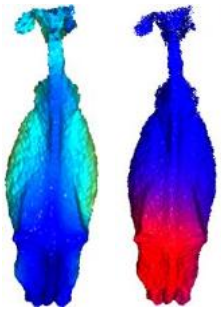
Ablation Test

To verify the impact of different improvement methods on model performance, ablation experiments were designed using PointNeXt as the baseline model. The effectiveness of the improvement methods was assessed using different modules; the experimental results are shown in Table 2.

Table 2

Melting test results

PointNeXt	Dynamic image convolution module	Sequence block	OA/%	mIoU/%	mAcc/%	mF1/%
√			88.71	80.68	83.79	85.55
√	√		89.35	84.72	87.10	89.40
√		√	88.89	82.44	85.83	88.20
√	√	√	91.43	84.33	87.92	89.74



Nota: "√" indicates the adoption of this module; "×" indicates not using this module

As shown in Table 2, adding dynamic graph convolutions to the baseline network effectively improved the model's recognition performance, with the overall accuracy, average precision, average recall, and average F1 score increasing by 0.64, 4.04, 3.31, and 2.85 percentage points, respectively.

This indicates that the use of this convolutional module effectively enhances the model's ability to detect local edge points, helping the network to extract key information from the rear of the cow more effectively. Following the incorporation of the selective sequence block, the overall accuracy, mIoU, average precision and average F1 score increased by 0.18, 1.76, 2.04 and 1.65 percentage points respectively. This indicates that the use of this sequence block helps to enhance global consistency and mitigate the fragmentation of local predictions. Building upon PointNeXt, by incorporating a dynamic graph convolutional module into the global feature layer and adding a selective sequence block to the downsampling layer of the encoder, results in increases of 2.72, 3.65, 4.13, and 4.19 percentage points in overall accuracy, average interaction ratio, average precision, and average F1 score, respectively. This indicates that the simultaneous incorporation of these two modules alongside the sequence block not only enhances sensitivity to curvature changes and boundary regions but also strengthens cross-regional semantic consistency and the ability to model long-range dependencies.

Heatmap visualization

Given the complex nature of the environment in which dairy cows are photographed, heatmaps were selected to visualise the model's recognition performance. A comparison of the heatmaps for the model before and after improvement is shown in Figure 11. As can be seen from Figure 11a, the heatmap of the pre-improvement model shows a relatively dispersed distribution when recognising the rear end of a dairy cow, focusing not only on the key area but also on the middle of the torso and the abdomen. Figure 11b, on the other hand, displays the heatmap visualisation results of the ME-PointNeXt model, which is an improvement based on the PointNeXt model. Following the improvement, the high-response areas are highly concentrated in the hindquarters region, whilst thermal responses in non-target areas are significantly suppressed, markedly reducing activation responses in irrelevant regions.

(a) (b)

Fig. 11 - Heatmap of the model before and after improvement

Discussion

This study employs a method combining 3D data acquisition with deep learning technology to propose a body condition scoring method for dairy cows based on point cloud segmentation. As shown by the comparative results in Figure 12, the improved model is able to accurately capture the rump region of the cow, with a small prediction error. However, the accuracy of the segmentation model has a certain impact on the accuracy of the body condition scoring. Deviations in the segmentation model, particularly segmentation errors in the hindquarters of dairy cows, can lead to prediction errors and inaccuracies in curvature calculations, resulting in significant discrepancies between automatic and manual body condition scores. For example, the incorrect prediction of the critical hindquarter region in Figure 13 led to an erroneous body condition score, thereby reducing the model's reliability. Although the segmentation model proposed in this study has seen a significant improvement in accuracy, it still has shortcomings and considerable room for optimisation. Future work could focus on refining the neural network architecture to improve segmentation accuracy, thereby providing reliable data support for the formulation of dairy cow feed.

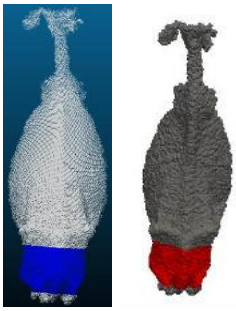


Fig. 12 - Comparison of Manual Point Cloud Annotation and ME-PointNeXt Model Segmentation

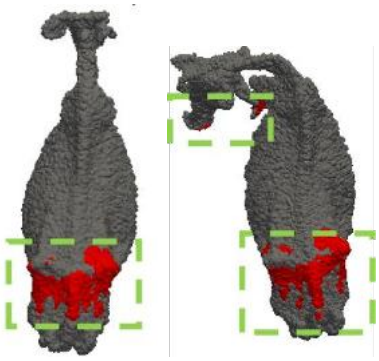

Fig. 13 - Typical Examples of Segmentation Errors

Table 3 presents data on the correlation between the ME-PointNeXt model's automated scores and manual scores. With ten Jersey cows assessed simultaneously, the discrepancy between the automated and manual scores was minimal, with inconsistencies observed in only two cows. This indicates that the method is suitable for assessing the body condition scores of dairy cows and validates the effectiveness of incorporating dynamic convolutional modules and selective sequence blocks into the PointNeXt model.

Table 3

Model scoring versus human scoring error

Cow number	Physical Condition Score	
	Smart Scoring	Manual scoring
20200314	3.25	3.25
20200722	4.00	4.00
20201105	3.25	**3.50**
20210130	3.50	3.50
20210518	4.25	4.25
20210909	3.75	3.75
20211224	4.00	**3.75**
20220214	4.25	4.25
20220607	3.75	3.75
20221031	3.50	3.50

To ensure the accuracy of the model for assessing the body condition score of dairy cows, this study employed the Mean Absolute Error (MAE), Root Mean Square Error (RMSE) and correlation coefficient (r) as performance metrics. For the same cattle shed, both manual scoring and model-based scoring were conducted simultaneously, with the results shown in Table 4. The mean absolute error, root mean square error and correlation coefficient were 0.15, 0.22 and 0.80 respectively, all of which indicate that the model-based scores show a high degree of consistency with the manual scores and are capable of accurately reflecting the actual body condition of the dairy cows.

$$MAE = \frac{1}{n}\sum_{i=1}^{n}\left|y_i - \hat{y}_i\right| \tag{1}$$

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(y_i - \hat{y}_i\right)^2} \tag{2}$$

$$r = \frac{\sum\left(y_i - \bar{y}\right)\left(\hat{y}_i - \bar{\hat{y}}\right)}{\sqrt{\sum\left(y_i - \bar{y}\right)^2 \sum\left(\hat{y}_i - \bar{\hat{y}}\right)^2}} \tag{3}$$

Here, n denotes the total number of samples; is the observed value for the *i-th* sample; is the predicted value for the *i-th* sample; is the arithmetic mean of all observed values; and is the arithmetic mean of all predicted values.

Table 4

Quantitative Error Analysis

Model	MAE	RMSE	r
E-PointNeXt	0.14	0.22	0.79

CONCLUSIONS

(1) By incorporating a dynamic convolutional module into the PointNeXt model, a point cloud segmentation model was proposed. Experimental results demonstrated that this model achieved higher overall accuracy and precision than the PointNeXt model when segmenting local point cloud data from the backs of dairy cows, thereby improving the segmentation accuracy of point cloud data from this region.

(2) By incorporating sequence blocks into the PointNeXt model, experiments have verified that this model demonstrates improved global interaction capabilities when extracting point cloud information from the rear of dairy cows, resulting in more accurate predicted point cloud edges. Compared to the PointNeXt model, this approach has improved the model's prediction accuracy.

(3) Building upon the point cloud segmentation results of the ME-PointNeXt model for the cow's back, an intelligent scoring system was applied to assess the cow's body condition, achieving high accuracy with minimal error. This validated the capability of the segmented point cloud data for body condition scoring.

ACKNOWLEDGEMENT

This study was funded by the Research Projects under the Shigatse Municipal Science and Technology Programme (RKZ2024ZY-03).

ABSTRACT

To address the low operating efficiency and uneven seeding associated with conventional seedling-production seeders, a cell-wheel seed-metering device was developed specifically for rapeseed blanket seedling production. The key components of the device were designed, and its seed-filling and seed-metering characteristics were analyzed. Using 'Ningza 1838' rapeseed as the test material, single-factor tests and multifactor response surface experiments were conducted. Seed-metering wheel rotational speed, seedling-tray conveying speed, and seed-box opening size were selected as the test factors, while the qualified seed-metering rate and missed-hill rate were used as the performance indicators. The results showed that the factors influencing the performance indicators, in descending order, were seed-box opening size, seedling-tray conveying speed, and seed-metering wheel rotational speed. The optimal parameter combination consisted of a seed-metering wheel rotational speed of 9.16 r·min^{-1}, a seedling-tray conveying speed of 0.45 m·s^{-1}, and a seed-box opening size of 22.80 mm. Under these conditions, the bench test yielded a qualified seed-metering rate of 94.41% and a missed-hill rate of 1.49%. These values were consistent with the predicted results, with deviations of less than 0.5 percentage points.

摘要

针对现有油菜育苗排种器作业效率低、播种均匀性差等问题，设计了一种窝眼轮式油菜育苗排种器，分析了充种与排种过程的力学特性与影响因素。以宁杂 1838 油菜种子为试验材料，以排种轮转速、秧盘输送速度、种箱开度为试验因素，以播种合格率及空穴率为性能评价指标，开展单因素和多因素响应面试验。结果表明：影响评价指标的主次顺序为种箱开度、秧盘输送速度和排种轮转速，最优参数组合为排种轮转速 9.16r·min^{-1}，秧盘输送速度 0.45m·s^{-1}，种箱开度 22.80 mm，在最优参数下的该条件下台架试验播种合格率为 94.41%，空穴率为 1.49%，与预测值误差小于 0.5 个百分点。

INTRODUCTION

Rapeseed is an important oil crop in China, with a planting area of more than 6.5 million hm² (*Wu et al., 2024; Deng.,2023)*. Its cultivation includes seedling transplanting and direct seeding. Compared with direct seeding, seedling transplanting can shorten the growth period in the field and effectively alleviate the contradiction of crop rotation, so it has been widely valued (*Lin et al.,2023*). Cultivating qualified and robust rapeseed blanket seedlings is the prerequisite for high-quality transplanting, and the quality of seedling sowing is crucial. The seed-metering device is the core component of the seedling-production system, and its performance directly influences seedling quality (*Wang et al.,2023*). Due to the characteristics of small size, light weight and large particle size variation of rapeseed seeds, problems such as missed seeding, multiple seeding, off-center seed placement and localized seed accumulation can readily occur during operation (*Cong J., 2014*), leading to an increase in the empty-cell rate and a decrease in the qualified rate. Therefore, developing a precision seeding device suitable for rapeseed blanket seedling production is important for improving seedling quality and, ultimately, rapeseed yield.

Seeding devices can be divided into pneumatic and mechanical types. Pneumatic precision seeders usually realize seed filling and metering by negative pressure adsorption or positive pressure ejection. They are characterized by strong single-seed separation ability and good adaptability to seed shape differences, and can theoretically maintain high precision at a relatively high operating speed (*Cao et al., 2021; Li et al., 2020*). Most studies focus on the optimization of seed-airflow dynamics.

Singh R.C et al. (2006) optimized the structure and operating parameters of pneumatic seeders for sowing different seeds such as mustard and peanut. *Albasheer et al. (2024)* designed a cylindrical pneumatic centralized seed metering device, which was suitable for rice, wheat and rapeseed through a double-cell wheel structure, with a field emergence rate of 88% and a coefficient of variation of 3.44%. *Akhalaya et al. (2021)* adopted a synchronous staggered double-disc and double-nozzle seed cleaning structure to solve the contradiction between seed adhesion and missed seeding, enabling compact double-row sowing. *Liao et al. (2018)* explored the influencing factors of seed suction performance of pneumatic precision seeders for small-sized seeds through seed suction and migration tests. *Li et al. (2019)* used EDEM numerical simulation to study the influence laws of various factors on seed population disturbance. *Gao et al. (2022)* proposed a conical hole seed disc, which was verified by theory, simulation and experiments to improve the performance of rapeseed precision seeders, significantly increasing the qualification index and reducing the rates of repeated and missed seeding.

However, despite these advances, pneumatic systems still face inherent limitations: the whole machine structure is complex, manufacturing and maintenance costs remain high, and the small size of rapeseed grains makes seeding consistency susceptible to air pressure fluctuations. Moreover, pneumatic seeders require dedicated air supply and vacuum systems, which increase energy consumption and limit their application in small-scale and hilly farming operations. Mechanical precision seeders generally achieve seed filling and metering through mechanical force. Typical types include grooved wheel, finger clamp, disc, hole wheel, and cell wheel type (*Liu Y et al., 2019; Wang et al., 2022; Li et al., 2025*). Most studies focus on device structure innovation and size optimization. *Maleki et al. (2006)* studied and evaluated the seed distribution uniformity of a multi-screw conveyor as a seeding device for grain drills, and found that its performance was superior to that of the traditional fluted roller device. *Karayel et al. (2022)* established a model between seed physical properties and optimal vacuum degree based on artificial neural network, with a prediction accuracy $R^2 > 0.99$, providing a basis for pressure regulation on demand. *Singh et al. (2005)* took cotton seeds as the object and obtained that the combination of 120° conical holes, 2 kPa vacuum degree and 0.42 m/s linear velocity could achieve a single-seed rate of 94.7%, providing a reference for the optimization of small seed seeders. *Lei et al. (2020)* analyzed the influences of cell length, cross-section size and cell depth on rapeseed filling performance through simulation, and proposed involute-shaped cells suitable for 1–3 seeds per hill of rapeseed. *Zhang et al. (2020)* analyzed the working process of the seeder, determined the spoon-wheel combination and the main parameters such as the size, installation number, installation inclination angle of the spoon-type cells and the rotating speed of the spoon wheel, and designed a rapeseed precision hill-seeding metering device with notched rectangular spoon-type cells. *Xing et al. (2019)* proposed a structure with staggered double circles of cells for rapeseed and three circles for wheat, as well as oblique conical cells by establishing a mechanical model of the sowing process. Among mechanical seeders, the cell wheel type stands out for its simple structure, ease of processing, and convenient seed cleaning, making it particularly suitable for small-seed crops like rapeseed.

However, a critical review of the existing literature reveals a significant scientific gap: most studies on cell wheel seeders for rapeseed have focused either on conventional direct seeding applications or on generalized seed metering for multiple crop types, with limited attention to the specific requirements of blanket seedling nursery production. The nursery seeding process imposes distinct demands—including precise control of 2–3 seeds per cell, compatibility with high-speed seedling tray conveying, and stable performance under continuous operation—that are not adequately addressed by existing designs. Furthermore, systematic investigations into the interactive effects of key operational parameters (metering wheel speed, tray conveying speed, and seed box opening) on seeding performance for blanket seedling applications remain scarce, and the underlying seed-filling mechanics have not been fully characterized for this specific context.

To address this gap, this study developed a novel cell-wheel seed-metering device specifically for rapeseed blanket seedling production. The cylindrical cell structure is simple, easy to manufacture, and convenient to clean. Although its seed-guiding performance is slightly inferior to that of conical or hemispherical cells, reliable seed filling and low seed damage can be achieved by optimizing the cell depth-to-diameter ratio. The principal innovations of the proposed device are threefold: (1) it is the first cell-wheel seed-metering device to be systematically designed and optimized for the nursery seeding stage of rapeseed blanket seedling production, with the cell geometry and arrangement tailored to the agronomic requirement of 2–3 seeds per tray cell; (2) it incorporates a synchronized seed-cleaning brush and seed-cleaning blade, enabling continuous removal of excess seeds without causing seed damage or cell blockage and thereby addressing a common failure mode in mechanical metering devices for small seeds; and (3) through comprehensive mechanical analyses of the seed-filling and seed-discharging processes, it establishes a theoretical basis for parameter optimization by directly linking operating parameters to seed-metering performance indices.

The specific objectives of this study were: (i) to design and fabricate a cell-wheel seed-metering device for rapeseed blanket seedling production, with the key structural parameters determined through theoretical analyses of the seed-filling and seed-metering processes; (ii) to investigate the effects of seed-metering wheel rotational speed, seedling-tray conveying speed, and seed-box opening size on the qualified seed-metering rate and empty-cell rate through single-factor and response surface experiments; and (iii) to determine the optimal combination of operating parameters through multi-objective optimization and validate the results through bench tests. The findings provide a reference for the structural optimization and parameter matching of seed-metering devices for rapeseed blanket seedling production and offer technical support for the development of precision seeding equipment for other small-seeded crops.

MATERIALS AND METHODS

Structure and Operating Principle of the Seed-Metering Device

The principal components of the rapeseed blanket-seedling seed-metering device include a cell-wheel seed meter, seed-cleaning brush, seed box, seed-guide plate, seed-box opening adjustment plate, seed-retaining plate, seed-cleaning blade, and continuously variable-speed motor (Fig. 1). The main technical parameters are listed in Table 1. The operating principle is as follows. Under the action of gravity, rapeseed seeds in the seed box pass through the seed outlet and enter the seed-filling zone under the guidance of the seed-guide plate. Driven by the motor, the seed-metering wheel and seed-cleaning brush rotate synchronously. Seeds enter the cells of the metering wheel under the combined effects of gravity and pressure from the seed mass. As the seed-metering wheel rotates, the seeds retained in the cells pass through the seed-retaining zone. The seed-cleaning brush continuously removes excess seeds from the cells and returns them to the seed-filling zone. The retained seeds continue to rotate with the metering wheel while being held in place by the seed-retaining plate. When the cells reach the seed-discharging zone, the seeds are no longer constrained by the seed-retaining plate and are discharged under the combined effects of gravity and the seed-cleaning blade. They then fall uniformly into the cells of the seedling tray carried by the conveyor belt, thereby completing the seed-metering process.

Table 1

Main parameters of the seed-metering device

No.	Parameter	Value
1	Seed-metering device type	Cell-wheel type
2	Cell shape	Cylindrical
3	Number of cells per circumferential row	90
4	Cell diameter [mm]	3
5	Cell depth [mm]	5
6	Center-to-center spacing between adjacent cells [mm]	20
7	Seed-metering wheel diameter [mm]	160
8	Seed-metering wheel circumference [mm]	512
9	Seed-metering wheel width [mm]	303
10	Number of axial cell rows	14

No.	Parameter	Value
11	Seeding rate [g·tray^{-1}]	3.28 ~ 5.33
12	Seeding rate adjustment method	Stepless adjustment

Figure 2 shows the cell arrangement on the developed surface of the seed-metering wheel, with the principal dimensions defined in Table 1. In Fig. 2, a is the circumferential spacing between adjacent cells, b is the axial center-to-center spacing between adjacent cells, c is the cell diameter, d is the width of the seed-cleaning groove, e is the depth of the seed-cleaning groove, and f is the cell depth. The number of axial cell rows was set to 14 based on the seedling-pickup cycle of the rapeseed blanket seedling transplanter *(Jiang et al., 2024; Wu et al., 2020)*.

Analysis of the Seed-Filling Process of the Seed-Metering Device

Cell geometry is a critical design parameter that directly affects seed filling, retention, and cleaning performance. In this study, cylindrical cells were selected based on the physical properties of rapeseed, manufacturing feasibility, and operational requirements. Rapeseed seeds are approximately spherical, with diameters of 2–3 mm and relatively smooth surfaces. The axisymmetric geometry of a cylindrical cell therefore provides uniform radial clearance around the seeds, facilitating entry into the cell and stable retention during wheel rotation. Compared with conical or hemispherical cells, cylindrical cells offer several advantages.

First, their simple geometry facilitates conventional machining or injection molding, helping ensure dimensional consistency and reduce manufacturing costs. Second, the straight cell walls reduce the wedging effect that may occur in tapered cells when slightly oversized seeds enter the cavity, thereby decreasing the risk of seed damage and cell blockage. Third, the uniform cross-section throughout the cell depth supports stable filling with the agronomically required 2–3 seeds per cell. The seeds can stack naturally within the cylindrical cavity rather than being forced into a narrowing space. Spoon-shaped or elliptical cells may improve single-seed metering in precision direct-seeding applications.

However, their irregular inlet geometry may restrict seed entry, while localized dead zones may retain seed dust and debris, potentially increasing the missed-seeding rate during continuous nursery operation. Cylindrical cells also facilitate seed cleaning. The seed-cleaning brush can sweep smoothly across the flat cell openings without snagging, while the seed-cleaning blade can dislodge seeds that remain partially retained in the cells. These functions may be less reliable with non-axisymmetric cell geometries. The selected cell diameter of 3 mm and depth of 5 mm were determined according to the rapeseed diameter of 2–3 mm, the target seeding rate, and the design requirements of cell-wheel seed-metering devices. This combination provides sufficient cell volume to accommodate 2–3 seeds while reducing the empty-cell rate and limiting excessive multiple seeding beyond the agronomic requirement.

When the cell wheel rotates into the seed-filling zone, rapeseed seeds enter the cells, thereby completing the seed-filling process, as shown in Fig. 3(a). The time available for seeds to enter the cells is a key factor affecting the filling performance of the seed-metering wheel. Therefore, to analyze the seed-filling process and optimize filling performance, the forces acting on an individual rapeseed seed were analyzed, and the required filling time was subsequently calculated.

Rapeseed seeds were simplified as spherical particles with uniform mass distribution and regular arrangement. The vertical pressure acting on a seed was assumed to result only from the weight of the overlying seed layer; lateral pressure, vibration, and other disturbances were neglected. During seed filling, a seed is mainly subjected to its weight G, centrifugal force F_2, Coriolis force F_3, the compressive force exerted by adjacent seeds F_1, the normal reaction force of the cell wall N, the friction force between the seed and the cell wall f_2, and the interseed friction force f_1. A coordinate system was established with the seed center as the origin, the direction normal to the cross-section of the seed-metering wheel as the x-axis, and the tangential direction as the y-axis, as shown in Fig. 3(b). The equations of motion are expressed as follows:

$$\begin{cases} ma_x = (F_1 + G)cos\,\theta + f_1 sin\,\theta - F_3 - F_2 - N \\ ma_y = f_2 + f_1 cos\,\theta - (F_1 + G) f_1 sin\,\theta \\ F_2 = mr\varpi^2 \\ F_3 = 2mv_r\varpi \\ f_1 = \mu_1 F_1 \\ f_2 = \mu_2 F_2 \\ G = mg \end{cases} \quad (1)$$

where: m is mass of a single seed, [kg]; θ is the acute angle between the direction of the centrifugal force acting on the seed and the vertical direction, [rad]; a_x is the normal acceleration of the seed, [m/s²]; a_y is the tangential acceleration of the seed, [m/s²]; r is the distance from the seed centroid to the center of the seed-metering wheel, [m]; ω is the angular velocity of the seed-metering wheel, [rad/s]; μ_1 is the coefficient of friction between seeds; μ_2 is the coefficient of friction between the seed and the cell wall.

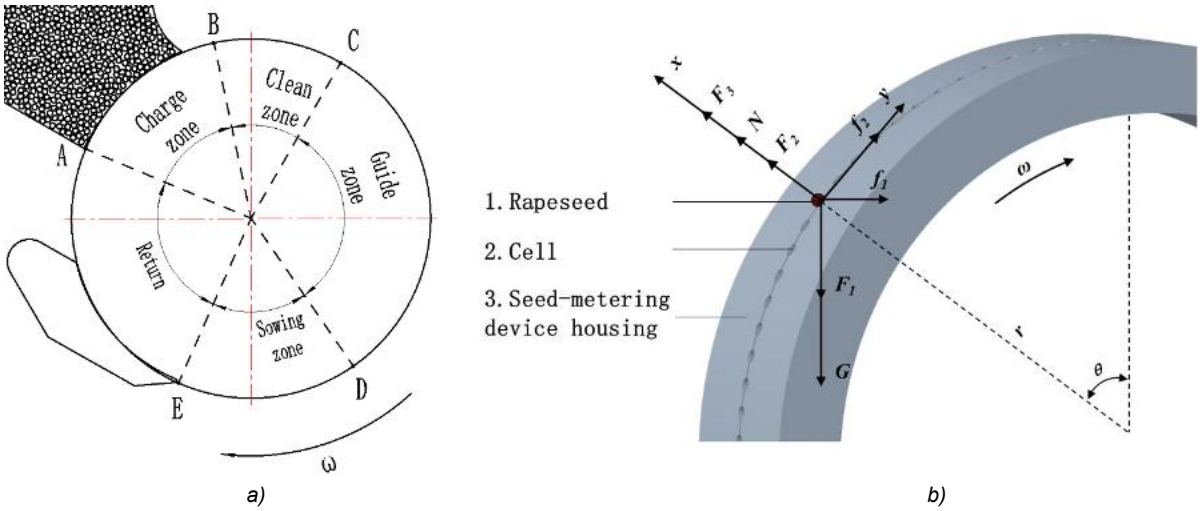

Fig. 3 - Seed-filling process and force analysis

a) Schematic of the seed-filling process; b) Free-body diagram of a single seed during seed filling

Rearranging Equation (1) yields:

$$\begin{cases} a_x = \frac{(mg+F_1)cos\,\theta + \mu_1 F_1 sin\,\theta - N}{m} - 2v_r\varpi - r\varpi^2 \\ a_y = \frac{\mu_2 F_2 + \mu_1 F_1 cos\,\theta - (F_1 + mg)sin\,\theta}{m} \end{cases} \quad (2)$$

According to the analysis of the seed filling process of a single seed, the following relationship exists between the normal displacement h of the seed centroid along the cross-section of the seed metering wheel (i.e., the hole depth) and its tangential acceleration a_x: According to the force analysis of a single seed during the filling process, the normal displacement h of the seed centroid along the cross-section of the seed-metering wheel, corresponding to the cell depth, is related to the normal acceleration a_x as follows:

$$h = \frac{1}{2} a_x t^2 \quad (3)$$

where: t is the time required for the seed to enter the cell, [s].

Combining Equations (2) and (3), the seed-filling time t *(s)* is obtained as:

$$t = \sqrt{\frac{2hm}{(mg+F_1)\cos\theta + \mu_1 F_1 \sin\theta - N - 2v_r\varpi m - mr\varpi^2}} \quad (4)$$

To improve seed-filling performance, the time required for seeds to enter the cells should be minimized. Because the angular range θ of the seed-filling zone is fixed, Equation (4) indicates that the filling time t is primarily affected by parameters such as seed mass m, cell depth h, and the interseed friction coefficient μ_1. The diameter of seeds from common rapeseed cultivars is approximately 2.5 mm. Based on the design criteria for cell-wheel seed-metering devices *(Cong, 2014)*, the cell diameter was set to 3 mm and the cell depth h to 5 mm.

Analysis of the Seed-Discharging Process of the Seed-Metering Device

After entering the seed-discharging zone, the seeds are no longer constrained by the cells or the seed-retaining plate. Under the action of gravity, they leave the cells with an initial velocity determined by the rotational motion of the seed-metering wheel and subsequently undergo projectile motion. The seed-discharge trajectory is shown in Fig. 4.

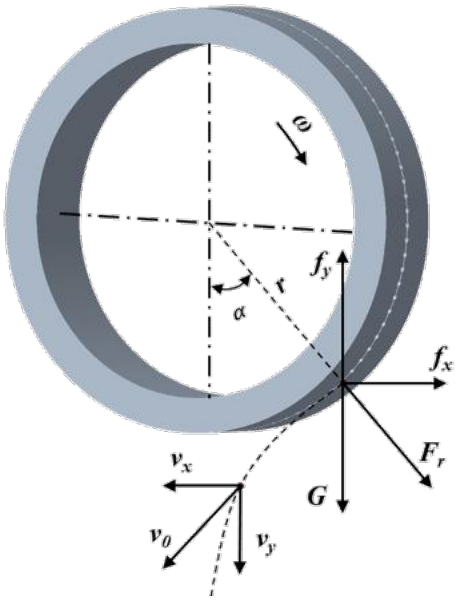

Fig. 4 - Force analysis of a seed during discharge

The initial velocity v_0 of the seed when it leaves the hole can be decomposed into horizontal and vertical components v_x and v_y. During the subsequent falling process, the seed is subjected to the combined action of gravity G, centrifugal force F_r and aerodynamic drag f. The gravity components along the x-axis and y-axis are expressed as ma_x and ma_y respectively, and the aerodynamic drag f is also decomposed into f_x and f_y accordingly. Thus, the equilibrium equations are obtained as follows:

$$\begin{cases} ma_x = -f_x - F_r \sin\alpha \\ ma_y = -F_r \cos\alpha - f_y \\ F_r = m\omega^2 r \end{cases} \quad (5)$$

where: m is the mass of a single seed, [kg]; α is angle between centrifugal direction of a single seed and vertical direction, [rad]; a_x is tangential acceleration of a single seed, [m/s²]; a_y is normal acceleration of a single seed, [m/s²]; r is distance from seed centroid to center of seed metering wheel, [m]; ω is angular velocity of seed metering wheel, [rad/s].

Rapeseed grains are small in size, light in weight, and fall over a short distance, so the effect of the drag force can be neglected. The movement of seeds during the seeding stage can be simplified as projectile motion. Decompose the movement into horizontal displacement x and vertical displacement y, the total displacement is denoted by Z, and the time elapsed during the seeding process is denoted by t.

The relationship among them can be expressed as follows:

$$\begin{cases} Z = \sqrt{x^2 + y^2} \\ v_0 = \omega r \\ v_x = v_0 \cos\alpha \\ x = v_x t \\ y = \frac{1}{2} g t^2 \end{cases} \quad (6)$$

From Equation (6):

$$Z = \sqrt{(\omega r t)^2 + \frac{1}{4} g^2 t^4} \quad (7)$$

According to Equation (7), the movement path of seeds depends on the angular velocity ω and the rotating radius r. Since the seed diameter is much smaller than the radius of the seed metering wheel, r can be approximated as the radius of the seed metering wheel. Reducing the values of ω and r can shorten the movement distance of seeds, thereby reducing the time required in the seed-dropping stage. With reference to the design of other cell-wheel seed-metering devices *(Cong, 2014)*, the radius of the seed-metering wheel was set to 80 mm. Because the angular velocity ω affects the seed-discharge speed, it should be kept as low as possible while still ensuring the required operating efficiency.

Experimental Conditions

The experiment was conducted at the test site of Yunma Agricultural Machinery Manufacturing Co., Ltd. in Yancheng, Jiangsu Province. The rapeseed cultivar used was Ningza 1838, with a seed diameter of 2–3 mm and a 1,000-seed weight of 4.1 g. The developed precision rapeseed seed-metering device was installed in place of the original precision rice seed-metering device on a 2BLY-280B rice seedling-production line (Fig. 6). Rigid plastic trays with overall dimensions of 560 mm × 280 mm × 30 mm (length × width × height) were used. To facilitate clearer counting of the rapeseed seeds during the experiment, quicklime powder was used in place of the seedling substrate employed in actual production.

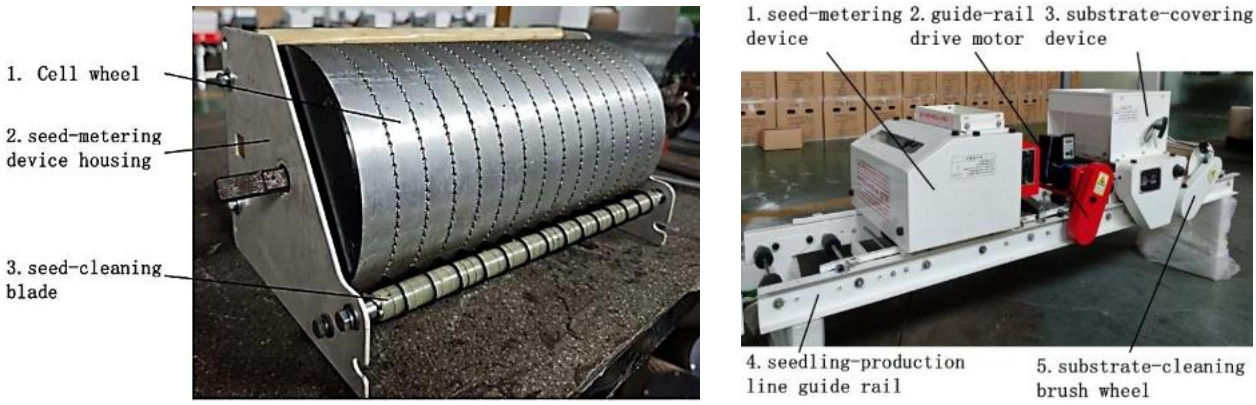

Fig. 5 - Seeder bench-test setup

According to the agronomic requirements for rapeseed mat-type seedling production *(National Technical Committee for Agricultural Machinery Standardization, 2021)*, 2–3 seeds per tray cell are considered appropriate. With reference to the relevant promotion and evaluation guidelines *(Ministry of Agriculture and Rural Affairs of the People's Republic of China, 2024)*, the qualified seed-metering rate and empty-cell rate were calculated using Equation (7). During each test, the operating parameters were adjusted and 10 consecutive trays were sown. After stable operation was achieved, the middle five trays were selected for evaluation. For each tray, five sampling areas were selected using the five-point sampling method, with 20 cells examined in each area, resulting in a total of 100 cells per tray.

The sampling method is shown in Figure 6.

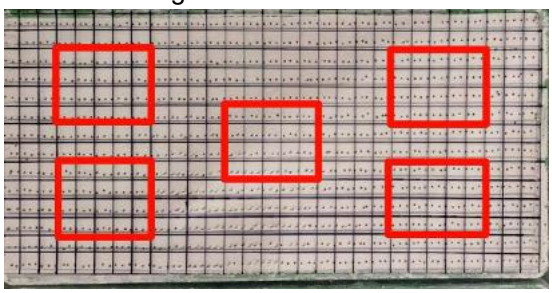

Fig. 6 - Sampling areas for seed counting in the seedling tray

The seed-metering performance indices were calculated as follows:

$$\begin{cases} R_j(\%) = \frac{H_j}{Z_j} \times 100 \\ R_K(\%) = \frac{N_k}{Z_k} \times 100 \end{cases} \quad (8)$$

where:

R_j is the qualified seed-metering rate, [%]; H_j is the number of qualified cells; Z_j is the total number of cells evaluated; R_k is the empty-cell rate, [%];N_k is the number of empty cells; Z_k is the total number of cells evaluated.

Single-factor experimental design

Based on previous studies *(Liu et al., 2025; Yu et al., 2025; Zhou et al., 2016)*, the rotational speed of the seed-metering wheel, the conveying speed of the seedling tray, and the seed-box opening size were selected as the experimental factors. Their effects on the qualified seed-metering rate and empty-cell rate were investigated. Each test was repeated five times, and the mean value was used for analysis. (1) With the seedling-tray conveying speed fixed at 0.45 $\mathrm{m \cdot s^{-1}}$ and the seed-box opening size fixed at 17 mm, the rotational speed of the seed-metering wheel was set to 7.6, 8.4, 9.2, 10.0, and 10.8 r·min⁻¹. The qualified seed-metering rate and empty-cell rate were then measured. (2) With the rotational speed of the seed-metering wheel fixed at 9.2 r·min⁻¹ and the seed-box opening size fixed at 17 mm, the seedling-tray conveying speed was set to 0.35, 0.40, 0.45, 0.50, and 0.55 m·s⁻¹ to evaluate its effect on seed-metering performance. (3) With the rotational speed of the seed-metering wheel fixed at 9.2 r·min⁻¹ and the seedling-tray conveying speed fixed at 0.45 m·s⁻¹, the seed-box opening size was set to 10, 13.5, 17, 20.5, and 24 mm for testing.

Effects of Seed-Metering Wheel Speed on Seeding Performance

As shown in Fig. 7, as the rotational speed of the seed-metering wheel increased, the qualified seed-metering rate initially increased and then decreased, whereas the empty-cell rate showed the opposite trend. This was mainly because an increase in rotational speed enhanced the mobility of the seed mass and strengthened the entrainment effect of the seed-metering wheel on the seeds, thereby facilitating seed entry into the cells and significantly reducing the empty-cell rate. The resulting improvement in seed-filling efficiency also increased the qualified seed-metering rate, indicating the presence of a relatively stable seed-filling range at intermediate rotational speeds. However, an excessively high rotational speed shortened the effective contact time between the seeds and the cells. Consequently, the seed-filling process could not be completed before the seeds were carried away from the seed bed. At the same time, the centrifugal effect became more pronounced, causing some seeds to leave the cells because of inertia. This resulted in insufficient filling, an increase in the empty-cell rate, and a decrease in the qualified seed-metering rate. Therefore, to maintain a qualified seed-metering rate above 90% while keeping the empty-cell rate within an acceptable range, the rotational speed of the seed-metering wheel should be set to 8.4–10 r·min⁻¹.

Effects of Seedling-Tray Conveying Speed on Seed-Metering Performance

As shown in Fig. 8, as the seedling-tray conveying speed increased, the qualified seed-metering rate initially increased and then decreased, whereas the empty-cell rate showed the opposite trend. Within the low-to-medium speed range, an increase in conveying speed improved the coordination between seed discharge

and tray movement, allowing the discharged seeds to enter the tray cells more accurately. This reduced missed seeding, sharply decreased the empty-cell rate, improved seed-distribution uniformity, and significantly increased the qualified seed-metering rate. When the conveying speed exceeded the critical value of 0.45 m·s^{-1}, two adverse effects occurred. First, the impact velocity of the seeds upon contact with the substrate in the seedling tray increased, resulting in seed bouncing and scattering and thereby reducing seeding uniformity. Second, the time interval during which each tray cell passed beneath the seed-discharge position became too short for the seeds to settle stably in the cells, leading to an increase in the empty-cell rate. Therefore, considering both seed-metering performance and production efficiency, a seedling-tray conveying speed of 0.40–0.50 m·s^{-1} was considered appropriate.

Effects of Seed-Box Opening Size on Seed-Metering Performance

As shown in Fig. 9, the qualified seed-metering rate decreased when the seed-box opening size increased from 10 to 13.5 mm, increased when the opening size increased from 13.5 to 17 mm, and then gradually decreased when the opening size exceeded 17 mm. The rate of decrease became smaller when the opening size exceeded 20.5 mm. The empty-cell rate initially decreased and then increased. As the seed-box opening size increased, the quantity of seeds entering the seed-filling zone also increased, producing two beneficial effects. First, increased interseed friction reduced the mobility of the seed mass and limited seed bouncing during the seed-filling process. Second, the increased pressure within the seed mass promoted more complete filling of the cells. However, when the opening size exceeded the critical value of 17 mm, excessive seed accumulation increased interseed compression and friction, potentially causing seed jamming and disrupting seed-metering uniformity. In addition, excessive seed accumulation in the seed passage prevented some cells from being completely filled. Therefore, the seed-box opening size was selected within the range of 10–24 mm.

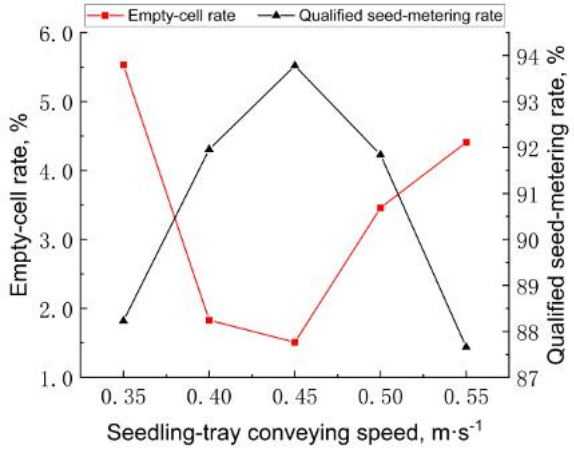

Fig. 8 - Effects of seedling-tray conveying speed on seed-metering performance

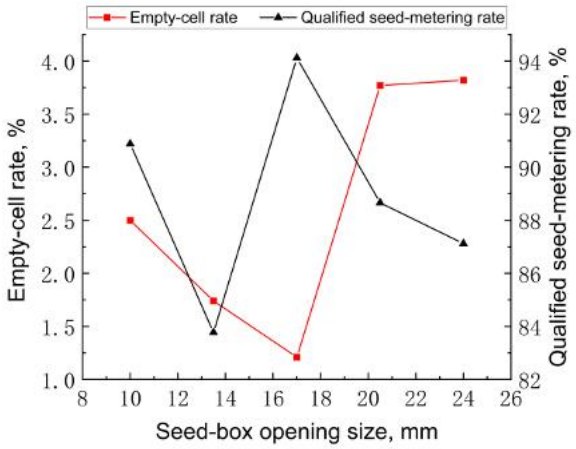

Fig. 9 - Effects of seed-box opening size on seed-metering performance

Experimental design

Based on the factor ranges determined from the single-factor experiments, a three-factor, three-level orthogonal experiment was conducted using the qualified seed-metering rate (R_j) and empty-cell rate (R_k) as the evaluation indices. The experimental factors and their levels are listed in Table 2. X_1, X_2 and X_3 represent the coded values of the seed-metering wheel rotational speed, seedling-tray conveying speed, and seed-box opening size, respectively. A total of 17 experimental runs were performed. Each run was repeated three times, and the mean value was used for analysis. The experimental results are presented in Table 3.

Table 2

Experimental factors and levels

Level	Seed-metering wheel rotational speed X_1 [r·min^{-1}]	Seedling-tray conveying speed X_2 [m·s^{-1}]	Seed-box opening size X_3 [mm]
-1	8.4	0.4	10
0	9.2	0.45	17
1	10	0.5	24

RESULTS

The experimental results are presented in Table 3. Regression analysis of the experimental data was performed using Design-Expert 13.0, and the following regression equations were obtained:

$$R_j = 93.78 - 0.39X_1 + 0.2662X_2 + 1.63X_3 - 0.75X_1X_2 + 0.04X_1X_3 + 0.7075X_2X_3 - 2.21X_1^2 - 2.86X_2^2 - 1.35X_3^2 \quad (9)$$

$$R_k = 1.58 + 0.9963X_1 - 0.345X_2 - 0.7138X_3 - 0.49X_1X_2 + 0.3025X_1X_3 + 0.295X_2X_3 + 1.22X_1^2 + 0.8123X_2^2 + 0.1847X_3^2 \quad (10)$$

The analysis of variance presented in Table 4 showed that both regression models were highly significant ($P < 0.01$), whereas the lack-of-fit terms were not significant ($P > 0.05$), indicating that the models adequately fitted the experimental data. The coefficients of determination, R^2, were 0.9985 and 0.9821 for the qualified seed-metering rate and empty-cell rate models, respectively. The corresponding adjusted R^2 values were 0.9966 and 0.9591, and the predicted R^2 values were 0.9942 and 0.7657. The coefficients of variation were 0.1571% and 9.64%, respectively. These results indicate good agreement between the predicted and experimental values. The order of influence of the experimental factors on seed-metering performance was seed-box opening size, followed by seedling-tray conveying speed and seed-metering wheel rotational speed.

Note: *Each treatment was replicated three times, and the reported values are the means.*

The analysis of variance indicated interaction effects among the seed-metering wheel rotational speed, seedling-tray conveying speed, and seed-box opening size. The corresponding response surfaces are shown in Fig.10.

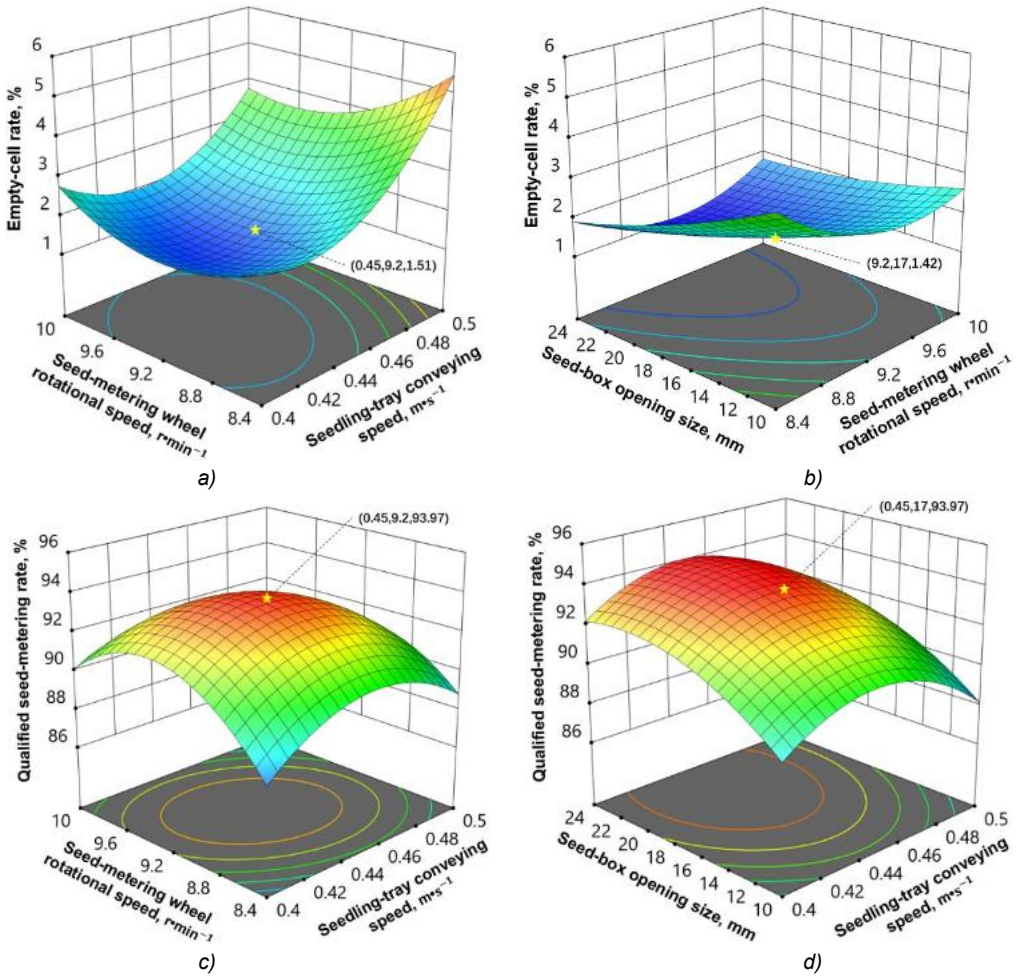

Fig. 10 - Response surfaces showing the interactive effects of seed-metering wheel rotational speed, seedling-tray conveying speed, and seed-box opening size on the qualified seed-metering rate and empty-cell rate

The interaction between X_1 and X_2 reflects the temporal and spatial coordination between the seed-discharge frequency and the rate at which tray cells pass beneath the discharge position (Figs. 10a and 10b). At low values of both X_1 and X_2, seed agitation and circulation in the filling zone are relatively weak, resulting in insufficient cell filling (Eq. 2). Meanwhile, the low rotational speed of the seed-metering wheel produces a low initial seed-release velocity, and the horizontal displacement of the seed during flight, (Eq. 6), remains relatively small. As both factors increase toward their intermediate levels, the seed-discharge frequency becomes better matched to the tray-cell passing frequency, allowing the seeds to land more accurately in the tray cells. This region therefore represents the optimal synchronization range, in which the qualified seed-metering rate reaches its maximum. When X_2 is high while X_1 remains low, the seed supply rate per unit time may be insufficient relative to the number of tray cells passing beneath the discharge position, resulting in a marked increase in the empty-cell rate. This represents a temporal mismatch between seed supply and tray-cell demand. Conversely, when X_1 is high while X_2 is low, seeds are discharged with greater initial velocity ($v_y = gt$) and may undergo increased bouncing or scattering after striking the substrate, thereby reducing the qualified seed-metering rate even when the seed supply is sufficient. The deterioration in performance at the highest combination of the two factors is attributed to the excessive rotational speed of the seed-metering wheel ($Fc > mg$), which may cause seeds to detach prematurely from the cells before reaching the optimal discharge position (Eq. 5). This leads to irregular landing positions and a sharp increase in the empty-cell rate. The interaction between X_1 and X_3 reflects the balance between the available seed-filling time and the pressure exerted by the seed mass at the cell entrance (Figs. 10c and 10d). At a small seed-box opening size (low X_3), the quantity of seeds entering the filling zone is limited, and the pressure exerted by the seed layer above the cells is relatively low. As X_1 increases, the effective seed-filling time decreases proportionally (Eq. 4), making it more difficult for seeds to enter the cells completely. Consequently, the qualified seed-metering rate decreases rapidly at small opening sizes. Increasing X_3 increases the amount of seed in the filling zone and enhances both interseed contact and the pressure exerted by the upper seed layer. Within an appropriate range, this promotes seed entry into the cells and improves the qualified seed-metering rate. However, when the opening size exceeds a critical value, approximately 17 mm according to the response-surface results, excessive seed accumulation may increase interseed compression and restrict the mobility of the seed mass. This can promote bridging or arching near the cell entrances, thereby obstructing seed flow and reducing the effective filling rate. The ridge observed in the response surface therefore indicates that an optimal combination of rotational speed and seed-box opening size is required: sufficient seed pressure is needed to promote filling, but excessive accumulation should be avoided to prevent flow obstruction. The gradual decline observed when the opening size exceeded 20.5 mm in the single-factor experiment shown in Fig. 9 may also be associated with this reduced seed mobility and localized bridging. Although the X_2X_3 interaction term was not significant for the qualified seed-metering rate (P=0.5922 , Table 4), it was significant for the empty-cell rate (P=0.0480). The seedling-tray conveying speed X_2 affects the relative horizontal position between the falling seeds and the moving tray cells, whereas the seed-box opening size X_3 influences the quantity of seeds supplied to the discharge zone. At a high conveying speed, the available time for each tray cell to pass beneath the discharge position is reduced, increasing the likelihood of positional misalignment. A larger seed-box opening size increases the seed flow rate and may intensify interseed collisions, bouncing, and scattering during discharge. Therefore, at higher conveying speeds, a moderately smaller opening size may help limit excessive seed flow and reduce collision-induced scattering. This interpretation is consistent with the slight shift in the optimal region observed in the response surface as X_2 increased from 0.4 to 0.5 m·s^{-1}.

Each response surface was constructed using the mean of three replicate measurements for each treatment combination listed in Table 3. The red asterisk (★) in each subfigure indicates the optimal operating point identified through multi-objective optimization.

Optimization and Verification

Using the optimization module in Design-Expert 13.0, multi-objective optimization was performed to minimize the empty-cell rate and maximize the qualified seed-metering rate. During the numerical optimization, the seedling-tray conveying speed (X_2) was fixed at 0.45 m·s⁻¹ for the following reasons: (i) this value corresponded to the optimal performance range identified in the single-factor experiment (Fig. 8) and was also consistent with the standard operating speed of commercial seedling-production lines, thereby ensuring compatibility with upstream and downstream operations; (ii) in practical production, the conveying speed is determined by the overall cycle time of the production line and is rarely adjusted during operation, whereas the seed-metering wheel rotational speed and seed-box opening size are the main parameters adjusted by operators to improve seed-metering quality; and (iii) fixing X_2 at its optimal value allowed the optimization to focus on the two most influential and practically adjustable factors, X_1 *and* X_3, thereby producing results that could be applied directly without changing the operating speed of the entire production line. Accordingly, the optimization objectives and constraints were defined as follows:

$$\begin{cases} minY_1(x1, x2, x3) \\ maxY_2(x1, x2, x3) \\ s.t. \begin{cases} 8.4 \leqslant x_1 \leqslant 10 \\ x_2 = 0.45 \\ 10 \leqslant x_3 \leqslant 24 \end{cases} \end{cases} \quad (10)$$

The optimal parameter combination obtained through numerical optimization was a seed-metering wheel rotational speed of 9.16 r·min⁻¹, a seedling-tray conveying speed of 0.45 m·s⁻¹, and a seed-box opening size of 22.80 mm. Under these conditions, the predicted qualified seed-metering rate and empty-cell rate were 94.15% and 1.12%, respectively. Three replicate bench verification tests were conducted using the optimal parameter combination. The measured mean qualified seed-metering rate was 94.41%, with a standard deviation of 0.23 percentage points and a 95% confidence interval of 93.85%–94.97%. The measured mean empty-cell rate was 1.49%, with a standard deviation of 0.036 percentage points and a 95% confidence interval of 1.40%–1.58%. The predicted qualified seed-metering rate of 94.15% and empty-cell rate of 1.12% both fell within the corresponding 95% confidence intervals of the measured values. The absolute deviations between the predicted and measured values were 0.26 and 0.37 percentage points, respectively, both of which were below the engineering tolerance threshold of 0.5 percentage points. The optimal parameter combination obtained through optimization was a seed-metering wheel rotational speed of 9.16 r·min⁻¹, a seedling-tray conveying speed of 0.45 m·s⁻¹, and a seed-box opening size of 22.80 mm. The predicted qualified seed-metering rate was 94.15%, and the predicted empty-cell rate was 1.12%. Subsequently, a bench verification experiment was conducted using this parameter combination. The experiment was repeated five times, and the mean qualified seed-metering rate and empty-cell rate were 94.41% and 1.49%, respectively. These results demonstrate that the regression models provide adequate predictive accuracy and reliability for practical operation.

CONCLUSIONS

(1) This study extends beyond parameter optimization by clarifying the underlying seed-filling and seed-discharge mechanisms of a cell-wheel seed-metering device designed for rapeseed blanket seedling production. Seed-metering performance was governed by three interacting mechanisms: the competition between the available seed-filling time and premature seed release, which was mainly affected by the seed-metering wheel rotational speed; the transition between pressure-assisted filling and seed bridging, which was mainly affected by the seed-box opening size; and the trade-off between landing accuracy and seed bouncing, which was mainly affected by the seedling-tray conveying speed. The cylindrical cells, with a diameter of 3 mm and a depth of 5 mm, together with the coordinated action of the seed-cleaning brush and blade, reduced cell blockage and seed damage and enabled stable metering of 2–3 seeds per tray cell.

(2) The validated regression models provided reliable predictions of seed-metering performance, with R^2 values of 0.9985 for the qualified seed-metering rate and 0.9821 for the empty-cell rate. The absolute deviations between the predicted and measured values were below 0.5 percentage points. The optimal parameter combination consisted of a seed-metering wheel rotational speed of 9.16 $r \cdot min^{-1}$, a seedling-tray conveying speed of 0.45 $m \cdot s^{-1}$, and a seed-box opening size of 22.80 mm. Because the optimization was conducted at the standard operating speed of the seedling-production line, the resulting parameter combination can be applied directly in practical operation. Factor significance order was: seed box opening > tray speed > metering wheel speed.

(3) This study has three main limitations. First, quicklime powder was used instead of the actual seedling substrate during the bench tests, which may have affected seed landing and bouncing behavior. Second, only the Ningza 1838 rapeseed cultivar was evaluated; therefore, other cultivars may require recalibration of the operating parameters. Third, the seedling-tray conveying speed was fixed during numerical optimization, and adaptive adjustment of the conveying speed was not investigated. Future research should include production-scale or field validation using actual seedling substrate, testing of multiple rapeseed cultivars, and the development of a closed-loop control system for adaptive parameter adjustment.

Keywords: *intelligent animal feeding system; multisource information acquisition; audio–video assisted localization; RFID-based identity verification; weight-based arrival confirmation*

ABSTRACT

With the increasing refinement of livestock feeding management, conventional manual feeding and record-keeping methods often fail to ensure reliable confirmation of individual animal arrival and accurate identity matching. This may result in ineffective feeding, feed misdelivery, missed feeding, and deviations from the prescribed feed amount. To address these limitations, an intelligent animal feeding system based on multisource information acquisition was developed. The system integrates camera-based monitoring with microphone-array sound-source localization to support target positioning and combines radio-frequency identification (RFID)-based identity verification with weight-based arrival confirmation to enable individualized feeding while minimizing animal–target mismatches. The system also collects body weight and environmental data to generate traceable individual records and supports data transmission and command delivery through an ESP8266 module using the Message Queuing Telemetry Transport (MQTT) protocol. A WeChat mini-program is integrated into the platform to provide remote control, feeding-plan configuration, and data visualization, as well as AI-assisted recognition and question-answering functions. Experimental results demonstrated that the proposed system successfully integrates intelligent feeding with multisource information acquisition. Under the combined audio–visual configuration, the target-positioning success rate reached 92.67%, while the combined RFID–weight configuration achieved a trigger accuracy of 93.33%. These results indicate that the system can support refined feeding management and improve process traceability.

摘要

随着饲喂管理逐步向精细化发展，传统人工饲喂与记录的方式难以保证个体到位确认与身份匹配，易出现无效投喂、误投漏投与饲喂量偏差等问题。为此，本文构建基于多源信息采集的动物智能饲喂系统。系统通过摄像头监测与麦克风阵列声源方位数据辅助定位，并结合 Radio Frequency Identification（RFID）身份确认与称重到位判定，实现个体化饲喂，避免对象错配；系统同步采集体重与环境参数，形成可追溯的个体记录，通过 ESP8266 与 Message Queuing Telemetry Transport（MQTT）实现数据上报与指令下发；微信小程序与平台对接，提供远端控制、方案配置与数据可视化，并集成 AI 辅助识别与问答服务。实验结果表明，本系统能够实现智能饲喂与信息采集的一体化运行，在音频与视频联合配置下，指向成功率为 92.67%；在 RFID 与称重联合配置下，触发准确率为 93.33%。上述结果可为精细化饲喂管理与过程溯源提供参考依据。

INTRODUCTION

Feeding is very important for both feed supply and animal observation. Relevant information is collected during the feeding process, and this information can help adjust feeding plans when the condition of the animals changes *(Kavlak et al., 2023; Gauthier et al., 2022)*. Traditional feeding methods mainly rely on manual operation and record keeping. Prolonged use of such practices may result in inconsistent feed allocation and fragmented records that are difficult to maintain continuously. Poor data continuity also limits timely adjustment of feeding plans and may reduce the effectiveness of long-term management *(Bhaskaran et al., 2024)*. Therefore, intelligent feeding systems generally need to support individualized feeding, continuous acquisition of key state information, and remote cloud-platform management simultaneously (*Leliveld et al., 2024; McCarthy et al., 2023*).

Although sensing and automation modules have been increasingly adopted in animal feeding management, existing solutions are mostly designed independently for single tasks. As a result, process fragmentation and non-uniform interfaces often arise during on-site integration and maintenance, and data and control interactions across modules are difficult to standardize, making it difficult to establish a unified workflow for feeding management *(Nyamuryekung'e et al., 2024)*. Existing intelligent feeding-related devices are typically used for individual functions such as feeding equipment control, RFID-based individual identification, weight acquisition, environmental monitoring, and audio-video behavior recognition. Representative examples include data cleansing for electronic feeding station data *(Garrido-Izard et al., 2022)*, individualized ration supply and precision-feeding strategy validation based on automatic feeders (*Ribas et al., 2024; Spinler et al., 2024; Durand et al., 2023*), behavior-oriented audio-video multimodal recognition *(Yang et al., 2025)*, and association analysis between environmental factors and health/behavior indicators (*Bus et al., 2025*). Furthermore, *Funk et al. (2024)* developed an online monitoring and abnormality warning method for individual feeding behavior based on a low-frequency RFID electronic feeding system, achieving abnormal decline detection in 2,826 finishing pigs, identifying 55.7% of stockperson-diagnosed events, and providing warnings 2.8 days in advance on average. *Decarie et al. (2025*) also proposed and validated a walk-over dynamic weighing system in commercial pig farms, enabling non-invasive automatic body weight estimation while pigs walked through the device and demonstrating the engineering feasibility of a standalone weight-acquisition device. However, because modules are often triggered independently by different hardware and software devices, feeding triggering and execution are easily affected by group-housing behavior, equipment layout, and communication conditions, resulting in missed triggers or record gaps. Data gathered from different sources cannot always be matched reliably, noise and missing data entries are also fairly common, and this raises the amount of work needed for follow-up data cleaning and system maintenance.

In animal feeding, a trigger based on only one signal is easily affected by occlusion, changes in animal posture, and surrounding conditions. These factors can cause false activation and inconsistent data acquisition. When visual information alone is used to control feeding activation, an animal may be detected before reaching the feeding position or before completing the arrival process. Premature detection may therefore lead to invalid triggering *(Scaillierez et al., 2024; Han et al., 2023)*. Weight-only triggering also lacks sufficient reliability. An animal may not stand completely inside the weighing area or may continue moving during measurement. The resulting variation in weight readings can reduce the reliability of the trigger decision *(Zhang et al., 2025)*. Time-based strategies are likewise difficult to align with the actual arrival time of individuals, because the arrival of a preset time point does not necessarily imply arrival at the feeding position, which may lead to empty feeding or repeated triggering *(Bus et al., 2024; Bus et al., 2023; Wallgren et al., 2025; Lagoda et al., 2025)*. Therefore, an organization method based on a controllable on-site process is required to improve the reliability of feeding execution *(Gaillard et al., 2022)* and to provide a stable event entry for multisource information acquisition.

To address these issues, this study designed and implemented an intelligent animal feeding system based on multisource information acquisition. The system uses a single feeding event as the basic operational unit and integrates audio-visual-assisted monitoring, RFID-based individual identification, weight-based arrival confirmation, feeding execution, environmental parameter acquisition, and remote data interaction into a unified workflow. This design establishes continuous associations among target confirmation, trigger decision-making, execution control, and process recording. The camera and microphone array provide visual positional feedback and acoustic directional assistance, respectively. RFID and weight information are jointly used for individual identity verification and arrival confirmation. The acquired body weight, environmental parameters, and device operating status are synchronously uploaded to a mini-program for record retrieval, trend visualization, feeding-plan configuration, and remote management. The system uses OpenMV and a K210 microphone array to support low-cost on-site deployment, local real-time processing, and direct integration

with the pan-tilt control system. A DHT11 sensor records the basic temperature and humidity conditions associated with feeding events and provides the environmental information required for functional validation of the prototype rather than high-precision environmental regulation.

On this basis, the study evaluates whether the proposed multisource information coordination mechanism can improve the reliability of target pointing and feeding triggering while supporting continuous process recording and traceability. Based on the complementary roles of different information sources in the feeding workflow, acoustic directional information is expected to assist target reorientation when visual tracking becomes temporarily unstable or is lost. Visual information is expected to provide more accurate positional feedback once the target enters the field of view. Their coordinated use is therefore expected to improve the continuity and stability of target pointing. When RFID identity confirmation is combined with weight measurement to confirm arrival, this method is likely to make the activation of feeding more reliable, but the system needs to wait until the weight reading is stable, and this may make the trigger time longer.

MATERIALS AND METHODS

Overall System Architecture

To achieve multisource information acquisition, this study develops an intelligent animal feeding system, which is mainly composed of two components: a feeding device and a WeChat mini-program. The STM32F103ZET6 microcontroller is employed to implement system control and task scheduling, and coordinate the operation of modules including audio-video assisted target monitoring, animal identity recognition, automatic feeding, and IoT-based environmental data acquisition. Information on animal identity, arrival status, body weight, environmental conditions and feeding execution status is correlated within the system and stored in a structured form. The ESP8266 module is adopted for wireless communication, MQTT supports bidirectional transmission of data and control commands, and the cloud server undertakes storage and forwarding of the relevant data. The WeChat mini-program allows users to view historical records and collected data, set feeding plans, and perform remote control of the system. Additionally, the platform supports centralized storage, remote access, and system maintenance. Figure 1 presents the overall architecture of the system.

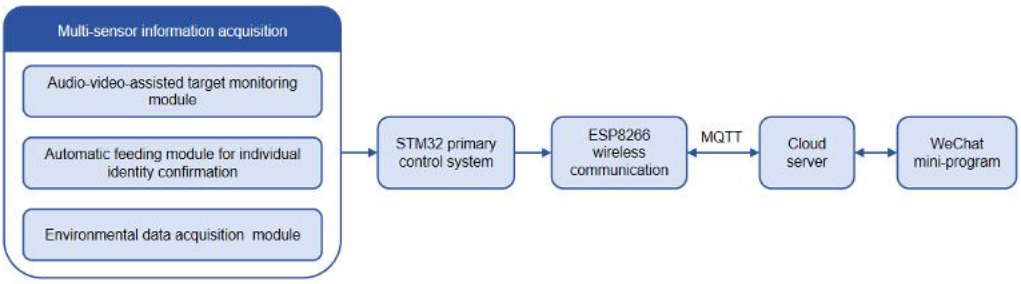

Fig. 1 - Structure diagram of system

Experimental Protocol

The prototype was tested in an indoor nursery pig house. Three weaned piglets were chosen for this experiment. Each piglet was equipped with an RFID ear tag. Their ages were between 21 and 28 days, and their body weight was around 6 to 8 kg. The whole test lasted for three straight days. During the test with combined audio and video for target pointing, a blue visual marker assisted the OpenMV camera with target tracking work, and it also provided support for the control of pan and tilt. Throughout the whole test process, the surrounding temperature stayed between 26 and 30℃, and the relative humidity was within the range of 50% to 65%. The feeding device, RFID reader, weighing platform, OpenMV camera, and K210 microphone array were installed around the feeding port. All devices were calibrated before formal testing.

A complete system operation was defined as a single event-level trial. Consecutive video frames and individual sensor readings were not treated as independent replicates. The audio–visual pointing test comprised a visual-only group, an acoustic-only group, and a combined audio–visual group. The feeding-trigger test comprised an RFID-only group, a weight-only group, and a combined RFID–weight group. Each group included 300 event-level trials, and cases of target loss, feed misdelivery, and missed feeding were included in the statistical analysis. The three piglets were used primarily to establish a representative on-site feeding scenario. Accordingly, the repetitions represented system-event-level replicates rather than animal-level biological replicates. The results were used solely to evaluate the feasibility and operational reliability of the prototype system and were not intended to support inferences regarding population-level production performance or behavioral patterns.

Hardware Design of the Animal Feeding Device

Primary control system

The system adopts STM32F103ZET6 as the main control chip, which is a 32-bit microcontroller manufactured by STMicroelectronics. Under the control and scheduling of the main control system, each subsystem cooperates closely to acquire parameter information from surrounding sensors and connect to the STM32 through GPIO and other interfaces, where local data encapsulation and state management are completed. Subsequently, data are uploaded to the cloud server through the WLAN subsystem, where storage and forwarding are performed and synchronized to the mini-program platform, facilitating real-time access to breeding information and remote management.

The process of the main control system based on STM32F103ZET6 is shown in Figure 2.

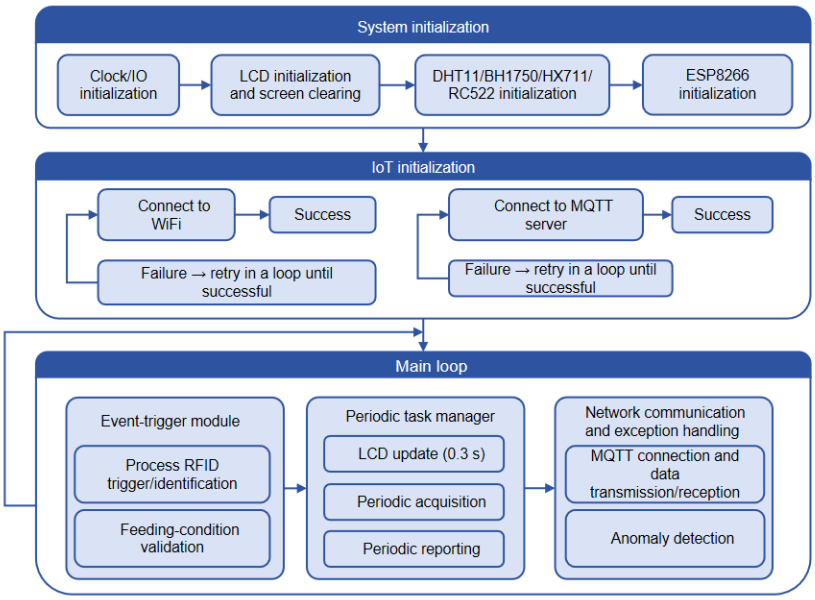

Fig. 2 - Flowchart of the Main Controller

Audio-Visual Assisted Target Monitoring Module

The target monitoring module combines an OpenMV camera with a K210 microphone array to continuously monitor animal targets in the feeding area and provide directional guidance. Visual and acoustic information is collected in parallel. When illumination is weak, the target is occluded, or image quality becomes unstable, the estimated sound direction provides an additional reference for target orientation. The combined sensing approach improves monitoring stability and increases the adaptability of the system under complex environmental conditions.

Target Tracking Based on Image Information

The image-based tracking unit uses an OpenMV module equipped with an OV7725 camera. An animal that enters the feeding range and carries a blue marker is regarded as the current target. OpenMV reads the video stream frame by frame and segments the blue region in the LAB color space using a preset threshold. The centroid offset relative to the image center is then calculated. A PID controller converts the offset into servo control signals and adjusts the pan and tilt angles. During the control process, the target is slowly moved back toward the center of the visual field. Real-time tracking state is maintained all the time. Meanwhile, the identity information of the animal is collected by the RFID reader and writer module. The main controller connects the RFID number with the target position sent back by the camera. The connected information is then used to make feeding records. It also offers support for data tracing work. The functional introduction of the OpenMV module is shown in Table 1.

Table 1

Functional Description of the OpenMV Module

Module Pin	Main Controller Pin	Specific Function
GND	GND	Ground
VIN(3.6-5)	VIN	Power input
UART1_RX	P0	UART receive
UART1_TX	P1	UART transmit

Module Pin	Main Controller Pin	Specific Function
CAN2_TX	P2	CAN bus transmit
CAN2_RX	P3	CAN bus receive
UART3_TX	P4	UART transmit
UART3_RX	P5	UART receive
P6	P6	Reserved analog output or general-purpose I/O
P7	P7	Servo control signal output (pan / horizontal)
P8	P8	Servo control signal output (tilt / pitch)
P9	P9	Reserved general-purpose I/O pin
BOOT0	BOOT	Boot mode selection
FRAMESYNC	SYN	Frame synchronization signal interface
3V3_OUT	3.3V	3.3 V power output
RESET	RST	Reset signal input

OpenMV initializes the camera and acquires image frames through the sensor module. Camera initialization includes sensor reset and configuration of the pixel format and image size. Automatic white balance is disabled to reduce the effect of color drift on detection based on preset thresholds. After initialization, OpenMV continuously captures frames in the main loop. Color blob detection and servo angle updates are performed on each frame to achieve pan and tilt tracking control. Table 2 lists the pixel format, image resolution, and frame skipping setting used during the warm-up stage of image acquisition.

Table 2

Image Acquisition and Operating Parameters

Parameter	Setting Value
Pixel format	RGB565
Image size	QQVGA 160 × 120
Frame-skipping warm-up	10frames
Automatic white balance	Disabled

Color blob detection is carried out on every single frame by the system after a steady image stream is acquired, and the pre-set LAB color threshold is applied in this process. Pixels are screened by the find_blobs() function based on the given threshold, connected regions that meet the detection condition are sorted into different groups. A group of candidate blobs is formed by the obtained regions. Candidate blobs are represented by bounding rectangles, and their centroid coordinates are output as position observations; the pixel discrimination rule is expressed in Equation (1).

To reduce target drift when multiple candidates are present, the system determines the primary target blob using the maximum bounding-rectangle area criterion, as shown in Equation (2), where w_k and h_k denote the width and height of the bounding rectangle of the k-th candidate blob, respectively.

$$M(x,y) = \begin{cases} 1, t_1 \le L(x,y) \le t_2, t_3 \le a(x,y) \le t_4, t_5 \le b(x,y) \le t_6 \\ 0, otherwise \end{cases} \quad (1)$$

Let $L(x,y)$, $a(x,y)$, and $b(x,y)$ denote the values of the three LAB color channels at pixel (x,y). The intervals (t_1,t_2), (t_3,t_4), and (t_5,t_6) represent the calibrated threshold ranges for the L, a, and b channels, respectively.

$$k^* = \underset{k}{\operatorname{argmax}} S_k, S_k = w_k \cdot h_k \quad (2)$$

After the individual target is determined, the system outputs the bounding rectangle and centroid coordinates as tracking results. The bounding rectangle is represented by the four-tuple (x,y,w,h), and conversion between the top-left and bottom-right coordinates is given in Equation (3). The centroid coordinates are obtained from color blob object processing and are used to characterize the target position in the current frame.

$$(x_1,y_1) = (x,y), (x_2,y_2) = (x+w, y+h) \quad (3)$$

To keep the target animal near the center of the field of view, the centroid deviation is calculated with the image center as the reference point. The control signal is then obtained through PID computation. The pitch error is defined as positive upward. The control signal is used to update the pan and tilt servo angles, thereby driving the pan-tilt unit to adjust and gradually return the target to the image center region, as defined in Equation (4). Here, c_x and c_y denote the centroid coordinates of the target, W and H are the image width and height, and w and h represent the width and height of the target bounding rectangle.

$$e_{pan} = c_x - \frac{W}{2}, e_{tilt} = c_y - \frac{H}{2} \quad (4)$$

In the single-target tracking scenario, the system selects the connected region with the largest area among the candidate blobs in each frame as the target marker and outputs its bounding rectangle and centroid coordinates. For visualization and debugging, the circular marker is enclosed by a bounding rectangle in each frame, and a cross marker is drawn at the centroid position to visualize detection and tracking status. The detection and annotation effects are shown in Figure 3.

Fig. 3 - Example of color blob detection with centroid visualization

Target Tracking Based on Audio Information

The system uses a K210 microphone array module as the acoustic sensing unit. The module receives audio information from the feeding area and the surrounding space and determines the direction of the sound source. The main controller is connected to the microphone array through the I^2S digital audio interface. A multichannel synchronous sampling path is built through this connection. Audio signals from different spatial positions can be received at the same time in this way. Multichannel synchronous sampling also provides basic support for sound source direction judgment. The directional information obtained from this process helps realize stable rough target positioning. It works under the conditions of weak light, blocked targets, or incomplete field of view information.

Two main functions are fulfilled by the K210 microphone array in this system. Multi-channel audio signals are collected by this module. The sound source direction of the target animal is calculated based on these signals. This direction information can reflect the position changes of the target's activity area. It provides early direction reference for the rotation of the camera and pan-tilt. The cost of video data collection is reduced in this way. The continuity of monitoring work is improved at the same time. Sound events can also reflect the activity state of the target animal. These events mainly include animal calls and collision noises generated during the feeding process. All kinds of related data are recorded by the system within the same feeding window. These data cover audio direction data, individual identity, body weight and environmental parameters. These records enrich the description of the animal's feeding state. They also provide reference for research on feeding quantity adjustment and related management applications.

The reproducibility of system integration needs to be guaranteed. For this purpose, the interface connections between the K210 microphone array module and the main controller are listed in Table 3. In addition to the I^2S audio signal lines, the module contains LED data and clock lines for directional display and on-site debugging.

Table 3

Pin Connections of the K210 Microphone Array Module

Module Pin	K210 Pin	Function Description
GND	GND	Ground
5V	5V	5 V power supply
BCLK	MIC_CK	I^2S bit clock
WS	MIC_WS	I^2S word select / frame sync
D0	MIC_D0	I^2S serial data output (Channels 0 and 1)
D1	MIC_D1	I^2S serial data output (Channels 2 and 3)
D2	MIC_D2	I^2S serial data output (Channels 4 and 5)
D3	MIC_D3	I^2S serial data output (center microphone channel)
LED_DA	LED_DA	LED data line
LED_CK	LED_CK	LED clock line

To obtain directional information from target animal sounds near the feeding area, the system calls the MIC_ARRAY function of the microphone array for multichannel audio acquisition. Real-time calculations are then performed on the K210. During operation, the system first obtains response intensities from different directions. The dominant direction of the sound source is displayed by the ring LED. Angle and operating status information are also displayed for on-site debugging and parameter calibration. Acoustic processing runs simultaneously with video acquisition, which allows sound and image information to be collected in parallel.

The sound source direction is calculated at fixed angular intervals of 30°. A threshold is first applied to the directional response intensities to remove directions with weak responses and reduce the effect of background noise. The reserved directional components are weighted and combined first. The main azimuth of the sound source is obtained through this step. Smoothing processing is performed afterwards. This step helps improve the stability of the output. Jitter during intermediate calculations is suppressed by recursive filtering. A moving average is used to process the final angle sequence. These two filtering operations prevent the output angle from changing frequently. These changes are caused by intermittent vocalizations or impulsive noise. The real-time response intensity in each angle range is used as the reference. The ring LED indicates the direction based on this reference. Continuous pointing toward the sound source is maintained. The smoothed azimuth angle is adopted as the servo steering input for this purpose. Approximate estimation of the sound source distance is required when distance reference information is needed. This work is completed with the installation calibration constant OneD_Distance. Relative changes of distance are reflected by the estimated distance. This estimated value is applied to reference display and steering control. This distance estimation is not suitable for high-precision ranging.

Servo Control

Some difficulties are caused by insufficient light or unstable target capture by the camera. To deal with these difficulties, the system applies the K210 microphone array to calculate the sound source direction. The calculated result is taken as the control input of the pan-tilt servo. The K210 acquires array audio signals through the I^2S interface and calculates the directional vector of the sound source in the horizontal plane based on directional energy distribution, thereby obtaining the azimuth angle. In addition, to suppress directional jitter caused by noise, recursive smoothing is applied to the directional vector components, and window averaging is applied to the output angle sequence to improve the stability of control inputs.

At the execution level, two servo control signals are configured as PWM outputs. The K210 timer generates control pulses on GPIO pins to drive the two degrees of freedom (pan and tilt) of the gimbal, enabling real-time pointing and maintenance toward the sound source direction. The system simultaneously outputs current directional information on the display and supports operating-mode switching via buttons. The servo PWM control flow is shown in Figure 4.

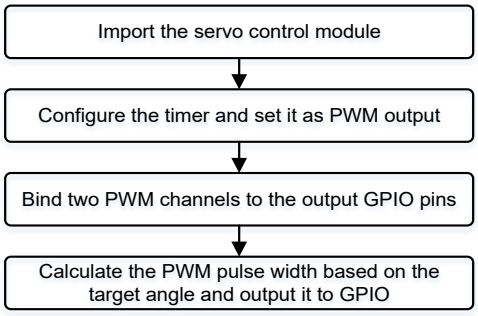

Fig. 4 - Servo control flow based on PWM

Automatic Feeding Module for Individual Identification

The intelligent feeding system is designed for large-scale captive breeding scenarios. Through a closed-loop process including individual identity confirmation, weight and status acquisition, feeding execution, and record uploading, the system realizes scheduled feeding at the individual level. Compared with manual feeding, this scheme can reduce human intervention and feeding errors and provide data support for subsequent growth assessment and traceable management.

Individual Information Acquisition Module

An RFID reader/writer module is installed near the feeding port to trigger identity recognition when an animal enters the feeding area. After obtaining the unique ear-tag number, the reader/writer uses it as an

individual index and binds it with acquired body weight, feeding status, and other information. These data are sent to the main controller or server through the wireless network, and feeding records as well as traceability data for multiple individuals are formed in the end.

Body Weight Information Acquisition Module

Body weight collection work is finished by the weighing module, and this module makes use of a load cell and a 24-bit A/D conversion chip (HX711) in the process. The load cell typically outputs a weak differential signal in the form of a Wheatstone bridge, while the HX711 performs high-gain amplification and high-resolution sampling and outputs digital values. During operation, the main controller reads sampled results at a fixed interval. To eliminate the dead weight of the scale body and installation bias, a tare operation is performed during initialization to record the no-load baseline value. During operation, the real-time sample value is differenced from the no-load baseline, and linear conversion is completed using a pre-calibrated proportional coefficient to obtain the current body weight. The final body weight result is bound to the RFID number read at the same moment and uploaded via the wireless network to the main controller or server for growth recording and feeding control.

Intelligent Feeder Module

(a) Structural diagram of the feeding device *(b) Detail view of the trough structure*

Fig. 5 - Structural diagram of the feeding device and trough

The feeding device and trough are illustrated in Figure 5. The device includes a storage hopper, a feed drop channel, a valve plate assembly, and a trough. An actuator rotates the valve plate so that the valve opening aligns with the feed outlet and the trough inlet at different operating stages. The position alignment controls the switching between feed discharge and closure. The valve changes the way of continuous manual material adding. The process becomes a set of adjustable opening and closing movements. The system uses identity checking and weighing results. It changes feeding ways for different individual situations.

For every single feeding event, the feeding parameters are figured out by the main controller based on the identified individual number and current body weight, and the computed result is changed into a valve plate angle command or an equivalent opening duration. The valve plate is adjusted and reset by the actuator as required by the control instruction. The controlled positioning process makes the feeding amount and feeding time repeatable. The valve plate is rotated in separate stages by the drive motor, and this action adjusts the feed output and pushes the whole feeding process forward. The angle control of the valve plate follows the alignment restrictions between the valve plate and the openings.

Environmental Data Acquisition Module

Light, temperature and humidity in the feeding region can affect animal activity and feeding status. Sensors for light, temperature and humidity are installed around the feeding place. These sensors are used to keep records of these environmental conditions. These sensors test light intensity, air temperature and air humidity at fixed time intervals. After the system begins to work, the main control device gets the sensors ready. It collects data from these sensors at regular periods. The system checks and changes the gathered data first. Then the data are shown on local equipment or sent through the communication device.

Light intensity is measured by the system using a BH1750 digital light sensor, and the collected data are sent through the I^2C bus. During initialization, the system configures the I^2C pins and the operating mode of the sensor. During data acquisition, the main controller first checks the device acknowledgment to confirm normal bus communication. The measurement result is then read and converted into a light intensity value that represents the illumination condition of the feeding area. The DHT11 sensor is used to collect temperature and

humidity data, and the whole collection process follows a single-wire timing protocol. During sampling, the main controller first sends a start signal. The data frame is then read according to the specified timing and checked for validity. When verification is successful, the temperature and humidity values are parsed. The sensor should be installed away from heating elements to reduce the effects of local heat sources and structural heat dissipation. Adequate air circulation should also be maintained around the sensor. The installation arrangement improves the stability and representativeness of the measurements. Figure 6 shows the flowchart of the light acquisition module, while Figure 7 shows the flowchart of the temperature and humidity acquisition module.

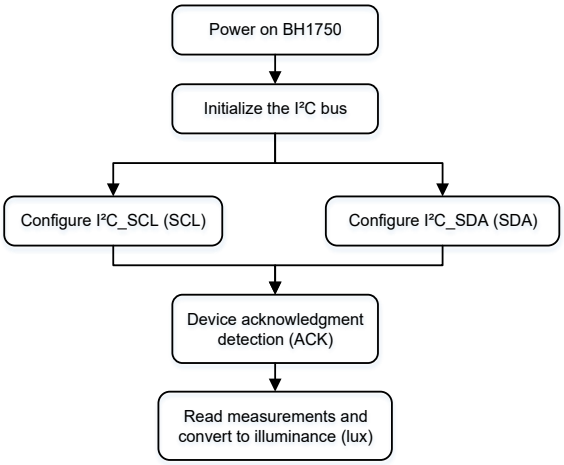

Fig.6 - Flowchart of the Light Control Module

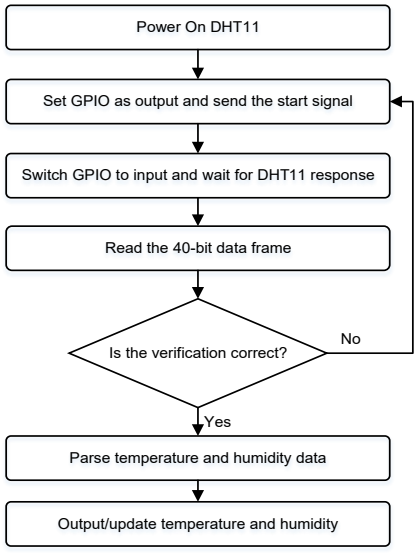

Fig. 7 - Temperature-Humidity Sensor Module Flowchart

Remote monitoring and control of the feeding device are implemented through an ESP8266 wireless communication module. The ESP8266 connects to the main control board through a serial interface and accesses the local area network in the feeding area. After startup, the module completes network access and establishes an MQTT connection with the IoT platform through the TCP-based MQTT protocol. The system publishes environmental parameters and other operating data to upstream topics at fixed intervals. The platform receives the published data for storage and interface display. The device also subscribes to downstream topics and receives control commands from the mini-program. The received commands support remote control and parameter configuration. Uploaded data are organized into structured fields. The fields include key environmental parameters such as temperature, humidity, and illumination. Device operating status fields may also be included. The structured format facilitates data parsing, storage, and trend visualization on the platform. The mini-program sends control messages to the device through the platform. After receiving a message, the device parses the command and performs the corresponding action or parameter update. Basic exception handling is included to support stable field operation. The communication module retries the connection after a connection failure and reconnects after a disconnection. The retry and reconnection mechanisms maintain the availability of data reporting and control links during network fluctuations.

Software Design of the Feeding System

The WeChat mini-program is taken as the interface for information aggregation and user interaction in this system. This platform offers centralized data display and remote control for livestock breeding, and it supports the combined workflow of production and marketing. For the hardware part, data from multiple sensors are collected by the STM32, and the operation of devices is also controlled by it. Wireless network connection and data transmission are supported by the ESP8266. The collected data are shown on the WeChat mini-program, and related control functions are also provided on it. Feeding information, body weight data, images and environmental data collected in the feeding area are sent to the mini-program at the same time. The information can be viewed and managed by users in real time. This integrated data flow helps realize precise feeding, and it also cuts down the waste of feed.

The device connects to a router or mobile hotspot through the ESP8266 and establishes an MQTT connection over TCP. The hardware publishes sensor data and device status to the pcTopic topic. The cloud server mqtt1tbtb.xyz forwards the published messages. The WeChat mini-program subscribes to pcTopic to receive and display the data. The mini-program also sends MQTT control commands for the remote operation of devices such as buzzers and lighting LEDs.

Client Side

The client interface is available to users and provides a unified entry point for product selection, intelligent services, and reservation services. The mini-program contains five pages, namely Home, Category, Recognition, Reservation, and Personal Center. The Home page brings together the main functions of the platform, including the animal encyclopedia, animal feeding, video monitoring, AI animal recognition, and AI-powered question answering. Users can quickly access remote feeding, status viewing, image recognition, and health service functions from the Home page. The Category page uses a layout with categories on the left and item lists on the right to display animals and related supplies. Users can add items to the shopping cart and complete checkout, forming a complete process from product browsing to order placement. The Recognition page allows users to upload an image by taking a photograph or selecting one from the album. The page then returns the pet recognition result and corresponding basic information. The Reservation page provides access to medical consultation and home service appointments. Users can complete and submit reservation information and review previous reservation records. The Personal Center provides the login entry and includes order viewing, About Us, online customer service, and sharing functions. Figure 8 presents the functional structure of the client interface.

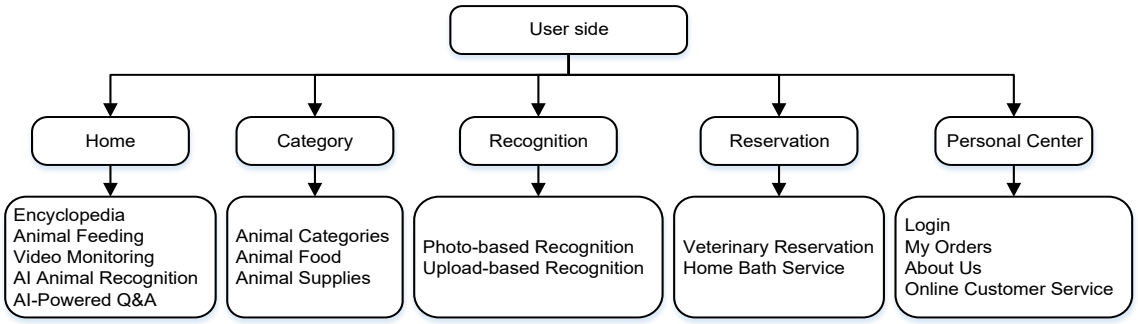

Fig. 8 - Functions of the client-side app

Deployment Side

This module serves to monitor and manage feeding work and surrounding environment in large-scale breeding sites in a unified way. A variety of sensing devices and video shooting devices are set up around feeding zones. These devices can work nonstop to gather various data. The collected information includes temperature, moisture, light intensity, animal weight and other related breeding indicators. Individual data and environmental data for each animal are aggregated using individual identifiers as indices, enabling feeding personnel to grasp group status in real time and providing a basis for subsequent intelligent feeding decisions and data analysis.

After data association is established between the mini-program and field devices, device acquisition results are synchronously transmitted to the mini-program for display. Uploaded data mainly include feeding information, body weight information, environmental information, and image information captured by the camera. Users can centrally view and compare state changes on the page, thereby assisting in feeding amount adjustment and management strategy optimization, reducing feed waste, and improving management efficiency. The deployment-side data acquisition and classification architecture is shown in Figure 9.

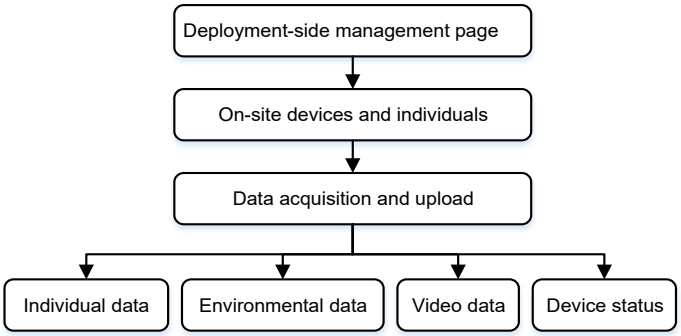

Fig. 9 - Deployment-Side Data Acquisition and Classification Architecture

On the deployment-side interface, users can centrally view individual and environmental data and remotely control lower-level actuators. The system establishes a wireless network connection through ESP8266, allowing the lower-level device to access the cloud message service as an MQTT client. The device uploads collected temperature, humidity, illumination, body weight, and device operational status to the cloud at the configured interval, and the cloud forwards the data through fixed data channels. After the mini-program connects to the cloud, it continuously listens to the data channel and receives new data in real time to refresh the page display.

For the control link, operations such as turning on the buzzer and turning off lighting are sent by the mini-program to the cloud control channel. The lower-level device continuously listens to the control channel and, after receiving control content, determines the required action according to predefined control fields, then drives actuators such as the buzzer and LED to respond. After execution, the lower-level device can upload the latest status again for synchronization on the mini-program interface. The mini-program control flow for the lower-level device is shown in Figure 10.

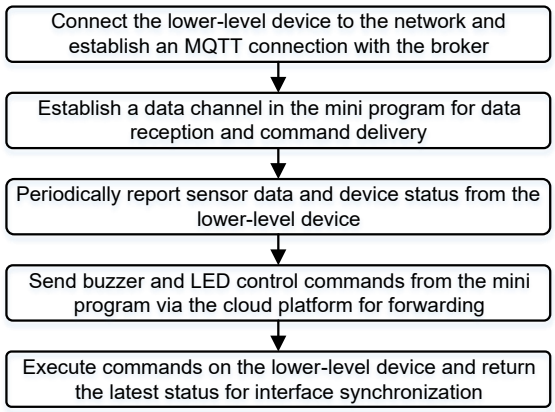

Fig. 10 - Mini-Program Control Flowchart for the Device Side

RESULTS

Test Results and Analysis

To verify the availability and trigger reliability of the system in practical feeding scenarios, comparative tests were conducted for (i) audio-video pointing and observation performance and (ii) feeding target confirmation and triggering performance. For the audio-video comparison, three experimental groups were set: video, audio, and audio and video. For the feeding trigger comparison, three experimental groups were set: RFID, weight, and RFID and weight. Each experimental group included 300 event-level trials. The final results were sorted and summed up based on the indexes shown in Table 4 and Table 5.

Table 4

Comparison Results of Audio-Video Pointing

Group	Configuration	Pointing Success Rate (%)	Loss Rate (%)	Mean Re-stabilization Time (ms)
A	Video	78.33	21.67	230
B	Audio	66.00	34.00	310
C	Audio and Video	92.67	7.33	145

The share of test runs with stable pointing is called pointing success rate. The stable state is kept during the whole fixed observation period. The loss rate describes the percentage of test cases. These cases include target loss or obvious direction error in pointing. The mean re-stabilization time refers to the average time required to restore stable pointing after target loss. It is used to rebuild stable pointing after the target is lost. Three hundred event-level test runs were arranged in each experimental group.

Three key indexes of the three test schemes are shown in Table 4. They are pointing success rate, loss rate and average re-stabilization time. For the video test group, the pointing success rate reached 78.33%. The loss rate of this group was 21.67%. The average re-stabilization time was 230 ms. For the audio test group, the pointing success rate was 66.00%. This rate was lower than the video group. The loss rate of the audio group reached 34.00%. This rate was higher than the video group. The average re-stabilization time was 310 ms. It was also longer than the video group. The test result of the audio group shows that only sound direction cues cannot offer enough stability. They cannot support stable pointing and continuous observation well. The test group using both audio and video got the best test effect. Its pointing success rate rose to 92.67%. The loss rate fell to 7.33%. The average re-stabilization time was reduced to 145 ms. When the target cannot be seen for a short time, or the pointing direction goes wrong, audio information can offer direction guidance. It helps to make the re-stabilization time shorter. After the target comes into the view range, video information provides clearer position feedback. It helps to keep pointing more stable. Using audio and video together obviously reduces the loss rate. It also increases the proportion of stable pointing. This improved performance makes on-site observation and debugging more continuous.

Table 5

Comparison Results of Feeding Target Confirmation and Triggering

Group	Decision Method	Trigger Accuracy (%)	Misdelivery Rate (%)	Missed-feeding rate (%)	Mean Trigger Delay (ms)
A	RFID	92.00	2.00	6.00	300
B	Weight	82.33	6.67	11.00	2500
C	RFID and Weight	93.33	2.00	4.67	2200

Trigger accuracy is defined as the proportion of cases in which the system successfully executes feeding when the target animal has arrived and the RFID identity matches. The misdelivery rate is defined as the proportion of cases in which feeding is still executed when the target has not arrived or the RFID identity does not match. The missed-feeding rate is defined as the proportion of cases in which the target animal has arrived and the identity matches, but the system does not execute feeding. Trigger delay is defined as the average time from the moment the animal arrives and is successfully recognized to the start of feeding execution. For the weight group, the trigger condition was that the weight reading exceeded a threshold and satisfied a stability-window condition. Identity matching was used only for statistical evaluation, with RFID used as the ground-truth label, and RFID did not participate in trigger decision-making for the weight group. Each experimental group included 300 event-level trials.

Table 5 reports the trigger accuracy, misdelivery rate, missed-feeding rate, and mean trigger delay for the three decision methods. For the RFID test group, the correct trigger rate was 92.00%. The wrong feeding rate was 2.00%. The missed feeding rate was 6.00%. The average trigger delay time was 300 ms. These test data show that RFID can finish target confirmation quickly. However, missed feeding may still occur. This situation appears when the animal does not stay in a stable position. It also happens when RFID signal reading conditions are influenced. For the weight test group, the correct trigger rate was 82.33%. The wrong feeding rate reached 6.67%. The missed feeding rate was 11.00%. The average trigger delay time was 2500 ms. The trigger delay time increased obviously. Both the wrong feeding rate and the missed feeding rate remained at relatively high levels. The unstable body posture of animals causes fluctuations in weight reading values. For this reason, the judgment method that only uses weight threshold has clear shortcomings. It has difficulty balancing trigger speed and trigger correctness. For the test group using both RFID and weight detection, the correct trigger rate rose to 93.33%. The wrong feeding rate fell to 2.00%. The missed feeding rate dropped to 4.67%. The average trigger delay time was 2200 ms. The results of the combined test show that RFID confirmation works effectively. It can reduce the risk of wrong feeding caused by target matching errors. Weight information improves the reliability of arrival determination. Although the joint decision sacrifices some triggering speed, it significantly improves trigger accuracy and feeding reliability and is therefore more suitable for long-term field operation.

Taken together, the two sets of comparative results indicate that the combined audio and video configuration improves the continuity of pointing and observation, reduces loss, and shortens re-stabilization time, whereas the combined RFID and weight decision improves feeding trigger accuracy and reduces misdelivery and missed delivery. These findings demonstrate that the system has good engineering usability under field conditions and can support target confirmation, information acquisition, and feeding execution during the feeding process.

Each of the 300 tests in every group was treated as one complete system event. After each event, the current decision state was cleared to minimize carryover between successive tests. Therefore, the results represent repeated observations at the system event level. The higher pointing success rate and shorter re-stabilization time obtained with the combined audio and video configuration may be explained by the complementary roles of the two information sources under different observation conditions. Visual information provides relatively accurate positional feedback when the target is clearly visible. Acoustic information is not used for precise localization. Instead, it provides a directional reference for pan-tilt reorientation when visual tracking is temporarily degraded or the target is lost. Previous studies have shown that variations in illumination, animal posture, and environmental conditions can affect the stability and generalization of visual monitoring systems in pigs *(Scaillierez et al., 2024; Han et al., 2023)*. The present results further show that acoustic directional information can provide supplementary cues when visual observations are limited, thereby improving monitoring continuity. This finding is consistent with previous studies on the complementary use of audio and visual information in animal monitoring *(Yang et al., 2025)*. In the feeding trigger process, RFID and weight information correspond to identity verification and arrival confirmation, respectively. Previous studies have commonly used RFID-based systems for individual identification and feeding behavior recording *(Funk et al., 2024)* or weighing devices to acquire body weight information *(Decarie et al., 2025)*. In the present system, both signals are incorporated into the same trigger decision. Feeding execution is therefore constrained by both individual identity and physical arrival at the feeding position. This approach was associated with improved trigger reliability in the present tests, although the stability check for the weight signal also increased trigger delay. Overall, the results indicate that the multisource information coordination mechanism improved monitoring continuity and feeding trigger reliability, thereby supporting the feasibility and operational reliability of the prototype system.

CONCLUSIONS

To meet the requirements of refined feeding and traceable management, this study designed and implemented an intelligent animal feeding system based on multisource information acquisition. The system uses STM32F103ZET6 as the control core, incorporates visual and audio sensing units, and integrates RFID-based identity recognition, weighing, and environmental parameter acquisition modules. When an animal enters the feeding area, the system can perform target monitoring and localization, individual identity confirmation, and acquisition of body weight and environmental parameters, and can upload the acquired results together with feeding execution status to form multi-target feeding records and a remote management link, thereby providing a feasible data basis for subsequent physiological assessment and traceability applications.

(1) The system uses an OpenMV camera to detect color blobs with preset color thresholds and to control pan and tilt tracking. A K210 microphone array provides directional information about the sound source. The acoustic direction is used to maintain target pointing when illumination is weak or camera observations are unstable. The combined sensing method improves continuous monitoring under complex lighting and occlusion conditions. Under the combined audio and video configuration, the pointing success rate was 92.67%, the loss rate was 7.33%, and the mean re-stabilization time was 145 ms.

(2) In multi-target feeding scenarios, an RFID reader and writer module at the feeding port obtains each animal's unique ear tag number, while an HX711-based weighing unit collects body weight information. Identity and body weight are then synchronously associated as key variables for each feeding event. The system also controls the feeding mechanism for individualized feeding. This changes feeding from a manual, experience-based process into one that is controllable, recordable, and reproducible. The workflow provides an implementation path for individualized and differentiated feeding. Under the combined RFID and weight configuration, the trigger accuracy was 93.33%, the misdelivery rate was 2.00%, the missed-feeding rate was 4.67%, and the mean trigger delay was 2200 ms.

(3) Different kinds of environmental data like temperature, humidity and light are collected by this system. Network connections are built through the ESP8266 device. MQTT is used to finish uploading data and sending commands. The WeChat mini-program serves as the information aggregation and interaction interface, enabling visualization of feeding records and body weight/environment trends, and supporting remote control and parameter configuration. Through multisource data acquisition and interaction, the system enables end-to-end monitoring and management.

Future work may introduce target tracking and re-identification algorithms to maintain continuous individual tracking in multi-target scenarios, reduce identity interruption caused by occlusion and interaction, and preserve individual identity as much as possible during unstable card reading or short-term occlusion. To enrich animal state information, non-contact sensors such as infrared and radar can be added to the existing device and aligned/fused with existing video and audio data to form more complete multi-target datasets. Based on continuously accumulated multisource data, animal health status can be predicted, health anomaly detection and risk alerts can be performed, and feeding adjustment recommendations can be generated, thereby further improving the level of refined management.

ACKNOWLEDGEMENT

ABSTRACT
Research on electric tractors has expanded rapidly; however, previous reviews have generally examined energy sources, powertrains, intelligent control, and supporting infrastructure separately. This narrative review establishes an integrated technology-chain framework encompassing energy supply, electric drive systems, energy management, power take-off (PTO) and hitch control, autonomous operation, simulation, standardization, and industrial deployment. The available evidence was synthesized and compared in terms of system performance, advantages, limitations, and technological maturity. The results indicate that battery-electric systems can reduce energy consumption and life-cycle environmental impacts but remain constrained by limited operating endurance, high battery costs, thermal-safety risks, and insufficient charging capacity. Hybrid and fuel-cell powertrains offer greater adaptability to varying operating conditions but introduce additional system complexity. Future research should prioritize standardized duty cycles, integrated simulation frameworks, modular energy-replenishment systems, reliability testing, and interoperability standards.

摘要
电动拖拉机研究发展迅速，但既有综述通常将能源来源、动力系统、智能控制和配套基础设施割裂讨论。本研究采用叙述性综述方法，建立了涵盖能源供给、电力驱动、能量管理、动力输出轴与悬挂控制、自主作业、系统仿真、标准体系及产业化应用的技术链框架，并从性能、优势、局限和成熟度等方面比较相关证据。结果表明，纯电动系统能够降低能源需求和全生命周期环境影响，但仍受续航能力、电池成本、热安全与充电能力制约；混合动力和燃料电池路线可提高工况适应性，却增加系统复杂性。未来应重点推进标准化作业循环、集成仿真、模块化能源补给、可靠性测试及互操作标准。

INTRODUCTION

Agricultural tractors must deliver high tractive power and power take-off (PTO) output under strongly variable loads, while reducing fossil-fuel use, local air pollutants, and greenhouse-gas emissions. Electric powertrains offer high conversion efficiency and precise torque control, but their benefits depend on the electricity mix, battery manufacture, duty cycle, and charging strategy. Life-cycle studies have reported substantial reductions in climate and resource impacts for battery-electric field systems, while also identifying battery production, purchase cost, mass, and operating range as important trade-offs *(Lagnelˆ v et al., 2021; Mousazadeh et al., 2011; Vogt et al., 2021)*.

This review used a structured narrative-synthesis protocol. Peer-reviewed English- and Chinese-language studies were identified in Web of Science Core Collection, Scopus, and CNKI using terms related to electric and hybrid tractors, batteries, electric drives, energy management, PTO/hitch control, autonomous navigation, and simulation. Searches prioritized 2015-2026 publications; earlier landmark prototypes, control methods, and life-cycle assessments were retained, and backward citation searching supplemented the results.

Studies were included when they addressed tractor-specific architecture, components, modeling, control, field testing, environmental performance, or deployment economics and supplied sufficient evidence for comparison. Because tasks, power classes, and metrics were heterogeneous, the evidence was grouped by technology chain and compared using reported indicators, advantages, limitations, and maturity rather than pooled statistically.

Unlike previous reviews focusing on individual subsystems or the status of domestic technological development *(Liu et al., 2022; Liu H.L. et al., 2024; Wang L. et al., 2025)*, this study links component-level advances to whole-vehicle integration and deployment readiness. It compares powertrain architectures; evaluates batteries, electric drives, energy management, PTO and hitch control, autonomous navigation, and simulation methods; and identifies cross-cutting bottlenecks to establish a staged research agenda. The proposed framework distinguishes laboratory-scale advances from field-ready capabilities.

Table 1

Literature retrieval and screening framework

Review stage	Database / source	Search topic	Selection criteria	Analytical use
Database retrieval	Web of Science Core Collection; Scopus; CNKI	Electric and hybrid tractors; batteries; electric drives; energy management; PTO/hitch control; autonomous navigation; simulation	Peer-reviewed English- or Chinese-language studies; priority period 2015–2026	Identify tractor-specific technical, environmental, and deployment evidence
Supplementary retrieval	Backward citation searching	Landmark prototypes, control methods, and life-cycle assessments	Earlier studies retained only when foundational to technological evolution	Trace development stages and preserve seminal evidence
Eligibility screening	Title, abstract, and full-text review	Architecture, components, modeling, control, field testing, environmental performance, and economics	Tractor-specific scope and sufficient quantitative or qualitative evidence for comparison	Exclude non-tractor studies and records with insufficient comparative evidence
Evidence synthesis	Included studies	Reported performance, advantages, limitations, and indicative maturity	Grouped by technology chain; no statistical pooling because tasks and metrics were heterogeneous	Support comparative tables, bottleneck analysis, and the staged research agenda

Although electric tractors have achieved notable advances in diversified power supply and intelligent control, they still face practical challenges in operational adaptability, high manufacturing costs, and large-scale industrial promotion. Focusing on key common technologies, core industry bottlenecks, and actual agricultural production needs, this study aims to advance the industrialization and practical application of electric tractors. The main research contents are as follows.

(1) Development overview: The technological evolution of electric tractors is reviewed across three generations, with emphasis on their technical configurations, characteristics, and limitations. Domestic and international development models are compared, and diversified powertrain and energy-supply technologies, including hybrid and solar-energy systems, are evaluated. This analysis clarifies the evolution of electric tractor technologies and provides a basis for improving operating endurance and adaptability to different applications, thereby supporting a differentiated development strategy for China's electric tractor industry.

(2) Core power technologies: Optimization strategies and technological advances in traction batteries, electric drive systems, energy management, and power coordination are examined to establish an integrated pathway for powertrain development.

(3) Intelligent control: Electric power steering, active suspension, autonomous navigation, and system simulation are reviewed to improve adaptability to field conditions and operational performance.

(4) Standard system and industrialization: Bottlenecks related to technologies, key components, standards, and supporting infrastructure are identified, and pathways toward industrialization are proposed to facilitate large-scale adoption.

Overall, this review supports technological innovation and industrial upgrading in the electric tractor sector, thereby contributing to the mechanized, intelligent, and environmentally sustainable development of agriculture in China.

TECHNOLOGICAL EVOLUTION AND POWER-SUPPLY CONFIGURATIONS

Development history and representative tractor models

The development of electric tractors falls into three stages. From the early 20th century to the 1970s was the wired power supply stage: Harbin Songjiang Tractor Factory developed China's first "Dianiu 28" electric tractor, powered by transmission lines with a 28 kW rated output, pioneering domestic research *(Yu et al., 2024a)* but not widely used due to grid limitations. From the 1970s to the early 21st century, it shifted from wired power to on-board batteries, enabling wheel driving and power take-off shaft control, with initial promotion driven by energy storage technology. Since the early 21st century, high-density battery technology has supported long-time light-load operation; intelligent functions and unmanned driving based on path planning have matured. Electric tractors covering a wide range of power ratings are currently being developed by numerous manufacturers *(Han, 2023)*.

International research has progressed from solar-assisted and battery-powered prototypes to autonomous platforms, hybrid powertrains, and farm-level energy planning. In addition to the life-cycle and farm-system analyses summarized above, prototype- and system-level studies have investigated tractor electrification, autonomous field robots, parallel-hybrid control strategies, hardware-in-the-loop validation, and series-hybrid powertrain sizing *(Dalboni et al., 2019; Estevez et al., 2024; Ghobadpour et al., 2021; Ghobadpour et al., 2022; Grimstad and From, 2017; Mocera and Somà, 2020; Mocera, 2021; Pedersen et al., 2006; Rosales et al., 2022; Ueka et al., 2013)*. Collectively, these studies demonstrate the technical feasibility of electric agricultural machinery; however, operating endurance under field conditions, implement integration, charging logistics, and economic viability remain dependent on the specific application.

Research and product development in China have pursued battery-electric, diesel-electric hybrid, and hydrogen fuel-cell technologies in parallel. High-power hybrid prototypes have focused on sustained operation under heavy loads, whereas smaller battery-electric tractors have been developed primarily for greenhouse, orchard, and transport applications. Representative projects have advanced dual-motor power coupling, electronically controlled continuously variable transmissions, distributed drive systems, and tractor-specific energy-management strategies *(Feng et al., 2023; Li et al., 2023; Wen et al., 2025)*. A major advantage is the ability to leverage the existing agricultural-machinery supply chain for rapid technological development. However, validation across diverse operating conditions remains limited, some high-end components still depend on imports, and charging and maintenance infrastructure is unevenly developed. Representative products are presented in Fig. 1.

(e) HB2204 *(f) E3404-8H* *(g) ET14100* *(h) E904i*

Fig. 1 - Representative electric tractor models developed in China and other countries

The comparison indicates that powertrain selection depends primarily on the duty cycle rather than following a uniform geographical pattern. Battery-electric systems are the most technologically mature option for low- and medium-power tasks with predictable daily energy requirements. Hybrid systems retain an advantage in prolonged, high-load operations, whereas hydrogen fuel-cell systems remain at the prototype or early demonstration stage because their potential vehicle-level benefits must be weighed against the challenges associated with hydrogen production, storage, and distribution.

Accordingly, Table 2 compares representative tractor platforms in terms of powertrain type, reported performance, advantages, limitations, and suitable applications.

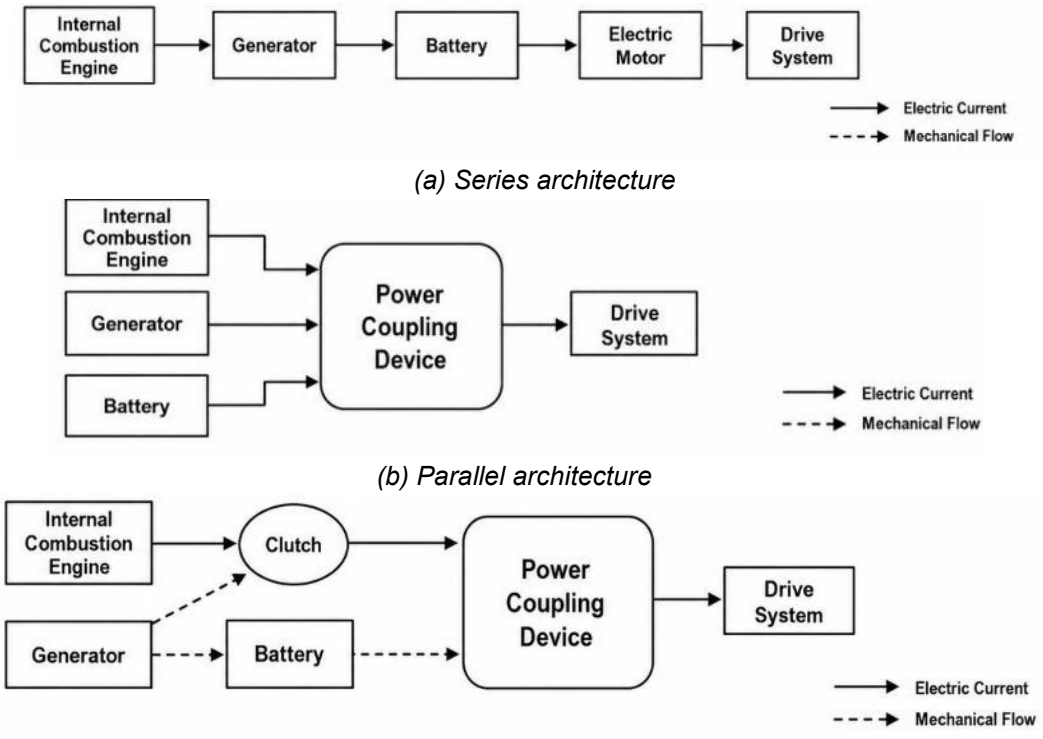

Table 2

Representative electric tractor platforms and their application characteristics

Representative platform	Power train or energy-supply type	Reported performance	Main advantage	Main limitation	Suitable application	Technology maturity
Dianiu 28 *(Yu et al., 2024a)*	Cable-powered electric	Rated power: 28 kW	Continuous power supply	Grid and cable restriction	Fixed-area work	Historical prototype
Solar-assisted prototype *(Mousazadeh et al., 2011)*	Solar-assisted battery-electric	≈14 t CO_2-eq annual reduction in case study	Lower life-cycle impact	Cost, mass and range	Light duty / demonstration	Prototype
Unmanned platform *(Chen et al., 2022)*	Battery electric; dual motor	2 × 7.5 kW; ≥3.5 h	Compact autonomous operation	Low power and endurance	Orchards / protected farming	Field prototype
Autonomous fleet *(Lagnelˆv et al., 2021)*	Battery-electric fleet	102 vs 293 kg CO_2-eq ha^{-1} y^{-1}	Life-cycle benefit	Charging coordination	Predictable field schedules	System simulation / pilot evidence
Terrain-aware platform *(Luo et al., 2024)*	Battery electric	Speed stability +45.09%; energy −9.51%	Terrain adaptation	Single test setting	Variable-soil traction	Field prototype
Field charging / exchange *(Wallander et al., 2025)*	Battery-electric farm system	Process time +5%; energy 37.5% of diesel	Near-diesel work rate	Grid and logistics sensitivity	Large coordinated farms	Farm-system modeling

Comparative assessment of diversified powertrain technologies

Electric tractor development in China currently integrates diverse powertrain and energy-supply technologies, including battery-electric, diesel-electric hybrid, biomass-based, solar-powered, and fuel-cell systems. These technologies are being explored to overcome the limitations of battery-electric tractors in terms of operating endurance and adaptability to different applications, and substantial progress has been achieved. However, the available technological options differ considerably in power performance, economic viability, environmental adaptability, and technological and industrial maturity.

(a) Series architecture

(b) Parallel architecture

(c) Power-split architecture

Fig. 2 - Architectures of hybrid electric powertrains

Diesel-electric hybrid systems can reduce engine transients and extend endurance while retaining rapid refueling. Series architectures simplify mechanical transmission and permit flexible engine operation; parallel and power-split layouts can achieve higher peak efficiency but require more complex coordination. Recent studies have used life-cycle-cost analysis, dynamic programming, model-predictive control, fuzzy following control, and hardware-in-the-loop testing to compare architectures and operating strategies *(Beligoj et al., 2022; Mocera, 2021; Zhang et al., 2023; Yan et al., 2024; Zhao et al., 2024a, 2024b; Pascuzzi et al., 2024)*.

The evidence is promising but remains dominated by prototypes, simulations, or individual duty cycles rather than multi-season commercial operation.

Solar energy is more viable as an auxiliary or farm-level energy source than as the sole source of traction power. Vehicle-mounted photovoltaic panels can supply low-power auxiliary systems and extend operating time, whereas rooftop or field-edge photovoltaic installations can provide electricity for battery charging or swapping stations. A solar-assisted plug-in hybrid tractor prototype achieved lower annual life-cycle emissions but remained constrained by battery weight and limited operating range *(Mousazadeh et al., 2011)*. Farm-system simulations further indicate that coordinated charging and battery swapping can maintain operational work rates while reducing energy consumption *(Wallander et al., 2025)*. Table 3 summarizes the advantages, limitations, and technological maturity of these solar-energy integration configurations.

Table 3

Comparison and technological maturity of solar-energy integration configurations

Integration configuration	Energy-system configuration	Reported performance	Main advantage	Main limitation	Technology maturity
Vehicle-mounted PV	PV + traction battery	Contribution to auxiliary power; tractor-specific field data remain limited	Utilizes otherwise unused vehicle surfaces	Area, shading, dust and mass	Concept / prototype
Solar-powered charging station	PV + stationary storage + charger	Output depends on solar irradiance and the sizing of the storage and charging systems	Separates solar-energy collection from the vehicle's available surface area	Land requirements and capital costs	Pilot / early deployment
Integrated farm-energy system	PV + grid + storage + fleet scheduling	Operational work rate depends on grid capacity, battery size, and logistical coordination	Supports multiple machines and peak-load management	Complex planning and seasonal use	System modeling / pilot

Biomass-derived fuels can utilize locally available agricultural residues and may reduce net fossil-carbon consumption. However, their relevance to electric tractors lies primarily in range-extender generators, farm microgrids, and hydrogen production rather than in the direct replacement of traction batteries. Studies of biodiesel, biomass gasification, and integrated biomass–solar systems have demonstrated the potential of locally sourced energy supplies *(Jing et al., 2025; Liu H., 2024; Sun et al., 2025; Wang D.G. et al., 2024)*. Nevertheless, feedstock logistics, gas-cleaning requirements, conversion efficiency, and seasonal feedstock availability limit their broader applicability. These technologies should therefore be evaluated at the farm-system level through comprehensive energy, emissions, and cost assessments.

Fuel-cell electric tractors offer fast refueling and high gravimetric energy density, but stack durability, hydrogen storage, thermal management, and fuel infrastructure remain decisive.

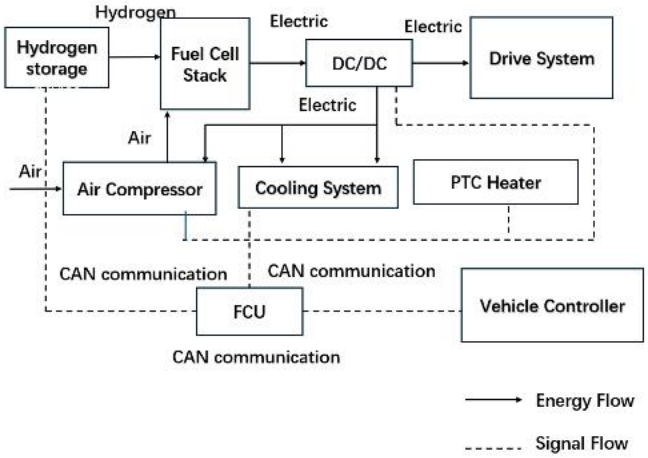

Fig. 3 - Fuel-cell electric tractor system architecture

Integrated electromechanical-hydraulic modeling has shown that optimized energy management can reduce hydrogen consumption and state-of-charge fluctuation under plowing and transport cycles *(Liu et al., 2023; Yu et al., 2024c; Zhang M. et al., 2025)*. Predictive control validated on a fuel-cell powertrain testbed also reduced damaging load cycling without sacrificing efficiency across three agricultural duty cycles *(Varlese et al., 2024)*. These results move the technology beyond concept analysis, but whole-tractor durability and farm-scale hydrogen supply still require field demonstration.

POWERTRAIN AND ENERGY MANAGEMENT TECHNOLOGIES

Battery systems and management

The power battery determines vehicle mass, available power, continuous operating time, thermal risk, and total cost. Lead-acid and nickel-metal hydride batteries retain niche advantages in cost or robustness, but lithium-ion chemistries dominate new electric-tractor designs because of their higher specific energy and cycle efficiency. Lithium iron phosphate prioritizes thermal stability and cycle life, whereas nickel-rich chemistries prioritize gravimetric energy density. Fig. 4 compares the principal performance trade-offs; the appropriate chemistry must be selected using task-level energy and peak-power demand, ambient temperature, packaging, and maintenance constraints rather than energy density alone.

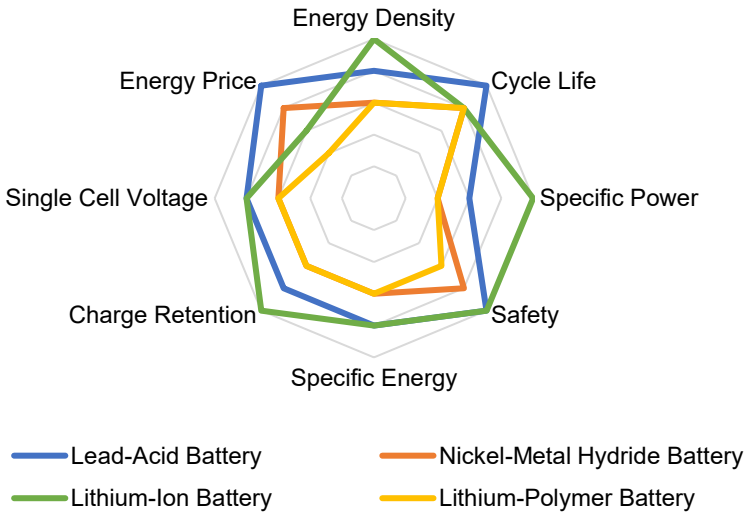

Fig. 4 - Comparison of battery technologies

Lithium-ion systems remain the practical baseline for current electric tractors. LFP cells are attractive for heavy-duty and harsh-environment applications because safety and cycle life are prioritized, while higher-energy chemistries can reduce pack mass for orchard, horticultural, and transport tasks. Battery sizing should also account for auxiliary hydraulic and PTO loads, which are often underrepresented when capacity is derived only from traction demand. Research on high-specific-energy systems and lithium-sulfur batteries indicates potential for future mass reduction, but field durability, cost, and safety validation remain incomplete *(Zhang et al., 2014; Wen et al., 2025)*.

Solid-state and sodium-ion batteries may eventually widen the feasible operating-temperature and cost envelope, but published tractor-specific evidence remains limited. Claims based on cell-level energy density cannot be transferred directly to pack or vehicle performance because structural protection, thermal management, state estimation, and power electronics add mass and losses. A defensible technology comparison therefore requires pack-level specific energy, usable depth of discharge, cycle life under pulsating loads, safety testing, and end-of-life recovery.

A tractor battery-management system must estimate state of charge and health, supervise voltage and temperature, balance cells, and enforce charge-discharge limits under rapidly changing traction, hydraulic, and PTO loads. The central challenge is not monitoring alone but reliable state estimation when current profiles, temperature, aging, and vibration differ markedly from standard road-vehicle cycles. Magneto-thermal coupling models have also been used to characterize battery temperature fields under dynamic loads *(Yang J.Q. et al., 2023)*.

Recent studies have combined filtering, power-frequency decomposition, condition recognition, and communication-network design to reduce battery peaks and improve energy allocation *(Xu et al., 2025; Xue et al., 2023; Zhang Q.H. et al., 2025)*. Data-driven estimators and digital twins can improve prediction, but they require representative field data, uncertainty bounds, and fail-safe behavior. Future validation should therefore report estimation error, computational load, aging sensitivity, and performance across multiple agricultural operations rather than a single simulated cycle.

Electric-drive architectures and control

Centralized drives preserve a conventional transmission path and therefore offer lower redesign cost, mature sealing and cooling, and straightforward maintenance. Their disadvantages are mechanical losses, limited independent wheel control, and reduced packaging flexibility. Distributed or wheel-side drives shorten the transmission path and enable independent torque allocation, but increase unsprung mass, sealing and thermal-management demands, controller coordination, and exposure to impact and mud.

For medium- and high-power tractors, dual-motor coupling provides an intermediate powertrain configuration that shifts motor operating points toward high-efficiency regions while maintaining mechanical robustness. Studies on the optimization of distributed-drive and coupled-drive systems have reported improvements in transmission efficiency and coverage of the operating range *(Li et al., 2023; Li et al., 2022)*. However, these comparisons are often based on different operating tasks and boundary conditions; therefore, the reported percentage improvements should not be considered directly transferable across systems or applications.

Motor selection must be matched to the actual low-speed, high-torque duty distribution. *Kwon et al. (2024)* found up to 7.9% difference in plowing energy consumption among motors with identical ratings but different efficiency-map distributions. This demonstrates that rated power alone is insufficient; frequent tasks, cooling limits, field-weakening operation, inverter losses, and gearbox ratios must be optimized jointly.

Distributed drive is therefore a promising architecture for precision traction and autonomous operation, but its present maturity is mainly prototype to early field-demonstration level. Centralized and coupled drives are more mature for near-term commercialization, especially where serviceability and component protection dominate the design decision.

Electric-drive control must maintain speed and traction while limiting wheel slip and energy loss under changing soil resistance. Rule-based and PID methods remain attractive for reliability and low computational demand, whereas fuzzy, observer-based, predictive, and learning-based controllers offer better adaptation at the cost of calibration, model, and validation burden.

Terrain-aware control provides a useful bridge between theoretical optimization and field operation. *Luo et al. (2024)* combined terrain-parameter identification, a sliding-mode observer, and optimal-slip control; hardware-in-the-loop and vehicle tests improved operating-speed stability by 45.09% and reduced total energy consumption by 9.51%. Other fuzzy and neural-network controllers have improved disturbance compensation, shift quality, and fault diagnosis *(Li Y. et al., 2024; Wang C.Y. et al., 2024; Yu et al., 2023; Yu et al., 2024b)*.

The main evidence gap is generalization. Many algorithms are evaluated on one soil, speed, implement, or simulated load. Future studies should disclose baseline controllers, sampling and computational requirements, uncertainty, and independent field validation across soil moisture, slopes, tire inflation, ballast, and PTO disturbances.

Hybrid power supply and energy management

A battery-supercapacitor hybrid energy-storage system separates energy demand from short-duration peak power. Passive topologies are simple but provide little control; semi-active topologies balance controllability, cost, and converter loss; fully active topologies provide the greatest power-allocation freedom but require two converters and more complex protection. Table 4 summarizes the functions, representative methods, benefits, limitations, and research priorities of key electric-tractor components and control systems.

Capacity sizing and control must be optimized together. Semi-active systems using fuzzy thresholds and genetic algorithms have reduced hourly power cost, while multi-objective allocation has reduced battery power fluctuation *(Li L.Q. et al., 2024a, 2024b; Xu et al., 2024)*. Deep-reinforcement-learning and predictive methods can further adapt power split to recognized agricultural conditions, but their robustness outside the training distribution remains a concern.

Table 4

Key electric-tractor components, control strategies, and research priorities

Component / strategy	Representative method	Reported indicator / advantage	Main limitation	Indicative maturity	Research priority
Battery and BMS	SOC/SOH estimation, balancing, thermal supervision	Reduces peak stress; safeguards usable energy	Aging, heat and limited field datasets	Commercial components; tractor validation developing	Pack-level safety and multi-season aging
Electric drive	Dual-motor coupling, terrain identification, slip control	Up to 7.9% motor-dependent plowing-energy difference; energy −9.51% in one terrain-aware test	Single-condition evidence and drivetrain complexity	Prototype to early field validation	Cross-soil and thermal validation
Hybrid storage	Semi-active DC/DC; fuzzy, optimization or predictive control	Buffers transient peak power and reduces battery fluctuation	Converter loss and sizing sensitivity	Laboratory / simulation to prototype	Joint sizing, aging and fault tolerance
PTO and hitch	Load following, force-position and fuzzy-PID control	Improves response and tillage-depth stability; metrics are not standardized	Impact loads and coupled dynamics	Prototype / subsystem field tests	Integrated standardized duty-cycle tests
Autonomous navigation	RTK-GNSS, sensor fusion, MPC and learning control	Centimeter-level guidance reported in controlled field studies	Perception uncertainty and functional safety	Field prototype; limited supervised deployment	Intervention, safety and energy metrics
Simulation / digital twin	Multi-domain models and HIL	Earlier controller verification and fault detection	Model fidelity and data interoperability	HIL established; digital twins emerging	Reusable models and parameter traceability

Semi-active topology is currently the most balanced research and prototype solution. Fully active systems may be justified for high-power tractors with severe load transients, whereas passive systems remain suitable only when cost and simplicity outweigh control performance. Technology selection should be supported by full-life-cycle converter loss, component aging, fault tolerance, and maintenance analysis.

Regenerative braking converts kinetic energy into electrical energy during deceleration, but tractor recovery potential is lower and more variable than in road vehicles because field speed is low, tire-soil adhesion is uncertain, and PTO or hydraulic loads may dominate the energy balance. Recovery control must therefore coordinate motor torque, friction braking, battery limits, wheel slip, and implement safety rather than maximize recovered energy alone. Fig. 5 summarizes the principal energy-management classes.

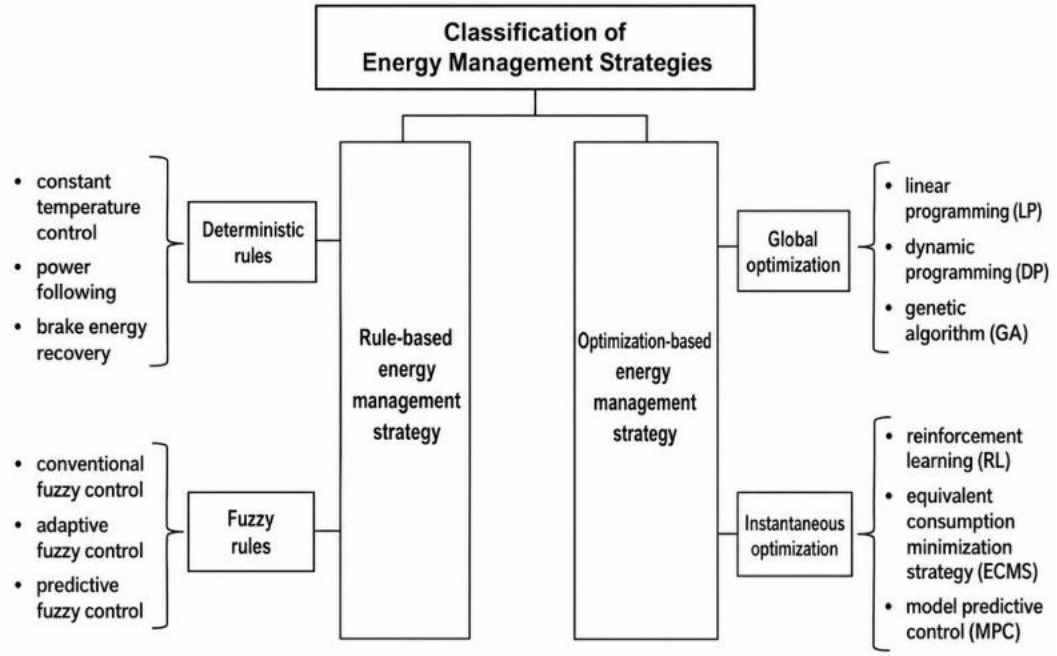

Fig. 5 - Classification of energy-management strategies

Rule-based strategies have low computational demand and predictable safety behavior, while model-predictive and learning-based methods can exploit load forecasts and repeated field patterns. International studies on off-road plug-in hybrids and parallel or series hybrid tractors report progress from offline global optimization toward operation recognition, predictive control, and real-time validation *(Ghobadpour et al., 2021; Mocera, 2021; Zhang et al., 2023; Yan et al., 2024; Zhao et al., 2024a)*. However, reported gains are not directly comparable because duty cycles, SOC boundaries, component maps, and baseline controllers differ.

Accordingly, advanced energy management should be evaluated against a transparent baseline using energy consumption, battery aging, hydrogen or fuel use, tracking error, computational time, and safety constraints. A numerical improvement obtained in one cycle is not sufficient evidence of technology readiness without real-time implementation and multi-condition field validation.

Current bottlenecks include weak adaptation to low-adhesion roads, saturation of battery charge acceptance during long descents, limited coordination among traction, hydraulic, hitch, and PTO subsystems, and the absence of standardized agricultural duty cycles. These gaps explain why many high-performing simulation strategies remain at laboratory or prototype maturity.

Agricultural operations require different combinations of vehicle speed, PTO speed, draft force, and hydraulic power. Adaptive strategies have improved cruising range, disturbance suppression, and PTO response *(Ding et al., 2024; Liao et al., 2024; Zhang et al., 2024; Zhou et al., 2024)*. Future controllers should identify the current operation and soil-load state online, but they must remain computationally lightweight and retain a validated fallback mode.

Power-output and PTO coordination

Electric tractors must divide available power among traction, PTO, hydraulic, and auxiliary loads. Mechanical coupling provides a direct and robust path for power splitting, whereas multi-motor architectures provide flexible electronic allocation. The latter can shift motor operating points and decouple traction from PTO speed, but increases inverter count, calibration effort, and fault-management requirements. A representative architecture is shown in Fig. 6.

Dual-motor coupling has expanded operating-mode coverage and improved plowing efficiency, but mechanical complexity and cost increase with the number of clutches and gear paths. Power-allocation strategies based on dynamic programming, Pontryagin's minimum principle, stochastic optimization, and load following have reduced equivalent fuel or energy consumption in specific tasks *(Li et al., 2019; Li T.H. et al., 2024; Zhang et al., 2023)*.

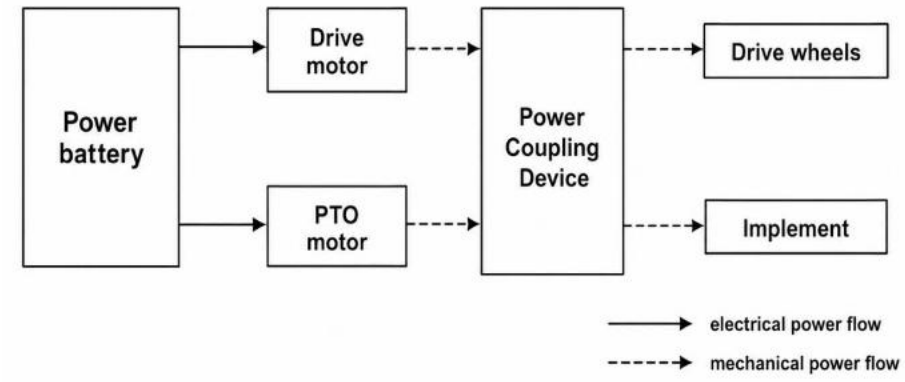

Fig. 6 - Power transmission system of the electric tractor

A key research priority is the integrated management of electrical, mechanical, hydraulic, and thermal systems, together with the development of standardized implement interfaces. Controller performance should be evaluated under simultaneous traction and PTO transients rather than only under steady-state loads. Evaluations should report torque reserve, PTO speed deviation, energy consumption, response time, and fault-recovery performance.

Load-following control is suitable for conventional operations involving variable draft; tractor–implement attitude coordination is required when working depth and posture determine agronomic quality; and multisource coupling is appropriate for high-power combined operations. These control modes are complementary rather than mutually exclusive. A field-ready system should switch between or blend them based on task recognition while maintaining slip, PTO speed, hitch position, and energy consumption within prescribed limits *(Xie et al., 2023; Yang F.Z. et al., 2023)*.

INTELLIGENT CONTROL AND DIGITAL DEVELOPMENT

Electric power steering replaces continuously driven hydraulic assistance with motor torque commanded from steering torque, angle, and vehicle-state signals. It improves controllability and enables automatic guidance, but agricultural deployment also requires high shock-load tolerance, sealing, redundancy, and safe manual fallback. Performance should be compared using steering effort, tracking error, response time, returnability, energy use, and fault behavior rather than road-feel metrics alone.

An electric hitch can regulate implement position and draft without continuous hydraulic throttling. Position, draft, and attitude feedback permit precise depth control, but motor and reduction mechanisms must withstand impact loads and contamination. Recent work has combined inclination sensing, force-position feedback, and fuzzy-PID coordination to improve body-implement attitude and tillage-depth stability *(Xie et al., 2024; Yang F.Z. et al., 2023; Zhang et al., 2022)*.

The main design trade-off is between the energy efficiency and controllability of electromechanical actuation and the overload capacity of hydraulics. Hybrid electro-hydraulic solutions may therefore remain preferable for high-power implements until compact actuators, impact protection, and thermal performance are validated.

Field evaluation should report depth error, draft-force fluctuation, settling time, energy consumption, mechanical temperature, and failure response across soil types and travel speeds. Without these common metrics, algorithm comparisons remain predominantly qualitative.

Autonomous navigation integrates GNSS/RTK, inertial sensing, perception, localization, path planning, and steering control. Early single-sensor guidance established the feasibility of automatic tractor steering, whereas later agricultural-robot studies emphasized modular platforms, sensor fusion, safety, task planning, and whole-farm economics *(Thuilot et al., 2002; Pedersen et al., 2006; Slaughter et al., 2008; Bechar and Vigneault, 2016; Grimstad and From, 2017; Shamshiri et al., 2018; Fountas et al., 2020; Lowenberg-DeBoer et al., 2020)*. For electric tractors, navigation accuracy must therefore be assessed together with energy use, implement performance, intervention frequency, and functional safety.

Linear, PID, optimal, model-predictive, and learning-based controllers provide different balances of computation, robustness, and curvature tracking. Recent tractor studies have used multi-body simulation, BeiDou/RTK, 5G monitoring, and resistance-adaptive control *(Jeon et al., 2023; Luo et al., 2025; Tian et al., 2024; Wang Q. et al., 2025)*. Commercial maturity is limited by obstacle perception, functional safety, remote supervision, and validation under dust, vibration, crop occlusion, and intermittent communication.

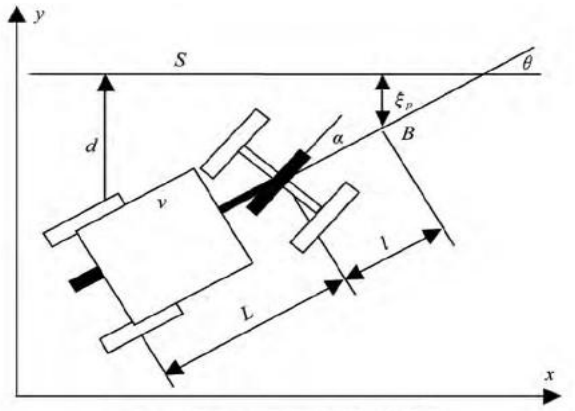

Fig. 7 - Tractor dynamic model

IoT integration can connect tractor, implement, operator, and service platform for condition monitoring and scheduling *(Wen and Wang, 2022; Zhao et al., 2023)*. However, interoperability, cybersecurity, data ownership, and degraded-mode operation must be treated as engineering requirements rather than later software additions.

System simulation and digital twins. General-purpose platforms such as MATLAB/Simulink, AMESim, ADAMS, AVL-Cruise, and multi-body tools support subsystem and vehicle development, but the literature still relies heavily on isolated models. Hardware-in-the-loop and model-based design have improved controller verification before field trials *(Mocera, 2021)*, while digital agricultural-robot platforms demonstrate the value of modular hardware and reusable software *(Grimstad and From, 2017)*. A tractor digital twin should link battery aging and thermal behavior with traction, PTO, hitch, hydraulics, navigation, and task-level energy demand, and should retain parameter provenance for reproducibility.

BOTTLENECKS AND DEVELOPMENT PRIORITIES

Technical, component, and infrastructure bottlenecks

First, continuous high-power operation remains constrained by pack mass, usable energy, thermal limits, and charging time. The relevant requirement is task energy per hectare or per workday, including PTO and hydraulic demand, rather than nominal vehicle range. Modular batteries, field charging, and exchange can reduce downtime, but require compatible interfaces and farm-level power planning *(Wallander et al., 2025)*.

Second, battery, motor, inverter, transmission, hydraulic, and PTO systems are still frequently optimized separately. Integrated optimization is needed to avoid response lag, oversizing, and energy transfer among subsystems. The absence of standardized agricultural duty cycles makes reported efficiency and endurance difficult to compare across studies.

Third, reliability evidence is weaker than performance evidence. Batteries, connectors, sensors, inverters, and distributed drives must tolerate dust, mud, water, chemicals, vibration, impact, and wide temperature ranges. Accelerated laboratory tests should be correlated with multi-season field data and accompanied by maintainability and fault-recovery analysis.

Components and standards. Tractor-specific component and interface standards remain incomplete. Communication, high-voltage safety, charging, battery exchange, electric implements, and diagnostic interfaces should be harmonized while permitting multiple power classes. Domestic localization should focus not only on nominal performance but also on consistency, sealing, thermal design, and service life.

Infrastructure and economics. Sparse rural charging, limited grid capacity, seasonal utilization, and insufficient service networks can offset powertrain advantages. Techno-economic and life-cycle studies show that outcomes are highly sensitive to annual use, electricity supply, battery replacement, charging strategy, and fleet logistics *(Mousazadeh et al., 2011; Lagnelˆ v et al., 2021; Vogt et al., 2021; Beligoj et al., 2022; Wallander et al., 2025; Ali et al., 2025)*. Broader automation studies likewise show that machine utilization, scale, labor substitution, and timeliness determine economic feasibility *(Pedersen et al., 2006; Lowenberg-DeBoer et al., 2020)*. Deployment assessments should therefore report scenario assumptions and sensitivity ranges rather than a single payback value.

Development priorities and research agenda

Technology and validation. Near-term research should prioritize validated tractor-specific batteries, high-efficiency low-speed motors, robust power electronics, and integrated traction-PTO-hitch control. Shared duty cycles and reporting metrics should be established for plowing, rotary tillage, seeding, transport, and mixed operations. These benchmarks should include energy per hectare, work rate, slip, PTO-speed error, component temperature, degradation, and failure response.

System integration and industrialization. Medium-term development should combine reusable multi-domain models, digital twins, condition-aware energy management, and modular charging or battery exchange. Long-term industrialization requires interoperable interfaces, functional-safety and cybersecurity requirements, recycling and second-life pathways, rural energy infrastructure, and total-cost and life-cycle assessment. A staged progression from simulation to hardware-in-the-loop, prototype, multi-condition field test, and multi-season demonstration would make maturity claims transparent and comparable.

CONCLUSIONS

Electric tractors have evolved from isolated prototypes into integrated battery-electric, hybrid, fuel-cell, and autonomous systems. The available evidence does not support a universally applicable powertrain architecture. Battery-electric systems are best suited to predictable low- and medium-power operations, hybrid systems remain practical for prolonged heavy-load operations, and fuel-cell systems offer rapid refueling but continue to be constrained by durability limitations and insufficient hydrogen infrastructure. Across all architectures, representative duty-cycle characterization and whole-system integration are more important than nominal component ratings.

A major limitation of the existing literature is its reliance on single-condition simulations and subsystem-level testing. Reported improvements are difficult to compare because studies differ in tractor power class, soil conditions, implements, reference systems, and evaluation metrics. International studies have demonstrated meaningful reductions in life-cycle environmental impacts and operating energy consumption. However, battery manufacturing, annual equipment utilization, charging logistics, and the electricity-generation mix can substantially influence these benefits. Performance claims should therefore be supported by uncertainty analyses and evidence concerning reliability, economic viability, and life-cycle impacts.

The highest research priorities include standardized agricultural duty cycles; pack-level safety and aging validation; integrated energy management for traction, PTO, and hitch systems; reusable multidomain models; modular field energy-replenishment systems; and interoperable standards for high-voltage systems and communication protocols. Technological progress should be demonstrated through a traceable validation sequence extending from simulation and hardware-in-the-loop testing to field trials conducted under multiple operating conditions and over multiple seasons. Such an evidence chain is essential for transforming promising algorithms and prototypes into reliable, economically viable, and scalable electric tractor systems.

Keywords: *agricultural residual film, mechanized recovery, mechanized film-impurity separation, resource utilization of residual film*

ABSTRACT
Agricultural plastic mulch films have significantly increased crop yields but have also caused severe residual film pollution. This review summarizes the research progress in residual film recovery machinery, intelligent monitoring systems, film–impurity separation technologies, and resource utilization methods, while analyzing the advantages, limitations, and development trends of different technologies. Post-harvest recovery equipment has been widely applied due to its strong adaptability and broad application range, whereas seedling-stage and pre-sowing recovery technologies still require improvements in automation and environmental adaptability. Intelligent monitoring technologies can enhance the evaluation of recovery processes, but their application is restricted by complex field environments. Vibrating, pneumatic, and water-washing separation technologies exhibit advantages in processing capacity, film purity, and impurity removal, respectively. Recycled pelletizing and wood–plastic composites are important resource utilization pathways, but they still face challenges related to cost and performance. In the future, residual film management will develop toward intelligent, efficient, and high-value utilization.

摘要
农业塑料覆盖膜提高了作物产量，但也造成严重的残膜污染。本综述总结了残膜回收机械、智能监测系统、膜杂分离技术及资源利用方法的研究进展，并分析了不同技术的优势、局限性和发展趋势。收获后回收设备因适应性强、应用范围广而得到广泛应用，而苗期和播前回收技术仍需提升自动化和环境适应能力。智能监测技术可提高回收过程评价水平，但复杂田间环境限制其应用。振动、气力和水洗分离技术分别在处理能力、膜纯度和杂质去除方面具有优势。再生造粒和木塑复合材料是重要资源化途径，但仍面临成本和性能挑战。未来残膜治理将向智能化、高效化和高值化方向发展。

INTRODUCTION
In the 20th century, with the rise of the plastics industry, plastic mulch cultivation technology emerged and gradually developed *(Wang et al., 2018; Briassoulis et al., 2013; Wei et al., 2019)*. Japan conducted relatively early research on plastic mulch technology, which greatly promoted crop production. Plastic mulches are widely used in vegetable and fruit production systems across Europe, particularly in Mediterranean countries such as Spain and Italy. Plasticulture is widely adopted in North America for the production of high-value crops such as strawberries, tomatoes and melons. China has a history of about 40 years in the application of plastic mulch cultivation. Among them, the plastic mulch coverage rate of cotton in Xinjiang is 96.6%, and that of peanut and tobacco in Shandong and Hubei reaches 100% *(Chen et al., 2020)*. However, with extensive use and large amounts of plastic mulch left in farmland after harvest (Fig.1(c)), mulch mainly made of polyethylene is difficult to decompose naturally. Inadequate post-treatment by farmers has led to soil and environmental pollution, reducing water infiltration, ventilation and moisture content, hindering water and nutrient transport, causing soil compaction, and inhibiting crop root growth *(Filipe et al., 2023)*. To date, 7.4 million tons of agricultural plastic films are consumed globally each year. Just 10% are recycled and 14% incinerated, while 76% enter landfills or the environment, creating major risks to ecosystems and human health (Fig.1(a)). In Europe, approximately 0.6 million tons of agricultural plastic waste are generated annually, of which about 24% are recycled *(Martín et al., 2018)*.

The U.S. has implemented plastic recycling initiatives, waste mulch film recycling is low (*Sarpong et al., 2024*). Soil residues account for 60%–80% of film mass, so recycling costs exceed regeneration benefits. Farmers use on-farm storage, paid landfilling or open burning, which emits heavy metals and dioxins and pollutes the environment *(Montoya et al., 2018).* The average residual mulch film content in long-term mulched farmland soils of China ranges from 60 to 90 kg/hm². A residual film concentration of 58.5 kg/hm² significantly inhibits crop root growth and hinders water and nutrient transport. (*Li et a., 2023*).

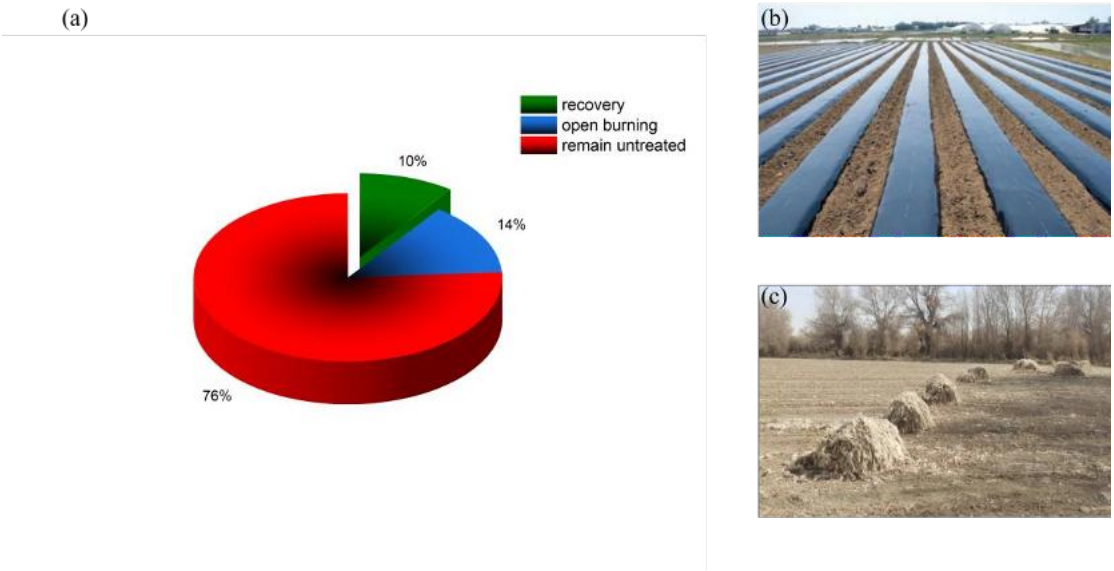

Fig. 1 – Usage of Agricultural Plastic Mulch

(a) The proportions of disposal approaches for waste agricultural plastic films worldwide; (b) Farmland Mulching; (c) Residual Mulch Accumulation in Farmland

Many reviews have discussed agricultural plastic films regarding their application, degradation, ecological risks and recycling technologies. Some analyzed plastic environmental behavior, while others evaluated residual film recovery machinery. Nevertheless, existing reviews focus merely on pollution assessment or general waste management. Comprehensive summaries of mechanized residual film recovery, intelligent detection, separation and resource utilization are scarce. The integration of recovery machinery with intelligent sensing and automation lacks systematic analysis *(Li et al., 2020; Wang et al., 2026; Yang et al., 2024)*.

This paper focuses on the core technical chain of residual film pollution control and systematically reviews related technologies, including recycling machine classification, intelligent systems, membrane-impurity separation, and resource utilization. It covers the whole-process system of mechanized recovery, intelligent monitoring, impurity separation, and resource regeneration, providing a research basis for technical optimization and equipment development. Systematic literature searches to identify research on agricultural residue film recovery, separation technologies, intelligent monitoring systems, and resource utilization pathways. Literature retrieval was conducted using Web of Science Core Collections, Scopus, ScienceDirect, SpringerLink, and Google Scholar databases. The search strategy combines keywords, including "agricultural plastic film," "residual film," "plastic cover film recycling," "film recycling equipment," "machine vision," "intelligent detection," "plastic separation," and "resource utilization." This review covers studies published between 2000 and 2026. After removing duplicate records, the retrieved articles are filtered according to the title, abstract, and full text, following preset inclusion and exclusion criteria. Subsequently, the selected studies were analyzed to summarize the findings.

KEY LINKS IN MECHANIZED RECYCLING OF RESIDUAL FILM

Farmland residual plastic film mainly includes two types: surface residual film and subsurface tillage layer residual film. Among them, surface residual film is classified into relatively intact film and fragmented film according to its morphology, while residual film in the tillage layer is entirely fragmented. Due to the short laying period and low degree of mechanical property degradation, relatively intact plastic film is relatively easy to recover. In contrast, fragmented residual film is scattered and exhibits severe mechanical property degradation, making it difficult to recover. Thus, fragmented residual film is the main target for residual film recovery.

Based on current practical recovery conditions, residual film collection and operation evaluation, film-impurity separation, and residual film processing and utilization are the key links in mechanized residual film recovery. In terms of mechanized residual film collection, residual film recovery equipment at different stages is used to lift and pick up residual film from both the surface and tillage layer, then transport it to a baling unit to complete baling and recovery *(Zhang et al., 2008a)*. During recovery evaluation, residual film image recognition, machine operation status monitoring, and operation area monitoring are adopted to identify residual film, monitor key components in real time, and detect picked, missed, and repeated areas in the field. In mechanized processing, baled residual film is first separated from straw and sand by film-impurity separation equipment *(Guo et al., 2011c)*, and then made into high-purity raw materials for plastic products through regenerative granulation technology, as shown in Fig. 2.

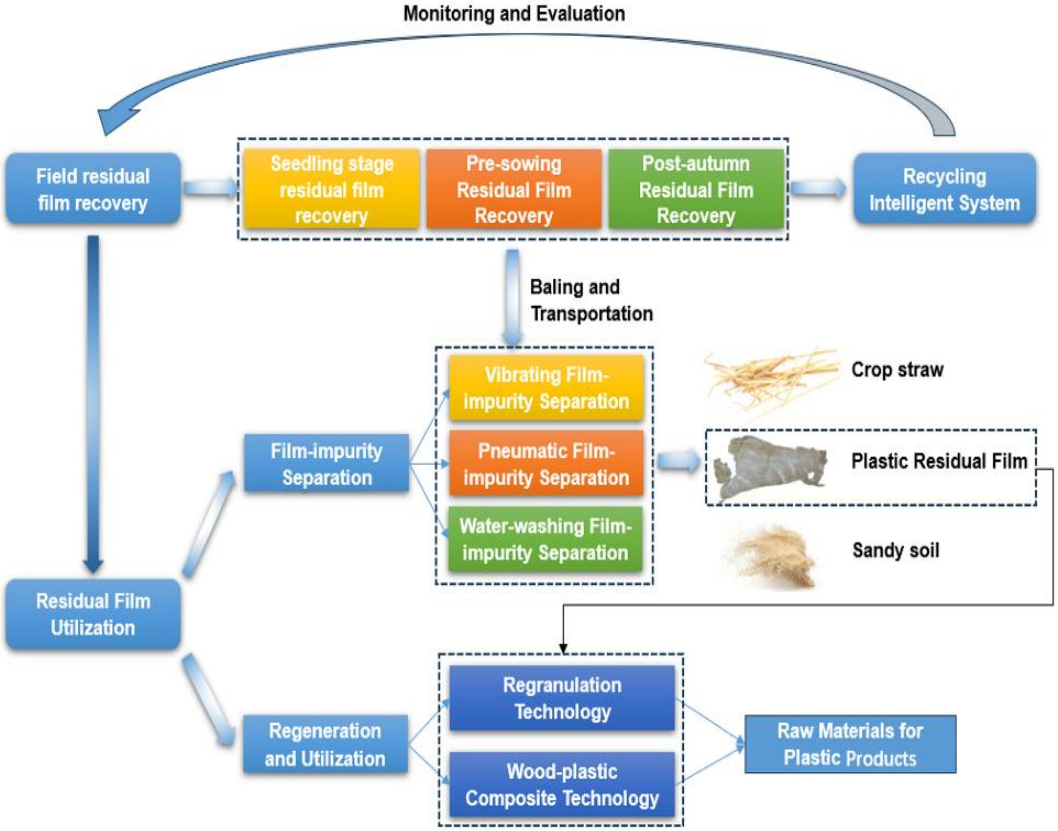

Fig. 2 – Key Processes of Mechanized Residual Film Recovery

MECHANIZED RECOVERY TECHNOLOGY, EQUIPMENT AND INTELLIGENT SYSTEM

In the early 20th century, some developed countries began research on residual film recovery machinery. Since the plastic film they used was generally thicker than 0.20 mm, film-soil separation was mainly achieved by relying on the relatively high tensile strength of the film itself, with research focused on winding mechanisms. Relevant research in China started in the 1980s. Affected by factors such as thin film thickness, low strength and easy damage, research has mainly focused on key components including film lifting and film collection *(Cheng et al., 2023)*. Due to regional agronomic differences, China has various residual film recovery machines, which can be categorized by operating period into seedling-stage, post-harvest and pre-sowing types, with post-harvest machines being the most widely applied. Accordingly, residual film recovery equipment is gradually integrating intelligent technologies, developing monitoring systems for field operation and recovery performance to realize intelligent upgrading *(Kou et al., 2023; Jin et al., 2023a)*.

Seedling-stage Residual Film Recovery Technology and Equipment

In China, residual plastic film is mainly recovered at the seedling stage before the first irrigation, as the film is relatively intact and easy to collect. The mainstream film rolling technology uses the inherent strength of plastic film to meet tension needs during film-soil separation, and is widely used for vegetable film recovery abroad and seedling-stage residual film recovery in China.

Early seedling-stage residual plastic film collectors were mostly semi-automatic, composed of frame, ground wheels, cutting blades, film lifters and cutoff discs *(Liu et al., 2024; Yang et al., 2010; Hu et al., 2016)*. They cut weeds first, lifted the film, and relied on manual pickup, leading to low efficiency. Accordingly, researchers worldwide developed fully automatic machines that wind residual film with rolling rollers and separate it from the soil using the film's inherent tensile force, offering higher efficiency and better adaptability for seedling-stage film recovery, Typical seedling-stage residual film recovery machines from various countries and their operating parameters are listed in Table 1.

Table 1

Representative Seedling-stage Residual Film Recovery Machines and Operating Parameters

Brand	Country	Picture	Operating speed	Working width	Advantages	Disadvantages
PS610 In-Season Plastic-Film Recovery Machine	USA		3–4 km/h	1.5m	It enables efficient pre-recycling with less residual film, intact mulch film, and continuous mechanized operation.	Recovery efficiency decreases under severe film fragmentation or soil embedding conditions.
ROCCA PMR-01 Plastic Mulch Retriever	USA		2–5 km/h	1.5–1.8 m	High-efficiency continuous collection with preliminary film–impurity separation.	Sensitive to film fragmentation and soil adhesion; limited adaptability and high cost.
MSM-3 type seedling-stage residual film recovery machine	CHN		2–3 km/h	1.2-1.8m	It features a compact design, high recovery efficiency, reduced soil contamination, and multi-row operation.	Affected by field conditions, with limited recovery of buried and fragmented film and limited adaptability.
Mulch film winding/recovery device	JPN		0.72–2.88km/h	0.9–1.2 m	Reduces film damage, improving recovery quality and resource-use efficiency.	Poor soil-film separation, low fragmented-film adaptability, low throughput, not for large-scale use.
Jaulent Industrie DTR	FRA		4–8km/h	1.5m	Simple structure, high efficiency, suitable for European vegetable fields, and capable of recovering film and drip lines.	Designed mainly for intact mulch films, with poor adaptability to fragmented films and limited film–soil separation capability.

However, the film-rolling seedling-stage residual film recovery equipment still relies on manual film guiding and unloading, with high labor intensity, low efficiency and insufficient tension control that easily causes film tearing, breaking or residue. To solve this, the floating synchronous film-rolling machine adopts a special mechanism to dynamically adjust the roller's speed and pressure according to real-time film conditions, ensuring uniform film stress and avoiding tearing or breaking *(Zhou et al., 2019)*.

Existing studies show that seedling-stage residual film recovery is mainly suitable for crops like corn with little need for later soil warming. The method varies with crop type, agronomy and production conditions. However, such recovery may increase water demand and soil compaction, especially in arid areas using under-film irrigation. Relevant technologies and equipment remain limited.

Autumn residual film recovery technologies and equipment

Post-harvest residual film recovery refers to the recovery operation conducted after crop harvest and before tillage, mainly targeting the plastic film used in the current season. As this operation is independent of crop harvesting, it avoids impacts on harvesting efficiency and crop quality, making it a widely applied method. However, plastic film is severely aged after harvest and disturbed by straw coverage, increasing operational difficulty.

Dense root stubbles after straw returning also cause fine residual film to hook and adhere, further complicating recovery *(Wang et al., 2017; Wu et al., 2025)*. In response, research institutions have developed corresponding equipment.

Current post-harvest recovery mainly includes two categories: one is single recovery dominated by drum-type devices, and the other is combined recovery integrating film collection, straw crushing and film baling.

1. Drum-type residual film recycler

Drum-type residual film recovery technology uses a toothed drum to collect residual film. As the drum rotates, residual film in the shallow tilled layer is hooked and attached to the teeth, then removed and collected by mechanical stripping or air blowing. According to the relative motion between the pick-up teeth and the drum, such recyclers are divided into concentric drum type and eccentric drum type *(Hu,2021; Zhang et al., 2023a)*.

Figure 4(a) shows the pick-up drum of a concentric drum-type residual film recycler. Its characteristic is that the elastic pick-up teeth are rigidly fixed to the drum body, with no relative movement between them during operation, and their rotational axes remain concentric. The residual film pick-up drum and the film stripping drum rotate in opposite directions. The elastic pick-up teeth on the pick-up drum pick up and clamp residual film from the tilled layer, then convey it to the stripping zone. Under the relative motion of the two drums, residual film attached to the pick-up teeth is effectively stripped by the stripping drum, and finally delivered to the residual film collection device, realizing continuous operations of film pick-up, conveyance, stripping and collection. Figure 4(d) shows the pick-up drum of an eccentric drum-type residual film recycler. Unlike the concentric type, the film pick-up teeth and the roller of the eccentric type can produce controllable relative movement. During operation, the pick-up teeth and the roller undergo periodic radial relative displacement to grasp, carry and separate residual film in the field. When the elastic pick-up teeth are fully extended, they fully contact residual film and complete the grasping operation. As the elastic teeth gradually retract, the grasped residual film moves with the teeth away from the working surface and then returns to the roller surface, creating conditions for subsequent film separation and cleaning.

2. Combined residual film recovery machine

Combined residual film recovery machines can be divided into combined straw crushing and returning machines with residual film recovery, and combined residual film recovery and film block baling machines. Compared with single residual film recovery, the combined operation mode integrates and optimizes processes, which can effectively reduce field operation times and the interference of straw on film recovery. Meanwhile, it realizes baling of residual film, significantly improves operation stability and simplifies subsequent treatment. Therefore, Chinese researchers have developed various combined residual film recovery machines *(He et al.,2013; Yu et al; 2016; He et al., 2023)*. As shown in Figure 5(c), the 4JMLQ-210 combined straw returning and residual film recovery machine is a tractor-mounted unit with front straw crushing and rear film recovery. During operation, high-speed rotating parts crush straw, break stubbles and level the field, preparing for film recovery. Residual film is then collected by film lifting, pickup and separation mechanisms.

One-pass operation achieves both straw returning and film pollution control. Figure 5(e) shows the MJY-1500 residual film picking and baling machine. It uses three sets of vertical hydraulic cylinders to compact film into square bales. This baler forms bales quickly with a high baling rate. Compared with conventional collection boxes, hydraulic compression greatly increases film density, easing transport and preventing secondary pollution. The structure is simple and reliable.

Technology and Equipment for Pre-sowing Residual Film Recovery

Pre-sowing residual film recovery is performed after tillage and land leveling but before sowing *(Wang et al., 2017)*. It can effectively increase the seedling emergence rate. At this stage, most residual film exists as fragments in the plough layer, making recovery difficult, so the windrowing method is mainly used *(Shen et al., 2024)*. As shown in Figure 6, the machine mainly used is a closely arranged spring-tooth residual film recovery machine. As the key working component, the spring teeth are usually made of manganese alloy materials such as No.60 or No.65 manganese steel, with an arc-shaped structure. During operation, the elastic teeth can pierce the residual film in the field, quickly hook and attach it to the tooth surface, thus completing residual film picking. When the machine reaches the end of the field, the collected residual film is then unloaded. However, most spring-tooth residual film recovery machines only pierce and pick up film, and unloading depends on manual work, which limits efficiency. To solve this problem, researchers have added a film unloading mechanism to the machine, as shown in Figure 6(c), realizing the integration of film picking, stripping and unloading, and effectively improving the automation and recovery efficiency. Compared with other film recovery machines, the spring-tooth type has a low recovery rate of only about 50% and high impurity content. Still, due to its simple structure, low cost and high efficiency, it has been widely used and promoted in northern China such as Xinjiang, Gansu and Inner Mongolia.

Residual film recycling machines have different application characteristics at different operation stages. Seedling-stage, autumn, and pre-sowing machines are designed for different residual film conditions, but challenges remain in adaptability, separation efficiency, and intelligent operation.

The characteristics, advantages, disadvantages, and development trends of different types of residual film recycling machines are summarized in Table 2.

Table 2

Characteristics and Future Development Trends of Residual Film Recycling Machines at Different Operation Stages

Type	Operation period	Residual film state	Advantages	Disadvantages	Future development directions
Seedling stage residual film recycling machine	Crop seedling stage	Relatively intact film	The residual film can be recovered timely with high film integrity, which reduces subsequent pollution.	Poor adaptability to fragmented film and soil-contaminated film; restricted by seedling crops	Adaptable mechanisms for diverse crops, planting systems, and film conditions.
Autumn residual film recycling machine	Crop postharvest stage	High fragmentation degree with obvious soil adhesion	It adapts well to fragmented and soil-contaminated films, supports large-scale operations, and is the most widely used residual film recovery equipment.	Fragmented and soil-contaminated films are difficult to separate, and complex structures increase energy consumption and reduce adaptability.	Enhanced separation, efficient fragmented film recovery, and multifunctional development.
Pre-sowing residual film recycling machine	Pre-sowing stage	Severe fragmentation and increased burial depth	Enables intact film recovery, simplifies film–soil separation, and improves field conditions for subsequent operations.	Complex structure, high energy consumption, and limited field adaptability.	Efficient fragmented film recovery, intelligent operation, and multifunctional development.

Intelligent System for Residual Film Recovery

The intelligent monitoring system for residual film recovery is an integrated intelligent system that integrates sensing, identification, positioning, computing and communication technologies. It mainly fulfills two functions: real-time monitoring of the operating status of key components during the operation of residual film recovery machines, and accurate monitoring of the effective operating area and recovery quality of the equipment.

1. Monitoring System for Key Components of Residual Film Recovery Machines

During operation, key components of residual film recovery machines often suffer from abnormal speed and damage due to entanglement by film and straw. Drive shaft speed directly affects recovery efficiency and quality. Proper speed ensures effective film picking and conveying, while abnormal speed reduces recovery performance. Thus, real-time speed monitoring of rotating parts is essential *(Xu, 2014; Jaumann et al., 2022)*. As shown in Figure 7, mature commercial intelligent monitoring systems from CASE, Massey Ferguson and Precision Planting enable key component monitoring, warning and fault diagnosis for residual film recovery machines, providing important references for China's research. Research on intelligent monitoring for residual film recovery machines in China started late and remains mostly in small-scale experiments. Using the 11FMJ toothed-chain residual film recovery machine, Chinese researchers developed a monitoring system that increased speed monitoring accuracy by 0.25%. They also proposed an STM32F103-based scheme to realize multi-parameter synchronous monitoring for drum-type machines, filling relevant technological gaps *(Ke et al., 2023; Xue et al., 2024)*.

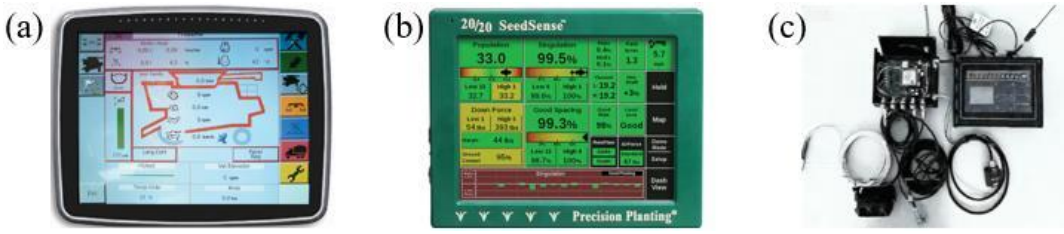

Fig. 7 – Key Component Monitoring System for Residual Film Recovery Machines

(a) FieldStar System (Coena et al., 2008) (b) 20/20 SeedSense System (Ding et al., 2018)
(c) Monitoring System for Key Components of Domestic Residual Film Recovery Machines

2. Residual Film Recovery Machine Operation Effect Monitoring System

The operation performance monitoring system for residual film recovery machines comprises two parts: an effective operation area monitoring system and a residual film image recognition system. Some countries have developed GPS-based agricultural machinery operation area monitoring methods *(Reid et al., 2000; Hamada et al., 2009)*, but these often suffer from overlapping tracks and poor boundary positioning accuracy *(Ji et al., 2012; Zhang et al., 2018)*. China's BeiDou Navigation Satellite System (BDS) has broken the technological monopoly. Its high-precision positioning provides key technical support for accurate monitoring of residual film recovery operation area. Based on BDS, Chinese researchers have developed an effective operation area monitoring system for residual film recovery machines, enabling precise calculation of effective operation area and resolving ineffective operation issues *(Zhao et Al., 2018; Zhang et al., 2020; Wang et al., 2025; Song et al., 2009)*. The residual film image recognition system detects residual films via image capture and computer vision algorithms, allowing quantitative evaluation of recovery performance. Image noise in complex fields greatly reduces model accuracy and robustness. With advances in artificial intelligence, residual film recognition has evolved from traditional machine learning to deep learning. Chinese scholars have developed lightweight detection models that achieve accurate segmentation of residual films in complex field environments while maintaining precision *(Liu et al., 2022; Ding et al., 2024; Zhang et al., 2021c; Zhai et al., 2022; Meng et al., 2025; Lu et al., 2025)*.

3. Challenges of intelligent monitoring systems under field conditions

Although deep learning-based intelligent recognition methods have achieved high detection accuracy under experimental conditions, their practical performance is still significantly affected by complex field environments. First, variations in weather conditions, solar elevation angles, and shadows caused by crops and agricultural machinery lead to constantly changing illumination conditions, thereby affecting image acquisition quality and target feature extraction. This issue is particularly significant for plastic mulch film with strong reflective properties, which is prone to local overexposure and feature loss *(Silwal et al., 2021)*. In addition, after long-term exposure to field environments, residual film surfaces are often covered with dust and soil particles, resulting in changes in their visual and spectral characteristics. These changes reduce the difference between residual film and the surrounding soil background, increasing the difficulty of image segmentation and target recognition. Meanwhile, residual film recovery operations are often accompanied by large amounts of straw and plant residues, which may overlap with residual film in images, causing false detections and missed detections and reducing the reliability of recognition systems *(Milioto et al., 2018)*. Furthermore, residual films partially buried in soil generally exhibit incomplete shapes, limited visible areas, and weak visual features, making it difficult for traditional image-based methods to achieve accurate recognition. Therefore, although intelligent monitoring technologies provide a new technical pathway for automated residual film recovery, complex and unstructured field environments remain a major factor restricting their large-scale application *(Murad et al., 2023)*.

Future research should focus on developing recognition models with stronger environmental adaptability and robustness. By integrating multi-source information, including RGB images, hyperspectral data, and environmental sensing data, the accuracy and stability of residual film detection under complex scenarios can be improved. Meanwhile, lightweight deep learning algorithms combined with edge computing technologies should be employed to achieve real-time target recognition. Furthermore, the deep integration of intelligent monitoring systems with automated residual film recovery equipment should be promoted to enable intelligent and autonomous residual film management, as illustrated in Fig. 8.

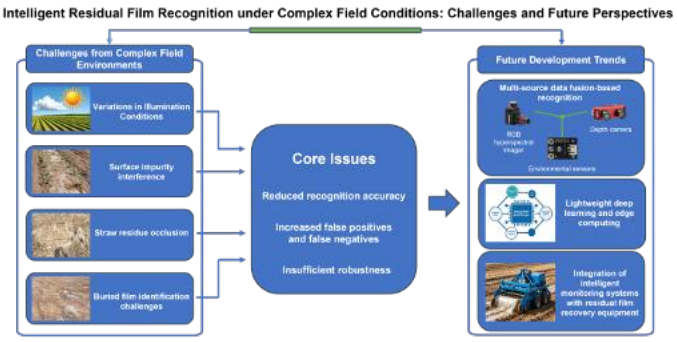

Fig. 8 – Intelligent Residual Film Recognition under Complex Field Conditions: Challenges and Future Perspectives

FILM-IMPURITY SEPARATION AND RESOURCE UTILIZATION

Although there are many types of residual film recovery machines, the recovered film mixtures have similar compositions, mainly consisting of strip or sheet old films, straw and soil clods, with varying proportions of each component. Severe entanglement between straw and residual film makes resource utilization difficult, and manual separation is inefficient and labor-intensive. Meanwhile, random stacking, burying and incineration of recovered residual film cause serious secondary pollution. Therefore, developing high-performance equipment for film-impurity separation and resource utilization is key to solving recycling challenges and achieving comprehensive control of farmland residual film *(Zhang et al., 2018)*.

Film-Impurity Separation Technology and Equipment

China has made initial progress in film-impurity separation technologies and equipment. Based on different power and working media, these technologies are mainly divided into three types: vibrating, pneumatic and water-washing *(Jiang et al., 2026)*.

1. Vibrating Film-Impurity Separation Technology and Equipment

Vibrating separation uses mechanical vibration to generate periodic oscillations, so that residual film and impurities are repeatedly thrown, bounced and slid during vibration. Based on differences in physical properties between film and impurities, they show different motion trajectories, thus achieving effective separation *(Zhang et al., 2022; Wei et al., 2018; Ruj et al., 2015)*. After mechanical recovery of farmland plastic film, the collected film-impurity mixture is complex, containing not only residual film, straw and gravel but also large amounts of soil, with severe soil wrapping on the film being especially prominent *(Guo et al., 2018b; Lubongo et al., 2022)*.To solve the resulting separation difficulties, Chinese scholars have carried out extensive research to improve separation efficiency *(You et al., 2018a; You et al.,2017b; Zhang et al., 2007d; Zhang et al., 2013)*. Figure 9(a) shows a vibrating film-soil separation device for residual film. After natural drying, the film-soil mixture collected from the field is conveyed by a belt to squeeze rollers for pre-compaction. Rotary cutters in the crushing unit then break up entangled straw and soil clods. Finally, the resulting mixture passes through a vibrating screen, which separates the residual plastic film from the soil.

Vibrating separators provide good separation and can effectively sort film from soil and stubble. They are stable, reliable and suitable for large-scale recovery. However, small and fine film pieces easily fall through the screen, lowering purity. They also adapt poorly to clay soil, where screens clog easily and reduce working efficiency.

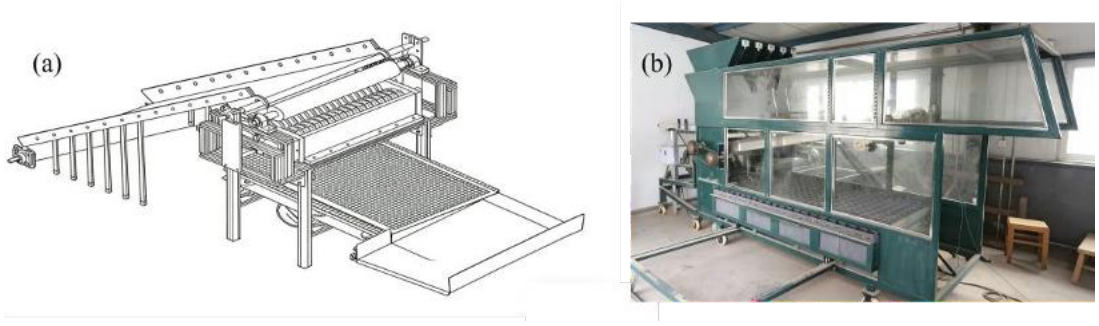

Fig. 9 – Vibrating film-impurity separation equipment

(a) Film-soil separation device (Liu et al., 2025) (b) Staggered Multi-Screen Film-Impurity Soil Removal Device (Peng, 2021)

2. Pneumatic Film-Impurity Separation Technology and Equipment

Pneumatic separation is based on the different responses of materials to airflow. Residual film has low density and low suspension velocity and is easily carried by airflow. In contrast, soil and straw have higher density and higher suspension velocity, so they tend to fall under gravity (*Anchieta e Silva; Shapiro et al., 2005*). By adjusting airflow path and velocity, film can be conveyed to a specific zone and separated *(Ma, 2024; Xie et al., 2024b)*. As shown in Figure 10(a), a pneumatic film-impurity separation device mainly consists of a fan, a rotary drum sieve, blades, a housing, a motor, and a film collection box. During operation, the fan generates airflow while the drum sieve rotates slowly. The residual film mixture (Figure 10(b)) enters the sieve through the inlet and is thrown as the sieve rotates, loosening the film. Due to the different air settling characteristics of residual film and impurities, the film is carried by airflow to the end of the sieve and into the film collection box (Figure 10(c)), while cotton stalks (Figure 10(d)) are pushed by blades to the discharge outlet, completing separation.

However, pneumatic separation requires continuous and sufficient air pressure to produce separating airflow, resulting in high power consumption, especially high energy costs for large-area operations. Restricted by environmental conditions, in humid environments, residual film adheres to impurities, reducing separation accuracy *(Kang et al., 2020; Guo et al., 2020a; Jin et al., 2022b)*.

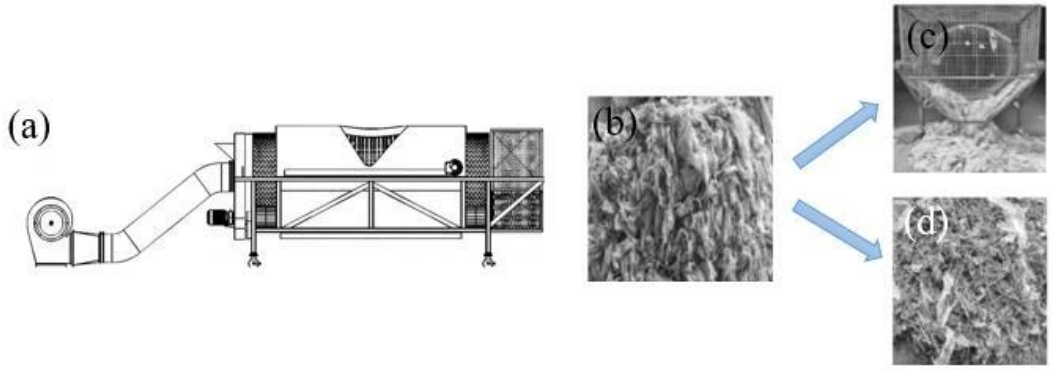

Fig. 10 – Pneumatic residual film-impurity separation device

3. Water-washing film-impurity separation technology and equipment

Water-washing separation uses the large differences in floating and settling behavior of flexible film, straw and soil particles in water. Under water flow impact and agitation, they show different trajectories and settling speeds, realizing efficient film-impurity separation *(Feng et al., 2026)*.

Water-washing separation has unique advantages in film-impurity separation, and researchers have conducted systematic research on relevant equipment. The impeller-driven water-washing separator (Fig. 11(a)) consists of a stalk collection box, stalk collection plate, water level sensor, separation tank, nozzles and water pump. During operation, cotton stalks float, residual film suspends in the middle layer, and soil settles at the bottom under water spraying. The impeller driven by the motor produces spiral thrust to enhance separation efficiency. Stalks and film are collected separately, and water is recycled through the pump. The countercurrent hook-type washing separator (Fig. 11(b)) effectively separates residual film from straw and soil. It overcomes the high soil content of air-separated film and the high energy and water consumption of ordinary washing devices *(Carvalho et al., 2010).* However, manual removal of film from the hooks reduces separation efficiency.

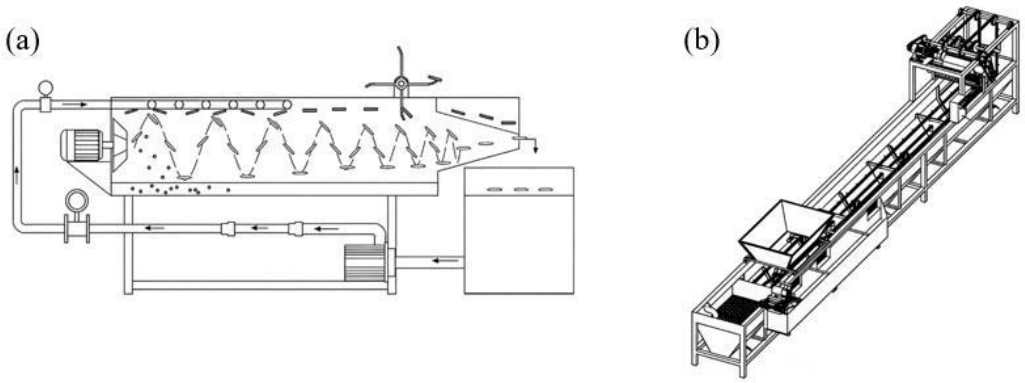

Fig. 11 – Water-washing film-impurity separation device

4. Comparison of Different Film-Impurity Separation Technologies

Table 3

Comparison of different film-impurity separation technologies

Separation technology	Advantages	Limitations	Applicable conditions
Vibrating separation	Simple structure, low energy consumption, high processing capacity, no water requirement	Limited removal ability for fine soil particles and strongly adhered impurities; affected by moisture content	Suitable for preliminary separation and large-scale treatment of relatively clean residual film

Separation technology	Advantages	Limitations	Applicable conditions
Pneumatic separation	High film purity; effective separation of lightweight impurities based on aerodynamic differences	High energy consumption; separation performance affected by material moisture and particle size	Suitable for removing lightweight impurities and improving recovered film purity
Water-washing separation	High separation efficiency; excellent removal of soil and organic impurities	High water consumption; requires wastewater treatment; high operating cost	Suitable for heavily contaminated residual film requiring high-quality recycling

Overall, vibrating separation is characterized by simple structure, low energy consumption, and high processing capacity, while pneumatic separation can improve recovered film purity through airflow classification. Water-washing separation provides superior impurity removal performance but requires considerable water resources and increases treatment costs. Future development of film-impurity separation technologies will focus on improving separation efficiency while reducing energy and resource consumption. Hybrid separation systems integrating vibrating screening, pneumatic classification, and water-assisted cleaning are expected to become a promising approach for handling complex residual film mixtures and achieving efficient, sustainable, and resource-oriented recycling.

Technology and equipment for resource utilization of residual film

Waste agricultural films obtained after film-impurity separation are mainly disposed of through reuse, landfilling, incineration, and resource recycling. Although several pathways have been developed for residual film utilization, their environmental benefits and technical feasibility vary considerably. Direct reuse has the lowest processing requirement and environmental burden, but it requires relatively intact and clean films, limiting its application for highly fragmented agricultural residues. Landfill and incineration can rapidly reduce waste volume; however, landfill may cause long-term environmental risks, while incineration requires strict emission control to avoid secondary pollution. In contrast, recycling and regeneration align with the concepts of sustainable agricultural development and circular economy, making it an ideal disposal method, but they require effective impurity removal and film purification because soil particles and organic residues can deteriorate processing stability and product quality. Wood-plastic composites offer an alternative pathway for low-quality residual films, although the influence of residual soil, additives, and polymer degradation on composite mechanical properties remains a major challenge. Currently, the treatment of waste agricultural films worldwide is gradually shifting toward resource utilization. The core technologies include regenerative granulation technology and wood-plastic composite technology, as shown in Figure 12. *(Zhang et al., 2017; Hu et al., 2019; Madrid et al., 2022).*

Regenerative granulation is a core technology for residual film recycling due to its high efficiency and simple process, which is mainly divided into dry and wet methods. Wet granulation is the mainstream process, using water for cleaning. It achieves high impurity removal and high-quality recycled pellets through crushing, washing, drying, melting and pelletizing, but consumes large amounts of water, requires wastewater treatment, and has high costs, making it suitable for large-scale projects with sufficient water. Dry granulation is water-free and removes impurities via mechanical crushing, friction screening and air separation. It features low energy consumption, low investment and potentially lower environmental impacts, suitable for water-scarce regions *(Lamtai et al., 2023)*, table 4 summarizes the comparison of the two technologies.

Table 4

Comparison between wet and dry granulation technologies for residual film recycling

Technique	Water consumption	Energy consumption	Impurity removal capacity	Product purity
Wet granulation	It requires a large amount of water as the medium and features high water consumption.	The drying step consumes a certain amount of energy.	Impurities can be further eliminated by water washing and centrifugation, and a favorable impurity removal effect can be obtained.	A large proportion of surface impurities can be removed, achieving high product purity.
Dry granulation	It requires no or minimal water, with extremely low water consumption.	It requires relatively high pressure or temperature, leading to high energy consumption.	Surface impurities tend to remain, resulting in inferior impurity removal performance.	Considerable surface impurities remain, leading to low product purity.

Residual film wood-plastic composite technology takes recycled agricultural film as the matrix, blends it with straw, wood chips and additives, and forms products via melt extrusion. The composite material combines plastic's water and corrosion resistance with wood-like appearance, and can be made into garden walkways, pallets, guardrails and building formworks *(Xia et al., 2020; Huang et al., 2021; Nukala et al., 2022)*.

Despite its potential, the application of residual film in wood-plastic composites faces several challenges. Residual soil particles and impurities can interfere with polymer–wood bonding, resulting in reduced mechanical strength and poor processing stability *(Turku et al., 2017; Ribeiro et al., 2023)*. In addition, repeated recycling may cause polymer chain degradation, which decreases tensile strength and impact resistance of composite products. Furthermore, the end-of-life management of wood-plastic composites containing recycled agricultural films remains challenging because their mixed polymer–biomass structure complicates further recycling. Future studies should focus on improving purification technologies, interface modification methods, and circular recycling strategies.

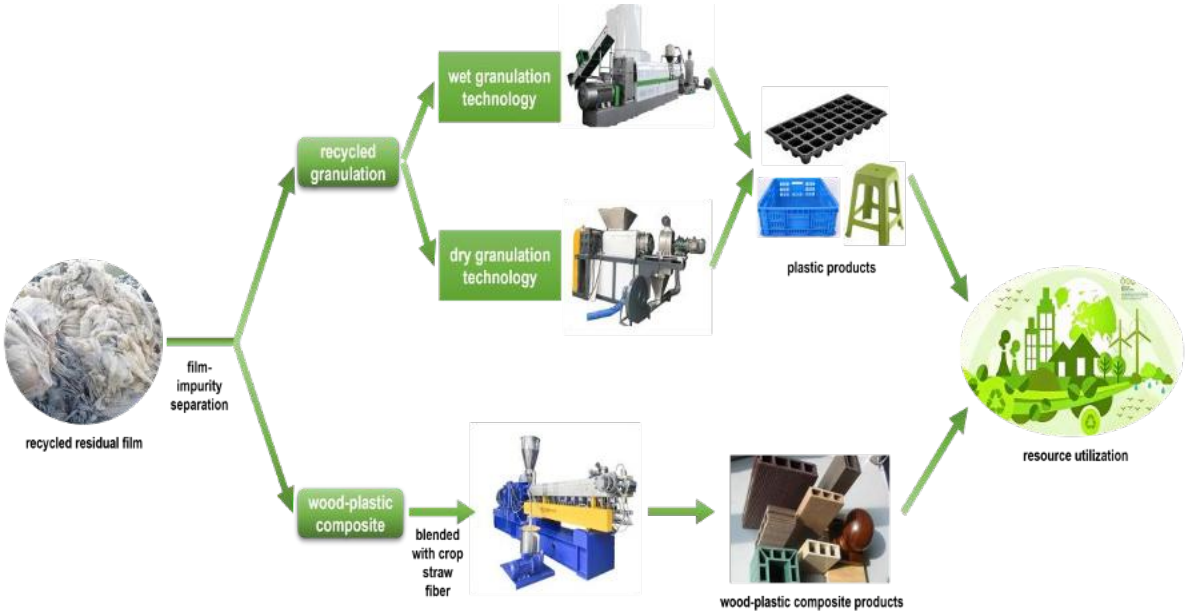

Fig. 12 – Resource utilization technology of residual film

SUMMARY AND OUTLOOK

This paper systematically reviews the core research progress throughout the entire process of farmland residual plastic film pollution control. Based on relevant research and application practices, the main conclusions are as follows: Mechanized recovery of residual film is the core link of pollution control, and an equipment system has been formed covering three key operation periods: seedling stage, post-harvest stage, and pre-sowing stage. Among them, post-harvest recovery is the most widely applied; seedling-stage recovery is developing toward automation; and pre-sowing recovery machinery is extensively used in arid agricultural areas of northern China, yet its recovery rate and automation level need to be improved. The intelligent system for residual film recovery has developed two core monitoring modules, enabling fault early warning, area measurement, and residual film identification. However, it remains in the experimental stage in China, lagging behind the commercialization level of foreign products. Membrane-impurity separation is a prerequisite for the resource utilization of residual film, and three existing types of equipment—vibratory, pneumatic, and water-washing separation—each have their advantages and disadvantages. The core technologies for the resource utilization of residual film are recycled granulation and wood-plastic composite technology, among which wood-plastic composite technology represents an important direction for the high-value utilization of residual film. At present, a full-process technical system has been established and is developing steadily with multi-stakeholder collaboration. Nevertheless, several bottlenecks still exist, restricting its large-scale and efficient application.

In view of the current technical bottlenecks in residual film pollution control and the demand for green and sustainable agriculture, future technologies and equipment will develop toward intelligence, high efficiency, coordination, and high value-added utilization. Key efforts include upgrading mechanized recovery equipment, developing new pickup mechanisms to improve the recovery rate of fragmented residual film, and optimizing combined machines and regionally adapted equipment.

Supported by Beidou navigation, AI and IoT, intelligent recovery technologies will be industrialized, with integrated management platforms and optimized algorithms to promote large-scale application. Membrane-impurity separation technologies and composite equipment will be optimized to solve existing problems, along with water-saving washing technologies to reduce costs. Resource utilization paths will be expanded by optimizing related processes, developing modification technologies, and exploring coordinated utilization with other agricultural solid wastes. Relevant standards and industrial chain mechanisms will be improved to form a sound cycle with government guidance, enterprise leadership and farmer participation, ultimately achieving "reduction, resource utilization and harmless treatment" to support green agriculture and plastic pollution control.

Keywords: *Chunking strategy, Apple fruitlets, Branch-leaf occlusion, YOLOv12n, Small-target detection*

ABSTRACT

A chunking strategy based on YOLOv12n has been proposed in this study to address challenges of young fruit detection for entire trees in dwarf and densely planted apple orchards, such as small young fruit volume, high similarity between fruit skin color and surrounding young leaves. This strategy divides an image into sub-images before feeding them into the network for training. Experimental results show that, compared with using only the YOLOv12n model for whole-image recognition, the chunking strategy achieved a precision of 85.57% and a recall of 62.54% in young fruit detection. In contrast, the YOLOv12n model alone, due to ineffective small-target capture and missing edge features, achieved a detection precision of less than 1% for young fruits, making effective detection nearly impossible. The introduction of the chunking strategy achieved a qualitative leap in young fruit detection performance. This strategy provides technical support for precise young fruit counting, subsequent accurate thinning, and growth dynamic monitoring in dwarf and densely planted orchards, and also offers a new implementation approach for small-target detection scenarios in orchards.

摘要

本研究提出了一种基于 YOLOv12n 的分块策略，以解决矮化密植苹果园整树幼果检测的难题，如幼果体积小、果皮颜色与周围幼叶高度相似等。该策略通过将图像分割为子图像后输入网络进行训练。试验结果表明，与仅使用 YOLOv12n 模型进行整图识别，分块策略的使用在幼果识别的准确率上达到 85.57%，召回率达到 62.54%，而单独使用 YOLOv12n 模型则因小目标捕捉失效、边缘特征遗漏，对幼果的检测准确率不足 1%，几乎无法完成有效检测，分块策略的引入实现了幼果识别性能的质的飞跃。该策略为矮砧密植果园幼果精准计数、后续精准疏果及生长动态监测等环节提供了技术支撑，也为果园小目标检测场景提供了新的实现思路。

1. INTRODUCTION

The development of intelligent and precise thinning devices is of great significance for improving the efficiency of the apple industry, reducing production costs, and achieving refined orchard management. Thinning is a key link in apple tree management *(Pawikhum et al., 2025)*. Proper thinning can improve fruit size and quality, maintain tree vigor, and extend the productive lifespan of trees *(Patiyal et al., 2024; Tang et al., 2023)*. Currently, the mainstream thinning methods include manual thinning, chemical thinning, and mechanical thinning. Although manual thinning allows precise control of fruit load, its efficiency is low and labor costs are high *(Du et al., 2024)*. Chemical thinning, while low in cost and simple to operate, is easily affected by climatic conditions, leading to unstable results *(Hussain et al., 2023)*. Mechanical thinning greatly improves efficiency and reduces labor input, but suffers from inaccurate young fruit detection and a tendency to damage fruits *(Hua et al., 2025)*. Therefore, the development of automated intelligent thinning devices is a direction for solving existing problems and promoting industrial upgrading *(Wang et al., 2025)*. The prerequisite for achieving such high-performance devices is the provision of a precise visual perception foundation for apple fruitlets, i.e., reliable detection and localization of young fruits, which directly affects the operational performance and practical value of the device.

Performance improvement of the visual perception module is inseparable from the technical support of deep learning in computer vision fields such as object detection *(Borugadda et al., 2026; Oba et al., 2025)*. Currently, some researchers have applied deep learning networks to fruit detection in complex scenes to enhance the adaptability of the vision module to field environments. *Fu et al. (2020)* improved ZFNet and VGG16 models based on Faster R-CNN for apple detection in dense-foliage fruit trees, achieving average precision improvements to 89.3% and 80.5% for the VGG16 and ZFNet models, respectively, with an average processing time of 0.181 seconds per image for VGG16, indicating almost no impact on processing speed. To quickly and accurately predict the positions of key points such as fruit picking points in complex field environments, *Ma et al. (2025)* proposed a joint detection model for strawberry targets and key points, STRAW-YOLO, based on the YOLOv8-pose network. The improved network achieved a keypoint detection precision of 91.6% and an average precision of 96.0%. *Zheng et al. (2021)* proposed a multi-scale feature fusion network, YOLO-BP, to recognize green citrus, achieving an average precision of 91.55%, but missed detections and false detections occurred in some partially occluded and overlapping fruit scenes. *Liu et al. (2024)* proposed a lightweight algorithm, Faster-YOLO-AP, to detect orchard apples, achieving an average precision of 85.3% for large targets but only 65.6% for small targets. Despite these good results in fruit detection, few studies have captured entire trees for fruit detection in the context of dense small targets such as apple fruitlets in dwarf and densely planted orchards *(Chen et al., 2024)*, to better meet the high precision and high reliability requirements of practical applications.

Compared with deep learning network improvements, the chunking strategy has potential to achieve better small-target detection performance in orchard scene images. Although object detection has developed rapidly, small-target detection remains a major challenge due to the small proportion of pixels occupied by small targets, limited semantic information, susceptibility to complex scene interference, and ease of clustering and occlusion *(Feng et al., 2024; Zhang et al.,2022; Hou et al., 2025)*. The dwarf and densely planted cultivation mode makes small-target detection scenes even more complex, as dense planting causes severe overlap of branches, leaves, and fruits, blurring target boundaries. The color and texture of fruits and leaves converge, and contrast decreases under complex lighting *(Gao et al., 2024)*. However, current small-target detection methods mainly focus on modifying widely used deep learning network architectures *(Wu et al., 2024; Liang et al., 2025)*. Although local performance is improved, effective features are severely attenuated after standard resize operations, and network customization for specific objects limits generalization capability *(Chen et al., 2025)*. In contrast, the chunking strategy preserves the original features of small targets directly through local high-resolution processing, while effectively increasing the number of datasets, avoiding insufficient feature learning during model training due to small dataset sizes, thus opening up a better solution for building a universal detection framework.

The potential of the chunking strategy in young apple fruit detection in large-field-of-view complex scenes is significant, but its practical application still faces multiple key challenges. Currently, limitations of the chunking strategy often lead to missed detections of small targets, such as ignoring dense small fruitlets when chunks are too large, or computational redundancy when chunks are too small *(Dang et al., 2025; Jiang et al., 2023)*. Therefore, it is necessary to determine the optimal chunk size and overlap rate to balance detection accuracy and computational efficiency while avoiding cutting of young fruits. It is also necessary to reduce the destruction of contextual information from the original image during chunking and minimize feature loss caused by local fragmentation. An efficient chunking result recombination strategy needs to be designed to eliminate duplicate detections or missed detection errors at boundaries. These issues have not been fully explored in current immature apple detection research. Therefore, the scientific design and optimization of the chunking strategy is the core prerequisite and implementation path for achieving efficient, high-precision, and large-scale detection of apple fruitlets under the dwarf and densely planted mode.

This study aims to address the key challenges in applying the chunking strategy to young apple fruit detection in dwarf and densely planted orchards. Through scientific chunking strategy design, the problems in young apple fruit detection are solved, and the ability to extract and classify fruit features in complex and diverse environments is enhanced. The chunking strategy is integrated with the YOLOv12n model to achieve accurate detection of dense, occluded apple fruitlets.

2. MATERIALS AND METHODS

This method includes six main processes. First, a mobile phone camera was used to collect images of young apple fruits.

The young apple fruits were annotated to establish a dataset of young apple fruits in dwarf and densely planted orchards. The dataset was divided into training and validation sets through data processing operations. Then, model training was carried out according to three different training strategies, and finally, detection results of young apple fruits in the dwarf and densely planted orchard environment were obtained. An overall schematic diagram of this method is shown in Fig. 1.

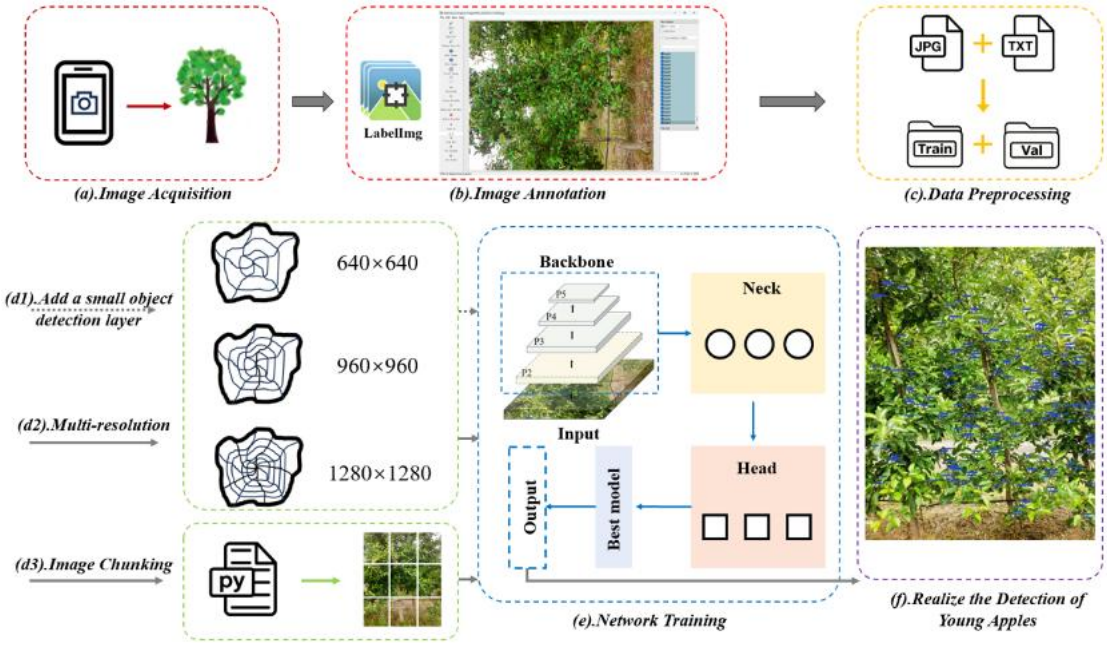

Fig. 1 - Schematic diagram of the overall workflow

2.1 Dataset

2.1.1 Image Acquisition of Young Apple Fruits

On May 16, 2025, images of "Gala" apples were collected at Xinyuan Fruit Industry Group Co., Ltd. in Weihai City, Shandong Province. The planting pattern of the studied apple trees was dwarf and densely planted *(Yuan et al., 2025; Ma et al., 2025)*, without bagging, with a row spacing of 3.5 meters and a plant spacing of 1 meter. The tree age was 7 years, and the length of the tree rows ranged from 30 to 240 meters. A mobile phone camera (Xiaomi Mix 2S) was used to collect images of young apple fruits at a distance of 2.6 meters from the tree row. The image resolution was 4032 × 3024 pixels. A total of 200 original images were collected and saved in JPG format. The acquisition scene is shown in Fig. 2.

Fig. 2 - Apple tree planting pattern and image acquisition method

2.1.2 Image Annotation and Data Preprocessing

Annotation of the young apple fruit dataset was completed using the labeling software LabelImg. The annotation box size was the bounding rectangle of the young fruit. After annotation, the resulting annotation file information was saved as .XML files, which contained key data such as the filename of the young fruit image, the coordinates of the four corners of the annotated rectangular region, and the target classification label. After annotation, the image dataset was split and augmented for training. The 200 images in the dataset were randomly divided into a training set of 160 images and a validation set of 40 images, a ratio of 8:2. After processing with the chunking strategy, the dataset was augmented, expanding the training set from 160 images to 5,600 images. Examples of images in the young apple fruit dataset and the scenes they contain are shown in Fig. 3, including various scenes such as dark lighting, normal lighting, leaf occlusion, and fruit stacking.

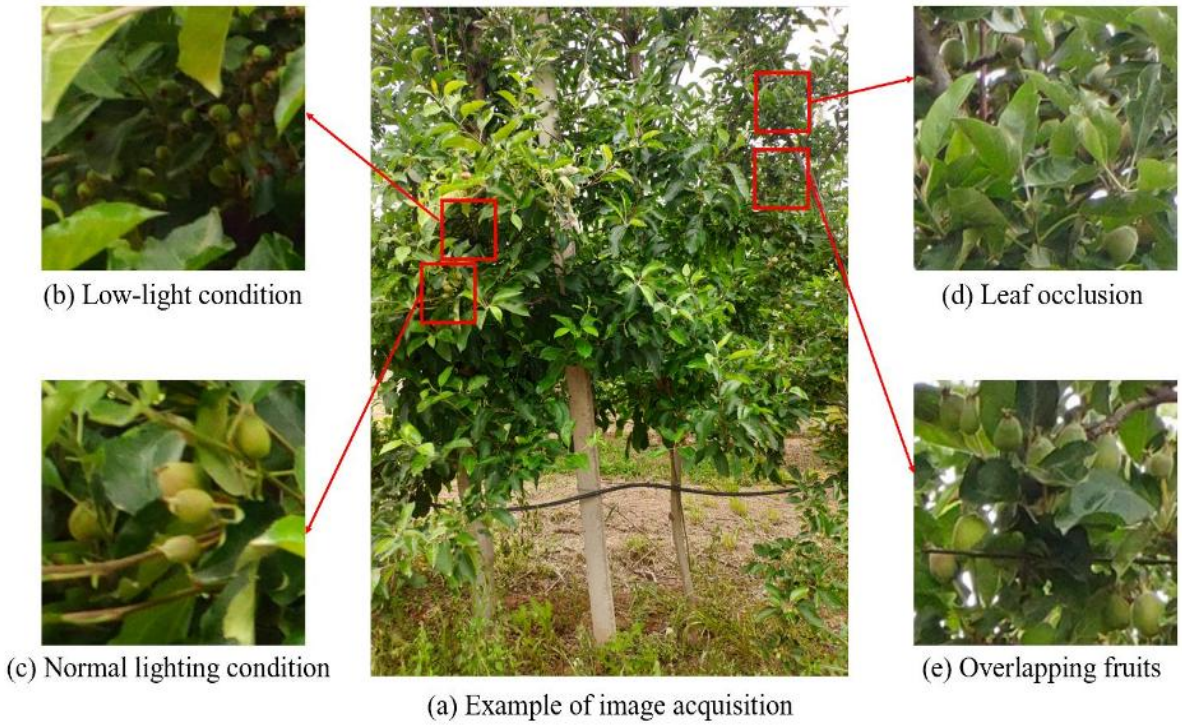

Fig. 3 - Apple samples from a dwarf and densely planted orchard

2.2 Methods

2.2.1 Multi-Resolution Strategy

YOLOv12n is an efficient lightweight model designed for general object detection tasks, with a model structure that includes a small-target detection mechanism suitable for real-time detection scenarios *(Zhang et al., 2025)*. Multiple studies have shown that its innovative region attention mechanism significantly improves the feature extraction efficiency of tiny targets by dynamically dividing feature maps and focusing on local regions. At the same time, the optimized multi-scale feature fusion architecture strengthens the retention of shallow, high-resolution details, effectively solving the problem of information loss of small targets in deep networks. Combined with lightweight design and position-aware enhancement technology, this model has significant advantages in high-precision small-target detection scenarios. Based on its breakthrough performance in balancing accuracy and efficiency, YOLOv12n was used to detect young apple fruits, and the resize parameters were set to 640 × 640, 960 × 960, and 1280 × 1280 to examine their impact on young apple fruit detection.

2.2.2 Adding a Small-Target Detection Layer Strategy

The detection head of YOLOv12n includes three detection layers: P3, P4, and P5 detection heads. Among them, the P3 detection head, which has the largest output feature map, is suitable for detecting small targets due to its smallest global receptive field and high spatial resolution, making it the small-target detection layer *(Wei et al., 2024; Jing et al., 2024)*. Similarly, the P5 detection head with the smallest output feature map is the large-target detection layer, and P4 is the medium-target detection head. Before chunking, the number of small targets was 26,558; after chunking, the number of small targets was 24,315, as shown in Table 1.

Table 1

Statistics of instance counts

Dataset	Images	Instances	Objects		
			Small Objects	Medium Objects	Large Objects
Training Set (Non-chunked)	160	20456	20455	1	0
Validation Set (Non-chunked)	40	6103	6103	0	0
Training Set (Chunked)	5600	22595	18655	3594	346
Validation Set (Chunked)	1400	6685	5660	901	124

Small targets accounted for a large proportion of the overall samples, placing higher demands on the performance of the small-target detection layer. Moreover, due to the small target size of young fruits in the images, their feature information was easily lost during detection, leading to missed detections. In this study, a newly added P2 detection head was set to detect tiny targets approximately 4×4 to 8×8 pixels in size to detect even smaller young apple fruits. The network structure diagram is shown in Fig. 4. Through a series of operations such as convolution, upsampling, and concatenation, feature maps suitable for tiny target detection were generated, thereby improving the detection accuracy of small young fruit targets. Similarly, this strategy was also evaluated at three resolutions, and both strategies were jointly used to comprehensively examine the effect of resolution changes on detection performance.

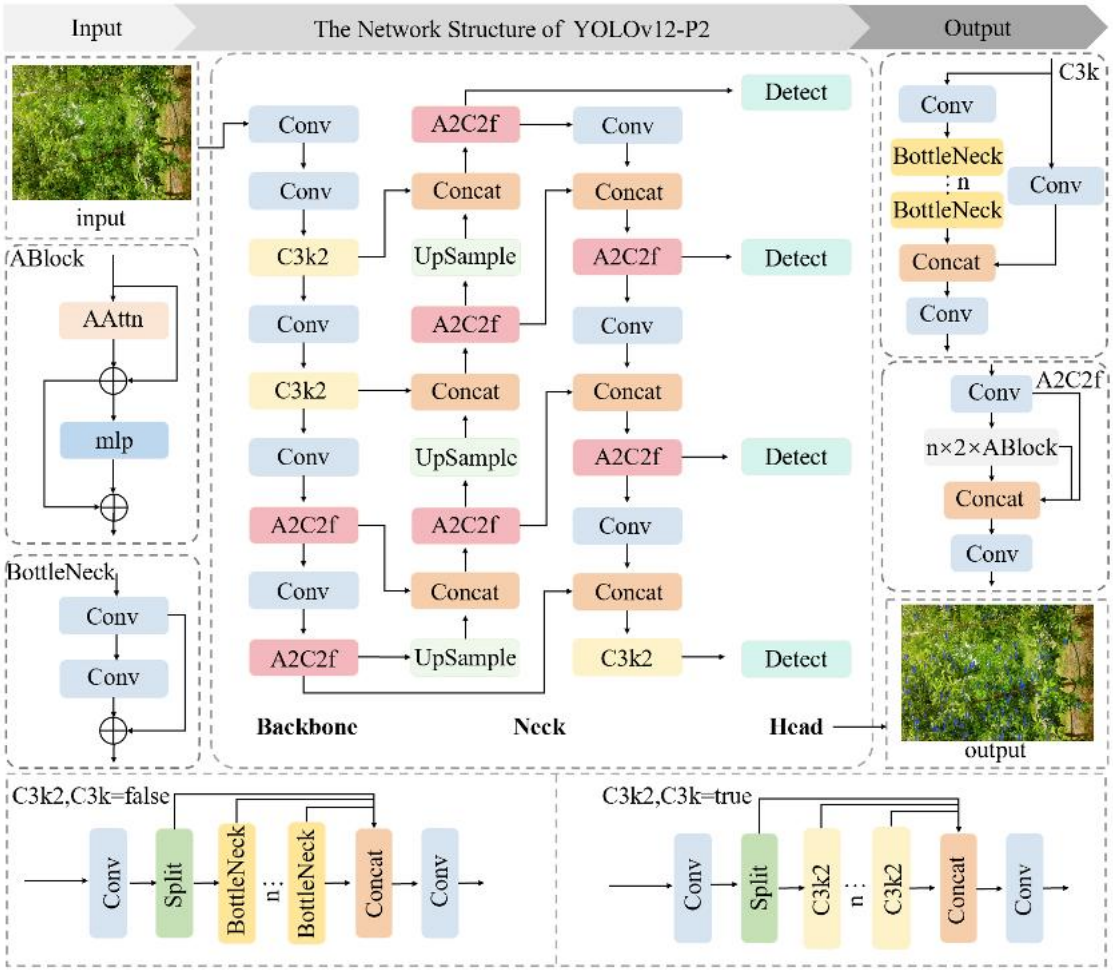

Fig. 4 - Network structure diagram of YOLOv12n-P2

2.2.3 Chunking Strategy

Young apple fruits occupy a very small proportion of pixels in the original image, which poses a challenge to current object detection models based on deep learning networks. Therefore, a chunking strategy was proposed to augment the data and increase the proportion of young apple fruit pixels in the image.

This algorithm started from the upper left corner of the image and progressively moved to the lower right, decomposing the originally large image into multiple small segmented images, each with a pixel size that met the input specifications of the training network. Some segmented images might contain no young apple fruits, while others had an increased proportion of young apple fruits. The traditional chunking method sequentially divides an image based on pixels. When a target crosses chunk boundaries or is unevenly distributed, it easily leads to feature fragmentation and loss of contextual information, affecting detection or counting accuracy. Therefore, a certain overlap was set between adjacent chunks to prevent missing young fruit information at the edges of the images due to chunking. As shown in Fig. 5, three black rectangular boxes represent three adjacent partitions, and the blue area represents the overlapping area between the three partitions.

The overlap length was calculated using formulas (1) and (2).

$$overlap = \frac{x'}{2x - x'} \tag{1}$$

$$overlap = \frac{y'}{2y - y'} \tag{2}$$

where:

$overlap$ is the overlap rate of the chunking strategy, [%]; x is the width of the chunked image on the horizontal axis, [pixel]; y is the height of the chunked image on the vertical axis, [pixel]; x' is the length of the overlapping part on the horizontal axis, [pixel]; y' is the length of the overlapping part on the vertical axis, [pixel].

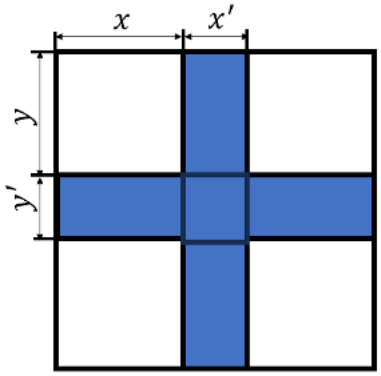

Fig. 5 - Examples of overlap rate setting and overlap region

After the overlap rate was set, the image information was read, and the number of chunks along the horizontal and vertical axes was calculated. The formulas for calculating the number of image chunks required are shown in formulas (3) and (4).

$$a = 1 + \left[\frac{w - x}{x - x'} \right] \tag{3}$$

$$b = 1 + \left[\frac{h - y}{y - y'} \right] \tag{4}$$

where:

a is the number of chunked images required on the horizontal axis; w is the width of the original image, [pixel]; b is the number of chunked images required on the vertical axis; h is the height of the original image, [pixel].

At the same time, to ensure that all young fruit information in the image could be detected, the results were rounded up. However, rounding up caused the relative coordinates of the edge images to exceed the original image during chunking, resulting in blank areas in the chunked images. To avoid this, the relative coordinates were shifted. An example of chunked image shifting is shown in Fig. 6.

The yellow box represents the original calculated partition position of the image, and the red box represents the corrected partition position of the image.

Fig. 6 - Example of chunked image shifting

The segmented small images were set to 640 × 640 pixels in this study to fit the network input size. The chunking strategy was also used to partition the XML annotation files and original label files to avoid re-labeling the label files after image chunking. The relative coordinate calculation formulas are shown in formulas (5) and (6).

$$x'_{\min} = x_{\min} - x_0 \tag{5}$$

$$y'_{\min} = y_{\min} - y_0 \tag{6}$$

where:

$x'_{\min}$ is the relative horizontal coordinate of the bounding box with respect to the chunked image, [pixel]; $y'_{\min}$ is the relative vertical coordinate of the bounding box with respect to the chunked image, [pixel]; $x_{\min}$ is the original horizontal coordinate of the bounding box with respect to the whole image, [pixel]; $y_{\min}$ is the original vertical coordinate of the bounding box with respect to the whole image, [pixel]; x_0 is the horizontal coordinate of the top-left corner of the chunked image, [pixel]; y_0 is the vertical coordinate of the top-left corner of the chunked image, [pixel].

The image to be detected was divided into regions as shown in Fig. 7. The black boxes indicate the chunk positions after setting the overlap rate, the red boxes indicate the chunk positions after shifting, and the blue boxes indicate the chunk positions for the last image. Finally, the detected chunked images were merged to restore their original size.

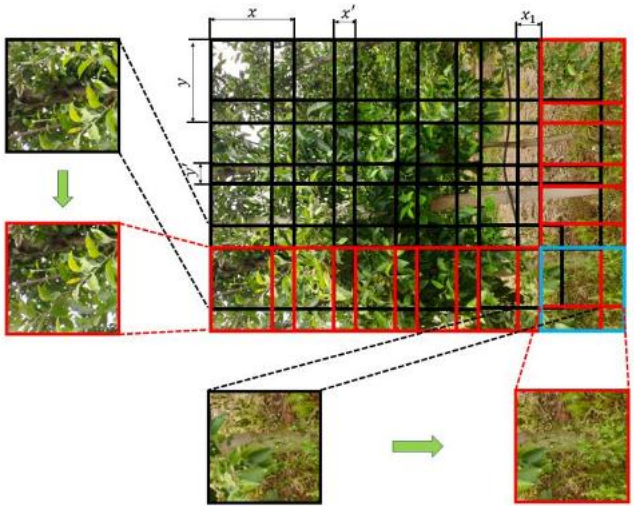

Fig. 7 - Chunk region division of the image to be detected

2.3 Experimental Platform and Training Parameters

The experimental model training platform used an NVIDIA GeForce RTX 4050 graphics card, a 13th Gen Intel(R) Core(TM) i7-13620H processor, and 6 GB of video memory. The network model was trained using the Windows 11 operating system, PyTorch 2.0.0 framework, CUDA 11.8, PyCharm editor, and Python 3.12 programming language. Stochastic gradient descent was used for training, with a momentum of 0.937 and a weight decay of 0.0005. The initial learning rate of the network was set to 0.01, and the number of network training epochs was 300.

2.4 Evaluation Metrics

To evaluate the performance of different strategies in recognizing young apple fruits, the following metrics were used: *Precision (P), Recall (R),* and *Average Precision (AP)*. *AP* is the area under the *P-R* curve and was used as a comprehensive metric reflecting network performance. The calculation formulas for P, R, and AP are shown in formulas (7), (8), and (9).

$$P = \frac{TP}{TP + FP} \times 100\% \tag{7}$$

$$R = \frac{TP}{TP + FN} \times 100\% \tag{8}$$

$$AP_i = \int_0^1 P_i(R_i) dR_i \tag{9}$$

where: TP (*True Positive*) is the number of correctly detected young apple fruits; *FP (False Positive)* is the number of incorrectly detected young apple fruits; *FN (False Negative)* is the number of young apple fruits that were not detected.

3. RESULTS

3.1 Comparison of Different Detection Models

To systematically evaluate the detection difficulty of this dataset and exclude performance anomalies caused by specific model implementations or training settings, four mainstream lightweight object detection models, YOLOv5n, YOLOv8n, YOLOv11n, and the baseline YOLOv12n, were selected to detect young apple fruits in the dwarf and densely planted orchard environment. The experimental results are shown in Table 2. The P values of YOLOv5n, YOLOv8n, and YOLOv11n on this dataset were only 0.10%, 0.29%, and 0.23%, respectively, and their *P* and *R* values were also below 1%. This result was highly consistent with the baseline performance of YOLOv12n used in this study, indicating that the extremely small size, dense distribution, severe leaf occlusion, and fruit stacking of young apple fruits in this dataset made it nearly impossible for current mainstream object detection models to learn effective young fruit features. These results together confirmed that the baseline model *AP* below 1% was not caused by specific code defects or training errors, but was an objective reflection of the extreme challenge of this dataset.

Table 2

Performance comparison of different detection models on the young apple fruit dataset

Model	Different resolutions	P (%)	R (%)	AP (%)
YOLOv5n	640×640	0.10	0.20	0.05
YOLOv8n	640×640	0.29	0.57	0.17
YOLOv11n	640×640	0.23	0.44	0.36
YOLOv12n	640×640	0.24	0.48	0.12

3.2 Comparison of Three Detection Methods

The performance of three methods in object detection tasks was compared. The experimental results are shown in Table 3. The chunking strategy significantly outperformed the other two methods, achieving an *AP* as high as 77.50%, an *R* of 62.54%, and a *P* of 85.57%, indicating that this method maintained high detection stability and accuracy even in complex scenes. Particularly in environments with many small targets and heavy occlusion, the chunking strategy effectively improved target detection and localization through local enhancement processing. As shown in Fig. 8e, the chunking strategy was the only method among the three that effectively recognized young fruits.

Table 3

Performance comparison of the three detection methods

Strategies	Different resolutions	P (%)	R (%)	AP (%)
YOLOv12n	640×640	0.38	0.75	0.20
	960×960	0.28	0.54	0.24
	1280×1280	0.31	0.61	0.20
YOLOv12n-P2	640×640	0.29	0.57	0.16
	960×960	0.24	0.48	0.13
	1280×1280	0.29	0.57	0.15
YOLOv12n-chunking	640×640	85.57	62.54	77.50

In contrast, the multi-resolution training and the small-target detection layer addition methods performed poorly in this experiment. The highest AP achieved by the multi-resolution training method was only 0.24%, and the highest R was only 0.75%, indicating that this method failed to effectively capture target features, possibly due to insufficient model training in adapting to scale variations. The method of adding a small-target detection layer also failed to significantly improve performance, with the highest AP reaching only 0.16% and the highest R only 0.57%, indicating that simply increasing network depth or the number of detection layers cannot fundamentally solve the problems of semantic loss and feature weakening in small-target detection. Although the multi-resolution training and small-target detection layer addition methods showed slight numerical improvements in P, R, and AP, their extremely low values indicated that these methods were practically unable to detect real targets, with severe missed detections. As shown in Figure 8, methods other than the chunking strategy produced almost no detection boxes.

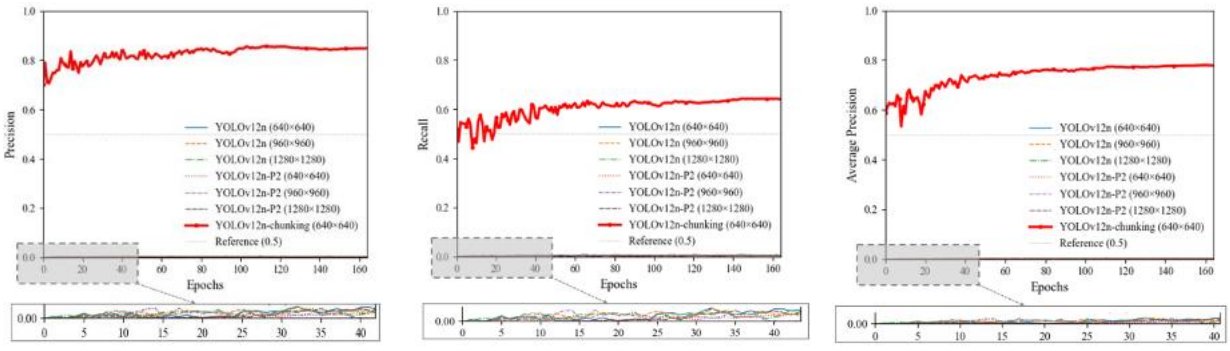

Fig. 8 - Detection effects of the three strategies

The superior performance of the chunking strategy was closely related to the growth characteristics of young apple fruits. Young fruits are typically small in the early stage, highly similar in color to leaves, and often occluded by branches and leaves, making detection extremely challenging *(Liu et al., 2023; Xu et al., 2024)*. When the network needs to process images containing many such tiny, highly similar targets, its receptive field and feature extraction capacity easily reach a bottleneck *(Lin et al., 2025)*. The chunking strategy physically increases the relative size and feature richness of each young fruit in the sub-images by dividing the high-resolution image into smaller sub-images, greatly alleviating the problem of weak small-target feature signals in the original image and enabling the network to capture key discriminative features more clearly. In contrast, although the other two methods enhanced small-target perception to some extent, they did not fundamentally change the proportional relationship between the target and the entire image, thus still suffering from many missed detections and false detections in complex backgrounds.

For small targets such as young apple fruits, a more complex network structure does not necessarily yield better results. Sometimes, a relatively simple and direct method, such as changing the input strategy, can bring more significant performance improvements. This finding is not entirely consistent with the conclusion of *Chutichaimaytar et al. (2025)*, who suggested increasing model depth and complexity to improve small-target detection accuracy. This discrepancy indicates that the optimal detection strategy may vary depending on the specific detection object and its environmental background. For objects with tiny features and complex backgrounds, ensuring that key features are fully represented is more effective than designing complex networks for difficult discrimination.

3.3 Effectiveness Analysis of Each Method

As shown in Figure 9, the performance curves of the three strategies indicate that the model performance achieved a breakthrough improvement after adopting the chunking strategy. The *AP* value significantly increased from less than 1.00% to 77.50%, and *R* and *P* reached 62.54% and 85.57%, respectively. The superior performance of this strategy stemmed from the physical partitioning of the image, which fundamentally increased the relative size of young fruits in the sub-images, allowing the network to capture clearer and richer feature information, thus effectively solving the fundamental problem of extremely weak small-target feature signals *(Wu et al., 2024)*. However, the main cost of this strategy was reduced computational efficiency. Because more sub-images needed to be processed and results fused, the detection time per image was several times that of the end-to-end model. Nevertheless, in offline high-precision analysis scenarios such as young apple fruit yield prediction, trading computation time for unparalleled detection accuracy is a necessary and acceptable trade-off.

(a) (b) (c)

Fig. 9 - Performance curve comparison of the three methods

(a) Comparison of precision curves of the three methods; (b) Comparison of recall curves of the three methods; (c) Comparison of average precision curves of the three methods.

The multi-resolution training strategy achieved AP values below 1% at different resolutions. The intention of this strategy was to enhance the scale invariance of the model, but its failure in young apple fruit detection was attributed to the fact that downsampling operations destroyed the already weak features of young fruits, while upsampling to higher resolutions could not create effective details but instead amplified image noise, interfering with model judgment *(Ma et al., 2022)*. Similar to the detection layer addition strategy, this method was lightweight but did not change the proportional relationship between the target and the entire image, thus having limited effect in addressing the specific difficulties of this study.

As a model enhancement method, the addition of a small-target detection layer aimed to improve small-target perception by introducing a shallower detection head. However, the experimental results did not meet expectations, with the highest AP reaching only 0.16%. The root cause of its failure was that the feature extraction bottleneck occurred in the early stage of the network. The extremely small size of young fruits meant that after several downsampling operations during feature extraction in the backbone network, the effective signal had severely attenuated or been lost. Subsequently, even with the introduction of a detection layer specifically designed for small targets, key information could not be recovered from the already confused feature maps. This strategy had negligible detection effects in the extremely challenging scenario of this study, characterized by extremely small targets and high-background similarity, and was only suitable for general detection tasks with relatively more prominent targets.

In contrast, the failure of the multi-resolution training and small-target detection layer addition strategies highlighted the particularity and challenges of young apple fruit detection. For targets with extremely small features and very low signal-to-noise ratios, traditional methods aimed at enhancing model perception may have limited effect. The most effective strategy is to start from the input side and fundamentally change the relationship between the target and the image scale through physical methods such as chunking, ensuring that the original features of the target are completely captured by the model. The results of this study provide important insights for the detection of similar small targets in agriculture: when the target is small to a certain extent, optimizing the data input strategy should take priority over designing complex models.

3.4 Performance Demonstration and Analysis of the Chunking Strategy

The overall detection effect showed that in real orchard environments with uneven lighting and cluttered backgrounds, the chunking strategy demonstrated excellent overall performance. The model successfully located and recognized tiny young fruit targets with high prediction confidence, as shown in Figure 10. This indicates that the strategy of enhancing local feature representation through chunking processing fundamentally solved the feature loss and receptive field mismatch problems in the baseline method, achieving extremely high recall and precision.

Fig. 10 - Overall detection effect of the chunking strategy and enlarged views of local areas

The enlarged local areas show the model's detailed performance in scenes with partial occlusion, boundary blur, extreme occlusion, and dense targets. While affirming the model's strengths, these examples also reflect its shortcomings and directions for improvement. In Fig.10a, a fruit with approximately 30%–40% leaf occlusion is shown. The model was able to effectively infer and recognize the fruit based on its visible features, providing a reasonable confidence level. This demonstrates the model's ability to complete features and reason under moderate occlusion. However, when the occlusion proportion increases further or the occlusion pattern becomes more complex, the model may still show decreased confidence or missed detections, indicating that its occlusion reasoning mechanism is not yet fully robust. In the future, adversarial occlusion training or structure-aware reasoning modules could be introduced to enhance adaptability to diverse occlusion patterns. In Fig.10b, the chunking strategy significantly improved the distinction between adjacent targets by enhancing local feature resolution. The model generated prediction boxes with accurate spatial positions and clear boundaries in this region, demonstrating excellent discrimination ability for highly overlapping targets. Nevertheless, when target edges are highly fused with the background, the model may still show boundary localization errors, suggesting that the current edge perception mechanism still has room for optimization. Subsequent work could incorporate edge enhancement operators or introduce boundary-aware loss functions to further improve localization accuracy. Fig.10c presents a boundary case of the current method. When a target is severely occluded or presents only very small local features, detection confidence decreases. In the future, introducing attention-based contextual reasoning modules *(Xu et al., 2023)* could allow the model to better utilize surrounding environmental information to infer the presence of extremely occluded targets. Fig.10d shows the model's excellent ability to distinguish dense targets. For closely clustered young fruit groups, the model did not incorrectly merge them into a single detection target but generated multiple independent and accurately bounded prediction boxes. However, when target spacing is extremely small and targets are heavily adhered to each other, the model may still suffer from duplicate detections or missed detections, indicating that its instance separation capability in extremely dense scenes needs strengthening. This demonstrates that the high-resolution local contextual information provided by the chunking strategy is crucial for distinguishing spatially adjacent targets with similar appearances.

4. CONCLUSIONS

This study addressed the problems of extremely small young apple fruit targets and high detection difficulty in dwarf and densely planted orchard environments by proposing a detection method based on the YOLOv12n-chunking strategy. Compared with methods such as multi-resolution training and adding a small-target detection layer, the chunking strategy adopted in this study achieved significant improvements in detection performance, with an *AP* of 77.50%, while the *AP* values of the multi-resolution training and small-target detection layer addition methods were both below 1%. The chunking strategy enhanced local feature expression through image preprocessing, effectively overcoming the detection bottlenecks caused by extremely small target scales and complex backgrounds, providing an effective solution for small-target agricultural detection in large-field-of-view orchard images. However, the current detection accuracy of 77.50% still has room for improvement. In the future, the dataset will be expanded with multi-season, multi-variety, and multi-weather-condition images, and lightweight design and advanced algorithms will be integrated to further improve the model's generalization ability and deployment suitability.

Keywords: *Buckwheat; dehulling; rotating drum; pressure deck; elastic contact surface; rotatable central composite design.*

ABSTRACT

A novel buckwheat dehulling device consisting of a rotating drum and a pressure deck with an elastic contact surface was developed to eliminate the need for grain size classification prior to dehulling. The geometry of the pressure deck was designed to match the shape of buckwheat grains, ensuring stable contact and effective dehulling across the commercial grain size range of 3–5 mm. The performance of the device was experimentally evaluated using a three-factor rotatable central composite design. The effects of drum rotational speed, working gap, and grain moisture content on the dehulling degree were investigated, and a quadratic regression model was established. The results showed that the maximum dehulling degree of 66.08% was achieved at a drum rotational speed of 846 rpm, a working gap of 4.2 mm, and a grain moisture content of 13.86%. The developed device demonstrates that optimizing the geometry and elastic properties of the pressure deck can significantly improve buckwheat dehulling efficiency while eliminating the need for prior grain size classification.

ХУРААНГУЙ

Сагаг будааг хэмжээний ангилалгүйгээр хальслах зорилгоор эргэх хүрд болон уян харимхай ажлын гадаргуутай, сагаг үрийн хэлбэрт тохируулан хийцлэгдсэн шахах декээс бүрдэх шинэ төрлийн хальслах төхөөрөмжийг боловсруулав. Шахах декний геометр хэлбэрийг сагаг үрийн хэлбэрт тохируулснаар 3–5 мм хэмжээтэй үрийг тогтвортой шахаж, үрийн гадаргууг жигд хальслах нөхцөлийг бүрдүүлсэн. Төхөөрөмжийн ажиллагааг гурван хүчин зүйлт төвийн зохиомжит ротатабель төлөвлөлтийн аргаар туршиж, хүрдний эргэлтийн давтамж, ажлын завсар, үрийн чийгийн агууламжийн хальслалтын зэрэгт үзүүлэх нөлөөг судлан шугаман бус регрессийн математик загвар байгуулсан. Туршилтын үр дүнгээр хүрдний эргэлтийн давтамж 846 эрг/мин, ажлын завсар 4.2 мм, үрийн чийгийн агууламж 13.86% байх үед хальслалтын зэрэг 66.08%-д хүрсэн. Судалгааны үр дүнгээс үзэхэд шахах декний геометр хэлбэр болон уян харимхай шинж чанарыг оновчтой сонгосноор сагаг будааг хэмжээний ангилалгүйгээр үр ашигтай хальслах боломжтой болохыг тогтоов.

INTRODUCTION

Various types of dehulling machines have been developed for cereal grain processing because differences in the anatomical structure and physical–mechanical properties of grains require different dehulling mechanisms. Grain shape, the adhesion strength between the hull and kernel, differences in the mechanical properties of the hull and kernel, and the elastic behavior of the grain determine the type and magnitude of the mechanical forces required during dehulling. Consequently, dehulling machines have been developed based on different operating principles to satisfy these technological requirements (*Chebotarev et al., 2004; Egorov et al., 2005; Tarasenko et al., 2017; Kent et al., 2018)*. Experimental studies on roller-type dehulling machines have been reported by *Kamst et al. (2002)*, *Adisa et al. (2016, 2020)*, *Mar'in et al. (2020)*, *Itodo et al. (2023)*, and *Cheng et al. (2026)*.

According to their operating principles, dehulling machines can be classified as compression–friction, compression–impact, impact–inertia, and combined systems. Based on the mode of operation, they are categorized as mechanical, aerodynamic, or combined machines. According to the characteristics of the working surfaces, they are further classified into rigid, elastic, abrasive, and fluid- or gas-assisted types *(Chebotarev et al., 2004; Egorov et al., 2005; Tarasenko et al., 2017).*

Previous experimental studies have shown that dehulling machines operating on the principles of compression, friction, and impact provide high processing efficiency while being relatively simple to control and adjust *(Itodo et al., 2023; Kamst et al., 2002; Mar'in et al., 2020; Oidov et al., 2025; Shitanda et al., 2001; Solanki et al., 2018; Upreti et al., 2022; Zhang et al., 2025)*. Consequently, these machines are widely used in industrial buckwheat processing.

Despite their effectiveness, conventional buckwheat dehulling machines require the grains to be classified into several size fractions before processing. Typically, buckwheat is separated into six size fractions (4.5, 4.2, 4.0, 3.8, 3.6, and 3.3 mm), and each fraction is processed using a different working clearance. Although this approach improves dehulling efficiency, it increases processing time, equipment complexity, energy consumption, and production costs.

To overcome these limitations, a new dehulling device has been developed that is capable of processing unsorted buckwheat within the commercial size range of 3–5 mm without preliminary size classification. The device consists of a rotating drum and a newly designed pressure deck whose geometry is adapted to the shape of buckwheat grains. During operation, the elastic contact surface of the pressure deck continuously presses the grains into the rotating drum while accommodating variations in grain size. The abrasive surface of the rotating drum then removes the hull without causing excessive grain breakage.

The successful operation of this device depends primarily on the elastic properties of the pressure deck material. If its elastic stiffness is lower than that required to generate sufficient contact pressure, larger grains cannot be properly compressed and effective dehulling cannot be achieved. Therefore, selecting an appropriate elastic material for the pressure deck makes it possible to maintain stable contact between grains and the rotating drum over a wide range of grain sizes, thereby eliminating the need for preliminary size classification.

The objective of this study was to experimentally evaluate the dehulling performance of the newly developed rotating drum–pressure deck device and to determine its optimal operating conditions using a three-factor rotatable central composite design. The effects of drum rotational speed, working gap, and grain moisture content on the degree of dehulling were investigated, and a quadratic regression model describing the dehulling process was established.

MATERIALS AND METHODS

The objective of this experimental study was to verify the theoretical model previously developed by the authors *(Oidov et al., 2025).* Under practical operating conditions and to evaluate the dehulling performance of unsorted buckwheat using a newly designed dehulling device consisting of a rotating drum and a pressure deck with an elastic contact surface (elastic coefficient ($k_m \approx 10\ N/mm$)). The study focused on identifying the operating conditions that maximize the degree of dehulling while preventing excessive grain damage.

Based on the theoretical analysis and previous studies, three operating parameters were selected as the main independent variables because they have the greatest influence on the dehulling process: drum rotational speed (X_1), working gap between the rotating drum and the pressure deck (X_2), and buckwheat moisture content (X_3). The response variable was the degree of dehulling (y), which was used as the optimization criterion.

The experimental material consisted of common buckwheat (*Fagopyrum esculentum* Moench) with a moisture content ranging from 9 to 16% (wet basis) and a grain size ranging from 3.2 to 5.0 mm. The selection of the experimental material and evaluation of its physical and mechanical properties were based on the methods and the engineering principles reported by *(Bonafaccia et al., 2003; Mohsenin., 1986; Altuntas et al., 2007; Rao et al., 2005).* The upper limit of 5 mm was used as the equivalent grain diameter in the design calculations because it represents the largest grain fraction processed by the machine and therefore corresponds to the most critical operating condition. The experimental apparatus consisted of a rotating drum and a newly developed pressure deck with an elastic contact surface, as illustrated in Fig. 1.

To investigate the combined effects of the selected factors while minimizing the number of experiments, a three-factor, second-order Central Composite Rotatable Design (CCRD) was employed. This experimental design enables the development of a quadratic regression model describing the relationship between the operating parameters and the degree of dehulling, while also allowing evaluation of interaction and quadratic effects. The design matrix comprised 20 experimental runs, including factorial, axial, and center points. For each experimental run, a sample of 100 buckwheat grains was processed, and the degree of dehulling was determined experimentally. The resulting data were subsequently analyzed using regression analysis and analysis of variance to determine the optimum operating conditions.

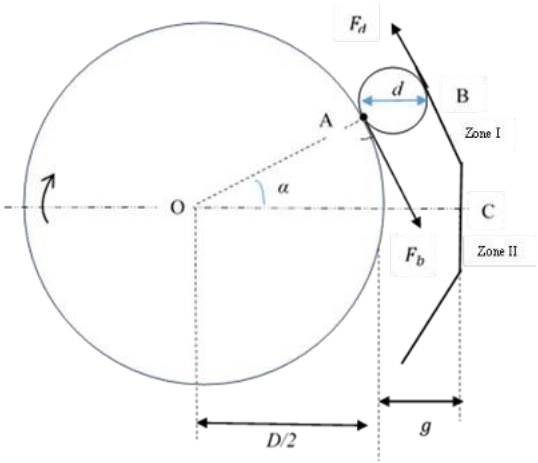

Fig. 1 - Schematic diagram of the rotating drum-pressure deck dehulling system and force analysis of a buckwheat grain

O - drum center; A – contact point between the drum and grain; B – contact point between the pressure deck and grain; F_b– friction force between the drum and grain; F_d – friction force between the pressure deck and grain; d_{eq}- equivalent grain diameter; D- drum diameter; g-working gap, α – grain position angle (measured from the horizontal centerline of the rotating drum).

Calculation of the Rotating Drum Diameter and Pressure Deck Length

The geometric parameters of the experimental dehulling device were determined from the kinematic conditions governing the entry of a buckwheat grain into the working gap between the rotating drum and the pressure deck Fig. 1. At contact point **A**, the rotating drum exerts a friction force F_b on the grain, whereas at contact point **B**, the pressure deck exerts a friction force F_d. In addition, normal reaction forces are generated at both contact points due to the elastic deformation of the grain. Owing the tetrahedral geometry of buckwheat grains, their rotational motion during feeding was assumed to be negligible, and the grains were therefore considered to undergo pure translational motion. This assumption is consistent with the principles of contact mechanics described by *Johnson., (1985),* and with the mechanical behaviors of biological materials reported by *Mohsenin., (1986).*

For the grain to be drawn into the working gap, the friction force generated by the rotating drum must exceed that generated by the pressure deck:

$$F_b > F_d \tag{1}$$

where F_b is the friction force between the rotating drum and the grain, and F_d is the friction force between the pressure deck and the grain.

The condition for grain entry can also be expressed in terms of the nip angle:

$$\tan\alpha < (f_b - f_d) \tag{2}$$

where α is the grain position angle, f_b is the coefficient of friction between the rotating drum and the grain, and f_d is the coefficient of friction between the pressure deck and the grain.

The friction coefficients were experimentally determined using the inclined-plane method described in our previous study *(Oidov et al., 2025)*. The measured values were $f_b = 0.47$ for the rotating drum and $f_d = 0.36$ for the pressure deck.

From the geometric relationship between the drum, grain, and working gap, the minimum drum diameter is determined by

$$D = \frac{d_{eq}cos\alpha - g}{(1 - cos\alpha)} \tag{3}$$

where D is the drum diameter, d_{eq} is equivalent diameter of the buckwheat grain, g is the working gap.

The equivalent diameter of the buckwheat grain was experimentally determined in our previous study *(Oidov et al., 2025)* by measuring the grain height of 100 randomly selected grains and converting it to the equivalent diameter using $d_{eq} = 4h/3$. Statistical analysis yielded an average equivalent diameter of $5.00 \pm 0.48\ mm$. The equivalent diameter is widely used for the engineering characterization of agricultural processing equipment because it provides a representative geometric for irregularly shaped biological materials (*Mohsenin, 1986; Rao et al., 2005*). Since the experimental material included grains with equivalent diameters of up to 5.0 mm, this value was adopted in the present design calculations as the representative grain size corresponding to the most critical operating condition for determining the minimum drum diameter. The working gap was selected as $g = 4$ mm.

Substituting these values into Equation (2),

$$\tan\alpha < (0.47 - 0.36) = 0.11$$

thus,

$$\alpha = \arctan(0.11) = 6.3^0$$

Using Equation (3),

$$D_{min} = \frac{5 \cdot cos(6.3^0) - 4}{1 - cos(6.3^0)} = 95 \text{ mm}$$

Accordingly, the selected drum diameter of 152 mm satisfies the design requirement: $D_{min} < D = 152\ mm$

The drum width was selected as 60 mm.

The minimum length of the pressure deck (working gap) is calculated from:

$$\alpha = arccos\frac{D_{min}+\delta}{D_{min}+d} \quad (4)$$

and

$$L_{min} = 2 \cdot \frac{\pi D_{min}}{360} \cdot \alpha \quad (5)$$

Substituting $D_{min} = 95\ mm$

$$\alpha = arccos\frac{95+4}{95+5} = 8.1^0;$$

$$L_{min} = 13.4\ mm$$

For the selected drum diameter $D = 152\ mm$,

$$L_{min} = 13.26\ mm$$

For the selected drum diameter of $D = 152\ mm$, the calculated minimum working gap length was $L_{min} = 13.26\ mm$. To ensure complete contact between the buckwheat grain and the abrasive surface during dehulling, the working section of the pressure deck was designed with a length of 15 mm. Based on these calculations, the experimental dehulling device was constructed with a drum diameter of 152 mm, a drum width of 60 mm, a working gap of 4 mm, and a pressure deck working length of 15 mm. These parameters were adopted in all subsequent experiments.

Mathematical Processing of Experimental Data

To evaluate the performance of the proposed dehulling device, the experiments were conducted according to a three-factor central composite rotatable design (CCRD). This design enables the effects of the main operating factors and their interactions to be evaluated efficiently while providing a quadratic regression model suitable for process optimization.

The response variable was the degree of dehulling (%), which was used as the optimization criterion. Based on previous studies *(Itodo et al., 2023; Kamst et al., 2002; Mar'in et al., 2020; Oidov et al., 2025; Shitanda et al., 2001; Solanki et al., 2018; Upreti et al., 2022; Zhang et al., 2025; Zhen et al., 2022)* and the theoretical analysis presented in this work, three independent variables were selected:

- $\boldsymbol{X_1}$ – drum rotational speed, n (rpm);
- $\boldsymbol{X_2}$ – working gap between the rotating drum and the pressure deck, g (mm);
- $\boldsymbol{X_3}$ – buckwheat grain moisture content, w (%).

The coded and actual levels of the experimental factors are presented in Table 1, while the corresponding experimental design matrix is given in Table 2.

Table 1

Experiment factors and their coded levels

№	Real factors and units of measurement	Marking	The rate at which factors change					
			-1	**0**	**+1**	**Δ**	**+1,68**	**-1,68**

The experimental data were analyzed using response surface methodology (RSM). A second-order polynomial regression model was developed to describe the relationship between the degree of dehulling and the operating factors. The homogeneity of the experimental variance was evaluated using Cochran's test, the statistical significance of the regression coefficients was determined using Student's t-test, and the adequacy of the regression model was verified using Fisher's F-test.

To homogeneity of variance was evaluated from six replicated experiments performed at the center point of the design.

$$G_t = \frac{max{S_i}^2}{\sum_i^n {s_i}^2} \quad (6)$$

where, G_t is the calculated Cochran statistic, ${S_i}^2$ is the variance obtained from the $i-th$ replicated experiment, $max{S_i}^2$ is the maximum variance among all experimental conditions, n is the number of replicated experiments.

The experimental variance at the center point was determined from

$$S_i^2 = \frac{\sum_i^{N_0}(y_i-\bar{y})^2}{N_0-1} \quad (7)$$

where S_i^2 is the experimental variance, N_0 is the number of replicated center-point experiments, y_i is the measured degree of dehulling, and $\bar{y}$ is the mean response.

The constants required for calculating the regression coefficients are presented in Table 3.

Table 3

Determinants and Constants for Rotatable Central Composite Design

Parameter	Symbol / Description	Value
Number of factors	n	3
Total number of experiments	N	20
Number of center-point experiments	N_0	6
Calculation constant	A	0.4537037
Calculation constant	B	0.8571429
Calculation constant	C	1.4285714

The auxiliary sums used for estimating the regression coefficients were calculated as

$$S_0 = \sum_{i=1}^{n} y_i \quad (8)$$

$$S_i = \sum_{i=1}^{n} (X_{\boldsymbol{i}} \cdot y_i) \quad (9)$$

$$S_{ij} = \sum_{i=1}^{n} (X_{\boldsymbol{ij}} \cdot X_{\boldsymbol{ji}} \cdot y_i), \qquad (i \neq j) \quad (10)$$

$$S_{ii} = \sum_{i=1}^{n} (X_{ii}^2 \cdot y_i) \quad (11)$$

where, S_0 is the sum of the response values, S_i is the weighted sum for the linear terms, S_{ij} is the weighted sum for the interaction terms, S_{ii} is the weighted sum for the quadratic terms.

The regression coefficients were calculated using Equations (12) - (15).

$$b_0 = \frac{2AB}{N}\left[S_0 B(n+2) - C\sum_{i=1}^{n} S_i\right] \quad (12)$$

$$b_i = \frac{CS_i}{N} \quad (13)$$

$$b_{ij} = \frac{C^2 S_{ij}}{BN} \quad (14)$$

$$b_{ii} = \frac{AC}{N}\left[S_{ii} C[B(n+2-n) + C(1-B)\sum_{i=1}^{n} S_{ii} - 2BS_0\right] \quad (15)$$

The variances of the regression coefficients were calculated using Equations (16) - (19).

$$s_{b_0}^2 = \frac{2AB(n+2)}{N} \cdot S_y^2 \quad (16)$$

$$s_{b_i}^2 = \frac{S_y^2}{N - N_0} \quad (17)$$

$$s_{b_{ij}}^2 = \frac{C^2}{N} \cdot S_y^2 \quad (18)$$

$$s_{b_{ii}}^2 = \frac{AC^2}{N}[B(n+1) - (n-1)] \cdot S_y^2 \quad (19)$$

The statistical significance of the regression coefficients was evaluated using Student's *t*-test.

RESULTS AND DISCUSSION

Statistical Analysis of the Regression Model

The calculated Cochran statistic was:

$$G_t = 0.47,$$

whereas the critical value was:

$$G_{cr} = 0.616.$$

Since:

$$G_t < G_{cr},$$

the experimental variances were considered homogeneous, confirming the reproducibility of the experimental data.

The calculated center-point variance was:

$$S_y^2 = 4.67$$

The results of the variance calculations are presented in Table 4.

Table 4

Evaluation of Variance at the Center Point of the Design

№	y_i	$(y_i - \bar{y})$	$(y_i - \bar{y})^2$	S_i^2
15	64	2.67	7.11	3.55
16	60	-1,33	1.78	0.89

№	y_i	$(y_i - \bar{y})$	$(y_i - \bar{y})^2$	S_i^2
17	61	-0.33	0.11	0.05
18	62	0.67	0.44	0.22
19	58	-3.33	11.11	**5.55**
20	63	1,67	1.78	1.39
	61.33		23.33	11.67

The statistical significance of the regression coefficients is presented in Table 5. Only statistically significant were retained in the final regression equation.

Table 5

Significance of Regression Coefficients

$\|b_i\|$	$b_i =$	t-criterion	Significant (Yes/No)
$\|b_0\|$	64.88	2.45	Y
$\|b_1\|$	1.58	1.48	Y
$\|b_2\|$	2	1.48	Y
$\|b_3\|$	1.6	1.48	Y
$\|b_{12}\|$	0.12	1.77	N
$\|b_{13}\|$	0.12	1.77	N
$\|b_{23}\|$	0.36	1.77	N
$\|b_{11}\|$	1.71	1.43	Y
$\|b_{22}\|$	2.04	1.43	Y
$\|b_{33}\|$	1.87	1.43	Y

The adequacy variance of the regression equation was calculated from

$$S_{ad}^2 = \frac{\sum_{i=1}^{n}(y_i - y_i^t)^2 - S_y^2(N_0 - 1)}{N - \frac{(n+2)(n+1)}{2} - (N_0 - 1)} \quad (20)$$

where, S_{ad}^2 is the adequacy variance, y_i is the experimental value, y_i^t is the value predicted by the regression model.

The Fisher criterion was determined as:

$$F_p = \frac{S_{ad}^2}{S_y^2} \quad (21)$$

The calculated value was:

$$F_p = 4.70$$

whereas the critical value was:

$$F_{cr} = 5.05$$

Since:

$$F_p < F_{cr}$$

the developed regression model was considered statistically adequate for describing the buckwheat dehulling process.

The comparison between the experimental and predicted values is presented in the Table 6.

10	56	57.41602	2.005114	20	63	64.18	1.3924
Σ					1219	1216.465	133.1686

Based on the experimental data, a second-order regression model describing the relationship between the degree of buckwheat dehulling and the operating parameters of the developed dehulling device was obtained:

$$y = 64.88 + 1.58X_1 + 2X_2 + 1.6X_3 - 1.71X_1^2 - 2.04X_2^2 - 1.87X_3^2. \quad (22)$$

The adequacy of the developed model was confirmed by Fisher's test ($F_{\text{p}} = 4.70 < F_{cr} = 5.05$), indicating that the regression equation provides adequately descries the experimental data. The maximum predicted degree of dehulling was $66.08\ \%$, obtained at the coded factor levels of $X_1 = 0.46, X_2 = 0.49$ and $X_3 = 0.43$. These values correspond to a drum rotational speed of 846 rpm, a working gap of 4.2 mm, and a buckwheat moisture content of 13.86%.

The optimum moisture content obtained in this study (13.86%) is consistent with the moisture range reported by *(Solanki et al., 2018)* for efficient buckwheat dehulling and is also in agreement with the experimental findings of *(Upreti et al., 2022)*. Although *(Zhang et al., 2025)* employed a grinding-disc dehuller operating on a different mechanical principle, they similarly reported that grain moisture content significantly influences dehulling performance.

The results further demonstrate that the dehulling efficiency is governed by the combined influence of drum rotational speed, working gap, and grain moisture content. The optimum operating conditions were located near the center of the experimental region rather than at its boundaries, indicating that excessive or insufficient values of the operating parameters reduce the degree of dehulling. Similar relationships between operating parameters and dehulling efficiency have also been reported for roller-type rice hullers *(Shitanda et al., 2001; Cheng et al., 2026)* and buckwheat dehulling machines *(Zhen et al., 2022)*.

Response Surface Analysis

The influence of the operating factors was further analyzed using response surface and contour plots generated from the regression model.

To illustrate the interaction between factors, one variable was fixed at its central coded level while the remaining two variables were varied.

Fig. 2, shows the response surface for the combined effect of drum rotational speed (X_1) and working gap (X_2) at the central moisture content ($X_3 = 0$).

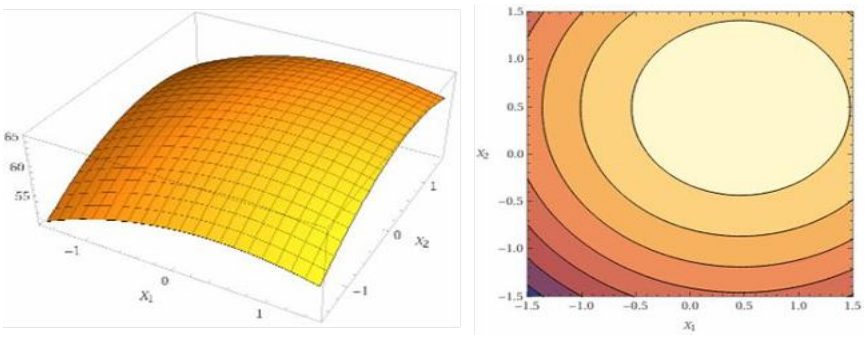

Fig. 2 - Response surface and contour plot of the degree of dehulling as a function of drum rotational speed and working gap ($X_3 = 0$)

Fig. 3, illustrates the interaction between drum rotational speed (X_1) and grain moisture content (X_3) while maintaining the working gap at its central level ($X_2 = 0$).

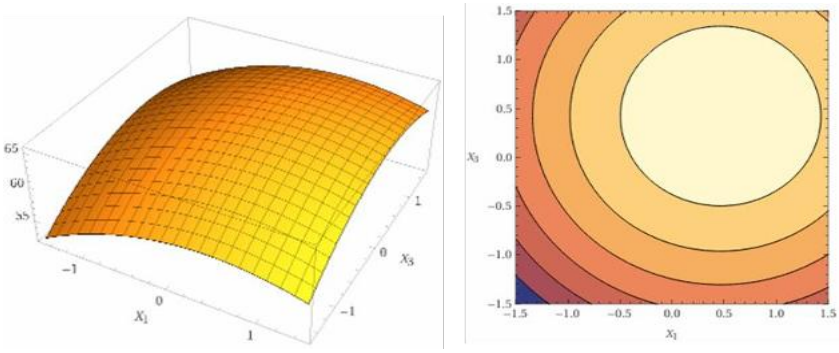

Fig. 3 - Response surface and contour plot of the degree of dehulling as a function of drum rotational speed and grain moisture content ($X_2 = 0$)

Fig. 4, presents the combined influence of working gap (X_2) and grain moisture content (X_3) at the central drum speed ($X_1 = 0$).

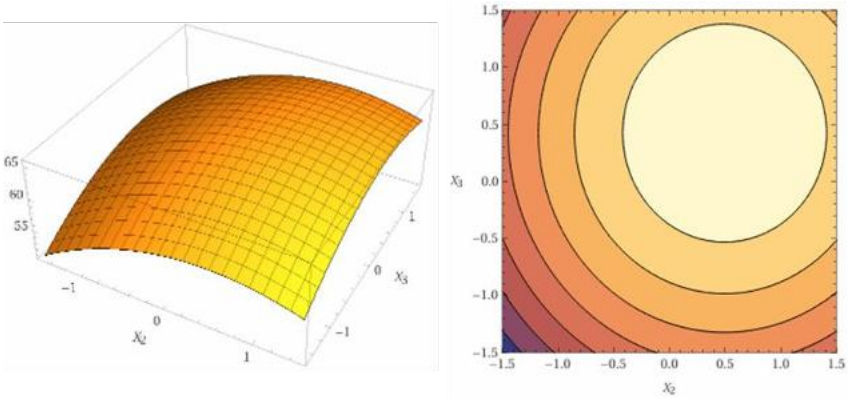

Fig. 4 - Response surface and contour plot of the degree of dehulling as a function of working gap and grain moisture content ($X_1 = 0$)

The response surface analysis demonstrated that drum rotational speed, working gap, and grain moisture content all had significant effects on the degree of buckwheat dehulling. The response surface indicate that the dehulling degree is governed by the combined interaction of these operating parameters, with the highest values occurring in the vicinity of the optimum conditions predicted by the regression model. Similar relationships between operating parameters and dehulling efficiency have been reported for roller-type rice hullers (*Shitanda et al., 2001; Cheng et al., 2026*) and buckwheat dehulling machines (*Solanki et al., 2018; Zhen et al., 2022*). The agreement between the response surface analysis and statistical optimization results confirms the reliability of the developed regression model for predicting the operating conditions that maximize the degree of dehulling.

Compared with conventional rubber-roll and impeller-type hullers reported by *(Shitanda et al., 2001*; *Solanki et al., 2018; Upreti et al., 2022),* the proposed rotating drum-pressure deck system achieves comparable dehulling performance while eliminating the need for preliminary grain size classification.

CONCLUSIONS

Experimental investigations of buckwheat dehulling using the developed dehulling device consisting of a rotating drum and a pressure deck with an elastic contact surface ($k_m \approx 10\ N/mm$) were successfully carried out using a three-factor central composite rotatable experimental design.

The main conclusions are as follows:

1. A statistically adequate second-order regression model describing the influence of drum rotational speed, working gap, and grain moisture content on the degree of buckwheat dehulling was developed and verified using Cochran's, Student's, and Fisher's statistical tests.
2. The optimum operating conditions predicted by the regression model were:
   - drum rotational speed: 846 rpm;
   - working gap: 4.2 mm;
   - buckwheat moisture content: 13.86%.

3. Under these operating conditions, the maximum predicted degree of dehulling reached 66.08**%**.
4. Response surface analysis demonstrated that the interaction of the operating factors significantly affects the dehulling performance. The use of an elastic pressure deck enables effective dehulling of buckwheat grains over the investigated size range without preliminary size classification.
5. The obtained results confirm the feasibility of the proposed dehulling principle and provide a basis for further optimization of the mechanical properties of the elastic pressure deck and the operating parameters of the dehulling device.

ABSTRACT

To address the instability of trajectory tracking in unmanned orchard inspection vehicles caused by satellite navigation signal attenuation and track slippage, an integrated control method based on pose correction and an improved Stanley controller was proposed. First, a pose-correction algorithm based on the interacting multiple-model extended Kalman filter (IMM-EKF) was developed. By incorporating the nonlinear dynamic characteristics of tracked vehicles, the algorithm improved the robustness of pose estimation under varying motion states and measurement conditions. Second, an improved Stanley trajectory-tracking controller incorporating feedforward control and dynamic parameter adjustment was designed based on the corrected pose estimates. By accounting for path curvature in advance, the controller optimized the control commands and reduced lateral and heading errors. Simulations conducted using the Robot Operating System (ROS) platform and field tests performed in an actual vineyard were used to evaluate the proposed method. At a representative operating speed of 1.0 m/s, the mean lateral error during continuous multi-route trajectory tracking was 0.019 m, and the mean root-mean-square error (RMSE) was 0.021 m. These results demonstrate that the proposed method can improve trajectory-tracking accuracy, stability, and smoothness under the tested orchard conditions.

摘要

针对果园复杂环境下卫星导航信号衰减与履带滑移引起的无人巡检车轨迹跟踪不稳定问题，本文提出了一种基于位姿修正与改进 Stanle 算法的综合控制方法。首先，构建了基于交互式多模型扩展卡尔曼滤波（IMM-E F）的位姿修正算法。该算法结合履带车辆非线性动力学特征，提高了车辆在运动状态和观测条件变化下的位姿估计鲁棒性。其次，基于修正后的位姿数据，设计了一种融合前馈控制策略与动态参数调整的改进 Stanle 轨迹跟踪控制器。该控制器通过提前考虑路径曲率信息，对轨迹跟踪控制指令进行优化，从而减小横向误差与航向误差。基于机器人操作系统（Ro ot O erat n S stem, ROS）平台的仿真分析与真实葡萄园环境下的实车试验结果表明，在 1 m/s 的典型作业速度下，车辆在多路线连续轨迹跟踪中的平均横向误差为 0.019 m，平均均方根误差（RMSE）为 0.021 m。结果表明，所提方法在测试果园条件下能够提高车辆轨迹跟踪的精度、稳定性与平顺性。

INTRODUCTION

As Chinese agricultural transformation and upgrading progresses, the automation and intelligentisation of orchard operations have become key means of alleviating labour shortages and reducing production costs (*Gao et al., 2021*). However, orchard environments are highly complex and unstructured, featuring undulating terrain, canopy obstruction and variable soil physicochemical properties, which pose a significant challenge to the autonomous navigation capabilities of unmanned inspection vehicles *(Xue et al., 2023)*. Recent studies from different agricultural regions have shown that orchard rows and dense tree canopies can seriously affect satellite-based navigation. Dense orchard canopies may prevent the reliable use of GPS signals *(Durand-Petiteville et al., 2018)*, and accurate robot localisation with respect to orchard row centre lines remains challenging because satellite signals are often obstructed by foliage *(Fei et al., 2022)*. Intermittent GNSS dropout in orchards can also significantly degrade navigation accuracy and requires auxiliary localisation methods such as LiDAR or INS *(Li et al., 2024)*. Particularly in complex orchard terrain, Global Navigation Satellite System (GNSS) signals are often attenuated or interrupted due to vegetation cover; coupled with the inherent slippage of tracked chassis when travelling on unpaved surfaces, this makes it difficult for traditional

navigation systems to provide continuous, high-precision position and attitude data, thereby leading to system oscillations and instability in trajectory tracking control.

For tracked and wheeled agricultural vehicles, track–soil and wheel–soil slip represent important sources of motion uncertainty. Slip estimation has been shown to be essential for the path-tracking control of autonomous agricultural vehicles operating on wet and deformable soils *(Han et al., 2019)*. In addition, kinematic models incorporating both translational slip and rotational slippage have been developed for trajectory prediction in tracked agricultural robots *(Zhao et al., 2024)*. These findings indicate that pose estimation, slip modelling, and trajectory tracking should be considered jointly when developing autonomous navigation systems for orchard inspection vehicles.

Stable, high-precision pose estimation is the cornerstone of autonomous navigation *(Zhou et al., 2021*). At present, autonomous navigation systems commonly employ data fusion techniques combining GNSS and Inertial Navigation Systems (INS) to compensate for the limitations of single GNSS signals; however, due to cost constraints on orchard operation vehicles, low-to-medium accuracy INS systems are highly prone to accumulating drift errors during prolonged signal blockage, making it difficult to meet high-precision positioning requirements *(Lv et al., 2025)*. In terms of filtering algorithms, the Extended Kalman Filter (EKF) is widely used for state estimation and noise filtering in non-linear systems; however, filters based on a single motion model struggle to accurately capture the complex non-linear dynamic behaviour of a vehicle under variable road conditions *(Zhang et al., 2014)*. To this end, the Interactive Multi-Model (IMM) algorithm demonstrates excellent adaptability to system behaviour, thanks to its ability to dynamically switch between multiple motion hypotheses *(Nie et al., 2021)*. The deep integration of IMM with the Extended Kalman Filter (EKF) enables effective addressing of the challenge of high-precision pose estimation for orchard operation vehicles under complex constraints.

In the field of trajectory tracking control, the Stanley algorithm is widely used for lateral control in autonomous vehicles due to its geometric intuitiveness and computational efficiency *(Thrun et al., 2006).* In response to the time-varying and uncertain nature of agricultural scenarios, many researchers have introduced improved geometric control, fuzzy control, optimisation algorithms and model predictive control (MPC) to enhance the tracking performance of agricultural vehicles *(Kayacan et al., 2015; Plessen and Bemporad, 2017; Wang et al., 2022; Xu et al., 2022).* For example, improved Stanley controllers have been used to reduce path-tracking errors of autonomous tractors, while MPC-based methods have been adopted to handle actuator constraints and improve tracking stability in agricultural machinery. However, the narrow row spacing, uneven terrain and frequent curved sections within orchards require the control system to be more proactive and robust. Existing improved methods still have limitations in terms of transient smoothness, adaptability to variable ground conditions, and tracking accuracy on curved paths *(AbdElmoniem et al., 2020; Wang et al., 2022).*

To address navigation challenges in complex orchards, this study proposes an integrated control framework combining IMM-EKF for precise pose correction and an improved feedforward Stanley algorithm. The proposed method uses IMM-EKF to reduce pose fluctuation caused by GNSS signal degradation and vehicle motion uncertainty, and introduces curvature feedforward into the Stanley controller to improve tracking response on curved paths. Simulations and field trials verify that this method can improve the accuracy, smoothness, and reliability of vehicle trajectory tracking under the tested orchard conditions.

To address navigation challenges in complex orchards, this study proposes an integrated control framework combining IMM-EKF for precise pose correction and an improved feedforward Stanley algorithm. Simulations and field trials verify that this method significantly enhances the accuracy, smoothness, and reliability of the vehicle trajectory tracking.

MATERIALS AND METHODS

Using dual-antenna GNSS-RTK positioning technology, the vehicle is able to determine its global position through absolute positioning. However, in real-world orchards, vehicles often need to operate in complex environments characterised by uncertainty and dynamic changes *(Zhou et al., 2014)*. For example, signal instability or unavailability caused by tree cover may affect the accuracy and reliability of absolute positioning. To overcome these challenges, this study introduces an attitude correction technique based on the Interactive Multiple Model Extended Kalman Filter (IMM-EKF). The IMM framework provides an adaptive state-estimation strategy for systems with switching motion modes or time-varying uncertainty by combining multiple model hypotheses according to their posterior probabilities (*Blom and Bar-Shalom, 1988; Li and Jilkov, 2005*). By integrating the IMM framework with the estimation capability of the EKF in nonlinear systems, the IMM-EKF can improve the robustness of vehicle pose estimation under varying motion and measurement

conditions (*Jwo et al., 2013*). Specifically, at each time step, the IMM-EKF first calculates the mixed initial state of each model based on the model transition probability and the state estimate from the previous time step. Then, each EKF sub-filter performs state prediction and measurement update. Finally, the posterior probability of each model is updated according to the measurement likelihood, and the EKF estimates are weighted and combined to obtain the integrated state estimate at the current time. The architecture of the IMM-EKF algorithm is shown in Figure 1.

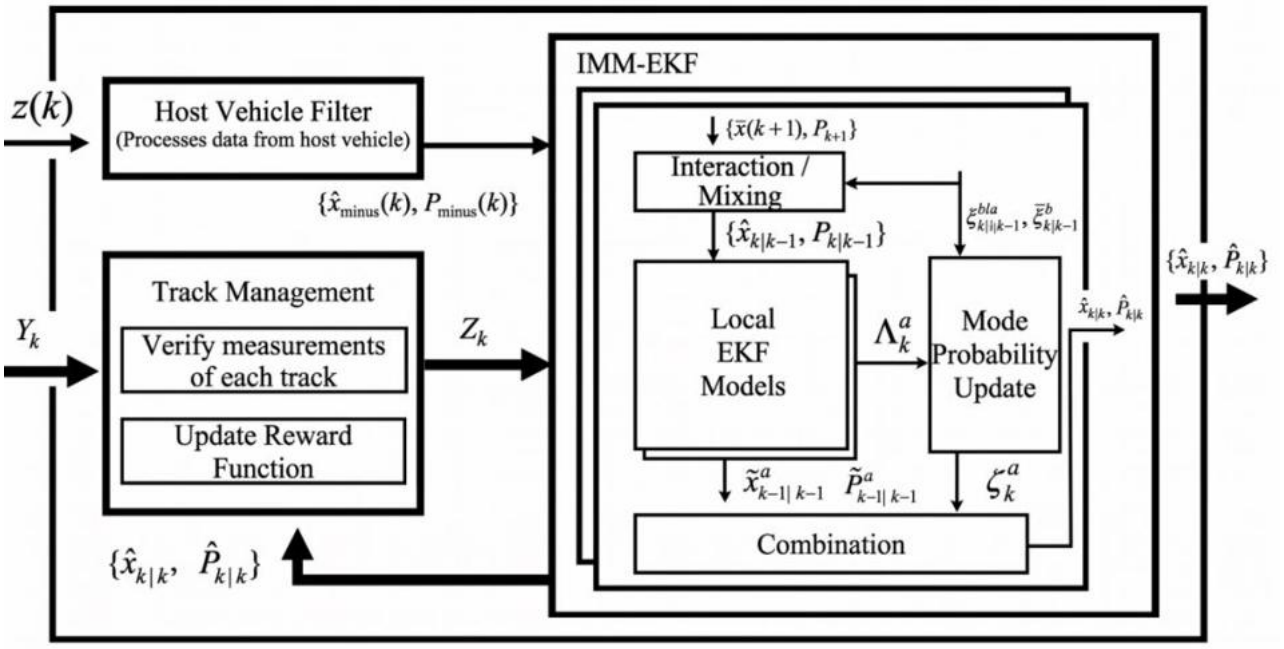

Fig. 1 - IMM-EKF algorithm architecture

This study employs a dual-antenna GNSS-RTK (Global Navigation Satellite System-Real Time Kinematic) system to obtain the vehicle's global position and attitude data. The system is based on real-time dynamic carrier phase differential technology. By calculating the relative positions of the master and slave antennas, it is capable of outputting high-precision global coordinates (longitude, latitude and altitude) as well as the vehicle's three-dimensional attitude angles (heading, pitch and roll) in real time *(Zhang et al., 2022)*.

To meet the requirements for subsequent non-linear dynamic modelling and trajectory tracking control, the system uses a standard Direction Cosine Matrix (DCM) to map the geodetic Cartesian coordinate system data obtained from GNSS-RTK to the local horizontal coordinate system *(Shan et al., 2018)*. Following the coordinate transformation, the absolute coordinates (x, y) and heading angle θ of the orchard operation vehicle in the planar coordinate system are extracted. These three state variables will serve directly as the initial observation inputs for the subsequent Interactive Multi-Model Extended Kalman Filter (IMM-EKF), which is designed to address signal attenuation and noise interference in environments where the signal is obscured by orchard canopies *(Wu et al., 2021)*.

The vehicle pose in the local planar coordinate frame is selected as the system state. The angular velocities of the left and right drive sprockets are treated as the control inputs, whereas the corresponding slip ratios and the vehicle slip angle are regarded as time-varying model parameters. These variables are used to characterize the effects of track slip on the vehicle motion *(Yang et al., 2022)*.

At discrete time step *k*, the longitudinal position, lateral position, and yaw angle of the tracked inspection vehicle are combined into the state vector:

$$\mathbf{x}_k = \begin{bmatrix} x_k \\ y_k \\ \theta_k \end{bmatrix} \quad (1)$$

where x_k and y_k denote the global longitudinal and lateral coordinates of the vehicle, respectively, in m, and θ_k denotes the vehicle yaw angle in rad, measured counterclockwise from the positive direction of the global *X*-axis.

The control input $\mathbf{u}_k$ (comprising the angular velocities of the left and right drive sprockets) and the slip-related parameter vector $\boldsymbol{\eta}_k$ are respectively defined as:

$$\mathbf{u}_k = \begin{bmatrix} \omega_{l,k} \\ \omega_{r,k} \end{bmatrix}, \boldsymbol{\eta}_k = \begin{bmatrix} i_{l,k} \\ i_{r,k} \\ \alpha_k \end{bmatrix} \quad (2)$$

Here, $i_{l,k}$ and $i_{r,k}$ are the real-time slip ratios of the left and right tracks, respectively, and α_k is the vehicle slip angle. Accordingly, the discrete-time nonlinear state equation is written as:

$$\mathbf{x}_{k+1} = f(\mathbf{x}_k, \mathbf{u}_k, \boldsymbol{\eta}_k) + \mathbf{w}_k \quad (3)$$

where $\mathbf{w}_k$ denotes the process noise.

Since the GNSS-RTK system directly measures the vehicle pose (x_k, y_k, θ_k), the observation model is linear, and its Jacobian is given by:

$$\mathbf{H}_k = \left.\frac{\partial h(\mathbf{x})}{\partial \mathbf{x}}\right|_{\mathbf{x}=\mathbf{x}_{k|k-1}} = \mathbf{I}_3 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad (4)$$

Since the standard prediction and measurement-update equations of the EKF are well established, they are not repeated here. In this study, the system nonlinearity mainly arises from the state-transition model $f(\cdot)$ whereas the observation model is linear, with H_k=I_3. Therefore, the following discussion focuses on the covariance prediction and the Jacobian matrix of the nonlinear state-transition model *(Yang et al., 2015)*.

On this basis, in order to quantify the uncertainty in the forecast, the process of updating the forecast state covariance P requires the introduction of a process noise covariance matrix, the calculation of which can be expressed as:

$$P_{k+1} = A_k P_k A_k^T + Q_k \quad (5)$$

Here, A_k is the Jacobian matrix of the system's dynamic model based on the current state estimate, reflecting how minute changes in the system's state variables affect the evolution of the system's overall state.

$$A_k = \begin{bmatrix} 1 & 0 & A_{K13} \\ 0 & 1 & A_{K23} \\ 0 & 0 & 1 \end{bmatrix} \quad (6)$$

$$A_{K13} = -\frac{r\left(\left(1-i_l\right)w_l + \left(1-i_r\right)w_r\right)(\sin(\theta) + \cos(\theta)\tan(\alpha))}{2} \quad (7)$$

$$A_{K23} = \frac{r\left(\left(1-i_l\right)w_l + \left(1-i_r\right)w_r\right)(\cos(\theta) - \sin(\theta)\tan(\alpha))}{2} \quad (8)$$

In particular, A_{K13} and A_{K23} are based on a vehicle kinematic model, taking into account the effects of slip ratio and wheel speed on changes in vehicle direction, and reveal the complexity of the interactions between state variables in a non-linear dynamic system.

$$Q_k = \begin{bmatrix} \sigma_{w_l}^2 & 0 & 0 \\ 0 & \sigma_{w_r}^2 & 0 \\ 0 & 0 & \sigma_\theta^2 \end{bmatrix} \quad (9)$$

$$P_k = \begin{bmatrix} \sigma_x^2 & 0 & 0 \\ 0 & \sigma_y^2 & 0 \\ 0 & 0 & \sigma_\theta^2 \end{bmatrix} \quad (10)$$

The process noise covariance accounts for the influence of random noise from various sources in real-world driving conditions—such as wheel speed noise and steering noise—on state estimation.

Based on the standard IMM framework, the weights of each motion model are dynamically updated using the model transition probability matrix, and the posterior probability is calculated using the likelihood function, ultimately outputting the fused optimal state estimate and covariance matrix.

In order to precisely control the vehicle movement along the desired path whilst performing a path-tracking task, it is essential to accurately calculate the path-tracking error, including lateral and heading errors. These errors serve as key indicators of the deviation between the vehicle's current state and its desired trajectory, and are crucial for designing effective control strategies.

Lateral error refers to the perpendicular distance between the vehicle's current position and the nearest point on the intended path. Let the actual position of the vehicle be denoted by (x_v, y_v), and determine the projection point (x_p, y_p) of the vehicle's current position onto the desired path, as shown in Figure 2.

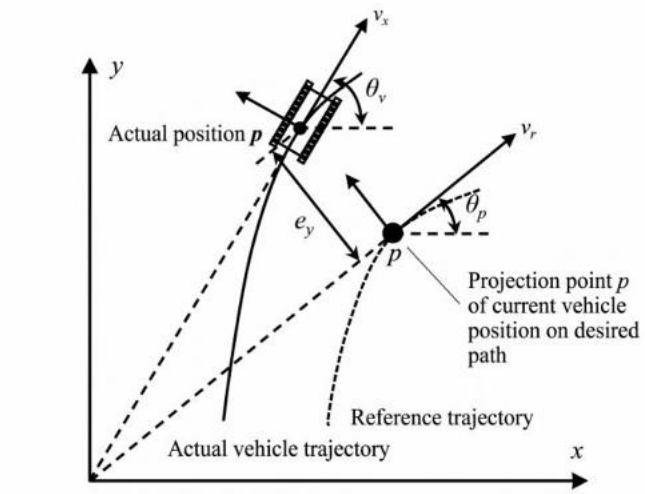

Fig. 2 - The correlation between the actual driving trajectory and the reference trajectory of the vehicle.

The lateral error e_y is given by the distance between the vehicle's actual position and its projected position on the desired path; the mathematical expression is:

$$e_y = \sqrt{(x_v - x_p)^2 + (y_v - y_p)^2} \cdot \mathrm{sgn}(y_v - f(x_v)) \quad (11)$$

Here, $\mathrm{sgn}(\cdot)$ is a sign function used to determine the direction of the error (whether the vehicle is to the left or right of the desired path). Heading error refers to the angular difference between the vehicle's current heading and the tangent direction of the desired path at its projection point. Let θ_v be the vehicle's actual heading angle; the tangent angle θ_p at the projection point (x_p, y_p) on the desired path can be obtained by differentiating $f'(x_p)$:

$$\theta_p = \arctan(f'(x_p)) \quad (12)$$

The course error e_θ can then be calculated as:

$$e_\theta = \theta_v - \theta_p, \quad e_\theta \in (-\pi, \pi] \quad (13)$$

The pose compensation module calculates the deviation between the actual trajectory and the desired trajectory, and adjusts the control inputs accordingly to achieve more precise trajectory tracking.

The expected trajectory can be expressed as a function:

$$y_r = f(x_r) \quad (14)$$

(x_r, y_r) denotes a point on the desired trajectory. The lateral error e_y and heading error e_θ between the vehicle's actual position and its desired position are defined as:

$$e_y = y - f(x) \quad (15)$$

$$e_\theta = \theta - \tan^{-1}(f'(x)) \quad (16)$$

Here, $f'(x)$ is the derivative of the expected trajectory at x, representing the direction of the tangent line to the trajectory.

Based on the findings of the above study, the pose estimates provided by the IMM-EKF are used to calculate the corrected lateral error $\hat{e}_y$ and heading error $\hat{e}_\theta$:

$$\hat{e}_y = \hat{y} - f(\hat{x}) \quad (17)$$

$$\hat{e}_\theta = \hat{\theta} - \tan^{-1}(f'(\hat{x})) \quad (18)$$

Using these corrected errors, a pose compensation module is designed to adjust the vehicle's control inputs in order to minimise these errors. The control input δ for pose compensation—namely, the vehicle's steering angle—can be adjusted using the following control law:

$$\delta = k_1 \cdot \hat{e}_y + k_2 \cdot \hat{e}_\theta \quad (19)$$

In this context, k_1 and k_2 are the control gains.

In order to further enhance the accuracy and stability of path tracking, the Stanley controller requires optimisation and refinement. Building upon the traditional Stanley method, the improved controller must not only accurately calculate path tracking errors but also adapt more flexibly to a variety of driving conditions, including different speeds, curvatures and changes in the external environment.

The improved Stanley control law is as follows:

$$\delta(t) = \arctan\left(\frac{k_e \cdot e_y(t)}{v(t)}\right) + k_\theta \cdot e_\theta(t) + \psi(t) \quad (20)$$

where: $e_y(t)$ - the lateral error at time t; $e_\theta(t)$ - the heading error at time t; $v(t)$ - the vehicle's speed; k_e - the adjustment coefficient for the lateral error; k_θ - the adjustment coefficient for the heading error.

Here, $\psi(t)$ represents the feedforward control term, which is expressed as follows:

$$\psi(t) = \arctan(k_\psi \cdot \frac{1}{g(t)}) \quad (21)$$

where: k_ψ — the feedforward control coefficient; $g(t)$ — the radius of curvature of the path at time t.

This control law responds directly to the current lateral and heading errors via the feedback term, whilst anticipating upcoming path changes via the feedforward term.

When designing a trajectory tracking control algorithm based on Stanley, the stability of the system must also be taken into account.

Given that the controller minimises the lateral error $\hat{e}_y$ and the yaw error $\hat{e}_\varphi$ by controlling the input δ, a Lyapunov function can be constructed to reflect these two errors, expressed as follows:

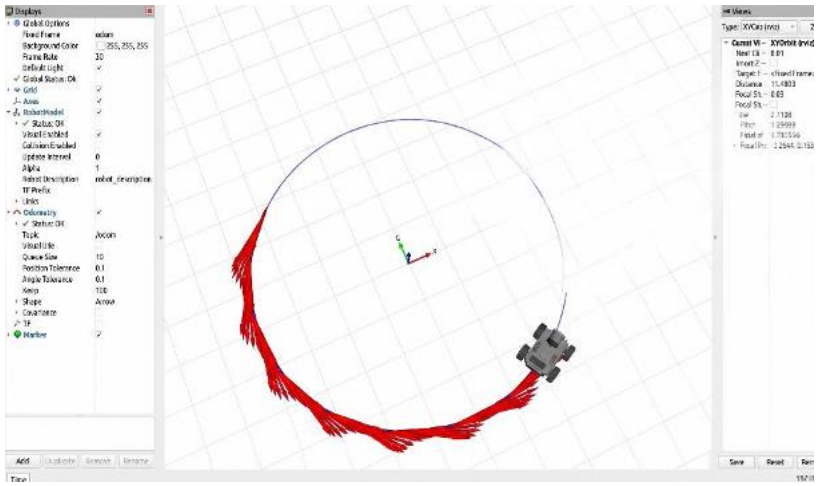
$$L = \frac{1}{2}(k_1 \hat{e}_y^2 + k_2 \hat{e}_\theta^2) \quad (22)$$

This function satisfies the condition that $L > 0$ holds for all $\hat{e}_y \neq 0$ or $\hat{e}_\varphi \neq 0$, and $L(0,0) = 0$, thereby fulfilling the first condition for a Lyapunov function.

Next, it is necessary to calculate $\dot{L}$, that is, the derivative of L with respect to time:

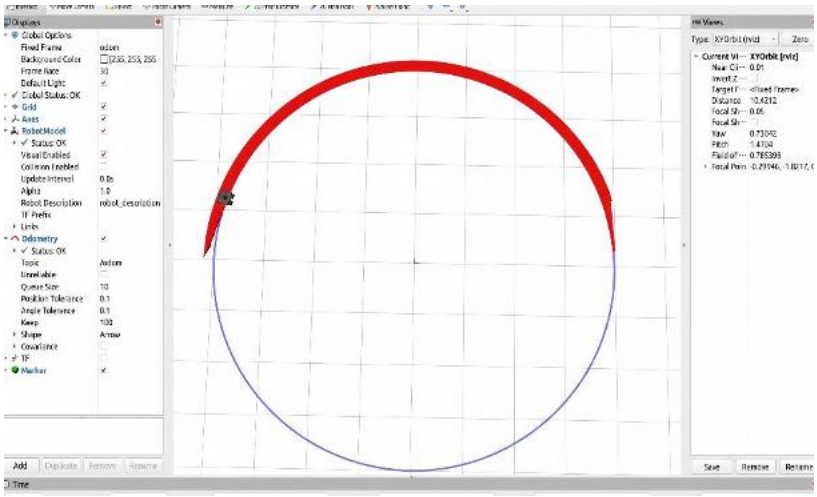
$$\dot{L} = k_1 \hat{e}_y \dot{\hat{e}}_y + k_2 \hat{e}_\theta \dot{\hat{e}}_\theta \quad (23)$$

Based on the system dynamics, $\dot{\hat{e}}_y$ and $\dot{\hat{e}}_\theta$ are determined by the vehicle's dynamic model and the control input δ; $\dot{\hat{e}}_y$ can be regarded as a function of lateral velocity, whilst $\dot{\hat{e}}_\theta$ can be regarded as a function of angular velocity.



Incorporating the control law into the analysis, the control input δ is designed to minimise $\hat{e}_y$ and $\hat{e}_\theta$. Stability analysis based on the Lyapunov function—namely, the expressions for $\dot{\hat{e}}_y$ and $\dot{\hat{e}}_\theta$—reveals a trend whereby the lateral and yaw errors decrease over time, thereby ensuring that the system converges within a specified error margin.

RESULTS



Precise trajectory tracking is the cornerstone of autonomous tracked vehicles, and this requires powerful and efficient algorithms.

To validate the performance and robustness of the proposed method, two simulation experiments were conducted: one involving straight-line path tracking control, and the other involving circular trajectory control.

A simulated orchard environment containing tree obstacles was created using ROS and Gazebo. A three-dimensional vehicle model with realistic physical and dynamic properties was then imported, and the sensor parameters were configured. Subsequently, a multimodel extended Kalman filter (EKF) framework was developed to fuse multisensor data. The framework dynamically updated the probability assigned to each motion model based on the observations and performed weighted fusion of the corresponding state estimates to obtain an optimal estimate of the vehicle pose. At the control level, a Stanley controller node was deployed to calculate the lateral tracking error by combining the predefined reference trajectory with the EKF-based state estimate. The controller then generated steering commands that enabled the vehicle to follow the prescribed path. Finally, RViz was used to visualize the planned and actual trajectories and the sensor outputs, as shown in Fig. 3(a). The controller and filter parameters were subsequently tuned to improve path-tracking stability, as shown in Fig. 3(b).

(a)

(b)

Fig. 3 - Trajectory tracking simulation experiment

To evaluate the performance of the control algorithm, different trajectory types, including straight and curved paths, were defined, and the vehicle's tracking accuracy, path-convergence rate, and robustness were assessed. The relevant state and control data were recorded by logging ROS topics during the simulation runs.

The simulation parameters were selected to reproduce real-world operating conditions as closely as possible. The vehicle's initial heading angle was set to 0.02 rad to represent the small initial orientation errors commonly encountered in practical applications. To reflect the physical constraints of an actual tracked vehicle, the maximum steering angular velocity was limited to 0.2 rad/s. In addition, the vehicle speed was set to 1.0 m/s to represent the typical low-speed operating conditions of tracked vehicles in the field.

The simulation results showed that the vehicle rapidly converged to the predefined reference path and subsequently followed it with high accuracy. However, an evaluation based solely on the mean error and standard deviation would provide an incomplete statistical characterization of tracking performance. Additional information, including the simulation duration, number of repeated runs, and confidence intervals, is required to quantify tracking stability more comprehensively.

For the straight-line path-tracking simulation shown in Fig. 4, the vehicle travelled at a constant speed of 1.0 m/s. Each simulation run lasted 120 s, and 20 independent trials were conducted to reduce the influence of random variability. The statistical results aggregated across the 20 trials were as follows: the mean lateral tracking error was 0.014 m, with a standard deviation of 0.0057 m and a 95% confidence interval of 0.0116–0.0164 m; the mean heading error was 0.002 rad, with a standard deviation of 0.0008 rad and a 95% confidence interval of 0.0017–0.0023 rad.

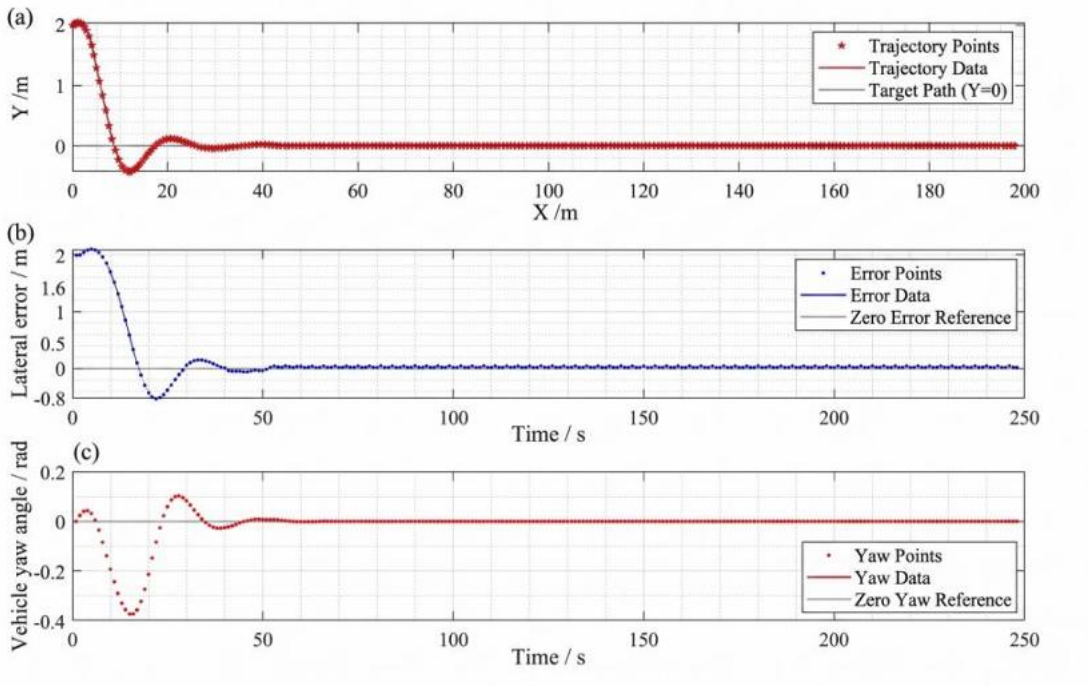


Fig. 4 - Straight-line path-tracking simulation and error.

As shown in Fig. 5, the circular trajectory-tracking simulation yielded a mean lateral error of 0.023 m, with a standard deviation of 0.0086 m, and a mean heading error of 0.033 rad, with a standard deviation of 0.021 rad. These results demonstrate that the proposed algorithm achieved accurate and stable trajectory tracking along a curved reference path.

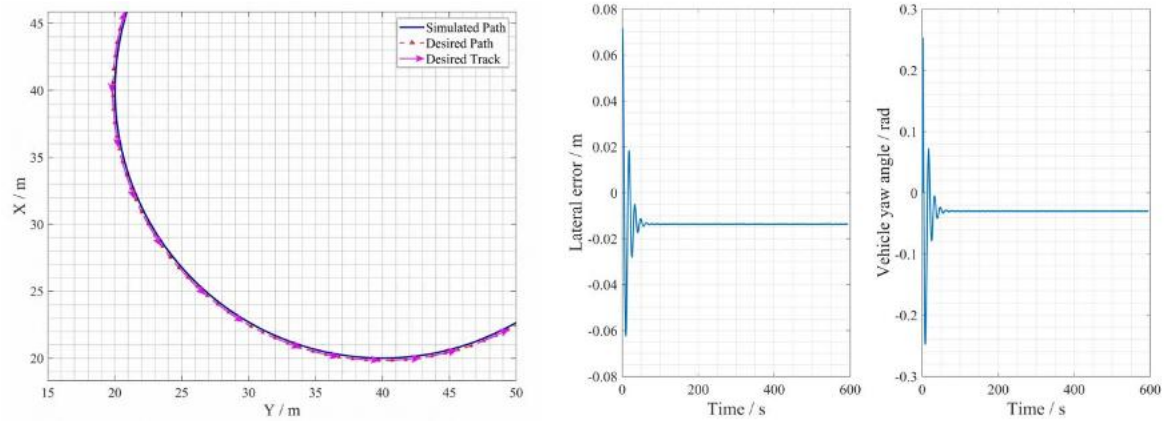

Fig. 5 - Simulated circular path-tracking error

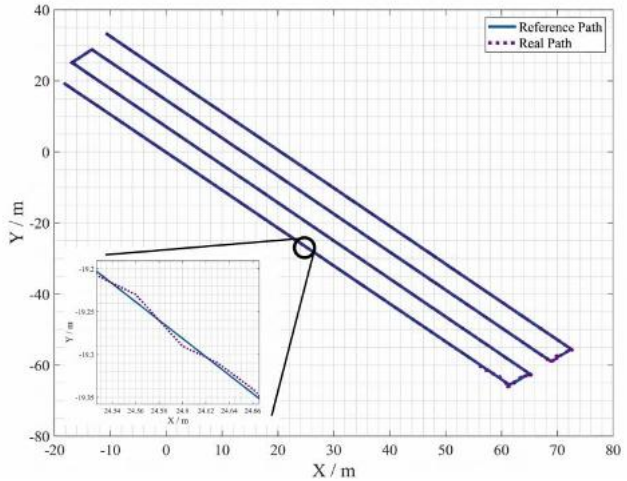
To evaluate the effectiveness of the proposed path-tracking algorithm under real operating conditions, field experiments were conducted in a vineyard. Fig. 6 shows the test site, which featured uneven terrain and inter-row weeds. Each vine row was 100 m long, and the row spacing ranged from 3.5 to 4.0 m.

Fig. 6 - Vineyard real-field scenario

Two field tests were conducted using the tracked orchard inspection vehicle: constant-speed straight-line trajectory tracking at 1.0 m/s and continuous trajectory tracking along multiple routes. Each test condition was repeated six times to improve the statistical reliability of the results. The straight test route was 100 m long, whereas the total length of the continuous multi-route trajectory was 480 m. Standardized initial conditions were applied, with nominal position and heading offsets set to zero. Before data recording, the maximum allowable initial position and heading deviations were limited to 0.03 m and 1.5°, respectively. Data acquisition began only after the GNSS-RTK positioning solution had remained stable for 3 s at the starting point and ended when the vehicle entered the predefined coordinate threshold at the endpoint. A GNSS-RTK receiver operating at 10 Hz recorded the vehicle's real-time position and heading. The relative deviation was defined as the ratio of the instantaneous lateral tracking error to the maximum allowable lateral offset from the reference trajectory. This dimensionless metric was calculated and statistically analysed across all repeated trials.

Fig. 7 shows the continuous multi-route trajectory-tracking trials conducted in the vineyard under operating conditions representative of autonomous orchard vehicles. The reference trajectories were generated and measured using a clearly defined procedure. Discrete waypoints were manually surveyed by static GNSS-RTK measurements at the row boundaries and turning zones, and a minimum turning radius of 2.5 m was applied to all inter-row turns. Cubic B-spline interpolation was then used to convert the discrete waypoints into smooth, continuously differentiable trajectories. All trajectory data were expressed in a local horizontal Cartesian coordinate system transformed from geodetic coordinates. Before the vehicle tests, the ground-truth reference trajectories were fully surveyed using static RTK measurements. The tracked vehicle followed the preplanned smooth trajectories stably across multiple vine rows, and the recorded trajectory curves demonstrated reliable tracking accuracy over uneven vineyard terrain.



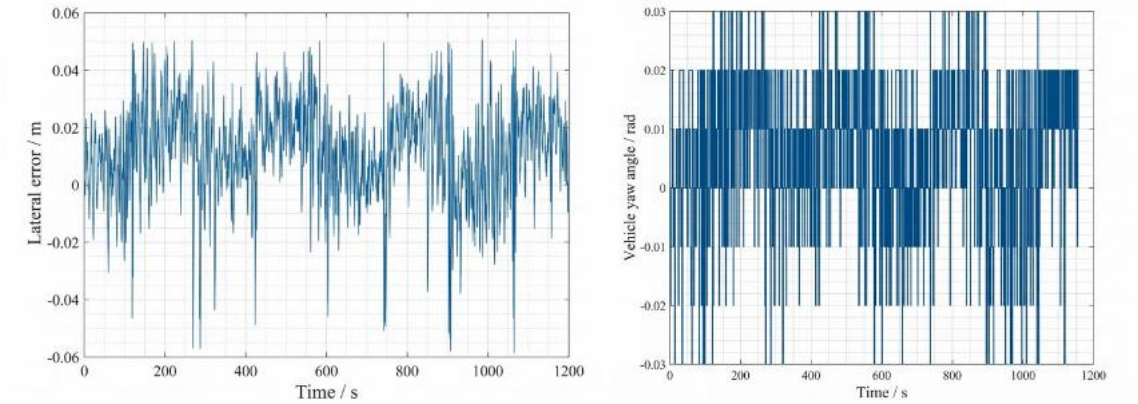


Fig. 7 - Continuous multi-route trajectory-tracking test

Fig. 8(a) shows the variation in lateral tracking error over time. The lateral error remained within 0.06 m throughout the test and exhibited increasingly stable fluctuations as the test progressed, with an apparent periodic pattern. Fig. 8(b) shows the variation in heading error over time. The heading error remained below 0.03 rad (approximately 1.72°) throughout the tracking process, indicating that the vehicle maintained stable heading alignment with the reference trajectory.

(a) Lateral tracking error over time (b) Vehicle yaw angle over time

Fig. 8 - Experimental results for continuous multi-route trajectory tracking

Analysis of the multi-route test data shown in Fig. 8 was used to quantify the tracking performance of the proposed algorithm. Across six repeated vineyard trials, the mean lateral RMSE was 0.021 m, while the steady-state heading error remained within ±0.03 rad. Compared with the baseline method combining a standard single-model EKF with the original Stanley controller, the proposed method reduced the mean lateral RMSE by 42.7% under identical vineyard conditions. The tracked vehicle maintained stable alignment with the reference trajectory and limited both lateral and heading errors to relatively low levels, demonstrating the applicability of the proposed method to vineyard navigation. Nevertheless, this study has several limitations. Only the low-speed operating condition of 1.0 m/s was evaluated, and tracking performance under severe slip or on steep terrain was not investigated.

Table 1

Statistical results for the absolute lateral tracking error during continuous multi-route trajectory tracking (Unit: meter)

Test	Maximum	Minimum	Mean	Standard deviation	RMSE
1	0.042	0.0000016	0.019	0.016	0.021
2	0.078	0.0000077	0.022	0.023	0.027
3	0.015	0.0000008	0.020	0.018	0.023
4	0.075	0.0000016	0.019	0.018	0.021
5	0.128	0.0000026	0.017	0.016	0.019
6	0.055	0.0000019	0.014	0.011	0.017

The data presented in Table 1 is derived from multiple repeated trials conducted along the planned route shown in Figure 8. To simulate real-world conditions, these trials were carried out on different dates. This approach aims to ensure that, whilst the route remains consistent, the appearance of the soil changes in the real world due to human activity and environmental influences, and that external noise, such as weather conditions, is also constantly varying.

Table 1 presents the absolute lateral-error statistics obtained from six repeated multi-route trajectory-tracking trials. An audit of the raw data identified two important inconsistencies. First, Trial 3 reported a maximum absolute lateral error of 0.015 m, together with a mean absolute error of 0.020 m and an RMSE of 0.023 m. These values are mathematically inconsistent because, for a set of non-negative absolute errors, neither the mean nor the RMSE can exceed the maximum observed value. The Trial 3 statistics were therefore recalculated.

Second, the reported minimum errors, including values such as 0.0000016 m, were below the practical measurement capability of the field GNSS-RTK system and were considered numerical noise rather than physically meaningful measurements. Accordingly, the minimum-error values were reported to a practical precision of 0.001 m.

After recalculating the trial statistics and standardizing the raw data, the aggregated results from the six tests were as follows. The mean maximum lateral error was 0.066 m, and the mean minimum detectable error, rounded to three decimal places, was 0.001 m. The overall mean absolute lateral error was 0.019 m, with a standard deviation of 0.017 m. The RMSE values for the individual trials ranged from 0.017 to 0.027 m, with a mean of 0.021 m. For every trial, the RMSE was lower than the corresponding maximum lateral error after calibration. These calibrated metrics characterize the lateral-error distribution of the proposed Stanley controller enhanced with IMM-EKF under uneven vineyard conditions and demonstrate its ability to limit lateral tracking deviations under canopy-induced signal attenuation and track-slip disturbances.

CONCLUSIONS

This study developed an integrated navigation framework combining IMM-EKF-based multimodel pose correction with a feedforward-enhanced Stanley controller for tracked orchard inspection vehicles operating under GNSS signal attenuation and track-slip disturbances. Simulations and vineyard field tests demonstrated measurable improvements in trajectory-tracking performance. At a constant speed of 1.0 m/s, the straight-line simulation achieved a mean lateral error of 0.014 m, while the multi-route field trials produced a mean lateral RMSE of 0.021 m. Compared with the baseline method combining a single-model EKF with the original Stanley controller, the proposed method reduced the mean lateral RMSE by 42.7% under identical orchard conditions.

This study nevertheless has several limitations. Only one low operating speed, 1.0 m/s, was evaluated, and all field experiments were conducted in a single vineyard with relatively mild terrain irregularities. Performance under more demanding conditions, including steep slopes and severe track slip, was not investigated, and the method was not cross-validated using different vehicle chassis. Future work will therefore focus on extending the method to variable-speed operation, conducting additional tests on sloped and highly slippery orchard terrain, integrating LiDAR- and vision-based positioning to reduce long-term localization drift, and evaluating the generalizability of the framework across different types of tracked agricultural vehicles. Overall, the proposed method provides experimentally supported guidance for centimetre-level autonomous trajectory tracking by unmanned orchard vehicles.

ABSTRACT

The number of main stem nodes in soybean is an important phenotypic trait for evaluating plant growth, varietal characteristics, and breeding potential. However, automatically detecting soybean main stem nodes under field conditions remains challenging because of plant occlusion, variations in illumination, and complex backgrounds, while manual counting is inefficient for large-scale phenotypic data acquisition. Therefore, this study proposes BGE-YOLOv11, a lightweight model for detecting soybean main stem nodes in complex field environments. Using an image dataset of soybean main stem nodes collected under field conditions, the model was developed by integrating a bidirectional feature pyramid network (BiFPN), Global–Local Self-Attention (GLSA), and EfficientHead into the YOLOv11n baseline to enhance multiscale feature representation and detection performance. The proposed model was evaluated in terms of precision, recall, mean average precision at an intersection over union threshold of 0.5 (mAP50), and model complexity. BGE-YOLOv11 achieved a precision of 94.9%, recall of 92.9%, and mAP50 of 97.6%, representing improvements of 3.9, 4.0, and 3.0 percentage points, respectively, over the YOLOv11n baseline. Moreover, the model contained only 1.87 million parameters, required 5.6 GFLOPs, had a memory footprint of 8.0 MB, and achieved an inference time of 3.0 ms. These results demonstrate that BGE-YOLOv11 improves detection performance while retaining a lightweight architecture. Nevertheless, its performance may be affected by severe occlusion and highly variable field conditions. Future research will focus on expanding the dataset and further improving the model's generalization ability. This study provides an effective method for the automated counting of soybean main stem nodes and the analysis of phenotypic traits.

摘要

大豆主茎节点数量是反映植株生长状态、品种特征和育种潜力的重要表型性状。然而，在实际田间环境中，由于植株遮挡、光照变化以及复杂背景干扰等因素，大豆主茎节点的自动检测仍面临挑战，而人工计数方法难以满足大规模表型数据获取需求。针对复杂田间环境下大豆主茎节点快速检测问题，本文提出了一种轻量化 BGE-YOLOv11 检测模型。基于田间采集的大豆主茎节点图像数据集，在 YOLOv11n 基础模型上引入 BiFPN、全局局部自注意力（GLSA）模块和 EfficientHead 检测头，以增强多尺度特征表达能力并提升节点检测性能。采用 Precision、Recall、mAP50 以及模型复杂度指标对所提出模型进行综合评价。结果表明，BGE-YOLOv11 模型的 Precision、Recall 和 mAP50 分别达到 94.9%、92.9%和 97.6%，相比 YOLOv11n 分别提升 3.9、4.0 和 3.0 个百分点。同时，该模型参数量降低至 1.87 M，浮点计算量仅为 5.6 G，模型大小为 8.0 MB，推理时间为 3.0 ms。结果表明，BGE-YOLOv11 在提高检测性能的同时保持了良好的轻量化特性。然而，在极端遮挡和复杂多变田间环境下，模型性能仍可能受到一定影响。未来研究将进一步扩充数据集规模，提高模型泛化能力。本研究为大豆主茎节点自动计数和表型性状分析提供了一种有效方法。

INTRODUCTION

At present, China is actively developing soybean varieties with high yield, superior quality, and strong adaptability to mechanized production (*Qu et al., 2022*). Heilongjiang Province, one of China's major soybean-producing regions, primarily cultivates determinate soybean varieties.

[1] *Hao Bi, currently pursuing a master's degree; Yiting Liu, currently pursuing a master's degree; Yanxu Jiao, currently pursuing a master's degree; Lingfeng Zhu, currently pursuing a master's degree; Xiuying Xu, Associate Professor, Doctor of Engineering.*

During soybean breeding and variety evaluation, accurate acquisition of plant phenotypic traits is essential for characterizing varieties and selecting superior breeding materials. The number of main stem nodes is an important agronomic trait reflecting soybean plant architecture. It affects plant height, stem structure, lodging resistance, and pod spatial distribution, and is closely associated with yield formation. Therefore, it serves as an important indicator for evaluating soybean growth status and yield potential (*Qiu et al., 2006*). However, under field conditions, soybean main stem node detection is affected by inter-plant occlusion, illumination variations, and complex backgrounds, resulting in inefficient and labor-intensive manual measurements that cannot satisfy the requirements of large-scale phenotypic data acquisition in breeding programs (*Liu et al., 2026*). Therefore, computer vision-based automatic detection of soybean main stem nodes is of great significance for improving phenotyping efficiency. With the development of high-throughput plant phenotyping technologies, automated acquisition of crop structural parameters and genetic evaluation has provided new approaches for intelligent breeding (*Fiorani & Schurr, 2013*).

With the rapid development of computer vision and deep learning, image-based crop phenotyping has become an important research direction in intelligent breeding and has been widely applied in agricultural object detection, disease recognition, and phenotypic parameter extraction (*McCarthy & Raine, 2022; Kamilaris & Prenafeta-Bold´, 2018*). For soybean main stem node detection, several deep learning methods have been explored. *Zhu et al. (2020)* improved the Mask-RCNN-plus network for soybean main stem phenotyping and achieved pixel-level segmentation and node counting. However, this method requires extensive pixel-level annotation and has high training costs and slow inference speed. *Yang et al. (2026)* proposed a YOLOv8_obb-based rotated object detection method to address field occlusion, scale variation, and small-object detection problems. By incorporating attention mechanisms and multi-scale feature fusion, the method improved node localization and achieved an average precision of 89.45%. Nevertheless, its relatively large model size limits its application in resource-constrained computing environments.

Besides CNN-based approaches, Transformer-based detectors, multi-model fusion methods, and three-dimensional vision techniques have also been investigated for soybean phenotyping. *Sun et al. (2026)* proposed an RT-DETR-based Transformer detection model with wavelet feature enhancement, achieving an average precision of 91.10%. However, its high computational complexity requires substantial hardware resources. *Zhou et al. (2023)* developed an SPP-extractor framework by combining YOLOv5s and U²-Net for soybean phenotypic information extraction under dense planting conditions, but the cascaded multi-model structure increased system complexity and inference time. *Cui et al. (2025)* applied three-dimensional point cloud technology for non-destructive soybean node measurement; however, this method relies on specialized acquisition equipment, resulting in high cost and operational complexity, which limits its application in rapid field phenotyping.

To overcome these limitations, researchers have conducted extensive studies on YOLO-based agricultural object detection models by introducing attention mechanisms, multi-scale feature fusion strategies, and lightweight network architectures (*Guo et al., 2021; Zhang et al., 2024*). However, many high-performance detection models still suffer from large parameter sizes, high computational complexity, and strong hardware requirements, restricting their application in resource-limited environments. Lightweight methods, including lightweight network design (*Vijayakanthan et al., 2026*), model pruning (*Ahsaei et al., 2026*), and knowledge distillation (*Jisan et al., 2026*), can effectively reduce computational costs. Nevertheless, achieving a balance among detection accuracy, inference speed, and model complexity remains challenging in agricultural intelligent detection. YOLOv11 provides strong feature extraction capability and efficient inference performance, making it a suitable baseline for soybean main stem node detection under complex field conditions (*Khanam & Hussain, 2024*).

Based on the above analysis, this study proposes a lightweight soybean main stem node detection model, BGE-YOLOv11, based on YOLOv11n. To address small-object characteristics, complex background interference, and insufficient feature representation in field environments, BiFPN-based weighted bidirectional feature fusion is introduced to enhance multi-scale feature interaction. A Global-Local Self-Attention (GLSA) module is incorporated to strengthen node feature representation and suppress background noise. Furthermore, the original detection head is replaced with the EfficientHead lightweight detection head to reduce model complexity while maintaining detection performance. This study aims to develop a lightweight detection model that achieves a balance between accuracy and computational efficiency, providing technical support for automated soybean phenotyping, breeding material selection, and intelligent breeding applications.

MATERIALS AND METHODS

Dataset Acquisition

To construct a field soybean main stem node detection dataset at the maturity stage, field experiments were conducted at the Anda Agricultural Science and Technology Park of Heilongjiang Bayi Agricultural University, Anda City, Heilongjiang Province, China. The determinate soybean cultivar Qinnong 13 was selected and planted using a single-row ridge planting pattern.

During image acquisition, field conditions involved inter-plant occlusion, interference from basal branches and senescent leaves, and complex soil backgrounds, resulting in unclear boundaries of some main stem nodes and increased annotation difficulty. To improve annotation accuracy, a local background-assisted acquisition strategy was adopted. A dark background curtain was placed behind the plants while retaining the natural soil environment at the plant base, reducing background interference while preserving field plant characteristics.

Soybean images were captured at the maturity stage using a Sony A7M3 full-frame camera. Images were collected at a fixed distance using a fixed-scale imaging protocol to ensure consistency. A total of 680 soybean plant images were obtained, with an original resolution of 4000 × 6000 pixels. All images were stored in JPEG format for subsequent annotation and model training.

Dataset Construction and Preprocessing

The collected soybean plant images were manually annotated using LabelImg. The main stem node was defined as the target category with the class name “Node”. Bounding box information, including center coordinates (x, y), width, and height, was recorded, and annotation files were generated in XML format for model training.

To prevent potential data leakage caused by augmentation, the original dataset was randomly divided into training, validation, and test sets at a ratio of 8:1:1 before data augmentation. The training set contained 544 images, while the validation and test sets each contained 68 images. Data augmentation was applied only to the training set, including brightness adjustment, rotation, horizontal flipping, vertical flipping, Cutout, random cropping, and translation. After augmentation, the training set was expanded to 1,408 images, resulting in a final soybean main stem node detection dataset containing 1,544 images. The validation and test sets maintained the original data distribution and were used for model optimization and final performance evaluation, respectively. Examples of augmented images are shown in Fig. 1.

Fig. 1 – Data augmentation examples for soybean plant images

BGE-YOLOv11 Model

To improve the performance of YOLOv11 for mature soybean main stem node detection under field conditions, a lightweight detection model named BGE-YOLOv11 was proposed to address challenges including inter-plant occlusion, weak small-object feature representation, and model complexity. Based on YOLOv11n, the proposed model incorporates improvements in feature fusion, attention mechanism, and detection head design. Specifically, BiFPN, a Global-Local Self-Attention (GLSA) module, and an EfficientHead detection head were introduced to enhance multi-scale feature representation and reduce computational complexity while maintaining detection accuracy. The overall architecture of BGE-YOLOv11 is shown in Fig. 2.

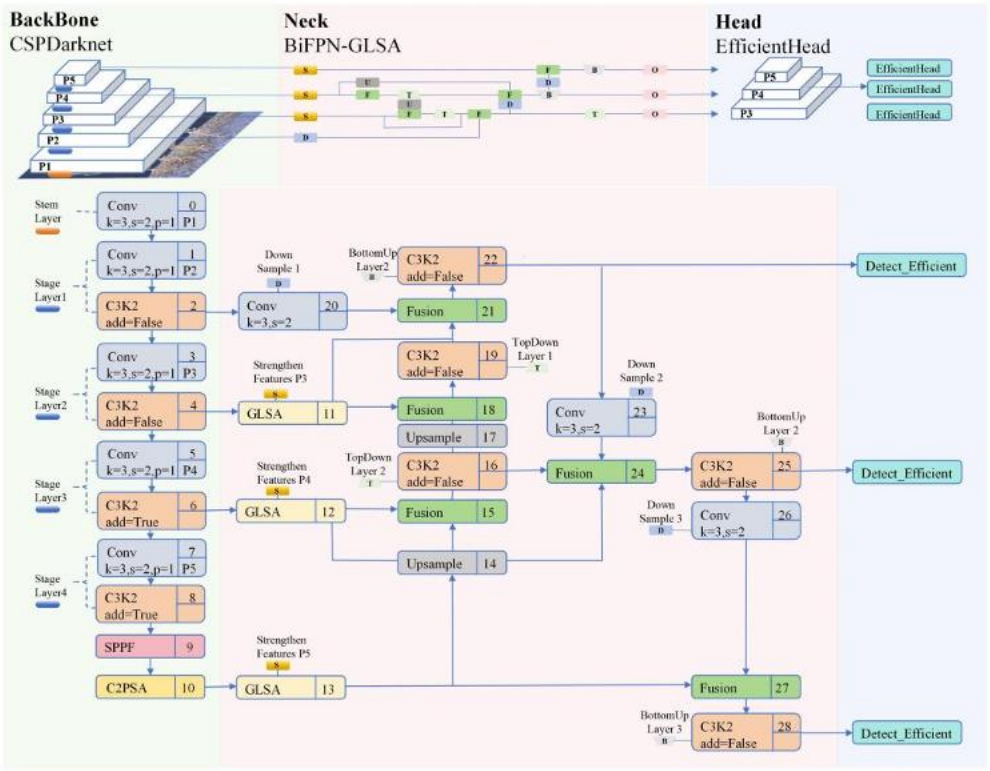

Fig. 2 – The improved BGE-YOLOv11 model structure

BiFPN Weighted Bidirectional Feature Pyramid Network

Inter-plant occlusion is a major challenge in mature soybean plants under field conditions, which may weaken multi-scale node features. The original PANet structure in YOLOv11 adopts a unidirectional feature aggregation strategy with fixed-weight feature fusion, limiting its ability to adaptively enhance occluded target features. This may result in insufficient cross-scale feature interaction and weak representation of small soybean main stem nodes.

To improve these limitations, a weighted bidirectional feature pyramid network (BiFPN) was introduced to replace the original PANet structure, forming an efficient multi-scale feature fusion module with enhanced occlusion robustness. The detailed architecture is shown in Fig. 3 (Doherty et al.,2025). By constructing bidirectional cross-scale connections and removing redundant feature nodes, BiFPN enables effective information exchange among different feature levels. Meanwhile, the learnable weighting mechanism adaptively adjusts the contribution of features from different scales, facilitating the fusion of high-level semantic information and low-level spatial details.

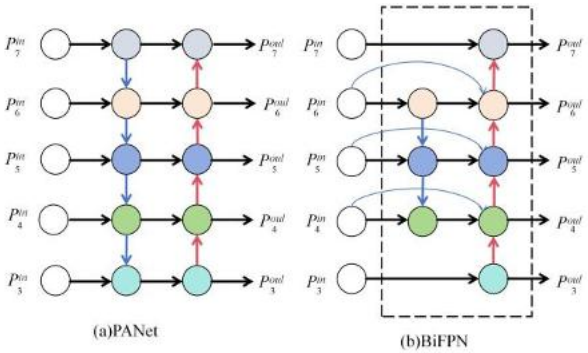

Fig. 3 – The network model structure diagram of PANet and BiFPN

During feature fusion, BiFPN adopts top-down and bottom-up pathways to achieve bidirectional information flow. Fast normalized weighted fusion is applied to reduce instability caused by feature weight differences. Compared with PANet, BiFPN improves multi-scale feature fusion quality with limited additional computational cost, thereby enhancing the feature representation of small and occluded soybean main stem nodes and improving detection performance under complex field conditions.

GLSA Global Local Self-Attention Module

Field-grown soybean plants often contain soil particles, senescent leaves, and scattered branches around the plant base, resulting in complex background interference. Meanwhile, the weak feature representation of small soybean main stem nodes makes accurate detection challenging. To enhance feature representation and suppress background noise while maintaining lightweight characteristics, a Global-Local Self-Attention (GLSA) module was embedded at the input of the neck feature pyramid.

Conventional convolutional neural networks have limited capability in modeling long-range dependencies and global contextual information, whereas standard self-attention mechanisms usually introduce high computational costs. Therefore, GLSA was adopted to improve global feature modeling capability under lightweight constraints (*Jia et al., 2026*). As shown in Fig. 4, GLSA employs a dual-branch parallel architecture. The local branch uses depthwise separable convolution to extract local detail features and preserve sensitivity to node edge and texture information. The global branch applies region-based self-attention to establish long-range dependencies among different regions with low computational overhead.

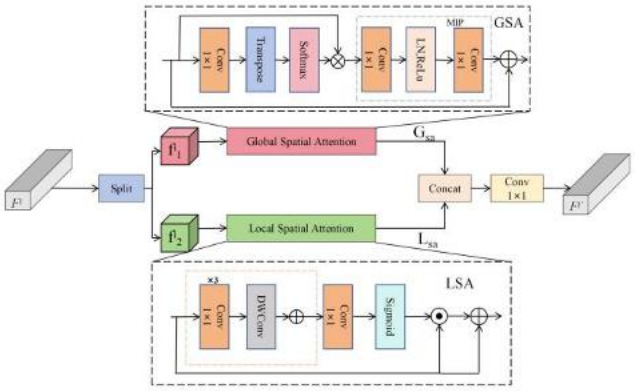

Fig. 4 – GLSA structure diagram

By embedding GLSA into the P3, P4, and P5 multi-scale feature layers before feature fusion, the model enhances target feature representation and reduces interference from complex field backgrounds. This design strengthens the feature responses of small soybean main stem nodes and provides more discriminative features for subsequent multi-scale feature fusion.

EfficientHead Lightweight Detection Head

The original YOLOv11 detection head has limited multi-scale feature alignment capability and inefficient channel information utilization, which may affect feature representation and localization performance. To improve detection performance while maintaining lightweight characteristics, an EfficientHead lightweight detection head was introduced to replace the original structure (Fig. 5) (*Jiang et al., 2025*).

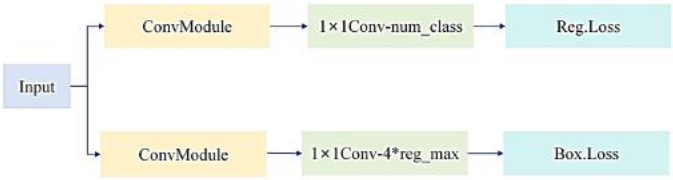

Fig. 5 – EfficientHead structure diagram

The proposed detection head integrates multi-scale feature alignment, lightweight channel attention, and dynamic localization decoding mechanisms. These designs enhance feature fusion, strengthen important soybean main stem node features, and suppress background interference. Without significantly increasing computational cost, EfficientHead improves the detection capability of weak-texture and occluded soybean main stem nodes while maintaining model lightweight characteristics.

Experimental Environment

The experiments were conducted using the PyTorch deep learning framework. The operating system was Windows 10, with an Intel® Core™ i7-14700HX CPU and an NVIDIA GeForce RTX 4060 Laptop GPU. The system was equipped with 16 GB of RAM and 8 GB of GPU memory. The software environment included Python 3.9, PyTorch 2.2.0, and CUDA 12.6. During model training, the input image size was set to 640 × 640 pixels, with a batch size of 16 and 200 training epochs.

The stochastic gradient descent (SGD) optimizer was adopted, with an initial learning rate of 0.01. Pre-trained weights were used for all models, and Mosaic augmentation was disabled during the final 10 epochs.

Model-Evaluation Index

For soybean main stem node detection, precision (P), recall (R), average precision (AP), mean average precision (mAP), and inference time were adopted to evaluate model performance. The corresponding calculation formulas are as follows:

$$P = \frac{TP}{TP+FP} \tag{1}$$

$$R = \frac{TP}{TP+FN} \tag{2}$$

$$AP = \sum_{i=1}^{N} P(i)\Delta R(i) \tag{3}$$

$$mAP = \frac{\sum_{i=1}^{k} AP_i}{k} \tag{4}$$

where TP, FP, and FN represent the numbers of true positive, false positive, and false negative detections of soybean main stem nodes, respectively. N denotes the number of samples, and k represents the number of categories.

To further evaluate the node counting performance of the proposed model, mean absolute error (MAE), root mean square error (RMSE), mean bias (Bias), and coefficient of determination (R^2) were introduced for quantitative analysis. The calculation formulas are as follows:

$$MAE = \frac{1}{N}\sum_{i=1}^{N} |y_i - \hat{y}_i| \tag{5}$$

$$RMSE = \sqrt{\frac{1}{N}\sum_{i=1}^{N} (y_i - \hat{y}_i)^2} \tag{6}$$

$$Bias = \frac{1}{N}\sum_{i=1}^{N} (\hat{y}_i - y_i) \tag{7}$$

$$R^2 = 1 - \frac{\sum_{i=1}^{N}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{N}(y_i - \bar{y})^2} \tag{8}$$

where $y_i$represents the manually counted number of soybean main stem nodes, $\hat{y}_i$ denotes the number of nodes predicted by the model, and N represents the number of samples.

RESULTS AND ANALYSIS

Comparison of Detection Performance of Basic Detection Network

To validate the effectiveness of BGE-YOLOv11, it was compared with representative object detection models, including YOLOv5n, YOLOv6n, YOLOv7n, YOLOv8n, YOLOv9t, YOLOv10n, YOLOv11n, YOLOv12n, and RT-DETR-L. All models were trained and tested on the same soybean main stem node dataset. FLOPs, number of parameters, precision (P), recall (R), average precision (AP), memory footprint, and inference time were selected as evaluation metrics. The results are shown in Table 1.

Table 1

Comparison of different object detection models for soybean main stem node detection

Model	FLOPs [G]	Params [M]	P [%]	R [%]	mAP50 [%]	Memory footprint [MB]	Inference time [ms]
YOLOv5n	5.8	2.18	90.80	88.70	94.30	9.1	1.4
YOLOv6n	11.5	4.15	90.30	88.20	94.00	16.9	1.5
YOLOv8n	6.8	2.68	90.90	89.20	94.60	11.1	2.3
YOLOv9t	6.4	1.73	90.50	89.00	94.30	7.8	3.5
YOLOv10n	6.5	2.26	91.70	87.50	94.30	11.3	2.5

Model	FLOPs [G]	Params [M]	P [%]	R [%]	mAP50 [%]	Memory footprint [MB]	Inference time [ms]
YOLOv11n	6.3	2.58	91.00	88.90	94.60	10.7	2.7
YOLOv12n	7.80	2.50	91.30	88.10	94.30	10.6	3.7
RTDETR-L	100.6	28.44	87.00	84.10	89.20	117.8	16.3
BGE-YOLOv11	5.6	1.87	94.90	92.90	97.60	8.0	3.0

As shown in Table 1, BGE-YOLOv11 achieved a precision of 94.9%, a recall of 92.9%, and an mAP50 of 97.6%, providing superior detection performance among the compared models. In terms of lightweight characteristics, BGE-YOLOv11 required only 5.6 G FLOPs, 1.87 M parameters, and 8.0 MB memory footprint. Meanwhile, its inference time was lower than YOLOv9t, YOLOv10n, YOLOv12n, and RT-DETR-L.

Compared with the baseline YOLOv11n, BGE-YOLOv11 improved precision, recall, and mAP50 by 3.9, 4.0, and 3.0 percentage points, respectively, while reducing FLOPs by 0.7 G and parameters by 0.71 M. These results demonstrate that BGE-YOLOv11 achieves an effective balance between detection accuracy and model lightweight characteristics.

Ablation Test

An ablation study was conducted to evaluate the contribution of each improvement module to the YOLOv11n-based soybean main stem node detection model. Based on the constructed soybean main stem node dataset, different model variants were compared to verify the effectiveness of each module. The results are shown in Table 2.

Table 2

Ablation test results

Model	BiFPN	GLSA	EfficientHead	FLOPs[G]	Params[M]	P[%]	R[%]	mAP50[%]	Memory footprint [MB]	Inference time[ms]
YOLOv11n	-	-	-	6.3	2.58	91.00	88.90	94.60	10.7	2.7
B-YOLOv11	✓	-	-	6.3	1.92	92.00	89.20	95.10	8.1	2.1
G-YOLOv11	-	✓	-	8.6	3.73	91.80	90.40	95.50	15.5	3.1
E-YOLOv11	-	-	✓	5.1	2.31	92.20	89.90	95.60	9.6	2.0
BG-YOLOv11	✓	✓	-	6.7	2.07	91.30	90.10	95.20	8.8	2.8
BE-YOLOv11	✓	-	✓	5.2	1.73	91.80	89.90	95.10	7.3	2.3
GE-YOLOv11	-	✓	✓	7.4	3.48	91.50	89.00	94.60	14.4	3.2
BGE-YOLOv11	✓	✓	✓	5.6	1.87	94.90	92.90	97.60	8.0	3.0

Note: ✓ indicates that the module is used; - indicates that the module is not used.

To investigate the contribution of each module in BGE-YOLOv11, BiFPN, GLSA, and EfficientHead were individually incorporated into the YOLOv11n baseline model. The ablation results are shown in Table 2.

The single-module experiments indicate that all three modules improved model performance to different degrees. After introducing BiFPN, the mAP50 increased to 95.10%, while the parameters decreased from 2.58 M to 1.92 M, demonstrating improved feature fusion capability with reduced model complexity. The integration of GLSA increased recall and mAP50 by 1.5 and 0.9 percentage points, respectively, indicating enhanced feature representation under complex field backgrounds. With EfficientHead, the mAP50 increased to 95.60%, while FLOPs and inference time decreased to 5.1 G and 2.0 ms, respectively, showing that this module effectively reduces computational cost while maintaining detection accuracy.

When all three modules were combined, BGE-YOLOv11 achieved the best overall performance. Compared with YOLOv11n, BGE-YOLOv11 improved precision, recall, and mAP50 by 3.9, 4.0, and 3.0 percentage points, reaching 94.90%, 92.90%, and 97.60%, respectively. Meanwhile, the parameters were reduced from 2.58 M to 1.87 M, FLOPs decreased from 6.3 G to 5.6 G, and memory footprint decreased from 10.7 MB to 8.0 MB, with only a 0.3 ms increase in inference time. These results demonstrate that BGE-YOLOv11 enhances detection accuracy while reducing model complexity, achieving an effective balance between detection performance and lightweight characteristics.

Model Recognition Results

Based on the model comparison results, YOLOv8n, YOLOv11n, YOLOv12n, and the proposed BGE-YOLOv11 were selected for soybean main stem node detection experiments. Quantitative performance evaluation and visual comparison experiments were conducted to further analyze the detection capability of different models. Three representative field scenarios were considered, including fully visible soybean plants, interference from senescent leaves and branches near the plant base, and inter-plant occlusion. The samples used for both visualization analysis and quantitative node counting evaluation were collected from field experiments. All models were evaluated using the same detection settings, with a confidence threshold of 0.5 and an IoU matching threshold of 0.45.

Quantitative Performance Statistical Test

To further evaluate the soybean main stem node counting capability of the proposed model under practical field conditions, an independent node counting validation dataset was constructed. The dataset contained 44 field-collected images, including 108 soybean plants and 1,384 main stem nodes. The node numbers were manually counted and recorded as ground truth for comparison with model predictions. This dataset was not involved in model training and was only used to assess the node recognition and counting performance under field conditions.

It should be noted that the Precision, Recall, and mAP50 values in Table 1 were calculated from the model test set and used to evaluate overall object detection performance. In contrast, the evaluation metrics in Table 3 were obtained from the independent field counting validation dataset and were used to assess the practical node counting capability of the models. Since these two evaluations represent different tasks and experimental scenarios, their results should not be directly compared.

Table 3

Quantitative evaluation of soybean main stem node counting performance

Model	TP	FN	FP	Total Ground-Truth Nodes	Detection Success Rate	Miss Rate	False Alarm Rate
BGE-YOLOv11	1333	51	149	1384	96.32%	3.69%	10.05%
YOLOv11n	1312	72	171	1384	94.80%	5.20%	11.52%
YOLOv8n	1312	72	166	1384	94.80%	5.20%	11.22%
YOLOv12n	1297	87	136	1384	93.71%	6.29%	9.50%

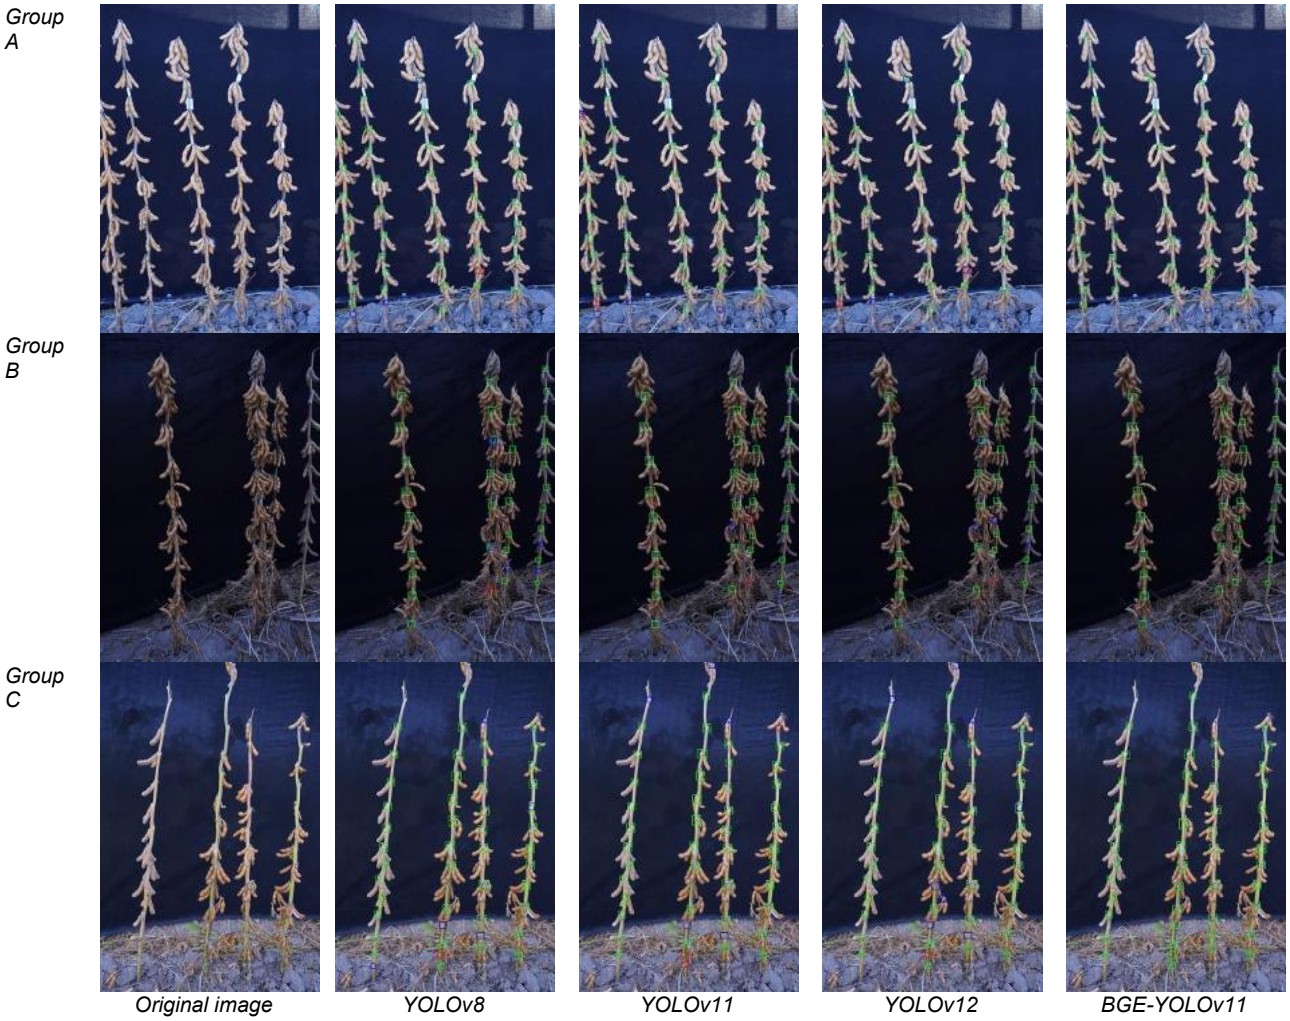
Note: TP, FN, and FP represent correctly detected, missed, and falsely detected nodes, respectively. Total ground-truth nodes = TP + FN. Detection success rate = TP/(TP+FN), miss rate = FN/(TP+FN), and false alarm rate = FP/(TP+FP).

As shown in Table 3, BGE-YOLOv11 achieved superior performance in soybean main stem node counting. The proposed model correctly detected 1,333 nodes, with a detection success rate of 96.32% and a miss rate of 3.69%. Compared with YOLOv11n, YOLOv8n, and YOLOv12n, BGE-YOLOv11 increased the number of correctly detected nodes by 21, 21, and 36, respectively, while improving the detection success rate by 1.52, 1.52, and 2.61 percentage points and reducing the miss rate by 1.51, 1.51, and 2.60 percentage points.

Regarding false detection control, BGE-YOLOv11 achieved a false alarm rate of 10.05%, which was lower than YOLOv11n and YOLOv8n but slightly higher than YOLOv12n. This result indicates that the proposed model improves feature extraction and node recognition under complex field conditions, achieving a better balance between detection accuracy and false detection control.

Visualization Effect Comparison Test

To further evaluate the detection performance of the proposed model under complex field conditions, the results under different scenarios were visualized and compared, as shown in Fig. 6. Green bounding boxes indicate correctly detected targets, blue bounding boxes represent missed targets, and red bounding boxes denote false detections.



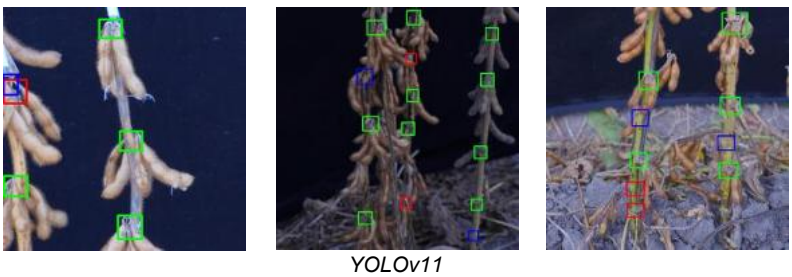


Fig. 6–Comparison of detection effects of four network models

As shown in Fig. 6, in Group A, YOLOv11n produced missed and false detections when soybean main stem nodes were located near image boundaries. YOLOv8n and YOLOv12n showed two or more detection errors, whereas BGE-YOLOv11 generated only one false detection at the basal stem region, demonstrating better boundary localization capability.

Under the severe occlusion conditions in Group B, BGE-YOLOv11 maintained relatively stable detection performance despite strong inter-plant overlap. However, missed detections still occurred in areas with densely distributed pods, while the baseline models exhibited more missed and false detections. In Group C, complex background interference from senescent leaves and scattered branches affected detection performance. Nevertheless, BGE-YOLOv11 achieved more reliable detection results, whereas the baseline models showed obvious false and missed detections.

Furthermore, BGE-YOLOv11 generally produced higher confidence scores than the baseline models, indicating improved feature extraction capability and more reliable node detection. Figure 7 shows enlarged views of the false and missed detection regions in Fig. 6. Compared with YOLOv11n, BGE-YOLOv11 improves node feature representation through enhanced feature extraction and multi-scale feature fusion, reducing missed detections under complex field conditions and achieving a better balance between detection accuracy and false detection control.

Prediction Error Evaluation of Soybean Main Stem Node Number

To further evaluate the soybean main stem node counting capability of the proposed model under field conditions, an independent dataset containing 44 field-collected images was used for node number estimation experiments. This dataset was not involved in model training or parameter optimization. The manually counted node numbers were used as ground truth, and MAE, RMSE, Bias, and R^2 were adopted to evaluate the estimation performance of YOLOv11n and BGE-YOLOv11. The results are presented in Table 4.

Table 4

Comparison of soybean main stem node number estimation performance among different models

Model	MAE	RMSE	Bias	R^2
BGE-YOLOv11	2.09	2.82	-0.86	0.96343
YOLOv11n	3.07	3.71	-2.57	0.93895

As shown in Table 4, BGE-YOLOv11 achieved better performance in soybean main stem node number estimation. Compared with YOLOv11n, BGE-YOLOv11 reduced MAE and RMSE by 0.98 and 0.89, respectively, and its Bias value was closer to zero, indicating lower estimation error and higher prediction stability. Meanwhile, the R^2 value of BGE-YOLOv11 increased from 0.93895 to 0.96343, demonstrating a stronger agreement between the estimated node numbers and the manually counted ground-truth values.

CONCLUSIONS

In this study, YOLOv11n was selected as the baseline model. By introducing the BiFPN module to enhance multi-scale feature fusion, incorporating the GLSA global-local self-attention module to improve small-object feature representation, and adopting the EfficientHead lightweight detection head to reduce computational cost, a lightweight BGE-YOLOv11 model was developed for soybean main stem node detection and counting. Experimental results demonstrated that the proposed model achieved an mAP50 of 97.6% under complex field conditions, with only 1.87 M parameters and an inference time of 3.0 ms. It improved detection accuracy while maintaining favorable lightweight characteristics, providing technical support for the automated acquisition of soybean phenotypic information.

Currently, this study mainly focuses on main stem node detection in mature soybean plants. In future work, the proposed method will be further extended to other phenotypic parameters, such as stem diameter and plant height, as well as different growth stages. Moreover, correlation models between phenotypic traits and yield-related characteristics will be established to provide data support for precision breeding.

ABSTRACT

Due to the anisotropy and small size of wheat roots, as well as the neglect of shear process effects on mechanical properties in existing wheat root-soil composite (WRSC) models, the establishment and parameter calibration of WRSC models remain inaccurate, hindering the precise analysis of the microscopic effects of furrow openers on WRSC during no-till sowing. This study aimed to develop an accurate and reliable WRSC model based on the discrete element method (DEM) using rapid particle filling and the Hertz-Mindlin with bonding contact model. Plackett-Burman tests identified particle shear modulus, inter-particle bonding radius, and bonding stiffness as significant factors affecting the ultimate shear force of wheat roots. Steepest ascent tests narrowed the optimal parameter ranges, and Box-Behnken test results were used to establish a quadratic regression model, leading to the optimal parameter combination: particle shear modulus of 7.96 MPa, inter-particle bonding stiffness of 4.13 GN/m³, and bonding radius of 0.32 mm. Actual and simulated shear tests on WRSC were conducted, and key parameters between wheat roots and soil particles were calibrated via steepest ascent tests with the ultimate shear force on the cutter as the target value: static friction coefficient of 0.8, bonding stiffness of 11 MN/m³, and critical stress of 11 MPa. Validation showed a relative error of 7.35% between simulated and actual shear resistance, indicating that the proposed WRSC model and parameters can effectively simulate field operations such as furrowing and rotary tillage.

摘要

针对玉米免耕播种时前茬小麦根系与开沟器相互作用过程分析复杂，且小麦根系的各向异性和直径较小等特点，现有根土复合体模型忽略小麦根系对对剪切过程力学特性的影响导致标定参数不准确的问题，该研究基于离散元法采用颗粒快速填充和 Hertz-Mindlin with bonding 粘结模型建立了一种准确性和可靠性较高的小麦根-土复合体模型。基于 Hertz-Mindlin bonding 粘结模型，采用颗粒快速填充的方法，构建小麦根系模型。通过 Plackett-Burman 试验发现颗粒剪切模量和颗粒间粘结半径、粘结刚度对小麦根系极限剪力有显著影响。通过最陡爬坡试验确定显著性影响参数最优区间的基础上，根据 Box-Behnken 试验结果建立了根系极限剪力与显著性影响参数的二阶回归模型并对其进行优化，得到显著性参数的最佳组合为：颗粒剪切模量 7.96 MPa、颗粒间粘结刚度 4.13 GN/m3、粘结半径 0.32 mm。其次，采用最陡爬坡试验方法，标定了小麦根-土间的关键参数。以切刀受到的极限剪力为目标值，基于小麦根-土复合体进行实际剪切和仿真剪切试验结果，标定得到小麦根系与土壤颗粒间的静摩擦系数为 0.8、粘结刚度为 11 MN/m3、临界应力为 11 MPa。最后，验证标定后的根-土复合体模型，结果显示仿真剪切阻力与实际剪切阻力间相对误差为 7.35%，表明基于离散元法建立的小麦根-土复合体模型可以用于模拟田间实际土壤环境。

INTRODUCTION

Conservation tillage is an important agricultural technology for improving soil quality, conserving water and moisture, and enhancing economic benefits. As a key link in conservation tillage, no-till and reduced-till sowing imposes higher requirements on the performance of furrow openers.

In the double cropping area of Guanzhong, Shaanxi Province, corn no-till sowing is carried out immediately after wheat harvest. Undecomposed wheat roots in the soil are closely bonded with soil particles, significantly increasing the working resistance of furrow openers and intensifying soil disturbance.

Traditional soil bin tests fail to reflect the actual field operating environment due to the absence of root factors, while the discrete element method provides an effective means to simulate complex root-soil interactions.

Yang et al. (1996) first explicitly proposed the concept of "soil-root composite" in their study on herbaceous plant roots. Since roots are tightly attached to soil, they reinforce soil structure and improve water absorption capacity. The combination of crop roots and soil is termed the root-soil composite, and it is assumed to partially satisfy the Mohr-Coulomb law. Currently, experimental methods are mainly used to study the shear resistance of root-soil composites. However, numerous factors influence shear resistance, broadly categorized into soil-related and plant root-related factors *(Chen et al., 2026)*, each encompassing multiple sub-factors. Consequently, experimental studies on composite shear resistance are labor-intensive and time-consuming. The discrete element method is a numerical computation technique for analyzing complex dynamic discrete systems, with distinct advantages in agricultural machinery research. With advancements in computer hardware and DEM theory, numerical simulation has been increasingly applied to study root-soil interactions due to its higher efficiency, season independence, and low cost *(Ji et al., 2012; Yang et al., 2014; Ji et al., 2014; Tian et al., 2015)*. Yang et al. established a soil model using DEM and a rigid lettuce root model via SolidWorks. However, their pull-out simulations failed to account for root deformation and bending, leading to significant discrepancies between simulated and actual results. *Lenaerts et al. (2014)*, *Li et al. (2016)*, and *Gao et al. (2020)* respectively established slender straw models using DEM, but the minimum particle units employed prevented cutting and separation. *Li et al. (2020)* and *Liu et al. (2018)* successfully developed flexible corn and spinach root models capable of bending and fracture using the Hertz-Mindlin with bonding model and rapid particle filling. To date, no literature has been published on the establishment of a wheat root-soil composite DEM model. Wheat roots differ significantly from corn and spinach roots in diameter and mechanical properties, necessitating the development of a dedicated DEM model for wheat root-soil composites.

To address the aforementioned issues, this study determined the morphological dimensions of wheat root models by analyzing the actual growth state of wheat roots in post-harvest soil, and constructed a complete flexible wheat root model using EDEM. Parameters of wheat roots, soil, and their interactions were calibrated through comparative validation of actual and simulated tests, aiming to improve the accuracy of the wheat root-soil composite DEM model. This research provides a foundation and reference for the establishment of DEM models for wheat root-soil composites and similar agricultural materials.

MATERIALS AND METHODS

Physical Properties of Materials

Physical Parameters of Wheat Roots

Roots of the wheat cultivar "Xinong 511" were sampled from the experimental field of Northwest A&F University on June 2, 2025. The experimental field was regularly fertilized prior to planting, meeting standard cultivation conditions, with manual weeding performed during the growing period before harvest the following year. A wheat-growing area of 1.5 m × 1.3 m (6 rows) was selected for statistical counting. Field investigations revealed that wheat grows in clusters with an inter-cluster spacing of 30 mm (Fig. 1).

Fig. 1 - Wheat growth status

Five clusters of wheat roots were collected using the five-point sampling method (Fig. 2a). Each cluster contained an average of 20 roots, which were twisted into a knot with a radius of approximately 6 mm at the upper end. Roots were densely distributed in the upper soil layer and sparsely in the lower layer (*Liu, 2008*) (Fig. 2c). Under actual field conditions, wheat roots are tightly bonded to the soil, functioning to reinforce the soil structure. Wheat possesses a fibrous root system consisting of primary and secondary roots (Fig. 2b), with negligible differences in diameter and ultimate shear force between the two root types. Considering computational efficiency and simulation speed, primary and secondary roots were modeled as a single root type (*Guo, 2008*).

（a）Wheat root samples *（b）Morphological structure of wheat roots*

Fig. 2 - Wheat root system sample and morphological structure

Ten roots were randomly selected from each cluster to measure physical parameters. The average length, diameter, and mass of wheat roots were 87.2 mm, 0.31 mm, and 0.521 g, respectively, with a mass per unit length of 1.195×10^{-4} g/mm.

Due to the anisotropy and small diameter of wheat roots, constructing a DEM model capable of both bending and fracture is challenging, resulting in limited research in this area. Drawing on previous studies (Liu, 2018) and combining physical parameters of wheat roots, a wheat root model was established using rapid filling with particles of 0.15 mm in diameter. The Hertz-Mindlin with bonding contact model was selected for inter-particle interactions.

To calibrate the particle density for root model filling in DEM, the particle density was iteratively adjusted until the mass per unit length of the simulated root model matched that of actual roots, as described by Eq. (1). The calibrated particle density was 87.6 kg/m³.

$$\frac{m_R}{l_R} = \frac{m_r}{l_r} \quad (1)$$

where: m_R, m_r—mass of actual and simulated roots, g;

l_R, l_r—length of actual and simulated roots, mm.

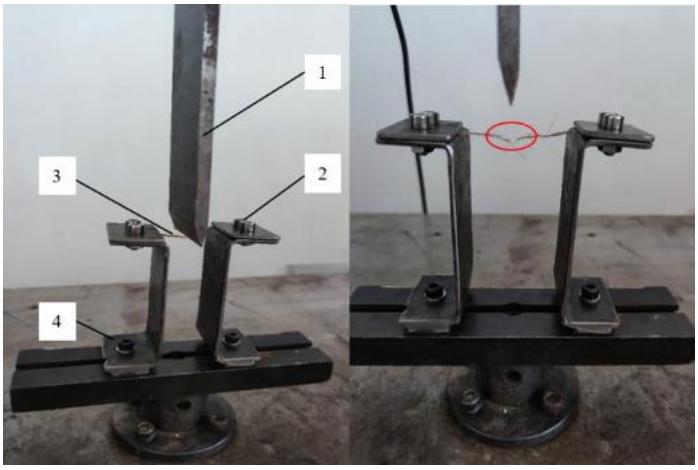
Basic Physical Parameters of Soil

Soil samples were collected after wheat harvest, with an average bulk density of 1.41 g/cm³ and soil compaction of 2.88 MPa. To realistically simulate soil particle fracture and breakage, the Hertz-Mindlin with bonding contact model was adopted based on the soil type of the experimental field. Simulation time decreases geometrically with increasing soil particle radius. Referring to previous studies on soil-tool interactions, spherical soil particles with a radius of 8 mm were used (*Ucgul et al., 2017; Ding et al., 2017; Zheng et al., 2016*). Soil material and contact parameters were determined through experimental measurements and literature review (*Ding et al., 2018; Guo et al., 2017; Wang et al., 2017*), as presented in Table 1.

Table 1

Basic parameters of soil discrete element model

Parameter	Value
Soil density/(kg·m^{-3})	1410
Soil Poisson's ratio	0.4
Soil shear modulus/(Pa)	6×10^{7}
Inter-soil dynamic friction coefficient	0.4
Inter-soil static friction coefficient	0.34
Inter-soil restitution coefficient	0.6
Inter-soil bonding radius/(mm)	8.5
Inter-soil bonding stiffness/(N·m^{-3})	2.4×10^{6}
Inter-soil critical stress/(Pa)	235000



Establishment of Discrete Element Model and Parameter Calibration Method

Wheat Roots

Actual shear tests were conducted on wheat roots to measure the ultimate shear force at root breakage. A DEM model of wheat roots was then established for shear simulations, and the ultimate shear force of the simulated model was obtained. Full-level tests were performed on key model parameters using the actual root ultimate shear force as the target value to establish a response equation and calibrate the key parameters.

Actual Shear Test of Wheat Roots

Referring to relevant shear test standards (*Lenaerts et al., 2014; Yuan, 2019*), actual shear tests were conducted to measure the ultimate shear force of roots (Fig. 3a). To prevent root breakage and slippage at the clamping points during testing, custom fixtures were fabricated, and both ends of the roots were wrapped in 16 mm-thick sponges in their natural state. Twenty wheat roots with consistent length and diameter were sheared at a speed of 4 mm/s using a DDL10 universal testing machine. Sixteen samples where root breakage occurred at the midpoint were selected to ensure fracture was induced by the cutter rather than clamping forces. The average ultimate shear force at root breakage was 3.7 N, with the fracture position shown in Fig.3b.

（a）Shear test *（b）Root fracture*

Fig. 3 - Actual root shear test

1.Cutter; 2.Custom fixture; 3.Wheat root; 4.Base

Simulation Model and Parameters of Wheat Roots

A DEM model of wheat roots consistent with the actual shear test was constructed in EDEM (Fig. 4). Assuming no relative sliding between root-filling particles, both static and dynamic friction coefficients between root particles were set to 1. The geometric models of the fixture and cutter were made of 65Mn steel. Material and contact parameters of wheat roots and 65Mn were determined through literature review (*Boac et al., 2014; Pan, 2012*). The density, Poisson's ratio, and shear modulus of 65Mn were 7865 kg/m³, 0.3, and 7.9×10^{11} MPa, respectively.

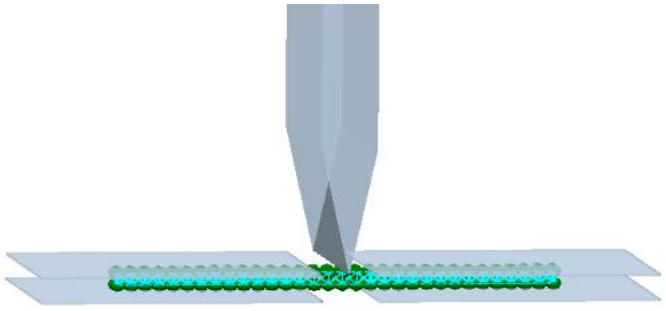


Fig. 4 - Shear simulation model

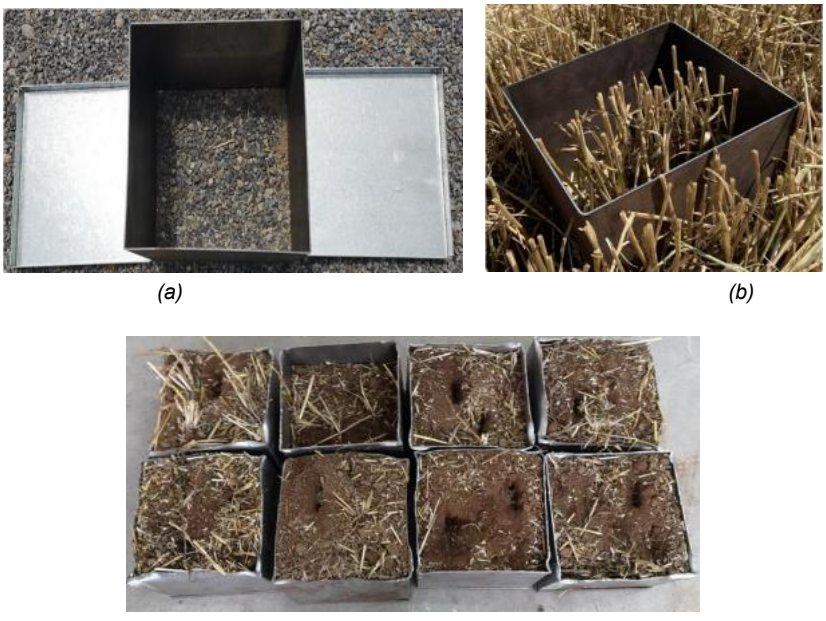
As determined earlier, the Hertz-Mindlin with bonding contact model was used for inter-particle interactions in wheat roots. Key parameters of this model include shear modulus, normal and tangential bonding stiffness, and bonding radius (*Ding et al., 2017; Zhang, 2012*). Since root-filling particles are randomly bonded, normal and tangential bonding parameters were set to be identical. Initial ranges of root particle model parameters were obtained through literature review and extensive shear simulation debugging, as listed in Table 2.

Table 2

Basic parameters of root model particles

Category	Simulation parameter	Value
Material parameters	Root density/(kg·m⁻³)	87.6
	Root Poisson's ratio	0.2-0.3a
	Root shear modulus/(MPa)	6-10a
Contact parameters	Root restitution coefficient	0.6-0.8a
	Root static friction coefficient	1
	Root dynamic friction coefficient	1
	Root-steel restitution coefficient	0.6-1a
	Root-steel static friction coefficient	0.35-0.6a
	Root-steel dynamic friction coefficient	0-0.02a
Bonding parameters	Bonding stiffness/(GN·m⁻³)	1-10a
	Critical stress/(MPa)	1-1.5a
	Bonding radius/(mm)	0.25-0.5a



Note: "a" indicates parameters to be screened.

Parameter Calibration Method for Wheat Root-Soil Complex Based on Ultimate Shear Force

Ultimate shear force is a key reference characteristic for calibrating WRSC models (*Yuan et al., 2020*). To obtain accurate contact and bonding parameters at the wheat root-soil interface, actual shear tests on WRSC were conducted following relevant literature methods (*Mak et al., 2012; Jiang et al., 2018; Zhao et al., 2019; Zheng et al., 2017*) to measure the ultimate shear force. Shear simulations of the WRSC model were then performed, and key parameters such as static and dynamic friction coefficients, bonding stiffness, and critical stress of the Hertz-Mindlin with bonding contact model at the root-soil interface were calibrated using the steepest ascent method.

Sampling of Wheat Root-Soil Complex

On the day after wheat harvest, areas with uniform soil conditions were selected in the middle of the field. Taking the center of wheat stubble as the sampling point, WRSC samples were collected using an uncovered iron box of 250 mm × 250 mm × 200 mm (Fig. 5a). The sampling process involved slowly driving the iron box into the soil with a hammer, excavating the soil around the box, and removing the box together with the WRSC. Sampling was repeated 8 times (Fig. 5b). To exclude the influence of stubble during modeling, above-ground stubble was cut off, retaining only the underlying wheat roots. The collected WRSC samples are shown in Fig. 5c. During storage and transportation, samples were wrapped in sponges to prevent fragmentation due to vibration.

(a) *(b)*

(c)

Fig. 5 - Root-soil complex field sampling (b) with iron box (a) and the sample (c)

Sampling of Wheat Root-Soil Complex

Shear tests on WRSC samples were conducted using a universal testing machine in the mechanical laboratory (Fig. 6) to measure the ultimate shear force when the cutter sheared the midpoint of wheat roots. To prevent cutter deviation during shearing, the shear speed was set to 2 mm/s (*Liu, 2018*). Each shear test was repeated 8 times, and the average ultimate shear force was 445 N.

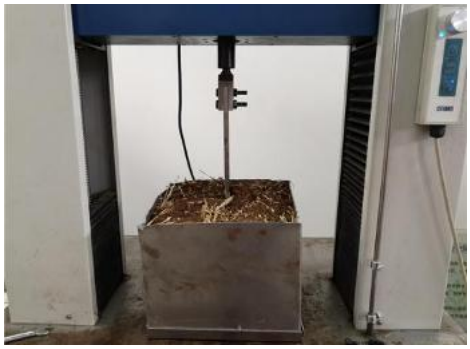


Fig. 6 - Shear test of root-soil complex

Previous studies by *Liu (2018)* and *Sun (2011)* indicated that friction and bonding forces between roots and soil are key factors contributing to the increased ultimate shear force of the complex. The Hertz-Mindlin with bonding contact model was therefore adopted for root-soil interactions. To reduce the number of parameters to be calibrated, the restitution coefficient and bonding stiffness at the root-soil interface were set to 0.6 and 1×10^{7} N/m³, respectively, based on literature review (*Asaf et al., 2007; Zheng et al., 2016*). The bonding radius between wheat roots and soil was determined to be 4 mm through DEM simulation debugging.

RESULTS AND DISCUSSION

Calibration Test Results and Analysis of Wheat Roots

As shown in Table 2, 9 parameters need to be determined for wheat root shear simulations. However, the influence of each parameter on root shear resistance varies (*Liu et al., 2016*). To screen parameters with significant effects on the ultimate shear force of the root model, Plackett-Burman test design was performed using Design-Expert software. Significance analysis of the 9 undetermined parameters was conducted through root shear simulation tests. Each parameter was set at two levels (high and low), encoded as +1 and -1, respectively. According to Plackett-Burman test design requirements, 3 sets of zero-level tests were included, resulting in a total of 15 shear simulation tests with different parameter combinations. The shear speed was set to 4 mm/s. Test parameters, levels, and simulation results are presented in Tables 3 and 4, respectively.

Table 3

Placket-Burman test parameter list

Parameter	Parameter No.	Parameter level	
		Low level (-1)	High level (+1)
Root Poisson's ratio	X1	0.2	0.3
Root shear modulus/(MPa)	X2	6	10
Root restitution coefficient	X3	0.6	0.8
Root-steel restitution coefficient	X4	0.6	1
Root-steel static friction coefficient	X5	0.35	0.6
Root-steel dynamic friction coefficient	X6	0	0.02
Bonding stiffness/(GN·m^{-3})	X7	1	10
Critical stress/(MPa)	X8	1	1.5
Bonding radius/(mm)	X9	0.25	0.5

Table 4

Placket-Burman experimental design and results

No.	X_1	X_2	X_3	X_4	X_5	X_6	X_7	X_8	X_9	Ultimate shear force/(N)
1	0	0	0	0	0	0	0	0	0	4.956
2	1	1	1	-1	-1	-1	-1	-1	1	7.165
3	1	1	-1	1	1	1	-1	-1	-1	1.403
4	-1	1	1	1	-1	-1	-1	1	-1	1.347
5	-1	-1	-1	1	-1	1	1	-1	1	4.273
6	1	-1	1	1	1	-1	-1	-1	1	4.085
7	0	0	0	0	0	0	0	0	0	4.956
8	-1	-1	1	-1	1	1	-1	1	1	4.119

No.	X_1	X_2	X_3	X_4	X_5	X_6	X_7	X_8	X_9	Ultimate shear force/(N)
9	-1	1	-1	1	1	-1	1	1	1	9.069
10	0	0	0	0	0	0	0	0	0	4.956
11	1	-1	1	1	-1	1	1	1	-1	3.491
12	-1	-1	-1	-1	-1	-1	-1	-1	-1	1.362
13	1	1	-1	-1	-1	1	-1	1	1	3.795
14	1	-1		-1	1	-1	1	1	-1	2.889
15	-1	1	1	-1	1	1	1	-1	-1	2.888

Analysis of variance (ANOVA) of simulation results was performed using Design-Expert software, and the effects of each parameter on ultimate shear force are presented in Table 5. Bonding radius, bonding stiffness, and root shear modulus were found to have significant effects on ultimate shear force, while other parameters had minimal impacts. Therefore, only these three parameters were considered in subsequent steepest ascent and screening tests.

Table 5

Placket-Burman significance analysis of test parameters

Parameter	Parameter No.	Effect	Sum of squares	Influence rate/%	Significance ranking
Root Poisson's ratio	X1	-0.038	4.408×10-3	6.090×10-3	9
Root shear modulus/(MPa)	X2	0.91	2.47	4.07	3
Root restitution coefficient	X3	0.051	2.95	0.011	8
Root-steel restitution coefficient	X4	0.24	0.18	0.24	7
Root-steel static friction coefficient	X5	0.50	0.76	1.05	6
Root-steel dynamic friction coefficient	X6	-0.99	7.701×10-3	3.42	4
Bonding stiffness/(GN·m^{-3})	X7	2.28	15.56	21.49	2
Critical stress/(MPa)	X8	0.59	1.04	1.44	5
Bonding radius/(mm)	X9	3.19	30.48	42.11	1

To further narrow the ranges of root shear modulus (G), bonding stiffness (K), and bonding radius (Rb), steepest ascent tests were conducted. Subsequently, Box-Behnken tests were performed to establish a response equation through regression analysis of these three parameters. Taking the actual root ultimate shear force as the target value, the optimal values of G, K, and Rb were obtained using Design-Expert software. The factor levels and simulation results of the steepest ascent tests are presented in Table 6.

Table 6

Steepest climbing test and results

No.	Shear modulus G (X_2)/(MPa)	Bonding stiffness K (X_7)/(GN·m^{-3})	Bonding radius Rb (X_9)/(mm)	Ultimate shear force F_R/(N)	Relative error/%
1	6	2	0.25	1.86	49.73
2	7	4	0.3	3.34	9.73
3	8	6	0.35	4.48	21.08
4	9	8	0.4	5.21	41.81
5	10	10	0.45	7.27	96.49

As shown in Table 6, relatively small relative errors were observed at levels 2 and 3. These levels were therefore selected as the low (-1) and high (+1) levels for Box-Behnken tests. The factor levels, test design, and results are presented in Tables 7 and 8, respectively. Quadratic polynomial ANOVA of simulation results was performed using Design-Expert software.

Table7

Box-Behnken test factor level table

Factor	Level		
	Low (-1)	Medium (0)	High (+1)
Shear modulus/(MPa)	7	7.5	8
Bonding stiffness/(GN·m^{-3})	4	5	6
Bonding radius/(mm)	0.3	0.325	0.35

Table 8

Steepest climbing test and results

No.	Shear modulus/(MPa)	Bonding stiffness/(GN·m⁻³)	Bonding radius/(mm)	Ultimate shear force F_R/(N)
1	7.5	5	0.325	3.55
2	7.5	6	0.35	4.36
3	7.5	4	0.3	3.42
4	7	5	0.3	3.18
5	8	6	0.325	3.56
6	7	4	0.325	3.64
7	7.5	5	0.325	3.55
8	8	5	0.35	4.02
9	8	4	0.325	3.82
10	7	5	0.35	3.92
11	8	5	0.3	3.25
12	7.5	5	0.325	3.55
13	7.5	5	0.325	3.55
14	7.5	5	0.325	3.55
15	7.5	4	0.35	4.74
16	7.5	6	0.3	3.05
17	7	6	0.325	3.94

Non-significant terms were eliminated to optimize the regression model while ensuring model significance and non-significant lack of fit. The ANOVA results of the optimized model are presented in Table 9.

Table 9

The Box-Behnken results of quadratic polynomial variance analysis after experimental optimization

Source of variation	Sum of squares	Degrees of freedom	Mean square	P-value
Model	3.36	6	0.49	< 0.0001**
Shear modulus G	0.090	1	0.090	0.0196*
Bonding stiffness K	0.078	1	0.078	0.0269*
Bonding radius Rb	2.83	1	2.83	< 0.0001**
G×Rb	0.16	1	0.16	0.0047**
K²	0.062	1	0.062	0.0433*
Rb²	0.14	1	0.14	0.0071**
Residual	0.10	9	0.011	
Lack of fit	0.10	5	0.020	
Pure error	0.000	4	0.000	
Total	3.50	16		

Fit statistics: R^2=0.9711; Adjusted R^2=0.9486; Coefficient of variation (CV)=2.85%; Adequate precision=21.786

Note: ** indicates extremely significant difference ($P < 0.01$); * indicates significant difference ($P < 0.05$).

As shown in Table 9, bonding radius (Rb), the interaction term of shear modulus and bonding radius (G×Rb), and the quadratic term of bonding radius (Rb^2) had extremely significant effects on the ultimate shear force of wheat roots. Shear modulus (G), bonding stiffness (K), and the quadratic term of bonding stiffness (K^2) had significant effects. The model exhibited high significance ($P < 0.01$), good reliability (CV=2.85%), excellent fit (R^2=0.9711, Adjusted R^2=0.9486 > 0.8), and high precision (adequate precision=21.786). The optimized regression equation is as follows:

$$F_R = 3.58 - 0.11 \times G + 0.60 \times R_b - 0.14 \times G \times K - 0.20 \times G \times R_b + 0.12 \times K^2 + 0.18 \times R_b^2 \quad (2)$$

To minimize the difference between simulated and actual ultimate shear forces of wheat roots, parameter optimization was performed using the optimization module of Design-Expert software. The optimal values were determined as follows: shear modulus of 7.96 MPa, bonding stiffness of 4.13 GN/m³, and bonding radius of 0.32 mm. Three repeated simulations were conducted with these optimal parameters, yielding ultimate shear forces of 3.725 N, 3.72 N, and 3.74 N, with relative errors of 0.68%, 0.54%, and 1.08%, respectively. The small relative errors indicate that the calibrated wheat root model exhibits shear resistance consistent with actual roots and can be used as a substitute for mechanical simulations.

Calibration Results and Analysis of Wheat Root-Soil Complex Parameters Based on Ultimate Shear Force

Establishment of the WRSC DEM model requires determining parameters such as static and rolling friction coefficients at the root-soil interface, as well as bonding stiffness, bonding stress, and bonding radius of the Hertz-Mindlin with bonding contact model. Based on the actual ultimate shear force of the WRSC, shear simulations of the WRSC model were performed to calibrate these key parameters (Fig. 7). The shear speed in simulations was consistent with that in actual tests. Referring to relevant literature (Lenaerts et al., 2014; Liu, 2018), the dynamic friction coefficient was set to 0.3. The effective ranges of the static friction coefficient, particle bonding stiffness, and particle bonding stress at the root-soil interface were determined as 0.3~0.9, 1~13 MN/m³, and 1~13 MPa, respectively.

Steepest ascent tests were conducted within the determined parameter ranges to simulate shear of the WRSC model. The factor levels and simulation results are presented in Table 10. At test No. 6, the shear resistance was 453 N with a relative error of 1.80% (< 5%). Thus, the calibrated parameters at the wheat root-soil interface were determined as follows: static friction coefficient of 0.8, bonding stiffness of 11 MN/m³, and critical stress of 11 MPa.

Table 10

Horizontal design of the steepest climbing test factors and shear simulation results

No.	Static friction coefficient f_{r-s}	Bonding stiffness τ_{r-s}/(MN·m^{-3})	Critical stress σ_{r-s}/(MPa)	Shear resistance/(N)	Relative error/%
1	0.3	1	1	322	27.64
2	0.4	3	3	346	22.25
3	0.5	5	5	361	18.88
4	0.6	7	7	383	13.93
5	0.7	9	9	410	7.87
6	0.8	11	11	453	1.80
7	0.9	13	13	506	13.71

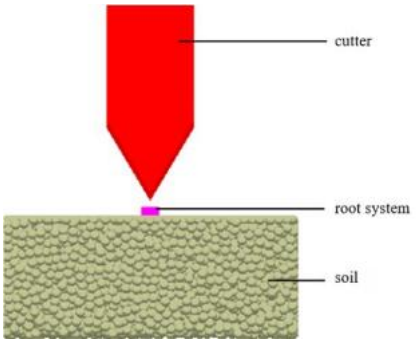

Fig. 7 - Shear simulation of root-soil complex

The calibrated static friction coefficient, bonding stiffness, and critical stress at the wheat root-soil interface were reconfigured in EDEM. Shear tests on the WRSC were then performed at the midpoint of wheat roots, and the cutter resistance-vertical displacement curve was exported after simulation (Fig. 8). The simulated shear resistance curve was found to be in good agreement with the actual curve. Within the depth range of 30-100 mm, the relative error between simulated and actual shear resistance was 7.32%, indicating that the calibrated WRSC DEM model can accurately simulate actual field soil conditions.

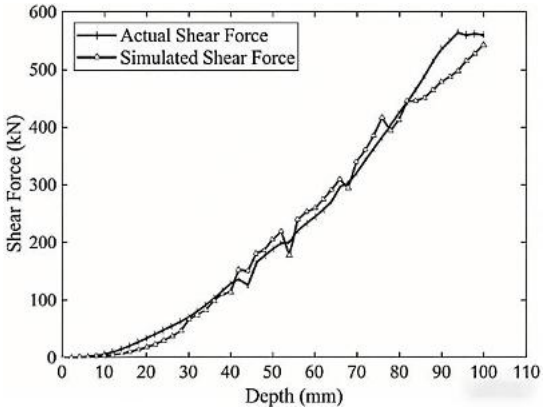

Fig. 8 - After parameter calibration, simulation and test cutter resistance-displacement curve

CONCLUSIONS

(1) A wheat root model was constructed using rapid particle filling and the Hertz-Mindlin with bonding contact model. Through Plackett-Burman screening tests and steepest ascent tests, inter-particle bonding radius, bonding stiffness, and particle shear modulus were identified as the significant parameters affecting the ultimate shear force of wheat roots. Using Box-Behnken design with ultimate shear force as the target value, the optimal parameters were calibrated as follows: root shear modulus of 7.96 MPa, inter-particle bonding stiffness of 4.13 GN/m³, and bonding radius of 0.32 mm.

(2) Actual and simulated shear tests were conducted on the WRSC. With the ultimate shear force on the cutter as the target value, key parameters at the root-soil interface were calibrated: static friction coefficient of 0.8, bonding stiffness of 11 MN/m³, and critical stress of 11 MPa.

(3) Validation of the WRSC model showed a relative error of 7.35% between the ultimate shear force of the calibrated model and the actual value, indicating that the DEM-based WRSC model can be used to simulate actual field soil environments.

ABSTRACT

This study focuses on the development of a multifunctional agricultural robotic platform. Previous articles in this series established the need for such a platform based on the specific soil and climatic conditions of the Republic of Armenia. Tests of a laboratory prototype indicated the need for further investigation of the platform's dynamic behavior, particularly during operation in orchards and agricultural fields on sloping terrain, which is common in Armenia. Particular attention was given to changes in platform inclination during turning maneuvers on slopes and to the yaw moment generated about the vertical axis in four-wheeled robotic platforms with independently controlled wheels. Based on a mathematical model of the chassis incorporating elastic elements (springs) and damping elements (shock absorbers), the differential equation governing the motion of the platform's center of mass was formulated, together with moment equations about the transverse and longitudinal axes passing through the center of mass. Analysis of these equations yielded the differential equations governing the platform's vertical oscillations. Expressions were subsequently derived for the displacement, velocity, acceleration, and jerk associated with the platform's free oscillations. These equations can be used to evaluate ride smoothness and determine the spring stiffness and shock-absorber damping coefficient required to achieve the desired suspension performance.

INTRODUCTION

In all countries ensuring food security has always been, and remains, one of the most pressing challenges facing agricultural production. The solving of this problem must involve the conservation and improvement of land resources, meeting environmental requirements, increasing production volumes, the production of environmentally friendly food products, full mechanization of agricultural production, and, particularly importantly, reducing of the energy intensity of these processes. It is evident that the stated problem is multidimensional, and its complete solution using existing technologies and technical means is objectively limited (*Abrosimov and Raykov, 2022; Bak and Jakobsen, 2004; Fontani et al., 2025; O'Meara, 2019; Ritchie, 2024*).

For this reason, two key trends have recently become central to agricultural production technological processes (*Abrosimov and Raykov, 2022; Markets and Markets, 2025; Navone et al., 2025; Tarverdyan et al., 2025*).

First, one of the fastest growing areas in recent years in agricultural production is precision and digital technologies in crop and livestock production.

Second, the direction without which it is impossible to effectively utilize and implement the information obtained through the above-mentioned technologies is the organization of robot-assisted agricultural production. This implies that the development and large-scale implementation of robotics play a central role in addressing the stated problem (*Abrosimov and Raykov, 2022; Navone et al., 2025; O'Meara, 2019; Ritchie, H., 2024)*.

Although the global agricultural robotics market is developing at an unprecedented rate (over the last five years alone, its volume has increased approximately 20-fold) (*Bak and Jakobsen, 2004; MarketsandMarkets, 2025*), the application of such systems in the agricultural sector of the Republic of Armenia remains highly limited. This is primarily due to their relatively high market price, making them inaccessible to the majority of local producers, and second, to their structural characteristics, which result in low operational reliability under the soil conditions of the Republic of Armenia (*Tarverdyan et al., 2025*).

It follows that the problem can be addressed through two approaches: either partial structural modifications should be made to existing robots, or a new universal robotic platform should be developed that is better adapted to the country's soil conditions (presence of stones of various sizes, fragmented terrain) and, importantly, is cost-effective.

For all mobile agricultural robots, the mobile platform is a critical component that plays a key role in the overall system performance of the system. It is therefore not surprising that researchers in this field have devoted significant efforts to the development of high-performance mobile platforms for agricultural robots, as well as to improving their control and positioning accuracy, since these issues are of crucial importance in precision agriculture (*Amin et al., 2025; Bayar et al., 2015; Lipiński et al., 2016; Qiu et al., 2018; Zagazezheva and Berbekova, 2021*).

The operational practice of agricultural robotic platforms over the last 20–25 years, as well as the results of numerous research studies, lead to a clear conclusion: from the perspective of accurate perception and response to external influences during agro-technological processes, minimal energy consumption, minimal soil damage, and high maneuverability, four-wheeled robotic platforms are preferred (*Akimov, 2017; Blasco et al., 2002; Cho et al., 2002*).

In addition, four-wheeled robotic platforms with independently controlled wheels provide high maneuverability and enable parallel motion of the vehicle during turning, allowing positional accuracy and orientation accuracy to be controlled independently (*Bak and Jakobsen, 2004; Cho et al., 2002; Orebäck and Christensen, 2003; Tarverdyan et al., 2025*).

Research on robotic platforms is primarily driven by the shortcomings and challenges identified during their operation. Current studies place significant emphasis on optimal control, stability, and ensuring smooth motion. In this regard, the studies conducted by a group of researchers are of particular interest *(Blasco et al., 2002; Fountas et al., 2020; Zakaria et al., 2024*), in which the authors demonstrate that integrated control systems (ICS)—such as combined steering and wheel torque control, suspension and wheel torque coordination, as well as the integration of steering control systems with suspension—provide superior performance characteristics for multi-axle mobile devices (Multi-axle Vehicles, MAV) compared with skid-steering control systems (SCS). In this optimal distribution approach, the target vehicle forces and yaw torque are distributed among the individual tire forces (*Ali et al., 2017; Li and Shi, 2017; Zakaria et al., 2024*).

Another group of researchers has approached the problem from the perspective of determining the critical speed and its more accurate estimation for a two-axle dynamic model. A 4×2-wheel configuration was

adopted as the vehicle model, and the acting forces and other lateral dynamic parameters were calculated for this model. The problem was analyzed in terms of the forces acting on the vehicle during turning and on inclined surfaces to ensure stability, taking into account the redistribution of reaction forces and variations in the tire–surface adhesion coefficient (*Ivanov et al., 2025*).

In a previous study devoted to this problem (*Tarverdyan et al., 2025*), the kinematic parameters of the motion subsystem of a robotic platform were examined in detail. In particular, the relationships between four independently steerable wheels, steering angles, and their angular velocities were established. Lateral forces arising during turning on a horizontal plane were also partially analyzed.

The present article is devoted to the investigation of the stability of robotic platform motion and conditions of lateral slip on sloped terrain, as well as to the assessment of motion smoothness based on the proposed model.

MATERIALS AND METHODS

Stability of Robotic Platform Motion on Inclined Surfaces

As previously noted, for robotic platforms intended to perform agro-technological operations, the four-wheel configuration with independently controlled wheels is considered preferable. The ability of the platform to perform parallel translational motion, in some cases without rotational turning, provides high maneuverability.

Independent control of all four wheels minimizes lateral slip, thereby reducing not only soil disturbance but also the wear of drivetrain components (*Bak and Jakobsen, 2004; Torii, 2000*).

Although the dynamics of a four-wheeled independently controlled system are inherently nonlinear and control is not straightforward, relatively simple control systems can still be effective at low operational speeds (2–6 km/h), (*Cho et al., 2002; MarketsandMarkets, 2025; Tarverdyan et al.,2025*). The conceptual scheme of the proposed robotic platform is presented in Figure 1. It consists of a platform frame (1), on which various agro-technological implements and devices are mounted; four drive wheels with independent actuation (2); a wheel steering control unit (3); and a wheel steering mechanism (4).

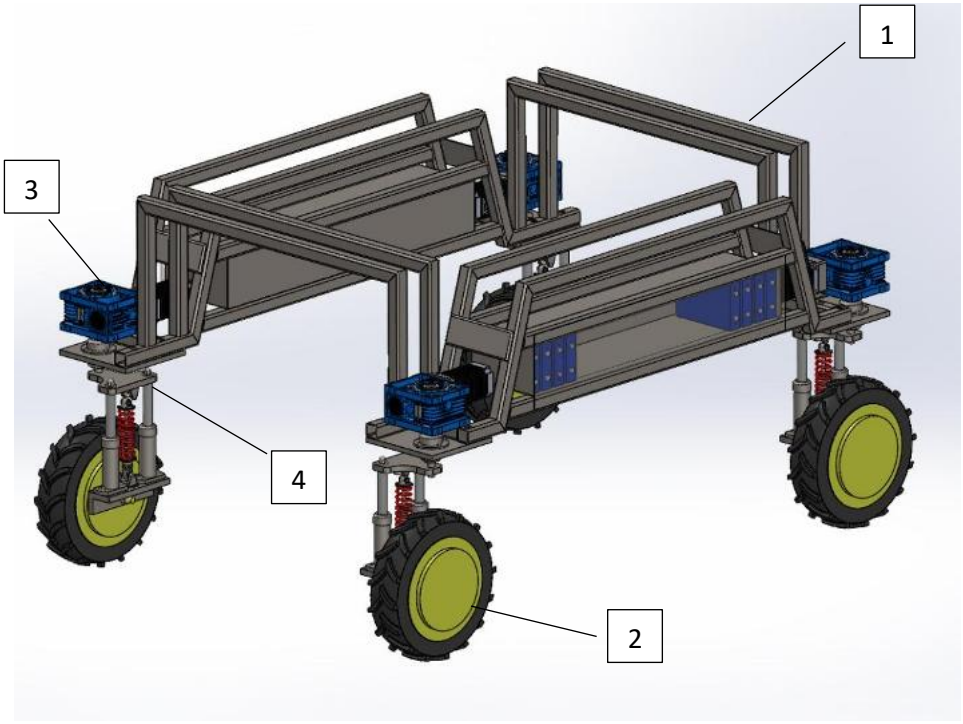

Fig. 1 - 3D model of the developed robotic platform

A detailed kinematic analysis of the locomotion subsystem of the developed robotic platform (*Tarverdyan et al., 2025*) yielded equations that make it possible to determine and refine the parameters used as the basis for programming the platform's turning motion on a horizontal surface.

As a result of the dynamic analysis, precise equations for determining lateral slip forces were obtained. These equations enable the development of a robotic platform drivetrain in which wheel slip during turning is minimized, thereby minimizing soil damage while ensuring operational reliability and durability (*Tarverdyan et al., 2025*).

An agricultural robotic platform can also perform agro-technological operations in fields located on sloped terrain, which is particularly characteristic of the Republic of Armenia. Under such conditions, during the development of the robotic platform, the issue of motion stability, especially during turning, becomes a key subject of analysis.

Assume that the robotic platform performs a turning maneuver on a planar slope inclined at an angle *β* where the rotation axis OO' is perpendicular to the inclined plane and is positioned upslope relative to the robotic platform (Figure 2). The geometric dimensions of the platform are – width B and length L. Since the goal is to develop a structure that is as symmetric as possible in terms of both geometry and mass distribution, it can be assumed that the center of mass coincides with point O_1', located at the intersection of the longitudinal (x_2) and transverse (y_2) symmetry axes of the platform. In this case $a = \frac{L}{2}, b = \frac{B}{2}$. Let the distance of the center of mass from the supporting plane CDEF be denoted by h, and the turning radius of the center of mass by R_0. The steering angles of the wheels are $\theta_1, \theta_2, \theta_3, \theta_4$, while the corresponding turning radii are R_1, R_2, R_3, R_4.

Let consider the turning motion of the robotic platform with a constant turning radius on a slope inclined at an angle β (Figures 2 and 3). Before determining the forces and reactions acting on the platform, it is necessary to account for the transformation of the slope inclination during rotational motion, since it directly affects the magnitude of the force components involved. Let the coordinate system xoy (Figure 3) be fixed to the inclined plane, where the y-axis is aligned with the transverse direction of the slope and the x -axis with the longitudinal direction, with the origin located at the center of rotation. When the rotation angle is φ = 0 (position $\mathcal{A}$ of the robotic platform), the transverse symmetry axis $y_1$of the robotic platform coincides with the y -axis, the longitudinal axis (x_1) inclination angle is β.

When φ = 90°, the axis x_1 becomes parallel to the y-axis $x_1 \parallel y$, while y_1 coincides with the x-axis and is inclined at angle β (Figure 2). When φ = 180°, the configuration becomes symmetric to position $\mathcal{A}$. For all intermediate positions (e.g., position B), the inclination of the robotic platform is characterized by angles β_1 and β_2, which are determined as follows:

$$\begin{cases} sin\beta_1 = sin\beta \cdot sin\varphi, \\ sin\beta_2 = sin\beta \cdot cos\varphi. \end{cases} \quad (1)$$

Let consider the analysis of the forces acting on the robotic platform during turning motion at an arbitrary intermediate position B within the range $0 \leq \varphi \leq 90^0$ (Figure 3) (within the interval $90 - 180^0$, the configuration is repeated symmetrically).

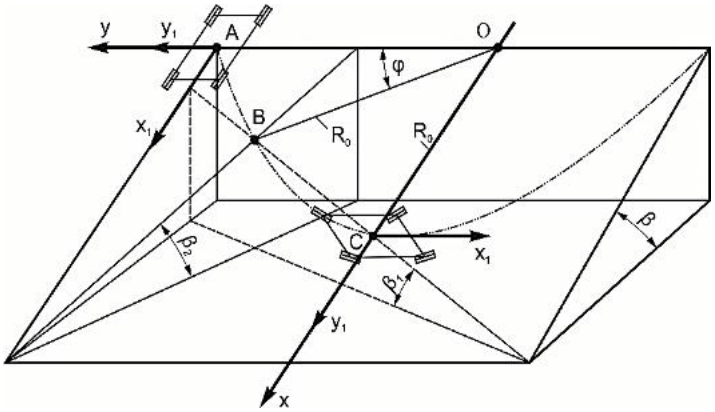

Fig. 2 - Schematic diagram of tilt-angle transformation during the turning motion of the robotic platform

At the specified position, the following forces and torques act on the robotic platform:

The gravitational force G acts at the center of mass and has three components: $G_x = G\cos\beta_1 \cdot sin\beta_2$, directed along the x_2 axis, $G_y = G sin\beta_1$ - directed along the y_2 axis, $G_z = G\cos\beta_1 \cdot \cos\beta_2$ – perpendicular to the inclined plane.

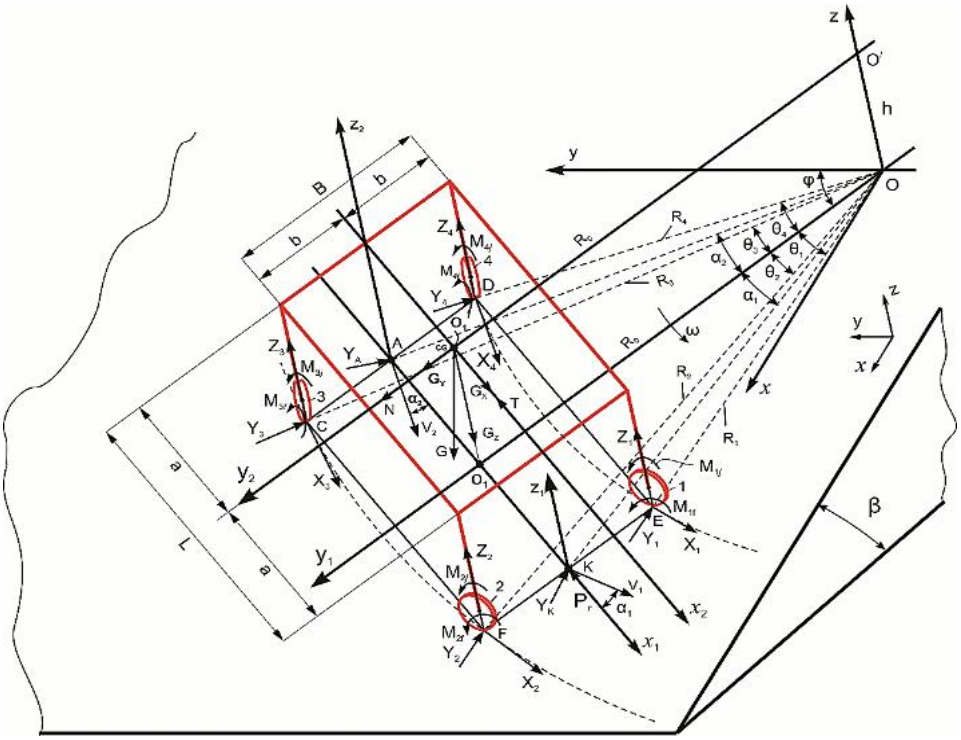

Fig. 3 - Kinematic and dynamic analysis scheme of the turning motion of the robotic platform on an inclined surface

At the wheel–ground contact surfaces, the support reactions Z_i, act normal to the supporting surface. The driving (tractive/tangential) forces $\mathrm{X_i}$ act at the wheel contact surfaces and are perpendicular both to the wheel radii (r_w) and to the turning radii R_i associated with rotation about point *O*. The lateral slip resistance forces Y_i, also act at the wheel–ground contact surfaces and are directed along the turning radii (R_i). In the general case, the wheels are also subjected to a torque of the rolling resistance (M_{if}).

The robotic platform is additionally subjected to inertial force factors. At the center of mass (O_1'), the longitudinal inertial force T acts along the x_2 axis, with its direction determined by the nature of the motion (acceleration or deceleration). The centrifugal force N associated with curvilinear motion acts along the y_2 axis. The wheels are also subjected to inertial torques (M_{ij}), as well as the inertial torque of the robotic platform associated with curvilinear motion about the z-axis, denoted by M_{j} (*Litvinov, 1971; Qiu et al., 2018; Zinoviev, 1975*).

To solve the problem of lateral slip of the robotic platform, it is first necessary to determine the support reactions at the wheel–ground contact surfaces, namely Z_1, Z_2, Z_3 *and* Z_4. By formulating the equilibrium equations with respect to the axes passing through the wheel support points ($\mathcal{CD}$, EF, CF and DE) and performing the corresponding transformations, the following equations are obtained:

$$\mathrm{Z}_1 + \mathrm{Z}_2 = \frac{\mathrm{G_z}}{2} + \frac{\mathrm{G}_x \cdot \mathrm{h}}{2a} - \frac{T \cdot \mathrm{h}}{2a} - \frac{4M_{\mathrm{ij}}}{2a} \tag{2}$$

$$\mathrm{Z}_3 + \mathrm{Z}_4 = \frac{\mathrm{G_z}}{2} - \frac{\mathrm{G}_x \cdot \mathrm{h}}{2a} + \frac{T \cdot \mathrm{h}}{2a} + \frac{4M_{\mathrm{ij}}}{2a} \tag{3}$$

$$\mathrm{Z}_1 + \mathrm{Z}_4 = \frac{\mathrm{G_z}}{2} + \frac{\mathrm{G_y} \cdot \mathrm{h}}{2b} - \frac{N \cdot \mathrm{h}}{2b} \tag{4}$$

$$\mathrm{Z}_2 + \mathrm{Z}_3 = \frac{\mathrm{G_z}}{2} + \frac{\mathrm{G_y} \cdot \mathrm{h}}{2b} + \frac{N \cdot \mathrm{h}}{2b} \tag{5}$$

Besides:

$$\mathrm{Z}_1 + \mathrm{Z}_2 + \mathrm{Z}_3 + \mathrm{Z}_4 = \mathrm{G_z} \tag{6}$$

Let's also introduce the following denotations:

$$\begin{cases} \mathrm{Z}_1 + \mathrm{Z}_2 = \mathcal{A} \\ \mathrm{Z}_3 + \mathrm{Z}_4 = B \\ \mathrm{Z}_1 + \mathrm{Z}_4 = C \\ \mathrm{Z}_2 + \mathrm{Z}_3 = \mathcal{D}. \end{cases} \Rightarrow \mathcal{A} + B = C + \mathcal{D} \tag{7}$$

Let us denote: $Z_1 = S$, where S is an arbitrary parameter. Then:

$$\begin{cases} Z_1 = S \\ Z_2 = \mathcal{A} - S \\ Z_3 = B - C + S = \mathcal{D} + S \\ Z_4 = C - S. \end{cases} \quad (8)$$

The parameter S characterizes the redistribution of the load among the supports, which does not alter the quantities $(Z_1 + Z_2)$, $(Z_1 + Z_4)$, $(Z_3 + Z_4)$ and $(Z_2 + Z_3)$, in other words, equilibrium is preserved, and the model is self-balancing (*Buchholz, 2023; Ilarionov, 2013; Litvinov, 1971*).

Using Equations (2), (3), (4), and (5), together with relations (6) and (8), and considering that $G_x = G\cos\beta_1 \cdot sin\beta_2$, $G_y = G sin\beta_1$, $G_z = G\cos\beta_1 \cdot \cos\beta_2$, where the angles β_1 and β_2 are determined from Equation (1), $N = \frac{G}{g}\omega^2 R_0$, $T = \frac{G}{g} \cdot \frac{dv}{dt}$, $M_{ij} = J_w \cdot \frac{d\omega_w}{dt}$ (J_w is the wheel torque of inertia, and $\frac{d\omega_w}{dt}$ is the angular acceleration of the wheel), and taking into account that uniform motion of the robotic platform is considered, the following equations are obtained for the support reactions:

$$\left.\begin{aligned} Z_1 &= \frac{G}{4}cos\beta_1 \cdot cos\beta_2 - \frac{h \cdot G}{2L} \cdot sin\beta_1 + \frac{G \cdot h}{2B}cos\beta_1 \cdot sin\beta_2 - \frac{G \cdot h \cdot \omega^2 R_0}{g \cdot L} \\ Z_2 &= \frac{G}{4}cos\beta_1 \cdot cos\beta_2 + \frac{G \cdot h}{2L} \cdot sin\beta_1 + \frac{G \cdot h}{2B}cos\beta_1 \cdot sin\beta_2 + \frac{G \cdot h \cdot \omega^2 R_0}{g \cdot L} \\ Z_3 &= \frac{G}{4}cos\beta_1 \cdot cos\beta_2 + \frac{G \cdot h}{2L} \cdot sin\beta_1 - \frac{G \cdot h}{2B}cos\beta_1 \cdot sin\beta_2 + \frac{G \cdot h \cdot \omega^2 R_0}{g \cdot L} \\ Z_4 &= \frac{G}{4}cos\beta_1 \cdot cos\beta_2 - \frac{G \cdot h}{2L} \cdot sin\beta_1 - \frac{G \cdot h}{2B}cos\beta_1 \cdot sin\beta_2 - \frac{G \cdot h \cdot \omega^2 R_0}{g \cdot L} \end{aligned}\right\}. \quad (9)$$

It should be noted that the obtained solutions satisfy condition (7) and correctly reflect the physical nature of the problem.

Assessment and improvement of the Motion Smoothness of the Robotic Platform

Ensuring the smooth motion of the developed robotic platform is an important issue, since it directly determines the accurate execution of agro-technical processes, the operational reliability and durability of its components—particularly the suspension system—and the reliable performance of the orientation and control system.

Figure 4. shows the schematic diagram of the suspension system of the developed robotic platform, which includes an elastic element (spring) (1), a coaxially mounted hydraulic damper (shock absorber) (2), pneumatic wheels (3) each equipped with an independent electric hub motors, and an independent wheel steering control unit (4).

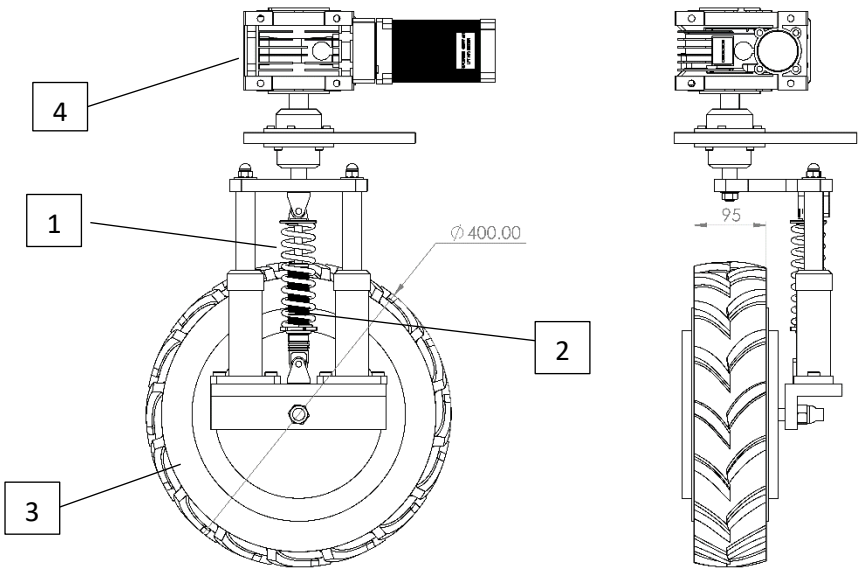

Fig. 4 - Schematic diagram of the suspension system of the robotic platform (all dimensions in *mm*)

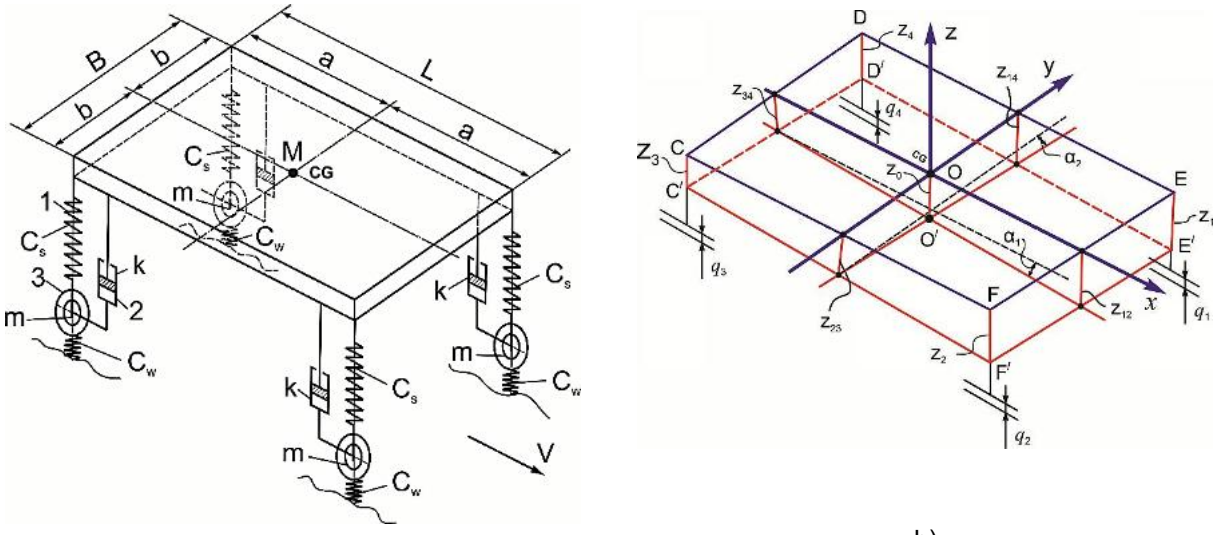
It should be noted that, based on the presented suspension system configuration, from an application standpoint it is important to analyze the vertical translational oscillations of the platform, as well as the angular oscillations in the longitudinal and transverse symmetry planes.

The computational scheme of the problem is presented in Figure 5.

The data required for solving the problem are as follows:



- the overall dimensions of the robot platform: length L, width B;
- the identical stiffness of all four suspension springs c_s;
- wheel stiffness c_w;
- the sprung mass of the robotic platform M;
- the mass of the assemblies located below the springs (unsprung mass) m;
- the damping coefficient of the shock absorbers *k*. Since the two elastic elements the suspension spring and the wheel are connected in series, their combined stiffness can be represented by a single equivalent stiffness coefficient (*Ilarionov, 2013; Litvinov, 1971*).

$$c = \frac{c_s \cdot c_w}{c_s + c_w}.$$

Several assumptions were adopted in solving the problem, which considerably simplify the analysis while having no significant influence on the results.

It is assumed that the robotic platform moves uniformly across field surface irregularities, with the wheels continuously rolling over them while maintaining uninterrupted contact with the ground. Under these conditions, the wheel axles undergo vertical displacements (q_i).

The self-weight of the robotic platform and the loads mounted on it are assumed to be distributed symmetrically with respect to the *x* and *y* axes, such that the center of gravity of the total mass coincides with the origin of the coordinate system (Figure 5).

a) b)

Fig. 5 - Scheme for determining the driving/motion smoothness of the robotic platform:

a) schematic diagram of the suspension system,

b) computational scheme of the platform vertical displacements

In addition, the following notations were adopted:

z_0- vertical displacement of the platform's center of mass caused by oscillations;

z_1; z_2; z_3; z_4- vertical displacements of points C; D; E and F respectively located above the wheel axles;

α_1; α_2 – rotational angles of the platform in the longitudinal and transverse planes of symmetry, respectively;

a - distances from the front (conventionally defined) and rear wheel axles to the y-axis of symmetry passing through the center of mass (a=L/2, since the robotic platform is designed to have a symmetric structure);

b- distance from the wheel suspension attachment points to the x-axis of symmetry passing through the center of mass ($b = \frac{B}{2}$);

ρ_1- radius of inertia of the robotic platform with respect to the y-axis;

ρ_2- radius of inertia of the robotic platform with respect to the x-axis.

It is evident that the solution of the problem involves six unknowns: z_1; z_2; z_3; z_4; z_0 and α_1 (in one case) and α_2 (in the other case). In such situations, it is useful to establish relationships among these unknowns. Considering the sprung part of the robotic platform as a rigid horizontal plate CDEF (Figure 5), as a result of its vertical linear oscillations, at an arbitrary instant it will occupy the position C′ D′ E′ F′ while remaining planar. In the general case of oscillations, it is assumed that the displacements at the indicated points above the wheel axles are different, namely z_1; z_2; z_3; z_4. Under these conditions, geometric relationships exist between these displacements, making it possible to simplify the solution of the problem. In the longitudinal plane of symmetry of the robotic platform (along the x-axis), the displacements of the front edge points, as the midlines of the corresponding rectangles, are expressed as $z_{12} = \frac{z_1+z_2}{2}, z_{34} = \frac{z_3+z_4}{2}$. From the scheme shown in Figure 5, it follows that:

$$z_{12} = z_0 + a_1 \mathrm{a}\,, \qquad z_{34} = z_0 - a_1 \mathrm{a} \tag{11}$$

From which:

$$a_1 = \frac{z_{12} - z_{34}}{L} = \frac{z_1 + z_2 - z_3 - z_4}{2L}\,.$$

Similarly, in the plane of lateral symmetry (along the y-axis), the displacements and the rotation angle of the platform are given by:

$$z_{14} = z_0 + a_2 \cdot \mathrm{b};\; z_{23} = z_0 - a_2 \cdot \mathrm{b} \tag{12}$$

$$a_2 = \frac{z_{14} - z_{23}}{B} = \frac{z_1 + z_4 - z_2 - z_3}{2B}. \tag{13}$$

From the scheme, the following relationships also hold: $z_0 = \frac{z_1+z_3}{2}$, $z_0 = \frac{z_2+z_4}{2}$, from which it follows that:

$$\left.\begin{aligned} z_2 + z_3 &= z_2 + z_4 \\ z_0 &= \frac{z_1 + z_2 + z_3 + z_4}{4} \end{aligned}\right\} \tag{14}$$

To formulate the equations of motions for the considered problem, the principles of rigid-body dynamics are applied (*Biderman, 1980; Buchholz, 2023; Zinoviev, 1975*).

Since in this stage the task is to study only the free oscillations of the robotic platform, the forces caused by terrain irregularities, which include terms proportional to q_i, can be neglected as external excitations. In this case, the differential equation of motion of the platform's center of inertia can be written in the following form:

$$M\frac{d^2 z_0}{dt^2} = \mathrm{k}\left(\frac{dz_1}{dt} + \frac{dz_2}{dt} + \frac{dz_3}{dt} + \frac{dz_4}{dt}\right) + c(z_1 + z_2 + z_3 + z_4) = 0. \tag{15}$$

The torque equations about the x and y axes passing through the center of inertia will be:

$$\mathrm{M}\rho_1^2\frac{d^2\alpha_1}{dt^2} + \mathrm{ka}\left(\frac{dz_1}{dt} - \frac{dz_2}{dt} - \frac{dz_3}{dt} + \frac{dz_4}{dt}\right) + c(z_1 - z_2 - z_3 + z_4) = 0, \tag{16}$$

$$\mathrm{M}\rho_2^2\frac{d^2\alpha_2}{dt^2} + \mathrm{k}b\left(\frac{dz_1}{dt} + \frac{dz_2}{dt} - \frac{dz_3}{dt} - \frac{dz_4}{dt}\right) + cb(z_1 + z_2 - z_3 - z_4) = 0. \tag{17}$$

By inserting the values of $\alpha_1, \alpha_2\ and\ z_0$ from the Equations of (11); (13) and (14) in the Equations of (15); (16) and (17), the following is obtained:

$$\mathrm{M}\cdot\frac{1}{4}\left(\frac{d^2 z_1}{dt^2} + \frac{d^2 z_2}{dt^2} + \frac{d^2 z_3}{dt^2} + \frac{d^2 z_4}{dt^2}\right) + \mathrm{k}\left(\frac{dz_1}{dt} + \frac{dz_2}{dt} + \frac{dz_3}{dt} + \frac{dz_4}{dt}\right) + C(z_1 + z_2 + z_3 + z_4) = 0, \tag{18}$$

$$\frac{\mathrm{M}\rho_1^2}{2L}\cdot\left(\frac{d^2 z_1}{dt^2} + \frac{d^2 z_2}{dt^2} - \frac{d^2 z_3}{dt^2} - \frac{d^2 z_4}{dt^2}\right) + \mathrm{ka}\left(\frac{dz_1}{dt} - \frac{dz_2}{dt} - \frac{dz_3}{dt} + \frac{dz_4}{dt}\right) + ca(z_1 - z_2 - z_3 + z_4) = 0, \tag{19}$$

$$\frac{\mathrm{M}\rho_2^2}{2B}\cdot\left(\frac{d^2 z_1}{dt^2} + \frac{d^2 z_4}{dt^2} - \frac{d^2 z_2}{dt^2} - \frac{d^2 z_3}{dt^2}\right) + \mathrm{k}b\left(\frac{dz_1}{dt} + \frac{dz_2}{dt} - \frac{dz_3}{dt} - \frac{dz_4}{dt}\right) + cb(z_1 + z_2 - z_3 - z_4) = 0. \tag{20}$$

To establish the relationships between Equations (18) and (19), (18) and (20) Equation (18) is multiplied by a and is added to (19), then (18) is multiplied by a and (19) is subtracted. In both cases, the resulting equations are divided by L. Similarly, Equation (18) is multiplied by *b* and added to Equation (20), and the resulting equation is divided by *B*. Equation (18) is then multiplied by *b* and Equation (20) is subtracted from the result, after which the resulting equation is divided by B. Considering the symmetry of the system, such that L=2a and B=2b, the following equations are obtained:

$$\mathrm{M}\left(\frac{\mathrm{a}^2+\rho_1^2}{2L^2}\right)\left(\frac{d^2z_1}{dt^2}+\frac{d^2z_2}{dt^2}\right)+\mathrm{M}\left(\frac{\mathrm{a}^2-\rho_1^2}{2L^2}\right)\cdot\left(\frac{d^2z_3}{dt^2}+\frac{d^2z_4}{dt^2}\right)+\mathrm{k}\left(\frac{dz_1}{dt}+\frac{dz_4}{dt}\right)+c(z_1+z_4)=0, \quad (21)$$

$$\mathrm{M}\left(\frac{\mathrm{a}^2-\rho_1^2}{2L^2}\right)\left(\frac{d^2z_1}{dt^2}+\frac{d^2z_2}{dt^2}\right)+\mathrm{M}\left(\frac{\mathrm{a}^2+\rho_1^2}{2L^2}\right)\cdot\left(\frac{d^2z_3}{dt^2}+\frac{d^2z_4}{dt^2}\right)+\mathrm{k}\left(\frac{dz_1}{dt}+\frac{dz_3}{dt}\right)+c(z_1+z_3)=0, \quad (22)$$

$$\mathrm{M}\left(\frac{\mathrm{b}^2+\rho_2^2}{2B^2}\right)\left(\frac{d^2z_1}{dt^2}+\frac{d^2z_4}{dt^2}\right)+\mathrm{M}\left(\frac{\mathrm{b}^2-\rho_2^2}{2B^2}\right)\cdot\left(\frac{d^2z_2}{dt^2}+\frac{d^2z_3}{dt^2}\right)+\mathrm{k}\left(\frac{dz_1}{dt}+\frac{dz_2}{dt}\right)+c(z_1+z_2)=0, \quad (23)$$

$$\mathrm{M}\left(\frac{\mathrm{b}^2-\rho_2^2}{2B^2}\right)\left(\frac{d^2z_1}{dt}+\frac{d^2z_4}{dt^2}\right)+\mathrm{M}\left(\frac{\mathrm{b}^2+\rho_2^2}{2B^2}\right)\cdot\left(\frac{d^2z_2}{dt^2}+\frac{d^2z_3}{dt^2}\right)+\mathrm{k}\left(\frac{dz_3}{dt}+\frac{dz_4}{dt}\right)+c(z_3+z_4)=0. \quad (24)$$

The Equations (21)–(22) and (23)–(24) are pairwise interrelated through their first and second terms Even in the particular case where $\mathrm{a}=\rho_1$ and $\mathrm{b}=\rho_2$, these interrelations are preserved. This indicates that the vertical oscillations of the considered robotic platform, characterized by the coordinates z_1; z_2; z_3 and z_4 are mutually coupled.

The following notation is introduced:

$$\mathrm{M}\left(\frac{\mathrm{a}^2+\rho_1^2}{2L^2}\right)=\mathrm{M}_1;\ \ \mathrm{M}\left(\frac{\mathrm{a}^2-\rho_1^2}{2L^2}\right)=\mathrm{M}_2;\ \mathrm{M}\left(\frac{\mathrm{b}^2+\rho_2^2}{2\mathrm{B}^2}\right)=\mathrm{M}_3;\ \ \mathrm{M}\left(\frac{\mathrm{b}^2-\rho_2^2}{2\mathrm{B}^2}\right)=\mathrm{M}_4.$$

The Equations (21) (22); (23) and (24) will take the following form:

$$\mathrm{M}_1\left(\frac{d^2z_1}{dt^2}+\frac{d^2z_2}{dt^2}\right)+\mathrm{M}_2\left(\frac{d^2z_3}{dt^2}+\frac{d^2z_4}{dt^2}\right)+k\left(\frac{d^2z_1}{dt}+\frac{d^2z_4}{dt}\right)+c(z_1+z_4)=0, \quad (25)$$

$$\mathrm{M}_2\left(\frac{d^2z_1}{dt^2}+\frac{d^2z_2}{dt^2}\right)+\mathrm{M}_1\left(\frac{d^2z_3}{dt^2}+\frac{d^2z_4}{dt^2}\right)+k\left(\frac{dz_2}{dt}+\frac{dz_3}{dt}\right)+c(z_2+z_3)=0, \quad (26)$$

$$\mathrm{M}_3\left(\frac{d^2z_1}{dt^2}+\frac{d^2z_4}{dt^2}\right)+\mathrm{M}_4\left(\frac{d^2z_2}{dt^2}+\frac{d^2z_3}{dt^2}\right)+k\left(\frac{dz_1}{dt}+\frac{dz_2}{dt}\right)+c(z_1+z_2)=0, \quad (27)$$

$$\mathrm{M}_4\left(\frac{d^2z_1}{dt}+\frac{d^2z_4}{dt^2}\right)+\mathrm{M}_3\left(\frac{d^2z_2}{dt^2}+\frac{d^2z_3}{dt^2}\right)+k\left(\frac{dz_3}{dt}+\frac{dz_4}{dt}\right)+c(z_3+z_4)=0. \quad (28)$$

The obtained equations enable to study the free oscillations of the robotic platform and also serve as a basis for the further investigation of its forced vibrations.

RESULTS AND ANALYSIS

Stability Conditions of the Robotic Platform Motion on Slopes

For the initial parameters of the developed robotic platform (L = 1.6m, B = 1.2m, G = 5000 N, h = 0.6m, ω = 0.278 s^{-1}, R_0 = 5m, β = 10^0) the following results are obtained for three characteristic positions using the derived equations:

when $\varphi=0^0$, $sin\beta_1=0$, $\beta_1=0$, $sin\beta_2=sin\beta$, $\beta_2=\beta$, $\mathrm{G_z}=\mathrm{G}\cos\beta_1\cdot\cos\beta_2=5000\cdot0.9848=4925\ N$;

when $\varphi=45^0$, $sin\beta_1=sin\beta\cdot sin\varphi=0.1222$, $sin\beta_2=sin\beta\cdot cos\varphi=0.1222$, $cos\beta_1=cos\beta_2=0.9925$, $\mathrm{G_z}=\mathrm{G}\cos\beta_1\cdot\cos\beta_2=5000\cdot0.9925=4962.5\ N$;

when $\varphi=90^0$, $sin\beta_1=sin\beta\cdot sin\varphi$, $\beta_1=\beta$, $\beta_2=0$, $G_z=G\cos\beta_1\cdot\cos\beta_2=5000\cdot0.9848=4925\ N$;

Substituting the numerical values into Equations (9), the following values are obtained for the support reactions:

when $\varphi=0^0$, $\mathrm{Z}_1=1355\ N$; $\mathrm{Z}_2=1515\ N$; $\mathrm{Z}_3=1095\ N$; $\mathrm{Z}_4=960\ N$, verification: $\mathrm{Z}_1+\mathrm{Z}_2+\mathrm{Z}_3+\mathrm{Z}_4=4925\ N=\mathrm{G_z}$;

when $\varphi=45^0$, $\mathrm{Z}_1=1195\ N$; $\mathrm{Z}_2=1562.5\ N$; $\mathrm{Z}_3=1265\ N$; $\mathrm{Z}_4=940\ N$, verification: $\mathrm{Z}_1+\mathrm{Z}_2+\mathrm{Z}_3+\mathrm{Z}_4=4962.5\ N=\mathrm{G_z}$;

when $\varphi=90^0$, $\mathrm{Z}_1=1004.5\ N$; $\mathrm{Z}_2=1458\ N$; $\mathrm{Z}_3=1458\ N$; $\mathrm{Z}_4=1004.5\ N$, verification: $\mathrm{Z}_1+\mathrm{Z}_2+\mathrm{Z}_3+\mathrm{Z}_4=4925\ N=\mathrm{G_z}$.

The discussion of the robotic platform overturning problem is of little practical significance, since its operational speeds (3 – 6 km/h) and field slope angles (up to 7^0) cannot create a situation in which, even in the most unfavorable position ($\varphi=90^0$) the support reactions Z_1 and Z_4 become equal to 0. In this regard, the analysis of lateral skidding is of primary importance.

To determine the resistance forces against lateral skidding, it is first necessary to determine the tangential reactions (X_i) developed at all driving wheels during rolling motion. It is known that these reaction forces are determined as follows:

$$X_i = P - f\mathrm{Z}_i$$

where P is the circumferential force acting on each driving wheel, f is the rolling resistance coefficient, for various soils $f = 0{,}10 \div 0{,}25$ (*Cho et al., 2002; Litvinov, 1971*), while for cultivated soils $f = 0{,}25$; Z_i is the reaction force at the wheel–ground contact surface. For the considered case:

$$P = \frac{M_m \cdot i \cdot \eta}{r_w} - \mathrm{J}_w \cdot \frac{d\omega_w}{dt} \cdot \frac{1}{r_w}$$

where; r – wheel diameter, M_m - a torque developed by the electric motor, i – a transmission ratio of the motor–wheel drivetrain, η – a drivetrain efficiency, J – a wheel moment of inertia, $d\omega_w$ – an angular acceleration of the wheel

Taking into account that, $\frac{d\omega_w}{dt} = \frac{1}{r_w} \cdot \frac{dv}{dt}$ the following expression is obtained:

$$X_i = \frac{M_m \cdot i \cdot \eta}{r_w} - \mathrm{J}_w \cdot \frac{1}{r_w^2} \cdot \frac{dv}{dt} - f\mathrm{Z}_i \quad (29)$$

Under uniform motion conditions $\frac{dv}{dt} = 0$, therefore:

$$X_i = \frac{M_w}{r_w} - f\mathrm{Z}_i \quad (30)$$

In the case under consideration, where all four wheels are driving wheels and are independently controlled, the tangential (reaction) forces are not equal in either magnitude and direction. As a result, a torque M_z is generated, causing the robotic platform to rotate in the plane of motion. This torque significantly affects lateral skidding.

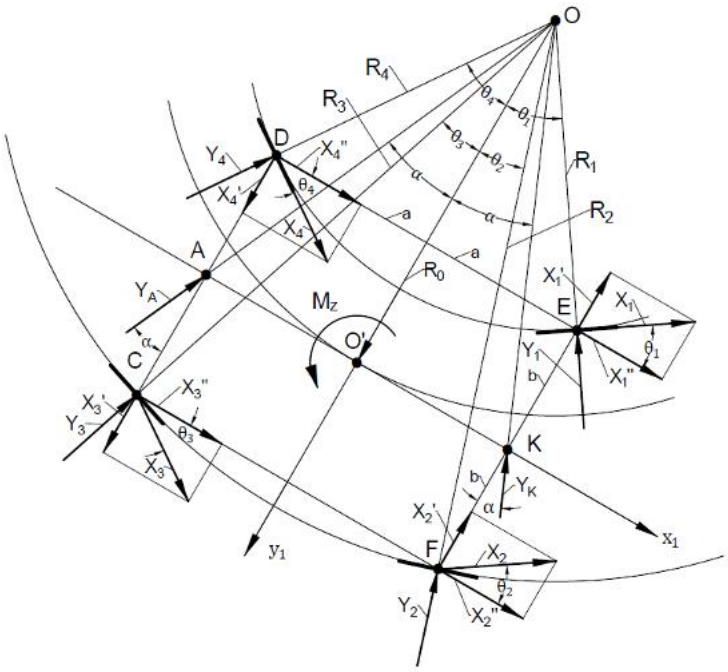


Fig. 6 - Schematic diagram for determining the torque about the vertical axis of the robotic platform

The value/magnitude of this torque is determined according to the scheme shown in Figure 6 as follows:

$$M_z = X_4' \cdot a + X_3' \cdot a + X_2' \cdot a + X_1' \cdot a - X_1'' \cdot b + X_2'' \cdot b + X_3'' \cdot b - X_4'' \cdot b,$$

$$M_z = (X_1 sin\theta_1 + X_2 sin\theta_2 + X_3 sin\theta_3 + X_4 sin\theta_4)a + (X_2 cos\theta_2 + X_3 cos\theta_3)b - (X_1 cos\theta_1 + X_4 cos\theta_4)b; \quad (31)$$

Taking into account that in the considered case $\theta_1 = \theta_4$; $\theta_2 = \theta_3$, for M_z Equation (32) becomes:

$$M_z = (X_1 + X_4)a \cdot sin\theta_1 + (X_2 + X_3)a \cdot sin\theta_2 + (X_2 + X_3)b \cdot cos\theta_2 - (X_1 + X_4)b \cdot cos\theta_1. \quad (32)$$

In the final equation, the forces X_1; X_2; X_3 and X_4 are determined by Equations (29) or (30). The problem of determining θ_1 and θ_2 as well as establishing the relationship between them, is comprehensively discussed in the work of *Tarverdyan et al. (2025)*. Therefore, the torque M_z is determined and for the indicated direction, it is always positive and at least equal to the sum of the first two terms of the equation.

After determining the force factors Z_i; X_i and M_z the lateral resistance (reaction) forces Y_1, Y_2, Y_3 and Y_4 can be determined. Naturally, these forces may be obtained from the dynamic equilibrium conditions of the robot platform; however, it should be emphasized that, in the analysis of the lateral drift phenomenon, the individual determination of these forces is not essential, since lateral skidding is caused by the pairwise combined lateral slip of the conventionally defined front and rear wheels. Proceeding from this consideration, the problem of determining the resultant forces $(Y_3 + Y_4)$ and $(Y_1 + Y_2)$ was examined.

Let the resultant force $(Y_1 + Y_2)$ be transferred to point K on the longitudinal axis of symmetry (x_2), and denote it by Y_K. Similarly, let the resultant $(Y_3 + Y_4) = Y_{\mathcal{A}}$ be applied at point $\mathcal{A}$. It should be noted that this transfer does not alter the mechanical effect of the force system, since the forces Y_1 and Y_2; Y_3 and Y_4 form pairwise concurrent force systems. Since a symmetric system is considered, $Y_{\mathcal{A}}$ and Y_K are inclined relative to the $y_1 - \text{axis}$ by the same angle α, where $tg\alpha = \frac{a}{R_0}$.

Considering the equilibrium condition of the torque of the forces acting on system with respect to the axes Z_1 and Z_2 passing through points $\mathcal{A}$ and K respectively, and using the schematic diagrams shown in Figures 3 and 6, the following equations are obtained:

$$\sum M_{Z_1} = 0; \quad -Y_{\mathcal{A}} cos\alpha \cdot 2a + M_z + M_j + G_y \cdot a + N \cdot a = 0;$$

$$\sum M_{Z_2} = 0; \quad Y_K cos\alpha \cdot 2a + M_z + M_j - G_y \cdot a - N \cdot a = 0; \quad \text{or}$$

$$Y_{\mathcal{A}} = \frac{M_z + M_j + G_y \cdot a + N \cdot a}{2a \cdot cos\alpha} \tag{33}$$

$$Y_K = \frac{N \cdot a + G_y \cdot a - M_z - M_j}{2a \cdot cos\alpha} \tag{34}$$

In these equations, the torque M_z is determined from Equation (32). The inertial torque M_j is determined as follows:

$$M_j = m\rho^2 \frac{d\omega}{dt},$$

where: m is the total loaded mass of the robot platform, ρ is the radius of inertia of the mass m with respect to Z axis perpendicular to the xoy plane and passing through the center of mass; $\frac{d\omega}{dt}$ is the angular acceleration of the rotational motion of the robot platform during turning (for uniform motion $\frac{d\omega}{dt} = 0$). G_y is the component of the gravitational force directed along the transverse axis of symmetry (y_2) of the platform:

$$G_y = G \cdot sin\beta \cdot sin\varphi.$$

N is the centrifugal force generated during turning motion:

$$N = m\omega^2 R_0.$$

Let us determine the magnitude of the lateral drift forces for the adopted initial numerical values, when $\varphi = 90^0$ and G_y attains its maximum value:

$$G_y = G \cdot sin\beta.$$

The numerical data are the same as in the previous example; in this case, the following additional data are also required:

$M_m = 150N \cdot m$; $\eta = 0.9$; $r_w = 0.2m$; $Z_1 = 1004N$; $Z_2 = 1458N$; $Z_3 = 1458N$; $Z_4 = 1004N$; $\theta_1 = 12^0$; $\theta_2 = 9^0$; $\alpha = 10^0$;

For these values, Equation (30) yields the following values for X_i. (assuming that the motion of the robot platform is uniform):

$X_1 = 349.0N$; $X_2 = 236.0N$; $X_3 = 236.0N$; $X_4 = 349.0N$.

Using Equation (32), the following value is obtained for M_z : $M_z = 46.3N \cdot m$; $G_y = 868N$; $N = 193.25N$ (as noted earlier, in the considered case it is assumed that $M_j = 0$).

Using Equations (33) and (34), the lateral drift forces ($Y_{\mathcal{A}}$ and Y_K) of the rear and front axles of the robotic platforms are obtained as:

$$Y_{\mathcal{A}} = 568.0\ N; Y_K = 508.8\ N.$$

For these values of lateral forces, lateral skidding will not occur provided that $(Z_3 + Z_4) \cdot \mu > Y_{\mathcal{A}}$ and $(Z_1 + Z_2) \cdot \mu > Y_K$, where μ is the coefficient of adhesion between the wheel and the supporting surface. For cultivated soil types $\mu = 0{,}4 \div 0{,}45$ (*Litvinov, 1971; Sineokov and Panov, 1977*). For the considered example:

$$(1004 + 1452) \cdot 0.45 > Y_{\mathcal{A}}.$$

$982.4\ N > 568.0\ N$, moreover,

$$982.4\ N > 508.8\ N.$$

Therefore, the condition excluding lateral skidding is satisfied.

Evaluating and Ensuring the Smooth Motion of the Robot Platform

It is well established that, for mobile vehicles—including the robot platform considered and analyzed in this study—the maximum smoothness of motion is ensured when $a = \rho_1$, and in the present case, also when $b = \rho_2$ (*Litvinov,1971; Tarverdyan et al., 2025; Zinoviev, 1975*). Under these conditions, $M_2 = 0$; $M_4 = 0$ and therefore, Equations (25), (26), (27), (28) take the following form:

$$M_1\left(\frac{d^2z_1}{dt^2}+\frac{d^2z_2}{dt^2}\right)+k\left(\frac{dz_1}{dt}+\frac{dz_4}{dt}\right)+c(z_1+z_4)=0, \quad (35)$$

$$M_1\left(\frac{d^2z_3}{dt^2}+\frac{d^2z_4}{dt^2}\right)+k\left(\frac{dz_2}{dt}+\frac{dz_3}{dt}\right)+c(z_2+z_3)=0, \quad (36)$$

$$M_3\left(\frac{d^2z_1}{dt^2}+\frac{d^2z_4}{dt^2}\right)+k\left(\frac{dz_1}{dt}+\frac{dz_2}{dt}\right)+c(z_1+z_2)=0, \quad (37)$$

$$M_3\left(\frac{d^2z_2}{dt^2}+\frac{d^2z_3}{dt^2}\right)+k\left(\frac{dz_3}{dt}+\frac{dz_4}{dt}\right)+c(z_3+z_4)=0. \quad (38)$$

The following notations are introduced:

$$\left.\begin{array}{l} z_1+z_2=R; \\ z_1+z_4=Q; \\ z_3+z_4=F; \\ z_2+z_3=N; \end{array}\right\} \quad \text{and also note that } R+F=Q+N \quad (39)$$

Then, combining Equations (35) and (37) yields:

$$\begin{cases} \dfrac{d^2R}{dt^2}+\dfrac{k}{M_1}\cdot\dfrac{dQ}{dt}+\dfrac{c}{M_1}\cdot Q=0; \\ \dfrac{d^2Q}{dt^2}+\dfrac{k}{M_1}\cdot\dfrac{dR}{dt}+\dfrac{c}{M_1}\cdot R=0. \end{cases} \quad (40)$$

Similarly, from Equations (36) and (38):

$$\begin{cases} \dfrac{d^2F}{dt^2}+\dfrac{k}{M_1}\cdot\dfrac{dN}{dt}+\dfrac{c}{M_1}\cdot N=0; \\ \dfrac{d^2N}{dt^2}+\dfrac{k}{M_3}\cdot\dfrac{dF}{dt}+\dfrac{c}{M_3}\cdot F=0. \end{cases} \quad (41)$$

It follows from the latter equations that systems (40) and (41) are identical, i.e., $F = R$; $N = Q$. Therefore, it is sufficient to solve only system (40).

The following substitutions are introduced:

$$X=\sqrt{M_1}\cdot R;\quad Y=\sqrt{M_3}\cdot Q \quad (42)$$

$$\alpha=\frac{k}{\sqrt{M_1\cdot M_3}};\quad \gamma=\frac{c}{\sqrt{M_1\cdot M_3}}. \quad (43)$$

The system of equations in Equation (40) can then be written as:

$$\begin{cases} X''+\alpha Y'+\gamma Y=0; \\ Y''+\alpha X'+\gamma Y=0. \end{cases} \quad (44)$$

The following notation is introduced:

$$X+Y=U;\quad X-Y=V \quad (45)$$

Adding and subtracting the equations in system (44) yields:

$$U''+\alpha U'+\gamma U=0; \quad (46)$$

$$V''-\alpha V'-\gamma Y=0. \quad (47)$$

The characteristic equation associated with Equation (46) will be:

$\varepsilon^2+\alpha\varepsilon+\gamma=0$; whose roots are:

$\varepsilon_{1,2}=\frac{-\alpha\pm\sqrt{\alpha^2-4\gamma}}{2}=\frac{-\alpha\pm i\sqrt{4\gamma-\alpha^2}}{2}=-\frac{\alpha}{2}\pm\frac{i\omega}{2}$, where $\omega=\sqrt{4\gamma-\alpha^2}$.

Since $4\gamma>\alpha^2$, the general solution of Equation (46) will be:

$$U(t)=e^{-\frac{\alpha t}{2}}\left(A_1 cos\frac{\omega}{2}t+A_2 sin\frac{\omega}{2}t\right). \quad (48)$$

The characteristic equation associated with Equation (47) is: $\xi^2-\alpha\xi-\gamma=0$, which has two real roots:

$\varepsilon_{1,2}=\frac{\alpha\pm\sqrt{\alpha^2+4\gamma}}{2}$, besides $\varepsilon_1=\frac{\alpha+\sqrt{\alpha^2+4\gamma}}{2}>0$.

The general solution of Equation (47) is therefore:

$$V(t)=A_3e^{\varepsilon_1 t}+A_4e^{\varepsilon_2 t}. \quad (49)$$

Because an exponentially increasing solution has no physical meaning in this context, the following condition $A_3 = 0$ is imposed.

Returning to the original functions R and Q and using Equations (42) and (45), the following is obtained:

$$R = \frac{U+V}{2\sqrt{M_1}}; Q = \frac{U-V}{2\sqrt{M_3}}, \text{ or}$$

$$R(t) = \frac{1}{2\sqrt{M_1}}\left[e^{-\frac{\alpha t}{2}}\left(A_1 cos\frac{\omega}{2}t + A_2 sin\frac{\omega}{2}t\right) + A_4 e^{\varepsilon_2 t}\right]; \quad (50)$$

$$Q(t) = \frac{1}{2\sqrt{M_3}}\left[e^{-\frac{\alpha t}{2}}\left(A_1 cos\frac{\omega}{2}t + A_2 sin\frac{\omega}{2}t\right) - A_4 e^{\varepsilon_2 t}\right]. \quad (51)$$

The solution to system (39) is now considered. Taking into account that $R + F = Q + N; \Rightarrow R = Q$, the solution can be expressed as:

$$z_1 = Q - z_4; \quad z_2 = R - Q + z_4; \quad z_3 = F - z_4.$$

where z_4 is an arbitrary function.

Using the geometric relationship among the vertical linear displacements given by Equation (14), the following expression is obtained:

$Q - z_4 + F - z_4 = R - Q + z_4 + z_4$, from which it follows that:

$$z_4 = \frac{2Q}{4} = \frac{Q}{2} = \frac{R}{2}.$$

Thus: $z_1 = z_2 = z_3 = z_4 = \frac{R}{2}$.

The initial conditions are: $\begin{cases} z_{i(0)} = \delta, & i = 1,2,3,4 \\ \dot{z}_{i(0)} = 0, & i = 1,2,3,4. \end{cases}$

Where δ is the static deflection of the elastic element (spring) of the suspension system under the static load.

$$\left.\begin{aligned} z_{1(0)} = \frac{R(0)}{2} = \delta \Rightarrow \frac{1}{4\sqrt{M_1}}(A_1 + A_4) \\ z_{2(0)} = \frac{Q(0)}{2} = \delta \Rightarrow \frac{1}{4\sqrt{M_3}}(A_1 - A_4) \end{aligned}\right\}, \text{ wherefrom}$$

$$\left.\begin{aligned} A_1 = 2\delta\left(\sqrt{M_1} + \sqrt{M_3}\right) \\ A_4 = 2\delta\left(\sqrt{M_1} - \sqrt{M_3}\right) \end{aligned}\right\} \quad (52)$$

The following condition is now applied: $\dot{z}_{i(0)} = 0$, $\dot{z}_{1(0)} = 0 = \frac{\dot{R}(0)}{2} = \frac{1}{4\sqrt{M_1}}\left(-\frac{\alpha}{2}A_1 + A_2\frac{\omega}{2} + A_4\varepsilon_2\right)$,

$$\dot{z}_{2(0)} = 0 = \frac{\dot{Q}(0)}{2} = \frac{1}{4\sqrt{M_3}}\left(-\frac{\alpha}{2}A_1 + A_2\frac{\omega}{2} - A_4\xi_2\right),$$

From the latter equations it follows that:

$$\begin{cases} A_2\frac{\omega}{2} = \frac{\alpha}{2}A_1 - A_4\varepsilon_2, \\ A_2\frac{\omega}{2} = A_4\varepsilon_2 + \frac{\alpha}{2}A_1, \end{cases}$$

from which it follows that:

$$A_4 = 0, \quad A_2 = \frac{\alpha A_1}{\omega} = \frac{2\delta\alpha}{\omega}\left(\sqrt{M_1} + \sqrt{M_3}\right). \quad (53)$$

From the condition $A_4 = 0$, it becomes evident that $\sqrt{M_1} = \sqrt{M_3}$, $M_1 = M_3$.

Thus, taking into account Equations (50), (51), (52) and (53), the following equation is obtained for the linear displacements of oscillation:

$$z_1 = z_2 = z_3 = z_4 = \frac{1}{4\sqrt{M_1}} \cdot e^{-\frac{\alpha t}{2}}\left(4\delta\sqrt{M_1} \cdot cos\frac{\omega t}{2} + \frac{4\delta\alpha}{\omega} \cdot \sqrt{M_1} sin\frac{\omega t}{2}\right).$$

Or, in final form:

$$z_{i(t)} = \delta e^{-\frac{\alpha t}{2}} \cdot \left(cos\frac{\omega t}{2} + \frac{\alpha}{\omega} \cdot sin\frac{\omega t}{2}\right) \quad (54)$$

Based on the analysis of the free oscillations of the robotic platform, the derived equations make it possible to determine the key oscillation parameters included in the characteristic performance indicators of the suspension system, namely the oscillation frequency, amplitude, and period, which determine the smoothness of motion (*Biderman, 1980; Ilarionov, 2013; Zinoviev,1975*). In addition, the final Equation (54) makes it possible to determine the oscillation velocity: $\left(\frac{dz}{dt}\right)$

The acceleration: $\left(\frac{d^2z}{dt^2}\right)$ and the rate of acceleration change, which is an important characteristic parameter in problems of this type: $\left(\frac{d^3z}{dt^3}\right)$.

Based on Equation (54), the equations derived from it, and the initial parameters of the robotic platform being developed, the following values were adopted: L=1,60 m; B=1,20 m; a=0,8 m; b=0,6 m; $\rho_1 = 0{,}8\ m$; $\rho_2 = 0{,}6\ m$; M=500 kg. Under these conditions: $M_1 = M_2 = M_3 = M_4 = 125$ kg, the equivalent stiffness coefficient of the suspension system is: $c_b = 66.65 \cdot 10^3 \frac{N}{m} = 66.65 \cdot 10^3 \frac{kg}{s^2}$, the average value of the resistance coefficient of a shock absorber: $k = 420 \frac{N \cdot s}{m} = 420 \frac{kg}{s}$, the vertical static deflection: $\delta = 0.01\ m$, and with calculated values:

$\alpha = \frac{k}{M_1} = \frac{420}{125} = 3.36\ s^{-1}$, $\frac{\alpha}{2} = 1.68\ s^{-1}$, $\omega = \sqrt{\frac{4c}{M_1} - \alpha^2} = \sqrt{\frac{4 \cdot 66.65 \cdot 10^3}{125} - (3.36)^2} = 46.06 s^{-1}$, the graphs of the obtained functions are presented in Figure 7.

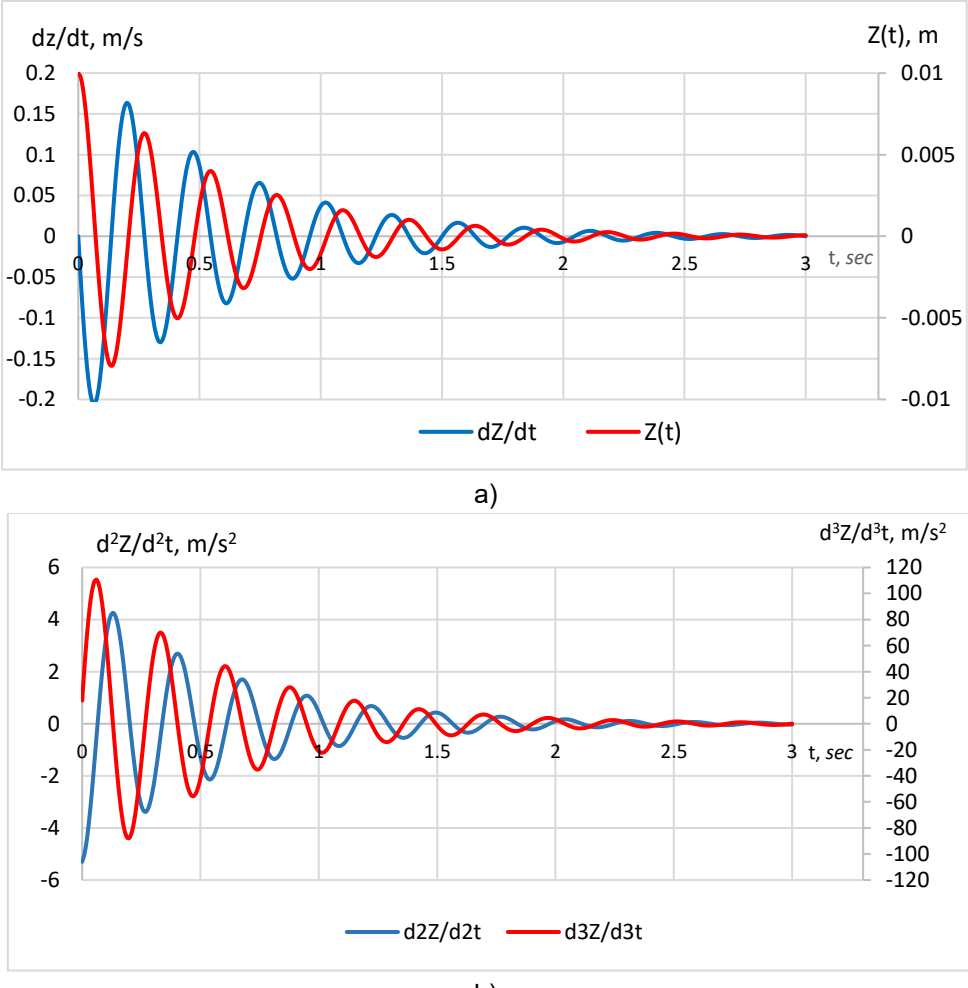

Fig. 7 - Graphs of the free oscillations of the robot platform

a) vertical displacements and velocities; b) velocities and accelerations.

The obtained analytical equations make it possible to select such stiffness values (c) for the elastic elements of the suspension system and such a damping coefficient (k), for the shock absorber (damper) that the required programmed parameters of the oscillatory motion are ensured.

Furthermore, the presented results and derived equations provide the basis for the next stage of the research, namely the investigation of the forced oscillations of the robotic platform.

CONCLUSIONS

As a result of the stability analysis of the developed agricultural robotic platform equipped with four driven and self-steering wheels operating on slopes, analytical equations were obtained that make it possible to determine the conditions of rollover and sideslip during turning motion, as well as the threshold values of the slope angle and the linear velocity of turning motion.

The magnitude of the torque about the vertical axis, which is characteristic particularly of four-wheeled robotic platforms with self-steering wheels operating on slopes and has a significant influence on skidding phenomenon, was determined.

Based on the analysis of the differential equation describing the motion of the robotic platform's center of mass and the torque equations with respect to the platform's transverse and longitudinal symmetry axes, the equations of the robotic platform's free oscillations were derived. The derived equations make it possible to determine the vertical displacements, velocities, accelerations, and variations of acceleration of the oscillatory motion, as well as choosing the stiffness of the shock absorber (damper) required to ensure smooth motion of the platform.

The obtained results are of considerable significance and provide a foundation for further investigations into the forced vibration behavior of the robotic platform.

ABSTRACT

This study focuses on the development of a multifunctional agricultural robotic platform. Previous articles in this series established the need for such a platform based on the specific soil and climatic conditions of the Republic of Armenia. Tests of a laboratory prototype indicated the need for further investigation of the platform's dynamic behavior, particularly during operation in orchards and agricultural fields on sloping terrain, which is common in Armenia. Particular attention was given to changes in platform inclination during turning maneuvers on slopes and to the yaw moment generated about the vertical axis in four-wheeled robotic platforms with independently controlled wheels. Based on a mathematical model of the chassis incorporating elastic elements (springs) and damping elements (shock absorbers), the differential equation governing the motion of the platform's center of mass was formulated, together with moment equations about the transverse and longitudinal axes passing through the center of mass. Analysis of these equations yielded the differential equations governing the platform's vertical oscillations. Expressions were subsequently derived for the displacement, velocity, acceleration, and jerk associated with the platform's free oscillations. These equations can be used to evaluate ride smoothness and determine the spring stiffness and shock-absorber damping coefficient required to achieve the desired suspension performance.

INTRODUCTION

In all countries ensuring food security has always been, and remains, one of the most pressing challenges facing agricultural production. The solving of this problem must involve the conservation and improvement of land resources, meeting environmental requirements, increasing production volumes, the production of environmentally friendly food products, full mechanization of agricultural production, and, particularly importantly, reducing of the energy intensity of these processes. It is evident that the stated problem is multidimensional, and its complete solution using existing technologies and technical means is objectively limited (*Abrosimov and Raykov, 2022; Bak and Jakobsen, 2004; Fontani et al., 2025; O'Meara, 2019; Ritchie, 2024*).

For this reason, two key trends have recently become central to agricultural production technological processes (*Abrosimov and Raykov, 2022; Markets and Markets, 2025; Navone et al., 2025; Tarverdyan et al., 2025*).

First, one of the fastest growing areas in recent years in agricultural production is precision and digital technologies in crop and livestock production.

Second, the direction without which it is impossible to effectively utilize and implement the information obtained through the above-mentioned technologies is the organization of robot-assisted agricultural production. This implies that the development and large-scale implementation of robotics play a central role in addressing the stated problem (*Abrosimov and Raykov, 2022; Navone et al., 2025; O'Meara, 2019; Ritchie, H., 2024)*.

Although the global agricultural robotics market is developing at an unprecedented rate (over the last five years alone, its volume has increased approximately 20-fold) (*Bak and Jakobsen, 2004; MarketsandMarkets, 2025*), the application of such systems in the agricultural sector of the Republic of Armenia remains highly limited. This is primarily due to their relatively high market price, making them inaccessible to the majority of local producers, and second, to their structural characteristics, which result in low operational reliability under the soil conditions of the Republic of Armenia (*Tarverdyan et al., 2025*).

It follows that the problem can be addressed through two approaches: either partial structural modifications should be made to existing robots, or a new universal robotic platform should be developed that is better adapted to the country's soil conditions (presence of stones of various sizes, fragmented terrain) and, importantly, is cost-effective.

For all mobile agricultural robots, the mobile platform is a critical component that plays a key role in the overall system performance of the system. It is therefore not surprising that researchers in this field have devoted significant efforts to the development of high-performance mobile platforms for agricultural robots, as well as to improving their control and positioning accuracy, since these issues are of crucial importance in precision agriculture (*Amin et al., 2025; Bayar et al., 2015; Lipiński et al., 2016; Qiu et al., 2018; Zagazezheva and Berbekova, 2021*).

The operational practice of agricultural robotic platforms over the last 20–25 years, as well as the results of numerous research studies, lead to a clear conclusion: from the perspective of accurate perception and response to external influences during agro-technological processes, minimal energy consumption, minimal soil damage, and high maneuverability, four-wheeled robotic platforms are preferred (*Akimov, 2017; Blasco et al., 2002; Cho et al., 2002*).

In addition, four-wheeled robotic platforms with independently controlled wheels provide high maneuverability and enable parallel motion of the vehicle during turning, allowing positional accuracy and orientation accuracy to be controlled independently (*Bak and Jakobsen, 2004; Cho et al., 2002; Orebäck and Christensen, 2003; Tarverdyan et al., 2025*).

Research on robotic platforms is primarily driven by the shortcomings and challenges identified during their operation. Current studies place significant emphasis on optimal control, stability, and ensuring smooth motion. In this regard, the studies conducted by a group of researchers are of particular interest *(Blasco et al., 2002; Fountas et al., 2020; Zakaria et al., 2024*), in which the authors demonstrate that integrated control systems (ICS)—such as combined steering and wheel torque control, suspension and wheel torque coordination, as well as the integration of steering control systems with suspension—provide superior performance characteristics for multi-axle mobile devices (Multi-axle Vehicles, MAV) compared with skid-steering control systems (SCS). In this optimal distribution approach, the target vehicle forces and yaw torque are distributed among the individual tire forces (*Ali et al., 2017; Li and Shi, 2017; Zakaria et al., 2024*).

Another group of researchers has approached the problem from the perspective of determining the critical speed and its more accurate estimation for a two-axle dynamic model. A 4×2-wheel configuration was

adopted as the vehicle model, and the acting forces and other lateral dynamic parameters were calculated for this model. The problem was analyzed in terms of the forces acting on the vehicle during turning and on inclined surfaces to ensure stability, taking into account the redistribution of reaction forces and variations in the tire–surface adhesion coefficient (*Ivanov et al., 2025*).

In a previous study devoted to this problem (*Tarverdyan et al., 2025*), the kinematic parameters of the motion subsystem of a robotic platform were examined in detail. In particular, the relationships between four independently steerable wheels, steering angles, and their angular velocities were established. Lateral forces arising during turning on a horizontal plane were also partially analyzed.

The present article is devoted to the investigation of the stability of robotic platform motion and conditions of lateral slip on sloped terrain, as well as to the assessment of motion smoothness based on the proposed model.

MATERIALS AND METHODS

Stability of Robotic Platform Motion on Inclined Surfaces

As previously noted, for robotic platforms intended to perform agro-technological operations, the four-wheel configuration with independently controlled wheels is considered preferable. The ability of the platform to perform parallel translational motion, in some cases without rotational turning, provides high maneuverability.

Independent control of all four wheels minimizes lateral slip, thereby reducing not only soil disturbance but also the wear of drivetrain components (*Bak and Jakobsen, 2004; Torii, 2000*).

Although the dynamics of a four-wheeled independently controlled system are inherently nonlinear and control is not straightforward, relatively simple control systems can still be effective at low operational speeds (2–6 km/h), (*Cho et al., 2002; MarketsandMarkets, 2025; Tarverdyan et al.,2025*). The conceptual scheme of the proposed robotic platform is presented in Figure 1. It consists of a platform frame (1), on which various agro-technological implements and devices are mounted; four drive wheels with independent actuation (2); a wheel steering control unit (3); and a wheel steering mechanism (4).

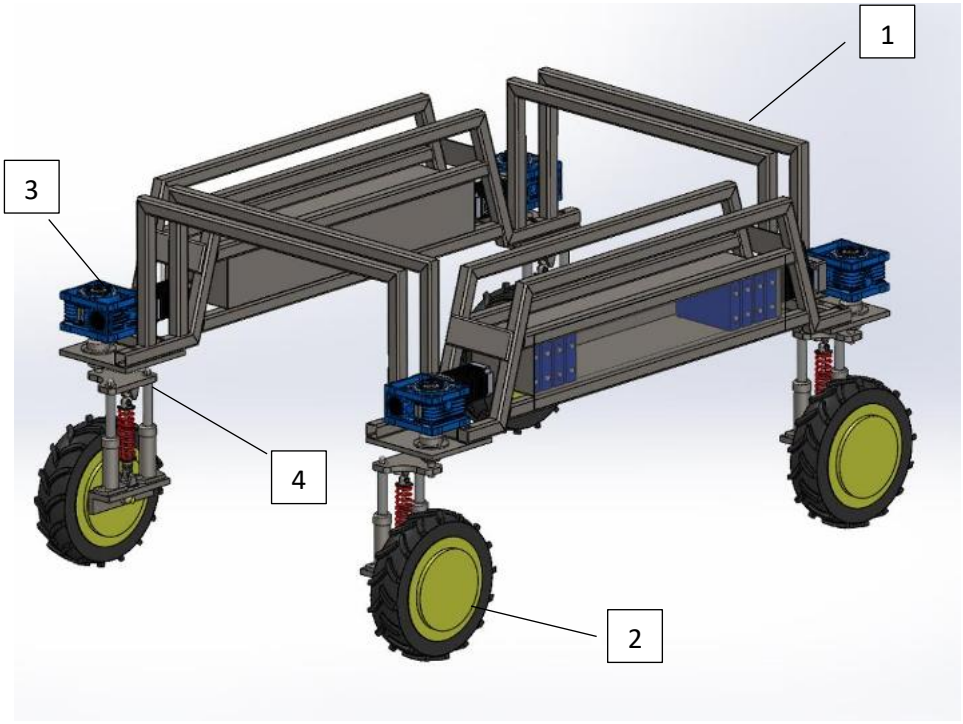

Fig. 1 - 3D model of the developed robotic platform

A detailed kinematic analysis of the locomotion subsystem of the developed robotic platform (*Tarverdyan et al., 2025*) yielded equations that make it possible to determine and refine the parameters used as the basis for programming the platform's turning motion on a horizontal surface.

As a result of the dynamic analysis, precise equations for determining lateral slip forces were obtained. These equations enable the development of a robotic platform drivetrain in which wheel slip during turning is minimized, thereby minimizing soil damage while ensuring operational reliability and durability (*Tarverdyan et al., 2025*).

An agricultural robotic platform can also perform agro-technological operations in fields located on sloped terrain, which is particularly characteristic of the Republic of Armenia. Under such conditions, during the development of the robotic platform, the issue of motion stability, especially during turning, becomes a key subject of analysis.

Assume that the robotic platform performs a turning maneuver on a planar slope inclined at an angle *β* where the rotation axis OO' is perpendicular to the inclined plane and is positioned upslope relative to the robotic platform (Figure 2). The geometric dimensions of the platform are – width B and length L. Since the goal is to develop a structure that is as symmetric as possible in terms of both geometry and mass distribution, it can be assumed that the center of mass coincides with point O_1', located at the intersection of the longitudinal (x_2) and transverse (y_2) symmetry axes of the platform. In this case $a = \frac{L}{2}, b = \frac{B}{2}$. Let the distance of the center of mass from the supporting plane CDEF be denoted by h, and the turning radius of the center of mass by R_0. The steering angles of the wheels are $\theta_1, \theta_2, \theta_3, \theta_4$, while the corresponding turning radii are R_1, R_2, R_3, R_4.

Let consider the turning motion of the robotic platform with a constant turning radius on a slope inclined at an angle β (Figures 2 and 3). Before determining the forces and reactions acting on the platform, it is necessary to account for the transformation of the slope inclination during rotational motion, since it directly affects the magnitude of the force components involved. Let the coordinate system xoy (Figure 3) be fixed to the inclined plane, where the y-axis is aligned with the transverse direction of the slope and the x -axis with the longitudinal direction, with the origin located at the center of rotation. When the rotation angle is φ = 0 (position $\mathcal{A}$ of the robotic platform), the transverse symmetry axis $y_1$of the robotic platform coincides with the y -axis, the longitudinal axis (x_1) inclination angle is β.

When φ = 90°, the axis x_1 becomes parallel to the y-axis $x_1 \parallel y$, while y_1 coincides with the x-axis and is inclined at angle β (Figure 2). When φ = 180°, the configuration becomes symmetric to position $\mathcal{A}$. For all intermediate positions (e.g., position B), the inclination of the robotic platform is characterized by angles β_1 and β_2, which are determined as follows:

$$\begin{cases} sin\beta_1 = sin\beta \cdot sin\varphi, \\ sin\beta_2 = sin\beta \cdot cos\varphi. \end{cases} \quad (1)$$

Let consider the analysis of the forces acting on the robotic platform during turning motion at an arbitrary intermediate position B within the range $0 \leq \varphi \leq 90^0$ (Figure 3) (within the interval $90 - 180^0$, the configuration is repeated symmetrically).

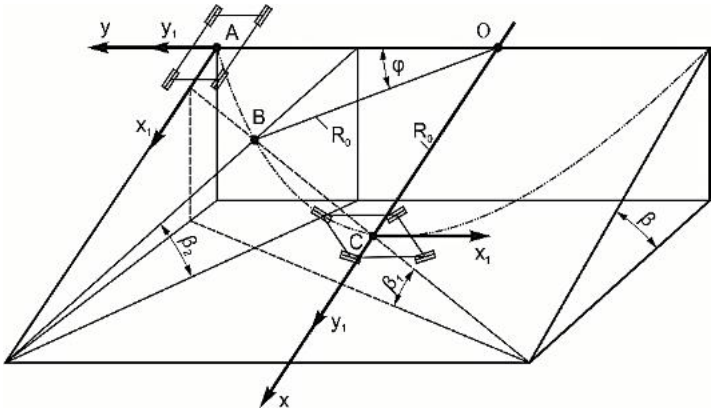

Fig. 2 - Schematic diagram of tilt-angle transformation during the turning motion of the robotic platform

At the specified position, the following forces and torques act on the robotic platform:

The gravitational force G acts at the center of mass and has three components: $G_x = G\cos\beta_1 \cdot sin\beta_2$, directed along the x_2 axis, $G_y = G sin\beta_1$ - directed along the y_2 axis, $G_z = G\cos\beta_1 \cdot \cos\beta_2$ – perpendicular to the inclined plane.

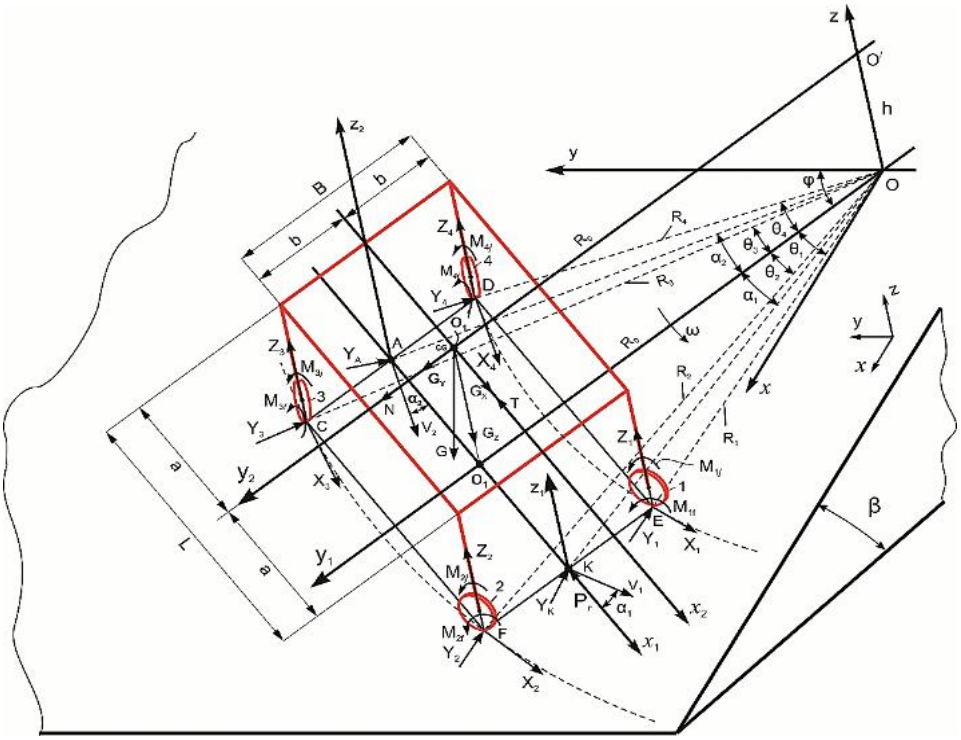

Fig. 3 - Kinematic and dynamic analysis scheme of the turning motion of the robotic platform on an inclined surface

At the wheel–ground contact surfaces, the support reactions Z_i, act normal to the supporting surface. The driving (tractive/tangential) forces X_i act at the wheel contact surfaces and are perpendicular both to the wheel radii (r_w) and to the turning radii R_i associated with rotation about point *O*. The lateral slip resistance forces Y_i, also act at the wheel–ground contact surfaces and are directed along the turning radii (R_i). In the general case, the wheels are also subjected to a torque of the rolling resistance (M_{if}).

The robotic platform is additionally subjected to inertial force factors. At the center of mass (O_1'), the longitudinal inertial force T acts along the x_2 axis, with its direction determined by the nature of the motion (acceleration or deceleration). The centrifugal force N associated with curvilinear motion acts along the y_2 axis. The wheels are also subjected to inertial torques (M_{ij}), as well as the inertial torque of the robotic platform associated with curvilinear motion about the z-axis, denoted by M_{j} (*Litvinov, 1971; Qiu et al., 2018; Zinoviev, 1975*).

To solve the problem of lateral slip of the robotic platform, it is first necessary to determine the support reactions at the wheel–ground contact surfaces, namely Z_1, Z_2, Z_3 *and* Z_4. By formulating the equilibrium equations with respect to the axes passing through the wheel support points ($\mathcal{CD}$, EF, CF and DE) and performing the corresponding transformations, the following equations are obtained:

$$\mathrm{Z}_1 + \mathrm{Z}_2 = \frac{\mathrm{G}_\mathrm{z}}{2} + \frac{\mathrm{G}_x \cdot \mathrm{h}}{2a} - \frac{T \cdot \mathrm{h}}{2a} - \frac{4M_{\mathrm{ij}}}{2a} \tag{2}$$

$$\mathrm{Z}_3 + \mathrm{Z}_4 = \frac{\mathrm{G}_\mathrm{z}}{2} - \frac{\mathrm{G}_x \cdot \mathrm{h}}{2a} + \frac{T \cdot \mathrm{h}}{2a} + \frac{4M_{\mathrm{ij}}}{2a} \tag{3}$$

$$\mathrm{Z}_1 + \mathrm{Z}_4 = \frac{\mathrm{G}_\mathrm{z}}{2} + \frac{\mathrm{G}_\mathrm{y} \cdot \mathrm{h}}{2b} - \frac{N \cdot \mathrm{h}}{2b} \tag{4}$$

$$\mathrm{Z}_2 + \mathrm{Z}_3 = \frac{\mathrm{G}_\mathrm{z}}{2} + \frac{\mathrm{G}_\mathrm{y} \cdot \mathrm{h}}{2b} + \frac{N \cdot \mathrm{h}}{2b} \tag{5}$$

Besides:

$$\mathrm{Z}_1 + \mathrm{Z}_2 + \mathrm{Z}_3 + \mathrm{Z}_4 = \mathrm{G}_\mathrm{z} \tag{6}$$

Let's also introduce the following denotations:

$$\begin{cases} \mathrm{Z}_1 + \mathrm{Z}_2 = \mathcal{A} \\ \mathrm{Z}_3 + \mathrm{Z}_4 = B \\ \mathrm{Z}_1 + \mathrm{Z}_4 = C \\ \mathrm{Z}_2 + \mathrm{Z}_3 = \mathcal{D}. \end{cases} \Rightarrow \mathcal{A} + B = C + \mathcal{D} \tag{7}$$

Let us denote: $Z_1 = S$, where S is an arbitrary parameter. Then:

$$\begin{cases} Z_1 = S \\ Z_2 = \mathcal{A} - S \\ Z_3 = B - C + S = \mathcal{D} + S \\ Z_4 = C - S. \end{cases} \quad (8)$$

The parameter S characterizes the redistribution of the load among the supports, which does not alter the quantities $(Z_1 + Z_2)$, $(Z_1 + Z_4)$, $(Z_3 + Z_4)$ and $(Z_2 + Z_3)$, in other words, equilibrium is preserved, and the model is self-balancing (*Buchholz, 2023; Ilarionov, 2013; Litvinov, 1971*).

Using Equations (2), (3), (4), and (5), together with relations (6) and (8), and considering that $G_x = G\cos\beta_1 \cdot sin\beta_2$, $G_y = G sin\beta_1$, $G_z = G\cos\beta_1 \cdot \cos\beta_2$, where the angles β_1 and β_2 are determined from Equation (1), $N = \frac{G}{g}\omega^2 R_0$, $T = \frac{G}{g} \cdot \frac{dv}{dt}$, $M_{ij} = J_w \cdot \frac{d\omega_w}{dt}$ (J_w is the wheel torque of inertia, and $\frac{d\omega_w}{dt}$ is the angular acceleration of the wheel), and taking into account that uniform motion of the robotic platform is considered, the following equations are obtained for the support reactions:

$$\left.\begin{aligned} Z_1 &= \frac{G}{4}cos\beta_1 \cdot cos\beta_2 - \frac{h \cdot G}{2L} \cdot sin\beta_1 + \frac{G \cdot h}{2B}cos\beta_1 \cdot sin\beta_2 - \frac{G \cdot h \cdot \omega^2 R_0}{g \cdot L} \\ Z_2 &= \frac{G}{4}cos\beta_1 \cdot cos\beta_2 + \frac{G \cdot h}{2L} \cdot sin\beta_1 + \frac{G \cdot h}{2B}cos\beta_1 \cdot sin\beta_2 + \frac{G \cdot h \cdot \omega^2 R_0}{g \cdot L} \\ Z_3 &= \frac{G}{4}cos\beta_1 \cdot cos\beta_2 + \frac{G \cdot h}{2L} \cdot sin\beta_1 - \frac{G \cdot h}{2B}cos\beta_1 \cdot sin\beta_2 + \frac{G \cdot h \cdot \omega^2 R_0}{g \cdot L} \\ Z_4 &= \frac{G}{4}cos\beta_1 \cdot cos\beta_2 - \frac{G \cdot h}{2L} \cdot sin\beta_1 - \frac{G \cdot h}{2B}cos\beta_1 \cdot sin\beta_2 - \frac{G \cdot h \cdot \omega^2 R_0}{g \cdot L} \end{aligned}\right\}. \quad (9)$$

It should be noted that the obtained solutions satisfy condition (7) and correctly reflect the physical nature of the problem.

Assessment and improvement of the Motion Smoothness of the Robotic Platform

Ensuring the smooth motion of the developed robotic platform is an important issue, since it directly determines the accurate execution of agro-technical processes, the operational reliability and durability of its components—particularly the suspension system—and the reliable performance of the orientation and control system.

Figure 4. shows the schematic diagram of the suspension system of the developed robotic platform, which includes an elastic element (spring) (1), a coaxially mounted hydraulic damper (shock absorber) (2), pneumatic wheels (3) each equipped with an independent electric hub motors, and an independent wheel steering control unit (4).

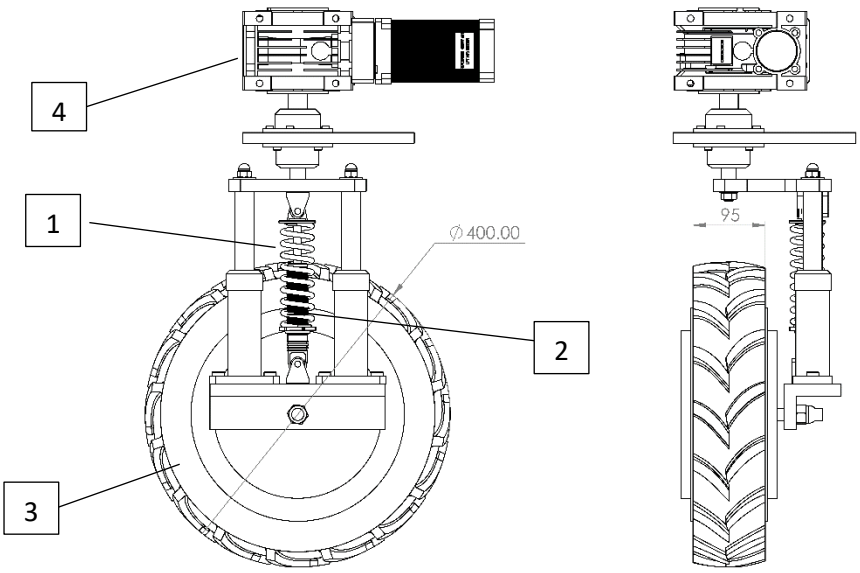

Fig. 4 - Schematic diagram of the suspension system of the robotic platform (all dimensions in *mm*)

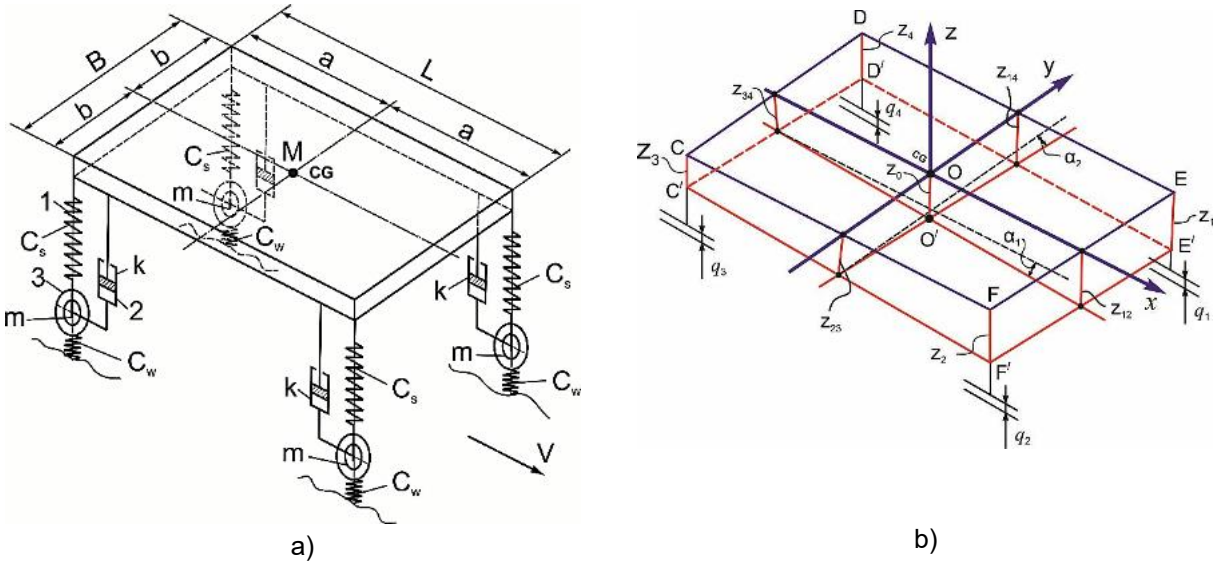
It should be noted that, based on the presented suspension system configuration, from an application standpoint it is important to analyze the vertical translational oscillations of the platform, as well as the angular oscillations in the longitudinal and transverse symmetry planes.

The computational scheme of the problem is presented in Figure 5.

The data required for solving the problem are as follows:



- the overall dimensions of the robot platform: length L, width B;
- the identical stiffness of all four suspension springs c_s;
- wheel stiffness c_w;
- the sprung mass of the robotic platform M;
- the mass of the assemblies located below the springs (unsprung mass) m;
- the damping coefficient of the shock absorbers *k*. Since the two elastic elements the suspension spring and the wheel are connected in series, their combined stiffness can be represented by a single equivalent stiffness coefficient (*Ilarionov, 2013; Litvinov, 1971*).

$$c = \frac{c_s \cdot c_w}{c_s + c_w}.$$

Several assumptions were adopted in solving the problem, which considerably simplify the analysis while having no significant influence on the results.

It is assumed that the robotic platform moves uniformly across field surface irregularities, with the wheels continuously rolling over them while maintaining uninterrupted contact with the ground. Under these conditions, the wheel axles undergo vertical displacements (q_i).

The self-weight of the robotic platform and the loads mounted on it are assumed to be distributed symmetrically with respect to the *x* and *y* axes, such that the center of gravity of the total mass coincides with the origin of the coordinate system (Figure 5).

a) b)

Fig. 5 - Scheme for determining the driving/motion smoothness of the robotic platform:

a) schematic diagram of the suspension system,

b) computational scheme of the platform vertical displacements

In addition, the following notations were adopted:

z_0- vertical displacement of the platform's center of mass caused by oscillations;

z_1; z_2; z_3; z_4- vertical displacements of points C; D; E and F respectively located above the wheel axles;

α_1; α_2 – rotational angles of the platform in the longitudinal and transverse planes of symmetry, respectively;

a - distances from the front (conventionally defined) and rear wheel axles to the y-axis of symmetry passing through the center of mass (a=L/2, since the robotic platform is designed to have a symmetric structure);

b- distance from the wheel suspension attachment points to the x-axis of symmetry passing through the center of mass ($b = \frac{B}{2}$);

ρ_1- radius of inertia of the robotic platform with respect to the y-axis;

ρ_2- radius of inertia of the robotic platform with respect to the x-axis.

It is evident that the solution of the problem involves six unknowns: z_1; z_2; z_3; z_4; z_0 and α_1 (in one case) and α_2 (in the other case). In such situations, it is useful to establish relationships among these unknowns. Considering the sprung part of the robotic platform as a rigid horizontal plate CDEF (Figure 5), as a result of its vertical linear oscillations, at an arbitrary instant it will occupy the position C′ D′ E′ F′ while remaining planar. In the general case of oscillations, it is assumed that the displacements at the indicated points above the wheel axles are different, namely z_1; z_2; z_3; z_4. Under these conditions, geometric relationships exist between these displacements, making it possible to simplify the solution of the problem. In the longitudinal plane of symmetry of the robotic platform (along the x-axis), the displacements of the front edge points, as the midlines of the corresponding rectangles, are expressed as $z_{12} = \frac{z_1+z_2}{2}, z_{34} = \frac{z_3+z_4}{2}$. From the scheme shown in Figure 5, it follows that:

$$z_{12} = z_0 + a_1 \mathrm{a}\,, \qquad z_{34} = z_0 - a_1 \mathrm{a} \tag{11}$$

From which:

$$a_1 = \frac{z_{12} - z_{34}}{L} = \frac{z_1 + z_2 - z_3 - z_4}{2L}\,.$$

Similarly, in the plane of lateral symmetry (along the y-axis), the displacements and the rotation angle of the platform are given by:

$$z_{14} = z_0 + a_2 \cdot \mathrm{b};\; z_{23} = z_0 - a_2 \cdot \mathrm{b} \tag{12}$$

$$a_2 = \frac{z_{14} - z_{23}}{B} = \frac{z_1 + z_4 - z_2 - z_3}{2B}. \tag{13}$$

From the scheme, the following relationships also hold: $z_0 = \frac{z_1+z_3}{2}$, $z_0 = \frac{z_2+z_4}{2}$, from which it follows that:

$$\left.\begin{aligned} z_2 + z_3 &= z_2 + z_4 \\ z_0 &= \frac{z_1 + z_2 + z_3 + z_4}{4} \end{aligned}\right\} \tag{14}$$

To formulate the equations of motions for the considered problem, the principles of rigid-body dynamics are applied (*Biderman, 1980; Buchholz, 2023; Zinoviev, 1975*).

Since in this stage the task is to study only the free oscillations of the robotic platform, the forces caused by terrain irregularities, which include terms proportional to q_i, can be neglected as external excitations. In this case, the differential equation of motion of the platform's center of inertia can be written in the following form:

$$M\frac{d^2 z_0}{dt^2} = \mathrm{k}\left(\frac{dz_1}{dt} + \frac{dz_2}{dt} + \frac{dz_3}{dt} + \frac{dz_4}{dt}\right) + c(z_1 + z_2 + z_3 + z_4) = 0. \tag{15}$$

The torque equations about the x and y axes passing through the center of inertia will be:

$$\mathrm{M}\rho_1^2\frac{d^2\alpha_1}{dt^2} + \mathrm{ka}\left(\frac{dz_1}{dt} - \frac{dz_2}{dt} - \frac{dz_3}{dt} + \frac{dz_4}{dt}\right) + c(z_1 - z_2 - z_3 + z_4) = 0, \tag{16}$$

$$\mathrm{M}\rho_2^2\frac{d^2\alpha_2}{dt^2} + \mathrm{k}b\left(\frac{dz_1}{dt} + \frac{dz_2}{dt} - \frac{dz_3}{dt} - \frac{dz_4}{dt}\right) + cb(z_1 + z_2 - z_3 - z_4) = 0. \tag{17}$$

By inserting the values of $\alpha_1, \alpha_2\ and\ z_0$ from the Equations of (11); (13) and (14) in the Equations of (15); (16) and (17), the following is obtained:

$$\mathrm{M}\cdot\frac{1}{4}\left(\frac{d^2 z_1}{dt^2} + \frac{d^2 z_2}{dt^2} + \frac{d^2 z_3}{dt^2} + \frac{d^2 z_4}{dt^2}\right) + \mathrm{k}\left(\frac{dz_1}{dt} + \frac{dz_2}{dt} + \frac{dz_3}{dt} + \frac{dz_4}{dt}\right) + C(z_1 + z_2 + z_3 + z_4) = 0, \tag{18}$$

$$\frac{\mathrm{M}\rho_1^2}{2L}\cdot\left(\frac{d^2 z_1}{dt^2} + \frac{d^2 z_2}{dt^2} - \frac{d^2 z_3}{dt^2} - \frac{d^2 z_4}{dt^2}\right) + \mathrm{ka}\left(\frac{dz_1}{dt} - \frac{dz_2}{dt} - \frac{dz_3}{dt} + \frac{dz_4}{dt}\right) + ca(z_1 - z_2 - z_3 + z_4) = 0, \tag{19}$$

$$\frac{\mathrm{M}\rho_2^2}{2B}\cdot\left(\frac{d^2 z_1}{dt^2} + \frac{d^2 z_4}{dt^2} - \frac{d^2 z_2}{dt^2} - \frac{d^2 z_3}{dt^2}\right) + \mathrm{k}b\left(\frac{dz_1}{dt} + \frac{dz_2}{dt} - \frac{dz_3}{dt} - \frac{dz_4}{dt}\right) + cb(z_1 + z_2 - z_3 - z_4) = 0. \tag{20}$$

To establish the relationships between Equations (18) and (19), (18) and (20) Equation (18) is multiplied by a and is added to (19), then (18) is multiplied by a and (19) is subtracted. In both cases, the resulting equations are divided by L. Similarly, Equation (18) is multiplied by *b* and added to Equation (20), and the resulting equation is divided by *B*. Equation (18) is then multiplied by *b* and Equation (20) is subtracted from the result, after which the resulting equation is divided by B. Considering the symmetry of the system, such that L=2a and B=2b, the following equations are obtained:

$$M\left(\frac{a^2+\rho_1^2}{2L^2}\right)\left(\frac{d^2z_1}{dt^2}+\frac{d^2z_2}{dt^2}\right)+M\left(\frac{a^2-\rho_1^2}{2L^2}\right)\cdot\left(\frac{d^2z_3}{dt^2}+\frac{d^2z_4}{dt^2}\right)+k\left(\frac{dz_1}{dt}+\frac{dz_4}{dt}\right)+c(z_1+z_4)=0, \quad (21)$$

$$M\left(\frac{a^2-\rho_1^2}{2L^2}\right)\left(\frac{d^2z_1}{dt^2}+\frac{d^2z_2}{dt^2}\right)+M\left(\frac{a^2+\rho_1^2}{2L^2}\right)\cdot\left(\frac{d^2z_3}{dt^2}+\frac{d^2z_4}{dt^2}\right)+k\left(\frac{dz_1}{dt}+\frac{dz_3}{dt}\right)+c(z_1+z_3)=0, \quad (22)$$

$$M\left(\frac{b^2+\rho_2^2}{2B^2}\right)\left(\frac{d^2z_1}{dt^2}+\frac{d^2z_4}{dt^2}\right)+M\left(\frac{b^2-\rho_2^2}{2B^2}\right)\cdot\left(\frac{d^2z_2}{dt^2}+\frac{d^2z_3}{dt^2}\right)+k\left(\frac{dz_1}{dt}+\frac{dz_2}{dt}\right)+c(z_1+z_2)=0, \quad (23)$$

$$M\left(\frac{b^2-\rho_2^2}{2B^2}\right)\left(\frac{d^2z_1}{dt}+\frac{d^2z_4}{dt^2}\right)+M\left(\frac{b^2+\rho_2^2}{2B^2}\right)\cdot\left(\frac{d^2z_2}{dt^2}+\frac{d^2z_3}{dt^2}\right)+k\left(\frac{dz_3}{dt}+\frac{dz_4}{dt}\right)+c(z_3+z_4)=0. \quad (24)$$

The Equations (21)–(22) and (23)–(24) are pairwise interrelated through their first and second terms Even in the particular case where $a=\rho_1$ and $b=\rho_2$, these interrelations are preserved. This indicates that the vertical oscillations of the considered robotic platform, characterized by the coordinates z_1; z_2; z_3 and z_4 are mutually coupled.

The following notation is introduced:

$$M\left(\frac{a^2+\rho_1^2}{2L^2}\right)=M_1;\ M\left(\frac{a^2-\rho_1^2}{2L^2}\right)=M_2;\ M\left(\frac{b^2+\rho_2^2}{2B^2}\right)=M_3;\ M\left(\frac{b^2-\rho_2^2}{2B^2}\right)=M_4.$$

The Equations (21) (22); (23) and (24) will take the following form:

$$M_1\left(\frac{d^2z_1}{dt^2}+\frac{d^2z_2}{dt^2}\right)+M_2\left(\frac{d^2z_3}{dt^2}+\frac{d^2z_4}{dt^2}\right)+k\left(\frac{d^2z_1}{dt}+\frac{d^2z_4}{dt}\right)+c(z_1+z_4)=0, \quad (25)$$

$$M_2\left(\frac{d^2z_1}{dt^2}+\frac{d^2z_2}{dt^2}\right)+M_1\left(\frac{d^2z_3}{dt^2}+\frac{d^2z_4}{dt^2}\right)+k\left(\frac{dz_2}{dt}+\frac{dz_3}{dt}\right)+c(z_2+z_3)=0, \quad (26)$$

$$M_3\left(\frac{d^2z_1}{dt^2}+\frac{d^2z_4}{dt^2}\right)+M_4\left(\frac{d^2z_2}{dt^2}+\frac{d^2z_3}{dt^2}\right)+k\left(\frac{dz_1}{dt}+\frac{dz_2}{dt}\right)+c(z_1+z_2)=0, \quad (27)$$

$$M_4\left(\frac{d^2z_1}{dt}+\frac{d^2z_4}{dt^2}\right)+M_3\left(\frac{d^2z_2}{dt^2}+\frac{d^2z_3}{dt^2}\right)+k\left(\frac{dz_3}{dt}+\frac{dz_4}{dt}\right)+c(z_3+z_4)=0. \quad (28)$$

The obtained equations enable to study the free oscillations of the robotic platform and also serve as a basis for the further investigation of its forced vibrations.

RESULTS AND ANALYSIS

Stability Conditions of the Robotic Platform Motion on Slopes

For the initial parameters of the developed robotic platform (L = 1.6m, B = 1.2m, G = 5000 N, h = 0.6m, ω = 0.278 s^{-1}, R_0 = 5m, β = 10^0) the following results are obtained for three characteristic positions using the derived equations:

when $\varphi=0^0$, $sin\beta_1=0$, $\beta_1=0$, $sin\beta_2=sin\beta$, $\beta_2=\beta$, $G_z=G\cos\beta_1\cdot\cos\beta_2=5000\cdot0.9848=4925\ N$;

when $\varphi=45^0$, $sin\beta_1=sin\beta\cdot sin\varphi=0.1222$, $sin\beta_2=sin\beta\cdot cos\varphi=0.1222$, $cos\beta_1=cos\beta_2=0.9925$, $G_z=G\cos\beta_1\cdot\cos\beta_2=5000\cdot0.9925=4962.5\ N$;

when $\varphi=90^0$, $sin\beta_1=sin\beta\cdot sin\varphi$, $\beta_1=\beta$, $\beta_2=0$, $G_z=G\cos\beta_1\cdot\cos\beta_2=5000\cdot0.9848=4925\ N$;

Substituting the numerical values into Equations (9), the following values are obtained for the support reactions:

when $\varphi=0^0$, $Z_1=1355\ N$; $Z_2=1515\ N$; $Z_3=1095\ N$; $Z_4=960\ N$, verification: $Z_1+Z_2+Z_3+Z_4=4925\ N=G_z$;

when $\varphi=45^0$, $Z_1=1195\ N$; $Z_2=1562.5\ N$; $Z_3=1265\ N$; $Z_4=940\ N$, verification: $Z_1+Z_2+Z_3+Z_4=4962.5\ N=G_z$;

when $\varphi=90^0$, $Z_1=1004.5\ N$; $Z_2=1458\ N$; $Z_3=1458\ N$; $Z_4=1004.5\ N$, verification: $Z_1+Z_2+Z_3+Z_4=4925\ N=G_z$.

The discussion of the robotic platform overturning problem is of little practical significance, since its operational speeds (3 – 6 km/h) and field slope angles (up to 7^0) cannot create a situation in which, even in the most unfavorable position ($\varphi=90^0$) the support reactions Z_1 and Z_4 become equal to 0. In this regard, the analysis of lateral skidding is of primary importance.

To determine the resistance forces against lateral skidding, it is first necessary to determine the tangential reactions (X_i) developed at all driving wheels during rolling motion. It is known that these reaction forces are determined as follows:

$$X_i = P - f\mathrm{Z}_i$$

where P is the circumferential force acting on each driving wheel, f is the rolling resistance coefficient, for various soils $f = 0{,}10 \div 0{,}25$ (*Cho et al., 2002; Litvinov, 1971*), while for cultivated soils $f = 0{,}25$; Z_i is the reaction force at the wheel–ground contact surface. For the considered case:

$$P = \frac{M_m \cdot i \cdot \eta}{r_w} - \mathrm{J}_w \cdot \frac{d\omega_w}{dt} \cdot \frac{1}{r_w}$$

where; r – wheel diameter, M_m - a torque developed by the electric motor, i – a transmission ratio of the motor–wheel drivetrain, η – a drivetrain efficiency, J – a wheel moment of inertia, $d\omega_w$ – an angular acceleration of the wheel

Taking into account that, $\frac{d\omega_w}{dt} = \frac{1}{r_w} \cdot \frac{dv}{dt}$ the following expression is obtained:

$$X_i = \frac{M_m \cdot i \cdot \eta}{r_w} - \mathrm{J}_w \cdot \frac{1}{r_w^2} \cdot \frac{dv}{dt} - f\mathrm{Z}_i \quad (29)$$

Under uniform motion conditions $\frac{dv}{dt} = 0$, therefore:

$$X_i = \frac{M_w}{r_w} - f\mathrm{Z}_i \quad (30)$$

In the case under consideration, where all four wheels are driving wheels and are independently controlled, the tangential (reaction) forces are not equal in either magnitude and direction. As a result, a torque M_z is generated, causing the robotic platform to rotate in the plane of motion. This torque significantly affects lateral skidding.

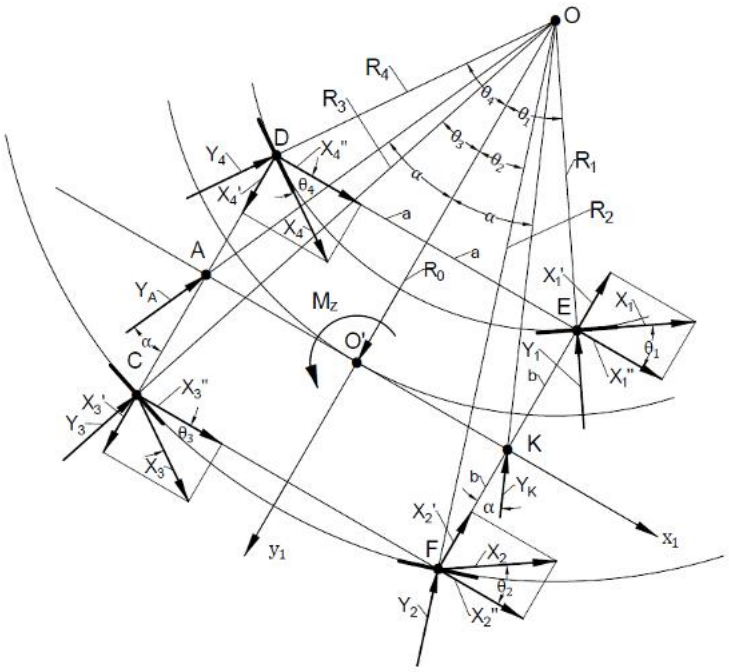


Fig. 6 - Schematic diagram for determining the torque about the vertical axis of the robotic platform

The value/magnitude of this torque is determined according to the scheme shown in Figure 6 as follows:

$$M_z = X_4' \cdot a + X_3' \cdot a + X_2' \cdot a + X_1' \cdot a - X_1'' \cdot b + X_2'' \cdot b + X_3'' \cdot b - X_4'' \cdot b,$$

$$M_z = (X_1 sin\theta_1 + X_2 sin\theta_2 + X_3 sin\theta_3 + X_4 sin\theta_4)a + (X_2 cos\theta_2 + X_3 cos\theta_3)b - (X_1 cos\theta_1 + X_4 cos\theta_4)b; \quad (31)$$

Taking into account that in the considered case $\theta_1 = \theta_4$; $\theta_2 = \theta_3$, for M_z Equation (32) becomes:

$$M_z = (X_1 + X_4)a \cdot sin\theta_1 + (X_2 + X_3)a \cdot sin\theta_2 + (X_2 + X_3)b \cdot cos\theta_2 - (X_1 + X_4)b \cdot cos\theta_1. \quad (32)$$

In the final equation, the forces X_1; X_2; X_3 and X_4 are determined by Equations (29) or (30). The problem of determining θ_1 and θ_2 as well as establishing the relationship between them, is comprehensively discussed in the work of *Tarverdyan et al. (2025)*. Therefore, the torque M_z is determined and for the indicated direction, it is always positive and at least equal to the sum of the first two terms of the equation.

After determining the force factors Z_i; X_i and M_z the lateral resistance (reaction) forces Y_1, Y_2, Y_3 and Y_4 can be determined. Naturally, these forces may be obtained from the dynamic equilibrium conditions of the robot platform; however, it should be emphasized that, in the analysis of the lateral drift phenomenon, the individual determination of these forces is not essential, since lateral skidding is caused by the pairwise combined lateral slip of the conventionally defined front and rear wheels. Proceeding from this consideration, the problem of determining the resultant forces $(Y_3 + Y_4)$ and $(Y_1 + Y_2)$ was examined.

Let the resultant force $(Y_1 + Y_2)$ be transferred to point K on the longitudinal axis of symmetry (x_2), and denote it by Y_K. Similarly, let the resultant $(Y_3 + Y_4) = Y_{\mathcal{A}}$ be applied at point $\mathcal{A}$. It should be noted that this transfer does not alter the mechanical effect of the force system, since the forces Y_1 and Y_2; Y_3 and Y_4 form pairwise concurrent force systems. Since a symmetric system is considered, $Y_{\mathcal{A}}$ and Y_K are inclined relative to the $y_1 - \text{axis}$ by the same angle α, where $tg\alpha = \frac{a}{R_0}$.

Considering the equilibrium condition of the torque of the forces acting on system with respect to the axes Z_1 and Z_2 passing through points $\mathcal{A}$ and K respectively, and using the schematic diagrams shown in Figures 3 and 6, the following equations are obtained:

$$\sum M_{Z_1} = 0; \quad -Y_{\mathcal{A}} cos\alpha \cdot 2a + M_z + M_j + G_y \cdot a + N \cdot a = 0;$$

$$\sum M_{Z_2} = 0; \quad Y_K cos\alpha \cdot 2a + M_z + M_j - G_y \cdot a - N \cdot a = 0; \quad \text{or}$$

$$Y_{\mathcal{A}} = \frac{M_z + M_j + G_y \cdot a + N \cdot a}{2a \cdot cos\alpha} \tag{33}$$

$$Y_K = \frac{N \cdot a + G_y \cdot a - M_z - M_j}{2a \cdot cos\alpha} \tag{34}$$

In these equations, the torque M_z is determined from Equation (32). The inertial torque M_j is determined as follows:

$$M_j = m\rho^2 \frac{d\omega}{dt},$$

where: m is the total loaded mass of the robot platform, ρ is the radius of inertia of the mass m with respect to Z axis perpendicular to the xoy plane and passing through the center of mass; $\frac{d\omega}{dt}$ is the angular acceleration of the rotational motion of the robot platform during turning (for uniform motion $\frac{d\omega}{dt} = 0$). G_y is the component of the gravitational force directed along the transverse axis of symmetry (y_2) of the platform:

$$G_y = G \cdot sin\beta \cdot sin\varphi.$$

N is the centrifugal force generated during turning motion:

$$N = m\omega^2 R_0.$$

Let us determine the magnitude of the lateral drift forces for the adopted initial numerical values, when $\varphi = 90^0$ and G_y attains its maximum value:

$$G_y = G \cdot sin\beta.$$

The numerical data are the same as in the previous example; in this case, the following additional data are also required:

$M_m = 150N \cdot m$; $\eta = 0.9$; $r_w = 0.2m$; $Z_1 = 1004N$; $Z_2 = 1458N$; $Z_3 = 1458N$; $Z_4 = 1004N$; $\theta_1 = 12^0$; $\theta_2 = 9^0$; $\alpha = 10^0$;

For these values, Equation (30) yields the following values for X_i. (assuming that the motion of the robot platform is uniform):

$X_1 = 349.0N$; $X_2 = 236.0N$; $X_3 = 236.0N$; $X_4 = 349.0N$.

Using Equation (32), the following value is obtained for M_z : $M_z = 46.3N \cdot m$; $G_y = 868N$; $N = 193.25N$ (as noted earlier, in the considered case it is assumed that $M_j = 0$).

Using Equations (33) and (34), the lateral drift forces ($Y_{\mathcal{A}}$ and Y_K) of the rear and front axles of the robotic platforms are obtained as:

$$Y_{\mathcal{A}} = 568.0\ N; Y_K = 508.8\ N.$$

For these values of lateral forces, lateral skidding will not occur provided that $(Z_3 + Z_4) \cdot \mu > Y_{\mathcal{A}}$ and $(Z_1 + Z_2) \cdot \mu > Y_K$, where μ is the coefficient of adhesion between the wheel and the supporting surface. For cultivated soil types $\mu = 0{,}4 \div 0{,}45$ (*Litvinov, 1971; Sineokov and Panov, 1977*). For the considered example:

$$(1004 + 1452) \cdot 0.45 > Y_{\mathcal{A}}.$$

$982.4\ N > 568.0\ N$, moreover,

$$982.4\ N > 508.8\ N.$$

Therefore, the condition excluding lateral skidding is satisfied.

Evaluating and Ensuring the Smooth Motion of the Robot Platform

It is well established that, for mobile vehicles—including the robot platform considered and analyzed in this study—the maximum smoothness of motion is ensured when $a = \rho_1$, and in the present case, also when $b = \rho_2$ (*Litvinov,1971; Tarverdyan et al., 2025; Zinoviev, 1975*). Under these conditions, $M_2 = 0$; $M_4 = 0$ and therefore, Equations (25), (26), (27), (28) take the following form:

$$M_1\left(\frac{d^2z_1}{dt^2}+\frac{d^2z_2}{dt^2}\right)+k\left(\frac{dz_1}{dt}+\frac{dz_4}{dt}\right)+c(z_1+z_4)=0, \quad (35)$$

$$M_1\left(\frac{d^2z_3}{dt^2}+\frac{d^2z_4}{dt^2}\right)+k\left(\frac{dz_2}{dt}+\frac{dz_3}{dt}\right)+c(z_2+z_3)=0, \quad (36)$$

$$M_3\left(\frac{d^2z_1}{dt^2}+\frac{d^2z_4}{dt^2}\right)+k\left(\frac{dz_1}{dt}+\frac{dz_2}{dt}\right)+c(z_1+z_2)=0, \quad (37)$$

$$M_3\left(\frac{d^2z_2}{dt^2}+\frac{d^2z_3}{dt^2}\right)+k\left(\frac{dz_3}{dt}+\frac{dz_4}{dt}\right)+c(z_3+z_4)=0. \quad (38)$$

The following notations are introduced:

$$\left.\begin{array}{l} z_1+z_2=R; \\ z_1+z_4=Q; \\ z_3+z_4=F; \\ z_2+z_3=N; \end{array}\right\} \quad \text{and also note that } R+F=Q+N \quad (39)$$

Then, combining Equations (35) and (37) yields:

$$\begin{cases} \dfrac{d^2R}{dt^2}+\dfrac{k}{M_1}\cdot\dfrac{dQ}{dt}+\dfrac{c}{M_1}\cdot Q=0; \\ \dfrac{d^2Q}{dt^2}+\dfrac{k}{M_1}\cdot\dfrac{dR}{dt}+\dfrac{c}{M_1}\cdot R=0. \end{cases} \quad (40)$$

Similarly, from Equations (36) and (38):

$$\begin{cases} \dfrac{d^2F}{dt^2}+\dfrac{k}{M_1}\cdot\dfrac{dN}{dt}+\dfrac{c}{M_1}\cdot N=0; \\ \dfrac{d^2N}{dt^2}+\dfrac{k}{M_3}\cdot\dfrac{dF}{dt}+\dfrac{c}{M_3}\cdot F=0. \end{cases} \quad (41)$$

It follows from the latter equations that systems (40) and (41) are identical, i.e., $F = R$; $N = Q$. Therefore, it is sufficient to solve only system (40).

The following substitutions are introduced:

$$X=\sqrt{M_1}\cdot R;\quad Y=\sqrt{M_3}\cdot Q \quad (42)$$

$$\alpha=\frac{k}{\sqrt{M_1\cdot M_3}};\quad \gamma=\frac{c}{\sqrt{M_1\cdot M_3}}. \quad (43)$$

The system of equations in Equation (40) can then be written as:

$$\begin{cases} X''+\alpha Y'+\gamma Y=0; \\ Y''+\alpha X'+\gamma Y=0. \end{cases} \quad (44)$$

The following notation is introduced:

$$X+Y=U;\quad X-Y=V \quad (45)$$

Adding and subtracting the equations in system (44) yields:

$$U''+\alpha U'+\gamma U=0; \quad (46)$$

$$V''-\alpha V'-\gamma Y=0. \quad (47)$$

The characteristic equation associated with Equation (46) will be:

$\varepsilon^2+\alpha\varepsilon+\gamma=0$; whose roots are:

$\varepsilon_{1,2}=\frac{-\alpha\pm\sqrt{\alpha^2-4\gamma}}{2}=\frac{-\alpha\pm i\sqrt{4\gamma-\alpha^2}}{2}=-\frac{\alpha}{2}\pm\frac{i\omega}{2}$, where $\omega=\sqrt{4\gamma-\alpha^2}$.

Since $4\gamma>\alpha^2$, the general solution of Equation (46) will be:

$$U(t)=e^{-\frac{\alpha t}{2}}\left(A_1 cos\frac{\omega}{2}t+A_2 sin\frac{\omega}{2}t\right). \quad (48)$$

The characteristic equation associated with Equation (47) is: $\xi^2-\alpha\xi-\gamma=0$, which has two real roots:

$\varepsilon_{1,2}=\frac{\alpha\pm\sqrt{\alpha^2+4\gamma}}{2}$, besides $\varepsilon_1=\frac{\alpha+\sqrt{\alpha^2+4\gamma}}{2}>0$.

The general solution of Equation (47) is therefore:

$$V(t)=A_3e^{\varepsilon_1 t}+A_4e^{\varepsilon_2 t}. \quad (49)$$

Because an exponentially increasing solution has no physical meaning in this context, the following condition $A_3 = 0$ is imposed.

Returning to the original functions R and Q and using Equations (42) and (45), the following is obtained:

$$R = \frac{U+V}{2\sqrt{M_1}}; Q = \frac{U-V}{2\sqrt{M_3}}, \text{ or}$$

$$R(t) = \frac{1}{2\sqrt{M_1}}\left[e^{-\frac{\alpha t}{2}}\left(A_1 cos\frac{\omega}{2}t + A_2 sin\frac{\omega}{2}t\right) + A_4 e^{\varepsilon_2 t}\right]; \quad (50)$$

$$Q(t) = \frac{1}{2\sqrt{M_3}}\left[e^{-\frac{\alpha t}{2}}\left(A_1 cos\frac{\omega}{2}t + A_2 sin\frac{\omega}{2}t\right) - A_4 e^{\varepsilon_2 t}\right]. \quad (51)$$

The solution to system (39) is now considered. Taking into account that $R + F = Q + N; \Rightarrow R = Q$, the solution can be expressed as:

$$z_1 = Q - z_4; \quad z_2 = R - Q + z_4; \quad z_3 = F - z_4.$$

where z_4 is an arbitrary function.

Using the geometric relationship among the vertical linear displacements given by Equation (14), the following expression is obtained:

$Q - z_4 + F - z_4 = R - Q + z_4 + z_4$, from which it follows that:

$$z_4 = \frac{2Q}{4} = \frac{Q}{2} = \frac{R}{2}.$$

Thus: $z_1 = z_2 = z_3 = z_4 = \frac{R}{2}$.

The initial conditions are: $\begin{cases} z_{i(0)} = \delta, & i = 1,2,3,4 \\ \dot{z}_{i(0)} = 0, & i = 1,2,3,4. \end{cases}$

Where δ is the static deflection of the elastic element (spring) of the suspension system under the static load.

$$\left.\begin{aligned} z_{1(0)} = \frac{R(0)}{2} = \delta \Rightarrow \frac{1}{4\sqrt{M_1}}(A_1 + A_4) \\ z_{2(0)} = \frac{Q(0)}{2} = \delta \Rightarrow \frac{1}{4\sqrt{M_3}}(A_1 - A_4) \end{aligned}\right\}, \text{ wherefrom}$$

$$\left.\begin{aligned} A_1 = 2\delta\left(\sqrt{M_1} + \sqrt{M_3}\right) \\ A_4 = 2\delta\left(\sqrt{M_1} - \sqrt{M_3}\right) \end{aligned}\right\} \quad (52)$$

The following condition is now applied: $\dot{z}_{i(0)} = 0$, $\dot{z}_{1(0)} = 0 = \frac{\dot{R}(0)}{2} = \frac{1}{4\sqrt{M_1}}\left(-\frac{\alpha}{2}A_1 + A_2\frac{\omega}{2} + A_4\varepsilon_2\right)$,

$$\dot{z}_{2(0)} = 0 = \frac{\dot{Q}(0)}{2} = \frac{1}{4\sqrt{M_3}}\left(-\frac{\alpha}{2}A_1 + A_2\frac{\omega}{2} - A_4\xi_2\right),$$

From the latter equations it follows that:

$$\begin{cases} A_2\frac{\omega}{2} = \frac{\alpha}{2}A_1 - A_4\varepsilon_2, \\ A_2\frac{\omega}{2} = A_4\varepsilon_2 + \frac{\alpha}{2}A_1, \end{cases}$$

from which it follows that:

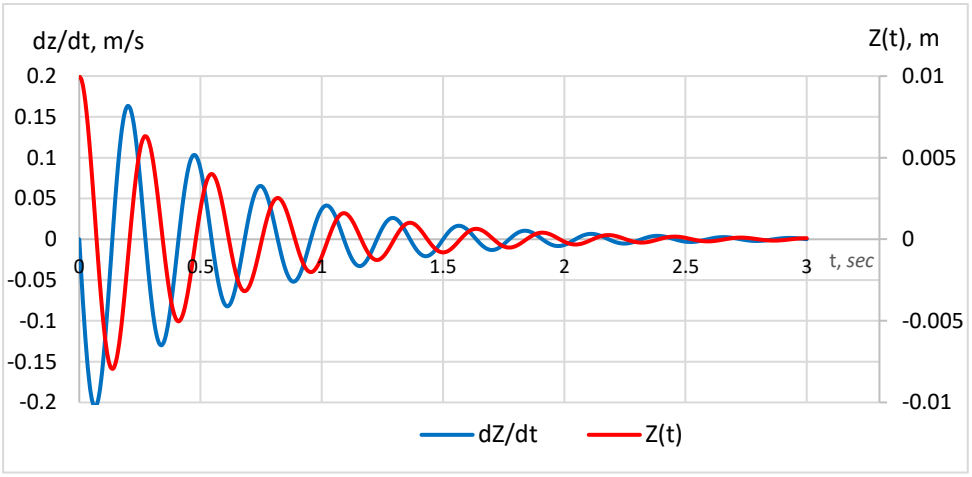
$$A_4 = 0, \quad A_2 = \frac{\alpha A_1}{\omega} = \frac{2\delta\alpha}{\omega}\left(\sqrt{M_1} + \sqrt{M_3}\right). \quad (53)$$

From the condition $A_4 = 0$, it becomes evident that $\sqrt{M_1} = \sqrt{M_3}$, $M_1 = M_3$.

Thus, taking into account Equations (50), (51), (52) and (53), the following equation is obtained for the linear displacements of oscillation:

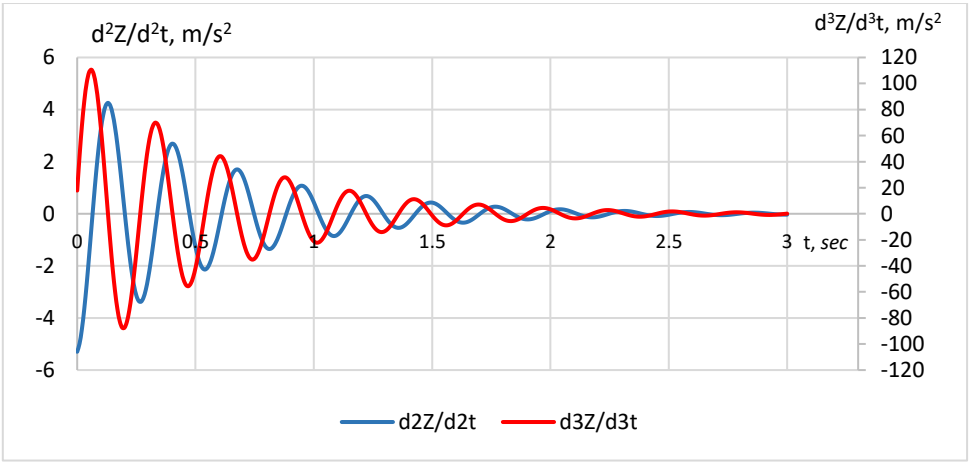
$$z_1 = z_2 = z_3 = z_4 = \frac{1}{4\sqrt{M_1}} \cdot e^{-\frac{\alpha t}{2}}\left(4\delta\sqrt{M_1} \cdot cos\frac{\omega t}{2} + \frac{4\delta\alpha}{\omega} \cdot \sqrt{M_1} sin\frac{\omega t}{2}\right).$$

Or, in final form:



$$z_{i(t)} = \delta e^{-\frac{\alpha t}{2}} \cdot \left(cos\frac{\omega t}{2} + \frac{\alpha}{\omega} \cdot sin\frac{\omega t}{2}\right) \quad (54)$$

Based on the analysis of the free oscillations of the robotic platform, the derived equations make it possible to determine the key oscillation parameters included in the characteristic performance indicators of the suspension system, namely the oscillation frequency, amplitude, and period, which determine the smoothness of motion (*Biderman, 1980; Ilarionov, 2013; Zinoviev,1975*). In addition, the final Equation (54) makes it possible to determine the oscillation velocity: $\left(\frac{dz}{dt}\right)$



The acceleration: $\left(\frac{d^2z}{dt^2}\right)$ and the rate of acceleration change, which is an important characteristic parameter in problems of this type: $\left(\frac{d^3z}{dt^3}\right)$.

Based on Equation (54), the equations derived from it, and the initial parameters of the robotic platform being developed, the following values were adopted: L=1,60 m; B=1,20 m; a=0,8 m; b=0,6 m; $\rho_1 = 0{,}8\ m$; $\rho_2 = 0{,}6\ m$; M=500 kg. Under these conditions: $M_1 = M_2 = M_3 = M_4 = 125$ kg, the equivalent stiffness coefficient of the suspension system is: $c_b = 66.65 \cdot 10^3 \frac{N}{m} = 66.65 \cdot 10^3 \frac{kg}{s^2}$, the average value of the resistance coefficient of a shock absorber: $k = 420 \frac{N \cdot s}{m} = 420 \frac{kg}{s}$, the vertical static deflection: $\delta = 0.01\ m$, and with calculated values:

$\alpha = \frac{k}{M_1} = \frac{420}{125} = 3.36\ s^{-1}$, $\frac{\alpha}{2} = 1.68\ s^{-1}$, $\omega = \sqrt{\frac{4c}{M_1} - \alpha^2} = \sqrt{\frac{4 \cdot 66.65 \cdot 10^3}{125} - (3.36)^2} = 46.06 s^{-1}$, the graphs of the obtained functions are presented in Figure 7.

a)

b)

Fig. 7 - Graphs of the free oscillations of the robot platform

a) vertical displacements and velocities; b) velocities and accelerations.

The obtained analytical equations make it possible to select such stiffness values (c) for the elastic elements of the suspension system and such a damping coefficient (k), for the shock absorber (damper) that the required programmed parameters of the oscillatory motion are ensured.

Furthermore, the presented results and derived equations provide the basis for the next stage of the research, namely the investigation of the forced oscillations of the robotic platform.

CONCLUSIONS

As a result of the stability analysis of the developed agricultural robotic platform equipped with four driven and self-steering wheels operating on slopes, analytical equations were obtained that make it possible to determine the conditions of rollover and sideslip during turning motion, as well as the threshold values of the slope angle and the linear velocity of turning motion.

The magnitude of the torque about the vertical axis, which is characteristic particularly of four-wheeled robotic platforms with self-steering wheels operating on slopes and has a significant influence on skidding phenomenon, was determined.

Based on the analysis of the differential equation describing the motion of the robotic platform's center of mass and the torque equations with respect to the platform's transverse and longitudinal symmetry axes, the equations of the robotic platform's free oscillations were derived. The derived equations make it possible to determine the vertical displacements, velocities, accelerations, and variations of acceleration of the oscillatory motion, as well as choosing the stiffness of the shock absorber (damper) required to ensure smooth motion of the platform.

The obtained results are of considerable significance and provide a foundation for further investigations into the forced vibration behavior of the robotic platform.

ABSTRACT

Winter potato cultivation in paddy fields in southern China can improve land-use efficiency and increase farmers' incomes. However, compared with those in northern China, paddy soils in southern China are generally heavy, cohesive, and compacted, resulting in poor mechanized potato-harvesting performance and restricting the development of the potato industry. To improve potato-soil separation efficiency under heavy clay soil conditions, a twin-roll soil-crushing device was installed ahead of a conventional chain-and-rod potato-soil separation device based on the characteristics of clayey soils in southern China. This configuration formed a two-stage separation process involving soil crushing followed by screening. The soil-crushing process was theoretically analyzed, a discrete element model of the soil-crushing and screening device was established, and the soil-crushing and potato–soil separation processes were numerically simulated. Response surface simulation experiments were conducted using rib height, number of ribs, and twin-roll rotational speed as the experimental factors, with soil-screening efficiency and the maximum force acting on the potato tubers as the response variables. The results showed that the twin-roll soil-crushing device effectively disturbed and crushed the soil during operation. Increasing the rib height and twin-roll rotational speed enhanced the soil-disturbance and crushing effects. The optimal structural and operating parameters of the twin-roll soil-crushing device were a rib height of 30 mm, three ribs, and a twin-roll rotational speed of 323.70 r/min. A simulation verification test conducted using these optimal parameters yielded a soil-screening efficiency of 72.80% and a maximum force acting on the potato tubers of 15.45 N. Field-test results showed that the potato harvester equipped with the soil-crushing device achieved a tuber damage rate of 0.285%, a skin-damage rate of 2.38%, and a tuber loss rate of 3.18%, thereby meeting the requirements of the applicable national standards. These findings provide a reference and technical support for the development of potato-harvesting machinery suitable for heavy clay soil conditions.

摘要

中国南方水稻田冬种马铃薯能提高土地利用率，促进农民增收，相较于北方，南方水稻田土壤黏重板结，常见马铃薯机械化收获作业效果不佳，制约了产业的发展。为了提高黏重土壤下薯土分离效率，本研究针对中国南方黏土土壤特点，在传统链杆式薯土分离装置前设计了对辊式碎土装置，形成“先破碎、后筛分”两级分离流程，提高薯土分离效率，对碎土过程进行了理论分析，构建了碎土筛分装置离散元模型并对土壤破碎和薯土分离过程进行了数值模拟。以碎土装置的凸棱高度、凸棱数量、对辊转速为试验因素，以土壤筛分效率和薯块最大受力为评价指标，开展了响应面仿真试验，结果表明，对辊式碎土装置在工作时对土壤起到了扰动和破碎作用，增加凸棱高度和提高对辊转速能够增加碎土装置对土壤的扰动和破碎作用。对辊式碎土装置的最优结构运行参数为凸棱高度 30 mm，凸棱数量为 3 个，对辊转速 323.0 r/m n，以此最优参数开展仿真验证试验，土壤筛分效率为 2.80%，薯块最大受力为15.45N。田间试验结果表明，配置有碎装置的马铃薯收获机伤薯率为0.285%，破皮率为2.38%，损失率为3.18%，满足国家标准要求。研究结果能为黏重土壤条件下马铃薯收获机具的研发提供参考和支撑。

INTRODUCTION

The annual potato planting area in China exceeds 6 million hectares, making the potato industry a vital pillar for promoting rural revitalization and ensuring national food security *(Li et al., 2022*). In the southern regions, cultivating potatoes in winter-idle rice fields enhances land-use efficiency and complements the market supply season, offering broad development prospects. However, potato-growing areas in the south are predominantly located in hilly and mountainous regions characterized by heavy, compact clay soils. Furthermore, the harvest season often coincides with the rainy season, leading to high soil moisture content. These harsh conditions pose severe challenges for mechanized harvesting (*Jiang et al., 2016*). Existing harvesting machinery, primarily designed for the loose, sandy soils of the north, struggles to adapt to southern clay soils, resulting in low soil-tuber separation efficiency and a low rate of exposed tubers (*Bei et al., 2021; Li et al., 2022; Lv et al., 2017*). Therefore, designing potato harvesting machinery tailored to heavy clay soil and hilly terrain is of great significance for the southern winter potato industry (*Wang et al., 2021; Zhang et al., 2021; Zhongcai et al., 2019; Zhou et al., 2021*).

To achieve efficient, low-loss potato harvesting in heavy clay soils, existing research has primarily explored mechanical structure innovations and operational parameter optimizations. In terms of mechanical structures, various separation mechanisms have been developed. For instance, digging devices with vibration functions have been designed to reduce digging resistance in sticky soils (*Lv et al., 2015*). Multi-stage chain-and-rod screening devices and concave-bar structures have been implemented to increase soil disturbance and enhance separation efficiency (*Xiaoxuan et al., 2024; Qingmiao et al., 2024*). Additionally, roller structures with staggered rod arrangements *(Shi et al., 2012)* and flexible rotary-vibration systems *(Xiang et al., 2020)* have been developed to reduce clogging and mechanical damage. Regarding operational parameters, studies have demonstrated that matching a "high frequency and low amplitude" vibration with appropriate linear velocities can improve the soil crushing rate and minimize tuber damage (*CAAMS, 2007; Li et al., 2016; Li et al., 2021*). Furthermore, recent studies have continuously emphasized the importance of optimizing machine-soil interaction mechanisms through Discrete Element Method (DEM) simulations to improve separation and digging performance in complex agricultural terrains (*Fu et al., 2023; Ge et al., 2025*).

Despite these advancements in screening structures and kinematics, a critical research gap remains: existing separation mechanisms are primarily designed to sieve pre-loosened soil rather than actively break hard, cohesive clods. Practical experiments indicate that severe soil compaction and high viscosity are the fundamental causes of incomplete soil-tuber separation in southern fields. Under such conditions, standard chain-and-rod or vibrating separation devices lack the initial mechanical impact required to shatter the compacted clay structure. Consequently, large, wet soil clods carry the tubers over the sieves without separating, rendering the subsequent screening stages ineffective. To overcome this bottleneck, it is imperative to introduce a robust, active soil-breaking mechanism prior to the main screening device to destroy the compacted soil structure at the earliest stage.

To address this gap, a twin-roll soil-crushing device was installed ahead of a conventional chain-and-rod separation conveyor. The protruding ribs on the rolls exert impact and shear forces on compacted clay clods, thereby promoting their fragmentation. Based on a theoretical kinematic analysis, a discrete element model of the soil-crushing and screening device was established to simulate the potato–soil separation process. A response surface methodology (RSM) simulation experiment was conducted using rib height, number of ribs, and twin-roll rotational speed as the experimental factors, with soil-screening efficiency and the maximum force acting on the potato tubers as the response variables. This study aimed to optimize the structural and operating parameters of the twin-roll soil-crushing device and provide a theoretical basis and technical reference for the development of efficient potato-harvesting machinery suitable for heavy clay soils.

MATERIALS AND METHODS

Structure of the twin-roll soil crushing device

The potato harvester equipped with a twin-roll soil-crushing device was designed for operation in the heavy clay soils of southern China. As shown in Fig. 1, the machine mainly comprises a digging shovel, disc coulters, a transmission system, a lateral conveying device, a debris-removal device, a potato–soil separation device, and a soil-crushing device. According to the *Agricultural Machinery Design Manual* (CAAMS, 2007), the potato–soil separation device was designed with a length of 1.75 m, and the chain-and-rod conveyor was inclined at an angle of 30° to the horizontal *(Ma et al., 2012; Zhou et al., 2021)*.

To facilitate the fragmentation of heavy, cohesive soil and improve the screening efficiency of the potato–soil separation device, the twin-roll soil-crushing device was installed between the digging shovel and the potato–soil separation device. The device consists of two rolls rotating in the same direction, with three to five protruding ribs arranged on the surface of each roll. During operation, the twin-roll soil-crushing device rotates rearward and conveys the potato–soil mixture toward the separation device. Simultaneously, the protruding ribs exert bending forces on the soil clods, causing them to fracture.

Development of the Simulation Model

Development of the Potato Tuber and Soil Models

During potato-harvester operation, the interactions among the potato tubers, soil, and soil-crushing device are highly complex. Soil clods undergo fragmentation under external excitation, whereas the crushing rolls can be regarded as rigid bodies. EDEM software was used to simulate the interactions among the potato tubers, soil, and soil-crushing device and thereby evaluate the performance of the device.

The particle model of the potato tuber is shown in Fig. 3. A multisphere clump model was used to represent the potato tuber *(Qingmiao et al., 2024)*, with its three principal dimensions set to 62 mm × 52 mm × 52 mm. The Hertz–Mindlin (no slip) contact model was applied to tuber-tuber, tuber-soil, and tuber-machine interactions. The soil particles were modeled as spheres with a radius of 3 mm. Considering the characteristics of heavy clay soils in southern China *(Bei et al., 2021; Ren et al., 2017)*, the Hertz–Mindlin with Bonding V2 contact model was used to simulate interparticle bonding within the soil. Based on the moisture-content range of heavy clay soils in southern China, the contact radius of the soil particles was set to 3.75 mm. The simulation parameters of the potato tubers and soil particles are presented in Table 1 *(Qingmiao et al., 2024; Xie et al., 2020)*. Some parameters for the soil-particle and metal-component models were obtained from the literature *(Minzhang et al., 2024; Linrong et al., 2018; Wei et al., 2019; Zhongcai et al., 2020)*, whereas the remaining parameters, including those of the potato-tuber model, were determined experimentally.

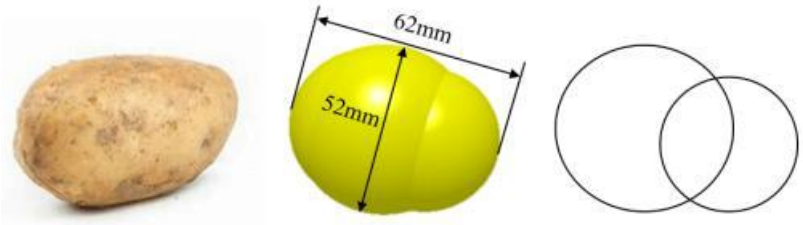

Fig. 2 - Multisphere particle model of a potato tuber

Table 1

Parameters of the Discrete Element Model

Parameter	Numerical value	Parameter	Numerical value
Poisson's ratio of potato tubers	0.5	Coefficient of static friction between potato tubers and rods	0.4
Shear modulus of potato tubers / MPa	1.366	Coefficient of rolling friction between potato tubers and rods	0.1
Potato-tuber density / (kg·m^{-3})	1100	Normal stiffness between soil particles / (N·m^{-1})	1.4 × 10^{6}
Coefficient of restitution between potato tubers	0.79	Maximum normal stress between soil particles / MPa	0.235
Coefficient of static friction between potato tubers	0.5	Tangential stiffness between soil particles / (N·m^{-1})	1 × 10^{6}
Coefficient of rolling friction between potato tubers	0.024	Poisson's ratio of the rod material	0. 3
Poisson's ratio of soil	0.38	Shear modulus of the rod material / MPa	3. 1 × 10^{5}
Shear modulus of soil / MPa	1	Density of the rod material / (kg·m^{-3})	7 800
Soil-particle density / (kg·m^{-3})	2670	Coefficient of restitution between soil particles and rods	0.16
Coefficient of restitution between soil particles	0.37	Coefficient of static friction between soil particles and rods	0.6
Coefficient of static friction between soil particles	0.6	Coefficient of rolling friction between soil particles and rods	0.35
Coefficient of rolling friction between soil particles	0.26	Coefficient of restitution between potato tubers and rods	0.5
Coefficient of restitution between potato tubers and soil particles	0.06	Coefficient of static friction between potato tubers and soil particles	0.5

Development of the Simulation Model of the Soil-Crushing and Screening Device

The geometric model of the soil-crushing and screening device is shown in Fig. 4. A particle factory measuring 1,100 mm × 1,000 mm × 600 mm was established at the front of the model to generate soil and potato-tuber particles. Below the particle factory, a conveyor belt was created using the moving-plane tool in EDEM to convey the potato–soil mixture rearward. The conveyor-belt speed was set to 1 m/s, corresponding to the forward speed of the potato harvester. A soil-compaction plate was positioned above the conveyor belt to compact the potato–soil mixture before it entered the harvesting components, thereby simulating compacted clay soil. The machine model consisted of a digging shovel, a twin-roll soil-crushing device, and a chain-and-rod potato–soil separation device, all of which were modeled as steel components. The rolls of the soil-crushing device were set to rotate rearward. The chain-and-rod separation device comprised 69 rods, each of which was assigned linear and circular motion cycles. A fixed time interval was applied between the motions of adjacent rods to simulate the continuous operation of the chain-and-rod device. In the model, the rod diameter was 11 mm *(Sun et al., 2019)*, the linear speed was 1.7 m/s, and the center-to-center spacing between adjacent rods was 50 mm. Accordingly, the time interval between the motions of adjacent rods was calculated to be 0.02941 s. Based on the dimensions and linear speed of the chain-and-rod separation device, the angular velocity of the rods in the circular-motion section was calculated to be 20.98765 rad/s, and the time required for one complete circulation was 2.64706 s. At the position of the shaking device, a sinusoidal translational motion perpendicular to the screening surface was applied to each rod at a frequency of 5 Hz to simulate the vibrational action of the device. A potato-and-soil collection bin was positioned behind the separation device to collect and quantify the residual soil and potato tubers discharged from the screening surface, thereby allowing the potato–soil separation performance to be evaluated.

Simulation Process and Parameter Settings

Before the simulation, a mixture of soil and potato-tuber particles was generated. A total of 600,000 soil particles forming the lower soil layer were generated between 0 and 0.8 s. The generation of 20 potato-tuber particles began at 0.5 s. Subsequently, 1,300,000 soil particles forming the upper soil layer were generated over a period of 0.4 s, beginning at 0.8 s. After all particles had been generated, the soil-compaction plate moved downward to compact the soil, forming a 180-mm-thick soil–potato–soil layered mixture. The conveyor belt was activated at 1.6 s and transported the potato–soil mixture rearward into the twin-roll soil-crushing device and the chain-and-rod potato–soil separation device. The total simulation duration was 6 s. The simulation time step was set to 20% of the Rayleigh time step, which was 1.037×10^{-4} s, and the data-saving interval was set to 0.1 s.

Simulation Test Method

Experimental Design

During operation, the structural and operating parameters of the twin-roll soil-crushing device affect both soil-screening efficiency and the likelihood of potato-tuber damage. To determine the optimal parameters of the soil-crushing device, a three-factor, three-level Box–Behnken response surface design was developed using Design-Expert software. Rib height h, number of ribs q, and twin-roll rotational speed n were selected as the experimental factors. The factor levels are presented in Table 2, and the experimental design is presented in Table 3. Simulation tests were then performed using the model described above, and the resulting data were used to optimize the parameters of the twin-roll soil-crushing device.

Table 2

Experimental factors and levels

Level	Factor		
	Rib height *h* / mm	Number of ribs *q* / pieces	Twin-roll rotational speed *n* / (r/min)
1	20	3	200
2	25	4	300
3	30	5	400

Measurement of Response Variables

Soil-screening efficiency *E* and the mean maximum force acting on the potato tubers *E* were selected as the response variables in the response surface experiment. Soil-screening efficiency was used to evaluate the combined soil-crushing and screening performance of the twin-roll soil-crushing device and the chain-and-rod separation device. In each simulation test, EDEM was used to determine the mass of residual soil collected in the potato-and-soil collection bin and the total mass of soil generated. Soil-screening efficiency was calculated as follows *(Sun et al., 2019)*:

$$E=1-\frac{M_r}{M_t}\times100\% \quad (1)$$

where, *E* is the soil-screening efficiency M_r is the mass of residual soil collected in the potato-and-soil collection bin, [kg]; M_t is the total mass of soil generated, [kg].

The force acting on the potato tubers was used as an indicator of their risk of mechanical damage during conveying and screening. EDEM was used to determine the maximum force experienced by each of the 20 potato tubers during each simulation test. The mean of these individual maximum values was then calculated and used as the force response variable.

RESULTS

Analysis of Soil Disturbance

The motion of the potato–soil mixture above the twin-roll soil-crushing device was visualized using the EDEM post-processing module. The soil particles were color-coded according to their velocity. Particles approaching red had higher velocities, indicating greater soil disturbance, whereas particles approaching blue-green had lower velocities and were subjected to less disturbance. The soil-particle disturbance produced by the twin-roll soil-crushing device is shown in Fig. 5.

As shown in Fig. 5, a distinct red region formed among the soil particles above the twin-roll soil-crushing device, indicating that the device effectively disturbed the soil and promoted clod fragmentation. As rib height *h* and twin-roll rotational speed *n* increased, the red region expanded, indicating enhanced soil disturbance and crushing. By contrast, when the number of ribs *q* increased from three to five, no marked change in the size of the red region was observed, suggesting that the number of ribs had a limited effect on soil disturbance within the investigated range.

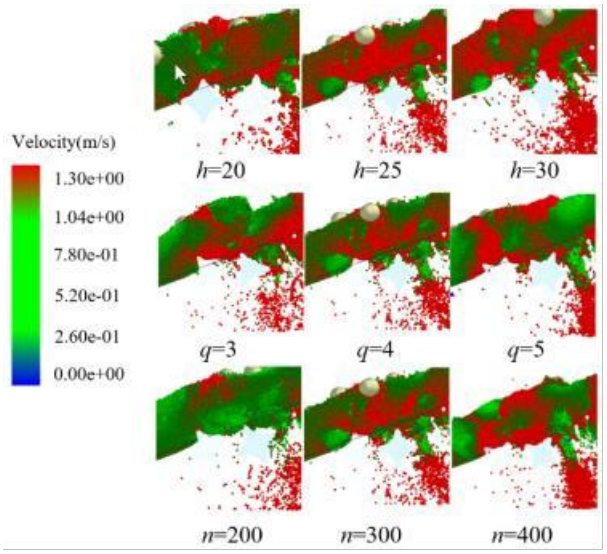

Fig. 5 - Soil-disturbance patterns under different operating conditions

Analysis of Response Surface Experiment Results

The response surface experiment results are presented in Table 3. Regression analysis and analysis of variance (ANOVA) were performed using Design-Expert software, and the results are presented in Table 4. The P-values of the regression models for soil-screening efficiency and the maximum force acting on the potato tubers were both less than 0.05, whereas the P-values of the lack-of-fit terms were greater than 0.05. Thus, both regression models were statistically significant and adequately fitted the experimental data. After removing nonsignificant terms with P-values greater than 0.10, the regression equations for soil-screening efficiency and the maximum force acting on the potato tubers were obtained, as given in Eqs. (2) and (3), respectively.

$$E = 69.14888 - 0.025552n - 12.22375q + 2.65918h + 0.003305nh + 0.344500qh - 0.000072n^2 - 0.089574h^2 \quad (2)$$

$$F = +63.94900 - 0.298455n - 24.2665q + 4.2125h - 0.0193nq + 0.00397nh + 0.000416n^2 + 4.0005q^2 - 0.11398005h^2 \quad (3)$$

Table 3

Parameter Optimization and Validation

Based on the regression Eqs. (2) and (3), numerical parameter optimization was performed using the optimization module in Design-Expert. The objective functions and constraints were defined as follows:

$$\begin{cases} \max E(n,\ q,\ h) \\ \min F(n,\ q,\ h) \\ 20\text{mm} \le A \le 30\text{mm} \\ B \in \{3,\ 4,\ 5\} \\ 200\text{r/min} \le C \le 400\text{r/min} \end{cases} \tag{4}$$

The optimal structural and operating parameters of the twin-roll soil-crushing device were a rib height h of 30.00 mm, three ribs (q =3), and a twin-roll rotational speed n of 323.70 r/min. The simulation model was configured using this optimal parameter combination, and a verification simulation was subsequently conducted. The resulting soil-screening efficiency was 72.80%, and the mean maximum force acting on the potato tubers was 15.45 N.

Verification Test

Based on the optimal structural and operating parameters determined above, a prototype of the twin-roll soil-crushing device was manufactured and installed on a 4U-1100 side-discharging potato harvester. Field tests were subsequently conducted in a paddy field in Liuyang City, Hunan Province, China. The potatoes, cultivar Xingjia No. 2, were grown using ridge cultivation, and the soil moisture content at the time of testing was 16.3%. The ridge height, ridge-top width, ridge-base width, and furrow width were 300, 700, 1,100, and 400 mm, respectively. The field-test conditions are shown in Fig. 6, and the results are presented in Table 5. The tuber damage rate, skin-damage rate, and tuber loss rate of the potato harvester equipped with the twin-roll soil-crushing device satisfied the requirements of the agricultural industry standard NY/T 648-2015 *(MOA, 2015)*.

CONCLUSIONS

To improve potato–soil separation under heavy clay soil conditions, a twin-roll soil-crushing device was installed ahead of a conventional chain-and-rod potato–soil separation device. The soil-crushing process was theoretically analyzed, a discrete element model of the soil-crushing and potato–soil separation system was developed, and the corresponding processes were simulated. The main conclusions are as follows:

（1） The twin-roll soil-crushing device effectively disturbed the soil and promoted clod fragmentation during operation. Increasing the rib height and twin-roll rotational speed enhanced the soil-disturbance and crushing effects. By contrast, the number of ribs had no marked effect on the observed soil-disturbance pattern within the investigated range.

（2） The response surface simulation results indicated that the optimal structural and operating parameters of the twin-roll soil-crushing device were a rib height of 30 mm, three ribs, and a twin-roll rotational speed of 323.70 r/min. A verification simulation conducted using this optimal parameter combination yielded a soil-screening efficiency of 72.80% and a mean maximum force of 15.45 N acting on the potato tubers.

（3） Field-test results showed that the potato harvester equipped with the twin-roll soil-crushing device achieved a tuber damage rate of 0.285%, a skin-damage rate of 2.38%, and a tuber loss rate of 3.18%. All three performance indicators satisfied the requirements of the national standards.

ABSTRACT

This study develops an artificial neural network (ANN) model to optimize the convective drying process of pear slices. Experimental data from drying at 50°C, 60°C, and 70°C were used to train an ANN with three hidden layers. The model predicted drying rate with high accuracy (98.823% validation fidelity), capturing the nonlinear relationship between moisture content, time, and drying rate. Results demonstrated that higher temperatures accelerated drying but required careful control to maintain quality. The ANN effectively identified optimal drying parameters, balancing energy efficiency and product quality preservation, providing a valuable tool for industrial drying process optimization.

REZUMAT

Acest studiu dezvoltă un model de rețea neurală artificială (ANN) pentru optimizarea uscării convective a feliilor de pere. Date experimentale de la uscarea la 50°C, 60°C și 70°C au fost folosite pentru antrenarea unei ANN cu trei straturi ascunse. Modelul a prezis viteza de uscare cu precizie ridicată (98,823% fidelitate de validare), capturând relația neliniară dintre umiditate, timp și viteză. Rezultatele au arătat că temperaturile mai mari accelerează uscarea, dar necesită control atent. ANN-ul a identificat parametrii optimi, echilibrând eficiența energetică și calitatea produsului, oferind un instrument valoros pentru optimizarea procesului industrial de uscare.

INTRODUCTION

Convective drying remains one of the most extensively utilized preservation techniques in the global food industry, particularly for perishable commodities like fruits and vegetables, which are subject to significant seasonal and geographical production constraints *(Sagar and Kumar, 2010)*. The core objective of this process is the controlled removal of moisture to a level that ensures microbial stability, thereby extending the product's shelf life. However, the challenge extends far beyond simple dehydration; it is equally critical to preserve the nutritional composition, color, texture, and overall sensory quality of the final product *(Sablani, 2006, Calín-Sánchez et al., 2022)*. Traditional approaches to optimizing the drying process have historically relied on empirical models and first-principles physics-based formulations. While these methods provide a foundational understanding, they often fall short in capturing the highly complex, non-linear, and dynamic relationships that exist between key process parameters such as air temperature, velocity, and humidity and the evolving physical and chemical properties of the biological material *(Erbay and Icier, 2010)*.

The inherent heterogeneity of biological matrices like pear slices, combined with the intricate interplay of heat and mass transfer phenomena during drying, creates a formidable barrier to developing universally applicable mathematical models *(Khan et al., 2022, Farid, 2019)*. These classical models, often based on Fick's law of diffusion or other simplified assumptions, struggle to accurately predict drying behavior across diverse fruit and vegetable types and under varying operational conditions *(Kalantari et al., 2022)*. This limitation has driven the search for more robust and flexible modeling tools capable of learning directly from experimental data without being constrained by a priori assumptions about the underlying physical mechanisms (*Lenart, 1996*).

In this context, Artificial Neural Networks (ANNs) have emerged as a powerful and versatile computational paradigm for modeling complex systems in food engineering *(Francik et al., 2024).* ANNs are data-driven, non-linear mapping functions inspired by the human brain's structure, which can learn intricate patterns and relationships from a set of input-output data pairs *(El-Mesery et al., 2025).* By leveraging experimental drying data, ANNs can effectively model the non-linear dynamics of the drying process, making them exceptionally well-suited for food drying applications where multiple interacting factors influence the final product quality *(Selvi et al., 2022).* The application of ANNs in convective drying offers significant potential for improving process efficiency, reducing energy consumption, and enhancing product quality through more precise prediction and control capabilities *(Đaković et al., 2023).*

One of the most immediate and valuable applications of ANNs in fruit drying is the accurate prediction of moisture content as a function of time, temperature, and other process variables. A well-trained ANN model would allow processors to anticipate the exact moisture content at any point during the drying cycle in real-time, without the need for disruptive and time-consuming offline measurements *(Tepe, 2024).* This capability is crucial for targeting specific, critical moisture levels required for optimal product stability, as different fruits have varying thresholds for microbial safety and quality preservation. Furthermore, ANNs can be used to model the instantaneous drying rate as a function of the current moisture content and process temperature, providing insights into the transition points between the constant-rate and falling-rate drying phases *(Kalsi et al., 2023).* This knowledge enables the development of more sophisticated, adaptive control strategies that can dynamically adjust process parameters to match the changing drying kinetics throughout the process, thereby preventing quality degradation from excessive heat exposure in the later stages.

The predictive power of ANNs extends to critical operational planning tasks. For instance, these models can reliably estimate the total drying time required to achieve a target moisture content at a specified set of drying conditions, which is essential for production scheduling and resource allocation in commercial operations *(Nguyen et al., 2025).* Conversely, they can also be used in an inverse manner to determine the optimal drying temperature and air velocity needed to reach a desired final moisture content within a predefined time frame, a common industry challenge that requires balancing throughput demands with stringent quality requirements *(Demir et al., 2023).* A particularly sophisticated application involves using ANNs to predict the critical moisture content, the point at which the drying rate begins its significant decline which is not a fixed value but varies with temperature and the specific physical structure of the fruit or vegetable being processed *(Das et al., 2018).*

Beyond basic process parameters, the true potential of ANNs lies in their ability to integrate moisture removal kinetics with final product quality outcomes. Advanced ANN models can be developed to predict key quality indicators-such as vitamin C retention, color change (ΔE), or textural hardness, based on the entire drying history *(Khan et al., 2022).* While such comprehensive models require a rich dataset that includes both drying kinetics and post-process quality analyses, they represent a paradigm shift from traditional time or energy – oriented optimization toward a holistic, quality driven process design optimization *(Asrate et al., 2025).* This approach is especially important for high-value fruits like pears, where even minor quality degradation during drying can significantly impact market value and consumer acceptance.

The ability of ANNs to interpolate accurately between tested experimental conditions and to modestly extrapolate to untested but approximate parameter ranges offers substantial practical and economic benefits for food processors *(Ming et al., 2021).* Rather than conducting extensive and costly new experiments for every new product variant or slight change in processing conditions, manufacturers can leverage validated ANN models to predict drying behavior for similar fruits and vegetables, drastically reducing product development time and resource expenditure *(Hossan et al., 2023).* This capability is increasingly valuable in a global food industry facing intense pressure to innovate, develop new dried products with optimized nutritional and sensory profiles, and simultaneously minimize energy consumption and environmental impact *(Spagnuolo et al., 2023).*

Ultimately, the integration of robust ANN based models into modern drying process control systems represents a clear pathway toward more intelligent, adaptive, and efficient food processing operations *(El-Mesery et al., 2025).* By enabling real-time prediction and dynamic adjustment of process parameters based on the current state of the product – which is also the aim of our study, these AI-driven models can help achieve the dual, and often competing, objectives of energy efficiency and superior product quality preservation that are central to the future of sustainable food manufacturing *(Yao et al., 2023).*

MATERIALS AND METHODS

To generate a robust experimental dataset for training the artificial neural network (ANN), a systematic series of convective drying experiments was conducted using the GUNT CE130 drying apparatus (GUNT Hamburg, Germany) as part of a structured research internship. The experimental protocol involved drying 1000 g batches of fresh pear slices (Pyrus communis L.), pre-cut to a uniform thickness of 3.0 mm using a precision slicer, as illustrated in Fig. 1. This standardization of slice thickness and initial mass ensured consistent starting conditions, a critical prerequisite for capturing reproducible drying kinetics and minimizing variability in the dataset. The CE130 convective drying system was configured with advanced process control and monitoring capabilities to ensure precise experimental conditions. Key components included a proportional-integral-derivative (PID) controller for maintaining channel temperature within ±0.5°C of the setpoint, an adjustable axial fan system for airflow regulation, and integrated sensors for real-time monitoring of channel temperature (accuracy: ±0.5°C) and relative humidity (accuracy: ±3% RH). A high-precision digital scale (KERN 440, Germany; resolution: 0.1 g) was located above the drying channel to continuously record mass loss of the pear samples, enabling detailed quantification of moisture ratio dynamics. All experimental parameters were controlled and logged via the manufacturer's proprietary software (CE130 v.16.1.3.4), which facilitated automated data acquisition at 5-minute intervals, thereby capturing high-resolution temporal profiles of the drying process.

Fig. 1 - Experimental setup of the GUNT CE130 convective dryer, including sample preparation, instrumentation, and data acquisition system

The experimental design incorporated three drying temperatures (50, 60, and 70 °C) at a constant hot air velocity of 2.0 m/s, selected to represent a range of industrially relevant conditions while elucidating the nonlinear thermal behavior of pear tissue. Each temperature condition was replicated several times to assess data reproducibility and statistical reliability. Prior to each trial, the drying channel was preheated to the target temperature, and ambient conditions (initial temperature: 22 ± 1 °C; relative humidity: 45 ± 5%) were recorded to account for environmental variability. The drying process was terminated when the pear slices reached a moisture content slightly below 15% (dry basis), a threshold determined through preliminary trials to balance product quality retention and energy efficiency.

Artificial neural network development training and validation. An artificial neural network (ANN) was developed and trained within Simcenter Amesim V2310 (Siemens Digital Industries Software) to model and optimize the convective drying kinetics of pear slices. The experimental dataset, acquired from the GUNT CE130 drying apparatus, was systematically partitioned into six subsets: three training datasets (TD_cd50C, TD_cd60C, TD_cd70C) and three validation datasets (VD_cd50C, VD_cd60C, VD_cd70C), corresponding to

the three drying temperatures (50, 60, and 70 °C). Each dataset comprised time-resolved measurements of drying time [min], moisture content (u) [%], and drying rate (du/dt) [%/min], with the latter derived from numerical differentiation of moisture loss profiles. These variables were selected as critical inputs and outputs to capture the transient behavior of the drying process, where du/dt [%/min] serves as a direct indicator of process efficiency.

Data preprocessing and model ANN configuration. The training and validation subsets were imported into Simcenter Amesim via a structured file directory, ensuring traceability and reproducibility of data handling (Fig. 2). The ANN architecture was configured with three hidden layers (30, 20, and 10 neurons), each employing hyperbolic tangent (tanh) activation functions to model the nonlinear relationships between input variables and drying rate. This configuration was selected through iterative hyperparameter tuning to balance model complexity and generalization capability, minimizing overfitting while retaining sufficient capacity to capture the intricate dynamics of moisture diffusion and heat transfer in pear tissue.

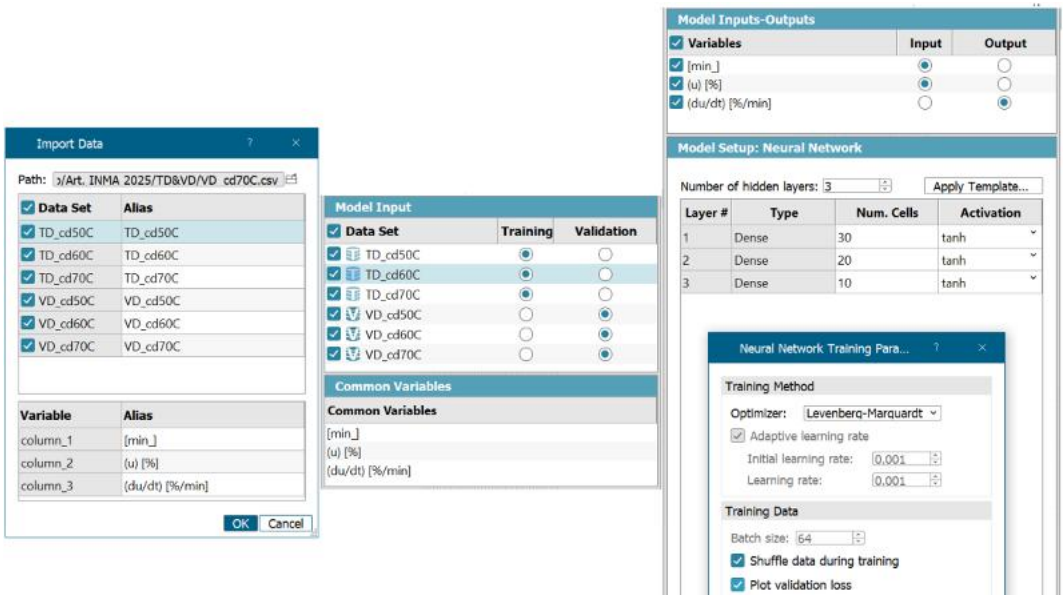

Fig. 2 - Software interface for ANN configuration, data partitioning, and training parameters in convective drying process optimization

Left: Data import and variable mapping for training (TD) and validation (VD) datasets (center) across 50°C, 60°C, and 70°C drying conditions. Right: ANN architecture (3 hidden layers with 30, 20, and 10 neurons) and input-output configuration (drying time and moisture content as inputs; drying rate as output). Right: Training parameters, including Levenberg-Marquardt optimization, adaptive learning rate, and batch size settings.

Training methodology and validation. The network was trained using the Levenberg-Marquardt (LM) optimizer, a robust algorithm well-suited for small-to-medium-sized datasets due to its rapid convergence and low computational overhead. Key training parameters included: adaptive learning rate (initial value: 0.001), dynamically adjusted during training to stabilize convergence; batch size: 64 samples, selected to balance gradient accuracy and training speed; data shuffling prior to each epoch to eliminate sequence bias; validation loss monitoring to prevent overfitting (Fig. 2, right panel).

ANN model design. The choice of du/dt as the primary output variable reflects its critical role in process optimization, as it directly quantifies the rate of moisture removal, a key metric for energy efficiency and product quality preservation. By focusing on this parameter, the ANN enables real-time prediction of drying dynamics, facilitating the identification of optimal operating parameters (e.g., temperature, airflow) that minimize energy consumption while avoiding thermal degradation of the fruit. The inclusion of drying time and moisture content as inputs ensures the model accounts for both temporal and state-dependent effects, providing a comprehensive representation of the drying process.

RESULTS

The experimental results of the convective drying process kinetics of pear slices across three temperature regimes (50°C, 60°C, and 70°C), establishing the empirical foundation for the artificial neural network model development. These systematic measurements capture the time-dependent moisture removal behavior and drying rate dynamics essential for understanding the physical mechanisms governing the drying

process. The data reveals clear temperature-dependent patterns that demonstrate the trade-off between processing speed and potential quality implications, providing critical insights for subsequent optimization of the drying parameters. This characterization serves as the basis for training the ANN model that will ultimately identify the optimal drying conditions while preserving product quality.

Fig. 3 illustrate the temperature-dependent moisture content evolution during convective drying, with 70°C achieving 14.5% moisture content at 180 minutes compared to 260 minutes at 50°C. The sigmoidal drying curves (with 3 slopes) reveal the characteristic heating period followed by active drying and approach to equilibrium moisture content, with higher temperatures accelerating the entire process.

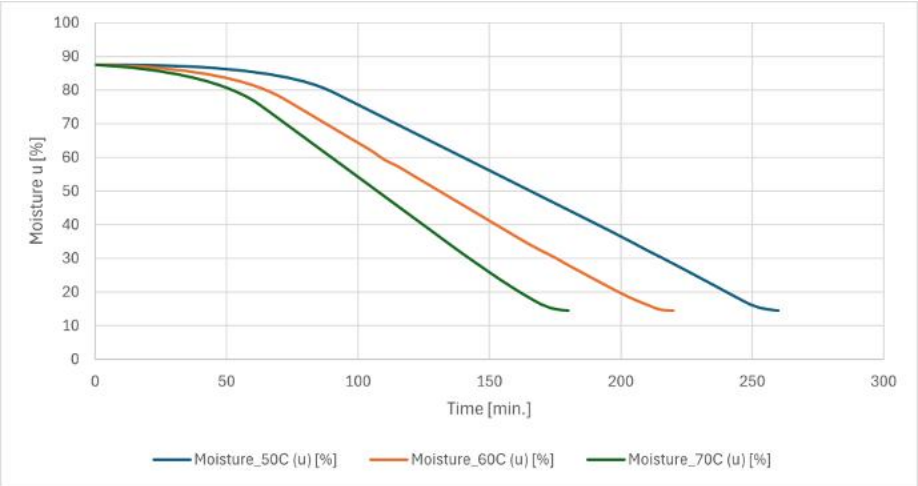

Fig. 3 - Moisture content evolution during convection drying of pear slices at 50°C, 60°C, and 70°C.

Fig. 4 presents the drying rate profiles showing temperature-dependent maximum rates of 0.57 %/min (70°C), 0.46 %/min (60°C), and 0.40 %/min (50°C), with first peak drying rate occurring progressively later as temperature decreases (70 minutes at 70°C, 75 minutes at 60°C and 95 minutes at 50°C). The curves exhibit the expected pattern of initial rate increase followed by a sharp decline, with higher temperatures reaching their maximum drying rates earlier and showing more pronounced falling rate periods. This information is essential for identifying the transition points between drying phases and optimizing energy input timing during the process.

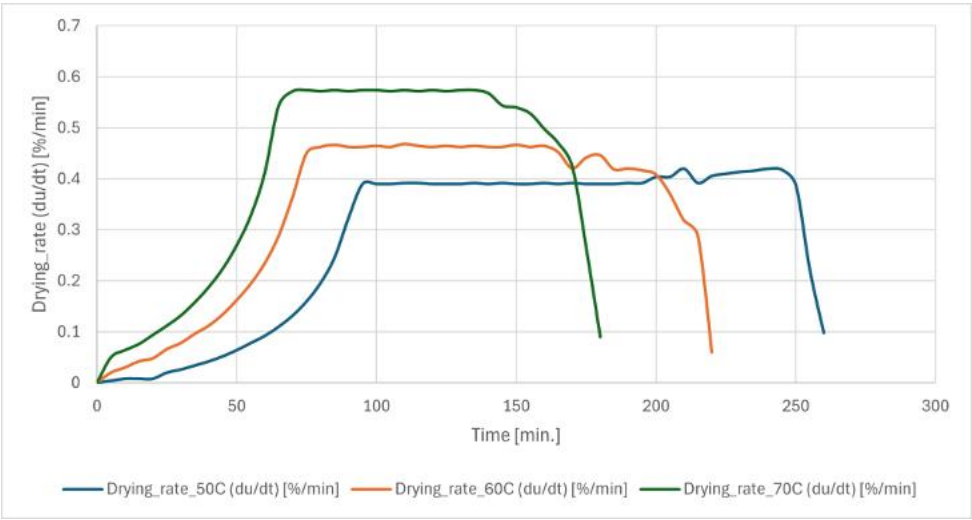

Fig. 4 - Drying rate profiles during convection drying of pear slices at 50°C, 60°C, and 70°C

Fig. 5 reveals the relationship between moisture content and drying rate, showing that maximum drying rates occur at different moisture contents: 74% (70°C), 76% (60°C), and 77% (50°C), with higher temperatures consistently demonstrating greater drying rates at equivalent moisture levels. The approximately linear decline during the falling rate period confirms diffusion-controlled drying behavior, with the steeper slopes at higher temperatures indicating enhanced moisture diffusivity. This relationship provides the critical basis for modeling drying kinetics and determining optimal operating parameters that balance process efficiency with product quality requirements.

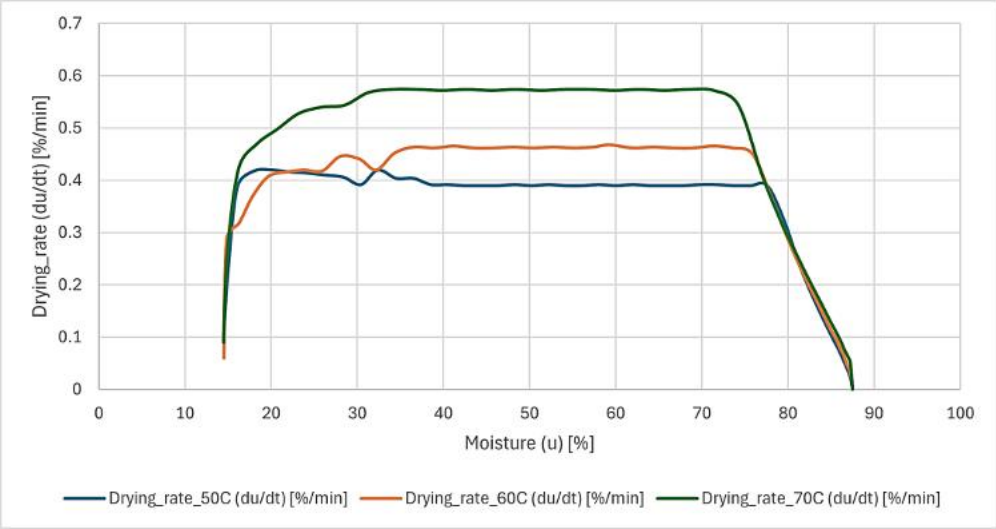

Fig. 5 - Relationship between moisture content and drying rate during convection drying of pear slices

The three trays presented in Fig. 6 display the final product appearance after completing the convective drying process at different temperature conditions, with the left tray representing the 50°C treatment, the middle tray the 60°C treatment, and the right tray the 70°C treatment. Visual examination reveals distinct but subtle differences in color, texture, and structural integrity among the samples, demonstrating the critical relationship between drying temperature and product quality. The 70°C treatment shows the most pronounced browning and edge curling, with some slices exhibiting significant shrinkage and deformation due to rapid moisture removal. The 50°C treatment maintains the most uniform light color and structural integrity, preserving the original shape of the pear slices with minimal deformation and shrinkage. The 60°C treatment demonstrates an intermediate quality profile, showing moderate color change while maintaining reasonable structural integrity. These visual differences align with the drying kinetics data presented in Figures 3-5, where higher temperatures accelerated moisture removal but potentially at the cost of quality degradation. The observed variations underscore the importance of temperature optimization for balancing process efficiency with product quality attributes such as color retention, texture, and visual appearance - factors that directly impact consumer acceptance and market value.

Fig. 6 - Final product quality of dried pear slices following convective drying at 50°C, 60°C, and 70°C

Fig. 7 presents the comprehensive performance evaluation of the trained ANN, demonstrating its capability to accurately predict drying behavior and establish a foundation for process optimization. Fig. 7 presents a comprehensive assessment of the ANN's predictive capability for drying rate (du/dt) in pear slice convective drying at 60°C. The top-left plot demonstrates successful training convergence, with training and validation losses both stabilizing below or around 0.01 after approximately 1,000 epochs, indicating effective learning without significant overfitting. The top-right plot reveals exceptional correlation between predicted and reference drying rate values ($R^2 > 0.99$), confirming the model's high prediction accuracy for this critical process parameter.

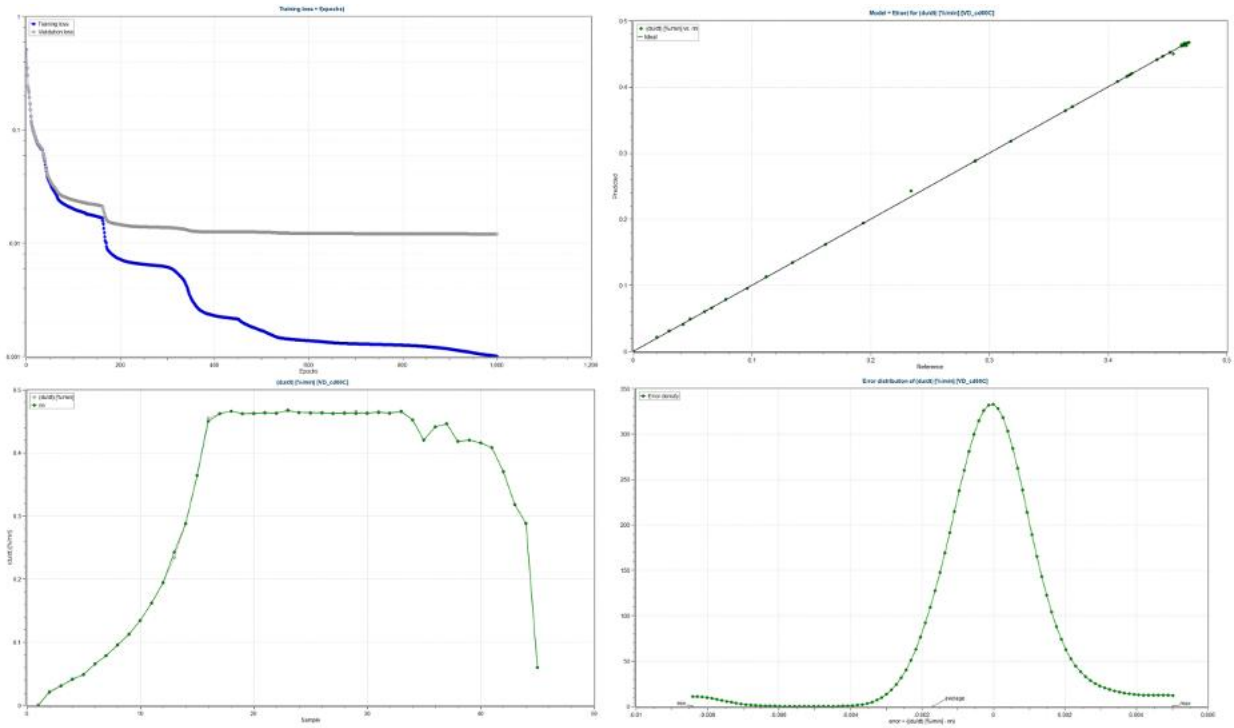

Fig. 7 - Performance evaluation of the artificial neural network model for predicting moisture loss rate during convective drying of pear slices

The bottom-left plot (from Fig. 7) illustrates how the ANN successfully captures the characteristic drying rate pattern, including the initial increase to maximum rate (reaching approximately 0.46-0.47 %/min) followed by the gradual decline during the falling rate period. The bottom-right error distribution follows a near-normal curve centered at zero with minimal deviation (average error < 0.002 %/min), demonstrating the model's reliability and absence of systematic bias. This high-precision drying rate prediction capability directly supports the ANN's application in dynamically adjusting drying parameters based on current process conditions, potentially optimizing energy consumption while maintaining product quality. As noted in the experimental results, understanding these drying rate patterns is crucial for identifying the critical moisture content where the drying rate begins to decline significantly, which is essential for determining when internal moisture diffusion becomes the rate-limiting step in the process.

Fig. 8. presents the detailed configuration and performance metrics of the artificial neural network developed for predicting drying rate (du/dt) in the convective drying of pear slices. The model demonstrates exceptional performance with a training fidelity of 99.881% and validation fidelity of 98.823%, confirming its robustness and generalization capability across the three temperature conditions. The high validation fidelity (98.823%) indicates the model's reliability in predicting the critical drying rate parameter, which is essential for understanding the transition from constant rate period to falling rate period at different temperatures. This predictive capability directly supports the optimization framework by enabling precise determination of when internal moisture diffusion becomes the rate-limiting step, allowing processors to dynamically adjust drying parameters for optimal energy efficiency while maintaining product quality.

Fig. 8 - Neural network architecture and performance metrics for drying rate prediction model

CONCLUSIONS

The present study successfully developed and validated an artificial neural network (ANN) model for optimizing the convective drying process of pear slices, demonstrating exceptional predictive capability for drying rate dynamics with 98.823% validation fidelity. The model accurately captured the complex nonlinear relationships between moisture content, drying time, and drying rate across three temperature regimes (50°C, 60°C, and 70°C), providing valuable insights into the drying kinetics of pear slices. Experimental results revealed that higher temperatures significantly accelerated the drying process, with 70°C achieving target moisture content (14.5 %) in 180 minutes compared to 260 minutes at 50°C, while also producing higher maximum drying rates (0.57 %/min at 70°C versus 0.40 %/min at 50°C).

The ANN model successfully identified the critical moisture content thresholds (74% at 70°C, 76% at 60°C, and 77% at 50°C) where the drying rate begins to decline significantly, enabling precise determination of when internal moisture diffusion becomes the rate-limiting step. This capability is essential for implementing adaptive control strategies that dynamically adjust drying parameters to balance energy efficiency with product quality preservation.

This research demonstrates that artificial neural networks represent a powerful tool for optimizing convective drying processes in the food industry, offering substantial advantages over traditional empirical models. The developed ANN model provides processors with the ability to predict drying behavior accurately, identify optimal operating conditions, and minimize energy consumption while maintaining critical quality parameters.

Future work should focus on expanding the model to incorporate additional quality indicators (such as color change, texture, and nutrient retention) and testing its applicability across different fruit varieties and drying configurations. The integration of such models into industrial control systems presents a promising pathway toward more intelligent, adaptive, and sustainable food processing operations that simultaneously optimize energy efficiency and product quality.

ACKNOWLEDGEMENT

The experimental data presented in this article were obtained during the project MC 336/30.11.2024 – Mobilities, code PN-IV-P2-2.2-MC-2024-0905, during the period 20.11.2024 - 29.11.2024, project whose theme was "Choosing the optimal technical drying parameters in the fruit dehydration process". This work was supported by a grant of the Ministry of Research, Innovation and Digitization (National Research Authority), CCCDI - UEFISCDI, project number PN-IV-P7-7.1-PTE-2024-0039, within PNCDI IV.

Keywords: *Falling-film evaporation, molasses ethanol wastewater, VOF method, Lee phase-change model, Liquid film thickness, Heat transfer coefficient*

ABSTRACT

To investigate the concentration of molasses ethanol wastewater, a two-dimensional numerical model of falling-film evaporation over horizontal tubes was developed. The model used the Volume of Fluid (VOF) method to capture the liquid-gas interface and was coupled with the Lee phase-change model. The model was validated by comparing the predicted liquid-film thickness and average heat-transfer coefficient with experimental data reported in the literature. The validated model was then used to systematically investigate the effects of spray density (0.10 ~ 0.30 kg/(m·s)) and heat-transfer temperature difference (2 ~ 8 °C) on the falling-film flow and evaporation performance of molasses ethanol wastewater. The results showed that the liquid-film thickness initially decreased and subsequently increased along the circumferential direction, reaching a minimum within the angular range of 90° ~ 120°. Increasing the spray density produced a thicker liquid film; nevertheless, the average heat-transfer coefficient increased monotonically by 23.0% ~ 27.2%, whereas the mass-transfer rate decreased by 19.3% ~ 25.1%. Increasing the heat-transfer temperature difference increased both the average heat-transfer coefficient and the mass-transfer rate. When the temperature difference increased from 2 to 8 °C, the mass-transfer rate increased 2.84 ~ 3.07-fold, and its effect on evaporation performance was substantially greater than that of spray density. Therefore, where operating conditions permit, a lower spray density combined with a higher heat-transfer temperature difference is recommended for the falling-film evaporative concentration of molasses ethanol wastewater.

摘要

为了处理糖蜜酒精废液的浓缩问题，基于流体体积法（VOF）和 Lee 相变模型，针对水平管外的降膜蒸发过程建立了一个二维数值模型。首先，通过将模拟得到的液膜厚度和平均传热系数与文献实验数据对比，验证了模型的可靠性。随后，利用已验证的模型系统研究了喷淋密度（0.10 ~ 0.30 kg/(m·s)）和传热温差（2~8 ℃）对糖蜜酒精废液降膜流动与蒸发性能的影响。结果表明：液膜厚度沿周向先减小后增大，在 90°~120°的圆周角范围内达到最小值。喷淋密度增大使液膜变厚，但平均传热系数单调上升（增幅为 23.0% ~ 27.2%），而质量传递速率则下降了 19.3% ~ 25.1%。提高传热温差同时增大了平均传热系数和质量传递速率。值得注意的是，当温差从 2℃升至 8 ℃时，质量传递速率增大了 2.84 ~ 3.07 倍，其对蒸发效率的影响远超喷雾密度。因此，建议在糖蜜酒厂废水的降膜蒸发浓缩过程中，在条件允许的情况下，可以采用低喷雾密度与高温差相结合的操作策略。

INTRODUCTION

Molasses ethanol wastewater is a high-strength organic effluent discharged during the fermentation of sugarcane molasses for alcohol production.

It is principally characterized by exceedingly high chemical oxygen demand, pronounced viscosity, intense coloration, and an abundance of suspended solids and dissolved organic matter (*Li et al., 2022*).

Liang Wang and Mingzhe Hu contributed equally to this work

In China, the cane molasses alcohol industry generates millions of tons of such wastewater annually, which, if discharged directly without adequate treatment, would provoke severe ecological consequences, such as eutrophication of water bodies and soil acidification accompanied by compaction, while concurrently representing a colossal waste of organic resources (*Chowdhary et al., 2018*). Among the various concentration techniques, falling-film evaporation is regarded as a comparatively definitive treatment strategy, owing to its small driving temperature difference, high heat transfer coefficient, compact equipment footprint, and compatibility with low-temperature heat sources (*Wang et al., 2026*).

A considerable body of research has examined the distribution of liquid film thickness during the falling-film process (*Wang et al., 2026*). Although increasing the tube spacing promotes falling-film evaporation, an excessively large spacing adversely affected the overall volume of the falling-film evaporator; therefore, elucidating the influence of tube spacing on film thickness could contribute to enhancing evaporator compactness while preserving its thermal performance (*Tahir et al., 2019*). *Ibrahim et al.* (*2020*) reported that, at a Reynolds number of 574, increasing the tube spacing from 10 mm to 40 mm reduced the film thickness by 26%. Moreover, investigations have revealed that the liquid film was circumferentially non-uniform. Nusselt (1916) indicated that the film thickness is symmetric about the circumferential angle of 90° and followed a trend of initially decreasing and subsequently increasing along the circumferential direction. For circumferential angles between 0° and 90°, the resultant tangential component of gravity consistently outweighed the viscous force, causing the film flow velocity to rise and the film thickness to diminish with increasing circumferential angle (*Qiu et al., 2015*). As the circumferential angle further increased, the viscous force progressively intensified, whereas the combined contribution of the tangential gravity component and the inertial force gradually diminished (*Zhao et al., 2018*). Within the circumferential angle range of 90° to 120°, the tangential gravity component, the inertial force, and the viscous force attained mutual equilibrium. Under these conditions, the circumferential film thickness reached its minimum (*Zhang et al., 2020*).

Relevant scholars have noted that, in horizontal-tube falling-film evaporators, the falling-film heat transfer coefficient is merely 50%–80% of the in-tube condensation heat transfer coefficient (*Dai et al., 2022*); consequently, augmenting the falling-film heat transfer coefficient constitutes the key to intensifying falling-film evaporator performance. Under convection-dominated regimes, three distinct academic viewpoints have emerged concerning the effect of spray density on horizontal-tube falling-film evaporation (*Ubara et al., 2021*): (1) The heat transfer coefficient increased with rising spray density (*Qi et al., 2010*). For example, *Chen et al. (1997)* experimentally demonstrated that the average Nusselt number increased with the Reynolds number over the range 800 < Re < 4000. (2) As the spray density increased, the heat transfer coefficient initially decreased and then increased (*Su and Ouyang, 2019*). (3) No clear correlation was observed between the heat-transfer coefficient and spray density (*Gong, 2017*).

Considerable research has also investigated the effects of fluid properties on heat transfer during falling-film evaporation. However, most studies have focused on applications such as seawater desalination, alcohol concentration, refrigeration, and air conditioning, and have primarily measured falling-film heat-transfer coefficients for fluids such as pure water *(Liu et al., 2021)*, brine *(Gong et al., 2016)*, and halocarbon refrigerants *(Jin et al., 2019)*. Consequently, systematic investigations on high-viscosity, complex organic fluids such as molasses distillery wastewater remain scarce, and their falling-film flow and heat transfer behaviors are poorly understood. To fill this knowledge gap, the present study adopted molasses ethanol wastewater as the working fluid. The Volume of Fluid (VOF) method was introduced to track the gas-liquid interface and was coupled with the Lee evaporation phase-change model, thereby establishing a mathematical framework for the falling-film evaporation of molasses ethanol wastewater. The reliability of the numerical model was verified by comparing the predicted liquid film thickness and heat transfer coefficient with experimental data reported in the published literature (*Jia, 2025; Parken et al., 1990*), rather than through experiments conducted in the present study. The local distributions of the liquid film thickness and the heat transfer coefficient during the evaporation of this high-viscosity fluid were analyzed, and the variation patterns of the Nusselt number together with local and average heat transfer coefficients were systematically examined. The findings were anticipated to provide both a theoretical basis and a numerical predictive tool for the design of falling-film evaporators intended for molasses ethanol wastewater, while simultaneously enriching the numerical research methodology applicable to the evaporation and concentration of high-viscosity, complex liquid feeds.

MATERIAL AND METHODS

Physical model and meshing

Molasses ethanol wastewater was uniformly sprayed onto the outer surface of a horizontal tube through a liquid distributor, forming a thin and even liquid film. As the film spreads, it absorbs the latent heat released by the condensation of steam inside the horizontal tube and subsequently evaporates (*Jia, 2025*). Due to the symmetry of the horizontal tube structure, only the half-tube region between adjacent dropping points is modeled to reduce the computational cost. Considering that the two-dimensional model requires only 1.7% of the mesh count of a three-dimensional model to accurately capture the gas-liquid interface distribution, the two-dimensional model is adopted to simulate the falling-film flow process. The geometric dimensions of the physical model depicted in Fig. 1 were as follows: the diameter of the liquid distribution opening at the top was 1 mm, and the distance from this opening to the first horizontal tube was 10 mm. To eliminate the influence of the distributor height on the falling-film behavior of the molasses ethanol wastewater, the upper one of the two horizontal tubes (with a diameter of 25.4 mm) was designated as the distribution tube, while the lower one served as the object of simulation.

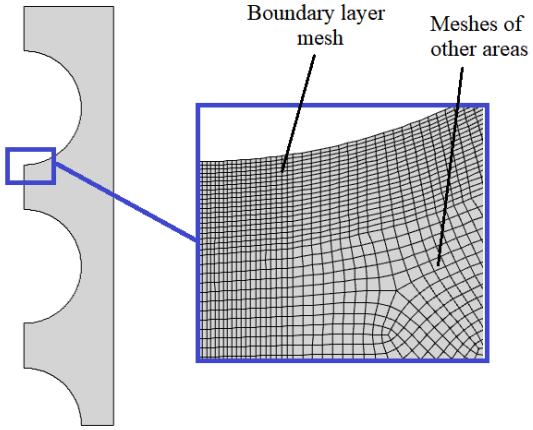

Fig. 1 - Physical model and meshing

As illustrated in Fig. 1, the physical model featured a relatively simple geometry, which was well suited for high-precision structured grids. As the contour of the molasses ethanol wastewater needed to be captured, boundary-layer grids were refined in the near-wall region of the horizontal tubes. The boundary layer comprised 20 layers; the thickness of the first layer was 0.2 mm, and each subsequent layer was 1.15 times as thick as the preceding one. The grid size in the remaining regions was set to 4 mm.

Governing equations

Before establishing the mathematical model, the following assumptions were made regarding the falling-film evaporation of molasses ethanol wastewater *(Wang, 2025)*: (1) the liquid film completely wets the tube surface; (2) only liquid-film flow over the outer surface of the horizontal tube is considered, and the tube wall thickness is neglected; (3) the tube wall temperature is uniform; and (4) the temperature dependence of the thermophysical properties of the molasses ethanol wastewater is neglected.

A numerical model of the falling-film evaporation process was established within an Eulerian framework using the Volume of Fluid (VOF) method. The liquid and gas phases were treated as a single fluid mixture sharing common velocity and pressure fields, and the liquid-gas interface was captured using the phase-volume fraction *(Jia et al., 2026)*.

The transport equation for the liquid-phase volume fraction (α_l), used to capture the liquid-gas interface is expressed as:

$$\frac{\partial \alpha_l}{\partial t} + \nabla \cdot \left(\alpha_l \vec{u}\right) = -\frac{\dot{m}}{\rho_l} \tag{1}$$

The vapor-phase volume fraction (α_v) is given by:

$$\alpha_v = 1 - \alpha_l \tag{2}$$

where: t is the time, s; $\vec{u}$ is the velocity vector, m/s; ρ_l is the density of the molasses ethanol wastewater, kg/m^3; $\dot{m}$ is the volumetric mass-source term associated with evaporation, (kg/(m·s)).

The mixture continuity equation is obtained by summing the mass-conservation equations for the liquid and gas phases *(Jia et al., 2026)*:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \left(\rho \vec{u}\right) = 0 \tag{3}$$

The density of the fluid mixture (ρ) is calculated as follows:

$$\rho = \alpha_l \rho_l + \alpha_v \rho_v \tag{4}$$

The momentum equation used in the model is given as follows (*Wang, 2025*):

$$\frac{\partial \left(\rho \vec{u}\right)}{\partial t} + \nabla \cdot \left(\rho \vec{u}\vec{u}\right) = -\nabla p + \nabla \cdot \left[\mu\left(\nabla \vec{u} + (\nabla u)^T\right)\right] + \rho g + F_\sigma \tag{5}$$

where: p is the pressure, Pa; g is the acceleration due to gravity, m/s^2; μ is the dynamic viscosity of the fluid mixture, Pa·s; F_σ is the surface-tension force per unit volume, N/m^3.

The dynamic viscosity of the fluid mixture is calculated using Eq. (6).

$$\mu = \alpha_l u_l + \alpha_v \mu_v \tag{6}$$

The energy equation is expressed as follows (*Jia et al., 2026*):

$$\frac{\partial \left(\rho c_p T\right)}{\partial t} + \nabla \cdot \left(\rho c_p \vec{u} T\right) = \nabla \cdot \left(\lambda \nabla T\right) - \dot{m} h_v \tag{7}$$

where: c_p is the specific heat capacity of the fluid mixture, J/(kg·K); T is the temperature, K; λ is the thermal conductivity of the fluid mixture, W/(m^2·K); $\dot{m}$ is the mass-transfer rate per unit volume (kg/(m^3·s)); h_v is the latent heat of vaporization, (J/kg).

c_p and μ are calculated using Eqs. (8) and (9).

$$c_p = \alpha_l c_{p,l} + \alpha_v c_{p,v} \tag{8}$$

The phase-change mass-source term is determined using the Lee model:

$$\dot{m} = r_e \alpha_l \rho_l \frac{T - T_{sat}}{T_{sat}} \tag{9}$$

where: r_e is the evaporation relaxation factor, s^{-1}; T_{sat} is the saturation temperature of the molasses ethanol wastewater, ℃;

F_σ in Eq. (5) is calculated using the continuum surface force model proposed by Brackbill (*Yang et al., 2024*):

$$F_\sigma = \sigma \left[\nabla \cdot \left(\frac{\nabla \alpha_l}{|\nabla \alpha_l|}\right)\right] \tag{10}$$

where σ is the surface-tension coefficient at the liquid-gas interface, N/m. The effect of the wall contact angle is incorporated by correcting the interface normal vector near the wall.

The thermophysical properties used in the governing equations are presented in Table 1.

Table 1

Thermal properties parameters

Name	Density / kg/m3	Specific heat capacity/ J/(kg·K)	Thermal conductivity W/(m·K)	Dynamic viscosity / Pa·s
Molasses ethanol wastewater	1096.7	3709	0.58	0.00851
Vapor	0.5542	2014	0.0261	1.34×10-5

Boundary conditions and Simulation Settings

The liquid distribution inlet on the upper side of the horizontal tube is set as a velocity inlet boundary condition, with the velocity set to 0.23 ~ 0.137 m/s to ensure that the spray density remains within the range of 0.010 ~ 0.030 kg/(m·s). The bottom of the horizontal tube is set as a pressure outlet boundary condition with a reference pressure of 0 Pa. The horizontal tube is set as a wall boundary condition, with a constant temperature of 62℃, 64℃, 66℃, and 68℃, respectively, and a contact angle of 60°.

Based on the spray density, the calculated Reynolds number indicates that the investigated Re ranges from 2 to 14, which is far below the turbulent threshold; therefore, in this study, the molasses alcohol waste liquid is considered to exhibit laminar flow.

The numerical simulation is performed using ANSYS Fluent 18.0 software. The pressure and velocity are solved using the Pressure-Implicit with Splitting of Operators (PISO) algorithm. The pressure term is spatially discretized using the PRESTO! scheme, while both the temporal term and the momentum term are discretized using the second-order upwind scheme. In the dynamic time-stepping settings, the maximum Courant number is 0.25.

Evaluations

In falling-film evaporation, the film thickness constituted the dominant thermal resistance during the evaporation process. The degree of uniformity in the film thickness distribution markedly influenced the evaporation rate of the descending liquid film; therefore, it was imperative to examine the film thickness of molasses ethanol wastewater during falling-film evaporation.

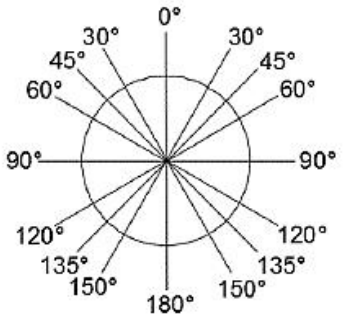

Fig. 2 - Local film thickness measurement method

As illustrated in Fig. 2, with the center of the horizontal tube taken as the origin and the vertically upward direction designated as 0°, straight lines were drawn at circumferential angles of 15°, 30°, 45°, 60°, 75°, 90°, 105°, 120°, 135°, and 150°. The length occupied by the liquid phase along each of these ten lines was extracted directly from Fluent, and this length was defined as the film thickness at the corresponding circumferential angle.

The average heat transfer coefficient served as a pivotal indicator for quantifying the heat transfer rate during the falling-film evaporation of molasses ethanol wastewater, and was determined as follows:

$$h_{ave} = \frac{q}{\Delta T} \tag{11}$$

where: h_{ave} was the average heat transfer coefficient, W/(m²·K); q was heat flux of the horizontal tube, W/m²; ΔT was the temperature difference, ℃.

RESULTS AND DISCUSSIONS

Verification

To ensure the relevance of the validation, the experimental cases cited from the literature were selected to closely match the key physical features of the present simulation, including the horizontal tube geometry (D = 25.4 mm), laminar falling-film flow regime, and constant wall-temperature thermal boundary condition. Although the working fluid in the referenced experiments was pure water, the present study focuses on molasses ethanol wastewater, the two fluids have comparable density and surface tension, though the viscosity of the wastewater is moderately higher. This viscosity difference is explicitly accounted for in the present model through the mixture property equations (Eq. (6)). Therefore, the validation results provide meaningful support for the reliability of the present model. Fig.3 presented a comparison between the simulated local film thickness and the experimental ones documented in the literature (*Jia, 2025*). It is evident from Fig.3 that the simulated film thickness conformed to the literature values, both exhibiting an initial thinning followed by a subsequent thickening, with a relative deviation of less than 5%. The falling-film evaporation process constituted a complex heat and mass transfer phenomenon characterized by dynamic coupling between the liquid and gas phases. To further substantiate the validity of the established model, it was necessary to verify its heat transfer characteristics.

Fig. 4 presents the simulated heat transfer coefficient for a smooth tube with the experimental data of *Parken et al.* (*1990*). As clearly observed from Fig. 4, the simulated heat transfer coefficient was in favorable agreement with the values reported in the literature, the relative deviation being below 5%. A synthesis of the analyses in Fig. 3 and Fig. 4 revealed that the developed mathematical model was capable of effectively capturing the physical trends and thermal performance characteristics of molasses ethanol wastewater during falling-film evaporation. It should be noted that, since the validation was performed against external literature data rather than experimental results obtained from the specific molasses ethanol wastewater under identical conditions, the numerical predictions of absolute values may bear inherent uncertainties. Nevertheless, the model demonstrates high reliability in capturing the underlying physical mechanisms and performance trends.

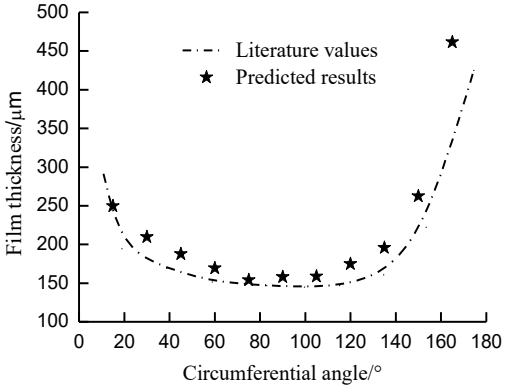

Fig. 3 - Comparison of the reported and simulated film thickness

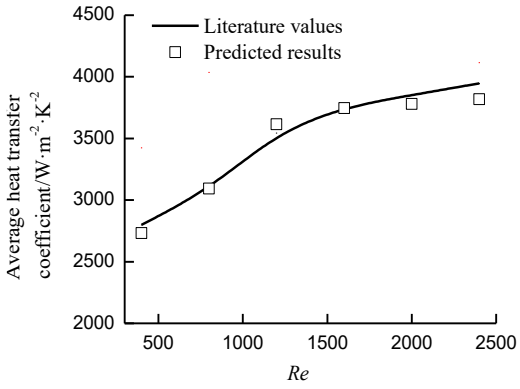

Fig. 4 - Comparison of the reported and simulated average heat transfer coefficient

To ensure the reliability of the numerical results, a systematic mesh-independence study was conducted before the main simulations. Three structured grids were generated with different refinement levels: a coarse mesh (13475 cells), a medium mesh (26669 cells), and a fine mesh (39863 cells). The average heat transfer coefficient and the minimum film thickness at 105° were selected as the evaluation criteria, using a typical operating condition (Γ = 0.20 kg/(m·s), ΔT = 6 °C). The average falling-film heat transfer coefficient decreased from 1724.84 W/(m²·K) for the medium mesh to 1703.72 W/(m²·K) for the finer mesh, with a reduction of only 1.22%. Therefore, the medium mesh can be considered an appropriate meshing scheme.

The effect of spray density

Fig. 5 shows the variation in local liquid film thickness with circumferential angle at spray densities ranging from 0.10 to 0.25 kg/(m·s). Despite differences in spray density, the circumferential distributions of the local film thickness exhibited similar trends. Specifically, as the circumferential angle increased, the film thickness initially decreased, attained its minimum within the circumferential angle of 90° ~ 120°, and subsequently increased.

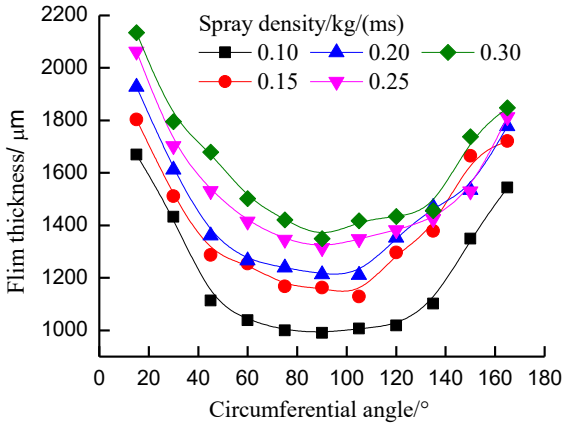

Fig. 5 - Local liquid film thickness at different spray densities

The change behavior of the local film thickness with respect to the circumferential angle conformed to the theoretical prediction derived from Nusselt's classical analysis. Furthermore, it was evident that the local film thickness progressively increased with rising spray density.

The reason was that under gravity, to maintain a steady laminar falling-film, the liquid film had to enlarge its cross-sectional area to handle a greater volumetric flow. An examination of the extent of this influence revealed that when the spray density was augmented from 0.10 to 0.15 kg/(m·s), the film thickness thickened by 16.66%, whereas an increase from 0.25 to 0.30 kg/(m·s) resulted in a mere 5.39% thickening. In accordance with the classical Nusselt laminar falling-film theory, the film thickness scaled with the spray density to the one-third power. Hence, when the spray density already resided within a high baseline range, an identical absolute increment (e.g., 0.05 kg/(m·s)) inevitably induced a pronounced attenuation in the relative increase of the film thickness.

The effect of spray density on the average heat-transfer coefficient is shown in Fig. 6. The average heat transfer coefficient increased monotonically as the spray density increased from 0.10 to 0.30 kg/(m·s), with a relative increase of 23.0% ~ 27.2%. When considered together with the results in Fig. 5, these findings indicate that although increasing the spray density produced a thicker liquid film and consequently increased conductive thermal resistance, the accompanying increase in flow rate raised the film velocity. This enhanced mixing within the liquid film and intensified interfacial disturbances, thereby reducing the thermal-boundary-layer resistance. These results are consistent with those of *Chen et al. (1997)*, who reported an increase in the Nusselt number with increasing film Reynolds number.

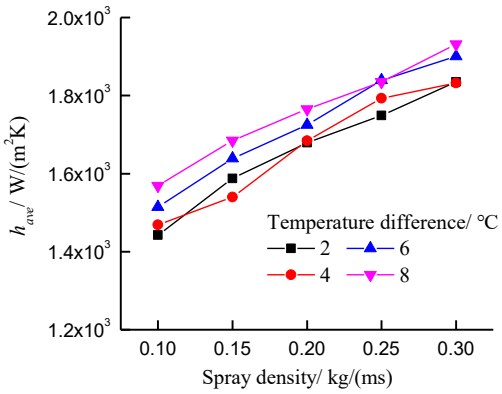

Fig. 6 - Average heat transfer coefficient with spray densities

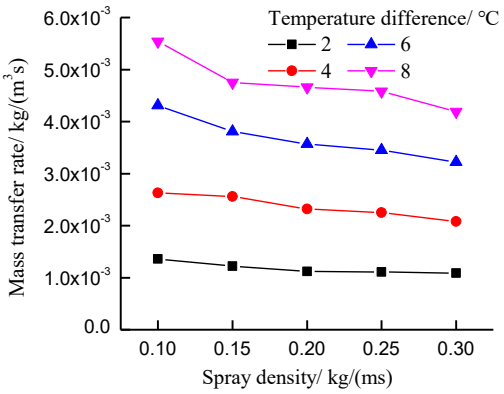

Fig. 7 - Mass volume rate with spray densities

Fig. 7 shows the variation in mass transfer rate with spray density during the falling-film evaporation of molasses ethanol wastewater. The mass transfer rate decreased progressively as the spray density increased. When the spray density increased from 0.10 to 0.30 kg/(m·s), the mass-transfer rate decreased by 19.3% ~ 25.1%. Although the higher flow rate enhanced convective heat transfer, as shown in Fig. 6, the corresponding increase in liquid-film thickness (Fig. 5) increased the heat-transfer distance between the tube wall and the liquid-gas interface. Consequently, the heat supplied at the wall was distributed over a larger liquid volume, reducing the heat available for evaporation per unit volume and thereby decreasing the volumetric mass-transfer rate. Therefore, a relatively low spray density is recommended for enhancing evaporation, provided that complete and stable wetting of the tube surface is maintained.

The effect of temperature difference

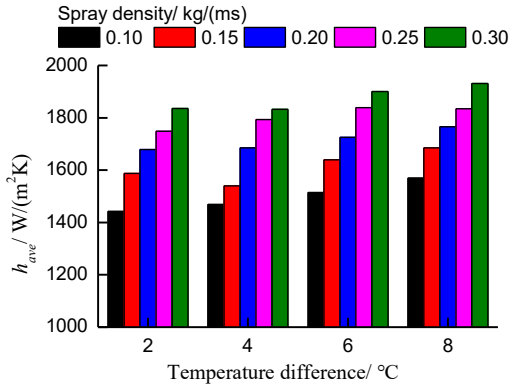

Fig. 8 - Average heat transfer coefficient with temperature difference

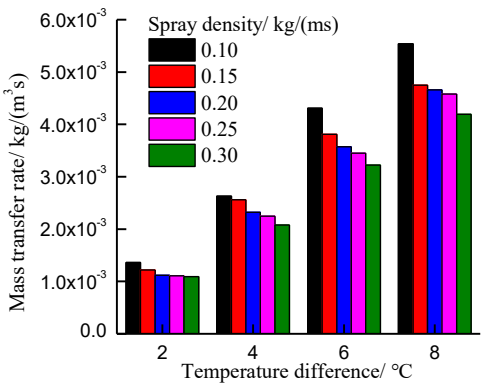

Fig. 9 - Mass volume rate with temperature difference

In addition to spray density, the heat-transfer temperature difference, which is the primary driving force for heat transfer and phase change during falling-film evaporation, requires systematic investigation. Figs. 8 and 9 show the variations in the average heat-transfer coefficient and mass-transfer rate, respectively, during the falling-film evaporation of molasses ethanol wastewater at temperature differences of 2, 4, 6, and 8 °C.

As shown in Fig. 8, the average heat-transfer coefficient increased with increasing temperature difference. At a spray density of 0.10 kg/(m·s), increasing the temperature difference from 2 to 8 °C increased the average heat-transfer coefficient from 1,442.48 to 1,569.14 W/(m²·K), corresponding to a relative increase of 8.8%. The larger temperature difference increased the wall-normal temperature gradient and intensified heat transfer from the inner region of the liquid film toward the liquid–gas interface. The resulting enhancement of evaporation and interfacial disturbance further promoted heat transfer through the liquid film.

As shown in Fig. 9, at a spray density of 0.10 kg/(m·s), increasing the temperature difference from 2 to 8 °C increased the mass-transfer rate from 1.36×10^{-3} kg/(m³·s) to 5.54×10^{-3} kg/(m³·s), with an amplification by a factor of 3.07. Even at the higher spray density of 0.30 kg/(m·s), at which the lowest mass-transfer rates were obtained, the value increased from 1.09×10^{-3} to 4.19×10^{-3} kg/(m³·s), registering a 2.84-fold increase. According to the Lee phase-change model (Eq. (9)), the phase-change mass-source term is positively related to the degree of superheat. As the temperature difference increased, the heat flux from the tube wall to the liquid film increased, allowing the wastewater near the liquid-gas interface to absorb sufficient latent heat and undergo evaporation. These results demonstrate that, within the investigated parameter ranges, increasing the heat-transfer temperature difference was more effective than varying the spray density in enhancing the instantaneous water-removal rate.

To quantitatively compare the relative effects of the two operating parameters, a normalized sensitivity index was defined as $S = (\varphi_{max} - \varphi_{min})/\varphi$. Over the investigated parameter ranges, $S_{\Delta T} = 1.24$, whereas $S_{\Gamma} = 0.11$, indicating that the effect of the heat-transfer temperature difference was approximately 11 times greater than that of spray density. This difference arises because the phase-change mass-transfer rate is directly related to the degree of superheat, whereas spray density affects mass transfer indirectly by altering liquid-film thickness, flow characteristics, and heat-transfer resistance.

CONCLUSIONS

A two-dimensional numerical model of the falling-film evaporation of molasses ethanol wastewater over the outer surface of a horizontal tube was developed using the Volume of Fluid (VOF) method coupled with the Lee phase-change model. The effects of spray density and heat-transfer temperature difference on heat- and mass-transfer performance were systematically investigated. The main conclusions are as follows:

(1) The developed model satisfactorily predicted the liquid-film thickness distribution and heat-transfer characteristics. The simulation results agreed well with experimental data reported in the literature, with relative deviations of less than 5%.

(2) The circumferential distribution of liquid-film thickness was consistent with classical Nusselt theory. As the circumferential angle increased, the film initially became thinner and subsequently thickened, reaching its minimum thickness within the angular range of 90° ~ 120°. Increasing the spray density increased the local film thickness. However, because laminar falling-film thickness is proportional to the cube root of spray density, the rate of film thickening gradually decreased as spray density increased.

(3) Within the spray-density range of 0.10 ~ 0.30 kg/(m·s), the average heat-transfer coefficient increased monotonically with spray density. By contrast, the volumetric mass-transfer rate decreased because the thicker liquid film distributed the supplied heat over a larger liquid volume. Increasing the heat-transfer temperature difference enhanced the thermal driving force, resulting in a moderate increase in the average heat-transfer coefficient and a pronounced increase in the mass-transfer rate. Sensitivity analysis indicated that the effect of temperature difference on the mass-transfer rate was more than one order of magnitude greater than that of spray density.

(4) Within the investigated ranges of spray density (0.10 ~ 0.30 kg/(m·s)) and heat-transfer temperature difference (2 ~ 8 °C), combining a relatively low spray density with a relatively high temperature difference is recommended for the falling-film evaporative concentration of molasses ethanol wastewater. However, the spray density should remain above the critical wetting rate to prevent dry-patch formation. Although a higher temperature difference substantially enhances evaporation, practical applications must also consider heat-source energy consumption and the increased risks of fouling and thermal degradation or carbonization of high-viscosity wastewater on the heated tube surface. Therefore, operating parameters should be comprehensively optimized together with equipment-cleaning intervals.

ABSTRACT

Egg appearance defect detection in conveyor-belt environments is challenged by irregular defect morphology, illumination variations, and the limited computational resources of intelligent sorting equipment, making it difficult to simultaneously achieve high detection accuracy and lightweight deployment. In this study, a lightweight detection model, termed YOLOv11n-DAL, is proposed to improve egg defect detection performance while reducing computational complexity. The proposed model integrates C3k2_DCNv4, ADown, and Detect_LSDECD modules into the YOLOv11n framework to enhance defect feature representation, improve effective information retention during downsampling, and reduce computational redundancy in the prediction stage. A conveyor-belt egg image dataset containing three categories, namely damaged, dirty, and good, was constructed. The dataset consisted of 1,730 original images, and the training set was expanded to 4,152 images through data augmentation. Comparative experiments and ablation studies were conducted to validate the effectiveness of the proposed model. The experimental results demonstrated that YOLOv11n-DAL achieved 95.2% Precision, 94.5% Recall, 94.8% F1-score, 96.7% mAP@0.5, and 95.8% mAP@0.5:0.95. Compared with the original YOLOv11n model, YOLOv11n-DAL reduced the number of parameters from 2.6 M to 1.7 M, GFLOPs from 6.3 to 4.8, and model size from 5.2 MB to 3.8 MB, while maintaining superior detection performance. The results indicate that YOLOv11n-DAL achieves an effective balance between detection accuracy and computational efficiency, providing a lightweight and practical solution for intelligent egg sorting systems in conveyor-belt environments.

摘要

传送带环境下鸡蛋外观缺陷检测受到缺陷形态不规则、光照变化以及智能分拣设备计算资源有限等因素影响，难以同时满足检测精度和轻量化部署需求。本文提出一种轻量化检测模型 YOLOv11n-DAL，在降低计算复杂度的同时提升鸡蛋缺陷检测性能。该模型将 C3k2_DCNv4、ADown 和 Detect_LSDECD 融合至 YOLOv11n 框架中，以增强缺陷特征表达能力、提高下采样过程中的有效信息保留能力，并降低预测阶段的计算冗余。本文构建了包含 damaged、dirty 和 good 三类的传送带鸡蛋图像数据集，包括 1730 张原始图像，训练集经数据增强后扩展至 4152 张。通过对比实验和消融实验对模型性能进行验证。实验结果表明，YOLOv11n-DAL 模型的 Precision、Recall、F1-score、mAP@0.5 和 mAP@0.5:0.95 分别达到 95.2%、94.5%、94.8%、96.7%和 95.8%。相比 YOLOv11n，所提出模型将参数量由 2.6 M 降低至 1.7 M，GFLOPs 由 6.3 降低至 4.8，模型大小由 5.2 MB 降低至 3.8 MB，同时保持更高检测性能。研究结果表明，YOLOv11n-DAL 能够在检测精度和计算效率之间取得良好平衡，为传送带鸡蛋智能分拣系统提供了一种轻量化解决方案。

INTRODUCTION

Eggs are important poultry products with high nutritional and economic value, and their external quality directly affects commercial grading, storage stability, transportation safety, and consumer acceptance. During collection, conveying, grading, and packaging, eggs are easily affected by mechanical impact, collision, and environmental contamination, resulting in defects such as cracks, shell breakage, and surface dirt. These defects not only reduce product value but may also increase potential food safety risks. Therefore, rapid, accurate, and non-destructive external-defect detection is essential for automated egg sorting and intelligent quality control in modern poultry processing systems (*Gautron et al., 2021; So and Kim, 2022; Yang et al., 2023; Atwa et al., 2024; Yu et al., 2025*).

Traditional manual inspection methods are still widely used in some egg-processing facilities. However, manual inspection is highly dependent on operator experience and is affected by fatigue, subjective judgment, and low efficiency, making it difficult to satisfy the requirements of high-speed industrial sorting. With the development of intelligent agricultural equipment, machine vision and deep learning technologies have gradually become effective solutions for agricultural product quality evaluation due to their advantages of rapid image acquisition, objective decision-making, and automated operation. In recent years, deep learning-based visual methods have been successfully applied to egg defect classification, eggshell crack detection, freshness evaluation, and online quality monitoring (*Turkoglu, 2021; Botta et al., 2022; Chen et al., 2023; Huang et al., 2023; Zhao et al., 2023; Yin et al., 2024; Çengel et al., 2025; Wu et al., 2025*).

Among deep learning-based object detection algorithms, the YOLO series has attracted extensive attention in agricultural visual applications because of its excellent balance between detection accuracy and computational efficiency (*Kanna et al., 2024; Gupta et al., 2025*). Compared with image classification methods, object detection algorithms can simultaneously achieve target localization and category recognition, making them more suitable for continuous conveyor-belt inspection scenarios. Recent studies have demonstrated that improved YOLO models can effectively enhance detection performance under complex agricultural environments. *Tang et al., (2026),* proposed an improved RT-DETR model for defective egg detection in edge-computing environments, demonstrating the effectiveness of advanced detection architectures for intelligent egg sorting applications. *Ma et al*., *(2025),* developed YOLO-TRS based on YOLO11 for tomato fruit ripeness and stem detection, demonstrating the effectiveness of YOLO11-based lightweight models in agricultural vision tasks. *Shi et al., (2025),* proposed an improved YOLOv11n-based model for missing-seed detection and counting, further confirming the potential of lightweight networks for intelligent agricultural equipment deployment. In addition, *Bing et al., (2025),* introduced improved feature extraction strategies into YOLOv8s for apple leaf lesion detection under complex backgrounds, indicating that feature enhancement is important for small-object detection tasks.

However, practical application of deep learning-based egg inspection systems still faces several challenges. First, egg defects such as small cracks, irregular damaged regions, and weak dirty spots usually exhibit unclear boundaries and low contrast, making them easily confused with eggshell texture, illumination variation, and conveyor-belt background interference. Second, some existing methods rely on image classification or specialized imaging systems, which limits their application in low-cost and high-speed sorting lines. Although hyperspectral and other advanced imaging technologies can improve defect visibility, their high equipment cost and complex configuration restrict large-scale industrial deployment. Third, large-scale detection networks generally require considerable computational resources, making them difficult to deploy on embedded devices and edge-computing platforms. YOLO11 provides a lightweight backbone-neck-head structure with improved computational efficiency; however, its original architecture still has limitations for fine-grained egg external-defect detection, since redundant feature fusion and repeated prediction-head operations increase computational overhead without proportionally improving sensitivity to irregular defect boundaries *(Jocher et al., 2024*).

In recent years, feature-enhancement and computational-optimization strategies for lightweight object detection networks have provided new research directions for addressing these problems. Deformable convolution was first introduced by *Dai et al. (2017)* to achieve flexible kernel deformation by learning content-adaptive sampling offsets, and was later refined into the more efficient DCNv4 by *Xiong et al. (2024)*; DCNv4-based modules have already been applied to irregular-target detection tasks outside agriculture, such as steel surface defect detection (*Zhu et al., 2025*). For efficient downsampling, *Wang et al. (2024)* proposed the ADown module in YOLOv9, which has since been used in YOLOv11-based agricultural detection models to preserve small-target features under complex backgrounds (*Wang et al., 2026*). For the detection head, Detail-Enhanced Convolution (DEConv), proposed by *Chen et al. (2024)* for image dehazing, enhances fine-detail representation without additional inference cost when combined with a lightweight shared convolutional head. Although each of these modules has been individually validated, their joint application to egg external-defect detection under conveyor-belt conditions has not yet been reported.

Based on the above, this study proposes a lightweight detection model, YOLOv11n-DAL, for egg external-defect detection under conveyor-belt conditions, in which three modules are jointly designed to improve detection accuracy while reducing model parameters and computational cost. Specifically, DCNv4 is introduced into the C3k2 structure of YOLOv11n to construct the C3k2_DCNv4 module, enhancing the representation of irregular defect features; ADown replaces the original downsampling convolution, reducing model size while improving feature preservation; and Detect_LSDECD combines a lightweight shared

convolutional structure with DEConv to reduce redundant prediction-head computation while enhancing detail sensitivity. Together, these modules achieve both improved accuracy and reduced model complexity, offering a feasible solution for resource-constrained conveyor-belt sorting equipment. A conveyor-belt egg image dataset containing the damaged, dirty, and good categories was constructed, and the proposed method was comprehensively evaluated.

MATERIALS AND METHODS

Data Collection and Dataset Construction

Egg images were collected from a conveyor belt located in Jining City, Shandong Province, China, from February 8 to February 10, 2026, using an iPhone 17 Pro Max. To reduce motion blur and improve image quality, the conveyor belt was temporarily stopped during image acquisition. A top-view imaging configuration was adopted, where the smartphone camera was positioned vertically above the conveyor belt and kept parallel to its surface. The shooting distance was approximately 10–60 cm, and the original image resolution was 3072 × 4096 pixels. The data collection environment involved a combination of natural light and indoor illumination conditions to simulate the lighting variations that may occur in practical egg inspection scenarios. Each egg was captured from only a single viewpoint to prevent potential data leakage caused by the same instance appearing across different subsets.

A total of 1730 original JPG images were retained. The category labels were determined according to the overall appearance characteristics of each egg. Eggs with cracks, shell breakage, or holes were labeled as damaged. Eggs exhibiting surface contamination, such as feces, blood stains, or mud stains, but without structural damage were labeled as dirty. Eggs without apparent defects were labeled as good. When an egg simultaneously exhibited both structural damage and surface contamination, it was consistently assigned to the damaged category, since structural defects represent more severe quality issues. Representative samples of the three categories are shown in Fig. 1.

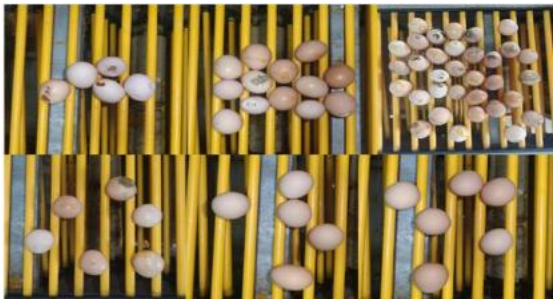

Fig. 1 - Representative images of the good, damaged, and dirty egg classes collected under conveyor-belt conditions

Dataset Annotation and Data Augmentation

The dataset was randomly divided into training, validation, and testing subsets at a ratio of 8:1:1, resulting in 1384, 173, and 173 images, respectively. Image annotation was manually performed using the Roboflow platform. Rectangular bounding boxes were generated to enclose the entire egg region. Data augmentation was applied only to the training set, including horizontal flipping, vertical flipping, ±90° rotation, ±10° random rotation, ±10° shearing, ±25% saturation adjustment, ±15% brightness adjustment, and noise injection with a maximum intensity of 2.24% pixels. For each original training image, three augmented images were generated, expanding the training set to 4152 images (Fig. 2).

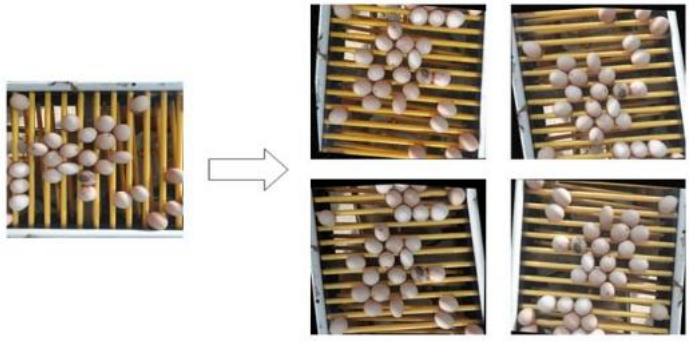

Fig. 2 - Examples of data augmentation effects

The final dataset contained 28,893 egg object instances in total. The numbers of instances belonging to the damaged, dirty, and good categories are summarized in Table 1.

Table 1

Distribution of annotated egg instances in the complete dataset.

Egg category	Annotated instances	Proportion (%)
damaged	8582	29.7
dirty	9449	32.7
good	10862	37.6
Total	28893	100.0

YOLOv11n-DAL Network Architecture and Improvement Methods

YOLOv11n was selected as the baseline because of its compact one-stage backbone–neck–head architecture and P3–P5 multi-scale prediction. To improve its sensitivity to small and irregular eggshell defects without increasing model complexity, YOLOv11n-DAL replaces the original C3k2 blocks with C3k2_DCNv4, adopts ADown for downsampling, and uses Detect_LSDECD as the prediction head. The overall architecture is shown in Fig. 3.

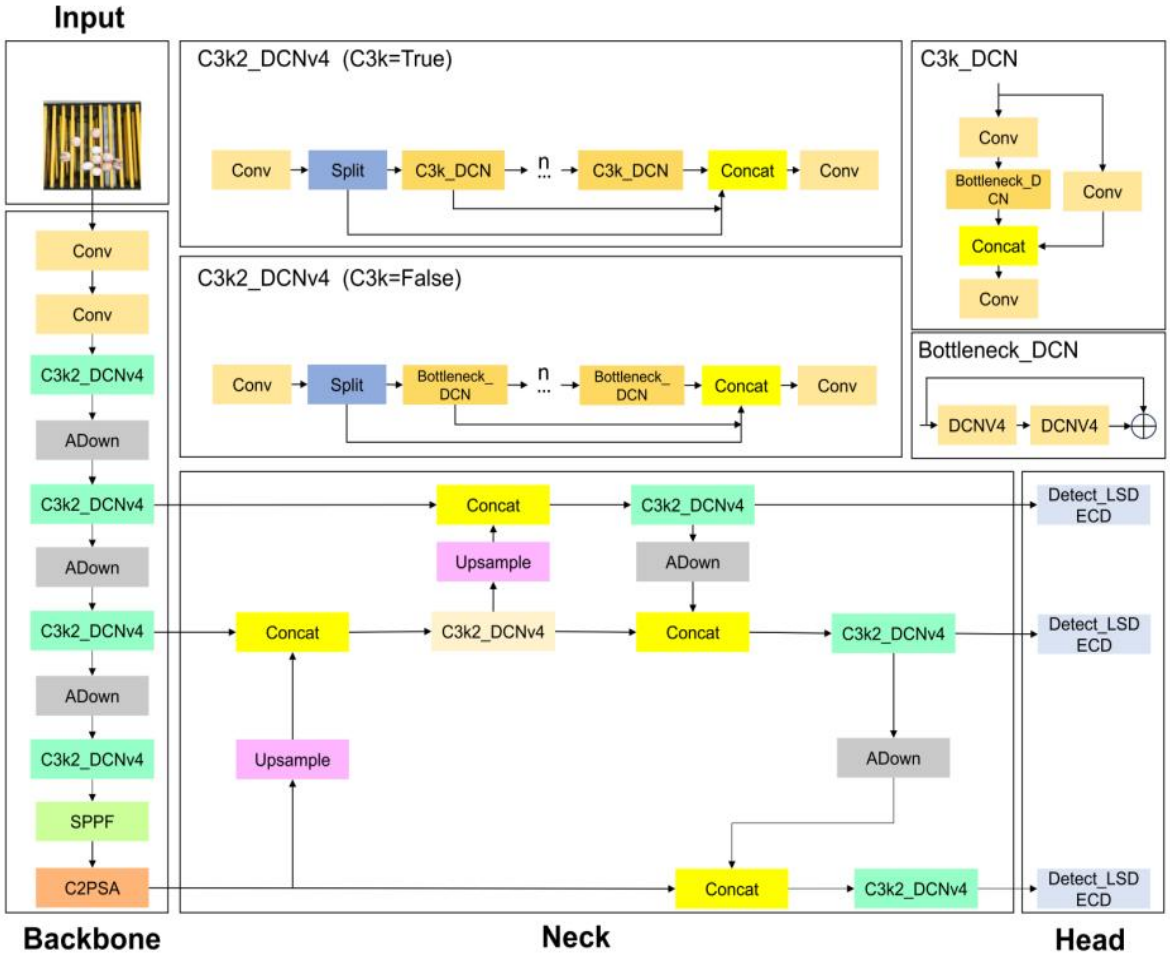

Fig. 3 - Overall architecture of the proposed YOLOv11n-DAL model for egg surface defect detection

C3k2_DCNv4 and ADown are deployed in the backbone and neck for adaptive feature extraction and efficient multi-scale transmission. Detect_LSDECD receives the P3, P4, and P5 feature maps and predicts the damaged, dirty, and good categories. The structures of the three improved modules are summarized in Fig. 4.

C3k2_DCNv4 Feature Extraction Module

C3k2_DCNv4 integrates deformable convolution into the C3k2 framework. As shown in Fig. 3, the input undergoes a 1×1 convolution, then splits into two branches.

One branch passes through *n* stacked C3k_DCN (or Bottleneck_DCN) blocks, while the other serves as a shortcut. The two branches are concatenated and fused by another 1×1 convolution. Each C3k_DCN block contains two DCNv4 layers with residual connections. DCN [Fig. 4(a)] learns offset fields to sample adaptively from irregular positions, improving the model's ability to handle geometric variations while maintaining efficiency.

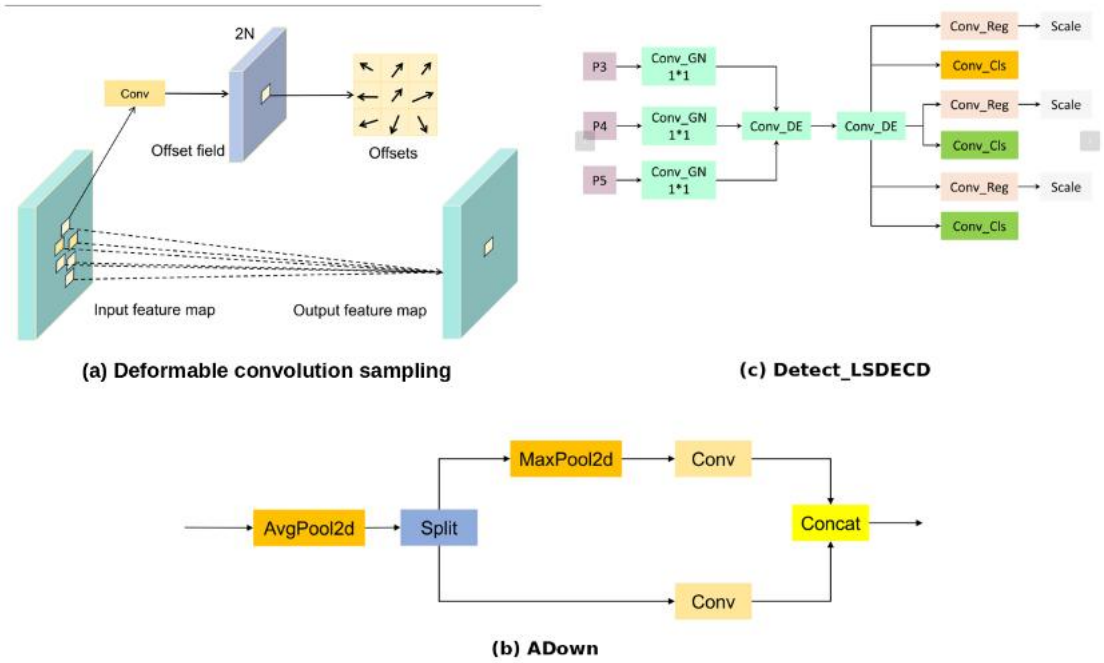

Fig. 4 - Structures of the improved modules in YOLOv11n-DAL
(a) Deformable convolution sampling; (b) ADown; (c) Detect_LSDECD

Unlike fixed-grid convolution, DCNv4 learns offsets according to target geometry:

$$y(p_0) = \sum_{k=1}^{K} w_k \; x(p_0 + p_k + \Delta p_k) \tag{1}$$

where x and y denote the input and output feature maps, p_0 is the current position, p_k is the regular sampling position, Δp_k is the learnable offset, and w_k is the convolution weight. This adaptive sampling is suitable for cracks, holes, broken-shell regions, and contaminants with irregular boundaries.

ADown Downsampling Module

ADown first applies average pooling and channel splitting. One branch uses a 3 × 3 stride-2 convolution, while the other uses max pooling followed by a 1 × 1 convolution; the two outputs are concatenated (Fig. 4(b)).

$$X_1, X_2 = \mathrm{Split}\big(\mathrm{AvgPool}(X)\big) \tag{2}$$

$$Y = \mathrm{Concat}(Y_1, Y_2) \tag{3}$$

where X is the input feature map, X_1 and X_2 are the two channel branches, $Y_1 = Conv_{3\times3,s=2}(X_1)$, $Y_2 = Conv_{1\times1}(MaxPool(X_2))$, and Y is the concatenated output. The dual-branch strategy combines average and maximum responses, helping preserve edge and texture information during downsampling.

Detect_LSDECD Detection Head

Detect_LSDECD first maps multi-scale features to a unified hidden dimension and then applies shared detail-enhanced convolutions, reducing repeated operations across detection layers (Fig. 4(c)).

$$F_i' = H_{\mathrm{shared}}\big(\mathrm{Conv}_{1\times1}(F_i)\big) \tag{4}$$

where F_i is the input of the i-th scale, $Conv_{1\times1}$ performs channel adjustment, H_{shared} denotes the shared feature extractor, and F_i' is the refined feature map.

$$B_i = \mathrm{DFL}(R_i), \quad C_i = \sigma(S_i) \tag{5}$$

where B_i and C_i are the predicted box and class probability, R_i and S_i denote the regression and classification outputs obtained from F_i', DFL denotes distribution-based box regression, and σ is the sigmoid function. Separate branches retain prediction quality while the shared extractor reduces head redundancy.

Training Environment and Parameter Settings

All models were trained and evaluated under the same experimental conditions to ensure a fair comparison. The hardware platform was equipped with an NVIDIA A10G GPU, and the software environment included Python 3.10.16, PyTorch 2.2.2, CUDA 12.1, and Ultralytics 8.3.9. The same training strategy and hyperparameter settings were applied to YOLOv11n-DAL and all comparison models. The main training hyperparameters are summarized in Table 2.

Table 2

Main training hyperparameter settings

Parameter	Value
Image size	640 × 640
Epochs	200
Batch size	16
Optimizer	SGD
Initial learning rate	0.01
Workers	10
close_mosaic	10

Model Performance Evaluation Indicators

Precision, Recall, F1-score, mAP@0.5, and mAP@0.5:0.95 were used to evaluate detection accuracy. Parameters, GFLOPs, and model size reflected model complexity. Inference speed was measured in FPS on a single GPU with batch size 1 and input size 640×640, including preprocessing, forward pass, and post-processing, Precision, Recall, and F1-score were calculated as follows:

$$\text{Precision} = \frac{TP}{TP + FP} \times 100\% \tag{6}$$

$$\text{Recall} = \frac{TP}{TP + FN} \times 100\% \tag{7}$$

where TP, FP, and FN denote true positives, false positives, and false negatives, respectively; P and R in Eq. (8) denote Precision and Recall.

$$F_1 = \frac{2PR}{P + R} \times 100\% \tag{8}$$

The mean Average Precision over N egg categories was calculated as:

$$mAP = \frac{1}{N}\sum_{i=1}^{N} AP_i \times 100\% \tag{9}$$

where AP_i is the Average Precision of the i-th category. $mAP@0.5$ uses an IoU threshold of 0.5, whereas $mAP@0.5{:}0.95$ averages thresholds from 0.5 to 0.95 in steps of 0.05.

Human Baseline Validation on the Test Set

To further evaluate the performance of YOLOv11n-DAL in practical egg appearance defect detection scenarios, a comparative experiment between manual inspection and model-based detection was conducted using 173 original images from the test set. Two inspectors with more than three years of experience in egg quality inspection were invited to participate in the experiment.

The two inspectors independently performed defect classification on the egg targets in each test image without communication or discussion. Each egg sample was categorized into one of three classes: damaged, dirty, or good. Precision, recall, and F1-score were calculated separately based on the independent annotations of the two inspectors, and the arithmetic mean of these metrics was used as the baseline performance of manual inspection.

Subsequently, YOLOv11n-DAL was evaluated on the same test set using identical evaluation metrics and calculation procedures. By comparing the Precision, Recall, and F1-score between the proposed model and the manual inspection baseline, the performance differences between YOLOv11n-DAL and experienced quality inspectors in egg appearance defect recognition were analyzed.

RESULTS

YOLOv11n-DAL Model Performance Analysis

To comprehensively evaluate the detection performance of the improved model, Precision, Recall, mAP@50, and mAP@50:95 were adopted as evaluation metrics to analyze the model's performance across different categories. Table 3 presents the per-class results. As shown, the mAP@50 values for the damaged, dirty, and good categories reached 97.9%, 95.2%, and 97.0%, respectively. The overall Precision, Recall, mAP@50, and mAP@50:95 of the model were 95.2%, 94.5%, 96.7%, and 95.8%, respectively.

Table 3

Performance comparison of the YOLOv11n-DAL model on different egg categories

Class	P (%)	R (%)	F1 (%)	mAP50 (%)	mAP50–95 (%)
damaged	96.6	95.3	96.0	97.9	97.7
dirty	94.6	91.4	93.0	95.2	94.3
good	95.2	97.0	95.6	97.0	95.3
all	95.2	94.5	94.8	96.7	95.8

The normalized confusion matrix and visualization results are presented in Fig. 5. Fig. 5(a) compares heatmaps generated by YOLOv11n and YOLOv11n-DAL. The proposed model produces more concentrated activations on egg and defect regions, with weaker responses on conveyor rollers. Fig. 5(c) also demonstrates more complete target coverage for densely distributed, partially occluded, and visually ambiguous eggs, corroborating the quantitative improvements.

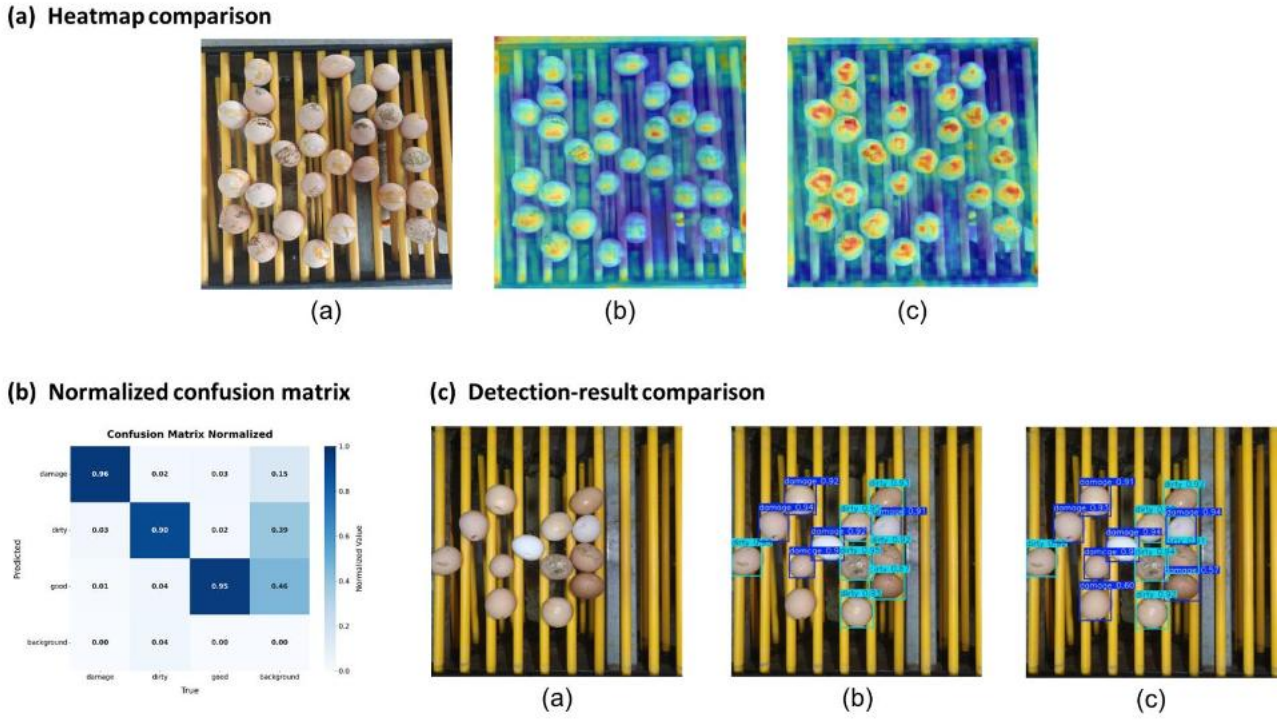

Fig. 5 - Visualization comparison between YOLOv11n and YOLOv11n-DAL: heatmaps (upper), normalized confusion matrix of YOLOv11n-DAL (lower left), and detection-result comparison (lower right)

The row-normalized confusion matrix in Fig. 5(b) shows class-wise recall of 96%, 90%, and 95% for damaged, dirty, and good, respectively. The dirty category remains comparatively more challenging, as slight stains, natural eggshell spots, shadows, and illumination-induced dark regions can appear visually similar. Some background false positives persist, indicating that weak defects and complex textures are the primary sources of missed or incorrect detections.

Ablation Experiments

To verify the effectiveness of the improved modules, ablation experiments were conducted using YOLOv11n as the baseline model. The effects of ADown, C3k2_DCNv4, and Detect_LSDECD were evaluated separately and jointly, and the results are shown in Table 4.

Table 4

Ablation study results of YOLOv11n-DAL

Exp.	ADown	DCNv4	LSDECD	P (%)	R (%)	F1 (%)	mAP50 (%)	mAP50–95 (%)	Params (M)	GFLOPs	Size (MB)
1	×	×	×	93.5	93.5	93.5	95.8	94.8	2.6	6.3	5.2
2	√	×	×	95.8	92.6	94.2	96.1	94.8	2.0	5.3	4.1
3	×	√	×	95.5	92.2	93.8	96.3	95.4	2.5	6.2	5.1
4	×	×	√	95.5	92.9	94.2	96.9	95.6	2.3	6.0	5.0
5	√	√	×	94.9	93.1	94.0	96.2	95.3	2.0	5.1	4.1
6	√	×	√	93.4	95.3	94.3	96.9	96.0	1.8	5.0	4.1
7	×	√	√	95.5	93.8	94.6	96.4	95.4	2.1	5.8	4.7
8	√	√	√	95.2	94.5	94.8	96.7	95.8	1.7	4.8	3.8

Note: AD denotes ADown, DCNv4 denotes C3k2_DCNv4, and LSDECD denotes Detect_LSDECD; √ indicates that a module is included, whereas × indicates that it is excluded; bold values indicate the best result for each metric.

Compared with the baseline model, incorporating ADown reduced the number of parameters, computational complexity, and model size from 2.6 M, 6.3 GFLOPs, and 5.2 MB to 2.0 M, 5.3 GFLOPs, and 4.1 MB, respectively, while maintaining comparable detection performance. When introduced individually, C3k2_DCNv4 and Detect_LSDECD increased mAP@0.5:0.95 from 94.8% to 95.4% and 95.6%, respectively, indicating their effectiveness in enhancing feature extraction and localization performance.

Furthermore, the combinations of ADown + C3k2_DCNv4 (Exp. 5), ADown + Detect_LSDECD (Exp. 6), and C3k2_DCNv4 + Detect_LSDECD (Exp. 7) were evaluated to investigate the complementary effects of the proposed modules. By integrating all three modules, the resulting YOLOv11n-DAL achieved the best overall performance, obtaining a precision of 95.2%, recall of 94.5%, F1-score of 94.8%, mAP@0.5 of 96.7%, and mAP@0.5:0.95 of 95.8%. Meanwhile, the model size was reduced to 1.7 M parameters, 4.8 GFLOPs, and 3.8 MB. These results indicate that the proposed modules simultaneously enhance detection accuracy while reducing computational cost and model size, demonstrating the effectiveness of YOLOv11n-DAL for lightweight object detection.

Comparison with Different Detection Models

To further evaluate the comprehensive performance of YOLOv11n-DAL, several representative detection models were selected for comparison, including YOLOv6, YOLOv8, YOLOv10, YOLOv11n, YOLO12n, YOLO26n, Hyper-YOLO, and RT-DETR-R18. All models were trained and tested under the same experimental conditions, and the results are shown in Table 5.

Table 5

Performance comparison results of different detection models

Model	P (%)	R (%)	F1 (%)	mAP50 (%)	mAP50–95 (%)	Params (M)	GFLOPs	Size (MB)	FPS
YOLOv6n	94.2	91.3	92.7	95.9	95.2	4.2	11.4	8.2	146.5
YOLOv8n	93.0	93.9	93.4	96.2	95.2	2.7	6.8	5.4	138.5
YOLOv10n	94.0	91.4	92.7	95.3	94.1	2.3	6.5	5.5	127.9
YOLOv11n	93.5	93.5	93.5	95.8	94.8	2.6	6.3	5.2	96.7
YOLO12n	95.0	94.0	94.5	96.7	95.8	2.5	6.3	5.3	78.5
YOLO26n	92.4	91.3	91.8	95.5	93.6	2.5	5.2	5.2	89.6
Hyper-YOLO	96.3	92.4	94.3	96.6	95.7	3.6	9.5	7.3	88.9
RT-DETR-R18	95.2	95.4	95.3	95.1	93.9	19.9	56.9	307.3	100.1
YOLOv11n-DAL	95.2	94.5	94.8	96.7	95.8	1.7	4.8	3.8	61.0

Note: Model size refers to the saved weight-file size generated by the corresponding implementation.

YOLOv11n-DAL achieves a precision of 95.2%, recall of 94.5%, F1-score of 94.8%, mAP@0.5 of 96.7%, and mAP@0.5:0.95 of 95.8%. It achieves the highest mAP@0.5 (96.7%) among all methods, tied with YOLO12n, while surpassing the baseline YOLOv11n by 0.7% in mAP@0.5 and 0.9% in mAP@0.5:0.95.

More importantly, these gains are achieved with only 1.7 M parameters, 4.8 GFLOPs, and 3.8 MB model size—a 34.6% reduction in parameters and 23.8% reduction in GFLOPs compared to the baseline. In contrast, RT-DETR-R18 requires 19.9 M parameters and 56.9 GFLOPs, and Hyper-YOLO requires 3.6 M parameters and 9.5 GFLOPs.

Inference speed is 61.0 FPS, lower than the baseline 96.7 FPS due to DCNv4-based feature fusion, but still well above the 30 FPS real-time requirement for industrial inspection. The compact model size (3.8 MB) also alleviates edge-device memory constraints, making YOLOv11n-DAL a more practical solution for edge deployment.

Comparison with Human Inspectors

To further evaluate the practical applicability of the proposed YOLOv11n-DAL, its performance was compared with that of human inspectors, as shown in Table 6.

Table 6

Detection performance of YOLOv11n-DAL vs. human inspectors on the test set

Method	P (%)	R (%)	F1 (%)
Inspector 1	91.3	91.3	91.0
Inspector 2	88.6	88.4	88.0
Average of manual inspectors	89.9	89.8	89.5
YOLOv11n-DAL	95.2	94.5	94.8

As shown in Table 6, the two inspectors achieved precision values of 91.3% and 88.6%, recall values of 91.3% and 88.4%, and F1-scores of 91.0% and 88.0%, respectively. The corresponding average values for manual inspection were 89.9%, 89.8%, and 89.5%, respectively. In comparison, YOLOv11n-DAL achieved a precision of 95.2%, recall of 94.5%, and F1-score of 94.8%, representing improvements of 5.3, 4.7, and 5.3 percentage points, respectively, over the average manual inspection performance.

These results indicate that YOLOv11n-DAL provides superior overall detection performance compared with manual inspection under conveyor-belt operating conditions. Moreover, the differences between the two inspectors indicate a certain degree of variability in manual inspection, which may be attributed to subjective judgment and differences in visual perception. In contrast, YOLOv11n-DAL provides a more consistent and automated detection process. Therefore, the proposed model demonstrates good potential for automated egg defect detection in conveyor-belt inspection scenarios.

Training Stability Analysis

To evaluate the robustness of YOLOv11n-DAL against training randomness, both YOLOv11n and YOLOv11n-DAL were independently trained five times using different random seeds (0–4), while maintaining the same dataset split, training strategy, and hyperparameter settings. The mean ± standard deviation of the five runs, together with paired t-test results and effect sizes, are summarized in Table 7.

Table 7

Training stability comparison between YOLOv11n and YOLOv11n-DAL over five runs

Metric	YOLOv11n (Mean ± SD)	YOLOv11n-DAL (Mean ± SD)	Δ	p-value	Cohen's d_z
P (%)	94.4 ± 0.7	94.9 ± 0.7	+0.5	0.373	0.5
R (%)	93.3 ± 0.2	94.1 ± 1.0	+0.8	0.187	0.7
F1 (%)	93.8 ± 0.4	94.5 ± 0.4	+0.7	0.047	1.3
mAP50 (%)	96.0 ± 0.2	96.8 ± 0.2	+0.7	0.010	2.0
mAP50–95 (%)	94.9 ± 0.2	95.6 ± 0.4	+0.7	0.028	1.5

Note: Values are presented as mean ± standard deviation over five independent runs with different random seeds (0–4).
Δ represents the performance improvement of YOLOv11n-DAL compared with YOLOv11n.
Statistical significance was evaluated using paired t-tests.
Cohen's dz represents the paired effect size.

As shown in Table 7, YOLOv11n-DAL achieved higher average performance than YOLOv11n across all evaluation metrics. Specifically, the proposed model improved Precision, Recall, F1-score, mAP@0.5, and mAP@0.5:0.95 by 0.5, 0.8, 0.7, 0.7, and 0.7 percentage points, respectively. The relatively small standard deviations (<1.1%) across repeated experiments indicate that both models exhibited stable training behavior.

The paired t-test results showed that the improvements in F1-score, mAP@0.5, and mAP@0.5:0.95 achieved statistical significance in the five repeated runs, with relatively large effect sizes. Although Precision and Recall improvements did not reach statistical significance, they remained consistently higher than the baseline model. Overall, the repeated experiments demonstrate that the performance gains of YOLOv11n-DAL are reproducible and not caused by a single random training process.

DISCUSSION

The experiments show that YOLOv11n-DAL improves detection accuracy while reducing model complexity rather than relying on a larger network. ADown contributes mainly to computational reduction, C3k2_DCNv4 strengthens the representation of irregular shell defects, and Detect_LSDECD reduces redundant prediction operations while enhancing fine-grained feature extraction. Their complementary effects explain the simultaneous improvements in F1-score and mAP and the reductions in parameters, GFLOPs, and model size.

It is noteworthy that the difference between mAP@0.5 and mAP@0.5:0.95 is relatively small in this study. For YOLOv11n-DAL, the gap between the two metrics was only 0.9 percentage points (96.7% vs. 95.8%), indicating that the model maintained stable localization performance under stricter IoU thresholds. This phenomenon is mainly attributed to the characteristics of the proposed dataset and annotation strategy. Unlike defect-region detection tasks that require precise localization of irregular crack or stain areas, the bounding boxes in this study were annotated for complete egg regions. Since eggs exhibit relatively regular elliptical shapes and clear boundaries from the background, the localization difficulty is relatively low, allowing the model to maintain high IoU overlap even under stricter evaluation criteria. In addition, the C3k2_DCNv4 module improves structural feature modeling through adaptive sampling, which further contributes to accurate object localization.

The dirty category remained more difficult than damaged and good because slight stains, natural eggshell spots, shadows, and illumination-induced dark regions may share similar visual characteristics. Partial occlusion and single-view acquisition also limit the visibility of some defects. Moreover, the dataset was collected using one device within a limited region and period, which may affect the generalization ability under different acquisition conditions. Therefore, further validation using multi-source datasets and diverse imaging conditions is required before large-scale deployment. In addition, the statistical analysis was conducted based on five repeated training runs (n=5), and the limited sample size may reduce the statistical power of significance tests. Moreover, no correction for multiple comparisons was applied; therefore, the statistical results should be interpreted as supportive evidence rather than definitive proof of superiority.

CONCLUSIONS

This study proposed YOLOv11n-DAL, a lightweight detection framework for egg external-defect inspection under conveyor-belt conditions. By integrating C3k2_DCNv4, ADown, and Detect_LSDECD into YOLOv11n, the proposed model enhanced irregular defect feature representation, improved feature preservation during downsampling, and reduced redundant prediction computation.

Compared with the baseline YOLOv11n, YOLOv11n-DAL achieved improved detection accuracy while reducing model complexity, with the parameters, GFLOPs, and model size reduced from 2.6 M, 6.3 GFLOPs, and 5.2 MB to 1.7 M, 4.8 GFLOPs, and 3.8 MB, respectively. The ablation experiments, comparative evaluations, and stability analysis demonstrated the effectiveness and reproducibility of the proposed optimization strategy.

The proposed model provides a feasible lightweight solution for automated egg external-defect detection in resource-constrained conveyor-belt sorting scenarios. Future work will focus on validating the model under more diverse acquisition conditions and conducting deployment tests on practical edge devices.

ABSTRACT

Seedling replenishment during the operation of high-speed ride-on rice transplanters still relies heavily on manual labor, thereby limiting the level of operational automation. To address this limitation, an automatic seedling-loading system comprising a longitudinal conveying mechanism, a lateral drive mechanism, and a tracking compensation mechanism was developed. Based on an STM32 embedded platform, a control strategy for detecting seedling shortages and performing precise seedling-loading operations was developed, enabling automatic shortage detection, lateral positioning, and targeted seedling replenishment. The main operating parameters—conveyor belt speed, lateral offset distance, and fore-aft tilt angle—were first investigated individually to determine their appropriate ranges. Subsequently, a second-order, three-factor, five-level rotatable orthogonal experiment was conducted. Seedling-loading success rate was used as the evaluation index, and a multifactor regression model was established to analyze the interactions among the factors. Bench tests were conducted to optimize the system parameters and determine the optimal parameter combination. Subsequent field trials confirmed the operational reliability of the system, with an average seedling-loading success rate of 90.67% over five batches of tests. The proposed system shows considerable potential for replacing manual loading of mat-type rice seedlings and provides a practical solution for advancing the full-process automation of rice transplanting operations.

摘要

在高速乘坐式插秧机作业过程中，补秧环节依赖人工、自动化程度不足。本文构建了由纵向输送装置、横向移动装置与随动装置组成的自动装秧系统，基于 STM32 嵌入式平台设计缺秧检测与执行机构控制逻辑，实现缺秧检测、横向定位与定点补秧。以输送带速度、横向偏移距离与前后倾斜角度为试验因素，开展单因素试验确定因素取值范围；采用三因素五水平二次旋转正交组合试验，以装秧成功率为评价指标建立多因素回归模型并分析各因素及其交互作用。通过台架试验优化关键参数。田间试验结果表明，系统完成 5 批次自动装秧任务，平均成功率为 90.67%。所研制的自动装秧系统能够实现毯状苗机插从缺秧识别到定点补秧的自动补秧作业，降低了补秧过程的人工依赖，可为水稻种植全程自动化提供技术支持。

INTRODUCTION

The development of agricultural machinery is steadily advancing toward full automation and intelligent operation *(Liu C.L. et al., 2020; Zhao C.J. et al., 2021*). Among various mechanized systems, rice transplanters have become a central component due to their widespread use and their role as key carriers of smart agricultural technologies *(Wang X., 2022)*. In recent years, the deployment of unmanned driving systems in rice transplanters has become increasingly common in China (*Liu X.W. et al., 2021; Yin Y.X. et al., 2022*). However, research on automatic seedling-loading systems specifically designed for high-speed ride-on rice transplanters remains limited. Consequently, the seedling-loading process continues to rely heavily on manual labor, which limits the realization of fully autonomous transplanter operations. Enhancing automation at this stage is thus critical for the practical implementation of unmanned rice farming systems. Studies on automatic seedling delivery have primarily focused on the mechanical design and technical development of systems that ensure the accurate transfer of mat-type or pot seedlings (*Liu M.H. et al., 2021; Deng G. et al., 2022; Liu M.H. et al., 2024; Xiao L.P. et al., 2018*). *Yu G.H. et al., (2024),* proposed a dual-belt longitudinal conveyor system integrated with lateral translation to realize automatic tray replenishment.

Wang X.F. et al., (2021), developed a push-type seedling delivery box that generates a dispensing opening through the relative motion of the box and its base, thereby improving replenishment reliability. *Fan Y.J. et al., (2016),* and *Yin C.et al., (2025),* introduced automated systems based on sliding-rail pushing and multi-layer tray delivery structures, aiming to reduce manual involvement through modular designs. These studies improved the efficiency and reliability of seedling replenishment through synchronized tray repositioning, push-type seedling delivery, and multi-layer tray conveying, respectively. However, relatively limited attention has been paid to seedling shortage detection, target positioning, and coordinated control of the seedling carrying platform. Despite these efforts, many of the existing devices remain at the conceptual or prototyping stage. In particular, performance issues such as poor vibration resistance under complex paddy field conditions and the lack of high-precision one-to-many seedling alignment persist. Robotic manipulation technologies may offer solutions in this regard (*Shen J.J. et al., 2023; Fountas S. et al., 2020; Bechar A. et al., 2017*).

Currently, multi-degree-of-freedom robotic systems have been widely applied in transplanting operations for crops like vegetables, corn, and tobacco. *Wang Z.Z. et al., (2017)*, employed a servo-driven module under PLC control to achieve accurate grasping and delivery of vegetable seedlings; *Shi T., (2015),* developed a fully automated corn transplanter with integrated seedling-picking and vertical delivery mechanisms; and *Chen B et al., (2024)*, used a staggered dual-disc configuration to improve the efficiency of a tobacco seedling feeding system. These studies demonstrate that Cartesian robotic systems, when combined with high-precision sensing technologies, can effectively address the challenges of automatic material handling in unstructured environments. Such insights provide valuable reference points for the design and control strategies of automatic seedling-loading systems tailored for paddy field operations (*Wu W.J. et al., 2016; Wang Z.Z. et al., 2019; Zhao C.L. et al., 2027*). However, existing systems still fall short in terms of operational stability, delivery precision, and system integration when exposed to real-world field disturbances. Developing a robust and adaptive automatic seedling-loading system remains a key technical challenge in advancing rice transplanter intelligence.

This study addresses the challenges posed by the distributed arrangement of multiple seedling-holding columns on high-speed ride-on rice transplanters, the difficulty in accurately aligning the conveying mechanism with the column requiring replenishment, and changes in their relative positions caused by the reciprocating lateral and vertical movements of the seedling-carrying platform. Based on a one-to-many seedling-replenishment concept, an automatic seedling-loading system comprising a longitudinal conveying mechanism, a lateral drive mechanism, and a tracking mechanism was developed. The lateral drive mechanism allows a single longitudinal conveying mechanism to move among multiple seedling-holding columns and align with the target column. The tracking mechanism accommodates the reciprocating lateral and vertical movements of the seedling-carrying platform, thereby reducing the relative positional deviation between the conveyor outlet and the target seedling-holding column. An STM32-based control system integrates seedling-shortage detection, lateral position feedback, and coordinated control of the lateral drive and conveyor motors, thus enabling the complete operational sequence of seedling-shortage detection, lateral positioning, and targeted seedling replenishment. The study focuses on developing and evaluating an automatic loading system for mat-type rice seedlings. To evaluate and optimize system performance, bench tests were conducted using three key operating factors: conveyor belt speed, lateral offset distance, and fore-aft tilt angle. The effects of these factors on the seedling-loading success rate were investigated, and their optimal combination was determined. The study ultimately aimed to establish a complete technical process—from seedling shortage detection to precise automatic replenishment—and provide a technical basis for structural optimization and overall performance improvement of automatic seedling-loading systems.

MATERIALS AND METHODS

Structure composition and working principle

In Fig. 1, the automatic seedling-loading system of the high-speed ride-on rice transplanter comprises four main components: ① a tracking mechanism, ② a lateral drive mechanism, ③ a longitudinal conveying mechanism, and ④ a lateral oscillation mechanism.

The front end of the mechanism is attached to the transplanter main body via the swing mechanism, which compensates for variations in machine posture and provides a stable front fulcrum for the loading structure. The rear end is connected to the seedling-carrying platform through a joint within the tracking mechanism, enabling synchronized moving with the carrier platform. The lateral drive mechanism, comprising a slide rail and rack-and-pinion assembly, is mounted at the rear of the rice transplanter body and drives the longitudinal conveying mechanism laterally.

The longitudinal conveying mechanism is mounted on the upper crossbeam of the sliding platform and conveys the seedlings longitudinally after alignment with the target seedling-holding column.

During automatic seedling loading, the operator manually places the seedling mats onto the belt of the longitudinal conveying mechanism. To initiate detection, the seedling mats must remain in firm contact with the detection switches mounted on the side baffles. Each seedling-holding column of the seedling platform is equipped with a seedling-shortage sensor. When a shortage is detected in any column, the control system activates the lateral drive mechanism, which moves the longitudinal conveying mechanism laterally toward the corresponding target position. Once the pull-wire displacement sensor confirms that the target position has been reached, the control system activates the conveyor drive motor to deliver the seedling mat to the column requiring replenishment. After leaving the conveyor belt, the seedling mat slides under gravity along the chute and into the target column, thereby eliminating the shortage and clearing the corresponding alarm signal. Upon completion of the replenishment operation, the longitudinal conveying mechanism automatically returns to its initial loading position and waits for the next seedling-shortage signal.

Key component design

(1) Longitudinal Conveying Mechanism

As shown in Fig. 2, the longitudinal conveying mechanism transports mat-type rice seedlings to replenish seedling shortages in the target columns of the seedling platform. It mainly comprises ① a connecting mechanism, ② a conveyor belt mechanism, ③ side baffles, ④ a support platform, ⑤ a drive unit, ⑥ a concave-convex roller assembly, and ⑦ a master-slave roller assembly. The conveyor belt mechanism is located at the top of the device and is supported by four structural members mounted on the support platform. The connecting mechanism is located at the rear of the conveyor belt mechanism, while the side baffles are installed on both sides of the conveyor belt to guide the seedling mats during loading and conveyance. The drive unit is located at the bottom of the device and transmits power to the conveyor system through a belt drive. The master-slave roller assembly consists of an intermediate drive shaft coupled to an external nylon roller. The assembly is mounted in bearing supports to prevent relative slippage between the nylon roller and the conveyor belt, thereby ensuring stable and reliable seedling conveyance. An MY5840-31ZY worm-geared DC motor is used to drive the longitudinal conveying mechanism. Under loaded conditions, the maximum torque required at the conveyor drive shaft was measured using a torque wrench and found to be 12.8 kgf·cm. The selected motor has a rated torque of 16 kgf·cm and a maximum load torque of 38 kgf·cm, thus satisfying the torque requirements of the longitudinal conveying mechanism. Based on the calculated transmission parameters, the conveyor belt can reach a maximum operating speed of 0.4 m/s, which meets the speed requirement for seedling replenishment.

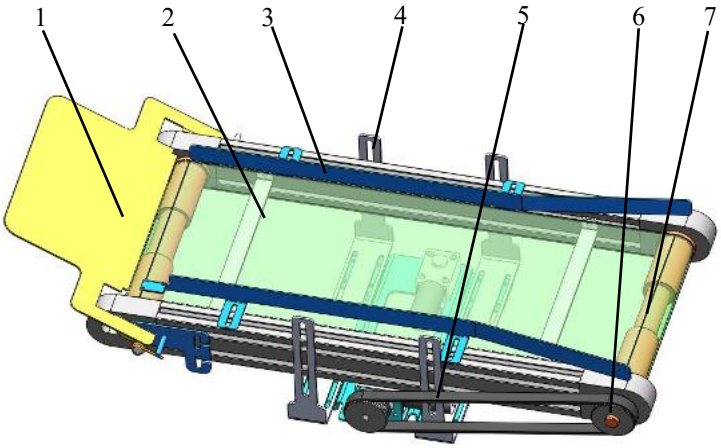

Fig. 2 - Schematic of the longitudinal conveying mechanism

1. Connecting mechanism; 2. Conveyor belt mechanism; 3. Side baffle; 4. Support platform; 5. Drive unit; 6. Concave-convex roller assembly; 7. Master-slave roller assembly

(2) Tracking mechanism

As shown in Fig. 3, the tracking mechanism is designed to accommodate the multidirectional motion of the seedling platform during operation. While awaiting a seedling-replenishment operation, the mechanism remains stationary relative to the seedling platform, thereby accommodating both lateral displacement and vertical offset. The mechanism mainly comprises ① a vertical slide rail, ② a horizontally movable beam, ③ an upper beam, ④ a horizontal slide rail, and ⑤ a lower beam. It is connected to the base plate through the lower beam and forms a sliding connection with the seedling platform. Its primary function is to enable the automatic seedling-loading system to move laterally in synchrony with the seedling platform while maintaining a stable relative height when the platform undergoes lifting, pitching, or swaying motions. To verify the structural feasibility of the conveying and positioning mechanisms, a SolidWorks interference check was performed for the longitudinal conveying mechanism throughout the full travel range of the lateral guide rail. The results showed no structural interference between the longitudinal conveying mechanism and the seedling platform. Furthermore, the position of the longitudinal conveying mechanism at the end of the lateral guide rail was selected as the worst-case operating condition, and a static deformation analysis was conducted on the 5-mm-thick aluminum-alloy base plate. The maximum displacement at the end of the base plate was less than 8 mm, indicating that the structure satisfied the basic positioning and conveying requirements of the automatic seedling-loading system.

Control system design

To achieve full automation of the rice seedling loading process, a dedicated control system was developed. In Fig. 4, the system uses the seedling shortage alarm signal from the high-speed ride-on rice transplanter as its input and employs an STM32-M3 microcontroller as the central processing unit.

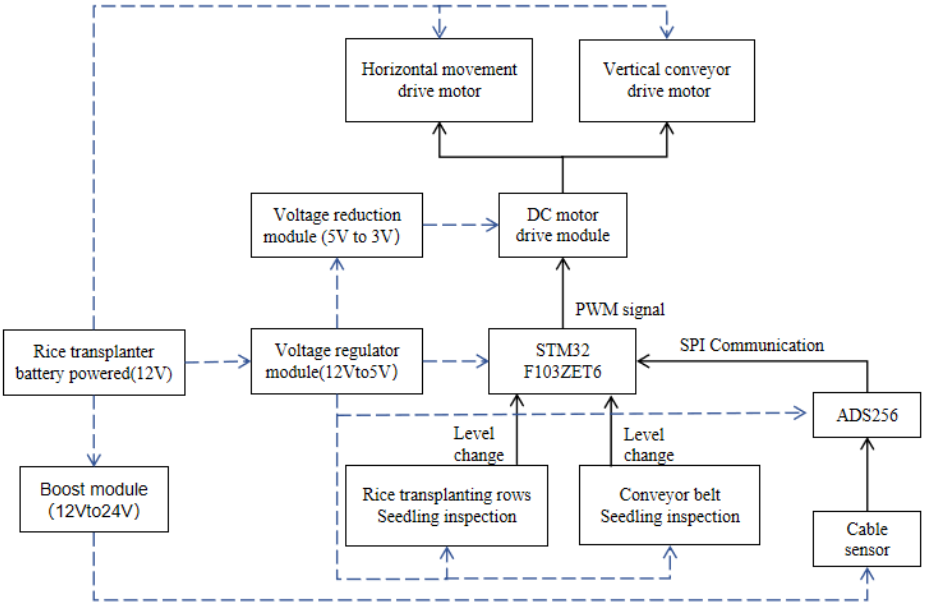

Fig. 4. System architecture of the automatic seedling-loading system

Note: The seedling-shortage switches detect the presence or absence of seedlings on the conveyor belt and in each seedling-holding column. The pull-wire displacement sensor measures the position of the laterally movable platform, and its signal is transmitted through the ADS1256 converter. Based on the detected seedling status and lateral-position feedback, the STM32 controller drives the lateral motor to align the longitudinal conveying mechanism with the target column and then activates the conveyor drive motor to complete the seedling-replenishment operation. Solid lines indicate control-signal or drive relationships, whereas dashed lines indicate power-supply connections.

The control architecture comprises four functional modules: ① seedling status detection, ② lateral position detection, ③ drive control, and ④ power management. A seedling-shortage switch installed on the rice transplanter detects the presence or absence of seedlings in each seedling-holding column of the seedling platform and determines whether the longitudinal conveying mechanism is ready to perform a replenishment operation.

An MPS-S-2500-V1-F pull-wire displacement sensor, used in conjunction with an ADS1256 analog-to-digital (A/D) converter, acquires real-time positional data from the laterally movable platform. The sensor has an output voltage range of 0–5 V, a linearity of ±0.15%, a repeatability of ±0.02%, a maximum operating speed of 1 m/s, and an IP65 ingress protection rating. The sensor output is acquired using the 24-bit ADS1256 A/D converter. Before the tests, the longitudinal conveying mechanism was sequentially aligned with the center of each seedling-holding column, and the corresponding digital output values were recorded as the calibrated target-position values for the respective columns.

Seedling shortage detection was performed using mechanically actuated switch sensors. When a seedling pressed the sensor lever, the corresponding controller input changed from a high level to a low level, and the system determined that seedlings were present at that position. When the lever was released, the system identified a seedling shortage. The shortage detection signal was assigned a relatively high interrupt priority to ensure timely recognition.

After identifying the seedling-holding column requiring replenishment and its corresponding lateral position, the STM32 controller employed a closed-loop control method based on position error and velocity feedback to regulate the PWM signal of the lateral drive motor, thereby moving the longitudinal conveying mechanism to the target shortage column. Once positioning was completed, the longitudinal conveyor motor was activated to perform point-specific seedling replenishment. The controller used a position-control cycle of 50 ms, during which the lateral positions measured by the pull-wire displacement sensor at the current and previous sampling instants were acquired.

The lateral velocity was then calculated from the difference between the two sampled positions:

$$V_k = \frac{x_k - x_{k-1}}{T_s} \quad (1)$$

where the two position variables denote the lateral positions at the current and previous sampling instants, respectively, and the sampling period is set to 50 ms. The controller considers both the distance between the target and current positions and the lateral velocity, and controls the lateral drive motor by adjusting the PWM duty cycle. As the mechanism approaches the target position, the PWM output is reduced to ensure that it stops smoothly at the seedling-holding column requiring replenishment. The conveyor belt of the longitudinal seedling conveying mechanism is then actuated to transport the seedlings and complete the replenishment operation, thereby enabling precise control of both the lateral moving mechanism and the conveyor belt mechanism.

The hardware configuration of the control system is shown in Fig. 5. It consists of the following components: ① a motor drive module, ② a main control unit, ③ an STM32F103ZET6 core board, ④ an A/D acquisition module, and ⑤ a boost module. The control system and the autonomous-driving controller are housed together in a sealed control box. To ensure reliable operation under field conditions, the control box is mounted within a protective frame that provides additional protection against water ingress, solar radiation, and mechanical vibration.

1. Motor driver module; 2. Main control unit; 3. STM32F103ZET6 core board; 4. AD acquisition module; 5. Boost module

In terms of software design, the system's logical workflow is illustrated in Fig. 6

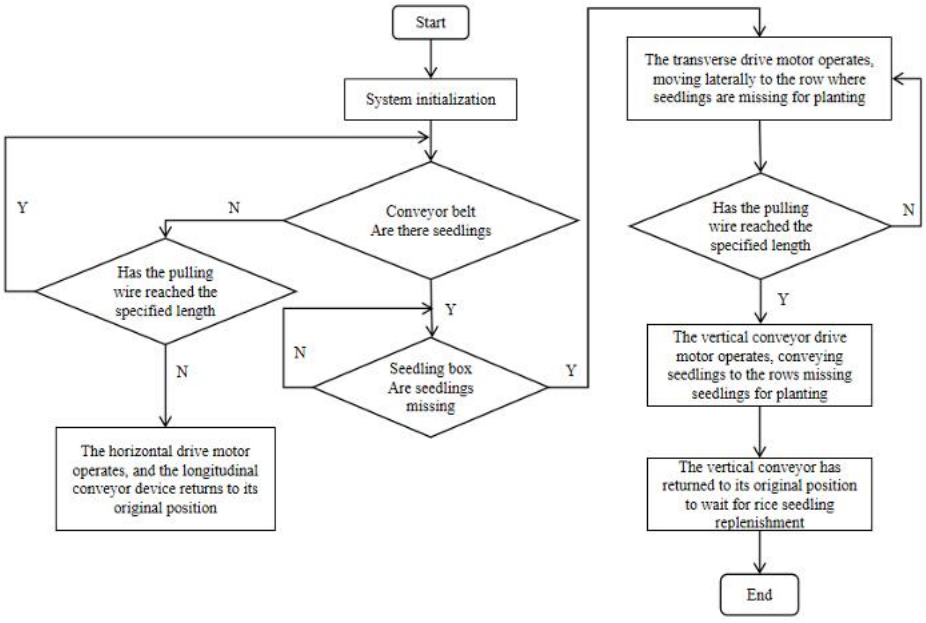

Fig. 6 - System flowchart of automatic seedling loading process

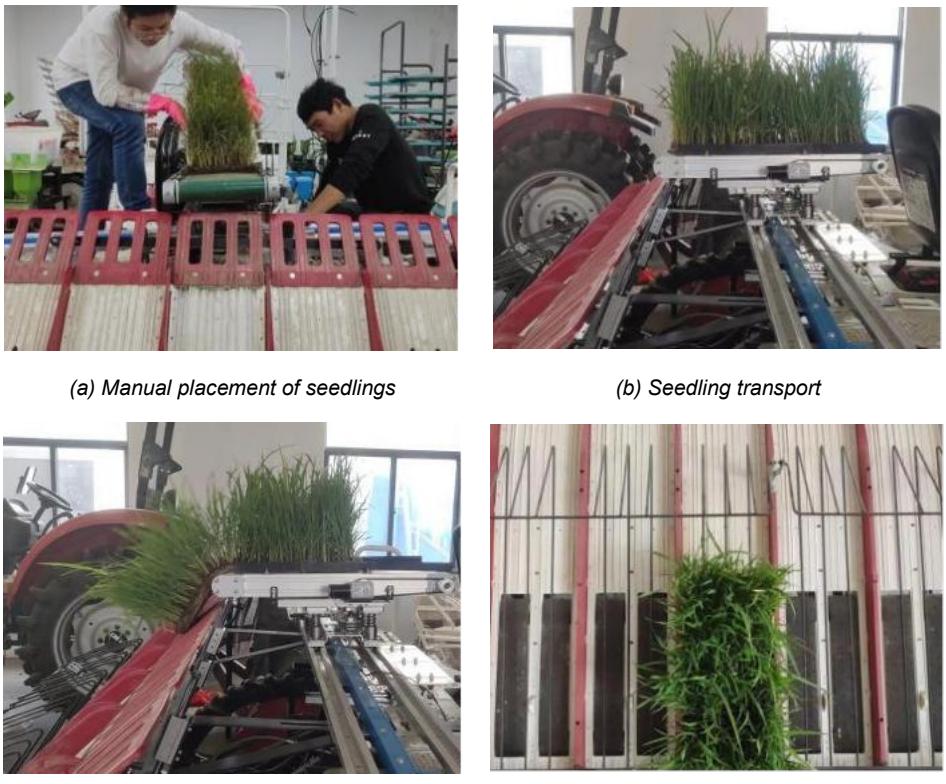
After the system is powered on, an initial self-check is performed, followed by the start of the replanting cycle. The control system continuously monitors the status of each seedling column in real time. When a missing seedling column is detected, the drive mechanism moves to the corresponding target position, and the conveying mechanism is activated to carry out the replanting operation. Upon completion of the replanting task, the system halts the conveyor motor and resets the mechanism to its initial position. It then proceeds to the next round of detection, thus enabling a closed-loop control process for fully automated seedling replenishment.

Bench test



(1) Single-factor experiment

Preliminary experiments verified the reliability of the seedling delivery device, demonstrating its ability to move synchronously with the transplanting platform. However, several key parameters were found to significantly influence the seedling loading success rate, including the conveyor belt speed, the lateral offset distance between the conveyor belt and the seedling column, the left-right tilt angle deviation between the conveyor belt and the seedling platform, the fore-aft tilt angle of the conveyor mechanism, and the height difference between the conveyor belt and the seedling platform. To determine the optimal value range for each factor and improve seedling loading performance, single-factor bench tests were carried out. The seedling loading success rate (C) was used as the evaluation index. A loading operation was considered successful if the result was comparable to manual loading and did not interfere with the transplanter's normal seedling grasping process; otherwise, it was classified as failed loading.

$$C=\frac{R}{Z}\times 100\% \quad (2)$$

where: R is the number of seedling trays successfully loaded (trays) and Z is the total number of seedling trays loaded (trays).

In Fig.7a, seedlings are manually placed onto the conveyor belt. The drive motor is then activated to initiate seedling transportation (Fig.7b). The motor speed is regulated via a speed controller, ensuring controlled moving of the seedlings. As the seedlings reach the end of the conveyor, they detach and drop into the seedling loading column, thereby completing the loading process (Fig. 7c and 7d).

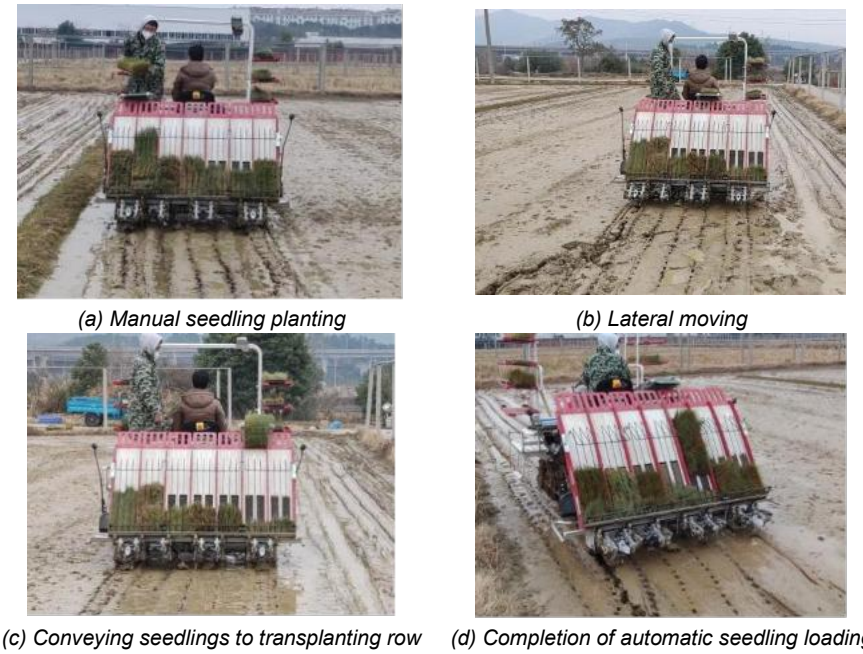
(c) Seedlings falling into seedling platform *(d) Completion of seedling loading*

Fig. 7 - Bench test process for seedling loading

(2) Multifactor experimental design

Based on the results of the single-factor experiments, the structure of the longitudinal conveying mechanism was optimized. Limit stops were installed to restrict the left-right tilt angle to within ±12°. By adjusting the longitudinal conveying mechanism along the vertical slide rail, the height difference between the conveyor belt and the seedling platform was maintained within 80 mm. Based on these modifications, the factor levels and coded values were determined from the ranges that yielded a seedling-loading success rate of 100% in the single-factor experiments. The selected factors were conveyor belt speed, lateral offset distance, and fore-aft tilt angle (Table 1).

Table 1



Factor level coding for experimental design

Encoded values	A: Conveyor belt speed (m/s)	B: Lateral offset distance (mm)	C: Fore-aft tilt angle (°)
−1.682	0.1	−17	−38
−1	0.2	−8.5	−24
0	0.3	0	−10
1	0.4	8.5	4
1.682	0.5	17	18
Horizontal interval value	0.1	8.5	14

Field verification experiment

To further evaluate the overall performance of the automatic rice seedling-loading system, field tests were conducted using the optimal combination of operating parameters obtained from the bench experiments. These tests aimed to verify the system's accuracy, stability, and reliability under actual field operating conditions.

On October 8, 2024, a field trial was conducted at the experimental field of Jiangxi Agricultural University. The experimental material consisted of 7-inch mat-type seedling trays, with seedlings aged 28 days, an average height of 15 cm, and a substrate moisture content of 28%. The seedlings were in healthy condition and met the agronomic requirements for mechanized rice transplanting. The automatic seedling loading process was divided into four stages (Fig. 9). Seedlings were firstly manually placed onto the longitudinal conveyor while the system awaited a seedling shortage signal. Once the seedling shortage detection system identified a column requiring replenishment, the longitudinal conveying mechanism was laterally positioned using the lateral moving device. The longitudinal conveyor belt was then activated to transport seedlings to the corresponding shortage column until the loading process was complete. A total of five batches of automatic seedling loading operations were performed, with 30 loading cycles per batch, successfully completing the loading of 150 seedling trays.

RESULTS AND ANALYSIS

Bench test results

(1) Single-factor experiment results

During the experiment, the conveyor belt speed was varied across 0.1, 0.2, 0.3, 0.4, 0.5, and 0.6 m/s; the lateral offset distance between the conveyor belt and the seedling carrier was set at 12, 13, 14, 15, 16, 17, and 18 mm; the left-right tilt angle deviation between the conveyor belt and the seedling carrier ranged from 0°, 2°, 4°, 6°, 8°, 10°, 12°, to 14°; the fore-aft tilt angle of the conveyor belt mechanism was tested at −35°, −30°, −25°, −20°, −15°, −10°, −5°, 0°, 5°, 10°, 15°, and 20°; and the height difference between the conveyor belt and the seedling carrier was set at 30, 40, 50, 60, 70, and 80 mm.

The statistical values corresponding to seedling loading success rates exceeding 60% were recorded, and their respective ranges are summarized in Table 2. Notably, a 100% success rate was achieved when the left-right tilt angle deviation reached ±12°, and the height difference ranged from 0 to 80 mm.

Table 2

Value ranges of key influencing factors for seedling loading performance

Category	Conveyor belt speed (m/s)	Lateral offset distance (mm)	Left/right tilt angle (°)	Fore-aft tilt angle (°)	Height difference (mm)
Upper limit	0.5	17	−12	18	80
Lower limit	0	−17	12	−38	0

(2) Results of the multifactor experiment

A three-factor, five-level quadratic rotatable orthogonal composite design was employed. The design comprised 20 experimental runs, including six replicates at the center point to evaluate experimental repeatability. Each run consisted of 10 seedling-loading trials, from which the seedling-loading success rate was calculated. The experimental results are presented in Table 3.

To evaluate the repeatability of the automatic seedling-loading system under identical parameter settings, the results of the six center-point runs were statistically analyzed. The center-point settings were a conveyor-belt speed of 0.3 m/s, a lateral offset distance of 0 mm, and a fore-aft tilt angle of −10°. The seedling-loading success rates obtained from the six center-point runs were 90%, 90%, 90%, 80%, 90%, and 90%, respectively. The mean success rate was 88.33%, with a standard deviation of 4.08 percentage points, a 95% confidence interval for the mean of 84.05%–92.62%, and a coefficient of variation of 4.62%. These results demonstrate that the automatic seedling-loading system exhibited good repeatability under identical bench-test conditions and operating parameters.

$$CV = \frac{S}{\bar{Y}} \times 100\% \quad (3)$$

where CV is the coefficient of variation, [%]; S is the standard deviation of the center-point results, [percentage points]; and $\bar{Y}$ is their mean value, [%].

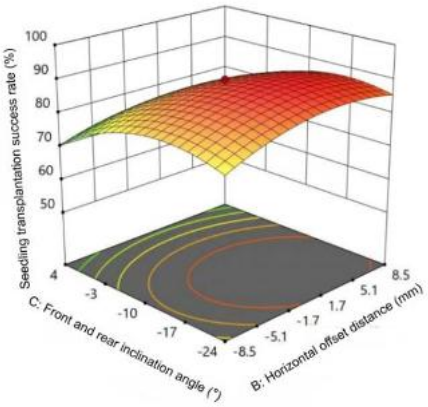
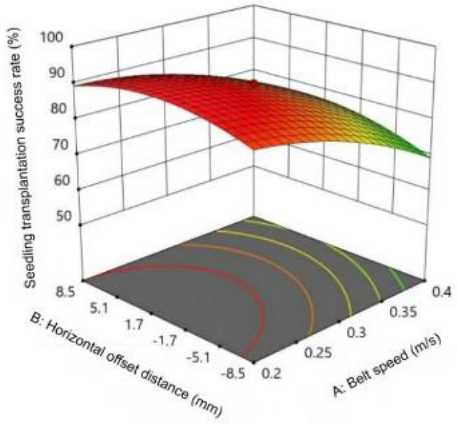
Total	3455	19			
R^2	0.9232				
Adjusted R^2	0.8541				
Signal-to-noise ratio	5.15				
Coefficient of variation	6.73%				



Note: P < 0.01 indicates highly significant and P < 0.05 indicates significant.

Analysis of variance indicated that the model's lack of fit was not significant (P > 0.05), suggesting that no unaccounted factors had a substantial influence on the rice seedling loading success rate. The coefficient of determination (R^2 = 0.9232) demonstrated an excellent model fit, reflecting high reliability and strong predictive capability. The overall model was statistically significant, and A, C, A^2, B^2, and C^2 had highly significant effects on the seedling loading success rate. Using Design-Expert software, the relationship between the multifactor response values and coded variables was analyzed, and a fitted regression equation was derived accordingly.



$$Y=88.41-8.13A+1.88B-5.63C+1.25AB+1.15AC-1.25BC-3.3A^2-4.55B^2-7.05C^2 \quad (2)$$

(a) Interaction between conveyor belt speed and fore-aft tilt angle

(b) Interaction between lateral offset distance and fore-aft tilt angle

(c) Interaction between conveyor belt speed and lateral offset distance

Fig. 8 - The influence of various factors on seedling loading success rate

Note: A denotes the conveyor belt speed, B denotes the lateral offset, and C denotes the fore-aft tilt angle. In (a), B was fixed at 0 mm; in (b), A was fixed at 0.3 m/s; and in (c), C was fixed at −10°. The response surfaces and contour plots were generated from the quadratic regression model of the seedling loading success rate and represent the model-predicted success rate under the combined variation of two factors.

The contour plots and response surface analyses of various factors affecting the rice seedling loading success rate were performed using MATLAB (Fig. 8). In Fig. 8a, when the lateral offset distance is 0 mm, the success rate exhibits a "first increase, then decrease" trend with increasing conveyor belt speed and fore-aft tilt angle. Moreover, fluctuations in success rate caused by changes in conveyor belt speed are more pronounced, indicating that conveyor belt speed has a stronger influence on the response variable than the fore-aft tilt angle. In Fig. 8b, when the conveyor belt speed is fixed at 0.3 m/s, the combined effects of lateral offset distance and fore-aft tilt angle on the success rate follow a "large first, then small" trend. The magnitude of variation caused by changes in lateral offset distance is more substantial, suggesting its greater impact relative to the tilt angle. In Fig. 8c, when the fore-aft tilt angle is −10°, the combined effect of conveyor belt speed and lateral offset distance still follows the "large first, then small" pattern. Additionally, significant fluctuations in the success rate are observed with changes in conveyor belt speed, reinforcing that this factor exerts a greater influence than lateral offset distance.

Based on optimization analysis conducted in Design-Expert, the optimal parameter combination for maximizing the rice seedling loading success rate was determined to be a conveyor belt speed of 0.238 m/s, a lateral offset distance of 2.261 mm, and a fore-aft tilt angle of −11.643°, yielding a predicted success rate of 93.39%. For ease of parameter adjustment, a validation experiment was conducted using rounded values: conveyor belt speed of 0.25 m/s, lateral offset distance of 2 mm, and fore-aft tilt angle of −11°. The experiment was repeated 20 times, resulting in 19 successful loadings and an actual success rate of 95%. The 95% confidence interval for the seedling loading success rate, calculated using the Wilson method, was 76.39%–99.11%. The relative error between the experimental result and the model prediction was 1.72%, confirming the accuracy of the regression model and the reliability of the optimized parameter combination.

Results of the field verification tests

The seedling-loading success rates for the individual batches are presented in Table 5. The second and third batches achieved the highest success rate of 100%, whereas the first and fifth batches had the lowest success rate of 83.3%. The mean success rate across the five batches was 90.67%, with a standard deviation of 8.64 percentage points and a range of 83.3%–100%. Based on the 150 field trials, the 95% Wilson confidence interval for the overall seedling-loading success rate was 84.94%–94.36%.

Table 5

Seedling-loading success rates obtained in the field trials

Trial batch	First	Second	Third	Fourth	Fifth
Seedling-loading success rate (%)	83.3%	100%	100%	86.7%	83.3%

Based on field observations and an analysis of the operating mechanism, the main factors contributing to the reduced seedling-loading success rate were identified as follows:

1) The lateral tilt and vertical displacement of the seedling platform significantly affected the seedling-loading success rate. Owing to uneven terrain, variations in mud depth, and other field conditions, irregular and uncontrollable torsional displacement occurred between the rice transplanter main body and the seedling platform. When the longitudinal conveying mechanism moved laterally to the end of the guide rail, its large lateral overhang, combined with the structural flexibility of the system, amplified this torsional displacement. Consequently, the conveyor outlet fell below the reference height of the seedling platform, hindering the effective delivery of the seedling mat into the target seedling-holding column.

2) Structural constraints and contact interference between the seedling mats and the seedling platform during loading adversely affected placement stability. When the seedling mats collided with the side baffles of the seedling platform, they tended to curl or become entangled with the retaining strips. Consequently, they could not settle properly at the bottom of the seedling-holding column, thereby reducing the seedling-loading success rate.

3) Lateral vibration of the rice transplanter reduced the measurement accuracy of the pull-wire displacement sensor, thereby affecting the alignment accuracy between the conveyor belt and the target seedling-holding column. This vibration caused deviations between the actual and target lateral positions of the longitudinal conveying mechanism, preventing accurate alignment with the column requiring replenishment.

Performance comparison of automatic seedling-handling systems

To evaluate the operating performance of the developed automatic seedling-loading system, representative automatic seedling-picking, feeding, and transplanting systems for which success-rate data were clearly reported were selected for comparison (Table 6). Under the optimized test conditions, the developed system achieved a seedling-loading success rate of 95.00%. This value was 6.77, 4.00, 5.00, and 0.83 percentage points higher than those reported by *Jin et al. (2018), Khadatkar et al. (2024), Han et al. (2019),* and *Chen et al. (2025)*, respectively, but 3.00 percentage points lower than that reported by *Kumar and Raheman (2012)*. The results indicate that the longitudinal conveying, lateral positioning, and seedling-shortage detection and control components operated cooperatively to achieve the automatic loading of mat-type rice seedlings. Because the studies differed in seedling type, stage of automated operation, experimental conditions, and criteria used to define success, the reported values should be interpreted only as indicators of system performance under the respective test conditions.

Table 6

Performance comparison of similar automatic seedling-handling systems

Study	Seedling type	Success rate (%)
Jin X. et al., (2018)	Pepper plug seedlings	88.23
Khadatkar A. et al., (2024)	Pepper and tomato plug seedlings	91.00
Kumar G.V.P. et al., (2012)	Vegetable paper-pot seedlings	98.00
Han L.H et al., (2019)	Vegetable plug seedlings	90.00
Chen M. et al., (2025)	Pepper plug seedlings	94.17
Present study	Mat-type rice seedlings	95.00

CONCLUSIONS

1) An automatic seedling-loading system for high-speed ride-on rice transplanters was developed. The system comprises a longitudinal conveying mechanism, a lateral drive mechanism, and a tracking mechanism. Based on an STM32 embedded platform, the control system integrates seedling-shortage detection, position acquisition, and actuator-control modules, enabling the coordinated execution of seedling-shortage detection, lateral positioning, and targeted seedling replenishment. The developed system successfully performed the automatic loading of mat-type rice seedlings.

2) Single-factor bench tests were conducted using conveyor-belt speed, lateral offset distance, and fore-aft tilt angle as the experimental factors to determine their appropriate ranges. Subsequently, a three-factor, five-level quadratic rotatable orthogonal composite design was employed, and a multifactor regression model of the seedling-loading success rate was established (R^2 = 0.9232). The overall regression model was statistically significant. Twenty verification tests were conducted using the optimized parameter settings of approximately 0.24 m/s, 2 mm, and −11°, resulting in a mean success rate of 95.00%. The overall success rate obtained in the field tests was 90.67%, demonstrating that the system could perform automatic seedling loading under actual paddy-field conditions. However, its performance was lower than that achieved under controlled bench-test conditions, indicating that complex field disturbances remain an important factor limiting stable system operation.

3) The triggering of the mechanical seedling-shortage switches was affected by the morphology of the seedling mats and their contact positions. The output signal of the pull-wire displacement sensor fluctuated owing to lateral oscillation and vibration of the rice transplanter main body. The tracking mechanism accommodated the normal lateral reciprocating and vertical movements of the seedling platform; however, its ability to compensate for irregular lateral oscillation, torsional displacement, and height variations at the ends of the guide rail remained limited. Therefore, the field adaptability of the current system requires further improvement. Future work will focus on improving the seedling-shortage detection method, vibration resistance of the position sensor, support structure at the guide-rail ends, and structural design of the tracking mechanism.

4) The field validation comprised five batches and a total of 150 automatic seedling-loading operations. These tests primarily demonstrated the short-term feasibility of the prototype under specific field conditions but were insufficient to fully assess its long-term operational reliability. Further multi-site, multi-season, and long-duration continuous-operation tests are required, with particular emphasis on evaluating wear of the mechanical connections and transmission components, conveyor-belt tension, sensor drift, motor temperature rise, and adaptability to muddy and waterlogged field conditions. In addition, the attitude of the seedling platform, vibration of the rice transplanter main body, and lateral-positioning error should be measured simultaneously to facilitate further optimization of the tracking mechanism, position-detection method, and control strategy.

Keywords: *Brassica napus; stem biomechanics; orthogonal strain; digital image correlation*

ABSTRACT
The key challenge in Brassica napus combine harvesting is achieving a balance between threshing rate and impurity rate, both of which are strongly influenced by stem breakage. This study investigated the breakage characteristics and static mechanical properties of Brassica napus stems from the middle and lower reaches of the Yangtze River using axial tensile tests combined with digital image correlation (DIC). The results showed that the fiber layer area of rapeseed *stems increased with stem diameter, and stem breaking force was significantly positively correlated with stem diameter. For stem diameters ranging from 7 to 16 mm, the breaking force ranged from 166.82 to 970.82 N and was described by the relationship* $F_b=42.064d_{x1}-92.894$. *The tensile strength of rapeseed stems ranged from 25.1 to 64.6 MPa, and a quadratic response surface model relating tensile strength to stem diameter and moisture content was established. DIC measurements of strain in the radial and axial orthogonal directions showed that axial deformation was substantially smaller than radial deformation, with an average axial strain of* $\varepsilon_y=4.22\pm2.23\times10^{-3}$ *and an average radial strain of* $\varepsilon_x=3.84\pm2.17\times10^{-2}$. *These findings improve the understanding of the mechanical response of rapeseed stems under tensile loading and provide a theoretical basis for optimizing threshing devices for efficient, low-damage rapeseed harvesting.*

摘要
油菜联合收割中的核心挑战是平衡物料的脱净率与破碎率，而这直接受到茎秆破碎程度的影响。本研究针对长江中下游地区的油菜植株，通过轴向拉伸试验配合数字图像相关技术，深入探讨茎秆的破碎条件和静态特性。研究结果显示，油菜茎秆的纤维层的面积随着茎秆直径的增大而增大，茎秆的拉断力和茎秆直径呈显著正相关。在直径为 7 至 16 mm 的油菜茎秆中，拉断力介于 166.82 N 到 970.82 N 之间，其与直径的关系表达为：$F_b=42.064d_{x1}-92.894$*。油菜茎秆的抗拉强度范围为 25.1 MPa 至 64.6 MPa，并建立了油菜茎秆的抗拉强度与油菜茎秆直径及含水率的二次响应面模型。使用数字图像技术对径向和轴向两个正交方向的应变进行测量，结果表明轴向变形显著小于径向变形，平均轴向应变为* $\varepsilon_y=4.22\pm2.23\times10^{-3}$，*径向应变为* $\varepsilon_x=3.84\pm2.17\times10^{-2}$。*这些结果不仅揭示了茎秆在受力过程中的机械响应规律，还为优化脱粒装置以实现高效低损伤的油菜籽收割提供了重要的理论依据。*

INTRODUCTION

Brassica napus is a predominant oil crop in China, playing a pivotal role in ensuring the supply of edible vegetable oil and enhancing farmers' economic returns (*Sun et al., 2026; Guo et al., 2024; Mazzilli et al., 2024*). With the transformation of rapeseed production from merely establishing crop acreage to achieving high-quality harvesting, combine harvesting technology has emerged as a critical factor in enhancing production efficiency and reducing labor costs (*Li et al., 2025; Shu et al., 2025*). In a rapeseed combine harvester, the threshing device is the core component that directly processes the crop mixture consisting of seeds, pods, and stems. Its operating performance directly affects harvest loss, breakage rate, and the load on the cleaning system (*Zhang et al., 2025*).

Guangchao Zhan, Lecture, Ph.D.; Yi Yang, Lecture, Ph.D.; Guodang Lian, Associate Professor, Ph.D.; Peng Zhang, Lecture, Ph.D.; Wangyuan Zong, Professor, Ph.D.

Extensive research indicates that grain loss and cleaning burden during mechanized rapeseed harvesting are intrinsically linked to the mechanical properties and fracture behavior of plant organs such as stems and pods (*Qing et al., 2021*). However, the majority of existing studies have prioritized the optimization of threshing parameters and the evaluation of overall machine performance, while the biomechanical responses of the rapeseed stem itself under typical loading conditions have received comparatively less attention.

During the threshing process of rapeseed combine harvesting, the drum and concave apply repeated beating, rubbing, and compression actions on the material. Consequently, the stems are subjected not only to axial tension, bending, and shear loads but also to complex stress states coupled with transverse compression (*Vlădut et al., 2023; Zhan et al., 2025*). Insufficient stem breakage often leads to the entrapment of pods and grains, thereby reducing threshing and separation efficiency. Conversely, excessive stem fragmentation generates substantial quantities of short segments and fine fibers, significantly increasing the separation burden on the cleaning system, degrading the airflow field and screening conditions, and ultimately resulting in increased cleaning losses and energy consumption (*Zhou et al., 2025; Yuan et al., 2024*). Therefore, a systematic investigation into the deformation and failure laws of rapeseed stems under typical loads, such as tension, from a plant biomechanics perspective is essential. Acquiring a comprehensive understanding of their critical fracture conditions and anisotropic mechanical properties holds significant theoretical value and engineering utility for the structural design and parameter matching of threshing devices (*Tang et al., 2024; Cujbescu et al., 2021; Vlăduț et al., 2022*).

Currently, research regarding the mechanical properties of rapeseed plants primarily concentrates on overall flexural strength, bending modulus, and parameter calibration based on Discrete Element Method simulations (*Guo et al., 2024; Guan et al., 2022; Hu et al., 2025*). In the context of mechanized harvesting conditions, scholars have analyzed stem breaking forces, pod threshing forces, and grain damage mechanisms by combining experimental and simulation approaches (*Sun et al., 2025; Han et al., 2024; Shan et al., 2024*). Some studies have explored the viscoelastic properties and constitutive relationships of rapeseed stems, demonstrating that their mechanical performance is significantly influenced by factors such as variety, moisture content, and nodal structure (*Ren et al., 2014; Lian et al., 2022; Sikorska et al., 2023*). However, these studies predominantly rely on traditional loading and measurement techniques or simulation model assumptions. Consequently, the strain data obtained are typically limited to single-point or local measurements, rendering it challenging to elucidate the full-field deformation characteristics and strain distribution patterns of rapeseed stems, which are heterogeneous and anisotropic biomaterials, under complex loading conditions.

Digital Image Correlation is a non-contact full-field displacement and strain measurement method based on grayscale image matching, distinguished by high measurement precision, broad material applicability, and flexible experimental configuration. In recent years, DIC technology has been widely applied in mechanical testing of materials such as steel and composites, capable of acquiring full-field strain information on specimen surfaces under tensile, compressive, and fatigue loads (*Fang et al., 2026; Wang et al., 2023*). By analyzing speckle images on a material's surface, this method can effectively capture local strain concentrations and damage evolution during deformation, offering a novel technical approach for investigating the deformation and damage of heterogeneous materials like plant stems.

It is noteworthy that reports on the orthogonal strain characteristics of rapeseed stems during uniaxial tensile processes such as axial-radial strain response, cross-sectional anisotropy, and the coupling effects of hollow structures remain scarce. On one hand, rapeseed stems possess hollow, multi-layered tissue structures with distinct fiber orientations, exhibiting significant orthotropic anisotropic deformation characteristics under tensile loads (*Xiao et al., 2026; Han et al., 2024; Parvin et al., 2021*). On the other hand, traditional measurement methods face limitations in simultaneously acquiring full-field strain data in both axial and radial directions during the stretching process, thereby restricting quantitative in-depth analysis of orthogonal strain characteristics and failure mechanisms. Full-field strain measurement based on DIC allows for the synchronous observation and quantitative characterization of axial and radial strains in rapeseed stems during stretching without altering the force boundary conditions of the specimen, providing an effective means to reveal these orthogonal strain properties.

In summary, in light of the significant impact of stem crushing behavior on threshing and cleaning performance during rapeseed combine harvesting, and addressing the current lack of research on orthogonal strain characteristics under tensile conditions, this study aims to employ DIC technology to conduct full-field measurement and analysis of the axial and radial strains of rapeseed stems during the tensile process.

This research seeks to explore the laws governing orthotropic anisotropic deformation and their relationship with structural parameters, thereby providing a theoretical basis and experimental support for understanding the working mechanisms of rapeseed threshing devices and optimizing their design parameters.

MATERIALS AND METHODS

Test Materials and Equipment

Observation of the internal structure of *Brassica napus* plants showed that the rapeseed stem is mainly composed of an outer fiber layer and an inner pith. The rapeseed stem is approximately cylindrical with neatly arranged fiber layers, as shown in figure 1. Assuming that the mechanical parameters in all radial directions (representing the bonding force between fiber layers) are equal, and the axial mechanical parameters primarily consist of the tensile strength of the fibers, the rapeseed stem can be regarded as an orthotropic material similar to wood and bamboo. Therefore, this paper investigates the axial and radial mechanical properties of rapeseed stem respectively.

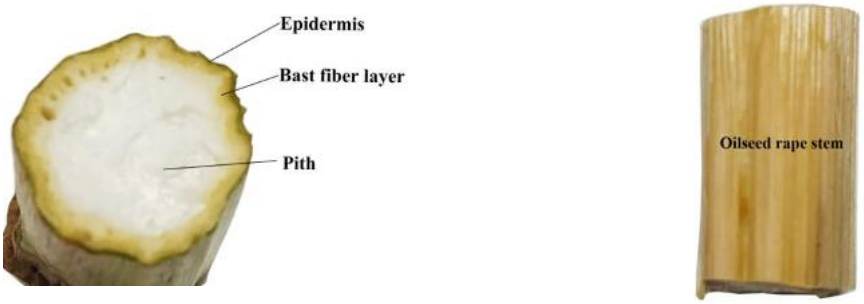

Fig.1 - Structure of rape stem

The test materials were mechanically precision-sown *Brassica napus* plants from the experimental field of Huazhong Agricultural University. The variety was *Brassica napus L*. 'Huayouza 62'. Three plots were randomly selected, and 12 rape plants were chosen from each plot. Healthy plants showing vigorous growth and free from pests or diseases were manually harvested. After harvesting, the rape stems were sectioned to obtain 200 mm segments below the first branch, with diameters ranging from 7 to 16 mm, to serve as the materials for tensile testing. To prevent moisture loss, the collected samples are stored in sealed bags.

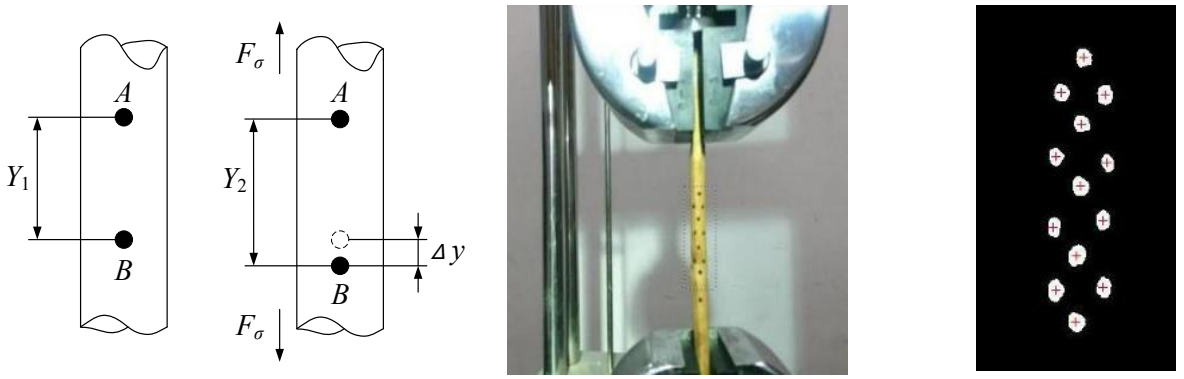
Tensile tests were conducted on the rapeseed stems to determine their axial breaking force, tensile strength, and axial and radial deformation. The main equipment used during the testing process included: a universal material testing machine, a Kinect v2 camera, a laptop computer, a vernier caliper, a marker pen, label paper, an OHAUS moisture analyzer (drying method), sealing bags, and scissors. Key instrument parameters are listed in Table 1.

Table 1

Parameters of the equipment

Equipment	Parameters	Values
RGM-3005 Universal Testing Machine	Maximum Load	5 KN
	Test Speed	0.001~500 mm/min
	Accuracy	±0.5 %
Kinect v2 Camera	Resolution	1920×1080 32bits
	Frame Rate	30 fps
OHAUS Moisture Analyzer	Heating Source	Halogen lamp
	Maximum Capacity	90 g
	Accuracy	0.001 g

Test Methods



During the tensile test, the stem diameter was first measured in two perpendicular directions using a vernier caliper, and the average was taken as the stem diameter. Excluding data on significant slippage and uneven stem cracks during the stretching process, a total of 36 sets of data were recorded in the experiment. Several feature points were marked with a marker pen within a 50 mm gauge section in the middle of the 200 mm long stem. Images of these points were recorded with a camera during stretching for subsequent extraction of axial and radial strains. During the test, the stem was clamped in self-tightening wedge grips to prevent slippage. A universal testing machine was used to apply the load at a constant speed of 20 mm/min.

F_b represents the maximum breaking force endured by the stem at break. This maximum breaking force was monitored in real-time by the universal testing machine and could be read immediately after the test concluded. The moisture content of each numbered stem was measured after testing.

In this experiment, image recognition technology is employed to measure the deformation per unit length of a rapeseed stem. A camera captures images of the stem, which are marked with distinct points for precise tracking. Using MATLAB, these marked points, A and B, are digitally identified to obtain their coordinates. The axial distance between these points before the application of stress is denoted as Y_1. When the stem is stretched to its breaking force, Fb, the new distance is recorded as Y_2. Thus, the axial deformation ε_y can be calculated. Since strain is the relative deformation per unit length of the stem, the spacing between feature points does not need to be converted to actual length, only the pixel changes between feature points in the image are used to calculate. Similarly, radial deformation, ε_x can also be calculated using identified coordinates. As shown in formula (1).

$$\begin{cases} \varepsilon_y = \dfrac{Y_2 - Y_1}{Y_1} \\ \varepsilon_x = \dfrac{X_2 - X_1}{X_1} \end{cases} \quad (1)$$

Prior to the experiment, each stem is marked using a marker to assist in subsequent image recognition, as depicted in figure 2. The setup involves connecting a Kinect v2 camera to a computer, ensuring that the camera is aligned directly with the marked points on the stem.

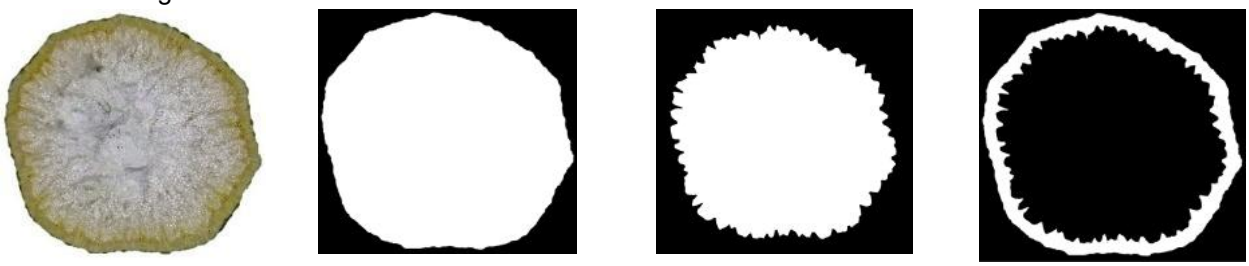
a. Axial deformation of stem b. Feature point marking c. Obtain the coordinates

Fig. 2 - Measuring orthogonal strain by digital image correlation

A caliper is employed to measure the diameter of each stem before testing. During the tensile test, the Kinect v2 camera is used continuously until the stems break, while the maximum breaking force is noted. Each broken stem is catalogued and sealed in a bag for moisture content measurement after the test. Post-experimentation, images captured by the Kinect v2 camera, both before stretching and at the point of breaking, are analyzed using image processing to calculate the radial and axial deformations of the stem. The experimental setup is illustrated in Figure 3.

Fig. 3 - Field of stem tensile test

In the tensile fracture test of rapeseed stems, significant differences were observed in the fracture modes, which can be categorized into three main types: a. Edge fracture; b. Central fracture; c. Tearing, as illustrated in figure 4.



To ensure the accuracy and comparability of experimental data, this study defines stems that exhibit a clean break through the center as the standard mode of fracture. This selection criterion is essential for excluding variations caused by edge effects or asymmetric tearing, thereby ensuring the data reflect the intrinsic tensile properties of the material.

a. Edge fracture b. Central fracture c. Tearing

Fig. 4 - Images of stem before and after tensile stress

The tensile strength of rapeseed stems is primarily governed by the fiber layer, whereas the contribution of the pith layer to the tensile strength is negligible compared with that of the fiber layer. Therefore, the connected domain of the fiber layer in the cross-section of rapeseed stems was extracted through image processing to calculate the area fraction of the fiber layer. Using a standard correction version with a known side length of 1 cm as a reference, convert the pixel area to the actual area. The processing workflow is illustrated in Figure 5.

a. Rapeseed stem cross-section b. Connected domain in the cross-section c. Connected domain of the pith d. Connected domain of the fiber layer

Fig. 5 – Image processing workflow for a rapeseed stem cross-section.

The tensile strength σ_b of rapeseed stems was calculated using the following equation:

$$\sigma_b = \frac{F_b}{S} \quad (2)$$

In Equation (2), F_b is the tensile breaking force of the stem, and S is the area of the fiber layer.

$$S = S_1 - S_2 \quad (3)$$

The area of the fiber layer can be calculated using Equation (3), where S_1 is the total area of the stem cross-section and S_2 is the area of the pith layer.

RESULTS

As shown in figure 5, the tensile breaking force of stems increases with stem diameter. For rapeseed stems with diameters ranging from 7 to 16 mm, the minimum breaking force is 166.82 N and the maximum breaking force is 970.82 N. The functional relationship between stem breaking force and stem diameter d_{x1} is given in equation 4.

$$F_b = 42.064 d_{x1} - 92.894 \quad (4)$$

Figure 6 illustrates the tensile strain of rapeseed stems with different diameters. Analysis indicates that the tensile strain of the stems shows no significant correlation with stem diameter. After removing outlier data points, the average values for radial and axial strain were calculated. The average axial strain was ε_y=4.22±2.23×10^{-3}, and the average radial strain was ε_x=3.84±2.17×10^{-2}. Comparing radial strain with axial strain in stems reveals that axial deformation is significantly smaller than radial deformation. This difference is mainly attributable to the longitudinal orientation of the fiber bundles in rapeseed stems, which provides greater resistance to axial deformation. Conversely, the hollow radial structure of rapeseed stems, when subjected to axial tension, facilitates greater contraction toward the center. Therefore, to thoroughly investigate the mechanical properties of rapeseed stems, their structural characteristics must be fully accounted for. This necessitates separate studies of stem mechanical behavior along both the axial and radial directions.

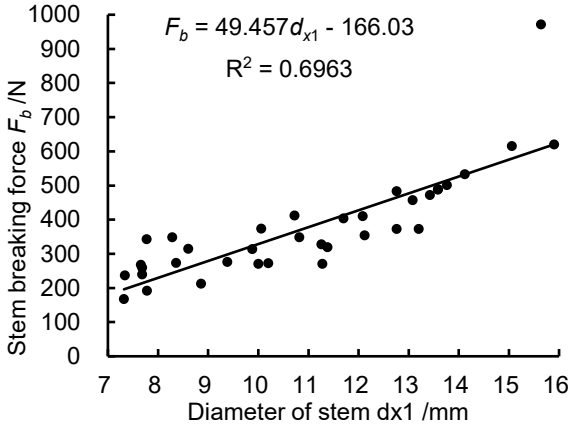


Fig. 5 - Effect of diameter on breaking force

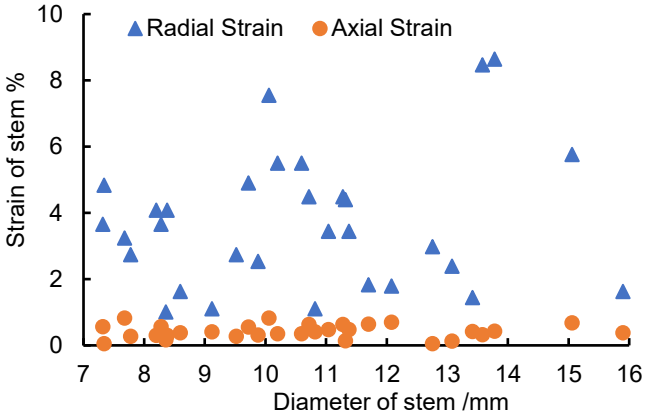

Fig. 6 - Effect of diameter on tensile strain

As shown in figure 7, the area of the rapeseed fiber layer increases with the increase of the diameter of the rapeseed stem, and an R-squared value of 0.9355 indicates a significant correlation between the area of the fiber layer and the size of the diameter. Figure 8 shows the relationship between the diameter of rapeseed stems and their tensile strength. It can be seen from the figure that the tensile strength of rapeseed stems decreases with the increase of stem diameter. The functional relationship between fiber area layer S and stem diameter d_{x1} is given in Equation 5.

$$S = 2.363d_{x1} - 13.135 \quad (5)$$

Figure 8 shows the relationship between the diameter of rapeseed stems and their tensile strength. It can be seen from the figure that the tensile strength of rapeseed stems decreases with the increase of stem diameter. The R value of 0.6617 indicates that the trend is not very obvious, and it is difficult to maintain consistent stem moisture content during the experiment. Therefore, it is necessary to add moisture content as an influencing factor to further analyze the tensile strength of the stem.

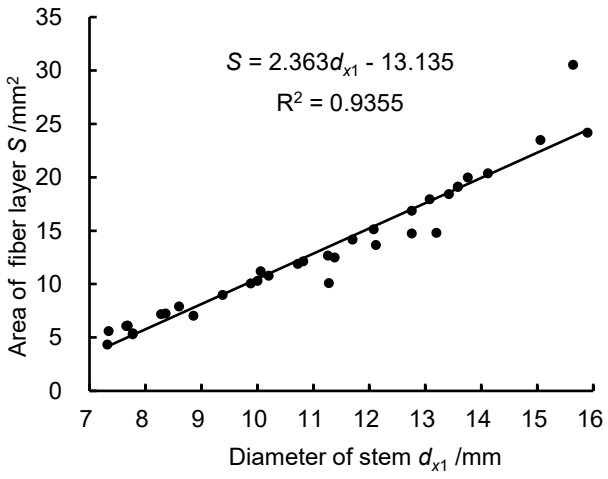

Fig. 7 - Effect of diameter on fiber area

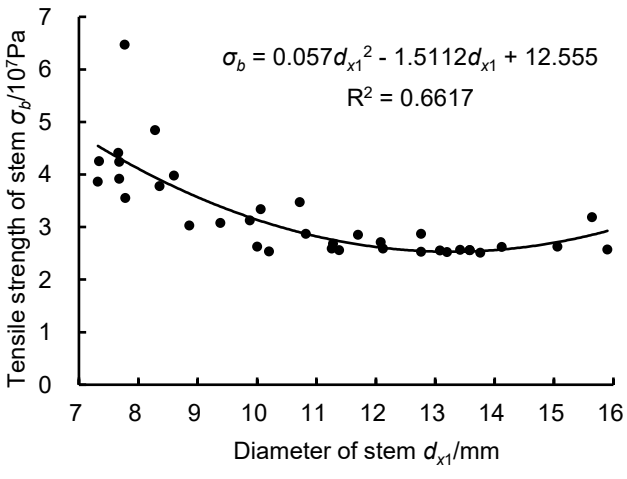

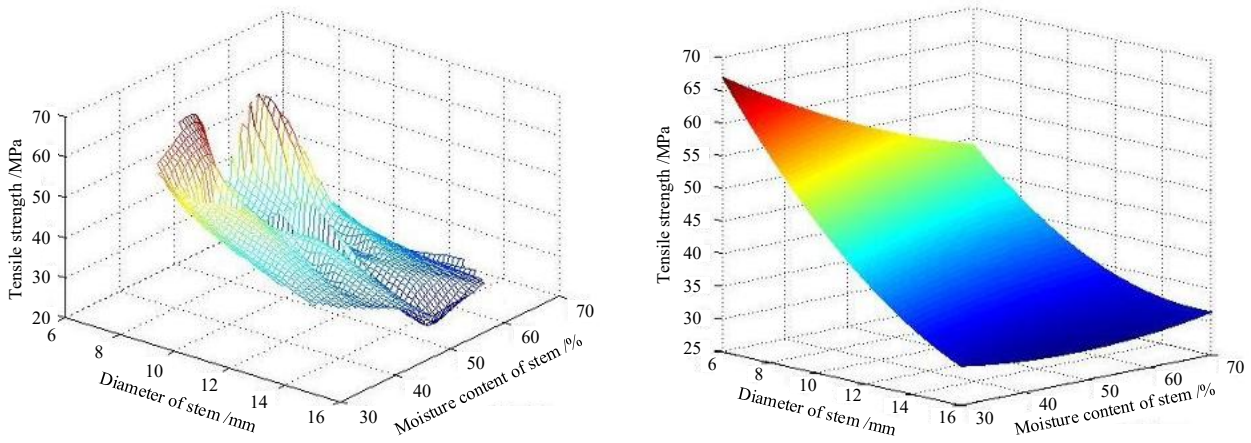

Fig. 8 - Effect of diameter on tensile strength

To investigate the combined effects of stem diameter and moisture content on tensile strength, tensile strength was measured for stems with different diameters and moisture contents, as shown in Table 2. To more clearly visualize the combined effects of stem diameter and moisture content on tensile strength, the measured data were fitted using the least-squares method to construct a three-dimensional response surface. The resulting surface plot, illustrating the relationship among stem diameter, moisture content, and tensile strength over the tested range, is presented in Figure 9.

Experimental Data from Rapeseed Stem Tensile Tests **Table 2**

Number	Mass (g)	Diameter (mm)	Tensile Breaking Force (N)	Moisture Content (%)	Tensile strength (MPa)
1	2.354	8.60	313.73	44.10	39.8

As shown in Figure 9, the tensile strength of rapeseed stems generally decreases with increasing stem diameter. Within the tested stem diameter range of 7–16 mm, the tensile strength exhibits considerable variability, with a minimum value of 25.1 MPa and a maximum of up to 64.6 MPa. In addition, Figure 9 comprehensively presents the combined influence of stem moisture content and diameter on tensile strength. It can be observed that changes in moisture content also alter the mechanical response of the stem material. Generally, as moisture content increases, the binding strength of hydrogen bonds between fibers and the lignin–hemicellulose matrix within the stem may weaken, leading to a decrease in tensile strength. However, the extent to which moisture content reduces tensile strength is not entirely consistent across different diameter classes; stems with larger diameters, owing to their greater structural redundancy, may be relatively less sensitive to changes in moisture content.

a. Mesh plot of the experimental data b. Regression equation surface plot

Fig. 9 - Effect of stem moisture content and diameter on tensile strength

Analysis indicates that both stem moisture content and diameter exert a significant influence. The experimental data were entered into EViews for optimization analysis of regression equation, where dx1 represents rapeseed stem diameter, dx_2 represents stem moisture content, and C denotes the constant term. The correlation test results of variables are shown in Table 3, the results show that the correlation coefficients between d_{x1} d_{x2} and d_{x1}, as well as between d_{x1}^2 d_{x2}^2 and d_{x1}, are all greater than 0.8, indicating strong collinearity. Therefore, the interaction term is not included in the regression model. The results of the analysis of variance for the experimental data are presented in Table 4.

Table 3

Correlation test results of variables

Variable	d_{x1}	d_{x2}	d_{x1}^2	d_{x2}^2	d_{x1} d_{x2}	d_{x1}^2 d_{x2}^2

The experimental data were processed using stem diameter d_{x1} and stem moisture content d_{x2} as variables to perform a quadratic polynomial regression analysis on tensile strength σ_b, yielding the regression equation 6.

$$\sigma_b = -1.3803d_{x1} - 0.4815d_{x2} + 0.0505{d_{x1}}^2 + 0.0047{d_{x2}}^2 + 23.9645 \quad (6)$$

CONCLUSIONS

Axial tensile tests combined with digital image correlation (DIC) systematically revealed the fundamental relationships among stem diameter, moisture content, and the fracture behavior of tensile strength. The breaking force exhibited a strong linear increase with stem diameter, whereas the tensile strength was well described by a quadratic response surface model as a function of both stem diameter and moisture content. Most notably, DIC strain measurements demonstrated pronounced mechanical anisotropy: the radial strain was approximately an order of magnitude larger than the axial strain, strongly indicating a lateral-dominated deformation mechanism prior to failure. Nevertheless, it should be emphasized that these quantitative results are subject to inevitable measurement uncertainties. Primary sources of error include the inherent biological variability among specimens, micro-slippage at the clamping interfaces, local moisture gradients within the stem tissue, and intrinsic noise in the DIC strain computation. Consequently, although the reported trends are considered physically meaningful, the absolute force and strain values should be applied with due caution when high precision is required.

Despite the above limitations, the strongly anisotropic strain behavior suggests that threshing elements designed to induce multi-axial stress states—such as combined bending, shear, and compression—rather than simple uniaxial tension, could more effectively suppress uncontrolled stem fracture, potentially contributing to reduced grain loss and improved seed cleanliness, pending further validation under dynamic and field conditions. These findings thus establish a critical bridge between the biomechanical properties of oilseed rape stems and the engineering optimization of combine harvester threshing units. Future work should progress beyond the quasi-static conditions employed here to dynamic loading regimes that better replicate the complex impact and bending actions encountered inside a threshing chamber. A systematic investigation of additional influential factors—including varietal differences, the maturity gradient along the stem, and internode position—is essential to enhance the generality and predictive power of the developed models. Furthermore, integrating the experimentally measured mechanical parameters into finite element simulations of the stem–threshing element interaction will enable virtual prototyping and parametric optimization. Coupling such simulations with field validation and real-time sensing of stem diameter and moisture content could lay the foundation for adaptive control strategies that autonomously regulate threshing parameters. Ultimately, this integrated approach holds great promise for achieving more efficient and cleaner rapeseed combine harvesting.

Keywords: *botrytis cinerea control, green extraction, ultrasound-assisted percolation, bioactive polyphenols, botanical fungicides, sustainable viticulture*

ABSTRACT

Sustainable management of gray mold (Botrytis cinerea) in viticulture necessitates eco-friendly alternatives to synthetic fungicides to alleviate chemical residue risks and combat emerging pathogen resistance. This study evaluated the biocontrol potential of botanical extracts derived from Allium sativum, Lavandula angustifolia, Salvia officinalis, Cannabis sativa, and Melissa officinalis, obtained via an optimized hybrid ultrasound-assisted percolation process. The optimal extraction parameters were determined to be a particle size of 30 mm, a solid-to-liquid ratio of 1:30, a system pressure of 7 bar, and an ultrasound power of 120 W over a 120-minute extraction duration, achieving high polyphenolic yields while maintaining process energy efficiency. In vitro antifungal screening via the poisoned food technique revealed that A. sativum extract exhibited the most potent inhibition against B. cinerea (78.62% on day 2 and 39.84% on day 7 at a 50% v/v concentration), followed by L. angustifolia (69.62% on day 2). In vivo evaluations on Vitis vinifera L. corroborated a concentration-dependent reduction in disease incidence following post-inoculation application. However, a progressive temporal decline in antifungal efficacy was observed across all crude extracts, highlighting the critical need for microencapsulation strategies or condensed application intervals (3–5 days) under field conditions. Overall, hybrid ultrasound-assisted percolation represents a highly efficient green extraction platform for recovering bioactive compounds suitable for integration into sustainable vineyard crop protection regimes.

REZUMAT

Managementul sustenabil al putregaiului cenușiu (Botrytis cinerea) în viticultură necesită identificarea unor alternative ecologice la fungicidele de sinteză, cu scopul de a diminua riscurile legate de reziduurile chimice și de a combate fenomenul de rezistență al patogenilor. Acest studiu a evaluat potențialul de biocontrol al extractelor botanice obținute din Allium sativum, Lavandula angustifolia, Salvia officinalis, Cannabis sativa și Melissa officinalis, procesate printr-o tehnologie optimizată de percolare hibridă asistată de ultrasunete. Parametrii optimi de extracție au fost stabiliți la o dimensiune a particulelor de material vegetal de 30 mm, un raport solid-lichid de 1:30, o presiune de 7 bar și o putere a ultrasunetelor de 120 W pe o durată de 120 de minute, obținându-se randamente ridicate de compuși polifenolici cu menținerea eficienței energetice a procesului. Evaluarea in vitro a activității antifungice prin metoda Mediului Toxic (Poisoned Food Technique) a arătat că extractul de A. sativum a prezentat cea mai puternică inhibiție împotriva B. cinerea (78.62% în ziua 2 și 39.84% în ziua 7 la o concentrație de 50% v/v), urmat de cel de L. angustifolia (69.62% în ziua 2). Testele in vivo efectuate pe Vitis vinifera L. au confirmat o reducere dependentă de concentrație a incidenței bolii în urma aplicării post-inoculare. Cu toate acestea, s-a observat o scădere progresivă în timp a eficacității antifungice pentru toate extractele brute, ceea ce subliniază necesitatea dezvoltării unor formulări microincapsulate sau a scurtării intervalelor de aplicare (3–5 zile) în condiții de câmp. În ansamblu, percolarea hibridă asistată de ultrasunete se dovedește a fi o platformă ecologică de extracție extrem de eficientă pentru recuperarea compușilor bioactivi capabili să fie integrați în strategii durabile de protecție a culturilor de viță-de-vie.

INTRODUCTION

Grapevine (*Vitis vinifera L.*) is one of the most economically important horticultural crops worldwide, with global grape production exceeding 77 million tons annually (*Ohana-Levi and Netzer, 2025; Butiuc-Keul and Coste, 2023*). However, grape yield and quality can be significantly affected by numerous phytopathogenic agents, among which *Botrytis cinerea*, the causal agent of gray mold, is one of the most important fungal pathogens of grapevine. Infection can cause berry deterioration and decay, with negative effects on grape yield, quality, and commercial value. Disease development is particularly favored by high-humidity conditions, while the difficulties associated with its control justify the interest in identifying effective and sustainable prevention and management methods (*Rahman et al., 2024; Jiang et al., 2023; De Simone et al., 2020; Jacometti et al., 2010*).

Under certain controlled conditions, *Botrytis cinerea* can contribute positively to wine quality through the phenomenon known as “noble rot” (*Hegyi et al., 2022*; *Negri et al., 2017*). *Azzolini et al., (2013),* showed that the controlled inoculation of grapes intended for passito wine production with selected *B. cinerea* strains can modify the aromatic profile, promoting the accumulation of volatile and terpenic compounds associated with the complex aromas of sweet wines. In the study (*Kelly et al., 2022*), the use of a 10% proportion of infected grapes in appassimento-style red wines resulted in only minor chemical and aromatic changes, without significantly affecting consumer acceptance. The article (*Thakur et al., 2018*) mentions *Tokaji Asz´* , *Sauternes, Beerenauslese*, and *Trockenbeerenauslese* among the best-known wines produced through “noble rot”. Botrytization promotes sugar concentration and the accumulation of compounds such as glycerol and gluconic acid, while also contributing to the development of characteristic honey, caramel, and dried-fruit notes typical of premium botrytized wines.

The control of *B. cinerea* relies largely on the use of synthetic fungicides. However, repeated use of chemical products may favor the selection of resistant pathogen populations, while concerns regarding the reduction of the environmental impact of plant protection products have stimulated research aimed at identifying alternative control methods (*Hahn, 2014; Sofianos et al., 2023; Tăbăraşu et al., 2025a; Nenciu et al., 2023)*. In this context, extracts obtained from medicinal and aromatic plants are of interest due to the diversity of bioactive compounds they contain and may represent natural sources of substances with antifungal activity (*Dėnė and Valiuškaitė, 2021; Oprescu et al., 2023*).

Several studies have highlighted the potential of garlic (*Allium sativum L.*) extracts for the control of *Botrytis cinerea*. Aqueous and ethanolic extracts have demonstrated the ability to inhibit both mycelial growth and conidial germination, with the effect being concentration-dependent and potentially reaching complete inhibition (*Daniel et al., 2015*). Furthermore, volatile compounds derived from garlic have proved effective in limiting disease development, highlighting the contribution of sulfur-containing compounds to the antifungal activity of this species (*Campa-Siqueiros et al., 2017*). Antifungal activity has also been demonstrated for extracts obtained from garlic peels, for which inhibition of *B. cinerea* mycelial growth of up to 57.57% was reported, together with a reduction in disease development in *in vivo* tests on strawberries (*Carreón-Delgado et al., 2023*).

Antifungal activity against *B. cinerea* has also been reported for sage extracts. *Rabilu et al., (2021),* evaluated aqueous extracts obtained from *Salvia officinalis subsp. lavandulifolia* and *Salvia officinalis subsp. major*, reporting inhibition of the pathogen’s mycelial growth. Efficacy depended on the extract concentration and the harvesting period of the plant material, with the maximum reported inhibition reaching 59.34%.

The antifungal potential of lavender and lemon balm extracts was evaluated by (*Kasmi et al., 2017)*, who assessed aqueous extracts of *Lavandula officinalis* and *Melissa officinalis* against *B. cinerea*. Under *in vitro* conditions, both extracts affected pathogen development, with the effects being concentration-dependent and varying according to the developmental stage of the fungus. Lavender extract exhibited particularly pronounced activity against spore germination, resulting in 79.65% inhibition at a concentration of 1 mg/mL, whereas lemon balm extract showed lower antifungal activity. In *in vivo* tests, the effects of both extracts were considerably weaker, indicating that the efficacy observed *in vitro* is not necessarily maintained under more complex biological conditions.

Compared with other plant species, the antifungal potential of hemp extracts against *Botrytis cinerea* has been less extensively studied, and the available literature in this field remains limited. In this context, *Kursa et al., (2024)*, highlighted the antifungal potential of extracts obtained from *Cannabis sativa L.* inflorescences against several phytopathogenic fungi. In the case of *B. cinerea*, antifungal activity was concentration-dependent, with the most pronounced effect observed for the 20% extract, for which inhibition values ranging from 45.00 to 75.42% were reported.

The available literature thus highlights the potential of plant extracts to inhibit *B. cinerea*, while also showing considerable variability in their efficacy depending on the plant species, concentration used, and experimental conditions. Moreover, existing studies have predominantly focused on individual plant species or employed different experimental conditions, thereby limiting direct comparisons of their efficacy. In this context, evaluating several plant extracts under the same experimental conditions may contribute to identifying the species with the greatest antifungal potential.

Therefore, the present study aimed to comparatively evaluate the antifungal activity of lavender (*Lavandula angustifolia*), lemon balm (*Melissa officinalis*), sage (*Salvia officinalis*), garlic (*Allium sativum*), and hemp (*Cannabis sativa*) extracts against *Botrytis cinerea* isolated from grapes, in order to determine their ability to inhibit pathogen development and to identify extracts with potential for the development of alternative methods for gray mold control.

MATERIALS AND METHODS

Plant material and preparation

The plant material of *Lavandula angustifolia* Mill., *Melissa officinalis* L., *Salvia officinalis* L., and *Allium sativum* L. was obtained from experimental crops established at the National Institute of Research–Development for Machines and Installations Designed for Agriculture and Food Industry (INMA Bucharest, Romania). Lavender, lemon balm, and sage were harvested between May and June by cutting the aerial parts approximately 10–15 cm above the soil surface. Garlic plants were manually harvested by removing the entire plants from the soil, and the whole plant was used for extract preparation. For *Cannabis sativa* L., the monoecious industrial cultivar '*Marideea*', developed at the Agricultural Research and Development Station Secuieni (ARDS Secuieni, Romania), was used. The buds and inflorescences were used for extract preparation.

After harvesting, the plant materials were sorted and cleaned to remove impurities and damaged tissues and subsequently cut into fragments of 8, 10, 20, and 30 mm. The plant materials were dried in a UFE 500 Model 100–800 laboratory oven (Memmert, Germany) at 40 °C until a final moisture content of 8–10% was reached.

Cannabis sativa L. *Lavandula angustifolia* *Melissa officinalis* *Salvia officinalis* *Allium sativum* L.

Fig. 1 - Dried plant materials prepared for shredding and processing using the hybrid ultrasound-assisted percolation

Preparation of plant extract

The plant extracts were obtained separately from dried and ground material of *Lavandula angustifolia*, *Melissa officinalis*, *Salvia officinalis*, *Allium sativum*, and *Cannabis sativa* using the hybrid ultrasound-assisted pressurized percolation extraction method previously described by (*Tăbărașu et al. 2024b, Tăbărașu et al., 2025c*). For each extraction batch, 400 g of plant material and 12 L of water were used, corresponding to a solid-to-liquid ratio of 1:30 (g/mL). An additional 7 L of water was used as a buffer solvent to fill the pipelines and auxiliary components of the extraction system, thereby ensuring proper system operation.

The extractions were performed using a hybrid extraction system consisting of a TIMATIC Duo percolator (Tecnolab SRL, Spello, Italy), adapted to operate with a single 12 L extraction chamber, and an UP400St ultrasonic generator (Hielscher Ultrasonics GmbH, Teltow, Germany) (Figure 2). The plant material was placed in permeable bags inside the extraction chamber, and water was used as the extraction solvent. The operating conditions were selected based on the results of previous studies (*Tăbărașu et al., 2024b; Tăbărașu et al., 2025c*), which identified the most efficient extraction parameters as an extraction time of 120 min, a pressure of 7 bar, and an ultrasonic power of 120 W. Pressurized percolation and ultrasonic treatment were applied simultaneously throughout the entire extraction process.

(a) (b)

Fig. 2 - Hybrid extraction equipment: (a) front view of the TIMATIC Duo extraction system; (b) rear view showing the Hielscher UP400St ultrasonic generator

At the end of the extraction process, the aqueous extracts obtained from each plant species were collected separately, filtered, and stored at 4 °C until further use in antifungal assays against *Botrytis cinerea*.

a) b) c) d) e)

Fig. 3 - Aqueous plant extracts obtained by ultrasound-assisted pressurized percolation

Based on previous studies, an extraction time of 120 min, a pressure of 7 bar, and an ultrasound power of 120 W were maintained as constant operating parameters. In the present study, the influence of plant material particle size was further evaluated using four fragmentation levels (8, 10, 20, and 30 mm), with 30 mm included as a reference condition based on its favorable performance in previous experiments.

Table 1

Experimental parameters used for the preparation of plant extracts

Parameter	Evaluated / selected values	Experimental approach
Plant material particle size	8, 10, 20, 30 mm	Variable
Extraction time	40, 60, 120 min	Variable
Extraction pressure	7 bar	Constant
Extraction power	120 W	Constant
Plant material	400 g	Constant
Solvent volume	12 L	Constant
Solvent	Water	Constant
Solid-to-liquid ratio	1:30 (w/v)	Constant

***Botrytis cinerea* isolation and culture conditions**

The *Botrytis cinerea* strain (ICDPP-BC-02) was obtained from the Microorganism Collection of the Bioproducts Laboratory for Plant Protection, Research and Development Institute for Plant Protection (ICDPP, Bucharest, Romania), and was originally isolated from grapes of the *Fetească albă* cultivar. Fungal identity was confirmed based on macroscopic and microscopic characteristics, together with phenotypic analysis of the metabolic profile using the Biolog Gen III MicroPlate™ system.

The pathogenicity of the isolate was confirmed prior to the antifungal assays by inoculating healthy grape berries and monitoring the development of characteristic gray mold symptoms. The fungal culture was maintained on Potato Dextrose Agar (PDA) at 4°C and periodically subcultured to preserve viability. For inoculum preparation, conidia were harvested from actively growing cultures and suspended in sterile distilled water containing 0.01% Tween 80.

In vitro antifungal activity of plant extracts

Antifungal effect of the plant extracts evaluated by the poisoned food method

Poisoned Food Technique is a standard *in vitro* microbiological method widely used to evaluate the antifungal activity of bioactive plant extracts or synthetic compounds against phytopathogenic fungi such as *Botrytis cinerea*. The method is based on the homogeneous incorporation of a defined concentration of the test extract into a sterile, melted agar growth medium, followed by solidification of the medium. Subsequently, a mycelial plug of *B. cinerea* is placed at the center of the Petri dish and incubated under controlled conditions. Antifungal activity is quantified by measuring the radial mycelial growth of the treated colonies and comparing it with that of the untreated control, with the percentage of mycelial growth inhibition calculated accordingly.

The plant extracts were tested at final concentrations of 10% and 20%. To prepare the experimental treatments, the appropriate amount of each extract was incorporated into 100 mL of Potato Dextrose Agar (PDA) previously cooled to approximately 45–50 °C. After addition of the extracts, the medium was thoroughly homogenized and aseptically poured into 90-mm-diameter Petri dishes, using 20 mL per plate. Five replicates were prepared for each extract and concentration, while PDA medium without plant extract served as the negative control. Approximately 1 h after medium solidification, each plate was aseptically inoculated at the center with a 5.5-mm-diameter mycelial disc, excised using a sterile cork-borer from the actively growing peripheral region of a 7-day-old *B. cinerea* colony. The inoculum discs were transferred using a sterile inoculating loop. The plates were subsequently sealed with Parafilm and incubated under a natural photoperiod at 22 ± 1 °C.

Antifungal activity was evaluated at 2, 5, and 7 days after inoculation by determining the mycelial growth of *B. cinerea*. The diameter of each colony was measured using a digital caliper along two perpendicular axes, and the mean of the two measurements was used for subsequent calculations. The initial diameter of the inoculum disc (5.5 mm) was subtracted from the measured colony diameter prior to calculating mycelial growth and the percentage of inhibition.

The percentage of mycelial growth inhibition (MGI) was calculated relative to the negative control using the following equation 1:

$$ICM(\%) = \frac{D_m - D_p}{D_m} * 100 \quad (1)$$

where:

D_m represents the mycelial growth diameter in the negative control, and D_p represents the mycelial growth diameter in the treatment containing the plant extract.

In vivo antifungal activity of the hydroalcoholic solutions on grape berries

The *in vivo* antifungal activity of the plant extracts against *Botrytis cinerea* was evaluated on grape berries of the Romanian wine grape cultivar *Fetească albă* (*Vitis vinifera* L. cv.). Healthy berries uniform in size and color, with no mechanical damage or visible symptoms of infection, were selected for the experiment.

Prior to inoculation, the berries were surface-disinfected by immersion in a 1% sodium hypochlorite solution for 2 min, followed by three consecutive rinses with sterile distilled water and drying under aseptic conditions. To verify the effectiveness of the disinfection procedure, a subset of surface-disinfected berries was maintained under the same experimental conditions without artificial inoculation with *B. cinerea*.

For controlled inoculation, each berry was superficially wounded to a depth of approximately 1 mm using a sterile needle. A 10 µL aliquot of a *B. cinerea* conidial suspension, adjusted to a concentration of 1×10^5 conidia/mL using a Thoma counting chamber, was applied to the wounded area. At 2 h after inoculation, aqueous extracts of *Lavandula angustifolia*, *Melissa officinalis*, *Salvia officinalis*, and *Allium sativum* were uniformly applied by spraying. Each extract was evaluated individually at concentrations of 5%, 10%, 15%, and 30%. The control treatment consisted of berries inoculated with *B. cinerea* and left untreated with plant extracts.

The experiment was conducted using a completely randomized design. Each treatment consisted of three biological replicates, with 30 grape berries per replicate, resulting in a total of 90 berries per treatment. After treatment application, the berries were maintained in closed plastic containers to ensure a high relative humidity of approximately 90–95% and incubated in the dark at 20 °C for 14 days. Gray mold development was evaluated 14 days after inoculation by determining disease incidence, expressed as the percentage of grape berries showing visible symptoms of *B. cinerea* infection relative to the total number of berries evaluated for each experimental treatment.

Disease incidence was calculated using the following equation 2:

$$DI(\%) = \frac{N_i}{N_t} * 100 \quad (2)$$

where DI represents disease incidence (%),N_i represents the number of grape berries showing visible gray mold symptoms, and N_t represents the total number of grape berries evaluated.

The treatment groups were structured as follows:

- Control: *Botrytis cinerea* inoculation, then after 4 hours sterile water;
- A1: *Botrytis cinerea* + 5% bio-solution in sterile water;
- A2: *Botrytis cinerea* + 10% bio-solution in sterile water;
- A3: *Botrytis cinerea* + 15% bio-solution in distilled water;
- A4: *Botrytis cinerea* + 30% bio-solution in distilled water.

Statistical analysis

Experimental data was analyzed using three-way Analysis of Variance (ANOVA). For the extraction experiment, extraction time, plant material particle size, and plant species were considered as fixed factors, and total polyphenol content was used as the response variable. For the in vitro antifungal assay, botanical extract type, treatment concentration, and incubation time were considered as fixed factors, and mycelial growth inhibition was used as the response variable. Main effects and all two-way and three-way interactions were evaluated. Prior to analysis, data normality and homogeneity of variance were verified. When significant effects were detected, mean comparisons were performed using Tukey's Honestly Significant Difference (HSD) post-hoc test at a significance level of α = 0.05.

RESULTS

Three-way analysis of variance (ANOVA) was performed to evaluate the effects of extraction time, plant material particle size, and plant species on the total polyphenol content obtained by hybrid ultrasound-assisted percolation. The analysis revealed highly significant effects of extraction time ($F_{2,120}$ = 14152.33, p < 0.001), particle size ($F_{3,120}$ = 32.75, p < 0.001), and plant species ($F_{4,120}$ = 1289.40, p < 0.001). Significant interactions were also observed between extraction time and particle size ($F_{6,120}$ = 30.50, p < 0.001), extraction time and plant species ($F_{8,120}$ = 122.62, p < 0.001), and particle size and plant species ($F_{12,120}$ = 2.82, p = 0.0019). Furthermore, the three-way interaction between extraction time, particle size, and plant species was significant ($F_{24,120}$ = 3.87, p < 0.001), indicating that the effect of particle size on polyphenol recovery depended simultaneously on extraction duration and plant species.

Tukey's HSD post-hoc analysis (α = 0.05) showed significant differences among all three extraction times (p < 0.001). The mean total polyphenol content increased from 11.46 mg GAE/100 g after 40 min to 18.45 mg GAE/100 g after 60 min and 29.22 mg GAE/100 g after 120 min, demonstrating the strong influence of extraction duration on polyphenol recovery under the experimental conditions.

Table 2

Extraction method improvement for hybrid ultrasound-assisted percolation technology

Extraction time (min)	Particle size (mm)	Pressure (bar)	Ultrasound power (W)	TPC *Cannabis sativa* (mg GAE/100g)	TPC *Lavandula angustifolia* (mg GAE/100g)	TPC *Melissa officinalis* (mg GAE/100g)	TPC *Salvia officinalis* (mg GAE/100g)	TPC *Allium sativum* (mg GAE/100g)
40	8	7	120	9.67±0.665	10.16±0.290	10.29±0.619	14.57±0.661	10.32±0.481

60	20	7	120	16.78±0.669	17.03±0.576	18.30±0.608	26.11±0.653	12.19±0.483
60	30	7	120	15.83±0.663	17.93±0.598	17.10±0.619	25.90±0.661	11.89±0.480
120	8	7	120	27.15±0.559	33.11±0.631	29.65±0.596	34.79±0.760	27.82±0.465
120	10	7	120	26.43±0.551	32.28±0.631	28.84±0.611	34.18±0.754	27.06±0.454
120	20	7	120	25.71±0.563	31.24±0.562	28.06±0.599	33.25±0.767	26.58±0.470
120	30	7	120	24.03±0.559	30.46±0.549	26.47±0.596	31.92±0.760	25.34±0.465

*TPC – Total polyphenol content

Significant differences were also observed among the plant species evaluated. Across all experimental conditions, *Salvia officinalis* exhibited the highest mean total polyphenol content (25.27 mg GAE/100 g), followed by *Lavandula angustifolia* (20.23 mg GAE/100 g), *Melissa officinalis* (19.25 mg GAE/100 g), *Cannabis sativa* (17.73 mg GAE/100 g), and *Allium sativum* (16.06 mg GAE/100 g). Tukey's HSD test indicated significant differences among all pairwise species comparisons ($p < 0.001$).

Particle size also significantly influenced polyphenol recovery. The overall mean values were 20.26, 19.90, 19.58, and 19.09 mg GAE/100 g for particle sizes of 8, 10, 20, and 30 mm, respectively. Tukey's HSD test indicated significant differences among the particle-size levels ($p < 0.05$). However, because significant interactions involving particle size were detected, particularly the significant three-way interaction, these overall means should be interpreted cautiously, as the magnitude and direction of the particle-size effect depended on both extraction time and plant species.

At the shorter extraction time of 40 min, the influence of particle size varied among plant species, whereas at 120 min smaller particle sizes generally resulted in higher polyphenol recovery. At 120 min, the differences between 8 and 30 mm were approximately 3.12, 2.65, 3.18, 2.87, and 2.48 mg GAE/100 g for *Cannabis sativa, Lavandula angustifolia*, *Melissa officinalis, Salvia officinalis*, and *Allium sativum*, respectively. Although reducing particle size increased polyphenol recovery at the longest extraction time, the additional gain obtained by reducing the material from 30 to 8 mm remained relatively limited compared with the additional energy requirements associated with intensive size reduction.

Overall, the statistical results demonstrate that extraction time exerted a major influence on polyphenol recovery, while the effect of particle size varied according to both extraction duration and plant species. Under the experimental conditions, the combination of a 120 min extraction time, 7 bar pressure, 120 W ultrasound power, and a 30-mm particle size therefore represents a practical technological compromise between polyphenol recovery and process efficiency.

In Vitro Antifungal Efficacy of Selected Essential Oils Against Botrytis cinerea

To address the need for sustainable crop protection solutions, this study evaluated the *in vitro* antifungal efficacy of selected essential oils against *Botrytis cinerea*, systematically characterizing the interaction between oil selection, working concentration, and time-dependent bioactivity retention to support the development of novel botanical formulations.

Table 3

Mycelial growth and growth inhibition of *Botrytis cinerea* in response to hydroalcoholic extract treatments determined by the Poisoned Food technique at 2, 5 and 7 days after inoculation

Hydroalcoholic extract	Concentration (%)	Growth inhibition (%)		
		2 days	*5 days*	*7 days*
Lavandula angustifolia	10	39.84±4.72	25.26 ± 3.91	15.84 ± 3.46
	20	47.14±4.15	32.18 ± 3.67	22.52 ± 3.21
	50	69.62±2.23	44.37 ± 2.84	30.26 ± 2.71
Salvia officinalis	10	40.47±4.75	25.82 ± 4.12	15.46 ± 3.74
	20	48.66±3.36	32.71 ± 3.18	22.12 ± 2.86
	50	58.05±1.53	42.46 ± 1.76	28.27 ± 1.82
Melisa officinalis	10	38.79±3.81	24.74 ± 3.52	14.63 ± 3.17
	20	43.06±0.58	28.47 ± 0.81	18.16 ± 0.94
	50	51.15±1.64	35.38 ± 1.73	23.27 ± 1.69
Allium sativum	10	37.12±0.87	29.85 ± 1.14	20.17 ± 1.26
	20	53.14±4.15	39.72 ± 3.68	28.18 ± 3.51
	50	78.62±2.23	60.36 ± 2.41	39.84 ± 2.63
Cannabis sativa	10	36.22±0.51	23.58 ± 0.73	14.41 ± 0.86
	20	46.24±1.9	31.52 ± 1.83	20.68 ± 1.79
	50	51.31±2.17	34.14 ± 2.08	22.26 ± 2.02
Control (water)	-	0	0	0

Hydroalcoholic extract	Concentration (%)	Growth inhibition (%)		
		2 days	*5 days*	*7 days*
Control (alcohol 6%)	-	3.84 ± 0.72	2.71 ± 0.68	1.96 ± 0.61
Control (chemical)	-	92.10 ± 1.84	94.76 ± 1.42	96.18 ± 1.17

Three-way analysis of variance (ANOVA) showed that mycelial growth inhibition of *Botrytis cinerea* was significantly affected by extract type, concentration, and incubation time ($p < 0.001$ for all three main effects). Incubation time had the largest effect ($F_{2,180} = 1808.64$, $p < 0.001$), followed by extract concentration ($F_{2,180} = 795.32$, $p < 0.001$) and extract type ($F_{4,180} = 145.49$, $p < 0.001$). Significant interactions were also detected between extract type and concentration ($F_{8,180} = 38.68$, $p < 0.001$), extract type and incubation time ($F_{8,180} = 2.59$, $p = 0.010$), and concentration and incubation time ($F_{4,180} = 24.87$, $p < 0.001$). Importantly, the three-way interaction among extract type, concentration, and incubation time was also significant ($F_{16,180} = 3.23$, $p < 0.001$), indicating that the effect of extract concentration on fungal growth inhibition varied according to both botanical species and incubation period.

Tukey's HSD post-hoc test ($\alpha = 0.05$) confirmed significant differences among several extract–concentration combinations at each evaluation time. At 2 days after inoculation, *Allium sativum* extract at 50% produced the highest mycelial growth inhibition (78.62 ± 2.23%), significantly exceeding all other botanical treatments. *Lavandula angustifolia* at 50% showed the second-highest inhibition (69.62 ± 2.23%) and was significantly more effective than the remaining botanical treatments, whereas Salvia officinalis at 50% produced an intermediate inhibition of 58.05 ± 1.53%. The 50% treatments of M*elissa officinalis and Cannabis sativa* showed statistically comparable inhibition values (51.15 ± 1.64% and 51.31 ± 2.17%, respectively).

A similar statistical pattern was observed after 5 days of incubation. The 50% A. sativum treatment remained significantly more effective than the other botanical treatments, with an inhibition of 60.36 ± 2.41%. *L. angustifolia* (44.37 ± 2.84%) and S. officinalis (42.46 ± 1.76%) formed an intermediate efficacy group and did not differ significantly from each other, while *M. officinalis* (35.38 ± 1.73%) and *C. sativa* (34.14 ± 2.08%) showed statistically comparable lower inhibition levels.

After 7 days, A. sativum at 50% continued to exhibit the highest inhibition (39.84 ± 2.63%) and remained significantly superior to all other botanical treatments. *L. angustifolia* (30.26 ± 2.71%) and S. officinalis (28.27 ± 1.82%) showed statistically similar intermediate activity, whereas *M. officinalis* (23.27 ± 1.69%) and *C. sativa* (22.26 ± 2.02%) exhibited the lowest inhibition among the 50% botanical treatments and did not differ significantly from each other.

Tukey's HSD analysis further indicated that the three incubation periods differed significantly within each extract–concentration combination ($p < 0.05$), confirming a progressive reduction in antifungal efficacy between days 2, 5, and 7. Overall, the statistical analysis demonstrates that the antifungal activity of the tested botanical extracts was concentration-dependent but progressively decreased with incubation time, with A. sativum showing the strongest and most persistent inhibitory effect, followed by *L. angustifolia* and *S. officinalis*. The significant three-way interaction indicates that the magnitude of these concentration- and time-dependent effects was specific to the botanical extract evaluated.

A general trend observed across all botanical extracts is the regressive dynamic of inhibition over time. The maximum efficacy recorded on day 2 was followed by a progressive decline in fungistatic effect on days 5 and 7. This phenomenon can be attributed to the gradual volatilization of bioactive compounds or the metabolic capability of the fungus to degrade plant secondary metabolites during advanced stages of mycelial growth. The analysis of experimental controls confirms that the suppressive effect is exclusively attributable to plant biosynthesizes; the 6% alcohol control variant recorded negligible inhibition (ranging between 3.84% and 1.96%), contrasting sharply with the synthetic chemical control, which exhibited persistent and near-total pathogen suppression, increasing from 92.10% on day 2 to 96.18% on day 7.

From an applied perspective, the findings suggest that while botanical extracts—particularly garlic and lavender—represent promising eco-friendly alternatives for mitigating *Botrytis cinerea* infestation, their limited persistence necessitates technological optimization.

To achieve plant protection comparable to synthetic chemical fungicides, higher application concentrations, microencapsulation of bioactive compounds, or repeated applications at short intervals of 3–5 days are recommended.

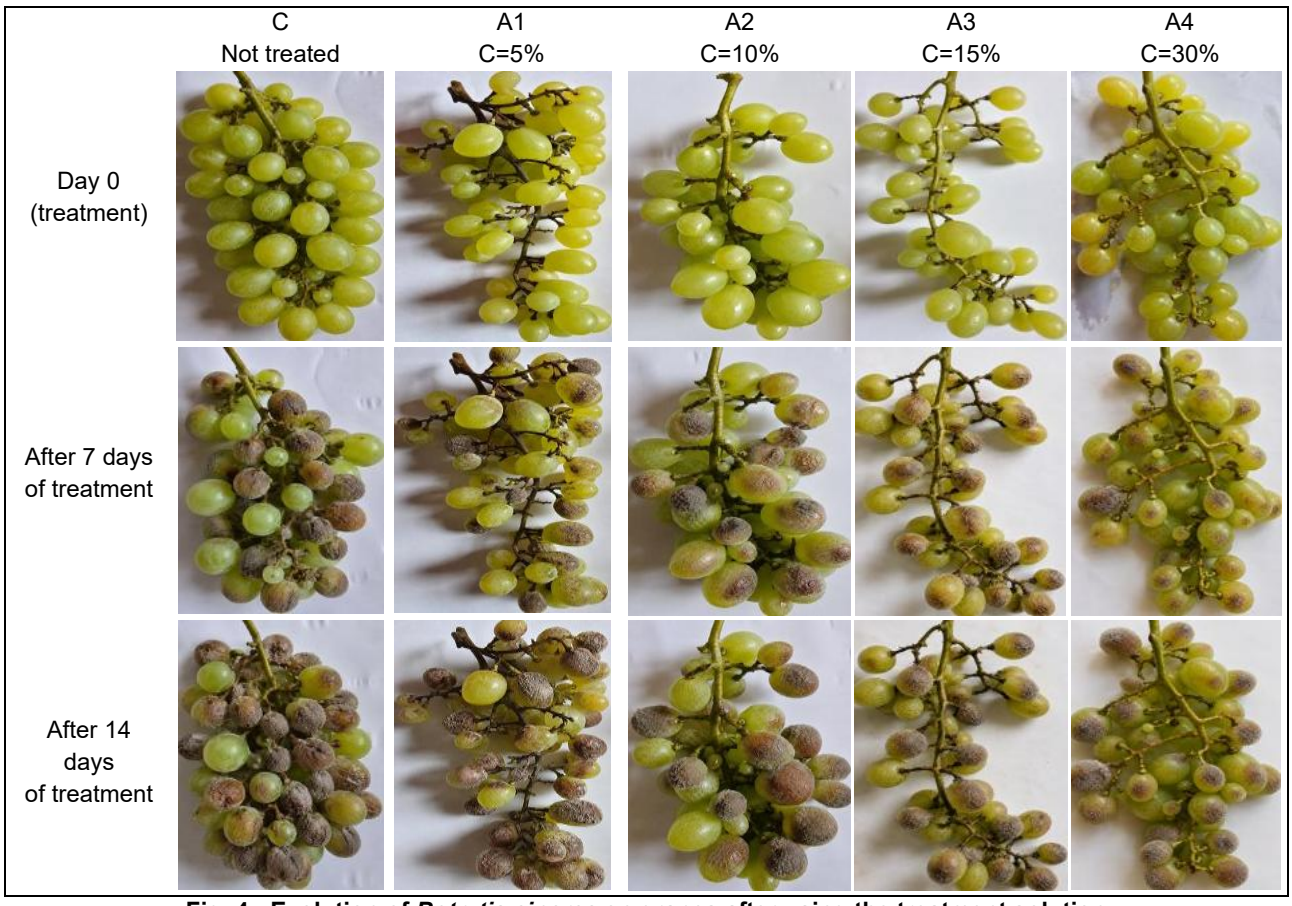

Fig. 4 - Evolution of *Botrytis cinerea* on grapes after using the treatment solution at different concentrations and time periods

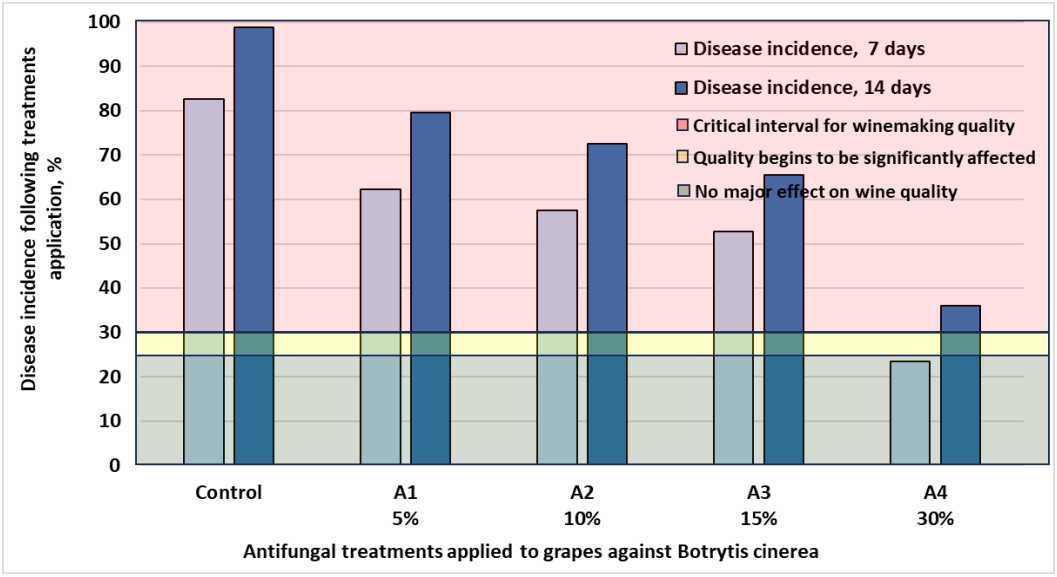

Fig. 5 - Impact of hydroalcoholic plant extracts on *Botrytis cinerea* incidence in grape clusters

The figure 5 demonstrates a clear concentration-dependent antifungal effect, with the incidence of *Botrytis cinerea* progressively decreasing as the concentration of the hydroalcoholic extracts increased. In the control, disease incidence increased from approximately 83% at 7 days to nearly 100% at 14 days, whereas treatments at 5–15% progressively limited infection development, although they were insufficient to maintain disease incidence below the thresholds associated with preserving grape quality. The 30% concentration showed the highest efficacy, reducing disease incidence to approximately 24% after 7 days and 36% after 14 days. The increase in incidence between the two assessment times indicates that the treatment did not completely suppress the infection but rather delayed and limited its progression, with the strongest effect observed at the highest concentration tested.

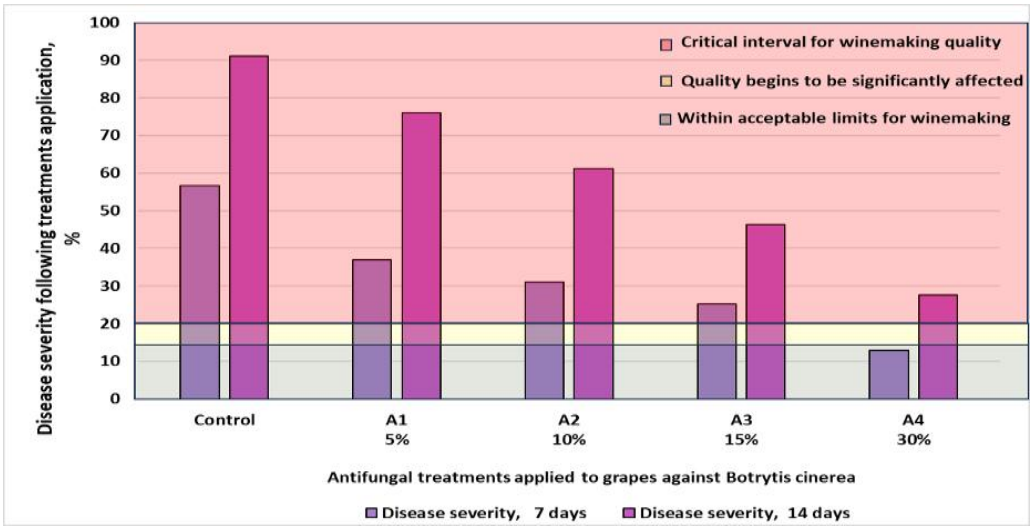

Fig. 6 - Impact of hydroalcoholic plant extracts on *Botrytis cinerea* disease severity in grape clusters

The figure 6 shows a progressive, concentration-dependent reduction in the severity of *Botrytis cinerea* infection. In the control, disease severity increased from approximately 57% after 7 days to 91% after 14 days, confirming the rapid progression of infection. Treatment with hydroalcoholic extracts limited disease development, with severity progressively decreasing as extract concentration increased, reaching approximately 13% at 7 days and 28% at 14 days for A4 (30%). The 30% concentration showed the highest efficacy, being the only treatment that maintained disease severity below 20% after 7 days and substantially limited its progression at 14 days. These results indicate that, although the extracts did not completely prevent disease progression over time, they exerted a clear concentration-dependent protective effect, with the greatest reduction in disease severity observed at the highest concentration tested.

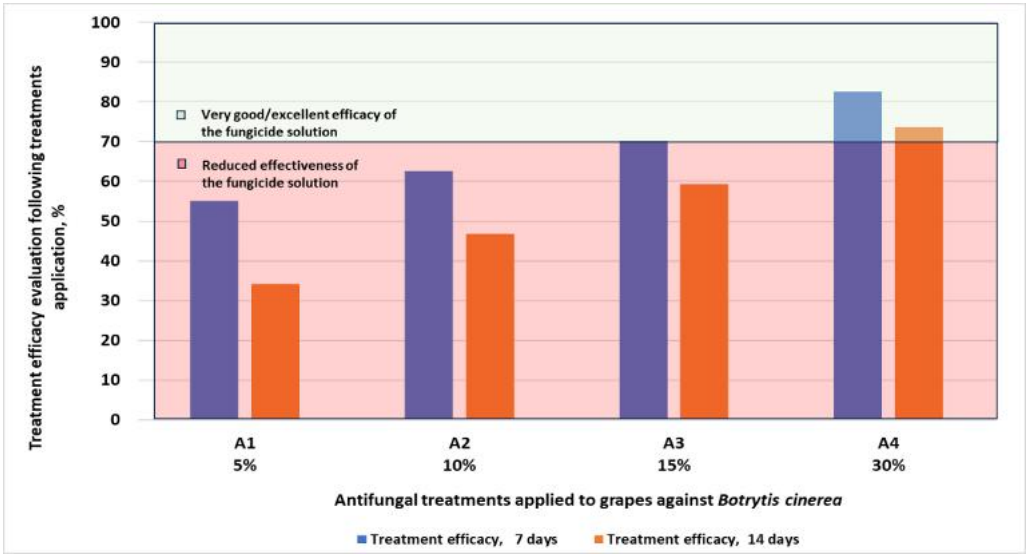

Fig. 7 - Treatment efficiency evaluation on antifungal treatment applied against *Botrytis cinerea* fungus

The figure 7 demonstrates a clear concentration-dependent increase in treatment efficacy against *Botrytis cinerea*. At 5% (A1), efficacy reached approximately 55% after 7 days but decreased to 34% after 14 days, indicating limited persistence of the antifungal effect. Increasing the concentration progressively improved treatment performance, with A2 (10%) and A3 (15%) reaching approximately 62% and 70% efficacy at 7 days, respectively. The highest efficacy was obtained with A4 (30%), reaching approximately 83% after 7 days and remaining at about 74% after 14 days, thus exceeding the 70% threshold associated with very good/excellent efficacy. Although efficacy decreased between 7 and 14 days for all treatments, the results indicate that the 30% concentration provided the strongest and most persistent antifungal effect, confirming the concentration-dependent response of *B. cinerea* to the hydroalcoholic extract treatment.

CONCLUSIONS

The findings of this study demonstrate that hybrid ultrasound-assisted percolation is a highly efficient green technology for recovering bioactive compounds from medicinal and aromatic plants, delivering rich polyphenolic profiles while preserving their structural integrity. Across the in vitro assays, the botanical extracts exhibited clear concentration-dependent antifungal efficacy against *Botrytis cinerea*. Among the single-plant treatments, garlic (*Allium sativum*) and hemp (*Cannabis sativa*) hydroalcoholic extracts achieved the most prominent inhibition of mycelial growth, effectively suppressing fungal development at elevated concentrations. Furthermore, the multi-extract formulation showed enhanced antifungal activity compared to individual extracts, indicating a synergistic action among diverse phytochemicals—such as organosulfur compounds, terpenes, and polyphenols—in disrupting fungal cell membranes and physiological pathways.

When evaluating these results against alternative botanical biopesticides, essential oils derived from aromatic species (e.g., *Lavandula angustifolia* or *Salvia officinalis*) often exhibit superior localized antifungal potency due to their high concentration of volatile lipophilic monoterpenes and sesquiterpenes (*Nenciu et al., 2026*). These volatile fractions penetrate fungal cell walls and disrupt membrane permeability more rapidly than hydroalcoholic extracts. However, pure essential oils present significant operational challenges, including high volatility, rapid photodegradation under field conditions, low extraction yields, and elevated production costs. Hydroalcoholic and aqueous extracts, by contrast, offer a broader spectrum of polar and non-polar phytocompounds, higher extraction yields, better environmental stability, and simpler, cost-effective scalability for bio-fungicide formulations.

Despite these promising biological properties, several practical limitations must be addressed before large-scale adoption. Hydroalcoholic extracts display lower physical persistence on plant tissue post-application, requiring frequent re-application during periods of high disease pressure. Additionally, batch-to-batch variation in secondary metabolite profiles—driven by environmental factors, harvest timing, and raw plant material quality—can result in inconsistent field efficacy.

Future research should focus on optimizing stability through eco-friendly nano-encapsulation or micro-emulsion delivery systems to protect volatile and sensitive polyphenolic compounds from solar degradation. Furthermore, extensive in vivo field trials on grapevine (*Vitis vinifera*) and horticultural crops are required to evaluate phytotoxicity, systemic host defense induction, optimal application timing, and long-term compatibility within integrated pest management (IPM) frameworks.

ACKNOWLEDGEMENT

This research was supported by Project ADER 16.1.1 /29.01.2024 Research on the potential for superior exploitation of the *Cannabis sativa* species for food purposes, funded by Ministry of Agriculture and Rural Development.

Keywords: *granular organic fertilizer, DEM calibration, fluted-wheel fertilizer metering device, fertilization uniformity, discrete element method, response surface methodology*

ABSTRACT
To address parameter optimization and fertilization uniformity of a fluted-wheel fertilizer metering device for granular organic fertilizer, a 3D-scanned fertilizer model was constructed, and an EDEM fertilization simulation model was established. The Poisson's ratio and elastic modulus of the fertilizer were determined using a texture analyzer. Drop tests were conducted to determine the coefficients of restitution between fertilizer particles and between the fertilizer and PA, PC, and PLA. Inclined-plane rolling tests were conducted to determine the rolling friction coefficients between the fertilizer and PA, PC, and PLA. A cylinder-lifting test for measuring the angle of repose, combined with EDEM simulations and a Design-Expert experimental design, was used to determine the static and rolling friction coefficients between fertilizer particles, as well as the static friction coefficients between the fertilizer and PA, PC, and PLA. By combining the discrete element method (DEM) with response surface methodology, the effects of the parameters on fertilization uniformity were ranked as follows: fluted-wheel inscribed-circle diameter > fluted-wheel lead angle > number of grooves; fertilizer-metering shaft rotational speed > fertilizer-discharge flap angle > effective working length of the fluted wheel. The optimal parameter combination was determined to be a fluted-wheel inscribed-circle diameter of 37 mm, 7 grooves, a fluted-wheel lead angle of 63°, an effective working length of the fluted wheel of 31 mm, a fertilizer-metering shaft rotational speed of 28 rpm, and a fertilizer-discharge flap angle of −1°. Soil-bin tests using 3D-printed fluted wheels with different structural parameters produced results that were generally consistent with the simulation results, providing a reference for the DEM-based optimization and design of fluted-wheel fertilizer metering devices.

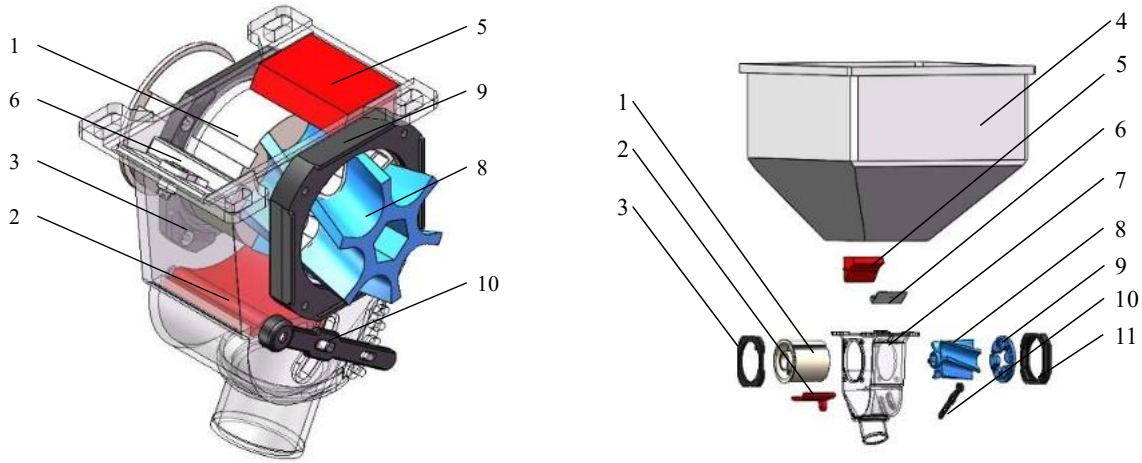
摘要
针对外槽轮式排肥器施用颗粒有机肥参数优化与施肥均匀性问题，构建肥料 3D 扫描模型，建立施肥 EDEM 仿真模型。通过质构仪，获得肥料泊松比和弹性模量；通过下落试验，获得肥料与肥料、PA、PC、PLA 的碰撞恢复系数；通过斜面滚动试验，获得肥料与 PA、PC、PLA 的滚动摩擦系数；通过休止角圆筒提升试验、EDEM 仿真，结合 Design-Expert 试验设计，测定肥料与肥料静摩擦系数、滚动摩擦系数，肥料与 PA、PC、PLA 的静摩擦系数。结合离散元法（DEM）与响应面法，获得参数对施肥均匀性的影响排序分别为：槽轮内接圆直径>槽轮升角>凹槽个数；排肥轴转速>排肥舌角度>槽轮有效工作长度。最优参数组合是：槽轮内接圆直径为37mm，凹槽数量为7，槽轮升角为63°，槽轮有效工作长度为31mm，排肥轴转速为28RPM，排肥舌角度为-1°。采用 3D 打印不同结构参数槽轮，土槽试验结果与仿真基本一致，为排肥器离散元优化设计提供参考

INTRODUCTION
Discrete Element Method (DEM) can simulate fertilizer and other discontinuous agricultural materials. EDEM is a simulation software based on DEM. It comprises a pre-processor for creating and initializing discrete element models, a solver for simulation and calculation, and a post-processing module for displaying and analyzing simulation results.

Published studies have primarily focused on the calibration of discrete element parameters for fertilizers, including intrinsic parameters, basic contact parameters, and contact model parameters; parameter optimization of fertilizer metering devices; and the optimization and design of fertilizer applicators based on EDEM simulations.

The accuracy of the fertilizer particle model, the fertilizer metering device model, and the discrete element parameters forms the basis for reliable EDEM simulations. Most fertilizer particle modeling methods have used single-sphere or multi-sphere models to approximate the actual particle geometry (*Adilet et al., 2021; Xie et al., 2021; Bivainis et al., 2023; Ma et al., 2025*). Experimental designs generated using Design-Expert software, physical angle of repose tests, and discrete element simulations have been used to calibrate the contact model parameters (*Adilet et al., 2021; Xie et al., 2021; Nouh et al., 2024; Ma et al., 2025*).

EDEM was used to simulate the fertilizer discharge process, determine optimal structural and operating parameters and evaluate fertilization performance. In order to enhance the uniformity of fertilizer application, EDEM simulation of a centrifugal fertilizer spreader with two shutter holes was employed to optimize the shutter hole position (*Hwang et al., 2021*). EDEM simulations were used to conduct single-factor and orthogonal tests on the inner diameter, pitch, outlet spacing, and number of screw starts of a blocking-wheel-type screw fertilizer metering device to determine the optimal structural parameters (*Zha et al., 2021*). EDEM simulation was used to establish a simulation model of a centrifugal spreader and evaluated the lateral uniformity of a granular cylindrical organic fertilizer application (*Zinkevičienė et al., 2021*). The structural design and parameters of outer groove wheel fertilizer metering device were studied according to fertilization performance simulated using discrete element modeling (*Zeng, et al., 2020; Wang, J. F. et al., 2023*). Focusing on optimizing the spreading uniformity of a vertical spiral rotor organic fertilizer applicator, EDEM simulations were employed to investigate the effects of rotor speed and rotor inclination angle (*Ștefan et al., 2025*).



Using the coefficient of variation of fertilization uniformity as the evaluation criterion, this study proposed a DEM parameter calibration procedure and an EDEM simulation method to optimize the key parameters of a fluted-wheel fertilizer metering device for granular organic fertilizer. The DEM contact parameters between the fertilizer and three materials used in the metering device (PA, PC, and PLA) were determined. Three structural parameters (the fluted-wheel inscribed-circle diameter, number of grooves, and fluted-wheel lead angle) and three operating parameters (the effective working length of the fluted wheel, fertilizer-metering shaft rotational speed, and fertilizer-discharge flap angle) were optimized. Soil bin tests were conducted to validate the performance of the optimized parameter combination.

MATERIALS AND METHODS

Simulation model and key parameters

Model and materials of fertilizer metering device

As shown in Fig. 1(a), the fluted wheel is the core component of the fertilizer metering device, with a mounting-hole diameter of 70 mm.

(a) Fluted-wheel fertilizer metering device (b) Exploded view of the fertilizer metering device

Fig. 1 - 3D model of the fertilizer metering device

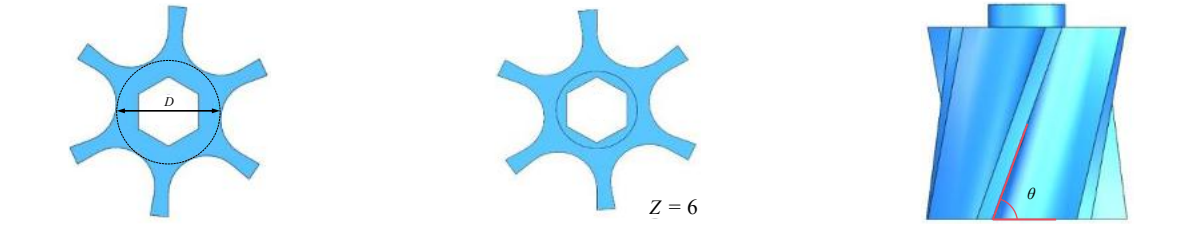
Table 1 details the materials used for different components of the fertilizer metering device, including PA, PC, and PLA.

Table 1

Materials of different components of the fertilizer metering device

No.	Component	Material
1	Blocking wheel	Polyamide (PA)
2	Fertilizer metering device housing	Polycarbonate (PC)
3	Fluted wheel	Polylactic acid (PLA)
4	Fertilizer discharge flap	Polyamide (PA)
5	Baffle	Polyamide (PA)

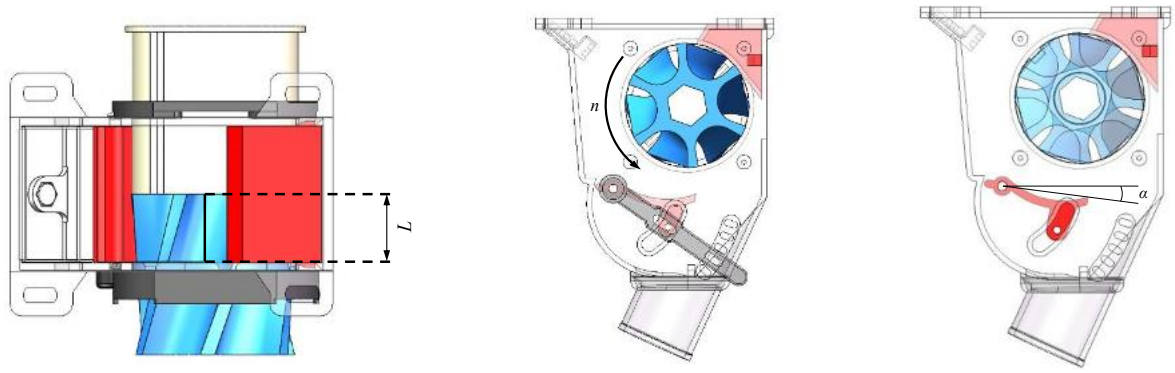
Key parameters of fertilizer metering device



Consistent with previous literatures (*Zeng et al. 2020; Wang Y. et al. 2023*), the fertilizing amount per circle *q* and the total fertilizing amount *Q* of a fluted-wheel fertilizer metering device can be calculated by:

$$q = L\,\gamma\,S\,\psi\,Z \tag{1}$$

$$Q = q\,n\,t \tag{2}$$



where, L is the effective working length of fluted wheel, cm; γ is the density of fertilizer, g/cm^3; S is the cross-sectional area of a single flute, cm^2; ψ is the filling coefficient of the groove; Z is the number of grooves; n is the fertilizer-metering shaft rotational speed, RPM; t is the time of fertilizer discharge, minute.

Fig. 2 shows the fluted-wheel inscribed-circle diameter D, the number of grooves Z, and the fluted-wheel lead angle θ. Fig. 3 shows the adjustable operating parameters, namely the effective working length L of the fluted wheel, the fertilizer-metering shaft rotational speed n, and the fertilizer-discharge flap angle α. According to Eqs. (1) and (2) and previous studies (*Zeng et al., 2020; Wang Y. et al., 2023; Wang J. F. et al., 2023*), these key parameters may affect the variables involved in the equations and thereby influence fertilization uniformity.

Fertilizer simulation model

This study used an amino acid organic fertilizer (China agricultural industry standard for organic fertilizer, NY525-2012), organic matter ≥ 45%, and total nutrient ($N+P_2O_5+K_2O$) ≥ 10%. The 100 fertilizer particles were randomly selected and measured using a digital display vernier caliper (DL 91200 with an accuracy of 0.01 mm) to obtain the fertilizer's average length, width, and thickness.

$$D = \sqrt[3]{LWT} \tag{3}$$

$$\phi = \frac{D}{L} \tag{4}$$

where: D is the equivalent diameter (mm); L is the average length (mm); W is the average width (mm); T is the average thickness (mm); Φ is the sphericity. The equivalent diameter D of the fertilizer was 4.29 mm, and the sphericity Φ was 97%. The proportion of particles in three intervals of large (D ≥ 5 mm), medium (4 mm < D < 5 mm), and small (D < 4 mm) were 15%, 80%, and 5%, respectively.

As shown in Fig. 4(a), the fertilizer particle was sprayed with a contrast enhancer (imaging agent), and was scanned using a 3D scanner (G5-630 with a scanning accuracy of 0.02 mm). To improve the accuracy of three-dimensional model of the fertilizer particle, the turntable was rotated approximately every 10 degrees to scan the particles, capturing surface characteristic data each time. As illustrated in Fig. 4(b), the completeness of the particle model was monitored in the software to ensure all surface feature data were acquired. After scanning, the 3D shell model of the fertilizer particle underwent noise removal and defect correction.

Fig. 5 - Three-dimensional model of fertilizer particles

DEM parameter calibration method

Poisson's ratio of the fertilizer

As shown in Fig. 6, a fertilizer particle was placed at the center of the platform of a texture analyzer (TA.XTplusC, force measurement accuracy: 0.0001 N). The particle was compressed using a rigid probe at a loading rate of 5 mm/min, with an initial trigger force of 0.375 N. Loading was stopped when the fertilizer particle fractured. The transverse and longitudinal dimensions of the particle were then measured after compression.

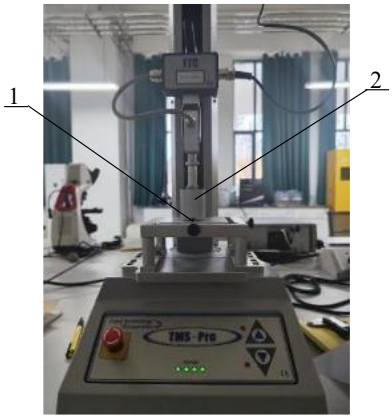

Fig. 6 - Measurement procedure using the texture analyzer

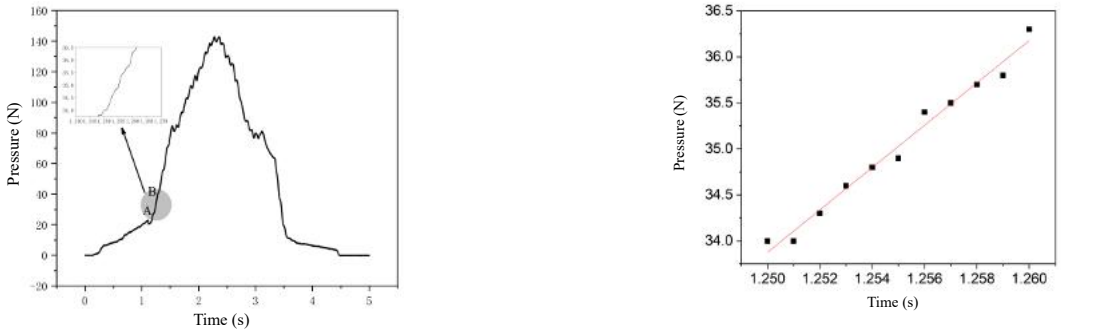
1. fertilizer particle, 2. probe

Poisson's ratio was calculated using Eq. (5). The test was repeated five times, and the mean value was used as the final result.

$$\mu = \frac{\varepsilon_T}{\varepsilon_L} = \frac{\Delta l / l}{\Delta d / d} \tag{5}$$



where: μ is the Poisson's ratio, ε_T is the transverse strain of the fertilizer particle, ε_L is the longitudinal strain of the fertilizer particle, Δl is the transverse deformation of the fertilizer particle (mm), l is the initial transverse dimension of the fertilizer particle (mm); Δd is the longitudinal deformation of the fertilizer particle (mm); d is the initial longitudinal dimension of the fertilizer particle (mm).

Elastic modulus of the fertilizer

The elastic modulus reflects a material's resistance to elastic deformation and was measured using a texture analyzer. Large fertilizer particles were selected and polished with sandpaper into cylindrical specimens. The prepared specimens were placed at the center of the loading platform and compressed using a rigid probe at a loading rate of 5 mm/min. The initial trigger force was set to 0.375 N. Fig. 7(a) shows the force–time curve, while Fig. 7(b) shows the force–time curve corresponding to the elastic deformation region. The elastic modulus was calculated using Eq. (6). The test was repeated five times, and the mean value was taken as the final result.

$$E = \frac{\sigma}{\varepsilon} = \frac{\Delta F / A}{v \cdot \Delta t / h} = \frac{h}{vA} \cdot \frac{\Delta F}{\Delta t} = \frac{kh}{vA} \tag{6}$$

where: E is the elastic modulus of the fertilizer (Pa), σ is the stress within the elastic limit, ε is the strain within the elastic limit, A is the cross-sectional area of the fertilizer specimen (mm²), ΔF is the force increment within the elastic deformation region (N), v is the loading speed of the texture analyzer (mm/s), h is the height of the fertilizer specimen (mm), k is the slope of the elastic deformation region of the force–time curve.

(a) force-time curve (b) linear fit of the elastic deformation region

Fig. 7 - Force–time characteristics of a fertilizer particle

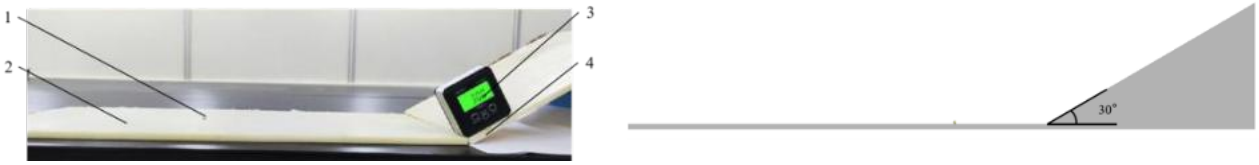
Coefficient of restitution of the fertilizer

The coefficient of restitution characterizes the degree of energy loss during a collision and can be expressed as follows:

$$e = \sqrt{\frac{l_2}{l_1}} \tag{7}$$

where: l_1 is the initial drop height (m) and l_2 is the rebound height (m).

As shown in Fig. 8, the complete rebound and subsequent falling process of the fertilizer particles was recorded during the free-fall test. The rebound height of the fertilizer particles was measured, and the test was repeated five times to obtain the mean value.



(a) coefficient of restitution test setup (b) slow-motion image of the rebound process

Fig. 8 - Coefficient of restitution test

1. ruler, 2. fertilizer granules, 3. background plate, 4. impact plate

Rolling friction coefficients between the fertilizer and PA, PC, and PLA

Fig. 9(a) shows the inclined-plane rolling test used in this study. Two plates made of the same material as the corresponding components of the fertilizer metering device were used. One plate was placed horizontally, while the other was inclined at 30° to the horizontal. Fertilizer granules were released from a position 100 mm above the horizontal plate and moved down the inclined plate under gravity. The rolling distance of the fertilizer granules on the horizontal plate was recorded, as shown in Table 2. The test was repeated five times, and the mean value was calculated. Fig. 9(b) shows the corresponding EDEM simulation of the fertilizer particle rolling test. As shown in Table 3, the rolling friction coefficient was varied within the range of 0.1-0.2 in the simulation tests. Each test condition was repeated five times, and the mean value was calculated.

(a) inclined-plane rolling test (b) EDEM simulation test

Fig. 9 - Calibration test for the rolling friction coefficient

1. fertilizer granule, 2. horizontal nylon plate, 3. digital inclinometer, 4. inclined nylon plate

Table 2

Results of the inclined-plane rolling test

Material pair	Mean rolling distance [mm]
Fertilizer - PA	212.09
Fertilizer - PC	244.09
Fertilizer - PLA	230.36

Table 3

Simulation results of the rolling test

Rolling friction coefficient / Material pair	0.10	0.12	0.14	0.16	0.18	0.20
Fertilizer - PA [mm]	357.21	276.33	232.41	195.63	152.67	136.89
Fertilizer - PC[mm]	389.47	311.96	263.25	226.34	179.35	146.23
Fertilizer - PLA[mm]	372.89	308.37	253.12	210.39	177.45	149.20

As shown in Table 4, Origin software was used to perform linear regression on the simulation data, and a fitting equation was obtained for each material pair. In the fitting equations, *y* represents the rolling distance of the fertilizer granules, and *x* represents the rolling friction coefficient. As shown in Table 5, the rolling friction coefficients between the fertilizer and PA, PC, and PLA were determined by substituting the experimentally measured rolling distances into the corresponding fitting equations.

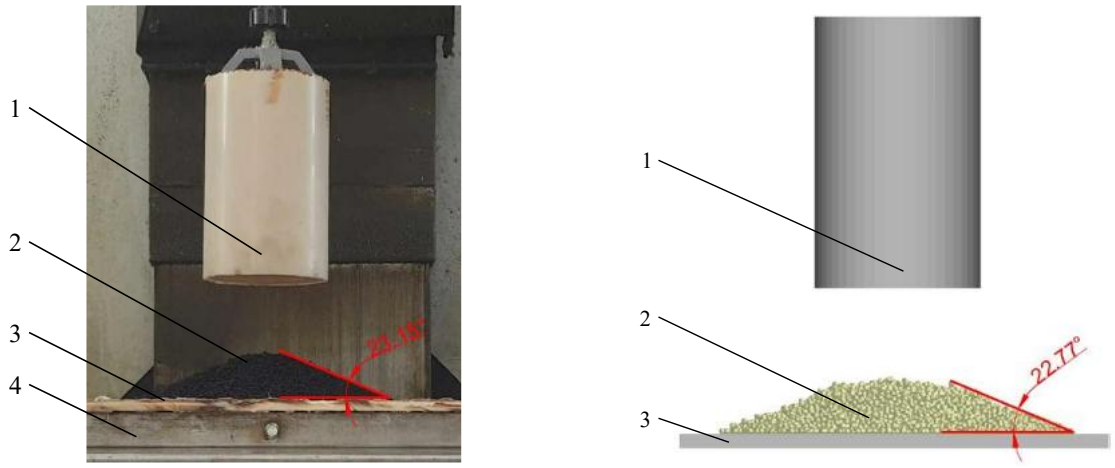
Table 4

Fitting equations for the rolling friction coefficients

Material pair	Fitting equation
Fertilizer - PA	y=−2154.20x+548.26
Fertilizer - PC	y=−2358.49x+606.54
Fertilizer - PLA	y=−2219.91x+578.22

Table 5

Coefficient of rolling friction between fertilizer and materials



Material pair	Rolling friction coefficient
Fertilizer - PA	0.156
Fertilizer - PC	0.154
Fertilizer - PLA	0.157

Contact parameter calibration method based on the angle of repose

Due to space limitations, this section describes the calibration procedure using polyamide (PA) as an example. The calibration procedures for the other two materials, PC and PLA, were similar.

Cylinder-lifting test for the angle of repose

Fig. 10(a) shows the physical angle-of-repose test conducted using a PA cylinder. The cylinder had an inner diameter of 100 mm and a height of 200 mm. It was clamped in the chuck of a CNC milling machine, and fertilizer granules were poured into the cylinder until it was approximately 60% full. The cylinder was then lifted vertically at a speed of 1000 mm/min. After lifting, an approximately conical fertilizer pile formed on the bottom plate. Images of the fertilizer pile were imported into AutoCAD 2021, and the angle measurement tool was used to determine the angle of repose. The test was repeated five times, and the mean value was calculated. The measured angle of repose of the fertilizer granules on PA was 22.57°.

(a) physical angle of repose test using a PA cylinder (b) EDEM simulation of the angle of repose test

Fig. 10 – Angle of repose test for fertilizer granules

1. bottomless cylinder, 2. fertilizer particle pile, 3. bottom plate, 4. CNC milling machine table

Discrete element simulation of the angle of repose

As shown in Fig. 10(b), the bottomless cylinder was placed in close contact with the bottom plate. The particle factory generated fertilizer particles until the cylinder was approximately 60% full, corresponding to about 1000 g, at a generation rate of 2000 g/s. The cylinder was then lifted vertically at the same speed used in the physical test (1000 mm/min) until a stable fertilizer pile was formed. A screenshot of the final particle pile was imported into AutoCAD®, and the angle measurement tool was used to determine the angle of repose.

Plackett-Burman test

Table 6 lists the factors used in the Plackett-Burman design generated using Design-Expert 13 software. Eight parameters were selected, with each parameter assigned a high level (+1) and a low level (−1). A center point was also included in the simulation design.

Table 6

Factors and levels of the Plackett-Burman design

Parameter	Factor	Low level (-1)	High level (+1)
X_1	Poisson's ratio of the fertilizer	0.1	0.5
X_2	Shear modulus of the fertilizer	1×10^6	1×10^7
X_3	Fertilizer–fertilizer coefficient of restitution	0.1	0.7
X_4	Fertilizer–fertilizer static friction coefficient	0.1	0.9
X_5	Fertilizer–fertilizer rolling friction coefficient	0.05	0.55
X_6	Fertilizer–PA coefficient of restitution	0.1	0.7
X_7	Fertilizer–PA static friction coefficient	0.1	0.9
X_8	Fertilizer–PA rolling friction coefficient	0.05	0.55

Table 7 presents the Plackett-Burman experimental design generated using Design-Expert 13 software. EDEM simulations were then conducted to determine the angle of repose for each test combination.

Table 7

Plackett–Burman experimental design and results

No.	X_1	X_2	X_3	X_4	X_5	X_6	X_7	X_8	Angle of repose [°]

13	0.5	1×10^7	0.1	0.9	0.55	0.7	0.1	0.05	35.19

Table 8 shows that the fertilizer-fertilizer static friction coefficient (X_4), fertilizer-fertilizer rolling friction coefficient (X_5), and fertilizer-PA static friction coefficient (X_7) significantly affected the angle of repose of the fertilizer. The effects of the remaining factors were not significant. Therefore, these three significant factors were selected for further analysis using the steepest ascent test and the Box-Behnken design.

Table 8

Significance analysis of the Plackett-Burman design

Factor	Effect	Sum of squares	F-value	*p*-value	Significance ranking
X_1	4.52	61.38	2.05	0.23	5

X_8	-3.75	42.19	1.41	0.30	6

Steepest ascent test

Table 9 presents the results of the steepest ascent test for the three significant factors. The relative error was minimized at test No. 2, indicating that the optimum region was located near this factor combination. Therefore, the factor levels corresponding to test No. 2 were selected as the center levels for the subsequent response surface design, with the adjacent lower and higher levels used as the low and high levels, respectively.

Table 9

Results of the steepest ascent test

No.	Fertilizer-fertilizer static friction coefficient (X_4)	Fertilizer-fertilizer rolling friction coefficient (X_5)	Fertilizer-PA static friction coefficient (X_7)	Angle of repose	Relative error

9	0.3	0.05	0.1	1.5
10	0.3	0.3	0.1	5.32
11	0.3	0.05	0.5	23.97
12	0.3	0.3	0.5	34.97
13	0.3	0.175	0.3	31.78
14	0.3	0.175	0.3	30.25
15	0.3	0.175	0.3	32.64

In Table 11, the model *p*-value was less than 0.0001, indicating that the regression model was highly significant. The *p*-value for lack of fit was 0.2485, which was greater than 0.05, indicating that the lack of fit was not significant and that the model adequately fitted the experimental data. The coefficient of determination (R^2) and adjusted coefficient of determination (R^2_{adj}) were 0.9936 and 0.9821, respectively, indicating a good agreement between the predicted and experimental values. The coefficient of variation (*CV*) was 8.24%, indicating acceptable experimental reproducibility. The adequate precision value was 27.8298, which was substantially greater than 4, indicating an adequate signal-to-noise ratio.

In Eq. (8), *A* (fertilizer–fertilizer static friction coefficient), *B* (fertilizer–PA static friction coefficient), *C* (fertilizer–fertilizer rolling friction coefficient), *AB* (interaction between the fertilizer–fertilizer static friction coefficient and the fertilizer–PA static friction coefficient), B^2 (quadratic term of the fertilizer–PA static friction coefficient), and C^2 (quadratic term of the fertilizer–fertilizer rolling friction coefficient) had highly significant effects on the angle of repose *θ*. The interaction term *AC* (interaction between the fertilizer–fertilizer static friction coefficient and the fertilizer–fertilizer rolling friction coefficient) had a significant effect on the angle of repose. The quadratic polynomial regression equation is expressed as follows:

$$\theta = 31.56 + 7.54A + 3.90B + 13.35C + 4.43AB + 3.35AC + 1.79BC - 2.22A^2 - 4.10B^2 - 11.01C^2 \quad (8)$$

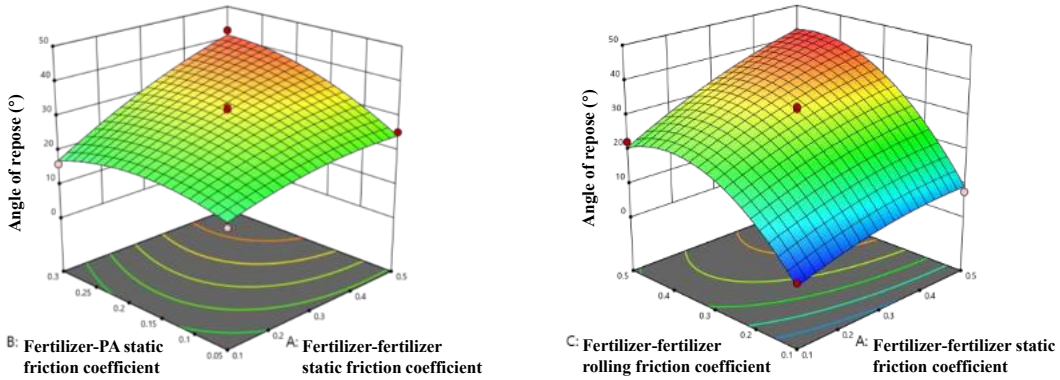

Table 11

Lack of fit	13.97	3	4.66	0.2485
Pure error	2.93	2	1.47	
Total	2648.01	14		
R^2 = 0.9936, R^2_{adj} = 0.9821, *CV* = 8.24%, degree of precision = 27.8298				

Note: "P < 0.01" indicates a highly significant effect, "0.01 < P < 0.05" indicates a significant effect, and P > 0.05 indicates a nonsignificant effect.

The angle of repose measured in the physical tests was used as the target value. As shown in Fig. 11, Design-Expert 13 software was used to optimize the three parameters and generate the response surface plots.

(a) fertilizer-PA static friction coefficient and fertilizer–fertilizer static friction coefficient

(b) fertilizer-fertilizer rolling friction coefficient and fertilizer-fertilizer static friction coefficient

Fig. 11 - Response surfaces of the interaction effects

The fertilizer–fertilizer static friction coefficient (*A*) was 0.402, the fertilizer–PA static friction coefficient (*B*) was 0.276, and the fertilizer–fertilizer rolling friction coefficient (*C*) was 0.177. The center values were used for the remaining parameters: the Poisson's ratio of the fertilizer was 0.3, the shear modulus of the fertilizer was 5.5×10^6 P_a, the fertilizer–fertilizer coefficient of restitution was 0.4, the fertilizer–PA coefficient of restitution was 0.4, and the fertilizer–PA rolling friction coefficient was 0.3. Three EDEM simulations of the angle of repose were conducted, yielding values of 22.10°, 22.34°, and 22.77°, respectively. The results were analyzed using a *t*-test, and $t = -1.442 < t_{0.05/2} = 2.776$, indicating that there was no significant difference between the simulated and experimentally measured angles of repose.

Contact parameter calibration results

The contact parameters between the fertilizer and the other materials (PC and PLA) were calibrated using the same procedure described above. As shown in Table 12, the calibrated fertilizer-fertilizer static and rolling friction coefficients obtained for the three material-based calibration tests were similar. Therefore, the mean fertilizer-fertilizer static friction coefficient and rolling friction coefficient were calculated as 0.413 and 0.181, respectively.

Table 12

Calibration results of fertilizer contact parameters

Contact parameter / Material pair	Fertilizer-material static friction coefficient	Fertilizer-fertilizer static friction coefficient	Fertilizer-fertilizer rolling friction coefficient
Fertilizer and PA	0.276	0.402	0.177
Fertilizer and PC	0.266	0.424	0.180
Fertilizer and PLA	0.173	0.412	0.187
Mean value		0.413	0.181

Fertilization EDEM simulation method

Coefficient of variation of fertilization uniformity

According to Chinese agricultural industry standard for technical specifications of quality evaluation for fertilizing machinery (*NY/T1003-2006, 2006*) and literature review (Bangu*ra et al., 2020; Ștefan et al., 2025*), coefficient of variation of fertilization uniformity (CVFU) was calculated using Equations (9), (10), and (11).

$$\bar{m} = \frac{1}{n}\sum m_i \tag{9}$$

$$s = \sqrt{\frac{\sum (m_i - \bar{m})^2}{n-1}} \tag{10}$$

$$\sigma = \frac{s}{m} \times 100\% \tag{11}$$

where: $\bar{m}$ is average mass of fertilizer of grid cell (g); m_i is fertilizer mass of the i-th experiment (g); n is number of experiments; s is standard deviation of n fertilizer discharge measurements; and σ is CVFU(%).

DEM parameter settings

As shown in Table 13, the fertilizer density was determined using the water displacement method, whereas the Poisson's ratio, density, and shear modulus of PA, PC, and PLA were obtained from the literature (*Zhang et al., 2019*). The remaining simulation parameters were obtained using the DEM parameter calibration procedures described above. Because the moisture content of the fertilizer granules was low, interparticle adhesion was considered negligible. The Hertz-Mindlin (no slip) model was therefore adopted as the contact model in the simulations.

Table 13

Discrete element parameters

Simulation parameter	Value	Simulation parameter	Value
Poisson's ratio of the fertilizer	0.314	Fertilizer-fertilizer coefficient of restitution	0.421
Poisson's ratio of PA	0.34	Fertilizer-PA coefficient of restitution	0.422
Poisson's ratio of PC	0.39	Fertilizer-PC coefficient of restitution	0.436
Poisson's ratio of PLA	0.43	Fertilizer-PLA coefficient of restitution	0.426
Fertilizer density (g/cm^3)	1.580	Fertilizer-fertilizer static friction coefficient	0.413
PA density (g/cm^3)	1.130	Fertilizer-PA static friction coefficient	0.276
PC density (g/cm^3)	1.200	Fertilizer-PC static friction coefficient	0.266
PLA density (g/cm^3)	1.240	Fertilizer-PLA static friction coefficient	0.173
Fertilizer elastic modulus (Pa)	9.8×10^7	Fertilizer-fertilizer rolling friction coefficient	0.181
PA shear modulus (Pa)	9.7×10^8	Fertilizer-PA rolling friction coefficient	0.156
PC shear modulus (Pa)	8.62×10^8	Fertilizer-PC rolling friction coefficient	0.154
PLA shear modulus (Pa)	1.3×10^9	Fertilizer-PLA rolling friction coefficient	0.157

EDEM simulation model

As shown in Fig. 12, Granule factory was set on fertilizer box. Total amount of fertilizer particles was 2 kg, and generation speed was 5 kg/s. Generation proportion of large, medium, and small fertilizer particles was 15%, 80%, and 5%, respectively. Forward speed of the fertilizer metering device was 1m/s. Grid bin group module was adopted, and 1000 mm was set as sampling area, divided into five areas on average (each cell size 200 mm x 1000 mm x 200 mm). Fertilizer quality of each cell was statistically analyzed. Coefficient of variation of fertilization uniformity was calculated using Equation (9), (10), and (11).

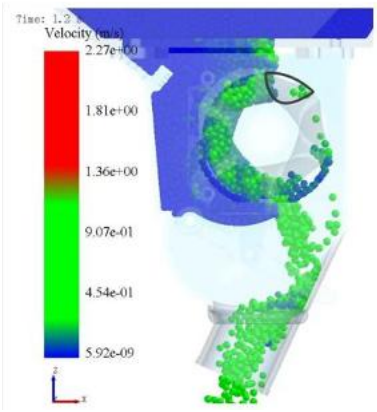
1. fluted-wheel fertilizer metering device, 2. DC motor, 3. three-point hitch frame, 4. fertilizer delivery tube, 5. fertilizer hopper, 6. fertilizer-metering shaft, 7. power supply, 8. DC motor controller

Fig. 13(a) shows the two 3D-printed fluted wheels used in the test. As shown in Fig. 13(b), the test apparatus was connected to the soil-bin tractor through a three-point hitch frame. The sampling grids shown in Fig. 13(c) were consistent with those used in the simulation described above. The sampling length was 1 m and was divided into five 200 mm sections. The forward speed of the soil-bin tractor was set to 1 m/s. A DC motor drove the fluted-wheel fertilizer metering device through the fertilizer-metering shaft, and the fertilizer granules were discharged through the fertilizer delivery tube onto the sampling grids. The mass of fertilizer collected in each grid was recorded. The coefficient of variation of fertilization uniformity (CVFU) was calculated using Eqs. (9)–(11). Five sections of the fertilizer strip were randomly selected as sampling intervals.

RESULTS



EDEM simulation of the fertilization process

Operation of the fertilizer metering device

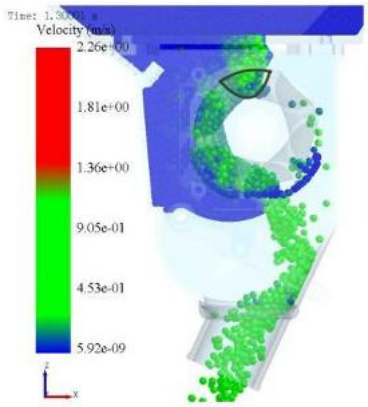


Fig. 14 shows a sectional view of the fluted-wheel fertilizer metering device, with particle velocity represented by the color scale. The structural parameters were as follows: fluted-wheel inscribed-circle diameter (D) of 38 mm, number of grooves (Z) of 6, and fluted-wheel lead angle (θ) of 65°.

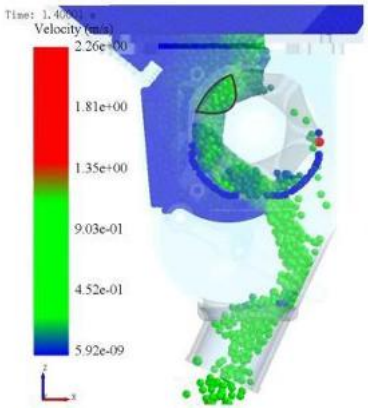
The operating parameters were an effective working length of the fluted wheel (*L*) of 35 mm, a fertilizer-metering shaft rotational speed (*n*) of 35 rpm, and a fertilizer-discharge flap angle (*α*) of 0°.



In Fig. 14, the groove outlined in black is used as an example. As the fluted wheel rotates counterclockwise, the interval from 1.2 to 1.3 s represents the fertilizer filling stage, during which fertilizer enters the groove under gravity and the action of the fluted wheel. The interval from 1.4 to 1.7 s represents the fertilizer conveying stage, whereas the interval from 1.8 to 1.9 s represents the fertilizer discharge stage. The particle velocities in the forcing layer were markedly higher than those in the driving layer. A distinct boundary between the forcing and driving layers, together with consistent groove filling, contributed to improved fertilization uniformity.

Fig. 14 - Movement of fertilizer particles within the fertilizer metering device

Fertilizer motion during the fertilization process

Fig. 15(a) shows the velocity distribution of fertilizer particles within the fertilizer metering device. Fig. 15(b) shows the trajectory of a single fertilizer particle, and Fig. 15(c) shows the variation in particle velocity with time. Region *ab* corresponds to the particle generation stage. The particle velocity initially increases and then decreases after the particle reaches the bottom of the fertilizer hopper. Region *bc* corresponds to the fertilizer filling stage, during which the particle velocity gradually decreases from its maximum value to its minimum value. In region *cd*, the particle moves together with the fluted wheel, and its velocity remains relatively stable. Region *de* corresponds to the discharge stage from the fluted wheel, during which interaction with the fertilizer-discharge flap causes substantial fluctuations in particle velocity. Region *ef* corresponds to the final fertilizer discharge stage, in which the particle velocity increases to 2.04 m/s before impact with the ground and then decreases.

Fig. 15 - Motion characteristics of fertilizer particles in the fertilizer metering device

Single-factor simulation test

Structural parameters

Fig. 16 shows that the CVFU generally decreased initially and then increased with changes in the structural parameters. The fluted-wheel inscribed-circle diameters of 34, 38, and 42 mm yielded the best results. Similarly, 5, 6, and 7 grooves produced better fertilization uniformity, while fluted-wheel lead angles of 60°, 65°, and 70° yielded the best results. Therefore, these parameter levels were selected for the subsequent multifactor tests.

(a) fluted-wheel inscribed-circle diameter (b) number of grooves (c) fluted-wheel lead angle

Fig. 16 - Single-factor tests of the structural parameters

Operating parameters

Fig. 17 shows that the coefficient of variation of fertilization uniformity generally decreased initially and then increased as the operating parameters changed. Effective working lengths of the fluted wheel of 20, 30, and 40 mm yielded the best results. Fertilizer-metering shaft rotational speeds of 25, 35, and 45 rpm also produced better performance, while fertilizer-discharge flap angles of −5°, 0°, and 5° gave the best results. Therefore, these operating parameter levels were selected for the subsequent multifactor tests.

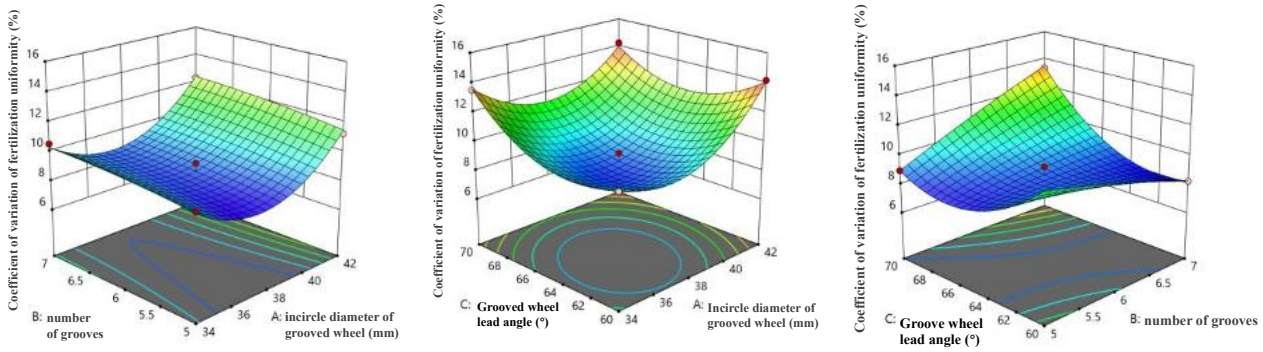
17	38	6	65	8.56

An analysis of variance (ANOVA) was performed on the regression model relating the structural parameters to the coefficient of variation of fertilization uniformity (CVFU), based on the results presented in Table 17. As shown in Table 17, the model was highly significant ($p < 0.01$). The structural parameters affected CVFU in the following order: fluted-wheel inscribed-circle diameter (A) > fluted-wheel lead angle (C) > number of grooves (B). The lack of fit was not significant, and the coefficient of determination (R^2) was 0.9907, indicating a good fit of the regression model.

Table 17



ANOVA of the regression model for structural parameters and CVFU

Source	Mean square	Degrees of freedom	*F* value	*p*-value	Significance

*Note: ** indicates a highly significant effect ($p < 0.01$), and * indicates a significant effect ($0.01 < p < 0.05$).*

Fig. 18(a) shows that, when the fluted-wheel lead angle was fixed at 65° (center level), the coefficient of variation of fertilization uniformity first decreased and then increased as the fluted-wheel inscribed-circle diameter increased from 34 to 42 mm. When the fluted-wheel inscribed-circle diameter was fixed, the coefficient of variation of fertilization uniformity gradually increased as the number of grooves increased from 5 to 7. Fig. 18(b) shows that, when the number of grooves was fixed at 6 (center level), the coefficient of variation of fertilization uniformity first decreased and then increased as the fluted-wheel inscribed-circle diameter increased from 34 to 42 mm.

When the fluted-wheel inscribed-circle diameter was fixed, the coefficient of variation of fertilization uniformity first decreased and then increased as the fluted-wheel lead angle increased from 60° to 70°. Fig. 18(c) shows that, when the fluted-wheel inscribed-circle diameter was fixed at 38 mm (center level), the coefficient of variation of fertilization uniformity gradually decreased as the number of grooves increased from 5 to 7. When the number of grooves was fixed, the coefficient of variation of fertilization uniformity first decreased and then increased as the fluted-wheel lead angle increased from 60° to 70°.

(a) fluted wheel incircle diameter and number of grooves

(b) fluted wheel incircle diameter and lead angle

(c) number of grooves and fluted wheel lead angle

Fig. 18 - Response surface diagram of the structural parameters

The regression equation relating the coefficient of variation of fertilization uniformity (σ) to A, B, and C was obtained based on the statistical analysis, as follows:

$$\sigma = 8.66 + 0.98A + 0.3938B + 0.7487C + 0.0675AB - 0.7825AC + 1.88BC + 2.46A^2 - 0.1545B^2 + 1.95C^2 \quad (12)$$

$$\begin{cases} \min \sigma(A,B,C) \\ A \in [34,42] \\ B \in [5,7] \\ C \in [60,70] \end{cases} \quad (13)$$

Eq. (13) presents the objective function and constraints used to optimize the structural parameters of the fluted-wheel fertilizer metering device. In Eqs. (12) and (13), σ is the coefficient of variation of fertilization uniformity [%], A is the fluted-wheel inscribed-circle diameter [mm], B is the number of grooves, and C is the fluted-wheel lead angle [°]. The numerical optimization module in Design-Expert software was used to solve the optimization problem. The optimal structural parameter combination was a fluted-wheel inscribed-circle diameter of 37 mm, 7 grooves, and a fluted-wheel lead angle of 63°, corresponding to a minimum predicted coefficient of variation of fertilization uniformity of 7.95%.

Optimization of operating parameters

The structural parameters were set to the center levels listed in Table 14, and the coefficient of variation of fertilization uniformity was used as the evaluation index. The simulation design and results are presented in Table 18.

Table 18

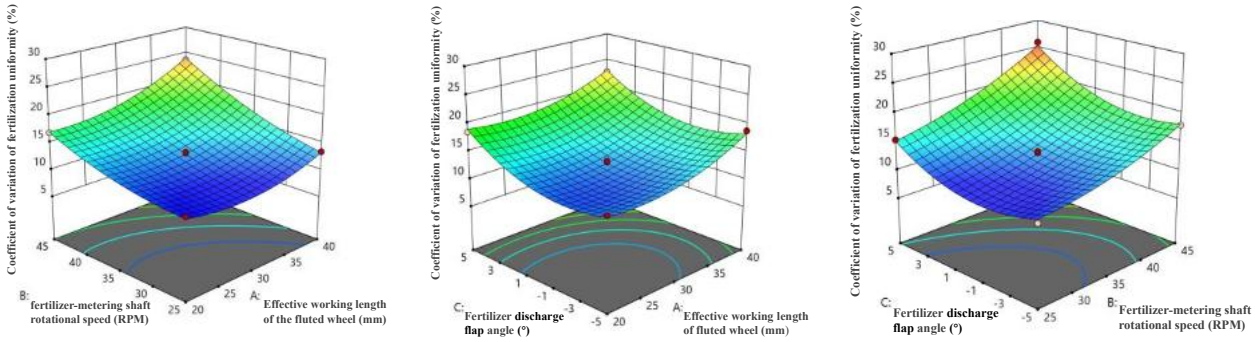
Simulation design and results for operating parameter optimization

No.	Effective working length of the fluted wheel	Fertilizer-metering shaft rotational speed	Fertilizer-discharge flap angle	Coefficient of variation of fertilization uniformity
	[mm]	[rpm]	[°]	[%]
1	20	25	0	11.35
2	40	25	0	13.37
3	20	45	0	16.87

No.	Effective working length of the fluted wheel	Fertilizer-metering shaft rotational speed	Fertilizer-discharge flap angle	Coefficient of variation of fertilization uniformity
	[mm]	[rpm]	[°]	[%]
4	40	45	0	23.67
5	20	35	-5	13.25
6	40	35	-5	18.76
7	20	35	5	18.53
8	40	35	5	22.71
9	30	25	-5	10.76
10	30	45	-5	17.94
11	30	25	5	15.35
12	30	45	5	25.96
13	30	35	0	13.09
14	30	35	0	12.08
15	30	35	0	12.81
16	30	35	0	13.36
17	30	35	0	13.32

As shown in Table 19, an analysis of variance (ANOVA) was performed on the regression model relating the operating parameters to the coefficient of variation of fertilization uniformity (CVFU), based on the simulation results presented in Table 18. The model was highly significant ($p < 0.01$). The operating parameters affected CVFU in the following order: fertilizer-metering shaft rotational speed (B) > fertilizer-discharge flap angle (C) > effective working length of the fluted wheel (A). The lack of fit was not significant, and the coefficient of determination (R^2) was 0.9907, indicating a good fit of the regression model.

Table 19



ANOVA of the regression model for operating parameters and CVFU

Source	Mean square	Degree of freedom	*F*-value	*p*-value	Significance
Model	330.55	9	82.74	< 0.0001	**
A	42.83	1	96.48	< 0.0001	**
B	141.2	1	318.1	< 0.0001	**
C	59.62	1	134.32	< 0.0001	**

C2	45.41	1	102.3	< 0.0001	**
Lack of fit	2.01	3	2.43	0.2049	

*Note: ** indicates a highly significant effect ($p < 0.01$), * indicates a significant effect ($0.01 < p < 0.05$).*

Fig. 19(a) shows that, when the fertilizer-discharge flap angle was fixed at 0° (center level), the coefficient of variation of fertilization uniformity first decreased and then increased as the effective working length of the fluted wheel increased from 20 to 40 mm. When the effective working length of the fluted wheel was fixed, the coefficient of variation of fertilization uniformity gradually increased as the fertilizer-metering shaft rotational speed increased from 25 to 45 rpm. Fig. 19(b) shows that, when the fertilizer-metering shaft rotational speed was fixed at 35 rpm (center level), the coefficient of variation of fertilization uniformity first decreased and then increased as the effective working length of the fluted wheel increased from 20 to 40 mm. When the effective working length of the fluted wheel was fixed, the coefficient of variation of fertilization uniformity first decreased and then increased as the fertilizer-discharge flap angle increased from −5° to 5°. Fig. 19(c) shows that, when the effective working length of the fluted wheel was fixed at 30 mm (center level), the coefficient of variation of fertilization uniformity gradually increased as the fertilizer-metering shaft rotational speed increased from 25 to 45 rpm. When the fertilizer-metering shaft rotational speed was fixed, the coefficient of variation of fertilization uniformity first decreased and then increased as the fertilizer-discharge flap angle increased from −5° to 5°.

The simulation results indicate that the fertilizer-metering shaft rotational speed and the effective working length of the fluted wheel affect the fertilizer filling process, which is consistent with previous findings (*Wang J. F. et al., 2023*), whereas the fertilizer-discharge flap angle affects the fertilizer discharge process.

(a) effective working length of fluted wheel and fertilizer-metering shaft rotational speed

(b) effective working length of fluted wheel and fertilizer discharge flap angle

(c) fertilizer-metering shaft rotational speed and fertilizer discharge flap angle

Fig. 19 - Response surfaces of the operating parameters

The regression equation relating the coefficient of variation of fertilization uniformity (σ) to *A*, *B*, and *C*, derived from the statistical analysis, is given in Eq. (14). The objective function and constraints for optimization of the operating parameters of the fluted-wheel fertilizer metering device are expressed in Eq. (15).

$$\sigma = 12.93 + 2.31A + 4.20B + 1.2C - 0.3325AB + 0.8575BC + 2.10A^2 + 1.29B^2 + 3.28C^2 \quad (14)$$

$$\begin{cases} \min \sigma(A,B,C) \\ A \in [20,40] \\ B \in [25,45] \\ C \in [-5,5] \end{cases} \quad (15)$$

where σ is the coefficient of variation of fertilization uniformity (%); *A* is effective working length of fluted wheel [mm]; *B* is the fertilizer-metering shaft rotational speed [rpm]; and *C* is the fertilizer discharge flap angle [°]. The numerical optimization module in Design-Expert software was used to determine the optimal solution. When the effective working length of the fluted wheel was 31 mm, the fertilizer-metering shaft rotational speed was 28 rpm, and the fertilizer-discharge flap angle was −1°, the minimum predicted coefficient of variation of fertilization uniformity was 10.33%.

Soil bin test results

Optimal structural parameter

As shown in Fig. 13(a), the test of the optimal structural parameters used a 3D-printed fluted wheel with the optimal structural parameter combination obtained from the simulation: a fluted-wheel inscribed-circle diameter of 37 mm, 7 grooves, and a fluted-wheel lead angle of 63°. The center levels listed in Table 15 (an effective working length of the fluted wheel of 30 mm, a fertilizer-metering shaft rotational speed of 35 rpm, and a fertilizer-discharge flap angle of 0°) were used as the operating parameters. As shown in Table 20, the mean CVFU was 8.68%. Compared with the simulated value of 7.95%, the relative error was 12.19%. This result is generally consistent with the ranges of the coefficient of variation reported in previous studies (*Wang Y. et al., 2023*).

Table 20

Soil-bin test results for the optimal structural parameters

Optimal operating parameters

As shown in Fig. 13(a), the test of the optimal operating parameters used a 3D-printed fluted wheel with the center-level structural parameters listed in Table 14: a fluted-wheel inscribed-circle diameter of 38 mm, 6 grooves, and a fluted-wheel lead angle of 65°. The fluted-wheel fertilizer metering device was set to the optimal operating parameters: an effective working length of the fluted wheel of 31 mm, a fertilizer-metering shaft rotational speed of 28 rpm, and a fertilizer-discharge flap angle of −1°. As shown in Table 21, the mean CVFU was 10.61%. Compared with the simulated value of 10.33%, the relative error was 2.71%.

Table 21

CONCLUSIONS

(1) This study proposed a calibration method for the discrete element simulation parameters of a granular organic fertilizer metering device. Measurements using a texture analyzer showed that the Poisson's ratio and elastic modulus of the fertilizer were 0.314 and 9.8×10^7 Pa, respectively. Coefficient of restitution tests showed that the fertilizer-fertilizer coefficient of restitution and the coefficients of restitution between the fertilizer and PA, PC, and PLA were 0.421, 0.422, 0.436, and 0.426, respectively. Rolling friction calibration tests showed that the rolling friction coefficients between the fertilizer and PA, PC, and PLA were 0.156, 0.154, and 0.157, respectively. The contact parameters between the fertilizer and the metering device materials were calibrated using a cylinder-lifting angle of repose test combined with EDEM simulations and a Design-Expert experimental design. The fertilizer-fertilizer static and rolling friction coefficients were 0.413 and 0.181, respectively, while the static friction coefficients between the fertilizer and PA, PC, and PLA were 0.276, 0.266, and 0.173, respectively.

(2) A discrete element simulation method was proposed to optimize the key parameters of a fluted-wheel fertilizer metering device. The coefficient of variation of fertilization uniformity was used as the evaluation index of fertilization performance. By combining the discrete element method (DEM) with response surface methodology, the effects of the parameters on fertilization uniformity were ranked as follows: fluted-wheel inscribed-circle diameter > fluted-wheel lead angle > number of grooves; fertilizer-metering shaft rotational speed > fertilizer-discharge flap angle > effective working length of the fluted wheel. Fluted wheels with the optimal and center-level structural parameters were fabricated by 3D printing and tested in a soil bin to validate the simulation results. The simulation and soil-bin tests identified two optimal parameter combinations: (1) a fluted-wheel inscribed-circle diameter of 37 mm, 7 grooves, and a fluted-wheel lead angle of 63°; and (2) an effective working length of the fluted wheel of 31 mm, a fertilizer-metering shaft rotational speed of 28 rpm, and a fertilizer-discharge flap angle of −1°.

Keywords: *environmental monitoring; illegal dumping detection; UAV inspection; change detection; deep learning; operational reliability.*

ABSTRACT

Illegal dumping in peri-urban and natural environments poses persistent challenges for environmental authorities, particularly when large areas must be inspected with limited personnel and budget. Reliable and scalable monitoring approaches are essential for practical environmental management. Unmanned Aerial Vehicles (UAVs) offer rapid spatial coverage, yet it remains unclear how complex the analysis must be to reliably detect waste sites in practice. This controlled pilot study evaluated the operational reliability of three UAV-based image analysis approaches (global statistical screening, classical change detection with colour filtering, and deep learning object recognition) under controlled field conditions. The field experiment used controlled contamination conditions so that the evaluation reflected practical detection reliability rather than algorithm benchmarking. The statistical method could not reliably identify localised waste, while change detection achieved moderate reliability (~72%; 29 of 40 evaluated acquisitions) but required reference imagery. The deep learning model achieved the highest site detection reliability (~93%; 37 of 40 evaluated acquisitions) and worked without baseline images. Its main advantage was improved object completeness rather than better identification of contaminated areas. These observations showed that monitoring workflow design matters more than increasing algorithmic complexity. A tiered strategy that combines broad screening with focused high-accuracy analysis can reduce inspection effort without compromising the results of inspection. The evaluated pilot framework supported the selection of monitoring approaches according to available resources, and the findings apply to the controlled, low-altitude field conditions (15 m above ground level, single test site) examined here rather than to fully validated multi-site operation.

REZUMAT

Depozitarea ilegală a deșeurilor în zone periurbane și în mediul natural reprezintă o provocare continuă pentru autoritățile de mediu, în special atunci când trebuie inspectate suprafețe extinse cu personal și bugete limitate. În acest scop, sunt necesare metode de monitorizare fiabile și scalabile pentru o gestionare practică a mediului. Vehiculele aeriene fără pilot (UAV) oferă o acoperire spațială rapidă, însă rămâne încă neclar cât de complexă trebuie să fie analiza pentru a detecta în mod fiabil siturile de deșeuri. Acest studiu-pilot, desfășurat în condiții controlate, a evaluat fiabilitatea operațională a trei abordări de analiză a imaginilor bazate pe UAV (analiza statistică globală, detecția clasică a schimbărilor cu filtrare de culoare și recunoașterea obiectelor prin învățare profundă) în condiții de teren controlate. Experimentul a utilizat condiții de contaminare controlate, astfel încât evaluarea să reflecte fiabilitatea practică a detecției, și nu performanța algoritmilor în sine. Metoda statistică nu a putut identifica în mod fiabil deșeurile localizate, în timp ce analiza detecției schimbărilor a atins o fiabilitate moderată (~72%; 29 din 40 de achiziții evaluate), dar a necesitat imagini de referință. Modelul de învățare profundă a obținut cea mai ridicată fiabilitate în detectarea siturilor cu deșeuri (~93%; 37 din 40 de achiziții evaluate) și a funcționat fără imagini de referință. Principalul său avantaj a fost îmbunătățirea prin completare a setului de obiecte detectate, mai degrabă decât o identificare mai bună a zonelor contaminate. Aceste observații arată că proiectarea fluxului de monitorizare este mai importantă decât creșterea complexității algoritmice. O strategie pe niveluri, care combină o analiză generală cu o analiză focalizată pe obținerea unei acurateți mai mari, poate reduce efortul de inspecție fără a compromite rezultatele inspecției.

Cadrul de lucru evaluat sprijină selectarea metodelor de monitorizare în funcție de resursele disponibile, iar rezultatele sunt valabile pentru condițiile de teren controlate, la altitudine redusă (15 m deasupra solului, un singur amplasament de test), examinate în acest studiu-pilot.

INTRODUCTION

Illegal dumping in peri-urban areas, waterways, agricultural fields, and natural reserves remains a common environmental problem. Ground-based inspections are labour-intensive, time-consuming, and often provide limited spatial coverage.

Illegal dumping affects soil, groundwater, biodiversity, and public health and is regulated within several European and international policy frameworks. The European Union Waste Framework Directive (Directive 2008/98/EC) establishes the legal basis for waste prevention, monitoring, and remediation obligations within Member States. Locating illegal disposal sites is required for regulatory compliance and enforcement. Waste monitoring is also aligned with the United Nations Sustainable Development Goals, particularly SDG 11 (Sustainable Cities and Communities) and SDG 12 (Responsible Consumption and Production), which promote environmentally sound waste management. Scalable and cost-efficient inspection methods therefore support environmental governance and sustainable urban management (*European Parliament and Council Directive, 2008; United Nations, 2015*).

UAV surveys combined with machine learning provide a practical alternative to ground inspections by enabling rapid coverage and automatic identification of potential waste hotspots. UAVs offer high spatial resolution and have become an established tool in environmental monitoring (*Manfreda et al., 2018*). However, their effectiveness depends not only on detection algorithms but also on acquisition strategy and survey design (*Torresan et al., 2017*). Recent studies have explored deep learning approaches for waste detection from aerial imagery. Reported results show promising detection accuracy but also reveal practical limitations such as dataset size requirements, variability of acquisition conditions, and lack of standardized datasets (*Youme et al., 2021; Sliusar et al., 2022; Mei et al., 2023; Wang et al., 2024*).

Experimental applications further illustrate these constraints. Deep neural networks have been used for marine litter detection and coastal debris mapping, where performance depends strongly on spatial resolution and scene complexity (*Fallati et al., 2019; Moy et al., 2018*). Other studies focus on spatial distribution mapping rather than individual object identification, highlighting the role of UAV surveys in environmental assessment workflows (*Gonçalves et al., 2020*).

Beyond object detection, UAVs have also been used for volumetric estimation and structural monitoring of waste sites. Applications include landfill volume modelling, settlement analysis, and combined UAV–terrestrial laser scanning workflows for improved topographic characterisation (*Filkin et al., 2022; Baiocchi et al., 2019; Son et al., 2020*).

Plastic waste detection has received particular attention across aquatic and terrestrial environments. Approaches range from deep semantic segmentation and hyperspectral discrimination to multisensor fusion and thermal infrared imaging (*Jakovljevic et al., 2020; Balsi et al., 2021; Maharjan et al., 2022; Topouzelis et al., 2019; Goddijn-Murphy et al., 2022; Yang et al., 2019*). These studies demonstrate that detection performance is influenced not only by algorithm choice but also by sensor characteristics, spatial resolution, and acquisition conditions. In UAV-based environmental applications, spatial resolution and acquisition geometry must be matched to the monitoring objective. Ground sampling distance and revisit frequency directly affect detectability, particularly for small or partially reflective objects such as plastic waste (*Pîrjol, 2018*).

Although UAV and AI tools are increasingly used, authorities still face uncertainty regarding how much analytical complexity is actually required in routine monitoring. In many situations, simpler approaches may already provide sufficient information, particularly when inspection resources are limited (*Gheres et al., 2025*).

This study therefore examines monitoring methodology rather than proposing a new detection algorithm. Three levels of analysis are compared in an operational context: basic statistical screening, change detection using classical computer vision techniques, and deep learning–based object recognition. The aim is to determine the minimum level of analysis needed for reliable site identification and to support the selection of appropriate monitoring strategies.

The main novelty of this work is therefore twofold and is stated here explicitly. First, the study provides an operational comparison of three distinct levels of image analysis (global statistical screening, classical change detection with colour filtering, and deep learning object recognition) applied to the same imagery, acquired with the same flight parameters and assessed with the same decision criterion, instead of comparing values reported on different benchmark datasets.

Second, the study separates two performance concepts that are usually reported together: site-level inspection triggering, that is, whether a survey correctly decides that a field inspection is needed, and object-level detection performance, that is, how completely the individual waste items are identified. This separation is what allows the minimum sufficient level of analysis to be identified for a given monitoring objective, and it is the element that distinguishes the present work from conventional algorithm benchmarking.

The dataset is used as a calibration scenario rather than a large training corpus. Controlled contamination conditions allow consistent comparison between methods while minimizing environmental variability.

MATERIALS AND METHODS

UAV Platform and Image Acquisition

The UAV system used in this study is a DJI Mini 2 (SZ DJI Technology Co., Ltd., Shenzhen, China), a lightweight quadrotor platform weighing 249 g, equipped with a 1/2.3" CMOS sensor capable of capturing 12 MP still images and 4K video.

Fig. 1 - DJI Mini 2 UAV platform used for image acquisition in this study

All imagery was acquired over the orchard garden of the Faculty of Biotechnical Systems Engineering, National University of Science and Technology Politehnica Bucharest. The drone was operated at a maximum altitude of 15 m above ground level (AGL), providing a spatial resolution of approximately 0.5 cm per pixel. Two reference images were captured: one depicting the undisturbed scene (baseline) and one after controlled placement of PET bottles and aluminium cans of varying sizes, colours, and shapes. This controlled setup enables direct verification of detection outputs across the three evaluated methods.

Colour-Based Image Representation. RGB Colour Model

The RGB colour space was used for initial statistical screening based on channel histogram comparison. Due to its sensitivity to illumination variation, RGB alone is not suitable for reliable outdoor segmentation but serves as a baseline reference for global scene changes (*Stan et al., 2025*).

The statistical screening criterion was defined as follows. For each of the three red–green–blue (RGB) channels the 256-bin histogram was normalised and compared between the baseline and the post-contamination image with the OpenCV correlation metric (cv2.HISTCMP_CORREL). A scene was flagged as changed when the correlation coefficient of at least one channel fell below 0.98. This threshold was derived from the data and not assumed: 15 repeated acquisitions of the undisturbed scene produced baseline-to-baseline channel correlations between 0.962 and 0.998 (mean 0.987), so 0.98 corresponds approximately to the lower quartile of the natural, illumination-driven variability of the site. The correlation criterion was preferred over histogram intersection or the chi-square distance because it is normalized, dimensionless and directly comparable between the three channels, which is the property required for a single global screening decision. These 15 undisturbed acquisitions are the same frames that form the uncontaminated part of the 40-frame evaluation set defined in the Experimental Setup subsection. The 0.98 correlation threshold was therefore calibrated on the evaluation imagery itself and not on an independent image set, and this is taken into account when the corresponding results are interpreted.

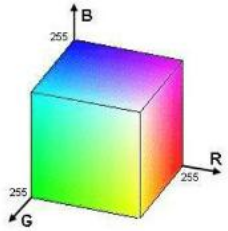

Fig. 2 - Conceptual illustration of RGB channel composition used as baseline reference for histogram comparison

HSV and HSL Colour Representations

The HSV and HSL colour representations were evaluated for colour-based segmentation of plastic waste. Both separate chromatic information from intensity, reducing sensitivity to illumination variations in outdoor scenes. In practice, HSV provided more stable threshold intervals for the tested objects, while HSL produced less consistent separation under shadow and reflective conditions. Consequently, HSV was selected for the segmentation stage.

The numerical hue–saturation–value (HSV) intervals applied in the segmentation stage were derived empirically from the acquired imagery rather than assumed. A total of 120 regions of interest containing polyethylene terephthalate (PET) bottles or aluminium cans and 120 regions of interest containing only vegetation, bare soil or shadow were sampled manually from the post-contamination frames. For the waste regions of interest, the 5th - 95th percentile range of the hue, saturation and value channels was computed (OpenCV convention, hue in the range 0-179) and rounded, which produced the two intervals used later for validation: dark blue (H 70-130, S 40-255, V 30-255) and cyan or light blue (H 50-100, S 40-255, V 100-255). The lower saturation bound of 40 removes desaturated soil and dry vegetation and the lower value bounds remove deep shadow pixels; these two classes were the dominant sources of false colour matches in the sampled background regions of interest. The 240 regions of interest were sampled from frames that also belong to the 40-frame evaluation set, so the hue–saturation–value intervals and the 5% coverage criterion were likewise calibrated on the evaluation imagery rather than on independent data. It should also be stated explicitly that these two intervals deliberately target only the blue and cyan chromatic cues that dominate the staged polyethylene terephthalate bottles: the validation stage was never intended to cover the complete range of colours and material classes placed in the scene, and it is applied as a colour-consistency filter on candidate regions rather than as a general waste classifier.

Neural Network Architecture: YOLOv8

A YOLOv8 single-stage object detection model was used to evaluate deep learning–based recognition performance. The model was retrained on a domain-specific dataset to detect PET bottles and aluminium cans under field conditions.

The pretrained YOLOv8 model (COCO dataset, 80 classes) does not include PET bottles or aluminium cans as dedicated categories. Retraining was therefore required to adapt the detector to the specific waste classes considered in this study. The YOLOv8s (small) variant was selected as a balance between detection performance and computational efficiency.

Dataset Preparation for YOLOv8 Retraining

A dedicated dataset was constructed consisting of 1130 images of PET bottles and aluminium cans placed in natural outdoor settings representative of field inspection conditions. Objects covered multiple brands, sizes, colours, and deformation states. Images were captured at varying distances (0.5–3 m), viewing angles, and illumination conditions to introduce intra-class variability while maintaining controlled environmental context. Annotations were created in YOLO format using Roboflow with two classes: *pet_bottle* and *aluminium_can*. Data augmentation included horizontal and vertical flips, HSV variation (±15%), and mosaic augmentation.

The dataset was split image-wise into 791 training images (70%), 226 validation images (20%) and 113 test images (10%), with no scene and no physical object appearing in more than one subset, and it was used to calibrate the detection workflow rather than to train a general-purpose detector. Diverse backgrounds, lighting conditions, and object appearances were intentionally included.

Fig. 4 - Selection of field-collected PET bottle and aluminium can images used for YOLOv8 retraining
(original images, acquired by the authors)

Retraining was performed for 100 epochs using the YOLOv8s (small) variant with a batch size of 16 and an initial learning rate of 0.01 reduced through cosine annealing. Training was executed on an NVIDIA T4 GPU (Google Colab). The model checkpoint with the highest validation mAP@0.5 was used for inference.

The validation subset was used exclusively for checkpoint selection (highest validation mean average precision at an intersection-over-union of 0.5, reached at epoch 87 of 100), and the 113-image test subset was processed only once, after the final checkpoint had been fixed, giving a mean average precision at an intersection-over-union of 0.5 of 0.83. The 40 unmanned aerial vehicle frames used for the operational evaluation reported in the Results section were fully independent from model training and from model selection: they were acquired in a separate flight session at 15 m above ground level in nadir orientation, whereas all 1130 dataset images were acquired at close range (0.5–3 m) on different dates and in different parts of the site. No evaluation frame, and no crop derived from an evaluation frame, was used at any stage of training, augmentation, validation or checkpoint selection.

The experimental site was selected to ensure controlled environmental conditions rather than geographic representativeness. The orchard contains mixed vegetation, variable illumination, and reflective surfaces typical of peri-urban dumping areas. Using a single controlled location isolates detection behaviour from geographic variability and is consistent with pilot validation procedures prior to multi-site deployment.

Experimental Setup

In environmental inspection scenarios, detection performance is evaluated in terms of operational reliability rather than pure computer vision accuracy. The objective is to determine whether a method can reliably trigger a site inspection when waste is present, not to optimize object-level classification metrics. Accuracy values are therefore interpreted as indicators of inspection reliability.

Site-level detection reliability was defined as the correct classification of a monitored area as contaminated or uncontaminated. A detection was considered successful if at least one waste object was correctly identified within the contaminated scene, triggering an inspection flag. To reduce random variability, each scenario was repeated with slight UAV repositioning (±0.5 m lateral shift). Each waste layout was captured 5 times and the undisturbed condition was captured 15 times, all within short temporal intervals and with identical flight parameters.

The evaluation set was identical for the three methods and consisted of 40 unmanned aerial vehicle frames acquired in the same session: 25 frames of the contaminated area (5 distinct spatial layouts of the waste objects, each captured 5 times) and 15 frames of the undisturbed area. Each method was therefore applied 40 times, which gives 40 site-level decisions per method and 120 site-level decisions in total.

For the change detection method, which requires a reference, each of the 25 contaminated frames was paired with a baseline frame from the same session, and the 15 undisturbed frames were processed as baseline-to-baseline pairs so that false alarms could be counted under identical processing conditions.

Site-level detection reliability R was computed as the proportion of correct site-level decisions over the complete evaluation set: R = (TPsite + TNsite) / Ntotal, with Ntotal = 40. Here TPsite is the number of contaminated frames (out of 25) in which at least one waste object was correctly localised, thereby raising the inspection flag, and TNsite is the number of undisturbed frames (out of 15) in which no inspection flag was raised. The denominator is therefore the total number of evaluated acquisitions and not the number of waste objects present in the scene; object counts are used only for the object-level metrics reported separately in the subsection Object-Level Detection Metrics.

Concerning the independence of the data used for threshold selection, the three methods were not evaluated under exactly the same conditions, and this difference should be clearly acknowledged. For the two classical approaches, the decision thresholds (the 0.98 histogram-correlation threshold, the two hue–saturation–value (HSV) ranges, and the 5% coverage criterion) were established using frames and regions of interest from the same 40-frame dataset used for evaluation. No separate calibration flight was carried out. Therefore, the reliability values reported below for the RGB histogram comparison and the OpenCV change-detection method with HSV filtering should be regarded as calibration-scenario results rather than as performance obtained on an independent test set. In contrast, the retrained YOLOv8 model was evaluated under fully independent conditions. Its training and validation data, as well as the data used for checkpoint selection, consisted of close-range images acquired during separate sessions, as described in the Dataset Preparation subsection. This difference in the evaluation procedure actually gives the classical methods an advantage. Consequently, the better performance of the deep learning approach reported in the Results section can be considered a conservative result rather than one caused by a more favourable evaluation setup. At the same time, this experimental design reflects a realistic operational situation, since threshold-based methods are commonly adjusted to the specific conditions of a site before deployment.

All experiments were conducted in the orchard garden of the Faculty of Biotechnical Systems Engineering. Following the baseline image acquisition, PET bottles (ranging from 0.5 L to 2 L, in transparent, blue, green, and branded varieties) and aluminium cans (330 mL, assorted brands) were distributed across a defined ground area. The UAV was repositioned using identical flight parameters (15 m AGL, nadir orientation) for post-contamination acquisition.

Fig. 5 - Baseline UAV image acquired at 15 m AGL over the experimental site (no waste present)

(original image, acquired by the authors)

Fig. 6 - Post-contamination UAV image showing PET bottles and aluminium cans distributed across the test area. Waste objects appear as reflective elements contrasting with the surrounding vegetation

(original image, acquired by the authors)

RESULTS

Method 1: RGB Histogram Channel Comparison

RGB channel histograms were computed using OpenCV (256 intensity bins per channel) and compared between baseline and contaminated scenes to assess global distribution shifts.

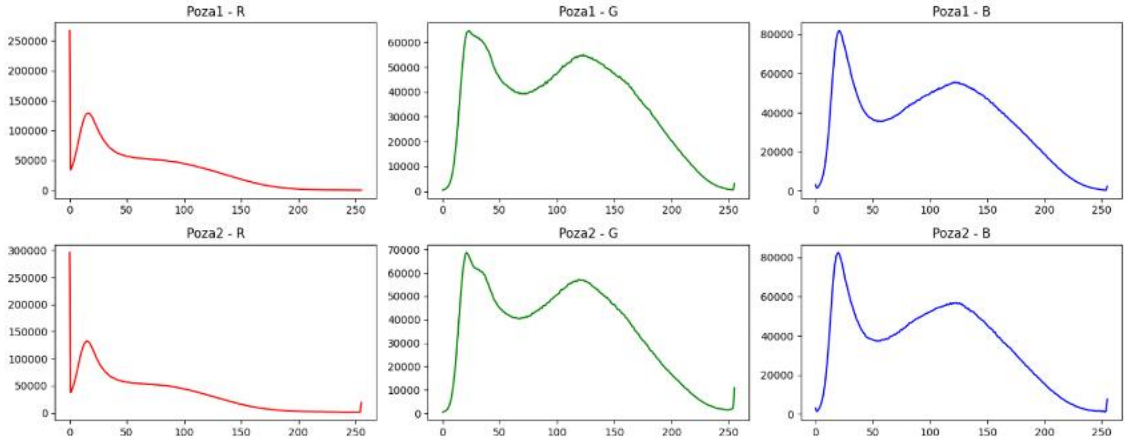

Fig. 7 - RGB channel histograms for the baseline image (Row 1) and contaminated image (Row 2). The distributions are nearly identical, indicating limited sensitivity to localised waste objects

(Original figure, produced by the authors)

The histogram pairs (Fig. 7) show minimal differences between the two scenes. This reflects the small spatial footprint of the waste objects relative to the full image and the reflective or semi-transparent nature of PET bottles, which blend with surrounding vegetation. As a result, global RGB statistics were insufficient for detecting localised contamination under these conditions and serve primarily as a baseline reference for comparison with more advanced methods.

Expressed in the terms defined in the Experimental Setup subsection, the correlation criterion flagged none of the 25 contaminated frames (0 of 25) and correctly classified 11 of the 15 undisturbed frames as unchanged, so the site-level reliability was (0 + 11) / 40 = 11/40 = 27.5%. The waste objects covered only 0.4-0.6% of the frame area, and the mean channel correlation between a baseline frame and its contaminated counterpart was 0.994, that is, higher than the correlation observed between two repeated captures of the undisturbed scene (0.962–0.998). This is the direct numerical reason why the global statistical approach is non-conclusive rather than merely imprecise: the signal produced by the waste is smaller than the natural variability of the scene. As stated in the Experimental Setup subsection, the 0.98 threshold was calibrated on these same frames, so this value describes calibration-scenario performance and not an independent test; a threshold transferred from another site would not be expected to perform better.

Method 2: OpenCV Change Detection with HSV Filtering

The second method combines temporal change detection (pixel-level image differencing) with spatial object filtering based on HSV colour masking, a classical approach used in environmental and surveillance monitoring (*Radke et al., 2005*). Similar threshold-based segmentation strategies have been applied in UAV imagery analysis for vegetation detection (*Torres-Sánchez et al., 2015*).

The processing steps were as follows:

Step 1 – Image alignment and differencing. The two images were resized to identical dimensions and the absolute pixel-wise difference was computed using cv2.absdiff(), producing a map highlighting changed regions.

Geometric alignment was obtained in two stages. First, both acquisitions were taken from the same programmed waypoint with the aircraft in hover-hold, at 15 m above ground level and with the gimbal oriented nadir, so that the residual horizontal displacement logged by the onboard global navigation satellite system and vision positioning remained within ±0.5 m; frames whose logged attitude deviated by more than 2° in pitch or roll from the baseline frame were discarded before processing. Second, the post-contamination frame was resized to the baseline dimensions and shifted by an integer pixel offset obtained by maximising the normalised cross-correlation of the two grayscale images over a ±30-pixel search window, computed only on the outer 15% of the frame, a border region that contains no waste objects. The residual misalignment after this correction was 1–2 pixels, that is, approximately 0.5–1 cm on the ground, which is smaller than the smallest object footprint considered. Only a translational correction was applied; sub-pixel and rotational residuals were not compensated, which is why feature-point registration is proposed as an improvement in the final part of

this section. The ±0.5 m quoted above is the position-hold envelope specified for the platform and not the displacement actually observed; at the stated ground sampling distance it would correspond to about 100 pixels, whereas the correlation search window of ±30 pixels covers approximately ±15 cm. The two values are reconciled by the acceptance procedure applied to the frames: the residual translational offset measured between each post-contamination frame and its baseline, before correction, was 6–24 pixels (approximately 3–12 cm on the ground) with a mean of 13 pixels (approximately 6.5 cm), so every accepted pair lay inside the search window. Three acquisitions exceeded the ±30-pixel window and were rejected and re-flown before the evaluation set was assembled; consequently all 40 frames used in the evaluation satisfy this criterion, and the search window was sized on the measured offsets rather than on the worst-case positioning specification.

Step 2 – Noise reduction and binarisation. The difference map was converted to grayscale and smoothed with a Gaussian blur (kernel 5×5, σ=10) to reduce high-frequency noise and minor registration artifacts. A fixed threshold (T=60) generated a binary mask in which values above the threshold corresponded to significant changes.

Step 3 – Contour extraction and filtering. External contours were extracted using cv2.findContours(). Contours with bounding box areas smaller than 1000 pixels were discarded. At the tested resolution of approximately 0.5 cm per pixel this threshold corresponds to a ground footprint of about 250 cm² and was set to suppress the small change blobs produced by vegetation movement between the two acquisitions. As a direct consequence, an isolated 330 mL aluminium can, whose bounding box covers approximately 310 pixels, falls below the threshold and is retained only when it merges with an adjacent object into a larger change region; this is one of the identified causes of the moderate object-level recall reported below.

Step 4 – HSV colour validation. For each candidate bounding box, the corresponding Region of Interest (ROI) was converted to HSV. Two mask intervals targeted typical waste colours: dark blue (H:70-130, S:40-255, V:30-255) and cyan/light blue (H:50-100, S:40-255, V:100-255). If more than 5% of ROI pixels satisfied either mask, the object was classified as PET waste and marked with a bounding box. The 5% coverage value was determined from the same sampled regions of interest used to derive the HSV intervals: true waste regions showed between 12% and 48% of pixels inside the two masks, whereas vegetation, soil and shadow regions remained below 2%, so any value between 3% and 10% separates the two populations; 5% was retained as the midpoint of that interval. This validation stage is intentionally restricted to blue and cyan colour cues and is not intended to detect the complete range of waste colours and classes staged in the experiment. Candidate regions corresponding to transparent, green or metallic objects are consequently rejected here even when the differencing step localised them correctly, which is a further identified cause of the moderate object-level completeness discussed below.

Fig. 8 - Output of the OpenCV change detection pipeline. Overlapping bounding boxes are visible due to the absence of Non-Maximum Suppression (NMS). Detection reliability under controlled conditions was approximately 72% (29 of 40 evaluated acquisitions)

(original figure, produced by the authors)

The method localised the main waste cluster and most individual objects, performing substantially better than the histogram-based approach. However, several limitations were observed. Illumination changes between acquisitions (e.g., sun angle or cloud cover) affected chromatic consistency and reduced stability.

The absence of Non-Maximum Suppression produced overlapping bounding boxes in partially occluded areas. False positives occurred when non-waste blue objects were present. In addition, the approach requires a clean baseline image of the same scene, limiting its use to monitoring scenarios where prior reference imagery exists.

In numerical terms, the change detection pipeline raised a correct inspection flag in 21 of the 25 contaminated frames and correctly returned no flag in 8 of the 15 undisturbed frames, which gives a site-level reliability of (21 + 8) / 40 = 29/40 = 72.5%, reported throughout as approximately 72%. The 7 false alarms on undisturbed frames were produced by illumination changes on reflective leaf surfaces between the two acquisitions of a pair, and the 4 missed contaminated frames corresponded to layouts containing only small isolated cans, which fall below the contour area threshold defined in Step 3. This value is likewise a calibration-scenario result, since the hue–saturation–value intervals and the coverage criterion were derived from the same imagery.

Method 3: Custom-Retrained YOLOv8 Neural Network

YOLOv8 was retrained on the 1130-image PET and aluminium can dataset described in Section 2.4. Inference was performed using the Ultralytics Python API with a confidence threshold of 0.3 and an Intersection-over-Union threshold of 0.7 for duplicate suppression. Detected objects were annotated with bounding boxes and saved to folder runs/detect/predict/.

Under the tested conditions, the retrained YOLOv8 reached approximately 93% site detection reliability (23 of the 25 contaminated frames were correctly flagged and 14 of the 15 undisturbed frames correctly returned no flag, that is (23 + 14) / 40 = 37/40 = 92.5%), representing the highest reliability among the evaluated methods. The model remained stable in the presence of partial occlusion, varied object orientations, and reflective surfaces that reduced the performance of the colour-based methods.

PET bottles of different sizes and colours were correctly identified in the test scene. The built-in NMS mechanism within the YOLO inference pipeline prevented duplicate bounding boxes. A representative detection example under field conditions is presented in Fig. 9.

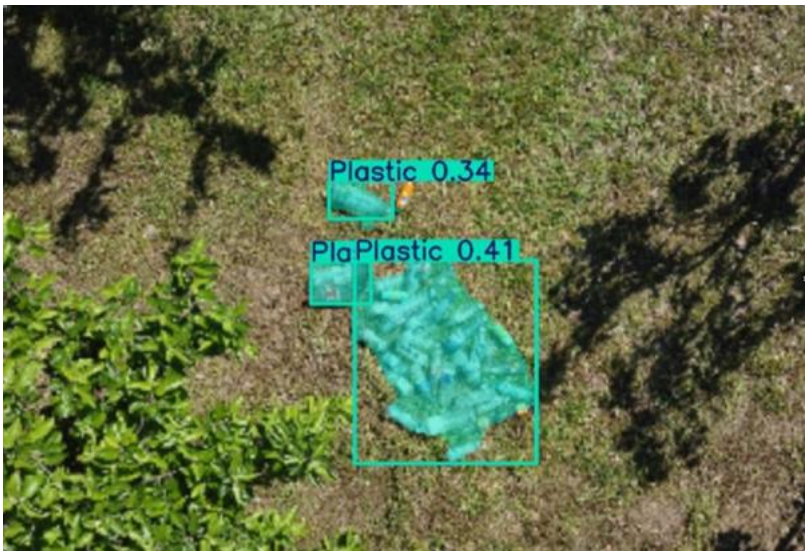

Fig. 9 - Site-level detection result obtained with the retrained YOLOv8 model. All but one waste object were identified, sufficient to trigger a positive inspection flag under the defined reliability criteria
(original figure, produced by the authors)

Unlike the change-detection approach, YOLOv8 does not require a reference image. Detection can therefore be performed on single acquisitions, which is relevant for surveys in areas without prior coverage. However, the approach requires dedicated computational resources for training, and its performance depends on the diversity and representativeness of the training dataset.

Object-Level Detection Metrics

Beyond site-level reliability, object-level detection was assessed using standard object detection metrics. The retrained YOLOv8 model reached a precision of approximately 0.90 and a recall of approximately 0.75, resulting in an F1-score of about 0.82. Mean average precision was approximately mAP@0.5≈0.80 and mAP@0.5:0.95≈0.52. These metrics were computed over the 25 contaminated evaluation frames, which contain 168 annotated waste objects in total (112 PET bottles and 56 aluminium cans).

The model returned 140 detections above the confidence threshold, of which 126 were true positives and 14 false positives, while 42 annotated objects were not detected; this gives a precision of 126/140 = 0.90, a recall of 126/168 = 0.75 and an F1-score of 0.82. Recall was lower than site-level reliability because small, partially occluded, or highly reflective objects were not always individually detected, even when the contaminated area was correctly classified. Such behaviour is consistent with monitoring tasks where confirming contamination presence is more relevant than detecting every individual item.

To evaluate robustness, inference was repeated under identical flight parameters using multiple image captures acquired within short temporal intervals. Variability in detection performance remained within ±3-5% for precision and recall (computed as the range of the precision and recall values across the five repeated captures of each of the five waste layouts), indicating stable behaviour under consistent environmental conditions. While the study does not address multi-site generalisation, the limited variability indicates stable performance under the tested conditions.

Comparative Performance Summary

Table 1 summarizes the key characteristics and operational monitoring characteristics of the three methods evaluated in this study. The site-level reliability values of the two classical methods are calibration-scenario values in the sense defined in the Experimental Setup subsection, whereas the YOLOv8 value was obtained with a model trained, validated and selected on independent imagery.

Table 1

Comparative summary of the three waste detection methods

Method	Core Technique	Site Detection Reliability	Baseline Required	Operational Processing Feasibility
RGB Histogram	Global colour distribution comparison	<30% (non-conclusive)	Yes	Yes
OpenCV Change Detection + HSV	Pixel differencing + HSV colour masking	~72%	Yes	Partially
YOLOv8 (retrained)	Custom deep learning detector	~93%	No	Yes

Note: the column Operational Processing Feasibility was rated with two criteria measured on the evaluation set: (a) the mean processing time per frame on the field configuration used in this study, a laptop with an Intel Core i7 processor, 16 GB of memory and no dedicated graphics card, and (b) the need for additional inputs or manual tuning during processing. The rating Yes means under 30 s per frame with no manual intervention (RGB histogram comparison, 0.8 s per frame; YOLOv8 inference, 2.1 s per frame on the processor and 0.35 s per frame on the NVIDIA T4 graphics card). The rating Partially means that the processing chain completes but requires a co-registered reference frame and manual re-tuning of the HSV intervals whenever object colours or illumination change (OpenCV change detection, 4.2 s per frame in addition to the alignment step). To ensure that the same definition is applied consistently to all three methods, the need for a reference image is not included in this rating. Instead, this requirement is reported separately in the *Baseline Required* column. The rating therefore considers only the requirements of the processing chain once the input images are available. Based on this definition, the RGB histogram comparison is rated *Yes*. Although it uses a reference frame, it compares global histograms and therefore does not require geometric co-registration or parameter adjustment during operation. The OpenCV change-detection method is rated *Partially*, not because it requires a reference image, but because the two images must be accurately aligned before comparison. In addition, the HSV intervals may need to be manually adjusted when object colours or illumination conditions change. YOLOv8 is rated *Yes* because it processes a single frame using fixed model parameters. Thus, the three ratings are based on the same criteria: processing time, co-registration effort, and the need for manual parameter tuning. This makes the ratings directly comparable across the three methods.

The contrast between object-level metrics and site-level reliability highlights the distinction between algorithm benchmarking and practical inspection needs. Missing individual items has limited impact on operational decisions if contamination presence is correctly identified. In this context, the combination of high precision and moderate recall is appropriate for screening scenarios in which UAV surveys are followed by targeted ground verification.

The subsections above report the direct experimental findings of the study. The subsections that follow (Analysis of Method Limitations, Toward Improved Waste Detection Systems, Environmental Monitoring Implications and Study Scope and Generalizability) contain the interpretation of those findings, the limitations of the experimental design and the directions proposed for future work, and are grouped here so that they remain clearly separated from the measured results.

Analysis of Method Limitations

The RGB histogram analysis method failed primarily due to the optical properties of the waste material. Transparent PET bottles at 15 m altitude act as highly reflective surfaces, reflecting the surrounding vegetation's spectral signature, thus making their contribution to the global colour histogram negligible. *Balsi et al. (2021)* reported similar challenges with transparent plastics in hyperspectral marine remote sensing, and the acquisition-dependent behaviour described by *Honkavaara et al. (2013)* suggests that global colour statistics are insufficient for localised waste mapping regardless of spectral resolution.

The OpenCV change detection pipeline overcomes the transparency problem by exploiting temporal changes (the appearance of new objects) rather than absolute colour. However, the method inherits the fundamental limitation of requiring a clean baseline image, which is unavailable in many operational contexts (e.g., post-event disaster assessments, areas with no prior UAV coverage). The fixed HSV threshold intervals are also susceptible to limitation when waste colours deviate from the assumed blue/cyan range – as would occur with red, yellow, or transparent bottles, or at different altitudes where atmospheric scattering modifies apparent hue. The absence of NMS is a practical limitation producing visually cluttered output; this could readily be addressed by applying cv2.dnn.NMSBoxes() to the detected bounding box list.

The retrained YOLOv8 model showed higher reliability than the classical methods but requires a domain-specific training corpus. Although the dataset contains 1130 training images, it remains limited in environmental diversity, as acquisitions were performed in a single site under controlled conditions. The model may struggle with out-of-distribution waste types (unusual colours, highly degraded bottles, dense overlapping clusters). Scale variation between training (ground-level photography) and inference (15 m AGL aerial) may also introduce domain shift, which was partially mitigated by including perspective-augmented crops in the dataset. Similar limitations have been widely reported for small object detection tasks, where limited pixel footprint and complex backgrounds reduce detection recall (*Ren et al., 2018; Kellenberger et al., 2018*). In operational monitoring, avoiding false alarms is often more critical than detecting every individual item. High precision reduces unnecessary field interventions, while moderate recall remains acceptable when aerial screening is followed by ground verification (*Gheorghe et al., 2024*).

The baseline-referenced approach is better suited to targeted surveillance contexts, such as periodically inspected protected areas, riverbanks, or infrastructure corridors. In these cases, reference imagery is typically available from previous inspection flights, making change-based detection a practical operational strategy.

While the experimental validation was conducted in a single controlled site, the environmental characteristics of the orchard – heterogeneous vegetation, variable illumination, reflective surfaces, and partial occlusion – represent common features of peri-urban dumping locations, which are known challenges in UAV-based remote sensing due to varying acquisition geometry and illumination conditions (*Honkavaara et al., 2013*). Detection performance mainly depends on ground sampling distance (GSD) and object size in pixels rather than on location (*Torresan et al., 2017*). At the tested altitude (15 m AGL, ~0.5 cm per pixel), standard PET bottles occupy sufficient pixel area to ensure detectability. Performance would likely decrease at higher altitudes or in dense vegetation. This relationship can be approximated from the ratio between object size and pixel size. The results should therefore be considered applicable to similar low-altitude UAV surveys.

Toward Improved Waste Detection Systems

Several improvements could further strengthen the proposed framework. Expanding the YOLOv8 training dataset beyond the current 1130 images to include aerial imagery acquired at multiple altitudes and additional waste classes (e.g., glass, cardboard, textiles) would improve generalisation. Instance segmentation models such as YOLOv8-seg could also enable pixel-level delineation and more precise estimation of contaminated surface area. The OpenCV pipeline could be refined through feature-point-based image registration (e.g., ORB with RANSAC homography) to reduce misalignment artifacts that occasionally generate spurious detections.

Multispectral or hyperspectral sensing may further enhance discrimination by exploiting the spectral contrast between plastics and natural materials, as previously reported by *Balsi et al. (2021)*.

From an operational perspective, deployment on embedded platforms such as NVIDIA Jetson devices could enable near real-time onboard inference during flight, reducing post-processing delays.

The proposed framework may support municipal dump site monitoring, GIS-based documentation of illegal dumping, emergency response assessments, and other environmental surveys using comparable UAV workflows.

Environmental Monitoring Implications

Environmental authorities rarely require exhaustive object inventories during initial inspections; instead, rapid identification of suspicious locations is typically sufficient to trigger field intervention, similar to zone-based environmental risk mapping approaches used in remote sensing (*Rozario et al., 2018*). The present results indicate that moderate-complexity approaches can detect contamination presence reliably, while deep learning mainly improves object-level completeness rather than site classification.

In practice, environmental surveillance programs may benefit from a tiered monitoring structure: wide-area screening using lower-cost detection followed by targeted high-accuracy analysis only where needed. This approach aligns with adaptive monitoring strategies discussed in environmental management literature (*Nichols and Williams, 2006*) and can reduce inspection effort and operational time. UAV imagery also provides georeferenced visual documentation that may support inspection reporting and enforcement procedures. Such tiered structures are consistent with established environmental decision-support practice (*Matthies et al., 2007*).

Study Scope and Generalizability

The dataset size reflects the methodological focus of the study rather than an attempt at statistical generalisation. While large datasets are necessary for training broadly transferable detectors, pilot environmental monitoring studies typically aim to evaluate workflow feasibility, acquisition constraints, and detection behaviour under realistic field conditions. The results should therefore be interpreted within the context of controlled validation rather than multi-site generalisation.

CONCLUSIONS

This study examined the feasibility of UAV-assisted waste monitoring workflows rather than benchmarking artificial intelligence performance. Inspection reliability was found to depend more on operational design – such as baseline availability, inspection objectives, and intervention criteria – than on algorithmic complexity alone. All results reported here were obtained under controlled, low-altitude field conditions (a single orchard site, 15 m above ground level, nadir acquisition, a ground sampling distance of approximately 0.5 cm per pixel and deliberately placed PET bottles and aluminium cans) and the conclusions are limited to that scope.

RGB histogram comparison was ineffective for detecting transparent PET waste against vegetation. OpenCV-based change detection with HSV filtering reached approximately 72% detection reliability under controlled conditions (29 of 40 evaluated acquisitions), a calibration-scenario value obtained with thresholds tuned on the same imagery, and proved useful when reference imagery was available, although sensitive to illumination variability and colour assumptions. The retrained YOLOv8 model achieved the highest site-level reliability (~93%; 37 of 40 evaluated acquisitions) and remained stable under occlusion, reflection, and colour variability without requiring a baseline image.

The main outcome of the study is an evaluated pilot monitoring framework linking analytical complexity to inspection reliability under the controlled conditions tested. The findings offer practical guidance for structuring UAV-based waste monitoring systems and may support decision-support workflows in which rapid aerial screening informs targeted field intervention.

Future developments may include expanding the dataset, exploring onboard inference, and integrating multispectral sensing. Overall, while higher analytical complexity improves object-level completeness, reliable contamination detection can already be achieved at moderate complexity levels under the conditions tested here, depending on operational objectives. Method selection should therefore follow monitoring needs rather than detection accuracy alone.

Keywords: *Drying rate, Fish, Moisture content reduction, Smoking technology, Smoking temperature*

ABSTRACT

A study was carried out to evaluate the performance of mobile and stationary fish smoking technologies. The experiment was conducted using a randomized block factorial design, with smoking temperature as a blocking factor. According to the investigation findings, at a smoking temperature of 90℃ and a smoking time of 4 hours, the maximum moisture content reduction of 81.4% was noted. In contrast, at a smoking temperature of 70 ℃ and a smoking time of 2 hours, the minimum moisture content reduction of 57.6% was noted for the electric fish smoker. Based on the test results of the electric fish smoker, at 90 ℃ of smoking temperature and 4 h of smoking time, the maximum drying rate of 0.69 kg h^{-1} was obtained. The findings verified that the maximum thermal efficiency of 69.8% was recorded at a smoking temperature of 90 ℃, and a smoking time of 2 h for the electric fish smoker. Based on comparative evaluation results, the moisture content reduction, drying rate, fuel consumption and thermal efficiency for the fuelwood fish smoker were found to be 66.17%, 0.38 kg h^{-1}, 4.8 kg kg^{-1} fish, and 37.9%, respectively. The study demonstrated that electric fish smoking technology significantly outperformed fuelwood smoking technology across all evaluated parameters. This study revealed that the electric fish smoking technology is strongly recommended for demonstration and scaling up to end users, particularly in areas where traditional fish smoking methods remain dominant.

INTRODUCTION

Fish is one of the most important sources of high-quality animal protein, essential fatty acids, vitamins, and minerals for billions of people worldwide. It contributes approximately 17% of the global population's intake of animal protein and provides essential nutrients, including omega-3 fatty acids, vitamins A and D, calcium, phosphorus, iron, and iodine (*Badoni et al., 2021*). Fish is generally ranked as the third largest source of animal protein in the world (*Tacon et al., 2025*). It is one of the most essential renewable natural resources and a key component of global food security. Over three billion people rely on fish as their primary source of protein (*Boyd et al., 2022*).

In addition to nutrition, fish play an important role in income generation, employment, industrial production (fish oil, fish meal, and animal feed), recreation, and ecological balance (*Bakhsh et al., 2023*).

According to *Bhujel (2024)*, global total fish production was approximately 193.7 million tons, of which 92.3 million tons came from capture fisheries and 101.4 million tons from aquaculture. In developing countries, fish contribute more than 50% of animal protein intake among coastal and rural populations (*Akpalu & Okyere, 2023)*. Ethiopia's annual fish production was estimated at 29,000 metric tons, mainly from lakes, rivers, reservoirs, and emerging aquaculture systems. However, the country has a much higher production potential under improved management and commercial aquaculture expansion (*Lakew, 2025*).

Despite its importance, fish is highly perishable due to its high moisture content (70–80%), which accelerates microbial growth and enzymatic spoilage (*Ali et al., 2022*). Under tropical conditions, fresh fish may spoil within 8–12 hours if not properly preserved. This rapid deterioration leads to significant post-harvest losses, especially in regions with limited cold storage facilities (*Abbas et al., 2024*). Globally, it is estimated that 20–35% of harvested fish is lost annually due to inadequate preservation, poor handling, and limited processing technologies (*Abelti & Teka, 2024*). These losses reduce food availability, lower market value, and negatively affect income generation for fish processors and traders.

To reduce these losses, various preservation methods such as drying, salting, fermentation, and smoking are widely used. Among these, smoking is one of the most important methods because it combines drying, heating, and chemical preservation effects, reducing moisture content from about 75–80% to 10–20%, thereby extending shelf life from hours to weeks or months (*Adeyeye, 2019*). Smoking also improves sensory qualities such as flavor, aroma, and texture, increasing consumer acceptability (*Puke & Galoburda, 2020*).

Traditional fish smoking systems, commonly made from mud, clay, metal drums, or open-fire structures using firewood, are widely used due to low cost and simplicity *(Idris et al., 2025*). However, they suffer from low thermal efficiency (10–20%), high fuel consumption (2.5–4.0 kg of wood per kg of fish), and uneven temperature distribution, which leads to inconsistent product quality and high operational costs (*Bujas et al., 2022*).

These limitations have encouraged the development of improved fish smoking technologies such as chorkor kilns, cabinet smokers, solar-assisted systems, and hybrid dryers (*Abiodun et al., 2021*). These technologies aim to improve heat transfer, airflow, fuel efficiency, and product quality. For example, solar integration can reduce fuelwood consumption by 35–60% (*Manaye et al., 2022*). One of the improved technologies is the electric fish smoking system, which reduces fuel consumption, processing time, and smoke contamination while enhancing drying rate, moisture reduction, thermal efficiency, and final product safety (*Tahir et al., 2020*). It is suitable for both small-scale and commercial processing due to better control of smoking conditions and improved product quality *(Akande & Adeyemi, 2016*).

As a research gap, there is still limited comparative evidence on the performance of mobile and stationary fish smoking technologies under similar operating conditions in Ethiopia. Most existing studies have focused either on traditional smoking methods or on single improved technologies, without adequately evaluating key performance indicators such as fuel efficiency, drying rate, thermal efficiency, processing time, product quality, and moisture reduction in a comparative framework (*Oyewole et al., 2025*). In addition, context-specific data on how these technologies perform under local fish processing conditions remains insufficient, particularly in developing regions where adoption decisions depend on cost, accessibility, and operational efficiency (*Shittu et al., 2021*). This lack of comprehensive, quantitative comparison creates a knowledge gap that limits informed selection and scaling of the most efficient and sustainable fish smoking system.

Continuous research is necessary to develop and evaluate efficient, low-cost, and environmentally sustainable fish smoking systems. The quantitative evaluation of moisture reduction, thermal efficiency, fuel utilization, drying characteristics, and product quality provides scientific evidence for selecting appropriate technologies and improving processing performance. Technology is critically important in fish processing because it drives improvements in productivity, processing, efficiency, and sustainability.

The main objective of this study is to investigate the key performance parameters of fish smoking technologies in terms of thermal efficiency, fuel consumption, moisture content reduction, product quality, and drying rate in order to improve fish preservation efficiency and reduce post-harvest losses. Therefore, this study aimed to evaluate the performance of mobile (electric) and stationary (fuelwood) tilapia fish species smoking technologies to generate performance metrics information for fish producers in Ethiopia.

MATERIALS AND METHODS

Study area

The study was conducted in Sebeta and Melkassa, two major agricultural research-oriented areas in central Ethiopia, which were selected for their contrasting agro-climatic conditions and suitability for evaluating fish smoking technologies. Sebeta, located approximately 25 km southwest of Addis Ababa at an altitude of about 2,200 m above sea level, experiences a subtropical highland climate with mean annual temperatures ranging from 10°C to 25°C and annual rainfall between 900 and 1,200 mm. Melkassa, situated in the East Shewa Zone of the Oromiya Region about 107 km southeast of Addis Ababa along the main road to Adama, lies at an altitude of approximately 1,550 m above sea level and has a semi-arid climate with mean annual temperatures ranging from 14°C to 32°C and annual rainfall of about 700–850 mm. Therefore, the selection of Sebeta and Melkassa enabled the study to evaluate fish smoking technologies under diverse environmental and operational conditions, thereby improving the reliability and applicability of the research findings.

Description of fish smoking technologies

The fish smoking technologies are widely used for fish preservation through moisture reduction and smoke treatment. Electric smoking technology uses electrically generated heat with controlled temperature and uniform drying conditions, resulting in higher thermal efficiency, faster processing time, improved product quality, and reduced environmental pollution. In contrast, fuelwood smoking relies on burning wood to produce heat and smoke, making it less efficient due to uneven heating, higher fuel consumption, longer drying time, and increased smoke emissions. Overall, electric fish smoking technology provides a cleaner, more efficient, and environmentally sustainable alternative to fuelwood smoking systems.

Mobile or electric fish smoking technology

The mobile or electric fish smoking technology shown in Figure 1 uses electrical energy as the primary heat source to smoke fish under controlled temperature and airflow conditions. The main components of the electric fish smoking technology include an electric heating element, which converts electrical energy into thermal energy for smoking fish; a smoking chamber, which is an insulated enclosure where fish are placed to ensure uniform heat and smoke distribution; and fish trays made of stainless steel to properly arrange fish for effective drying and smoking. A temperature control system, consisting of thermostats, controllers, or sensors, is used to regulate and maintain the desired smoking temperature, while a fan or air circulation system ensures even distribution of heat and smoke throughout the chamber. In addition, insulation materials surround the chamber to minimize heat loss and enhance thermal efficiency. The power supply system, including electrical wiring, switches, plugs, and control panels, provides and regulates electric power to the smoker. An exhaust outlet removes excess smoke, moisture and hot air while maintaining proper airflow, and an oil collector gathers fish oil, water droplets, and residues for improved hygiene and easier cleaning.

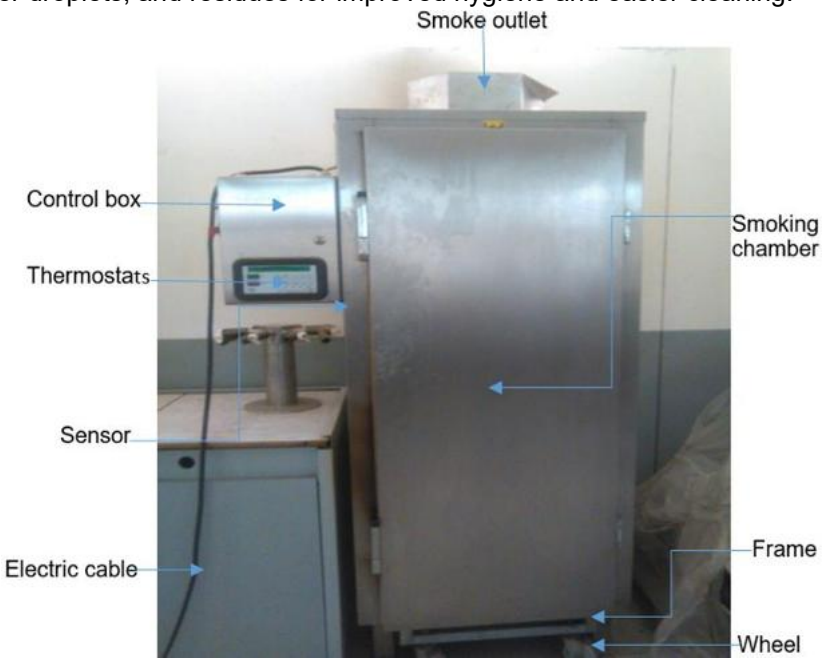

Fig. 1 - Mobile or electric fish smoking technology

This smoking chamber, as shown in Figure 1, has an overall length of 600 mm, height of 1400 mm, and width of 500 mm and is made from aluminum with a thickness of 3 mm to enhance fish quality, marketability, and acceptability. The outer part of the cabinet is made from mild steel with a length of 650 mm, height of 1500 mm, width of 550 mm, and a thickness of 1.5 mm, which covers the inner part of the chamber, and between them, there is an aluminum foil that minimizes heat loss. The developed smoker was portable; it moved from place to place, and the chamber was supported by a flexible frame.

Fig. 2 - Fish tray

Fig. 3 - Stove

Stationary or fuelwood fish smoking technology

The stationary or fuelwood fish smoking technology, as shown in Figure 4, uses firewood as the primary source of heat for smoking fish. In this system, fish are placed on trays inside a smoking chamber, where heat generated from burning wood removes moisture while smoke imparts desirable flavor, color, and preservative compounds. The main components of the fuelwood fish smoking technology include: the combustion chamber, where firewood is burned to produce heat and smoke; the smoking chamber, where fish are dried and smoked under controlled conditions; fish trays made of wire mesh, perforated metal, or wood for uniform arrangement and proper smoke circulation; a smoke outlet to regulate smoke flow and ventilation; firewood as the heat source; and insulated brick walls that retain heat and improve smoking efficiency.

Fig. 4 - Stationary or fuelwood fish smoking technology

The fish smoking mechanism in this system is hanged type and a laying type of fish smoking mechanism on a fish tray. The fish tray can hold smoking fish; it is constructed from wire mesh with a length of 950 mm, a width of 850 mm and a height of 300 mm. There are four trays; each tray contains 25 tilapia fish species, so that one hundred fish can be smoked at once a time. In the case of vertically smoking fish hung by a hook made from a rod. The fish are hung on the hanger with a crossed arrangement to optimize the smoke heat air contact. The heat transfers from the combustion chamber to the smoking chamber by convention with concrete pipe. This heat transfer occurs within the smoking cabinet, like a fish tray and a fish smoking chamber. The wood used for smoking fish in this case was Acacia (Girar). This smoking chamber uses wood as a source of energy. No burning of the smoker due to combustion from oil drops on the heat source because smoking & combustion chambers are developed separately.

Materials

The materials used in this study were selected to support the investigation of smoking technologies, ensure accurate performance evaluation, and maintain product safety and quality. The materials generally used in this research work were fish samples, controlled fuel sources, and precise measuring instruments, which enabled a comprehensive assessment of fish smoking performance under different operational conditions. The selection of materials was based on availability, durability, heat resistance, cost-effectiveness, and suitability for fish smoking operations under local conditions in Sebeta and Melkassa.

Fish material

The fresh tilapia fish species was the primary raw material used for the smoking experiments. The fish samples of uniform size and species were selected to minimize variability in processing outcomes. Typically, freshwater species commonly available in local waters were used. The fish were obtained immediately after harvesting to ensure freshness, with initial moisture content estimated at approximately 70–80% *(Sabu & Sasidharan, 2020*). Before smoking, the fish were washed thoroughly with clean water to remove dirt, slime, and blood residues, and then allowed to drain under hygienic conditions.

Fig. 5 - Experimental material; a) before adding salt, b) after adding salt

Fuel materials

The electrical energy and fuelwood were the main fuel sources used for generating heat and smoke in the mobile and stationary smoking technologies. The hardwood species were selected due to their higher calorific value and slower burning characteristics compared with softwoods in the case of a stationary smoker. The fuelwood was cut into uniform sizes to ensure consistent combustion rates.

Measurement device

The range of instruments was used to evaluate the performance of the fish smoking technologies quantitatively. These included a digital weighing balance for measuring fish weight before and after smoking. Moisture meter or oven-drying apparatus for determining moisture content reduction. Thermocouples and digital thermometers for monitoring temperature distribution inside smoking chambers. Stopwatch for recording processing time. A hygrometer for measuring relative humidity in the smoking environment. Calorimeter for estimating fuel energy value. These instruments were essential for ensuring accurate measurement of thermal efficiency, drying rate, and process consistency (*Nwakuba, 2016*).

Cleaning and hygiene materials

During experimentation, to ensure food safety and hygienic processing conditions, several cleaning materials were used during the preparation and handling of fish samples and equipment. These included clean water, food-grade detergents, disinfectants, and clean cloths. The proper sanitation practices were applied to reduce contamination risks during smoking (*Geraldo et al., 2024*).

Packaging and storage materials

After smoking, fish products were stored and evaluated using appropriate packaging materials. These included polyethylene bags, plastic containers, and aluminum foil packs to prevent moisture reabsorption and contamination. Storage materials were selected based on their ability to preserve product quality during short-term evaluation periods (*Nizio et al., 2023*).

Methods

The study employed an experimental and comparative approach to evaluate fish smoking technologies under controlled conditions. The key performance indicators, including thermal efficiency, fuel consumption, moisture content reduction, processing time, and sensory quality, were systematically measured. The methodology ensured reliable, quantitative, and reproducible assessment of smoking technologies suitable for improving fish preservation systems in rural and peri-urban processing environments.

Sample collection and preparation

Sample allocation to mobile smokers: A total of 270 Nile tilapia were used in the experiment. The fish were randomly assigned to mobile smoking technology. Each temperature treatment consisted of three replications, with 15 fish per replication, resulting in 45 fish per treatment. Therefore, the mobile smoker processed a total of 270 fish for the experiment.

Sample allocation to mobile and stationary smokers for comparative evaluation: A total of 90 Nile tilapia were used in the experiment. The fish were randomly allocated to two smoking treatments: a mobile electric smoker and a stationary fuelwood smoker. Each treatment was replicated three times, with 15 fish per replication, resulting in 45 fish per treatment. Thus, 45 fish were assigned to the mobile electric smoker and 45 fish to the stationary fuelwood smoker. Random allocation of fish to treatments and replications was used to minimize experimental bias.

Test conditions: Both the mobile electric smoker and the stationary fuelwood smoker were evaluated using the same sample load of 15 Nile tilapia per replication under identical experimental conditions. Fish of similar size and weight were used, and the smoking trials were conducted under the same ambient environmental conditions. The same smoking temperatures and processing durations were maintained for both technologies to ensure that any observed differences in performance were attributable to the smoking technology rather than variations in sample load or environmental conditions.

The fresh fish samples were collected immediately after harvest from the Sebeta research center. The tilapia fish species commonly available in the study areas were selected to reflect typical processing conditions. The fish were sorted based on uniform size and weight to minimize variability in smoking performance. Before smoking, the fish were washed thoroughly using clean water to remove slime, blood, and surface impurities. The fish were then drained for approximately 15–30 minutes under hygienic conditions (*Bedane et al., 2022*). The initial weight and moisture content were recorded before loading into the smoking chambers. The experimental fish were healthy Nile tilapia with an average initial body weight of 250 ± 20 g and an average total length of 26.0 ± 1.5 cm (mean ± standard deviation).

Fig. 6 - Dimension and weight measurement of the tilapia fish species

Smoking procedure

The smoking process was conducted separately for each smoking technology under similar environmental conditions. A predetermined quantity of fish was loaded into each smoking chamber for both technologies. The power supply system contained electrical wiring, switches, plugs, and control panels that provide and regulate electric power to the smoker. The fuelwood was ignited in the combustion chamber, and fire intensity was controlled to maintain a temperature range between 70°C and 90°C, which is optimal for fish smoking (*Alakali et al., 2017*). The temperature inside the smoking chamber was monitored using thermocouples placed at different locations to assess heat distribution. The smoking process continued until the fish reached the desired dryness level.

Measurement of performance parameters

Key performance parameters commonly evaluated include thermal efficiency, fuel consumption, drying rate, smoking time, moisture reduction, processing capacity, and sensory acceptability. Several quantitative parameters were measured to evaluate the performance of each smoking technology. After smoking, fish samples were removed and allowed to cool at ambient temperature before post-processing measurements were taken. The total smoking duration was recorded for each treatment.

Moisture content reduction

The moisture content was determined using the oven-drying method. Final moisture content was used to assess product stability and shelf life potential. The fish samples were weighed before and after drying to calculate moisture loss using Equation (1), the formula by *Ojotu et al. (2024)*.

$$\text{Moisture loss (\%)} = \frac{W1-W2}{W1} x100 \quad (1)$$

Drying rate

The drying rate was calculated using Equation (2), based on the reduction in moisture content over the smoking period (*Ojotu et al., 2024*).

$$\text{Drying rate (kg h}^{-1}) = \frac{\text{Moisture removed (kg)}}{\text{Time(h)}} \quad (2)$$

Fuel Consumption

The fuelwood consumption was measured by weighing the amount of wood used before and after each smoking session. The fuel consumption of an electric fish smoking technology is commonly expressed as the amount of electrical energy used during smoking relative to the quantity of fish processed or moisture removed. The total fuel consumed per kilogram of smoked fish was calculated using Equations (3) and (4) by *Sintali et al. (2023)*.

$$\text{Fuel consumption } (F_{cw}) = \frac{\text{Total fuel used (kg)}}{\text{Mass of smoked fish (kg)}} \quad (3)$$

$$\text{Fuel consumption } (F_{ce}) = \frac{E \times t}{Wf} \quad (4)$$

Electrical energy equivalent conversion

To enable comparison between the electric and fuelwood smoking technologies, the electrical energy consumed by the mobile electric smoker was converted to an equivalent fuelwood mass based on the energy content of the fuelwood. Electrical energy consumption was first recorded in kilowatt-hours (kWh) using an energy meter. This conversion was used solely to provide an energy-equivalent comparison between the mobile electric smoker and the stationary fuelwood smoker. The equivalent fuelwood consumption was then calculated using the lower heating value (LHV) of fuelwood according to the following Equations (5) and (6) by *Sintali et al. (2023)*.

$$\text{Equivalent fuelwood (kg)} = \frac{\text{Electrical energy (kWh)}}{\text{LHV of fuelwood (MJ kg}-1)} \text{x}3.6 \quad (5)$$

$$\text{Equivalent fuelwood consumption (kg kg}^{-1}\text{fish)} = \frac{\text{Equivalent fuelwood}}{\text{Mass of fish processed}} \quad (6)$$

where 3.6 is the conversion factor from 1 kWh to 3.6 MJ, and the LHV of air-dried fuelwood was assumed to be 16 MJ kg^{-1}, equivalent fuelwood in (kg), and mass of fish processed in (kg).

Determination of fuelwood calorific value: The calorific value of the fuelwood was not measured experimentally. Instead, the lower heating value (LHV) of air-dried fuelwood was obtained from literature. An LHV of 16 MJ kg^{-1} was used for the calculations, which is within the typical range reported for air-dried hardwood fuelwood. This value was used to estimate the energy equivalent of the fuelwood consumed during the smoking process.

Thermal efficiency

The thermal efficiency of each smoking technology was estimated using Equations (7) and (8) by comparing the useful energy utilized for moisture removal to the total energy content of the fuelwood and electricity. The thermal efficiency of an electric fish smoking technology is generally expressed as the ratio of the useful heat utilized for moisture evaporation from the fish to the total electrical energy supplied to the smoker formula by *Sintali et al. (2023)*.

$$\text{Thermal efficiency for fuelwood (\%)} = \frac{\text{Energy usd for drying}}{\text{Total fuel energy input}} \text{x}100 \quad (7)$$

$$\text{Thermal efficiency for electric (\%)} = \frac{Mw \times Lv}{Ein} \quad (8)$$

where, W_1 = initial weight of fresh fish, W_2 = final weight after smoking, F_c = fuel consumption (kWh kg^{-1} fish), E = electrical power rating of the smoker (kW), t = smoking time (hours), W_f = weight of fish processed (kg), ηth = thermal efficiency (%), Mw = mass of water evaporated from fish (kg), Lv = latent heat of vaporization of water (Kj kg^{-1}) (commonly 2257 Kj kg^{-1}), and Ein = total electrical energy supplied to the smoker (kJ).

Sensory evaluation

The sensory quality of smoked fish was evaluated using a semi-trained panel of 10–15 individuals familiar with fish products. The evaluation was conducted under controlled conditions to minimize bias. The attributes assessed included: color**,** aroma**,** texture**,** taste and overall acceptability. Panelists evaluated coded samples using a 9-point hedonic scale to ensure blind assessment. Mean sensory scores were calculated for each smoking technology (*Rossetto et al., 2024*).

Selection and training of sensory panelists: Sensory evaluation was conducted by semi-trained panelists selected from staff and food science experts familiar with fish and fish products. Panelists were selected based on their willingness to participate, good health, normal sensory perception (including taste, smell, and vision), and prior experience in food sensory evaluation. Before the evaluation, the panelists received a 30-minute training session on the evaluation procedure and the quality attributes to be assessed. During training, reference smoked fish samples were used to familiarize panelists with the evaluation criteria and to improve consistency among assessors. Drinking water was provided for palate cleansing between samples, and samples were presented in a randomized order using coded identifiers to minimize bias.

Ethical considerations: Before the sensory evaluation, all panelists were informed about the study's objectives and procedures. Written informed consent was obtained from each participant before participation. Participation was voluntary, and panelists were free to withdraw from the evaluation at any time without consequence. The sensory evaluation involved the consumption of smoked fish prepared under hygienic conditions and posed minimal risk to participants. All personal information and evaluation responses were kept confidential and used solely for research purposes. The study was conducted in accordance with institutional ethical guidelines for research involving human participants.

Fig. 7 - Sensory evaluation of smoked fish by the panelists

Experimental design

The experiment was carried out by randomized block factorial design with smoking temperature as a blocking factor and the levels of smoking temperature with smoking time taken as a treatment combination. Each experiment is to be replicated three times to ensure reliability and reduce experimental error, to have 18 experimental units (3×2×3 = 18). Quantitative data, including moisture content reduction, drying rate, fuel consumption, thermal efficiency, and sensory evaluation scores, were considered as experimental treatments. Each treatment consisted of 45 fish, with 15 fish allocated to each of three replications, resulting in a total of 270 fish for the six treatments. Random allocation of fish to treatments and replications was used to minimize experimental bias and ensure the reliability of the results.

Statistical data analysis

The collected data were analyzed using Statistix 8 software and Statistical Package for Social Sciences software (SPSS version 25.0). Confidence intervals of 95% was used to show the significant effect of the independent variable on the dependent variable. The mean separation between treatment means was conducted by least significance difference (LSD) at a 5% level. Comparative analysis between stationary and mobile smoking technologies was conducted. Descriptive statistics such as mean and standard deviation were computed for all measured parameters. The data were subjected to two-way analysis of variance (ANOVA) by following the appropriate procedure.

RESULTS AND DISCUSSION

Effects of smoking temperature and time on performance indicators

The results indicate that smoking temperature and smoking time have a significant influence on moisture content reduction, drying rate, energy consumption, and thermal efficiency of the electric or mobile fish smoking technology. The findings suggest that maintaining an optimal combination of smoking temperature and time is critical for achieving efficient drying performance, leading to a marked reduction in moisture content, lower fuel consumption, and higher thermal efficiency in electric fish smoking technology. The optimum operating conditions were generally observed within a smoking temperature range of 70–90°C and a smoking time of 2–4 hours. A similar trend was reported by *Adepoju et al. (2018)*. The electric or mobile fish smoking technology was evaluated at three smoking temperature levels (70, 80, and 90°C) and two smoking time levels (2 and 4 h) to assess its performance. The test results indicated that the electric smoker performed efficiently in fish smoking under controlled temperature and time conditions.

Effects of smoking temperature and time on moisture content reduction

Analysis of variance for the effects of smoking temperature, smoking time, and the interaction effect on the moisture content reduction of the mobile or electric fish smoking technology was presented in Table 1. The analysis of variance indicated that the main effects of smoking temperature, smoking time, and the interaction effect were significant at the 5% level (Table 1), as the P-values were less than 5%. The results revealed that the moisture content reduction of a fish smoking technology was influenced by smoking temperature, smoking time, and the interaction effect.

Table 1

Analysis of variance (ANOVA) for moisture content reduction

* = significant, ** = non-significant, P < 0.05, significant at 5 % level, P>0.05, non-significant at 5% level.

In accordance with the investigation findings, the moisture content reduction ranged from 57.6 % to 81.4 %, as illustrated in Figure 8.

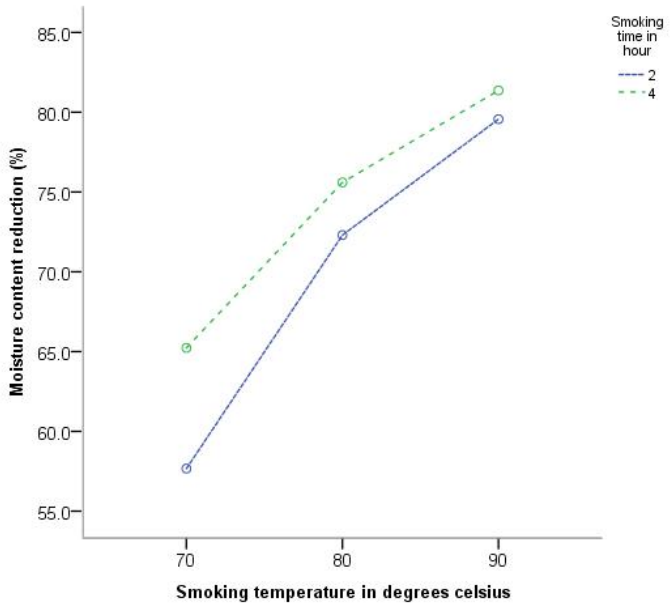

Fig. 8 - Effects of smoking temperature and time on moisture content reduction

The smoking technology moisture content reduction increased from 57.6 % to 81.4% when the smoking temperature increased from 70 to 90 ℃, whereas the smoking temperature increased, the moisture content reduction tended to rise; on the other hand, smoking time began to increase. Based on the result, the moisture content reduction was directly associated with the smoking time and also directly associated with the smoking temperature of the technology. From the investigation results, at 90 ℃ of smoking temperature and 4 h smoking time, the maximum moisture content reduction of 81.4% was noted; also, at 70 ℃ smoking temperature and 2 h smoking time, the minimum moisture content reduction was noted, as it was verified. It was observed that an increase in smoking temperature and time led to a marked reduction in moisture content, as higher thermal energy enhanced the evaporation and diffusion of water from fish tissues. This study's finding is related to the previous research findings conducted by *Toworfe et al. (2023).*

Effects of smoking temperature and time on drying rate

The analysis of variance for the main effects of smoking temperature, smoking time, and the interaction effect on the drying rate of the mobile fish smoking technology. Analysis of variance showed that the effect of smoking temperature and smoking time was significant at a 5% level because the value for P found in Table 2 was lower than 0.05, based on the result, and their interaction effect was also significant at a 5% level. As a result, the main effect of smoking temperature and smoking time could influence the drying rate of a smoking technology; also, the interaction effect did influence the drying rate.

Table 2

Analysis of variance (ANOVA) for drying rate

Sources	DF	SS	MS	F	P	
Replication	2	0.00163	0.00082

Smoking time	1	0.00681	0.00681	680.56	0.0000	*
ST ×St	2	0.00018	0.00009	8.89	0.0060	*
Error	10	0.00010	0.00001			
Total	17	0.10965				

* = significant, ** = non-significant, P < 0.05, significant at 5 % level, P>0.05, non-significant at 5% level.

From the investigation outcomes, it was revealed that the smoking technology drying rate ranged from 0.47 to 0.69 kg h^{-1}, as demonstrated in Figure 9.

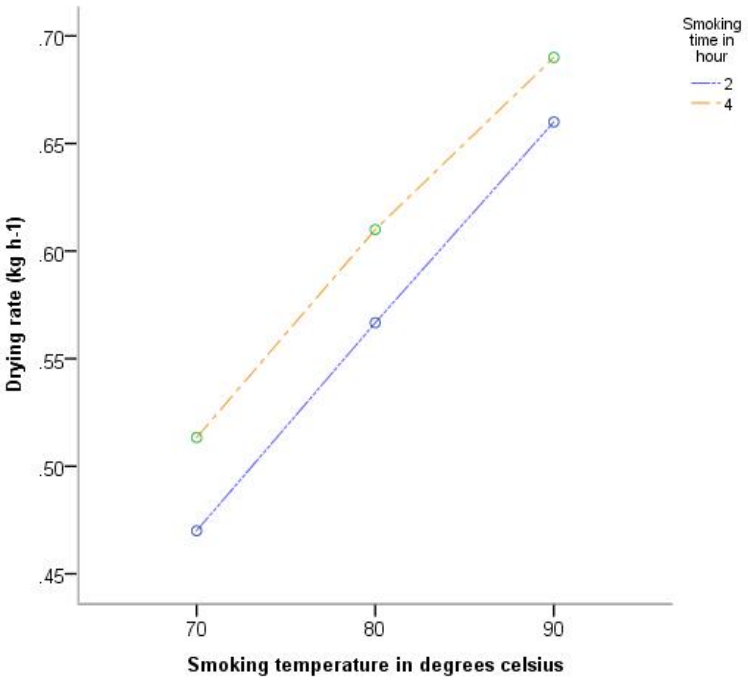

Fig. 9 - Effects of smoking temperature and time on drying rate

So, the drying rate increased from 0.47 to 0.69 kg h^{-1} as the smoking temperature increased from 70 to 90 ℃. The drying rate tends to increase as the smoking temperature and smoking time increase. It demonstrated that a direct association exists between the smoking temperature and smoking time of the drying rate. Generally, at 90 ℃ of smoking temperature and 4 h of smoking time, the maximum drying rate of 0.69 kg h^{-1} was obtained, whereas at 70 ℃ and 2 h smoking time, the minimum drying rate of 0.47 kg h^{-1} was obtained. The drying rate increased with rising temperature due to enhanced heat transfer and moisture migration; however, the rate gradually decreased over time as the moisture gradient between the fish surface and interior diminished. The previous studies in the literature relating results were reported by *Sintali et al. (2023a)*.

Effects of smoking temperature and time on fuel consumption

Analysis of variance for the effects of smoking temperature, smoking time, and the interaction effect on the fuel consumption of the mobile fish smoking technology was presented in Table 3. The analysis of variance indicated that (Table 3) the main effect of smoking temperature and smoking time was significant at a 5% level, depending on the result obtained, because the value for P found was less than 0.05, as well as the interaction effect was significant due to the value obtained for P was lower than 5% (P<5%). Depending on the findings, fuel consumption was impacted by the main effects, whereas it was also affected by the interaction effect.

Table 3

Analysis of variance (ANOVA) for fuel consumption

Sources	DF	SS	MS	F	P	
Replication	2	0.10858	0.05429			
Smoking temperature	2	8.82194	4.41097	754.16	0.0000	*
Smoking time	1	0.37267	0.37267	63.72	0.0000	*
ST ×St	2	0.19034	0.09517	16.27	0.0007	*
Error	10	0.05849	0.00585			
Total	17	9.55203				

* = significant, ** = non-significant, P < 0.05, significant at 5 % level, P>0.05, non-significant at 5% level.

Based on the investigation results, it was found that the fuel consumption ranged from 0.5 to 2.49 kg of fuel kg^{-1} smoked fish, as shown in Figure 10.

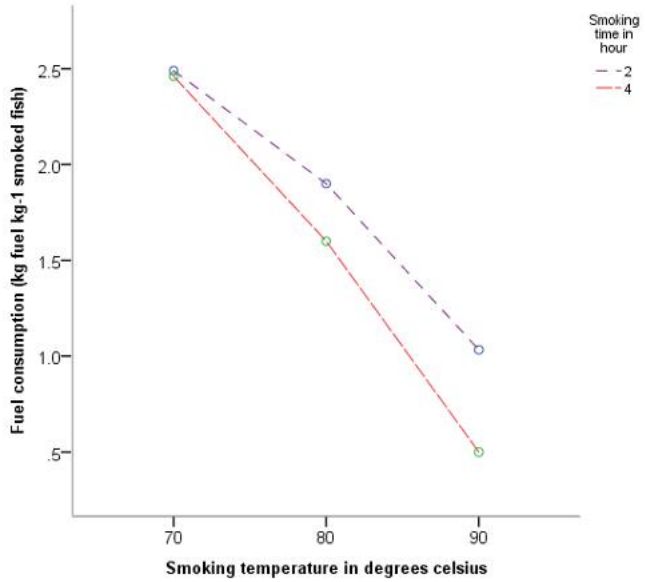

Fig. 10 - Effects of smoking temperature and time on fuel consumption

The fuel consumption reduced from 2.49 to 0.5 kg fuel kg^{-1} smoked fish as the smoking temperature rose from 70 to 90 ℃. By adjusting the smoking temperature and smoking time, fuel consumption was expected to decline as well. It demonstrated that the smoking temperature and smoking time had a reverse association with fuel consumption. According to the findings, at a smoking temperature of 90 ℃ and a smoking time of 4h, the smallest fuel consumption was observed at 0.5, whereas at a smoking temperature of 70℃ and a smoking time of 2 h, the highest fuel consumption was observed at 2.49 for the smoking technology.

Regarding fuel consumption, the results showed that higher temperatures and longer smoking durations increased total electrical energy use due to continuous heater operation and elevated power demand. A similar funding pattern for the smoker was reported by *Taherzadeh-Shalmaei et al. (2021)*.

Effects of smoking temperature and time on thermal efficiency

Analysis of variance for the effect of smoking temperature, smoking time, and interaction on the thermal efficiency of mobile fish smoking technology is presented (Table 4). Based on the findings, the analysis of variance revealed that the effect of smoking temperature and smoking time was significant at the level of five per cent due to the values for P obtained were lower than 0.05; however, the interaction effect was non-significant. According to the outcomes, the thermal efficiency was affected by smoking temperature and smoking time without their interaction effect.

Table 4

Analysis of variance (ANOVA) for thermal efficiency

Sources	DF	SS	MS	F	P	
Replication	2	9.45	4.727			
Smoking temperature	2	1361.56	680.780	1160.2	0.0000	*
Smoking time	1	58.32	58.320	99.41	0.0000	*
ST ×St	2	3.64	1.820	3.10	0.0895	**
Error	10	5.87	0.587			
Total	17	1438.84				

* = significant, ** = non-significant, P < 0.05, significant at 5 % level, P>0.05, non-significant at 5% level.

Based on the investigation results, the mean thermal efficiency of the mobile fish smoking technology varied from 45.6% to 69.8% with increasing smoking temperature from 70 to 90 ℃, whereas thermal efficiency increased from 45.6% to 69.8%. Figure 11 illustrates that the thermal efficiency of the technology tended to increase with the increase of smoking temperature and decreased with smoking time, which means thermal efficiency had a direct relationship to the smoking temperature and was inversely associated with smoking time.

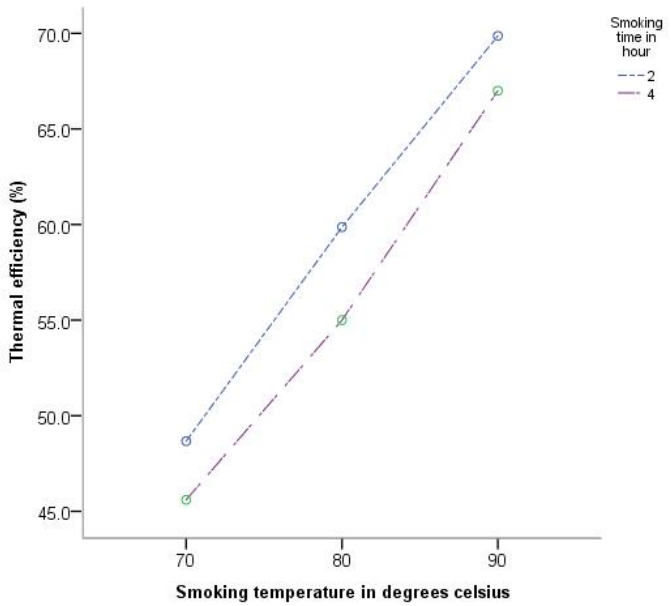

Fig. 11 - Effects of smoking temperature and time on thermal efficiency

The maximum thermal efficiency of 69.8% was recorded at a smoking temperature of 90 ℃, and a smoking time of 2 h, whereas the minimum thermal efficiency was 45.6 recorded at a smoking temperature of 70 ℃, and a smoking time of 4 h. It was found that thermal efficiency improved with controlled increases in temperature and proper smoking duration, as more input energy was effectively converted into useful heat for moisture removal. This study's finding result is similar to the previous research conducted by *Nwakuba et al. (2025)*.

Mean separations of treatment means

The least significance difference all pairwise comparisons test of moisture content reduction, drying rate, fuel consumption and thermal efficiency for mobile fish smoking technology were carried out for each treatment was given below in Table 5 then this analysis was subjected to the least significance difference all pairwise comparisons test of dependent variables for three levels of smoking temperature and two levels of smoking time to know significant differences among treatment means, So, the least significance difference all pairwise comparisons test showed (Table 5) that there were 6 groups (a, b, c, d, e and f) for test of moisture content reduction, drying rate and thermal efficiency for treatment, all 6 means are significantly different from one another but for test of fuel consumption for treatment, there are 4 groups (a, b, c, and d) in which the treatment means were not significantly different from one another at 5% level based on least significance difference all pairwise comparisons test.

Table 5

Comparisons between treatment means for the mobile fish smoking technology

S_T = Smoking temperature, S_t = Smoking time

Comparative evaluation of fish smoking technologies

This study demonstrated that electric fish smoking technology significantly outperformed fuelwood smoking systems across all evaluated parameters. The technology achieved an 81.4% improvement in moisture content reduction, reduced drying time by 0.69 kg h^{-1}, lowered fuel consumption by 2.49 kg kg^{-1} of fish smoked, increased thermal efficiency by 69.8%, and enhanced sensory acceptability by 48%. These findings confirm that electric fish smoking technology provides a more efficient, energy-saving, and high-quality fish processing method compared to fuelwood systems. The findings of this study demonstrate that both fish smoking technologies can significantly enhance fish preservation efficiency, improve product quality and safety, and reduce post-harvest losses.

Moisture content reduction

The moisture content of fish before and after smoking showed a clear difference between fuelwood and electric smoking technologies. Both systems reduced moisture significantly; however, the electric system achieved a greater reduction, resulting in safer storage conditions.

Table 6

Moisture content reduction in fish smoking technologies

Smoking technologies	Initial moisture (%)	Final moisture (%)	Moisture content reduction (%)
Stationary technology	78.05 ± 0.38	26.4 ± 0.2	66.17 ± 0.05
Mobile technology	78.1 ± 0.15	14.5 ± 0.22	81.4 ± 0.51

The electric smoking technology achieved a final moisture content of 14.5%, which is below the critical safe storage threshold of 15%. This level is ideal for long-term preservation and significantly reduces microbial growth risk. In contrast, the stationary smoker retained 26.4% moisture, which is insufficient for long-term storage and increases susceptibility to spoilage.

Drying rate

The drying rate varied significantly between smoking technologies as indicated in Table 7. The electric smoking technology increases drying rate by approximately 0.69 kg h^{-1}, which significantly increases the shelf life of fish. This faster drying is due to higher and more stable internal temperature (70–90°C), improved smoke circulation system, reduced moisture boundary layer resistance and enhanced energy transfer efficiency.

Table 7

Drying rate

Smoking technologies	Drying rate (kg h^{-1})	Total smoking time (h)	Smoking temperature (℃)
Stationary technology	0.38 ± 0.01	4	90
Mobile technology	0.69 ± 0.015	4	90

Thermal efficiency and fuel consumption

As indicated in Table 8, the thermal efficiency of electric fish smoking technology was higher, but the fuel usage was considerably lower in the electric smoking system.

Table 8

Thermal efficiency and fuel consumption

Smoking technologies	Thermal efficiency (%)	Fuel consumption (kg kg^{-1} fish)	Fuel saving
Stationary technology	37.9 ± 0.1	4.8 ± 0.05	low
Mobile technology	69.8 ± 0.78	2.49 ± 0.1	high

The electric fish smoking technology achieved approximately 69.8% of the maximizing of thermal efficiency due to an enclosed combustion chamber design, reduced heat leakage, efficient smoke recycling within the system and improved insulation materials. Fuelwood systems suffer from heat losses, leading to inefficient fuel use and higher operating costs. The electric smoker thus offers both environmental and economic benefits by reducing deforestation pressure and energy waste.

Based on the comparative evaluation of both electric and fuelwood fish smoking technologies, the results obtained for evaluation parameters in Figure 12 were higher in the case of electric fish smoking but lower in the fuelwood smoker, except for fuel consumption. The findings strongly support the adoption of electric fish smoking technologies in regions such as Sebeta and Melkassa, where traditional processing systems remain dominant.

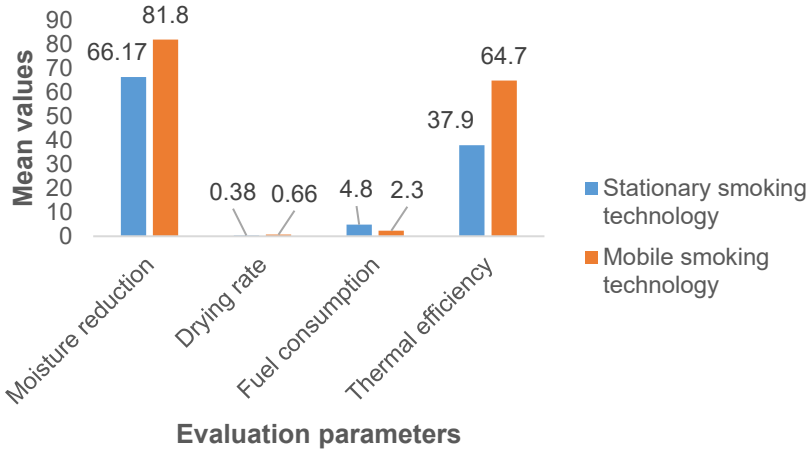

Fig. 12 - Comparative evaluation of smoking technologies

Sensory evaluation of smoked fish for the technologies

Sensory evaluation showed significantly higher acceptability scores for fish processed using improved technology.

Table 9

Sensory evaluation scores (9-point hedonic scale)

Attribute	Stationary smoking technology	Mobile smoking technology
Color	6.4 ± 0.049	8.8 ± 0.05
Aroma	6.7 ± 0.15	8.9 ± 0.06
Texture	6.3 ± 0.03	8.6 ± 0.03
Taste	6.5 ± 0.1	8.8 ± 0.05
Overall Acceptability	6.8 ± 0.17	8.7 ± 0.04

The results obtained in Figure 13 showed that the electric fish smoker consistently achieves higher sensory scores across all parameters. This improvement is due to uniform smoke penetration, controlled heating preventing burning, better moisture balance in the final product and reduced contamination from ash, but the fuelwood energy sourced smoker products showed darker coloration and slightly burnt flavor as well as reducing consumer preference. The same funding pattern for fish smoking technologies was reported by *Tahir et al. (2020).* This study was limited to tilapia fish, specific smoking conditions, and the experimental setup; therefore, the findings may not be directly applicable to other fish species or commercial-scale operations. Future studies should evaluate these technologies under diverse environmental conditions, processing parameters, and large-scale production systems.

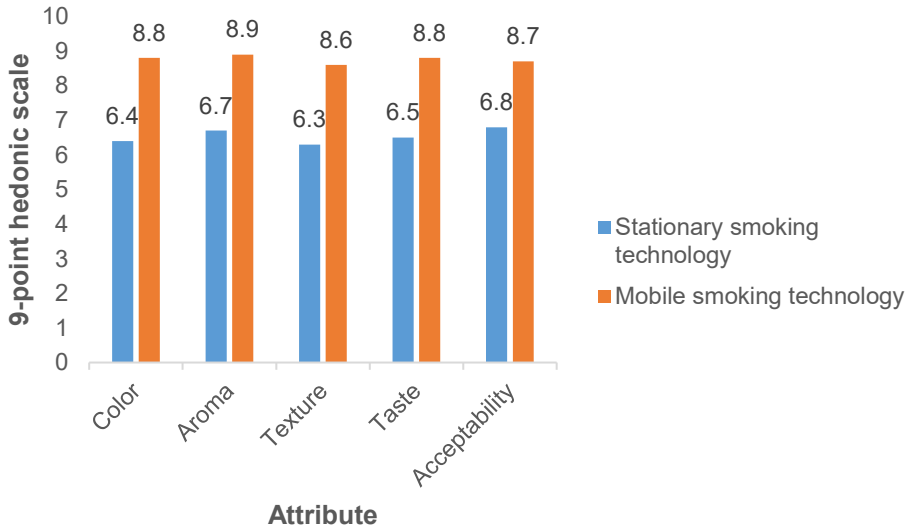

Fig. 13 - Sensor evaluation of smoked fish

CONCLUSIONS

The electric or mobile fish smoking technology was experimentally investigated at three levels of smoking temperature (70, 80, and 90°C) as well as two levels of smoking time (2 and 4 h) in terms of key performance indicators for the tilapia fish species. According to the investigation findings, with increasing smoking temperature from 70 °C to 90°C, the moisture content reduction increased from 57.6% to 81.4%; the drying rate increased from 0.47 kg h^{-1} to 0.69 kg h^{-1}, the thermal efficiency rose from 45.6% to 69.8%, and the fuel consumption reduced from 2.49% to 0.5%. Based on the analysis of variance results, the smoking temperature, smoking time and their interaction effects could influence the moisture content reduction, drying rate, fuel consumption, and thermal efficiency of an electric fish smoker; however, the combination effect did not influence thermal efficiency. The least significant difference all pairwise comparisons test revealed that the treatment means were significantly different from one another at 5% level, except for the test of fuel consumption for treatment based on the comparisons test. The comparative evaluation was carried out for electric and fuelwood fish smoking technologies with respect to key performance indicators. The study revealed that electric fish smoking technology significantly outperformed fuelwood smoking systems across all evaluated parameters. This study was limited to tilapia fish, specific smoking conditions, and the experimental setup; therefore, the findings may not be directly applicable to other fish species or commercial-scale operations. The study revealed that the electric fish smoking technology is strongly recommended for demonstration and scaling up to end users, particularly in areas where traditional smoking methods remain dominant.

ABSTRACT

To meet the maneuverability and terrain-adaptability requirements of agricultural machinery operating in hilly and mountainous areas, an electronically controlled tracked chassis was designed and developed. Based on a theoretical analysis of chassis terrain-crossing capability and stability, a multibody dynamic model was established using RecurDyn to simulate the dynamic response of the chassis under typical operating conditions. The chassis trajectory and variations in dynamic stability were analyzed. A physical prototype was then manufactured and tested under multiple operating conditions on actual road surfaces. The chassis achieved a maximum straight-line travel speed of 4 km/h on level ground, a maximum uphill and downhill travel speed of 2 km/h, a maximum climbing angle of 18°, a maximum trench-crossing width of 500 mm, and a turning radius not exceeding 675 mm. The simulation and experimental results were in close agreement, with a maximum relative error of 11%, demonstrating the predictive accuracy of the multibody dynamic model. The developed chassis exhibited good terrain-crossing capability and operational stability. This study provides a theoretical basis and technical support for the development and application of small agricultural machinery in hilly and mountainous areas.

中文摘要

针对丘陵山地复杂地形对农机装备机动性与适应性的要求，本文设计开发了一款小型履带式电控底盘。基于多体动力学底盘通过性及稳定性理论分析，运用 RecurD n 仿真软件构建底盘动力学模型，模拟底盘在典型工况下的动态响应特性，并对其运动轨迹及系统稳定性变化规律进行仿真分析。对研制样机进行实际路况条件下多工况性能测试，当平地直行最大速度为 4 m/h，上下坡最大速度为 2 m/h 时，最大坡度角为 18°，跨越壕沟最大宽度为 500mm，最小转向半径小于 6 5mm。仿真与试验结果表明，构建的多体动力学模型具有较高的预测精度，底盘在复杂地形下具有良好的通过性与稳定性，相对误差均≤11%。研究为丘陵山地小型农机装备研发提供了可靠的理论依据与技术支撑。

INTRODUCTION

From the perspective of global agricultural development trends, the efficient utilization of agricultural resources in hilly and mountainous areas has become a crucial direction for countries to enhance comprehensive agricultural productivity and expand production boundaries. In regions with limited arable land and diverse topography, the mechanization of agriculture in hilly and mountainous areas is not only vital for local agricultural modernization but also a key component of national agricultural strategies *(HU et al., 2025; Jin et al., 2023; Jiang et al., 2025)*. Due to the complex terrain and insufficient agricultural infrastructure, the promotion and application of agricultural mechanization in hilly and mountainous areas lag far behind those in plain regions. Accelerating the modernization of agriculture have become urgent problems *(Sun et al., 2024; Xiong et al., 2023; Chen, 2025)*. The small tracked electronic control chassis, with its advantages of low ground pressure ratio and strong terrain adaptability, is conducive to the operation of mountainous mechanized equipment *(Ding et al., 2025; Buzunov et al., 2023; Belloni et al., 2024; Liu et al., 2025; Chen et al., 2024; Zemánek and Neruda, 2021)*.

Xiaolian LÜ, Prof.; Jiankang HUANG, B.S. Stud; Ruijuan SU, M.S. Stud; Yang ZHANG, M.S. Stud; Xiaorong LÜ,Prof.

As the core traveling and load-bearing component of agricultural machinery, the dynamic performance of the chassis is a key technical link that restricts the development of agricultural machinery equipment. Scholars have conducted extensive research on chassis, and obtained many achievements *(Archut et al., 2026; Baek et al., 2020; HIDALGO et al., 2015; Grazioso et al., 2023; Yun et al., 2023; Ugenti et al., 2023; HUANG et al., 2025)*. *Mirosław et al. (2025)* developed a model of an articulated UGV (unmanned ground vehicle), and studies on the influence of clearances in the steering and track systems on the directional stability of articulated tracked UGVs. *Dudzińskiand and Chołodowski (2021)* established an internal resistance model for the tracked chassis to optimize energy efficiency. *Pei et al. (2025)* examines the climbing performance of the crawler harvester chassis to solve the problems of running ability and stability of the chassis of the crawler combine harvester during mechanical operation. *Komissarov (2025)* developed a simulation model of a high speed tracked vehicle power train with step track gear boxes to be inserted as a subsystem into a highly computationally efficient model of the tracked vehicle curvilinear motion. Existing research mostly focuses on chassis structure design and conventional performance testing, and the study of chassis dynamic response laws under complex and variable working conditions in hilly and mountainous areas is still not deep enough. Traditional physical testing has high costs and long cycles, making it difficult to comprehensively and accurately obtain chassis dynamic characteristics. Dynamic simulation technology can effectively compensate for the shortcomings of testing. This article takes the self-designed electrically controlled tracked chassis in hilly and mountainous areas as the research object, systematically conducts dynamic theoretical analysis of chassis operating performance. The research provides technical support for promoting the mechanization and intelligence of agricultural equipment in hilly and mountainous areas.

MATERIALS AND METHODS

Overall Structure and Parameters

This article has completed the modular integrated design of an electronically controlled tracked chassis. The chassis consists of a frame, a track traveling mechanism, a steering system, a braking mechanism, an electric drive unit, a control system, and a power supply. The overall configuration is shown in Fig. 1. The basic technical parameters are shown in Table 1. The chassis uses STC89C52 microcontroller as the main control chip to build a remote wireless remote-control system. The system integrates modules such as speed display, Bluetooth communication, encoder, motor drive controller, drive motor, power battery, and data acquisition. The matching principles of various hardware parameters have been clarified, and the core control logic has been formulated. Implementing closed-loop regulation of driving speed and brake pressure threshold through PID algorithm is to achieve precise steering control. The designed chassis has a driving speed of 2-4 km/h, a maximum climbing ability of 20°, and a maximum crossing trenches width of 550 mm. The chassis has remote control and flexible steering characteristics, which can meet the needs of multi working conditions in hilly and mountainous areas.

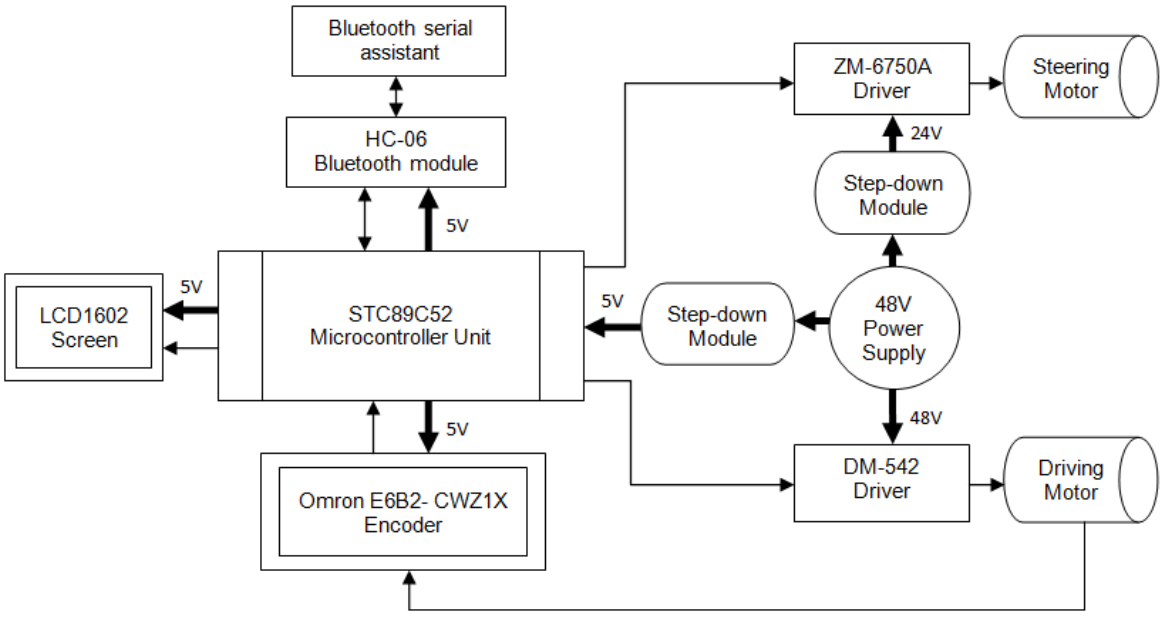
Table 1

Track Chassis Parameters

Name	Parameter	Name	Parameter
Length × Width ×Height/mm	1000×650×200	Drive sprocket diameter /mm	210
Wheelbase /mm	860	Support wheel diameter /mm	150
Track gauge /mm	470	Guide wheel diameter /mm	190
Track ground-contact length /mm	680	Climbing angle /°	20
Track width /mm	150		

Overall Scheme of the Control System

To achieve wireless remote control and real-time monitoring of the tracked chassis, a measurement and control system was designed with the STC89C52 microcontroller as the main controller. The system primarily consists of a microcontroller minimal system, power module, motor drive module, wireless communication module, and speed monitoring and display module. The overall scheme is shown in Figure 2. The microcontroller minimal system serves as the core control unit, responsible for command reception, logical operations, signal parsing, and motion control. The power module uses a 48 V lithium battery as the primary power source, employing a voltage step-down regulation method to provide 5 V operating voltage for the microcontroller and output stable 24 V through a voltage step-down module, ensuring reliable and stable power supply for the encoder and stepper motor. The motor drive section adopts a dual-channel drive architecture, with the DC brushless motor using the ZM-6750A driver (Operating voltage range: DC32~60 V; Capable of handling peak currents below 50 A); the stepper motor employs the DM-542 driver (Operating voltage range: DC24~50 V; Output current range: 1.0~4.2 A). Wireless communication utilizes the HC-06 Bluetooth module to establish a stable communication link with the mobile app, ensuring reliable transmission of remote control commands and data interaction. Speed monitoring employs the Omron E6B2- CWZ1X rotary encoder, installed at the DC brushless motor shaft end, to collect real-time actual speed data of the driven wheels. The display module uses an LCD1602 screen (Operating voltage range: 4.8~5.2 V), and powered directly by the microcontroller, enabling real-time display of the chassis speed and visualizing the operational status. During system operation, Bluetooth serial assistant of the mobile phone sends control commands, which are transmitted via the Bluetooth module to the microcontroller. After signal parsing and computation, the microcontroller outputs corresponding drive signals to control the motor drivers, thereby enabling functions such as starting, stopping, steering, and speed adjustment of the tracked chassis, ensuring stable system operation, rapid response, and reliable control.



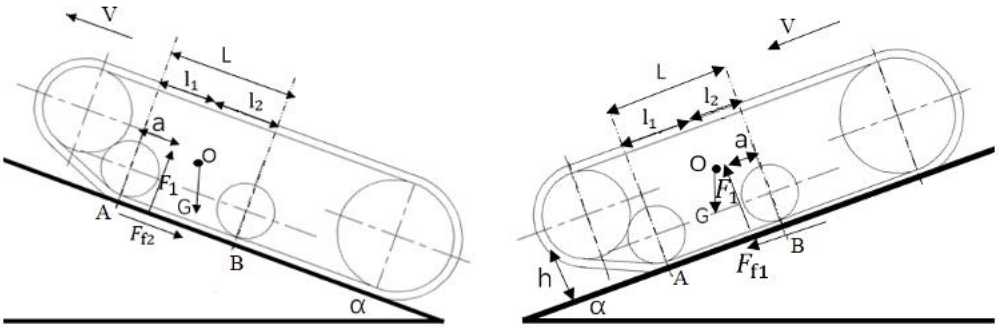


Fig. 2 - The Overall scheme block diagram of control system

Dynamic Performance Analysis of the Chassis

The climbing capability, trench-crossing performance, and steering characteristics of the tracked chassis are key indicators of its operational stability and adaptability to complex terrain. Under idealized operating conditions, mechanical modeling and force analysis of the chassis under different operating conditions provide a theoretical basis for structural design and parameter matching. The forces acting on the chassis during uphill and downhill travel are shown in Fig. 3.

(a) Uphill (b) Downhill

Fig. 3 - Force analysis diagram of the chassis climbing

V-Chassis forward speed, m/s; O-chassis center of mass; G-chassis gravity, N; α - slope, °; h-ground clearance of the center of mass, mm; F_1- ground support force of the chassis, N; a-distance between the support wheel and the support force, mm; L - distance between the support wheel A and the support wheel B, mm; l_1- distance between the support wheel A and the center of mass, mm; l_2- distance between the support wheel B and the center of mass, mm

When the chassis is stable uphill, the force on the vehicle body is balanced, and it can be obtained.

$$\begin{cases} F_1 a - G l_1 \cos\alpha - G h \sin\alpha = 0 \\ F_1 = G \cos\alpha \end{cases} \quad (1)$$

Thus, it can be obtained.

$$a = \frac{l_1 \cos\alpha + \mathrm{h} \sin\alpha}{\cos\alpha} \quad (2)$$

The critical condition for chassis overturning is $a = 0$.

The maximum uphill angle is:

$$\alpha_{max,\mathrm{up}} = \tan^{-1}\frac{l_1}{\mathrm{h}} = 25° \quad (3)$$

The maximum downhill angle is:

$$\alpha_{max,\mathrm{down}} = \tan^{-1}\frac{l_2}{\mathrm{h}} = 22° \quad (4)$$

When the chassis crosses the trench, the force distribution and key geometric parameters are shown in Fig. 4.

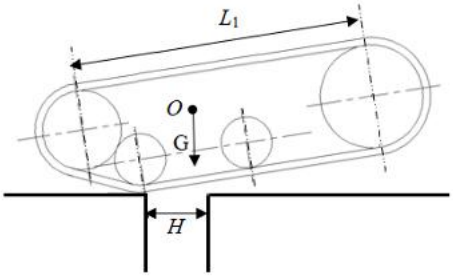

Fig. 4 - Force analysis diagram of tracked chassis crossing trenches

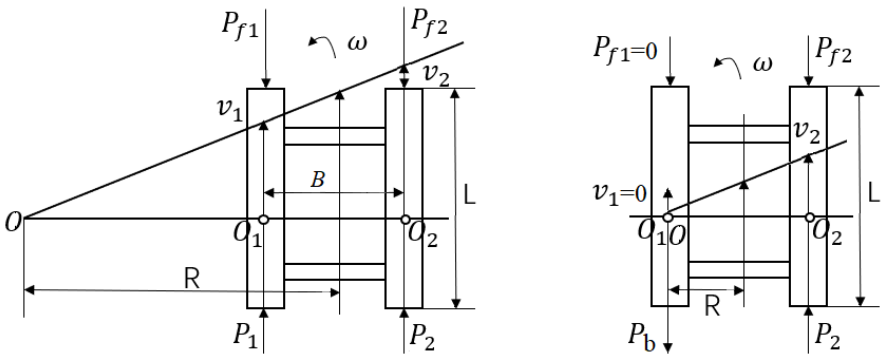

H - maximum width of the chassis crossing the trench, mm; L_1 - distance between the drive sprocket and the guide wheel, mm; O - the center of mass of the chassis; G - chassis gravity, N.

The theoretical maximum trench width of the chassis can be derived:

$$H = \sqrt{(\frac{L_1}{2})^2 + \mathrm{h_1}^2} + r = 581 \text{ mm} \quad (5)$$

where: r - drive sprocket radius, mm; h_1 - guide wheel height, mm.

Mechanical analysis of typical working conditions of chassis steering: the differential steering and unilateral braking steering. The force situation during chassis steering is shown in Fig. 5.

(a) Differential steering (b) Unilateral braking steering

Fig. 5 - Chassis steering performance analysis diagram

O - theoretical steering center of tracked chassis vehicles; O_1,O_2 - instantaneous turning center of the inner and outer track contact sections; v_1,v_2 - the inner and outer track line velocities, m/s; R - steering radius, m; L - the track ground-contact length, m; B - the track gauge, m; P_1,P_2 - the inner and outer track driving force, N; P_{f1},P_{f2} - inner and outer track rolling resistance, N; P_b - track braking force, N; ω - chassis angular velocity, rad/s.

During chassis steering, the following relationship can be obtained:

$$\begin{cases} \omega = \frac{v_2 - v_1}{B} \\ R = \frac{B}{2} \cdot \frac{v_2 + v_1}{v_2 - v_1} \end{cases} \quad (6)$$

where: ω - chassis angular velocity; v_1 - the inner track line velocities; v_2 - the outer track line velocities; B - the track gauge; R - steering radius.

The maximum adhesion of the left and right tracks is:

$$P_{\varphi 1} = P_{\varphi 2} = \frac{1}{2} G\varphi \quad (7)$$

where: $P_{\varphi 1}$ - the maximum adhesion of the left; $P_{\varphi 2}$ - the maximum adhesion of the right; G - the gravity of track chassis; φ - adhesion coefficient.

The rolling resistance of the left and right tracks is:

$$P_{f1} = P_{f2} = \frac{1}{2} G\, f \quad (8)$$

where: P_{f1} - the inner track rolling resistance; P_{f2} - the outer track rolling resistance; G - the gravity of track chassis; f - rolling resistance coefficient.

The steering resistance torque is:

$$M_f = \frac{\mu G L}{4} \quad (9)$$

where: M_f - the steering resistance torque; μ - the average resistance coefficient of steering; G - the gravity of track chassis; L - the track ground-contact length.

The steering torque is:

$$M_1 = \frac{B}{2} P_1 - \frac{B}{2} P_2 \quad (10)$$

where: B - the track gauge; P_1 - the inner track driving force; P_2 - the outer track driving force.

When $M_1 \gg M_f$, the following relationship can be obtained:

$$\frac{L}{B} \ll \frac{2(\varphi - f)}{\mu} \quad (11)$$

In this article, the L of the tracked chassis is designed to be 680 mm and B is 470 mm. The minimum turning radius of the tracked chassis is theoretically less than the sum of the wheelbase and track width. The radius of the chassis unilateral braking steering is 620 mm.

Development of the Multibody Dynamic Simulation Model

To balance dynamic-response fidelity and computational efficiency, the chassis model was simplified to include the main load-bearing frame and the track traveling mechanism. The track traveling mechanism was modeled using the dedicated Track/HM module in RecurDyn, and the constraint relationships among the components were defined, as shown in Fig. 6. The road surface was modeled using the built-in Ground module in RecurDyn. The main simulation parameters are presented in Table 2.

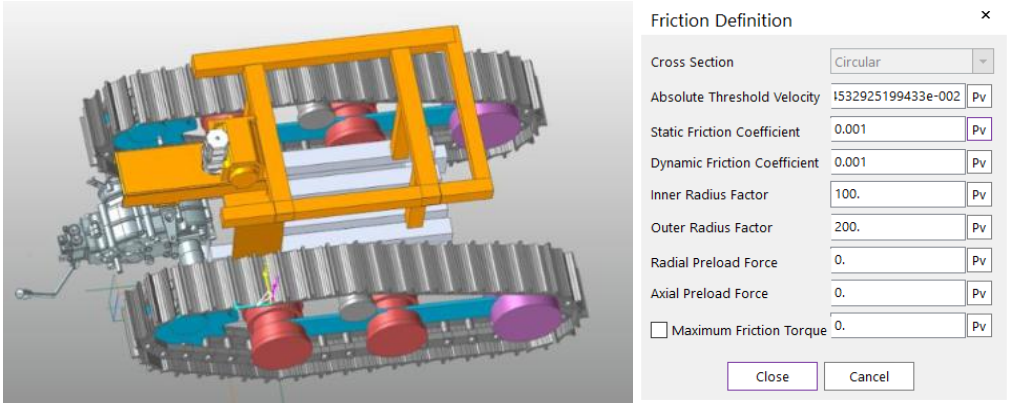

Fig. 6 - Development of the multibody dynamic model of the tracked chassis

Table 2

The road surface characteristic parameters

Parameter	Value
Cohesive deformation modulus of soil k / (N·$m^{-(n+1)}$)	0.417
Frictional deformation modulus of soil k_φ/(N · $m^{-(n+2)}$)	2.19×10^{-2}
Soil deformation exponent n	0.5
Soil cohesion c_i/ kPa	4.14×10^{-3}
Internal friction angle / (°)	13
Shear deformation modulus k_s	25
Sinkage ratio	0.05

Chassis performance was comprehensively evaluated in terms of driving stability, terrain-crossing capability, and steering maneuverability using the chassis pitch angle relative to the ground, center-of-mass displacement, center-of-mass velocity, steering angular acceleration, drive-sprocket angular velocity, and chassis angular displacement as evaluation indicators. The simulation conditions were as follows:

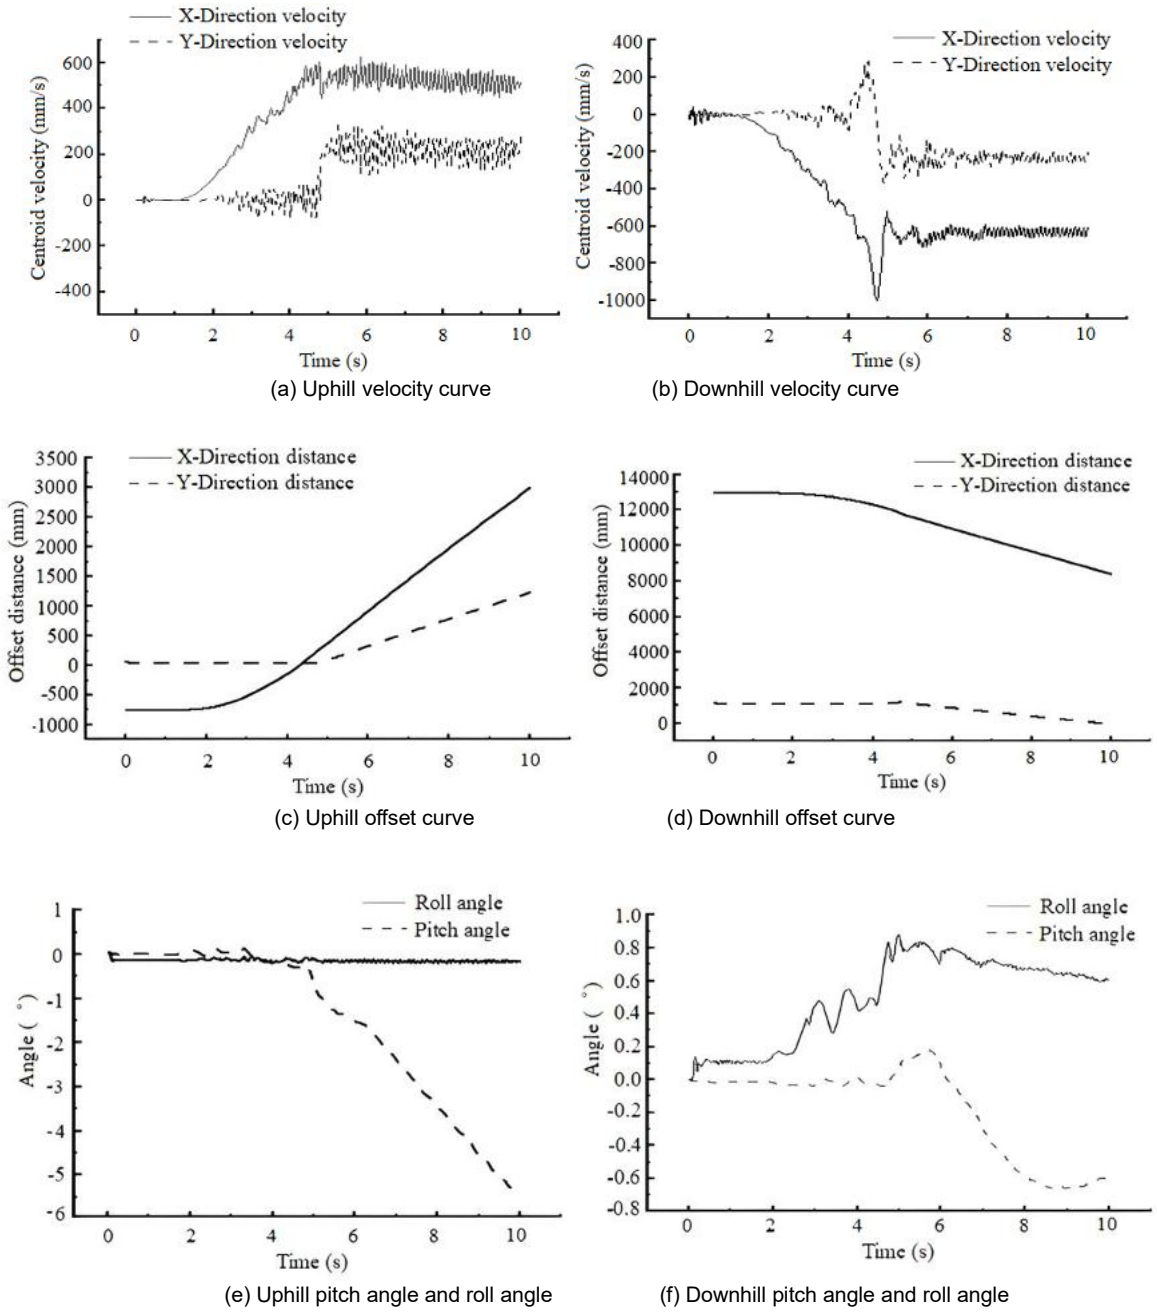
(1) Climbing-performance simulation: The slope angle was set to 20°, the travel speed to 2 km/h, and the drive-sprocket angular velocity to ω=5.32 rad/s. The simulation duration was 10 s, with 500 computational steps.

(2) Trench-crossing simulation: The travel speed was set to 3 km/h, and the drive-sprocket angular velocity was set to ω=7.93 rad/s. The STEP function was used to control the variation in drive-sprocket angular velocity STEP (TIME, 1,0,3, -7.93). The simulation duration and number of computational steps were the same as those used in the climbing simulation.

(3) Steering-performance simulation: Two steering modes — single-track braking and pivot steering — were simulated to determine the minimum turning radius. For single-track braking, the right track was braked while the left track continued to travel at 2 km/h, corresponding to a drive-sprocket angular velocity of ω=5.29 rad/s. The function expression for the right drive sprocket was STEP (TIME, 1,0,4,5.29) +STEP (TIME, 5,0,7, -5.29) +STEP (TIME, 8,0,9,5.29), and the speed function for the left drive sprocket was STEP (TIME, 1,0,4,5.29). When performing a Pivot steering, the driving speed was set to 1.5 km/h, the drive sprocket angular velocity ω=3.96 rad/s, the speed function of the right drive sprocket was STEP (TIME, 1,0,2,3.96), and the speed function of the left drive sprocket was STEP (TIME, 1,0,2, -3.96). Pivot steering was achieved by driving the two tracks at equal angular-velocity magnitudes in opposite directions, and the simulation duration and number of computational steps were the same as those used in the preceding simulations.

Field Performance Test Scheme

Test objective: The field tests were conducted to verify the accuracy of the chassis dynamic model, evaluate the dynamic performance of the chassis, and validate the structural design parameters and simulation results. The climbing, trench-crossing, and steering performance of the chassis was investigated.



Test object and method: The test object was the independently developed electronically controlled tracked chassis, and the field-test conditions were consistent with the simulation conditions. Climbing performance was evaluated using the maximum stable climbing angle. The ability of the chassis to travel smoothly on slopes ranging from 5° to 20° was tested. Each operating condition was tested three times and was considered successful only if the chassis completed all three trials. Trench-crossing performance was evaluated using the maximum safe trench-crossing width, with trench widths ranging from 0.30 to 0.55 m.

Each trench width was tested three times and was considered successfully traversed only if all three trials were completed. Steering performance was evaluated using the turning radius during single-track braking. Four steering modes were tested: forward left turn, forward right turn, reverse left turn, and reverse right turn. The largest stable turning radius measured among the four steering modes was taken as the steering-performance value.

RESULTS AND DISCUSSION

Multibody Dynamic Simulation Results

The climbing-performance and trench-crossing simulation results are shown in Figs. 7 and 8, respectively, while the steering-performance results are presented in Fig. 9. Based on the actual steering mode of the chassis, the trajectory of its center of mass during single-track braking on a clay road surface was simulated, as shown in Fig. 10.
