The simulation results were analyzed as follows. As shown in Figs. 7(a) and 7(b), during uphill travel, the mean values of *Vx* and *Vy* were 0.53 and approximately 0.23 m/s, respectively. During downhill travel, *Vx* remained relatively stable within the range of 0.5–0.6 m/s, while the mean *Vy* was 0.23 m/s. The simulated velocity of the chassis center of mass was consistent with the calculated value, supporting the validity of the dynamic model. As shown in Figs. 7(c) and 7(d), at approximately 4 s during both uphill and downhill travel, the displacement in the X-direction began to decrease gradually, while the center of mass exhibited considerable vertical displacement in the Y-direction. After the chassis had fully entered the slope, its center-of-mass displacement continued to increase approximately linearly with time, although the rate of increase decreased slightly. As shown in Figs. 7(e) and 7(f), the pitch and roll angles remained close to zero during most of the uphill process. Near the end of the climb, both angles increased slightly but remained below 6°. During downhill travel, the pitch and roll angles fluctuated more noticeably, with a maximum roll angle of 0.9°. As shown in Fig. 8(a), the center-of-mass velocity fluctuated considerably while the chassis crossed the trench between 2 and 4 s. After trench crossing was completed, the velocity rapidly stabilized, indicating effective drive-speed regulation. As shown in Fig. 8(b), the center-of-mass displacement in the Y-direction remained nearly constant, indicating negligible lateral deviation perpendicular to the direction of travel. The chassis began to enter the trench at 2 s, after which the corresponding vertical-displacement curve decreased approximately linearly. This behavior was consistent with the velocity fluctuations and load variations occurring during trench crossing. As shown in Fig. 8(c), the roll angle exhibited periodic oscillations during trench crossing, while the pitch angle remained below 8° throughout the process. As shown in Figs. 9(a) and 9(b), the angular acceleration varied smoothly during steering, indicating stable steering-power output without marked impact loading. As shown in Figs. 9(c) and 9(d), the single-track braking maneuver proceeded smoothly and steadily. As shown in Figs. 9(e) and 9(f), the chassis initially completed a 90° right turn and subsequently continued traveling in a straight line until the end of the simulation, producing a regular turning trajectory. During pivot steering, the chassis also exhibited a rapid steering response. The simulated trajectory of the chassis center of mass during single-track braking on a clay road surface is shown in Fig. 10. The maximum turning radius was 650 mm, corresponding to an error of 4.85% relative to the theoretical design value.

Field Performance Test Results

The field test results are shown in Figure 11.

(a) climbing and trench-crossing performance

(b) turning radius under different steering conditions

Fig. 11 - Analysis of performance test results for small electronically controlled tracked chassis

Analysis of the experimental results yielded the following findings: (1) The maximum climbing angle of the chassis was 18°, with a relative error of no more than 11% compared with the simulated value. These results validated the accuracy of the climbing dynamic model and demonstrated that the chassis could meet the climbing requirements of operations in hilly and mountainous areas. The deviation was mainly attributed to differences between the actual operating conditions and the idealized model, including track–ground adhesion, track characteristics, and chassis mass distribution. (2) The maximum trench-crossing width measured during the field tests was 500 mm, with a relative error of no more than 10% compared with the simulated value. The results confirmed the reliability of the trench-crossing dynamic model and indicated that the chassis structure could traverse common trench obstacles in hilly and mountainous areas. The deviation was mainly caused by differences in ground conditions, track–ground contact characteristics, chassis attitude, and load distribution between the field tests and the idealized model. (3) The single-track braking tests yielded a maximum turning radius of 675 mm under the different steering conditions, with a relative error of no more than 3.70% compared with the simulated value. The close agreement between the experimental and simulated results validated the developed dynamic model and theoretical analysis method. The steering flexibility and accuracy of the chassis met the requirements for operation in confined spaces in hilly and mountainous areas.

CONCLUSIONS

(1) The multibody dynamic model developed for the electronically controlled tracked chassis under typical operating conditions demonstrated adequate accuracy and applicability. The relative errors for climbing and trench-crossing performance were within 11%, while the relative error in turning radius under different steering conditions was within 3.70%. The model accurately represented the dynamic response of the chassis during operation in hilly and mountainous terrain, providing a reliable theoretical basis for evaluating chassis travel performance and optimizing the track traveling mechanism.

(2) The independently developed electronically controlled tracked chassis met the operational requirements for complex terrain in hilly and mountainous areas. Field-test results showed that the chassis achieved the design targets for climbing, trench crossing, and steering, while maintaining smooth and stable motion. The measured motion parameters under the different operating conditions agreed closely with the theoretical and simulation results. The chassis exhibited good adaptability to uneven terrain and complex ground conditions, thereby confirming the feasibility and practicality of the track traveling mechanism design.

Keywords: *Cucumber seeds, Radicle length estimation, Keypoint detection, High-throughput plant phenotyping*

ABSTRACT

Radicle length is an important phenotypic trait for evaluating the growth-promoting effects of plant growth-promoting rhizobacteria on cucumber seeds. However, conventional manual measurement is time-consuming, labor-intensive, and prone to subjective errors, while existing radicle phenotyping systems still suffer from insufficient throughput. To address these limitations, this study proposes an automatic radicle length estimation method for germinated cucumber seeds based on GermHRNet. First, a YOLOv8-p2s model was used to automatically detect seed instances in Petri dish images. Subsequently, a GermHRNet keypoint detection network was developed to accurately localize radicle keypoints. A high-resolution cross-scale feature enhancement module and a dynamic coordinate feature enhancement module were introduced to improve feature representation and keypoint localization accuracy for slender and curved radicles. Finally, radicle length was estimated using a polyline-based pixel distance accumulation strategy according to the detected keypoint coordinates. Experimental results showed that the proposed method achieved an average precision, average recall, and percentage of correct keypoints of 90.6%, 92.2%, and 88.2%, respectively. The mean absolute error, root mean square error, normalized mean absolute error, normalized root mean square error, and coefficient of determination for radicle length estimation were 0.51 mm, 0.61 mm, 6.06%, 7.25%, and 0.98, respectively. Under a CPU-only environment without GPU acceleration, the proposed method achieved a throughput of 3.38 × 10^4 seeds/h. The proposed method enables rapid and accurate radicle length acquisition without specialized equipment and provides an efficient technical solution for large-scale microbial strain screening and seed phenotyping.

摘要

黄瓜种子胚根长度是评价植物促生根际菌促生效应的重要表型参数，但传统人工测量费时费力且主观性强，而现有胚根表型采集系统也存在通量不足的问题。为此，本研究提出一种基于 ermHRNet 的发芽黄瓜种子胚根长度自动估测方法。首先，利用 YOLOv8- 2s 模型实现培养皿中种子个体的自动检测。随后，构建 ermHRNet 关键点检测网络，实现胚根关键点的准确定位。通过引入高分辨率交叉特征增强模块和动态坐标特征增强模块，提高了细长弯曲胚根的特征表达与关键点定位精度。最后，基于关键点坐标采用多段折线像素距离累积方法实现胚根长度估测。结果表明：关键点检测的平均精度、平均召回率和正确关键点百分比分别达到 90.6%、92.2% 和 88.2%；长度估测的平均绝对误差、均方根误差、归一化平均绝对误差、归一化均方根误差和决定系数分别为 0.51 mm、0.61 mm、6.06%、 .25%和 0.98；在普通设备 CPU 推理且未启用 PU 加速的环境下，单机处理通量可达 3.38×10^4 粒/h。该方法无需专业设备即可实现发芽黄瓜种子胚根长度的准确、快速获取，可为大规模菌株筛选及种子表型分析提供高效技术支撑。

INTRODUCTION

Cucumber is widely used as a representative crop for investigating root development in plant physiology and plant–microbe interaction studies because of its short growth cycle, clear phenotypic characteristics, and high sensitivity to environmental changes *(Shaik et al., 2025).* In studies involving plant growth-promoting rhizobacteria (PGPR), cucumber seeds are commonly used as experimental materials to evaluate the growth-promoting potential of microbial strains and their combinations *(Fu et al., 2026).* Radicle length is one of the most important phenotypic indicators of early root development, as it directly reflects seed germination status and the regulatory effects of microbial metabolites on root growth. However, PGPR screening usually requires the evaluation of a large number of candidate strains, which places high demands on both the efficiency and accuracy of radicle length measurement. At present, radicle length measurement still largely depends on manual operation, which is time-consuming, labor-intensive, and susceptible to subjective errors. Although several automated seed phenotyping systems, such as TPN-Pheno-ZM1 *(Top Cloud-Agri Technology Co., Ltd., 2026)* and OpenPheno *(Hu et al., 2025)*, have been developed to improve measurement efficiency, their throughput for radicle length measurement remains limited. For example, the TPN-Pheno-ZM1 system can process only approximately 1,000 seeds within 2 h. Therefore, developing an accurate, efficient method for automatic radicle length estimation is of practical importance for high-throughput microbial screening and seed phenotyping.

To realize automatic radicle length estimation in germinated seeds, image semantic segmentation has been widely used to extract radicle regions and estimate length based on contour or skeleton information *(Wu et al., 2024; Zhao et al., 2025)*. However, segmentation-based methods are highly dependent on image quality and segmentation accuracy. When radicles are curved, slightly lifted from the filter paper, adherent to the background, or partially blurred, these methods are prone to structural discontinuities, boundary errors, and mis-segmentation, which may further affect length estimation. Compared with segmentation-based methods, keypoint detection provides a more structured representation by localizing critical anatomical or morphological positions of the target *(Li et al., 2026).* This strategy reduces the dependence on complete pixel-level segmentation and can provide a more robust representation of complex radicle morphology. In recent years, keypoint detection has been increasingly applied to agricultural phenotyping tasks. For example, *Chen et al. (2025)* developed an improved LTHRNet model for accurate localization and pose estimation of pineapple fruit keypoints. *Yuan et al. (2026)* proposed CLR-YOLO-Pose based on YOLO-Pose, which improved keypoint detection performance under complex scenarios and enabled high-precision measurement of peduncle length. *He et al. (2024)* introduced DEKR-SPrior based on a bottom-up keypoint detection framework for phenotypic analysis of soybean pods in complex field environments. *Pan et al. (2025)* developed the PFLO model to reconstruct plant skeletons from keypoints for high-precision maize phenotyping. *Wu et al. (2023)* improved HRNet by incorporating a Ghost module and developed a lightweight keypoint detection model for grape stem recognition in complex cluster structures. *Niu et al. (2025)* introduced an attention mechanism into YOLOv11-Pose to achieve whole-plant keypoint localization and phenotypic parameter extraction in maize. *Chen et al. (2024)* improved skeleton extraction and phenotypic parameter acquisition for individual rice tillers by integrating the CBAM module into a cascaded pyramid network. These studies demonstrate the potential of keypoint detection for plant phenotyping. However, most existing methods focus on relatively large plant organs, such as fruits, stems, pods, tillers, or whole plants, which usually have more distinct structural features. In contrast, germinated seed radicles are small, slender, curved, and sometimes structurally discontinuous in images. As a result, keypoint detection for germinated seed radicles remains insufficiently investigated, and a dedicated methodological framework is still lacking.

In summary, automatic radicle length estimation still faces two main challenges. First, existing measurement methods often rely on manual operation, specialized imaging devices, or low-throughput processing workflows, making them difficult to apply to large-scale microbial strain screening. Second, current keypoint detection methods have limited capability in preserving fine structural details of small and slender targets, which may lead to unstable or inaccurate keypoint localization when radicles show obvious curvature, complex poses, adhesion to the filter paper, or blurred root tips.

To address these challenges, this study proposes a GermHRNet-based automatic radicle length estimation method for germinated cucumber seeds. Based on the high-resolution network (HRNet), the proposed method enhances the keypoint detection framework to improve the representation of fine radicle structures and the localization stability of curved radicles. Specifically, YOLOv8-p2s is first used to detect individual seed instances in Petri dish images. Then, GermHRNet is constructed to localize radicle keypoints accurately.

To improve the representation of slender radicle structures, a high-resolution cross-scale feature enhancement strategy was introduced. In addition, a coordinate-aware dynamic feature enhancement strategy was further incorporated to enhance spatial coordinate awareness and reduce keypoint displacement caused by radicle curvature. Finally, radicle length is estimated using a polyline-based pixel-to-millimeter accumulation method. The proposed method aims to provide an accurate, rapid, and high-throughput technical solution for cucumber seed radicle phenotyping and large-scale PGPR screening.

The main contributions of this study are summarized as follows:

1) An automated radicle phenotyping framework integrating seed detection, keypoint localization, and radicle length estimation was developed for germinated cucumber seeds, providing an efficient technical solution for large-scale PGPR screening.

2) A GermHRNet-based keypoint detection model was proposed to improve the localization accuracy of small, slender, and curved radicles. The model enhances fine-grained structural representation and spatial coordinate perception for complex radicle morphology.

3) A polyline-based radicle length estimation strategy was established to achieve accurate radicle length quantification without relying on pixel-level segmentation, thereby improving robustness under curved and partially blurred radicle conditions.

4) The proposed framework achieved accurate and high-throughput radicle phenotyping under CPU-only deployment conditions, demonstrating its practical potential for low-cost agricultural phenotyping applications.

MATERIALS AND METHODS

Data Acquisition and Dataset Construction

High-Throughput Image Acquisition System

To satisfy the requirements for high-quality and large-scale image acquisition in radicle phenotyping, a high-throughput imaging system for germinated seeds was designed and developed in this study, as shown in Fig. 1. The system consisted of three main modules: image acquisition, image processing, and data management.

Fig. 1 - High-throughput image acquisition system for germinated seeds

For image acquisition, the system consisted of an industrial camera produced by Jierui Weitong Co., Ltd., China, an aluminum-alloy frame, and a standardized Petri dish holder. Images were acquired at a resolution of 1600 × 1200 pixels. During image acquisition, the vertical distance between the camera lens and the Petri dish plane was fixed at 42 cm to ensure consistent imaging conditions. The holder accommodated up to 12 Petri dishes with a diameter of 9 cm in a single acquisition, allowing batch image acquisition. A reference ruler was placed in the imaging plane for scale calibration, and the calibrated scale factor was approximately 6 pixels/mm. This scale factor was used to convert the estimated radicle length from pixel units to physical length.

For image processing, the system provided basic preprocessing functions. Original images containing multiple Petri dishes were automatically divided into individual dish images. In addition, image parameters such as brightness, sharpness, and resolution could be adjusted to improve image consistency and reduce quality differences among samples. These preprocessing procedures provided standardized data for subsequent seed detection, keypoint localization, and radicle length estimation.

For data management, the system supported centralized storage and standardized organization of acquired images and related experimental data. This facilitated dataset construction, sample retrieval, and subsequent model training and evaluation.

The developed imaging system provided a standardized and efficient platform for high-throughput radicle phenotyping of germinated cucumber seeds.

High-Throughput Image Acquisition

The cucumber seeds used in this study were from the cultivar Zhongnong No. 6 and were provided by the State Key Laboratory of Crop Biology at Shandong Agricultural University. Before the germination experiment, healthy, well-filled, and morphologically uniform seeds were manually selected to reduce the influence of seed quality variation on radicle phenotyping. The selected seeds were placed in standard Petri dishes with a diameter of 9 cm and incubated in a constant-temperature incubator at 25 °C under dark conditions for 48 h. After germination, seed images were acquired using the custom-built high-throughput image acquisition system shown in Fig. 1. Each original image contained 12 Petri dishes, as illustrated in Fig. 2, and the average acquisition time for one original image was approximately 0.35 s. A total of 220 original images were collected, including 2,640 Petri dishes and 34,793 germinated cucumber seeds. These images were used for subsequent seed detection, radicle keypoint annotation, model training, and radicle length estimation.

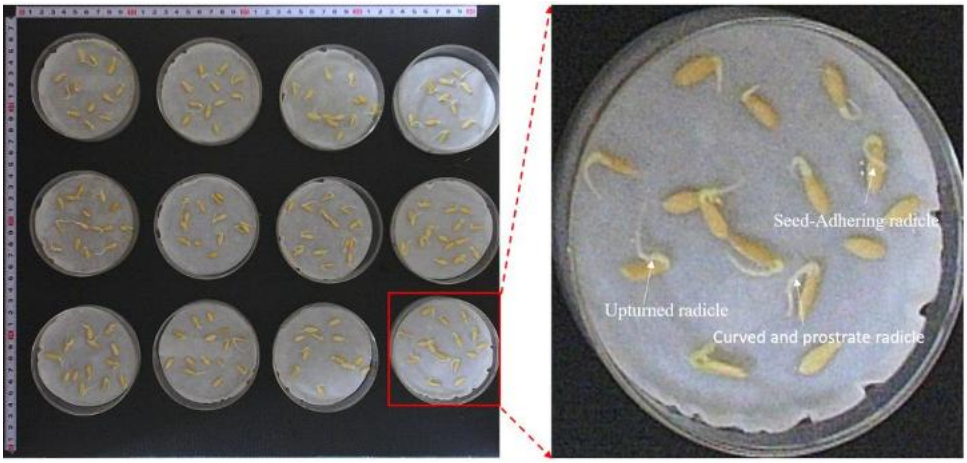

Fig. 2 - Images of germinated cucumber seeds

Dataset Construction

After image acquisition, the 220 original images were divided into two datasets: CucumberSeeds-1 and CucumberSeeds-2. CucumberSeeds-1 contained 100 original images with 15,653 seeds and was used for model training, validation and testing. The dataset was divided into training, validation and test sets at a ratio of 8:1:1. Since each original image contained 12 Petri dishes and a large number of seed instances, an automatic cropping procedure was used to convert the original multi-dish images into single-dish images. This operation increased the effective number of samples and provided clearer local image information for fine-grained radicle feature learning. After cropping, the dataset included 960 training images, 120 validation images and 120 test images. CucumberSeeds-2 contained 120 original images with 19,140 seeds and was used to evaluate the high-throughput phenotyping performance of the proposed method.

The LabelMe annotation tool was used to construct the radicle keypoint dataset. Each seed was annotated with a bounding box and four radicle keypoints, namely the radicle base, pre-bending point, post-bending point and root tip. As shown in Fig. 3, the four-keypoint annotation scheme was determined through preliminary experiments. When fewer than four keypoints were used, the curved morphology of the radicle could not be sufficiently represented, resulting in larger length estimation errors. When more than four keypoints were used, annotation complexity and computational cost increased, but the improvement in estimation accuracy was limited. Therefore, the four-keypoint strategy was adopted to balance length estimation accuracy, annotation efficiency and computational efficiency.

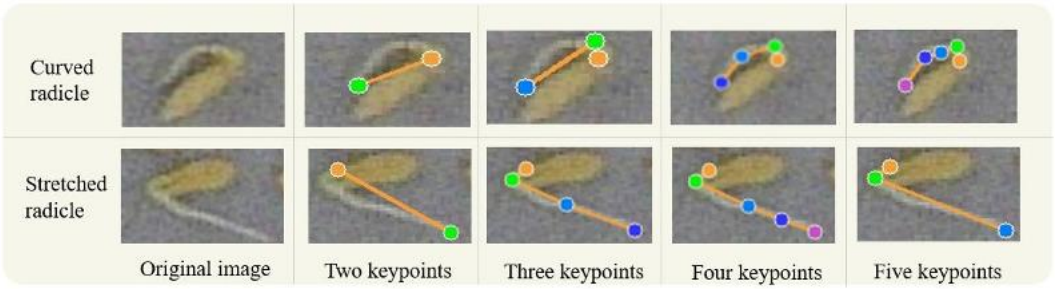

Fig. 3 - Keypoint annotation strategy

Automatic Detection of Individual Cucumber Seeds

To accurately localize individual cucumber seeds in densely distributed Petri dish images, an object detection framework was used as the first step of the proposed method. Germinated cucumber seeds are small and densely distributed, and overlap or partial occlusion may occur among adjacent seeds. Therefore, representative models from different object detection paradigms were selected for comparison, including one-stage detectors, SSD, YOLOv8-p2s, YOLOv8s and YOLO11s; the two-stage detector Faster R-CNN; and the Transformer-based detector DETR.

Each Petri dish image was input into the detection model to obtain the bounding box coordinates and confidence score of each seed instance. The detection results were then used to crop or constrain valid single-seed regions for subsequent radicle keypoint localization. By comparing the detection performance of different models in dense small-object scenarios, the model with the best overall performance was selected as the seed detection module. This step provided accurate spatial priors for radicle keypoint detection and reduced the interference caused by background regions, seed overlap and dense distribution.

Radicle Keypoint Detection Model for Cucumber Seeds

To accurately localize radicle keypoints of individual cucumber seeds, this study proposed a top-down keypoint detection network named GermHRNet. GermHRNet was developed based on HRNet and used HRNet-W32 as the backbone. By maintaining parallel multi-resolution branches throughout the network, the model preserved high-resolution feature representations during feature extraction, which is important for detecting small and slender radicle structures. The overall architecture of GermHRNet is shown in Fig. 4.

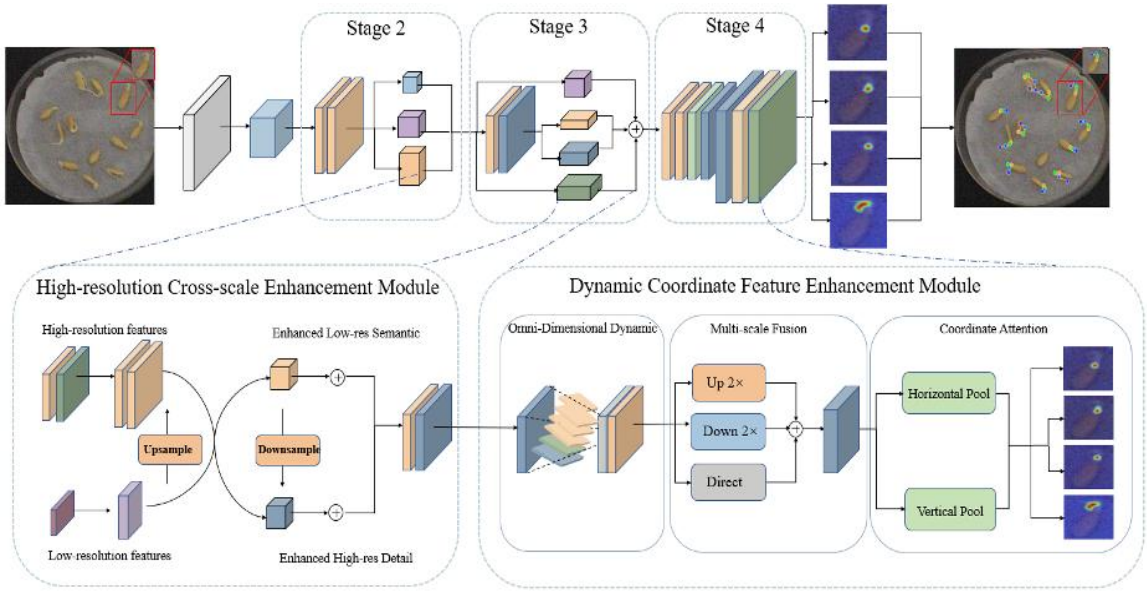

Fig. 4 - Architecture of GermHRNet

To reduce the loss of fine structural information in deeper layers, a High-resolution Cross-scale Enhancement Module (HCEM) was introduced before the multi-scale fusion stage in Stage 3. HCEM maintained the parallel multi-resolution structure of HRNet and established bidirectional cross-scale information pathways. This allowed high-resolution detail features and low-resolution semantic features to interact before fusion, thereby improving the representation of continuous radicle structures and reducing missed keypoint detections.

To further improve localization accuracy, a Dynamic Coordinate Feature Enhancement Module (DCFE) was incorporated into Stage 4. DCFE combined omni-dimensional dynamic convolution blocks, multi-scale feature fusion and coordinate attention. The dynamic convolution blocks adaptively enhanced feature representation according to radicle morphology, while the coordinate attention mechanism introduced directional positional information to guide the network toward key regions such as root tips and bending points. With these designs, the proposed network improved the stability and accuracy of keypoint localization for curved radicles and reduced localization errors caused by complex radicle poses.

High-Resolution Cross-Scale Enhancement Module (HCEM)

Built upon HRNet, a High-Resolution Cross-Scale Enhancement Module (HCEM) is introduced prior to the multi-scale fusion stage (Stage 3). The architecture of HCEM is shown in Fig. 5.

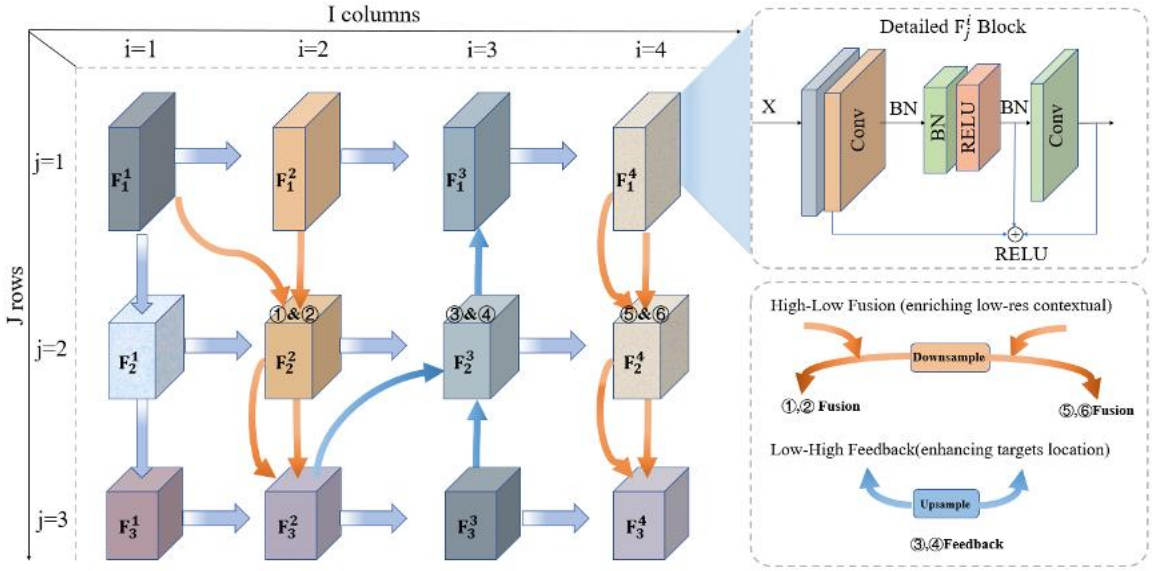

Fig. 5 - Architecture of the High-Resolution Cross-scale Enhancement Module

Considering that the slender and continuous radicle structure depends heavily on spatial resolution and fine-grained details, repeated downsampling leads to reduced spatial resolution and loss of fine-grained information *(Ni et al., 2025)*, thereby affecting the localization of critical radicle regions. Within a parallel multi-resolution framework, the module is organized as a grid-structured network composed of basic residual blocks arranged in i columns and j rows. For the output node F_i^j at the i-th column and j-th row, the computation is defined as follows.

$$F_i^j = X + ReLU\left(BN\left(Conv_2\left(ReLU(BN(Conv_1(X)))\right)\right)\right) \quad (1)$$

where X denotes the input feature map, $Conv_1$ and $Conv_2$ represent two consecutive convolutional layers, BN denotes batch normalization, and $ReLU$ represents the activation function. This structure employs two consecutive convolutional layers with a residual connection, enabling the extraction of discriminative local features while alleviating the vanishing-gradient problem and preserving spatial information.

To enhance feature interaction across different resolution branches, HCEM constructs a bidirectional cross-scale information flow. At even-column nodes, such as nodes ①, ②, ⑤ and ⑥, high-resolution features are downsampled using convolutional operators with a stride of 2 and injected into lower-resolution branches. This process introduces fine-grained spatial cues and alleviates localization ambiguity in low-resolution features caused by enlarged receptive fields. At odd-column nodes, such as nodes ③ and ④, global contextual information from low-resolution branches is upsampled using nearest-neighbor interpolation and propagated to high-resolution branches. This process provides global structural guidance, enabling the network to infer keypoint locations more accurately under radicle bending conditions.

Therefore, HCEM improves the complementarity between high-resolution spatial details and low-resolution semantic context, thereby enhancing the localization accuracy of slender and curved radicles.

Dynamic Coordinate Feature Enhancement Module (DCFE)

Based on HRNet, a Dynamic Coordinate Feature Enhancement Module (DCFE) was introduced in Stage 4. This module was designed to reduce keypoint displacement caused by morphological variations of radicles through joint feature enhancement across spatial, channel and scale dimensions. DCFE consists of three components: an Omni-dimensional Dynamic Block (OD Block), a multi-scale feature fusion module and a Coordinate Attention (CA) module. The overall structure is illustrated in Fig. 6.

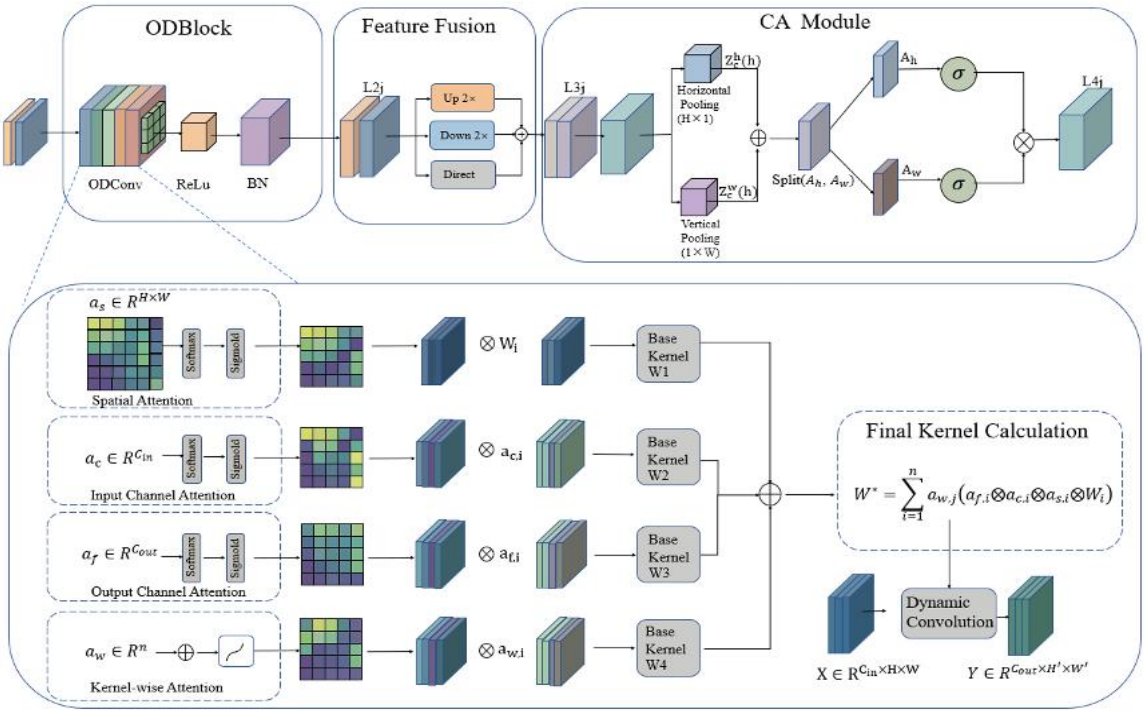

Fig. 6 - Architecture of the Dynamic Coordinate Feature Enhancement Module

The OD Block generates adaptively modulated dynamic convolution kernels based on the contextual information of the input feature map X, enabling the network to adjust feature responses according to radicle morphology. The output Y can be expressed as:

$$\mathrm{Y} = W^*(X) * X \tag{2}$$

where $W^*(X)$ denotes the dynamically generated convolution kernel conditioned on the input feature map X, and $*$ represents the convolution operation. This process performs weighted aggregation of a base kernel pool across four attention dimensions: spatial attention $\mathrm{a_s} \in \mathrm{R^{H\times W}}$ captures pixel-level features of local radicle morphology; input channel attention $\mathrm{a_c} \in \mathrm{R^{C_{in}}}$ and output channel attention $\mathrm{a_f} \in \mathrm{R^{C_{out}}}$ dynamically select the most relevant feature channels for keypoint localization; and kernel−wise attention $\mathrm{a_w} \in \mathrm{R^n}$ enables nonlinear combinations of base kernels. The resulting dynamic convolution kernel is calculated as follows:

$$W^* = \sum_{i=1}^{n} a_{w,i}\left(a_{f,i} \otimes a_{c,i} \otimes a_{s,i} \otimes W_i\right) \tag{3}$$

where W_i denotes the $i-\mathrm{th}$ base convolution kernel, n is the number of base kernels, and ⊗ multi-scale feature fusion module aligns features at different scales by applying upsampling and denotes element-wise multiplication with broadcasting when necessary. This omni-dimensional parameter modulation enables the network to adaptively adjust the receptive field and response intensity of convolutional operators according to different degrees of radicle curvature.

The multi-scale feature fusion module aligns features at different scales by applying upsampling and downsampling operations to the input feature $L_{2,j}$ followed by feature aggregation. This process combines fine-grained spatial details and semantic information, providing a more discriminative feature representation for radicle keypoint localization.

To further enhance spatial positional encoding, a coordinate attention mechanism was incorporated. First, pooling kernels with sizes of (H,1) and (1,W) were used to aggregate spatial information along the horizontal and vertical directions, respectively:

$$Z_c^h(h) = \frac{1}{W}\sum_{0\le i<W} X_c(h,i), Z_c^w(w) = \frac{1}{H}\sum_{0\le j<H} X_c(j,w) \quad (4)$$

where $Z_c^h(h)$ and $Z_c^w(w)$ denote the horizontal output at height h and the vertical output at width w for the $c-$th channel, respectively. The terms $\frac{1}{W}$ and $\frac{1}{H}$ are normalization factors representing averaging pooling. Specifically, $\sum X_c(h,i)$ represents accumulation along the width direction, compressing each row into a single value while preserving positional accuracy along the height dimension. Similarly, $\sum X_c(j,w)$ represents accumulation along the height direction, compressing each column into a single value while preserving positional information along the width dimension.

The aggregated feature maps are then concatenated, convolved, and split to generate two independent directional weights A_h and A_w. After Sigmoid activation, these weights are applied as attention masks to the feature map:

$$L_{4j} = X \otimes \sigma(A_h) \otimes \sigma(A_w) \quad (5)$$

where σ denotes the sigmoid activation function.

This module enhances the network's ability to capture keypoints in curved radicle regions and effectively reduces localization errors. By integrating dynamic convolution, multi-scale feature fusion and coordinate attention, DCFE strengthens spatial consistency in critical regions and improves the accuracy and robustness of keypoint localization.

Radicle Length Estimation and Validation Method

In the radicle length estimation stage, the two-dimensional pixel coordinates of the detected keypoints, including the radicle base, bending points and root tip, were first obtained from the keypoint detection results. These keypoints were then connected sequentially along the radicle growth direction to form a central path. The line segments between adjacent keypoints were regarded as piecewise linear approximations of the radicle structure *(Bagchi et al., 2025)*. The Euclidean distance of each segment was calculated to obtain its pixel length, and the total radicle length in pixels was estimated by cumulative summation. The calculation can be expressed as follows:

$$L_{pixel} = \sum_{k=1}^{m-1} \sqrt{(x_{k+1}-x_k)^2 + (y_{k+1}-y_k)^2}$$

where L_{pixel} is the radicle length in pixels, m is the number of detected keypoints, and (x_k, y_k) denotes the pixel coordinate of the $k-$th keypoint.

A pixel-to-millimeter scale factor was calibrated using the reference ruler in the image acquisition system. The radicle length in pixels was then converted into the actual physical length as follows:

$$L_{mm} = L_{pixel} \times S$$

where L_{mm} denotes the estimated radicle length in millimeters, and S represents the calibrated pixel-to-millimeter scale factor. Through this procedure, automatic radicle length estimation was achieved based on the predicted keypoint coordinates.

To validate the effectiveness of the proposed keypoint-based estimation method, the estimated radicle lengths were compared with manually measured ground-truth values. The manual measurements were used as reference values for accuracy evaluation. In addition, to evaluate the efficiency of automated radicle phenotyping, the total inference time of the complete pipeline, including object detection and keypoint detection, was recorded and analyzed. This evaluation was used to assess the high-throughput capability of the proposed method.

Experimental Parameter Settings

During the object detection training stage, the AdamW optimizer was used with an initial learning rate of 0.001 and a weight decay coefficient of 0.0005. The batch size was set to 16, and the model was trained for 300 epochs. Pretrained weights were used for network initialization to accelerate convergence and improve the initial training stability.

Table 1

Experimental environment configuration

Environment	Details
Programming Language	Python 3.10.15
Operating System	Windows 11

Environment	Details
Deep Learning Framework	PyTorch 2.2.2
CUDA Version	11.8
GPU	NVIDIA RTX 4090
CPU	Intel Core i9-14900KF

For keypoint detection training, the Adam optimizer was adopted with an initial learning rate of 0.0001. The batch size was also set to 16, and the model was trained for 300 epochs. Automatic mixed precision (AMP) training was implemented using NVIDIA Apex to accelerate training and reduce GPU memory consumption. The experimental environment is summarized in Table 1.

Evaluation Metrics

In the comparative experiments for seed instance detection, precision (P), recall (R) and mean average precision (mAP) were used as evaluation metrics *(Rana et al., 2026)*. Precision and recall were used to evaluate the correctness and completeness of seed detection, respectively. The mAP was calculated by first computing average precision (AP) at intersection over union (IoU) thresholds ranging from 0.50 to 0.95 in increments of 0.05 and then averaging the AP values across all thresholds. This metric provides a comprehensive assessment of the localization accuracy and detection performance of the object detection models.

In the radicle keypoint detection experiments, average precision (AP), average recall (AR) and percentage of correct keypoints (PCK) were adopted to evaluate model performance *(Duan et al., 2025)*. AP and AR were calculated according to the COCO (Common Objects in Context) keypoint evaluation protocol, with object keypoint similarity (OKS) used to quantify the similarity between predicted and ground-truth keypoints. Both metrics were averaged over OKS thresholds ranging from 0.50 to 0.95 in increments of 0.05 to characterize the overall accuracy and recall of keypoint detection. PCK was calculated using normalized Euclidean distance, with the longer side of the ground-truth bounding box of each target instance used as the normalization reference. The distance threshold coefficient α was set to 0.05 to evaluate keypoint localization accuracy.

In the radicle length estimation and validation experiments, mean absolute error (MAE), root mean square error (RMSE), coefficient of determination (R^2), normalized mean absolute error (nMAE), and normalized root mean square error (nRMSE) were used to quantitatively evaluate estimation accuracy *(Tan et al., 2025)*. MAE and RMSE were used to quantify the absolute errors between the estimated and ground-truth values, whereas R^2 was used to evaluate the goodness of fit between them. The nMAE and nRMSE were calculated by dividing MAE and RMSE, respectively, by the overall mean of the ground-truth radicle lengths and expressing the resulting ratios as percentages. These normalized metrics quantify the estimation errors relative to the actual radicle length.

In the high-throughput validation experiments, throughput (T) was used to evaluate the efficiency of radicle length acquisition *(Poorter et al., 2023)*. Throughput was defined as the number of seeds processed per hour.

RESULTS AND ANALYSIS

Comparative Experiment on Seed Instance Detection

To select the most suitable detector for cucumber seed localization, six object detection models, including YOLOv8-p2s, YOLOv8s, YOLO11s, Faster R-CNN, DETR and SSD, were compared. The quantitative results are shown in Table 2.

Table 2

Comparison of different object detection models

Model	P%	R%	mAP%
YOLOv8-p2s	98.2	97.9	98.3
YOLOv8s	97.4	97.4	97.8
YOLOv11s	98.0	97.7	97.7
Faster R-CNN	94.9	95.6	94.0
DETR	93.2	97.3	95.4
SSD	95.0	95.3	96.1

YOLOv8-p2s achieved the best overall performance, with precision, recall and mAP values of 98.2%, 97.9% and 98.3%, respectively. Compared with YOLOv8s and YOLO11s, the mAP of YOLOv8-p2s increased by 0.5 and 0.6 percentage points, respectively. It also outperformed SSD, DETR and Faster R-CNN by 2.2, 2.9 and 4.3 percentage points in mAP, respectively. These results indicate that YOLOv8-p2s has better localization accuracy and robustness for densely distributed cucumber seeds.

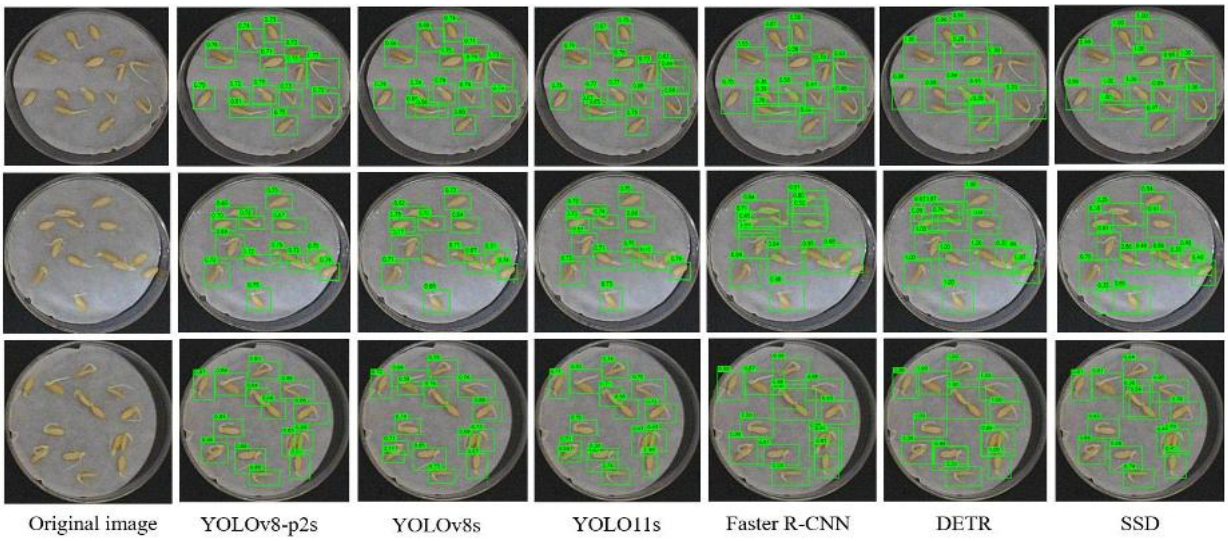

Fig. 7 - Visual comparison of seed instance detection results produced by different object detection models.

Representative detection results are shown in Fig. 7. Under dense small-object conditions, the compared models showed different types of errors, including missed detections, redundant detections and inaccurate localization. YOLOv8s and YOLO11s exhibited missed detections in densely distributed regions, which may be related to the loss of fine-grained features during downsampling. Faster R-CNN tended to generate redundant bounding boxes in crowded regions because of excessive proposal generation. DETR showed limited local detail perception for small targets, resulting in merged detections in clustered regions. SSD produced less accurate bounding boxes, mainly due to insufficient semantic representation in shallow feature maps. In comparison, YOLOv8-p2s produced more compact and accurate bounding boxes by introducing the high-resolution P2 feature layer, which improved the representation of small seed targets and reduced duplicate or missed detections.

Based on the quantitative results and visual comparisons, YOLOv8-p2s was selected as the seed detection model for subsequent radicle keypoint detection and length estimation.

Ablation Study of GermHRNet

To quantitatively evaluate the contributions of the proposed modules, ablation experiments were conducted on the High-resolution Cross-scale Enhancement Module (HCEM) and the Dynamic Coordinate Feature Enhancement Module (DCFE). The performance of each model configuration was evaluated using AP, AR and PCK, as summarized in Table 3.

Table 3

Comparison of ablation experiments with different improvements

Experiment No.	Improvement strategy		AP(%)	AR(%)	PCK(%)
	HCEM	DCFE			
1	×	×	87.5	89.8	86.7
2	√	×	89.6	91.2	87.7
3	×	√	88.7	90.4	87.9
4	√	√	90.6	92.2	88.2

Experiment 1 used the original HRNet as the baseline model, achieving AP, AR and PCK values of 87.5%, 89.8% and 86.7%, respectively. After introducing HCEM in Experiment 2, the AP, AR and PCK increased to 89.6%, 91.2% and 87.7%, respectively, indicating that HCEM enhanced cross-scale feature interaction and improved the structural representation of slender radicles.

In Experiment 3, only DCFE was added to the baseline model, achieving AP, AR and PCK values of 88.7%, 90.4% and 87.9%, respectively. The relatively higher PCK suggests that DCFE improved spatial localization accuracy by enhancing dynamic feature adaptation and coordinate-aware representation, especially for curved regions and root tips.

When both HCEM and DCFE were integrated in Experiment 4, GermHRNet achieved the best performance, with AP, AR and PCK values of 90.6%, 92.2% and 88.2%, respectively. These results show that HCEM and DCFE provide complementary improvements: HCEM strengthens multi-scale structural representation, while DCFE enhances keypoint localization accuracy. Their combination effectively improves the overall accuracy and robustness of radicle keypoint detection.

Comparative Experiment of GermHRNet

To comprehensively evaluate the effectiveness of the proposed GermHRNet, it was compared with five representative keypoint detection methods, namely HRNet, RTMPose, UDP, ViTPose and SimplePose. AP, AR and PCK were used as evaluation metrics, and the quantitative results are presented in Table 4.

Table 4

Comparison of different radicle keypoint detection models

Model	AP(%)	AR(%)	PCK(%)
GermHRNet	90.6	92.2	88.2
HRNet	87.5	89.8	86.7
RTMPose	88.1	90.2	85.0
ViTPose	87.4	90.0	85.4
UDP	86.7	89.3	86.1
SimplePose	86.0	89.2	86.4

As shown in Table 4, GermHRNet achieved the best performance across all evaluation metrics. Compared with the baseline HRNet, GermHRNet improved AP, AR and PCK by 3.1, 2.4 and 1.5 percentage points, respectively. Compared with other representative methods, GermHRNet also consistently outperformed RTMPose, ViTPose, UDP and SimplePose. Specifically, compared with RTMPose, GermHRNet improved AP, AR and PCK by 2.5, 2.0 and 3.2 percentage points, respectively. Compared with ViTPose, the corresponding improvements were 3.2, 2.2 and 2.8 percentage points. Compared with UDP, the improvements were 3.9, 2.9 and 2.1 percentage points. Compared with SimplePose, the improvements reached 4.6, 3.0 and 1.8 percentage points, respectively.

These consistent improvements across multiple metrics indicate that the proposed model has better keypoint detection performance for germinated cucumber seed radicles. In particular, the improvement in PCK suggests enhanced spatial localization accuracy, which is essential for accurately capturing complex radicle structures. Therefore, GermHRNet provided more accurate and stable keypoint localization, especially under challenging conditions involving curved radicles, blurred root tips and densely distributed seeds.

To further evaluate the qualitative performance of different methods, representative visualization results are shown in Fig. 8. Existing methods exhibited several types of errors, including keypoint displacement in curved regions, inaccurate localization of root tips, and redundant or missing detections in densely distributed seed regions. CNN-based methods, such as HRNet and SimplePose, showed localization deviations in some cases, which may be related to the loss of fine spatial details caused by repeated downsampling. ViTPose demonstrated strong global modeling capability, but it still showed limitations in capturing fine-grained local structures of slender radicles. RTMPose and UDP improved coordinate regression or decoding strategies; however, their feature representation ability was still insufficient for accurately modeling complex radicle morphology. In contrast, GermHRNet alleviated these problems by integrating cross-scale feature enhancement and dynamic coordinate-aware representation. The proposed HCEM improved structural continuity through bidirectional multi-scale feature interaction, while DCFE enhanced spatial localization accuracy through dynamic convolution and coordinate attention. As a result, GermHRNet produced keypoint predictions that were more consistent with the actual radicle morphology, particularly in challenging regions such as bending points and root tips.

Overall, both quantitative and qualitative results demonstrate that GermHRNet improves the accuracy and robustness of radicle keypoint localization, validating the effectiveness of the proposed architecture.

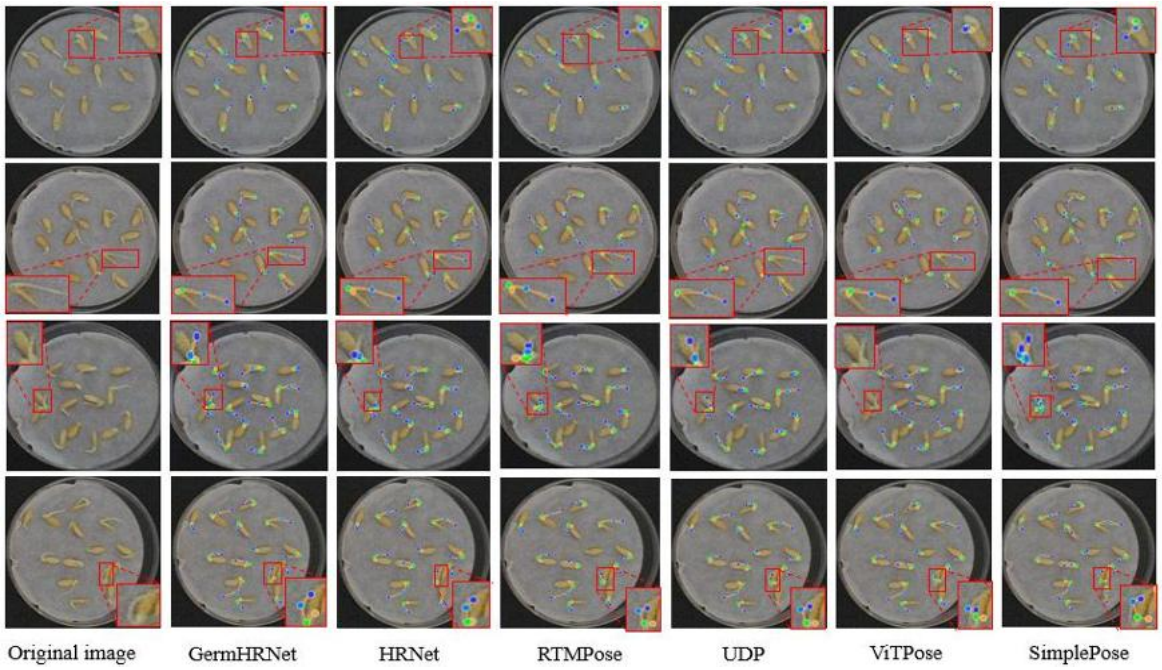

Fig. 8 - Keypoint detection results of germinated cucumber seeds using different models

Radicle Length Validation Experiment

To evaluate the accuracy of GermHRNet for automatic radicle length estimation, a quantitative validation experiment was conducted on all germinated seeds contained in the 120 test-set images. The ground-truth radicle lengths were obtained as follows. First, two experimenters manually measured the radicles corresponding to all seeds in the 120 images using a vernier caliper with a precision of 0.1 mm. Curved radicles were carefully straightened before measurement to obtain their full lengths. Subsequently, a third experimenter reviewed and confirmed all measurement results, and the final confirmed values were used as the ground-truth radicle lengths.

The distribution of the ground-truth radicle lengths in the test set was then statistically analyzed. The mean radicle length was 8.41 mm, with a standard deviation of 4.06 mm. The median was 7.92 mm, and the values ranged from 1.50 to 20.65 mm. This distribution included cucumber seed samples at different degrees of germination, indicating that the test set adequately represented variations in radicle growth during the germination process.

To comprehensively evaluate the overall estimation performance, the error metrics were subsequently calculated. The results showed that the MAE, RMSE, and R^2 were 0.51 mm, 0.61 mm, and 0.98, respectively. As shown in Fig. 9, the data points in the regression plot were closely distributed around the reference line (y=x), indicating strong agreement between the estimated and ground-truth values and a relatively low overall estimation error.

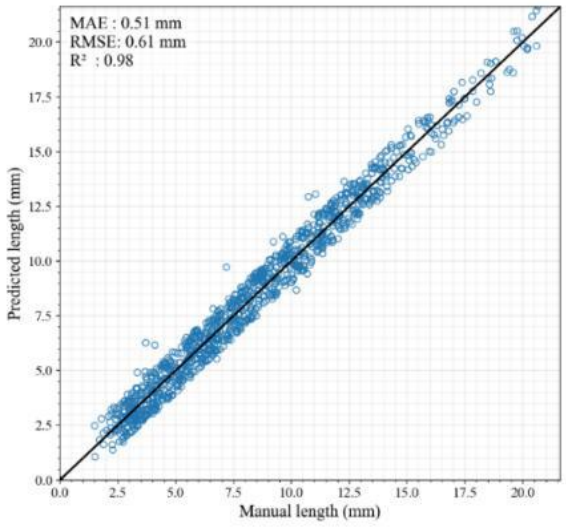

Fig. 9 - Regression analysis of predicted versus ground-truth radicle lengths

To further quantify the relative magnitude of the estimation errors, normalized error metrics were calculated using the mean ground-truth radicle length of 8.41 mm as the normalization reference. The nMAE and nRMSE were 6.06% and 7.25%, respectively. These results indicate that the estimation errors accounted for only a small proportion of the mean ground-truth radicle length, further demonstrating the high accuracy of GermHRNet for automatic radicle length estimation.

Throughput Validation Experiment

To validate the high-throughput processing capability and computational stability of the proposed radicle length estimation method, 120 original images from the CucumberSeeds-2 dataset were used for experimentation. These images contained a total of 19,140 germinated cucumber seeds. The dataset was randomly divided into 10 independent experimental groups, with each group containing 12 original images. All experiments were conducted on a CPU-only platform without GPU acceleration. The hardware configuration is shown in Table 5.

Table 5

Hardware configuration for CPU-only throughput validation

Environment	Details
Programming Language	Python 3.13.2
Operating System	Windows 64-bit (x64)
Memory (RAM)	16 GB
Processor (CPU)	AMD Ryzen 7 7435H (3.10 GHz)

The runtime statistics for the 10 experimental groups are presented in Table 6.

Table 6

Throughput evaluation results of the proposed method under CPU-only conditions

Group No	Seeds Per Original Image	Prep. [s]	Det. [s]	Kpt. [s]	Len [s]	Total [s]	T [seeds/s]
1	175	0.20	0.88	17.31	0.12	18.51	9.45
2	166	0.23	0.86	16.52	0.11	17.72	9.37
3	167	0.23	0.86	16.55	0.11	17.75	9.41
4	160	0.24	0.83	16.01	0.11	17.19	9.31
5	165	0.22	0.79	16.35	0.11	17.47	9.44
6	162	0.21	0.84	16.16	0.11	17.32	9.35
7	150	0.22	0.81	14.93	0.10	16.06	9.34
8	150	0.22	0.85	14.84	0.10	16.01	9.37
9	149	0.20	0.81	14.80	0.10	15.91	9.37
10	151	0.24	0.82	14.97	0.10	16.13	9.36

Each group contained 12 original images, and the reported time values were averaged per original image within each group. Abbreviations: Prep. = image preprocessing time; Det. = object detection time; Kpt. = keypoint detection time; Len. = radicle length estimation time; Total = total processing time per original image; T = throughput, expressed as seeds per second.

As shown in Table 6, the average processing time per original image ranged from 15.91 s to 18.51 s, with an overall mean of approximately 17.01 s. The relatively small variation in processing time indicates good computational stability of the entire pipeline under different seed densities. Among all processing steps, keypoint detection accounted for the largest proportion of the total processing time, whereas image preprocessing, object detection and length estimation required relatively short computation times.

Based on the average throughput across the 10 experimental groups, the proposed system achieved a processing capacity of approximately 3.38×10^4 seeds/h on a single machine. Compared with manual measurement, which processes approximately 120 seeds/h, the proposed method substantially improved radicle length acquisition efficiency. These results demonstrate that the proposed method has strong high-throughput processing capability and is suitable for large-scale cucumber seed phenotyping and microbial strain screening.

CONCLUSIONS

To address the limitations of low efficiency, subjective measurement errors and insufficient throughput in germination tests for plant growth-promoting rhizobacteria (PGPR) screening, this study proposed an automatic radicle length estimation method for germinated cucumber seeds based on GermHRNet. The proposed framework achieved automated analysis from seed localization and radicle keypoint detection to radicle length quantification. The main conclusions are as follows.

1) A GermHRNet-based keypoint detection network for germinated cucumber seed radicles was developed. To improve feature representation for slender and curved radicle structures, cross-scale feature enhancement and coordinate-aware dynamic feature modeling strategies were incorporated into the HRNet backbone. The proposed model achieved AP, AR and PCK values of 90.6%, 92.2% and 88.2%, respectively, outperforming the compared mainstream keypoint detection models. These results demonstrate that the proposed framework improved the accuracy and robustness of radicle keypoint localization under complex morphological conditions.

2) A polyline-based radicle length estimation strategy was proposed for curved radicle estimation. Based on the detected keypoint coordinates, radicle length was estimated through multi-segment polyline pixel accumulation. The proposed method achieved MAE, RMSE, nMAE, nRMSE, and R^2 values of 0.51 mm, 0.61 mm, 6.06%, 7.25%, and 0.98, respectively, showing strong agreement with manual measurements. These results indicate that the proposed method can satisfy the accuracy requirements of radicle phenotyping and seed vigor evaluation.

3) The proposed method demonstrated strong high-throughput processing capability. Throughput experiments showed that the proposed framework achieved a processing capacity of approximately 3.38×10^4 seeds/h on a CPU-only platform. Compared with manual measurement (~120 seeds/h), the proposed method improved radicle length acquisition efficiency by approximately 282-fold. These results demonstrate the practical potential of the proposed framework for large-scale cucumber seed phenotyping and PGPR screening applications.

Although GermHRNet achieved favorable performance in radicle keypoint detection and automatic length estimation for germinated cucumber seeds, several limitations remain. First, the experiments were limited to seeds from a single cucumber cultivar and a specific germination stage. Further investigation is therefore required to determine how variations in radicle morphology across different cultivars and germination stages affect keypoint detection and length estimation performance. Second, all experimental data were acquired using a single imaging system under controlled laboratory conditions. Consequently, the generalizability of the model across different imaging devices and illumination conditions has not yet been fully validated.

To address these limitations, future studies will conduct external validation using different cucumber cultivars, germination stages, and imaging conditions to further assess the robustness and applicability of the model. In addition, lightweight deployment and real-time integration of the proposed framework with image acquisition systems will be further investigated to improve computational efficiency and system stability, thereby providing a more efficient and reliable solution for high-throughput and standardized seed phenotyping.

ACKNOWLEDGEMENT

This research was funded by the Potato Innovation Program for the Chief Expert of Shandong Province (Grant No. SDAIT-16-01).

Keywords: *maize, inclined spoon-disc, seed-metering, parameter optimization*

ABSTRACT

To address the problems of multiple seeding, missed seeding, and insufficient operational stability commonly encountered during the operation of precision maize seed-metering devices, an inclined spoon-disc seed-metering device was designed in this study. The seed-metering process of maize kernels within the device was analysed, and the key components, including spoon wheel, partition plate, and seed-metering wheel, were structurally designed. Bench tests were conducted using a JPS-16 seed-metering device performance testing system. First, single-factor tests were performed to investigate the effects of metering-wheel rotational speed, overall inclination angle, and seed-layer height on the qualified index, multiple index, and miss index. Subsequently, a three-factor, five-level quadratic regression orthogonal rotational combination experiment was conducted using the metering-wheel rotational speed, overall inclination angle, and seed-layer height as the experimental factors. Optimization was performed with the objective of maximizing the qualified index. The optimal parameter combination was determined to be a seed-metering wheel rotational speed of 25 r·min^{-1}, an overall inclination angle of 27°, and a seed-layer height of 71.9 mm. Under these conditions, the model-predicted qualified index was 96.5%. In the verification tests, the average qualified index was 95.0%, with a relative error of 1.5% compared with the predicted value. The results can provide a reference for the structural design and operating-parameter optimization of inclined spoon-disc precision maize seed-metering devices.

摘要

针对玉米精量排种器在作业过程中易出现重播、漏播及排种稳定性不足的问题，本文设计了一种倾斜勺盘式排种器。分析玉米籽粒在排种器内的工作过程，并对排种勺轮、隔板及导种轮等关键部件进行了结构设计。在 JPS-16 排种器性能测试系统上开展台架试验。首先通过单因素试验分析排种轮转速、整体倾斜角和种层高度对合格率、重播率和漏播率的影响；在此基础上，以排种轮转速、整体倾斜角和种层高度为试验因素，开展三因素五水平二次回归正交旋转组合试验。以合格率最大为目标进行优化，得到较优参数组合为排种轮转速 25 r·min^{-1}、整体倾斜角 27°、种层高度 71.9 mm，模型预测合格率为 96.5%。验证试验中合格率平均值为 95.0%，与预测值的相对误差为 1.5%。研究结果可为倾斜勺盘式玉米精量排种器的结构设计和作业参数优化提供参考。

INTRODUCTION

Maize is one of the major grain crops in China and plays an important role in ensuring food security and maintaining stable agricultural production (*Chen et al., 2025*). With the continuous expansion of large-scale maize cultivation and the advancement of fully mechanized production, increasingly stringent requirements have been imposed on planting efficiency, consistency of plant spacing, and the quality of precision single-seed placement (*Baghooee et al., 2024*).

The quality of maize planting directly affects seedling emergence uniformity, crop population structure, and subsequent yield formation. As the core component of a precision planter, the seed-metering device largely determines planting performance. Therefore, improving the operational performance of the seed-metering device is of great significance for enhancing maize planting quality (*Ding et al., 2024*).

Currently, precision maize seed-metering devices can be broadly classified into mechanical and pneumatic types. Pneumatic seed-metering devices use negative- or positive-pressure airflow to perform seed pickup, singulation, and seed release (*Bakirov et al., 2025*). They offer high metering accuracy and good adaptability to high-speed operation and have therefore been widely used in large precision planters. However, these devices generally require a fan, an air chamber, and a pneumatic circuit, and they impose stringent requirements on system airtightness and pressure stability (*Gao et al., 2023*). Consequently, the overall machine structure is relatively complex, and the manufacturing and maintenance costs are comparatively high. Common mechanical seed-metering devices include finger-pickup, cell-wheel, pocket-wheel, and spoon-disc types. Among them, spoon-disc seed-metering devices use seed spoons to directly scoop individual kernels from the seed mass, offering a straightforward seed-pickup mechanism, a compact structure, and good adaptability (*Li et al., 2024*).

The seed-metering performance of a spoon-wheel seed-metering device is jointly affected by several factors, including the spoon geometry, rotational speed of the metering wheel, installation inclination angle of the seed-metering device, seed-layer height, and physical properties of the seeds. When the rotational speed of the metering wheel is too low, the seed spoons remain in contact with the seed mass for a relatively long period and may carry multiple kernels simultaneously, thereby increasing the probability of multiple seeding (*Cortez et al., 2020*). By contrast, when the rotational speed is excessively high, the residence time of the seed spoons in the filling zone is shortened, making it difficult for kernels to enter the spoon cavities in time and remain stably retained, which can readily result in missed seeding. The inclination angle of the seed-metering device changes the gravitational components acting on the kernels and the accumulation state of the seed mass in the filling zone, thereby affecting the seed-filling and singulation processes. Seed-layer height directly influences the number of kernels near the seed spoons and the pressure exerted by the seed mass. An excessively low seed layer may lead to insufficient seed filling, whereas an excessively high seed layer may cause multiple-kernel filling and increase the difficulty of seed singulation (*Lin et al., 2026*). Therefore, analysis of a single factor alone cannot accurately reflect the actual operating state of the seed-metering device, and the interactions among these factors require further investigation (*Sun et al., 2025*).

Previous studies have optimized the cell dimensions, seed-spoon geometry, rotational speed of the metering disc, and installation angle of mechanical seed-metering devices through theoretical analysis, discrete element simulation, and bench testing, and satisfactory seed-metering performance has been achieved (*Koller et al., 2016*). However, some studies have focused primarily on individual structural parameters of the metering wheel or seed-pickup elements, while relatively limited attention has been paid to the continuity of kernel transfer from the seed spoons to the seed-metering wheel, as well as the seed-retaining and seed-release processes. In addition, interactions and mutual constraints may exist among the rotational speed of the metering wheel, overall inclination angle, and seed-layer height (*Wang et al., 2026*). Consequently, the optimum level of an individual factor may not correspond to the optimal parameter combination under the combined effects of multiple factors (*Yang et al., 2025*). It is therefore necessary to consider the entire seed-metering process, analyse the key operating parameters and their interactions, and establish a regression model capable of describing the variation in seed-metering performance (*Zhao et al., 2026*).

Based on the above considerations, an inclined spoon-disc precision maize seed-metering device was designed in this study. The device uses a spoon-type metering wheel to perform seed scooping and singulation. A partition plate is employed to achieve the directional transfer of kernels from the spoon cavities to the seed-metering wheel, while the seed-metering wheel and housing jointly complete the seed-retaining and seed-release processes. First, the key components, including spoon wheel, partition plate, and seed-metering wheel, were structurally designed, and the movement of maize kernels within the seed-metering device was analysed. Subsequently, single-factor tests were conducted using Zhengdan 958 maize kernels to investigate the effects of seed-metering wheel rotational speed, overall inclination angle, and seed-layer height. Finally, a three-factor, five-level quadratic regression orthogonal rotatable combination design was employed to analyse the effects of the individual factors and their interactions on the qualified index. The operating parameters were then optimized and verified through bench tests. This study aims to provide a theoretical and experimental basis for the structural improvement and operating-parameter selection of inclined spoon-disc seed-metering devices.

MATERIALS AND METHODS

Structure and Operating Principle of the Seed-Metering Device

The inclined spoon-disc seed-metering device mainly consists of front and rear seed-metering housings, a seed-metering shaft, a spoon wheel, a partition plate, a seed-metering wheel, a brush, two end covers, and

bearings, as shown in Fig. 1. The front and rear seed-metering housings are assembled to form the enclosed working chamber and provide support and positioning for the internal components. The spoon wheel and seed-metering wheel are driven by the same power source through a mechanical transmission system. They rotate synchronously in the same counterclockwise direction at a transmission ratio of 1:1. A fixed phase relationship is maintained between the spoon cavities and the corresponding U-shaped grooves of the seed-metering wheel, ensuring accurate seed transfer at the designed angular position.

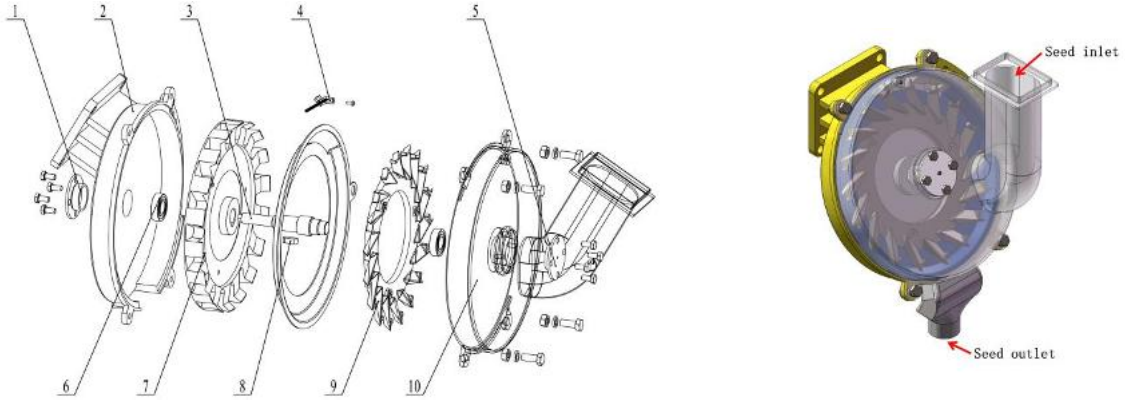

Fig. 1 - Structure of the inclined spoon-disc seed-metering device

1. Rear end cover; 2. Rear seed-metering housing; 3. Seed-metering shaft; 4. Brush; 5. Front end cover; 6. Deep-groove ball bearing; 7. seed-metering wheel; 8. Partition plate; 9. Spoon wheel; 10. Front seed-metering housing.

The movement of maize kernels within the seed-metering device consists of five successive stages: seed pickup, seed clearing, seed transfer, seed retention, and seed discharge, as shown in Fig. 2. During the seed-pickup stage, maize kernels enter the seed-filling zone at the bottom of the device and are captured by the spoon cavities. In the seed-clearing zone, excess kernels retained in unstable positions are removed under the combined effects of gravity, centrifugal force, and inter-kernel interactions, leaving one kernel in each spoon cavity. When the spoon reaches the seed-transfer zone, the retained kernel passes through the arc-shaped opening of the partition plate and enters the corresponding U-shaped groove of the seed-metering wheel.

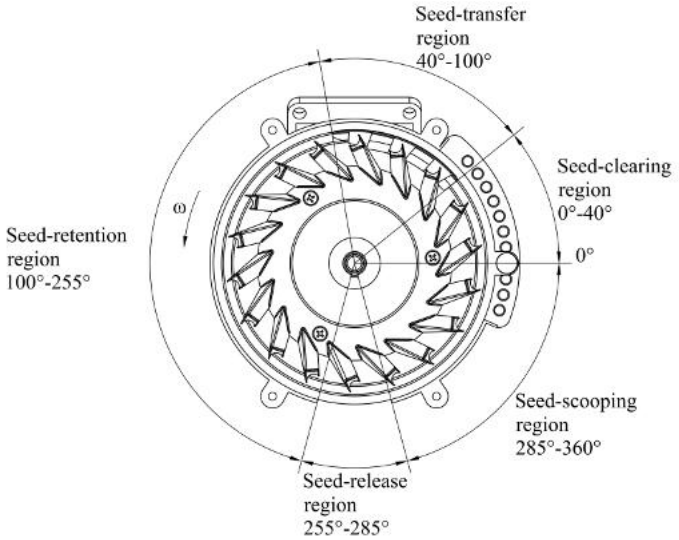

Fig. 2 - Operating process of the inclined spoon-disc seed-metering device

During the seed-retention stage, the kernel is constrained by the U-shaped groove and the seed-metering housing and is carried stably to the seed outlet. At the outlet, the structural constraint is removed, allowing the kernel to leave the groove under gravity and inertia and fall into the seed furrow. The proposed configuration reduces abnormal seed motion through the coordinated action of its components. The single-kernel spoon cavity and the seed-clearing process reduce multiple seed pickup.

The combined constraint of the U-shaped groove and the seed-metering housing prevents premature seed release. The dimensional matching among the spoon cavity, partition-plate opening, and U-shaped groove, together with an appropriate operating clearance, reduces kernel lodging and blockage. The arc-shaped transfer path and smooth structural transition reduce collision, squeezing, and seed damage.

Moreover, the fixed 1:1 transmission ratio and phase relationship between the spoon wheel and seed-metering wheel ensure that each spoon cavity aligns with the corresponding U-shaped groove at the designed transfer position, thereby preventing delayed seed transfer.

Design of spoon wheel

Because the device developed in this study is primarily intended for precision single-seed maize planting, the structural configuration, principal dimensions, and kinematic characteristics of spoon wheel must be appropriately designed and analysed. A schematic diagram of the spoon cavity in the spoon wheel is shown in Fig. 3.

Fig. 3. Schematic diagram of the spoon cavity in spoon wheel

Based on the operating principle of the seed-metering device, maize-kernel length was selected as the characteristic dimension for determining the spoon-cavity size. Kernel length was defined as the maximum dimension along the longitudinal axis of an individual maize kernel. To ensure that maize kernels can enter the spoon cavity smoothly, the cavity diameter should be slightly larger than the mean kernel length. Therefore, the dimensional relationship between the spoon cavity and the maize kernel was expressed as:

$$2R=L+\delta \quad (1)$$

where L is the mean length of the Zhengdan 958 maize kernels, mm; R is the radius of the cylindrical spoon cavity, mm; and δ is the diametral design allowance, mm.

In this study, the mean length of the Zhengdan 958 maize kernels was 12.0 mm. Considering variations in kernel dimensions, changes in kernel orientation during entry into the spoon cavity, and manufacturing errors of the spoon cavity, the reasonable range of the design allowance was determined to be 0.5–1.5 mm. To balance seed-filling reliability and single-seed pickup performance, the intermediate value of δ=1.0 mm was selected. The corresponding spoon-cavity radius was R=6.5 mm. The selected allowance provides sufficient clearance for reliable kernel entry while preventing excessive enlargement of the spoon cavity. Combined with the removal of unstable excess kernels in the seed-clearing zone, the selected cavity size facilitates single-seed pickup and reduces the probability of multiple seed pickup.

The main design parameters of the spoon disc also include the number of seed spoons (Z_1), the pitch-circle radius of the spoon disc (r_1), and the outer radius of spoon wheel (r_2). Among these parameters, A schematic diagram of spoon wheel designed in this study is shown in Fig. 4. The angle (θ_2) is defined as the central angle between two adjacent seed spoons.

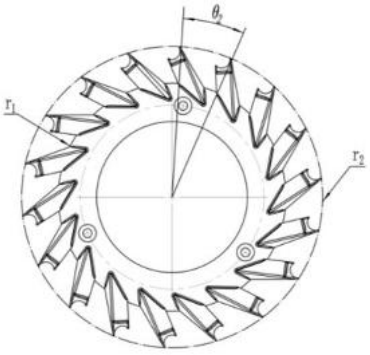

Fig. 4 - Structure of the spoon disc

According to Eq. (2), an increase in the number of seed spoons results in a decrease in the angular spacing between adjacent spoons. At a constant rotational speed of the seed-metering device, a greater number of kernels can therefore be discharged during each revolution of the spoon disc. When the required

plant spacing remains unchanged, increasing the number of seed spoons can increase the operating speed of the planter while maintaining the same seeding rate.

$$Z_1 = \frac{360°}{\theta_2} \tag{2}$$

Based on the practical requirements of this study, the number of seed spoons was set to (Z_1=18). Accordingly, the pitch-circle radius of the spoon disc was determined as (r_1=83) mm, and the outer radius of spoon wheel was (r_2=115) mm. In addition, three M6 through-holes were uniformly arranged on the spoon disc at angular intervals of 120°, enabling spoon wheel to be securely connected to the seed-metering wheel.

Structural Design of the Partition Plate

The partition plate has an annular disc-shaped structure and is installed between the seed-metering housing and the cover. It is secured by a positioning structure and remains stationary during operation. A schematic diagram of the partition plate is shown in Fig. 5. A sector-shaped seed-transfer opening is arranged in the upper part of the partition plate. The starting position of the opening is located 15° forward of the vertical direction, and its opening angle is set to 65°; therefore, the seed-transfer angle of the partition plate is θ_3 = 65°. When the partition plate is adjusted to its highest position, the starting point of the seed-transfer zone is located at the arc-shaped opening. The angle between the horizontal direction and the line connecting this point to the centre of the partition plate is defined as θ_4, while the endpoint of the seed-transfer zone is located at the terminal end of the arc-shaped groove.

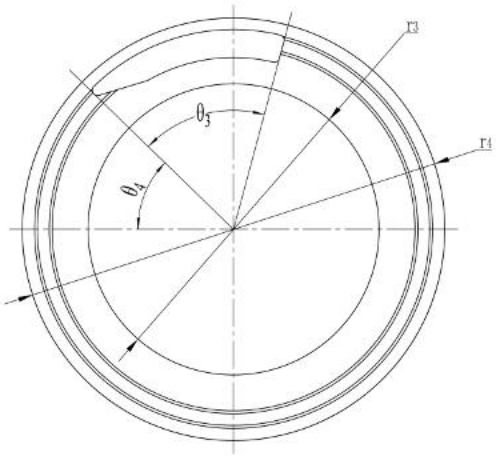

Fig. 5 - Structural schematic of the partition plate

Two positioning grooves are arranged along the lower outer edge of the partition plate. During assembly, the grooves are fitted into the seed-discharge opening at the lower part of the seed-metering device housing to restrict the rotation of the partition plate and prevent positional misalignment. Because the partition plate operates in coordination with the seed-metering spoon wheel and the seed-metering wheel, its structural dimensions should be determined according to the dimensions of these two components. Therefore, the following geometric relationships exist among the three components:

$$r_1 = r_3 \tag{3}$$

$$r_4 = r_5 \tag{4}$$

where r_3 is the inner radius of the partition plate, mm; r_4 is the outer radius of the partition plate, mm; and r_5 is the radius of the seed-metering wheel, mm.

Structural Design of the Seed-Metering Wheel

The seed-metering wheel is generally mounted on the main shaft of the seed-metering device and rotates synchronously with the spoon wheel. To ensure that the working circumferences of the two components coincide at the seed-transfer position, their working radii were designed to be equal, as expressed in Eq. (5). The seed-metering wheel has a cylindrical body with several uniformly distributed U-shaped seed grooves around its circumference. The number of seed grooves is equal to the number of spoon cavities on the spoon wheel, enabling the kernels delivered by the spoon wheel to be received smoothly. The spoon wheel and the

seed-metering wheel are axially separated by the partition plate, with an axial operating clearance of 0.5 mm. The manufacturing tolerance of both the spoon wheel and the seed-metering wheel was controlled within ±0.1 mm. A schematic diagram of the seed-metering wheel is shown in Fig. 6.

$$r_5 = r_2 = 115mm \tag{5}$$

$$\theta_5 = \frac{\theta_2}{2} = 10° \tag{6}$$

$$s_1 = d_1 \tag{7}$$

$$Z_2 = Z_1 = 18 \tag{8}$$

where (s_1) is the height of the seed-metering wheel, mm; (d_1) is the width of the seed outlet, mm; θ_5 is the angle of a single U-shaped groove, °; θ_2 is the angular spacing between two adjacent seed spoons on the spoon-type seed-metering wheel, °; and (Z_2) is the number of U-shaped seed grooves on the seed-metering wheel.

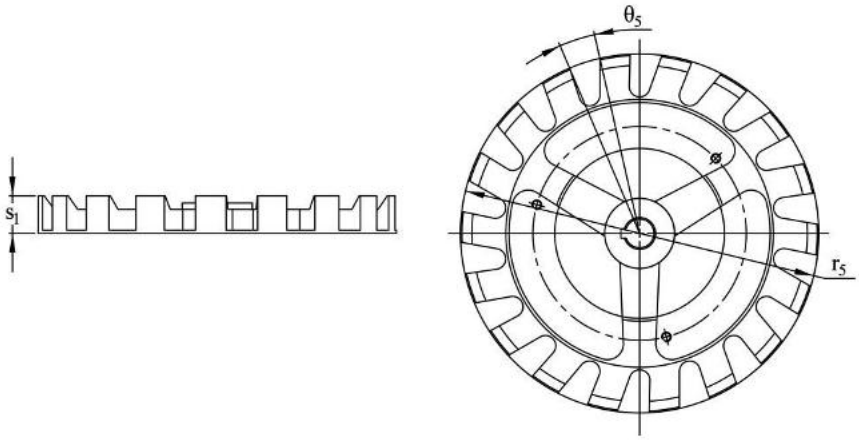

Fig. 6 - Schematic diagram of the seed-metering wheel

Bench Test

The bench tests were conducted using a JPS-16 seed-metering performance test system at the Key Laboratory of Intelligent Agricultural Machinery and Equipment, Heilongjiang Bayi Agricultural University. The system mainly consisted of a seed-metering-device mounting platform, a conveyor belt, an industrial camera, a control unit, an oil-applying and scraping device, and an illumination chamber. The conveyor belt was 0.9 m wide, and its speed was continuously adjustable from 0 to 16 km·h^{-1}. The seed-metering shaft speed ranged from 0 to 150 r·min^{-1}, with measurement and control accuracies of ±0.1% and ±0.5%, respectively. A computer-vision method was used to identify seed positions and calculate the spacing between adjacent seeds. The image-acquisition width was 400 mm, the acquisition frequency was 30–60 frames·s^{-1}, the seed-spacing resolution was 1 mm, and the mean measurement error was within ±2 mm. Before each test, the conveyor-belt speed, seed-metering shaft speed, and image-detection system were calibrated. The inclination angle was set and measured using the test system, with an accuracy of ±0.1°. The seed-layer height was measured using a steel ruler with 1-mm graduations, with an accuracy of ±1 mm. Data acquisition was initiated after the seed-metering device reached a stable operating state. Each test lasted 90 s, and 300 consecutive seed spacings were selected for statistical analysis. The tests were conducted at an ambient temperature of 20 ± 5 °C and a relative humidity of 40%–70%. Each treatment was repeated five times, and the mean value was used for subsequent analysis. Zhengdan 958 maize seeds were used in the experiments. The qualified index (A), multiple-seeding index (D), and miss-seeding index (M) were calculated using Eqs. (9)–(11), respectively (*Wang et al., 2026*).

$$A = \frac{n_1}{N} \times 100\% \tag{9}$$

$$D = \frac{n_2}{N} \times 100\% \tag{10}$$

$$M = \frac{n_3}{N} \times 100\% \tag{11}$$

Single-Factor Tests

To determine the effects of seed-metering wheel rotational speed, overall inclination angle, and seed-layer height on the performance of the inclined spoon-disc seed-metering device, three single-factor tests were conducted. The factor ranges were selected based on the operating range of the test system, preliminary tests, and the requirements of maize precision seeding. Maize kernels from the same cultivar, seed lot, and size grade were used throughout the tests. The treatment order within each single-factor test was randomized to reduce systematic errors. Except for the factor under investigation, all other operating and environmental conditions were kept constant. Each treatment was repeated five times, and 300 consecutive seed spacings were evaluated in each repetition. The arithmetic mean of the five repetitions was used as the final result. The qualified index, miss-seeding index, and multiple-seeding index were selected as the performance indicators, and the data were statistically analysed using IBM SPSS Statistics 26.0. To investigate the effect of seed-metering wheel rotational speed, the overall inclination angle and seed-layer height were maintained at 22.5° and 60 mm, respectively, while the rotational speed was set to 14, 17, 20, 23, 26, and 29 r·min^{-1}. To evaluate the effect of the overall inclination angle, the rotational speed and seed-layer height were maintained at 21 r·min^{-1} and 60 mm, respectively, while the inclination angle was set to 15°, 18°, 21°, 24°, 27°, and 30°. To examine the effect of seed-layer height, the rotational speed and overall inclination angle were maintained at 21 r·min^{-1} and 22.5°, respectively, while the seed-layer height was set to 40, 48, 56, 64, 72, and 80 mm.

Multi-Factor Test

Based on the single-factor test results, a three-factor, five-level central composite rotatable design was employed to investigate the individual and interaction effects of seed-metering wheel rotational speed, overall inclination angle, and seed-layer height on seed-metering performance. The qualified index, multiple-seeding index, and miss-seeding index were selected as the response variables. The experimental runs were conducted in a randomized order. Each run was repeated five times, and the response values were expressed as the mean ± standard deviation. The coded factor levels are presented in Table 1, and the experimental design and results are presented in Table 2.

Table 1

Coded levels of the experimental factors

Coded value	Factor

1.682	27.8	30	80
1	25	27	71.9
0	20.8	22.5	60
-1	16.7	18	48.1
-1.682	13.9	15	40

RESULTS AND DISCUSSIONS

Effect of Seed-Metering Wheel Rotational Speed on Seed-Metering Performance

Under an overall inclination angle of 22.5° and a seed-layer height of 60 mm, the effects of seed-metering wheel rotational speed on seed-metering performance are shown in Fig. 7. As the rotational speed of the seed-metering wheel increased from 14 to 23 r·min^{-1}, the qualified index increased from 85.1% to 96.3%, representing an increase of 11.2 percentage points. Meanwhile, the multiple-seeding index decreased from 9.6% to 1.6%, a reduction of 8.0 percentage points, and the miss-seeding index generally decreased from 4.1% to a relatively low level. When the rotational speed was further increased to 29 r·min^{-1}, the qualified index decreased to 87.4%, whereas the miss-seeding index increased markedly to 9.5%. In contrast, the multiple-seeding index increased only slightly to 2.3%. At a relatively low rotational speed, the seed spoons remained within the seed mass for a longer period, thereby increasing the likelihood of capturing multiple maize kernels simultaneously. Moreover, the relatively weak centrifugal effect acting on the kernels in the seed-clearing zone made it difficult for excess kernels located outside the spoon cavity to fall back into the seed mass in a timely manner, resulting in a relatively high multiple-seeding index. As the rotational speed increased, the disturbance exerted by the seed spoons on the seed mass became stronger. Consequently, excess kernels were more readily detached from the spoon cavities under the combined effects of gravity, centrifugal force, and inter-kernel collisions. This gradually reduced the multiple-seeding index and consequently increased the qualified index.

Table 2

The experimental design and results

Coded value	Factor			Qualified index y_1 (%)	multiple-seeding index y_2 (%)	miss-seeding index y_3 (%)

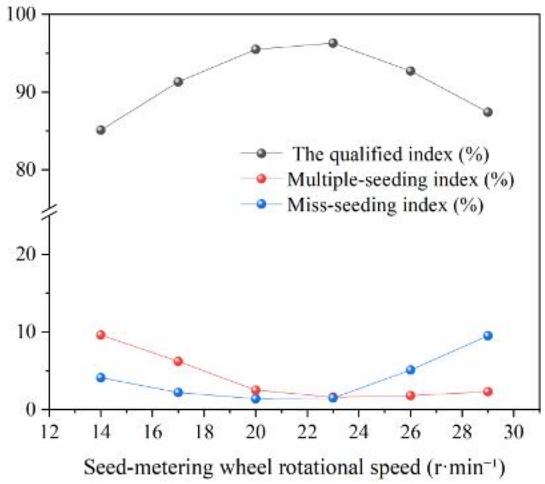

Fig. 7 - Effects of seed-metering wheel rotational speed on seed-metering performance

Effect of Overall Inclination Angle on Seed-Metering Performance

At a seed-metering wheel rotational speed of 21 r·min^{-1} and a seed-layer height of 60 mm, the effects of the overall inclination angle on seed-metering performance are shown in Fig. 8. As the overall inclination angle increased from 15° to 24°, the qualified index increased from 89.2% to 96.5%, corresponding to an increase of 7.3 percentage points. Meanwhile, the multiple-seeding index decreased from 3.1% to 1.7%, and the miss-seeding index decreased from 7.7% to 1.6%. When the inclination angle was further increased to 30°, the qualified index decreased to 91.7%, whereas the multiple-seeding index increased to 6.4% and the miss-seeding index increased slightly to 2.2%. At a relatively small overall inclination angle, the maize kernels were insufficiently concentrated in the seed-pickup zone under the action of gravity.

Consequently, the probability of effective contact between the seed spoons and the kernels was relatively low, making the spoon cavities more likely to remain unfilled and resulting in a higher miss-seeding index. As the inclination angle increased to an appropriate level, the component of gravitational force acting on the seed mass along the plane of the seed-metering disc increased. This promoted the movement of kernels

toward the seed-pickup zone and improved the filling conditions of the seed spoons, thereby reducing the miss-seeding index and increasing the qualified index.

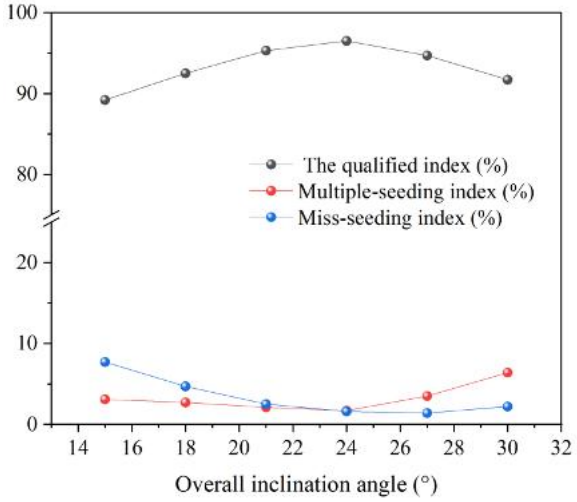

Fig. 8 - Effects of overall inclination angle on seed-metering performance

Effect of Seed-Layer Height on Seed-Metering Performance

At a seed-metering wheel rotational speed of 21 r·min^{-1} and an overall inclination angle of 22.5°, the effects of seed-layer height on seed-metering performance are shown in Fig. 9. As the seed-layer height increased from 40 to 64 mm, the qualified index increased from 88.6% to 96.4%, corresponding to an increase of 7.8 percentage points. Meanwhile, the miss-seeding index decreased from 9.2% to 0.9%, representing a reduction of 8.3 percentage points, whereas the multiple-seeding index increased only slightly from 2.1% to 2.6%. When the seed-layer height was further increased to 80 mm, the qualified index decreased to 90.5%, while the multiple-seeding index increased to 7.1% and the miss-seeding index increased to 2.3%. At a relatively low seed-layer height, fewer kernels were available for capture by the seed spoons within the seed-pickup zone. In addition, the contact pressure exerted by the seed mass on the seed spoons was insufficient, increasing the likelihood of unfilled spoon cavities and consequently resulting in a higher miss-seeding index. As the seed-layer height increased, both the number of kernels and the pressure exerted by the seed mass within the seed-pickup zone increased. This enhanced the probability of kernels entering the spoon cavities, thereby markedly reducing the miss-seeding index and gradually increasing the qualified index.

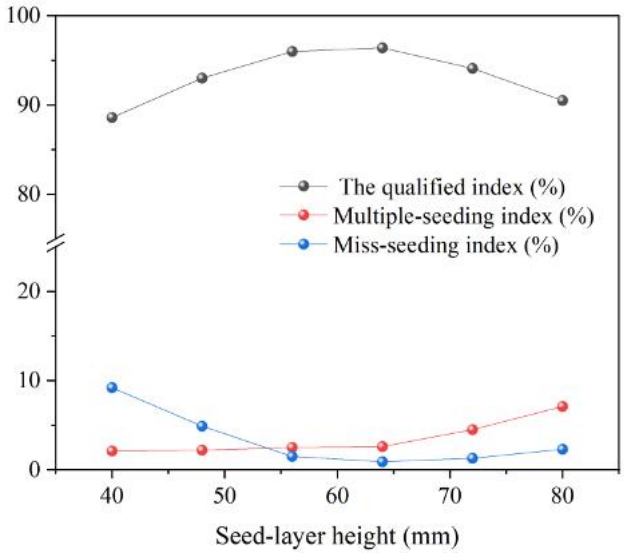

Fig. 9 - Effects of seed-layer height on seed-metering performance

Results and Analysis of the Central Composite Rotatable Design

The qualified index is an important indicator for evaluating the operating performance of the inclined spoon-disc seed-metering device. The analysis of variance for the regression model of the qualified index is presented in Table 3.

The model yielded an (F)-value of 6.88 with (P<0.01), indicating that the established quadratic regression model was highly significant. Significant regression relationships were observed between the qualified index and the rotational speed of the seed-metering wheel, the overall inclination angle, and the seed-layer height. The (P)-value for the lack-of-fit term was 0.1073, indicating that the lack of fit was not significant and that the model adequately described the relationships between the investigated factors and the qualified index. After eliminating the nonsignificant terms while retaining a significant overall model and a nonsignificant lack of fit, the regression equation for the qualified index in terms of coded variables was established as follows:

$$y_1 = 89.18 + 0.64x_1 - 1.11x_2 + -0.25x_3 + 0.03x_1x_2 + 0.005x_1x_3 + 0.009x_2x_3 - 0.04{x_1}^2 - 0.005{x_2}^2 - 0.004{x_3}^2 \quad (12)$$

where y_1 is the qualified index; x_1 is the coded value of the seed-metering wheel rotational speed; x_2 is the coded value of the overall inclination angle; and x_3 is the coded value of the seed-layer height.

Interaction Effect of Metering-Wheel Rotational Speed and Overall Inclination Angle

When the seed-layer height was fixed at 60 mm, the combined effects of seed-metering wheel rotational speed and overall inclination angle on the qualified index are shown in Fig. 10. As the rotational speed of the seed-metering wheel increased, the qualified index generally exhibited an initial increase followed by a subsequent decrease. Variations in the overall inclination angle resulted in markedly different changes in the qualified index at different rotational speeds. At relatively low rotational speeds, the seed spoons remained within the seed mass for a longer period, increasing the likelihood of simultaneously capturing multiple maize kernels and consequently increasing the multiple-seeding index. As the rotational speed increased further, the time available for the seed spoons to pass through the seed-pickup zone was shortened, making it difficult for the kernels to enter the spoon cavities completely and remain stably retained. This increased the probability of missed seeding and ultimately reduced the qualified index. The overall inclination angle altered the accumulation pattern and force direction of the maize kernels within the seed-pickup zone. At a relatively small inclination angle, the kernels were insufficiently concentrated toward the seed-pickup zone, resulting in a lower probability of effective contact between the kernels and the seed spoons. An appropriate increase in the inclination angle improved kernel accumulation and contact conditions, thereby facilitating seed filling.

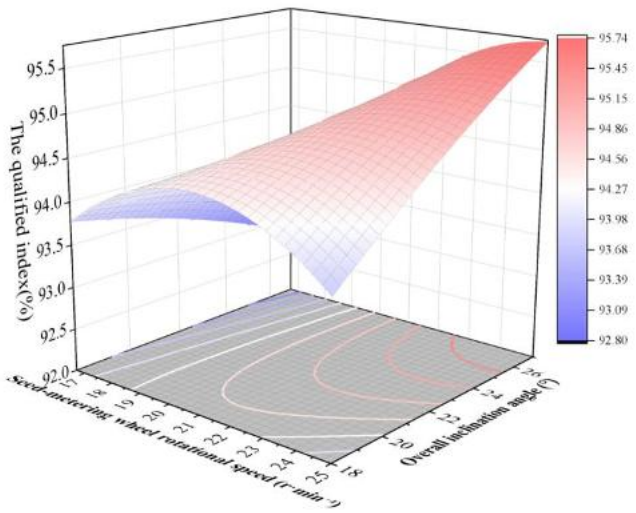

Fig. 10 - Effects of seed-metering wheel rotational speed and overall inclination angle on the qualified index

Interaction Effect of Seed-Metering Wheel Rotational Speed and Seed-Layer Height

When the overall inclination angle was fixed at 22.5°, the combined effects of seed-metering wheel rotational speed and seed-layer height on the qualified index are shown in Fig. 11. The response surface exhibited an arch-shaped profile, with a higher central region and lower peripheral regions, indicating that appropriate ranges existed for both the seed-metering wheel rotational speed and seed-layer height. As either the rotational speed or seed-layer height increased, the qualified index generally exhibited an initial increase followed by a decrease. At a relatively low seed-layer height, the number of kernels available for capture by the seed spoons in the seed-scooping region was limited. Moreover, the pressure exerted by the seed mass on the seed spoons was insufficient, increasing the likelihood of empty spoon cavities as the seed spoons passed through the seed mass and consequently increasing the miss-seeding index. An appropriate increase in seed-layer height enhanced the probability of contact between the kernels and seed spoons, improved the seed-filling conditions, and thereby increased the qualified index.

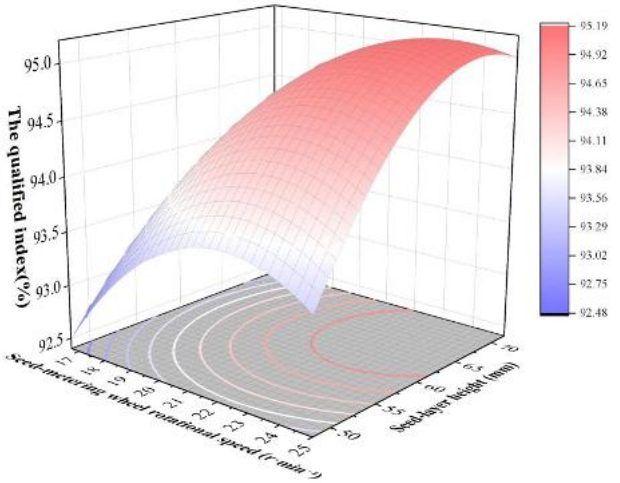

Fig. 11 - Effects of seed-metering wheel rotational speed and seed-layer height on the qualified index

Interaction Effect of Overall Inclination Angle and Seed-Layer Height

When the rotational speed of the seed-metering wheel was fixed at 20.85 r·min^{-1}, the combined effects of overall inclination angle and seed-layer height on the qualified index are shown in Fig. 12. The response surface exhibited more pronounced curvature along the seed-layer-height axis, whereas the variation along the overall-inclination-angle axis was relatively gradual. This indicated that seed-layer height had a greater effect on the qualified index than the overall inclination angle. As the seed-layer height increased, the qualified index initially increased and subsequently decreased. At a relatively low seed-layer height, an insufficient number of kernels were present around the seed spoons, increasing the likelihood of incomplete seed filling. As the seed-layer height increased, both the number of kernels and the pressure exerted by the seed mass in the seed-filling region increased, thereby enhancing the probability of kernel capture by the seed spoons.

However, with a further increase in seed-layer height, the probability of multiple kernels simultaneously entering a spoon cavity increased. Meanwhile, the intensified friction and compression among the kernels hindered the removal of surplus kernels, leading to an increase in the multiple-seeding index and a corresponding decrease in the qualified index.

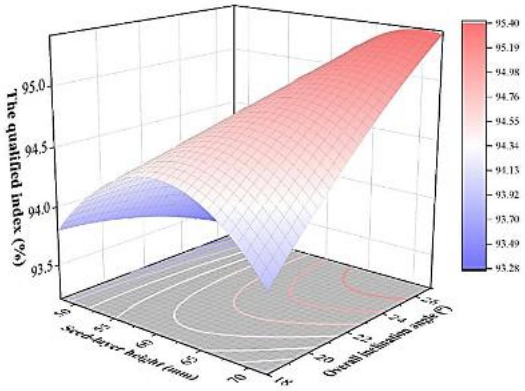

Fig. 12 - Effects of overall inclination angle and seed-layer height on the qualified index

To determine the optimal parameter combination, an optimization model was established within the factor ranges of the three-factor, five-level quadratic orthogonal rotatable design, with the qualified index maximized and the miss-seeding and multiple-seeding indices minimized as the optimization objectives, as shown in Eq.(13).

$$\begin{cases} \max y_1 \\ \min y_2 \\ \min\ y_3 \\ s.t. \begin{cases} 13.9 \le x_1 \le 27.8 \\ 15 \le x_2 \le 30 \\ 40 \le x_3 \le 80 \end{cases} \end{cases} \tag{13}$$

The numerical optimization module in Design-Expert software was used to solve the established regression model for the qualified index. Based on the fitting results obtained from the 23 experimental runs, the qualified index was set as the optimization objective to be maximized within the complete five-level ranges of the experimental factors. The theoretically optimal parameter combination was determined as follows: a seed-metering wheel rotational speed of 25 r·min^{-1}, an overall inclination angle of 27°, and a seed-layer height of approximately 71.9 mm. Under these conditions, the qualified index predicted by the regression model was approximately 96.5%. Bench validation tests were subsequently conducted using the optimized parameter combination, as shown in Fig. 13.

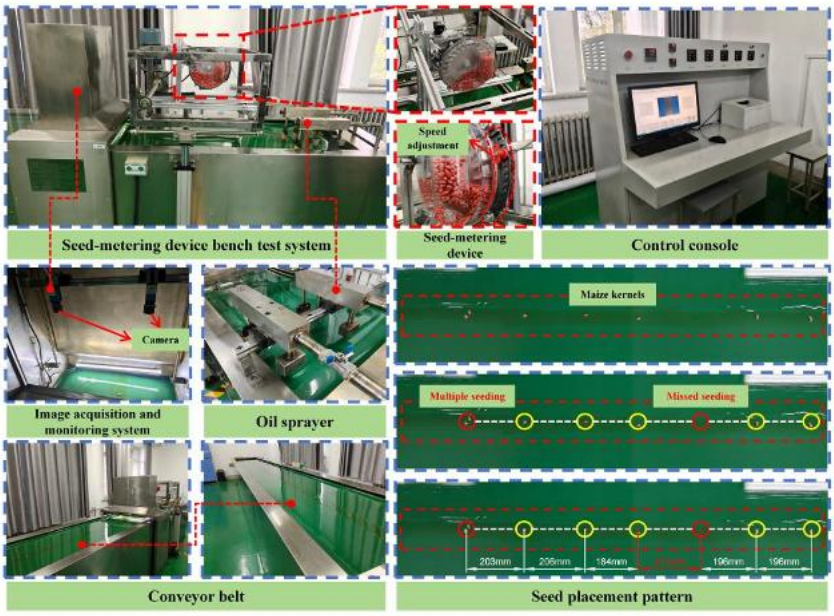

Fig. 13 - Results of the bench validation test under the optimized parameter combination

Three replicate tests were performed, and the mean qualified index was used as the validation result. The mean qualified index obtained experimentally was 95.0%, with a relative error of 1.5% compared with the model-predicted value. The experimental result was in good agreement with the predicted result, demonstrating that the established regression model had satisfactory predictive accuracy and that the optimized parameter combination was reasonable and reliable.

CONCLUSIONS

(1) An inclined spoon-disc seed-metering device was developed in this study. The spoon wheel and seed-metering wheel were driven synchronously at a transmission ratio of 1:1 and maintained a fixed phase relationship, ensuring that each spoon cavity was accurately aligned with the corresponding U-shaped groove at the designated seed-transfer position and thereby enabling precision maize seeding. In addition, the seed-metering wheel rotational speed, overall inclination angle, and seed-layer height exhibited pronounced nonlinear effects on seed-metering performance. Regression analysis showed that the rotational speed had the greatest effect on the qualified index, followed by the seed-layer height, whereas the main effect of the overall inclination angle was comparatively weak. A significant interaction was observed between the rotational speed and overall inclination angle, indicating that the appropriate inclination angle varied with rotational speed. These findings demonstrate that optimal seed-metering performance cannot be achieved by optimizing a single parameter independently; rather, the operating parameters must be properly coordinated.

(2) Multi-objective optimization identified the optimal parameter combination as a seed-metering wheel rotational speed of 25 r·min^{-1}, an overall inclination angle of 27°, and a seed-layer height of 71.9 mm. Under these conditions, the qualified index predicted by the regression model was 96.5%, whereas the mean qualified index obtained from the validation tests was 95.0%, corresponding to a relative error of 1.5%. The close agreement between the predicted and experimental results indicates that the established regression model can reliably describe and optimize the seed-metering performance within the investigated ranges. Future studies will assess the adaptability of the device to different maize cultivars, conduct high-speed and field validation tests, and further evaluate its seed-metering performance under a broader range of operating conditions.

ABSTRACT
To address the lack of contact parameters for seed ginger and the insufficient accuracy of existing discrete element models used in simulations of seed ginger machinery, a discrete element modeling and contact parameter calibration method for irregularly shaped seed ginger was proposed. A discrete element model of seed ginger was constructed using 3D laser scanning and an adaptive multi-sphere filling method. The contact parameters between seed ginger and steel were calibrated using free-fall collision tests, inclined-plane tests, and combined inclined-plane–horizontal-plane tests. Using the angle of repose as the response variable, the optimal parameter combination was determined through steepest ascent tests and response surface methodology. The relative error between the simulated angle of repose and the value measured in the bench test was 2.24%. The results provide a modeling basis for the optimization and design of key components of seed ginger machinery and for investigating the dynamic interaction mechanisms among seed ginger particles.

摘要
针对生姜播种机械仿真研究中姜种接触参数缺失、模型精度不足的问题，提出一种不规则姜种的离散元建模与接触参数标定方法。基于三维激光扫描与多球自适应填充方法构建姜种离散元模型；采用自由落体碰撞法、斜面法及斜面-平面组合法标定姜种与钢材间接触参数；并以休止角为响应指标，结合最陡爬坡试验与响应面试验，获得最优参数组合，仿真休止角与台架试验实测值的相对误差为2.24 %。研究结果可为生姜播种机械关键部件优化设计及颗粒群动态互作机理研究提供模型基础。

INTRODUCTION
Ginger is a vital specialty vegetable and medicinal crop in China, ranking first globally in both planting area and total yield, with stable and continuously growing market demand. Currently, ginger sowing operations face challenges such as labor shortages and low efficiency *(Yang et al., 2022)*. The irregular shape of seed ginger and their distinctive features like surface protrusions and nodes impose stringent requirements on single-seed picking and bud orientation during mechanized sowing. However, establishing a granular simulation model using the discrete element method enables precise analysis of microscopic force interactions, providing a crucial tool for the design verification and simulation optimization of key components in ginger sowing machinery *(Zhao et al., 2025)*. Accurate calibration of seed ginger-related contact parameters and the construction of discrete element models have become essential foundations for ensuring the rational design of core sowing machinery components and the accuracy of virtual simulations.

Currently, numerous researchers have conducted studies on the construction and parameter calibration of discrete element models for conventional crops. *Lu et al., (2023),* and others simulated the natural stacking and sowing processes of wheat seeds, effectively addressing the challenge of balancing simulation accuracy and computational time in the multi-sphere method. *Shi Linrong et al., (2018)* employed the slice modeling method to construct a potato seed model and validated the effectiveness of the stacking angle simulation parameters through physical experiments. *Lu Qi et al., (2023),* and others developed a soil-seed interaction model, determining contact parameter values using the response surface method.

[1] *Zhang Jinbiao[1], Ph.D. Stud.; Cheng Jin, * Ph.D.; Liu Lin, Ph.D.; Hou Jialin, Prof. Ph.D.; Hou Rui, Ph.D.; Zhou Qiwei.; Li Yuhua, Ph.D.*

Xia Junfang et al., (2024), *Liao Yitao et al., (2020)*, and *Shi Ruijie et al., (2022),* combined simulation with bench tests to accurately obtain contact parameters for rice straw, rapeseed stems, and sesame stems, providing foundational data for low-loss harvesting technologies. Other scholars have also conducted relevant research on the establishment of discrete element simulation model and parameter calibration of crops and products such as alfalfa (*Chen et al., 2023*), sunflower (*Guo et al., 2025*), tea (*Du et al., 2025*), quinoa (*Liu et al., 2020*), maize (*Jia et al., 2020*), coated cotton-seeds (*Wang et al., 2021*), sweet sorghum seeds (*Yang et al., 2026*) and millet threshing mixtures (*Huang et al., 2026*). These studies predominantly employed a combination of physical experiments and simulation to optimize parameters but primarily focused on regular-shaped, single-mechanical-property agricultural granular materials. Under external loading, seed ginger exhibits dynamic mechanical responses, including friction and collision, as well as asymmetric stacking behavior characterized by the angle of repose, which differ fundamentally from those of conventional crop materials.

To address the complex stacking behavior caused by the irregular shape of seed ginger, a parameter calibration optimization procedure was established based on steepest ascent tests and response surface methodology, providing a calibration approach suitable for irregular block-shaped seed materials. This study systematically reports key physical and mechanical properties of seed ginger during sowing, addressing a gap in the existing research and providing an accurate modeling basis for further investigation of dynamic interaction mechanisms in mechanical ginger sowing and for the optimized design of key components.

MATERIALS AND METHODS

Determination of physical properties of seed ginger

In order to obtain the basic physical characteristic parameters of seed ginger, this study selected "Laiwu Big Ginger" with intact scales after germination as the experimental object. This variety has strong growth potential and a yield of about 30 t/hm^2. It is the main cultivated variety in Shandong region and has certain representativeness. Regarding the shape of seed ginger Based on the principle of "moderate block size, typical shape, and full scale", seed ginger were randomly spread out on the open space due to their complex and irregular characteristics. Then, the five point sampling method (Fig.1) was used, with 40 seed ginger randomly taken from each sampling point, for a total of 200 seed ginger as the measurement samples. Using the AES-G5 electronic scale, the average mass of the sample monomer was 68.5 g. The volume was measured using the drainage method, and the average density of the seed ginger was calculated to be 1094.7 kg/m^3. The average moisture content of the seed ginger was determined to be 64.38% using the standard drying method. The external dimensional parameters of seed ginger were measured and statistically analyzed using a vernier caliper with an accuracy of 0.1 mm. Considering the typical irregular block structure of seed ginger, this study selected the maximum radial size of the main body of seed ginger at the thick end and the minimum radial size at the thin end as the external dimensional parameter indicators. The results are shown in Table 1.

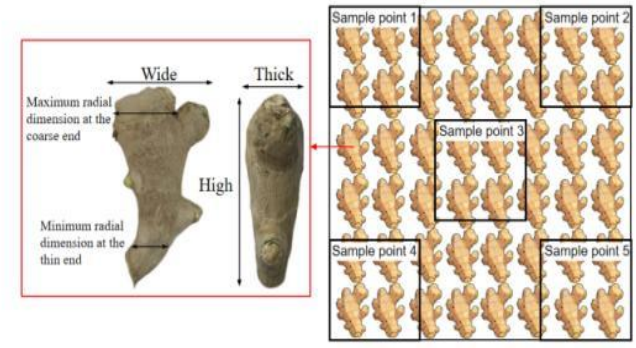

Fig. 1 - Five point sampling method

Table 1

Measurement results of external dimensions parameters of seed ginger during sowing period

Project	High[mm]	Width[mm]	Thickness [mm]	Maximum radial dimension at the coarse end[mm]	Minimum radial dimension at the thin end[mm]
Max	125.2	74.3	35.6	42.5	17.8
Min	72.7	52.6	24.9	35.4	12.4
Mean	93.8	63.7	31.7	37.8	14.7
Standard Deviation	13.7	9.3	5.8	2.9	3.1

The Poisson's ratio, elastic modulus, and shear modulus of seed ginger were determined through compression tests *(Sun et al., 2025)*. Cylindrical pulp specimens with a diameter of 10 mm and a length of 20 mm were prepared and placed on the lower compression platen of a TA-XT2i texture analyzer. The pre-compression speed of the upper platen was set to 60 mm/min, the compression speed to 5 mm/min, and the compression distance to 5 mm. Ten replicate compression tests were conducted. The radial dimensions of the specimens before and after compression were measured, and the mean Poisson's ratio μ of seed ginger was calculated using Eq. (1) as 0.46. Compression was then continued until the cylindrical specimen completely collapsed. The test was repeated ten times, and the maximum load *F* within the elastic deformation stage and the corresponding axial deformation ΔL were recorded. According to Eq. (2), the mean elastic modulus E of seed ginger was calculated as 2.97 MPa, as shown in Table 2. The shear modulus G was subsequently calculated using Eq. (3), yielding a mean value of 1.02 MPa.

$$\mu = \left|\frac{\varepsilon_t}{\varepsilon_a}\right| = \frac{\Delta d / d}{\Delta h / h} = \frac{\Delta dh}{\Delta hd} \tag{1}$$

$$E = \frac{Fh}{S\Delta L} \tag{2}$$

$$G = \frac{E}{2(1+\mu)} \tag{3}$$

where: μ is Poisson's ratio; ε_t is the radial deformation of the sample, [mm]; ε_a is the axial deformation of the sample, [mm]; Δd is the radial size change, [mm]; d is the radial original size, [mm]; Δh is the axial size change, [mm]; h is the axial original size, [mm]. E is the elastic modulus, [MPa]; F is the maximum load during the elastic stage, [N]; S is the compressive cross-sectional area, [mm^2]; ΔL is the compression deformation of the sample at the maximum load, [mm]; G is the shear modulus, [MPa].

Table 2

Compare and analyze the mechanical properties of seed ginger with typical agricultural bulk materials *(Zhou et al., 2023; Cai et al., 2024; Zhang et al., 2025; Zhang et al., 2022)*, as shown in Table 3. Compared with high-stiffness particles such as wheat and beans, seed ginger exhibits markedly lower stiffness. Compared with root and tuber crops such as potatoes, water chestnuts, yams, and sweet potatoes, seed ginger has a higher Poisson's ratio.

The typical low stiffness and high deformation physical characteristics of ginger provide a reliable theoretical basis for the selection and parameter configuration of low stiffness contact models in subsequent

discrete element simulations, which result in high viscous resistance and asymmetric contact phenomena during dynamic collisions and natural accumulation processes.

Table 3

Comparison of mechanical properties of typical agricultural bulk materials

Name	Wheat	Soybean	Potato	Water Chestnut	Yam	Sweet Potato	Ginger
Type	Cereals	Legumes	Roots and Tubers	Roots and Tubers	Roots and Tubers	Roots and Tubers	Roots and Tubers
Elastic Modulus	37	180	5.65	5.433	3.92	3.22	2.97
Poisson's Ratio	0.30	0.40	0.42	0.395	0.4	0.28	0.46

Construction of Discrete Element Model

During the sowing period, seed ginger exhibit a significant irregular block structure, and it is difficult to accurately reflect their complex boundary contours using conventional single sphere or ellipsoid models. The multi-sphere adaptive filling model can flexibly approach the irregular block structure and angle characteristics by adjusting the number, radius and spatial arrangement of the constituent spheres, and also simplify the contact between particles with complex shapes as the interaction between spheres. This study utilized a high-precision 3D laser scanner (Accuracy: 0.02 mm; Resolution: 0.02 mm; Scanning speed: 2,800,000 points/s) to obtain 3D point cloud data on the surface of ginger samples, and imported it into Geomagic Studio software for reverse engineering processing. During the processing, the focus is on preserving the coarse and fine end contour features of seed ginger, and then using HyperMesh software for mesh partitioning and optimization to export high-precision 3D geometric models of seed ginger. The three-dimensional model was imported into EDEM software. Based on the multi-sphere combination method, a small ball with a radius of 2 mm was selected to discretize and fill the model. The smoothing value was set to 3, and the total number of spheres was 6988. The discrete element model of ginger seeds was constructed (Fig. 2).

Seed ginger is a kind of granular material with large size, and the particles will not adhere and agglomerate with each other due to the effect of water and chemical substances, the measured mechanical parameters of seed ginger were directly assigned in EDEM software, and the Hertz Mindlin (no slip) contact model was selected. This setting accurately reproduces the high viscosity resistance and asymmetric stacking behavior of seed ginger, laying the foundation for precise calibration of subsequent contact parameters.

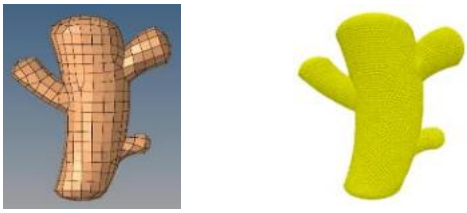

Fig. 2 - Seed ginger simulation model

Coefficient of restitution between seed ginger and steel

The coefficient of restitution is a dimensionless parameter that characterizes the ability of two colliding bodies to recover kinetic energy after impact *(Guo et al., 2023)*. In this study, the coefficient of restitution between seed ginger and a steel plate was measured using a free-fall collision test. A smooth steel plate was fixed horizontally on the base, and 30 seed ginger samples were randomly selected and released from rest from a vertical height of 200 mm. After impact with the steel plate, the samples rebounded. A 1 mm grid was placed in the background as a reference scale, and the rebound process was analyzed frame by frame using a high-speed camera. The mean maximum rebound height h_r was 38.6 mm. According to Eq. (4), the coefficient of restitution *e* between seed ginger and steel was calculated as 0.439. A corresponding simulation model was established in EDEM. The particle factory generated seed ginger particles with zero initial velocity, and the seed ginger–steel coefficient of restitution was set to 0.439. The particles were allowed to fall freely under gravity and collide with the steel plate. The simulation data storage interval was 0.01 s, the total simulation time was 20 s, and the time step was 4.501×10^{-7} s. Considering both computational accuracy and efficiency, the minimum fluid-grid porosity setting was specified such that the grid size was three times the particle diameter. The center-of-mass trajectories of the seed ginger particles were tracked using the post-processing tools. The mean maximum rebound height after impact was 34.9 mm, corresponding to a simulated coefficient of restitution of 0.418.

The relative error between the simulated coefficient of restitution and the bench-test value of 0.439 was 4.78%, indicating that the established discrete element model of seed ginger could adequately reproduce the actual collision characteristics. Therefore, the coefficient of restitution *e* between seed ginger and the steel plate was set to 0.439. The experimental setup and simulation process are shown in Fig. 3.

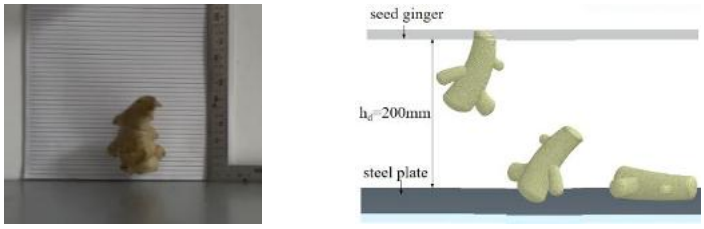

Fig. 3 - Calibration test for the coefficient of restitution between seed ginger and steel

$$e = \sqrt{\frac{h_r}{h_d}} \tag{4}$$

where: e is the coefficient of restitution; h_r is the maximum rebound height of the seed ginger, [mm].

Sliding friction coefficient between ginger and steel

The sliding friction coefficient between seed ginger and a steel plate was measured using the inclined-plane method *(Jiang et al., 2023)*. The longitudinal axis of the seed ginger was aligned parallel to the long side of the steel plate. A digital inclinometer was attached to one side of the plate, and one end of the plate was raised slowly and uniformly to increase the inclination angle. When the seed ginger was on the verge of sliding, the inclination angle was recorded as the critical sliding angle α_1. The test was repeated 30 times, yielding a mean critical sliding angle of 25.75°. According to Eq. (5), the sliding friction coefficient f_1 between seed ginger and the steel plate was calculated as 0.482. For simulation validation, the sliding friction coefficient between the discrete element model of seed ginger and the steel plate model was set to 0.482. A simulation model corresponding to the bench test was established, and the inclination angle of the plate was gradually increased until the seed ginger model began to slide. The critical sliding angle obtained from the simulation was 24.90°, corresponding to a simulated sliding friction coefficient of 0.464. The relative error between the simulated and experimentally measured values was 3.73%, indicating good agreement. Therefore, the sliding friction coefficient f_1 between seed ginger and the steel plate was set to 0.482. The bench-test and simulation procedures are shown in Fig. 4.

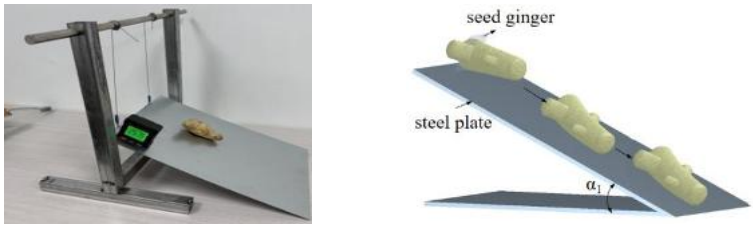

Fig. 4 - Calibration test for the sliding friction coefficient between seed ginger and steel

$$f_1 = \tan\alpha_1 \tag{5}$$

Rolling friction coefficient between seed ginger and steel

In this study, the rolling friction coefficient between seed ginger and steel was measured using a combined inclined-plane and horizontal-plane method. The seed ginger was placed on a steel plate inclined at an angle α_2 of 45°, with its longitudinal axis aligned with the long side of the plate, and was released from rest at a vertical height N of 200 mm above the horizontal plane. The seed ginger accelerated while rolling down the inclined plate and then transitioned smoothly onto the horizontal steel plate, where it decelerated under the action of rolling friction until coming to rest. The test was repeated 30 times, and the mean rolling distance M on the horizontal plate was 178 mm. According to Eqs. (6) and (7), the rolling friction coefficient f_2 between seed ginger and the steel plate was calculated as 0.308. A simulation model with the same dimensions was established in EDEM. The calibrated coefficient of restitution and sliding friction coefficient, together with the rolling friction coefficient to be validated, were assigned to the seed ginger particle model. A seed ginger particle with zero initial velocity was generated at a height of 200 mm. After 30 simulation runs, the mean horizontal rolling distance was 192 mm, corresponding to a simulated rolling friction coefficient of 0.324. The relative error between the simulated and experimentally measured values was 5.19%, indicating good agreement and supporting the validity of the calibrated parameter. Therefore, the rolling friction coefficient f_2 between seed ginger and the steel plate was set to 0.308. The bench-test and simulation procedures are shown in Fig. 5.

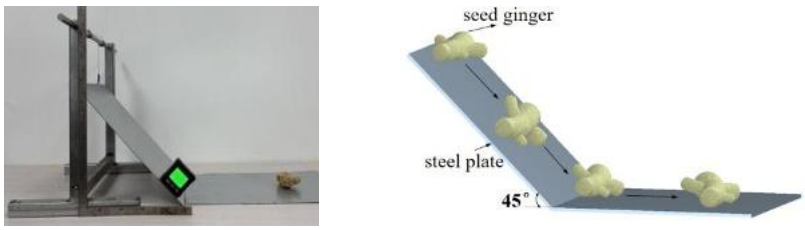

Fig. 5 - Calibration test for the rolling friction coefficient between seed ginger and steel

$$f_2\left(B+M\cos\alpha_2\right)=M\sin\alpha_2 \tag{6}$$

$$B=\frac{N}{\sin\alpha_2} \tag{7}$$

where: α_2 is the inclination angle of the steel plate, [°]; B is the rolling distance of the seed ginger along the inclined plane, [mm]; M is the horizontal rolling distance of the seed ginger, [mm].

Calibration of contact parameters between seed ginger particles

Given the complex and irregular shape of seed ginger, it is difficult to ensure the accuracy of directly measuring seed ginger–seed ginger contact parameters using bench tests alone. The angle of repose can reflect the combined effects of interparticle friction, collision, and asymmetric accumulation behavior. In this study, the experimentally measured angle of repose was used as the target response value. Based on the parameter ranges determined from the bench tests, the seed ginger–seed ginger coefficient of restitution, sliding friction coefficient, and rolling friction coefficient were selected as the experimental factors, and a three-factor, three-level orthogonal test was conducted to determine the optimal combination of contact parameters.

To determine the range of the seed ginger–seed ginger coefficient of restitution, a double-inclined-plane collision method was used *(Xia et al., 2019)*, as illustrated in Fig. 7. Two inclined planes, each set at an inclination angle of 45°, were fixed on the test bench. Seed ginger slices were closely arranged over the working surfaces of the inclined planes to form seed ginger–seed ginger collision layers. The vertical heights from the collision points on the two inclined planes to the horizontal plane were set to H_1 = 200 mm and H_2 = 500 mm, respectively. An intact seed ginger sample was released from rest from a vertical height K of 200 mm above the impact point on the inclined plane. After collision, the sample was projected from the inclined plane and eventually landed on a horizontal plane covered with coordinate paper. The corresponding horizontal travel distances Z_1 and Z_2 were recorded. The test was repeated 30 times, and the seed ginger–seed ginger coefficient of restitution e_1 was calculated using Eqs. (8)–(10). The preliminary range of e_1 was determined to be 0.15–0.65.

$$e_1=\frac{2\sqrt{V_X^2+V_Y^2}\cdot\cos\left[45^\circ+\arctan\left(\frac{V_Y}{V_X}\right)\right]}{\sqrt{0.8g}} \tag{8}$$

$$V_X=\sqrt{\frac{gZ_1Z_2\left(Z_1-Z_2\right)}{\left(0.4Z_2-Z_1\right)}} \tag{9}$$

$$V_Y=\frac{0.5V_X}{Z_2}-\frac{gZ_2}{2V_X} \tag{10}$$

where: Z_1 is the horizontal landing distance corresponding to the first inclined plane, [m]; Z_2 is the horizontal landing distance corresponding to the second inclined plane, [m]; V_X is the horizontal velocity component after collision with the inclined plane, [m/s]; V_Y is the vertical velocity component after collision with the inclined plane, [m/s]; g is the acceleration due to gravity, [m/s^2].

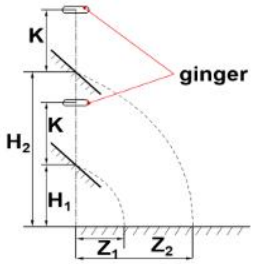

Fig. 6 - Schematic diagram of the bench test for measuring the coefficient of restitution between seed ginger samples

Sliding and rolling friction coefficients between seed ginger samples

In this study, a modified inclined-plane method and a combined inclined-plane and horizontal-plane method were used to determine the preliminary ranges of the seed ginger–seed ginger sliding and rolling friction coefficients. A representative seed ginger sample was cut longitudinally, and the cut pieces were closely arranged and fixed onto the surface of a steel plate to form a seed ginger friction surface. During the sliding test, an intact seed ginger sample was placed on the friction surface as the sliding body, with its longitudinal axis aligned parallel to that of the seed ginger pieces fixed to the plate. One end of the friction plate was raised slowly and uniformly, and the critical inclination angle at the onset of macroscopic sliding was recorded. Thirty seed ginger samples were tested, and the seed ginger–seed ginger sliding friction coefficient f_3 was calculated using Eq. (5), yielding a range of 0.37–0.87. For the rolling friction test, the inclination angle was fixed at 45°. A seed ginger sample was positioned at a vertical height D of 200 mm above the horizontal plane, with its transverse orientation perpendicular to the longitudinal direction of the seed ginger pieces on the friction surface. The sample rolled to the end of the inclined plate along an approximately curved trajectory and subsequently landed on the contact surface. The horizontal distance to the first landing point, Z_3, was recorded. Thirty seed ginger samples were tested, and the seed ginger–seed ginger rolling friction coefficient f_4 was calculated using Eq. (11), yielding a range of 0.32–0.82. The bench-test procedures are shown in Fig. 7.

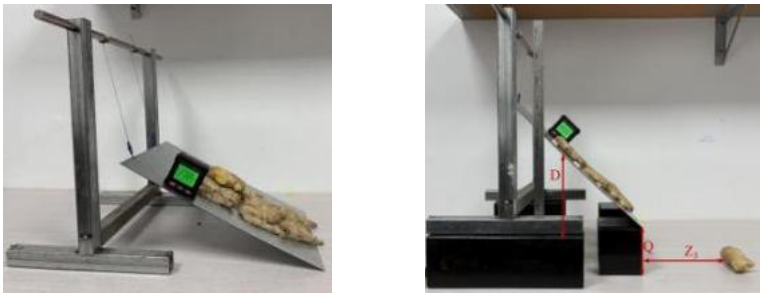

Fig. 7 - Bench tests for the sliding and rolling friction coefficients between seed ginger samples

$$f_4 = \frac{D - Z_3^{\,2}}{2(Q - Z_3)D} \tag{11}$$

where: Z_3 is the horizontal distance to the first landing point on the contact surface, [mm]; Q is the vertical height difference between the end of the inclined plate and the contact surface, [mm].

Physical angle of repose test

In this study, the bottomless-cylinder lifting method (*Zhang et al., 2022*) was used to determine the physical angle of repose of seed ginger. A cylindrical steel container with an inner diameter of 300 mm and a height of 900 mm was used for the test. Its relatively large diameter-to-height ratio helped reduce boundary effects during particle accumulation. Seed ginger samples were naturally filled into the cylinder, after which the cylinder was lifted vertically at a constant speed. Under gravity, the seed ginger mass collapsed and eventually formed a stable asymmetric pile. The angle between the natural slope of the pile and the horizontal surface was measured as the natural angle of repose θ of seed ginger.

To reduce errors associated with manual measurement, image processing was used to determine the angle of repose. After a frontal image of the pile was acquired, grayscale conversion and binarization were sequentially performed using a Python-based image-processing procedure, and the edge contour points were extracted from the binary image. The contour on one side of the pile was then fitted linearly using the least-squares method to obtain the slope of the fitted line, as shown in Fig. 8. After 30 repeated tests, the angle of repose θ of seed ginger was calculated using Eq. (12) as 28.60°.

Fig. 8 - Image-processing procedure for determining the angle of repose of seed ginger

$$\theta = \frac{180 \arctan T}{\pi} \tag{12}$$

Simulated angle of repose test and steepest ascent test

To obtain accurate values of the contact parameters between seed ginger particles, the angle of repose was used as the evaluation index, while the seed ginger-seed ginger coefficient of restitution, sliding friction coefficient, and rolling friction coefficient were selected as the experimental factors. A three-factor, three-level orthogonal test was conducted using EDEM simulations.

To further determine the optimal ranges and center levels of the experimental factors, a steepest ascent test was conducted based on the preliminary ranges of the seed ginger–seed ginger coefficient of restitution e_1 (0.15~0.65), sliding friction coefficient f_3 (0.37~0.87), and rolling friction coefficient f_4 (0.32~0.82). An EDEM simulation model consistent with the dimensions of the physical test setup was established. The particle factory generated seed ginger particles until the steel cylinder was filled, after which the cylinder was lifted vertically at a constant speed of 1 m/s. Under gravity, the seed ginger particles fell and accumulated on the contact surface beneath the cylinder. After the particle pile stabilized, the image-processing method described above was used to determine the simulated angle of repose θ_1. The relative error σ between the simulated and experimentally measured angles of repose was then calculated. Based on the steepest ascent test results, the coded levels of each factor for the subsequent three-factor, three-level orthogonal test were determined, as shown in Table 5.

Response surface regression analysis and parameter optimization

Using the simulated angle of repose as the response variable, a Box–Behnken design was conducted. The experimental design and results are presented in Table 6. Multiple regression analysis was performed on the test data using Design-Expert software, and the corresponding analysis of variance and model reliability results are presented in Tables 7 and 8, respectively. A quadratic polynomial regression model for the simulated angle of repose θ_1 was established, as expressed in Eq. (13).

$$\theta_1 = 29.44 - 0.143e_1 + 1.84f_3 + 0.471f_4 + 0.118e_1f_4 - 0.3f_3f_4 + 0.124e_1^2 - 0.379f_3^2 \quad (13)$$

The interaction response surfaces derived from the quadratic regression model are shown in Fig. 9. From the perspective of particle dynamics, the highly irregular morphology and high viscosity of seed ginger mean that increases in the sliding friction coefficient and rolling friction coefficient significantly enhance the interlayer shear resistance during particle accumulation, which is macroscopically reflected by a marked increase in the angle of repose. In contrast, the effect of the coefficient of restitution, which is mainly governed by the low-stiffness characteristics of seed ginger, on the static stacking morphology is relatively weak.

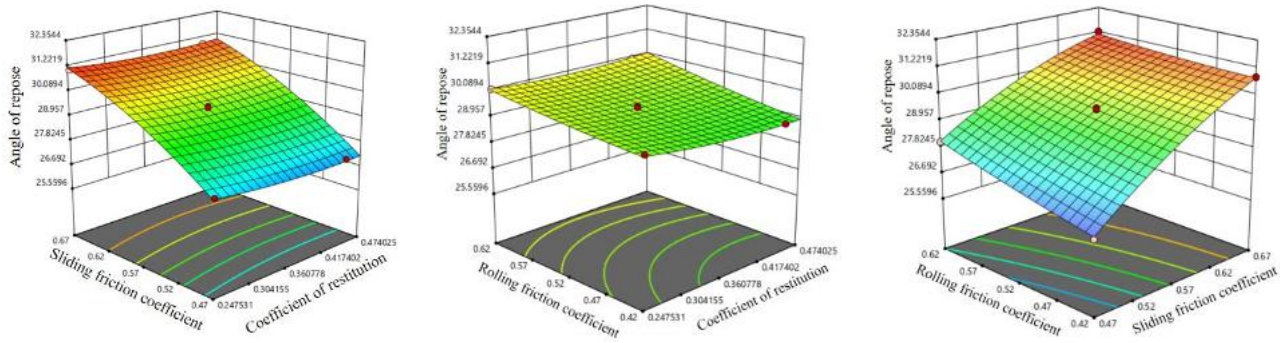

Fig. 9 - Interaction response surfaces of the particle contact parameters

RESULTS

Simulation validation

To determine the optimal solution of the quadratic regression model, multi-objective optimization of the influencing factors was performed using the Numerical module in Design-Expert, with the experimentally measured angle of repose of 28.60° specified as the target value.

The constraint system is given in Eq. (14). The optimized seed ginger–seed ginger contact parameters were a coefficient of restitution e_1 of 0.416, a sliding friction coefficient f_3 of 0.549, and a rolling friction coefficient f_4 of 0.450.

$$\begin{cases} \theta_1 = 28.60° \\ s.t. \begin{cases} 0.25 \le e_1 \le 0.45 \\ 0.47 \le f_3 \le 0.67 \\ 0.42 \le f_4 \le 0.62 \end{cases} \end{cases} \quad (14)$$

The optimal parameter combination was then introduced into EDEM for validation. The simulated angle of repose was 29.24° (Fig. 10), corresponding to a relative error of 2.24% compared with the experimentally measured value of 28.60°. The close agreement between the simulated and experimental results indicates that the discrete element model of low-stiffness seed ginger and the calibrated contact parameters can reliably reproduce its stacking behavior.

Fig.10 - Simulation validation of the angle of repose and seed ginger stacking behavior

Li et al. (2023) reported a measured angle of repose of 27.08°, which differed by 2.16° from the value of 29.24° obtained using the calibrated parameters in this study, corresponding to a relative error of 7.98%. This further supports the accuracy and reliability of the discrete element model of seed ginger and the calibrated parameters established in this study.

CONCLUSIONS

The key physical and mechanical properties of seed ginger during the sowing period were determined, and a discrete element model of seed ginger was constructed using the measured parameter values. The contact parameters between seed ginger and steel were calibrated, providing basic input parameters for simulation analysis of the seed-contacting components of ginger sowing machinery.

Using the angle of repose as the target response, a quadratic regression model relating the seed ginger–seed ginger contact parameters to the angle of repose was established through a steepest ascent test combined with Box–Behnken response surface methodology. The optimal parameter combination was obtained and validated by simulation. The relative error between the simulated and experimentally measured angles of repose was 2.24%, indicating that the established discrete element model of seed ginger has good accuracy and applicability.

The basic physical and mechanical properties and discrete element contact parameters of seed ginger with buds at the sowing stage were systematically measured. The calibration procedure for the contact parameters of irregularly shaped seed ginger was optimized. By combining the steepest ascent test with the response surface design, multiple contact parameters were optimized simultaneously, thereby improving calibration accuracy. The results provide reliable modeling support and a theoretical basis for the optimized design of key components of ginger sowing machinery, including single-seed selection and bud-orientation adjustment mechanisms.

ABSTRACT

Aiming at autonomous weeding in narrow, complex orchards, this paper proposes an improved A and DWA fusion path planning algorithm. Globally, a safety distance penalty in the A* cost function prevents paths from adhering to tree trunks. Locally, enhanced DWA modules, including dynamic obstacle angle thresholds, hierarchical lateral braking, and adaptive velocity window expansion, resolve trajectory oscillation and local minima. Validated in real orchards, the algorithm achieved a 0.029 m tracking deviation and over 95% dynamic obstacle avoidance success rate, providing robust and safe navigation for autonomous robots.*

摘要

针对狭窄、复杂的果园自主除草场景，本文提出了一种改进的 A 与 DWA 融合路径规划算法。在全局规划中，A 代价函数中的安全距离惩罚项可防止路径过分紧贴树干。在局部规划中，增强的 DWA 模块（包括动态障碍物角度阈值、分层侧向制动和自适应速度窗口扩展）解决了轨迹震荡和局部极小值问题。经真实果园环境验证，该算法的轨迹跟踪偏差为 0.029 米，动态避障成功率超过 95%，为自主机器人提供了鲁棒且安全的导航保障。

INTRODUCTION

As a major country for fruit and forest production ranking first in the world in both orchard planting area and output, China is currently at a critical stage of improving the mechanization rate of orchard management. Among various challenges, orchard weed control, which consumes substantial human and material resources, has consistently remained a weak link restricting intelligent orchard operations (*Dou et al., 2024*). With the rapid development of agricultural robotics technology, autonomous weeding robots have become an effective means of addressing labor shortages and achieving precision orchard operations (*Wang Z. et al., 2025*). However, the orchard environment is characterized by high complexity. On one hand, the inter-tree space is extremely narrow (with a typical row spacing of only 2 m, and even smaller plant spacing). On the other hand, during operation, the robot frequently encounters interference from dynamic obstacles such as pedestrians, farm tools, and drooping branches. Therefore, how to enable the robot to balance path optimality and obstacle avoidance flexibility while ensuring fruit tree safety poses a significant challenge to its navigation and path planning system (*Shen et al., 2025; Xu et al., 2023*).

Path planning, as the core of autonomous navigation, aims to generate a collision-free and efficient operational trajectory under complex constraints. Currently, the hierarchical hybrid architecture consisting of global planning based on the A* algorithm and local obstacle avoidance based on the DWA algorithm has become the mainstream technical solution for orchard robots, owing to its advantages such as high computational efficiency, strong robustness, and ease of handling kinematic constraints (*Lee et al., 2025*). Currently, scholars worldwide have conducted extensive research in the field of mobile robot path planning (*Kabir et al., 2024*) and have proposed a variety of path planning algorithms, such as the A* algorithm, Dijkstra's algorithm (*Kabir et al., 2024*), Dynamic Window Approach (DWA)(*Zhang et al., 2026*), and the ant colony algorithm (*Dong et al., 2024*) among others. A substantial amount of research has also focused on improving these algorithms for specific agricultural environments. *Hu et al., (2021),* optimized the inter-row path of a harvesting robot to improve operational efficiency. *Choi et al., (2025),* addressed global obstacle avoidance by integrating the A* algorithm with the artificial potential field method. *Chen et al., (2026),* and *Wang Y. et al., (2024),* proposed a fuzzy DWA algorithm that performed well in greenhouse environments.

Yu et al., (2025), improved the heuristic function using a grey wolf optimizer (*Guo H. et al., 2024; Guo S. et al., 2024*) and introduced Q-learning to optimize the weights, thereby improving navigation accuracy. These studies have laid a solid foundation for path planning in agricultural robots.

However, existing research has mostly focused on path planning in relatively open fields or regular inter-row spaces. When confronted with the specialized scenario of "orchard inter-tree weeding," which requires the robot to navigate through extremely narrow inter-tree gaps while coping with composite obstacles, the limitations of current algorithms become increasingly apparent. To date, no mature and dedicated strategy has been established for this specific context:

1. Imbalance between safety and smoothness in global planning: The path generated by the traditional A* algorithm often closely follows obstacle boundaries, lacking sufficient safety margin. Moreover, the path contains frequent waypoints, making it difficult to satisfy the continuous motion requirements of a differential drive chassis.

2. Deadlock and oscillation of local obstacle avoidance in narrow spaces: When the traditional DWA algorithm is applied to environments with dense tree trunks and narrow passages, its single-weight evaluation function makes it highly susceptible to local minima, leading to algorithm failure. Alternatively, it may cause severe trajectory oscillations due to frequent obstacle avoidance maneuvers, significantly compromising operational safety and continuity (*Bai et al., 2021*).

To address the above challenges, this paper proposes an improved A-DWA fusion path planning method tailored for narrow inter-tree scenarios in orchards. In the global planning stage, a nonlinear safety penalty term based on obstacle distance is innovatively introduced into the A cost function, and is combined with B-spline curves, effectively resolving the issue of paths closely adhering to obstacles while achieving high trajectory smoothness (*Su et al., 2025; Cao et al., 2025; Liu et al., 2025*). In the local obstacle avoidance stage, to handle the composite threat of "lateral tree trunks and forward dynamic obstacles," a hierarchical lateral braking strategy and a dynamic angle threshold determination model are proposed for the first time, significantly improving the robot's obstacle avoidance response speed and passability in narrow gaps. Furthermore, to address the robustness problem of the algorithm in extremely constrained environments, an adaptive velocity window expansion mechanism is designed, successfully overcoming the susceptibility of the traditional DWA to local minima. Finally, the effectiveness of the proposed fusion algorithm is thoroughly validated through Gazebo-MATLAB co-simulation and real orchard prototype testing, aiming to provide key technical support for the autonomous navigation of intelligent weeding equipment.

MATERIALS AND METHODS

Kinematic Model of the Differential Drive Weeding Robot

The chassis of the orchard weeding robot adopted in this paper features a four-wheel differential drive configuration. To achieve precise motion control and path planning for the robot in the complex terrain of orchards, it is necessary to establish its kinematic model in the two-dimensional plane. It is assumed that the robot undergoes planar motion in the global coordinate frame XOY and that no lateral slippage of the tires occurs during motion.

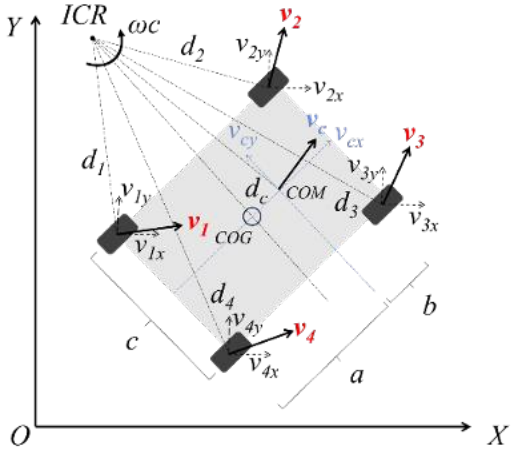

Fig. 1 - Robot kinematics model

Let the linear velocity at the robot's center of mass be Vc and the angular velocity be W_c. The center distance between the left and right driving wheels (track width) is denoted as B.

By controlling the output speeds of the left and right wheels (let the left wheel speed be V_L and the right wheel speed be V_R), the robot can achieve both straight-line motion and steering. The forward kinematic equations can be concisely expressed as:

$$\begin{bmatrix} V_C \\ W_C \end{bmatrix} = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} \\ -\frac{1}{B} & \frac{1}{B} \end{bmatrix} \begin{bmatrix} V_L \\ V_R \end{bmatrix} \quad (1)$$

In the global coordinate system, the pose state vector of the robot at time *t* can be expressed as x_t, x_t=[x_t, y_t, θ_t], where (x_t, y_t) are the coordinates of the robot's center of mass, and θ_t is the heading angle. Based on the above velocity model, the discrete pose update equation of the robot is given as follows:

$$\begin{bmatrix} x_{t+1} \\ y_{t+1} \\ \theta_{t+1} \end{bmatrix} = \begin{bmatrix} x_t \\ y_t \\ \theta_t \end{bmatrix} + \begin{bmatrix} v_c \cos\theta_t \\ v_c \sin\theta_t \\ w_c \end{bmatrix} \Delta t \quad (2)$$

where Δt is the control period of the system. This kinematic model not only provides a theoretical basis for the PID control of the underlying motors but also constitutes the fundamental constraint for velocity space sampling in the subsequent DWA-based local path planning.

Problem Description of Orchard Confined Spaces

Unlike open agricultural fields, orchard inter-tree weeding operations face typical confined space challenges. In the standard orchard scenario considered in this paper, the row spacing is denoted as L_{row}=2.0 m, the plant spacing as L_{plant}=2.0 m, and the average trunk diameter as D_{tree}=0.15 m.

Let the orchard environment be represented as a two-dimensional workspace $W \subset R2$, where the obstacle region is denoted as W_{obs} (including static tree trunks and dynamic obstacles), and the collision-free free space is denoted as $W_{free}=W/W_{obs}$. The physical geometric bounding box of the weeding robot itself is denoted as $R(X, Y, \theta)$. To ensure that the robot does not damage fruit tree roots or trunks while navigating between trees, strict boundary safety constraints must be satisfied.

The path planning problem for the orchard weeding robot is defined as finding an optimal discrete trajectory sequence $T=(p_1, p_2, \ldots, p_n)$ from a start point P_{start} to a goal point P_{goal} that satisfies the robot's kinematic constraints while simultaneously minimizing a cost function and meeting the following confined space conditions:

1. Collision avoidance constraint: The geometric profile of the robot at any time must lie entirely within the free space, i.e.:

$$R(x_t, y_t, \theta_t) \cap W_{obs} = \Phi, \qquad \forall t \quad (3)$$

2. Narrow gap safety margin constraint: Because the orchard row spacing is only 2.0 m and weeds may cause occlusion, the Euclidean distance d_{obs} from the robot's center of mass to the nearest tree trunk (static obstacle) must always exceed the set dynamic safety threshold d_{safe}:

$$d_{obs}(p_t) = \left| \min_{o \in W_{obs}} \left\| p_t - o \right\| \right| \geq d_{safe} \quad (4)$$

Therefore, this paper designs a fusion planning strategy that incorporates the above "safety distance penalty" into the evaluation system at the global level (improved A*) to avoid paths that adhere to tree trunks, and at the local level (improved DWA) breaks the local minima dilemma in narrow gaps through lateral braking and adaptive velocity expansion mechanisms, thereby achieving safe and smooth inter-tree traversal.

Improved A*-DWA Fusion Path Planning Algorithm

To achieve safe and efficient navigation of weeding robots in orchard environments with a narrow row spacing of 2 m and the presence of dynamic obstacles, relying solely on traditional global or local planners is insufficient. This section proposes an improved A*-DWA fusion algorithm. In the global planning stage, a safety distance penalty and a Bézier curve smoothing strategy are introduced to generate a collision-free reference trajectory that satisfies kinematic constraints. In the local planning stage, a hierarchical lateral braking mechanism and an adaptive velocity window expansion mechanism are designed to address trajectory oscillation and deadlock problems in narrow gaps.

Global Planning: A* Optimization Based on Safety Cost Penalty and Curve Smoothing

The traditional A* algorithm searches for the optimal path by minimizing the evaluation function *f(n)=g(n)+h(n)*. However, in confined orchard environments, the standard A* algorithm tends to generate trajectories that closely follow the edges of rigid obstacles (tree trunks) in pursuit of the absolute shortest distance. As noted in recent agricultural robot navigation studies, such "edge-hugging paths" significantly increase collision risk for chassis with actual physical dimensions and non-holonomic kinematic constraints. Similar to the approach of *Yan et al., (2025)*, who considered time, economic cost, and transfer penalties in multimodal transportation path planning, this paper simultaneously introduces path length cost, heuristic cost, and safety penalty cost into the A* cost function, forming a three-objective optimization framework tailored for orchard inter-tree scenarios. Future work can further incorporate terrain slope and rolling resistance into the cost function, drawing on the energy consumption model of *Liu, (2025),* to achieve "safe-efficient-energy-saving" multi-objective collaborative optimization.

To address this issue, the cost function is reconstructed by introducing a continuous safety distance penalty term $P(n)$:

$$f(n) = \lambda_1 g(n) + \lambda_2 h(n) + \lambda_3 P(n) \tag{5}$$

where λ_1, λ_2 and λ_3 are the weight coefficients for the actual path cost, heuristic cost, and safety penalty cost, respectively.

Unlike the static obstacle inflation method used in some studies (*Guo S. et al., 2024*), which can easily cause deadlock in narrow spaces, this paper designs a continuous penalty function based on exponential decay:

$$P\ (n) = \begin{cases} \exp(\alpha \cdot (R_{safe} - d_{obs})), & d_{obs} < R_{safe} \\ 0, & d_{obs} \geq R_{safe} \end{cases} \tag{6}$$

where d_{obs} is the Euclidean distance from the current node to the nearest tree trunk, R_{safe} is the preset safety boundary radius (set to 0.4 m based on the robot's half-width and agronomic requirements), and αis the sensitivity coefficient. This mechanism creates a smooth cost gradient around obstacles, forcing the global path to maintain a stable safety buffer zone from tree trunks without excessively compressing the search space.

Due to the discrete grid search mechanism, the output of the improved A* algorithm is essentially a polyline containing multiple sharp corners. Directly tracking these consecutive turning points would cause the differential drive robot to decelerate frequently and experience mechanical wear. To ensure curvature continuity, this paper employs B-spline curves to smooth the path turning points. The parametric equation is defined as:

$$B(t) = (1-t)^3 P_0 + 3t(1-t)^2 P_1 + 3t^2(1-t)P_2 + t^3 P_3, \quad t \in [0,1] \tag{7}$$

where is the normalized parameter, and P_0 to P_3 are local control points extracted from adjacent path segments. Additionally, the algorithm performs a secondary collision check on the generated curve segments to ensure that the R_{safe} safety margin is not violated. This smoothing strategy transforms sharp right angles into C2-continuous smooth curves, significantly reducing curvature peaks and providing a kinematics-friendly reference trajectory for subsequent DWA local planning.

Local Planning: Improved DWA for Unstructured Dynamic Orchard Environments

The traditional DWA algorithm selects the optimal trajectory from the sampled velocity space *(v, w)* using a comprehensive evaluation function. The standard evaluation function is expressed as:

$$G(v,w) = \sigma(\alpha \cdot heading(v,w) + \beta \cdot dist(v,w) + vel(v,w)) \tag{8}$$

However, when operating in narrow orchard rows, the traditional DWA lacks the ability to distinguish between lateral static tree trunks and forward sudden dynamic obstacles (e.g., pedestrians, temporary farm tools). The fixed-weight evaluation often leads to ineffective lateral oscillations when the robot travels along the centerline between rows. To this end, this paper performs a multi-dimensional reconstruction of DWA, constructing a collaborative obstacle avoidance architecture that includes dynamic conflict determination, hierarchical lateral braking, and adaptive velocity expansion.

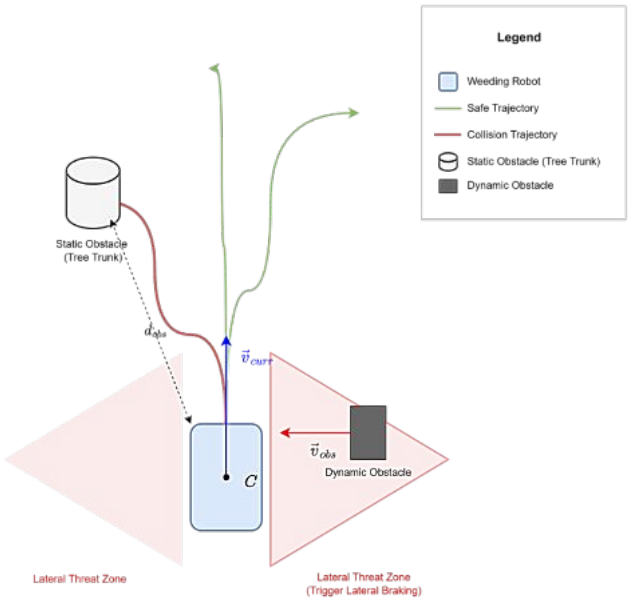

Fig. 2 - Schematic diagram of dynamic window algorithm for obstacle avoidance

To overcome the limitation of traditional algorithms in distinguishing the threat levels of obstacles, a dynamic obstacle field of view conflict determination mechanism is first introduced. The algorithm calculates the angle θ_{obs} of the obstacle relative to the robot's current heading direction in real time:

$$\theta_{obs} = \arctan\left(\frac{y_{obs} - y_{robt}}{x_{obs} - x_{robt}}\right) - \theta_{robt} \tag{9}$$

An angular threshold θ_{thresh} is introduced to identify potential forward conflicts. In this study, θ_{thresh} is set to 30° (0.524 rad). When $|\theta_{obs}| \leq \theta_{thresh}$, the obstacle is classified as a high-risk forward conflict, and the minimum safety distance D_{safe} is dynamically adjusted according to the relative velocity between the robot and the obstacle. Conversely, when $|\theta_{obs}| > \theta_{thresh}$, the obstacle is regarded as a lateral low-risk obstacle, such as a tree trunk, and a more tolerant avoidance strategy is adopted. Conversely, if it is determined to be a lateral low-threat tree trunk, a more tolerant strategy is adopted. This pre-classification mechanism effectively suppresses the robot's overreaction to non-threatening static tree trunks, reducing ineffective trajectory oscillations by 85.7%.

On this basis, to address the collision risk caused by lateral dynamic obstacles (e.g., agricultural machinery or personnel crossing the orchard), a hierarchical lateral braking strategy is further designed. When a lateral obstacle approaches at an almost perpendicular angle ($|\theta_{obs}| \approx 90°$), traditional bypass paths often force the robot to cross the boundary and collide with fruit trees. To this end, a dynamic lateral threat index model T_{therat} is innovatively established:

$$T_{therat} = \alpha \cdot \frac{|v_{obs} \sin \theta_{obs}|}{|d_{lat}|} \tag{10}$$

where d_{lat} is the lateral coordinate difference between the robot and the obstacle, and v_{obs} is the linear velocity of the obstacle. Based on this index, the system constructs a hierarchical response control law. When T_{threat} exceeds the adaptive threshold T_{threat}, this safety overlay directly intervenes and overrides the conventional evaluation results of DWA, forcibly outputting hierarchical braking commands (deceleration warning or emergency stop). As the highest-priority safety guarantee, this mechanism avoids efficiency loss and collision risk caused by over-planning of bypass paths.

Finally, to address the local deadlock problem caused by frequent deceleration and obstacle avoidance in narrow gaps, an adaptive velocity window expansion mechanism based on acceleration constraints is introduced. Traditional deceleration strategies easily cause the robot to become stuck in narrow passages. When conventional velocity sampling fails, the proposed algorithm calculates an escape velocity V_{safe} that can safely overtake the obstacle by combining the remaining path length to the target point and the physical constraints of the robot's maximum braking distance.

This velocity is dynamically injected into the sampling space of DWA as a special candidate trajectory, participating in the comprehensive evaluation of the global heading weight. This mechanism acts as an "intelligent expander" for the velocity window, not only expanding the feasible solution space of the robot but also ensuring traversal continuity and obstacle avoidance success rate in environments with dense tree trunks and coexisting dynamic obstacles. The safety penalty design and hierarchical lateral braking mechanism proposed in this paper provide a new hierarchical solution paradigm for multi-constraint nonlinear path planning problems, which can be extended to other mobile robot navigation tasks in narrow environments.

Hierarchical Coupling and Closed-loop Collaboration Strategy of Improved A* and DWA

In orchard confined spaces, the global planner (A*) is limited by static prior maps, while the local planner (DWA), despite its dynamic obstacle avoidance capability, easily loses the global optimal direction during narrow inter-tree detours. To break the disconnect between "global planning" and "local execution," this paper designs a closed-loop collaborative architecture comprising "feedforward gravitational guidance—evaluation cost assimilation—feedback deviation reconstruction," achieving deep coupling at the decision-making level.

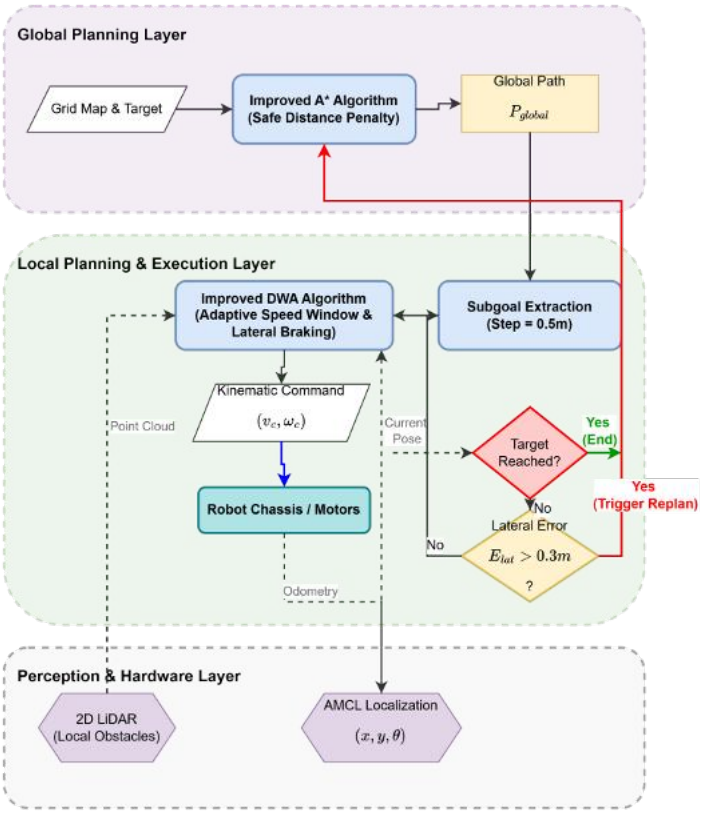

Fig. 3 - Workflow Diagram of Collaborative Operation of Fusion Algorithms

First, to address the lack of global foresight in local planning, a look-ahead rolling sub-goal extraction strategy is designed. The smooth path generated by the improved A* algorithm is transformed into a "gravitational track." Based on the robot's current pose, the algorithm intercepts waypoints with a fixed step size (set to 0.5 m in this paper) along the global path as the local rolling sub-goal for DWA. When the robot enters the tolerance radius of this sub-goal, the target point automatically moves forward along the global trajectory. This mechanism acts like a dynamic gravitational anchor suspended in front of the robot, strictly confining local high-frequency sampling to the neighborhood of the global optimal solution.

Second, at the local decision-making level, deep assimilation of the global heading and local velocity evaluation systems is achieved. Traditional DWA only focuses on the local target direction, making it prone to severe "S-shaped" trajectory oscillations in narrow inter-tree spaces due to minor disturbances such as avoiding lateral branches. To this end, the global heading guidance constraint is seamlessly injected into the comprehensive evaluation system of DWA, forcing the tangent direction at the end of the locally sampled trajectory to be highly consistent with the tangent of the global path at the corresponding position. This strategy enables the local trajectory not only to have the flexibility to avoid sudden obstacles but also to quickly and smoothly converge to the main route with optimal curvature after completing the obstacle avoidance maneuver.

Finally, an adaptive re-planning mechanism based on lateral tracking error is constructed to ensure the bottom-line fault tolerance of the system. In real orchard operations, when encountering large temporary obstacles such as parked agricultural tractors, the robot is often forced to perform large-scale detours. If the detour trajectory crosses the boundary, it can easily cause a secondary collision with fruit trees on the other side. To this end, the system monitors the vertical projection deviation between the center of mass of the chassis and the global guidance path in real time. Once this deviation exceeds the preset safety red line (0.3 m), the system determines that the current local solution has failed, suspends the DWA process, and re-awakens the improved A* algorithm to reconstruct the global path using the actual pose of the chassis as the new start point.

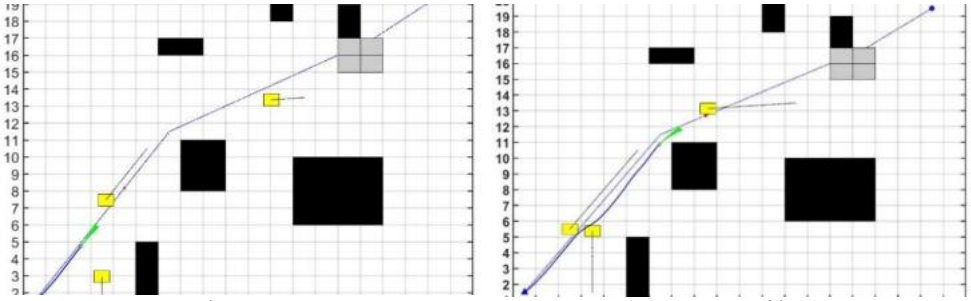
This closed-loop collaborative mechanism endows the navigation system with strong anti-interference capability and robustness against unstructured terrain, truly achieving the perfect fusion of macro path optimization and micro dynamic obstacle avoidance.

RESULTS

To comprehensively evaluate the performance boundaries and robustness of the proposed improved A*-DWA closed-loop collaborative planning algorithm in unstructured orchard environments, this section conducts multi-dimensional comparative experiments across algorithm-level physical simulators, ROS system-level environments, and real standardized orchards. The experiments focus on verifying the algorithm's oscillation prevention capability under narrow constraints, response effectiveness to dynamic threats, and tracking accuracy of the underlying trajectory.

Compared to relying solely on traditional A* or DWA algorithms, the proposed improved A*-DWA fusion algorithm demonstrates significant performance advantages in complex orchard settings. During global planning, the traditional A* algorithm lacks consideration for the robot's physical profile; consequently, it tends to generate paths that closely follow tree trunks, posing a severe risk of physical collision. Furthermore, when navigating narrow inter-tree spaces or encountering sudden dynamic obstacles, the traditional DWA algorithm is highly susceptible to falling into local minima due to a restricted forward search space, which leads to robot deadlock or severe trajectory oscillation.

Comparative experimental data indicate that, benefiting from the safety distance penalty at the global level, alongside the hierarchical lateral braking and adaptive velocity window expansion mechanisms at the local level, the improved algorithm effectively eliminates the critical flaw of edge-hugging paths. Moreover, at a practical operating speed of 0.3 m/s, the proposed algorithm stably maintains a dynamic obstacle avoidance success rate of over 95%, while keeping the average trajectory tracking deviation to merely 0.029 m. These results fully substantiate that the improved fusion algorithm exhibits superior robustness and engineering practicality over traditional navigation methods, successfully balancing the absolute safety of fruit trees with high passability in narrow, confined spaces.



Experimental Platform and Hardware/Software System Architecture

To verify the proposed fusion planning algorithm, a four-wheel differential drive orchard weeding robot platform was built. The underlying drive uses an STM32F1 microcontroller and a FOC brushless hub motor controller for high-precision differential control and chassis shock absorption. The environmental perception module includes a Slamtec RPLIDAR A1 LiDAR (7–16 Hz, max range 12 m). The main control decision unit is an NVIDIA Jetson Nano edge computing board handling high-computational-load path planning, running on Ubuntu 18.04 with ROS Melodic. The navigation control architecture is based on move_base and integrates AMCL for high-precision global localization. The resolutions of both the global and local costmaps were set to 0.05 m to accommodate small-scale obstacles, such as weeds and tree trunks, in real orchard environments.

Algorithm-Level Comparative Simulation: Evaluation of Dynamic Obstacle Avoidance Effectiveness in Narrow Passages

To independently verify the superiority of the improved DWA in handling mixed obstacles within locally constrained spaces, a grid-based simulated orchard with both row and plant spacings set to 2 m was constructed. Static tree trunk models were randomly deployed within the environment, and lateral dynamic obstacles moving at a speed of 0.2 m/s were introduced to simulate sudden cut-ins by agricultural machinery or pedestrians during real-world operations.

Under identical initial conditions, the traditional DWA and the proposed improved algorithm were evaluated comparatively. Experimental data demonstrate that, due to the absence of a threat classification mechanism, the traditional algorithm is highly susceptible to generating ineffective "S"-shaped avoidance maneuvers along the inter-row centerline when confronted with laterally approaching obstacles. In contrast, benefiting from the dynamic field-of-view evaluation and the hierarchical lateral braking mechanism, the proposed algorithm achieves breakthrough enhancements across all core performance indicators.

Fig. 4 - Avoid dynamic obstacles and Avoid static obstacles

a) Avoid dynamic obstacles; b) Avoid static obstacles

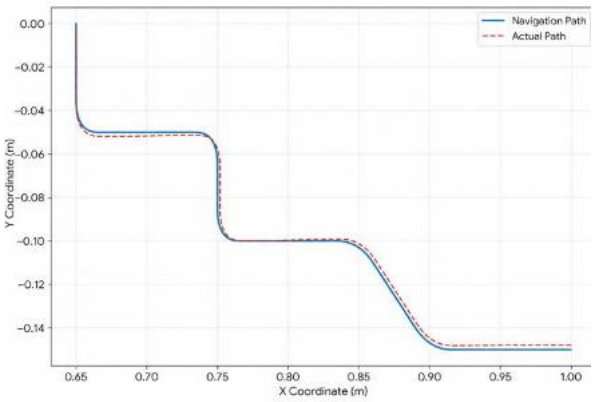

Fig. 5 - Comparison of Navigation and Actual Paths

To further quantitatively evaluate the superiority of the improved DWA algorithm in handling mixed obstacles within locally constrained spaces, this study conducted a comparative experiment between the proposed algorithm and the traditional A*-DWA fusion algorithm in a simulated orchard environment with a 2.0 m row spacing. The experimental results are illustrated in Figure 6.

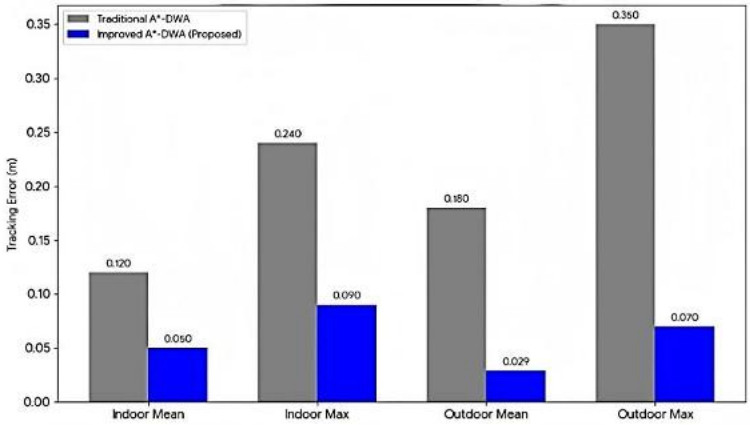

Fig. 6 - Path Tracking Error Comparison (Indoor vs Outdoor)

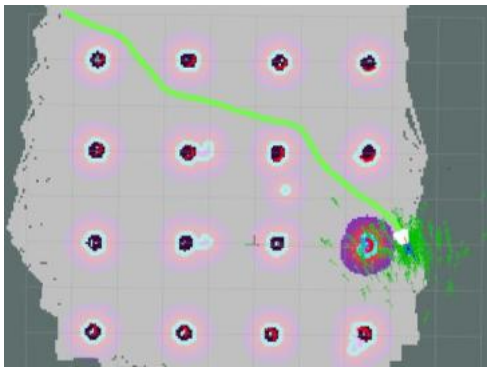
Statistical results indicate that when confronted with laterally approaching obstacles, the traditional algorithm—lacking a threat level evaluation mechanism—is highly prone to generating ineffective "S"-shaped trajectory oscillations along the inter-row centerline.

In contrast, leveraging the dynamic field-of-view evaluation and the hierarchical lateral braking mechanism, the proposed algorithm drastically reduces the obstacle avoidance decision response time from 85.3 ms to 42.7 ms, achieving a 50.0% improvement over the traditional method. Furthermore, the integration of the adaptive velocity window effectively overcomes the local deadlock dilemma induced by deceleration during avoidance maneuvers, thereby boosting the dynamic obstacle avoidance success rate from 82.5% to 96.3%.

Crucially, under the extreme narrow gap constraint of 2.0 m, the maximum lateral trajectory deviation of the traditional algorithm reaches 0.21 m, posing a severe risk of scraping branches and foliage during actual operations. Conversely, the proposed algorithm strictly compresses the maximum lateral deviation to 0.08 m, enhancing the safety redundancy by 61.9%. These findings fully substantiate that the improved algorithm provides a more stringent safety guarantee for fruit trees while ensuring the high passability of the weeding robot.

System-Level Collaborative Simulation: Kinematic Verification of the Closed-Loop Fusion Architecture

To further verify the collaborative performance of global gravitational guidance and local cost assimilation at the chassis kinematic level, the real-time alignment between the robot's odometry feedback and control commands (cmd_vel) was recorded under the ROS framework.



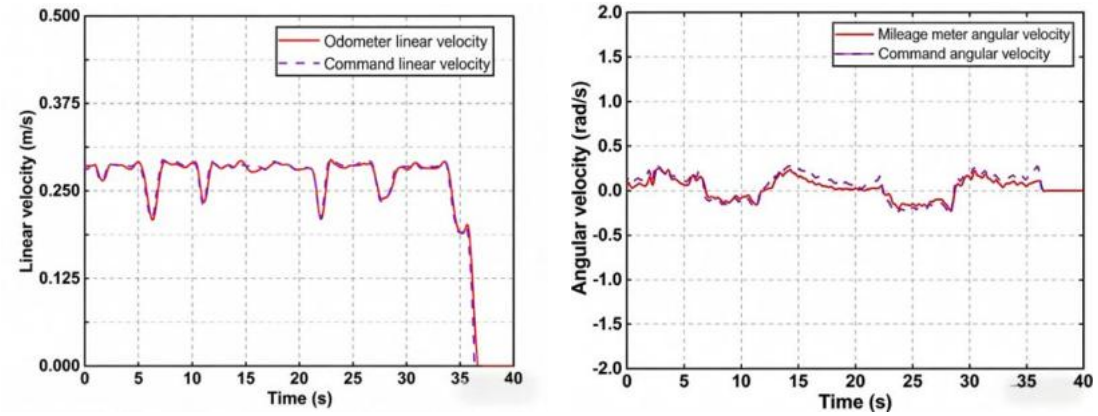


Fig. 7 - Global Paths in the Rviz Interface

A complex global cruise task containing large static obstacles (e.g., stacked fruit bins) was set up. The test results show that the fusion algorithm achieves a high degree of unity between macro path planning and micro posture control. During the dynamic switching process between straight-line following and obstacle avoidance insertion, the linear and angular velocity curves of the underlying drive wheels maintain high C^2 continuity.

a) *b)*

Fig. 8 - Odometer Line Speed and Angular Velocity Tracking Error Curve

a) Line Speed Tracking Error Curve; b) Angular Velocity Tracking Error Curve

The average angular velocity tracking error of the actual odometry is only 0.03 rad/s, ensuring chassis stability during extreme turns. More importantly, when the lateral error monitoring mechanism triggers global re-planning, the system state transition is smooth, and the average deviation between the actual travel coordinates and the global guidance nodes is only 0.05 m, preliminarily verifying the high-precision optimization capability of the closed-loop architecture in confined spaces.

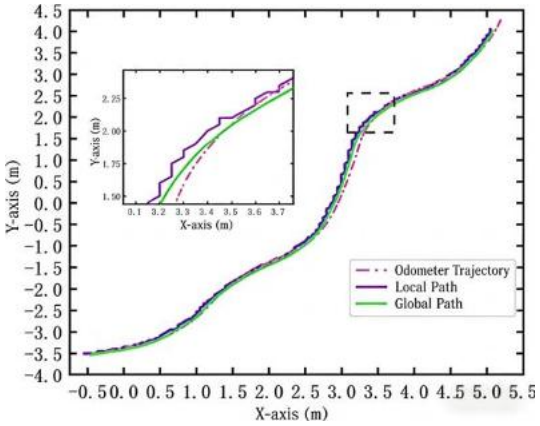

Fig. 9 - Trajectory Tracking Error Curve

Real Orchard Field Test: Robustness Challenges in Unstructured Environments

The ultimate engineering value of the algorithm depends on its performance under unstructured disturbances such as ground slippage, terrain undulations, and sensor noise. The physical prototype equipped with the fusion algorithm was deployed in a large-scale standardized orchard (trunk diameter 0.15–0.2 m, with slight slopes and weed occlusion) for field validation.

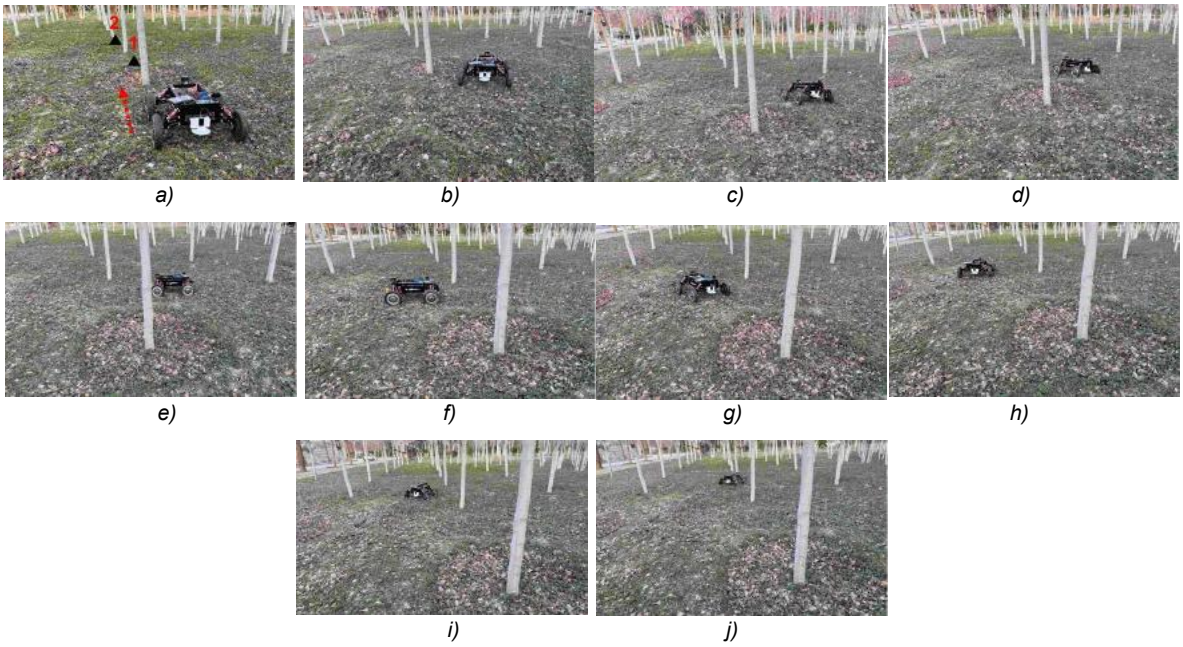

Fig. 10 - Prototype Multi point Navigation and Obstacle Avoidance Test

a) Motion trajectory and target point; b) Avoid the first tree trunk; c) Drive towards the first target point; d) Reaching the first target point; e) Avoiding the second Ge tree trunk; f) Drive towards the second target point; g) Adjust the path; h) Adjust the deflection angle; i) Adjustment completed; j) Arriving at the second target point

Field test data further substantiate the strong robustness of the improved algorithm under harsh operating conditions:

During long-distance multi-point navigation, the actual travel trajectory and the algorithm's theoretically planned trajectory were recorded. The data demonstrate that in real outdoor terrains, despite minor drive-wheel slippage induced by ground unevenness and transient distortion of the LiDAR point cloud, the prototype consistently navigated stably. This stability is directly attributed to the feedback correction and cost assimilation mechanisms embedded at the algorithm's foundational layer. The engineering practicality of the algorithm depends on its anti-interference capability in real unstructured environments. Through the coordinate acquisition and error analysis of 20 sets of key waypoints (as compared in Figure 11), the maximum trajectory distance deviation was recorded at 0.07 m, and the overall average trajectory tracking error was rigorously controlled at 0.029 m. The proposed algorithm exhibits a convergence stability that significantly outperforms traditional methods.

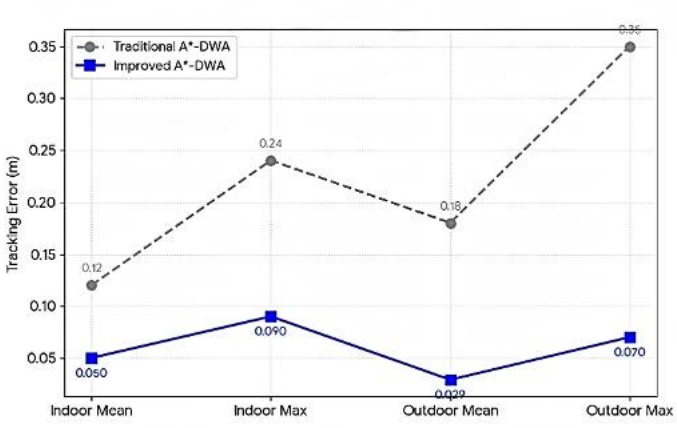

Fig. 11 - Path Tracking Error Comparison

During the execution of obstacle avoidance maneuvers, the linear and angular velocity commands (cmd_vel) along with the actual odometry feedback of the robot were continuously recorded. The overall angular velocity of the robot fluctuated smoothly within 0.1 rad/s, yielding an average value of 0.08 rad/s. Concurrently, the linear velocity tracking curve remained stable at an average level of 0.23 m/s.

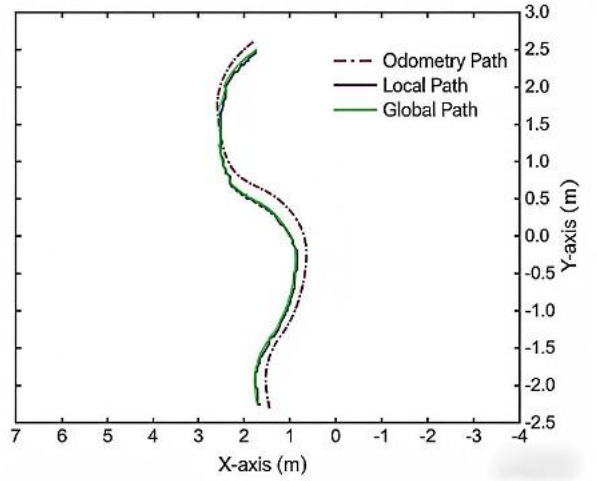

Fig. 12 - Trajectory tracking errors in an orchard environment

A minor fraction of the maximum errors (approaching 0.07 m) primarily occurred in the undulating ridge areas at the orchard's edge. Although ground unevenness induced minor drive-wheel slippage and local transient distortion of the LiDAR point cloud, the system rapidly suppressed error divergence. Benefiting from the feedback correction and cost assimilation mechanisms embedded at the algorithm's foundational layer, the extreme values were strictly confined within the absolute safety threshold of 0.1 m.

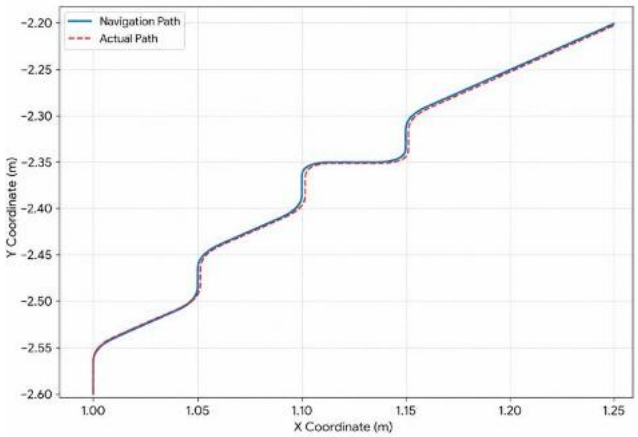

Fig. 13 - Improved Comparison: Navigation and Actual Path

Under harsh operating conditions characterized by drive-wheel slippage induced by ground unevenness and transient distortion of the LiDAR point cloud, the average trajectory tracking deviation of the traditional DWA algorithm exhibits a prominent divergent trend as the operational distance increases, with the maximum deviation reaching up to 0.35 m. In contrast, through the mechanisms of "cost assimilation" and "foundational feedback deviation reconstruction," the proposed algorithm achieves a closed-loop coupling between macroscopic path optimization and microscopic dynamic obstacle avoidance.

During several hours of high-intensity operational testing, the prototype never experienced deadlocks or severe trajectory oscillations triggered by sensor noise. The experimental data conclusively affirm that the improved fusion algorithm, while possessing high-precision optimization capabilities, exhibits exceptional environmental robustness. It fully satisfies the stringent requirements imposed on navigation systems for autonomous weeding operations in standardized orchards.

CONCLUSIONS

To meet the navigation and obstacle avoidance requirements of orchard weeding robots, this study proposed and validated an improved A*-DWA fusion algorithm. The main achievements are as follows:

1. An improved A*-DWA fusion navigation algorithm was proposed. By introducing modules for dynamic obstacle angle threshold determination, hierarchical lateral braking, and adaptive velocity window expansion, a "global-local-safety" hierarchical architecture was constructed, effectively suppressing trajectory oscillation and response delays. Simulations show that in scenarios with coexisting static and dynamic obstacles, the algorithm reduces obstacle avoidance response time by 50.0%, decreases trajectory oscillation frequency by 85.7%, and achieves a dynamic obstacle avoidance success rate of 96.3%.

2. Multi-scenario system validation was completed. Mapping, multi-point navigation, and dynamic obstacle avoidance tests were conducted in both simulated and real orchard environments. The system achieves full-process autonomous operation with high trajectory tracking accuracy (average deviation 0.05 m indoors, 0.029 m outdoors) and a dynamic obstacle avoidance success rate >95%, verifying the algorithm's effectiveness, robustness, and engineering practicality in real-world scenarios.

Keywords: *Yimeng Mountain jujubes, Angle of repose, Box-Behnken test, The optimal parameter*

ABSTRACT
Accurate discrete element method (DEM) parameters are essential for simulating key operations in jujube postharvest processing, such as pneumatic cleaning during mechanical harvesting. The fundamental physical properties of Yimeng Mountain jujubes were systematically measured. A jujube particle template was constructed using the multi-sphere method, and the Hertz–Mindlin (no slip) contact model was adopted. The jujube simulation model was generated by filling the particle template with multiple spheres of different diameters. The static friction coefficient between jujubes ranged from 0.41 to 0.69, while that between jujubes and a steel plate ranged from 0.40 to 0.54. The rolling friction coefficient between jujubes ranged from 0.16 to 0.30, whereas that between jujubes and a steel plate ranged from 0.11 to 0.24. The coefficient of restitution between Yimeng Mountain jujubes, determined using a high-speed camera, ranged from 0.41 to 0.54, while that between jujubes and a steel plate ranged from 0.46 to 0.61. A Plackett–Burman screening design was conducted, and the results showed that the Poisson's ratio of jujube, the static friction coefficient between jujubes, and the static friction coefficient between jujubes and the steel plate were the three dominant factors. The steepest ascent method was then used to narrow the ranges of these significant parameters. Subsequently, a Box–Behnken design was employed to establish a quadratic regression model relating the angle of repose to the three significant factors. Using the experimentally measured angle of repose of 28.08° as the optimization target, the optimal simulation parameters were determined as follows: a Poisson's ratio of 0.32, a jujube–jujube static friction coefficient of 0.52, and a jujube–steel static friction coefficient of 0.47. The relative error between the simulated and experimentally measured angles of repose was 2.17%, further confirming the accuracy and reliability of the calibrated simulation parameters.

摘要
为沂蒙山红枣风选机械化采收等关键环节的仿真提供准确的离散元模型参数，本文通过物理试验精准测定红枣的物性参数.本文对红枣颗粒模板进行单球形颗粒填充的方法,采用 Hertz-Mindlin (no slip)模型。红枣模拟模型是通过合并许多不同直径的球体而创建的使用 EDEM 软件的单个球形颗粒进行填充。采用斜面仪测得沂蒙山红枣之间的静摩擦系数为 0.41-0.69，沂蒙山红枣与钢板之间的静摩擦系数为 0.40-0.54。沂蒙山红枣之间的动摩擦系数为 0.16-0.30，沂蒙山红枣与钢板之间的动摩擦系数为 0.11-0.24。采用高速摄像机测得沂蒙山红枣与沂蒙山红枣的恢复系数为 0.41-0.54，沂蒙山红枣与钢板的碰撞恢复系数 0.46-0.61。开展 Plackett-Burman 试验筛选出对堆积角有显著影响的参数为：红枣泊松比、红枣-红枣静摩擦系数和红枣-钢静摩擦系数，进一步通过最陡爬坡试验确定显著性参数最优范围区间。通过 Box-Behnken 试验，建立堆积角与显著性参数的二阶回归模型，并以物理试验得到堆积角(28.08°)目标值进行优化求解，得到最优仿真参数：红枣泊松比为 0.32、红枣-红枣静摩擦系数为 0.52、红枣-钢静摩擦系数为 0.47。仿真堆积角与物理堆积角的相对误差为 2.17%。进一步验证了仿真试验和标定后仿真参数的真实性和可靠性。

INTRODUCTION
Yimeng Mountain jujube is a species in the genus Ziziphus, in the family Rhamnaceae. As a fruit-bearing tree, it provides substantial nutritional benefits and notable therapeutic qualities. A vital step in the production process is the collection of Yimeng Mountain jujubes. It has considerable seasonality and significant labour intensity. Jujube fruits during the ripening stage undergo natural desiccation on the tree before harvest. This technique optimally utilises solar and thermal resources *(Chu et al., 2012; Muqaddas et al., 2025)*. It can significantly enhance fruit quality. Winnowing machines are used in the Yimeng Mountain region for remove impurities during jujube harvesting.

Complex contact forces arise during the pneumatic separation process, both between jujube fruits and between the fruits and steel surfaces. These forces are difficult to measure directly using conventional experimental methods. Simulation can therefore be used to investigate the interaction mechanisms between jujube fruits and machinery during pneumatic separation, providing a basis for optimizing key equipment components and reducing fruit losses.

Research into basic agricultural materials has progressed significantly in recent years. These materials include soil *(Hao et al., 2025; Ji et al., 2025)*, straw *(Huang et al., 2025; Zhu et al., 2026)*, and seeds. The discrete element method has become an important approach for studying such problems. *Liu et al., (2025),* used the discrete element method to calibrate Cyperus esculentus seeds and determined the optimal parameter combination to overcome issues of irregular shape and uneven surface in high-speed precision seeding. *Ma et al., (2025),* investigated ruminant protein supplement pellets. They measured basic physical properties and contact characteristics, and built a discrete-element model. Using the angle of repose as an evaluation index in orthogonal tests, the optimal parameter combination was identified. *Gu et al., (2025),* calibrated the discrete element parameters of mustard leaf stems to visualise cutting and support numerical simulation; *Geng et al., (2026),* used the discrete element method to build a breakable 'Atlantic' potato seed model; *Chen et al., (2025),* established a paddy rice physical model with the multi-sphere (MS) approach. Validation tests were carried out using the cylinder-lifting method and the discharge mass-flow method. *Zheng et al., (2025),* focused on Fritillariae Thunbergii Bulbus (FTB). They developed a discrete element model of FTB using the Hertz-Mindlin bonding model. It took the maximum shear force as the evaluation index. The bond parameters in the model were then validated accordingly. *Yu et al., (*2025*),* developed DEM models of mallow and oats via the multi-sphere manual filling approach. These models were coupled with Fluent for gas-solid simulations. The study systematically analysed seed flow characteristics and seeding consistency in the distributor under varying inlet velocities and mass flow rates. *Li et al., (2026),* focused on dried safflower filaments. They calibrated the filament parameters by combining physical experiments with simulation tests. *Li et al., (2025)* selected Pizhou white garlic as the research object. Using EDEM software, a breakable, flexible discrete element model of garlic seed was built, and its bond parameters were calibrated. *Chen et al., (2024),* focused on optimising parameters for a pepper seeding device. A 3D seed model was constructed using reverse engineering. Key parameter ranges were then systematically determined. The discrete element method was used to study particle interactions and motion patterns. This approach helps reveal the mechanisms underlying particle–particle interactions and thus optimises key process parameters of equipment *(Ji et al., 2024*; *Zhou et al., 2023)*. Accurate discrete element method (DEM) parameters are essential for simulating key operations in jujube post-harvest processing, such as pneumatic cleaning during mechanical harvesting. However, research on accurate parameter calibration for jujube trees in Yimeng Mountain remains relatively limited.

This study accurately measured the intrinsic parameters of Yimeng Mountain jujubes through physical experiments. The free-fall principle and the inclined plane method were used. It determined the ranges of the coefficient of restitution, the static friction coefficient, and the rolling friction coefficient. The MATLAB software processed images of both the physical and simulated angles of repose. The edge contour was then fitted to obtain the angle of repose. The angle of repose from physical tests served as the evaluation index. Significant factors were screened using the Plackett-Burman design, followed by the steepest ascent and the Box-Behnken tests to determine the optimal simulation parameters. This study provides accurate discrete element model parameters for simulations of key processes, such as mechanised pneumatic harvesting of Yimeng Mountain jujubes.

MATERIALS AND METHODS

Determination of basic physical parameters

This study focuses on Yimeng Mountain jujubes as the research subject. Yimeng Mountain jujubes are bright red in colour, with thick flesh, small pits, a crisp texture when fresh, and a smooth, mellow taste when dried. One hundred jujubes were randomly selected, and the dimensions of each fruit were measured using a digital Vernier calliper with an accuracy of 0.02 mm. The three characteristic dimensions (length L, width W, and thickness T) were recorded. The volume of the Yimeng Mountain jujubes was measured using a graduated cylinder with a resolution of 1 mL. The moisture content was determined using the oven-drying method. The mean of the replicate measurements was taken as the final value. The experimental results are presented in Table 1.

Table 1

Basic physical properties of Yimeng Mountain jujubes

Parameter	Value
Mean dimensions (L×W×T)/mm × mm × mm	30.98×20.53×18.89
Mean mass (g)	4.64
Mean density (kg•m^3)	746
Mean moisture content (%)	18.58

Determination of the static friction coefficient

Jujubes were fixed to a plate using adhesive to form a jujube contact surface (Fig. 1a). A test jujube was placed on the surface, and the test plane was gradually inclined anticlockwise. When the jujube began to slide, the inclination was stopped and the corresponding angle displayed by the digital inclinometer was recorded. The static friction coefficient between jujubes was calculated using Eq. (1).

To determine the static friction coefficient between jujubes and steel, Yimeng Mountain jujubes were placed directly on the steel test surface, and the same procedure was followed (Fig. 1b). The static friction coefficient between jujubes ranged from 0.41 to 0.69, while that between jujubes and the steel plate ranged from 0.40 to 0.54.

$$\gamma = \tan\alpha \tag{1}$$

where, γ is the static friction coefficient and α is the inclination angle of the test plane, (°).

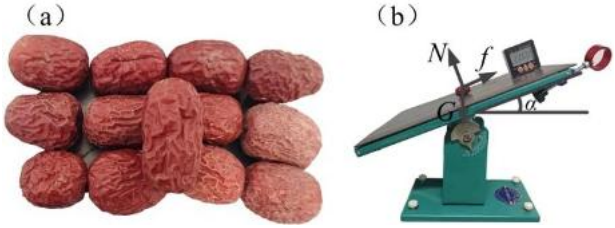

Fig. 1 - Measurement of the static friction coefficient
(a) Jujube contact surface; (b) Inclined-plane test setup

Determination of the rolling friction coefficient

The rolling friction coefficient was determined using a procedure similar to that used for the static friction coefficient. The inclination angle of the test plane was gradually increased until the jujube began to roll. The corresponding angle displayed by the digital inclinometer was then recorded. The rolling friction coefficient was calculated using Eq. (2). The rolling friction coefficient between jujubes ranged from 0.16 to 0.30, while that between jujubes and the steel plate ranged from 0.11 to 0.24.

$$\gamma_1 = \tan\alpha_1 \tag{2}$$

where, γ_1 is the rolling friction coefficient and α_1 is the critical inclination angle at which rolling begins.

Determination of the coefficient of restitution

During the mechanical harvesting and cleaning of Yimeng Mountain jujubes, collisions occur both among the fruits and between the fruits and machine components, which may cause skin damage and internal injury. Therefore, the coefficient of restitution is an important contact parameter. The test setup for determining the coefficient of restitution is shown in Fig. 2 (*Hou et al., 2020*). Two impact surfaces were prepared: a steel plate and a plate formed by closely arranged Yimeng Mountain jujubes. Individual jujubes were released from rest from a fixed height of 400 mm and allowed to collide with the corresponding impact surface. After impact, the jujubes rebounded upward. The entire collision process was recorded using a high-speed camera, and the rebound characteristics were obtained through image post-processing.

The coefficient of restitution between Yimeng Mountain jujubes ranged from 0.41 to 0.54, while that between Yimeng Mountain jujubes and the steel plate ranged from 0.46 to 0.61.

$$e = \frac{v_2}{v_1} \tag{3}$$

where, v_1, and v_2 are the relative velocities before and after collision, respectively, m.s^{-1}.

The Yimeng Mountain jujubes were assumed to undergo free fall under the action of gravity. The normal velocity immediately before impact was calculated using the work–energy theorem.

$$v_1 = \sqrt{2gH} \tag{4}$$

The normal velocity immediately after impact was calculated as follows:

$$v_2 = \sqrt{2gh} \tag{5}$$

Therefore, the coefficient of restitution can be expressed as:

$$e = \sqrt{\frac{h}{H}} \tag{6}$$

where, H is the drop height before impact, mm; and h is the maximum rebound height after impact, mm.

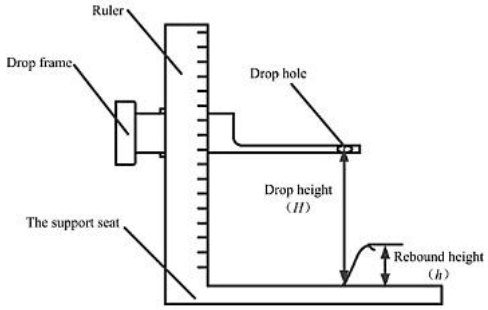

Fig. 2 - Schematic diagram of the test principle for coefficient of restitution

Angle of repose test

The angle of repose is defined as the angle between the slope of a granular pile and the horizontal plane. In the experiment, the inner diameters of the upper and lower openings of the funnel were 200 mm and 40 mm, respectively, and the vertical distance from the lower opening of the funnel to the horizontal test surface was 200 mm. A 200 g sample of Yimeng Mountain jujubes was placed in the funnel and allowed to fall freely onto the test surface, forming a conical pile. After the pile stabilized, the angle between the pile slope and the horizontal plane was taken as the experimentally measured angle of repose of the Yimeng Mountain jujubes. Images of the pile contour were captured using a camera and processed in MATLAB R2022b.

The images were imported using the imread function, converted to grayscale using rgb2gray, and then binarized using a fixed-threshold method. The region of interest was cropped, and the binary image was inverted. Internal holes in the target region were filled using the imfill function to improve the morphological integrity of the pile image. Edge detection was then performed to extract the contour of the jujube pile, and the coordinates of the boundary points were obtained. The first 50% of the boundary-point data were selected for coordinate transformation. A first-order polynomial was fitted to the transformed boundary points using the least-squares method. The angle of repose was subsequently calculated from the arctangent of the fitted slope. The fitting procedure is illustrated in Fig. 3. Each test was repeated 10 times, and the mean value was taken as the final result. The mean angle of repose of the Yimeng Mountain jujubes was 28.08°.

Fig. 3 - Image-processing procedure for determining the angle of repose
(a) Original image; (b) Morphological processing; (c) Contour extraction and fitting

Establishment of the simulation model

The fundamental physical properties of the Yimeng Mountain jujubes were determined through preliminary physical tests. A three-dimensional geometric model (particle template) was constructed in Creo based on the measured fruit dimensions. The model was exported in STEP format and imported into EDEM. The Hertz–Mindlin (no slip) contact model was adopted. To balance computational efficiency and model fidelity, the jujube particle model was constructed using the multi-sphere method. The particle template was filled with multiple spheres of different diameters in EDEM to generate the discrete element model of a jujube, as shown in Fig. 4a.

A simulation of the angle of repose test was then established using the same geometric dimensions as those employed in the physical test. A particle factory was positioned above the funnel to generate Yimeng Mountain jujube particles, which subsequently fell into the funnel under gravity.

The particle generation rate was 50 g/s, and a total particle mass of 200 g was generated. The particles continued to fall and accumulate on the test surface until the pile became stable. The angle between the pile slope and the horizontal test surface was taken as the simulated angle of repose. The particle size was kept constant throughout the simulation. The total simulation time was 4 s, the Rayleigh time step was set to 12%, the data-saving interval was 0.02 s, and the grid size was set to three times the minimum particle radius.

Simulation parameter calibration

Plackett-Burman test

The Design-Expert software was used for the Plackett-Burman test design. Test parameters were selected based on physical tests. The remaining simulation parameters were obtained from the relevant literature *(Du, 2022; Li, 2022; Shi et al., 2021; Zhou et al., 2022)*. Parameters exerting substantial influence on the response value were identified using the Plackett-Burman design. The principal elements that substantially affected the target response were identified. The parameters in Table 2 are encoded as +1 for maximum values and -1 for minimum values. At the end of each group of simulated trials, the angle of repose was measured using the same method employed in actual tests.

Table 2

Parameter ranges for the Plackett–Burman design

Code	Parameter	Low level (-1)	High level (+1)
X_1	Poisson's ratio of jujube	0.20	0.46
X_2	Shear modulus of jujube (MPa)	0.38	0.52
X_3	Jujube–jujube coefficient of restitution	0.41	0.54
X_4	Jujube–jujube static friction coefficient	0.41	0.69
X_5	Jujube–jujube rolling friction coefficient	0.16	0.30
X_6	Jujube–steel coefficient of restitution	0.46	0.61
X_7	Jujube–steel static friction coefficient	0.40	0.54
X_8	Jujube–steel rolling friction coefficient	0.11	0.24

Steepest ascent test

Based on the results of the Plackett–Burman design, a steepest ascent test was conducted for the significant parameters identified through the screening analysis. The relative error between the simulated and experimentally measured angles of repose was used as the evaluation index to determine the optimal ranges of the simulation parameters. The nonsignificant parameters were fixed at their mean values. The relative error between the simulated and experimentally measured angles of repose was calculated using Eq.(7).

$$\psi = \left| \frac{\theta - \theta_s}{\theta} \right| \times 100\% \quad (7)$$

where, ψ is the relative error between the simulated and experimentally measured angles of repose, %; θ_s is the simulated angle of repose, (°). θ is the experimentally measured angle of repose, (°).

Box - Behnken design

The optimal ranges of the significant factors were determined through the steepest ascent test and were subsequently used to define the factor levels. The angle of repose was selected as the response variable. A Box–Behnken design was then conducted for the significant parameters to determine the optimal parameter combination. The coded factor levels used in the simulation are presented in Table 3.

Table 3

Coded levels of the significant parameters

Coded level	Parameter		
	X_1	X_4	X_7
-1	*0.25*	*0.46*	*0.43*
0	*0.30*	*0.52*	*0.46*
+1	*0.36*	*0.57*	*0.48*

RESULTS

Analysis of the Plackett-Burman test results

The angle of repose of jujube particles on the steel plate was influenced by multiple factors. A Plackett-Burman test was therefore conducted to evaluate the significance of each factor. A total of 12 experimental runs were performed, and each run was repeated three times. The mean value was used for subsequent analysis. The experimental design and results are presented in Table 4, while the significance analysis of the Plackett–Burman factors is presented in Table 5. The screening results showed that X_1, X_4 and X_7 had significant effects on the angle of repose of the jujubes. Therefore, these three factors were selected for further analysis and optimization.

Table 4

Plackett–Burman design and simulation results

No.	Parameters								Angle of repose θ/(°)
	X_1	X_2	X_3	X_4	X_5	X_6	X_7	X_8	
1	1	-1	-1	-1	1	-1	1	1	30.28

Analysis of the steepest ascent test results

The design and results of the steepest ascent test are presented in Table 6. As the Poisson's ratio of jujube and the jujube-jujube and jujube-steel static friction coefficients increased, the simulated angle of repose also increased. The relative error between the simulated and experimentally measured angles of repose first decreased and then increased. Run 3 produced the minimum relative error of 3.36%; therefore, its factor levels were selected as the centre point for the subsequent Box–Behnken design.

Table 6

Design and results of the steepest ascent test

No.	Parameters			Angle of repose (°)	Relative error (%)
	X_1	X_4	X_7		
1	0.20	0.41	0.40	21.34	24%
2	0.25	0.46	0.43	24.82	11.61%
3	0.30	0.52	0.46	27.06	3.36%
4	0.36	0.57	0.48	29.64	5.56%
5	0.41	0.63	0.51	32.44	15.53%
6	0.46	0.69	0.54	35.86	27.71%

Analysis of the Box–Behnken design results

The Box–Behnken experimental design and simulation results are presented in Table 7. Multiple regression analysis was performed on the simulation results, and a quadratic regression model for the simulated angle of repose was established as follows:

$$\theta = 27.43 - 0.72X_1 + 2.3X_4 + 1.33X_7 - 1.67X_1X_4 - 1.12X_1X_7 - 0.025X_4X_7 - 0.24X_1^2 + 2.05X_4^2 + 0.93X_7^2 \quad (8)$$

where, X_1 is the Poisson's ratio of jujube; X_4 is the jujube–jujube static friction coefficient; X_7 is the jujube–steel static friction coefficient.

The analysis of variance (ANOVA) for the quadratic regression model is presented in Table 8. X_1, X_4, X_7, X_1X_4, X_1X_7, X_4^2, X_7^2 had a significant impact on the angle of repose. The fitted angle of repose regression model had $P < 0.0001$. The lack-of fit term was $P=0.6438 > 0.05$. The model fit was good. The lack of fit was not significant. The coefficient of determination R^2 of the regression equation was 0.9898. The modified coefficient of determination R^2 was 0.9767, and the coefficient of variation CV was 1.33%. These results indicate that the regression model has good predictive ability and can be used to analyse and optimize the angle of repose.

Determination of the optimal parameters and experimental validation

The optimization objective was to minimize the difference between the simulated and experimentally measured angles of repose. The quadratic regression model was optimized using the experimentally measured angle of repose as the target value. Among the candidate solutions, the parameter combination closest to the mean values obtained from the physical measurements was selected. The optimal simulation parameters were determined as follows: Poisson's ratio, 0.32; jujube-jujube static friction coefficient, 0.52; and jujube-steel static friction coefficient, 0.47. To validate the calibrated discrete element parameters, the optimized parameter combination was used in EDEM simulations. Three repeated simulation tests were conducted, yielding angles of repose of 27.24°, 29.26°, and 29.58°. The mean simulated angle of repose was 28.69°, with a standard deviation of 1.04°. The relative error compared with the experimentally measured angle of repose of 28.08° was 2.17%. The close agreement between the simulated and experimental results further confirms the reliability and applicability of the calibrated simulation parameters.

DISCUSSION

In this study, the fundamental physical properties of Yimeng Mountain jujubes were systematically measured, and a three-dimensional geometric model incorporating their dimensional and morphological characteristics was established. A multi-sphere particle model was then developed in EDEM, in which the jujube geometry was represented by an assembly of spheres with different diameters. The coefficient of restitution, static friction coefficient, and rolling friction coefficient were determined using free-fall and inclined-plane tests. Images from both the physical and simulated angle-of-repose tests were processed in MATLAB, and the pile contours were fitted to determine the corresponding angles of repose. The experimentally measured angle of repose was used as the calibration target. Significant factors were identified using a Plackett–Burman design, followed by a steepest ascent test and Box–Behnken design to determine the optimal simulation parameters. Using the experimentally measured angle of repose as the optimization target, the calibrated parameters were determined as follows: Poisson's ratio of jujube, 0.32; jujube–jujube static friction coefficient, 0.52; and jujube–steel static friction coefficient, 0.47. The relative error between the simulated and experimentally measured angles of repose was 2.17%.

However, the calibration was conducted under ambient laboratory conditions, and the effects of variations in moisture content, temperature, and ripening stage on the contact parameters were not systematically investigated. Although the angle-of-repose test is widely used as a benchmark for evaluating bulk material behaviour, it represents only one quasi-static flow condition. Therefore, the calibrated parameters may not provide the same level of accuracy under highly dynamic conditions, such as high-velocity pneumatic conveying or rapid discharge. Validation using additional bulk-behaviour tests, such as shear-cell tests, hopper discharge tests, or direct shear tests, would further strengthen the general applicability of the calibrated parameter set. In addition, the present study focused primarily on jujube–jujube and jujube–steel contact parameters. Under actual harvesting and postharvest handling conditions, jujubes may also come into contact with materials such as rubber belts, plastic screens, and plant debris. Extending the calibration to these additional contact pairs would improve the practical applicability of the DEM model.

CONCLUSIONS

(1) The fundamental physical and contact parameters of Yimeng Mountain jujubes were determined through physical tests. The jujube–jujube static friction coefficient ranged from 0.41 to 0.69, while the jujube–steel static friction coefficient ranged from 0.40 to 0.54. The jujube–jujube rolling friction coefficient ranged from 0.16 to 0.30, whereas the jujube–steel rolling friction coefficient ranged from 0.11 to 0.24. The jujube–

jujube coefficient of restitution, determined using a high-speed camera, ranged from 0.41 to 0.54, while the jujube–steel coefficient of restitution ranged from 0.46 to 0.61.

(2) The measured physical and contact parameters were used to define the initial ranges of the DEM parameters. A Plackett–Burman design was conducted to screen the factors affecting the angle of repose. The Poisson's ratio of jujube, the jujube–jujube static friction coefficient, and the jujube–steel static friction coefficient were identified as the dominant factors. A steepest ascent test was then performed to further narrow the ranges of these parameters.

(3) A Box–Behnken design was subsequently employed to establish a quadratic regression model relating the angle of repose to the three dominant factors. Using the experimentally measured angle of repose of 28.08° as the optimization target, the optimal simulation parameters were determined as follows: Poisson's ratio of jujube, 0.32; jujube–jujube static friction coefficient, 0.52; and jujube–steel static friction coefficient, 0.47. The relative error between the simulated and experimentally measured angles of repose was 2.17%, indicating good agreement between the simulation and physical test results.

The calibrated parameters provide a basis for DEM simulations of key operations in the mechanical harvesting and postharvest handling of Yimeng Mountain jujubes, particularly pneumatic cleaning and separation processes, and can support further investigation of jujube motion and interaction behaviour during these operations. However, the present study adopted the Hertz–Mindlin (no slip) contact model, which is commonly used for dry, noncohesive particle systems in EDEM. Future work will consider more detailed contact and damage models, such as Bonding V2, to represent the skin and flesh of jujubes and to investigate fruit damage during harvesting. The effects of fruit morphology on DEM model accuracy will also be examined further.

Keywords: *agricultural-machinery lamp cover, wind-blown sand erosion, yaw angle, Eulerian–Lagrangian approach, polycarbonate*

ABSTRACT
Wind-blown sand erosion threatens agricultural-vehicle lamp covers, yet the effects of wind speed and yaw angle have not been sufficiently quantified. A one-way coupled Eulerian–Lagrangian CFD model of a full-scale isolated polycarbonate (PC) lamp cover was combined with gas-jet erosion tests on flat PC specimens for trend-level comparison. Wind speeds of 10–30 m/s and yaw angles of −30° to 30° were investigated, with erosion predicted using the Oka model. Erosion was concentrated near the windward leading edge and downstream surface, whereas the maximum pressure remained closer to the stagnation region. The mean and maximum erosion rates followed power-law relationships with exponents of 2.70 and 2.31, respectively. From −30° to 30°, the mean erosion rate increased by 28.3%, 57.0%, and 13.9% at 10, 20, and 30 m/s, respectively. At 30 m/s, the maximum erosion rate increased by 55.8% from 0° to 30°. At 20 m/s, the erosion concentration factors were 13.31, 5.45, and 9.54 at −30°, 0°, and 30°, respectively. Over the same yaw-angle range, the experimental mass loss increased by 212.5%, 115.4%, and 88.9%, while the surface roughness increased by 23.9%, 18.9%, and 20.1%. After normalization, the numerical and experimental indicators exhibited consistent yaw-angle-dependent trends (R^2 = 0.9481, RMSE = 0.0822, MAE = 0.0671). Within the investigated conditions, the model successfully captured the relative erosion trends, and the combined indicators supported the assessment of localized erosion risk.

摘要
风沙冲蚀对农用车辆灯罩的服役性能构成威胁，但风速与偏航角对其冲蚀特性的影响尚未得到充分量化。本文建立全尺寸孤立灯罩的单向耦合欧拉–拉格朗日 CFD 模型，并结合平板聚碳酸酯试样气固射流冲蚀试验进行趋势对比。研究考虑 10–30 m/s 的风速和−30°–30°的偏航角，并采用 Oka 模型预测冲蚀。结果表明，冲蚀主要集中于迎风前缘及其下游表面，而压力峰值更接近滞止区域。平均冲蚀率和最大冲蚀率均与风速呈幂律关系，其指数分别为 2.70 和 2.31。偏航角由−30°增至 30°时，10、20 和 30 m/s 下的平均冲蚀率分别增加 28.3%、57.0%和 13.9%。在 30 m/s 下，最大冲蚀率由 0°至 30°增加 55.8%。在 20 m/s 下，−30°、0°和 30°对应的冲蚀集中系数分别为 13.31、5.45 和 9.54。在相同偏航角范围内，试验质量损失分别增加 212.5%、115.4%和 88.9%，表面粗糙度分别增加 23.9%、18.9%和 20.1%。归一化后的数值与试验指标均呈现出一致的偏航角依赖变化规律。（R^2 = 0.9481，RMSE = 0.0822，MAE = 0.0671）。在本文研究条件下，该模型能够反映相对冲蚀变化趋势，综合指标可为局部冲蚀风险评估提供依据。

INTRODUCTION
Modern agricultural machinery is widely used for crop production, land reclamation, and material transport in arid, semi-arid, and desertified agricultural regions, where near-ground flows frequently contain wind-blown sand and dust particles *(Li et al., 2025; Yan et al., 2024)*. These particles are transported mainly through saltation and suspension, and their motion is governed by wind velocity, turbulence intensity, surface roughness, and particle inertia *(Kok et al., 2012; Shao and Lu, 2000)*. During field operation, vehicle motion and crosswinds may generate stagnation, acceleration, and flow-separation regions around frontal surfaces, thereby modifying particle trajectories, impact velocity, and local incidence conditions. Repeated particle impacts on exposed transparent components may consequently cause pits, scratches, material loss, and progressive optical degradation *(Zhao et al., 2021)*.

Solid-particle erosion is a surface-degradation process governed by particle kinetic energy, impact angle, and material response. Its principal damage modes include cutting, ploughing, plastic deformation, and localized fracture *(Bellman and Levy, 1981; Deng, 2025; Finnie, 1960; Hutchings, 1981; Sundararajan, 1991)*, while erosion severity is influenced by impact velocity, particle characteristics, and material toughness. For agricultural-machinery lamp covers, wind-blown sand erosion may lead to material removal, surface roughening, haze formation, and reduced light transmittance, thereby affecting illumination range and field-boundary recognition during night-time or dusty operation. Failure analyses of automotive headlamp lenses have also shown that surface degradation and cracking may compromise the functional integrity of transparent lighting components *(Ferreira and Lins, 2019)*. Polycarbonate (PC) is widely used for transparent vehicle components because of its optical transparency, low weight, and impact resistance *(Katsamberis et al., 1998)*. Its erosion response is closely associated with resilience, impact-energy absorption, and local deformation under repeated particle impacts *(Xie et al., 2019)*. The gradual accumulation of pits, grooves, and scratches may therefore alter both the surface condition and optical performance of PC lamp covers exposed to wind-blown sand.

Previous studies of wind-blown sand and solid-particle erosion have focused mainly on turbomachinery components and wind-turbine blades *(Alqallaf et al., 2020; Hamed et al., 2006; Wang et al., 2024)*. These studies show that wind velocity, particle mass flow rate, particle characteristics, and wall impact angle strongly influence erosion location and intensity, providing a basis for understanding particle transport and wall collision in gas–solid flows *(Deng, 2025)*. However, curved transparent components on agricultural machinery exhibit different geometrical boundaries and local flow conditions. Under yawed wind-blown sand inflow, changes in the incoming-flow direction redistribute the velocity field, pressure gradient, particle concentration, and impact-angle distribution around the lamp cover. The resulting variation in the position, intensity, and spatial concentration of high-erosion regions therefore requires further quantitative analysis.

Eulerian–Lagrangian and CFD–DEM approaches have been applied to gas–particle transport in agricultural equipment and aeolian-sand systems *(Bi et al., 2023; Chen et al., 2025; Li et al., 2025; Zhang et al., 2025)*. These methods enable particle trajectories, impact conditions, and erosion distributions to be evaluated under controlled operating conditions. However, mean erosion alone cannot fully characterize local peak damage, particularly when erosion becomes spatially concentrated under yawed inflow. Therefore, both overall erosion severity and localized erosion characteristics should be considered when assessing the erosion risk of exposed transparent components.

The objectives of this study are to: (1) establish a one-way coupled Eulerian–Lagrangian framework for predicting wind-blown sand transport and erosion on a full-scale isolated agricultural-machinery lamp cover; (2) quantify the effects of wind speed and yaw angle on the mean erosion rate, maximum erosion rate, and erosion concentration factor; (3) identify variations in erosion-prone regions and the spatial concentration of erosion under different operating conditions; and (4) conduct gas-jet erosion tests on flat PC coupons to determine whether mass loss, surface roughness, and surface morphology follow the parametric trends predicted numerically.

MATERIALS AND METHODS

Numerical simulation

Governing Equations and Numerical Models

A one-way coupled Eulerian–Lagrangian CFD model was developed to simulate air–sand two-phase flow around an agricultural-machinery lamp cover under wind-blown sand conditions. The airflow was solved as a continuous phase using the Reynolds-averaged Navier–Stokes equations, while sand-particle trajectories were tracked in a Lagrangian framework. Owing to the low particle volume fraction, particle feedback on the airflow was neglected *(Elghobashi, 1994)*. The SST k–ω model was adopted to account for adverse pressure gradients and flow separation near the curved lamp-cover surface *(Menter, 1994)*. Identical numerical schemes and convergence criteria were applied to all wind-speed and yaw-angle cases to ensure consistent comparison.

After convergence of the continuous-phase solution, the sand-particle trajectories were calculated. Interparticle collisions were neglected, and the particle equation of motion was formulated according to Newton's second law:

$$m_p \frac{d\mathbf{v}_p}{dt} = \mathbf{F}_D + m_p\mathbf{g} + \mathbf{F}_{other} \quad (1)$$

where m_p is the particle mass, $\boldsymbol{v}_p$ is the particle velocity vector, $\boldsymbol{F}_D$ is the drag force exerted by the fluid on the particle, and $\boldsymbol{F}_{\mathrm{other}}$ includes the pressure-gradient force and Saffman lift force. The drag force was determined from the local relative velocity, particle Reynolds number, and drag coefficient.

Material loss caused by particle impact was evaluated using the Oka erosion model *(Oka et al., 1997; Oka et al., 2005a; Oka and Yoshida, 2005b)*. In the model, the erosion ratio is determined by the particle impact angle, impact velocity, particle diameter, and material-related coefficients:

$$E(\alpha, V_p, d_p) = E_{\mathrm{ref}} g(\alpha) \left(\frac{V_p}{V_{\mathrm{ref}}}\right)^{k_v} \left(\frac{d_p}{d_{\mathrm{ref}}}\right)^{k_d} \quad (2)$$

The impact-angle correction function is expressed as:

$$g(\alpha) = (\sin\alpha)^{n_1}[1 + H_v(1 - \sin\alpha)]^{n_2} \quad (3)$$

where $E(\alpha, V_p, d_p)$ is the ratio of eroded material mass to incident particle mass; E_{ref} is the reference erosion ratio; $g(\alpha)$ is the impact-angle correction function; and α is the particle impact angle. V_p and d_p denote the particle velocity immediately before wall impact and the particle diameter, respectively, whereas V_{ref} and d_{ref} are the corresponding reference values. H_v is the hardness coefficient used in the Oka model, n_1 and n_2 are the impact-angle coefficients, and k_v and k_d are the velocity and diameter exponents, respectively.

The parameters used in the simulations are listed in Table 1. The reference erosion ratio was 2.141×10^{-4}, while the reference velocity and particle diameter were 104 m/s and 3.26×10^{-4}m, respectively. The hardness coefficient was 1.34, resulting in impact-angle coefficients $n_1 = 0.7397$ and $n_2 = 1.8228$. The velocity and diameter exponents were 2.3257 and 0.19, respectively. The same parameter set was applied to all wind-speed and yaw-angle conditions, without case-specific adjustment.

Table 1

Parameters used in the Oka erosion model

Parameter	Symbol	Value	Unit
Reference erosion ratio	E_{ref}	2.141×10^{-4}	-
Hardness coefficient	H_v	1.34	-
Impact-angle coefficient	n_1	0.7397	-
Impact-angle coefficient	n_2	1.8228	-
Reference velocity	V_{ref}	104	m/s
Velocity exponent	k_v	2.3257	-
Reference particle diameter	d_{ref}	326	μm
Diameter exponent	k_d	0.19	-

Note: *$d_{ref} = 326\ \mu m$ is the reference diameter in the Oka model, whereas the actual particle diameters followed a log-normal distribution within the specified particle-size range.*

The default Oka-model parameter set was used without independent calibration for the present quartz-sand–PC system. Therefore, the calculated erosion rates were used primarily to compare spatial distributions and relative variations among operating conditions rather than to predict absolute material loss.

The local erosion rate was calculated from the particle mass flow rates associated with the trajectories striking each wall-face cell:

$$\dot{m}''_{\mathrm{e},f} = \frac{1}{A_f} \sum_{j=1}^{N_f} E(\alpha_j) \dot{m}_{\mathrm{p},j} \quad (4)$$

where $\dot{m}''_{e,f}$ is the erosion rate of the f-th wall-face cell, A_f is the area of the cell, N_f is the number of particle trajectories striking the cell; and $\dot{m}_{p,j}$ is the mass flow rate represented by the j-th particle trajectory.

The mean and maximum erosion rates over the lamp-cover surface are defined as:

$$\dot{m}''_{e,\mathrm{avg}} = \frac{\sum_{f=1}^{N} \dot{m}''_{e,f} A_f}{\sum_{f=1}^{N} A_f}, \dot{m}''_{e,\max} = \max_{1\le f\le N} \left(\dot{m}''_{e,f}\right) \quad (5)$$

where $\dot{m}''_{e,\mathrm{avg}}$ and $\dot{m}''_{e,\max}$ denote the mean and maximum erosion rates, respectively, and N is the total number of wall-face cells on the agricultural vehicle lamp cover. The mean erosion rate characterizes the overall material loss from the lamp-cover surface, whereas the maximum erosion rate reflects the severity of localized erosion. These two parameters are used to evaluate the overall erosion level and local damage concentration under different wind-speed and yaw-angle conditions.

Geometric Model and Computational Domain

A three-dimensional model of a representative **PC lamp cover used on agricultural machinery** was constructed to investigate its wind-blown sand erosion characteristics. The external contour and curvature of the exposed lamp-cover surface were retained, whereas mounting structures and internal optical components

were omitted. The adjacent body panels, grille, bumper, and other surrounding vehicle structures were not included; therefore, the lamp cover was treated as an isolated component in the computational domain. The resulting model had overall dimensions of approximately 415 mm × 431 mm × 201 mm.

Because the surrounding vehicle body was excluded, the calculated results represent the aerodynamic and erosion responses of the isolated lamp cover and are primarily applicable to comparative analyses of wind speed and yaw angle.

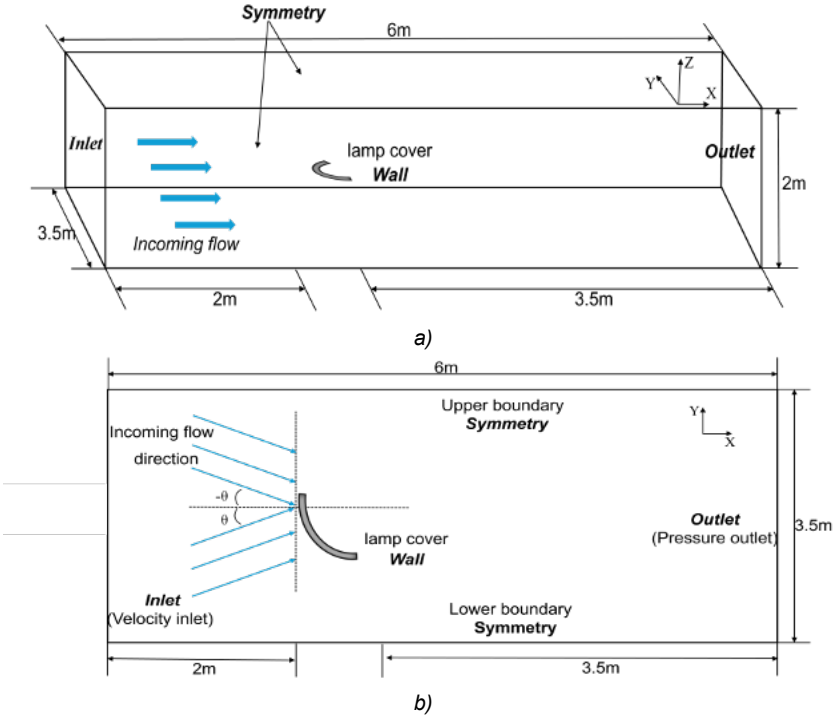

Fig. 1 - Schematic of the computational domain

a) three-dimensional computational domain; b) top view and definition of the yaw angle

As shown in Figure 1(a), the computational domain extended 2 m upstream and 3.5 m downstream of the lamp cover, with overall dimensions of 6 m × 3.5 m × 2 m. This arrangement limited the blockage ratio to less than 3% and reduced the influence of the outer boundaries on the flow around the lamp cover. The inlet and outlet were specified as a velocity inlet and a pressure outlet, respectively, while the remaining outer boundaries were treated as symmetry boundaries.

The yaw angle θ was defined as the angle between the incoming-flow direction and the central normal axis of the lamp cover, as illustrated in Figure 1(b). Five yaw-angle conditions, −30°, −15°, 0°, 15°, and 30°, were considered. A Cartesian coordinate system was adopted, with the X-axis aligned was aligned with the inflow direction at the 0° reference condition, the Y-axis oriented transversely, and the Z-axis directed vertically. Different yaw conditions were imposed by rotating the inlet velocity vector while keeping the computational domain unchanged.

Mesh Generation and Grid Sensitivity Verification

The computational domain was discretized using polyhedral cells, which are well suited to the curved lamp-cover surface and its surrounding flow field. Prism layers were generated along the lamp-cover wall to resolve the near-wall flow. The boundary-layer mesh consisted of 15 layers with a total thickness of 5 mm and a growth rate of 1.2. Local refinement was applied to the windward surface, regions of pronounced curvature, and areas expected to experience high erosion. This mesh arrangement provided sufficient resolution of the near-wall flow and particle impacts without imposing excessive computational cost.

Grid sensitivity was examined using three meshes under a wind speed of 20 m/s, a particle mass flow rate of 2 g·s^{-1}, and a yaw angle of 0°. As reported in Table 2, increasing the cell count from 0.68×10^6 to 1.24×10^6 changed the mean and maximum erosion rates by 2.22% and 2.37%, respectively. Further refinement to 1.83×10^6 cells reduced the corresponding changes to 0.72% and 1.04%. The medium and fine meshes therefore produced closely comparable results, with all variations remaining below 5%. Considering both numerical accuracy and computational cost, the mesh containing 1.24×10^6 cells was selected for the subsequent simulations.

Table 2

Results of the grid-independence study

Number of cells (10^6)	Mean erosion rate (10^{-9} kg·m^{-2}·s^{-1})	Variation (%)	Maximum erosion rate (10^{-9} kg·m^{-2}·s^{-1})	Variation (%)
0.68	1.35	--	7.58	--
1.24	1.38	2.22	7.76	2.37
1.83	1.39	0.72	7.84	1.04

Gas-Jet Sand Erosion Experiment

Gas-jet sand erosion tests were conducted to examine the effects of wind speed and specimen orientation on the mass loss, surface roughness, and surface morphology of PC coupons, and to compare the resulting parametric trends with the numerical predictions *(ASTM International, 2018)*. As shown in Figure 2(a), the test system comprised an air compressor, a pressure regulator, an abrasive feed unit, a nozzle, a specimen rotation stage, and a material recovery chamber. Compressed air entered the nozzle after pressure regulation, where quartz sand particles were entrained and accelerated by the high-speed airflow. The particles then struck the specimen at the prescribed velocity and orientation. The rotation stage controlled the specimen position and yaw angle, while the recovery chamber collected the particles after impact. Surface morphology and local roughness after erosion were examined using the digital microscope shown in Figure 2(b).

a) *b)*

Fig. 2 - Experimental instruments

a) wind–sand erosion test system; b) extended-depth-of-field imaging system.

To introduce an asymmetric reference orientation comparable with the installed lamp cover in its installed position, the specimen was mounted with an initial nozzle angle of α_0=15°. The distance from the nozzle outlet to the specimen center was fixed at $S = 200$ mm, as illustrated in Figure 3. The 0° yaw condition corresponded to the installation reference position rather than normal impact. With α_0 held constant, the specimen rotation stage was adjusted to obtain yaw angles of −30°, −15°, 0°, 15°, 30°. The same nominal yaw-angle range was used in the numerical and experimental cases to facilitate trend comparison.

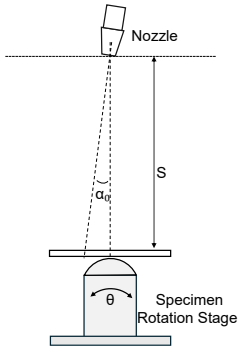

Fig. 3 - Initial nozzle orientation and definition of the specimen yaw angle

The principal test conditions are listed in Table 3. PC specimens were eroded by quartz sand at nominal nozzle-exit air velocity of 10, 20, and 30 m/s. Each test lasted 60 s and was independently repeated three times. Specimen mass was measured before and after erosion using an analytical balance with a resolution of 0.001 g. The measured mass loss, surface roughness, and surface morphology were used to compare the effects of wind speed and yaw angle with the corresponding numerical trends.

Table 3

Experimental conditions for gas-jet sand erosion tests

Parameter	Value
Specimen material	Polycarbonate (PC)
Specimen size	40 mm × 40 mm × 3 mm
Particle material	Quartz sand
Particle density	2650 kg/m^3
Particle size	50–250 μm
Nozzle inner diameter, D_n	6 mm
Sand mass flow rate, $\dot{m}_s$	2.5 g/s
Nominal air velocity	10, 20, and 30 m/s
Initial nozzle angle, α_0	15°
Yaw angle, θ	−30°, −15°, 0°, 15° and 30°
Nozzle–specimen distance, S	200 mm
Exposure time	60 s
Number of repetitions	3

RESULTS

Numerical simulation results and analysis

Effect of Yaw Angle on Surface Erosion and Pressure Distributions

Figure 4 compares the surface erosion-rate and pressure distributions on the agricultural-machinery lamp cover at 20 m/s under different yaw angles. As shown in Figure 4(a), erosion was mainly concentrated near the windward leading edge and the adjacent downstream surface, whereas the leeward region remained at a relatively low erosion level. As the yaw angle changed from −30° to 30°, the high-erosion region gradually expanded, while its main location remained near the windward leading edge. This distribution is associated with particle inertia in the curved flow. Because particles cannot instantaneously follow strongly turning streamlines, they may retain wall-directed momentum and impact the windward region. A similar dependence of wind-sand transport on local flow-field modification was reported by *Yan et al., (2024)*.

The pressure contours in Figure 4(b) show a maximum near the windward stagnation region, followed by a downstream decrease. Although the pressure and erosion distributions partially correspond, the erosion peak is located slightly downstream of the pressure maximum. This offset reflects the different dynamics of the gas and particle phases: pressure is governed by gas-phase stagnation, whereas erosion depends on particle impact velocity and angle. Particle inertia may therefore shift the strongest impact away from the pressure peak. This interpretation is consistent with *Oka et al., (2005a)*, who identified impact velocity and impact angle as key parameters controlling solid-particle erosion.

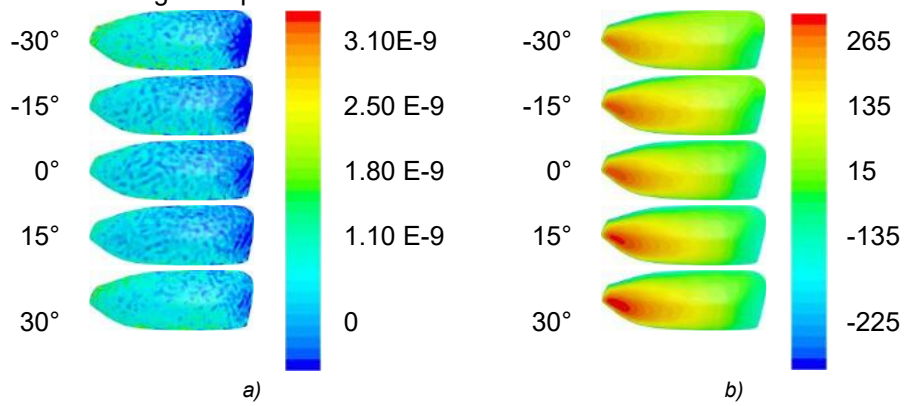

Fig. 4 - Surface erosion-rate and gauge-pressure distributions at 20 m/s under different yaw angles

a) Erosion rate distribution (kg·m^{-2}·s^{-1}); b) surface gauge-pressure distribution (Pa)

Effects of Wind Speed and Yaw Angle on Erosion Characteristics

Figure 5 shows that increasing wind speed markedly intensified surface erosion on the agricultural vehicle lamp cover, whereas yaw angle mainly changed the spatial distribution of erosion on the curved surface. As shown in Figure 5(a), the mean erosion rate generally increased as the yaw angle changed from −30° to 30° at the same wind speed, with increases of 28.3%, 57.0%, and 13.9% at 10, 20, and 30 m/s, respectively.

Higher wind speed increases particle impact velocity and energy transfer, thereby increasing the overall erosion magnitude, which reached its highest level at 30 m/s. In contrast, yaw modifies particle trajectories and incidence conditions, and its relative influence was most pronounced at 20 m/s. This non-monotonic yaw sensitivity may arise from the combined effects of particle-impact intensity and yaw-induced trajectory redistribution. This result is similar to *Li et al., (2025)*, who identified wind speed as a dominant factor in aeolian-particle transport.

As shown in Fig. 5(b), the mean erosion rate increased with wind speed according to a power-law relationship with an exponent of approximately 2.70. This velocity dependence is consistent with the Oka erosion model, indicating that the fitted exponent characterizes the velocity sensitivity of the present flow–particle–erosion system rather than representing an intrinsic material constant of PC.

In contrast to the mean erosion rate, Fig. 5(c) shows an approximately U-shaped variation in the maximum erosion rate with yaw angle. At 30 m/s, the maximum erosion rate increased from approximately 2.13×10^{-8} kg·m^{-2}·s^{-1} at 0° to 3.33×10^{-8} kg·m^{-2}·s^{-1} at 30°, corresponding to an increase of approximately 56%. Figure 5(d) further shows a power-law dependence on wind speed, with an exponent of approximately 2.31 and R^2=0.9704. The U-shaped response indicates that local peak erosion is more sensitive to spatial non-uniformity than the mean erosion. Yawed flow may normalize particle impacts within the windward region, increasing maximum erosion without a proportional increase in mean erosion.

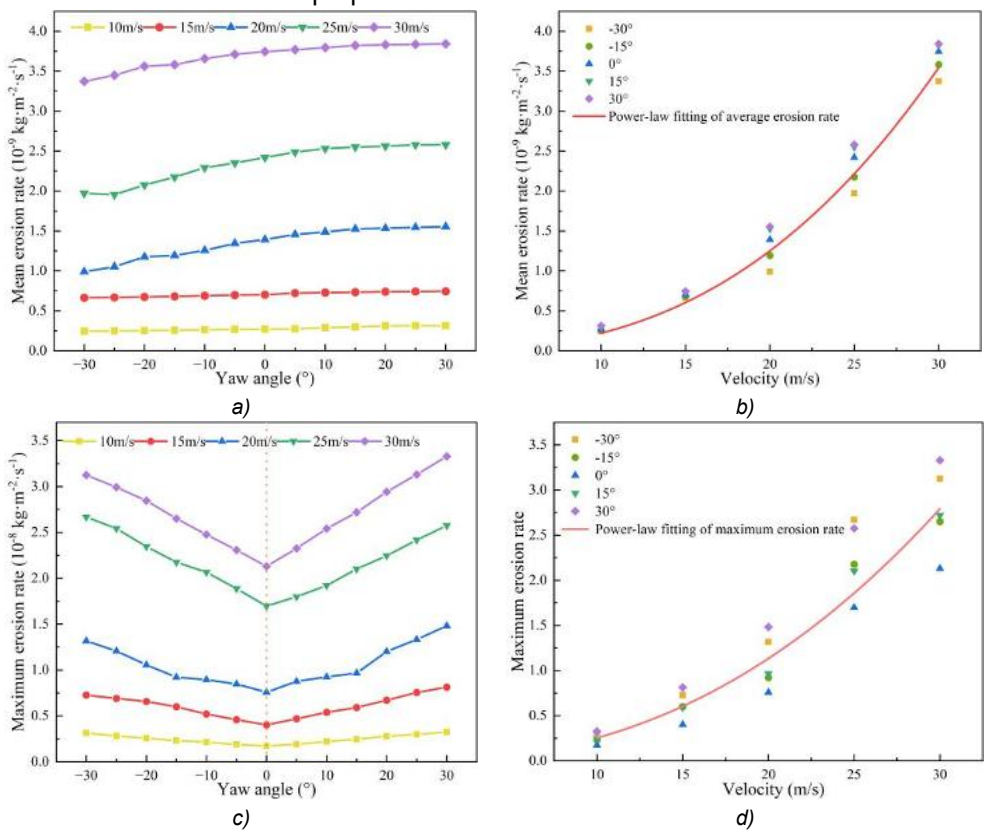

Fig. 5 – Erosion rate under different wind speeds and yaw angles

a) Mean erosion rate–yaw angle; b) Mean erosion rate–wind speed;
c) Maximum erosion rate–yaw angle; d) Maximum erosion rate–wind speed

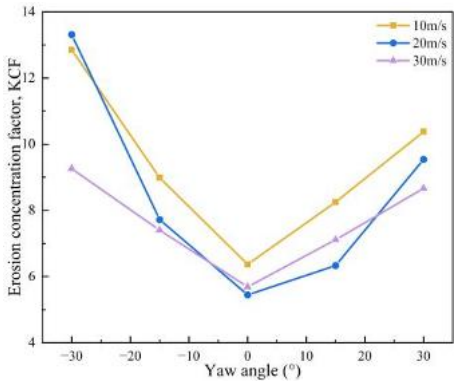
To quantify the spatial concentration of erosion damage, the erosion concentration factor KCF was introduced as the ratio of the maximum erosion rate to the mean erosion rate:

$$KCF = \frac{E_{\max}}{E_{\text{avg}}} \tag{6}$$

where KCF is a dimensionless index describing the deviation of local peak erosion from the mean erosion level. $E_{\max}$ is the maximum erosion rate in the exposed region under the same condition, and E_{avg} is the corresponding mean erosion rate.

For clarity and to facilitate direct comparison with the experimental conditions, only the cases at 10, 20, and 30 m/s are presented in Figure 6. KCF was lowest near 0° and increased toward larger yaw angles; at 20 m/s, the values at −30°, 0°, and 30° were 13.31, 5.45, and 9.54, respectively. The variation in KCF primarily reflects changes in the spatial concentration of erosion rather than in the overall erosion intensity. Near 0°, particle impacts are distributed relatively broadly, reducing the difference between $E_{\max}$ and E_{avg}.

Under yawed conditions, asymmetric flow redistributes particle impacts and may increase their spatial concentration, causing the local peak to rise relative to the mean. This behaviour is physically analogous to the non-uniform particle-impact erosion discussed by *Hamed et al., (2006)*. Notably, the high KCF at −30°, despite a non-maximum E_{avg}, indicates that mean erosion alone may underestimate normalize damage. Therefore, E_{avg}, E_{max}, and KCF should be considered jointly to characterize both erosion severity and spatial concentration.



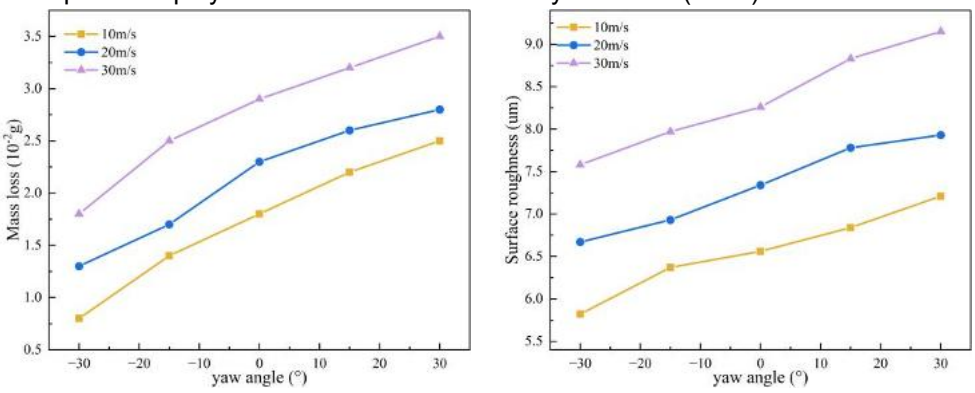


Fig. 6 – Variation of the KCF with yaw angle at different wind speeds

Erosion Damage and Surface Morphology Evolution of PC

Figure 7(a) shows that mass loss increased with both wind speed and yaw angle. From −30° to 30°, the mean mass loss increased by 212.5%, 115.4%, and 88.9% at 10, 20, and 30 m/s, respectively. The observed response is associated with changes in particle-impact momentum and incidence conditions. Higher wind speed increases particle momentum and impact energy, promoting local deformation and progressive material removal. Meanwhile, yaw modifies the relative normal and tangential impact components; the former favors indentation and deformation, whereas the latter promotes grooving and scratching. Their combined variation therefore alters the efficiency of material removal. In contrast, *Zhao et al., (2021),* reported a non-monotonic dependence of glass erosion on particle impact angle. This difference is physically reasonable because yaw angle is not equivalent to the local impact angle, which also depends on particle trajectory and surface orientation, while PC and glass exhibit different mechanical responses.

Surface roughness showed a similar overall trend in Figure 7(b). From −30° to 30°, the mean roughness increased from 5.82 to 7.21 μm, 6.67 to 7.93 μm, and 7.62 to 9.15 μm at 10, 20, and 30 m/s, representing increases of 23.9%, 18.9%, and 20.1%, respectively. The increase in surface roughness reflects the accumulation and overlap of pits, grooves, and displaced material. This result is similar to the deformation-related erosion response of polymeric materials discussed by Xie et al. (2019).

a) *b)*

Fig. 7 – Erosion characteristics of PC specimens

a) mass loss; b) surface roughness.

Figure 8 presents representative surface morphologies of PC specimens along a stepwise comparison path in which either yaw angle or wind speed was varied between adjacent conditions. At 10 m/s, increasing the yaw angle from −30° to −15° increased the density of isolated irregular defects, while relatively smooth regions remained visible. At a constant yaw angle of −15°, increasing the wind speed to 20 m/s enlarged the characteristic size of the defects and promoted local overlap. A further increase in yaw angle to 15° produced more densely distributed and partially interconnected damage features.

At the same yaw angle, increasing the wind speed to 30 m/s resulted in locally concentrated roughening, whereas increasing the yaw angle to 30° led to a more widespread and relatively continuous roughened surface. These changes are consistent with the increases in mass loss and surface roughness shown in Figure 7, indicating that enhanced material removal was accompanied by the accumulation, enlargement, and overlap of surface defects. Irregular local features may be associated with impact-induced deformation, while elongated and groove-like traces suggest the contribution of tangential abrasion. The observed surface degradation therefore reflects the combined effects of repeated particle impacts, local deformation, and abrasive material removal. The coexistence of impact-induced deformation and tangential abrasion is consistent with the combined deformation and cutting mechanisms reported in solid-particle erosion studies.

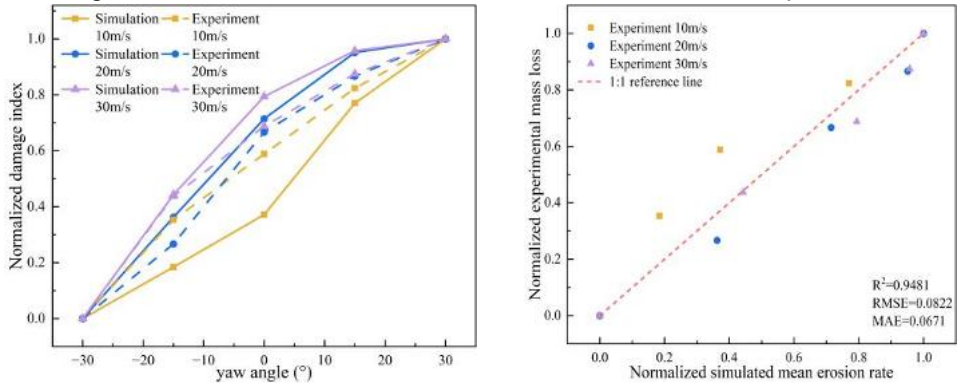
Comparison between Numerical and Experimental Erosion Trends

To eliminate the difference in magnitude and units between the simulated mean erosion rate and the experimental mass loss, the two indicators were independently normalized within each wind-speed group using min–max normalization:



$$D_{i,j}^{*} = \frac{D_{i,j} - D_{min,j}}{D_{max,j} - D_{min,j}} \tag{7}$$

where $D_{i,j}^{*}$ is the normalized value of the i-th yaw-angle condition in the j-th wind-speed group; $D_{i,j}$ is the corresponding original value; and $D_{\min,j}$ and $D_{\max,j}$ are the minimum and maximum values of the same indicator within that wind-speed group, respectively. The simulated mean erosion rate and experimental mass loss were normalized separately using the same procedure. The resulting dimensionless indicators were used to compare their relative variations with yaw angle rather than their absolute magnitudes.

Figure 9(a) compares the normalized mean erosion rate with the normalized experimental mass loss. At all three wind speeds, both quantities generally increased as the yaw angle varied from −30° to 30°, indicating a consistent yaw-dependent response. This agreement can be attributed to the common dependence of both indicators on particle–surface interaction conditions. Variations in yaw alter the relative direction between the particle-laden flow and the exposed surface, thereby modifying particle trajectories, local incidence conditions, and the effective impact area. This result is similar to that reported by *Li et al. (2025)*, where numerical predictions and experimental measurements exhibited consistent variation trends in aeolian-particle transport. The remaining differences at intermediate yaw angles may be associated with the distinct geometrical and loading conditions of the two configurations of the two approaches: the simulation represents spatially averaged erosion over a curved lamp cover, whereas the experiment measures cumulative mass loss from a flat PC specimen subjected to jet impingement.

The correlation analysis in Figure 9(b) yielded R^2=0.9481, RMSE = 0.0822, and MAE = 0.0671, with most points distributed close to the 1:1 reference line. Because min–max normalization was performed separately within each wind-speed group, these statistics quantify similarity in the yaw-dependent variation rather than absolute predictive accuracy. The relatively high R^2 together with the low error metrics further indicate a consistent trend-level agreement between the numerical and experimental results, suggesting that both approaches capture the same variation pattern with respect to yaw angle.

The correlation analysis in Figure 9(b) yielded R^2=0.9481, RMSE = 0.0822, and MAE = 0.0671. Most data points were distributed near the 1:1 reference line, indicating close agreement between the relative variations of the numerical and experimental indicators. Because min–max normalization was performed independently within each wind-speed group, these statistics characterize similarity in the yaw-angle-dependent trends rather than absolute predictive accuracy. The high R^2 and relatively small errors therefore support trend-level agreement between the simulated mean erosion rate and experimental mass loss.

a) *b)*

Fig. 9 - Comparison between normalized numerical and experimental erosion indicators

a) Comparison of normalized simulation and experimental results;
b) Correlation between normalized simulation and experimental results

Fig.10 further quantifies the differences between the normalized numerical and experimental responses.

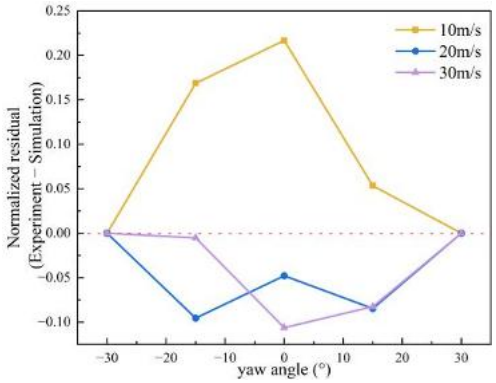


Fig. 10 - Residuals between normalized simulation and experimental results

Positive residuals occurred mainly at 10 m/s, indicating that the normalized experimental mass loss exceeded the corresponding normalized mean erosion rate at several intermediate yaw angles. At 20 and 30 m/s, negative residuals occurred more frequently at intermediate yaw angles, indicating comparatively higher

normalized numerical values. This change in residual sign is likely related to differences in particle incidence, near-wall velocity, dispersion, and effective impact area between the curved lamp cover and the flat PC specimen. Despite these local deviations, both indicators retained the same overall yaw-dependent tendency. This result is similar in validation outcome to *Yan et al., (2024)*, whose wind-tunnel experiments supported the reliability of CFD predictions for wind–sand flow. The residual analysis therefore supports comparative evaluation of erosion response across wind-speed and yaw-angle conditions rather than direct prediction of experimental mass loss.

CONCLUSIONS

The wind-blown sand erosion characteristics of a PC lamp cover for agricultural machinery were investigated using one-way coupled Eulerian–Lagrangian simulations and controlled gas-jet erosion tests. The main conclusions were as follows:

(1) Erosion concentrated near the windward leading edge and adjacent downstream surface, whereas the leeward region was weakly affected. The pressure maximum occurred in the stagnation region, but the erosion maximum shifted downstream, suggesting that the spatial separation between the pressure and erosion maxima was associated with the combined effects of particle impact velocity, impact angle, local particle flux, and the near-wall flow field.

(2) Wind speed strongly influenced erosion intensity within the investigated range. Mean and maximum erosion rates followed power laws with exponents of approximately 2.70 and 2.31. As yaw changed from negative to positive values, the mean erosion rate generally increased, while the maximum erosion rate showed a U-shaped variation with a minimum near 0°.

(3) The erosion concentration factor KCF reflected localized damage. At 20 m/s, its values at −30°, 0°, and 30° were 13.31, 5.45, and 9.54, respectively. The high value at −30° showed that a relatively low mean erosion rate could coexist with pronounced local erosion concentration. Mean erosion rate, maximum erosion rate, and KCF should therefore be considered together.

(4) The coupon tests showed increasing mass loss and surface roughness with wind speed and yaw angle, accompanied by an increase in the density and coverage of surface defects. The normalized mean erosion rate followed the experimental mass-loss trend (R^2 = 0.9481, RMSE = 0.0822, MAE = 0.0671). Because the numerical and experimental configurations differed, this agreement supports relative trend prediction rather than absolute quantitative validation of the full-scale lamp-cover model.

Keywords: *double-layer floating plate*, *liquid sloshing*, *pesticide tank*, *UAVs*

ABSTRACT
Liquid sloshing in pesticide tanks is a major factor affecting the stability of plant-protection unmanned aerial vehicles (UAVs). A double-layer floating plate was developed to improve sloshing suppression. A series of experiments was conducted to measure the sloshing-induced force under horizontal sinusoidal displacement excitation. The results showed that the double-layer floating plate provided superior sloshing suppression over a wider range of liquid depths. An intermediate-sized floating plate also significantly reduced the sloshing-induced force at specific liquid depths, making it suitable for installation within the limited space available inside pesticide tanks.

摘要
药箱内液体晃动是影响植保无人机飞行稳定性的重要因素之一。为提高液体晃动抑制性能设计了双层弹性约束浮板，并实验测量了水平正弦位移激励下的液体晃动力。结果表明双层浮板在更宽的液体深度范围内具有更优异的抑制晃动能力。同时，中等面积的浮板在某些液体深度也可以显著减小晃动力，从而方便布置于药箱的狭小空间。

INTRODUCTION
With the development of agricultural aviation technology, the use of unmanned aerial vehicles (UAVs) has quickly increased over past decade in China. Apart from agricultural information monitoring, fertilizing, seeding, and pest and disease monitoring, one important role of these UAVs are pesticide spraying for their efficient operation and minimal damage properties *(Kartal et al., 2025)*. For the plant protection UAVs, many studies have done such as path planning *(Huang et al., 2023)*, spraying systems design, spraying decisions, downwash airflow *(Fan et al., 2023)*, and droplet drift and deposition *(Kharim et al., 2019)*.

The attitude and velocity of the UAVs may change violently during the operation process involving of take-off, landing, turn around and barrier-avoidance. So, the liquid sloshing occurs almost inevitably in the pesticide tank. Sloshing is the motion of the free liquid surface. Most of the time during the pesticide spraying process, the pesticide container has a free liquid surface. So, the liquid sloshing is prone to occur when the attitude and velocity of the tank change. The fluid sloshing can introduce large complex disturbance forces and torques and the center of mass shifting, which affect the position and attitude stability of the UAVs. Not only is it difficult to ensure the accuracy of the trajectory and spraying, but also it endangers the safety of the drone. The liquid sloshing in plant protection UAVs has attracted the attention of many researchers *(Sun et al., 2024)*. Apart from the reasonable shape design of the container *(Ahmed et al., 2022)*, one effective way to suppress liquid sloshing is to install rigid or flexible bulkheads *(Liu et al., 2025; Park et al., 2025; Raja et al., 2023; Ren et al., 2023; Raja et al., 2023)*, grilles *(Li et al., 2017; Ru et al., 2023; Yu et al., 2020)*, perforated baffles *(Nimisha et al., 2022; Wang et al., 2023; Wang et al., 2026)*, and other similar structures inside the vessel.

Jizhou Zheng, associate professor; Chengbin Zhang, staff with master degree of engineering; Yixuan Sun, undergraduate student; Lin ZHU, postgraduate student; Yan Zhang, associate professor

To reduce liquid impact load induced by sloshing, moving baffles that contain a spring system were introduced *(Kim et al., 2018)*. A kind of floating baffle that can move up and down along two slide rails was adopted to reduce sloshing at different liquid levels *(Yu et al., 2017; Zhang et al., 2025)*.

Bulkheads or baffles that placed horizontally or vertically can suppress the liquid sloshing effectively, especially in the case of multilayer boards. However, the mass of these boards will definitely reduce the payload of the UAVs. For the multi-rotor electric drones that are widely used in plant protection operation, it's definitely something to keep in mind. Based on this consideration, the author used low-density foam to make the baffle and introduced an elastically constrained floating plate to suppress liquid sloshing in the pesticide tank of plant protection UAVs *(Zheng et al., 2023)*. The experimental results show that the liquid sloshing suppression capability is improved to some extents and the sloshing suppression effect depends on the relative location between the free surface and the floating plate.

Based on this discovery, the research is further extended and a double-layer elastically constrained floating plate is proposed in this article. A series of experiments are conducted to investigate the liquid sloshing suppression performance of this new structure, and the underlying physical mechanism is strived to explore.

MATERIALS AND METHODS

Experimental setup

The experiment is carried out on a 6-degree-of-freedom motion simulator that moves horizontally in a sinusoidal function form to drive the liquid in a rectangular tank to slosh, as shown in Fig. 1.

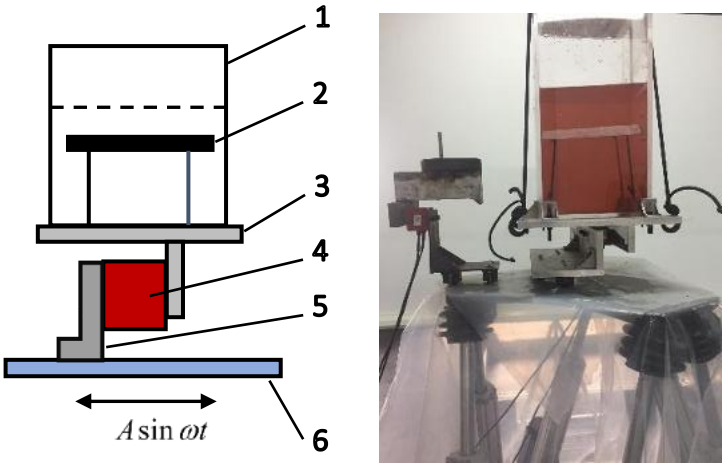

Fig. 1 - Schematic (left) and onsite photo (right) of experiment setup

1-tank; 2-elastically constrained floating plate; 3-T-shaped bracket; 4-force sensor; 5-L-shaped bracket; 6-movement simulator

The internal dimensions of the transparent acrylic rectangular tank are 230 × 220 × 400 mm (length× breadth× height), and the thickness of the walls is 10 mm.

The sloshing force is measured by a force sensor that based on the stress-strain relation and a corresponding dynamic strain instrument. The inertial force of the tank and the T-shaped bracket is synchronously measured by a specially designed mass block and another force sensor, and removed in following data processing procedure.

The square-shaped floating plate is made of foam material with a thickness of 20 mm. Three different side lengths of the square, i.e.,100, 150 and 200 mm, are adopted in different cases. Corresponding to these three lengths, the ratio of the area of the floating plate to the cross-sectional area of the tank is 20%, 45% and 79% respectively.

The floating plate is connected to the fixed point on the bottom of the tank with elastic rubber ropes. The elasticity recovery coefficient of the rope is determined as 67 N/m after undergoing tensile tests on a testing machine and fitting. The length of the rubber rope is set to 150 mm for the single-layer floating plate, and the lengths of the two rubber ropes are both 75 mm for the series-connected double-layer floating plate. In other words, the total length of the rope is the same for these two kinds of floating plate.

The liquid used in the experiment is tap water. Some paint is added in the water for the convenience of observation.

Experimental cases

Basic conditions

During the spraying process, the liquid inside the pesticide tank of the plant protection drone is constantly consumed, causing the liquid depth to change. To reflect the liquid sloshing suppression ability of the floating plate at different liquid depths, six liquid depths are considered, namely 100 mm, 150 mm, 200 mm, 250 mm, 300 mm and 350 mm.

The natural frequency of the liquid depends on the tank's length and the liquid depth that can be calculated according to the formula listed as follows *(Ibrahim, 2005)*.

$$\omega_n = \sqrt{g \frac{n\pi}{l} \tanh \frac{n\pi h}{l}} \tag{1}$$

where:

ω_n is the n-th order natural frequency of the liquid, [rad/s];

n is the order of the liquid sloshing frequency, n = 1,2,3….;

g is the acceleration due to gravity, [m/s^2], and g = 9.8 m/s^2;

l and h are is the tank length in the direction of excitation and the liquid depth respectively, [m].

The first-order natural frequency plays a critical role in liquid sloshing. So, experimental conditions focus on the vicinity of the first-order natural frequency in this article. The first-order natural frequency f in Hz is adopted in experiments for convenience. According to the formula (1), the first natural frequencies of six depths above-mentioned are 1.725 Hz, 1.811 Hz, 1.834 Hz, 1.839 Hz, 1.841 Hz and 1.841 Hz, respectively.

The horizontal displacement of the motion simulator, denoted by $x(t)$, is expressed as:

$$x(t) = A \sin(\omega t) \tag{2}$$

where:

A is the amplitude of the horizontal displacement, [m];

ω is the excitation frequency generated by the motion simulator, [rad/s];

t is the time of motion, [s].

After many trials, A = 5 mm is chosen as the excitation amplitude. Either small amplitude or violent sloshing can be got by changing excitation frequency at this amplitude. The duration time for each case is set to 60 seconds.

To get different amplitude sloshing, the excitation frequency is adopted as 0.5 f - 1.2 f (with an interval of 0.1 f). It should be noted that the sloshing phenomenon is more severe when approaching the first natural frequency, so two excitation frequencies are further introduced, i.e., 0.95 f and 1.05 f.

In the subsequent experiments, the liquid depth and excitation frequency are used as basic conditions. In other words, the sloshing forces at different liquid depth and excitation frequency will be measured for all kinds of floating plate. The number of floating plate layers and the area of the floating plates are the focus of this research, so they are served as control variables.

The number of layers

In previous studies *(Zheng et al., 2003)*, only one elastically contained floating plate is used which has been described in detail. Based on this layout, another floating plate and elastic ropes are added. Namely, two floating plates are used which connect with rubber ropes and arrange in a series form. Here, the former is called as a single-layer floating plate and the latter is named as a double-layer one. At this stage, the focus is on examining the impact of the number of floating board layers on the ability to suppress sloshing. So, the area of the floating plate keeps as same, and the area ratio of floating plate is 79% in both single-layer and double-layer floating plate.

To analyze the effect of the different floating plate arrangement on suppressing liquid sloshing, experiments were also conducted to measure the liquid sloshing force without any floating plate.

The areas of the double-layer floating plate

The cross-sections of the container may change at different position and there are accessories such as pumps and tubes in the pesticide tank of plant protection UAVs. It means that the space available may be limited for arranging the floating plate. Therefore, a smaller floating plate may be needed in practical applications.

Based on the first stage experiment, the floating plate with different sizes are used in the double-layer floating plate to analyze the influence of area on the sloshing suppression effect. In the first case, both the upper and the lower floating plate have the same area ratio. In other words, the areas of two floating plates change synchronously. Three area ratios are adopted, i.e., 20%, 45% and 79%. In the second case, the area ratio of the upper floating plate keeps as 79%, but the lower one has the area ratio of 20%, 45% and 79%, respectively.

RESULTS

The effect of the number of layers

At each liquid depth, horizontal displacement excitations with different frequencies were applied to the tank without any floating plate, with the single-layer floating plate, and with the double-layer floating plate. The liquid sloshing force was measured using the strain-type force sensors, and the results are shown in Fig. 2. Where, three configurations are indicated as 'without plate', ‘single-layer’ and ‘double-layer’, respectively.

The blue curve shown in the figure is the theorical liquid sloshing force in a rectangular tank that given in following formula *(Ibrahim, 2005)*

$$F = A\omega^2 \rho l w h \left\{ 1 + \sum_{n=1}^{\infty} \left[\frac{8 \tanh \frac{(2n-1)\pi h}{l}}{\frac{(2n-1)^3 \pi^3 h}{l}} \frac{\omega^2}{\omega_n^2 - \omega^2} \right] \right\} \tag{3}$$

where: F is the sloshing force, [N];

ρ is the density of the liquid, [kg/m^3], and the density of water is 1000 kg/m^3;

w is the liquid width, [m].

The other variables and values have already been given earlier.

It needs to be pointed that the theoretical sloshing force is given based on linear theory. The sloshing force tends towards infinity at the natural frequency, and it isn’t been fully drawn for clarity.

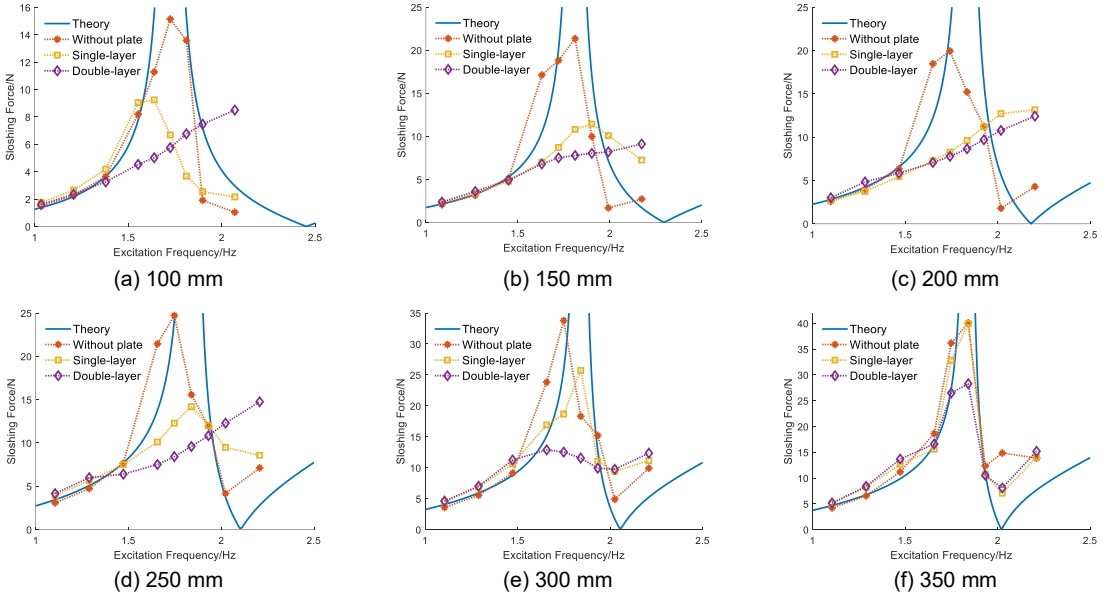

Fig. 2 - Liquid sloshing force at different liquid depths

It can be seen that the sloshing suppression effect of single-layer and double-layer floating plates varies at different liquid depths. Therefore, the following discussion will be based on the liquid depth.

When the excitation frequency is 0.6, 0.7, and 0.8 times the first-order natural frequency (i.e. 0.6 f, 0.7 f and 0.8 f), the experimental values agree well with the theoretical ones at all liquid depths, as shown in the figure. The reason is that the amplitude of liquid sloshing is relatively small at these excitation frequencies, meeting the small-amplitude sloshing assumption in formula (2). This also indicates that the sloshing force measurement system in this article is reasonable and reliable.

Moreover, it also can be seen that the sloshing force with a single-layer or double-layer floating board is not significantly different from that without any floating board at all liquid depths and these three excitation frequencies. This implies that the float plate is not very effective in suppressing slight movements of the liquid. Therefore, the main concerns are put on the large amplitude sloshing of the liquid near its natural frequency.

Fig. 2(a) shows the liquid sloshing force when the liquid depth is 100 mm. It can be seen that the sloshing force decreases from 11 N to 9 N and 5 N for without plate, single-layer and double-layer floating plate at 0.95 f. When the excitation frequency is equal to 1.0 f, the sloshing forces under these cases are 15N, 7N and 5N, respectively. The elastic rope length of the single-layer floating board is 150 mm, which is greater than the liquid depth. Therefore, the floating board remains in a floating state and cannot effectively suppress the movement of the liquid. However, the elastic rope length of the lower section of the double-layer floating plate is 75 mm, which is less than the depth of the liquid. The elastic rope is stretched by the buoyancy of the lower floating plate. On one hand, the lower floating plate rises to a position near the free liquid surface. On the other hand, the movement of the lower floating board is restricted by the elastic cord. As a result, neither the floating board nor the free liquid surface can move violently in the vertical direction. In other words, the liquid can hardly move freely, but only moves horizontally along with the tank. Therefore, the sloshing force for the double-layer floating plate exhibits characteristics of an inertial force that increases with the increase of the excitation frequency.

When the liquid depth equals the rope length of the single-layer floating plate, i.e., 150 mm, the elastic rope begins to bear the tension generated by the upwards movement of the plate. It means that the elastic rope can rebound to some extent if large amplitude liquid sloshing occurs. Therefore, it exhibits relatively good sloshing suppression effect near the natural frequency. As for the double-layer floating plate, the lower plate is completely submerged in the liquid and the lower elastic rope is fully stretched at this depth. So, the sloshing of the liquid below the lower plate is completely suppressed. Meanwhile, the small amount of liquid above the lower floating plate hardly moves vertically due to the suppression of the upper floating plate. Thus, the sloshing force still maintains the inertial force characteristics.

Both single-layer and double-layer floating plate are submerged below the free liquid surface when the liquid depth is 200 mm. The elastic rope is fully stretched for both cases so that the liquid sloshing is effectively suppressed. The sloshing force is about 8 N at 0.95 f, which is 40% of that without any plate. The sloshing forces for the two kinds of floating plate exhibit an inertial force characteristic and are almost the same except for a few frequencies.

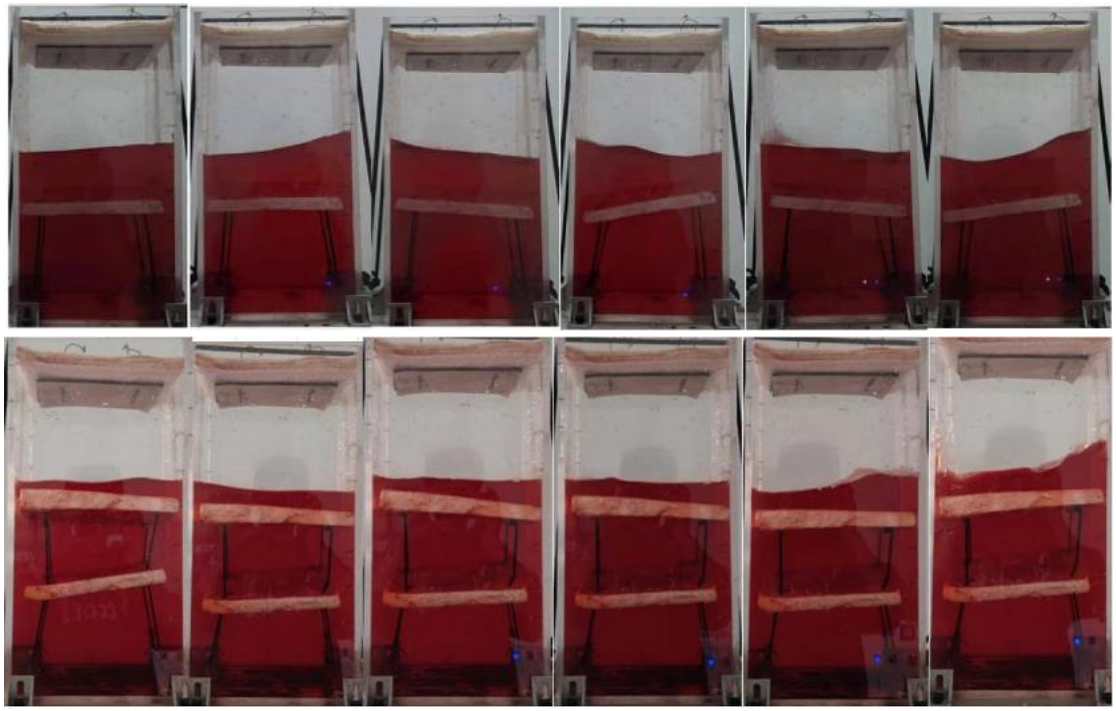
When the depth is 250 mm, the sloshing forces exhibit characteristics similar to those at the liquid depth of 150 mm. However, the formation mechanism of the sloshing force for the single-layer floating plate is different. The floating plate is totally submerged and the elastic rope is fully stretched. Thus, the liquid below the plate moves with the tank and the sloshing force with inertial force characteristics generates. But the liquid on the floating plate (about 50 mm deep) can move freely. This part of the liquid will experience significant oscillation when the excitation frequency is close to the natural frequency, resulting in relatively large dynamic forces. For the double-layer floating plate, both segments of the elastic rope are fully stretched. The upper floating plate is closer to the free liquid surface, and all the liquid cannot move freely. Therefore, the sloshing force still remains in the form of the inertial force. As for the magnitude of the sloshing forces at natural frequency, they are 25 N, 14 N and 8 N for without plate, single-layer and double-layer floating plate, respectively. In other words, the sloshing force can be reduced about half or two-third by single-layer or double-layer floating plate.

When the liquid depth reaches 300 mm, the maximum sloshing forces for three cases are 33 N, 25 N and 12 N, respectively. The suppression strength and effective range of the double-layer plate are both greater than those of the single-layer plate.

The sloshing forces at all frequencies for the single-layer floating plate are basically the same as those without plate when the liquid depth is 350 mm. It implies that the sloshing suppression capability is almost completely lost. Although the double-layer floating plate still functions, the range is limited to a narrow frequency band. The reason is that the floating plate locates a deeper position below the free surface and the liquid on the floating plate is no longer restricted by the floating plate.

Overall, the double-layer floating plate has a wider effective range and better suppression capability than the single-layer floating plate. To intuitively understand the sloshing suppression effect of the floating plate, the typical waveforms of the free liquid surface under different excitation frequencies are shown in Fig.3.

Where, the liquid depth is 250 mm and the excitation frequency is 0.7 f, 0.8 f, 0.9 f, 1.0 f, 1.1 f, and 1.2 f, respectively.



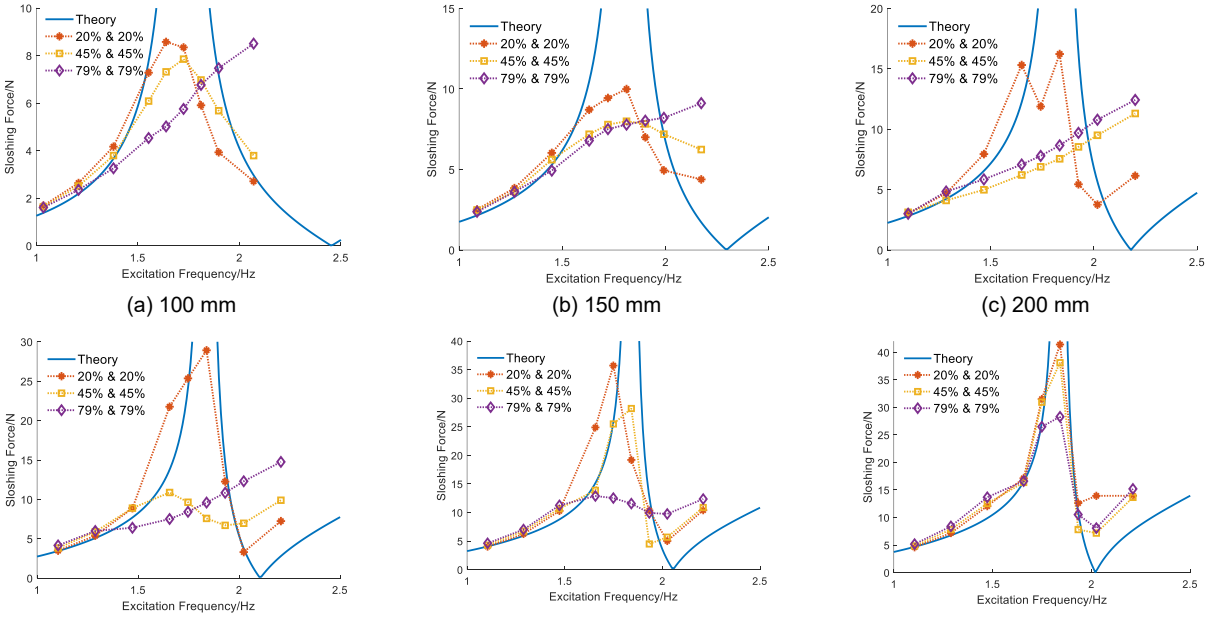


Fig. 3 - Snapshots of free surface (top: single-layer floating plate; bottom: double-layer floating plate; from left to right: 0.7 f, 0.8 f, 0.9 f, 1.0 f, 1.1 f, and 1.2 f)

It can be seen that the upper plate of the double-layer floating plate is closer to the free liquid surface than the single-layer floating plate because of larger buoyancy. The sloshing of the liquid above the floating plate can be suppressed by the floating plate and large amplitude sloshing hardly occurs even if at the natural frequency.

The effect of the areas of the floating plate

As mentioned earlier, the influence of the plate areas on the sloshing suppression effect of the double-layer floating plate is divided into two cases. The results under the first case are given here. The liquid sloshing force at different depth is shown in Fig. 4 when the areas of two plates change synchronously.

(a) 100 mm (b) 150 mm (c) 200 mm

(d) 250 mm (e) 300 mm (f) 350 mm

Fig. 4 - Liquid sloshing force at different liquid depths

Apart from the liquid depth of 350 mm, the double-layer floating plate with the largest area ratio (i.e. 79%) shows excellent sloshing suppression performance. Over a wide range of liquid depths, the sloshing force exhibits characteristics of inertial force because the movement of the upper part of liquid is almost completely suppressed by the floating plate.

Comparing the liquid sloshing forces with those of without any plate shown in Fig. 2, it can be got that the double-layer floating plate with the smallest area ratio (i.e. 20%) has good sloshing suppression capability at smaller liquid depths. At the liquid depth of 100 mm, 150 mm and 200 mm, the maximum sloshing force is about 9 N, 10 N and 16 N, reduced by about 40%, 52% and 20%, respectively. However, the sloshing suppression effect almost disappears totally at liquid depths higher than 250 mm. On one hand, smaller plate areas have less impact on the sloshing of the upper free liquid. On the other hand, smaller areas mean less buoyancy from the floating plates, and thus the position of the upper floating plate is lower than that of a larger floating plate. This also reduces the effect of the floating plate on the upper layer of liquid. Therefore, the double-layer floating plate with the smallest area ratio is more likely to fail under larger liquid depth conditions. In other words, the small area of the floating plate is a disadvantage for the liquid sloshing suppression. A larger area is preferred if there is enough space available in the container.

Compared with the floating plate that have the largest area ratio, the double-layer floating plate with the moderate area ratio (i.e. 45%) has relatively weaker liquid sloshing suppression performance when the liquid depth is equal to or greater than 300 mm. The difference of the liquid sloshing force is about 10 N-17 N near the natural frequency. The situation is similar when the liquid depth is 100 mm but the difference is not so significant. It is determined by the fact that the sloshing force of the liquid is relatively small at this depth. However, the situation changes obviously within the range of medium liquid depths (i.e. 150 mm – 250 mm). The sloshing force of medium-sized floating plate is not significantly different from that of large-sized floating plate, especially near the natural frequency. The maximum difference of the sloshing force is less than 5 N. It means that the double-layer floating plate can still effectively suppress liquid sloshing even if the area ratio is less than 50%. This makes it possible to arrange the double-layer floating plate within the limited space of the pesticide container.

The typical wave shapes of the free liquid surface for the double-layer floating plate with the smallest and medium area ratio are shown in Fig. 5. Where, the liquid depth is 250mm and the excitation frequency is also 0.7 f -1.2 f. The waveforms for the double-layer floating plate with the largest area have been shown in Fig. 3, so they are not given again.

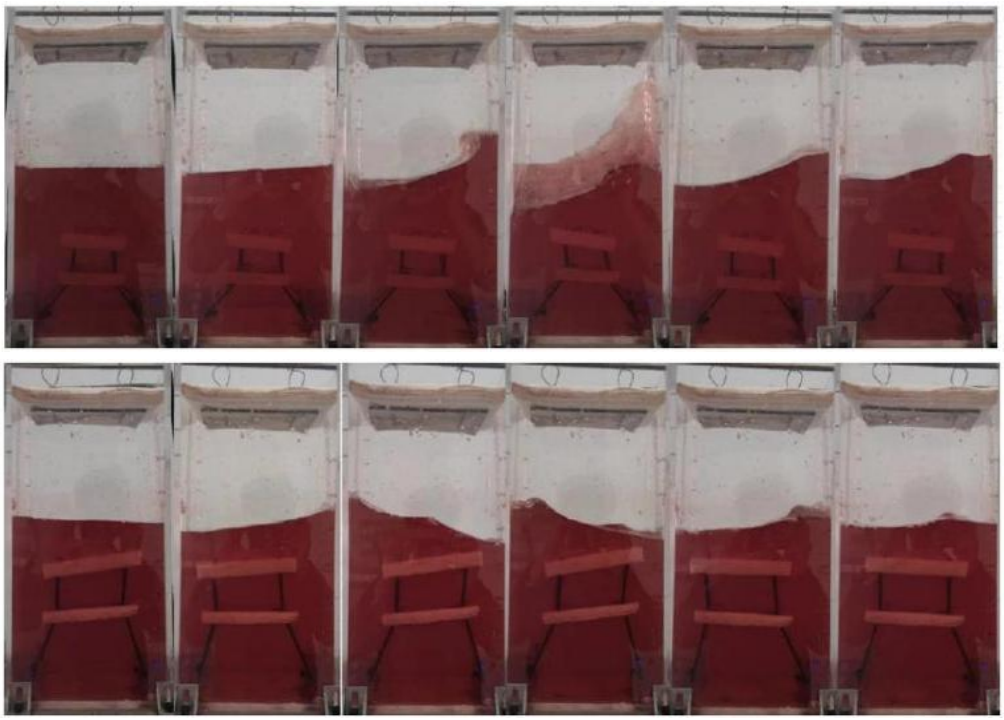

Fig. 5 - Snapshots of the liquid free surface (top: 20% and 20%; bottom: 45% and 45% from left to right: 0.7 f, 0.8 f, 0.9 f, 1.0 f, 1.1 f, and 1.2 f)

It can be seen that the double-layer floating plate with the smallest area ratio exhibits large amplitude sloshing near the natural frequency, which is similar to the case without any plate. However, the situation is much better for the double-layer floating plate with medium area ratio. Although the sloshing amplitude of the free surface is relatively large at $0.9f$ and $1.0f$, the sloshing force does not increase significantly.

According to the experimental results above mentioned, the size of the floating plate that is close to the free liquid surface seems to have a greater influence on the sloshing of the liquid. Therefore, the experiment under the second case were further carried out. That is, the upper floating plate keeps the largest area, and the lower floating plate is the smallest or medium area. The liquid sloshing forces at different depths are shown in Fig. 6 when only the area of lower plate changes.

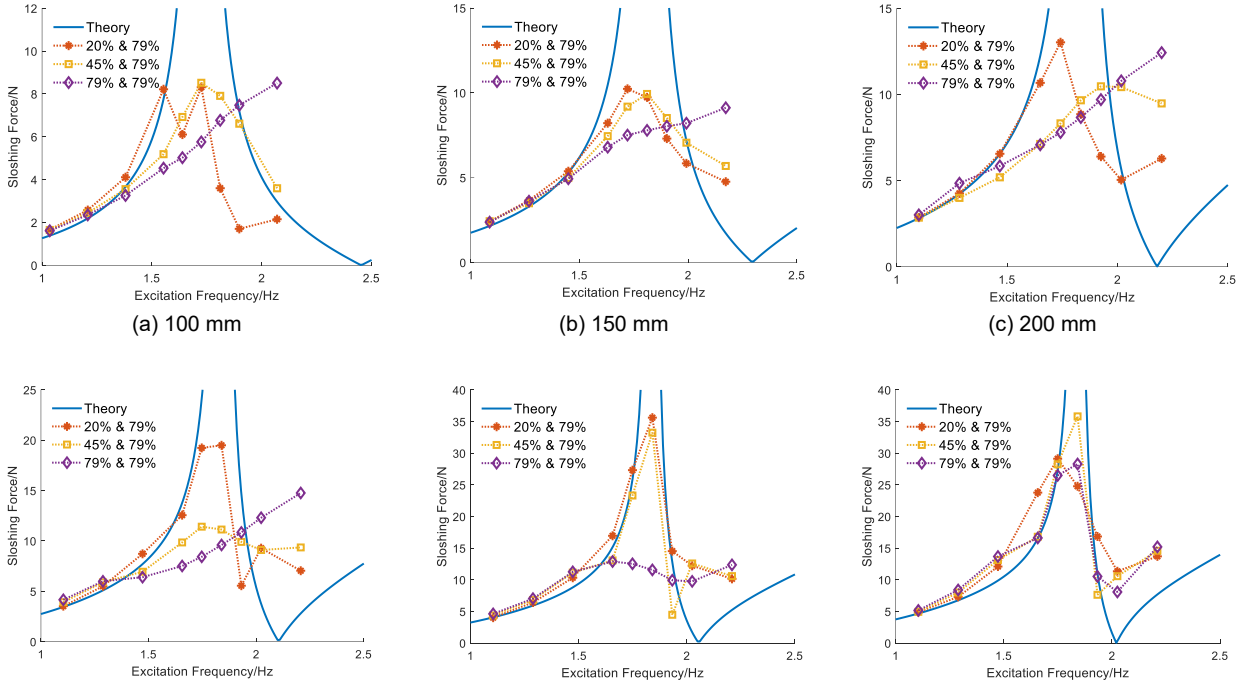

Fig. 6 - Liquid sloshing force at different liquid depths

When the liquid depth is equal to 100 mm and 150 mm, the maximum sloshing force for the smallest and medium area lower plate is about 8 N and10 N, respectively. The forces are almost equal to those of both floating plate with the same area. The reason is that only the lower floating plate functions at these liquid depths. The similar situation occurs at the liquid depth of 300 mm and 350 mm. The peak of the sloshing force near the natural frequency means that large amplitude liquid sloshing appears and the sloshing suppression performance of the floating plate decreases to some extent. The largest difference occurs at the liquid depth of 250 mm. The maximum sloshing force is 19 N for the double-layer floating plate composed of areas ratio of 20% (lower layer) and 79% (upper layer), while the maximum sloshing force is 28 N for the double-layer floating plate with the smallest area. This illustrates the role of the upper floating plate area in damping the motion of the upper liquid.

Overall, compared with configurations in which the area ratios of both floating plates were increased simultaneously, increasing only the area of the upper floating plate did not significantly reduce the sloshing-induced force. Moreover, the sloshing force exhibits some unusual changes at certain liquid depths and excitation frequencies. The reason may lie in the change of the direction of the tension of the upper elastic rope, which makes the interaction between the upper floating plate and the liquid more complex. It is necessary to further study its mechanism with the help of numerical simulations and other methods in order to apply the double-layer floating plate in complex situation.

The typical wave shape of the free surface is shown in Fig. 7 where the liquid depth is 250 mm.

Fig. 7 - Snapshots of the liquid free surface (top: 20% and 79%; bottom:45% and 79%; from left to right: 0.7 f, 0.8 f, 0.9 f, 1.0 f, 1.1 f, and 1.2 f)

It can be seen that large amplitude sloshing occurs near the natural frequency for the area combination of 20% and 79%, while the sloshing amplitude is relatively small for the area combination of 45% and 79%. It is consistent with the changes of the measured sloshing forces shown in Fig.6 (d).

CONCLUSIONS

To improve sloshing suppression in practical applications, a double-layer floating plate was developed based on the single-layer configuration. The effects of the structural parameters of the double-layer floating plate were investigated by measuring the sloshing-induced force at different liquid depths and excitation frequencies. The underlying sloshing-suppression mechanism was also preliminarily examined. The main conclusions are as follows:

(1) The double-layer floating plate provided superior sloshing suppression over a wider range of liquid depths and excitation frequencies.

(2) The medium-sized double-layer floating plate also exhibited effective sloshing suppression at specific liquid depths, indicating its suitability for installation within tanks with limited internal space.

(3) In this study, low- and high-amplitude sloshing conditions were generated by varying the excitation frequency. Both the sloshing-induced forces and the suppression performance of the floating plates were evaluated under steady-state excitation. During actual UAV operation, however, sudden changes in attitude or velocity may produce transient sloshing. Therefore, future work should develop a measurement and data-acquisition system incorporating strain gauges and a microcontroller to capture transient sloshing-induced forces and moments during flight.

Keywords: *agricultural tractor, failure mechanism, service record, engine operating hour, reliability, mechanical engineering*

ABSTRACT
Agricultural tractors are repairable mechanical systems whose service records can provide insight into how failure mechanisms evolve over their operating life. This study analysed 200 failure cases recorded for 75 Zetor tractors. Failure causes were classified into six mechanism categories and compared across four engine operating-hour classes. The relationship between operating-hour class and failure mechanism was evaluated using contingency tables, chi-square tests, Cramer's V, odds ratios, and correspondence analysis. Sealing-related failures predominated in the dataset, whereas material/manufacturing and electrical causes were more prevalent during the early stages of operation, and wear-, friction-, and fatigue-related mechanisms became more prominent at higher operating hours. The findings provide a basis for service planning and the assessment of tractor reliability.

STRESZCZENIE
Ciągniki rolnicze są naprawialnymi układami mechanicznymi, a dane serwisowe mogą wskazywać, jak mechanizmy uszkodzeń zmieniają się w trakcie eksploatacji. W pracy przeanalizowano 200 przypadków uszkodzeń zarejestrowanych dla 75 ciągników marki Zetor. Przyczyny uszkodzeń pogrupowano w sześć kategorii mechanizmów i porównano w czterech klasach motogodzin pracy silnika. Zastosowano tabele kontyngencji, statystykę chi-kwadrat, współczynnik V Cramera, ilorazy szans oraz analizę korespondencji. Największy udział w zbiorze danych miały mechanizmy uszczelnieniowe, natomiast wady materiałowo-wykonawcze i elektryczne częściej występowały we wczesnej fazie eksploatacji, a mechanizmy zużyciowo-tarciowe w późniejszych zapisach serwisowych.

INTRODUCTION

Agricultural tractors are complex repairable machines that combine mechanical, hydraulic, pneumatic, electrical and control subsystems. In the discipline of mechanical engineering, they can be treated as mobile technical systems exposed to variable loads, vibration, contamination, thermal cycles, lubricant ageing, environmental effects and operator-dependent usage patterns. Their failure behaviour is important because breakdowns may interrupt agrotechnical operations during short seasonal windows and can increase maintenance costs, downtime and logistic pressure on service networks.

Reliability engineering describes the performance of technical systems using concepts such as failure occurrence, maintainability, availability, lifetime distribution and risk of degradation during operation (*Birolini, 2017; Blischke and Murthy, 2000; O'Connor and Kleyner, 2012; Rausand and Hoyland, 2004*). In many repairable systems, the life cycle is often interpreted through early-life failures, random failures and wear-out failures. However, these phases should not be treated only as statistical intervals. From a mechanical engineering perspective, they should also be linked with loads, material response, contact conditions, lubrication, sealing quality, electrical continuity and structural integrity. This interpretation is consistent with failure-mechanism analysis, which connects observed failure symptoms with the physical processes that caused them (*Tinga, 2013; Zio, 2009*).

A complete lifetime dataset is required to estimate reliability functions, failure intensity or hazard rates with high confidence (*Birolini, 2017; Rausand and Hoyland, 2004*). In agricultural service practice, however, available data are often more limited. Service databases may include only failed cases, incomplete exposure histories, repair descriptions or non-standardised cause descriptions. Such data are not sufficient for estimating absolute failure probability in the whole tractor population, but they can still be useful for analysing the internal structure of recorded failures. This distinction is important because an incomplete service dataset may still indicate which physical mechanisms are more frequent at different stages of recorded operation.

The practical importance of maintenance and diagnostic data in agricultural machinery has been confirmed in several recent studies. Tractor maintenance planning, reliability support systems and replacement strategies have been analysed using field, service and decision-support approaches (*Atli, 2024; Kataev et al., 2024; Kolhe et al., 2024; Mishra and Satapathy, 2023*). Diagnostic and predictive-maintenance methods have also been applied to tractor transmission systems and agricultural machinery components (*da Silva et al., 2019; Jardine et al., 2006; Mobley, 2002; Moubray, 1997*). Other studies have examined failures and reliability models of farm tractors and working parts exposed to abrasive or variable operating conditions (*Durczak and Selech, 2022; Mikolajczak and Napiorkowski, 2016; Napiorkowski and Gonera, 2020; Paman et al., 2024*). These works show that service and field information can support engineering decisions, but they also indicate that the interpretation of failure records depends strongly on the quality and structure of the available data.

Recent developments in agricultural engineering additionally show that tractor operation can be described with increasing detail using mission profiles, CAN-BUS data, GNSS records, working cycles and operational analytics (*Angelucci and Mattetti, 2024; Gˆ tz et al., 2025; Mattetti et al., 2021*). These studies are important because they link machine use with real operating conditions. At the same time, many service organisations still rely on ordinary workshop records rather than continuous sensor-based monitoring. Therefore, there is a practical need for simple methods that can extract engineering information from historical service records, even when these records do not contain complete exposure data.

From a mechanical engineering viewpoint, the physical interpretation of the recorded cause is essential. A sealing failure may indicate a different technical problem than a short circuit, a material defect, a seized actuator, a fractured pipe or excessive wear of a transmission component. Therefore, the service cause can be transformed into a mechanism-oriented variable that supports feedback to design, manufacturing quality control, warranty analysis and maintenance planning. This interpretation is also consistent with contemporary agricultural engineering studies, where machine behaviour, material properties, reliability, operational data and environmental aspects are jointly analysed (*Angelucci and Mattetti, 2024; Kim and Kim, 2023; Lovarelli and Bacenetti, 2019; Mattetti et al., 2021; Scolaro et al., 2021; Zelazinski et al., 2023*).

Categorical-data methods are useful when service records are grouped into operating-time classes and mechanism categories. Contingency tables, the Pearson chi-square test, Cramer's V, odds ratios and correspondence analysis allow the researcher to describe associations between two categorical variables without assuming a continuous failure-time distribution (*Agresti, 2019; Friendly and Meyer, 2015; Greenacre, 2017; McHugh, 2013*). In the present context, these methods are not used to build a complete reliability model. They are used to determine whether the structure of recorded failure mechanisms changes across engine operating hour classes.

The research gap addressed in this paper is the limited use of ordinary service records for identifying operating-time-dependent failure mechanisms of agricultural tractors. Previous studies have often focused on failure frequency, maintenance planning, diagnostic methods or general reliability indicators, whereas fewer studies have transformed workshop failure causes into physical mechanism categories and analysed their distribution across operating-time classes. The objective of the study was therefore to analyse how recorded failure causes of Zetor tractors were distributed across engine operating hour classes. The working assumption was that early service records would contain a relatively higher contribution of material, manufacturing, assembly and electrical faults, whereas later records would show a higher contribution of wear-, friction- and fatigue-related mechanisms.

MATERIALS AND METHODS

The empirical material consisted of historical service failure records of Zetor agricultural tractors. The dataset contained 200 diagnostic service cases recorded for 75 unique vehicle identification numbers. Each record included the tractor model, engine operating hours (EOH; the source records used the Polish term motogodziny, abbreviated as “mth”), observed symptom, assembly group, damaged part, failure cause, labour

cost, parts cost and total repair cost. The dataset contained recorded failures only; therefore, it was not used to estimate failure probability, reliability function or hazard rate.

The operating time indicator was discretised into four classes: 0-250 EOH, 251-500 EOH, 501-750 EOH and more than 750 EOH. These intervals were used as practical stages of recorded operation: early operation, initial regular operation, intermediate operation and later recorded operation. The descriptive characteristics of the dataset are presented in Table 1.

Table 1

Characteristics of the analysed service failure dataset

Characteristic	Value
Number of service failure cases	200
Number of unique VIN identifiers	75
Minimum [EOH]	2
Maximum [EOH]	1498
Mean [EOH]	414.69
Median [EOH]	390
Number of EOH classes	4
Number of mechanism categories	6

The original service causes were translated from Polish service terminology and grouped into six failure-mechanism categories. The grouping was performed on the basis of the physical interpretation of the cause, not on the basis of the failed subsystem. This distinction is important because the same subsystem may fail through several mechanisms. For example, a pneumatic or hydraulic component may fail because of a sealing fault, material defect, contamination or wear. The taxonomy used in the analysis is shown in Table 2.

Table 2

Failure-cause taxonomy used for mechanism-based analysis

Failure-mechanism category	Original service causes included in the category
Sealing-related	damaged sealing surface; damaged sealing collar; damaged seals; damaged cylinder seal
Material/manufacturing	material defect; defective weld or soldering; inaccurate machining; defective thread; defective battery cell
Electrical	short circuit; burnout; no continuity; broken wire
Wear/friction/fatigue	seizure; excessive wear; excessive clearance; cracking
Assembly/structural	faulty assembly; unriveting; pipe fracture; bending; fracture
Other/contamination/joint	delamination; impurities; clogging; functional fault

Following general recommendations for categorical and count-data analysis (*Agresti, 2019; Friendly and Meyer, 2015*), three statistical measures were used to describe the association between operating-time class and failure-mechanism category. First, the Pearson chi-square statistic was calculated from the contingency table, as shown in Equation (1):

$$\chi^2 = \sum_{i=1}^{r} \sum_{j=1}^{c} \frac{(O_{ij} - E_{ij})^2}{E_{ij}} \quad (1)$$

where:

O_{ij} – observed frequency in row i and column j;

E_{ij} – expected frequency in row i and column j under the assumption of independence;

r – number of rows in the contingency table;

c – number of columns in the contingency table.

The strength of association was expressed using Cramer's V, as given in Equation (2):

$$V = \sqrt{\frac{\chi^2}{n \cdot min(r-1,\ c-1)}} \quad (2)$$

where: n – total number of observations included in the contingency table;

$min(r - 1, c - 1)$ – the smaller dimensional correction factor used to normalise the chi-square statistic.

For early-life comparison, the odds ratio for each failure-mechanism category was calculated using the 0-250 EOH class versus all later records, as shown in Equation (3):

$$OR = \frac{(a+0.5)(d+0.5)}{(b+0.5)(c+0.5)} \quad (3)$$

where:

OR – odds ratio for the occurrence of a given failure mechanism in early-life service cases compared with later service cases;

a – number of early-life cases with the analysed failure mechanism;

b – number of early-life cases without the analysed failure mechanism;

c – number of later service cases with the analysed failure mechanism;

d – number of later service cases without the analysed failure mechanism;

0.5 – Haldane–Anscombe continuity correction added to each cell to stabilise the odds-ratio estimate when sparse cells occur.

Finally, correspondence analysis was used as an exploratory graphical method to visualise associations between EOH classes and failure-mechanism categories. The map was not treated as a predictive model; it was used to support interpretation of the contingency structure.

RESULTS

The overall distribution of failure-mechanism categories is shown in Figure 1. The largest category was sealing-related failures, which included 90 service cases and represented 45.0% of the dataset. Material/manufacturing mechanisms accounted for 37 cases, electrical mechanisms for 32 cases and wear/friction/fatigue mechanisms for 23 cases. Assembly/structural and other/contamination/joint mechanisms were less frequent.

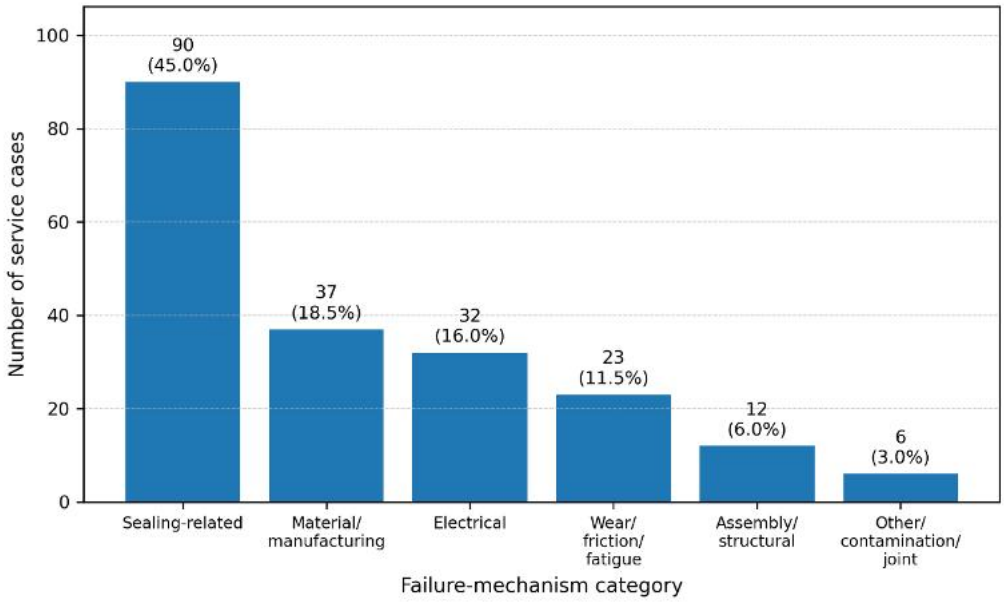

Fig. 1 - Distribution of failure-mechanism categories in the analysed service records

The predominance of sealing-related causes is mechanically meaningful. Many tractor assemblies operate with hydraulic oil, lubricants, compressed air or coolant, and their functional reliability depends on the integrity of seals, collars, sealing surfaces and joints. A sealing fault may therefore appear in different subsystems, but it represents one common physical mechanism that can be targeted by improved material selection, assembly control and early leakage inspection.

The cross-classification of EOH classes and failure-mechanism categories is presented in Table 3.

Table 3

Contingency table of engine operating hour class and failure-mechanism category

EOH class	Sealing-related	Material/ manufacturing	Electrical	Wear/ friction/ fatigue	Assembly/ structural	Other/ contamination/ joint	Total
0-250	18	14	11	2	3	4	52
251-500	38	16	8	10	4	2	78
501-750	29	7	10	5	4	0	55
>750	5	0	3	6	1	0	15
Total	90	37	32	23	12	6	200

The chi-square statistic calculated according to Equation (1) was 31.25, with 15 degrees of freedom and p = 0.008. Cramer's V calculated according to Equation (2) was 0.228. This indicates a weak-to-moderate but interpretable association between operating-time class and failure-mechanism category.

The percentage structure by EOH class is illustrated in Figure 2.

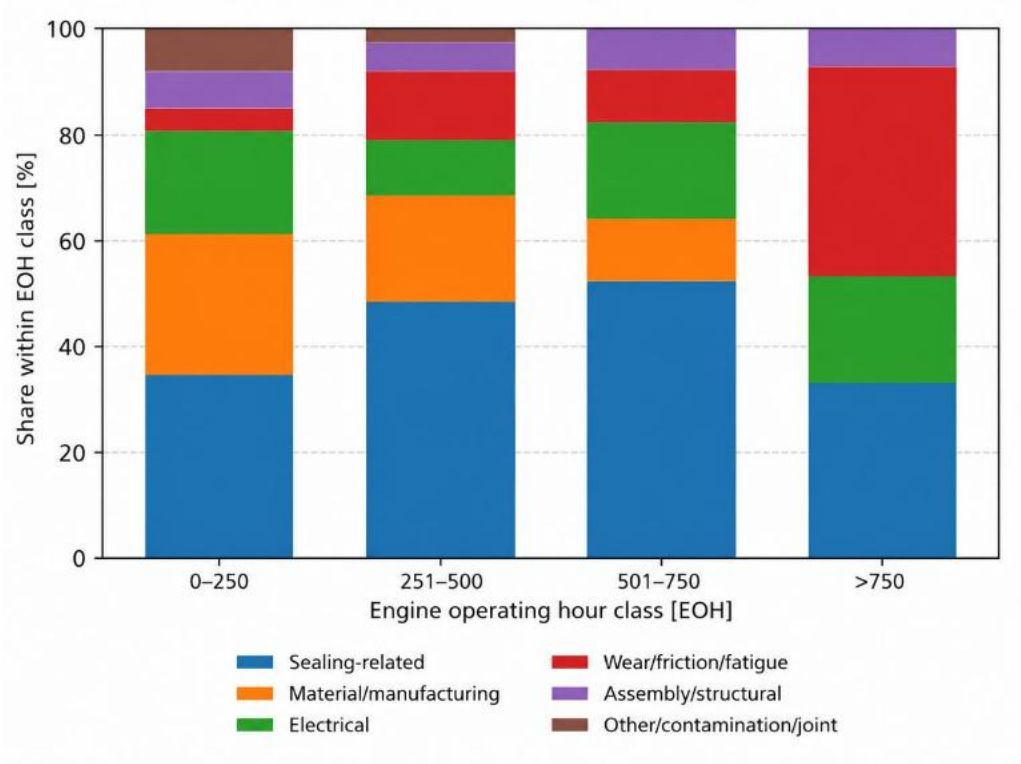

Fig. 2 - Failure-mechanism structure across engine operating hour classes

In the 0-250 EOH class, material/manufacturing and electrical mechanisms together accounted for 48.1% of records, while wear/friction/fatigue accounted for only 3.8%. In the >750 EOH class, wear/friction/fatigue represented 40.0% of recorded cases. Sealing-related mechanisms remained important in all classes, but they were particularly visible in the 251-500 and 501-750 EOH classes.

The early-life odds ratios calculated according to Equation (3) are presented in Table 4.

Table 4

Early-life odds ratios for failure-mechanism categories

Failure-mechanism category	0-250 EOH	>250 EOH	OR	95% CI
Sealing-related	18	72	0.57	0.30-1.08
Material/manufacturing	14	23	2.01	0.95-4.25
Electrical	11	21	1.64	0.74-3.65
Wear/friction/fatigue	2	21	0.29	0.08-1.13
Assembly/structural	3	9	1.04	0.29-3.69
Other/contamination/joint	4	2	5.44	1.12-26.39

Values above 1.0 indicate that the category was relatively more frequent in the 0-250 EOH group than in later records. Material/manufacturing mechanisms had an odds ratio of 2.01, while electrical mechanisms had an odds ratio of 1.64. Wear/friction/fatigue mechanisms had an odds ratio of 0.29, confirming their lower occurrence in early records and higher occurrence after 250 EOH.

The correspondence analysis map is presented in Figure 3.

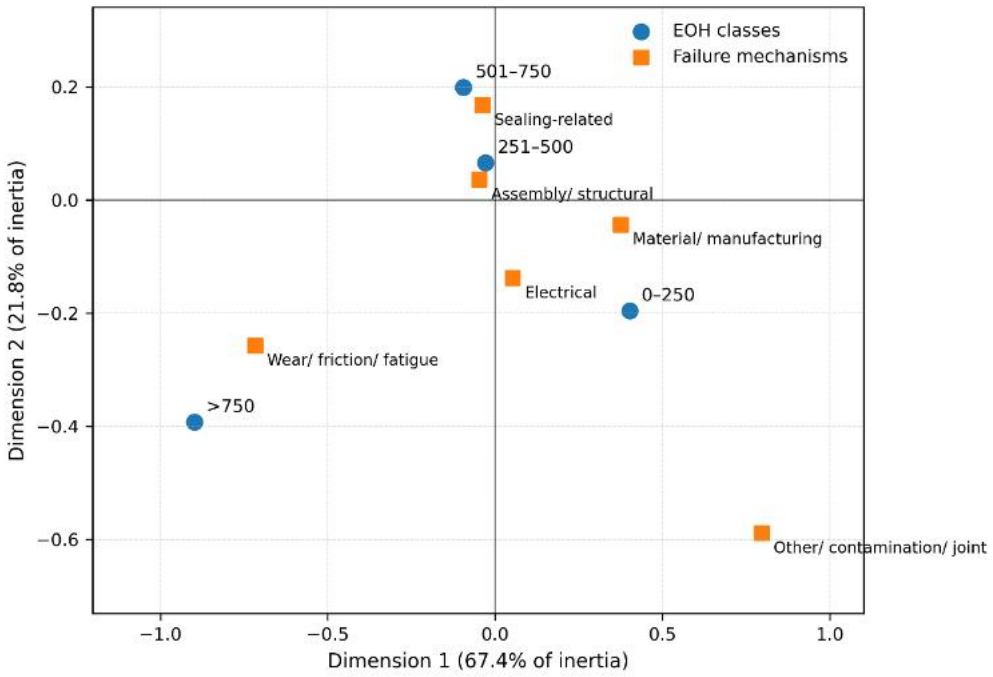

Fig. 3 - Correspondence analysis map of EOH classes and failure-mechanism categories

The first two dimensions explained 89.2% of the total inertia. The 0-250 EOH class was located closer to material/manufacturing, electrical and other/contamination/joint categories. The >750 EOH class was located closest to wear/friction/fatigue mechanisms. The 251-500 and 501-750 EOH classes were positioned nearer to sealing-related mechanisms, which reflects the high contribution of sealing faults in these operating ranges.

To connect the mechanism-oriented view with the mechanical structure of the tractor, the failure mechanisms were also compared across aggregated subsystem classes. The percentage structure is presented in Figure 4. Cabin/control failures were dominated by sealing-related causes associated mainly with gas springs, locks and cabin fittings. Electrical/starting failures were mostly electrical or material/manufacturing in nature. Engine/cooling and pneumatic/braking classes showed mixed mechanisms, which confirms that subsystem names alone do not fully explain the physical origin of the failure.

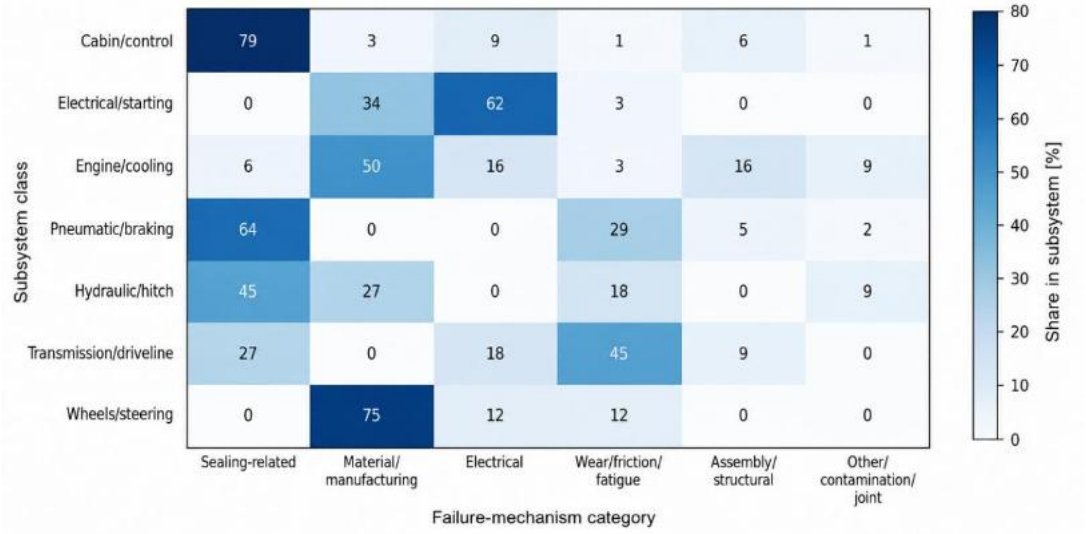

Fig. 4 - Failure-mechanism share within aggregated tractor subsystem classes

Values inside the cells represent shares of mechanism categories within a given subsystem class, [%].

Table 5 confirms that the mechanism-oriented approach adds information that is not visible in a subsystem-only classification.

Table 5

Dominant failure mechanism in each aggregated subsystem class

Subsystem class	Dominant mechanism	Share [%]	Secondary mechanism
Cabin/control	Sealing-related	79.1	Electrical
Electrical/starting	Electrical	62.1	Material/manufacturing
Engine/cooling	Material/manufacturing	50.0	Electrical
Pneumatic/braking	Sealing-related	64.3	Wear/friction/fatigue
Hydraulic/hitch	Sealing-related	45.5	Material/manufacturing
Transmission/driveline	Wear/friction/fatigue	45.5	Sealing-related
Wheels/steering	Material/manufacturing	75.0	Electrical

Cabin/control and pneumatic/braking were dominated by sealing-related mechanisms, whereas electrical/starting was dominated by electrical mechanisms. Hydraulic/hitch and transmission/driveline had more mixed patterns, which suggests that their maintenance cannot be reduced to a single inspection action. For these assemblies, a technician should consider leakage, wear, material condition and adjustment simultaneously.

Table 6 summarises the mechanical interpretation of the identified failure-mechanism categories and indicates their practical implications for tractor servicing, inspection planning and maintenance decision-making.

Table 6

Mechanical interpretation and practical service implications of failure-mechanism categories

Failure mechanism	Mechanical interpretation	Service implication
Sealing-related	Loss of tightness, damaged sealing surface, collar or elastomer element	Leakage inspection, cleanliness control, seal material and surface check
Material/manufacturing	Defect originating from material quality, machining, weld, thread or component manufacture	Quality feedback, incoming component control, warranty monitoring
Electrical	Short circuit, burnout, interrupted continuity or wiring defect	Connector, wiring, switch and protection-system inspection
Wear/friction/fatigue	Seizure, excessive wear, excessive clearance or cracking during operation	Lubrication, adjustment, clearance, load and friction-pair control
Assembly/structural	Faulty assembly, bending, fracture or loss of mechanical connection	Assembly procedure verification and structural inspection
Other/contamination/joint	Impurities, clogging, functional fault or joint degradation	Filtration, cleaning, fluid quality and functional testing

The mechanism-oriented interpretation presented in Table 6 expands the meaning of the numerical results. The high share of sealing-related failures indicates that tightness should be treated as one of the central reliability problems in the analysed tractor records. This category included failures of sealing surfaces, collars and seals, and it appeared in several subsystem classes. Therefore, the result should not be interpreted only as a problem of one assembly group. It rather indicates a cross-system mechanism associated with leakage, contact surface condition, elastomer quality, installation accuracy, contamination and pressure or temperature variation during operation.

The operating-time distribution of mechanisms also has a clear engineering meaning. In the 0-250 EOH class, material/manufacturing and electrical mechanisms were more visible than wear/friction/fatigue mechanisms. This pattern is consistent with the interpretation of early service records as a period in which hidden defects of manufacturing, assembly, component quality, wiring, connectors or protection systems may become visible. In this stage, inspection activities should therefore include targeted checks of sealing surfaces, threaded joints, welded or soldered parts, wiring continuity, connectors and hydraulic or pneumatic tightness. The early-life odds ratios support this interpretation because material/manufacturing and electrical categories had values above 1.0, whereas wear/friction/fatigue had a value below 1.0.

For later operation, especially above 750 EOH, the increasing contribution of wear/friction/fatigue mechanisms suggests a different service logic. In these cases, maintenance should pay more attention to lubrication quality, friction pairs, clearances, seizure risk, fatigue cracking and components exposed to cyclic loads.

This transition from quality-related and electrical mechanisms toward wear-related mechanisms is consistent with the general mechanical interpretation of repairable systems. However, the present dataset does not include non-failed tractors or complete exposure histories, so it cannot be used to estimate the absolute probability of failure or to construct a complete bathtub curve.

The subsystem-mechanism comparison confirms that a parts-based classification is not sufficient for engineering interpretation. Cabin/control and pneumatic/braking failures were dominated by sealing-related mechanisms, electrical/starting failures were mostly electrical or material/manufacturing in nature, whereas hydraulic/hitch and transmission/driveline groups showed more mixed patterns. This means that the same subsystem may require different corrective actions depending on the underlying physical mechanism. For example, a hydraulic failure may require leakage inspection, material-quality feedback, contamination control or wear assessment, depending on the coded cause.

From a service-management perspective, the results show that ordinary workshop records can support more than spare-parts logistics and can contribute to maintenance support systems and strategic maintenance management (*Kataev et al., 2024; Tsang, 2002*). If a record is coded only as a replacement of a component, it mainly supports inventory planning and repair-cost accounting. If the same record is additionally coded as sealing-related, electrical, material/manufacturing, assembly-related or wear-related, it becomes useful for design feedback, warranty monitoring and maintenance planning. This distinction is important in mechanical engineering because the same external symptom may result from different degradation processes and may require different preventive actions.

The obtained association between EOH class and failure-mechanism category was statistically significant but not strong. Cramer's V indicated a weak-to-moderate association, which is reasonable for field service data affected by variable tractor use, operator behaviour, maintenance history, environmental exposure and recording practices. Therefore, the results should be interpreted as evidence of an interpretable structure in the recorded service cases, not as a deterministic rule for all tractors. The value of the approach lies in its ability to organise incomplete service data into mechanically meaningful categories and to identify where targeted inspections may be most useful.

The practical recommendation is that warranty-period servicing should not be limited to routine replacement or adjustment. Early inspections should include quality-control-oriented checks of sealing elements, electrical connections, threads, welds, machined surfaces and hydraulic or pneumatic tightness. In contrast, later inspections should increasingly focus on lubrication, friction pairs, clearances, fatigue-sensitive elements and components exposed to cyclic or abrasive loading. Such a distinction can help service organisations adapt inspection priorities to the operating-time class of the tractor.

The study also has several limitations that should be considered when applying the findings to other service networks. The dataset covers a single tractor brand and a single historical set of service records. Information on non-failed tractors, the exact population at risk, and complete maintenance histories was unavailable. Therefore, the results characterize the distribution of recorded failure mechanisms rather than the failure probability of the entire tractor population in service. Future research should integrate failure-mechanism classification with cost data, downtime, warranty status, operating conditions, and complete exposure histories to develop more robust reliability and maintenance decision-support models.

CONCLUSIONS

1. The analysed service dataset contained enough information to distinguish six practical failure-mechanism categories of agricultural tractors: sealing-related, material/manufacturing, electrical, wear/friction/fatigue, assembly/structural and other/contamination/joint mechanisms.
2. The strongest group of recorded mechanisms was sealing-related failure, which represented 45.0% of all service cases. This confirms that sealing elements are a critical reliability area in repairable tractor systems.
3. The association between EOH class and failure-mechanism category was statistically visible. The chi-square test gave $p = 0.008$ and Cramer's V was 0.228, indicating a weak-to-moderate but interpretable structure in the service records.
4. Material/manufacturing and electrical mechanisms were relatively more visible in the 0-250 EOH class, whereas wear/friction/fatigue mechanisms were more visible in later records, especially above 750 EOH.
5. The same tractor subsystem may be affected by different physical mechanisms. Therefore, maintenance decisions should combine subsystem information with mechanism-oriented interpretation of the service cause.

6. For maintenance practice, early service inspections should emphasise sealing, electrical and quality-control-related defects, while later inspections should increasingly focus on wear, friction, fatigue, lubrication and clearance-related mechanisms.
7. The method supports mechanical reliability assessment from incomplete service records, but it should not be treated as a replacement for full lifetime reliability modelling based on complete exposure data and non-failed observations.

ACKNOWLEDGEMENT

This research received no external funding. The authors acknowledge that the analysis was based on historical service records of agricultural tractors. AI-assisted tools were used only to support language editing, formatting and checking of the manuscript; the authors verified all calculations, interpretations and references.

ABSTRACT

The utilization of machine vision and image processing techniques enables the recognition of corn stalks in complex field conditions, thereby enhancing the efficiency and accuracy of corn stalk identification. Initially, images of corn stalks are captured using a camera, followed by Gaussian filtering to effectively reduce noise within the images. Subsequently, RGB and HSV color segmentation is applied to the corn stalk images to isolate the component V, which most distinctly differentiates the corn stalks from the background. Threshold segmentation is then conducted on component V, establishing a threshold range to identify and extract the corn stalks from the background. Morphological operations are employed to enhance the fullness of the image. Finally, grid division is performed, using the coverage area of the straw as a feature to assign density values to corn straw in various sub-regions, ultimately generating a distribution grade map of corn straw. The results indicate that when the straw coverage rate ranges from 25% to 80%, the discrepancy between the corn straw recognition rate obtained through threshold segmentation and the manually measured straw coverage rate is less than 5%, satisfying the requirements for subsequent real-time variable spraying of corn straw decomposition agents.

摘要

运用机器视觉和图像处理的方法可实现玉米秸秆田间复杂条件下的识别，提高玉米秸秆田间识别效率和精度。首先通过摄像头对田间玉米秸秆进行采集，将采集到的田间玉米秸秆图像进行高斯滤波处理，有效消除图像中的噪音；然后对玉米秸秆图像进行 RGB 和 HSV 颜色分割，找出玉米秸秆与背景区分最明显的分量 V；再对分量 V 进行阈值分割处理，设定阈值范围，将玉米秸秆从背景中识别提取出来，运用形态学运算，使图像更加饱满；最后进行网格划分，以秸秆覆盖率面积作为特征，将不同子区域内的玉米秸秆密度进行赋值，生成玉米秸秆的分布等级图。结果表明：秸秆覆盖率为 25%~80%时，通过阈值分割的玉米秸秆识别率与人工测量的秸秆覆盖率结果误差小于 5%，能够满足后续玉米秸秆腐解剂实时变量喷施作业要求。

INTRODUCTION

During the 14th Five-Year Plan period, several forward-looking research directions have been strategically identified to encourage the exploration and development of new concepts, theories, and methods. These efforts are intended to promote innovation in scientific research paradigms and interdisciplinary integration. With the rapid advancement of technology, machine vision has become increasingly important not only in industry but also in agriculture and forestry, placing higher demands on its application in complex environments. Currently, employing machine vision to identify various plants and fruits has emerged as a prominent research focus. In China, the vast grain output and abundant straw resources have led to traditional practices that primarily involve burning straw for fuel. This approach results in a low resource utilization rate and contributes significantly to environmental pollution *(Chang, 2022a; Chang, 2022b; Kurumayya, 2025)*.

In alignment with the priority development areas outlined in the National Natural Science Foundation of China's "14th Five-Year Plan" and the "Five-way Comprehensive Utilization of Straw" initiative, this study employs a treatment method that integrates machine vision technology with straw fertilization.

[1] *Wenlong LI, Lecturer; Qiuyan Liang*, Professor (Corresponding author); Liuxuan MA, Professor; Lianyang Wang, Professor;*
[2] *Ning Dai, Lecturer (Corresponding author);*

The application of variable spraying of decomposers facilitates the decomposition of corn straw and its subsequent return to the field, thereby improving the efficiency of straw resource utilization. *Su Boni et al*. employed median filtering, mean filtering, and Wiener filtering to address salt-and-pepper noise in strawberry images. Their findings indicated that median filtering provided the most effective denoising results. Jinli Diamond utilized 14 texture features for the identification and localization of cucumbers; however, this approach requires substantial computational resources, rendering it impractical. Consequently, ongoing enhancements are necessary *(Wang et al., 2021; Su et al., 2018; Gao, 2022; Yang et al., 2023; Niu et al., 2025)*.

Research on the identification of corn stalks remains incomplete and has yet to achieve full automation. This paper initiates an investigation into the identification of corn stalks. Initially, corn stalk images undergo processing through an image preprocessing method. Subsequently, a color space model, in conjunction with morphological processing operations, is employed to execute threshold segmentation, effectively isolating the corn stalks from the background. The variable spraying device is then regulated based on the percentage of the corn stalk coverage area, facilitating the decomposition and return of corn stalks to the field (*Niu et al.*, 2024; *Ding et al., 2022a; Ding et al., 2022b; Deng, Wang, & Zhang, 2020; Niu et al.*, *2024)*.

MATERIALS AND METHODS

Experimental conditions

The corn stalk images were collected in Heping Village, Xiangyang District, Jiamusi City, Heilongjiang Province. The data collection occurred from September to October 2022, between 09:00 and 15:00. A mobile phone was utilized for capturing the images, which were taken under natural light conditions. To enhance data diversity and improve the model's generalization ability, images of corn stalks were gathered under various environmental conditions and distribution scenarios. Subsequently, the collected images underwent manual screening, resulting in the selection of those with stalk distribution percentages of 20% to 33%, 33% to 50%, 50% to 66%, 66% to 80%, and 80% to 90%. The selected images are presented in Figure 1. To further enhance the model's recognition accuracy, additional corn stalk images were sourced from the internet and incorporated into the self-captured image set. The flowchart illustrating the research on the identification of corn stalks in the field soil background is depicted in Figure 2 *(Wang; Dongxiang MA, 2023; Yasin et al., 2025)*.

Fig. 1 - Image of corn straw collection

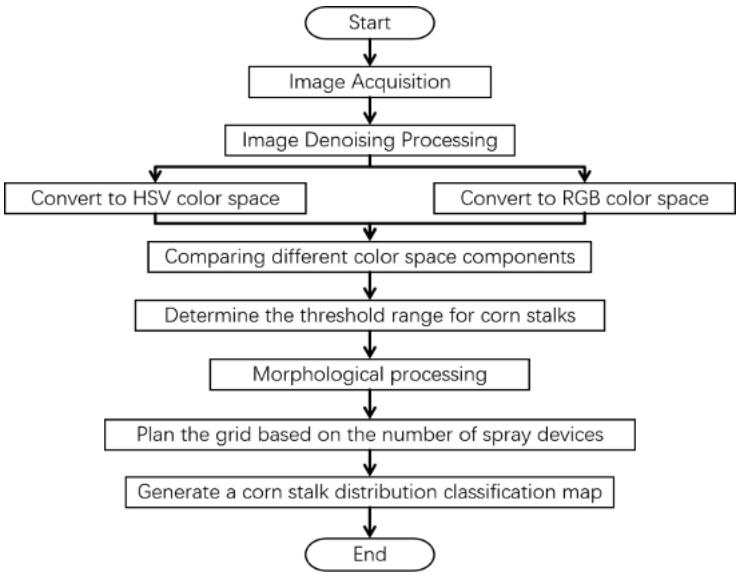

Fig. 2 - Flow chart of corn straw identification

Image color segmentation method

Images of corn stalks were captured using a camera. These images were subsequently analyzed and processed with PyThon-OpenCV, initially converting them into the RGB color space. Following this, the images were transformed into the HSV color space, allowing for a comparison with the RGB color space to identify the color component that provided the most effective separation between the corn stalks and the soil background. The corn stalks were isolated from the background using threshold segmentation, after which morphological processing techniques were employed to enhance the representation of the corn stalks *(Liu et al., 2024*).

Image filtering processing

This paper employs a denoising method that integrates Gaussian filtering with median filtering. Initially, Gaussian filtering is applied to the image prior to color space conversion. This technique utilizes the Gaussian function to smooth the image by computing the weighted average of pixels within a specified neighborhood around each pixel, thereby mitigating the impact of noise and effectively reducing high-frequency noise. The mathematical representation is provided in Equation (1), and the resulting image is illustrated in Figure 3. Subsequently, before the binarization process, median filtering is performed for further denoising. In this step, the median value of the pixel intensities within a defined area surrounding the central pixel replaces the original pixel value, effectively eliminating salt-and-pepper noise or impulse noise. The corresponding expression is detailed in Equation (2), and the processed image is depicted in Figure 4 *(Shah et al., 2022; Suneetha & Reddy, 2021; Latorre-Carmona, 2024)*.

$$(x)=\frac{1}{2\pi\sigma^2}e^{-\frac{x^2+y^2}{2\sigma^2}} \quad (1)$$

$$\hat{f}(x,y)=\underset{(i,j)\in S_{(x,y)}}{\text{median}}\{g(i,j)\} \quad (2)$$

Fig. 3 - Gaussian filter denoising process

Fig. 4 - Median filter denoising process

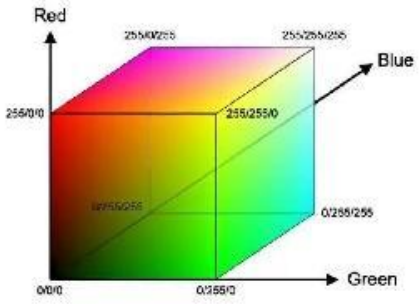
Color space model

The RGB color space is the most widely recognized method for representing colors, with its color space model illustrated in Figure 5. Any color F in a color image can be created by mixing the three primary colors: R (red), G (green), and B (blue) in varying proportions, as expressed in Equation (3) *(Togban & Ziou, 2025; Mengibar-Rodriguez & Chamorro-Martinez, 2022)*:

$$F=r[R]+g[G]+b[B] \quad (3)$$

where: R - red component; G - green component; B - blue component.

This color space accurately represents colors, as it has not been converted to other color spaces, resulting in minimal loss of image information. Following image processing, the image is subsequently processed through the RGB color space, with the outcome depicted in Fig. 6.



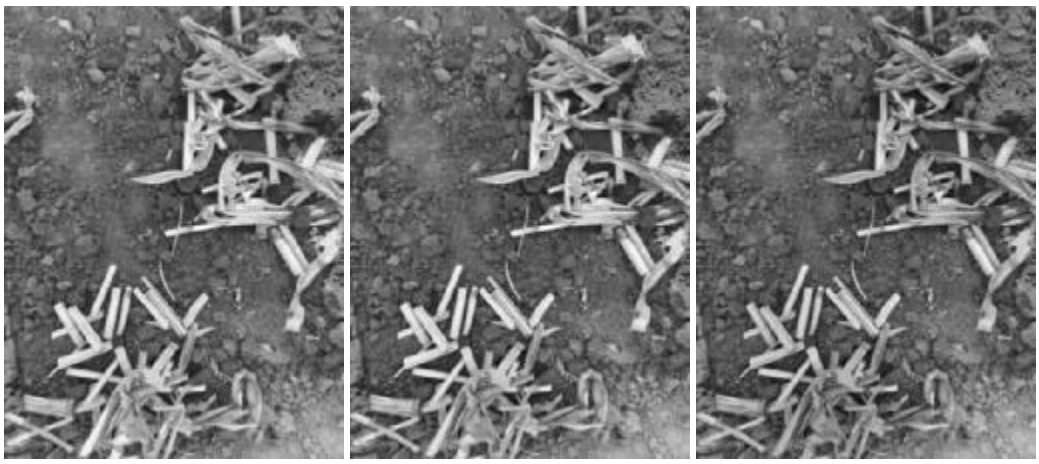


Fig. 5 - RGB color space model

(a) R component (b) G component (c) B component

Fig. 6 - RGB component map

The HSV color space is a color model defined by the attributes of Hue, Saturation, and Value, commonly referred to as a hexagonal cone model. The representation of this color space is illustrated in Fig. 7 *(Kamiyama & Taguchi, 2021; Yan, Li, & Hirota, 2021)*.

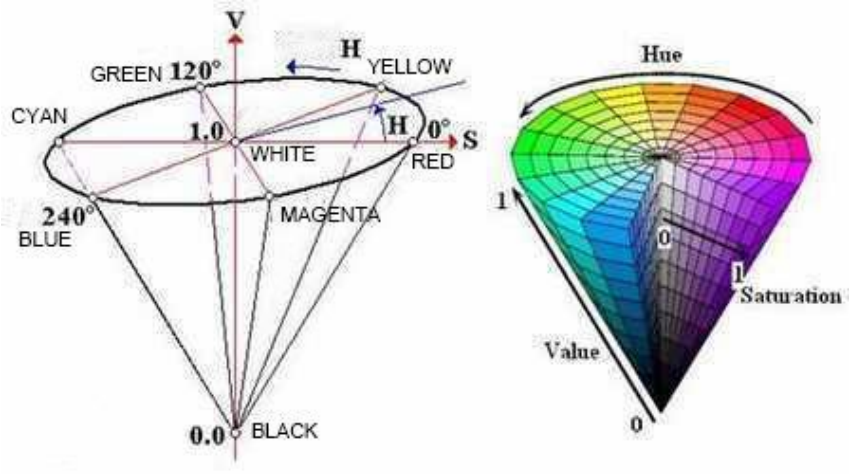

Fig. 7 - HSV color space model

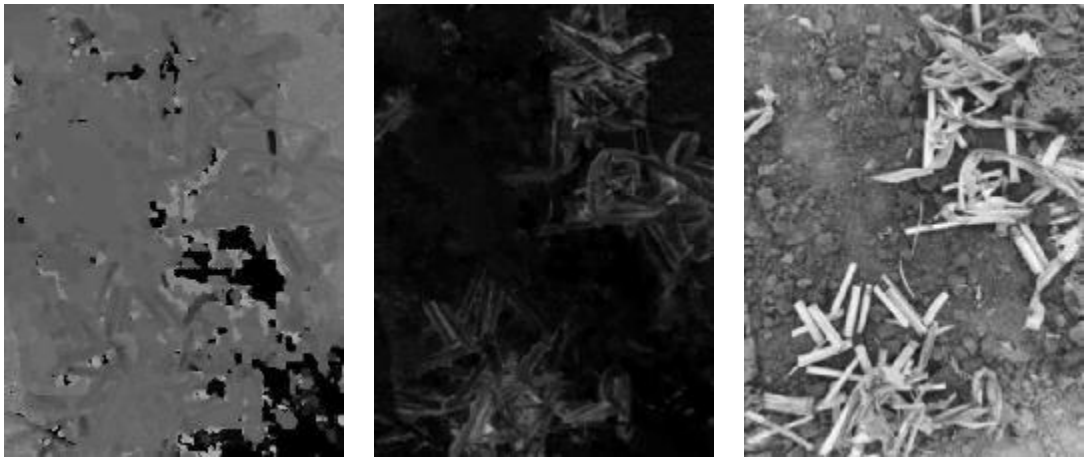
The conversion relationship expression between this model and the RGB color space model is shown in Equation (4), that is:

$$H = \begin{cases} 0^{\circ}, & \text{if Max} = \text{Min} \\ 60^{\circ} \times \frac{G-B}{Max-Min} + 0^{\circ}, & \text{if Max} = R \text{ and } G > B \\ 60^{\circ} \times \frac{G-B}{Max-Min} + 360^{\circ}, & \text{if Max} = R \text{ and } G < B \\ 60^{\circ} \times \frac{G-B}{Max-Min} + 120^{\circ}, & \text{if Max} = G \\ 60^{\circ} \times \frac{G-B}{Max-Min} + 240^{\circ}, & \text{if Max} = B \end{cases} \quad (4)$$



$$S = \begin{cases} 0, & \text{if Max} = 0 \\ \frac{Max-Min}{Max} = 1 - \frac{Min}{Max}, & \text{otherwise} \end{cases} \quad (5)$$

$$V = Max \quad (6)$$

where: Max - the maximum among R, G, and B;

Min - the minimum among R, G, and B

Subsequently, the preprocessed image undergoes processing in the HSV color space. A comparison is made between the components of the RGB color space model and those of the HSV color space model to identify the component that most effectively distinguishes corn stalks from the background. The diagram of the HSV color space components is presented in Fig. 8.

(a) H com onent ( ) S com onent (c) V com onent

Fig. 8 - HSV component map

By comparison, it can be seen that among the six components, the differences between the corn stalks and the soil background in component V are more obvious.

Research on recognition algorithms

As indicated in Section 2, the V component exhibits the most pronounced distinction effect. Consequently, threshold segmentation is applied to the V component, enabling the identification of corn stalks through this method.

The image acquisition process using industrial cameras is influenced by various unstable factors, including perspective, distance, light source, reflection, occlusion, and shadow, which can significantly affect image recognition outcomes. Additionally, noise interference may occur during both the acquisition and transmission of images. Consequently, preprocessing the images is essential to eliminate this noise and ensure the accuracy of subsequent results.

Image smoothing processing

To mitigate the effects of image noise generated during acquisition and transmission on image processing, it is essential to perform denoising prior to processing to enhance the resolution of image features. Image denoising involves applying filtering techniques to smooth the image, recalculating the value of each pixel to align it more closely with the values of neighboring pixels.

The commonly used image smoothing processing methods are as follows:

Mean filtering

Mean filtering is a linear filtering algorithm that employs a template to conduct convolution operations on the target image. This method replaces the value of each target pixel with the average pixel value of its surrounding neighborhood, thereby enhancing denoising effects and making the desired target more prominent.

$$(x,y)=\frac{1}{M}\sum_{(k,l)\square N} f(i,j) \quad (7)$$

Median filtering

Median filtering is a technique that employs a template to execute convolution operations on a target image. This process replaces the pixel value at a given point with the median of the pixel values within its neighborhood. Consequently, the surrounding pixel values are adjusted to approximate the true values, effectively eliminating isolated noise points.

$$\hat{f}(x,y)=\underset{(i,j)\in S_{(x,y)}}{\text{median}}\{g(i,j)\} \quad (8)$$

Gaussian filtering

Gaussian filtering involves the weighted averaging of the entire image. The value of each pixel is determined by the weighted average of its own value and those of neighboring pixels. When the mean μ is 0:

$$(x)=\frac{1}{2\pi\sigma^2}e^{-\frac{x^2+y^2}{2\sigma^2}} \quad (9)$$

In Gaussian filtering for denoising, the value of σ is crucial, as it dictates the dimensions of the filter template. A larger template results in increased blurring of the edge information of the particles. This article compares the denoising effects of three different templates $3\times3(\sigma=0.65)$, $5\times5(\sigma=1.43)$, $7\times7(\sigma=1.79)$, with the results illustrated in Figure 9.

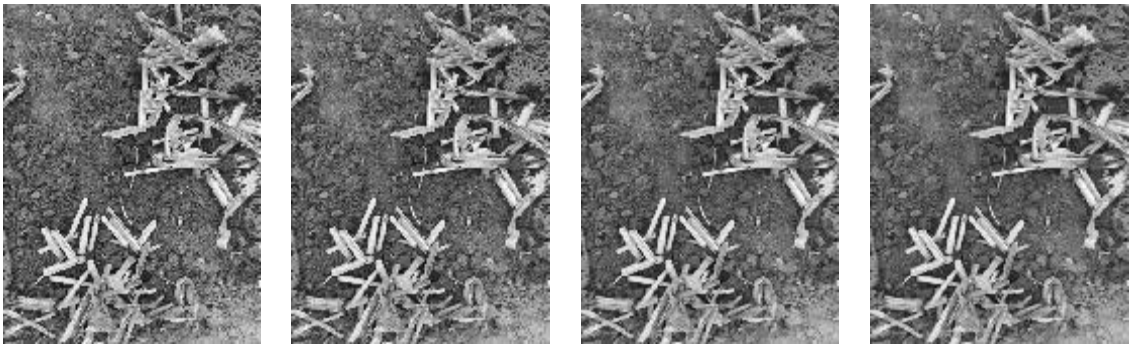


Fig. 9 - Gaussian filtering effect

Comparative analysis of the experimental effects of Gaussian filtering reveals that an increase in template weight significantly suppresses image noise. When utilizing templates of the same size, a comparison of various filtering processes demonstrates that $5\times5(\sigma=1.43)$ template Gaussian filtering effectively reduces noise while preserving edge information, resulting in favorable outcomes.

Image grayscale processing

The image data captured by industrial cameras is typically in color, comprising a combination of three channel vectors. For instance, in the RGB color model, each color channel ranges from 0 to 255. Consequently, color images require substantial storage space, which significantly impacts the speed of image processing. In contrast, grayscale images consist of a single channel without color, also ranging from 0 to 255. In the case of a binary grayscale image, white is represented by 255 and black by 0.

Common image grayscale conversion algorithms:

Single-channel component method

According to the requirements, one of the R, G, or B components in the color image is taken as the gray value of the image.

$$V_{gary1}=R \quad (10)$$

$$V_{gary2}=G \quad (11)$$

$$V_{gary3}=B \quad (12)$$

Maximum value method

The maximum brightness among the R, G, and B components in the color image is taken as the gray value of the grayscale image.

$$V_{gary}=\max(R, G, B) \quad (13)$$

Average value method

Take the average luminance of the R, G, and B components in the color image as a gray value.

$$V_{gary}=(R, G, B)/3 \quad (14)$$

Weighted average method

Based on their importance and other indicators, the three components are weighted and averaged with different weights.

$$V_{gary}=(\omega_r*R+\omega_g*G+\omega_b*B)/3 \quad (15)$$

where: $\omega_r, \omega_g, \omega_b$ - respectively the weights of R, G, and B.

Research shows that the grayscale effect of the image is the best when the following conditions are met. That is:

$$V_{gary} = 0.299 * R + 0.578 * G + 0.114 * B \quad (16)$$

The following figure is the grayscale image, as shown in Figure 10.

Fig. 10 - Image binarization

Image binarization processing

Color images captured by industrial cameras are converted into grayscale images. Following this, image binarization processing transforms the grayscale images into black-and-white images. Image binarization involves assigning pixel grayscale values of 0 or 255, thereby creating a pronounced black-and-white effect throughout the image and decreasing the overall data size.

A comparison of the preprocessing results presented in Figures 9 and 10 reveals that the application of image smoothing effectively removes target information while eliminating noise interference. The image processed through Gaussian filtering exhibits distinct edges, free from noise or artifacts, thereby facilitating subsequent image processing.

Morphological processing

Following the threshold segmentation of corn stalks, the desired outcome is frequently not attained. Consequently, morphological operations must be employed to enhance the completeness of the target. Morphology is among the most prevalent techniques in image processing. Its fundamental principle involves utilizing a specific structural element to measure or extract corresponding shapes or features from the input image, thereby facilitating further image analysis and target recognition. The commonly employed morphological processing methods are illustrated in Figure 11.

Image erosion

The erosion operation serves to "shrink" the selected area, effectively removing edges and speckles. It smooths the edges of the image area and reduces the number of pixels within that area; however, this process may result in the disconnection of adjacent components.

Image dilation

Dilation is the process of expanding a selected area, which smooths the edges of the image region, increases the pixel count within that region, and may connect previously unconnected components. However, regions that were originally separate will remain distinct and will not merge, despite any pixel overlap.

Open operation

The procedure for the opening operation involves initially executing the erosion operation, followed by the expansion operation. This sequence effectively eliminates isolated and small points, smooths rough edge lines, and ensures that the original area remains largely unchanged, akin to a "deburring" effect.

Closing operation

The procedure for the closed operation involves initially executing the expansion operation, followed by the erosion operation. This sequence effectively connects cavities within the area and merges isolated points outside into a single entity. The overall appearance and area of the region remain largely unchanged, akin to the effect of "filling the gaps."

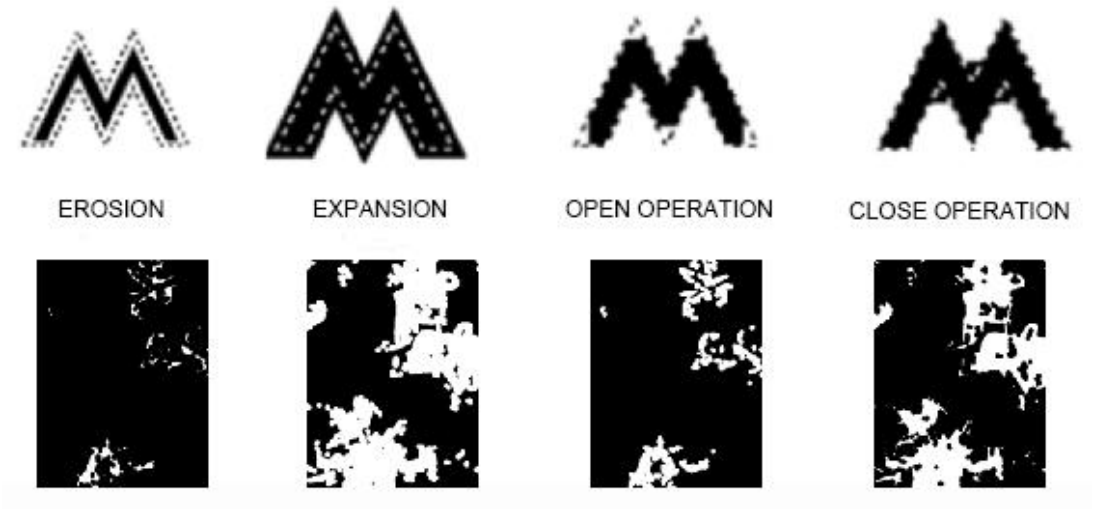

Fig. 11 - Morphological processing methods

This paper employs the closed operation method for image processing. This approach fills the gaps between corn stalks without thickening the edge contours, thereby connecting scattered targets within the image. As a result, the operational complexity is diminished, and efficiency is enhanced.

Image threshold segmentation method

The threshold is established based on specific requirements, incorporating various restrictive conditions to isolate the target from the image background. Threshold segmentation primarily relies on the disparity in gray values between the target and other objects within the background. This method filters the pixels in the image that satisfy the criteria determined by the gray values of the target pixels, thus enabling the segmentation of target features.

Fixed threshold segmentation

Fixed threshold segmentation represents the most basic and straightforward method of threshold segmentation. The underlying principle involves establishing a gray value, denoted as T. If the gray value of a pixel is less than T, it is assigned a value of 0 (i.e., black). Conversely, if the gray value exceeds T, it is assigned a value of 255 (i.e., white).

$$(x)=\begin{cases} 0, & x<T \\ 255, & x>T \end{cases} \quad (17)$$

Large law threshold segmentation

The OTSU method was introduced by Japanese researcher Nobuyuki Otsu in 1979. This method binarizes and segments images by identifying threshold pairs that maximize the inter-class variance between the foreground and background, thereby minimizing the likelihood of misclassification. However, the effectiveness of this segmentation diminishes when there is a substantial area difference between the target and the background, or when the gray levels of the target and background exhibit significant overlap.

Interval threshold segmentation

In a manner akin to fixed-threshold segmentation, the fixed threshold is modified to an interval threshold. If a pixel's threshold falls within this interval, its gray value is assigned a value of 255 (i.e., white). Conversely, if a pixel's threshold does not reside within the specified range, its gray value is designated as 0 (i.e., black).

The working environment described in this paper is complex, influenced by various factors, including light conditions, shooting angle, the presence of weeds, and the timing of straw collection, all of which affect straw color. Consequently, this study employs the interval threshold segmentation method to analyze the acquired images.

RESULTS

Experimental verification

Images of corn stalks in the field were captured using cameras. A total of fifteen images, representing varying coverage rates of corn stalks, were obtained and subsequently compared with the manually measured straw coverage rates.

Among the 15 selected images, the straw coverage rates were categorized into ranges: three images each for 20% - 33%, 33% - 50%, 50% - 66%, 66% - 80%, and 80% - 90%. The results of the two measurements are summarized in Figure 12. The figure illustrates that the corn stalk recognition algorithm developed in this study exhibits higher measurement accuracy within the straw coverage range of 25% to 80%, achieving an error of less than 5%.

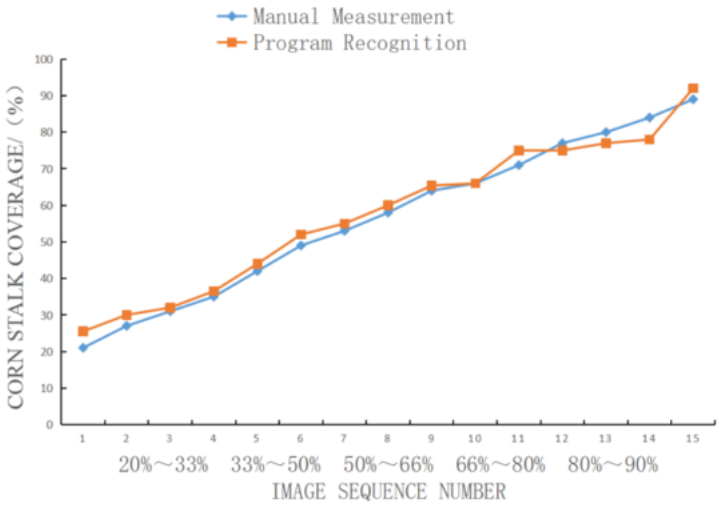

Fig. 12 - Straw cover comparison curve

Corn stalk identification

Heilongjiang Province, recognized as China's leading corn-growing and corn-producing region, generates a substantial quantity of corn stalks. Following the autumn harvest, a portion of these stalks is recycled and reused; however, a significant number are either burned or left to decay in the fields, representing a considerable waste of resources. Corn stalks are abundant in organic matter and contain various nutrients essential for plant growth. The effective utilization of these nutrients can significantly enhance soil fertility and decrease reliance on chemical fertilizers. Consequently, the decomposition and utilization of corn stalks hold considerable research significance.

Following the autumn harvest, corn stalks are crushed by harvesters and dispersed across the fields. The crushing is relatively uniform, resulting in a brownish-yellow color that contrasts markedly with the black soil characteristic of Northeast China. Consequently, this study employs color and area as the primary features for segmentation.

First, images of straw distribution in the field are captured using a camera. These images undergo several processing steps, including grayscale conversion, denoising, binarization, morphological processing, and grid division. Ultimately, a straw distribution grade map is generated, as illustrated in Figure 13.

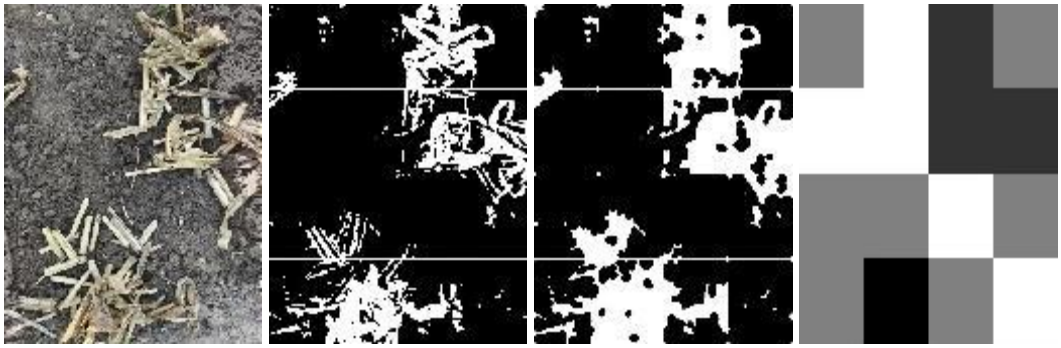

Fig. 13 - Corn straw identification

The figure illustrates that within each small cell, an increase in the area of straw corresponds to a progressively darker color of the cell. The classification is divided into four grades. If the straw area within a small cell is less than 5% of the total cell area, it is deemed to contain no straw. When the straw area comprises 5% to 33% of the cell area, it is categorized as level 1. If the straw area constitutes 33% to 66% of the cell area, it is classified as level 2. Finally, when the straw area exceeds 66% of the cell area, it is designated as level 3.

CONCLUSIONS

The HSV color space was chosen for this study after comparing three color models: RGB, HSV, and L*a*b*. Subsequently, the color images were converted to grayscale. To mitigate noise in the images, Gaussian filtering and median filtering techniques were employed. Among three threshold segmentation methods—fixed threshold, OTSU threshold, and interval threshold—the interval threshold method was selected based on its suitability for the actual working environment. The analysis focused on the color and shape characteristics of corn stalks, utilizing color as the segmentation feature to distinguish the stalks from the background. Area was then used as a feature to create a distribution grade map of the corn stalks. The corn stalk recognition algorithm, which relies on interval threshold segmentation, is straightforward and exhibits targeted effectiveness. When the straw coverage rate ranges from 25% to 80%, the recognition accuracy remains high, with an error margin of less than 5%.

Keywords: *tobacco transplanter; automatic seedling picking; planting mechanism; machine–soil–seedling interaction; machine vision; digital twin*

Abbreviations: *AI – artificial intelligence; CV – coefficient of variation; DEM – discrete element method; FPS – frames per second; GNSS – Global Navigation Satellite System; LCA – life-cycle assessment; LCC – life-cycle cost; MBD – multibody dynamics; MCU – microcontroller unit; MTBF – mean time between failures; MTTR – mean time to repair; PLC – programmable logic controller; RGB-D – red–green–blue plus depth; ROI – return on investment; UAV – unmanned aerial vehicle; YOLO – You Only Look Once.*

ABSTRACT

This review examines tobacco transplanting machinery, focusing on regional adaptation, automated seedling handling, planting mechanisms, coupled modeling, intelligent sensing, and field robustness. A narrative search covered English- and Chinese-language literature and standards through June 2026, selecting evidence by tobacco relevance or transferable similarity. High-throughput automation suits standardized production; hilly areas require compact, maneuverable, agronomically adaptable machines. Progress includes compliant seedling picking, buffered conveying, zero-relative-velocity planting, machine–soil–seedling modeling, machine vision, and digital twins. Constraints include seedling variability, adhesive soils, slope-induced disturbances, sensing degradation, and life-cycle cost. Future systems should integrate nursery standards, robust perception, decision-oriented digital twins, and modular electrification.

摘要

烟草移栽是连接育苗与大田生产的劳动密集型环节；丘陵碎片化地块、黏重红壤以及膜上移栽和井窖深栽等区域性农艺要求，进一步增加了装备适配难度。本文采用结构化叙述性检索，覆盖截至 2026 年 6 月的中英文文献与标准，并依据烟草相关性以及苗体形态、机构、土壤互作、感知任务或验证方法的可迁移性筛选证据。本文比较了不同区域的移栽装备技术路线，重点综述取苗、送苗、栽植、机-土-苗耦合建模以及感知与控制技术。研究表明，标准化平原或设施生产场景适宜采用高通量自动化装备，而丘陵烟区更需要小型化、模块化和高鲁棒性机具。现阶段的主要瓶颈包括钵苗一致性不足、高频作业与低损伤之间的矛盾、土壤黏附、传感器性能衰减以及较高的全寿命周期成本。未来应协同推进育苗标准化、柔性末端执行器、多模态感知、数字孪生和轻量化电动底盘的发展。

INTRODUCTION

Tobacco transplanting links nursery production to field establishment and directly affects plant spacing, planting depth, and early establishment. The global harvested area was approximately 3.2 million ha in 2023, with China accounting for roughly one third *(WHO, 2022; WHO, 2023a; WHO FCTC, 2025)*. Because the operation requires synchronized seedling separation, transport, soil or mulch penetration, placement, and covering, failure in one module can propagate through the entire cycle *(Jia et al., 2018; Wang X.B. et al., 2025; Yuan et al., 2023)*. Mechanization can reduce repetitive manual labor and improve spatial uniformity. Industry-wide fiscal data should not be interpreted as farm-level profitability, and labor-saving claims should still be considered alongside occupational and environmental costs *(IMTMA, 2024; WHO, 2023b)*. The present review therefore keeps these contextual issues concise and concentrates on the engineering problem.

These constraints are particularly acute in the hilly tobacco-growing regions of southwestern China, including Yunnan, Guizhou, and adjacent production areas. Fragmented plots, variable slopes, narrow access roads, and sticky red soils constrain machine dimensions and traction, while single-ridge, mulch-film, and well-cellar practices differ substantially from standardized vegetable transplanting. Historical national zoning data assigned 53.57% of tobacco planting area and 57.01% of commercial leaf volume to the Southwest tobacco-growing region *(Zhu, 2008)*. Because this regional classification is not equivalent to a slope-based definition and the data are historical, these percentages should not be interpreted as a current national share of 'hilly tobacco land'; no current nationally harmonized slope-class statistic was identified in authoritative public sources. Nevertheless, the historical concentration, together with continuing research on tobacco-specific crawler, electric, and well-cellar machines in these regions, demonstrates the engineering importance of hilly-area mechanization *(Bai et al., 2025; Wang B. et al., 2024; Xu L., 2024; Zhao Y., 2024)*. Consequently, a machine that performs well on level ground may lose planting-depth consistency, accumulate soil, or become difficult to maneuver on slopes.

Meanwhile, automated transplanting has progressed from purely mechanical mechanisms to compliant end-effectors, electromechanical control, machine vision, navigation, coupled simulation, and digital-twin-based quality monitoring. These advances create new opportunities but also reveal a persistent gap between laboratory performance and field reliability. High picking success obtained with uniform seedlings does not necessarily ensure stable operation when substrate moisture varies. Likewise, visual-detection accuracy may decline under dust, vibration, and rapidly changing illumination, and highly automated equipment may be economically unattractive when annual utilization is low *(Luo et al., 2022; Wang X.B. et al., 2025; Zhao Q. et al., 2026)*.

In this review, an intelligent transplanter is defined as a transplanting machine that uses sensing, state estimation, and/or programmable control to adapt seedling handling, mechanism timing, navigation, or quality decisions to observed conditions. Conventional and semi-automatic mechanisms are discussed as engineering baselines, compatible modules, or low-cost alternatives; they are not classified as intelligent unless they provide condition-aware or closed-loop functions. With this functional boundary established, the following paragraph explains how the evidence used to evaluate these machine functions was identified and screened.

The evidence base was assembled as a structured narrative review rather than a meta-analysis. Searches from database inception to 30 June 2026 covered Web of Science Core Collection, Scopus, Google Scholar, CNKI, and Wanfang, supplemented by citation tracing and publisher and standards websites. English and Chinese terms combined tobacco or plug seedling with transplanter, seedling picking or feeding, planting mechanism, well-cellar, vision or navigation, digital twin, DEM or MBD, field performance, safety, cost, and life cycle. Eligible records reported traceable evidence on mechanisms, modeling, sensing and control, safety, economics, or field performance; untraceable or engineering-irrelevant records were excluded.

Non-tobacco evidence was retained only when it shared an explicit engineering interface with tobacco: plug or root-block handling, planting trajectory, soil-tool interaction, sensing or control task, or validation method; crops are labeled in quantitative tables. Such evidence informs mechanisms, methods, and failure modes, not tobacco performance. Values are not treated as benchmarks unless crop, machine, seedling, soil, speed, and protocol are comparable.

Section 1 relates regional production conditions to machine architecture; Section 2 compares picking, conveying, and planting mechanisms; Section 3 evaluates coupled modeling, perception, AI, edge computing, and mechatronic integration; Section 4 examines deployment bottlenecks, safety, sustainability, and economics; Section 5 translates evidence gaps into short- and medium-term milestones; and the Conclusions summarize the review's principal contributions.

1. TECHNOLOGICAL ROUTES AND REGIONAL ADAPTATION

1.1 HIGH-THROUGHPUT AUTOMATION IN STANDARDIZED PRODUCTION

International tobacco-specific mechanization provides an important baseline. A U.S. self-feeding system handled cell-strand or bare-root material at about 100-140 plants/min under controlled conditions, while Japanese research developed a high-clearance mechanically fed tobacco transplanter *(Suggs et al., 1987; Asai and Miyake, 1989)*. European developments broadened this evidence base: an Italian DGNSS-RTK-assisted vine-cutting transplanter demonstrated automated georeferenced placement under different topographic conditions, and a precision three-row synchronized transplanter developed by Spanish/U.S. researchers addressed cross-row spatial and temporal coordination *(Mazzetto and Calcante, 2011; Pérez-*

Ruiz and Slaughter, 2021). These studies show that feeder reliability, positioning, and operator-machine coordination are system constraints. Robotic research subsequently established automated seedling-handling feasibility, with *Kutz et al. (1987)* representing an early milestone. Contemporary systems integrate perception, end effectors, and tray logistics: recent work used selective seedling assessment or plant-factory vision and automated tray handling *(Li M. et al., 2025; Liu W. et al., 2024b)*. The engineering question is whether the complete system can make reliable decisions at production speed.

High-throughput systems in protected horticulture commonly integrate tray indexing, parallel or multichannel handling, pneumatic assistance, and machine vision. Reviews of plug-seedling transplanting technologies indicate that protected-environment machines increase throughput by parallelizing picking and separating grading, transfer, and planting operations *(Habineza et al., 2023; Liu W. et al., 2023)*. Nevertheless, a higher nominal cycle frequency does not necessarily yield greater effective productivity. As seedling uniformity deteriorates, missed picks, substrate fragmentation, blockages, and operator interventions may increase rapidly. The appropriate design objective is therefore the maximum stable throughput sustained over an operating period, not the maximum instantaneous frequency.

The same principle applies to kinematic studies of dibbling and planting mechanisms. To control planting angle and uprightness, forward speed must be synchronized with the relative velocity between the planting component and the ground, the opening and closing phases of the planting element, and the instant of seedling release *(Iqbal et al., 2021)*. Compact, field-oriented automatic transplanters further demonstrate that robotic or mechanized picking can be integrated into multirow or mobile platforms. However, whole-machine performance continues to depend strongly on tray standardization, seedling mechanical properties, and reliable transfer between modules *(Ji D. et al., 2024; Khadatkar et al., 2023; Zhou et al., 2024)*.

1.2 COMPACT AND PRECISION-ORIENTED ROUTES FOR SMALL FIELDS

In East Asian production systems characterized by small, fragmented fields, equipment development places greater emphasis on compact dimensions, maneuverability, and repeatable mechanism timing. Compact electrically driven transplanters demonstrate how automatic conveying, picking, and planting can be integrated within a restricted machine width. Similarly, recent field tests of greenhouse cabbage equipment in Korea show that the capacities of the collection and transplanting modules must be coordinated at the system level *(Chen M. et al., 2025; Reza et al., 2025)*. Mechanical precision and compact integration remain attractive because they can reduce dependence on sensors; however, increased mechanism density makes accessibility, modularity, and maintainability more important.

Low-cost, manually assisted transplanters remain appropriate when farm scale, terrain, and service capacity do not justify full automation. Their engineering value lies in reducing repetitive bending, improving placement regularity, and increasing work rate without presuming that the most highly automated architecture is necessarily the most economical. In hilly tobacco-growing areas, semi-automatic guide-tube and duckbill machines may therefore remain competitive when they are lightweight, repairable, and tolerant of variable seedlings, even as fully automatic systems advance *(Jia et al., 2018; Wang X.B. et al., 2025)*. The relevant benchmark is the cost and quality per successfully transplanted area under local operating conditions, rather than the level of automation alone.

1.3 CHINA: FROM SEMI-AUTOMATIC MACHINES TO REGION-ADAPTED INTELLIGENT SYSTEMS

The development of Chinese tobacco transplanters has followed a region-adaptive pathway because production conditions differ markedly between the northern plains and the hilly southwest. Early integrated tobacco-machine designs established a foundation for mechanized transplanting *(Fei and Yan, 2018)*, while conventional guide-tube and duckbill machines remain useful where low cost and straightforward maintenance are priorities. Well-cellar production in hilly areas has stimulated the development of auger-type hole formers, electric drives, and tracked self-propelled platforms. Hydraulic and mechanical well-cellar systems, zero-relative-velocity planting concepts, and high-speed hole-forming devices have progressively addressed the requirements of deep planting and small mulch openings *(Fan et al., 2020a; Fan et al., 2020b; Jing, 2025; Wang L., 2025)*.

Automated seedling handling has advanced in parallel. Dual-tray staggered picking, compliant or pneumatic separation, multi-adaptive feeding, and low-cost motion-control architectures are intended to increase cycle frequency while limiting rigid contact with stems and substrate blocks *(Chen B. et al., 2024; Li G. et al., 2025; Shao et al., 2021; Zheng et al., 2025)*. Crawler platforms and microcontroller-based pneumatic control have lowered the entry barrier to field automation. Nevertheless, these field systems remain more

sensitive than semi-automatic machines to seedling variability and environmental disturbances *(Bai et al., 2025; Li H.M. et al., 2024; Xu L., 2024)*.

Perception and autonomous functions are increasingly being integrated into this hardware base. Fuzzy control for missed-plant prevention, deep-learning-based seedling grading, GNSS/vision navigation, machine-vision-assisted low-damage handling, and tobacco-transplant recognition illustrate the transition from preset mechanism timing to condition-aware control *(Jin X. et al., 2020; Li T. et al., 2023; Liu Z. et al., 2026; Xin et al., 2022; Zhang S. et al., 2026)*. Digital-twin-based online quality inspection extends this concept by linking physical signals to predicted spacing, uprightness, and operating quality *(Zhao Q. et al., 2026)*. The central question is whether these functions remain reliable after prolonged exposure to dust, vibration, occlusion, and field variability.

Figure 1 summarizes this regional design logic. The comparison is not intended as a ranking of technological sophistication; rather, it shows that the preferred architecture depends on nursery-system standardization, field scale, terrain, agronomic practices, and local service capacity.

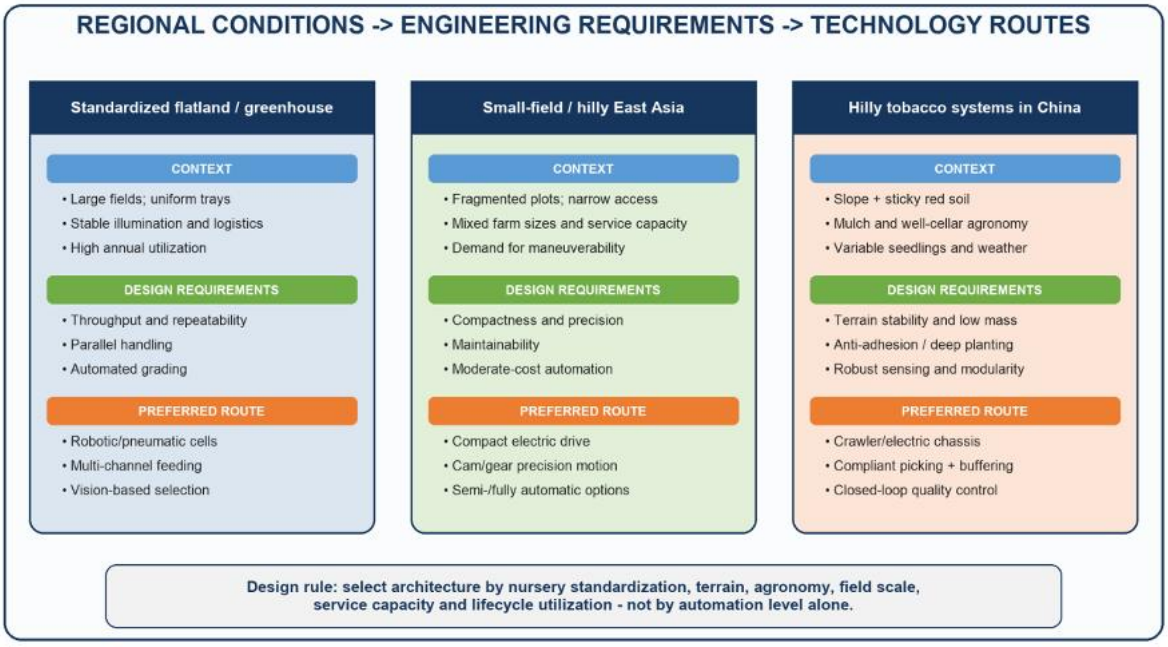

Fig. 1 - Regional production conditions and corresponding technological routes for transplanting machinery

Table 1

Cross-regional comparison of transplanter development routes

Context / crop scope	Dominant objective	Typical technical route	Main strength	Key limitation for tobacco transfer
Protected systems vegetables; flowers	High stable throughput	Multi-channel robotic/pneumatic handling, vision grading	High cycle frequency and repeatability	Requires uniform trays/seedlings and stable environment
East Asia cabbage; vegetables	Mobility and precise motion	Compact chassis, gear/cam trajectories, moderate automation	Good maneuverability and mechanical repeatability	Complex transmissions; limited flexibility when agronomy changes
Low-capital systems tobacco; vegetables	Low cost and ergonomics	Manual or semi-automatic guide-tube/duckbill machines	Simple, repairable, low investment	Throughput limited by operator feeding
Hilly China tobacco	Agronomic adaptation and robustness	Crawler/electric chassis, well-cellar hole forming, flexible picking, sensing	Matches deep planting, mulch and slope constraints	Seedling inconsistency, soil adhesion and sensor reliability remain limiting

2. KEY MECHANISMS FOR AUTOMATIC TOBACCO TRANSPLANTING

2.1 SEEDLING PICKING: FROM RIGID GRIPPING TO FORCE-DECOUPLED EXTRACTION

Seedling picking is typically the first bottleneck encountered as the operating frequency of an automatic transplanter increases. Existing mechanisms can be classified broadly as direct-clamping or force-decoupled extraction systems. Direct clamping applies force to the stem or substrate block before removing the seedling from the tray. Although this approach offers a compact structure and short cycle time, its safe operating window depends on stem strength, root binding, substrate moisture, and adhesion between the substrate block and tray wall. Reviews and experimental studies consistently identify missed picks, stem damage, and substrate breakage as the principal failure modes *(Huang M. et al., 2023; Wang N. et al., 2021; Wang X. et al., 2023)*. Recent flexible multi-pin grippers further demonstrate that penetration geometry, squeezing force, and extraction speed must be optimized jointly rather than independently *(Han L. et al., 2025)*.

Trajectory and contact design can mitigate these failures. Oblique insertion followed by straight extraction, optimized cam paths, and whole-row mechanisms have been used to improve contact geometry and synchronize picking with downstream transfer *(Chen B. et al., 2024; Li Z., 2023; Xie et al., 2020)*. Coupled discrete-element and multibody simulations also allow mechanism–substrate interactions to be evaluated before physical prototyping *(Hou et al., 2023)*. A recent flexible gripper achieved reliable picking through oblique penetration, gradual squeezing, and vertical extraction, demonstrating the benefit of distributing contact through the substrate block rather than relying on a single rigid pull *(Han L. et al., 2025)*. Although reported success rates above 90% are encouraging, direct comparisons remain difficult because tray type, seedling age, substrate moisture, and even the definition of success are not standardized.

A second design strategy reduces stem loading by separating or redistributing the force required to detach the substrate block. Top-clamping-and-pulling, top-pushing/stem-clamping, and oblique multi-tine end-effectors either separate loosening from transport or distribute the extraction force across a larger root-block volume *(Hu J. et al., 2022; Liu W. et al., 2024a; Zhang N. et al., 2024; Zhang X.D. et al., 2023)*. For loose substrates, discrete-element calibration has been used to optimize an end-effector specifically for substrate mechanics, illustrating how material behavior can be incorporated directly into gripper design. Alternating dual-tray mechanisms can also reduce waiting time between operating cycles *(Liu C. et al., 2025)*. These benefits are obtained at the cost of a longer or more tightly coordinated action sequence and greater sensitivity to timing errors.

A notable shift in recent research is the use of plant and substrate mechanical properties instead of geometry alone. Studies of flexible multi-pin gripping, stem-damage modeling, and low-damage machine vision indicate that gripping force, penetration depth, impact acceleration, contact area, and substrate integrity should be treated as explicit design constraints *(Han L. et al., 2025; Xi et al., 2026; Xin et al., 2022)*. For tobacco seedlings, a useful next step would be to define a measurable damage envelope linking stem diameter, substrate moisture, root binding, and extraction resistance to allowable force and acceleration. Such an envelope would enable servo trajectories and compliant grippers to be tuned to the actual seedling batch rather than to a nominal specimen.

2.2 SEEDLING CONVEYING AND BUFFERING: DECOUPLING FAST PICKING FROM STABLE PLANTING

A high-frequency picking mechanism provides little benefit if seedlings reach the planter with an unstable orientation. Unconstrained free-fall transport can cause rolling and impact, whereas direct robot-to-soil placement assigns the manipulator responsibility for the entire cycle. Buffered or relay-type conveying offers a practical compromise by decoupling rapid tray-handling operations from the slower, near-zero-relative-velocity planting event. The buffer can absorb timing differences, correct orientation, and reduce the sensitivity of the planting mechanism to brief disturbances in seedling picking *(Fang et al., 2021; Shao et al., 2021)*.

Tray feeding and pre-loosening also require attention because high extraction resistance may dominate the failure rate. A rotary tray-feeding device that flexed the tray before picking reduced extraction resistance and improved picking success for rapeseed plug seedlings, illustrating how upstream tray mechanics can lessen the load on the end-effector *(Chen H. et al., 2025)*. Tobacco feeding devices based on structural guidance are intended to preserve seedling orientation during transfer, whereas compact automatic machines coordinate picking and feeding within a restricted spatial envelope *(Yan et al., 2020; Zhao X. et al., 2022)*. Flexible finger-and-chain conveying has produced similar benefits for fragile seedlings by reducing abrupt speed changes *(Ning et al., 2025)*.

Accordingly, the performance of a conveying system should be assessed using metrics broader than transport capacity alone. Relevant indicators include transfer success, orientation deviation at planter entry, residence-time variability, impact acceleration, and blockage probability over repeated cycles. This system-

level perspective is particularly important for tobacco because large leaves may interfere with guides even when the substrate block is transferred successfully.

2.3 PLANTING MECHANISMS: MATCHING TRAJECTORY TO SOIL, MULCH AND PLANTING DEPTH

Duckbill planters remain widely used because a single mechanism can open the soil or mulch, receive and release the seedling, and initiate soil closure. Their principal kinematic requirement is to minimize horizontal relative velocity at the lowest point of the trajectory. Early elliptical-gear planetary mechanisms established deterministic noncircular transmissions as a means of shaping planting trajectories *(Chen J. et al., 2012; Yu G. et al., 2011)*. Tobacco-transplanter studies and subsequent mechanism optimization have focused on phase synchronization and the relationship between forward speed and release timing *(Iqbal et al., 2021; Ji J. et al., 2015; Xiong, 2025)*. Inadequate compensation for forward motion can elongate the planting hole, enlarge the mulch opening, or tilt the seedling. However, a purely kinematic optimum cannot represent resistance from the soil, mulch, or substrate block.

In mulch-film transplanting, the design problem extends beyond kinematics because the planting component interacts simultaneously with the film, soil, and substrate block. Studies of tobacco and other mulched crops show that planter geometry, penetration angle, and release control determine both film-opening size and seedling uprightness *(Li Y. et al., 2025; Yang W., 2019; Zhang W. et al., 2024)*. European field evidence from central Italy further showed 95-99% transplant success for savoy cabbage, fennel, and lettuce with a modified transplanter operating in both tilled and no-till soils, while also revealing crop- and spacing-specific skip risk *(Frasconi et al., 2019)*. Coupled machine-soil-pot models confirm that soil resistance and pot posture can shift the actual trajectory away from the ideal path *(Jin X. et al., 2025)*. Similarly, machinery-plant-soil modeling in rice transplanting demonstrates the value of representing impact and soil interaction when analyzing seedling damage *(Xue et al., 2022)*. Collectively, these studies indicate that a planting mechanism should not be optimized solely in a multibody model without a calibrated representation of the working medium.

Guide-tube and cup-type planters are structurally simpler and well suited to semi-automatic machines. In these systems, the seedling descends by free or constrained fall; tube inclination, inner-wall friction, and the opener's relative position determine its final orientation. High-speed imaging and dynamic analysis have been used to replace disordered tumbling with more stable sliding, while timing studies coordinate guide-tube discharge with planter opening *(Wu et al., 2022; Yin D. et al., 2021)*. This simplicity is advantageous in hilly tobacco production, although throughput remains closely coupled to manual feeding or upstream automatic orientation.

Well-cellar planting imposes a different engineering requirement: the machine must form a deep, narrow, and stable hole while minimizing wall collapse and mulch damage. Tobacco-specific planter and hole-forming studies have investigated auger rotational speed, penetration rate, soil discharge, anti-blocking geometry, planting-element design, and modal vibration *(Fan et al., 2020a; Fan et al., 2020b; Jiang X. et al., 2024; Liu W., 2017; Peng, 2025; Shi Y., 2023; Xu S. et al., 2024; Zhang D. et al., 2021)*. Recent continuous zero-relative-velocity well-cellar systems and high-speed dual-hole-forming devices seek to maintain hole quality as field capacity increases *(Jing, 2025; Wang L., 2025; Yang Y., 2025)*. A major remaining need is to relate hole geometry and wall stability to soil moisture and texture instead of validating a mechanism at a single soil state.

Table 2

Engineering comparison of key mechanism families

Mechanism / crop scope	Principle	Reported engineering advantage	Primary failure modes	Best-fit conditions	Priority metric
Direct clamp tobacco; pepper; tomato	Grip stem or substrate and extract directly	Short action chain; high potential frequency	Stem damage, substrate breakage, missed picking	Uniform seedlings with sufficient root binding	Success + damage severity + force margin
Eject + gripper tobacco; vegetables	Loosen block from below, then grasp	Lower peak extraction load; wider tolerance	Longer cycle; timing and alignment errors	Variable tray adhesion; fragile blocks	Extraction resistance + timing error
Buffer/relay tobacco; rapeseed; vegetables	Temporary storage and controlled handover	Decouples pick frequency from planting event	Orientation drift, blockage, impact	Automatic systems with multi-stage timing	Entry-angle deviation + impact acceleration

Mechanism / crop scope	Principle	Reported engineering advantage	Primary failure modes	Best-fit conditions	Priority metric
Duckbill tobacco; pepper; tomato	Penetrate/open/release/close in one cycle	Compact integrated operation; mulch compatibility	Dragging, large film tear, tilted seedlings	Mulched or bare soil with controlled trajectory	Relative ground speed + uprightness
Guide-tube/cup tobacco; vegetables	Seedling slides/falls into opened furrow/hole	Simple, inexpensive, maintainable	Rolling, collision, timing dependence	Semi-automatic and low-cost systems	Orientation at outlet + missed planting
Well-cellar auger tobacco	Rotary or impact formation of deep narrow hole	Matches deep-planting tobacco agronomy	Soil adhesion, blockage, wall collapse	Hilly tobacco regions using well-cellar planting	Hole geometry + wall stability + power

3. ENABLING TECHNOLOGIES FOR INTELLIGENT TRANSPLANTERS

3.1 MACHINE–SOIL–SEEDLING COUPLED MODELING AND COMPLIANT DESIGN

Multibody dynamics and discrete-element modeling have become important tools for moving transplanter design beyond trial-and-error geometry. Mechanism models are well suited to trajectory, acceleration, and phase analyses, whereas DEM represents soil and substrate-block contact. Coupling these approaches enables designers to evaluate how resistance and impact alter a nominal motion path. Applications include picking devices, planter–soil interactions, and hole-forming systems *(Hou et al., 2023; Jin X. et al., 2025; Zhang Q. et al., 2025)*. These methods are most informative when their parameters are calibrated against physical measurements rather than selected solely for numerical convenience.

The same principle applies to adhesion reduction. Sticky red soil can increase draft, prevent complete duckbill closure, and disrupt hole geometry. Studies of bionic microtextured tillage surfaces demonstrate that surface morphology can modify soil adhesion and resistance, suggesting a transferable strategy for tobacco-contact components *(Wang Z. et al., 2026)*. Future transplanting studies should therefore combine contact-angle or adhesion measurements with soil-moisture and texture characterization so that anti-adhesion surfaces are designed for a defined operating envelope.

Table 3

Quantitative evidence for coupled machine-soil-seedling modeling

Study / crop or system	Model / task	Validation	Reported quantitative evidence	Computational reporting used in this review
Jin et al. (2025), dryland vegetable pot seedlings (species not specified)	EDEM-RecurDyn; soil-pot seedling-planting device	Field comparison	Mean errors: soil backflow 2.14%; soil disturbance 2.46%; verticality 1.86%	Not ranked: platforms and computational-cost units were not harmonized
Hou et al. (2023), pepper	DEM-MFBD; pepper picking/depositing	Bench validation after coupled optimization	Picking success 97.92%; substrate loss 2.21%; errors versus regression predictions 0.49% and 3.8%, respectively	Not ranked: platforms and computational-cost units were not harmonized
Xue et al. (2022), rice	Machine-plant-paddy-soil numerical coupling	Physical transplanting validation (abstract-level evidence)	No numerical value reproduced because the full text was not accessible during this review	Not ranked: platforms and computational-cost units were not harmonized

Note: Full texts were available and checked for 2 of the 3 studies (Jin et al., 2025; Hou et al., 2023). For Xue et al. (2022), only the publisher abstract and indexed record were accessible; therefore, no numerical validation value was transcribed. Crop, soil, calibration, response variables, solvers, and coupling frameworks differ, so neither accuracy nor computational cost is ranked. Table 3 reports study-level evidence; proposed system gates appear in Table 7.

Compliant end-effectors constitute the mechanical counterpart to this modeling approach. Pneumatic, elastomeric, and force-limited grippers can attenuate impact and accommodate a broader range of seedlings than rigid clamps. Their performance should be evaluated in terms of force–displacement behavior, fatigue life, and contamination tolerance rather than short-duration laboratory picking success alone. In field machinery, a compliant element that is difficult to clean or whose stiffness changes after repeated cycles may introduce a new reliability problem.

3.2 PERCEPTION, NAVIGATION AND ONLINE QUALITY INSPECTION

Machine vision is used for seedling grading, selective picking, low-damage handling, planting-posture assessment, and missed-plant detection. Improved YOLO-based methods can distinguish seedling condition or transplanting targets, while RGB-D data support three-dimensional positioning and obstacle avoidance *(Li T. et al., 2023; Xin et al., 2022; Zhang S. et al., 2026; Zhao S. et al., 2022)*. More recent systems extend vision beyond recognition: selective transplanting uses perceived condition to determine which seedling to pick, YOLO-RDS estimates post-transplant uprightness, and UAV imagery combined with detection and tracking quantifies missed tobacco transplants at field scale *(Jin X. et al., 2024; Li M. et al., 2025; Su et al., 2025)*. These applications move perception toward a closed operational quality loop rather than an isolated classification task.

Research integrating machine vision with GNSS suggests a pathway toward autonomous field navigation *(Liu Z. et al., 2026)*. Nevertheless, tobacco transplanting involves disturbances that are underrepresented in many benchmark datasets, including large flexible leaves, changing canopy appearance, soil splash, mulch reflections, dust, and chassis vibration. The UAV-based tobacco study by *Su et al. (2025)* is particularly informative because it achieved useful field-scale evaluation while identifying limited scenario coverage as an unresolved generalization issue. Consequently, models trained under one agronomic background may attain high test accuracy yet exhibit lower operational availability when transferred to different soils, mulch conditions, or regions. Datasets should therefore represent disturbance levels and failure cases, and field studies should report the proportion of operating time for which the perception module remains valid.

Digital-twin-based quality inspection provides a framework for integrating physical signals, machine states, and predicted operating quality. A plant-factory transplanting study combined vibration data with virtual equipment models for online monitoring *(Chen K. et al., 2023)*, while broader agricultural-machinery research has described digital twins as bidirectional physical–virtual frameworks for equipment life-cycle applications *(Guo et al., 2023)*. Tobacco-specific research has further linked field and machine information to online quality indicators *(Zhao Q. et al., 2026)*. These layers should remain conceptually distinct: coupled DEM–MBD or other numerical models explain mechanisms, sensing estimates the current state, and a digital twin becomes operationally meaningful only when updated information supports parameter adjustment, fault warnings, or maintenance decisions within a useful time horizon.

Table 4

Reported perception performance (task-specific; not a universal leaderboard)

Study / task	Model	Reported accuracy	Speed / size	Robustness / comparison boundary
Su et al. (2025), tobacco UAV missed-plant assessment	YOLOv5s	P 75.1%; R 75.4%; mAP 75.8%	16.8 ms/image; 14.1 MB	Same self-constructed dataset; direct baseline
Su et al. (2025), tobacco - same dataset	YOLOv8s	P 72.6%; R 72.2%; mAP 72.9%	51.0 ms/image; 42.7 MB	Directly comparable with YOLOv5s; newer family was not superior here
Su et al. (2025), tobacco - same dataset	YOLOv11s	P 74.9%; R 75.1%; mAP 75.2%	17.8 ms/image; 19.6 MB	Directly comparable; accuracy close to YOLOv5s
Su et al. (2025), tobacco - same dataset	Improved YOLOv5s	P 79.0%; R 79.6%; mAP 81.1%	17.2 ms/image; 14.2 MB	With DeepSORT on field videos: Mm 4.1%, Mf 9.1%, MOTA 78.5%, 19.9 FPS; no cross-region test

Study / task	Model	Reported accuracy	Speed / size	Robustness / comparison boundary
Jin et al. (2024), vegetable seedlings (species not specified)	YOLO-RDS	mAP 97%; field accuracy 92.56%; mean relative error 3.09%	22 FPS	Absolute angle error 0–3°; different task/data, so not comparable with UAV rows

Within the shared dataset of *Su et al. (2025)*, YOLOv5s exceeded YOLOv8s in both mAP (75.8% versus 72.9%) and latency (16.8 versus 51.0 ms/image), demonstrating that a newer detector family is not automatically superior for small UAV targets. The improved YOLOv5s–DeepSORT pipeline yielded a missed-detection rate of 4.1%, a false-detection rate of 9.1%, a multiple-object tracking accuracy of 78.5%, and 19.9 FPS on field videos, but the single-site dataset does not establish cross-region robustness. Target-hardware testing is equally important: UAM-YOLO reported more than 175 FPS on its development platform but 10.57 FPS on a Qualcomm QCS6490 edge platform, illustrating the desktop-to-edge performance gap *(Su et al., 2025; Wang X.R. et al., 2026)*. Edge-deployment choices should therefore be based on end-to-end latency, energy consumption, thermal headroom, and operating-time availability rather than mAP alone. Compact convolutional detectors and sensor-fusion pipelines currently provide a stronger basis for deterministic real-time control than large language models (LLMs). LLMs may assist with maintenance-information retrieval, log summarization, and operator interaction, but safety-critical motion should remain under verified deterministic control. Cloud dependence also introduces latency, connectivity, and data-governance risks.

3.3 LOW-COST MECHATRONIC INTEGRATION AND FIELD ROBUSTNESS

The transition from prototype mechanisms to deployable intelligent machines depends on a control architecture that connects sensors, actuators, seedling-handling modules, and the chassis. Studies on the motion control of whole-row or reciprocating picking mechanisms have shown that shaped velocity profiles and coordinated multiaxis timing can reduce vibration at higher operating frequencies *(Shi J. et al., 2025)*. Integrated robotic systems likewise show that vision, tray logistics, and end-effector motion must be synchronized as a single production cycle rather than optimized independently *(Liu W. et al., 2024b)*. Automatic separation, air-assisted picking, and flexible feeding impose the same requirement for pneumatic–mechanical coordination *(Shao et al., 2021; Zhang B. et al., 2024; Zheng et al., 2025)*.

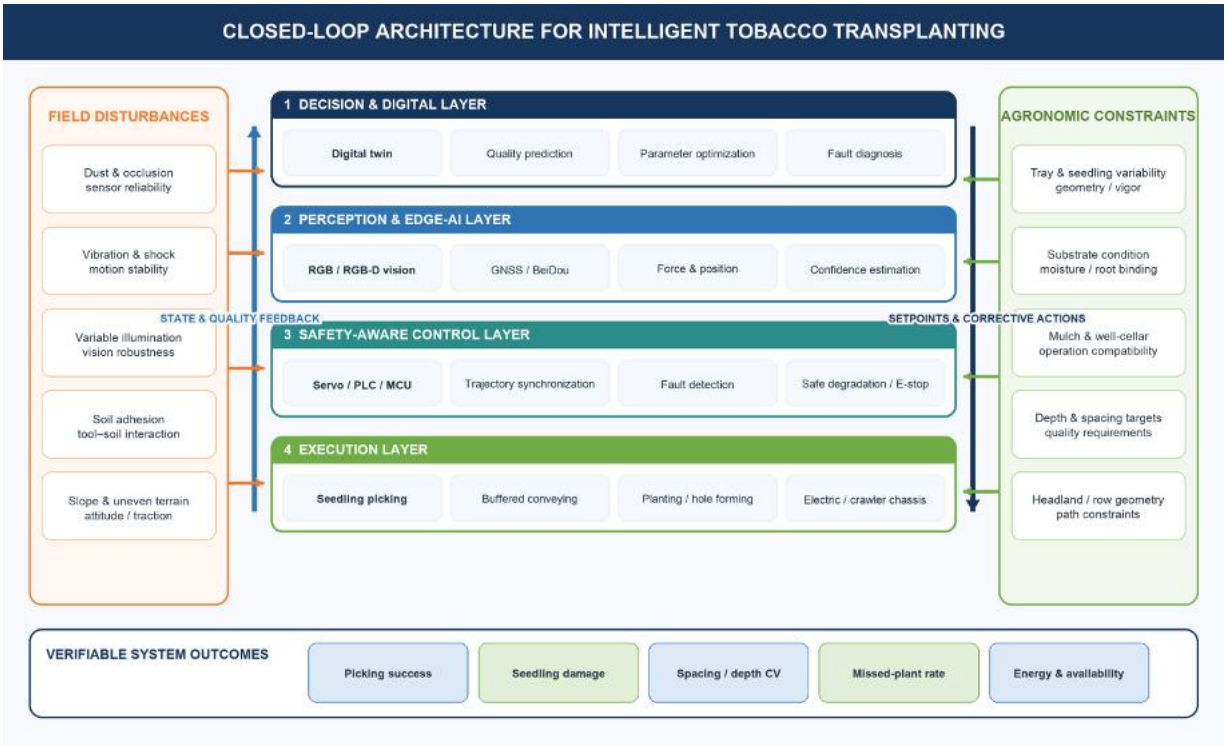

Fig. 2 - Closed-loop layered architecture, disturbance pathways, and performance feedback for intelligent tobacco transplanting

Source: synthesized by the authors from the reviewed literature.

For hilly tobacco production, control performance must be evaluated together with maintainability, energy consumption, and field availability. Industrial servos and PLCs may provide excellent laboratory control, but field machines must also tolerate dust, mud, voltage fluctuations, and maintenance by local service personnel. A miniaturized electrically driven plug-seedling transplanter demonstrated the practical advantages of compact electric actuation; however, its bench and field results also illustrate why module-level success should not be equated with whole-machine field performance *(Chen M. et al., 2025)*. Reviews of agricultural chassis for hilly and mountainous terrain further identify power, travel, steering, leveling, and navigation as coupled subsystems rather than independent design choices *(Jiang Y. et al., 2025)*. Lightweight electric tobacco platforms with microcontroller-based control should therefore be evaluated for slope stability, thermal load, battery endurance, contamination tolerance, and fault recovery over complete working days *(Bai et al., 2025; Li H.M. et al., 2024; Wang B. et al., 2024)*.

4. BOTTLENECKS FOR FIELD DEPLOYMENT

4.1 NURSERY–MACHINE MISMATCH AND AGRONOMIC DIVERSITY

The most fundamental barrier to fully automated transplanting often lies outside the machine itself. Seedling height, stem strength, root binding, substrate moisture, and tray geometry determine extraction resistance and the safe gripping window. When these properties vary, a mechanism optimized for one batch may cause missed picks or damage in another. Consequently, increasingly sophisticated end-effectors do not eliminate the need for nursery standardization *(Wang N. et al., 2021; Zhang X., 2021)*. A practical standard should specify not only nominal tray dimensions but also measurable tolerances for substrate integrity and seedling mechanical properties.

Agronomic diversity creates a second mismatch. Northern flatland tobacco may use ridge, row-spacing, and planting-depth configurations that differ from those used for well-cellar tobacco in the southwest. If the chassis, feeder, planter, hole former, and mulch-handling components are tightly integrated without standardized interfaces, a change in agronomic practice may require redesign of the entire machine. Modular connections, parameter-adjustable actuators, and software-defined timing can improve cross-regional reuse, provided that interface requirements are specified early in the design process.

4.2 HILLY TERRAIN AND ADHESIVE SOILS

Slope alters chassis attitude and, consequently, the penetration angle of the planting or hole-forming element. Wheel or track slip and shifts in the center of gravity can transform a well-tuned laboratory trajectory into an inclined hole or variable planting depth. Research on unmanned farms emphasizes that machine-friendly field infrastructure should be developed alongside autonomous equipment *(Luo et al., 2024)*. Similarly, a recent review of agricultural chassis for hilly and mountainous regions indicates that power, travel, steering, leveling, navigation, and path tracking must be designed as an integrated platform *(Jiang Y. et al., 2025)*. For hilly tobacco production, structural mass, track geometry, active or adaptive leveling, attitude sensing, and field accessibility should therefore be treated as system-level requirements rather than addressed by increasing traction power alone.

Sticky red soil imposes a direct tribological constraint. Soil accumulation on duckbills, press wheels, or augers increases resistance and may prevent complete opening or closing. Current well-cellar and hole-forming studies provide valuable kinematic and structural optimization, but field robustness must be validated across soil-moisture levels and repeated operating cycles *(Fan et al., 2020b; Jiang X. et al., 2024; Xu S. et al., 2024)*. Anti-adhesion microtextures, low-surface-energy coatings, and active cleaning devices are promising only if their durability, sensitivity to contamination, and effects on planting quality are quantified under representative red-soil conditions.

4.3 THE SPEED–DAMAGE–ROBUSTNESS TRADE-OFF

Increasing cycle frequency raises acceleration, inertial loading, and contact frequency, but the available literature quantifies speed–quality deterioration more often than direct plant injury. Direct injury evidence from rice seedling separation shows that the damaged stem-area ratio generally remained below 2% at 100–150 rpm, whereas at 300 rpm the median exceeded 8% for 40-day seedlings; maximum impact load and damaged-area ratio were strongly correlated ($\rho > 0.93$, $p < 0.001$) *(Xi et al., 2026)*. These results are seedling-age- and mechanism-specific and cannot be transferred quantitatively to tobacco. In a pepper transplanter, increasing the operating rate from 80 to 120 plants/min reduced overall transplanting success from 97.5% to 90.0% *(Chen M. et al., 2025)*. In a dryland tomato test, increasing the rate from 45 to 96 plants/min increased spacing CV from 6.6% to 8.9% and the missed-transplanting rate from 1.7% to 2.8% *(Wang Y.W. et al., 2018)*. Collectively,

these findings support a speed–damage or speed–quality trade-off across crop-specific mechanisms, but they do not establish a nonlinear speed–damage curve for tobacco. The nonlinear-threshold hypothesis therefore remains to be tested in tobacco using matched seedling batches and direct injury measurements *(Chen Z. et al., 2026; Xi et al., 2026)*.

A comparable trade-off exists in sensing. Additional cameras and sensors can improve observability, but they also increase the number of failure points, calibration demands, and power consumption. In dusty, vibration-prone fields, robustness may be improved more effectively by combining a limited number of complementary sensors with self-diagnostics and confidence estimation than by simply adding channels. Field-grade intelligent transplanters should therefore support graceful degradation: when a perception module becomes unreliable, the machine should transition to a reduced but safe operating mode rather than stop unnecessarily or continue issuing erroneous commands.

Table 5

Empirical evidence for speed–quality trade-offs and damage risk

Study / crop	Operating rate	Observed response	Boundary of inference
Chen et al. (2025), pepper	80 → 120 plants/min	Overall success 97.5% → 90.0%; at 120 plants/min, picking 95.83% and depositing 94.78%	Direct speed sweep, but physical damage was not reported separately
Wang Y.W. et al. (2018), dryland tomato	45 → 96 plants/min	Spacing CV 6.6% → 8.9%; missed rate 1.7% → 2.8%	Direct speed sweep; quality loss, not a tobacco damage curve
Karayel et al. (2023), tomato/watermelon	0.4 m/s in the reported field protocol	Spacing CV 3.52–5.55%; only disc type damaged >3%; survival >90%	Mechanism comparison; no within-machine speed sweep
Xi et al. (2026), rice seedling separation	100–150 rpm versus 300 rpm	Damaged stem-area ratio generally <2% at 100–150 rpm; median >8% for 40-day seedlings at 300 rpm; ρ(Fmax, damage) >0.93 ($p < 0.001$)	Direct internal stem-damage evidence, but crop, seedling age and separation mechanism differ from tobacco field transplanting

The available evidence supports a speed–quality trade-off but does not establish a universal speed–damage relationship for tobacco. A defensible experiment should test at least three speeds on the same machine and seedling batch, report confidence intervals, and simultaneously quantify damage severity, missed plants, spacing CV, and field capacity.

4.4 ECONOMICS, MAINTAINABILITY AND SERVICE CAPACITY

A technically advanced transplanter may fail commercially if its capital cost and seasonal utilization are mismatched with farm scale. Full automation adds servomotors, pneumatic components, controllers, cameras, and wiring, increasing both manufacturing cost and the expertise required for troubleshooting. In fragmented tobacco-production systems, financial viability may depend on cooperative ownership or professional contracting services rather than individual purchase. Accordingly, cost per successfully transplanted hectare and annual machine availability are more informative deployment metrics than purchase price alone.

Maintainability should be treated as a primary design variable. Sensors and actuators should be accessible; connectors should be protected from mud and vibration; diagnostic information should be intelligible to field technicians; and critical spare parts should be standardized. Remote fault diagnosis may reduce downtime, but it cannot compensate for an architecture that is inherently difficult to inspect or repair. Region-adapted intelligent machines should therefore combine automation with an explicit service and maintenance strategy.

Table 6

Transparent LCC and ROI framework for intelligent transplanter adoption

Component	Included variables	Minimum evidence	Reporting rule
Annualized ownership	Purchase, financing, depreciation, insurance, housing	Local quotations and accounting records	Report currency/base year and discount rate

Component	Included variables	Minimum evidence	Reporting rule
Operating	Energy/fuel, labor, consumables, transport	Metered energy + time-and-motion records	Include charging losses and operator/support labor
Reliability	Planned service, failures, spares, downtime	MTBF, MTTR and seasonal availability logs	Value lost field windows explicitly
Benefit	Labor displaced, timeliness, quality/yield effects, service revenue	Matched field comparison	Do not monetize unmeasured yield gains
Decision	LCC/ha = discounted total cost / successful area; ROI = (discounted benefits - costs)/costs	Sensitivity by annual hectares and service life	Report break-even utilization, not purchase price alone

Published studies of tobacco transplanters rarely report comparable purchase prices, maintenance records, or annual utilization, so a tobacco-specific currency ROI cannot yet be calculated without speculative assumptions. European system analysis of agricultural robotics likewise identifies vehicle capacity and positioning-system cost as major economic drivers *(Pedersen et al., 2006)*. Cross-crop cases further demonstrate the controlling effect of utilization. A survey of six U.S. greenhouse firms evaluated a USD 125,000 transplant robot: under the average scenario, automated cost was USD 0.010 per cutting versus USD 0.014 manually, ten-year NPV was USD 105,807, and discounted payback was 4.8 years *(Adegbola et al., 2019)*. An Indonesian rice-transplanter rental case reported a break-even use of 27.96 ha/year, B/C ratio of 1.02, IRR of 20.79%, and payback of 4.84 years; increasing annual working days shortened the reported payback *(Asmara et al., 2024)*. These values are not transferable cost estimates for hilly tobacco because crop, wage, currency/base year, machine duty, and service model differ. Their transferable lesson is methodological: annual throughput, utilization, labor substitution, and service organization must be included explicitly. Table 6 converts this evidence into a reproducible tobacco field-data requirement for comparing individual ownership, cooperative ownership, and contracting scenarios.

The gates in Table 7 are provisional engineering targets, not standards or pooled estimates. The ≥95% picking-success gate is set below the best reported values used in this review: 97.92% for pepper in *Hou et al. (2023)*, 97.5% overall success at 80 plants/min in *Chen M. et al. (2025)*, and 95-99% transplant success across three vegetable crops in Italian tilled/no-till field tests by *Frasconi et al. (2019)*. The ≤3% damage/miss screen is consistent with 2.21% substrate loss in *Hou et al. (2023)* and a 2.8% missed-transplanting rate in dryland tomato at 96 plants/min in *Wang Y.W. et al. (2018)*. The 5% CV screen is informed by, but is not equivalent to, the 3.52-5.55% spacing CV reported for tomato/watermelon by *Karayel et al. (2023)*; it is not a validated tobacco depth limit. Because the reviewed studies did not report comparable full-period perception availability, seasonal availability, or fouling duration, the ≥95%, ≥90%, and ≥1 h values are protocol-design targets rather than literature bests and require multi-site calibration.

Table 7

Field bottlenecks, engineering responses and proposed validation thresholds

Bottleneck	Engineering response	Recommended validation	Why it matters	Exploratory gate (basis explained in text; not a standard)
Variable plug seedlings	Nursery tolerances + compliant/force-limited end-effector	Success rate, damage severity, extraction-force distribution across batches	Separates mechanism quality from unusually uniform test seedlings	Picking success ≥95%; damage ≤3% over ≥3 seedling batches
Slope and chassis attitude	Lightweight crawler, attitude sensing, self-leveling or trajectory compensation	Depth CV, uprightness, slip rate and stability on defined slopes	Directly measures field adaptation	Depth CV ≤5%; missed plants ≤3%; report defined slope classes
Sticky red soil	Anti-adhesion geometry/material + active cleaning	Draft/torque, adhesion mass, hole-quality decay over repeated cycles	Captures progressive fouling, not just first-cycle performance	Hole dimensions within agronomic tolerance after ≥1 h continuous work

Bottleneck	Engineering response	Recommended validation	Why it matters	Exploratory gate (basis explained in text; not a standard)
Dust/vibration/ill umination	Multimodal sensing, confidence estimation, rugged mounting	Detection/navigation availability over full working period	Measures robustness rather than single-image accuracy	mAP plus ≥95% perception availability; safe fallback tested
High automation cost	Modular architecture and standardized components	Cost per hectare, annual utilization, MTBF/MTTR	Connects technical design with adoption feasibility	Seasonal availability ≥90%; MTBF/MTTR and LCC/ha reported

4.5 SAFETY, STANDARDIZATION AND HUMAN-MACHINE INTERACTION

Autonomous and electric transplanting introduces hazards beyond conventional guarding, including unintended motion, failure to detect people or obstacles, communication loss, battery thermal events, and unsafe recovery after sensor degradation. Internationally, ISO 18497 Parts 1–4:2024 address design principles, obstacle protection, autonomous operating zones, and verification for partially automated to autonomous agricultural machinery; ISO 25119 covers safety-related control systems; ISO 10975:2023 covers auto-guidance on operator-controlled machines; and IEC 62619:2022 addresses industrial lithium-battery safety *(ISO, 2024; ISO, 2019; ISO, 2023; IEC, 2022)*. In China, GB/T 39521-2020 covers agricultural auto-guidance but identically adopts the now-superseded ISO 10975:2009 edition, revealing an update gap relative to ISO 10975:2023. GB/T 16754-2021 specifies emergency-stop design principles, GB/T 41678.1-2022 covers higher-voltage electrical/electronic systems in agricultural machinery, and GB/T 46270-2025 specifies a BeiDou-based agricultural automatic-driving system. The mandatory general agricultural-machinery safety standard GB 10395.1-2025 has been published and is scheduled to take effect on 1 November 2026 *(SAC, 2020; SAC, 2021; SAC, 2022; SAC, 2025a; SAC, 2025b)*. A safety case for a tobacco transplanter should include accessible emergency stops, fail-safe stopping, guarded pinch points, battery isolation, ingress and thermal protection, audible and visual state indication, defined autonomous operating zones, obstacle detection, and documented residual risks. Compliance with general standards is necessary but not sufficient; machine-specific validation is still required on slopes, near workers, and during blockage clearing.

4.6 ENVIRONMENTAL SUSTAINABILITY AND LIFE-CYCLE BOUNDARIES

Electrification can eliminate machine-level tailpipe emissions and improve low-speed controllability, but its overall environmental benefit depends on the electricity mix, battery production and replacement, machine utilization, mass, service life, and end-of-life management. Consistent with ISO 14040 and ISO 14044, a comparative life-cycle assessment should state its goal and scope; define a functional unit, such as one successfully transplanted hectare; document inventory boundaries and data quality; and separate inventory results from impact assessment and interpretation *(ISO, 2006a; ISO, 2006b)*. The boundary should include embodied impacts of the machine and battery, energy supply and charging losses, maintenance, transport, interactions with mulch, and disposal, and should report both energy demand and greenhouse-gas emissions. Sensitivity analysis should vary battery life, annual utilization, electricity mix, and machine service life because these parameters can reverse comparisons between electric and combustion platforms. Design priorities include appropriately sized batteries, high-efficiency actuators, repairable modules, durable anti-adhesion surfaces, and battery take-back programs. These requirements prevent the label “electric” from being used as a sufficient proxy for sustainability.

5. RESEARCH PRIORITIES

First, nursery and machine design should be linked through measurable interface standards. Plug dimensions alone are insufficient; allowable ranges should also be specified for substrate moisture, root binding, stem diameter, seedling height, and extraction resistance. These specifications would allow end-effectors and feeding systems to be tested against representative variability rather than an idealized batch. Existing studies of picking, feeding, and damage provide a technical basis for developing such standards *(Wang X. et al., 2023; Xi et al., 2026; Zhang N. et al., 2024)*.

Second, compliant end-effectors should progress from passive flexibility to closed-loop interaction. Force or displacement sensing, elastic elements, and model-based motion profiles can regulate contact according to seedling and substrate conditions. Recent flexible multi-pin and DEM-optimized end-effectors provide useful starting points because they explicitly link geometry and operating parameters to root-block

mechanics *(Han L. et al., 2025; Liu W. et al., 2024a)*. The objective is not to minimize gripping force unconditionally, but to maintain a robust force margin that guarantees extraction without damage. Closed-loop compliance should also be designed for contamination tolerance, fatigue resistance, and ease of cleaning.

Third, field perception should be evaluated in terms of operational availability and generalizability. Multimodal vision, depth sensing, and GNSS can complement one another, but the system should also estimate confidence and detect sensor degradation. Datasets and experiments must represent dust, mud, leaf occlusion, variable illumination, mulch reflections, and vibration. Post-transplant uprightness monitoring and UAV-based missed-plant assessment demonstrate that quality can be measured after planting; however, cross-scenario validity must be demonstrated rather than assumed *(Jin X. et al., 2024; Su et al., 2025)*. Ultimately, online quality inspection should update machine parameters or trigger corrective actions instead of remaining a post-operation monitoring layer *(Zhao Q. et al., 2026)*.

Fourth, machine–soil–seedling models and digital twins should be linked to experimentally verifiable decisions. DEM, multibody dynamics, and other coupled numerical models can predict contact forces, soil resistance, impact, and trajectory deviations; machinery–plant–soil modeling provides a transferable example of how damage mechanisms can be analyzed beyond ideal kinematics *(Hou et al., 2023; Jin X. et al., 2025; Xue et al., 2022)*. Digital twins add value when physical measurements update the virtual model and the resulting state estimate supports a decision, as illustrated by monitoring of transplanting equipment and broader agricultural-machinery frameworks *(Chen K. et al., 2023; Guo et al., 2023; Zhao Q. et al., 2026)*. A meaningful closed loop should adjust penetration timing, motion profiles, cleaning intervals, or maintenance actions and subsequently demonstrate improved planting quality or a lower failure rate.

Fifth, platforms for hilly regions should prioritize lightweight, modular electrification. Electric drives simplify low-speed control and support distributed actuation, while modular planters, feeders, and hole-forming units allow one chassis to serve multiple agronomic configurations. Research on miniaturized electric transplanters and reviews of agricultural chassis for hilly terrain provide a practical basis for integrating electric drive, compact packaging, leveling, and navigation instead of treating electrification as battery substitution alone *(Chen M. et al., 2025; Jiang Y. et al., 2025)*. The engineering challenge is to balance energy capacity, slope safety, structural mass, and serviceability. Crawler and electric tobacco-transplanter studies provide a tobacco-specific basis for this development *(Bai et al., 2025; Wang B. et al., 2024; Zhao Y., 2024)*.

Finally, the field requires common reporting protocols. Studies of seedling picking should report seedling variability, picking success, damage, and force-related indicators. Planting studies should report depth, spacing, uprightness, missed-plant rate, and mulch damage under defined soil and speed conditions. Evaluations of intelligent functions should report full-period availability and recovery from faults in addition to algorithmic accuracy. Consistent reporting would help distinguish genuine technological advances from performance that depends on favorable test conditions.

Table 8 applies the same provisional gates as research milestones, not current tobacco standards; medium-term availability targets must be recalibrated from multi-region seasonal data.

Table 8

Measurable short- and medium-term research milestones

Priority	Short-term horizon	Short-term measurable milestone	Medium-term horizon	Medium-term measurable milestone
Nursery-machine interface	0-2 y	Measure extraction force, moisture, stem diameter and root binding across ≥3 batches	3-5 y	Inter-laboratory protocol and crop/region-specific tolerance bands
Closed-loop compliant picking	0-2 y	≥95% success and ≤3% damage across defined batch variability	3-5 y	Full-day field validation with fatigue/contamination and fault recovery
Robust perception/edge AI	0-2 y	Public disturbance-labeled dataset; latency, energy and availability reported	3-5 y	Cross-region validation with ≥95% operating-time availability and safe degradation
Models/digital twins	0-2 y	Report calibration, error, hardware and wall-clock cost	3-5 y	Online parameter or maintenance decision shown to improve field KPI

Priority	Short-term horizon	Short-term measurable milestone	Medium-term horizon	Medium-term measurable milestone
Electric/autonomous platform	0-2 y	Battery endurance, slope stability, emergency-stop and obstacle tests	3-5 y	Seasonal LCC/LCA plus standards-aligned autonomous-zone validation
Common reporting	0-2 y	Core KPI dictionary and minimum test metadata	3-5 y	Multi-site benchmark with shared protocols and uncertainty intervals

CONCLUSIONS

Tobacco transplanting machinery is evolving from mechanism-centered equipment into integrated systems that couple nursery quality, seedling handling, soil interaction, chassis motion, sensing, and control. The available international evidence indicates that no single transplanter architecture is universally superior: high-throughput automation is effective in standardized production, whereas hilly tobacco-growing areas require compact, maneuverable, and agronomically adaptable machines.

At the mechanism level, the most important transition is from rigid, single-action designs to force-decoupled picking, buffered conveying, and planting trajectories that explicitly account for soil and seedling interactions. Reported high success rates demonstrate technical feasibility, but field performance remains difficult to compare because seedling properties, soil conditions, and disturbance levels are not reported consistently.

For intelligent tobacco transplanters, the principal bottleneck is system robustness rather than the availability of individual algorithms. Vision, navigation, coupled simulation, and digital twins will have practical value only if they remain functional under dust, vibration, slope, and soil adhesion and if their outputs trigger corrective machine actions. The next generation of equipment should therefore integrate nursery standardization, compliant end-effectors, rugged multimodal sensing, decision-oriented digital twins, and lightweight modular electric chassis, while treating life-cycle cost and maintainability as explicit design objectives.

The key takeaways arising from these conclusions are:

(1) Machine architecture should be selected according to terrain, agronomic practice, nursery uniformity, service capacity, and annual utilization; automation level alone does not define a performance hierarchy.

(2) Cross-crop technology transfer is most defensible at the level of mechanisms, sensing methods, and validation protocols; tobacco-specific constraints associated with well-cellar planting, mulch, and hilly soils still require dedicated field tests.

(3) DEM–MBD models, perception systems, and digital twins are useful only when simulation error, computational cost, field availability, and decision benefit are reported together.

(4) Available evidence supports a speed–quality trade-off, but no universal speed–damage curve has been established for tobacco; matched, multispeed experiments should therefore be prioritized.

(5) Safety, LCC/ROI, and LCA should be treated as design inputs for electric and autonomous machines rather than as post hoc claims.

ABSTRACT

This study proposes an artificial intelligence-based method for the automatic identification of natural groups of mechanical behaviour in rose hip seeds (Rosa canina). The method combines compression testing with unsupervised machine learning techniques, namely Principal Component Analysis (PCA) and K-means clustering, while creep tests are analysed separately to assess the time-dependent mechanical behaviour of the seeds. This approach enables the identification of distinct mechanical patterns and the objective classification of samples according to their response to mechanical loading. The unsupervised multivariate analysis was performed using mechanical features extracted from compression tests conducted on 25 individual rose hip seeds (n = 25), with each individual compression test generating a force–displacement dataset comprising 934 experimental data points. Each cluster was analysed separately in terms of the experimentally determined mechanical parameters. For each group, the mean values of maximum compression force (F_{max}), displacement at maximum force (x_{max}), deformation energy, and initial stiffness were calculated. The results revealed the existence of two main categories of mechanical behaviour. The first group was characterized by an average maximum force of approximately 141 N and a displacement at maximum force of 0.73 mm, indicating seeds with high mechanical strength. The second group exhibited an average maximum force of approximately 75 N and a displacement at maximum force of 0.85 mm, corresponding to seeds that were more deformable and less resistant to compression. The seeds were tested at a moisture content of 2.79% (wet basis), determined thermo-gravimetrically. To validate cluster separation and reduce the dimensionality of the dataset, Principal Component Analysis (PCA) was applied. The quality of clustering was assessed using the silhouette index, which indicated a satisfactory separation of samples according to their mechanical response. PCA revealed that the main differences between clusters were associated with maximum force, absorbed energy, and initial stiffness values, confirming the existence of distinct categories of mechanical behaviour within the analysed seed batch.

REZUMAT

Lucrarea de fata propune o metodă bazată pe inteligența artificială pentru identificarea automată a unor categorii distincte de comportament mecanic al semințelor de măceș (Rosa canina). Metoda integrează încercările de compresiune cu tehnici de învățare automată nesupravegheată, respectiv Analiza Componentelor Principale (PCA) și algoritmul K-means, în timp ce testele de fluaj sunt analizate separat pentru caracterizarea răspunsului mecanic al semințelor în timp. Această abordare permite evidențierea și clasificarea obiectivă a diferitelor tipuri de răspuns mecanic la compresiune. Analiza multivariată nesupravegheată a fost realizată utilizând caracteristici mecanice extrase din testele de compresiune efectuate pe 25 de semințe individuale de măceș (n = 25), fiecare test individual de compresiune generând un set de date forță–deplasare alcătuit din 934 de puncte experimentale. Fiecare cluster a fost analizat separat din punctul de vedere al parametrilor mecanici determinați experimental. Pentru fiecare grup au fost calculate valorile medii ale forței maxime de compresiune (F_{max}), deplasării la forța maximă (x_{max}), energiei de deformare și rigidității inițiale. Rezultatele au evidențiat existența a două categorii principale de comportament mecanic. Primul grup a fost

caracterizat printr-o forță maximă medie de aproximativ 141 N și o deplasare la forța maximă de 0,73 mm, indicând semințe cu rezistență mecanică ridicată. Al doilea grup a prezentat o forță maximă medie de aproximativ 75 N și o deplasare la forța maximă de 0,85 mm, corespunzând unor semințe mai deformabile și cu o rezistență mai redusă la compresiune. Semințele au fost testate la un conținut de umiditate de 2,79% (bază umedă), determinat prin metoda termogravimetrică. Pentru validarea separării clusterelor și reducerea dimensionalității setului de date a fost aplicată Analiza Componentelor Principale (PCA). Calitatea grupării a fost evaluată utilizând indicele silhouette, care a indicat o separare satisfăcătoare a probelor în funcție de răspunsul lor mecanic. Analiza PCA a evidențiat faptul că principalele diferențe dintre clustere au fost asociate cu valorile forței maxime, energiei absorbite și rigidității inițiale, confirmând existența unor categorii distincte de comportament mecanic în cadrul lotului de semințe analizat.

INTRODUCTION

The need to identify and utilize new food resources with high nutritional and energy value, together with the continuous growth of the global population, has led to a significant increase in research efforts in this field worldwide. All available food resources can contribute, to a greater or lesser extent, to ensuring food security and meeting the nutritional requirements of the population. However, the efficiency of their utilization depends on their nutritional characteristics, availability, and the sustainability of production and valorisation processes (*Chen and Kates, 1994*) .

By combining state-of-the-art computational algorithms with the ability of modern computer systems to rapidly process very large volumes of data, researchers are now able to efficiently identify and evaluate solutions to complex problems whose direct experimental investigation may be costly, difficult, or time-consuming. In this way, optimized technical solutions can be obtained, capable of reproducing the behaviour of real physical phenomena with a high degree of accuracy within a reasonable time frame.

In this context, rose hip seeds (*Rosa canina*), derived from a perennial plant that is resistant to low temperatures, grows optimally in sunny or slightly shaded areas, and requires moderate irrigation, are of particular interest due to their nutritional and functional value (*Yildiz and Alpaslan, 2012*). The plant is characterized by delicate pale pink flowers followed by intensely red fruits (as shown in Fig. 1), which are well known for their high content of bioactive compounds, particularly vitamin C, polyphenols, and antioxidants (*Marmol et al., 2017*). Beyond its mechanical and technological relevance, *Rosa canina* has attracted considerable scientific interest due to the valuable chemical composition and diverse biological properties of its fruits and other plant components. *Demir and Özcan (2001)* highlighted the chemical and technological properties of wild rose fruits, while *Polumackanycz et al. (2020)* reported the rich phenolic composition and associated biological properties of dog rose fruits and leaves. The broader potential of *Rosa canina* has also been addressed through pharmacognostic investigations (*Oproshanska et al., 2021*) and through its use as a phytogenic source in animal nutrition (*Stătescu et al., 2025*). Collectively, these studies emphasize the considerable biological, nutritional, and technological value of *Rosa canina* and support continued research aimed at improving the characterization and valorisation of this plant and its derived materials.

Fig. 1 – Rosa hip (rosa canina), wild: a) fruits; b) seeds

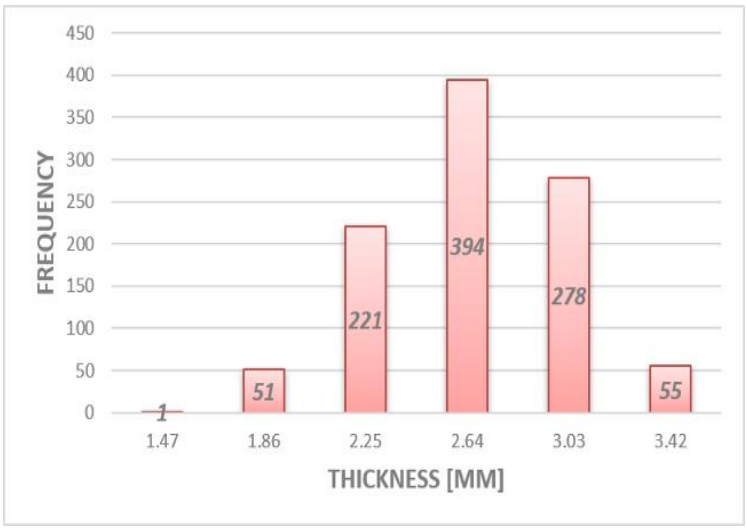
The mechanical behaviour and fracture resistance of agricultural seeds under compressive loading have been extensively investigated because of their relevance to handling, processing, grinding, and size-reduction operations. *Paulsen, (1978),* investigated the fracture resistance of soybeans subjected to compressive loading, while *Gupta and Das, (2000),* analysed the fracture resistance of sunflower seeds and kernels under compression.

Similar investigations were subsequently conducted by *Łysiak (2007),* who characterized the fracture toughness of pea seeds using Weibull analysis, and by *Khodabakhshian et al., (2010)*, who evaluated the mechanical properties of sunflower seeds and kernels under compressive loading. In addition to the intrinsic mechanical properties of the biological material, experimental factors such as moisture content, seed dimensions, loading rate, and loading orientation can substantially influence the force and energy associated with seed fracture, as investigated for cumin seeds by *Saiedirad et al., (2008).* The importance of specimen orientation and moisture level was also addressed by *Dowd et al., (2019),* in their study of cottonseed fracture resistance. These studies demonstrate that the mechanical response of seeds is strongly dependent on both material characteristics and testing conditions, emphasizing the importance of controlling moisture content, loading orientation, and compression conditions when evaluating fracture behaviour.

Ionescu et al., (2025), investigated the influence of grinding time on the particle size distribution of rose hip powder, highlighting its direct implications for various applications in the food and pharmaceutical industries. The authors emphasized that improvements in solubility, stability, and bioavailability form the basis for the development of new rose hip powder-based products tailored to the specific requirements of different industrial sectors. In addition, *Gokduman (2026)* conducted a comprehensive study on the main physical and mechanical characteristics of rose hip fruits, analysing parameters such as dimensions, mass, firmness, and the mechanical behaviour of the fruits under detachment and puncture loading conditions. Indentation techniques have also been extensively employed for the mechanical characterization of materials, with *Evans et al. (2013)* investigating nano-indentation methods for compliant materials and *Han et al. (2015)* analysing the factors influencing micro-indentation measurements.

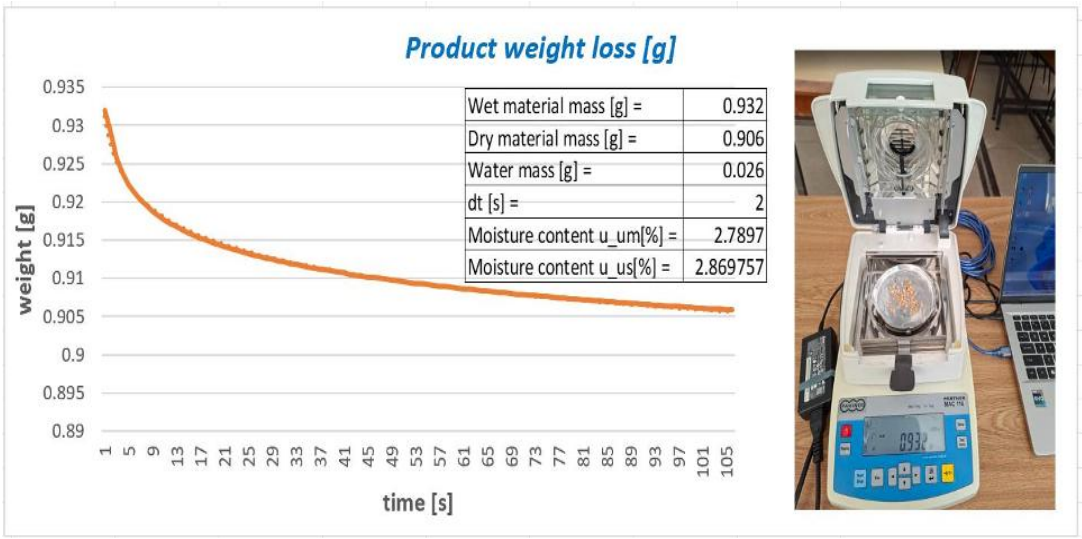
The application of machine learning techniques for the characterization of elastic, viscoelastic, stress relaxation, and creep behaviour of agri-food materials has been addressed in numerous recent studies, including those conducted by *Xu (2020)*, *Biswas et al. (2020)*, *Li et al. (2021)*, and *Singh et al. (2026)*.

These studies propose and validate various predictive models based on machine learning algorithms that are capable of accurately estimating the characteristic parameters of creep and stress-relaxation phenomena. Their findings contribute to a deeper understanding and improved modelling of the rheological behaviour of agri-food materials.



The main objective of the present study is the theoretical and experimental investigation of the mechanical behaviour of rose hip seeds subjected to compression and creep tests, as well as the identification of natural groups of mechanical response using unsupervised machine learning techniques. Mechanical features extracted from the force–displacement curves were analysed using Principal Component Analysis (PCA) and the K-means clustering algorithm in order to reveal distinct patterns of mechanical behaviour. The proposed approach enables an objective characterization of the mechanical response of the seeds and provides relevant insights into the mechanisms of deformation, energy absorption, and structural failure.

MATERIAL AND METHOD



Rose hip seeds (*Rosa canina* L.) used in the experiments were obtained from mature fruits and cleaned prior to testing. The seeds were recovered after separation of the fruit pulp and subsequently dried until hygroscopic equilibrium was reached. Before mechanical testing, they were stored in plastic containers under laboratory conditions at a temperature of 22 ± 2 °C and a relative humidity of approximately 30%.

For the dimensional characterization of the experimental batch, 1,000 seeds were analysed and their thickness distribution was determined. The results revealed an approximately normal distribution, with most seeds exhibiting thickness values between 2.25 and 3.03 mm. The physical characterization of the rose hip seeds also included the determination of the thousand-seed weight (TSW), which was found to be 19.64 g. Together with the dimensional distribution presented in Figure 2a, this parameter indicates a relatively high degree of uniformity of the experimental batch used for the compression and creep tests. Seed dimensions were measured using a digital micrometre (measuring range: 0–25 mm, resolution: 0.001 mm, accuracy: ±0.001 mm; PR China). Seed mass was determined using the precision balance integrated into the PARTNER MAC 110 moisture analyser (RADWAG, Poland), with a maximum capacity of 110 g and a resolution of 1 mg. The same instrument was subsequently used for the thermo-gravimetric determination of seed moisture content. The moisture content of the rose hip seeds was determined thermo-gravimetrically using a PARTNER MAC 110 moisture analyser. The initial sample mass was 0.932 g and the final dry mass was 0.906 g, corresponding to a water loss of 0.026 g. The resulting moisture content was 2.79% on a wet basis, equivalent to 2.87% on a dry basis (Fig. 2b).

A unimodal distribution can be observed, with the highest frequency recorded for a thickness of 2.64 mm, corresponding to 394 seeds (39.4% of the total). An additional 278 seeds (27.8%) exhibited a thickness of approximately 3.03 mm, while 221 seeds (22.1%) had a thickness of approximately 2.25 mm. The results show that more than 89% of the analysed seeds had thickness values ranging from 2.25 to 3.03 mm, indicating a high degree of dimensional uniformity within the experimental batch. The small number of seeds with extreme thickness values, approximately 1.47 mm and 3.42 mm, suggests limited data dispersion and the absence of a significant number of outliers.

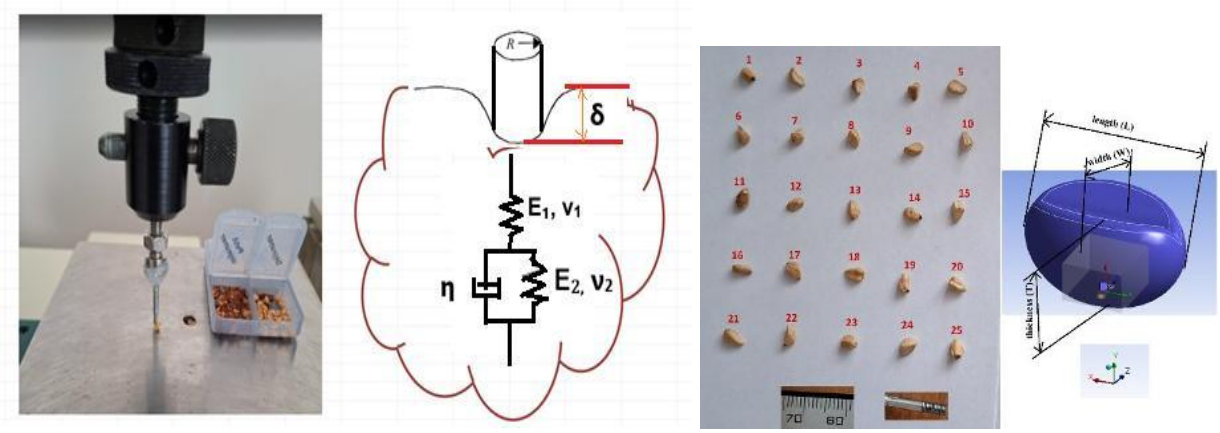
(b) thermo-gravimetric determination of seed moisture content using the PARTNER MAC 110 moisture analyser

Mechanical tests were performed using a Hounsfield 1K universal testing machine, equipped with a load cell appropriate for the investigated force range (0–1000 N) and controlled through QMat 5.50 software. Mechanical compression tests were performed using a Hounsfield 1K universal testing machine (Hounsfield Test Equipment Ltd., UK), equipped with a 1000 N load cell with a force measurement accuracy of 0.01 N and controlled through QMat 5.50 software. A crosshead speed of 15 mm/min was used for all specimens. Since this loading rate is higher than that commonly employed for strictly quasi-static testing of agricultural biological materials, its potential influence on the measured force–deformation response should be considered when interpreting the results. The experiments were carried out using a cylindrical indenter with a radius of 1.4 mm. Compression tests were conducted on 25 seeds randomly selected from the analysed population. Each specimen was tested only once, and the force–deformation data were continuously recorded throughout the loading process.

Stiffness was determined by calculating the slope of the linear portion of the force–deformation curve, while the fracture energy was calculated as the area under the curve up to the failure point. Similar mechanical evaluation procedures based on force–deformation curves have been reported for small fruits and other biological materials. (*Gageanu et al., 2021, Gˆ kduman, 2026*).

Compression tests were performed at a crosshead speed of 15 mm/min. For each of the 25 compression tests, representative mechanical features were extracted from the force–displacement curve, including maximum compression force, displacement at maximum force, deformation energy, initial stiffness, mean force, RMS force, fracture index, and number of force peaks (*Stryjecka et al., 2024*). These variables were standardized using z-score normalization and subsequently analysed using Principal Component Analysis (PCA) and K-means clustering.



Creep tests were carried out by applying a constant load of 25 N for a period of 600 s. The evolution of deformation over time was continuously monitored, allowing the viscoelastic behaviour of the rose hip seeds to be evaluated. Data obtained from the creep tests were not included in the PCA or K-means analysis.

For the description of the creep behaviour of rose hip seeds, the Zener Standard Linear Solid (SLS) viscoelastic model, shown in Fig. 3, was employed. This model consists of an elastic element with modulus E_1, connected in series with a Kelvin–Voigt element composed of an elastic spring with modulus E_2 and a viscous dashpot characterized by the viscosity coefficient η. The Zener model is widely used to describe the viscoelastic behaviour of biological materials because it simultaneously represents the instantaneous elastic response and the time-dependent deformation. Within the model, the parameter E_1 characterizes the instantaneous elastic stiffness of the material, E_2 describes the delayed elastic component associated with relaxation and creep phenomena, while η represents the internal viscous resistance to deformation.

Data Analysis and Machine Learning.

Representative mechanical features were extracted from the force–displacement curves, including the maximum compression force, displacement at maximum force, deformation energy, initial stiffness, and the viscoelastic parameters determined using the Zener model (Fig. 3b).

To identify natural groups of mechanical behaviour, an unsupervised machine learning approach was employed. Dimensionality reduction of the dataset was performed using Principal Component Analysis (PCA), while sample clustering was carried out using the K-means algorithm. Figures 3c present the 25 seeds used for compression testing. The principal geometrical dimensions of the rose hip seed are defined in Figure 3d as length (L), width (W), and thickness (T). In the present experimental campaign, thickness was the dimension systematically measured and used for the dimensional characterization of the seed batch.

a) *b)* *c)* *d)*

Fig. 3 – Experimental system used for the mechanical characterization of rose hip seeds

(a) force sensor of the Hounsfield 1K universal testing machine employed for compression tests; (b) Standard Linear Solid (SLS) viscoelastic model, also known as the Zener model, used to describe the viscoelastic behaviour of the seeds; (c) rose hip seeds used in the compression tests (n = 25); (d) schematic representation of the principal seed dimensions: length (L), width (W), and thickness (T)

Before applying Principal Component Analysis (PCA), all mechanical features were standardized using the z-score normalization method in order to eliminate the influence of differences in scale among the variables. The normalization was performed according to the following equation:

$$z_{ij} = \frac{x_{ij} - \mu_j}{\sigma_j} \quad (1)$$

where x_{ij} is the original value of the variable, μ_j is the mean value of the variable, and σ_j is its standard deviation. The quality of the obtained clusters was evaluated using the silhouette index, calculated according to the following equation:

$$s(i) = \frac{b(i)-a(i)}{max[a(i),b(i)]} \quad (2)$$

where $a(i)$ represents the average distance between sample i and all other samples within the same cluster, while $b(i)$ represents the smallest average distance between sample i and the samples belonging to a different cluster.

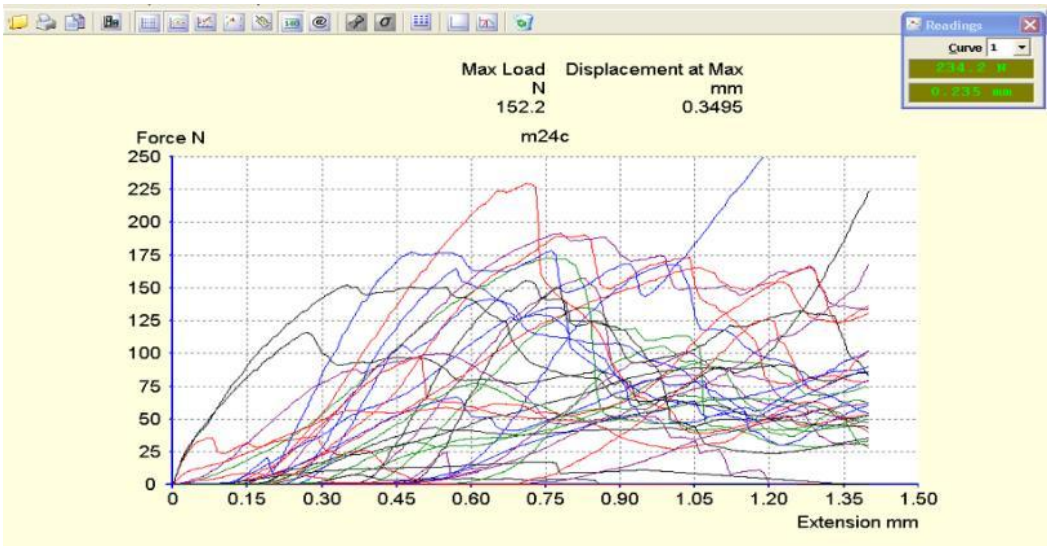
The silhouette index ranges from −1 to 1. Values close to 1 indicate very good cluster separation, values close to 0 suggest overlap between clusters, whereas negative values indicate a possible misclassification of samples. In the present study, silhouette analysis was used to determine the optimal number of clusters and to evaluate the performance of the K-means algorithm.

RESULTS

The mechanical properties of rose hip seeds are essential for evaluating their behaviour during grinding processes and for optimizing powder production technologies. Similar mechanical assessments focused on compression, fracture, and fragmentation processes have also been reported for various medicinal and aromatic plants. In these studies, parameters such as maximum compression force, deformation energy, and stiffness have been identified as important indicators for the design and optimization of grinding and mechanical processing equipment for plant materials (*Yilmaz and Gökduman, 2015; Stan et al., 2014*).

Figure 4 shows the force–displacement curves obtained from compression tests performed on individual rose hip seeds. During the compression tests, the load was applied in the vertical direction, along the Y-axis, as illustrated in Figure 3d. The same loading configuration was maintained for all tested seeds.

A significant variability in the mechanical response can be observed, as evidenced by differences in the maximum force, displacement at failure, and overall curve shape. Some specimens exhibit a progressive increase in force followed by a sudden drop, associated with the fracture of the internal structure, whereas others display a more deformable behaviour characterized by gradual force increases and multiple successive fracture events. In some cases, the maximum force values exceed 200 N, indicating substantial differences in mechanical strength among the analysed seeds.



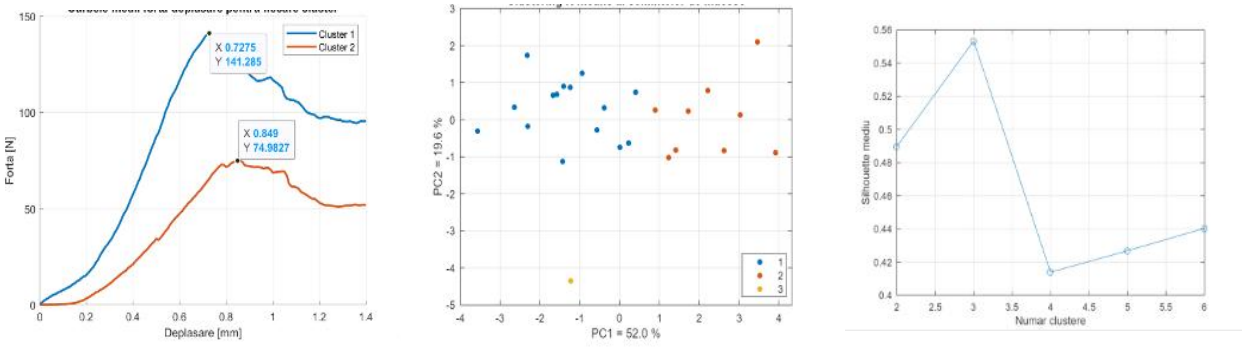


Fig. 4 – Force–displacement curves of rose hip seeds obtained from compression tests

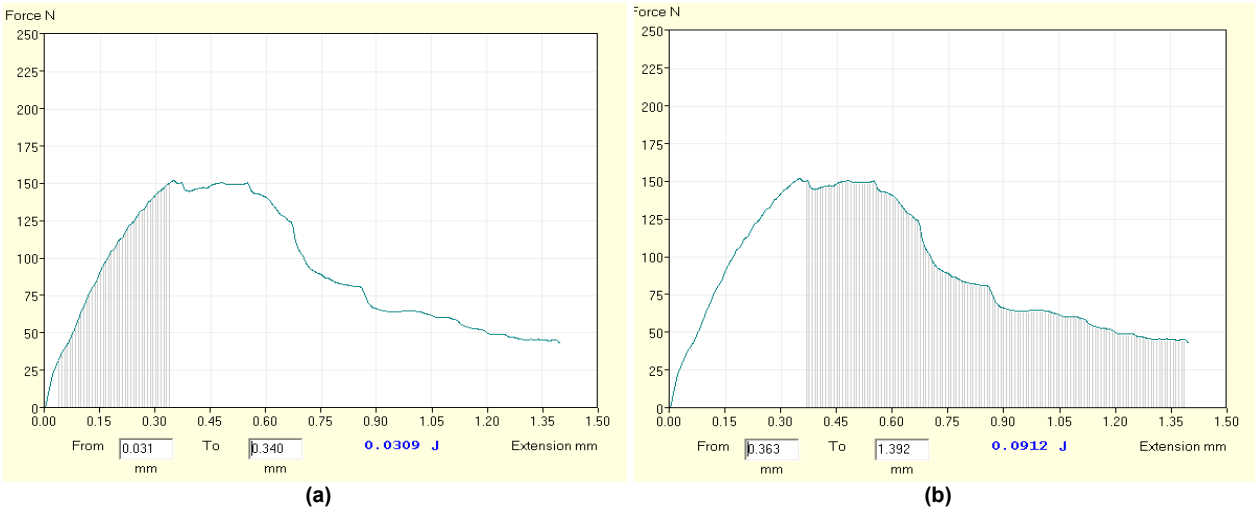
In the absence of predefined classes, the force–displacement curves were analysed using unsupervised machine learning techniques to identify natural groups of mechanical behaviour among the rose hip seeds. Representative mechanical features were extracted from each force–displacement curve, including maximum force, displacement at maximum force, deformation energy, initial stiffness, mean force, RMS value, fracture index, and number of peaks. The data were standardized and analysed using Principal Component Analysis (PCA), while sample clustering was performed using the K-means algorithm.

Cluster analysis revealed the existence of two main categories of mechanical behaviour, shown in Fig. 5. Cluster analysis revealed two principal categories of compression behaviour. Cluster 1 was characterized by higher maximum force and deformation energy, indicating greater mechanical resistance. Cluster 2 exhibited lower maximum force and energy values and greater deformability, corresponding to a mechanically less resistant response.



a) b) c)

Fig. 5 - Identification of the mechanical behaviour of rose hip seeds using unsupervised machine learning techniques

(a) mean force–displacement curves of the resulting clusters; (b) projection of samples in the PCA space (PC1–PC2); (c) evaluation of the optimal number of clusters using the silhouette index

The distribution of samples in the PCA space confirms the separation between the two groups. Furthermore, silhouette analysis indicates that the three-cluster solution provides the best mathematical separation of the data. However, one of the clusters is represented by a very small number of observations and can therefore be interpreted as an outlier group. Consequently, from a physical and mechanical perspective, the behaviour of the seeds can be adequately described by two principal categories of compression response. In Fig. 5b, Cluster 3 consists of a single point (or only a very small number of points). This indicates that the algorithm identifies this sample as a separate group because its mechanical characteristics differ substantially from those of the remaining data. Figure 5c shows the variation of the silhouette index as a function of the number of clusters.

Figure 6 presents a representative force–displacement curve obtained during the compression of a rose hip seed belonging to Cluster 1 (mechanically rigid/high-strength seeds). An initial increase in force can be observed up to approximately 150 N, followed by a resistance plateau associated with the redistribution of internal stresses. At a displacement of approximately 0.7 mm, a sudden drop in force occurs, indicating the primary fracture of the seed structure. Following this event, the mechanical response is characterized by a gradual decrease in force, which is typical of the progressive fragmentation and compaction of the resulting material.

(a) (b)

Fig. 6 - Representative force–displacement curve of a Cluster 1 seed (mechanically rigid/high-strength seeds)

(a) energy absorbed within the viscoelastic region and up to the yield point (E = 0.0309 J); (b) energy absorbed after exceeding the yield point and until the end of the compression process (E = 0.0912 J)

The energy value of 0.0309 J, determined between the point corresponding to the elastic limit at a displacement of 0.031 mm and the yield point at a displacement of 0.340 mm (Fig. 6a), highlights the ability of the seed to absorb mechanical energy before the onset of irreversible deformation. This value reflects the resistance of the internal structure to compression and suggests a relatively rigid mechanical behaviour, characterized by an initial stage of controlled deformation prior to the initiation of cracking or structural failure processes. Figure 6b presents the mechanical energy absorbed by the seed within the deformation range from 0.363 mm to 1.392 mm, determined by integrating the force–displacement curve. The obtained value, 0.0912 J, reflects the seed's capacity to absorb energy after reaching the yield point, including the processes of cracking, fracture, and progressive compaction of the resulting fragments. The energy absorbed during this stage is approximately three times greater than that accumulated within the viscoelastic region, highlighting a significant capacity for energy dissipation under compressive loading.

A comparative analysis of the two energy intervals shows that approximately 75% of the total absorbed energy is dissipated after the onset of irreversible deformation. This result suggests a progressive failure mechanism of the seed structure, characterized by the successive development of cracks and the gradual fragmentation of the material, rather than by a sudden and instantaneous fracture.

Figure 7 highlights the creep behaviour of rose hip seeds subjected to a constant load of 25 N for a duration of 600 s. The final creep deformation values were 0.018 mm, 0.027 mm, and 0.067 mm for the three analysed specimens, confirming the existence of significant variability in the viscoelastic response within the experimental batch. It can be observed that, although all specimens were tested under identical conditions, the deformation recorded after 600 s differed considerably, which may be attributed to structural and geometrical differences among the seeds. The observed behaviour confirms the viscoelastic nature of the biological material and its ability to develop progressive deformation under constant loading. Furthermore, the relatively low creep displacement values indicate good structural stiffness and high resistance to permanent deformation. The obtained results suggest that rose hip seeds are capable of withstanding long-term mechanical loading with limited deformation, an important aspect for handling, transportation, storage, and mechanical processing operations.

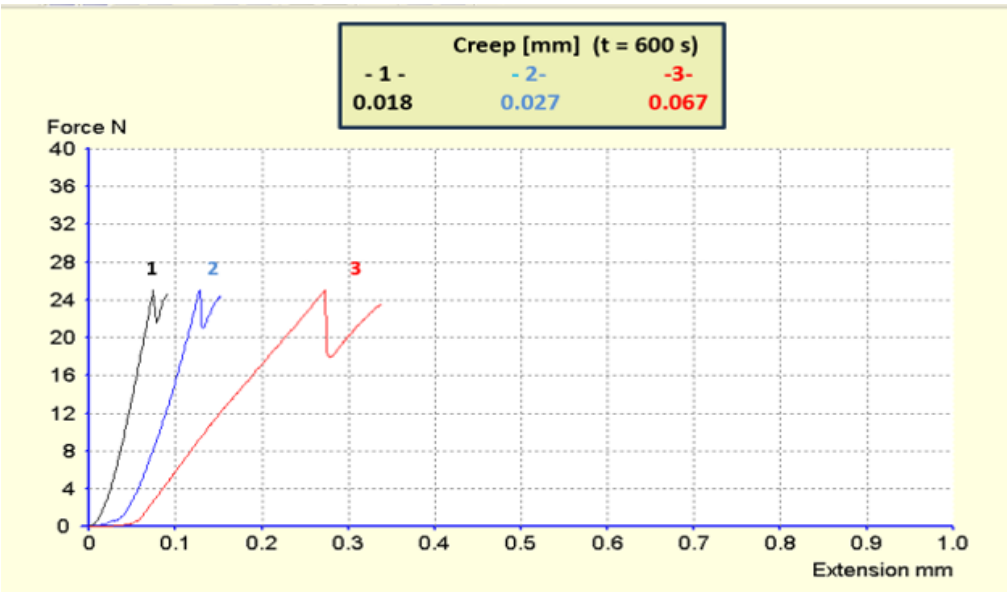


Fig. 7 – Creep behaviour of rose hip seeds under a constant load of 25 N for 600 s

Figure 8 presents the evolution of the applied force during the creep test for the three rose hip seed specimens. After reaching the maximum load of approximately 25 N, all specimens exhibited an initial decrease in the measured force, followed by a gradual increase throughout the 600 s creep period. The force increased from values ranging between 18–21.5 N to approximately 24–25 N at the end of the test. This behaviour suggests the occurrence of compaction and structural reorganization processes within the rose hip seeds, leading to a progressive increase in resistance to deformation under sustained loading. The observed response indicates that, following the initial accommodation phase, the internal structure becomes increasingly resistant to further deformation, resulting in the gradual recovery of the measured force toward the imposed load level.

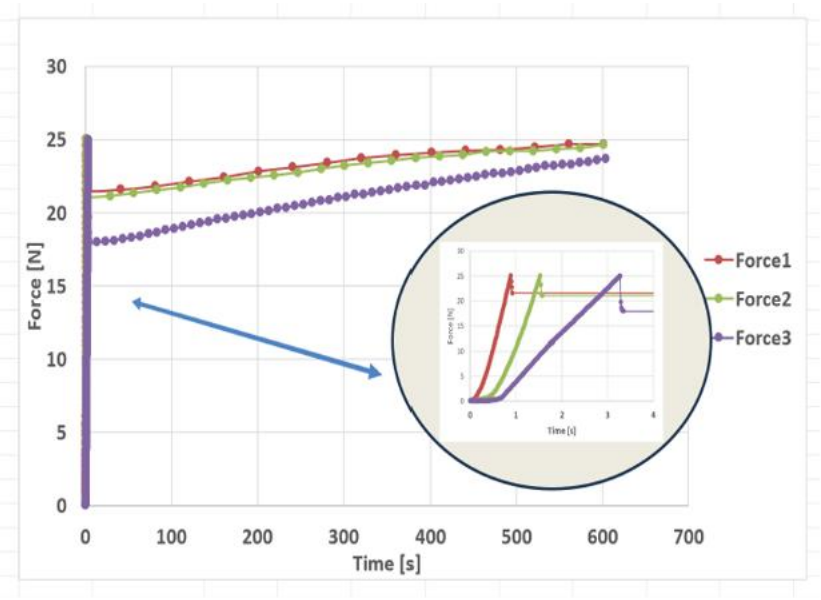

Fig. 8 – Variation of force with time during creep testing of rose hip seeds, showing the initial force decrease followed by a gradual recovery toward the imposed load of 25 N

From an experimental perspective, an interesting finding is that the force does not relax over time but instead tends to recover toward the initial value of 25 N, indicating a behaviour different from that of many conventional polymeric materials and characteristic of compact granular plant structures. After the initial compaction and local structural failure, the material does not continue to soften but rather exhibits a progressive increase in resistance to compression. This behaviour may be associated with material densification, a reduction in internal porosity, an increase in the contact surfaces between particles, and a redistribution of stresses within the seed structure. From the standpoint of granular material mechanics, the observed response resembles a strain-hardening phenomenon induced by compaction.

The force distribution over time confirms that all specimens were tested under similar loading conditions. Therefore, the differences subsequently observed in creep deformation can be attributed primarily to the specific viscoelastic properties of each seed rather than to variations in the applied load.

Figure 9 presents the variation of deformation as a function of time for the three rose hip seed specimens subjected to a constant load of 25 N for 600 s. A progressive increase in deformation can be observed for all specimens, which is characteristic of the creep behaviour of viscoelastic materials. During the initial stage of the test, an instantaneous deformation occurs, associated with the elastic component of the mechanical response, followed by a slow and continuous increase in deformation throughout the entire loading period.

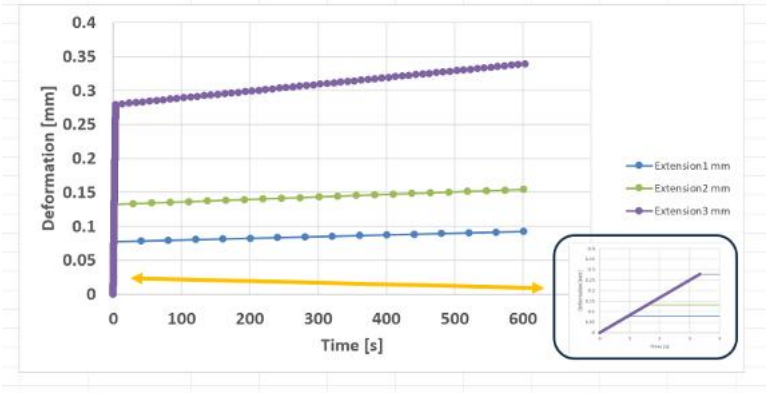

Fig. 9 - Time-dependent deformation (creep) of rose hip seeds under a constant compressive load of 25 N

Specimen 3 exhibited the highest deformation, increasing from approximately 0.28 mm to 0.34 mm after 600 s, indicating a greater susceptibility to time-dependent deformation. Specimen 2 displayed an intermediate behaviour, with deformation values ranging from approximately 0.14 mm to 0.16 mm, whereas Specimen 1

showed the lowest displacement values, approximately 0.08–0.09 mm. The differences observed among the three curves highlight the variability of the viscoelastic properties of the analysed seeds and suggest the existence of internal structural differences that influence their deformation capacity under long-term mechanical loading. Nevertheless, the relatively low slopes of the creep curves indicate good dimensional stability and high resistance to permanent deformation.

For the description of the creep behaviour of rose hip seeds, the Zener Standard Linear Solid (SLS) viscoelastic model was employed. The viscoelastic model parameters E_1, E_2, and η can be determined from the experimental creep data using the values of the initial deformation, final deformation, and deformation at an arbitrary time t. Thus, the instantaneous elastic modulus E_1 can be determined using the following relationship:

$$E_1 = \frac{3P0}{8R} \cdot \frac{1}{\delta(0)} \quad (3)$$

where $\delta(0)$ represents the initial penetration depth, or the instantaneous deformation, occurring immediately after the application of the constant load P_0.

The modulus E_2, associated with the delayed elastic component, can be determined using the following relationship:

$$E_2 = \frac{3P0}{8R} \cdot \frac{1}{\delta(\infty)-\delta(0)} \quad (4)$$

where $\delta(\infty)$ represents the asymptotic deformation reached at a very long time, corresponding to the equilibrium state of the creep process under the applied constant load.

The dynamic viscosity coefficient η can be calculated using the following relationship:

$$\eta = \frac{P0 \cdot t}{8R} \cdot \frac{1}{[\delta(\infty)-\delta(0)] \cdot \ln[\frac{\delta(\infty)-\delta(0)}{\delta(\infty)-\delta(t)}]} \quad (5)$$

Considering the applied load P_0 and the indenter radius R = 1.4 mm, the instantaneous elastic modulus E_1 and the delayed elastic modulus E_2 were determined using Eqs. (3) and (4). The viscosity coefficient η was calculated using Eq. (5) for a creep time of t = 300 s. The obtained values are summarized in Table 1.

Table 1

Experimental creep parameters and viscoelastic parameters determined using the Zener model for rose hip seeds

Sample	$P0$ [N]	$\delta(0)$ [mm]	$\delta(600)$ [mm]	E_1 [GPa]	E_2 [GPa]	η [GPa·s]
1	21.57	0.074	0.092	0.078	0.321	46.308
2	21.05	0.128	0.155	0.044	0.209	30.128
3	18.03	0.281	0.34	0.018	0.072	10.399

The results reveal a progressive decrease in the elastic moduli E_1 and E_2 from Specimen 1 to Specimen 3, indicating a reduction in structural stiffness and an increase in material deformability. Similarly, the viscosity coefficient η exhibits decreasing values, suggesting a lower resistance to time-dependent deformation. Specimen 1 displays the most rigid viscoelastic behaviour, whereas Specimen 3 is characterized by the greatest susceptibility to creep and progressive deformation under constant loading.

The literature indicates that cereal grains exhibit time-dependent and viscoelastic mechanical behaviour, although at low loads and short loading times the elastic response may become predominant and the load–deformation relationship remains approximately linear (*Mohsenin, 1966; Shelef and Mohsenin, 1967*). Similarly, the rose hip seeds investigated in the present study exhibited a time-dependent response under constant loading; however, the 600 s creep tests enabled the progressive deformation and associated viscoelastic behaviour to be clearly identified.

For biological materials considered nearly incompressible, the evolution of the penetration depth (deformation) over time can be expressed by the following relationship (*Cheng et al., 2000*):

$$\delta(t) = \frac{3P0}{8RE1}[-(\frac{E1}{E2})\, e^{-(\frac{E2}{3\eta})t} + (1+\frac{E1}{E2})] \quad (6)$$

Following the approach used by *Shelef and Mohsenin (1967)* for cereal grains, the influence of Poisson's ratio may be expressed through the correction factor $k = 1 / (1 - \nu^2)$, with $1 < k < 1.33$.

This range corresponds mathematically to $0 < \nu < 0.49$. Since Poisson's ratio was not independently determined for the rose hip seeds investigated in the present study, the calculated elastic parameters should be regarded as apparent, model-dependent values rather than intrinsic material constants.

The relatively limited number of compression specimens (n = 25) should be considered when interpreting the PCA/K-means results, which are therefore regarded as exploratory evidence of natural patterns within the investigated batch rather than as a definitive population-level classification. Regarding the creep experiments (n = 3), despite the limited number of specimens, a relatively consistent time-dependent response was observed under identical loading conditions, with the differences being mainly associated with seed dimensions. Considering this consistency and the relatively long duration of each individual test (600 s), the three experiments were considered adequate for a descriptive assessment of the creep phenomenon within the scope of the present study, without claiming statistical representativeness for the entire rose hip seed population.

A limitation of the present study is the crosshead speed of 15 mm/min used during compression testing, which is higher than the loading rates commonly employed for strictly quasi-static testing of agricultural biological materials. Therefore, a possible influence of the loading rate on the measured force–deformation response cannot be excluded. Future studies should investigate lower loading rates and systematically evaluate their effects on maximum compression force, stiffness, deformation energy, and fracture behaviour.

CONCLUSIONS

The exploratory application of unsupervised machine learning techniques (PCA and K-means) to the mechanical features extracted from the compression tests enabled the identification of natural groups of mechanical behaviour. The results revealed two main categories within the investigated seed batch: one group characterized by high mechanical strength and stiffness, and a second group exhibiting greater deformability and lower resistance to compression.

The Zener (SLS) viscoelastic model made it possible to determine the parameters E_1, E_2, and η, revealing differences in the time-dependent mechanical response of the tested specimens. The progressive decrease in the elastic moduli and viscosity coefficient was associated with increased deformability and reduced resistance to creep.

The proposed methodology, combining conventional mechanical testing with modern data analysis and unsupervised machine learning techniques, provides a useful approach for investigating the mechanical behaviour of rose hip seeds and may be extended to other biological materials used in the food and pharmaceutical industries.

ABSTRACT

Efficient classification of tobacco coated seeds is critical for seed quality assurance in the tobacco industry, yet the nearly identical appearance of coated seeds renders manual sorting labor-intensive and unreliable. Existing automated solutions either lack the precision required for distinguishing sub-millimeter size differences or are too computationally demanding for deployment on edge devices in seed processing facilities. To bridge this gap, this study proposes a lightweight classification model, EMC-YOLO, based on an improved YOLOv10n. This model optimizes YOLOv10n in three aspects: first, replacing the original backbone network with EfficientViT, balancing low computational requirements and global feature extraction capabilities; second, introducing an improved multi-scale spatial pyramid attention (MSPA) into the neck network, utilizing parallel dilated convolution to optimize feature fusion; third, employing the CARAFE operator for upsampling to enhance the edge restoration effect of small targets. Experiments show that the precision, recall, and mAP@0.5 of EMC-YOLO reach 95.12%, 91.20%, and 93.01%, respectively, representing improvements of 2.12, 1.20, and 1.01 percentage points over the original model. Simultaneously, the model reduces the number of parameters by 71%, computational load by 75%, and weight volume by 68.1%. This model achieves high-performance detection with low resource consumption, providing a technical reference for automated seed quality inspection. Validation on a designed seed detection platform under simulated production conditions yielded a coating qualification rate of 95.50%, meeting the 95% industrial benchmark, and confirming the practical feasibility of the proposed method for automated quality inspection in tobacco seed processing lines.

摘要

烟草包衣种子的精准分级对保障种子质量至关重要，然而包衣种子外观高度相似，人工分选劳动密集且易出错。现有自动化方案或精度不足以区分亚毫米级尺寸差异，或计算量过大难以部署于种子加工场景中的资源受限边缘设备。为此，本研究提出一种基于改进 YOLOv10n 的轻量级分类模型 EMC-YOLO。该模型通过三方面优化 YOLOv10n：第一，使用 EfficientViT 替换原主干网络，兼顾低计算量与全局特征提取能力；第二，在颈部网络引入改进的多尺度空间金字塔注意力（MSPA），利用并行空洞卷积优化特征融合；第三，采用 CARAFE 算子进行上采样，提升小目标的边缘恢复效果。实验显示，EMC-YOLO 的精确率、召回率及 mAP@0.5 分别达到 95.12%、91.20%和 93.01%，较原模型提升了 2.12、1.20 和 1.01 个百分点。同时，模型参数量减少 71%，计算量降低 75%，权重体积缩小 68.1%。该模型能在低资源消耗下实现高性能检测，为种子自动化质量检测提供了技术参考。在设计的种子检测平台上进行模拟生产条件下的验证，包衣合格率达 95.50%，超过 95%的行业基准，验证了所提方法在烟草种子自动化质量检测中的实际可行性。

INTRODUCTION

As a major economic crop in China, flue-cured tobacco leads global production in both scale and yield (*Han, 2025*). Seed coating improves seed quality and yield, driving growth in the tobacco industry (*Javed et al., 2022*). However, coated seeds share nearly identical shapes, sizes, and colors, making visual classification difficult (*Zinsmeister et al., 2020*). Manual sorting is slow, labor-intensive, and error-prone, creating a significant bottleneck in seed processing workflows. Given that China produces over 2 million tons of flue-cured tobacco annually, even a modest improvement in seed sorting efficiency can yield substantial economic benefits across

the industry. Thus, there is an urgent demand for efficient, automated sorting and quality control technologies deployable in tobacco seed processing lines.

Traditional image processing uses phenotypic features like size and shape (*Ozaktan et al., 2024*), but 2D visual data cannot capture internal properties, resulting in low accuracy. Other methods, such as chemical analysis or electronic noses (*Fu Jie, 2024*), require complex conditions and damage the samples. For small seeds, these traditional approaches often fail to extract enough features to distinguish subtle differences (*Reena S. et al., 2025*).

Deep learning has transformed image recognition by automatically capturing complex features through neural networks (*Yinglong Li, 2022*). This technology enables precise recognition in agriculture (*Feng Y. et al., 2023*) and handles large datasets effectively (*Wang D. et al., 2022*). Recent studies have optimized networks for small-target detection in agricultural contexts. For example, *Ye et al. (2022),* integrated additional micro-scale detection heads into YOLOv5 for densely-planted Chinese fir seedling identification, improving detection recall for small, overlapping targets but increasing model complexity. *Li J. et al., (2022),* developed Pineapple-Aerial-YOLO with a dedicated small-scale target enhancement framework, achieving improved localization at the expense of higher computational overhead. *Wu et al., (2023),* modified the YOLOv4 architecture with Res2block and depthwise separable convolutions for weed detection, reducing the parameter count of the originally heavy backbone while maintaining competitive detection accuracy.

Despite these advances, recognizing coated tobacco seeds remains challenging. Their sub-millimeter size variations and nearly identical surface morphology demand high detection precision, which typically requires deeper architectures with substantial parameter counts. Conversely, lightweight models designed for edge deployment in seed processing facilities often sacrifice fine-grained discrimination capability (*Li C. et al., 2021; Hamid et al., 2022*). To bridge this gap between detection accuracy and model efficiency, EMC-YOLO, an improved YOLOv10n model, is proposed. It replaces the backbone with EfficientViT, substantially reducing parameters while preserving global feature extraction; introduces a C2f_MSFA mechanism with parallel dilated convolution for adaptive multi-scale feature fusion; and employs CARAFE upsampling for content-aware edge recovery—thereby achieving high detection accuracy with substantially reduced computational requirements. This work contributes to the application of machine-vision-based detection methods in agricultural seed quality inspection, an increasingly important direction in agricultural engineering.

MATERIALS AND METHODS

Establishment of the dataset

Dataset

The dataset of coated tobacco seeds used in this study was independently collected and constructed. The seeds were provided and coated by the Sanming Branch of the Fujian Tobacco Agricultural Science Research Institute, while image acquisition was conducted in the laboratory of Fujian Agriculture and Forestry University. The acquisition equipment consisted of a Hikvision 20-megapixel MV-SC200 industrial camera and a 25-megapixel MVL-KF1224M industrial lens. The images were captured at a resolution of 5472 × 3648 pixels and saved in JPG format. To minimize background interference, black light-absorbing velvet was laid on the workbench. The coated seeds were scattered across the shooting area to simulate their natural distribution after output from a coating machine, ensuring each seed could be effectively captured. The image acquisition setup, consisting of the industrial camera, lens, black velvet-covered sample stage, and LED light source, is shown in Fig. 1

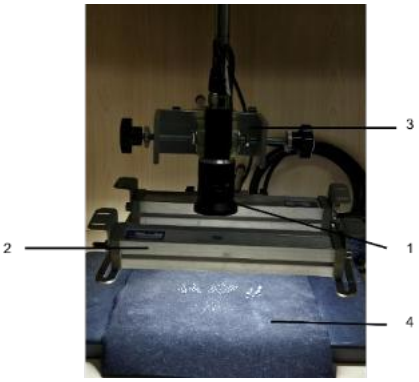

Fig. 1 – Image acquisition setup for coated tobacco seeds

1. industrial camera; 2. LED light source; 3. bracket; 4. black light-absorbing velvet

All collected images were manually annotated using the AnyLabeling tool. By drawing bounding boxes to precisely locate every coated seed, a dataset suitable for object detection tasks was constructed. Each seed instance is accompanied by bounding box annotation information to support deep learning model training. According to the national standard for tobacco seeds (GB/T 21138-2019, 2019), the coated seeds were categorized into four classes: qualified seeds (1.6mm–1.8mm), undersized seeds (< 1.6mm), oversized seeds (> 1.8mm), and damaged seeds (insufficient coating coverage with the seed clearly exposed). Considering that a single test batch contains 100 coated seeds, the number of seeds per image was controlled to under 200. All images were taken under indoor lighting supplemented by LED tubes, and a total of 320 original images were manually annotated using boxes tangent to the seed outlines. The types of coated tobacco seed samples are shown in Figure 2.

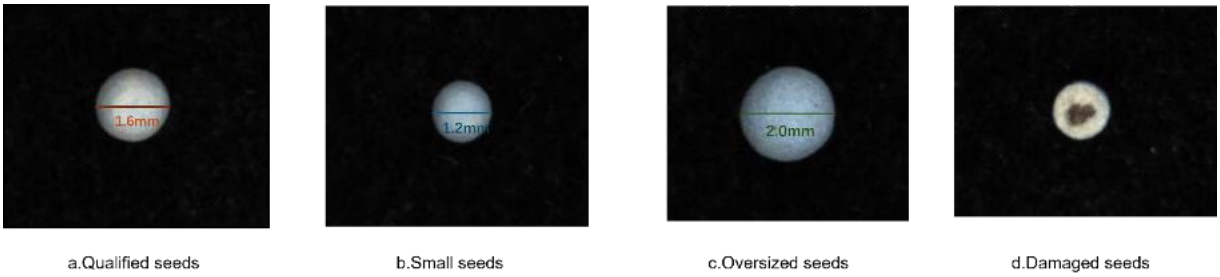

Fig. 2 – Type of coated seeds collected

Data augmentation

To enhance model generalization and environmental adaptability, a multi-dimensional data augmentation scheme was implemented. This approach effectively expands the parameter search space and simulates real-world factory conditions, such as lighting fluctuations, occlusion, and varied target postures. Specifically, the system integrates photometric and geometric transformations, including random rotation, horizontal flipping, brightness adjustments, and random cropping, each with a probability of 0.5.

The dataset was divided into training, validation, and test sets at an 8:1:1 ratio, comprising 1024, 128, and 128 images, respectively. By fusing these augmentation strategies, the spatial and visual diversity of the training data was significantly improved, effectively reducing overfitting and ensuring robust performance across diverse industrial scenarios.

Improvement of the tobacco coating seed detection model of YOLOv10n

To accurately detect small and densely distributed coated tobacco seeds, this study proposes an improved model, EMC-YOLO, based on the YOLOv10n architecture (*Wang et al., 2024*). While maintaining a lightweight design, the model optimizes feature extraction, fusion, and upsampling as shown in Figure 3.

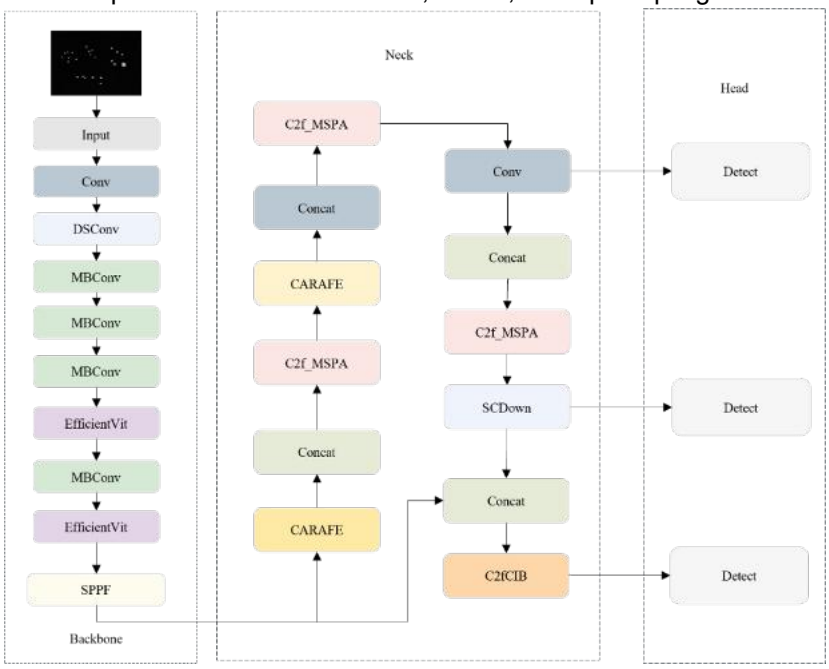

Fig. 3 – The network structure of EMC-YOLO

First, the original backbone is replaced with EfficientViT to enhance global modeling and fine-grained feature capture through grouped attention mechanisms while reducing parameters. Second, a Multi-Scale Spatial Attention (MSFA) module is introduced in the neck, utilizing multi-branch dilated convolutions and channel weighting for dynamic feature selection to better distinguish varying seed sizes. Finally, the CARAFE module replaces traditional upsampling to strengthen edge recovery and small-target detection through content-aware feature reorganization.

Efficient ViT backbone network

Due to the small diameter and subtle surface features of tobacco coated seeds, traditional backbones often lose discriminative textures during deep downsampling. To enhance feature extraction for tiny targets, this study introduces EfficientViT (*Liu X. et al., 2023*) to replace the original backbone, as shown in Fig. 4.

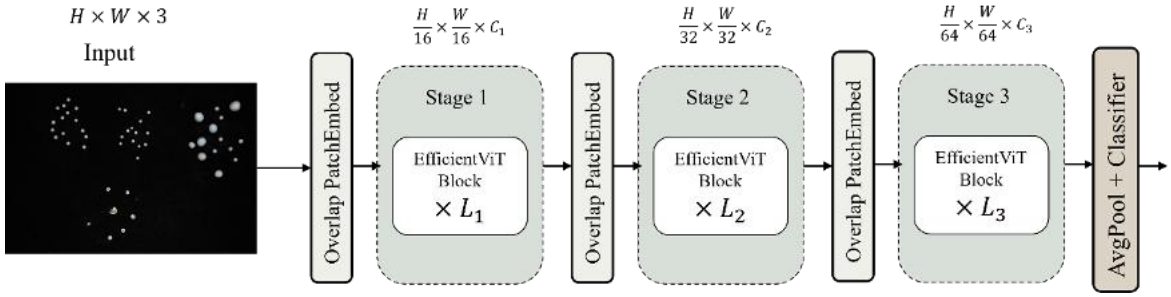

Fig. 4 – The network structure of EfficientViT

The advantage of EfficientViT lies in its core unit, the EfficientViT Block. As illustrated in Fig. 5, this unit features a unique FFN-CGA-FFN sandwich structure. Its operational mechanism utilizes the Cascaded Group Attention (CGA), which splits feature channels and transmits them layer-wise to create specialized attention heads. These heads focus on diverse features such as seed contours, coating integrity, and surface cracks. This hierarchical approach enables the model to accurately extract key semantics from complex reflections or background interference while minimizing computational redundancy.

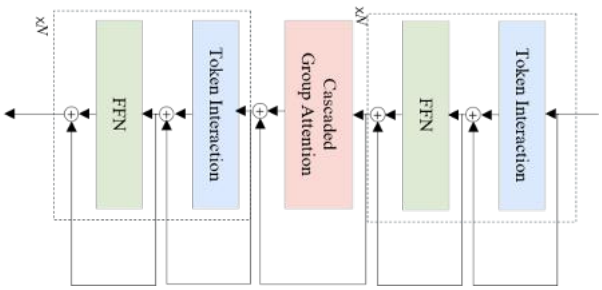

Fig. 5 – The structure of EfficientViT Block

Multi-scale spatial attention mechanism module

To address the continuous scale variation in the grain size of different varieties and batches of tobacco coated seeds, this study, inspired by the Multi-scale Spatial Pyramid Attention (MSPA) (*Yang Yu et al., 2024*), designed a Multi-scale Spatial Attention module (MSFA), whose detailed structure is shown in Fig. 6.

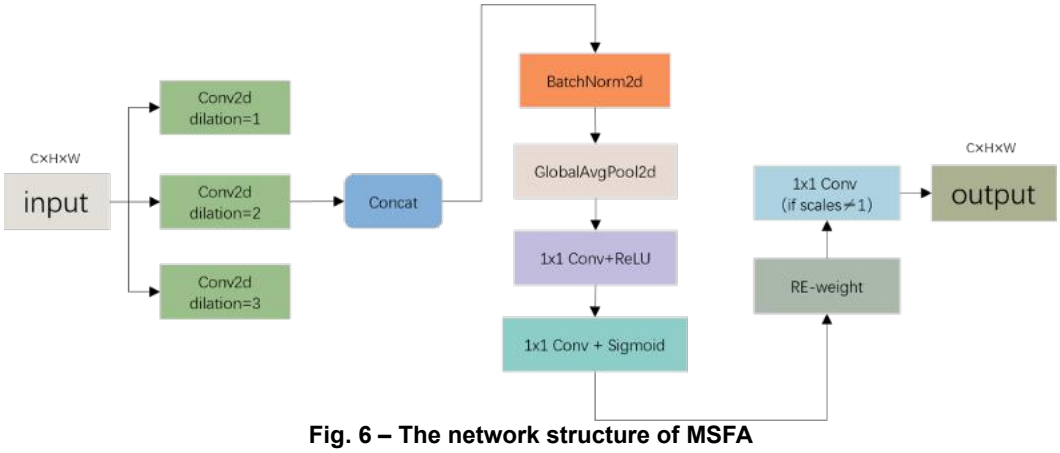

Fig. 6 – The network structure of MSFA

The original C2f module in YOLOv10 relies on fixed receptive fields *(Wang A. et al., 2024)*, which is sensitive to scale changes and lacks adaptive weighting, thus limiting the network to local information. To compensate, MSFA utilizes parallel dilated convolution branches to construct diverse receptive fields. Unlike the original MSPA, this study recalibrated the dilation rates and optimized spatial feature aggregation to suit the dense distribution of seeds. Through a dynamic feature selection mechanism, the module adaptively assigns higher weights to corresponding scale branches based on target size, simultaneously capturing local details and global context.

To further improve feature fusion, MSFA is integrated into the C2f structure to form the C2f_MSFA module (Fig. 7). This integration effectively addresses the limitations of the original C2f in processing scale-sensitive targets and enhances capture sensitivity during the feature fusion stage.

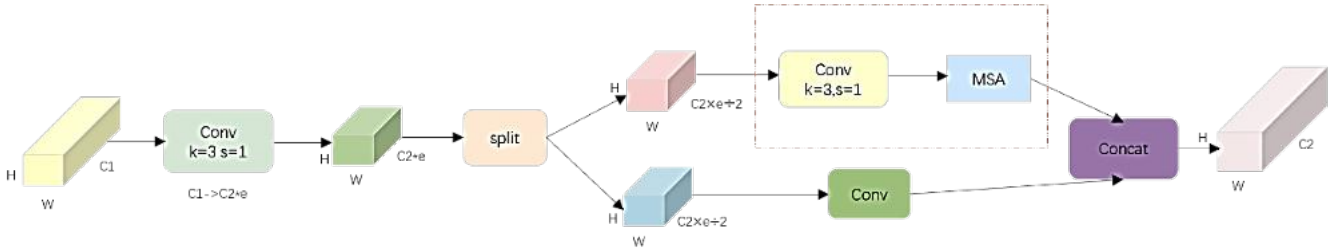

Fig. 7 – The network structure of C2f_MSFA

Sampling operator on CARAFE

In the upsampling stage, the original bilinear interpolation in YOLOv10 often ignores global semantic information (*Wang D. et al., 2022*), leading to blurring and artifacts at seed edges. Consequently, this study adopts the CARAFE content-aware upsampling module (*Wang J. et al., 2019*), with its structure shown in Fig. 8.

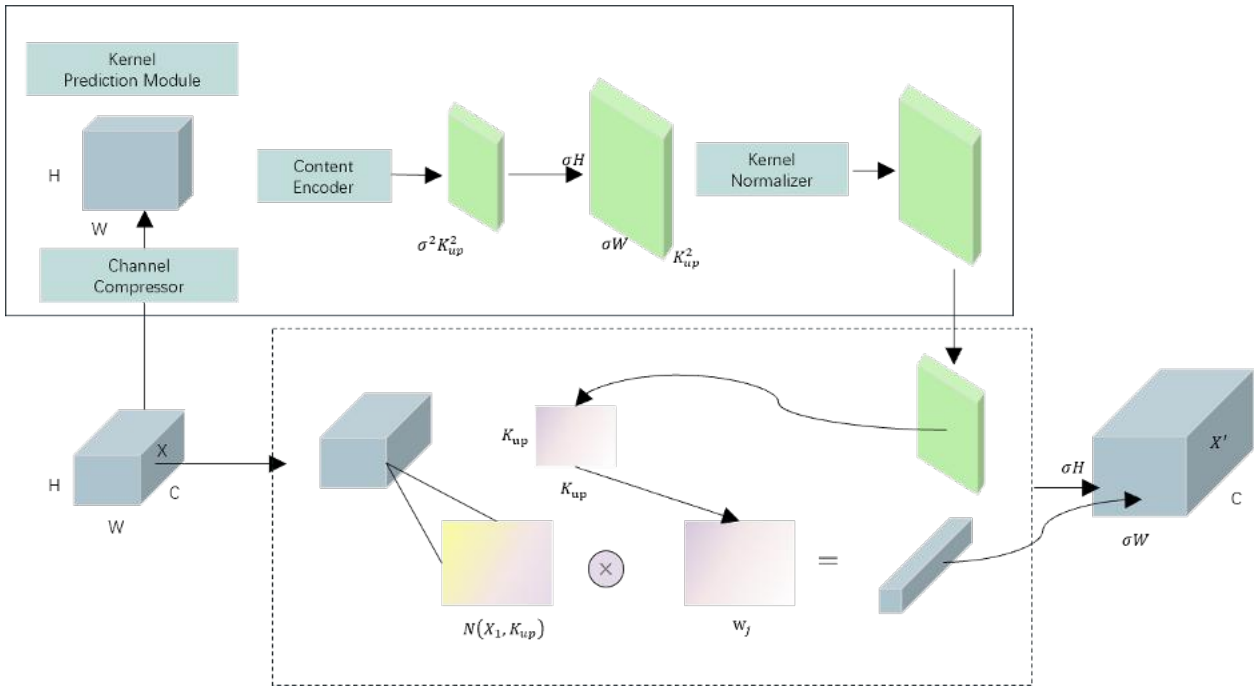

Fig. 8 – The network structure of CARAFE

Unlike traditional operators, CARAFE possesses content-aware capabilities. Its kernel prediction module dynamically generates exclusive kernels for each pixel by analyzing the local context between the seed and its surroundings. Subsequently, the reassembly module uses these adaptive kernels for dynamic feature aggregation. This mechanism allows the model to perceive boundary transitions and perform intelligent enhancement rather than mechanical pixel filling. Experimental results show that CARAFE effectively compensates for traditional interpolation deficiencies, significantly improving the recovery fidelity of tiny target edges and ensuring more precise localization.

RESULTS

Experimental results and analysis

Experimental indicators

To evaluate the performance of the tobacco seed classification model, core metrics such as Precision, Recall, and Mean Average Precision (mAP@0.5) are adopted. Specifically, mAP@0.5 reflects the model's detection stability when the Intersection over Union (IoU) threshold is set to 0.5. Regarding computational efficiency, resource consumption is quantified through the number of Parameters (Params) and Floating Point Operations (FLOPs). To better verify the effectiveness and robustness of the model, this study primarily selects mAP50 as the key evaluation metric.

Comparative experiment

To verify the effectiveness of the proposed EMC-YOLO model, it was compared with several lightweight object detection models, including NanoDet, YOLOv5n, YOLOv8n, and YOLOv10n. The results are summarized in Table 1.

Table1

Contrast test

Model	P/%	R/%	mAP@0.5/%	GFLOPs	Weights/MB
NanoDet	0.85	0.5	0.90	8.3	4.2
YOLOv5n	0.92	0.91	0.91	7.1	5.3
YOLO8n	0.93	0.91	0.92	8.1	6.3
YOLOv10n	0.93	0.90	0.92	63.4	33.5
EMC-YOLO	0.95	0.91	0.93	16.0	10.7

As seen in Table 1, EMC-YOLO outperforms the other lightweight models across all key accuracy metrics. Compared to NanoDet, YOLOv5n, YOLOv8n, and YOLOv10n, it achieves:

- +10.0%, +3.0%, +2.0%, and +2.0% improvement in Precision
- +41.0%, +0.0%, +0.0%, and +1.0% improvement in Recall
- +3.0%, +2.0%, +1.0%, and +1.0% improvement in mAP@0.5

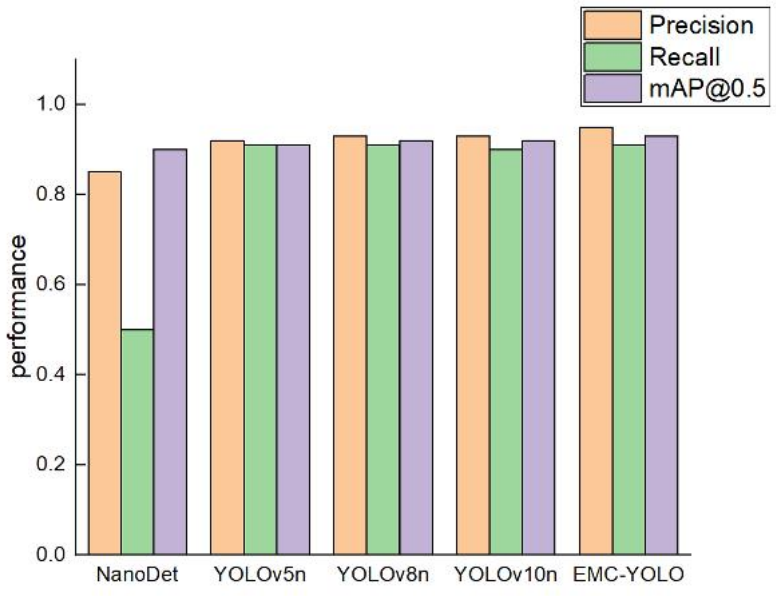

Fig. 9 – Comparison of detection performance of different models

As shown in Fig. 9, EMC-YOLO achieves the highest precision of 0.95 and the highest mAP@0.5 of 0.93 among the five models, which are 2 and 1 percentage points higher than those of YOLOv8n and YOLOv10n, respectively. The recall of EMC-YOLO is 0.91, similar to that of the other lightweight models.

EMC-YOLO achieves an optimal balance between performance and resource efficiency, reducing GFLOPs by 75% and weight size by 68.1% compared to YOLOv10n. These improvements enhance deployment flexibility and operational stability, making the model highly suitable for automated intelligent sorting of coated tobacco seeds.

Visualization of test results

To assess real-world robustness, a visual comparison between YOLOv10n and EMC-YOLO was conducted (Figure 10). The results show that EMC-YOLO provides superior localization with bounding boxes more accurately fitting seed boundaries. Notably, in small-size discrimination, EMC-YOLO correctly distinguished "undersized" from "qualified" seeds, whereas YOLOv10n missed 2 undersized and 4 qualified instances. Furthermore, EMC-YOLO eliminated the misclassification of 5 normal seeds as "oversized" and successfully detected damaged seeds missed by the baseline model. In dense regions, EMC-YOLO maintained high precision without the overlapping or missed detections observed in YOLOv10n. These results confirm that EMC-YOLO is significantly more robust for fine-grained classification, offering improved localization, fewer false positives, and higher recall under complex sorting conditions.

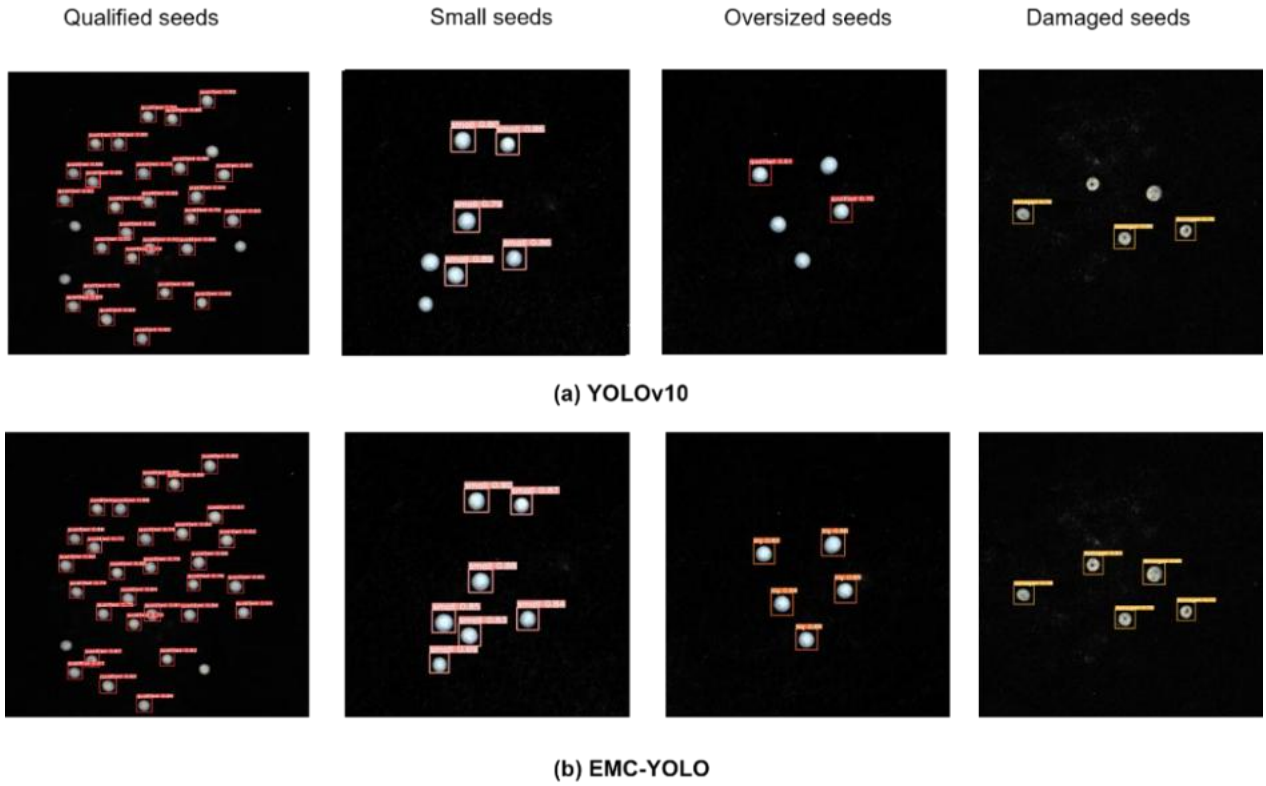

Fig. 10 – Comparison of different algorithm detect results

Ablation experiment

To evaluate the individual contribution of each improvement module, ablation experiments were conducted using YOLOv10n as the baseline. Modules tested include the EfficientViT, C2f_MSFA, and CARAFE mechanisms. All models were trained under identical conditions, and performance was evaluated using Precision (P), mAP@0.5, GFLOPs, and Parameters. The results are presented in Table 2.

The results show that:

- EfficientViT significantly reduced parameters from 16.5M to 4.9M and FLOPs by 75%, providing an efficient lightweight foundation for the model.
- C2f_MSFA improved mAP@0.5 to 0.91, effectively capturing fine-grained seed features through multi-scale modeling and dynamic weight allocation.
- CARAFE enhanced small-target localization and boundary detail recovery, further stabilizing detection performance.
- The final EMC-YOLO model, integrating all three modules, achieved a precision of 95% and mAP@0.5 of 0.93. Compared to the baseline, it achieved a 1% accuracy gain while reducing parameters by 71%, ensuring superior stability for industrial seed screening.

Table2

Ablation experiment

Number	EfficientViT	C2f_MSFA	CARAFE	P/%	R/%	mAP/%	Parameters/M	FLOPs/G	Model size/MB
1	×	×	×	0.93	0.90	0.92	16455016	63.4	33.5
2	√	×	×	0.88	0.58	0.68	4943528	8.9	10.9
3	×	√	×	0.91	0.88	0.91	2911751	9.1	6.2
4	×	×	√	0.90	0.86	0.90	2836080	8.5	6.1
5	×	√	√	0.91	0.88	0.91	3051855	9.3	6.5
6	√	×	√	0.95	0.90	0.92	4445608	14.9	9.9
7	√	√	×	0.94	0.91	0.92	4661380	15.8	10.4
8	√	√	√	0.95	0.91	0.93	4801484	16.0	10.7

Notes: "x" indicates not using this module; "√" indicates the adoption of this module; P is the precision rate; R is the recall rate; mAP is the average precision mean.

Practical application and validation

Design of the seed detection platform

To validate the practical applicability of the proposed EMC-YOLO model in a production-relevant environment, a tobacco coated seed detection platform was constructed in a factory setting, as shown in Fig. 11a. The platform mainly consists of an industrial camera, a camera stand, and a computer. The industrial camera is fixed above the sample stage by the camera stand to capture high-resolution images of the coated seeds, and the captured images are transmitted to the computer for real-time detection and classification using the EMC-YOLO model.

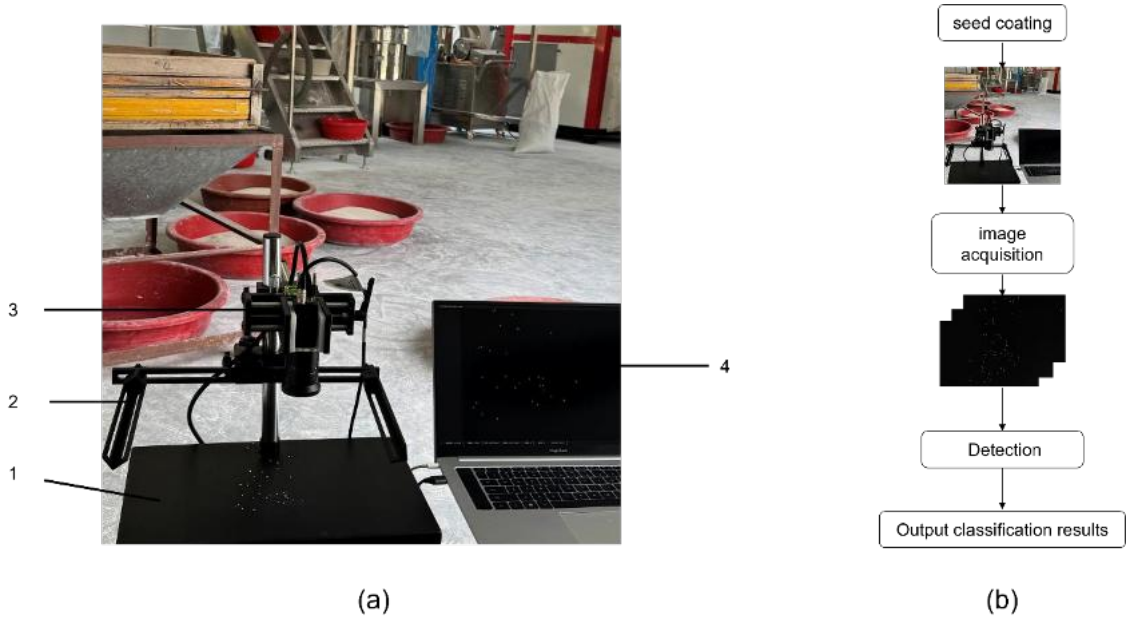

Fig.11 – Detection platform and workflow

a) detection platform: 1. camera bracket; 2. industrial camera; 3. outlet of coating machine; 4. Computer
b) workflow

Platform workflow

After the coating process is completed, the coated seeds are placed on the sample stage, and the industrial camera is triggered to capture images. The acquired high-resolution images are transmitted to the computer through a data interface, where the EMC-YOLO model performs real-time multi-class detection and classification, outputting the count and proportion of seeds in each category. The workflow of the detection process is shown in Fig. 11b. The platform serves as a quality inspection aid for the coating machine, enabling operators to quantitatively assess the performance of the coating process without requiring a physical seed sorting mechanism.

Coating quality validation experiment

To further verify the performance of the proposed model in the experimental device, EMC-YOLO was compared with YOLOv10n, YOLOv8n, and YOLOv5n in terms of detection results. YOLOv5n exhibited more missed detections; although YOLOv10n and YOLOv8n performed well in certain aspects, their detection accuracy was inferior to that of EMC-YOLO. This result further confirms the feasibility and practicability of the EMC-YOLO model in practical applications. The detection comparison is shown in Fig. 12.

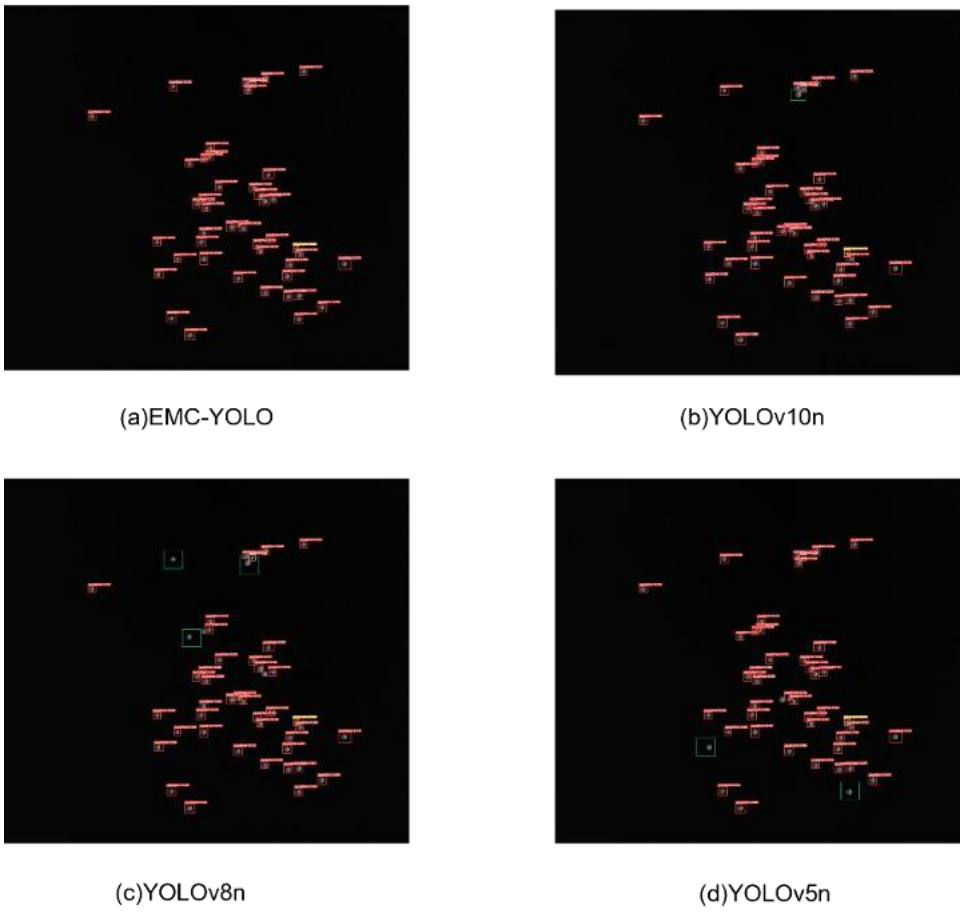

Fig. 12 – Comparison tests of device end models

To evaluate the coating quality of seeds produced by the coating machine, a batch validation experiment was conducted. A total of 200 tobacco coated seeds were directly collected from the coating machine output. The seeds were placed on the sample stage in four batches of approximately 50 seeds each, and each batch was independently imaged and classified by the EMC-YOLO model. The coating qualification rate was calculated as the ratio of qualified seeds (1.6–1.8 mm) to the total number of seeds tested. The classification results of the four batches are summarized in Table 3.

Table3

Coating quality validation

Batch	Total number	Number of qualified seeds	Particle size compliance/%
1	50	48	96.0
2	50	46	92.0
3	50	48	96.0
4	50	49	98.0

As shown in Table 3, a total of 200 tobacco coated seeds were tested in four batches. Among them, 191 seeds were determined to be qualified, with an overall coating qualification rate of 95.50%, reaching the 95% threshold specified by GB/T 21138-2019. The test results also indicated that this model could effectively distinguish between qualified and unqualified seeds. Overall, the designed platform meets the requirements of practical applications and provides a reliable solution for the automatic quality inspection of tobacco coated seeds during the coating process.

CONCLUSIONS

By optimizing the YOLOv10n architecture, this study developed the EMC-YOLO model for the intelligent recognition and classification of coated tobacco seeds. The main conclusions are as follows:

1. The EMC-YOLO model integrates EfficientViT, C2f_MSFA, and CARAFE to deal with the small target size and subtle size differences of coated tobacco seeds. The precision, recall, and mAP@0.5 reached 95.12%, 91.20%, and 93.01%, which are 2.12, 1.20, and 1.01 percentage points higher than those of YOLOv10n. The accuracy for undersized seeds improved by 15%. With only 4.8M parameters and a 10.7 MB weight size, the model is suitable for deployment on edge devices.

2. The three modules worked together to improve the model. EfficientViT reduced the computational cost while keeping the global features. C2f_MSFA improved multi-scale feature fusion through dynamic weighting. CARAFE recovered the edges of small targets. These changes reduced missed detections and false detections under complex conditions, such as reflective surfaces and dense seed distributions.

3. A detection platform was built in a factory to test the model. Compared with YOLOv10n, YOLOv8n, and YOLOv5n, EMC-YOLO showed fewer missed detections and higher accuracy. In the validation experiment, 200 coated seeds were tested in four batches, and 191 seeds were classified as qualified. The coating qualification rate was 95.50%, which meets the national standard. The platform can be used as a quality inspection tool for the coating machine. Future work will focus on deploying the platform in actual seed processing lines and extending it to more coated seed varieties. These efforts are expected to promote the wider application of machine-vision-based detection methods in agricultural seed processing.

ABSTRACT

Aeroponic cultivation has emerged as a promising technology for improving potato minitubers production under controlled conditions. This study evaluated the effects of three cultivation systems (aeroponics, hydroponics, and conventional cultivation) and four potato genotypes (Azaria, Brasovia, Cosiana and Cezarina) on plant growth and minitubers production. Plant height, number of minitubers per plant and minitubers weight per plant were assessed. Analysis of variance reveals a statistically significant effect of the cultivation method on plant height at one month ($p < 0.01$) and a highly significant effect on plant height at two months, as well as on the number and weight of minitubers per plant ($p < 0.001$). The variety has a statistically significant effect on plant height at one month ($p < 0.01$) and a highly significant effect on the other parameters analyzed ($p < 0.001$). The interaction between cultivation method and variety is insignificant for plant height at one month ($p > 0.05$), but becomes highly significant for plant height at two months and for production traits ($p < 0.001$), indicating a differentiated response of the varieties to the conditions specific to each cultivation method. Hydroponic cultivation stimulated early plant growth one month after transplanting, whereas aeroponic cultivation resulted in the greatest plant height two months after transplanting. The aeroponic system also produced the highest number of minitubers (37.26 per plant) and the greatest minitubers weight (357.11 g per plant), significantly exceeding both hydroponic and conventional systems. Among the evaluated genotypes, Cosiana, Brasovia and Azaria showed superior minitubers production compared with control cultivar Cezarina. The results demonstrate the high potential of aeroponic cultivation for efficient potato minitubers production and support the implementation of advanced soilless technologies.

REZUMAT

Cultura aeroponică reprezintă o tehnologie promițătoare pentru îmbunătățirea producției de minituberculi de cartof în condiții controlate. Acest studiu a evaluat efectele a trei sisteme de cultură (aeroponică, hidroponică și cultura convențională) și a patru genotipuri de cartof (Azaria, Brasovia, Cosiana și Cezarina) asupra creșterii plantelor și producției de minituberculi. Au fost evaluate înălțimea plantei, numărul de minituberculi per plantă și greutatea minituberculilor per plantă. Analiza variației evidențiază un efect semnificativ statistic al metodei de cultură asupra înălțimii plantelor la o lună ($p < 0,01$) și un efect foarte semnificativ asupra înălțimii plantelor la două luni, precum și asupra numărului și greutății minituberculilor per plantă ($p < 0,001$). Soiul prezintă un efect semnificativ statistic asupra înălțimii plantelor la o lună ($p < 0,01$) și un efect foarte semnificativ asupra celorlalți parametri analizați ($p < 0,001$). Interacțiunea dintre metoda de cultură și soi este nesemnificativă pentru înălțimea plantelor la o lună ($p > 0,05$), dar devine foarte semnificativă statistică pentru înălțimea plantelor la două luni și pentru caracterele de producție ($p < 0,001$), indicând un răspuns diferențiat al soiurilor la condițiile specifice fiecărei metode de cultură. Cultura hidroponică a stimulat creșterea timpurie a plantei la o lună după transplantare, în timp ce cultura aeroponică a dus la cea mai mare înălțime a plantei la două luni după transplantare. Sistemul aeroponic a produs, de asemenea, cel mai mare număr de minituberculi (37,26 per plantă) și cea mai mare greutate a minituberculilor (357,11 g per plantă), depășind semnificativ atât sistemele hidroponice, cât și cele convenționale. Printre genotipurile evaluate, Cosiana, Brasovia și Azaria au prezentat o producție superioară de minituberculi în comparație cu cultivarul martor, Cezarina. Rezultatele demonstrează potențialul ridicat al culturii aeroponice pentru producția eficientă de minituberculi de cartof și susțin implementarea tehnologiilor avansate de cultivare fără sol în sistemele românești de producție a cartofului de sămânță.

INTRODUCTION

Feeding the expanded global population nutritiously and sustainably will require substantial improvements to the food system. The main challenge will be to produce more food using the same or fewer resources while reducing waste (*Devaux, 2021*). The increasing challenges associated with climate change, water scarcity, soil degradation, and the growing demand for high-quality planting material have stimulated the development of innovative crop production systems (*Tunio et al., 2020*; *Balasundram et al., 2023*; *Deguine, 2023*; *Salma and Kaushal, 2024*). Traditional seed potato production systems are characterized by a low multiplication rate (1:6) and a high risk of disease accumulation (*Sadawarti et al., 2026*). Controlled environment agriculture (CEA), including hydroponic and aeroponic cultivation systems, has gained increasing attention as a promising approach for improving productivity while reducing resource consumption and environmental constraints (*Benke and Tomkins, 2017*; *Eldridge et al., 2020*; *Kozai et al., 2020; Shamshiri et al., 2021; Cheema et al., 2024; Silva Filho et al., 2024; Wang, 2024*). Within this framework, soilless culture systems are increasingly adopted as a major technological component in the modern greenhouse industry (*Savvas and Gruda, 2018*). The technological innovations in solid and non-solid substrate cultivation have significantly improved the controllability of the root environment and the production stability (*Sharma et al., 2024*). Aeroponic cultivation has gained considerable attention in recent years due to its potential to enhance plant growth, nutrient-use efficiency. In aeroponic systems, plant roots are suspended in the air and periodically supplied with a nutrient-rich mist, improving root-zone oxygenation and nutrient availability (*Eldridge et al., 2020*). The aeroponic method is highly efficient (*Sinha, 2025*), requiring less space and less water than even the most optimized hydroponic systems (*Kumari and Kumar, 2019*). Compared with conventional cultivation, aeroponic cultivation considerably reduces water and substrate requirements (*Oljača et al., 2024; Hartinger et al., 2025*). Previous studies have demonstrated that aeroponics can substantially increase the multiplication rate of potato minitubers compared to conventional cultivation methods (*Ritter et al., 2001; Buckseth et al., 2016; Çalışkan et al., 2021*). Recent investigations have also highlighted the advantages of aeroponic systems for producing disease-free plantlets and improving minituber yield under controlled environmental conditions (*Tunio et al., 2020*; *Salma and Kaushal, 2024*). In addition, aeroponic systems allow successive harvesting during the vegetation period, thereby increasing multiplication efficiency (*Brocic et al., 2022*; *Buckseth et al., 2024*; *Oljača et al., 2024*). Multiple harvests not only increase the total number of tubers by 36%, but also improve tuber quality with adjustable tuber size and reduced the number of rotten tubers per plot (*Dianawati, 2025*). Research interest in aeroponic potato cultivation has intensified in recent years due to the possibility of integrating automated monitoring systems, sensors and controlled environmental conditions for optimizing plant growth and productivity. Recent studies have emphasized the importance of genotype, nutrient management and environmental control for maximizing minituber production efficiency under aeroponic conditions (*Cheema et al., 2024*; *Silva Filho et al., 2024*). *Farran and Mingo-Castel (2006)* demonstrated that both planting density and harvesting interval significantly influence minituber yield, with shorter harvesting intervals resulting in higher production efficiency. *Singh et al. (2025)* reported that in the aeroponic system for the production of potato minitubers, crop performance is significantly influenced by the interaction between cultivar, planting date and planting density. Studies conducted in an aeroponic system have demonstrated that this technology allows for the efficient differentiation of potato genotypes according to root system characters, nitrogen use efficiency and production capacity, providing a valuable tool for breeding programs oriented towards the efficient use of resources (*Tiwari et al., 2022*).

Although aeroponic cultivation has the potential to increase potato minituber production, its performance with local genotypes in Eastern Europe remains insufficiently studied. This study compares aeroponic, hydroponic, and conventional cultivation systems using four potato genotypes grown under controlled conditions in Romania. Plant growth, minituber number, and minituber weight were evaluated. It was hypothesized that improved root-zone aeration and nutrient availability in the aeroponic system would enhance productivity compared with the other cultivation systems. The findings contribute to the development of more sustainable potato minituber production systems in Romania.

MATERIALS AND METHODS

Experimental site and plant material

The experiment was conducted in 2025 at the National Institute of Research and Development for Potato and Sugar Beet (NIRDPSB) Brașov, Romania. Four potato (*Solanum tuberosum* L.) genotypes obtained through *in vitro* propagation were evaluated: Azaria, Brasovia, Cosiana, and Cezarina, the latter being

used as the control cultivar. Virus-free *in vitro* plantlets, belonging to the four cultivars, were transplanted and cultivated using three cultivation systems: hydroponic, aeroponic, and conventional systems.

Experimental design

The experiment was organized as a bifactorial trial in a completely randomized design with three replicates. Two experimental factors were studied: the cultivation system and the genotype. Factor A comprised three cultivation systems: hydroponics, aeroponics, and conventional cultivation (control), while Factor B consisted of four potato genotypes. Plant growth and minituber production parameters were evaluated throughout the experimental period.

Hydroponic and conventional cultivation systems

For the hydroponic and conventional cultivation systems, transplanting of the *in vitro* plantlets was carried out at the end of May 2025 in a conventional insect-proof greenhouse without temperature control. The nutrient solution pH was maintained at 5.8 ± 0.2, while electrical conductivity (EC) was set at 1.0 mS cm^{-1} during the first week after transplanting and gradually increased to 2.0 mS cm^{-1} over the following two weeks. In the hydroponic system, perlite was used as the growth substrate, and the nutrient solution was supplied daily each morning for 2 h, utilizing the same formulation as the aeroponic system. The conventional cultivation system served as the control and consisted of plants grown in a peat-based substrate under greenhouse conditions. Plants in this system were irrigated daily with water for 2 h to maintain adequate substrate moisture throughout the experimental period. No nutrient solution was supplied to the pots, as was done in the hydroponic and aeroponic systems. Instead, a foliar fertilizer was applied weekly to provide supplemental nutrients and support normal plant development. The conventional system was managed according to a substrate-based cultivation approach and was therefore intentionally maintained without continuous nutrient delivery through the irrigation water, in contrast to the hydroponic and aeroponic systems. This distinction was part of the experimental design and allowed the biological performance of the soilless hydroponic and aeroponic systems to be compared with a conventional substrate-based cultivation system under greenhouse conditions.

Aeroponic cultivation system

For the aeroponic system, transplanting was performed at the beginning of June 2025. Plants were cultivated under controlled environmental conditions using artificial lighting. The aeroponic system was installed in a growth room with temperature and humidity control. The aeroponic system developed at NIRDPSB Brașov was equipped with automated sensors for monitoring and controlling nutrient solution pH, electrical conductivity (EC), and temperature. Recent advances in digital agriculture have further increased the potential of aeroponic production systems. The integration of sensors, automated nutrient management, environmental monitoring, and data-driven decision support systems enables precise control of cultivation conditions and contributes to improved crop performance (*Balasundram et al., 2023; Wang, 2024*). Such technologies are particularly relevant for seed potato production, where uniformity, phytosanitary quality, and multiplication efficiency are critical factors determining the success of the production chain. Figure 1 illustrates images of minituber harvesting obtained via the aeroponic method.

The nutrient solution pH was maintained at 5.8 ± 0.2, while the EC was adjusted to 1.0 mS cm^{-1} during the first week after transplanting and gradually increased to 2.0 mS cm^{-1} over the following two weeks, remaining at this level until the end of the harvesting period. The chemical composition of the nutrient solution corresponded to the following ionic concentrations: macronutrients (in mg L^{-1}) - N: 104, P: 60.3, K: 148, Ca: 16 mg, Mg: 50.4, and S: 48; micronutrients (in mg L^{-1}) - Fe: 0.192, Mn: 0.080, Zn: 0.024, B: 0.016, Cu: 0.016, Mo: 0.006, and Co: 0.003. Plant roots were suspended inside the aeroponic chamber and sprayed with the nutrient solution for 20 seconds at 10-minute intervals, resulting in an automated delivery frequency of approximately 6 cycles per hour.

Air temperature was kept at 20 °C during the day and 18 °C during the night, while the relative humidity ranged between 65% and 70%. The nutrient solution temperature was regulated at 18 °C using a cooling system. The artificial photoperiod was adjusted according to the plant development stage as follows: 16 h of light during the first week after transplanting to reduce transplant stress, 15 h after one month, 14 h after six weeks, and 13 h after two months of cultivation.

The aeroponic cultivation unit used in this study represents a prototype system currently undergoing patent application procedures. Therefore, certain engineering details have been withheld due to ongoing

intellectual property protection requirements. However, all cultivation parameters relevant to plant growth and experimental reproducibility are fully detailed herein.

Fig. 1 - Visual aspects of the aeroponic cultivation system and minituber production: (top) root-zone development, stolon architecture, and manual sequential harvesting of potato minitubers inside the aeroponic chambers; (bottom) sorted potato minitubers demonstrating distinct phenotypic characteristics and size uniformity among the evaluated genotypes

Measurements

Plant height was measured one month and two months after transplanting, from the stem base to the top of the canopy. At harvest, the number of minitubers per plant and total minituber weight per plant were recorded for all experimental treatments. For minitubers from aeroponic culture, 8 sequential harvests were performed. For those from classical culture and hydroponic culture, only one harvest was performed. In the aeroponic system, only minitubers larger than 15 mm were included in the statistical analysis. In the hydroponic and conventional systems, no minitubers smaller than 15 mm were obtained. The study primarily focused on the biological performance of the cultivation systems in terms of plant growth and minituber production efficiency.

Statistical analysis

Experimental data were analyzed using two-way analysis of variance (ANOVA) to evaluate the effects of the cultivation system, genotype, and their interaction. Mean comparisons were performed using Duncan's multiple range test at $p < 0.05$. All statistical analyses were carried out using the POLYFACT software package (developed for polyfactorial agricultural experiments). Additionally, regression analysis was performed to evaluate the relationships between plant growth parameters and minituber yield components, with Microsoft Excel (Microsoft Corp., Redmond, WA, USA) utilized for regression modeling, coefficient of determination (R^2) calculation, and graphical representation

RESULTS

The present study demonstrated the clear superiority of aeroponic cultivation over hydroponic and conventional systems for potato minituber production under Romanian conditions. Aeroponics significantly increased plant growth, minituber number, and minituber biomass, indicating that optimized root-zone conditions can substantially improve potato productivity under controlled environments. Overall, the present results support the hypothesis that aeroponic cultivation provides a more favorable environment for potato growth and minituber production than hydroponic or conventional systems. The consistency of the observed responses with previous investigations (*Eldridge et al., 2020; Buckseth et al., 2024; Cheema et al., 2024; Oljača et al., 2024; Silva Filho et al., 2024; Hartinger et al., 2025*) strengthens the evidence supporting the adoption of aeroponic technologies for minituber potato production.

Local and general context

Aeroponic potato cultivation in Romania is currently primarily limited to research applications. Nevertheless, our findings demonstrate its strong potential for optimizing minituber production under controlled conditions. Aeroponics is mainly used in potato cultivation for the production of minitubers as high-quality planting material. This method enables the rapid production of a large number of healthy tubers, originating from pathogen-free plants obtained through in vitro techniques.

Technological advantages and limitations

Despite its obvious advantages, aeroponics also has certain limitations, including high initial costs for infrastructure and equipment, the need for continuous monitoring and advanced technological management,

dependence on stable energy sources for optimal system operation, and variability in response depending on cultivar and growing conditions. These aspects may limit large-scale adoption, especially in traditional agricultural systems. In Romania, previous research on the hydroponic method for potato cultivation has shown superior results compared to the conventional method (*Tican, 2018; Tican et al., 2018a*; *Tican et al., 2025*). While studies on aeroponic methods had also been carried out, early systems were inefficient and failed to yield results comparable to international standards (*Tican et al., 2018b*). More recently, *Tican et al. (2026)* presented results regarding minituber production using an aeroponic system across different cultivation periods.

Plant height

The cultivation system exerted a highly significant influence on plant height one month after transfer, indicating that the cultivation system strongly affected the early vegetative growth of potato plants. Furthermore, cultivar also had a very significant effect on plant height, confirming the important role of genotype in growth expression. By two months after transfer, the effect of the cultivation system became even more pronounced (Table 1). Similar observations regarding the influence of soilless systems on plant development were reported by *Ritter et al. (2001)*, who demonstrated that aeroponic and hydroponic systems stimulate vegetative growth compared to conventional cultivation. Consistent with these findings*, Buckseth et al. (2016)* and *Tunio et al. (2020*), emphasized the favorable effect of aeroponics on potato plant growth and physiological activity.

One month after transfer, the hydroponic system significantly stimulated the initial growth of the plants, while two months later, the aeroponic system ensured the most intense stem elongation (Table 2). At the second determination, aeroponics generated the highest mean plant height (89.77 cm), exceeding the conventional system by more than 50 cm. This was due to the superior oxygenation and nutrient availability inherent to the aeroponic system, which enhanced both stem elongation and plant vigor. Consistent results were presented by *Eldridge et al. (2020)*, who mentioned that hydroponic systems provide stable root-zone conditions during early plant development.

Table 1

Analysis of variance

Source of variation	Sum of squares	DF	Mean square	*F*
Analysis of variance for plant height 1 month after transfer				
Cultivation system (*a*)	172.02	2	86.01	20.45 **(6.94; 18.00)
Cultivar (*b*)	283.06	3	94.35	8.30 **(3.16; 5.09)
Cultivation system (*a*) x Cultivar (*b*)	50.27	6	8.38	0.73 ns (2.66; 4.01)
Analysis of variance for plant height 2 months after transfer				
Cultivation system (*a*)	17413.50	2	8706.75	135.86 **(6.94; 18.00)
Cultivar (*b*)	7482.23	3	2494.08	77.02 **(3.16; 5.09)
Cultivation system (*a*) x Cultivar (*b*)	2505.36	6	417.56	12.90 **(2.66; 4.01)

Note: DF, degrees of freedom; ** significant for $p < 0.01$. Values in parentheses represent the critical *F*-values ($F_{0.05}$; $F_{0.01}$)

The differences observed among cultivars demonstrate the strong influence of genotype on vegetative growth and adaptation to intensive cultivation systems. The Cosiana and Brasovia cultivars exhibited the highest values for plant height (Table 3), indicating a superior capacity to exploit favorable growth conditions.

The interaction between cultivation system and genotype significantly influenced plant height, particularly two months after transfer (Tables 4 and 5). At the first evaluation, differences among cultivation systems were less pronounced, although hydroponic cultivation stimulated early vegetative growth in certain cultivars, especially Cosiana and Brasovia. At the second evaluation, aeroponic cultivation markedly enhanced plant growth for all analyzed genotypes, with the highest values recorded for Cosiana and Brasovia.

Minituber number and weight per plant

Analysis of variance revealed highly significant effects of the cultivation system, genotype, and their interaction on minituber number and weight per plant (Table 6). These results indicate that both technological factors and genetic background strongly influence the efficiency of minituber production under controlled cultivation environment. The significant effect of the cultivation system confirms the importance of root environment optimization for improving tuber initiation and biomass accumulation. The significant genotype effect suggests that potato varieties differ in their capacity to adapt to intensive soilless cultivation systems. In addition, the significant interaction between the cultivation system and genotype indicates that the varietal response depends on the cultivation environment, emphasizing the importance of selecting suitable genotypes for aeroponic production systems.

Aeroponic method led to highest number of minitubers/plant (37.26), the difference of 32.59 minitubers, compared to the classical method, being very statistically significant (Table 7). The hydroponic method achieved a mean number of 9.25 minitubers/plant, a value higher than the control, but the difference of 4.58 minitubers compared to the control method was not statistically significant. The results highlight the efficiency of the aeroponic method, by this method the number of minitubers increased by almost 7.97 times compared to the classical method and 4 times compared to the hydroponic method.

LSD (p <0.05) = 2.86; (p < 0.01) = 3.92; (p < 0.001) = 5.34				LSD (p <0.05) = 37.69 g; (p < 0.01) = 51.68 g; (p < 0.001) = 70.35 g.		

Note: Means within the same column followed by the same letter do not differ significantly according to Duncan's multiple range test (p <0.05). *** = highly significant at p < 0.001.

The analysis of cultivar influence (Table 8) highlights significant genetic differences regarding minituber formation and biomass accumulation. The highest values of minitubers number/plant were recorded for Cosiana (21.99 minitubers/plant), Azaria (20.50 minitubers/plant) and Brașovia (20.38 minitubers/plant) varieties with positive, highly statistically significant differences compared to the control variety Cezarina (5.38 minitubers/plant). Regarding the weight of minitubers/plant, the same trend is observed. Cosiana variety achieved the highest value (234.20 g), followed by Azaria (227.67 g/plant) and Brașovia (223.87 g), with very statistically significant differences (196.96 g, 190.43 g and 186.63 g), compared to the control variety Cezarina (37.24 g).

The aeroponic method led to an increase in the number of minitubers for the Azaria, Brasov and Cosiana varieties, obtaining very significant positive differences (41.56; 43.84; 44.28 minituber/plant) compared to the classical method (Table 9).

LSD (p <0.05) = 65.27 g; (p < 0.01) = 89.52 g; (p < 0.001) = 121.85 g.					LSD (p <0.05) = 70.88 g; (p < 0.01) = 103.46 g; (p < 0.001) = 159.47 g.			

Note: ns = not significant; * = significant at $p < 0.05$; ** = significant at $p < 0.01$; *** = highly significant at $p < 0.001$.

The combined effect of the cultivation system and genotype (Table 10) further confirms the superiority of aeroponic systems in enhancing minituber biomass production, recording very significant positive differences compared to the classical method for Azaria, Brasovia, and Cosiana (317.94; 402.5; 390.81 g). All cultivars exhibited maximum minituber weight under aeroponic conditions, with Brasovia, Cosiana, and Azaria showing the most pronounced responses. Hydroponics produced intermediate values, while conventional cultivation resulted in the lowest biomass accumulation, reflecting the physical and physiological constraints of soil-based growth. The superior response recorded for the Cosiana, Brasovia, and Azaria cultivars indicates that genotype plays an essential role in the adaptation to intensive soilless systems. In addition to increasing the number of minitubers, aeroponic cultivation significantly enhanced minituber biomass accumulation. The greater minituber weight recorded under aeroponic conditions may reflect a more efficient allocation of assimilates toward tuber development resulting from optimal root development and continuous nutrient availability.

Regression analysis

Regression analysis revealed a strong positive correlation between plant height and the number of minitubers produced per plant (R = 0.81, p < 0.01), indicating that greater vegetative development was associated with increased minituber production (Figure 2). In the aeroponic system, where water and nutrients are continuously available, vegetative development is often an indicator of the plant's ability to support the tuberization process. The study by *Silva Filho et al.* (2024) confirms a direct correlation between early vegetative growth indicators measured 21 days after transplantation and the final production of minitubers in an aeroponic system, an aspect that is also strongly supported by the findings in this study.

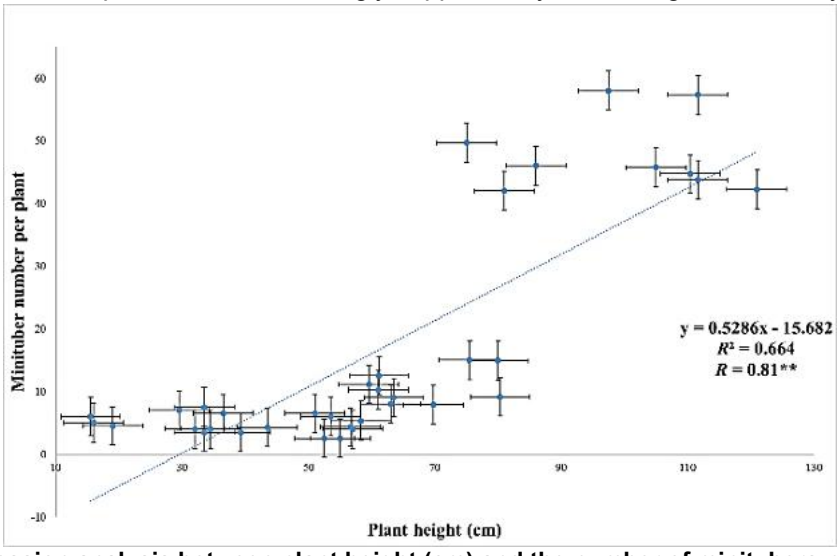

Fig. 2 - Linear regression analysis between plant height (cm) and the number of minitubers per plant across the evaluated potato genotypes and cultivation systems (** indicates significance at $p < 0.01$).

Limitations and practical implications

Although aeroponics requires a higher initial investment and careful technological management, its capacity to generate high yields of healthy planting material makes this technology promising for the modernization of potato minitubers production in Romania. However, the magnitude of the response differed among genotypes, suggesting that genetic factors strongly influence the ability of plants to exploit the favorable root environment provided by aeroponic systems. An alternative interpretation highlights that part of the observed differences stems not only from the independent cultivation system effects but also from the complex interaction between genotype and specific environmental conditions maintained during cultivation. Therefore, additional studies involving a larger number of genotypes, different nutrient management strategies, and multi-season evaluations would be valuable for confirming the stability of these responses.

Results and Discussions are recommended to be presented as a single section, using subheadings if needed. Be clear and easy to understand but complete and concise in stating and discussing the findings, comparing results with previous works and proposing explanation for the result obtained. All the data of this section must be accompanied by appropriate statistical analyses. Avoid comparisons or contrast which are not relevant to your findings. Avoid any type of speculation unsupported by the data obtained.

CONCLUSIONS

Aeroponic cultivation significantly improved potato plant growth, minituber number and weight compared to hydroponic and conventional cultivation systems. The superiority of the aeroponic system became more evident during advanced vegetation stages.

The aeroponic method leads to obtaining the largest number of minitubers (37.26/plant).

The number of minitubers was ~8 times higher than the classical method and ~4 times higher than the hydroponic method, highlighting the superior efficiency of the aeroponic system;

Among the analyzed genotypes, Cosiana, Brasovia, and Azaria showed superior adaptability to intensive soilless culture systems, recording the highest values for plant development and minituber production. The interaction between the cultivation system and genotype demonstrated that the varietal response plays an important role in the efficiency of minituber production.

The hydroponic method offered intermediate results, but the differences compared to the control were not statistically significant.

The obtained results confirm the potential of aeroponics as an efficient technology for the production of healthy potato planting material in Romania and support its future use in modern minitubers potato production systems.

ACKNOWLEDGEMENT

This research work was carried out with the support of National Institute of Research and Development for Potato and Sugar Beet Brașov and also was financed by Ministry of Research, Innovation and Digitalization, from PN 23 19 01 01 Project “Research on increasing the performance process of the potato minitubers production using an intelligent aeroponic system”, period 2023-2026. We mention that for aeroponic system we are in the process of filing patent applications.

***Keywords:** carrot roots; spiral cleaner; soil separation; mechanical damage; angular velocity; entry orientation.*

ABSTRACT

This study combined two complementary criteria for evaluating a spiral cleaner for carrot roots: the spatial distribution of separated soil and the occurrence of mechanical damage. A laboratory test rig with a V-shaped cleaning trough formed by cantilevered spiral springs and driven brushes equipped with elastic rods was used. Nantes carrot roots were tested at cleaner-shaft angular velocities of 27.2, 31.4, and 35.6 rad·s^{-1} and in two entry orientations: tail-end-first and thicker-end-first. Separated soil was collected in three consecutive zones along the transport path. Mechanical damage was assessed immediately after cleaning and again after 24 h using samples of 100 roots. Zone I accounted for 38–48% of the separated soil, Zone II for 33–41%, and Zone III for 11–28%. Increasing the angular velocity shifted soil separation toward the inlet section. The proportion of undamaged roots decreased from 66% to 44% for the tail-end-first orientation and from 75% to 59% for the thicker-end-first orientation. The thicker-end-first orientation resulted in 9–15 percentage points more undamaged roots and reduced the combined proportion of cracks, broken tail ends, and impact bruises from 13–25% to 5–14%. Under the tested conditions, an angular velocity of 27.2 rad·s^{-1} with the thicker-end-first orientation was identified as the preferred low-damage operating condition. The results provide a basis for further multifactor optimization incorporating residual adhering soil, throughput, and energy consumption as additional evaluation criteria.

РЕЗЮМЕ

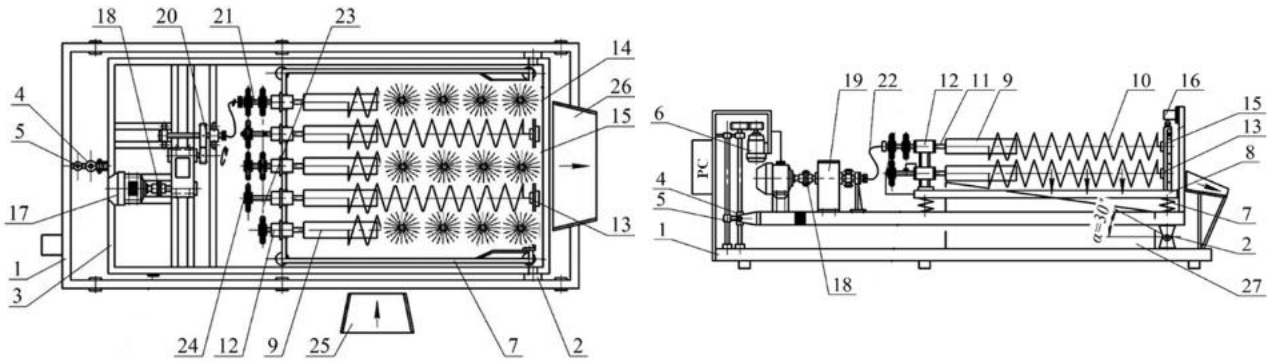
У дослідженні поєднано два взаємодоповнювальні критерії оцінювання спірального очисника коренеплодів моркви: просторовий розподіл відокремленого ґрунту та виникнення механічних пошкоджень. Використано лабораторну установку з V-подібним очисним руслом, утвореним консольними спіральними пружинами і приводними щітками з еластичними прутками. Коренеплоди моркви сорту «Нантська» досліджували за кутових швидкостей обертання валів 27,2; 31,4 і 35,6 рад·с$^{-1}$ та двох орієнтацій подавання: хвостовою або товстішою частиною вперед. Відокремлений ґрунт збирали у трьох послідовних зонах за довжиною транспортування. Механічні пошкодження оцінювали безпосередньо після очищення та повторно через 24 год у вибірках по 100 коренеплодів. У зоні I відокремлювалося 38-48% ґрунту, у зоні II – 33-41%, у зоні III – 11-28%. Зі збільшенням кутової швидкості процес зміщувався до початкової ділянки русла. Частка непошкоджених коренеплодів зменшилася з 66 до 44% за руху хвостовою частиною вперед і з 75 до 59% за руху товстішою частиною вперед. Друга орієнтація забезпечила на 9-15 відсоткових пунктів більше непошкоджених коренеплодів та зменшила сумарну частку тріщин, обламаних хвостових частин і плям від удару з 13-25 до 5-14%. За досліджених умов переважним малотравматичним режимом визначено режим, що відповідає 27,2 рад·с$^{-1}$ за подавання коренеплодів моркви товстішою частиною вперед.

INTRODUCTION

Cleaning the carrot-root heap after digging must simultaneously remove soil impurities and plant residues while preserving the marketable integrity of the produce. This task is complicated by the elongated shape of the roots, the small local contact area with the working elements, and differences in mechanical strength between the crown and tail sections.

Data on the geometric and mechanical properties of carrots indicate that impacts, local compression and bending may cause skin abrasions, cracks, internal bruising and tail-end breakage (*Jahanbakhshi et al., 2018; Nath et al., 2019; Stopa et al., 2017; Stopa et al., 2019; Xia et al., 2021*). Such damage impairs storability and reduces the proportion of marketable roots.

Modern carrot harvesters use digging shares, clamping-and-conveying belts, topping devices and cleaning units. Studies of these assemblies show that performance depends strongly on operating speed, working-element geometry and root orientation during interaction (*Jin et al., 2016; Jin et al., 2020; Rybacki et al., 2024; Wang et al., 2025a; Wang et al., 2025b; Yasmeen et al., 2023; Zeng et al., 2018; Zhao et al., 2024*). Machine-vision systems are also being developed for rapid defect detection; however, they do not eliminate the need for a mechanically gentle process (*Zhou et al., 2023*).



Spiral working elements are promising for separating heaps of root and tuber crops because they combine conveying, screening of fine impurities and self-cleaning from adhering moist soil. Scientific principles developed for potatoes and other root crops confirm that angular velocity, spiral geometry and the interaction scheme affect separation intensity and product damage (*Bulgakov et al., 2017; Bulgakov et al., 2018; Guo and Campanella, 2017; Hevko et al., 2020; Hoffmann et al., 2018; Issa et al., 2020*). However, direct transfer of such operating modes to carrots is inappropriate because of their elongated shape and the greater vulnerability of the tail end.

Recent studies on optimized conveying and separation systems for *Panax notoginseng* and potato have combined bench or field experiments with coupled simulation, while whole-machine studies on *Panax notoginseng* and white radish have emphasized the importance of controlling crop damage (*Chen et al., 2024; Pan et al., 2025; Wang et al., 2023; Xiao et al., 2023; Zhang et al., 2016*). These results provide useful quantitative benchmarks, but their operating modes and quality indices are not directly transferable to a dedicated carrot cleaner because carrot roots are elongated, orientation-sensitive and readily bruised.

In previous studies, soil separation and carrot damage were considered separately, preventing an integrated assessment of the technological trade-off between cleaning intensity and root preservation. The objective of this study was to determine the effects of spiral-cleaner shaft angular velocity and carrot-root entry orientation on the distribution of separated soil along the cleaning trough and on the pattern of mechanical damage, and to identify the preferred low-damage operating mode within the investigated factor range.

MATERIALS AND METHODS

Experimental studies were conducted using a laboratory spiral-cleaner test rig (Fig. 1). An intermediate frame 3 was attached to the main frame *1* by a hinge *2*; its inclination was adjusted by a screw mechanism *4* with a guide *5* and actuator *6*. A working-unit frame *8* was mounted on elastic supports *7*. Each spiral working element comprised a drum *9*, a cylindrical spring *10*, a shaft *11* and a bearing assembly *12*. The free end of each spiral rested, through bracket *13*, on a movable support *15* connected to vibrator *16*. Spiral springs *10* and driven cleaning brushes *14* formed a V-shaped cleaning trough.

a) b)

Fig. 1 – Schematic of the laboratory test rig:

a – top view; b – side view

1 - main frame; 2 - hinge; 3 - intermediate frame; 4 - screw mechanism; 5 - guide; 6 - actuator; 7 - elastic supports; 8 - working-unit frame; 9 - drum; 10 - cylindrical spring; 11 - shaft; 12 - bearing housing; 13 - bracket; 14 - cleaning brushes; 15 - movable support; 16 - vibrator; 17 - electric motor; 18 - coupling; 19 - continuously variable transmission; 20 - spur gear transmission; 21 - drive shaft; 22 - flexible shaft; 23, 24 - chain drives; 25 - feed chute; 26 - discharge chute; 27 - soil collection tray

The bottom and one side surface of the trough were formed by cantilevered spiral springs whose turns conveyed the material from the inlet towards the outlet. The opposite side surface was formed by flat driven brushes with elastic rods. Rotation of the spirals provided axial conveying and allowed soil to pass through the inter-turn gaps, while the brushes assisted root movement and removal of fine impurities. The mutual overlap of adjacent spirals promoted self-cleaning. General views of the test rig, working elements, cleaning trough and soil-collection zones are shown in Fig. 2.

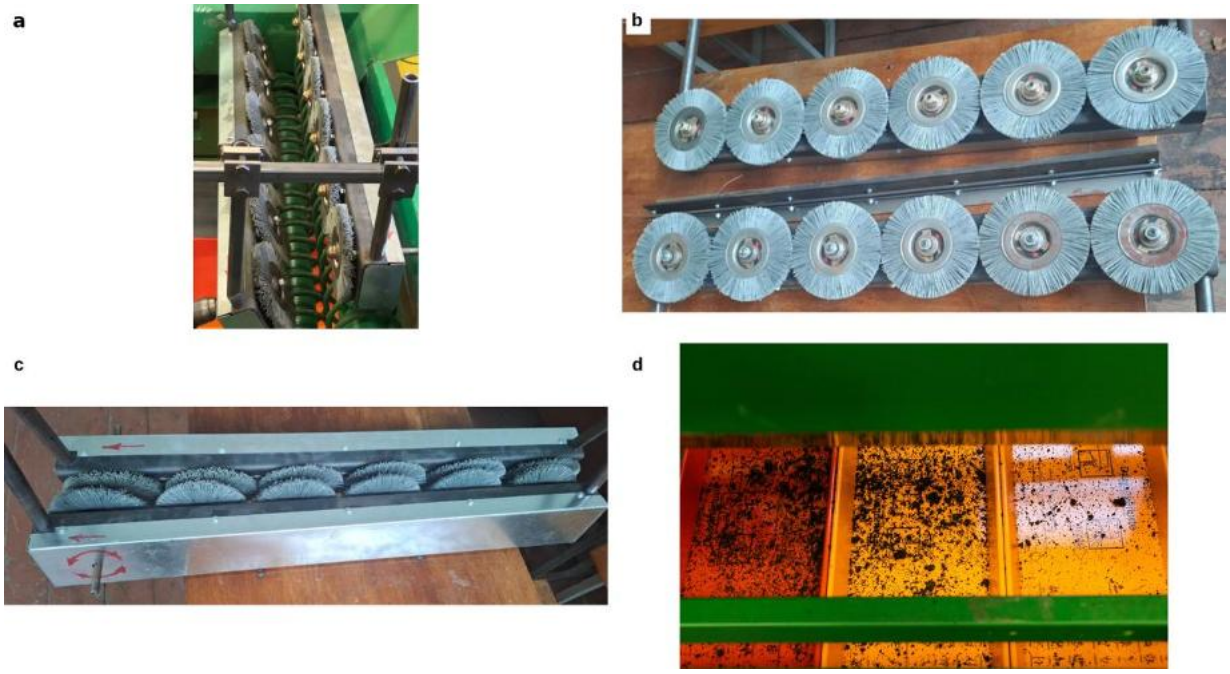


Fig. 2 – Components of the experimental test rig:
a – general view; b – frames with driven brushes; c – cleaning trough; d – trays for collecting soil by zone

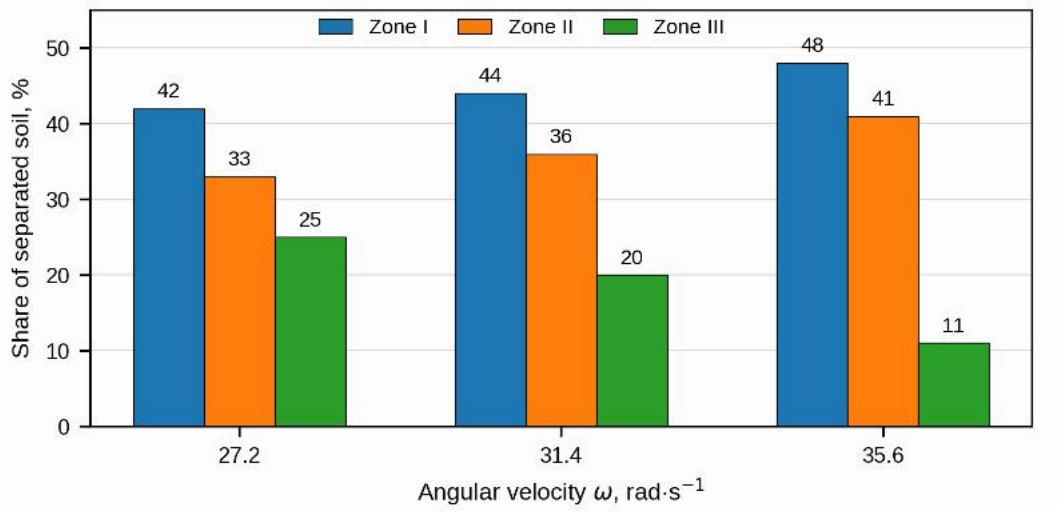
Pre-dug roots of the Nantes carrot cultivar, predominantly elongated-cylindrical in shape, were used in the experiments. No cleaning elements were used during digging. Roots without initial mechanical damage were selected, transported separately and weighed on an electronic balance with 0.1 g resolution. The permissible mass deviation within each experimental group was ±5 g. For damage assessment, all adhering soil was removed from the roots beforehand so that surface defects would not be obscured.

Table 1

Factors and experimental conditions

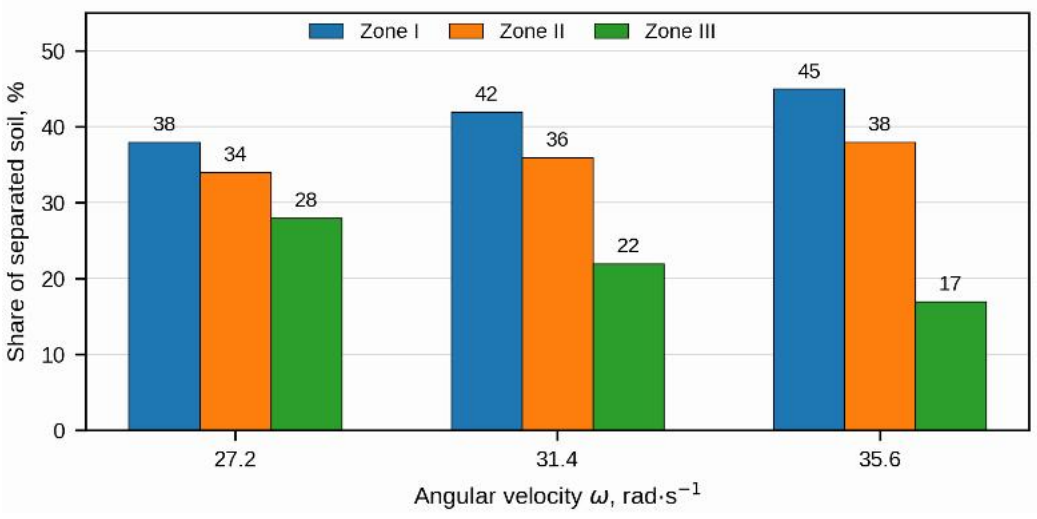
Parameter or indicator	Levels / assessment procedure	Unit / note
Shaft angular velocity, ω	27.2; 31.4; 35.6	rad·s^{-1}
Entry orientation A	tail-end-first	–
Entry orientation B	thicker-end-first	–
Number of replicate soil-separation test series	3	for each operating mode
Damage-assessment sample size	100	roots per operating mode (600 total)
Assessment of latent impact damage	repeat inspection after 24	h

Experimental design and scope. Two complementary experimental series were performed for each of the six operating modes: (i) zonal collection of soil released from roots carrying adhering soil and (ii) mechanical-damage assessment using roots from which adhering soil had been removed before testing. The soil-separation series comprised three replicate test runs per mode with group masses matched to within ±5 g. The damage distribution was determined from 100 roots per mode (600 roots in total).



Along the transport direction, the cleaning trough was conventionally divided into three consecutive sections. Zone I represented the initial impact-separation interaction, Zone II the steady-state cleaning stage, and Zone III the completion of cleaning before discharge. Soil passing through the working surface was collected in three separate trays. The share attributed to each zone was calculated as the mass of soil in the corresponding tray divided by the total mass collected in all three trays and was expressed as a percentage.

After passing through the cleaning trough, each root was inspected in two stages. Immediately after the test, skin abrasions, scratches, cracks and tail-end breakage were recorded. A second inspection was performed after 24 h to detect darkened bruises resulting from impact or severe local compression. The dimensions of damaged areas were measured with a vernier caliper. For each operating mode, the percentage distribution among six categories was calculated: 1 – no damage; 2 – skin abrasions; 3 – scratches; 4 – cracks; 5 – broken tail end; 6 – impact bruise.



Statistical analysis. The primary damage endpoint was the proportion of undamaged roots. A secondary endpoint, termed severe damage, combined cracks, broken tail ends and impact bruises. Wilson 95% confidence intervals were calculated for both endpoints. The effect of entry orientation across the three angular-velocity strata was assessed with the Cochran-Mantel-Haenszel test, and ordered trends across angular velocity were tested with the Cochran-Armitage trend test. All tests were two-sided with $\alpha = 0.05$. Because the available zonal soil data consisted of mode-level shares that sum to 100%, the soil-separation distribution was analyzed descriptively; no ANOVA or claim of a global optimum was made.

RESULTS

Under all operating modes, the largest proportion of separated soil was collected at the beginning of the cleaning trough. In the tail-end-first orientation, Zone I accounted for 42, 44 and 48% of the separated soil at ω = 27.2, 31.4 and 35.6 rad·s^{-1}, respectively. The share in Zone III decreased from 25 to 11%. In the thicker-end-first orientation, the share in Zone I was 38-45%, whereas that in Zone III was 17-28% (Fig. 3).

a)

b)

Fig. 3 – Distribution of separated soil along the cleaning trough:
a – tail-end-first orientation; b – thicker-end-first orientation

Increasing angular velocity shifted the separation process towards Zone I in both entry orientations: its share increased by 6-7 percentage points, whereas the share in Zone III decreased by 11-14 percentage points. This indicated intensification of the initial interaction between the roots, spirals and brushes. With thicker-end-first feeding, the distribution along the trough was slightly more uniform: the Zone I share was 2-4 percentage points lower and the Zone III share 2-6 percentage points higher than with tail-end-first feeding.

Mechanical damage. Five types of defect were recorded: skin abrasions, scratches, cracks, broken tail ends and impact bruises, the last of which became clearly visible after 24 h (Fig. 4). The delayed appearance of impact bruises confirmed the need for two-stage inspection, because a single inspection immediately after cleaning would have underestimated the proportion of damaged roots. The delayed appearance of impact bruises confirmed the need for a two-stage inspection, as inspection conducted only immediately after cleaning would have underestimated the proportion of damaged roots.

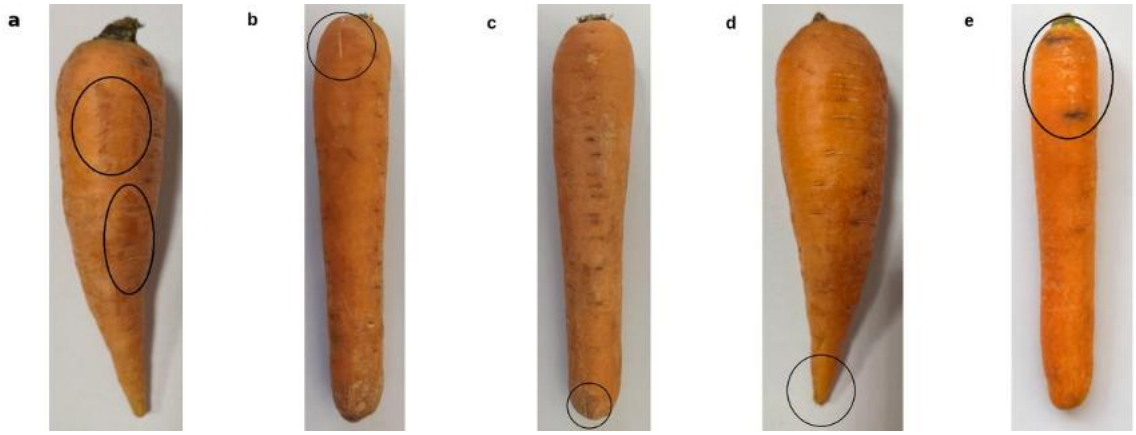


Fig. 4 – Types of mechanical damage to carrot roots:
a – skin abrasion; b – scratch; c – crack; d – broken tail end; e – impact bruise

In the tail-end-first orientation, the proportion of undamaged roots decreased from 66% at 27.2 rad·s^{-1} to 56% at 31.4 rad·s^{-1} and 44% at 35.6 rad·s^{-1}. All damage categories increased simultaneously: skin abrasions from 11 to 16%, scratches from 10 to 15%, cracks from 5 to 10%, broken tail ends from 5 to 8%, and impact bruises from 3 to 7% (Fig. 5a). Thus, increasing angular velocity intensified both superficial and structural defects.

In the thicker-end-first orientation, 75, 68 and 59% of roots remained undamaged at the three angular velocities, respectively (Fig. 5b). These values were 9, 12 and 15 percentage points higher than for the opposite orientation. The difference was particularly pronounced for more severe damage. The combined proportions of cracks, broken tail ends and impact bruises in the tail-end-first orientation were 13, 18 and 25%, compared with 5, 8 and 14% in the thicker-end-first orientation. Thus, the advantage of the thicker-end-first orientation increased with angular velocity.

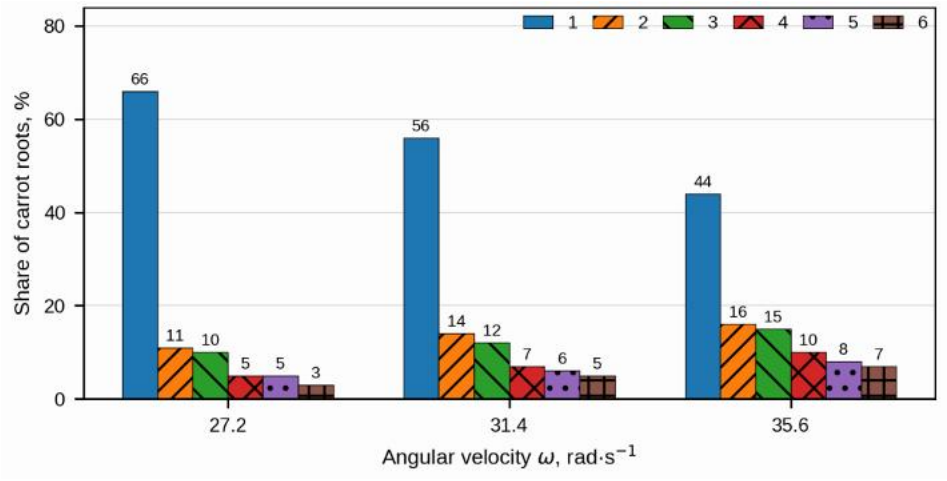

Table 2

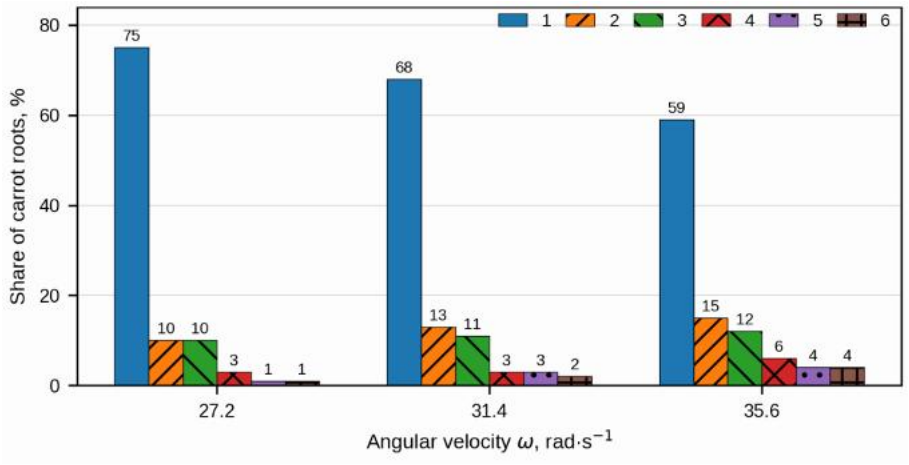
Statistical summary of mechanical-damage endpoints (n = 100 roots per operating mode)



Entry orientation	Angular velocity, ω, rad·s^{-1}	Undamaged roots, % (95% CI)	Severe damage, % (95% CI)
tail-end-first	27.2	66 (56.3-74.5)	13 (7.8-21.0)
tail-end-first	31.4	56 (46.2-65.3)	18 (11.7-26.7)
tail-end-first	35.6	44 (34.7-53.8)	25 (17.5-34.3)
thicker-end-first	27.2	75 (65.7-82.5)	5 (2.2-11.2)
thicker-end-first	31.4	68 (58.3-76.3)	8 (4.1-15.0)
thicker-end-first	35.6	59 (49.2-68.1)	14 (8.5-22.1)

Note: severe damage = cracks + broken tail ends + impact bruises; confidence intervals are Wilson intervals.

Across angular-velocity strata, thicker-end-first feeding increased the odds that a root remained undamaged (common OR = 1.69, 95% CI 1.20-2.36; p = 0.002) and reduced the odds of severe damage (common OR = 0.42, 95% CI 0.26-0.70; p < 0.001). The proportion of undamaged roots decreased significantly with angular velocity for both tail-end-first (p = 0.002) and thicker-end-first (p = 0.016) feeding, whereas severe damage increased (p = 0.029 and p = 0.026, respectively).

1 – no damage; 2 – skin abrasions; 3 – scratches; 4 – cracks; 5 – broken tail end; 6 – impact bruise

DISCUSSION

Integrated assessment of operating modes. The two experimental components yielded a consistent mechanical interpretation. Thicker-end-first feeding resulted in a somewhat more even distribution of separated soil along the trough while reducing peak loading on the vulnerable tail end. The lowest damage level was obtained at ω = 27.2 rad·s^{-1} in the thicker-end-first orientation: 75% of roots had no visible defects, and the combined proportion of cracks, broken tail ends and impact bruises was 5%. However, the spatial distribution of separated soil is not equivalent to absolute cleaning efficiency because the available data did not include a complete balance of residual adhering soil for each operating mode. The identified mode should therefore be regarded as preferable according to the damage-minimization criterion, while final optimization for production conditions should consider a set of indicators: residual adhering soil, total separation, throughput, energy consumption and the proportion of mechanically damaged roots.

Comparison with published systems. A *Panax notoginseng* conveying-separating device achieved a separating rate of 93.60% and a screening rate of 92.64% under optimized bench conditions (*Wang et al., 2023*), while a self-propelled *Panax notoginseng* harvester reported a 96.8% net harvesting rate and 1.6% root damage (*Zhang et al., 2016*). Optimized potato separation systems reported 97.8% separation with 1.16% tuber damage (*Chen et al., 2024*) and 96% separation with 2% damage (*Pan et al., 2025*). A self-propelled white-radish combine reported 4.99% damage and 1.64% impurity (*Xiao et al., 2023*).

The 5% severe-damage proportion obtained here at 27.2 rad·s^{-1} with thicker-end-first feeding is close to the white-radish benchmark but higher than the 1.16-2% values reported for optimized Panax and potato systems. This comparison is indicative rather than direct: the cited studies evaluated whole harvesters or soil-crop complexes and used different damage thresholds, whereas the present protocol also counted superficial abrasions, scratches and bruises visible only after 24 h.

In addition, the present soil metric describes where separated soil was collected along the cleaner and is not an absolute separation efficiency or conveying rate. Consequently, the scientific contribution is the quantified effect of root orientation and angular velocity on the cleaning-damage trade-off.

In conclusion, it is particularly noteworthy that the movement of carrot roots within the cleaning channel of the newly developed soil-removal device differs substantially from that observed for other root crops. Furthermore, it's important to keep in mind that carrot roots themselves have specific shapes and sizes that are not comparable to those of potatoes, sugar beets, table beets, or fodder beets. This is particularly true for other root crops, such as *Panax notoginseng*, which cannot be effectively cleaned using the proposed device.

These two factors—the specific size and shape of carrot roots and the specialized design of the developed cleaner, which was specifically intended for cleaning carrot roots during harvesting—limit the relevance of direct comparisons with other root crops and cleaning devices. Consequently, the cleaning and damage results obtained in this study should not be directly compared with those reported for other root crops or cleaner designs. Moreover, the developed cleaner is unlikely to provide effective cleaning for root crops with substantially different morphological characteristics. The cleaning channel itself, consisting of spirals and a brush wall, was designed and manufactured solely for testing the cleaning of carrot roots from soil impurities using other types of cleaners and different types of root crops, is unlikely to be useful or relevant to scientists and designers.

Limitations and future work. The laboratory study used pre-dug Nantes roots, controlled entry orientation and a limited range of shaft speeds. Field-scale optimization should retain replicate-level tray masses and quantify residual adhering soil, total separation, throughput, energy consumption and random-orientation effects under varying soil moisture and root-size distributions. A future DEM-MBD model should be calibrated and validated against measured root trajectories, contact loads, zonal soil mass distributions and the observed damage categories; such a model was outside the scope of present experimental study.

CONCLUSIONS

1. An integrated method for evaluating the spiral cleaner was proposed, combining determination of the spatial distribution of separated soil in three cleaning-trough zones with two-stage inspection of mechanical damage to carrot roots.

2. Zone I accounted for 38-48% of the separated soil, Zone II for 33-41%, and Zone III for 11-28%. As angular velocity increased from 27.2 to 35.6 rad·s^{-1}, the Zone I share increased and the Zone III share decreased, indicating that intensive separation shifted towards the inlet of the trough.

3. The proportion of undamaged roots decreased from 66 to 44% in the tail-end-first orientation and from 75 to 59% in the thicker-end-first orientation. The latter orientation yielded 9-15 percentage points more undamaged roots and reduced the combined proportion of cracks, broken tail ends and impact bruises from 13-25% to 5-14%. Across all three angular-velocity strata, the common odds ratio for an undamaged root was 1.69 (95% CI 1.20-2.36; $p = 0.002$), while the odds of severe damage were reduced to 0.42 (95% CI 0.26-0.70; $p < 0.001$).

4. Under the tested conditions, $\omega = 27.2$ rad·s^{-1} in the thicker-end-first orientation was identified as the preferred operating mode according to the damage-minimization criterion. Establishing a global optimum will require a complete balance of residual adhering soil, together with measurements of throughput and energy consumption. Future work should also include field validation and development of a quantitatively validated DEM-MBD model.

ABSTRACT

To enable automatic and precise flower transplanting, a soil pickup and separation device was designed for substrate filling in greenhouse flower transplanting operations. The soil-conveying mechanism of the soil pickup auger was analyzed through theoretical analysis and discrete element simulation. Taking the soil pickup quantity and its coefficient of variation as the evaluation indices, the effects of auger rotational speed, soil penetration depth, and pitch were investigated and optimized using Box-Behnken response surface methodology. The simulation results showed that the optimal operating parameters were an auger rotational speed of 115.7 rpm, a soil penetration depth of 39.28 mm, and a pitch of 149.26 mm. Based on the optimized parameters, a prototype was fabricated and field tests were conducted. The measured soil pickup quantity was 4.13 kg, and the corresponding coefficient of variation was 1.44%, with relative errors of 3.05% and 4.00%, respectively, compared with the simulation results. The validation results demonstrated that the device operated stably and could achieve accurate and efficient substrate filling.

摘要

为实现花卉移栽过程的自动化与精准化，针对温室环境下花卉自动移栽机的作业需求，本文设计了一种用于软质花盆基质填充的取分土装置。结合理论分析与离散元仿真明确取土搅龙推土机理，以取土量及变异系数为指标，用 Box-Behnken 响应面法优化转速、入土深度和螺距。仿真结果表明，当转速为 115.7 r·min⁻¹、入土深度为 39.28 mm、螺距为 149.26 mm 时，取土性能最优。基于优化结果试制样机并开展田间试验，实际取土量为 4.13 kg，变异系数为 1.44%，与仿真预测值的相对误差分别为 3.05%与 4.00%。试验结果表明，该装置结构合理、工作稳定，可实现花盆基质的精准高效填充。

INTRODUCTION

The floral industry is a high-value sector of global agricultural trade. Driven by emerging markets and consumption upgrades, global flower demand continues to grow—the market exceeded $51.16 billion in 2024. As a major producer and consumer, China's floral exports reached $516 million in 2024, a year-on-year increase of 17.78% *(Gu et al., 2025)*. Against this backdrop, the comprehensive mechanization of flower production is not only crucial for enhancing the competitiveness of the flower industry and supporting its sustainable development, but also a key step in promoting rural revitalization and achieving agricultural modernization *(Cheng et al., 2023)*.

Flower transplanting primarily involves two core steps: growing medium filling and seedling planting. Growing medium filling is a prerequisite that directly affects operational efficiency and quality. However, it remains largely manual in China, resulting in high labor intensity and inconsistent quality, and making it difficult to meet the demands of large-scale production *(Zhou et al., 2018)*. Although some studies have addressed matrix filling mechanisms *(Minglani et al., 2021, Xu et al., 2020, He et al.,2023)* and transplanting apparatus optimization *(Zhao et al., 2020, Zhao et al., 2022, Tian et al., 2022, Tian et al.,2023, Ji et al., 2022, Tong et al., 2024, Hu et al., 2022)*, most focus on single functional modules or theoretical simulation analyses. There is still a lack of integrated soil pickup and separation devices specifically designed for automatic transplanting on greenhouse ridges, as well as systematic experimental studies of their operating performance and parameter effects.

Moreover, existing soil pickup devices often perform poorly under variable field conditions, such as uneven ridge surfaces and differences in soil properties, resulting in fluctuations in soil pickup quantity and filling uniformity. To address these challenges, this study develops an integrated soil pickup and separation device, optimizes its operating parameters using EDEM simulation and response surface methodology, and validates its performance through field tests. The aim is to provide a reliable and precise soil-handling solution for automatic flower transplanting and to support the development of more efficient, stable, and intelligent transplanting equipment.

MATERIALS AND METHODS

Structure and Working Principle

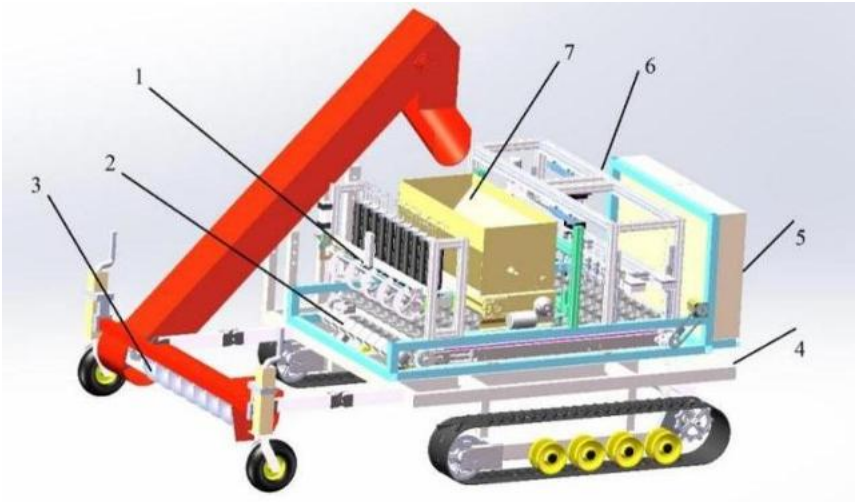

Fig.1 - Schematic diagram of the automatic flower transplanter

1-Soil sampling device; 2-Flowerpot Conveyor System; 3-Soil pickup Device; 4-Frame and Traveling Mechanism; 5-PLC Control Unit; 6-Seedling Transplanting Device; 7-Soil Storage Device

The automatic flower transplanter, shown in Fig. 1, integrates pot separation, substrate filling, hole punching, seedling transplanting, and ridge placement. It consists of a traveling mechanism, a PLC control system, and soil-handling units, enabling the fully automatic transfer of plug seedlings into cultivation pots.

The automatic flower transplanter is equipped with a tracked chassis to provide mobility, with a high-power DC motor serving as the drive unit. During operation, soil is collected and conveyed to the storage unit for uniform filling of soft nursery pots. The operating process is as follows: vacuum suction cups remove pots from stacked racks; the pots are conveyed individually for precise substrate filling; holes are vertically formed in the filled pots; seedlings are transplanted into the holes to ensure close root-soil contact; and finally, the pots are guided into the cultivation ridges through sequential guide plates, thereby achieving uniform placement along the ridges.

DESIGN OF SOIL PICKUP AND SEPARATION DEVICE

Design of Soil pickup and Lifting Unit

The soil pickup and lifting unit consists of a soil lifting box measuring approximately 2100 mm in length and 1800 mm in height after inclined installation, along with a housing, soil-lifting baffle, soil pickup auger, height adjustment mechanism, and soil discharge chute opening as shown in Fig. 2. The chain is positioned at a 40°angle to the ground, with four chain links between adjacent soil-lifting baffles at a pitch of 40 mm. Rotating shaft of the soil pickup auger has a length of 1100 mm and a diameter of 40 mm, while the helical blades feature an outer diameter of 150 mm and a thickness of 2 mm.

The soil pickup auger consists of a rotating shaft and helical blades (*Bulgakov et al., 2023*), while the soil-lifting baffles are composed of steel plates and rigid PVC strips, as shown in Fig. 3. During transplanting operations, the motor drives the auger to rotate and convey soil laterally beneath the baffles. The chain then drives the baffles upward, lifting the soil to the discharge opening.

The soil pickup quantity can be adjusted by changing the engagement length between the externally threaded rocker and the internally threaded square tube. Rotating the rocker outward moves the auger away from the ridge surface, thereby reducing soil pickup, whereas rotating it inward moves the auger closer to the ridge surface, thereby increasing soil pickup.

Design of the Soil Storage and Separation Unit

The soil storage and separation unit (*Li et al., 2019; Feng et al., 2022*) consists of a soil storage box, a conveyor-belt tensioning mechanism, a brushed DC motor, a soil separation quantity adjustment mechanism, a soil separation baffle, a conveyor belt, and a soil separation auger, as shown in Fig. 4. Soil discharged from the chute enters the storage box, is conveyed toward the separation baffle, and is then distributed uniformly into the flowerpots. The soil separation quantity adjustment mechanism, consisting of an adjustment knob, a gear set, and an adjustment plate, changes the gap between the adjustment plate and the conveyor belt by varying the meshing position of the gears, thereby enabling precise soil filling for 10 flowerpots per cycle. The conveyor-belt speed must also be properly adjusted: excessive speed may cause soil accumulation or clogging at the belt-baffle gap, whereas insufficient speed may result in inadequate filling.

Because of structural constraints, the soil discharge chute can only be installed on one side, which may cause soil accumulation near the discharge point. A soil separation auger is therefore used to improve soil conveying and distribution. The auger shaft is supported by F206 bearings and is provided with mounting holes at predetermined intervals, through which the blades are bolted. The shaft has a total length of 955 mm, including an 830 mm conveying section. The mounting holes have a diameter of 15 mm, the blade spacing is 40 mm, and 16 blades are arranged symmetrically around the shaft.

Analysis of Soil Particle Conveying Characteristics

Soil particles conveyed by the helical blades of the soil separation auger undergo combined axial translation and circumferential rotation. To investigate this motion behavior in detail, the forces acting on individual soil particles and their velocity components during conveying were analyzed using a single-particle analysis method.

Dynamic Analysis

The resultant force F exerted by the helical blade on soil particle P can be decomposed into an axial component F_z along the auger axis and a tangential component F_t. At the same time, particle P is subjected to a normal force F_n from the helical surface and a tangential friction force f_1, as shown in Fig. 5.

Under the combined action of F_t and f_1, P tends to rotate around the auger axis. When F_t is moderate, this rotational tendency is restrained by the combined effects of gravity and the frictional force exerted by the housing. When F_t becomes excessively large, the tendency of particle P to roll increases, thereby reducing the axial conveying efficiency. The force balance of particle P can be expressed by Eq. (1).

$$\begin{cases} F_z = F\cos(\alpha+\beta) \\ F_t = F\sin(\alpha+\beta) \\ f_1 = \mu F_n = F_n \tan\alpha \end{cases} \quad (1)$$

For soil particles to move axially along the auger shaft, the axial driving force must exceed the axial resistance acting on the particles. This condition can be expressed by Eq. (2).

$$\begin{cases} F_n\cos\beta > f_1\sin\beta \\ F_n\cos\beta > F_n\tan\alpha\sin\beta \\ \alpha+\beta < 90^\circ \end{cases} \quad (2)$$

where F is the resultant force exerted by the helical surface on particle P, N; F_n is the normal force exerted by the helical surface N; f_1 is the tangential friction force along the helical surface N; F_z is the axial component of the resultant force along the auger shaft N; F_t is the circumferential component of the resultant force N; α is the friction angle of particle P, °; β is the helix angle of the soil pickup auger °; μ is the sliding friction coefficient between particle P and the helical surface; s is the pitch of the soil pickup auger [mm]; and r is the radial distance from particle P to the auger axis [mm].

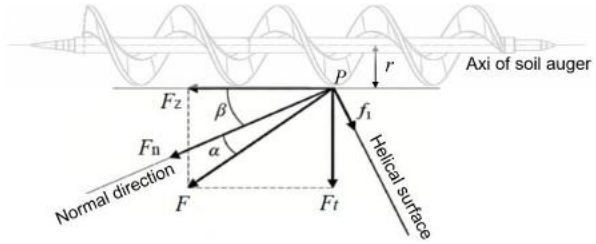

Fig. 5 - Force analysis of a soil particle under the action of the helical blade

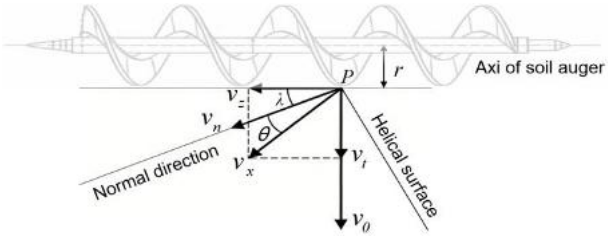

Fig. 6 - Velocity analysis of a soil particle during conveying by the helical blade

Kinematic Analysis

As shown in Fig. 6, the initial velocity of soil particle P is the circumferential velocity V_0 associated with the rotation of the helical blade. If the friction between the particle and the rotating blade is neglected, particle P moves with an absolute velocity V_n along the normal direction of the helical surface. In practice, however, friction causes the actual velocity of particle P to deviate from this direction, resulting in a velocity V_x. This velocity can be decomposed into an axial component V_z along the auger shaft and a circumferential component V_t. The velocity relationships of particle P are given in Eqs. (3) and (4).

$$\begin{cases} V_t = V_x\sin(\alpha+\beta) \\ V_z = V_x\cos(\alpha+\beta) \\ V_0 = wr = \dfrac{2\pi n}{60}r = \dfrac{ns}{60\tan\beta} \\ V_x = \dfrac{V_n}{\cos\alpha} = \dfrac{V_0\sin\beta}{\cos\alpha} = \dfrac{ns\cos\beta}{60\cos\alpha} \end{cases} \quad (3)$$

$$\begin{cases} V_z = \dfrac{ns}{60}(\cos^2\beta - \cos\beta\sin\beta\tan\alpha) \\ V_t = \dfrac{ns}{60}(\cos\beta\sin\beta + \cos^2\beta\tan\alpha) \end{cases} \quad (4)$$

where:

V_x is the actual velocity of particle P considering friction with the rotating blade m/s; V_n is the velocity of particle P along the normal direction of the helical surface m/s; V_0 is the circumferential velocity induced by auger rotation m/s; V_z is the axial velocity component along the auger shaft m/s; V_t is the circumferential velocity component m/s; and n is the rotational speed of the soil pickup auger , rpm.

PERFORMANCE SIMULATION AND OPTIMIZATION OF SOIL PICKUP DEVICE

Transplant Ridge Modeling

Soil samples of 200 g were collected from the ridge surface using the five-point sampling method. The particle size distribution was determined by sieve analysis, showing that particles of 0~1 mm, 1~2 mm, and >2 mm accounted for 70.8%, 14.2%, and 15.0%, respectively. A soil trough of 120 mm (length) × 1250 mm (width) × 200 mm (height) was established in EDEM to simulate the transplanting ridge. To balance simulation efficiency and accuracy, the simulated particle size was set to three times the actual average particle size. Spherical, columnar (three-sphere), and blocky (four-sphere) particles were constructed based on a single sphere with a radius of 3 mm, and generated in the trough according to the measured mass proportions *(Li et al., 2023, He et al., 2024, Huan et al., 2025, Han et al., 2025)*.

Motion Settings for the Soil-Lifting Baffles

A simplified simulation model of the soil pickup and separation device was established in SolidWorks 2022 and imported into EDEM 2023, as shown in Fig. 7. The chain was omitted, and the soil storage unit was simplified as an open box. To simulate the periodic motion of the baffles (*Zhao et al., 2020*), 21 baffles were generated at equal time intervals. Their motion was divided into the following cycle: inclined downward movement → rotation near the auger → inclined upward movement → rotation near the discharge opening → return to the initial position.

Simulation Parameter Settings

The 25s simulation included particle generation and soil filling (0~5.0s), followed by auger rotation and forward movement (5.0~25.0s) with sequential soil lifting. Motion parameters are in Table 1.

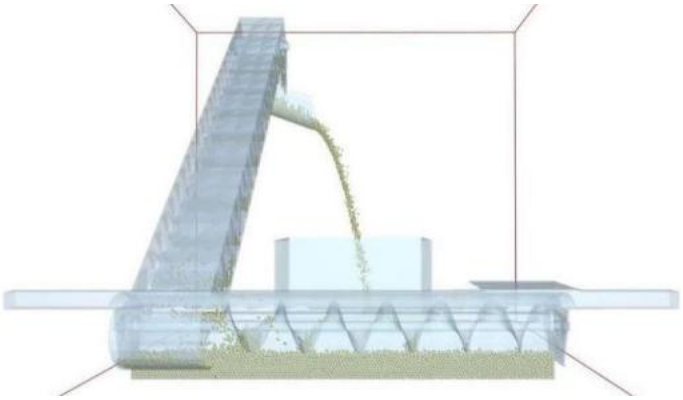

Fig. 7 - EDEM simulation model

Table 1

Motion parameters of the auger shaft and soil-lifting baffles

Auger shaft		Soil lifting baffle	
rotational angular velocity / rad.s^{-1}	13.8	duration of initial inclined descent/s	0.08
forward velocity / m.s^{-1}	0.02	duration of rotation near the auger/s	0.23
		duration of inclined ascent/s	1.56
		duration of rotation near the discharge opening/s	0.23
		duration of return inclined descent/s	1.48
		ascent/descent velocity/m/s	1.2
		rotational angular velocity/rad/s	13.8

Simulation Contact Model and Setting of Material Contact Parameters

Considering the moisture content and cohesiveness of the soil particles, the Hertz–Mindlin with JKR contact model was selected because it can represent the adhesive behavior of moist, cohesive particles under the actual operating conditions of the soil pickup and lifting device (*Han et al., 2023)*. The basic physical property parameters of various materials involved in the study are shown in Table 2, and the contact mechanical property parameters between different materials are presented in Table 3.

Table 2

Physical properties of the materials

Material	Density (kg/m³)	Elastic Modulus (Pa)	Shear Modulus (Pa)	Poisson's Ratio
Soil Particles	1526	2.808×10^{6}	1.080×10^{6}	0.30
Rigid PVC Sheet Strip	1282	1.056×10^{7}	4.000×10^{6}	0.32
Q235 Carbon Steel	7830	7.270×10^{10}	1.963×10^{11}	0.35

Table 3

Contact parameters between materials

Contact pair	Coefficient of Restitution	Coefficient of Static Friction	Coefficient of Rolling Friction
Soil Particles-Soil Particles	0.45	0.89	0.43

Parametric Optimization Simulation Test

To obtain the optimal soil pickup and lifting performance of the device, the operating parameters of the soil pickup auger were optimized, including auger rotational speed, soil penetration depth, and pitch.

Optimization Test Design

To investigate the effects and interactions of the operating parameters of the soil pickup auger, a three-factor, three-level Box-Behnken response surface simulation design was conducted. The coded levels of the experimental factors are presented in Table 4.

Table 4

Coded levels of the experimental factors

Coded level	Test Factor		
	Rotational Speed X_1 (r.min^{-1})	Soil Penetration Depth X_2 (mm)	Pitch X_3 (mm)
-1	90	30	130
0	110	40	150
1	130	50	170

Evaluation Indexes of Optimization Test

The evaluation indices used in the optimization test were the soil lifting quantity, Y_1, and the coefficient of variation of the soil lifting quantity, Y_2. These indices were calculated using Eq. (5).

$$\begin{cases} Y_1 = \dfrac{\sum_{i=1}^{m} x_i}{\phi} \\ Y_2 = \dfrac{\sigma}{Y_1}\times 100\% \\ \sigma = \sqrt{\dfrac{\sum_{i=1}^{m}(x_i - Y_1)^2}{\phi - 1}} \end{cases} \quad (5)$$

where x_1 is the mass of soil in the soil storage box at the i-th measurement kg; ϕ is the number of measurements; σ is the standard deviation of the soil mass in the soil storage box during the simulation; Y_1 is the soil lifting quantity kg; and Y_2 is the coefficient of variation of the soil lifting quantity, %.

RESULTS

Results of Optimization Test

The simulation results of the optimization experiments are presented in Table 5, where X_1 and X_2 represent the coded values of the experimental factors. Multivariate regression fitting and analysis of variance (ANOVA) were conducted on the simulation results of the optimization experiments using Design-Expert 12.0 software, with the results shown in Table 6. The P-values of all models were less than 0.05, indicating that the models were significant and the ANOVA results had high reliability. In addition, the P-values of the lack-of-fit terms were all greater than 0.05, meaning the lack-of-fit terms were not significant and the ANOVA results had

a high degree of fitting. For the response surface model of soil lifting quantity, Y_1, the terms X_1, X_2, X_1X_2, X_1X_3, X_2^2 and X_3^2 had highly significant effects on the response, while X_3 and X_2X_3 had significant effects. For the response surface model of the coefficient of variation of soil lifting quantity Y_2, the terms X_1, X_2, X_3, X_1X_2, X_1X_3 and X_1^2 had highly significant effects, and X_3^2 had a significant effect.

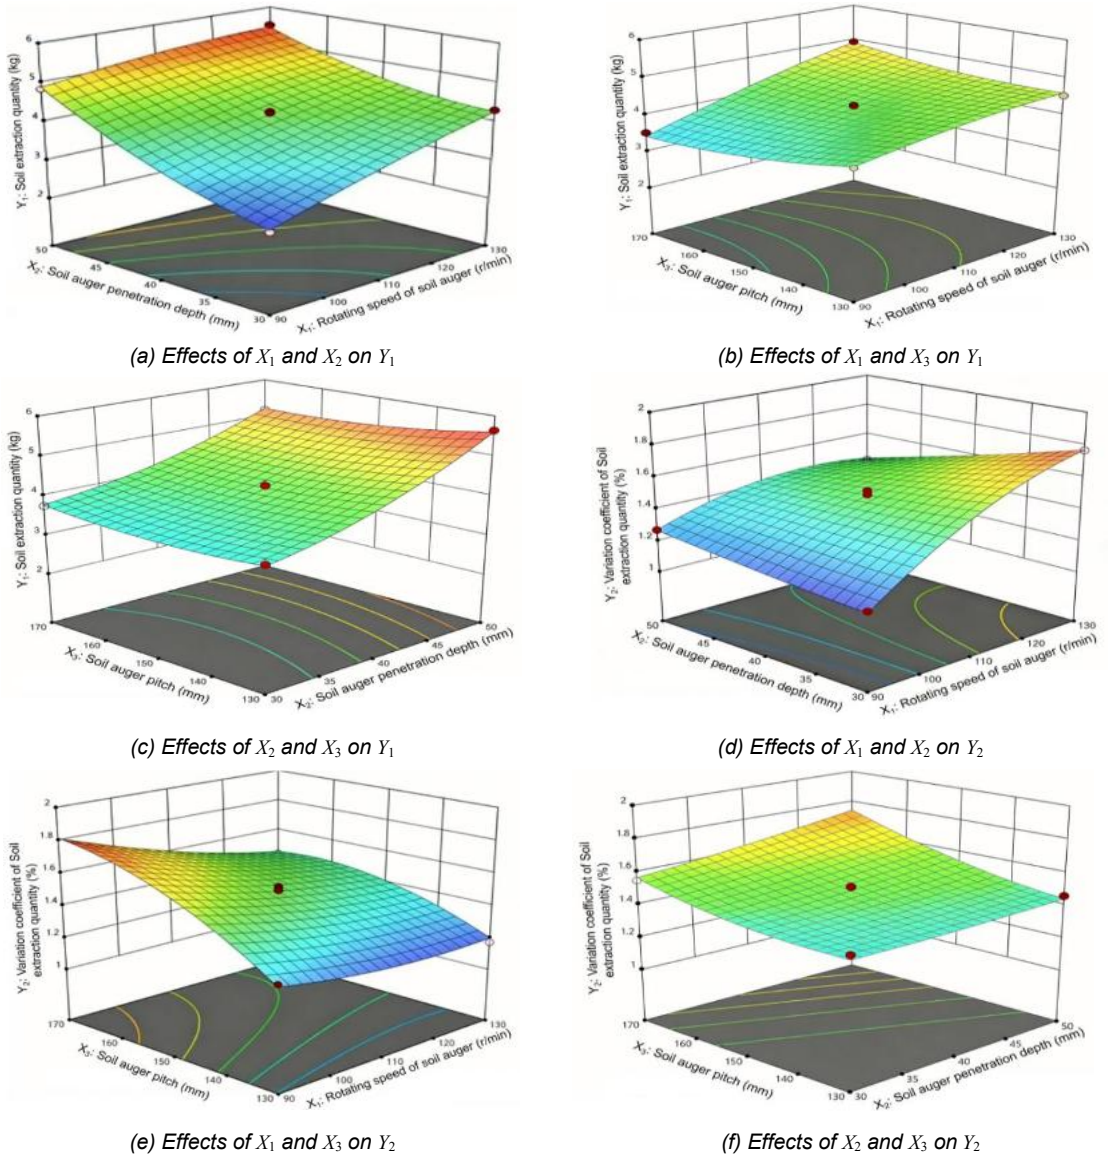
X_2X_3	0.0506	1	7.38	0.0299*	0.0003	1	0.2830	0.6112
X_1^2	0.0358	1	5.22	0.0562	0.0081	1	7.07	0.0325*
X_2^2	0.2430	1	35.44	0.0006**	0.0231	1	20.29	0.0028**
X_3^2	0.0888	1	12.95	0.0088**	0.1035	1	90.86	< 0.0001**
Residual	0.0480	7			0.0080	7		
Lack of Fit	0.0353	3	3.71	0.1187	0.0044	3	1.62	0.3185
Pure error	0.0127	4			0.0036	4		
Total	8.53	16			0.5683	16		

Note: **: P<0.01 (indicates a highly significant effect); *: P<0.05 (indicates a significant effect); no symbol: *P*>0.05 (indicates not significant).

With the model significance guaranteed and the lack-of-fit terms confirmed to be non-significant, the non-significant terms for the response were eliminated, and the optimized regression equations for soil lifting quantity Y_1 and the coefficient of variation of soil lifting quantity Y_2 were obtained as follows:



$$Y_1 = 7.70 + 0.5150x_1 + 0.8263x_2 - 0.0788x_3 - 0.2300x_1x_2 + 0.2350x_1x_3 - 0.1125x_2x_3 + 0.2402x_2^2 + 0.1453x_3^2 \quad (6)$$

$$Y_2 = 1.49 + 0.1975x_1 - 0.0538x_2 - 0.1138x_3 - 0.1150x_1x_2 - 0.0700x_1x_3 - 0.0937x_1^2 + 0.0437x_3^2 \quad (7)$$

The results of analysis of variance (ANOVA) indicated that the coefficients of determination (R_1^2=0.9944, R_2^2=0.9860) and adjusted coefficients of determination (R_1^2adj=0.9871, R_2^2adj=0.9679) of the fitted models all approached 1.00, which demonstrated that the regression models possessed an extremely high fitting accuracy and strong correlation.

Interaction Analysis of the Regression Models

To investigate the effects of the interaction between the experimental factors on the soil lifting quantity Y_1 and its coefficient of variation Y_2, response surface analysis was performed on the ANOVA results of the optimization experiments via Design-Expert 12, as shown in Fig. 8.

(a) Effects of X_1 and X_2 on Y_1

(b) Effects of X_1 and X_3 on Y_1

(c) Effects of X_2 and X_3 on Y_1

(d) Effects of X_1 and X_2 on Y_2

(e) Effects of X_1 and X_3 on Y_2

(f) Effects of X_2 and X_3 on Y_2

Fig. 8 - Effects of the experimental factors on soil lifting quantity and its coefficient of variation

As shown in Fig. 8(a), Y_1 increased gradually with increasing rotational speed and increased sharply with increasing soil penetration depth, indicating that soil penetration depth had the greater effect. As shown in Fig. 8(b), Y_1 increased continuously with increasing rotational speed, while changes in pitch had only a slight effect, indicating that rotational speed was the more influential factor. As shown in Fig. 8(c), Y_1 increased markedly with increasing soil penetration depth and changed only slightly with pitch, confirming that soil penetration depth had the greater effect. As shown in Fig. 8(d), Y_2 increased sharply with increasing rotational speed but only gradually with increasing soil penetration depth, indicating that rotational speed had the stronger effect. As shown in Fig. 8(e), Y_2 increased rapidly with increasing rotational speed and remained nearly unchanged with changes in pitch, indicating that rotational speed was the dominant factor.

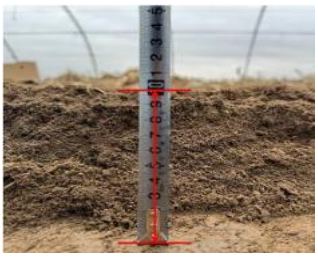
As shown in Fig. 8(f), Y_2 decreased gradually with increasing soil penetration depth and also decreased with increasing pitch, indicating that soil penetration depth had the greater influence. Overall, the response surface analysis indicates that the interaction between rotational speed and soil penetration depth has an important effect on soil lifting performance, which is consistent with the ANOVA results.

Optimal Parameter Combination

To ensure that the soil lifting quantity met the requirements of practical operation while maximizing the stability of the soil lifting process, the operating parameters were optimized. The optimal parameter combination was an auger rotational speed of 116 rpm, a soil penetration depth of 40 mm, and a pitch of 150 mm. Three repeated simulation validation tests were conducted, and the mean values were used to evaluate the optimization results. The resulting soil lifting quantity, Y_1, was 4.26 kg, and the coefficient of variation of soil lifting quantity, Y_2, was 1.50%. These values were in good agreement with the predicted optimization results.

FIELD TRIALS

Test Conditions



The field trials were conducted at the experimental field of Rongliang Ecological Agriculture Co., Ltd. in Heishan County. A laser tachometer was used to adjust the auger rotational speed, an electronic balance was used to measure the soil lifting quantity, and a tape measure was used to evaluate ridge flatness. The field test procedure is shown in Fig. 9(a).

(a) Soil Pickup Process

(b) Selection of Measurement Sections

(c)Surface Levelness Measurement

Fig. 9 - Field test

Test Methods and Content

The experimental design methodology and measurement procedures were based on the preceding simulation tests and relevant literature. To enhance the reliability of field trial data and comprehensively evaluate the performance of the soil pickup device, which the surface levelness Y_3 was measured. Manual measurement methods were employed, with a tape measure used to select one measurement section every 3 meters along the transplanted ridges. The vertical distance from the surface of randomly sampled points, which each measurement section to the reference plane was measured, it is shown in Figs. 9(b) and 9(c).

The primary evaluation metrics for the tests include soil lifting quantity, coefficient of variation for soil lifting quantity, and surface levelness. Each test group was replicated three times, with calculations performed according to Equations (8).

$$Y_3 = \sqrt{\frac{\sum_{j=1}^{n}(a_{kj}-a_k)^2}{n_k-1}} \tag{8}$$

where n_k represents number of test points in the k-th measurement; a_{kj} represents measure the vertical distance from the ground surface to the horizontal reference line before and after the k-th measurement at the j-th equidistant point, mm; a_k represents vertical distance from the ground surface to the horizontal reference line before and after the k-th soil pickup operation, mm; Y_3 represents surface levelness, mm.

Experimental Results and Analysis

Three suboptimal parameter combinations closely resembling the optimal operating parameter combination were selected from Table 5. Each combination underwent three replicate trials, with results averaged. The field trial outcomes are presented in Table 7.

Table 7

Field experiment results

Group Number	Rotational speed	Soil penetration depth	Pitch	Soil lifting quantity/ kg	Coefficient of variation of soil lifting quantity/ %	Surface levelness / mm
1	130	30	150	4.35	1.82	110
2	90	50	150	5.03	1.55	90
3	130	40	130	4.66	1.61	100
4	116	40	150	4.13	1.44	100

The field test results showed that, under the optimal operating parameter combination determined from the simulation, the soil lifting quantity, Y_1, was 4.13 kg and the coefficient of variation of soil lifting quantity, Y_2, was 1.44%. Compared with the simulation results, the relative errors were only 3.05% and 4.00%, respectively. Under the same parameter combination, the surface levelness, Y_3, was approximately 100 mm. The close agreement between the field test and simulation results verifies the accuracy and reliability of the numerical simulation model.

CONCLUSIONS

A soil pickup and separation device for an automatic flower transplanter was designed in this study. The structural parameters of the key components were determined, and the soil-conveying characteristics of the helical blades of the soil pickup auger were analyzed.

Through parameter optimization based on simulation, the optimal operating parameters were determined as follows: auger rotational speed of 116 rpm, soil penetration depth of 40 mm, and pitch of 150 mm. Under these conditions, the simulated soil lifting quantity, Y_1, was 4.26 kg, and the coefficient of variation of soil lifting quantity, Y_2, was 1.50%.

Field tests conducted under the optimal operating conditions yielded a soil lifting quantity of 4.13 kg and a coefficient of variation of 1.44%. The relative errors compared with the simulation results were 3.05% and 4.00%, respectively. The measured surface levelness, Y_3, was approximately 100 mm. The close agreement between the simulation and field test results indicates that the structural design and numerical model are reliable. The device can meet the soil-handling requirements of automatic flower transplanting operations and provides a basis for its further application in greenhouse production.

ABSTRACT

To prevent mechanical damage to tree trunks during cultivation of orchard inter-row and near-trunk areas, agrotechnical requirements prescribe leaving a certain uncultivated soil area around each trunk as a plant protection zone. When the working unit is periodically displaced relative to the tree-row axis by forced motion, an additional untreated soil area remains outside the plant protection zone. Its size is influenced by several factors, including the diameters of the rotary tiller and tree trunk, the lengths of the swing arm carrying the tiller and the sensing probe that actuates the hydraulic system, the tractor travel speed, and the piston-rod velocities of the hydraulic cylinder. Among these factors, the present study considers the principal kinematic factor: the influence of the backward motion of the hydraulic-cylinder piston rod toward the inter-row space and its forward motion toward the tree row, which provide and regulate the transverse displacement of the tiller relative to the tree-row axis, on the size of the untreated soil area. Using a grapho-analytical method for drive mechanism analysis, the equations of motion of the vertical-axis rotary tiller during tree-trunk bypass were derived for the backward motion of the hydraulic-cylinder piston toward the inter-row space and the forward motion toward the tree row. The resulting motion trajectories are cycloids. To characterize them, the concept of a bypass kinematic parameter was introduced: $\Lambda = V_c/V_m$, representing the ratio of the circumferential velocity of the tiller's transverse-radial motion to the tractor forward velocity. The size, shape, and position of the untreated soil area outside the plant protection zone relative to the tree trunk are determined by the value of the bypass kinematic parameter, which, for a given tractor speed, depends on the backward and forward velocities of the hydraulic-cylinder piston rod. It was established that, for given structural and kinematic parameters of the tillage machine, regulating the volume of oil supplied to the hydraulic cylinder makes it possible to minimize the untreated soil area outside the plant protection zone around the tree trunk.

INTRODUCTION

The technological process of soil cultivation in the near-trunk and inter-trunk zones of orchards plays an important role in increasing fruit yield, its primary objectives being weed control and loosening of the upper soil layers *(Cabrera-Pérez et al., 2022; Manzone et al., 2020; Hanson et al., 2016).*

Despite the existence of various weed-control methods — including thermal, chemical, laser, and other techniques — mechanical weed control remains the most widely applied approach at present. This method is environmentally friendly, sustainable, and effective; it improves soil aeration and increases crop productivity, which explains its widespread application in horticulture *(Morin, 2020; Gagliardi et al., 2023; Gagliardi et al., 2024; Zawada et al., 2023; Parasca et al., 2024; Liu et al., 2023; Pergher et al., 2019)*.

It should be noted that one of the most important agrotechnical requirements for mechanical orchard maintenance is to prevent damage to the tree trunk and root system by the working unit during near-trunk cultivation. In particular, the risk of uprooting the tree must be completely eliminated (*Manayenkon et al., 2017*). To meet this requirement, a prescribed uncultivated area is maintained around the tree trunk, referred to as the *plant protection zone* (Fig. 1).

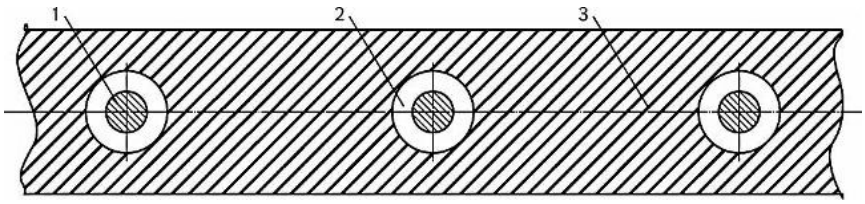

Fig. 1- Schematic representation of the inter-trunk and near-trunk cultivation areas in accordance with agrotechnical requirements

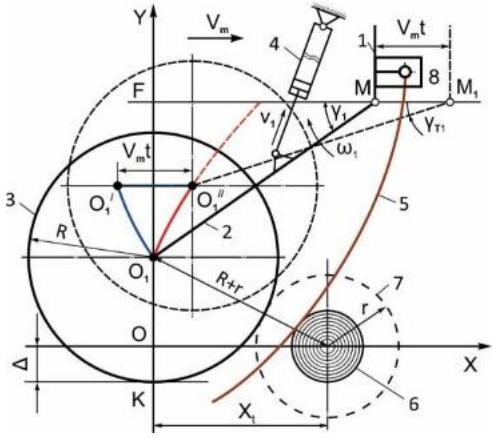
1- tree trunk, 2- plant protection zone, 3- cultivated area.

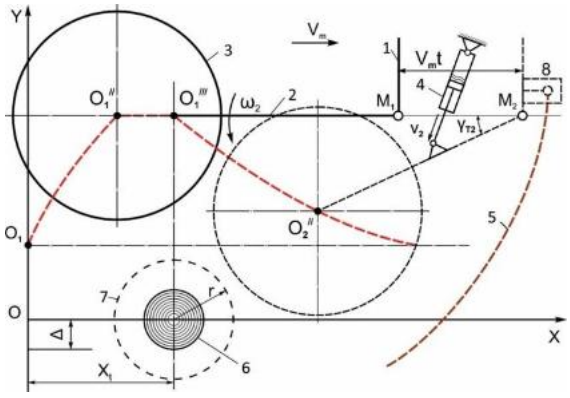
To implement the above-mentioned process, various types of tillage equipment operating on different principles may be used, including rotary tillers, harrows, sweep blades, and cultivators *(Kostandinov et al., 2016)*. Regardless of the tillage method and the type of technical equipment employed, the working units must be capable of performing periodic transverse displacements relative to the tree-row axis.

Among modern orchard tillage machines, rotary tiller units equipped with a turning section and a working body with a vertical axis of rotation have recently become widely used *(Rzaliev et al., 2025)*. As a rule, these machines cultivate both the inter-trunk and near-trunk zones in a single pass. Operational practice and experimental studies of currently used rotary tiller machines demonstrate that, during the cultivation of inter-trunk and near-trunk zones, an untreated soil area remains between the plant protection zone and the area cultivated by the working unit while bypassing the tree trunk *(Papyan & Harutyunyan, 2024; Inter-Row Machine, EP 3 824 708 A1, 2021; Wang et al., 2023)*.



The objective of this study is to determine a trajectory of rotary tiller motion during tree-trunk bypass that prevents the tiller from entering the plant protection zone while simultaneously ensuring a minimum distance between the tiller contour and the plant protection zone boundary. It is evident that such an approach will also ensure the minimum possible area of untreated soil remaining outside the plant protection zone.

MATERIALS AND METHODS



The object of the study was a rotary tiller machine with a vertical axis of rotation, intended for the cultivation of near-trunk and inter-trunk zones in intensive orchards and vineyards, was selected. Its structural and design schemes are presented in Fig. 2 a, b. According to the classification of automatic control systems, the machine may be categorized as an *astatic indirect-action system*, in which the automatic control system maintains the prescribed parameter independently of the magnitude of external disturbances. In the present case, there is no static correspondence between the mutual positions of the working unit and the sensing probe, while the extreme positions of the working unit are determined either by the full stroke of the hydraulic-cylinder piston or by external limiters.

The developed rotary tiller machine consists of a transverse frame (1), a swing arm rotating in the radial direction (2) mounted on the frame by means of a hinge joint, a rotary tiller with a vertical axis of rotation (3) fixed to the swing arm, a hydraulic cylinder (4) actuating the swing arm, the sensing probe (5) mounted on the frame, and an inductive sensor assembly (8).

The operating principle of the rotary tiller machine is as follows. Prior to contact with a tree trunk, the hydraulic cylinder (4) is in its extended (open) position, while the rotary tiller (3) mounted on the swing arm is located within the tree row. In order to ensure overlap between successive passes during field operation, the contour of the tiller is laterally offset from the tree-row axis by a value Δ (Fig. 2a,b).

a)

b)

Fig. 2- Schematics for deriving the equations of motion of the center of the vertical-axis rotary tiller during tree-trunk bypass:

a) backward motion of the hydraulic-cylinder piston; b) forward motion of the hydraulic-cylinder piston

The bypass of the tree trunk by the tiller is conventionally divided into two stages. Stage 1**:** from the moment the signal probe contacts the tree trunk until the end of contact and stage 2: after the probe–trunk contact is terminated, when the tiller, in the free state of the probe, returns again into the tree row. In the first stage, the signal probe (5), mounted on the frame (1), upon encountering the tree trunk (6), rotates and, via inductive sensors, transmits a signal to the electromagnetic hydraulic distributor. Due to the change in the position of the distributor spool, the direction of the oil flow supplied to the hydraulic cylinder is reversed. As a result, the piston of the hydraulic cylinder moves backward, and through the rotation of the swing arm about point M, the tiller is withdrawn from the tree row (Fig. 2a). In the second stage, when the contact between the probe and the tree trunk ceases, the probe returns to its initial position under the action of a spring. A reverse signal is transmitted from the inductive sensor to the hydraulic distributor, and the forward movement of the hydraulic-cylinder piston causes the tiller to re-enter the tree row (Fig. 2b).

During tree-trunk bypass, the turning section of the rotary tiller machine performs a complex motion, consisting of a rotation about point M with radius $L = |O_1M|$ and a translational motion with velocity V_m in the direction of tractor forward motion.

For deriving the equations of motion of the tiller center, the coordinate system is defined such that the X-axis is aligned with the longitudinal direction of the tree row, while the ordinate axis passes through the initial position of the tiller center O_1 .

During the withdrawal phase from the tree row (first stage), over a time interval t_1, the center O_1 of the tiller rotates about point M from its initial position by an angle of $\gamma_1 - \gamma_{т1}$. As a result, point O_1 moves to position O_1'. However, since during the same time interval t_1 the translational motion of the tractor with velocity V_m also occurs, point O_1' is further displaced by a distance $V_m t_1$ in the direction of motion, reaching position O_1'' . The coordinates of point O_1'' can be written as:

$$\begin{cases} x_1 = V_m t_1 + L(cos\gamma_1 - cos\gamma_{т1}) \\ y_1 = R - \Delta + L(sin\gamma_1 - sin\gamma_{т1}), \end{cases} \quad (1)$$

where:

V_m is the tractor forward (translational) velocity, $[m/s]$; t_1-is the time interval during which the tiller center O_1 rotates about point M through the angle $\gamma_1 - \gamma_{т1}$; $[s]$; γ_1-is the initial installation angle of the tiller relative to the direction of machine motion $(\angle O_1MF)$, $[deg]$; $\gamma_{т1}$ is the current bypass angle $(\angle O_1''M_1F)$, $\left(\gamma_{т1} \in [\gamma_1,\ 0]\middle|\begin{matrix}\gamma_{т1}^{max} = \gamma_1 \\ \gamma_{т1}^{min} = 0\end{matrix}\right)$, $[deg]$; L is the length of the swing arm of the tiller $(|O_1M|)$, $[m]$; R is the radius of the tiller, $[m]$; Δ is the overlap width/value between adjacent passes of the tiller, $[m]$.

At the end of the first stage of bypass, the position of the tiller relative to the tree trunk is determined by the length of the sensing probe. In the case of a long probe, the tiller begins entering the inter-tree zone relatively late, thereby increasing the area of untreated soil around the tree trunk. Conversely, if the probe is excessively short, the risk of the tiller entering the plant protection zone and damaging the tree trunks increases.

Assume that the first stage of tree-trunk bypass ends when the centers of the tiller and the tree trunk lie on the same line, i.e., when the contact between the tree trunk and the sensing probe terminates. This means that the extreme point of the probe will also be located on the line connecting the centers of the tree trunk and the tiller. Depending on the kinematic parameters of the technological process, situations may arise in which, after the tiller center O_1 has rotated through a prescribed angle about point M, contact between the probe and the tree trunk is still maintained. In this case, the tiller continues only its translational motion along the segment $|O_1''O_1'''||$ (Fig. 2b). Starting from point O$_1$"", the second stage of bypass begins through the forward motion of the hydraulic-cylinder piston, and the tiller is displaced back toward the tree row (Fig. 2b).

For the specified section, $|O_1'''O_2''|$, the equations of the tiller motion may be written in the following form:

$$\begin{cases} x_2 = x_1^{max} + V_m\ t_2 + L\left(cos_{\gamma_{т1}}^{min} - cos\gamma_{т2}\right) \\ y_2 = R - \Delta + L(sin\gamma_1 - sin\gamma_{т2}), \end{cases} \quad (2)$$

where: x_1^{max} is the abscissa of the tiller center at the end of the first stage of bypass, $[m]$; t_2 is the duration of the second stage of bypass, $[s]$; $\gamma_{т2}$ is the current bypass angle of the tiller during its motion toward the tree row $(\angle O_2''M_2F)$; $\left(\gamma_{т2} \in [0,\ \gamma_1,]\middle|\begin{matrix}\gamma_{т2}^{max} = \gamma_1 \\ \gamma_{т2}^{min} = 0\end{matrix}\right)$, $[deg]$;.

The actuation mechanism of the swing arm of the rotary tiller machine may be represented as a slotted-link mechanism with one degree of freedom, in which the rotation of the swing arm of length $L = |MO_1|$ about point M is determined by the variation of the distance $S = |DB|$ (forward and backward motions of the hydraulic-cylinder piston) *(Artobolevkiy, 1988; Smirnov, 2014)* (Fig. 3).

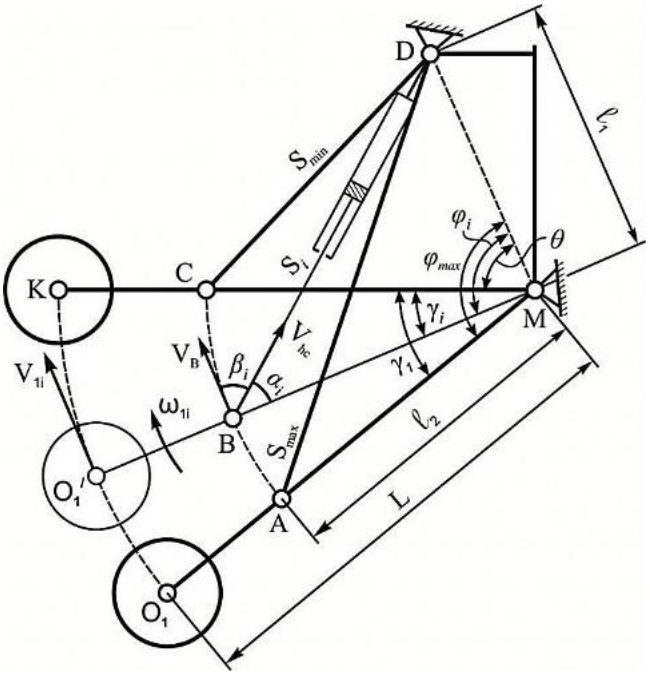


Fig. 3 - Scheme for determining the angular velocity of the swing arm

According to the scheme:

$$\gamma_i = \varphi_i - \theta, \tag{3}$$

where:

φ_i is the current angle formed between the swing arm and the line connecting the fixed kinematic pairs M and D, $(\angle AMD)$, $\left(\varphi_i \in [\varphi_{max}, \theta] \middle| \begin{matrix} \varphi_{max} = \gamma_1 + \theta \\ \varphi_{min} = \theta \end{matrix}\right)$, $[deg]$; θ is a structural parameter (constant geometric angle), $[deg]$.

The kinematic relationship between the rotation angle φ_i of the swing arm and the distance S_i may be expressed by the following equation for triangle (ΔDMB):

$$S_i^2 = l_1^2 + l_2^2 - 2l_1 l_2 cos\varphi_i, \tag{4}$$

from which:

$$\varphi_i = arccos\frac{l_1^2 + l_2^2 - S_i^2}{2l_1 l_2}, \tag{5}$$

where:

$S_i = S_{max(min)} \mp \Delta S$ - represents the current extension value of the hydraulic cylinder, $\left(S_i \in [S_{max},\ S_{min}] \middle| \begin{matrix} S_{max} = |AD| \\ S_{min} = |CD| \end{matrix}\right)$, $[m]$; $\Delta S = V \cdot t_i$- is the displacement of the hydraulic-cylinder piston per unit time, $[m]$; V is the velocity of the hydraulic-cylinder piston, $[m/s]$; l_1 is the length of the line connecting the fixed kinematic pairs M and D, $[m]$; l_2 is the distance from point M to point A, where the hydraulic cylinder is connected to the swing arm, $[m]$.

The angular velocity analogue of the swing arm is obtained by differentiating Eq. (5) with respect to S. Multiplying the resulting equation by the velocity of the driving link — namely, the hydraulic-cylinder piston velocity $\left(\frac{dS_i}{dt}\right)$, yields the angular velocity of the swing arm:

$$\omega_i = \frac{d\varphi_i}{dS} = \frac{S_i}{l_1 l_2} \cdot \frac{1}{\sqrt{1 - \left(\frac{l_1^2 + l_2^2 - S_i^2}{2 l_1 l_2}\right)^2}} \cdot \frac{dS_i}{dt}. \quad (6)$$

where:

ω_i is the angular velocity, [s^{-1}].

Because the backward velocity V_1 and the forward velocity V_2 of the hydraulic-cylinder piston are different, with $V_1 > V_2$, the angular velocities of the swing arm in the corresponding sections of motion also differ. Accordingly, for a swing arm of length $L = |MO_1|$, the angular velocities of the swing arm during the backward and forward motions of the hydraulic cylinder piston are given, respectively, by:

$$\omega_1 = \frac{S_{max} - \Delta S}{l_1 l_2} \cdot \frac{1}{\sqrt{1 - \left(\frac{l_1^2 + l_2^2 - (S_{max} - \Delta S)^2}{2 l_1 l_2}\right)^2}} \cdot \frac{d(S_{max} - \Delta S)}{dt} \quad (7)$$

$$\omega_2 = \frac{S_{min} + \Delta S}{l_1 l_2} \cdot \frac{1}{\sqrt{1 - \left(\frac{l_1^2 + l_2^2 - (S_{max} + \Delta S)}{2 l_1 l_2}\right)^2}} \cdot \frac{d(S_{min} + \Delta S)}{dt}, \quad (8)$$

where:

$V_1 = \frac{d(S_{max} - \Delta S)}{dt}$ is the backward velocity of the piston, $[m/s]$; $V_2 = \frac{d(S_{min} + \Delta S)}{dt}$ is the forward velocity of the piston, $[m/s]$.

Knowing the angular velocities of the swing arm in the corresponding sections, the respective circumferential velocities of the tiller center may be determined:

$$V_1 = L \cdot \omega_1 \quad (9)$$

$$V_2 = L \cdot \omega_2. \quad (10)$$

The backward and forward velocities of the hydraulic-cylinder piston are also determined by the following equation:

$$v_{1(2)} = \frac{Q \cdot \mu}{F_{1(2)} \cdot 60 \cdot 1000}, \quad (11)$$

where:

$F_{1(2)}$ are the effective piston areas in the rod-side and piston-side chambers of the hydraulic cylinder $[m^2]$; μ is the efficiency coefficient of the hydraulic system, $\mu = 0{,}85 - 0{,}95$.

The effective piston areas on the rod side and piston side of the hydraulic cylinder are, respectively:

$$F_1 = \pi \frac{(D^2 - d^2)}{4}, \quad F_2 = \pi \frac{D^2}{4},$$

where: D is the piston diameter, and d is the piston-rod diameter, $[m]$.

The objective of the study is to determine the optimal relationship between the tractor forward velocity and the circumferential velocity of the swing arm rotating about point M, such that the untreated soil area remaining outside the plant protection zone around the tree trunk is minimized.

RESULTS AND ANALYSIS

The ratio of the circumferential velocity of the tiller center about point M, i.e., the swing-arm mounting point, to the tractor forward velocity is defined as the *bypass kinematic parameter* and expressed as:

$$\Lambda_i = V_i / V_m, \tag{12}$$

where:

$V_i = L\omega_i$ is the circumferential velocity of the tiller center about point M (ω_i is the angular velocity of the swing arm).

During the first stage of tree-trunk bypass, corresponding to the backward motion of the hydraulic-cylinder piston, the angular velocity of the tiller center about point M is $\omega_1 = \frac{|\gamma_1 - \gamma_{T1}|}{t_1}$, whereas during the motion of the tiller toward the tree row, corresponding to the forward motion of the hydraulic-cylinder piston, the angular velocity is $\omega_2 = \frac{|\gamma_{T1}^{min} - \gamma_{T2}|}{t_2}$. These angular velocities may also be determined from Eqs (7) and (8). Substituting the relation $\Lambda = V_c / V_m$ into Eqs. (1) and (2), and taking into account that $V_c = \omega \cdot L$, the equations of motion of the tiller center O_1 for the backward and forward motions of the hydraulic-cylinder piston take the following form:

For the backward motion of the piston:

$$\begin{cases} x_2 = x_1^{max} + L\left(\dfrac{\left|\gamma_{T1}^{min} - \gamma_{T2}\right|}{\Lambda_2} + cos\gamma_{T1}^{min} - cos\gamma_{T2}\right) \\ y_2 = R - \Delta + L(sin\gamma_1 - sin\gamma_{T2}), \end{cases} \tag{13}$$

For the forward motion of the piston:

$$\begin{cases} x_2 = x_1^{max} + L\left(\dfrac{\left|\gamma_{T1}^{min} - \gamma_{T2}\right|}{\Lambda_2} + cos\gamma_{T1}^{min} - cos\gamma_{T2}\right) \\ y_2 = R - \Delta + L(sin\gamma_1 - sin\gamma_{T2}), \end{cases} \tag{14}$$

where:

$\Lambda_1 = \frac{\omega_1 t_1}{V_m}$ is the bypass kinematic parameter during the first stage of tree-trunk bypass (backward motion of the hydraulic-cylinder piston); $\Lambda_2 = \frac{\omega_2 t_2}{V_m}$ is the bypass kinematic parameter during the second stage of tree-trunk bypass (forward motion of the hydraulic-cylinder piston); x_1^{max} is the abscissa corresponding to the centers of the tiller and the tree trunk at the end of the first stage of bypass.

It is evident that the angles $|\gamma_1 - \gamma_{T1}|$ and $\left|\gamma_{T1}^{min} - \gamma_{T2}\right|$ vary over equal intervals, but at different rates, which is due to the difference between the forward and backward velocities of the hydraulic cylinder piston; specifically, the forward velocity is lower than the backward velocity.

From the equation defining the bypass kinematic parameter $\Lambda = V_c / V_m$, it follows that, at a constant tractor forward velocity, its value depends on the circumferential velocity of the rotary tiller's center relative to point *M*. This velocity, in turn, depends on the forward and backward velocities of the hydraulic-cylinder piston.

Since the piston velocities differ during the forward and backward motions of the hydraulic cylinder, the values of the bypass kinematic parameter also differ along the corresponding sections of the tree trunk bypass trajectory; moreover, $\Lambda_s < \Lambda_b$.

In order to prevent the rotary tiller from entering the plant protection zone and damaging the tree trunk and root system, it is necessary that the distance from any point of the tiller center trajectory to the center of the tree trunk be greater than or equal to the sum of the radii of the tiller and the plant protection zone: $R + r$ (Fig. 2).

Thus, for the trajectory section corresponding to the first stage of tree trunk bypass, Eq. (15) can be written as follows:

$$\sqrt{(x_1 - x_t)^2 + y_1^2} \geq R + r, \tag{15}$$

Similarly, for the trajectory section corresponding to the second stage of tree-trunk bypass, Eq. (16) can be written as follows:

$$\sqrt{(x_2 - x_t)^2 + y_2^2} \geq R + r, \tag{16}$$

where:

x_1 and y_1 are the current coordinates of the rotary tiller center during the first stage of bypassing; x_2 and y_2 are the current coordinates of the tiller's center during the second stage of bypassing; $x_t = \sqrt{2R(r+\Delta)}$ is the abscissa of the tree trunk center (Fig. 2a).

The problem is analyzed for a specific set of geometric and kinematic parameters of the rotary tiller.

Consider the kinematics of a rotary tiller with a vertical axis of rotation, equipped with rotary tiller of diameter $D = 0{,}35$ m and a swing arm length $L = 0{,}38$ m during tree trunk bypassing.

It is assumed that the tractor forward travel speed is $V_m = 0{,}75$ m/s, the overlap between adjacent passes of the rotary tiller is $\Delta = 0{,}05$ m, and the angular position of the tiller relative to the direction of the aggregate motion is $(\angle O_1MF)$ $\gamma_1 = 35^0$ (Fig. 2a). Therefore, during the first stage of tree-trunk bypass, the angle of rotation of the rotary tiller about point M varies from 35^0 to 0^0, while during the second stage, when returning to the tree row, it varies from $0^0$to 35^0. The maximum displacement of the rotary tiller center along the ordinate axis from the initial position is determined as $|O_1F| = |O_1M| \cdot sin\gamma_1 = 0{,}38 \cdot sin35 \approx 0{,}22$ m (Fig. 2a). The length of the line connecting the fixed kinematic pairs M and D is $l_1 = 0{,}3$ m, while the distance from point M to point A, where the hydraulic cylinder is connected to the swing arm, is $l_2 = 0{,}35$ m (Fig. 3).

The rotation angle of the sensing probe is adjusted so that the inductive sensors generate a signal for the backward motion of the hydraulic cylinder when the distance between the rotary tiller contour and the probe becomes equal to the width of the plant protection zone, i.e., 0.05 m.

To actuate the swing arm, a hydraulic cylinder of type 40-25-160 is selected, with the following principal parameters: piston diameter: $D = 0{,}04$ m, piston rod diameter: $d = 0{,}025$ m, stroke length: $h = 0{,}16$ m, $S_{max} = 0{,}51$ m, $S_{min} = 0{,}35$ m.

Table 1 presents the variation ranges of the swing-arm angular velocities calculated using Eqs. (7) and (8), the circumferential velocities of the rotary tiller center calculated using Eq. (9), and the bypass kinematic parameter calculated using Eq. (11), for the forward and backward motions of the hydraulic cylinder at different volumetric flow rates of oil supplied to the cylinder.

Table 1

Values of the rotary tiller center velocity and bypass kinematic parameter at different hydraulic oil flow rates ($V_m = 0,75$ m/s)

Oil flow rate, Q, L/min	Swing arm angular velocity, s^{-1}		Circumferential velocity of the rotary tiller center, m/s		Bypass kinematic parameter, Λ	
	Backward motion, ω_1 (7)	Forward motion, ω_2 (8)	Backward motion, V_1 (9)	Forward motion, V_2 (10)	Backward motion, Λ_1 (12)	Forward motion, Λ_2 (12)
10	1.025-0.76	0.46-0.63	0.39-0.29	0.17-0.24	0.52-0.38	0.23-0.32
15	1.54-1.14	0.7-0.94	0.58-0.43	0.27-0.36	0.77-0.57	0.36-0.48
20	2.05-1.51	0.93-1.26	0.78-0.57	0.35-0.48	1.04-0.76	0.47-0.64
30	3.08-2.28	1.39-1.89	1.17-0.87	0.53-0.72	1.56-1.16	0.7-0.96
40	4.1-3.03	1.86-2.51	1.56-1.15	0.71-0.95	2.08-1.53	0.94-1.28
50	5.13-3.8	2.3-3.14	1.95-1.44	0.87-1.19	2.6-1.92	1.16-1.61

Based on the system of Eqs. (13) and (14), as well as the data presented in Table 1, the trajectories of motion of the rotary tiller center were plotted for different values of the hydraulic oil flow rate supplied to the hydraulic cylinder and for different values of the bypass kinematic parameter (Fig. 4).

Among the trajectories shown in Fig. 4, the optimal one should be considered the trajectory in which the edge of the rotary tiller moves at the minimum possible distance from the plant protection zone, while simultaneously satisfying conditions (15) and (16). It is evident that, in this case, the uncultivated area outside the plant protection zone will also be minimal.

Fig. 5 shows the variation in the distance between the centers of the rotary tiller and the tree trunk as a function of the bypass kinematic parameter.

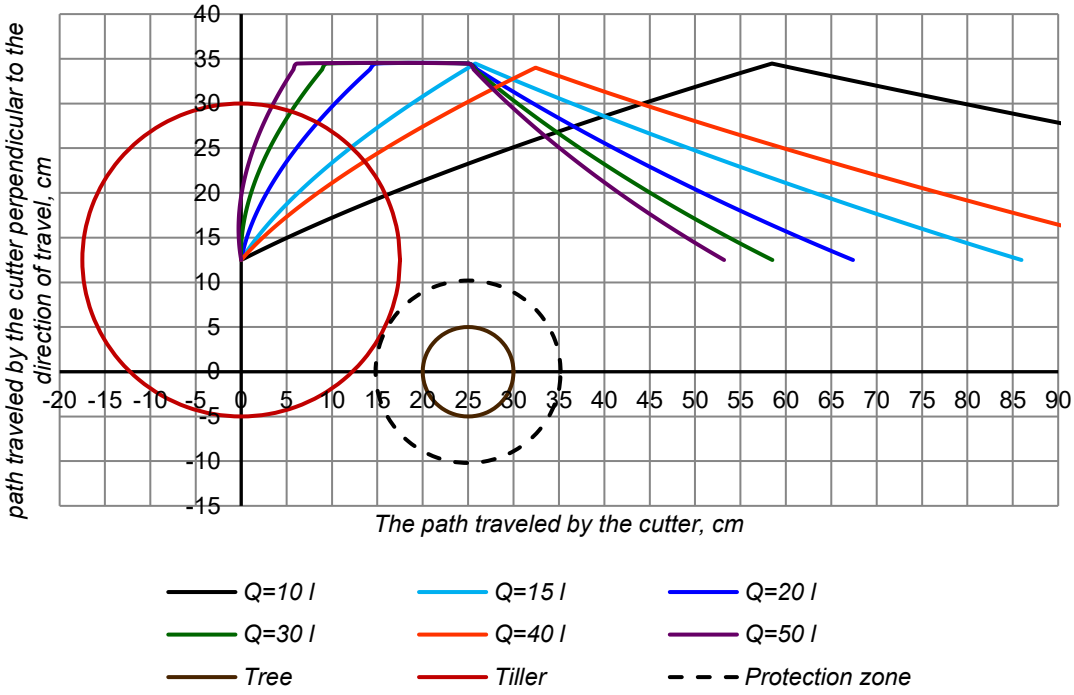

Fig. 4 - Trajectories of the rotary tiller center at different hydraulic oil flow rates, *Q*, and corresponding values of the bypass kinematic parameter, *Λ*

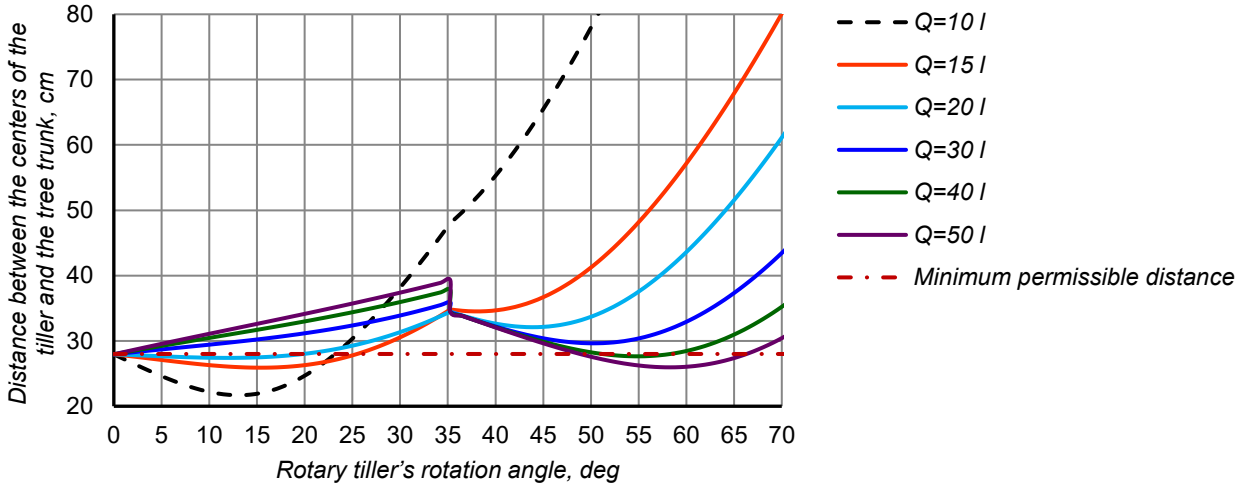

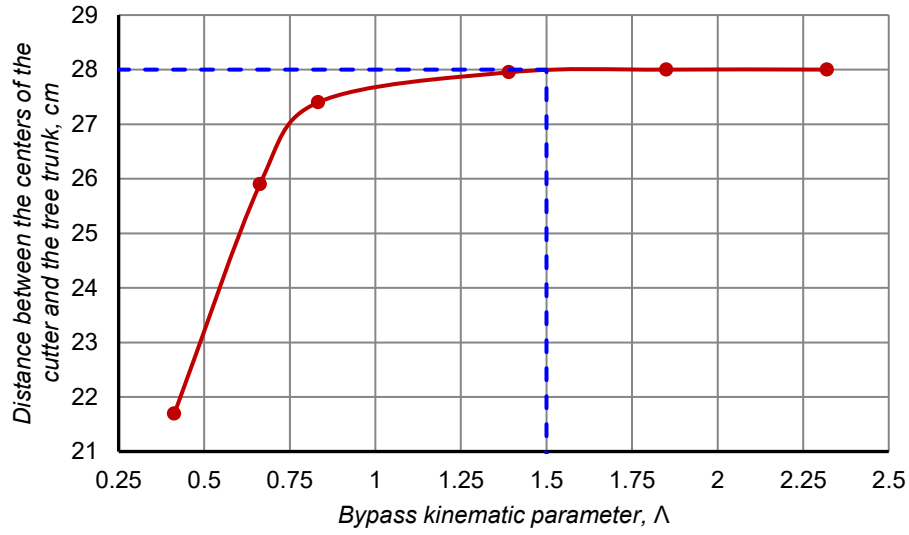

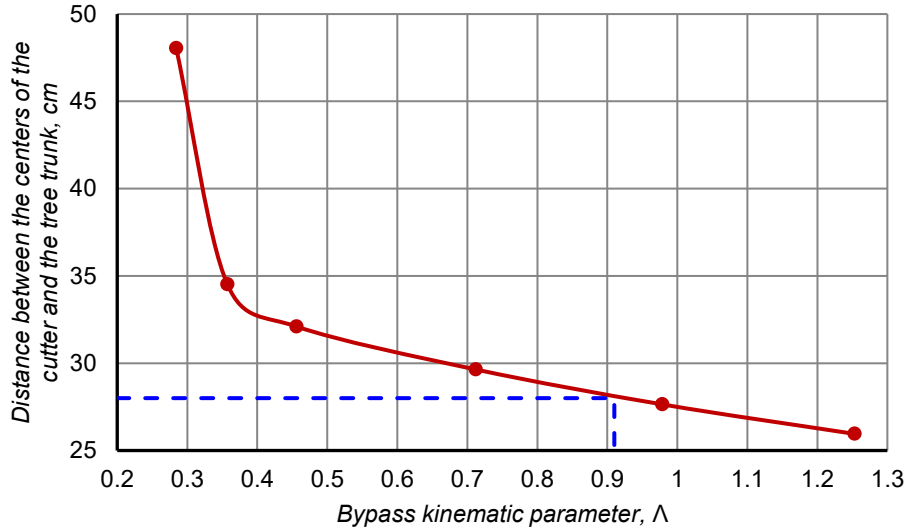

Fig. 5 - Variation in the distance between the centers of the rotary tiller and the tree trunk s a function of the bypass kinematic parameter

The graphs in Figs. 6a and 6b show the variation of the minimum values of the distance between the centers of the rotary tiller and the tree trunk during the first and second stages of tree trunk bypassing, respectively, for different values of the bypass kinematic parameter.

a)

b)

Fig. 6 - Variation in the minimum distance between the centers of the rotary tiller and the tree trunk for different values of the bypass kinematic parameter:
a) first stage, b) second stage

Analysis of the plotted trajectories shows that, during the first stage of tree trunk bypassing, the optimal value of the bypass kinematic parameter is $\Lambda_1 = 1{,}5$, while during the second stage the optimal value is $\Lambda_2 = 0{,}91$.

When selecting the hydraulic system parameters, the value of Λ_2, corresponding to the second stage of tree trunk bypassing, should be taken as the reference, from which the corresponding value of Λ_1 for the first stage is obtained.

In the example considered, the optimal value for the second stage is $\Lambda_2 = 0{,}91$, which corresponds to $\Lambda_1 = 1{,}16$ for the first stage. Therefore, for a machine travel speed of $V_m = 0{,}75$ m/s and the selected hydraulic cylinder of type 40-25-160 the specified values of the bypass kinematic parameters are achieved at a hydraulic oil flow rate of approximately $Q \approx 30$ l/min in the hydraulic cylinder (Table 1).

CONCLUSIONS

The study showed that, for automatically controlled working units operating on an astatic principle during cultivation of near-trunk and inter-trunk areas in vineyards and intensive orchards, the kinematic parameter based solely on the circumferential velocity of the rotary tiller is insufficient to determine the optimal tiller trajectory and minimize the untreated soil area outside the plant protection zone around tree trunks. Therefore, to more adequately characterize the rotary bypass motion, the concept of the *bypass kinematic parameter* was introduced. The analysis showed that this parameter more accurately reflects the kinematic characteristics of the rotary tiller during tree-trunk bypass.

It was established that, for given agrotechnical requirements, operating conditions, and known structural parameters of the machine, regulation of the hydraulic oil flow rate supplied to the hydraulic cylinder makes it possible to vary the forward and backward velocities of the piston and, consequently, the values of the bypass kinematic parameter. In this way, a tree-trunk bypass trajectory can be obtained that minimizes the untreated soil area outside the plant protection zone.

Keywords: *biomimetic tobacco planter; penetration resistance; soil adhesion; discrete element method; Box–Behnken design*

ABSTRACT
To address the high penetration resistance and severe soil adhesion of tobacco planting devices operating in wet, clayey soil, a biomimetic planting device was designed using a Gaussian multi-peak function and characteristic curves derived from multiple bird beaks. The peak parameters, including height, position, and width, were optimized using discrete element method (DEM) simulations and response surface methodology. The resulting biomimetic profile reduced penetration resistance and soil adhesion, thereby improving tobacco transplanting performance. The optimized prototype exhibited a penetration resistance of 18.7 N and an adhered soil mass of 14.98 g, representing reductions of 60.47% and 40.56%, respectively, compared with the conventional prototype.

摘要
为解决烟草栽植器在湿黏土壤中阻力大、粘附严重的问题，本文基于高斯多峰函数融合多种鸟喙特征曲线，研制了一款仿生栽植器。结合离散元 (DEM) 仿真，利用响应面法优化了波峰参数（高度、位置和宽度）。该仿生曲线可以有效降低了渗透阻力、改善了土壤附着力，并提升了烟草移栽性能。优化后样机穿透阻力为 18.7 N，黏附质量为 14.98 g，相比于传统样机，分别减少了 60.47% 和 40.56%。

INTRODUCTION
Mechanized tobacco transplanting is strongly influenced by the interaction between the planter and the soil environment. As the primary soil-engaging component, the planter repeatedly penetrates the soil and plastic mulch during transplanting operations. Under wet and cohesive clay conditions, this repeated penetration may generate considerable penetration resistance and severe soil adhesion on the planter surface (*Obour et al., 2019; Xu et al., 2024*). These problems not only increase operational resistance and accelerate the wear of soil-engaging components, but may also adversely affect transplanting quality by causing excessive mulch damage, irregular planting holes, and seedling displacement. Therefore, reducing penetration resistance and soil adhesion is essential for improving the operational performance and reliability of tobacco planting equipment.

Biomimetic design has been increasingly applied to agricultural soil-engaging components by transferring the functional geometric or surface characteristics of biological organisms to engineering structures. Existing biomimetic approaches can generally be divided into two categories: surface microstructure modification and macroscopic contour optimization. Surface-based biomimetic designs typically reproduce the non-smooth or low-adhesion characteristics of biological surfaces. *Tong et al.* investigated the geometric features and wettability of dung beetle cuticles and demonstrated their potential for reducing soil adhesion on tillage implements (*Tong et al., 2005*). *Chen et al.* developed a pangolin-inspired concave microstructure that disrupted the interfacial water film and reduced the jacking force by 18.7% (*Chen et al., 2020*). *El Salem et al* verified that convex bionic surface configurations can break the continuity of soil-tool interfacial water films, decrease the actual contact area between soil and metal matrix, and achieve favorable anti-adhesion performance within viscous wet clay environments (*El Salem et al., 2023*).

Sheng Ding, M.S. Stud. Eng; Ao Shan, M.S. Stud.Eng; Chencan Xiao, M.S. Stud. Eng; Qing Jiang, Prof. Ph.D. Eng.

Similar discontinuous surface structures have also shown potential for reducing tillage resistance and soil adhesion under wet and cohesive soil conditions (*Niu et al., 2022; Zhang et al., 2025*).

In contrast, macroscopic contour optimization focuses on extracting and reproducing characteristic geometries from biological digging, burrowing, or penetrating organs. *Liu et al.* combined the morphological characteristics of the oriental mole cricket foreleg with soil mechanics to improve the digging performance of a cassava harvester (*Liu et al., 2014*). *Li et al. (2026)* investigated the soil burrowing mechanism of earthworms and *Liu et al. (2023)* developed a biomimetic furrow opener based on the head contour of an earthworm, whereas *Wu et al. (2021)* established a biomimetic mathematical model for subsoiling components based on biological geometric characteristics. These studies demonstrated that biomimetic contour optimization can effectively modify soil–tool interaction and reduce soil-engaging resistance. More recently, composite biomimetic strategies have been explored by combining different biological characteristics. *Guan et al. (2022*) integrated biological morphology with hydrophobic surface modification, while *Liu et al. (2024)* combined earthworm- and pangolin-inspired characteristics to reduce soil contact and adhesion.

Despite these advances, most existing biomimetic soil-engaging components are still based on simplified representations of a single biological feature (*Lei et al., 2024; Li et al., 2016; Lin et al., 2025; Sun et al., 2020; Wang et al., 2025*). Such single-feature designs may not fully satisfy the simultaneous requirements of low penetration resistance and reduced soil adhesion under the repeated dynamic penetration conditions encountered during tobacco transplanting. In addition, a unified mathematical framework capable of integrating complementary geometric characteristics from multiple biological prototypes into a continuously adjustable and optimizable contour remains insufficiently developed. Therefore, a multi-source biomimetic design method is needed to systematically combine different morphological characteristics and quantitatively optimize the resulting planter geometry.

To address this limitation, this study proposes a Gaussian multi-peak biomimetic design method for tobacco planters by integrating the characteristic beak contours of four bird species: the Common Kingfisher, Common Quail, Water Rail, and Common Ostrich. These biological prototypes were selected because they exhibit distinctly different beak geometries, including slender, short and robust, decurved, and broad profiles. The extracted contours were represented using a unified Gaussian multi-peak function, which enabled continuous and quantitative adjustment of peak height, peak position, and peak width. A Plackett–Burman screening design and a Box–Behnken response surface methodology were combined with discrete element method (DEM) simulations to identify the key geometric parameters and optimize the planter with respect to penetration resistance and soil adhesion. Furthermore, soil-particle velocity fields and disturbance characteristics were analyzed to investigate the mechanisms by which the optimized multi-peak contour promotes lateral soil diversion, tangential particle motion, and reduction of the frontal compression zone. The results provide a theoretical and methodological basis for designing tobacco planting components with reduced penetration resistance and improved anti-adhesion performance.

MATERIALS AND METHODS

Bionic Design

To address the high penetration resistance and severe soil adhesion encountered by tobacco planters during high-speed and repeated penetration into wet and cohesive soil, four bird species with distinctly different beak morphologies were selected as biological prototypes: the Common Kingfisher (S1), Common Quail (S2), Water Rail (S3), and Common Ostrich (S4), as shown in Fig. 1. The Common Kingfisher has a slender and approximately conical beak with a relatively small tip angle and a smooth longitudinal profile *(Crandell et al., 2019*). The Common Quail has a shorter and more robust beak with concentrated curvature variation near the anterior region (*Zhang X.Y. et al., 2021*). The Water Rail has a slender and moderately decurved beak *(Bouzid et al., 2023*), whereas the Common Ostrich has a broader profile with a comparatively large obtuse tip angle (*Zhang R. et al., 2021*). These four beak geometries represent different morphological characteristics and provide a diverse geometric basis for multi-source biomimetic contour integration and subsequent parametric optimization.

The bird images used for contour extraction were obtained from publicly available online sources, with an approximate original resolution of 1200 × 800 pixels. Original camera and lens metadata were not available because the images were obtained from public online sources. Therefore, image selection was controlled by lateral-view orientation, clear beak boundaries, and the absence of obvious perspective distortion. To ensure reliable contour extraction, only images showing the beak approximately in lateral view, with clear and unobstructed boundaries and no obvious perspective distortion, were selected.

Because this study focused on normalized geometric profiles rather than absolute biological dimensions, all extracted coordinates were normalized to a dimensionless scale before curve fitting to minimize the effects of differences in image scale.

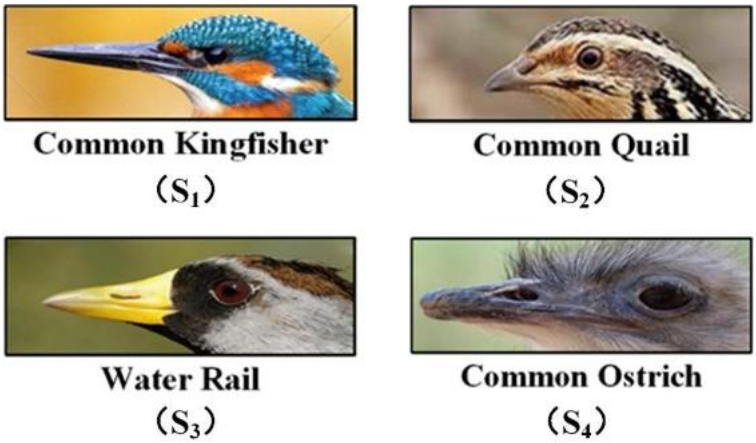

Fig. 1 - Images of the bionic prototypes for the selected bird beaks

The beak-contour extraction procedure is illustrated in Fig. 2. Image processing was performed using MATLAB R2023b (MathWorks, Natick, MA, USA). Grayscale conversion, Otsu thresholding, Canny edge detection, and contour-coordinate extraction were successively conducted. The extracted upper-beak contour was then resampled into 100 equally spaced points along the arc length for subsequent dimensionless normalization and Gaussian multi-peak fitting. The extracted contours were then corrected by affine transformation so that the beak tip coincided with the coordinate origin and the principal longitudinal axis was aligned with the horizontal axis. The normalization equations were:

$$x^* = \frac{x - x_{min}}{x_{max} - x_{\min}}, y^* = \frac{y - y_{\min}}{y_{max} - y_{\min}} \quad (1)$$

x and y are the original contour coordinates; x_{min} and x_{max} are the minimum and maximum values of the x-coordinates, respectively; y_{min} and y_{max} are the minimum and maximum values of the y-coordinates, respectively; and x^* and y^* are the normalized dimensionless coordinates.

To achieve a unified parametric representation of the different bird-beak contours, a Gaussian multi-peak function was used to fit the normalized contour data:

$$f(x) = \sum_{i=1}^{n} a_i e^{-\left(\frac{x-b_i}{c_i}\right)^2} \quad (2)$$

where: $f(x)$ is the fitted value at position x; n is the total number of Gaussian terms; i denotes the current Gaussian component; and a_i, b_i, and c_i represent the peak height, peak position, and peak width of the i -th Gaussian component, respectively.

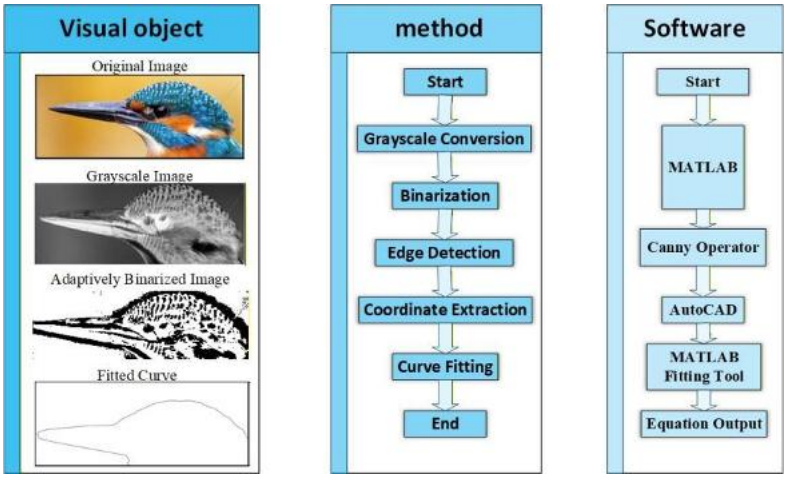

Fig. 2 - Flowchart of image processing and contour extraction

The Gaussian multi-peak function was selected because it can flexibly describe complex biological contours using a limited number of independent parameters, while each parameter has an explicit geometric meaning that allows complex beak morphologies to be converted into continuous, adjustable, and quantifiable engineering design variables. In addition, this parametric representation facilitates subsequent Plackett–Burman screening and Box–Behnken response-surface optimization, thereby reducing the dimensionality of the optimization problem and improving computational efficiency.

The goodness of fit was evaluated using both the coefficient of determination (R^2) and the root mean square error ($RMSE$), calculated as:

$$RMSE = \sqrt{\frac{1}{N}\sum_{j=1}^{N}\left(y_j - \hat{y}_j\right)^2} \quad (3)$$

where:

N is the number of sampled contour points; y_j is the actual normalized contour coordinate of the j-th sampling point; and $\hat{y}_j$ is the corresponding fitted value. The Gaussian multi-peak parameters and fitting evaluation indices of the four bird-beak contours are summarized in Table 1. The R^2 values ranged from 0.9506 to 0.9908, while the $RMSE$ values ranged from 0.0192 to 0.0445, indicating that the Gaussian multi-peak function adequately represented the principal geometric characteristics of the four bird-beak contours.

Table 1

Bionic planter curve parameters

Coefficient	Beak ID

Structural Design

The planter is the main soil-engaging component in tobacco transplanting and adopts a symmetrical double-valve structure to perform hole formation and seedling release simultaneously. The overall structure is shown in Fig. 3. Its motion is controlled by a linkage mechanism consisting of a pull rod, a rotating shaft, and two movable plates. During the downward stroke, the external driving mechanism actuates the pull rod, causing the two movable plates to rotate outward around the shaft and open the duckbill at the predetermined depth. During the return stroke, the assembly returns to its initial position under the combined effects of the return spring and gravity, preparing for the next working cycle.

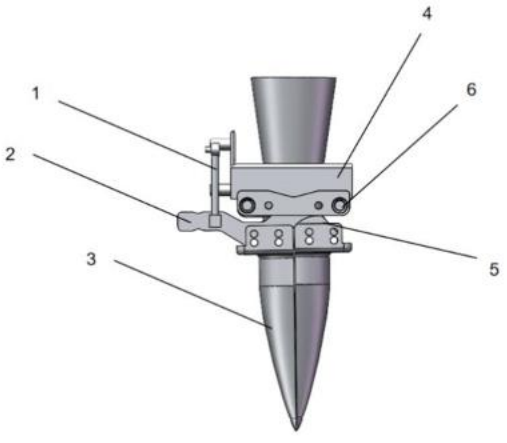

Fig. 3 - Overall structure diagram of the bionic planter

(1) Pull rod (2) Movable plate I (3) Planter (4) Planter bracket (5) Movable plate II; (6) Rotating shaft

The three-dimensional model of the planter was developed using SolidWorks 2024. The main body was designed using 304 stainless steel and was intended for fabrication by metal additive manufacturing. The planter geometry was exported from SolidWorks 2024 as a binary STL surface model and imported into EDEM. A custom STL export resolution was used, with the unit set to millimeters, a surface deviation tolerance of 0.154 mm, and an angular tolerance of 10°. The overall dimensions of the planter were 110 mm × 250 mm × 100 mm, with a wall thickness of 2 mm. The calculated mass based on the CAD model was 0.676 kg, and a nominal dimensional tolerance of ±0.5 mm was specified in the design.

The internal cavity of the planter was dimensioned to ensure compatibility with seedlings cultivated in standard 128-cell plug trays. The seedling plug had an upper diameter of 30 mm, a lower diameter of 10 mm, and a height of 40 mm, as shown in Fig. 4(a). For the subsequent discrete element simulation, the complex morphology of the actual tobacco seedling was simplified and represented by a regular geometric model to establish the internal geometric boundary of the planter, as shown in Fig. 4(b). This simplification reduced the computational complexity associated with complex leaves, stems, and irregular plug geometry. Since the present study mainly focused on the interaction between the external planter surface and wet cohesive soil, particularly the maximum penetration resistance and soil adhesion mass, the detailed morphology of the actual seedling was not explicitly modeled. However, this simplification may neglect local contact and posture variations between the actual seedling and the inner wall of the planter. No separate sensitivity analysis was conducted for the simplified seedling geometry; therefore, its influence on simulation accuracy was not quantitatively assessed. The proposed design was intended to address two major constraints associated with the regional soil conditions: the strong interfacial adhesion of high-moisture clay, which causes severe soil adhesion and accumulation on the planter surface, and the high penetration resistance generated by compacted soil. Typical field soil conditions are shown in Fig. 5. Therefore, the integration of multiple bird-beak characteristic curves into the planter design is intended to reduce soil adhesion and penetration resistance.

Fig. 5 - Field soil exhibiting high penetration resistance and strong adhesion

Experimental Design

To identify the main factors controlling the soil-engaging performance of the planter, the experimental design was conducted in two stages.

First, a Plackett–Burman (PB) screening design was used to evaluate the six morphological parameters (a_1, b_1, c_1, a_2, b_2, and c_2) and identify the factors influencing the maximum penetration resistance (Y_1) and soil adhesion mass (Y_2). These six parameters were derived from the two-term Gaussian multi-peak function, in which each Gaussian term was defined by three independent parameters corresponding to peak height, peak position, and peak width. Therefore, the six parameters jointly characterized the complete geometry of the biomimetic contour.

The maximum penetration resistance (Y_1) was selected to characterize the mechanical resistance encountered by the planter during soil penetration and was closely related to operational energy consumption. The soil adhesion mass (Y_2) was used to quantify the amount of wet cohesive soil retained on the planter surface, which may affect the continuous operating performance of the planter.

The factor levels, configured as high (+1) and low (-1) levels, were determined according to the geometric parameter ranges extracted from the four bird-beak prototypes, thereby ensuring that the investigated design space had a clear biological basis. The factor levels are given in Table 2.

Second, based on the PB screening results, the three factors exerting the greatest influence on soil-engaging performance were selected for further analysis of interaction effects and parameter optimization using a three-factor, three-level Box–Behnken design (BBD), with coded levels of -1, 0, and +1. For three factors, the standard BBD consisted of 12 factorial combination points and five center-point runs, resulting in a total of 17 experimental runs. All design points were simulated under identical numerical settings. The five center-point runs were used to estimate the pure error and evaluate the numerical repeatability of the response surface model.

Table 2

Factors and levels of the Plackett-Burman experimental design

Factor	Low level (-1)	High level (+1)
a_1	0.9486	0.9894
b_1	0.8856	0.9900
c_1	0.3577	0.4189
a_2	0.3034	0.4918
b_2	0.2378	0.3532
c_2	0.1322	0.1861

The interaction dynamics of these experimental runs were simulated using EDEM 2024 software. The Hertz-Mindlin with JKR cohesion contact model was used to represent the cohesive behavior and interfacial adhesion characteristics of wet cohesive clay.

The soil particles were represented by three types of particle aggregates, namely single-sphere, double-sphere, and triple-sphere particles, with particle sizes ranging from 1.5 to 3.0 mm. The proportions of single-sphere, double-sphere, and triple-sphere particles were 60%, 25%, and 15%, respectively, and a total of 100,000 particles were generated in the soil bin.

The particles were generated, allowed to settle under gravity, and then statically compacted using a flat compaction plate to reproduce natural field soil conditions. The penetration simulation was started after the compacted soil bed became stable, as indicated by a low and nearly constant total kinetic energy and no obvious change in bed height. The planter material was modeled as 304 stainless steel.

The setup of the simulation model is shown in Fig. 6, and the complete list of the intrinsic and contact mechanics parameters is given in Table 3.

The Euler integration scheme was adopted, with a fixed time step of 6.47855×10^{-5} s, corresponding to 20% of the Rayleigh time step. The total simulation time was 2.5 s, and simulation data were saved at intervals of 0.001 s. The simulations were performed using the CPU solver with 12 CPU cores. All simulations were conducted on a workstation equipped with a 12th Gen Intel Core i5-12400F processor and 32 GB of RAM.

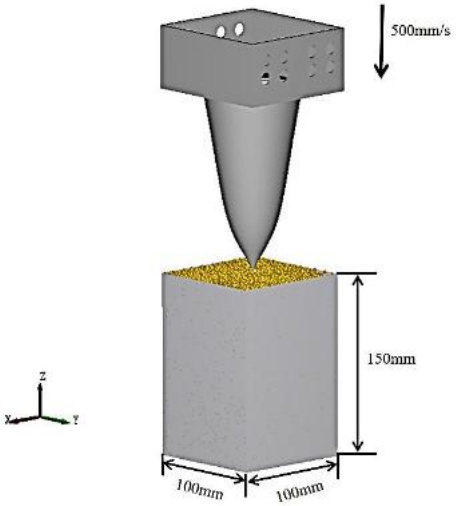

Fig. 6 - Discrete Element Method (DEM) simulation model

Table 3

Intrinsic and contact parameters of the discrete element simulation model

Item	Parameter	Value
Soil properties	Soil density / kg·m⁻³	2760
	Soil Poisson's ratio	0.35
	Soil shear modulus / MPa	1.5
Stainless-steel properties	Stainless steel density / kg·m⁻³	7850
	Stainless steel Poisson's ratio	0.3
	Stainless steel shear modulus / MPa	7x10^4
Soil-soil contact parameters	Soil-soil JKR surface energy / J·m⁻²	4.982
	Coefficient of restitution	0.411
	Coefficient of static friction	0.78
	Coefficient of rolling friction	0.148
Soil–stainless-steel contact parameters	Soil-stainless steel JKR surface energy / J·m⁻²	2.027
	Coefficient of restitution	0.599
	Coefficient of static friction	0.711
	Coefficient of rolling friction	0.015

Statistical analysis and response surface modeling were performed using Design-Expert 13.0.5.0 software (Stat-Ease Inc., Minneapolis, MN, USA), with the significance level set at α = 0.05. The adequacy of the regression models was evaluated using ANOVA, R^2, adjusted R^2, predicted R^2, lack-of-fit test, and adequate precision. Residual diagnostics were conducted using normal probability plots of residuals, residuals versus predicted values, and Cook's distance. The predictive performance of the models was further evaluated by comparing the predicted responses with the corresponding results from independent DEM numerical verification.

RESULTS

Analysis of Key Parameter Screening Tests

The Plackett–Burman screening results are shown in Table 4. The maximum penetration resistance (Y_1) ranged from 25.21 N to 34.12 N, and the soil adhesion mass (Y_2) ranged from 12.40 g to 21.80 g, indicating that the Gaussian contour parameters had an obvious influence on the soil-engaging performance of the planter.

To quantify the relative influence of each parameter, the main effects and percentage contributions were calculated from the screening results. For penetration resistance, a_2 showed the largest positive effect, with a contribution of 54.83%, followed by c_2 and b_2, with contributions of 27.38% and 13.50%, respectively. This indicates that the front-end peak height was the dominant factor increasing penetration resistance, while a larger peak width helped reduce resistance by producing a smoother surface transition.

For soil adhesion mass, c_2 was the dominant factor, with a contribution of 72.00%, followed by a_2, with a contribution of 12.79%. This result indicates that the peak width mainly controlled soil adhesion by affecting the smoothness of the planter surface and the sliding behavior of wet cohesive soil. The effects of the back-end parameters a_1, b_1, and c_1 were relatively small for both response variables.

As shown in the standardized Pareto charts in Fig. 7, the front-end Gaussian parameters a_2, b_2, and c_2 had greater effects on the two response variables than the back-end parameters. Therefore, a_2, b_2, and c_2 were selected as the key design variables for the subsequent Box–Behnken response surface optimization, while a_1, b_1, and c_1 were fixed in the following optimization process.

Table 4

Plackett-Burman experimental design scheme and response results

Box–Behnken Design and Response Surface Model Fitting

According to the Plackett–Burman screening results, the peak height (a_2), peak position (b_2), and peak width (c_2) were selected as the main biomimetic parameters affecting the soil-engaging performance of the planter. A three-factor, three-level Box–Behnken design was used to analyze the effects of these parameters and their interactions on the maximum penetration resistance (Y_1) and soil adhesion mass (Y_2). The coded levels of the three factors are listed in Table 6, and the design matrix and corresponding EDEM simulation results are shown in Table 7.

Table 6

Factors and coded levels of Box-Behnken design

Coded level	Factor		
	a_2	b_2	c_2
1	0.4918	0.3532	0.1861
0	0.3983	0.2955	0.1592
-1	0.3048	0.2378	0.1322

Table 7

Response surface experimental design and EDEM simulation results

Standard Order	Factor			Penetration Resistance [N]	soil adhesion mass [g]
	a_2	b_2	c_2		
1	-1	-1	0	21.9	14.21
2	1	-1	0	35.11	21.24
3	-1	1	0	18.8	12.56
4	1	1	0	32.46	20.54
5	-1	0	-1	20.54	15.56
6	1	0	-1	33.85	20.35
7	-1	0	1	18.6	12.48
8	1	0	1	28.34	18.43
9	0	-1	-1	22.59	17.36
10	0	1	-1	19.46	18.96
11	0	-1	1	20.85	15.12
12	0	1	1	17.65	15.86
13	0	0	0	24.15	16.52
14	0	0	0	23.98	16.41
15	0	0	0	24.32	16.65
16	0	0	0	24.05	16.38
17	0	0	0	24.21	16.55

As shown in Table 7, the maximum penetration resistance ranged from 17.65 N to 35.11 N, and the soil adhesion mass ranged from 12.48 g to 21.24 g. The five center-point runs showed small variations. The penetration resistance values of the center points were 24.15, 23.98, 24.32, 24.05, and 24.21 N, with a mean value of 24.14 N and a standard deviation of 0.13 N. The corresponding soil adhesion mass were 16.52, 16.41, 16.65, 16.38, and 16.55 g, with a mean value of 16.50 g and a standard deviation of 0.11 g. These results indicate that the DEM simulation had good numerical repeatability under the same simulation conditions.

The ANOVA results of the fitted models are shown in Table 8. The quadratic model for penetration resistance was extremely significant (p < 0.0001), with R^2, adjusted R^2, and predicted R^2 values of 0.9916, 0.9808, and 0.8676, respectively. The adequate precision was 30.7602, which was much higher than the recommended threshold of 4. For penetration resistance, the linear terms a_2, b_2 and c_2 were all extremely significant (p < 0.01). The interaction term a_2c_2 was significant (p = 0.0467), while a_2b_2 and b_2c_2 were not significant. The quadratic terms a_2^2, b_2^2, and c_2^2 were also significant, indicating a nonlinear relationship between the front-end contour parameters and penetration resistance.

The linear model for soil adhesion mass was also extremely significant (p < 0.0001), with R^2, adjusted R^2, and predicted R^2 values of 0.9343, 0.9192, and 0.8665, respectively. The adequate precision was 25.7831, indicating that the model had sufficient signal for response prediction within the selected design space.

For soil adhesion mass, a_2 and c_2 were extremely significant (p < 0.01), whereas b_2 was not significant (p = 0.9962). This result indicates that soil adhesion was mainly affected by peak height and peak width rather than peak position.

Although the lack-of-fit terms of both models were significant (p < 0.05), this may be attributed to the nonlinear friction, collision, cohesion, and adhesion behavior between wet clay particles and the biomimetic planter surface in the DEM simulation. Considering the high model significance, high R^2 values, and adequate precision values, the fitted models were considered acceptable for empirical optimization within the selected design space. However, they should not be interpreted as universal prediction models outside the investigated factor ranges.

The PRESS values of the penetration resistance model and soil adhesion mass model were 60.39 and 13.76, respectively. These values, together with the predicted R^2 values, were used to evaluate the predictive performance of the fitted regression models within the selected design space.

Table 8

Analysis of variance (ANOVA) for the regression models of penetration resistance and soil adhesion

Model Diagnostic Analysis

The diagnostic plots of the fitted response surface models are shown in Fig.8. For both response models, most residual points were approximately distributed along the reference line in the normal probability plots, indicating that no serious deviation from normality was observed. In the residuals versus predicted values plots, the residuals were generally distributed around zero, suggesting that the fitted models could describe the response trends within the selected design space.

The Cook's distance plots showed that several design points had relatively high influence on the fitted models. This may be related to the nonlinear friction, collision, cohesion, and adhesion behavior of wet cohesive soil particles during DEM simulation. These points were not removed because they corresponded to valid parameter combinations in the Box–Behnken design. Therefore, the regression models were used as empirical optimization models within the investigated factor ranges, and the optimized results were further evaluated by independent DEM numerical verification.

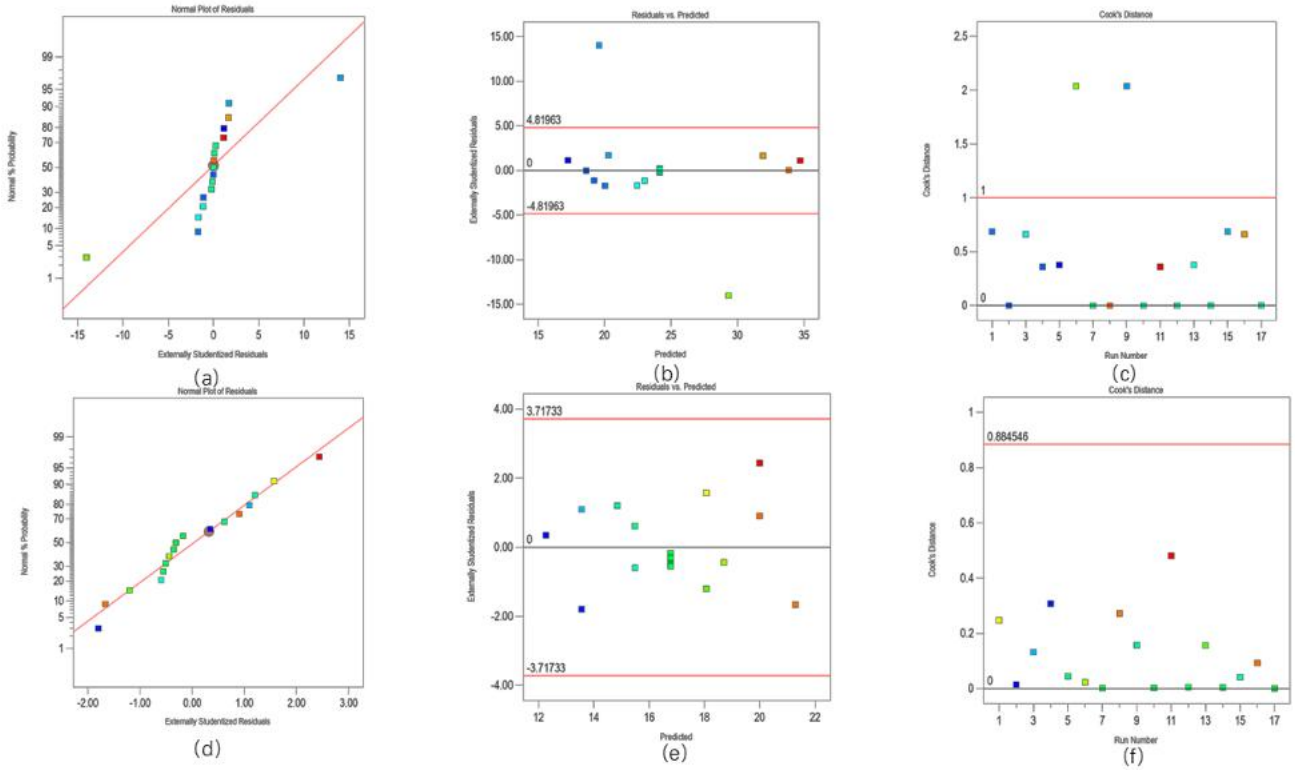

Fig. 8 - Diagnostic plots of the fitted response surface models

(a) normal probability plot of residuals for Y_1; (b) residuals versus predicted values for Y_1; (c) Cook's distance for Y_1; (d) normal probability plot of residuals for Y_2; (e) residuals versus predicted values for Y_2; (f) Cook's distance for Y_2.

According to the BBD analysis, the real factor regression equations of maximum penetration resistance (Y_1) and the soil adhesion mass (Y_2) for the peak height (a_2), peak position (b_2) and peak width (c_2) are as follows:

$$Y_1 = -63.274 - 253.027a_2 + 168.751b_2 + 1351.039c_2 + 20.853a_2b_2 - 354.191a_2c_2 - 11.254b_2c_2 + 464.440{a_2}^2 - 340.838{b_2}^2 - 3951.177{c_2}^2 \quad (4)$$

$$Y_2 = 10.703 + 34.425a_2 - 0.022b_2 - 47.959c_2 \quad (5)$$

Response Surface Analysis

The response surface plots are shown in Fig. 9. For penetration resistance, the response surfaces of the a_2 b_2 and b_2 c_2 interactions were relatively smooth, which is consistent with the ANOVA results showing that these two interaction terms were not significant (p > 0.05). This indicates that changing the peak position (b_2) did not strongly alter the effect of peak height or peak width on penetration resistance.

In contrast, the interaction between a_2 and c_2 had a significant effect on penetration resistance (p < 0.05). When a_2 was high, the penetration resistance remained relatively high, because a larger front-end peak increased the frontal soil-breaking area and enhanced soil compression. When a_2 was low and c_2 was high, the penetration resistance decreased. This indicates that a lower peak height helped reduce frontal compression, while a larger peak width produced a smoother surface transition and promoted soil sliding along the planter surface.

For soil adhesion mass, the response surface showed an approximately linear trend. Soil adhesion increased with increasing a_2 and decreased with increasing c_2. This result indicates that the peak height and peak width mainly controlled soil adhesion by changing the local contact and sliding behavior between wet clay and the planter surface. Therefore, the protrusion height and surface smoothness should be jointly optimized to achieve both resistance reduction and adhesion reduction.

(a) a_2 and b_2 on penetration resistance (Y_1); (b) b_2 and c_2 on Y_1; (c) a_2 and c_2 on Y_1; (d) a_2 and c_2 on soil adhesion (Y_2)

Objective Function Establishment and Parameter Optimization

The objective is to minimize both the maximum penetration resistance (Y_1) and soil adhesion (Y_2) with the physical constraints of the planter's structure.

The optimization model is as follows:

$$\begin{cases} min\, Y_1 = f_1(a_2, b_2, c_2) \\ min\, Y_2 = f_2(a_2, b_2, c_2) \\ s.t. \\ 0.3048 \le a_2 \le 0.4918 \\ 0.2378 \le b_2 \le 0.3532 \\ 0.1322 \le c_2 \le 0.1861 \end{cases} \quad (6)$$

The desirability function method was used to integrate the two response variables into an overall desirability index (D) calculated as follows:

$$D = (d_1(Y_1) \times d_2(Y_2))^{\frac{1}{2}} \quad (7)$$

where: d_1 and d_2 are the individual desirability values for penetration resistance and soil adhesion.

The optimization objective was to minimize both the maximum penetration resistance (Y_1) and soil adhesion mass (Y_2) within the selected design space. The desirability function method in Design-Expert was used to integrate the two response variables into a comprehensive desirability index. The optimized parameter combination was a_2 = 0.30, b_2 = 0.35, and c_2 = 0.19, with an overall desirability value of 0.893. Under this condition, the predicted penetration resistance and soil adhesion mass were 16.14 N and 12.40 g, respectively.

Other optimization algorithms, such as genetic algorithms and particle swarm optimization, were also considered. However, the present optimization problem involved only three continuous design variables and two response objectives, and the fitted response surface models provided explicit regression equations within the selected design space. Therefore, the desirability function method was adopted because it could directly integrate penetration resistance and soil adhesion mass into a single interpretable optimization index. Population-based optimization algorithms may be considered in future work when more design variables, structural constraints, or experimental validation data are included.

Parameter Optimization and Numerical Verification

To evaluate the optimized parameter combination, the optimized planter model was reconstructed and an independent DEM simulation was conducted under the same numerical conditions. Since this study focused on numerical optimization, the verification was based on DEM simulation rather than laboratory or field experiments. Therefore, the verification results should be interpreted as numerical verification within the DEM framework. The soil particle velocity fields of the conventional prototype, the four single bird-beak biomimetic profiles (S_1–S_4), and the optimized multi-peak profile are shown in Fig. 10.

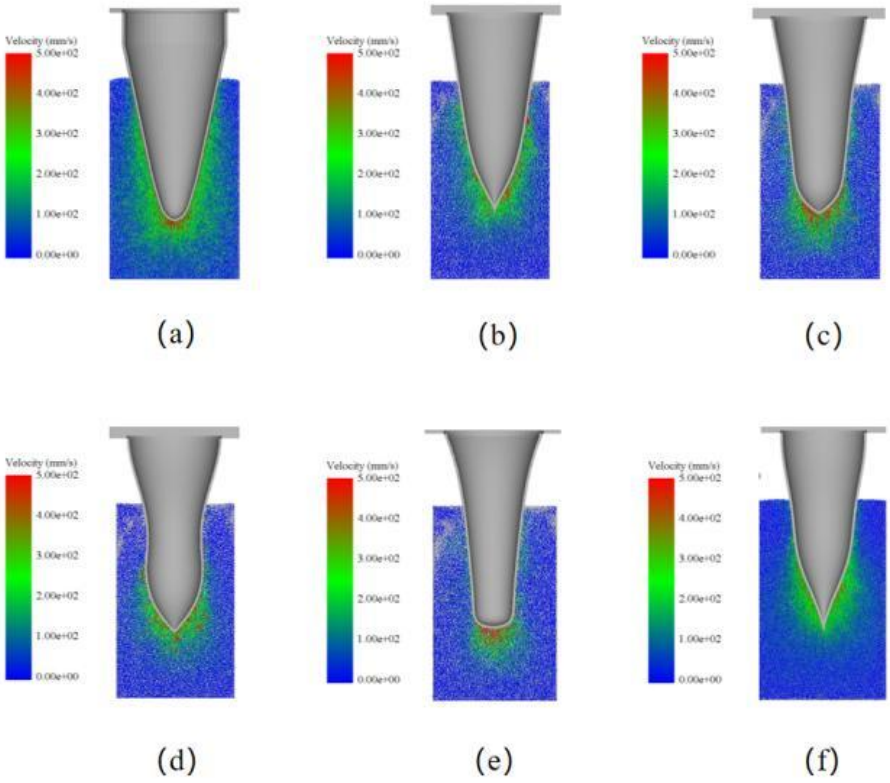

Fig. 10 - Comparison of soil particle velocity fields for different planter profiles

(a) Conventional (b-e) Bionic prototypes S_1-S_4 (f) Optimized multi-peak bionic profile

As shown in Fig. 10(a), the conventional planter produced a wide V-shaped high-velocity disturbance zone during soil penetration, indicating strong frontal compression and large-scale soil disturbance. In contrast, the optimized multi-peak biomimetic planter generated a narrower and more streamlined disturbance zone, and the soil particles tended to move along the planter surface, as shown in Fig. 10(f). This indicates that the dominant soil motion changed from frontal compression to tangential sliding, thereby reducing local soil compaction and weakening soil accumulation on the planter surface.

To quantitatively evaluate the resistance-reduction and anti-adhesion effects, the penetration resistance and soil adhesion mass were extracted for all planter profiles, as shown in Fig. 11. The maximum penetration resistance of the conventional prototype was 47.30 N, whereas that of the optimized biomimetic planter was 18.70 N, corresponding to a reduction of 60.47%. The soil adhesion mass decreased from 25.20 g for the conventional prototype to 14.98 g for the optimized planter, corresponding to a reduction of 40.56%.

As shown in Table 9, the predicted penetration resistance and soil adhesion mass were 16.14 N and 12.40 g, respectively, while the corresponding DEM verification values were 18.70 N and 14.98 g. The relative errors were 15.86% and 20.81%, respectively. Although the DEM verification values were higher than the predicted values, the optimized model showed a consistent reduction trend and was therefore acceptable for evaluating the optimization direction. Mechanistically, the optimized peak height and peak width produced a smoother transition of the planter surface, which reduced frontal soil compression and promoted tangential soil sliding. This change in soil motion reduced penetration resistance and weakened the retention of wet cohesive soil on the planter surface. Overall, the optimized multi-peak configuration achieved coupled reductions in penetration resistance and soil adhesion mass.

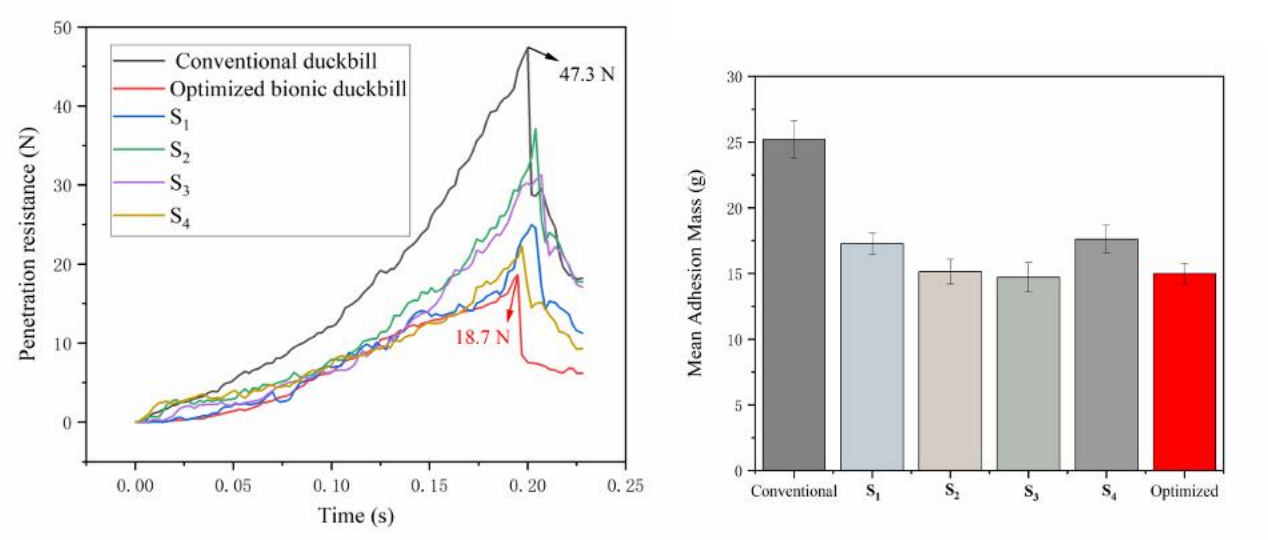

Fig. 11 - Soil-engaging performance of different planter profiles

(a) Penetration resistance curves (b) Mean adhesion mass

Table 9

Numerical verification results of the optimized parameter combination

Response	Predicted value	DEM verification value	Relative error [%]
Y_1 / [N]	16.14	18.70	15.86
Y_2 / [g]	12.40	14.98	20.81

CONCLUSIONS

In this study, a Gaussian multi-peak biomimetic tobacco planter was designed by integrating the characteristic beak contours of multiple bird species. DEM simulation, Plackett–Burman screening, Box–Behnken response surface optimization, and independent DEM numerical verification were used to evaluate the effects of the biomimetic contour parameters on penetration resistance and soil adhesion mass.

The Plackett–Burman screening results showed that the front-end Gaussian parameters a_2, b_2, and c_2 had greater effects on penetration resistance and soil adhesion mass than the back-end parameters. Therefore, a_2, b_2, and c_2 were selected as the key variables for response surface optimization. Based on the Box–Behnken design and desirability function method, the optimized parameter combination was obtained as a_2 = 0.30, b_2 = 0.35, and c_2 = 0.19. Under this condition, the predicted penetration resistance and soil adhesion mass were 16.14 N and 12.40 g, respectively. The independent DEM verification values were 18.70 N and 14.98 g, with relative errors of 15.86% and 20.81%, respectively.

Compared with the conventional planter, the optimized multi-peak biomimetic planter reduced the maximum penetration resistance from 47.30 N to 18.70 N and reduced the soil adhesion mass from 25.20 g to 14.98 g, corresponding to reductions of 60.47% and 40.56%, respectively. The optimized profile also showed better combined resistance-reduction and anti-adhesion performance than the single bird-beak biomimetic profiles.

The soil particle velocity field showed that the optimized multi-peak profile reduced the wide V-shaped frontal disturbance zone and promoted soil motion along the planter surface. This indicates that the dominant soil motion changed from frontal compression to tangential sliding, thereby reducing local soil compaction and weakening the retention of wet cohesive soil on the planter surface.

It should be noted that the verification in this study was based on independent DEM simulation rather than laboratory or field experiments. Therefore, the results should be interpreted as numerical verification within the selected design space. Future work will focus on prototype fabrication and experimental validation under actual tobacco transplanting conditions.

ABSTRACT

Airborne dust generated during straw pickup can impair operating visibility and local air quality; however, the respective contributions of mechanical particle detachment and aerodynamic entrainment in flail-type pickup headers remain insufficiently quantified. This study combined discrete element method (DEM) and computational fluid dynamics (CFD) analyses with field measurements to investigate these two processes. A bonded corn root stubble–soil DEM model was established in EDEM, and the bond fracture rate was used to characterize the relative degree of particle detachment. The effects of ground clearance (30–90 mm), rotor speed (4100–5300 rpm), forward speed (0.5–1.5 m/s), plant spacing (200–300 mm), and row spacing (300–500 mm) were evaluated. CFD simulations were then used to characterize the time-averaged airflow field within the pickup-header housing. Increasing the ground clearance from 30 to 90 mm reduced the bond fracture rate by 44.5%, whereas increasing the rotor speed from 4100 to 5300 rpm increased it by 52.3%. By relating the DEM particle-detachment states to the CFD flow-field characteristics, three dust-generation pathways were identified: stubble fragmentation, root extraction, and direct entrainment of loose surface particles. Rotor speed affected both mechanical detachment and airflow entrainment at the header inlet. Field measurements showed that the selected low-dust operating condition, with a ground clearance of 75 mm, rotor speed of 4400 rpm, and forward speed of 0.75 m/s, reduced total suspended particulate (TSP), PM_{10}, and $PM_{2.5}$ concentrations by 62.2%, 58.4%, and 53.8%, respectively, compared with the dust-intensive condition. By linking particle detachment, airflow entrainment, and field measurements within a mechanism-based framework, this study clarifies the effects of operating parameters on dust generation and provides a basis for selecting low-dust operating parameters and improving pickup-header inlet design.

摘要

秸秆捡拾过程中产生的扬尘会降低作业视野并恶化局部空气质量，但锤爪式捡拾割台中机械颗粒脱离与气流卷吸各自对扬尘形成的作用仍缺乏充分的定量认识。本研究将相互独立的离散元法(DEM)分析、计算流体动力学(CFD)分析与田间测试相结合，对上述两类过程进行了研究。利用 EDEM 建立玉米根茬—土壤粘结颗粒模型，并采用粘结键断裂率表征颗粒相对脱离程度，考察离地高度(30-90 mm)、锤爪转速(4100-5300 r m)、前进速度(0.5-1.5 m/s)、株距(200-300 mm)和行距(300-500 mm)的影响。随后利用 CFD 模拟分析捡拾割台壳体内部的时均气流特征。离地高度由 30 mm 增加至 90 mm 时，粘结键断裂率降低 44.5%；锤爪转速由 4100 r m 增加至 5300 r m 时，粘结键断裂率提高 52.3%。通过将 DEM 获得的颗粒脱离状态与 CFD 流场特征对应分析，推断出三条扬尘产生途径：根茬破碎、根茬拔除以及土壤表面松散颗粒的直接气流卷吸。锤爪转速同时影响机械颗粒脱离和入口气流卷吸。田间试验表明，相较于高扬尘工况，离地高度 5 mm、锤爪转速 4400 r m、前进速度 0.5 m/s 的低尘工况使 TSP、PM_{10}和 $PM_{2.5}$浓度分别降低 62.2%、58.4%和 53.8%。本研究通过在统一的机理框架下关联颗粒脱离、气流卷吸和田间实测结果，阐明了作业参数影响扬尘形成的作用途径，可为低尘作业参数选择及捡拾割台入口结构改进提供依据。

INTRODUCTION

Agricultural field operations can generate substantial airborne particulate matter through the disturbance of soil and crop residues. Total suspended particulate (TSP), particulate matter with an aerodynamic diameter below 10 μm (PM_{10}), and particulate matter below 2.5 μm ($PM_{2.5}$) can deteriorate local air quality and operating conditions, and their emission levels vary with machinery type, soil condition, and operating intensity (*Çarman*

et al., 2023; Chen et al., 2017; Zhang et al., 2023; Chen et al., 2024). Mechanized straw recovery reduces open-field residue burning, but straw pickup itself can generate considerable dust (*Yang et al., 2022*). In a flail-type pickup header, high-speed flails fragment root stubble and detach adhered soil, while rotor-induced negative pressure at the housing inlet entrains detached and loose surface particles. Reported TSP concentrations during harvesting can reach 1500-3000 μg/m^3, and $PM_{2.5}$ may account for 30%-45% of airborne dust (*Zhang et al., 2021; Xu et al., 2022a*). Therefore, source-oriented dust control should address both mechanical detachment and aerodynamic entrainment.

The discrete element method (DEM) has been extensively applied to agricultural machinery–soil interactions. Bonded-particle approaches provide a means of representing cohesive failure and particle separation in granular materials (*Cundall and Strack, 1980; Potyondy and Cundall, 2004*). Agricultural DEM studies have investigated soil–tool interaction, tillage and furrow opening, soil-aggregate fracture, rotary-tillage burial and mixing, and straw–soil–cutting processes (*Zhao et al., 2021; Aikins et al., 2021; Aikins et al., 2023; Du et al., 2022; Foldager et al., 2022; Li et al., 2025*). However, the use of bond failure to characterize particle detachment specifically during high-speed flail interaction with a root stubble–soil composite remains limited.

Computational fluid dynamics (CFD) is well suited to resolving airflow organization and particle-transport conditions within agricultural machinery. Previous studies have applied CFD to optimize airflow distribution in combine-harvester cleaning systems, analyze dust diffusion during harvesting, and evaluate dust-suppression structures (*Liang et al., 2020; Xu et al., 2022b; Xu et al., 2023*). These studies demonstrate that internal airflow plays an important role in dust transport and dispersion. However, existing CFD research has mainly focused on cleaning devices, overall dust diffusion, or suppression structures, while the relationship between the near-ground inlet flow of a flail-type pickup header and the formation of different dust-generation pathways remains insufficiently quantified.

Accordingly, two limitations remain relevant to flail-type straw pickup. First, the mechanical detachment of particles from the root stubble-soil system and their subsequent aerodynamic entrainment have generally been examined as separate processes. Second, the extent to which controllable operating parameters simultaneously affect these two processes has not been clarified through field validation. Therefore, the present study used independent DEM and CFD analyses, rather than a fully coupled DEM-CFD model, and integrated their results with field measurements. The objectives were to: (1) quantify the effects of ground clearance, rotor speed, forward speed, plant spacing, and row spacing on particle detachment; (2) characterize the time-averaged internal flow field and relate its principal regions to potential dust-generation pathways; and (3) evaluate a selected low-dust operating condition using field measurements of TSP, PM_{10}, and $PM_{2.5}$. The main contribution is a mechanism-based framework linking operating parameters to both mechanical detachment and aerodynamic entrainment.

MATERIALS AND METHODS

Structure and Working Principle of the Flail-Type Pickup Header

The flail-type pickup header consists mainly of a flail rotor, housing, mounting frame, transmission system, deflector, and conveying auger (Fig. 1). The main structural parameters are listed in Table 1.

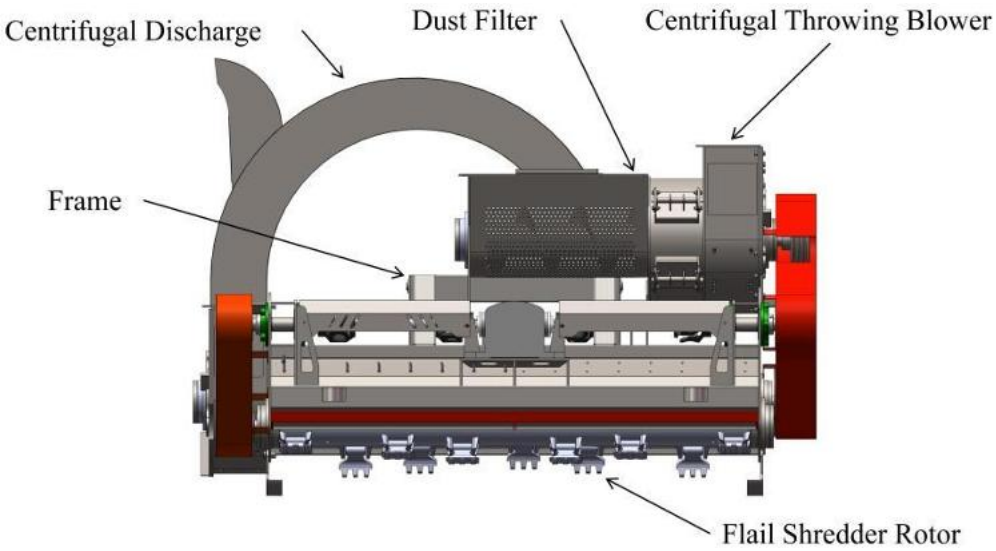

Fig. 1 - Overall Structure

Table 1

Main structural parameters of flail-type pickup header

Parameter	Value
Diameter of flail roller (mm)	180
Length of flail roller (mm)	2200
Number of flails	22
Length of flail (mm)	160

During operation, the rotor turns at 4100-5300 rpm while the machine advances. The flails strike the exposed root stubble without directly contacting the soil surface. Detached material is thrown upward and transported along the housing by the flails and the rotor-induced airflow before entering the conveying auger.

Discrete Element Model of the Root Stubble-Soil Composite

A DEM model of the corn root stubble-soil composite was established in EDEM. Root stubble and 0-100 mm surface-soil samples were obtained from the test field. Material, bonding, and contact parameters were adopted from previously calibrated and validated models for the same material system and operating region (*Zhuo et al., 2025; Xu et al., 2024*).

Table 2

Intrinsic material parameters

Material	Density (kg/m³)	Poisson's Ratio	Shear Modulus (MPa)
Corn Root Stubble	107.5	0.3	6.5
Soil Particles	1646	0.42	4.6
Flail	7850	0.3	79000

The Hertz-Mindlin with Bonding V2 contact model was applied to soil particles and root stubble, as this model can effectively simulate the cohesive forces between moist soil particles (*Potyondy and Cundall, 2004; Aikins et al., 2021*). The bonding parameters are listed in Table 3.

Table 3

Bonding parameters

Contact Pair	Stiffness per Unit Area (N/m³)	Critical Stress (MPa)	Bonding Radius (mm)
Root-Root	2.2×10^6	2.45	1.38
Soil-Soil	5×10^5	0.31	1.65
Root-Soil	6.5×10^5	0.31	1.38

The contact parameters are listed in Table 4.

Table 4

Contact parameters

Contact Type	Coefficient of Static Friction	Coefficient of Rolling Friction	Coefficient of Restitution
Soil-Soil	0.62	0.1	0.55
Soil-Root Stubble	0.42	0.21	0.6
Soil-Flail	0.60	0.10	0.3
Root Stubble-Flail	0.60	0.10	0.5

The soil bin was generated by natural packing. Root stubble was represented by 2-4 mm bonded spheres, with an approximate diameter of 25 mm and burial depth of 200 mm. Stubble units were arranged according to the prescribed plant and row spacings. The pickup geometry was imported from SolidWorks, and the rotor was assigned simultaneous rotation and forward translation. The time step was 3.6% of the Rayleigh time step.

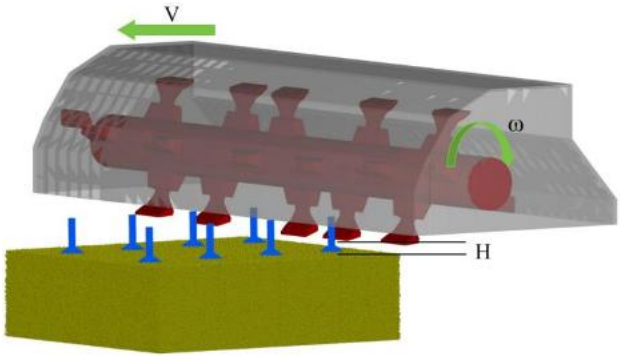

Fig. 2 - Schematic diagram of flail–root stubble interaction

Key Indicators

Because the flails did not directly contact the soil surface, bond failure was used to characterize particle detachment from the stubble-soil matrix. A bond was considered broken when the local stress exceeded its strength limit; the released particles could then be ejected by mechanical impact and subsequently entrained by airflow.

The bond fracture rate η was calculated as the ratio of the number of broken bonds, N_b, to the initial number of bonds, N_0:

$$\eta = \frac{N_b}{N_0} \times 100\% \quad (1)$$

The index was extracted from EDEM post-processing and used to compare the relative degree of particle detachment among operating conditions.

Single-Factor Experiment Design

Five factors were evaluated by single-factor simulations: ground clearance (H), rotor speed (ω), forward speed (v), plant spacing (Δx), and row spacing (Δy). When one factor was varied, the remaining factors were fixed at their intermediate levels (Table 5).

Table 5

Single-factor simulation scheme

Test Number	Operational parameters				
	Ground Clearance	Rotor Speed	Forward Speed	Plant Spacing	Row Spacing
	H (mm)	*ω* (rpm)	*v* (m/s)	Δ*x* (mm)	Δ*y* (mm)
1	30	4700	1	250	400
2	45	4700	1	250	400
3	60	4700	1	250	400
4	75	4700	1	250	400
5	90	4700	1	250	400
6	60	4100	1	250	400
7	60	4400	1	250	400
8	60	4700	1	250	400
9	60	5000	1	250	400
10	60	5300	1	250	400

Test Number	Operational parameters				
	Ground Clearance	Rotor Speed	Forward Speed	Plant Spacing	Row Spacing
	H (mm)	*ω* (rpm)	*v* (m/s)	Δ*x* (mm)	Δ*y* (mm)
11	60	4700	0.5	250	400
12	60	4700	0.75	250	400
13	60	4700	1	250	400
14	60	4700	1.25	250	400
15	60	4700	1.5	250	400
16	60	4700	1	200	400
17	60	4700	1	225	400
18	60	4700	1	250	400
19	60	4700	1	275	400
20	60	4700	1	300	400
21	60	4700	1	250	300
22	60	4700	1	250	350
23	60	4700	1	250	400
24	60	4700	1	250	450
25	60	4700	1	250	500

In addition to the single-factor simulations, two combined operating conditions were simulated for comparison with the subsequent field measurements. The selected low-dust condition was set at a ground clearance of 75 mm, a rotor speed of 4400 rpm, and a forward speed of 0.75 m/s, whereas the dust-intensive condition was set at 30 mm, 5300 rpm, and 1.0 m/s, respectively. Plant spacing and row spacing were maintained at 250 and 400 mm for both conditions. The DEM model parameters and bond-fracture-rate calculation method were kept consistent with those used in the single-factor simulations.

CFD Model of the Internal Flow Field of the Pickup Header

The internal flow field was modeled in ANSYS Fluent 2020R2. The housing, rotor region, inlet, outlet, and a closed ground boundary were retained, while small features with negligible aerodynamic influence were omitted (Fig. 3).

The computational domain was divided into a rotating rotor region and a stationary housing region connected by an interface. A steady multiple-reference-frame (MRF) model was used to obtain the time-averaged flow field. The MRF approach had previously been validated for the same pickup system by comparing simulated and measured inlet pressure distributions at 35 bench-test points *(Wang et al., 2024b)*.

The mesh contained 14.8 million cells. A pressure-based steady solver, the realizable k-ε turbulence model *(Shih et al., 1995)*, and air as the continuous phase were used. The inlet was specified as a pressure inlet, the conveying channel as the outlet, and the rotor walls moved with the rotating reference frame.

The DEM and CFD simulations were conducted independently and did not constitute a fully coupled DEM-CFD simulation. The DEM analysis was used to characterize the relative degree and spatial features of particle detachment from the root stubble-soil system, whereas the CFD analysis was used to characterize the time-averaged airflow within the pickup-header housing. To relate the two analyses, the locations and modes of particle detachment obtained from DEM were compared with the characteristic airflow regions predicted by CFD. Detachment caused by direct flail impact was examined in relation to the high-speed rotation zone, while disturbance at the root-soil interface was evaluated together with the near-ground inlet flow. In addition, the near-ground inlet velocity was compared with the estimated entrainment thresholds to assess the potential for direct lifting of loose surface particles. Accordingly, the proposed dust-generation pathways were interpreted from complementary mechanical and aerodynamic evidence rather than derived from particle trajectories in a coupled DEM-CFD simulation.

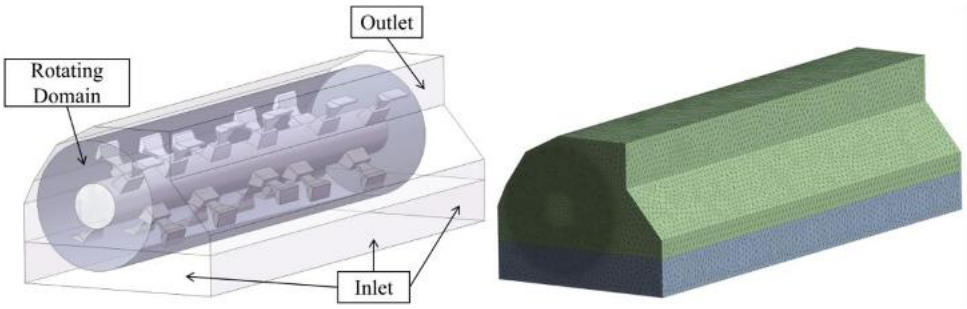

Fig. 3 - Computational Domain and Grid for the Flow Field

Field Experiment

Field tests were conducted in a corn field in Togtoh County, Inner Mongolia, China (40°20′N, 111°30′E; Fig. 4). Measured plant spacing (240-260 mm), row spacing (390-410 mm), and stubble diameter (23-28 mm) were consistent with the DEM settings.

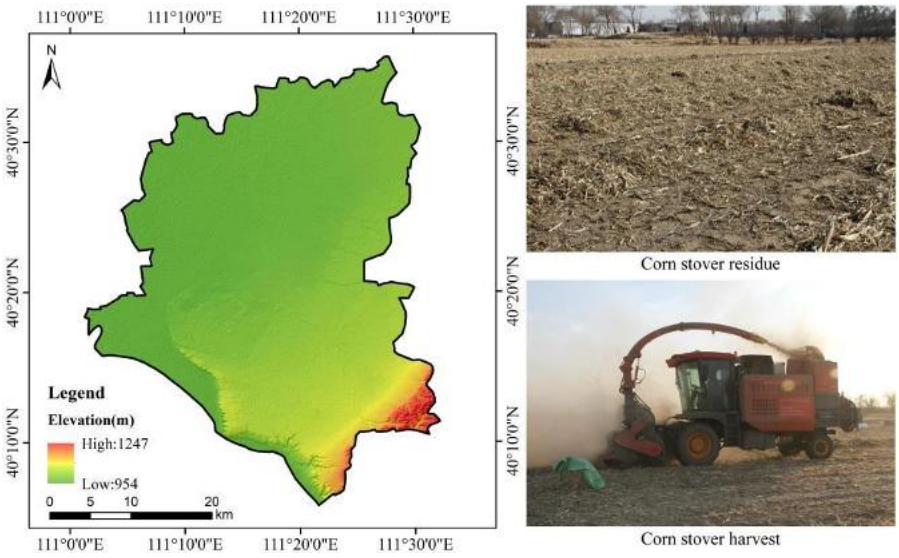

Fig. 4 - Overview of the study area

Two operating conditions were compared using a 4JKZ-240 straw feed baler harvester: a selected low-dust condition (75 mm ground clearance, 4400 rpm rotor speed, and 0.75 m/s forward speed) and a dust-intensive condition (30 mm, 5300 rpm, and 1.0 m/s). The sampling point was located directly above the pickup header (Fig. 5).

Fig. 5 - Installation Location of the Particulate Sampler

Each operating condition was evaluated in three independent field runs (n = 3). Each replicate consisted of a separate 10-min harvesting pass conducted under the same operating-parameter setting, with particulate sampling performed independently for each run.

The measured concentrations are reported as mean ± standard deviation. TSP was collected on glass-fiber filters with a KB-6120 atmospheric sampler at 100 L/min and determined gravimetrically; size-fractionated samples were collected simultaneously. Filters were conditioned for 24 h at 25 ± 1°C and 50 ± 5% relative humidity before weighing.

$$C = \frac{(m_2 - m_1)}{(Q \times t)} \times 10^6 \quad (2)$$

In Eq. (2), C is the TSP mass concentration (μg/m^3), m_1 and m_2 are the filter masses before and after sampling (g), Q is the sampling flow rate (m^3/min; 0.100 m^3/min in the present experiments), and t is the sampling duration (min). Each replicate was sampled for 10 min.

Statistical comparisons between the two operating conditions were performed using a two-sided Welch's t-test because the measured variability differed between conditions. Statistical significance was evaluated at $p < 0.05$. Given the limited number of field replicates (n = 3 per condition), the statistical results were interpreted together with the observed effect magnitude and descriptive variability.

Aerodynamic Entrainment Threshold Calculation

To evaluate the aerodynamic entrainment potential of soil particles near the pickup-header inlet, the threshold friction velocity was estimated using the simplified relationship proposed by *Shao and Lu (2000)*. The reported wind-speed dependence of agricultural-soil dust flux (*Wang et al., 2021; Wang et al., 2024a*) was further used to estimate the relative change in entrainment intensity among different rotor speeds.

$$u_{*t} = \sqrt{A_N \left[\frac{(\rho_p - \rho_a)}{\rho_a} gd \right]} \quad (3)$$

where u_{*t} is the threshold friction velocity (m/s), A_N is the dimensionless coefficient in the Shao-Lu model, ρ_p and ρ_a are the particle and air densities, respectively, g is gravitational acceleration, and d is the particle diameter. In this study, A_N was set to 0.0123 according to *Shao and Lu (2000)*.

The original Shao-Lu relationship is expressed in terms of friction velocity, whereas the CFD results provide the characteristic mean velocity in the inlet entrainment region. Therefore, the threshold friction velocity was converted into an equivalent mean-flow threshold velocity as follows:

$$U_t = \frac{U}{u_*} u_{*t} = A \sqrt{\left[\frac{(\rho_p - \rho_a)}{\rho_a} gd \right]} \quad (4)$$

where U_t is the equivalent mean-flow threshold velocity, U is the characteristic mean inlet velocity, u_* is the corresponding friction velocity, and A is the effective velocity-conversion coefficient:

$$A = \sqrt{A_N} \frac{U}{u_*} \quad (5)$$

For a first-order engineering estimate, the relationship between the mean velocity and friction velocity was obtained from the Darcy-Weisbach formulation:

$$\frac{U}{u_*} = \sqrt{\frac{8}{f}} \quad (6)$$

where f is the Darcy friction factor. The Blasius correlation for smooth turbulent flow, $f = 0.3164\ \mathrm{Re}^{-0.25}$, was adopted. Based on a characteristic inlet velocity of 5-18 m/s, a hydraulic diameter of approximately 0.2 m, and an air kinematic viscosity of 1.5×10^{-5} m^2/s, the Reynolds number was estimated to be 6.7×10^4-2.4×10^5. The corresponding Darcy friction factor was 0.0143-0.0197, giving $U/u_* \approx 20.2 - 23.7$. Substitution into Eq. (5) yielded an effective coefficient range of 2.24-2.62. A representative intermediate value of $A = 2.43$ was therefore adopted to calculate the equivalent mean-flow threshold velocities of particles with different diameters.

The threshold-exceedance ratio was calculated as the ratio of the upper inlet velocity obtained from CFD to the equivalent mean-flow threshold velocity of each representative particle diameter. The relative entrainment flux among rotor speeds was estimated using the cubic relationship between dust flux and airflow velocity reported in previous studies.

The conversion was introduced to enable a consistent comparison between the threshold friction velocity derived from the Shao-Lu relationship and the characteristic inlet velocity obtained from CFD.

The resulting equivalent mean-flow threshold velocity therefore serves as a comparative criterion for evaluating the aerodynamic entrainment potential of particles under different rotor-speed conditions. The Darcy-Weisbach and Blasius relationships provide the velocity-conversion framework under turbulent-flow conditions, while the actual pickup-header inlet flow remains spatially non-uniform because of rotor-induced rotation and local acceleration. Accordingly, the calculated threshold-exceedance ratio is used to compare relative entrainment intensity among operating conditions rather than to represent an exact local entrainment threshold at every point in the inlet region. Similarly, the cubic relationship between dust flux and airflow velocity is used to estimate the relative change in entrainment intensity rather than the absolute dust mass flux.

RESULTS

Effects of Operating Parameters on Particle Detachment

Under the reference condition of a rotor speed of 4700 rpm, a ground clearance of 60 mm, and a forward speed of 1.0 m/s, the dynamic flail-root stubble interaction was divided into four stages according to the flail position, stubble deformation, and particle detachment state: approach, impact, cutting and fragmentation, and separation and ejection (Fig. 6). Substantial bond breakage occurred during the impact and cutting stages. The detached particles acquired initial velocity from the flail impact and could subsequently be entrained and transported by the airflow inside the housing. The effects of the five operating parameters on bond fracture rate are presented in Figs. 7 and 8.

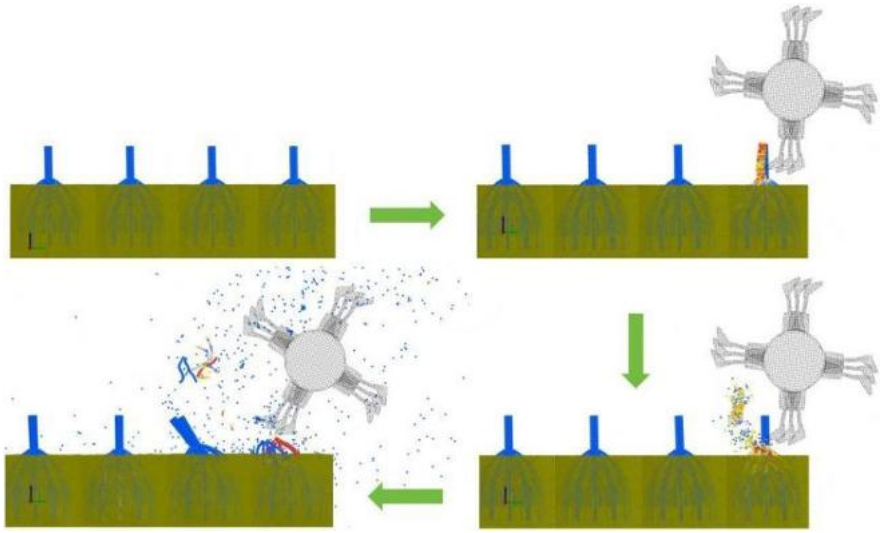

Fig. 6 - Dynamic interaction process between the flail and root stubble

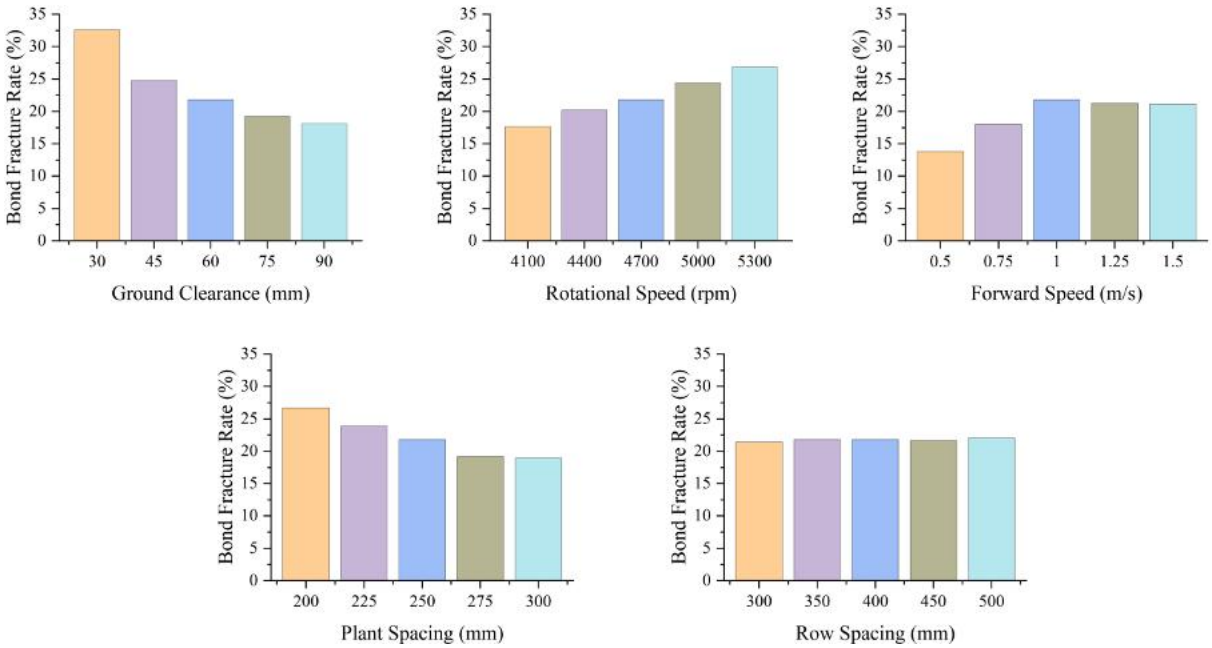

Fig. 7 - Effects of Operating Parameters on the Bond Fracture Rate

Increasing ground clearance from 30 to 90 mm reduced the bond fracture rate from 32.6% to 18.1% (44.5%), because higher clearance shifted flail action upward and reduced disturbance of the strongly bonded root-soil region.

Increasing rotor speed from 4100 to 5300 rpm raised the bond fracture rate from 17.6% to 26.8% (52.3%), as higher speed increased both impact energy and the number of impacts per unit travel distance.

Increasing forward speed from 0.5 to 1.5 m/s raised the bond fracture rate from 13.8% to 21.1%, although the change was only 0.7 percentage points between 1.0 and 1.5 m/s. Forward speed mainly affected the number of stubble contacts per unit time rather than the energy of individual impacts.

Increasing plant spacing from 200 to 300 mm reduced the bond fracture rate from 26.7% to 18.9% because fewer stubble units were encountered per unit area. Plant spacing is an inherent field condition rather than an adjustable machine parameter; therefore, it was evaluated only to characterize its influence on bond fracture rate and was not included in the selection of operating parameters.

Row spacing had the weakest effect: the bond fracture rate varied only from 21.4% to 22.0% over 300-500 mm, with no consistent monotonic trend.

The absolute variation associated with each factor is compared in Fig. 8.

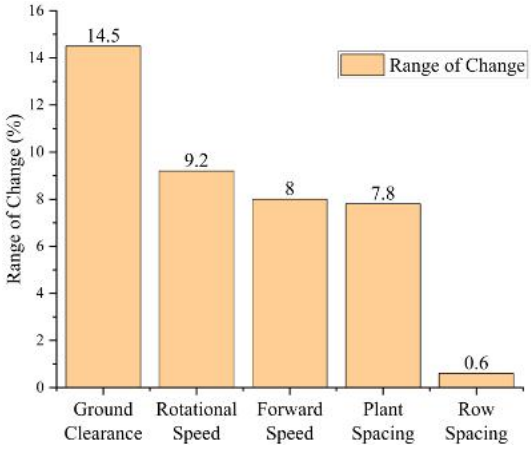

Fig. 8 - Comparison of Factors' Influence on Bond Fracture Rate

The influence order was ground clearance (14.5 percentage points) > rotor speed (9.2) > forward speed (8.0) > plant spacing (7.8) > row spacing (0.6). Thus, ground clearance and rotor speed were the principal controllable factors.

Based on the bond fracture trends within the tested parameter ranges, the candidate low-dust ranges were 60-75 mm for ground clearance, 4400-4700 rpm for rotor speed, and 0.75-1.0 m/s for forward speed. A condition of 75 mm ground clearance, 4400 rpm rotor speed, and 0.75 m/s forward speed was selected for subsequent combined DEM simulation and field comparison.

The observed effects of ground clearance and rotor speed are consistent with the general trend reported in previous agricultural-dust studies that stronger mechanical disturbance tends to increase particulate emissions. Significant differences in dust emissions have been reported among different tillage implements, with more intensive soil disturbance generally associated with higher particulate concentrations (*Çarman et al., 2023*). Agricultural tillage, planting, and harvesting operations have also been shown to generate measurable PM10 and PM2.5 emissions under field conditions (*Chen et al., 2017*). The present results extend these observations to a flail-type straw pickup header and further indicate that ground clearance and rotor speed are the principal controllable parameters governing mechanical particle detachment. The aerodynamic role of rotor speed is further examined through the CFD analysis in the following section.

Internal Flow Field of the Pickup Header and Analysis of Dust Sources

Steady MRF calculations were performed at 4100, 4700, and 5300 rpm to characterize the time-averaged internal flow field and its role in dust entrainment.

Velocity Field Distribution Characteristics

At 4700 rpm, the flow field was divided into four regions according to velocity magnitude and direction:

(1) High-speed rotation zone: airflow adjacent to the rotor formed a strong tangential shear layer, with typical velocities of 80-137 m/s and localized peaks of 153.3 m/s.

(2) Wall-guidance zone: airflow followed the curved inner housing wall at 30-60 m/s, supporting upward material transport.

(3) Inlet entrainment zone: negative pressure drew external air inward and upward through the lower opening at 5-18 m/s, providing the principal pathway for near-ground particle entrainment.

(4) Conveying-channel zone: downstream airflow was comparatively stable at 15-30 m/s and aligned with the channel axis.

The velocity distributions at the three rotor speeds are shown in Fig. 9.

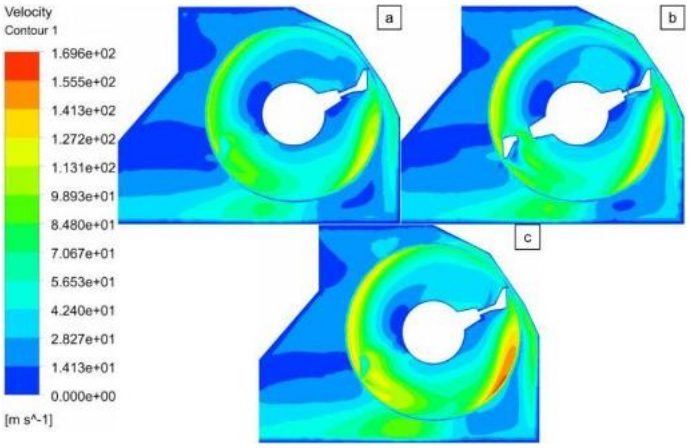

Fig. 9 - Velocity Contour Plot. (a) 4100 rpm; (b) 4700 rpm; (c) 5300 rpm

Increasing rotor speed raised velocities throughout the housing. For each 600 rpm increase, the upper velocity range in the high-speed zone increased by approximately 15-20 m/s, while the upper velocity in the inlet entrainment zone increased by about 4 m/s. The latter trend directly strengthened aerodynamic dust entrainment.

Mechanistic Interpretation of Dust Sources

Three dust-generation pathways were interpreted by relating the DEM detachment states to the corresponding CFD flow regions. Stubble-fragmentation dust originated from direct flail impact and was subsequently transported by the rotating airflow; root-extraction dust resulted from low-clearance disturbance of the root-soil interface followed by near-ground airflow entrainment; and airflow-entrainment dust consisted of loose surface particles lifted directly by the inlet flow. The first pathway increased with rotor speed, whereas the second was mainly associated with ground clearance.

Threshold-Based Comparison of Airflow Entrainment

The measured soil particle-size distribution and the calculated threshold velocities are shown in Fig. 10 and Table 6, respectively.

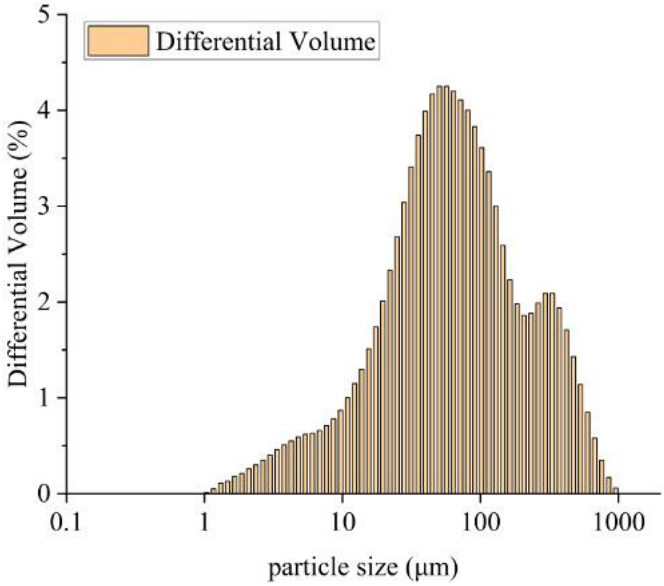

Fig. 10 - Particle Size Distribution

Table 6

Estimated threshold velocities for different particle size fractions

Particle Size (μm)	Equivalent Threshold Velocity (m/s)	Cumulative Volume Percentage (%)
10	0.89	9.38
50	1.99	48.95
100	2.81	68.70
200	3.97	83.72
300	4.87	89.68
500	6.29	96.85

Five monitoring points were placed on a horizontal plane 5 mm above the ground (Fig. 11). The upper inlet velocities of 12.7-16.1 m/s exceeded the recalculated equivalent mean-flow threshold velocities for all representative particle diameters up to 500 μm. Differences among rotor speeds therefore reflected the degree of threshold exceedance rather than whether entrainment occurred.

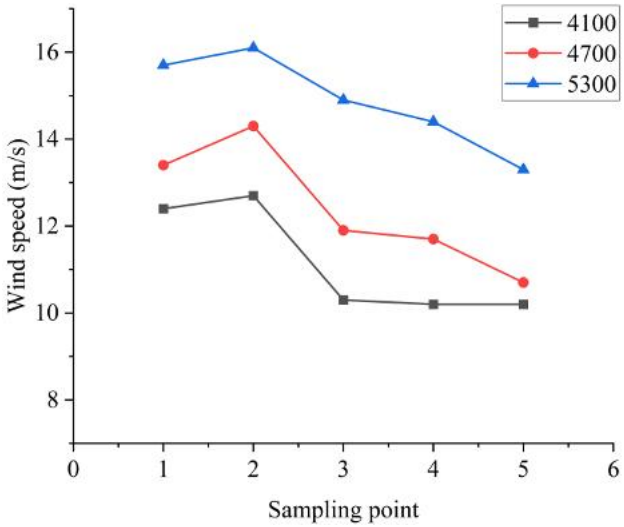

Fig. 11 - Wind Speed Comparison at Measuring Points

The threshold-exceedance ratios and bond fracture rates are compared in Table 7.

Table 7

Comprehensive comparison of airflow entrainment intensity and bond fracture rate at different rotor speeds

Rotor Speed (rpm)	Inlet Velocity Upper Limit (m/s)	Threshold-Exceedance Ratio U/U_t			Bond Fracture Rate (%)
		10-μm particle	50-μm particle	300-μm particle	
4100	12.7	14.3×	6.4×	2.6×	17.6
4700	14.3	16.1×	7.2×	2.9×	21.8
5300	16.1	18.1×	8.1×	3.3×	26.8

From 4100 to 5300 rpm, the velocity-to-threshold ratio increased by 26.8% for representative 10, 50, and 300 μm particles. Based on the calculation method described above, the estimated relative entrainment flux at 5300 rpm was approximately 2.04 times that at 4100 rpm.

Over the same speed range, the bond fracture rate increased by 52.3%. Rotor speed therefore produced a combined mechanical-aerodynamic effect: it increased the quantity of detached particles and simultaneously strengthened their entrainment. This mechanism predicts a larger change in measured dust concentration than in bond fracture rate alone and supports limiting rotor speed to 4400-4700 rpm.

Field Validation and Size-Resolved Particulate Concentrations

The background TSP concentration measured at the sampling point before operation was 56 μg/m³.

The combined DEM simulations yielded bond fracture rates of 34.6% for the dust-intensive condition and 19.1% for the selected low-dust condition, corresponding to a reduction of 44.8%. Field measurements showed the same trend: mean TSP concentration decreased from 3696.0 ± 515.6 to 1397.1 ± 229.2 μg/m3 (62.2%). The difference in TSP concentration between the two operating conditions was statistically significant according to a two-sided Welch's t-test (t = 7.057, p = 0.0076). The larger measured reduction relative to the bond fracture rate is consistent with simultaneous suppression of mechanical detachment and airflow entrainment.

The bond fracture rate should be interpreted as an indicator of the relative degree of particle detachment rather than as a direct predictor of airborne dust concentration. This index quantifies bond failure within the DEM model but does not account for particle size, the fraction of detached particles that actually becomes airborne, subsequent transport and deposition, re-entrainment of loose surface material, or ambient background particles. Therefore, the 44.8% reduction in bond fracture rate and the 62.2% reduction in measured TSP should not be expected to exhibit a one-to-one quantitative relationship. Their consistent trend supports the proposed mechanical-detachment mechanism, while the larger reduction in measured TSP is compatible with the simultaneous weakening of aerodynamic entrainment.

Size-fractionated measurements were used to determine whether the selected low-dust condition also reduced respirable and fine particulate concentrations.

Under the selected low-dust condition, PM_{10} and $PM_{2.5}$ accounted for 68.4% and 22.3% of TSP, respectively; under the dust-intensive condition, the corresponding proportions were 62.2% and 18.3% (Fig. 12).

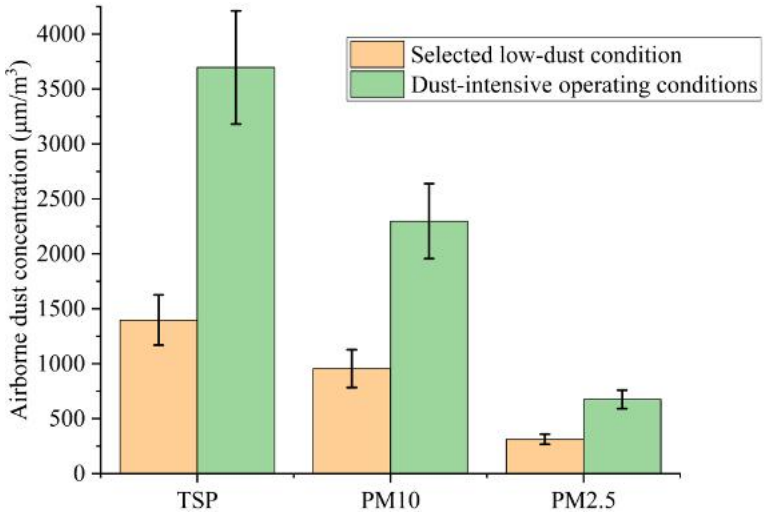

Fig. 12 - Particulate matter concentrations under different operating conditions.

Although the fine-particle proportions were slightly lower under the dust-intensive condition because coarse fragmentation debris increased, the absolute PM_{10} and $PM_{2.5}$ concentrations rose from 955.4 and 312.2 μg/m³ to 2297.4 and 675.2 μg/m³. The selected low-dust condition therefore reduced PM_{10} and $PM_{2.5}$ concentrations by 58.4% and 53.8%, respectively.

The measured TSP concentrations also provide useful context relative to previous harvesting studies. The TSP concentration of 1397.1 μg/m³ under the selected low-dust condition was slightly below the previously reported range of approximately 1500-3000 μg/m³ for harvesting operations, whereas the dust-intensive condition reached 3696.0 μg/m³ and exceeded this range (*Zhang et al., 2021; Xu et al., 2022a*). $PM_{2.5}$ accounted for 18.3%-22.3% of TSP in the present tests, which was lower than the 30%-45% proportion reported in previous harvesting studies (*Zhang et al., 2021; Xu et al., 2022a*). This difference may reflect variations in crop type, soil condition, machine structure, sampling position, and the relatively large contribution of coarse fragments generated by high-speed flail impact. Therefore, direct comparison of absolute concentrations among studies should be made cautiously.

These results demonstrate that parameter adjustment reduced both total and fine particulate emissions; however, the short sampling duration and fixed sampling location do not constitute a full occupational exposure assessment.

CONCLUSIONS

Ground clearance and rotor speed governed dust generation through different but interacting mechanisms. Ground clearance primarily affected mechanical particle detachment by changing the position of flail interaction relative to the strongly bonded root-soil region, whereas rotor speed influenced both impact-induced detachment and the strength of the inlet airflow. Relating the DEM particle-detachment characteristics to the CFD flow-field regions supported three mechanism-based dust-generation pathways: stubble fragmentation, root extraction, and direct airflow entrainment of loose surface particles.

Field measurements further showed that the selected combination of increased ground clearance and moderate rotor speed substantially reduced TSP, PM_{10}, and $PM_{2.5}$ concentrations relative to the dust-intensive condition, demonstrating the practical potential of operating-parameter adjustment for dust mitigation. The results also indicate that reducing excessive inlet negative pressure while maintaining pickup performance represents a promising direction for structural improvement.

Several limitations should be acknowledged. The DEM and CFD analyses were conducted independently rather than through fully coupled particle-flow simulation, and the bond fracture rate represents particle detachment rather than airborne dust concentration itself. Field validation was also limited to two operating conditions, a single field environment, three short-duration replicates per condition, and a fixed sampling position. Future studies should therefore examine a wider range of crops, soil conditions, and operating parameters; employ longer-duration and multi-point field measurements; investigate transient or coupled particle-airflow interactions; and evaluate pickup-header inlet modifications that reduce direct particle entrainment without compromising pickup efficiency.

ABSTRACT
To address the problems of low manual pickup efficiency and severe soil accumulation in existing shovel-type pickup devices used for segmented potato harvesting, a composite pickup device consisting of a grid-type segmented pickup shovel and a flexible lifting wheel was designed. A potato-soil-machine discrete element simulation model was established using EDEM to optimize structural parameters, including grid spacing, and to investigate the effects of operating parameters, including forward speed, digging depth, and lifting-wheel speed, on pickup performance. The simulation results showed that grid spacing was negatively correlated with the loss rate and positively correlated with the damage rate. An optimized grid spacing of 25 mm reduced the damage rate to 2.21% and the loss rate to 3.70%, while effectively reducing potato jamming. As the forward speed and lifting-wheel speed increased, the loss rate decreased, whereas the damage rate increased. Digging depth had a nonlinear effect on the loss rate, which initially decreased and then increased, reaching its minimum at a digging depth of 100 mm, whereas the damage rate continuously decreased with increasing digging depth. Field tests yielded an average loss rate of 3.88% and an average damage rate of 2.24%, meeting the operational requirements for potato harvesting.

摘要
针对马铃薯分段收获中人工捡拾效率低和现有铲式捡拾装置易壅土的问题，设计了一种由栅栏分段式捡拾铲与柔性拨薯轮组成的复合式捡拾装置。基于 EDEM 软件建立了薯-土-机离散元仿真模型，优化栅栏间距等结构参数并探究了前进速度、入土深度和拨薯轮转速等作业参数对捡拾性能的影响。仿真结果表明：栅栏间距与损失率负相关，与伤薯率正相关；优化后的 25 mm 栅栏间距使伤薯率降至 2.21%，损失率为 3.70%，显著减少了薯块卡滞现象；前进速度和拨薯轮转速增加时，损失率下降而伤薯率上升，入土深度对损失率呈先降后升的非线性影响，100 mm 时最优，对伤薯率则持续降低。田间试验平均损失率为 3.88%，伤薯率为 2.24%，满足马铃薯收获作业要求。

INTRODUCTION
Potato mechanized harvesting can be divided into combine harvesting and segmented harvesting. At present, segmented harvesting is still the predominant method in hilly areas with many small fields *(Wang et al., 2023)*. In segmented harvesting, the preliminary operations such as vine killing, digging, separation, and windrowing have achieved a relatively high level of mechanization. However, the pickup operation still relies heavily on manual labor, resulting in high labor intensity and low efficiency (*Dorokhov et al., 2022*). Therefore, developing a low-damage, high-efficiency potato pickup device is of great significance for improving the mechanization level of segmented potato harvesting and reducing labor costs.

Existing pickup devices can be mainly divided into two categories. The first category is shovel-type pickup devices represented by flat shovels, triangular shovels, and bionic shovels, which are currently widely used and usually adopt a single-stage flat structure. These devices have high forward resistance and severe soil accumulation, which easily cause potatoes to roll back into the furrow and increase the loss rate. However, they can achieve continuous feeding and high operational efficiency *(Beznosyuk et al., 2022; Yang et al., 2025; Mamatov and Karimov, 2023)*.

[1] *Zheng Ma (Professor), Jianjiao Huang (Master's degree student), Shuai Wang (Assistant Researcher), Yaoming Li (Professor), Zhiqiang Song (Assistant Researcher)*

The second category is rotary pickup devices represented by spring-tooth and disc types. They achieve intermittent grasping through rotating components, which avoids large amounts of soil being drawn in, enables targeted picking of potatoes, reduces operational resistance, and alleviates the burden of subsequent potato-soil separation. Nevertheless, these devices are prone to causing damage due to collisions with potatoes, and the forward speed and rotational speed cannot be too high; otherwise, missing picking may occur, limiting the overall operational efficiency *(Lu et al., 2023; Yang et al., 2024; Toure and Wei, 2023)*. Addressing the shortcomings of existing pickup devices, this study designed a composite pickup device consisting of a grid-segmented pickup shovel and a flexible lifting wheel. The device uses the grid structure of the pickup shovel to perform preliminary screening of the potato-soil mixture to alleviate soil accumulation, improves the pickup rate through the horizontal section of the segmented shovel surface, and reduces collision damage by means of the flexible lifting wheel's active rotary conveying action.

The discrete element method has been widely applied in research on potato-soil separation, digging resistance analysis, and structural optimization of equipment, as it can effectively simulate the complex interactions among potatoes, soil, and machinery. Based on this method, this study established a potato-soil-machine discrete element simulation model using EDEM software. The grid spacing of the pickup shovel was taken as a key parameter for optimization, and single-factor simulation experiments were conducted to systematically analyze the effects of forward speed, digging depth, and lifting wheel speed on picking performance. Finally, the operational performance of the device was verified through field experiments, confirming that the composite pickup device under optimized parameters meets the requirements for low-damage and low-loss potato pickup harvesting. This study provides a theoretical basis and technical reference for the optimal design of potato pickup equipment.

MATERIALS AND METHODS

Design of the composite pickup device

The specific structure of the composite pickup device is shown in Fig. 1. It mainly consists of a depth-limiting wheel, a height adjustment plate, a pickup shovel, a lifting wheel, a frame, etc. Its core is a composite structure in which the pickup shovel and the lifting wheel work synergistically: combining the advantages of continuous feeding and high efficiency of the traditional flat pickup shovel, while drawing on the targeted picking concept of the spring-tooth pickup device. By using the active conveying of the lifting wheel to replace the passive pushing of the shovel surface, effective pickup of potatoes is achieved.

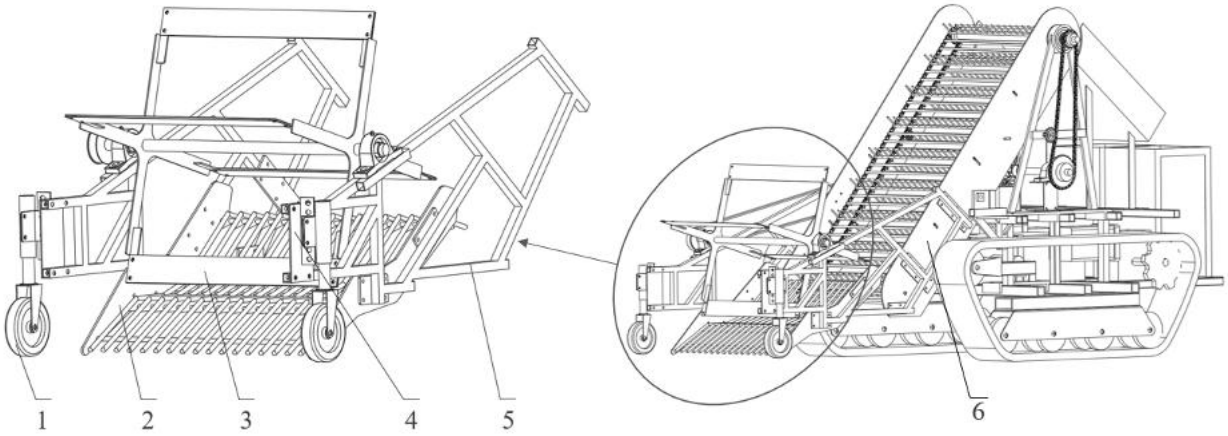

Fig. 1 - Structural schematic of the combined pickup device

1. Depth-limiting wheel 2. Pickup shovel 3. Lifting wheel 4.Height adjustment plate 5. Frame 6. Conveying and lifting device

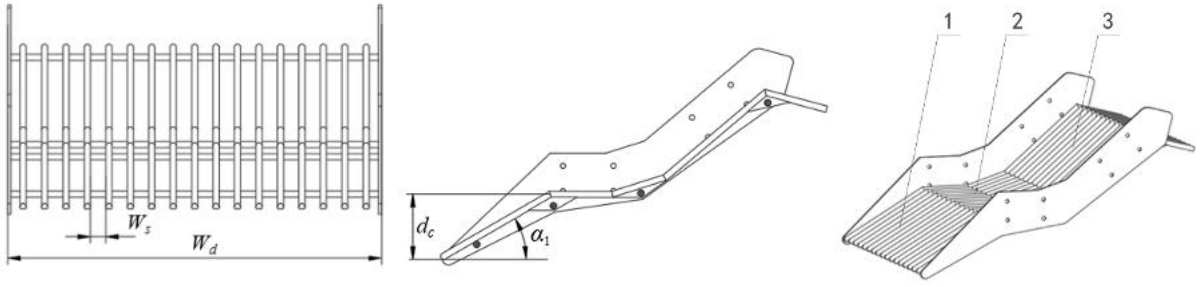
Before operation, the depth-limiting wheel is adjusted to fit the side of the ridge. During operation, the potato-soil mixture is initially screened by the grid structure of the pickup shovel, and the potatoes remain on the shovel surface. The lifting wheel rotates to generate an active conveying force, smoothly pushing the potatoes off the shovel surface and onto the subsequent conveying and lifting device, finally completing the collection and bagging of potatoes. To adapt to terrain fluctuations, a compression spring is built into the depth-limiting wheel: when compressed, the spring drives the wheel to lift adaptively, buffering impacts and maintaining the working depth, thereby ensuring pickup quality. The main parameters of the composite pickup device are shown in Table 1.

Table 1

Main parameters of the composite pickup device

Item	Value
Overall dimensions (L×W×H) / (mm×mm×mm)	1039 × 818 × 906
Working width / mm	600
Applicable ridge width / mm	≤800
Applicable ridge height / mm	100–200
Number of ridges worked	1

Grid-segmented pickup shovel



The pickup shovel is the core component of the pickup device. Structural innovations were made based on the traditional flat pickup shovel:

(1) The traditional shovel surface was optimized into a grid structure to preliminarily screen the potato-soil mixture and reduce traveling resistance.

(2) The single-stage shovel surface was reconstructed into a three-stage "inclined–horizontal–inclined" structure: the digging stage screens the soil and picks up underground potatoes (those buried beneath the soil surface); the horizontal stage forms a zero-inclination pickup platform to improve the pickup rate; a smooth transition section is added at the junction between the horizontal stage and the lifting stage to eliminate geometric discontinuities and enhance the low-damage performance of the device; the lifting stage works together with the lifting wheel to raise the potatoes to a certain height for subsequent conveying; and a guide section is provided at the end of the lifting stage to achieve impact-free connection with the conveying and lifting device.

According to the agrotechnical requirements for potato planting in hilly areas, the ridge width ranges from 600 to 800 mm. After digging, potatoes are scattered on the ridge surface with a distribution width of approximately 450 mm and a surface distribution depth of less than 40 mm *(Ahmad and Sharma, 2023)*. To ensure that the pickup shovel completely covers the potato distribution area, the shovel width W_d was designed as 600 mm. The resistance on the shovel surface increases with the entry angle, considering energy saving and soil penetration performance, the entry angle α_1 is generally taken as 20°- 30° *(Wei et al., 2023)*. To shorten the horizontal projection length of the pickup shovel, the upper limit of the entry angle, 30°, was chosen. The digging depth d_c of the pickup shovel should be controlled between 80 -120 mm. Based on this, the length of the first segment of the pickup shovel was set to 200 mm.

The three-axis size distribution of potatoes ranges from 30 to 160 mm *(Wang et al., 2023)*. To prevent small-sized potatoes from becoming embedded or stuck in the grid gaps, the grid spacing of the pickup shovel should be smaller than the minor axis of potatoes. In existing potato harvesting equipment, the grid spacing is mostly designed with reference to the bar spacing of the conveying and lifting chain or the separation conveyor chain, with typical values of 30 - 40 mm *(Bulgakov et al., 2021)*. During such conveying processes, potatoes mainly move with the conveyor chain under their own weight, without significant active pressing action between the potatoes and the grid; therefore, the grid spacing is mainly determined based on passing ability and soil sieving performance. Unlike conventional conveying structures, the pickup device designed in this study uses a lifting wheel to actively convey the potato tubers. When passing through the grid area, potatoes are subjected not only to gravity but also to the contact thrust applied by the lifting wheel, which may press them into the grid gaps. Consequently, the traditional grid spacing parameters are not directly applicable to the design of the present device. Considering the potato size distribution and existing equipment design experience *(Wei et al., 2023)*, the grid spacing W_s was preliminarily set to 30 mm, which will be further optimized through discrete element simulations. The specific structure and parameters of the grid-segmented pickup shovel are shown in Fig. 2.

Flexible lifting wheel

Although the grid structure of the pickup shovel enables preliminary screening of the potato-soil mixture, thereby alleviating soil accumulation and reducing loss due to accumulation as well as forward resistance, it also brings a new problem: after soil and potatoes are separated, the potatoes lose the pushing effect of the soil, becoming stranded on the pickup stage of the shovel and difficult to effectively pushed forward and lifted. To address this issue, a lifting wheel is added above the pickup shovel. The lifting wheel is covered with a flexible material (canvas) and generates an active conveying force when rotating. When potatoes remain on the shovel surface, the paddles of the lifting wheel, with a relatively large contact area, smoothly push the potatoes off the shovel surface, avoiding the surface bruising and impact damage caused by the direct rigid collision of spring teeth or fingers in existing studies.

Although the lifting wheel draws on the active conveying concept of the spring-tooth pickup device, its mode of action is different: the spring-tooth pickup device relies on the spring teeth to directly grasp potatoes on the soil surface, and if the grasping fails, it results in missed pickups. In contrast, in the present design, potatoes continuously enter the shovel surface through the forward motion of the pickup shovel, and the lifting wheel only plays an auxiliary pushing role without undertaking the "grasping" function, thus not causing missed pickups. Therefore, the pickup efficiency is mainly inherited from the high-efficiency continuous feeding characteristic of the traditional flat shovel, achieving a balance between targeted potato picking and a high pickup rate.

To facilitate the smooth entry of potatoes into the subsequent elevator conveyor, the lifting wheel needs to push the potatoes up along the lifting section of the pickup shovel to a certain height. As shown in Fig. 3, from point A to point B for the potato, the relationship between the lifting wheel radius and the potato lifting height is given by the following formula:

$$H = \sqrt{2Rd - d^2}sin\beta + dcos\beta + R - Rcos\beta \quad (1)$$

where: H is the potato lifting height, mm;

β is the inclination angle of the third segment of the pickup shovel, (°);

d is the short-axis dimension of the potato, mm;

R is the minimum radius of the lifting wheel, mm.

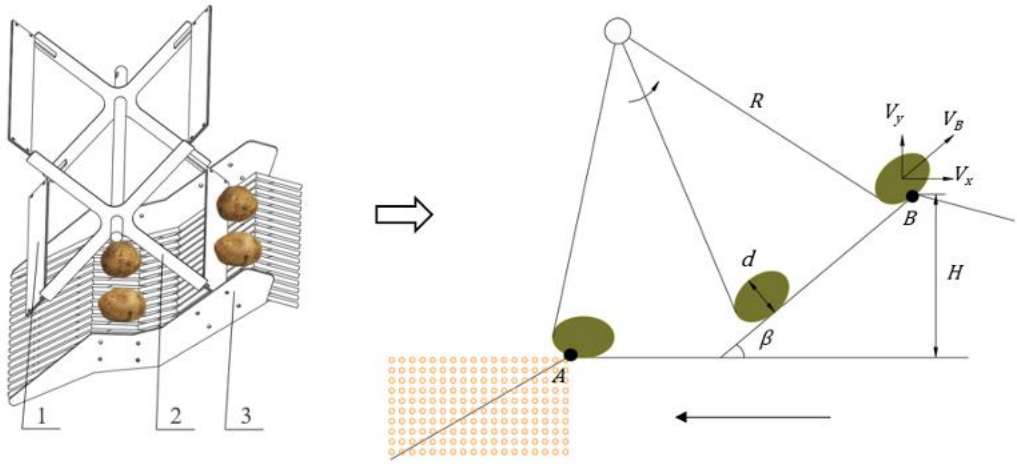

Fig. 3 - Schematic diagram of potato processing

1.Paddle; 2. Lifting wheel; 3. Pickup shovel

At the detachment position (point B), when the potato reaches the highest point with the lifting wheel, it is thrown out along the lifting stage of the pickup shovel and enters the subsequent conveying and lifting device. To facilitate the detachment of the potato from the lifting wheel paddle, the horizontal component of velocity V_X should be greater than the vertical component V_Y, i.e., $V_B cos\beta > V_B sin\beta$. From this, β should be less than 45°. To shorten the horizontal dimension of the pickup shovel and achieve better lifting effect, the inclination angle β of the lifting stage of the pickup shovel was preset to 40°.

Based on the measured distribution range of potato three-axis dimensions, the minimum short-axis dimension d of the potato was taken as 30 mm. To ensure the potato smoothly enters the subsequent conveying and lifting device, the minimum lifting height was set to 150 mm. From equation (1), the lifting wheel radius $R \geq 231$ mm, so R = 300 mm was adopted.

Establishment of the discrete element model

Soil and potato particle models

Soil particles were modeled using spherical particles with a radius of 5 mm. To characterize the actual soil particle size distribution, based on the investigation results of soil particle size in hilly areas (<1 mm: 8.44%, 1- 2 mm: 23.12%, 2 - 5 mm: 37.68%, >5 mm: 30.76%) *(Issa et al., 2025; Chen et al., 2024)*, scaling factors of 0.1, 0.3, 0.5, and 2.0 times were set in the EDEM particle factory, corresponding to generated spherical particles with diameters of 0.5, 1.5, 2.5, and 10.0 mm, and the number generated was allocated according to the mass proportions.

Based on the measured average three-axis dimensions of potatoes, two types of simulation particle models were established: spherical-like and ellipsoidal. The spherical-like potato model had a short axis of 60 mm and a long axis of 66 mm; the ellipsoidal potato model had a short axis of 50 mm and a long axis of 85 mm. These were formed as discrete element models using multi-sphere aggregates. The two types of potato particle models are shown in Fig. 4. To reflect the size variation of tubers in the field, a random scaling factor of 0.6 -1.5 times was applied to the base models in the EDEM particle factory to generate particles covering the range of small, medium, and large tubers.

(a) Spherical-like potato (b) Ellipsoidal potato

Fig. 4 - Simulation model of potato particles

Referring to field conditions, a soil bin and potato ridge model were established: the soil bin length was 7000 mm, the ridge bottom width was 800 mm, the ridge surface width was 600 mm, and the ridge height was 150 mm. The particle factory for potatoes was placed at a height of 400 mm above the soil surface, allowing the potato tubers to fall freely and form a distribution close to the field scattering state. Based on the estimated actual potato yield, a total of 21 kg of potatoes was generated.

Simulation parameter settings

The basic characteristic parameters of the materials are shown in Table 2 *(Li et al., 2023; Wang et al., 2023; Pan et al., 2025)*. The Hertz–Mindlin (no slip) model was used for contacts between particles and the machine components, whereas the Hertz–Mindlin with JKR model was used for particle–particle contacts. The rolling friction model was the standard rolling friction model. The interaction parameters for contact are shown in Table 3 *(Yan et al., 2023; Pan et al., 2026; Foldager et al., 2022)*. The simulation time step was set to 20% of the Rayleigh time step, calculated to be approximately 1.2×10^{-5} s. The data save interval was set to 0.01 s *(Maraveas et al., 2025).*

Table 2

Basic simulation parameters

Parameter	Poisson's ratio	Density / (kg/m³)	Shear modulus / Pa
Potato	0.47	1047	1.99×10^6
Soil	0.25	1240	1.00×10^6
Steel	0.30	7800	7.00×10^{10}
Rubber plate	0.30	1800	3.85×10^7

Table 3

Interaction simulation parameters

Interaction pair	Coefficient of restitution	Coefficient of static friction	Coefficient of rolling friction
Potato-Potato	0.60	0.48	0.03
Soil-Soil	0.13	0.56	0.27
Potato-Soil	0.53	0.50	0.01
Potato-Steel	0.65	0.28	0.16
Soil-Steel	0.28	0.49	0.57
Soil-**Canvas**	0.12	0.66	0.54
Potato-**Canvas**	0.71	0.51	0.20

Evaluation indicators

Referring to the quality evaluation indicators for self-propelled potato combine harvesters in JB/T 14285-2022 "Potato Harvesting Machinery" *(JB/T 14285-2022, 2022)*, and considering the actual working conditions of pickup operations, the performance evaluation indicators for the device were determined as follows: loss rate ≤ 4%, damage rate ≤ 2.5%.

Previous studies typically take the potato extrusion force damage threshold as 100 N *(Yang et al., 2024)*. However, multiple low-stress collisions may also cause cumulative tissue damage. To establish a more practical warning value, a preloading test was conducted on the potato variety used in this study (Qingshu No.9). The results showed that when the extrusion force reached approximately 60 N, slight surface indentations and softening began to appear on the tubers. Therefore, referring to existing damage thresholds and combining with the observations from the pre-test, a more conservative value of 60 N was adopted as the damage risk warning value, which is used to characterize potentially high-risk force events rather than the critical value for actual visible damage.

RESULTS AND ANALYSIS

Initial simulation and problem diagnosis under baseline operating parameters

In the initial design, the grid spacing of the pickup shovel was set to 30 mm. To diagnose whether there were any jamming or damage issues under this structural parameter, referring to typical potato harvesting operating conditions and the design experience of similar pickup devices *(Lu et al., 2023)*, a set of conventional operating parameters was selected as the baseline: forward speed of 0.40 m/s, digging depth of 100 mm, and lifting wheel speed of 20 r/min. A simulation of the pickup process was carried out under these operating conditions, as shown in Fig. 5.

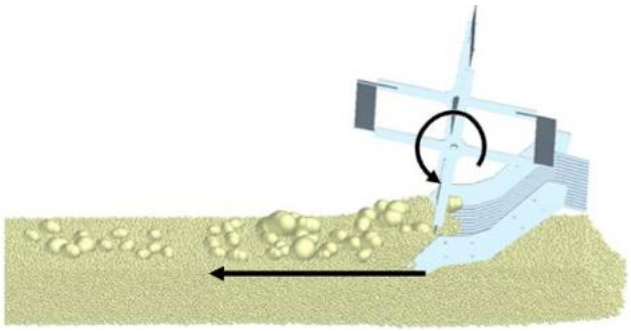

Fig. 5 - Simulation experiment of the pickup process

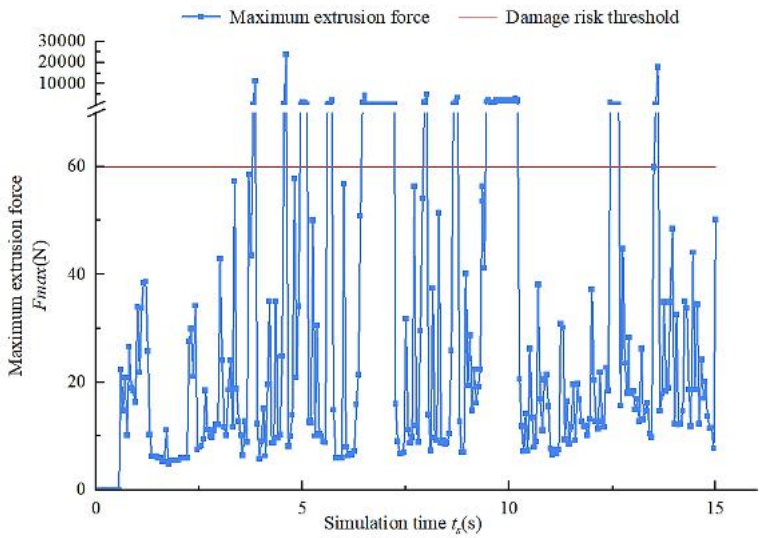
The time-history curve of the maximum extrusion force during the pickup process was extracted, as shown in Fig. 6. The maximum extrusion force on potatoes during pickup was recorded at intervals of 0.1 s. The red horizontal line in the figure indicates the damage risk warning value of 60 N.



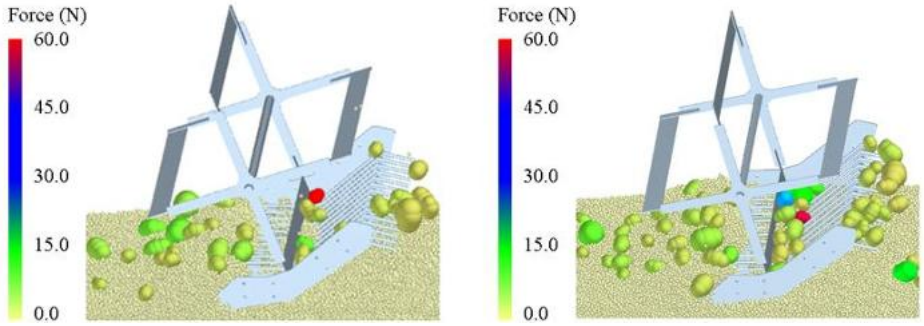


Fig. 6 - Time-history curve of extrusion force during potato pickup process (grid spacing 30 mm)

As shown in Fig. 6, during the 15 s pickup process, a total of 10 damage risk events with extrusion force exceeding 60 N occurred, with an average frequency of approximately once every 1.5 s. Among them, during the intervals of 6.4 - 7.2 s and 9.5 - 10.2 s, the high extrusion force states lasted for about 0.9 s and 0.8 s, respectively, and the risk events were mainly concentrated in the period of 3.8 - 13.6 s, indicating that under the initial grid spacing of 30 mm, the potatoes experienced a significant sustained compression phenomenon during the pickup process. To further analyze the causes of high extrusion forces, typical risk periods were selected for observation, and the results are shown in Fig. 7. It can be seen that during the periods of 6.4 -7.2 s and 9.5 - 10.2 s, potato jamming in the grid gaps occurred. After small-sized potatoes or the tips of potatoes became embedded in the grid gaps, they were constrained by the grid structure under the continuous conveying action of the lifting wheel, making it difficult to detach in time, thus forming a sustained compression state.

(a) Potato jam at simulation time 6.4-7.2 s (b) Potato jam at simulation time 9.5-10.2 s

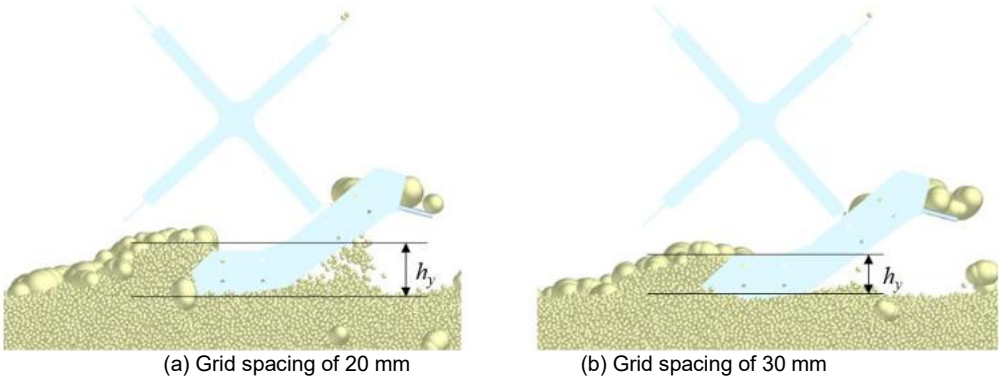

Fig. 7 - Abnormal conditions of potato during pickup process (grid spacing 30 mm)

The analysis suggests that although the 30 mm grid spacing can theoretically effectively prevent small-sized potatoes from falling through the gaps, due to the irregular shapes and random postures of the potatoes, their tips or local protruding parts are still prone to becoming embedded in the grid gaps. Once a potato tuber is embedded, under the continuous conveying action of the lifting wheel, it is easy to form a local "embedding–sustained compression" state, causing the extrusion force to remain at a high level for a certain period, with consecutive sampling points exceeding the 60 N risk warning value.

Combining the analysis of the extrusion force time-history curve and the particle motion state, it can be seen that the high extrusion force events did not occur randomly but showed a clear correspondence with potato jamming, exhibiting a certain regularity. This indicates that the initial 30 mm grid spacing is close to the minor axis size of some small-sized potato tubers, which easily induces tuber embedding and sustained compression. Therefore, it is necessary to further optimize the grid spacing parameter to reduce the risks of potato jamming and mechanical damage.

Single-factor optimization of grid spacing

Based on the clogging and potato damage risks observed in the initial simulation, a single-factor sensitivity analysis was conducted using grid spacing as the test factor. Five levels were selected: 20, 22.5, 25, 27.5, and 30 mm, among which 30 mm was the initial design value. The operating parameters were kept constant for all treatments: forward speed of 0.40 m/s, digging depth of 100 mm, and lifting wheel rotational speed of 20 r/min. Each treatment was simulated three times.

(a) Grid spacing of 20 mm (b) Grid spacing of 30 mm

Fig. 8 - Soil accumulation under different grid spacings of the pickup device

The simulation results showed that grid spacing had a significant influence on soil screening performance and potato conveying behavior. As shown in Fig. 8, when the grid spacing was small (e.g. 20 mm), the soil passed slowly through the grid gaps, resulting in obvious soil accumulation at the front of the pickup shovel. Potatoes tended to accumulate on the shovel surface. As the device moved forward, the accumulated soil caused potatoes in front of the shovel to roll backward or fall back into the ridge bottom, preventing them from entering the pickup shovel smoothly and thereby increasing the loss rate. With increasing grid spacing (e.g. 30 mm), the soil screening capacity improved, the soil accumulation height h_y at the front of the pickup shovel decreased significantly, and the potato passing performance improved, resulting in a lower loss rate.

However, when the grid spacing became excessively large, although soil separation was improved, potatoes were more likely to become embedded in the grid gaps and jam between adjacent rods. Under the continuous conveying action of the lifting wheel, this led to sustained compression and an increase in potato damage rate. The variation trends of simulated damage rate and simulated loss rate under different grid spacings are shown in Fig. 9.

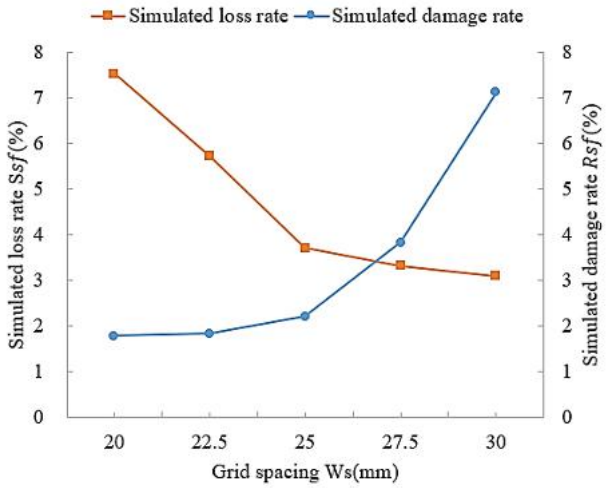

Fig. 9 - Simulated damage rate and simulated loss rate under different grid spacings

As shown in Fig. 9, with the increase of grid spacing, the simulated loss rate showed an overall downward trend, indicating that a larger spacing is beneficial for soil sieving and potato passage. When the grid spacing increased from 20 mm to 30 mm, the simulated loss rate decreased from 7.52% to 3.10%. At the same time, the simulated damage rate increased from 1.79% to 7.11%, indicating that excessive grid spacing significantly increases the risk of potatoes becoming embedded in the gaps and experiencing jamming and compression. Among the tested spacings, the damage rates at 20 mm and 22.5 mm were relatively low, but the loss rates reached 7.52% and 5.71%, respectively, indicating poor pickup performance. At 27.5 mm and 30 mm, the loss rates were low, but the damage rates increased significantly. A comprehensive comparison of the results shows that, under the premise that the damage rate does not exceed the design requirement of 2.5%, the grid spacing of 25 mm corresponds to the lowest loss rate of 3.70%, with a damage rate of 2.21%, demonstrating the best overall performance. Therefore, 25 mm was determined as the optimal grid spacing.

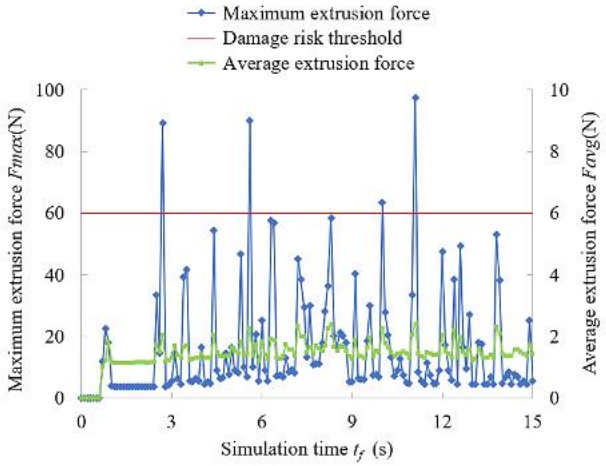
Force validation after optimization

Simulation was conducted again using the optimized grid spacing of 25 mm, and the time-history curve of potato extrusion force during the pickup process was extracted, as shown in Fig. 10. A total of 150 valid sampling points were obtained. Among them, only four isolated sampling points exceeded the 60 N damage warning threshold, occurring at 2.7 s (89.2 N), 5.6 s (90.0 N), 10.0 s (63.5 N), and 11.1 s (97.3 N), accounting for approximately 2.6% of the total sampling points. For the remaining 97.4% of the sampling points, the maximum extrusion force remained within the safe range.

Compared with the initial 30 mm grid spacing, the optimized 25 mm grid structure no longer showed continuous jamming events involving multiple consecutive sampling points exceeding the threshold. The peak extrusion force was controlled below 100 N, and the overall loading level was significantly reduced. This indicates that the optimized grid spacing effectively alleviated sustained compression of potatoes during the pickup process.

The analysis suggests that after reducing the grid spacing, potatoes were less likely to become embedded in the grid gaps. The contact mode gradually changed from “embedded compression” to “surface sliding contact”, thereby reducing the probability of continuous high-load events. In addition, the average extrusion force remained at a relatively low level after optimization, indicating that the interaction between the lifting wheel and potatoes was mainly characterized by transient contact and flexible conveying, without obvious accumulation or sustained compression.

These results demonstrate that the 25 mm grid spacing not only ensures effective soil screening and smooth potato passage, but also effectively suppresses tuber embedding and jamming, significantly reducing the risk of mechanical damage. Therefore, it can be considered an optimal structural parameter that achieves a good balance between low loss rate and low damage rate.



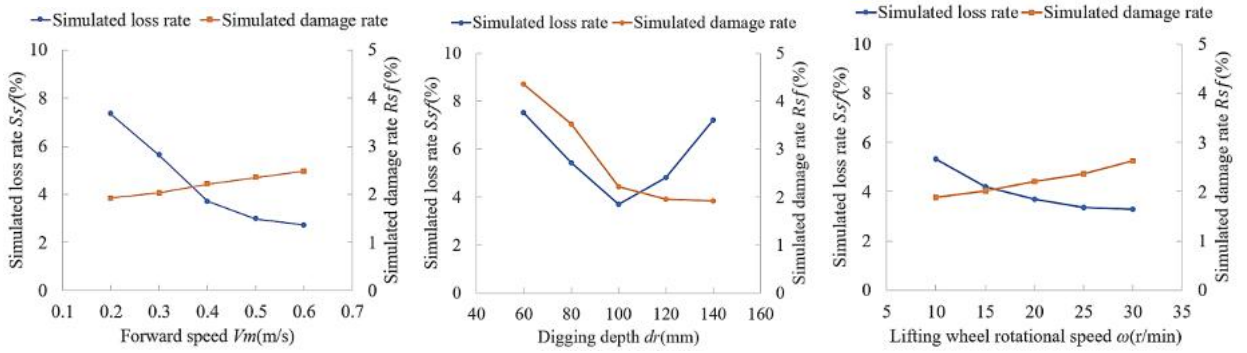


Fig. 10 - Time-history curve of extrusion force during the potato pickup process (optimized grid spacing 25 mm)

Single-factor analysis of the influence of operating parameters on pickup performance

On the basis of determining the optimal grid spacing (25 mm), single-factor simulation tests were carried out to further investigate the influence trends of the overall forward speed, digging depth of the pickup shovel, and lifting wheel speed on the pickup performance. The value ranges of forward speed and digging depth were set with reference to relevant studies on shovel-type pickup devices *(Yang et al., 2024)*, while the value range of lifting wheel speed was determined based on the operating parameters of a spring-tooth pick up device with a similar radius *(Lu et al., 2023*). Accordingly, the forward speed was preliminarily set at 0.2 - 0.6 m/s, the digging depth at 60 - 140 mm, and the lifting wheel speed at 10 - 30 r/min. When testing one factor, the other two factors were kept at their intermediate levels (forward speed 0.40 m/s, digging depth 100 mm, lifting wheel speed 20 r/min). Each parameter combination was simulated three times, and the average values were taken. The influence trends of forward speed, digging depth, and lifting wheel speed on the simulated loss rate and simulated damage rate are shown in Fig. 11(a), (b), and (c), respectively.

(a) Effect of forward speed on pickup performance

(b) Effect of digging depth on pickup performance

(c) Effect of lifting wheel speed on pickup performance

Fig. 11- Effect of operating parameters on picking performance

Analysis of the experimental results yields:

(1) Effect of forward speed: As the forward speed increased from 0.20 m/s to 0.60 m/s, the simulated loss rate decreased significantly (from 7.35% to 2.72%), while the simulated damage rate increased slowly (from 1.92% to 2.48%). A higher forward speed gives the potato-soil mixture sufficient inertia to be transported backward quickly, reducing soil accumulation and buildup, thereby lowering the loss rate.

However, a higher speed also increases the relative collision speed between potatoes and the pickup shovel, leading to a slight increase in the damage rate. When the forward speed exceeded 0.50 m/s, the damage rate approached the design upper limit of 2.5%, and the decrease in loss rate leveled off, indicating that further increasing the forward speed has limited marginal effect on improving pickup performance.

(2) Effect of digging depth: The simulated loss rate exhibited a U-shaped curve with increasing digging depth, first decreasing and then increasing. It was highest at 60 mm (7.52%), lowest at 100 mm (3.70%), and then rose to 7.20% at 140 mm. The simulated damage rate, in contrast, continuously decreased (from 4.36% at 60 mm to 1.92% at 140 mm). When the digging depth was too shallow (60 mm), the end of the digging stage of the pickup shovel was prone to emerge from the soil surface, causing potatoes to stagnate and roll off, resulting in a high loss rate. Moreover, the shallow depth meant less soil and more direct collisions, leading to a higher damage rate. As the digging depth increased, the buffering effect of the soil was enhanced, and the damage rate continued to decrease. However, when the depth exceeded 100 mm, soil accumulation worsened, causing the loss rate to rise again.

(3) Effect of lifting wheel speed: As the lifting wheel speed increased from 10 r/min to 30 r/min, the simulated loss rate continuously decreased from 5.34% to 3.28%, while the simulated damage rate continuously increased from 1.89% to 2.63%. Increasing the speed effectively alleviated soil accumulation and enhanced the active conveying capacity, thereby reducing missed pickup losses. However, excessively high speeds increased the frequency and velocity of collisions between the paddles and the potatoes, leading to a higher damage rate.

Field experiment and simulation comparison

Experimental conditions

The field experiment was conducted in November 2025 at the potato experimental field of the College of Agricultural Engineering, Jiangsu University (Fig. 12). Measurements showed that the ridge bottom width was 800 mm, the ridge surface width was 600 mm, the ridge height was 150–200 mm, and the soil was loam. Before the experiment, the soil moisture content and bulk density were measured: moisture content was determined by the oven-drying method, and bulk density by the cutting ring method, with five sampling points and three repetitions for each. The results showed an average soil moisture content of 14.2% and an average bulk density of 1.28 g/cm³. The test variety was "Qingshu No. 9". Potatoes were manually and randomly placed on the ridge surface according to their field distribution state, with some buried 5–6 cm into the soil to simulate exposed and buried potatoes. The test area length was 10 m, and the total mass of potatoes placed was approximately 30–35 kg. After the test, the picked and missed potatoes were separately collected and weighed, and the damaged potatoes were also picked out and weighed.

Fig. 12 - Field test of potato pickup harvesting

Experimental results and comparison with simulation

Field tests were conducted using the optimized parameter combination (grid spacing of 25 mm, forward speed of 0.40 m/s, digging depth of 100 mm, lifting wheel speed of 20 r/min), and the results are shown in Table 4.

Table 4

Field experiment results of potato pickup harvesting

Indicator	1	2	3	4	5	Mean ± SD
Loss rate Y_1 (%)	3.45	4.24	3.76	4.15	3.82	3.88 ± 0.32
Damage rate Y_2 (%)	2.18	2.31	2.22	2.34	2.15	2.24 ± 0.08

From Table 4, it can be seen that the average loss rate in the field test was 3.88% and the average damage rate was 2.24%, indicating that the designed composite pickup device can meet the operational requirements for potato pickup and harvesting under the optimized grid spacing. Meanwhile, the test results are in good agreement with the simulated predicted values (loss rate 3.70%, damage rate 2.21%), with relative deviations of 4.97% and 1.4%, respectively, further verifying the reliability of the EDEM simulation model and the damage warning method. The deviations mainly stem from the presence of soil clods, stones, and slightly higher surface unevenness in the field compared to the simulation settings, which caused localized soil accumulation and a very small number of missed potatoes. In summary, the composite pickup device with a grid spacing of 25 mm can achieve both low loss and low damage operational requirements.

CONCLUSIONS

(1) To address the problems of low manual picking efficiency, susceptibility to soil accumulation, and high damage rate of existing pickup devices during segmented potato harvesting, a composite potato pickup device consisting of a grid-segmented pickup shovel and a flexible lifting wheel was designed. This device enables preliminary screening of the potato-soil mixture and active conveying, effectively reducing soil accumulation and mechanical damage to potatoes.

(2) A potato–soil–machine discrete element simulation model was established using EDEM to optimize the grid spacing and conduct single-factor simulation analyses. The results showed that increasing the grid spacing was beneficial for reducing the loss rate but increased the risk of potato embedding and jamming, leading to a higher damage rate. After comprehensive comparison, a grid spacing of 25 mm was determined as the optimal value, corresponding to a simulated loss rate of 3.70% and a simulated damage rate of 2.21%. The single-factor simulation analyses also indicated that as the forward speed and lifting wheel speed increased, the simulated loss rate showed an overall decreasing trend while the simulated damage rate gradually increased. Digging depth exhibited a non-linear effect on pickup performance: the simulated loss rate first decreased and then increased with increasing digging depth, whereas the simulated damage rate decreased overall.

(3) Field tests were conducted using the optimized grid spacing (25 mm) and operating parameters. The results showed an average loss rate of 3.88% and an average damage rate of 2.24%, both better than the industry standard requirements (loss rate $\leq$ 4%, damage rate $\leq$ 2.5%), verifying that the designed composite pickup device under the optimized parameters can meet the operational requirements of low loss and low damage.

ABSTRACT
Post-mining substrates are spatially heterogeneous and require site-specific diagnosis before biomass cultivation. This study documents the establishment and three-year monitoring of a 4,500 m² field platform on a coal-mining waste dump in Petrila, Romania. Nine 500 m² plots were used: three fixed-crop reference plots (designated as controls in the original project records) and six plots under a balanced cyclic rotation of maize (Zea mays), soybean (Glycine max) and sweet sorghum (Sorghum bicolor). Amendment treatments formed part of the wider experimental layout but are not evaluated in the present manuscript. Baseline measurements at eight points in June 2023 included instrument-reported volumetric water content (VWC), temperature, penetration resistance, field pH and semi-quantitative N-P-K screening, complemented by preliminary potentially toxic element screening. Mean VWC was 26.6 ± 4.2% at 5 cm and 20.0 ± 4.3% at 15 cm; mean temperatures were 18.2 ± 1.3 and 16.7 ± 1.1°C. Mean penetration resistance across seven complete profiles was 1.05 ± 0.28 MPa and increased with depth. Field pH averaged 7.1 ± 0.1, and the available laboratory summary prioritised Cu and Ni for follow-up. All crops reached reproductive development. Preliminary operational harvest totals were 85, 263 and 487 kg in 2023, 2024 and 2025, respectively; these values are reported descriptively only and are not interpreted as crop yield because harvested area, crop-specific contributions and moisture basis were not documented consistently. The nine crop-year elemental records are likewise treated as single descriptive observations displaying apparent crop-year differences in the reported Cu, Ni, Zn and Pb values; no inferential comparison among crops or years and no conclusion on soil-to-plant transfer or bioaccumulation is made.

REZUMAT
Substraturile post-miniere sunt eterogene spațial și necesită diagnoză specifică înaintea cultivării biomasei. Studiul documentează înființarea și monitorizarea pe trei ani a unei platforme de 4.500 m² pe halda Petrila. Au fost utilizate nouă parcele de 500 m²: trei parcele de referință cu cultură fixă (desemnate drept martor în documentația inițială a proiectului) și șase cu rotație echilibrată de porumb (Zea mays), soia (Glycine max) și sorg zaharat (Sorghum bicolor). Tratamentele cu amendamente au făcut parte din configurația experimentală extinsă, dar nu sunt evaluate în prezentul manuscris. Caracterizarea inițială din iunie 2023, în opt puncte, a inclus umiditatea volumetrică raportată de instrument, temperatura, rezistența la penetrare, pH-ul de teren și screeningul N-P-K, completate de screeningul preliminar al elementelor potențial toxice. Umiditatea medie a fost 26,6 ± 4,2% la 5 cm și 20,0 ± 4,3% la 15 cm, iar temperaturile 18,2 ± 1,3 și 16,7 ± 1,1°C. Rezistența medie la penetrare pentru șapte profile complete a fost 1,05 ± 0,28 MPa și a crescut cu adâncimea. pH-ul mediu a fost 7,1 ± 0,1, iar sinteza de laborator a prioritizat Cu și Ni pentru monitorizare. Toate culturile au ajuns la dezvoltare reproductivă. Totalurile operaționale preliminare ale biomasei recoltate au fost de 85, 263 și 487 kg în 2023, 2024 și, respectiv, 2025; aceste valori sunt raportate exclusiv descriptiv și nu sunt interpretate ca producții agricole, deoarece suprafața recoltată, contribuțiile specifice fiecărei culturi și baza de umiditate nu au fost documentate consecvent. Cele nouă înregistrări cultură-an privind compoziția elementală sunt, de asemenea, tratate ca observații descriptive individuale, evidențiind diferențe aparente între combinațiile cultură-an în valorile raportate pentru Cu, Ni, Zn și Pb; nu se realizează comparații inferențiale între culturi sau ani și nu se formulează concluzii privind transferul sol-plantă ori bioacumularea.

INTRODUCTION

Post-mining substrates are radically different from agricultural soils in that the excavation, transportation and deposition of the substrate disturb natural horizons and produce combinations of coarse fragments, poorly aggregated fine material and low organic matter matrices. These conditions can limit water retention, nutritional availability and root penetration, and metal(loid)s may add further limitations (*Agbeshie et al., 2024; Castellanos-Barliza and León-Peláez, 2023; Ghosh et al., 2020; Ruiz et al., 2023; Uzarowicz et al., 2025*). Thus, revegetation at field scale should be based on site-specific baseline data to distinguish between initial physical and chemical constraints and later changes during vegetation development (*Miguel et al., 2023; Yuan et al., 2023*).

However, total concentrations of potentially toxic elements (PTEs) alone do not allow proving mobility, bioavailability or ecological risk. Phytomanagement, which integrates monitoring of contaminants and the establishment of vegetation and functional indicators of soil, is increasingly proposed for the production of non-food biomass on degraded land (*Borbón-Palomares et al., 2024; Ceacero-Moreno et al., 2026; Conesa et al., 2026; Paniagua-López et al., 2024*). Maize, soybean and sweet sorghum differ in architecture, nutritional demand and environmental tolerance; sorghum is particularly relevant as a high-biomass crop under marginal conditions (*Kharytonov et al., 2019; Osman et al., 2023*). Mining-derived substrates can also be explored for non-food conversion routes, however feedstock origin can influence product composition and consequently needs elemental supervision before valorisation (*Roman et al., 2025*). Results from conventional maize-soybean systems cannot be easily extrapolated to post-mining substrates without field validation (*Hou et al., 2025*).

Recent geochemical investigations from the broader Petrila mining-waste setting provide important context for the present study. *Dunca et al. (2025)* documented pronounced spatial heterogeneity in heavy-metal burdens and used the geoaccumulation index (Igeo) and contamination factor (Cf) to identify Ni as a main contaminant requiring priority monitoring. *Ioniță (2026)* reported, based on a 2022-2024 dataset covering Ramura 1-4, a gradual decrease in mean pH (from 6.72 to 6.31), an increase in Eh (from 312 to 342 mV), and an annual increases of approximately 3-7% in total Cr, Cu and Ni. A separate redox-focused investigation *(Ioniță et al., 2026)* demonstrated marked intra-dump heterogeneity, including oxidising alkaline upper sectors, wetter near-neutral to slightly acidic/reducing lower sectors, and local extractable Cr(VI) hotspots. Together, these studies show that geochemical conditions across the broader Petrila mining-waste setting are spatially and temporally heterogeneous and strengthen the need for temporally resolved, paired substrate-plant monitoring; they are used here as contextual evidence and are not merged with the present biomass-monitoring dataset.

From an agricultural-engineering perspective, crop establishment on reconstructed or post-mining land is controlled by coupled soil-machine-crop interactions. Heavy machinery traffic can increase soil strength and penetration resistance and can reduce hydraulic functioning, while restored mine soils are particularly vulnerable to recompaction *(Schäffer et al., 2007; Obour and Ugarte, 2021)*. Mechanical reconstruction and surface/subsurface tillage can improve mine-soil physical conditions and vegetation establishment *(Fulton and Wells, 2005; Angel et al., 2018)*. In soils with a high coarse skeletal fraction, stone content directly affects planter workability, admissible forward speed and sowing quality *(Toscano et al., 2022)*. For perennial and other energy crops, georeferenced UAV and multispectral monitoring can complement ground observations with spatially explicit information on canopy development and biomass *(Impollonia et al., 2022)*.

A practical knowledge gap exists between laboratory-scale remediation studies and the engineering steps to convert an untreated heterogeneous mining surface into a repeatable field platform. The site-specific baseline method is in agreement with European and FAO soil-management frameworks (*European Commission, 2021; FAO, 2017*). This study fills that gap using the Petrila platform, and views the 2023-2025 record as a descriptive baseline, not as a demonstration of remediation efficacy. The originality of this work is documentation of field-scale platform establishment, balanced crop rotation and multi-year elemental surveillance under clearly controlled inferential settings. We asked four questions: (Q1) what was the spatial and depth-related variability of VWC, temperature, penetration resistance, and pH characteristic of the baseline campaign; (Q2) which PTEs were prioritised for follow-up by preliminary laboratory screening; (Q3) could maize, soybean and sweet sorghum be repeatedly established under the operational constraints of a coarse post-mining substrate; and (Q4) what interannual patterns were observed in harvested biomass and elemental composition during 2023-2025 in the absence of plot-level analytical replication?

Previous studies have generally addressed individual components of this chain - mine-soil reconstruction/tillage, traffic-induced compaction, planter performance on stony soils, or remote crop monitoring - rather than documenting the end-to-end conversion of an untreated coarse post-mining surface into a repeatable field platform. The specific contribution of the Petrila study is therefore the integrated engineering workflow linking baseline diagnosis, adaptation of mechanical preparation to site constraints, operational crop establishment and multi-year surveillance on the same 4,500 m² field platform. The novelty lies in this field-scale integration and traceable workflow, not in demonstrating amendment efficacy or statistically confirmed yield improvement.

MATERIALS AND METHODS

Study site and environmental context

The field study was conducted on Branch IV of the Petrila coal-mining waste-dump complex, Valea Jiului, Hunedoara County, Romania (locality-level reference ≈45.450° N, 23.419° E; central elevation ≈708 m a.s.l.). Waste deposition in the wider sector ceased in 2015. The mining-derived substrate contains weathered marl and sandstone fragments, a clay-rich matrix, coal fragments and abundant coarse material; before preparation, vegetation consisted of discontinuous herbs, shrubs and birch regrowth. No previous agricultural use or systematic soil-amendment programme was documented (*Sorică et al., 2024*).

Baseline measurements and soil sampling were performed in June 2023 and sowing was completed in late June. Petroșani station data for May-June 2023 (13.3°C/77 mm and 19.8°C/113 mm, respectively) are reported only as campaign context. Comparable seasonal meteorological series for 2024-2025 were not retained in the manuscript dataset; therefore, climate-year effects were not modelled and cannot be separated from interannual crop responses.

Official annual and seasonal climatological characterisations published by the Romanian National Meteorological Administration for 2023-2025 were consulted *(ANM, 2023-2025)*. They confirm substantial interannual thermal and pluviometric differences, but a complete Petroșani station-level growing-season series directly comparable with the archived May-June 2023 station values could not be reconstructed for all three years. To avoid mixing local station observations with non-equivalent national or seasonal summaries, meteorology is retained as contextual information only and is not used as an explanatory covariate for year-to-year biomass differences.

Experimental design and inferential scope

A 5,000 m^2 perimeter was delimited, with approximately 4,500 m^2 used as nine 500 m^2 main plots. Three plots were designated as fixed-crop controls in the original project records and are treated here as fixed-crop reference plots (L1-1 maize, L2-1 soybean and L3-1 sweet sorghum). Six plots followed a balanced three-year cyclic rotation: L1-2/L1-3 maize→sorghum→soybean; L2-2/L2-3 soybean→maize→sorghum; and L3-2/L3-3 sorghum→soybean→maize. The wider project layout also contained amendment subplots. However, treatment identity, application rate, composition and application metadata are not available in the archived dataset used for this manuscript. Accordingly, amendment treatments are excluded from analysis and interpretation; no comparison of biochar versus digestate and no causal amendment effect is estimated.

Fig. 1 - Field establishment workflow for the Petrila biomass-crop platform

Baseline in situ measurements and traceability

Eight operationally selected points (P11-P14 and P21-P24) provided spatial coverage while avoiding plot margins, traffic tracks and conspicuous stone accumulations, consistent with the sampling-strategy principles of ISO 18400-104:2018 but not with a probability-based survey. Instrument-reported VWC and soil temperature were measured at 5 and 15 cm. The equipment inventory lists a FieldScout TDR 300 and an ML2x probe, but the archived field table does not identify which probe generated the reported VWC values; the readings are therefore not interpreted as substrate-calibrated absolute water contents. Penetration resistance was measured with a FieldScout SC 900 at 2.5 cm increments from 2.5 to 15 cm, with one profile per point; P11 showed refusal below 5 cm. Cone geometry, insertion speed and repeated insertions were not retained. Field pH and N-P-K were screened once per point with an electronic tester; N-P-K outputs are used only as semi-quantitative screening.

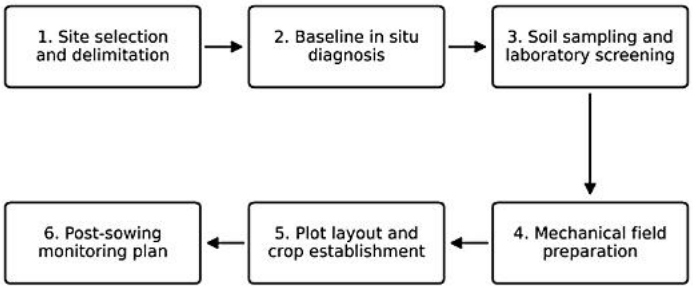

Fig. 2 - Baseline measurement, sampling and crop-establishment workflow

Soil sampling and laboratory screening

Soil samples associated with the in situ network were dried, homogenised and prepared according to the project laboratory workflow and the pretreatment principles of ISO 11464:2006. The available project summary was compared with Romanian reference values from Order no. 756/1997 and identified Cu and Ni as elements requiring follow-up. Sample-level concentrations, digestion details, calibration records, blanks, duplicates, certified reference materials, recoveries and LOD/LOQ were not available in the manuscript dataset. Accordingly, the soil laboratory evidence is used only for qualitative prioritisation, not for contamination classification, bioavailability assessment or risk calculation.

Mechanical preparation and crop establishment

Coarse stones and spontaneous vegetation were removed, the perimeter was staked, and shallow surface mobilisation was performed with a tracked hydraulic excavator because coarse fragments and irregular microrelief obstructed small conventional equipment. Maize hybrid Oituz, soybean variety Eugen and sweet sorghum variety SAȘM 2 were established at crop-appropriate depths using a common 50 × 20 cm geometry (100,000 planting positions ha^{-1}) to standardise field operations (Jităreanu et al., 2020). A one-row manual seeder was abandoned after repeated clogging, and planting positions were opened and covered manually. The common geometry is an operational standardisation, not an agronomic optimum for all three species. Detailed annual records of re-sowing, irrigation, supplementary fertilisation, soybean inoculation, plant-protection interventions and harvest stage were not retained in the manuscript dataset.

The maize, soybean and sweet sorghum crops were used here as experimental biomass crops on degraded post-mining land. Harvested material from the trial was not intended for human food or animal feed, and the present dataset is not used to support any food-chain safety claim.

Biomass elemental-composition monitoring

Above-ground biomass (stems and leaves) of maize, soybean and sorghum was monitored annually from 2023 to 2025. The archived analytical workflow records grinding, homogenisation, acid digestion with HNO_3/H_2O_2 and measurement by ICP-MS (PerkinElmer NexION 1000) for Cu, Pb, Co, Ni, Cr, Zn, Ba, Cd, B, Mo, As and Hg, reported in mg/kg. The supplied dataset contains one reported value for each crop-year combination and does not retain biological replication, plot/subplot identity, detailed sample-drying and aliquot procedures, instrument-calibration parameters, internal standards, blanks, certified reference materials, recoveries or element-specific LOD/LOQ. Therefore, values are reproduced as reported and interpreted descriptively. A dash in the 2023 file for Ba, As or Hg denotes absence of a reported value, not non-detection.

The original laboratory certificates/reports and the missing calibration/QA-QC records were not available in the archived dataset. Consequently, the elemental entries in Tables 2a-2b are retained as archived project-reported values for transparency only. Repeated exact entries such as 1.00 and 0.25 mg/kg are not treated as confirmed quantified concentrations, reporting limits or non-detects, and no regulatory, threshold-based or accumulation interpretation is assigned to them.

Statistical analysis

Analyses were descriptive because point selection was operational, the baseline comprised one campaign and the biomass file lacked plot-linked replication. VWC, temperature and pH were summarised by mean, SD, coefficient of variation and range across eight points; 5- versus 15-cm differences were summarised descriptively. For penetration resistance, site summaries used seven complete profiles, while the valid P11 readings were retained graphically. Biomass elemental values were tabulated by crop-year only. Reported annual harvested-biomass totals (85, 263 and 487 kg) were retained as operational totals only because harvested area, crop-specific mass and moisture basis were not documented consistently. No hypothesis tests, treatment-effect estimates, bioaccumulation factors or soil-to-plant transfer factors were calculated.

Table 1 and Figures 3-4 therefore present descriptive summary statistics only (mean, SD, CV, range and depth-wise summaries), not inferential hypothesis tests. For biomass elemental composition, each crop-year entry is a single reported analytical record; crop species or years cannot be treated as statistical replicates without pseudoreplication. Consequently, additional inferential tests on the archived biomass values would not be statistically valid.

RESULTS AND DISCUSSION

Operational establishment

The 4,500 m² platform was established despite stoniness, irregular microrelief and local slope. Tracked-excavator surface mobilisation followed by manual seed placement provided a workable field solution after the one-row seeder repeatedly clogged. This demonstrates operational feasibility, not superiority of the preparation method or agronomic optimality. Similar constraints from coarse fragments and reconstructed structure are widely reported for post-mining substrates (*Agbeshie et al., 2024; Ruiz et al., 2023; Uzarowicz et al., 2025*).

The field sequence also illustrates the engineering constraint imposed by the coarse skeletal fraction: equipment capable of shallow surface mobilisation remained workable, whereas the one-row seeder repeatedly clogged and could not maintain reliable seed placement. This is consistent with planter-workability studies showing that stoniness reduces admissible operating speed and increases dynamic loads at the soil-planter interface *(Toscano et al., 2022)*.

Crop rotation, reproductive development and harvested biomass

Maize, soybean and sweet sorghum reached reproductive development in all three years. The field notes describe ears in maize, panicles in sorghum and pods in soybean; because these observations were not quantified at plot level, they are treated only as evidence of reproductive establishment. The reported annual harvested-biomass totals were 85 kg in 2023, 263 kg in 2024 and 487 kg in 2025. These values are not interpreted as yield improvement because harvested area, crop-specific contributions and fresh-/dry-mass basis were not retained consistently. The balanced rotation reduced persistent association of a crop with a single field position, but the non-randomised layout and missing plot-level harvest data prevent causal partitioning of crop, rotation, amendment and year effects.

Accordingly, the manuscript uses these masses only as operational harvest totals and not as statistically validated crop-yield estimates.

Baseline water, temperature, pH and N-P-K response

During the June 2023 campaign, instrument-reported VWC ranged from 19.0-30.9% at 5 cm (26.6 ± 4.2%; CV 16.0%) and 12.2-25.3% at 15 cm (20.0 ± 4.3%; CV 21.5%). All eight points were wetter at 5 cm, with a paired depth difference of 6.6 ± 1.9 percentage points. Mean temperature was 18.2 ± 1.3°C at 5 cm and 16.7 ± 1.1°C at 15 cm. Field pH ranged from 7.0 to 7.3 (7.1 ± 0.1), whereas the semi-quantitative N-P-K response was 'very low' at all points. These observations describe one campaign only; near-neutral pH does not imply adequate fertility or low PTE pressure (*Haghighizadeh et al., 2024; Ceacero-Moreno et al., 2026*). Standardised laboratory pH and nutrient analyses are required for agronomic interpretation.

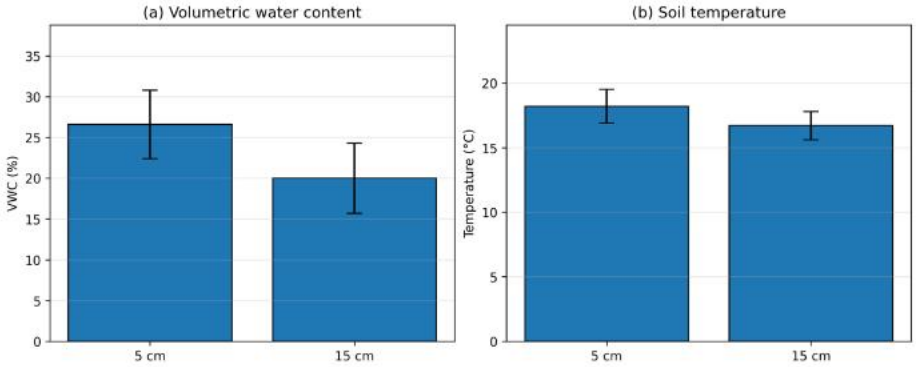

Fig. 3 - Mean VWC and soil temperature at 5 and 15 cm in June 2023 (mean ± SD; n = 8)

Table 1

Baseline observations from the June 2023 campaign

Point	VWC 5 cm (%)	VWC 15 cm (%)	T 5 cm (°C)	T 15 cm (°C)	Field pH	Mean PR 2.5-15 cm (MPa)
P11	19.0	12.2	18.2	17.5	7.0	NA*
P12	27.3	18.0	18.0	16.7	7.3	1.13
P13	21.6	16.3	20.5	17.0	7.3	0.79
P14	29.9	22.0	17.7	15.9	7.0	0.87
P21	29.4	20.7	18.4	18.7	7.2	0.76
P22	25.7	21.6	17.5	16.1	7.0	1.51
P23	30.9	25.3	16.0	15.2	7.2	0.98
P24	28.8	23.9	19.5	16.7	7.1	1.29
Mean ± SD	26.6 ± 4.2	20.0 ± 4.3	18.2 ± 1.3	16.7 ± 1.1	7.1 ± 0.1	1.05 ± 0.28†

** P11 had valid penetration readings only at 2.5 and 5.0 cm and was excluded from the complete-profile mean. † n = 7 complete profiles. N-P-K response was „very low" at all eight points.*

Penetration resistance

Across the seven complete profiles, mean penetration resistance was 1.05 ± 0.28 MPa (CV 26.5%), with point means from 0.76 to 1.51 MPa. The depth-specific mean increased from 0.49 MPa at 2.5 cm to 1.52 MPa at 15 cm; P11 was incomplete because of local refusal below 5 cm. The profile demonstrates small-scale mechanical heterogeneity and greater resistance to root penetration in the deeper measured layer under the moisture conditions of the baseline campaign. It does not justify a universal compacted/not-compacted classification because penetration resistance also depends on water content, particle-size distribution, bulk density, coarse fragments and measurement protocol (*Miguel et al., 2023; Ruiz et al., 2023*).

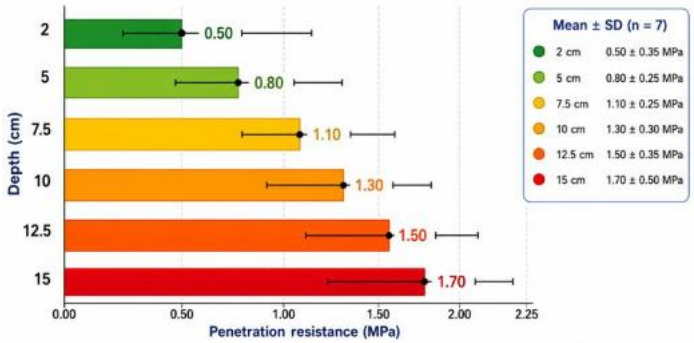

Fig. 4 - Mean penetration-resistance profile for seven complete baseline profiles.

Penetration resistance increased with depth, indicating greater mechanical resistance to root penetration in the deeper measured layer under the moisture conditions of the baseline campaign.

In agricultural-engineering terms, the observed profile links substrate mechanics with crop establishment. Increasing penetration resistance implies a progressively less favourable mechanical environment for root elongation, while machinery traffic can further increase soil strength; therefore, preparation should create a workable rooting layer while limiting unnecessary traffic and recompaction

(Schäffer et al., 2007; Obour and Ugarte, 2021). On reclaimed mine soils, ripping and combined surface/subsurface tillage have been shown to reduce soil strength and improve vegetation establishment *(Angel et al., 2018)*. At Petrila, increasing penetration resistance indicated a root-zone mechanical constraint that motivated site-adapted surface preparation and low-traffic operations; the coarse skeletal fraction subsequently limited seeder operation, necessitating manual seed placement, after which all three crops reached reproductive development. Root growth itself was not measured, so this sequence is interpreted mechanistically rather than as a measured root-response pathway.

Preliminary Potentially Toxic Elements screening

The available laboratory summary prioritised Cu and Ni for follow-up: Cu was described as above the Romanian normal value but below the sensitive-use alert threshold, while some Ni results were described as near or locally above that alert threshold. Pb and Cd were not identified as relevant exceedances in the summary. Because sample-level concentrations and analytical QA/QC were unavailable, Order no. 756/1997 (*Ministry of Waters, Forests and Environmental Protection, 1997*) is used only as a historical screening reference, and no site-wide contamination, mobility or ecological-risk class is assigned. This distinction is important because total concentration does not directly represent bioavailability or plant exposure (*Borbón-Palomares et al., 2024; Ceacero-Moreno et al., 2026; Paniagua-López et al., 2024*).

This qualitative prioritisation is consistent with recent dump-scale studies, which identified Ni as a major contamination priority and showed that pH/Eh conditions and metal concentrations vary in both space and time across the Petrila complex *(Dunca et al., 2025; Ioniță, 2026; Ioniță et al., 2026)*. These external geochemical results support the need for continued monitoring but do not substitute for paired, plot-linked substrate and plant measurements in the present experiment.

Archived biomass elemental records, 2023-2025

The archived biomass file comprised nine crop-year elemental records, reproduced in Tables 2a-2b for transparency. Because the corresponding analytical certificates, full calibration/QA-QC documentation, LOD/LOQ information and plot-linked replication were unavailable, these entries are treated as nominal project-reported values rather than analytically validated concentrations for quantitative comparison. The manuscript therefore does not rank crops or years by elemental concentration, calculate annual concentration means for inference, compare the values with regulatory thresholds, or infer species-specific accumulation capacity.

Because these are single crop-year records rather than replicated plot-level observations, no statistical test of differences among crops or years is performed, and the apparent differences are treated as preliminary, hypothesis-generating patterns only.

The apparent differences among the archived crop-year records may plausibly reflect crop identity, seasonal conditions, growth dilution, substrate mineralogy, pH/redox status and changes in element availability, but these mechanisms were not tested here. Without verified analytical reporting metadata and paired plot-level substrate-plant data, the elemental records cannot be interpreted quantitatively as temporal trends, bioaccumulation or soil-to-plant transfer. Cu and Ni remain priorities for future replicated monitoring because they were also identified as relevant in the separate soil-screening and site-geochemistry datasets. Exact repeated values (1.00 and 0.25 mg/kg) and missing Ba/As/Hg entries must be resolved from laboratory certificates before any quantitative use.

Table 2a

Archived reported biomass elemental values, 2023-2025 (units as supplied: mg/kg): Cu, Pb, Co, Ni, Cr and Zn

Sample	Crop	Year	Cu	Pb	Co	Ni	Cr	Zn

Note:„-" *indicates that no value was present in the supplied dataset and does not mean zero or <LOD. Exact values of 1.00 and 0.25 mg/kg are reproduced as reported and require confirmation against laboratory certificates before interpretation as quantified values or reporting limits.*

Implications for subsequent biomass monitoring

The current record establishes an initial elemental-surveillance baseline but does not demonstrate biomass safety. If non-food thermochemical conversion is pursued, PTEs should be quantified in replicated harvested tissues and conversion products because feedstock origin and process conditions can influence product composition (*Roman et al., 2025*). Future work should preserve plot/subplot identity, use replicated paired substrate-plant sampling, document full QA/QC and LOD/LOQ, and report crop-specific dry-matter yield per unit area.

Future monitoring can also be strengthened by georeferenced UAV/multispectral surveys synchronized with field observations. Vegetation indices, canopy height and repeated spatial imagery can provide non-destructive information on crop development and biomass heterogeneity and can guide plot-level sampling; such approaches have been demonstrated for high-throughput phenotyping and biomass/yield prediction in Miscanthus *(Impollonia et al., 2022)*.

In addition, perennial non-food energy crops such as Miscanthus should be evaluated in future field trials as complementary candidates under the evolving pH and redox conditions documented at the Petrila dump.

Study limitations

Two limitation groups constrain inference. Design limitations include one operationally selected baseline network, one baseline campaign and systematic rather than randomised crop/treatment allocation. Data-retention limitations include missing amendment dose/composition metadata, incomplete annual crop-management and meteorological records, non-normalised harvest totals, crop-year aggregation of elemental data, absence of plot-linked biological/analytical replication, and incomplete laboratory QA/QC and LOD/LOQ documentation. The absence of plot-linked analytical replication is a design/data-retention limitation, not evidence of treatment equivalence. Consequently, treatment effects, statistically confirmed temporal trends, bioaccumulation factors, soil-plant transfer factors and safe-valorisation thresholds cannot be inferred from the present dataset.

The present results should therefore be considered preliminary and hypothesis-generating; confirmatory conclusions require additional seasons with replicated, plot-linked measurements and complete analytical QA/QC.

CONCLUSIONS

- A 4,500 m² field platform with nine 500 m² plots was operationally established on a heterogeneous mining-derived substrate in Petrila; maize, soybean and sweet sorghum reached reproductive development under the adopted field preparation and crop-rotation scheme.

- The reported 2023-2025 harvested masses are operational totals only; because harvested area, crop-specific contributions and fresh-/dry-mass basis were not documented consistently, they are not comparable agricultural yields and no year-to-year yield increase is inferred.

- The June 2023 baseline showed clear spatial and depth-related heterogeneity: the 5-cm layer was wetter and warmer than the 15-cm layer, field pH was near neutral, N-P-K screening was very low, and penetration resistance increased with depth under the measured moisture conditions.

- Preliminary laboratory screening prioritised Cu and Ni for follow-up, while the archived 2023-2025 biomass records displayed apparent crop-year differences in the reported Cu, Ni, Zn and Pb values. No conclusion is drawn regarding either the presence or the absence of soil-to-plant transfer or bioaccumulation, because paired substrate-plant data and plot-level replication were unavailable; treatment effects likewise cannot be inferred.

- Subsequent monitoring should retain plot/subplot identity, quantify crop-specific dry-matter yield, pair substrate and plant samples, document amendment properties and seasonal conditions, and apply full analytical QA/QC with explicit LOD/LOQ before evaluating remediation performance or biomass valorisation safety.

- The findings are preliminary and should be used to design confirmatory monitoring rather than to support causal, food-chain-safety or remediation-efficacy claims.

ACKNOWLEDGEMENT

This work was developed within the project „Establishment and Operationalization of a Competence Centre for Soil Health and Food Safety", Specific Project 2: „Restoring Soil Health on Non-Productive Land through Biomass Crops for Sustainable Energy - Soil-Biomass-Sustainability (SoBioSus)", Contract no. 760005/30.12.2022, code 2. The authors acknowledge the project partners' contributions to field mapping, measurements, laboratory screening and crop establishment.

ABSTRACT

Precision agriculture requires advanced digital solutions capable of continuously monitoring environmental conditions and pest dynamics in orchard ecosystems. This paper presents the development, integration, and experimental validation of a digital system dedicated to orchard crop monitoring. The proposed system integrates a smart pheromone trap equipped with an HD camera, a meteorological monitoring station, an autonomous photovoltaic power supply system, and a wireless communication module for real-time data transmission. The experimental model was designed to support automatic pest detection and continuous acquisition of climatic parameters associated with pest and pathogen development. The monitoring architecture combines environmental sensing, image acquisition, local data processing, and cloud-based communication. Functional testing was conducted under controlled orchard conditions over a 30-day monitoring period. The obtained results demonstrated stable autonomous operation, reliable wireless communication, and accurate environmental monitoring. The average deviations compared with a reference meteorological station were within ±0.4 °C for air temperature, ±2.5% for relative humidity, and ±0.3 m/s for wind speed. The smart trap achieved pest identification accuracy higher than 90% for target species. The photovoltaic system ensured autonomous operation for more than 72 h without direct solar radiation. The developed digital platform represents a scalable solution for integrated pest management and precision orchard monitoring applications.

REZUMAT

Agricultura de precizie necesită soluții digitale avansate, capabile să monitorizeze continuu condițiile de mediu și dinamica dăunătorilor din ecosistemele pomicole. Lucrarea prezintă dezvoltarea, integrarea și validarea experimentală a unui sistem digital destinat monitorizării culturilor pomicole. Sistemul propus integrează o capcană inteligentă cu feromoni, echipată cu cameră HD, o stație meteorologică, un sistem autonom de alimentare fotovoltaică și un modul de comunicație wireless pentru transmiterea datelor în timp real. Modelul experimental a fost proiectat pentru detectarea automată a dăunătorilor și achiziția continuă a parametrilor climatici asociați dezvoltării dăunătorilor și patogenilor. Arhitectura sistemului combină senzori de mediu, achiziție de imagini, procesare locală a datelor și comunicație prin platformă cloud. Testarea funcțională a fost realizată în condiții controlate de livadă, pe o perioadă de monitorizare de 30 zile. Rezultatele obținute au demonstrat funcționare autonomă stabilă, comunicație wireless fiabilă și monitorizare meteorologică precisă. Abaterile medii față de o stație meteorologică de referință au fost de ±0,4 °C pentru temperatura aerului, ±2,5% pentru umiditatea relativă și ±0,3 m/s pentru viteza vântului. Capcana inteligentă a obținut o precizie de identificare a dăunătorilor mai mare de 90% pentru speciile țintă. Sistemul fotovoltaic a asigurat funcționarea autonomă timp de peste 72 h fără radiație solară directă. Platforma digitală dezvoltată reprezintă o soluție scalabilă pentru managementul integrat al dăunătorilor și monitorizarea de precizie a culturilor pomicole.

INTRODUCTION

The transition toward precision agriculture has accelerated the development of intelligent monitoring systems capable of continuously evaluating environmental conditions and phytosanitary risks in orchard ecosystems. Modern orchard management requires rapid access to accurate information regarding climatic variability, pest dynamics, and pathogen development in order to optimize crop protection strategies and reduce production losses (*Nicolì et al., 2024; Yakovenko et al., 2023*).

Conventional monitoring methods are generally based on manual field inspections and periodic observations performed by specialists. These approaches require significant labor resources, generate delayed responses, and are strongly influenced by operator experience. In addition, traditional monitoring does not provide continuous data acquisition, which limits the possibility of identifying early infestation stages and accurately predicting pest evolution (*Karar et al., 2021; Rustia et al., 2023*).

Recent advances in digital agriculture enabled the integration of environmental sensors, wireless communication technologies, artificial intelligence, and image processing systems into autonomous monitoring platforms. These technologies support real-time acquisition and analysis of environmental and biological data, allowing rapid identification of critical conditions associated with pest outbreaks and disease development (*Fuentes-Peñailillo et al., 2024; Karunathilake et al., 2023; Masi et al., 2023; Zude-Sasse et al., 2021*).

Smart pheromone traps represent one of the most important technological solutions currently used for integrated pest management in orchard crops. By combining pheromone attraction systems with digital imaging and automated analysis algorithms, these devices can continuously monitor insect populations and reduce the dependence on manual observations. Studies demonstrated that machine vision and neural network approaches can significantly improve pest identification accuracy and increase monitoring efficiency in orchard ecosystems (*Čirjak et al., 2022; İtmeç and Zorlu, 2025; Kumar et al., 2025; Suto, 2022*).

Meteorological parameters also have a major influence on pest and pathogen activity. Air temperature, relative humidity, precipitation, solar radiation, and wind conditions directly affect insect development cycles, infection risks, and migration intensity. Consequently, integrating weather monitoring with automatic pest detection provides a more accurate basis for predictive phytosanitary management (*Rajput et al., 2024*; *Tudi et al., 2021; Yeshiwas et al., 2026*).

Experimental studies conducted in precision horticulture demonstrated that intelligent monitoring systems based on environmental sensors, wireless communication modules, and automated image acquisition can provide accurate and continuous information regarding pest activity and orchard microclimate conditions. Field experiments performed in orchard ecosystems confirmed that integrating meteorological monitoring with digital pest detection improves the efficiency of phytosanitary management and supports early identification of infestation risks (*Łągiewska and Panek-Chwastyk, 2025; Pascoal et al., 2024; Wang et al., 2025*).

Developments in Internet of Things technologies and cloud-based agricultural platforms also demonstrated the applicability of autonomous monitoring infrastructures in orchard crops. The integration of wireless sensor networks, automated image acquisition systems, and real-time communication platforms enables continuous monitoring over extended agricultural areas while reducing labor requirements and operational costs. Several studies reported that intelligent monitoring architectures contribute to improved pest surveillance efficiency, optimized pesticide application, and increased sustainability of horticultural production systems (*Liakos et al., 2018; Pivoto et al., 2021; Talaviya et al., 2020; Verdouw et al., 2021*).

The main objective of the research was the realization of a functional experimental model capable of continuously monitoring environmental parameters and pest activity under orchard conditions. The study also aimed to evaluate the operational stability, energy autonomy, communication reliability, and monitoring accuracy of the developed system. The proposed monitoring platform contributes to the implementation of precision horticulture technologies by supporting real-time decision-making, reducing manual intervention, and improving the efficiency of integrated pest management strategies in orchard ecosystems.

MATERIALS AND METHODS

1. General architecture of the experimental monitoring system

The experimental model was developed as an integrated digital system dedicated to continuous monitoring of orchard crops. The monitoring platform combined environmental sensing modules, smart pest detection equipment, autonomous energy supply, and wireless communication infrastructure within a unified operational architecture.

The developed system included the following main components:

- intelligent meteorological station;
- smart pheromone trap equipped with HD camera;
- electronic acquisition and control module;
- autonomous photovoltaic power supply system;
- wireless communication infrastructure;
- cloud-based monitoring platform.

The experimental model was developed as an integrated digital system dedicated to continuous monitoring of orchard crops. The monitoring platform combined environmental sensing modules, smart pest detection equipment, autonomous energy supply, and wireless communication infrastructure within a unified operational architecture.

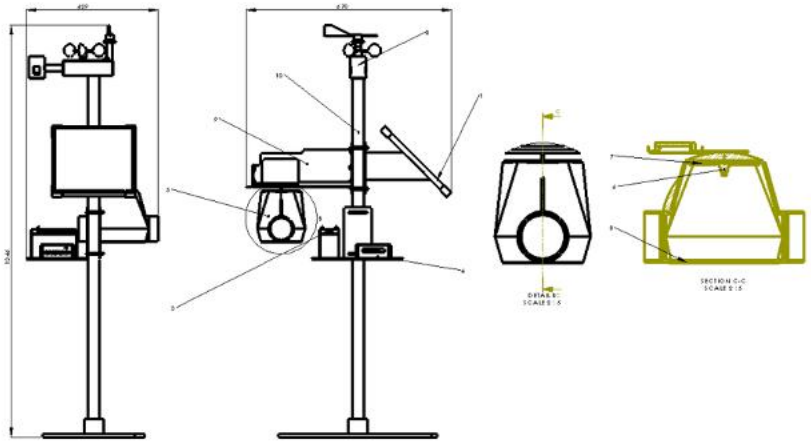

Fig. 1 – General architecture of the experimental orchard monitoring system

1 – solar panel with support arm; 2 – smart meteorological station; 3 – 12 V battery; 4 – support plate for the control unit; 5 – pheromone insect trap; 6 – pest monitoring camera; 7 – LED strip; 8 – adhesive pheromone plate; 9 – pheromone trap mounting arm; 10 – support pipe structure

2. Smart meteorological station

The meteorological station was designed for continuous monitoring of climatic parameters associated with pest activity and pathogen development in orchard ecosystems.

The monitoring station integrated: air temperature sensor; relative humidity sensor; anemometer; wind direction sensor; rainfall sensor; solar radiation sensor.

The sensors were mounted on an anodized aluminum support structure resistant to corrosion and outdoor environmental exposure.

The monitored parameters included: air temperature, °C; relative humidity, %; wind speed, m/s; precipitation intensity, mm/h; solar radiation, W/m².

Fig. 2 – Experimental meteorological station used for continuous orchard environmental monitoring

The experimental meteorological station was installed under orchard field conditions and connected to the acquisition and communication module for real-time environmental monitoring. Table 1 presents the main climatic parameters monitored by the experimental meteorological station together with the corresponding measurement units and sensing components used within the developed monitoring platform.

Table 1

Climatic parameters monitored by the experimental station

Parameter	MU	Sensor type
Air temperature	°C	Digital thermal sensor
Relative humidity	%	Capacitive sensor
Wind speed	m/s	Anemometer
Wind direction	°	Wind vane
Precipitation	mm	Rain gauge
Solar radiation	W/m²	Pyranometer
Parameter	Unit	Sensor

3. Smart pheromone trap

The smart pheromone trap represented the central monitoring component of the experimental system. The trap was designed for automatic detection and monitoring of orchard pests, especially Lepidoptera and Diptera species. The trap structure included: UV-resistant polymer housing; pheromone compartment; HD digital camera; LED illumination system; support and suspension elements.

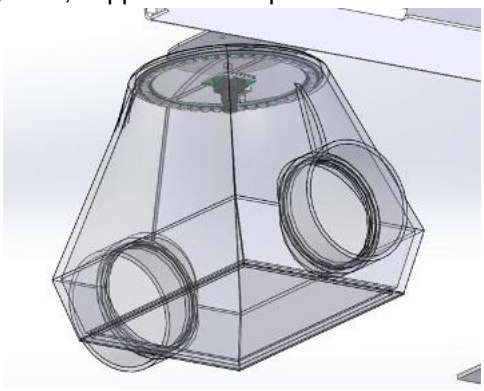

Fig. 3 – Smart pheromone trap integrated into the monitoring system

The HD camera periodically captured images of the adhesive monitoring surface. The integrated LED system ensured uniform illumination during low-light acquisition conditions.

4. Electronic acquisition and control module

The electronic acquisition module coordinated all sensing, communication, and energy management operations within the experimental monitoring system.

The module performed: environmental data acquisition; image acquisition control; LED activation management; local data storage; wireless communication control; energy monitoring.

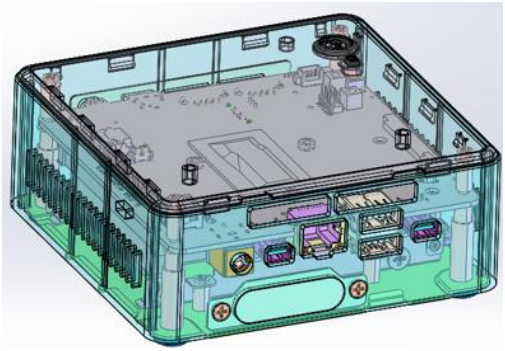

Fig. 4 – Electronic acquisition and control module integrating communication, sensing, and energy management subsystems

The electronic components were integrated into an IP65 protective enclosure to ensure operational stability under field conditions.

5. Autonomous photovoltaic power supply system

The developed monitoring platform used an autonomous photovoltaic energy system for continuous operation under orchard conditions.

The energy subsystem included: monocrystalline photovoltaic panel, 50 W; accumulator, 12 Ah; solar charge controller.

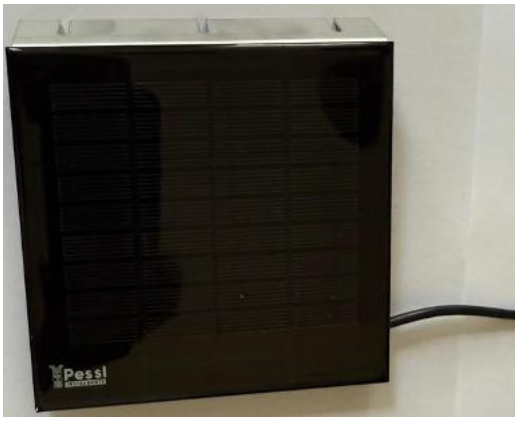

Fig. 5 – Monocrystalline photovoltaic panel integrated into the autonomous orchard monitoring system

The photovoltaic panel was mounted on an adjustable metallic structure oriented southward to maximize solar energy conversion efficiency.

6. Wireless communication and data transmission

The developed monitoring system used wireless communication technologies for remote data transmission and cloud synchronization.

The communication subsystem supported: Wi-Fi communication; 4G transmission; local data storage during signal interruption; automatic synchronization after communication recovery.

Table 2

Data acquisition and transmission configuration

Monitoring operation	Acquisition interval
Meteorological measurements	30 min
Automatic image acquisition	6 h
Data synchronization	12 h

The acquired environmental data and captured images were periodically transmitted to a cloud-based monitoring platform.

7. Experimental setup and monitoring procedure

The experimental monitoring system was installed in an apple orchard located in a lowland horticultural area. The monitoring campaign was conducted during the vegetation season over a period of 30 consecutive days.

Fig. 6 – Integrated experimental monitoring platform installed under orchard field conditions

The experimental monitoring campaign was conducted in an apple orchard at the Research Institute for Fruit Growing Pitești-Mărăcineni, Mărăcineni, Argeș County, Romania, over 30 consecutive days during the vegetation season. The meteorological monitoring unit incorporated Pessl Instruments sensors for air temperature, relative humidity, wind speed and direction, precipitation, and global solar radiation. Air temperature and relative humidity were measured using a HYT221-based sensor, with an operating temperature range of −40 to +125 °C and a relative humidity range of 0–100% RH; the nominal accuracies were ±0.2 °C within the 0–60 °C range and ±2% RH at 23 °C within the 0–90% RH range. Wind speed was measured using a three-cup anemometer with a measurement range of 0–30 m/s and a nominal tolerance of ±0.5 m/s for wind speeds up to 5 m/s and ±10% above 5 m/s. Wind direction was measured over a range of 0–359°, with a nominal tolerance of ±5°. Precipitation was recorded using a double tipping-bucket rain gauge with a resolution of 0.2 mm and a nominal accuracy of ±5%. Global solar radiation was measured using a Pessl Instruments IM506D pyranometer, based on a photodiode sensing element, with a measurement range of 0–2000 W/m², a spectral response of 300–1100 nm, and a maximum absolute error of ±5% (typically approximately ±3%).

The smart pheromone trap was equipped with a Raspberry Pi High Quality Camera based on a Sony IMX477R stacked, back-illuminated CMOS sensor, with a resolution of 12.3 megapixels (4056 × 3040 pixels), a sensor diagonal of 7.9 mm, and a pixel size of 1.55 × 1.55 µm. The camera was fitted with an 8 mm C/CS-mount lens, providing a fixed optical configuration for imaging the adhesive monitoring surface. Images of the adhesive plate were automatically acquired at 6 h intervals. An integrated LED illumination system provided uniform illumination of the monitoring area under low-light conditions, thereby reducing variations in image quality caused by ambient lighting conditions.

The smart-trap evaluation targeted the codling moth (Cydia pomonella) using a conventional pheromone trap with an adhesive plate and a species-specific pheromone lure. A total of 120 images acquired during the 30-day monitoring campaign were evaluated by comparing automatic detections with manual visual counts. Identification accuracy was calculated as the percentage of correctly identified target insects relative to the total number manually confirmed. Energy autonomy was evaluated with the 12 Ah battery fully charged and without direct solar radiation, while maintaining normal acquisition and communication intervals. The system remained fully operational for more than 72 h without external charging.

8. Functional performance evaluation

The environmental measurements obtained from the developed meteorological station were compared with the values recorded by a reference weather station installed in the same orchard area.

The transmission efficiency was evaluated using the relation:

$$\eta = \frac{N_r}{N_t} \cdot 100 \ [\%] \tag{1}$$

where:

η – transmission success rate, [%];
N_r – received data packets, [-];
N_t – transmitted data packets, [-].

The mean deviation of environmental measurements was calculated using:

$$MAD = \frac{1}{n} \cdot \sum_{i=1}^{n} |x_i - x_{ref}| \tag{2}$$

where:

MAD – mean absolute deviation, [°C, m/s, mm, W/m²];
x_i – measured value, [°C, m/s, mm, W/m²];
x_{ref} – measured value, [°C, m/s, mm, W/m²].
n – number of measurements, [-].

The pest detection accuracy of the smart trap was evaluated by comparing automatically detected insect counts with manual observations performed during the experimental monitoring campaign.

RESULTS

1. *Functional validation of the experimental monitoring system*

The developed experimental system operated continuously during the monitoring campaign under orchard environmental conditions. The integrated platform successfully performed simultaneous acquisition of meteorological parameters and automatic pest monitoring using the smart pheromone trap equipped with HD image acquisition capabilities.

The experimental model demonstrated stable operation during continuous field deployment, while the wireless communication subsystem ensured periodic transmission of environmental and biological data to the cloud-based monitoring platform. No significant interruptions of operation were observed during the experimental period.

The modular architecture of the developed monitoring system also facilitated rapid installation, maintenance operations, and reconfiguration according to orchard monitoring requirements.

2. *Environmental monitoring results*

The environmental monitoring subsystem continuously recorded climatic parameters associated with pest activity and pathogen development during the experimental orchard monitoring campaign.

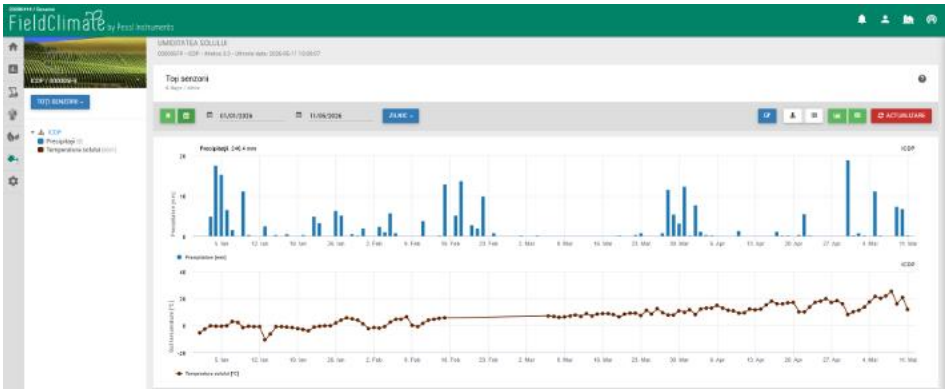

Fig. 7 – Cumulative precipitation recorded during the experimental orchard monitoring campaign

The cumulative precipitation values progressively increased throughout the monitoring campaign, exceeding 120 mm during the analyzed period. Several rainfall accumulation intervals above 15-20 mm were recorded during short time periods, generating elevated humidity conditions within the orchard ecosystem. These environmental conditions favored fungal pathogen development and increased the phytopathological vulnerability of monitored crops.

The environmental monitoring results demonstrated significant climatic variability during the experimental campaign. The cumulative precipitation exceeded 120 mm, while accumulated chilling units surpassed 800 units and accumulated degree-days exceeded 250 °C above the 10 °C thermal threshold. The recorded temperature values varied between approximately -4 °C and 28 °C, with several daily thermal amplitudes above 12 °C. These environmental conditions generated favorable intervals for pest biological activity and phytopathological development. The continuous monitoring platform successfully identified critical climatic periods associated with increased infestation and infection risks, confirming the applicability of the developed system for predictive orchard management and precision phytosanitary monitoring.

3. *Monitoring pest activity in pome fruit crops*

The developed monitoring platform successfully identified the correlation between environmental conditions and phytopathological risks in orchard crops during the experimental campaign. The recorded climatic data indicated cumulative precipitation exceeding 120 mm, accumulated degree-days above 250 °C, and temperatures ranging from approximately -4 °C to 28 °C. Under these conditions, the estimated aphid attack risk exceeded 60% during intervals characterized by temperatures above 18 °C and relative humidity values higher than 70%, while codling moth activity intensified at temperatures between 20 °C and 24 °C. The monitoring system also detected increased fire blight and apple scab infection risks following precipitation accumulation periods above 5-10 mm and relative humidity levels exceeding 80%, confirming the applicability of the developed platform for predictive phytopathological monitoring and precision orchard management.

Fig. 8 – Peach leaf curl infection risk estimated during the experimental monitoring campaign

The obtained results demonstrated that continuous acquisition and integration of climatic and biological data enabled rapid identification of critical environmental intervals associated with increased pest activity and pathogen infection probability in orchard ecosystems.

4. Monitoring phytopathological risks in stone fruit crops

The developed monitoring platform successfully identified the correlation between environmental conditions and phytopathological risks in orchard crops during the experimental campaign. The recorded climatic data indicated cumulative precipitation values exceeding 120 mm, accumulated degree-days above 250 °C, and temperatures ranging from approximately -4 °C to 28 °C. Under these environmental conditions, elevated pest activity and increased pathogen infection probability were observed, especially during intervals characterized by relative humidity values higher than 70-80% and moderate temperatures favorable for biological development.

Table 3 presents the main environmental conditions recorded during the experimental campaign together with the estimated phytopathological and pest infestation risks identified using the developed digital monitoring platform.

Table 3

Estimated phytopathological risks identified during the experimental monitoring campaign

Monitored parameter	Observed condition	Estimated risk level
Aphid infestation risk	RH > 70%; T > 18 °C	Moderate to high
Codling moth activity	T = 20-24 °C	High
Fire blight infection risk	Precipitation > 10 mm	Moderate to high
Apple scab infection risk	RH > 80%	High
Shot-hole disease risk	Prolonged humidity	Moderate
Moniliosis infection risk	T = 17-23 °C; RH > 75%	High
Peach leaf curl infection risk	T = 10-18 °C	Moderate to high

The obtained results demonstrated that increased humidity conditions, precipitation accumulation above 5-10 mm, and temperatures between 18 °C and 24 °C generated favorable environments for pest biological activity and pathogen development. The developed monitoring platform successfully identified critical phytopathological risk intervals and enabled continuous evaluation of orchard environmental conditions during the experimental campaign.

5. Communication performance and operational stability

The wireless communication subsystem ensured stable transmission of environmental and biological data throughout the experimental campaign. The transmission success rate exceeded 99% under stable communication conditions and remained above 90% in areas characterized by reduced signal intensity.

The implemented retransmission mechanism prevented significant data losses during temporary communication interruptions. The photovoltaic energy subsystem also ensured continuous autonomous operation for more than 72 h without direct solar radiation exposure.

The obtained results confirmed the operational stability, autonomous capability, and applicability of the developed digital monitoring platform for long-term precision orchard management applications.

CONCLUSIONS

The developed platform combined environmental sensing technologies, smart pheromone traps, autonomous photovoltaic energy supply, wireless communication infrastructure, and cloud-based data visualization within a unified precision agriculture architecture.

The experimental results confirmed stable and reliable operation of the monitoring system under orchard field conditions during the 30-day monitoring campaign. The environmental monitoring subsystem successfully recorded climatic parameters associated with pest activity and pathogen development, while the smart pheromone trap enabled automatic monitoring of insect population dynamics.

The obtained results demonstrated that cumulative precipitation values exceeding 120 mm, accumulated degree-days above 250 °C, and relative humidity values higher than 70-80% generated favorable environmental conditions for increased pest activity and phytopathological risk development. Elevated codling moth activity was observed at temperatures between 20 °C and 24 °C, while fungal infection risks intensified following precipitation accumulation periods above 5-10 mm.

The wireless communication subsystem ensured reliable real-time data transmission, with transmission success rates exceeding 99% under stable signal conditions. The photovoltaic power supply system also demonstrated high operational autonomy, maintaining continuous system functionality for more than 72 h without direct solar radiation exposure.

The developed digital monitoring platform proved suitable for predictive phytopathological management and precision orchard monitoring applications. The integration of climatic monitoring, automated pest detection, and real-time communication technologies enabled rapid identification of critical environmental intervals associated with increased infestation and infection probability.

The obtained results confirmed the applicability of the proposed monitoring architecture for modern precision horticulture systems, contributing to improved crop protection efficiency, reduced manual intervention, and enhanced sustainability of orchard management practices.

ACKNOWLEDGEMENT

This work was supported by the Romanian Research and Innovation Ministry, through the Project entitled “ADER 25.2.1 Digital system for monitoring orchard crops” – Ctr. 25.2.1./20.09.2023

Keywords: *crop rotation, grasslands influence, yields, temporary grassland*

ABSTRACT
Temporary grasslands are recognized both for their ecological functions, such as nutrient cycling, soil quality, and also for their potential role within crop rotation frameworks. While many studies have shown the agronomic and environmental benefits of permanent grasslands, fewer have analysed the impact of temporary grassland phases as precursors, influencing coming crops in terms of system stability or yield. Results are often mixed or contradictory in the academic literature, due to methodological limitations or insufficient statistical power. The current long-term study (2008-2014) investigates the role of grassland as a precursor to suitable arable crops (potatoes, spring wheat, silage maize and forage turnips), on a rotation-based empiric design, focusing on temporal variability, yield fluctuations and the broader agronomical context in which these changes occur. Using multi-year data, we look at crop yield performance, and discuss results offering suggestions for future research. To account for structural yield differences among crops, yields were standardized within crop categories, allowing for a unified analytical framework. Results from factorial ANOVA models indicate that grassland phases contribute to yield stabilization rather than a uniform increase in production of other crops, with outcomes influenced by crop type and stationary area conditions. Our results suggest that grasslands have the potential to enhance system resilience and are valuable for sustainable crop production under increased environmental uncertainty.

REZUMAT
Pajiștile temporare sunt recunoscute atât pentru funcțiile lor ecologice, cum ar fi ciclul nutrienților, calitatea solului, cât și pentru rolul lor potențial în cadrul rotației culturilor. Deși multe studii au arătat beneficiile agronomice și de mediu ale pajiștilor permanente, mai puține au analizat impactul pajiștilor temporare ca precursori, influențând culturile viitoare în ceea ce privește stabilitatea sistemului sau producţiei. Rezultatele sunt adesea mixte sau contradictorii în literatura academică, din cauza limitărilor metodologice sau a statisticii insuficiente. Studiul actual, pe termen lung (2008-2014), investighează rolul pajiștilor ca precursor al culturilor pretabile în arabil (cartof, grâu de primăvară, porumb siloz și sfeclă furajeră), pe baza unui design empiric bazat pe rotație, concentrându-se pe variabilitatea temporală, fluctuațiile producţiei și contextul agronomic mai larg în care au loc aceste schimbări. Folosind date multianuale, analizăm performanța producţiei culturilor și discutăm rezultatele oferind sugestii pentru cercetări viitoare. Pentru a ține cont de diferențele structurale de randament între culturi, randamentele au fost standardizate în cadrul categoriilor de culturi, permițând un cadru analitic unificat. Rezultatele modelelor factoriale ANOVA indică faptul că pajiștile contribuie la stabilizarea producţiei, mai degrabă decât la o creștere uniformă a producției altor culturi, rezultatele fiind influențate de tipul de cultură și de condițiile staționare zonale. Rezultatele noastre sugerează că pajiștile au potențialul de a spori rezistența sistemului și sunt valoroase pentru producția agricolă durabilă în condiții de incertitudine crescută a mediului.

INTRODUCTION
Sustainable agricultural systems emphasize the use of crop rotation systems and the inclusion of temporary grasslands as strategies to enhance soil fertility, increase nutrient retention and boost system resilience. Temporary grasslands are commonly linked to improved soil structure, favourable biological activity and enhanced organic matter contents, factors that can increase yield in the right climatic conditions (*Bender et al., 2018, Dragomir et al., 2023*).

Despite the aforementioned theoretical advantages, empirical results in field data remain inconsistent, often exhibiting mixed results. Some studies report yield increases in arable crops after a grassland precursor, while others observe neutral or crop-specific effects. A key limitation of the academic literature lies in the heterogeneity of crop types, different soil types found in a wide variety of climatic conditions, and data collected from vastly different experimental designs, which often limit the statistical power of statistical analyses.

This study tries to address some limitations by adopting an integrated analytical model which evaluates yield responses across crops. As reflected by the domain-specific literature, the main advantages that crop rotation provides are: improving soil fertility (*Al-Musawi et al., 2025, Yang et al., 2024*), reducing soil erosion *(Moldavan et al., 2024*), weeds control (*Bender et al., 2018, Weisberger et al., 2019*), increasing soil water uptake and storage (*Shah et al., 2021, Xiao et al., 2025*) reducing greenhouse gas emission from agricultural fields (*Murakami and Iizumi 2025, Saghai et al., 2025, Yang et al. 2024*), reducing mineral fertilizer requirements (*Gokhale and Sharma, 2023, Tzemi et al., 2024*) and improving yields (*Murakami and Iizumi, 2025, Syromiatnykov et al., 2026*).

The inclusion of grasslands in crop rotation presents advantages in terms of productivity (*Wozniak, 2021, Szkutnik-Sroka et al., 2024, Xiao et al., 2025*) and economical returns (*Hassaan et al., 2024, Otto et al., 2023, Smith et al., 2017*), as well as taking into account other functions, such as the protection of water quality (*Mancinelli et al., 2025*), soils (*Francis et al., 2024, Struijk et al., 2026, Ungureanu et al., 2015*), biodiversity (*Li et al., 2019, Chopin et al., 2026, Choudhary et al., 2026*), landscape conservation and its regulatory role of biogeochemical cycles (*Dragomir et al., 2023, Mocanu, 2018, Page et al., 2025*).

Grasslands leave an appreciable amount of biomass in the soil that improves soil fertility (*Li et al., 2019, Frelih-Larsen et al., 2022, Szkutnik-Sroka et al., 2024*). Organic fertilization of land is an operation that has a positive influence on the humus content and physical properties of the soil (*Ball et al., 2005, Zhong et al., 2021, Zheng et al., 2023*). Since the usage of organic fertilizers can be difficult and expensive, the recommended procedure is to perform a rotation between grasslands and crops that are suitable for a specific area (*Fang et al., 2025, Socolar et al., 2021*).

This paper presents the results obtained by the Research-Development Institute for Grassland Brașov from Romania, in the experimental field from Făgăraș Country, during the period 2008-2014. The objective of long-term study was to investigate the role of grassland as a precursor to suitable arable crops, on a rotation-based empiric design, focusing on temporal variability, yield fluctuations and the broader agronomical context in which these changes occur. Although data collection ended in 2014, our multi-year design remains directly relevant to current climate-adaptation and sustainability frameworks, which continue to rely on crop diversification practices, including temporary grasslands as a low-input strategy for stabilizing yields under increased climate variability.

MATERIALS AND METHODS

The experimental field was located in the Făgăraş Country (a central zone of Romania), on the land of a mixed farm in Drăguș, Brașov County, at an altitude of 520 m. The soil type of the experimental field was Podzolic, with the soil acidity ranging from weak to moderate acid, with value of pH between 4.8 to 4.9 and moderate excess humidity *(Mocanu et al., 2018*). The block method was used, with the experimental field being composed of 3 blocks, each block having 5 variations alternated in 4 repetitions. The experimental field scheme is shown in Fig. 1.

The crop rotation took into account suitable crops for this area and the farm requirements, and consisted of: temporary grassland (grasses + perennial legumes), potato, forage turnips, spring wheat, and silage maize (*Mocanu et al., 2018*).

A complex mineral fertilizer, for the temporary grassland variants, was applied as follows (Mocanu et al., 2018): in 2008 – $N_{100}P_{100}K_{100}$, in 2009 – $N_{50}P_{50}K_{50}$, in 2010 – $N_{50}P_{50}K_{50}$, in 2012 – $N_{50}P_{50}K_{50}$, in 2013 – $N_{100}P_{100}K_{100}$ and in 2014 – $N_{50}P_{50}K_{50}$.

For the temporary grassland, a mixture was used in the following percentage: Grasses 70% and Legumes 30% (*Dragomir et al., 2023, Mocanu et al., 2018*), consisting of species and varieties such as: perennial grasses (*Dactylis glomerata* MAGDA, *Festuca pratensis* TRANSILVAN, *Festuca arundinacea* ADELA, *Phleum pratense* TIROM and *Lolium perenne* MATHILDE) and perennial legumes (*Trifolium pratense* ALTASWEDE, *Trifolium repens* RIVENDEL and *Lotus corniculatus* – LOTANOVA).

Fig. 1 - Scheme of the experimental field in Făgăraș Country
(Mocanu et al., 2018)

Climatic conditions varied among years (Table 1): 2012, 2013, 2014 were dry, 2010 was rainy, and 2008, 2009 and 2011 had normal values, with precipitation amounts close to the multiannual average (*Mocanu et al., 2018*).

[Table 1]

Climatic conditions in Făgăraș Country (*Mocanu et al., 2018*)

		2008	2009	2010	2011	2012	2013	2014
Average air temperatures, [°C]	Annual average	8.5	8.9	9.3	10.6	8.8	9.1	9.5
	MAA	7.9	7.9	7.9	8.0	8.0	8.0	8.0
	Deviation	0.6	+1.0	+1.4	+2.6	+0.8	+1.1	+1.5
Atmospheric precipitation [l·m^{-2}]	Annual amount	633.6	674.6	841.3	573.5	493.0	491.7	491.3
	MAA	651.5	647	647	600.0	600.0	600.0	600.0
	Deviation	-17.9	+27.6	+194.3	-26.5	-107.0	-108.3	-108.7

MAA-Multi Annual Average

From the data presented in Table 2, it results that the soil on which the experimental field was located, in the 0...10 cm profile, is strongly acidic, poorly supplied in P and moderately supplied in K, and in the 10...20 cm area, the soil is strongly acidic, very poorly supplied in P and poorly supplied in K.

[Table 2]

The main agrochemical properties of the soil (*Mocanu et al., 2018*)

No.	**Sampling depth** (cm)	**pH**	**Hydrolytic Acidity**	**Sum of Bases**	**V** (%)	**Humus** (%)	**Nitrogen Index**	**P-AL**	**K-AL**
			me at 100 g soil					(ppm)	(ppm)
1	0...10	4.8	10.5	4.8	31.3	1.84	3.70	10.8	90.0
2	10...20	4.9	10.0	4.0	28.5	7.87	2.24	7.4	36.0

Next, the yields of potato, spring wheat, silage maize, and forage turnip grown in rotation after at least one year of temporary grassland are analysed.

Potato yields

In 2009 (normal values in terms of precipitation), potato production was 25.60 t/ha for the A1 alternative (preceding crop: temporary grassland 1st Year) and 35.10 t/ha for the B2 option (preceding crop: temporary grassland 1st Year).

In 2010 (rainy), potato production was 29.50 t/ha for the A5 option (preceding crop: 2009-temporary grassland 1st Year; 2008-silage maize), 27.20 t/ha for B1 (preceding crop: 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year), 26.30 t/ha for C2 (preceding crop: 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year).

In 2012 (dry), potato production was 11.47 t/ha for the B4 option (preceding crop: 2011- temporary grassland 1st Year; 2010-silage maize; 2009-forage turnip; 2008-temporary grassland 1st Year), compared to 13.97 t/ha for C1 (preceding crop: temporary grassland, 4th Year).

In 2013 (dry), potato production was 22.16 t/ha for the A3 group (preceding crop: 2012-temporary grassland 2nd Year; 2011-temporary grassland 1st Year; 2010-silage maize; 2009-forage turnip; 2008-spring wheat), compared to 31.27 t/ha for the B2 option (preceding crop: 2012-forage turnip; 2011-temporary grassland 1st Year; 2010-spring wheat; 2009-potato; 2008-temporary grassland 1st Year) and respectively 29.14 t/ha for C2 (preceding crop: 2012-silage maize; 2011-temporary grassland 1st Year; 2010-potato; 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year).

In 2014 (dry) potato production was 29.90 t/ha for the A2 option (preceding crop: 2013-forage turnip; 2012-temporary grassland 2nd Year; 2011-temporary grassland 1st Year; 2010-forage turnip; 2009-spring wheat; 2008-potato), compared to 41.70 t/ha for B3 (preceding crop: 2013-spring wheat; 2012-silage maize; 2011-temporary grassland 1st Year; 2010-forage turnip; 2009-spring wheat; 2008-temporary grassland 1st Year) and respectively 37.70 t/ha for the C4 alternative (preceding crop: 2013-forage turnip; 2012-spring wheat; 2011-temporary grassland 1st Year; 2010-forage turnip; 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year).

Spring wheat yields

In 2009 (standard in terms of precipitation), the spring wheat production was 3.580 t/ha for option A2 (preceding crop: 2008-potato) and 4.370 t/ha for B3 (preceding crop: temporary grassland 1st Year). In the case of option B3, a positive influence of temporary grassland on spring wheat yield is observed, materializing as a 22 % production increase.

In 2010 (a rainy year) the spring wheat production was 2.075 t/ha in the case of option A1 (preceding crop: 2009-potato; 2008-temporary grassland 1st Year), 1.990 t/ha for option B2 (preceding crop: 2009-potato; 2008-temporary grassland 1st Year), 2.112 t/ha in the case of C3 (preceding crop: 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year).

In 2012 (a dry year), the spring wheat production was 4.253 t/ha for the B1 option (preceding crop: 2011-temporary grassland 1st Year; 2010-potato; 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year), compared to 3.858 t/ha in the case of C4 (preceding crop: 2011-temporary grassland 1st Year; 2010-forage turnip; 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year). It can observe that a good production was obtained in both variants, after temporary grassland 2nd Year followed by a potato and forage turnip crop, respectively.

In 2013 (a dry year), the spring wheat production was 2.553 t/ha in the case of option A4 (preceding crop: 2012-temporary grassland 3rd Year; 2011-temporary grassland 2nd Year; 2010-temporary grassland 1st Year; 2009-silage maize; 2008-forage turnip), compared to 3.267 t/ha for B3 (preceding crop: 2012-silage maize; 2011-temporary grassland 1st Year; 2010-forage turnip; 2009-spring wheat; 2008-temporary grassland 1st Year) and respectively 3.508 t/ha for option C5 (preceding crop: 2012-temporary grassland 1st Year; 2011-temporary grassland 1st Year; 2010-silage maize; 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year).

In 2014 (a dry year), the spring wheat production was 4.312 t/ha for option A3 (preceding crop: 2013-potato; 2012-temporary grassland 2nd Year; 2011-temporary grassland 1st Year; 2010-silage maize; 2009-forage turnip; 2008-spring wheat), compared to 3.190 t/ha in the case of B2 (preceding crop: 2013-potato; 2012-forage turnip; 2011-temporary grassland 1st Year; 2010-spring wheat; 2009-potato; 2008-temporary grassland 1st Year) and respectively 3.550 t/ha for the C3 option (preceding crop: 2013-silage maize; 2012-forage turnip; 2011-temporary grassland 1st Year; 2010-spring wheat; 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year).

Silage maize yields

In 2009 (standard levels of precipitation) the silage maize yield was 47.81 t/ha GM-Green Mass (19.64 t/ha DM-Dry Matter) in case of option A4 (preceding crop: 2008-forage turnip) and 48.48 t/ha GM (21.31 t/ha DM) in case of B5 (preceding crop: temporary grassland 1st Year). In B5, a positive effect of meadow on silage maize yield was observed, resulting in a 1.4% increase.

In 2010 (a rainy year), the silage maize production was 41.63 t/ha GM (14.89 t/ha DM) in the case of A3 (after: 2009-forage turnip; 2008-spring wheat), 37.60 t/ha GM (12.60 t/ha DM) for B4 (preceding crop: 2009-forage turnip; 2008-temporary grassland 1st Year), 53.10 t/ha GM (16.45 t/ha DM) in the case of C5 (preceding crop: 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year).

In 2012 (a dry year), the silage maize production was 8.95 t/ha GM (5.09 t/ha DM) in B3 (preceding crop: 2011-temporary grassland 1st Year; 2010-forage turnip; 2009-spring wheat; 2008-temporary grassland 1st Year), compared to 10.10 t/ha GM (6.17 t/ha DM) in the case of C2 (preceding crop: 2011- temporary grassland 1st Year; 2010-potato; 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year). In option C2, a positive influence of the temporary grassland on the silage maize production is observed, with a production increase of 12.85 %.

In 2013 (a dry year), silage maize production was 64.51 t/ha GM (25.28 t/ha DM) in the case of A5 (preceding crop: 2012-temporary grassland 2nd Year; 2011-temporary grassland 1st Year; 2010-potato; 2009-temporary grassland 1st Year; 2008- silage maize), compared to 50.81 t/ha GM (19.95 t/ha DM) in the B1 option (preceding crop: 2012-spring wheat; 2011-temporary grassland 1st Year; 2010-potato; 2009- temporary grassland 2nd Year; 2008-temporary grassland 1st Year) and respectively 52.73 t/ha GM (22.28 t/ha DM) for C3 (preceding crop: 2012-forage turnip; 2011-temporary grassland 1st Year; 2010-spring wheat; 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year). For option A5, a positive influence of meadow (preceding crop: meadow 2 years) on silage maize production is observed, with a production increase of 26.96 % compared to B1 and 22.34 % compared to option C3.

In 2014 (a dry year), silage maize production was 45.12 t/ha GM (17.53 t/ha DM) in the case of the A4 design (preceding crop: 2013-spring wheat; 2012-temporary grassland 3rd Year; 2011-temporary grassland 2nd Year; 2010-temporary grassland 1st Year; 2009-silage maize; 2008- forage turnip), compared to 32.00 t/ha GM (12.84 t/ha DM) for B5 (preceding crop: 2013-temporary grassland 4th Year; 2012-temporary grassland 3rd Year; 2011-temporary grassland 2nd Year; 2010-temporary grassland 1st Year; 2009-silage maize; 2008-temporary grassland 1st Year) and respectively 45.00 t/ha GM (16.96 t/ha DM) on option C1 (preceding crop: 2013-temporary grassland 1st Year; 2012- potato; 2011-temporary grassland 4th Year; 2010-temporary grassland 3rd Year; 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year).

Forage turnip yields

In 2009 (standard year in terms of precipitation), the production of forage turnip was 56.30 t/ha in A3 (preceding crop: 2008-spring wheat) and 51.80 t/ha in B4 (preceding crop: temporary grassland 1st Year). For option B4, a negative influence of meadow on forage turnip production is observed, with a production decrease of 7.99 %.

In 2010 (a rainy year), the production of forage turnip was 68.10 t/ha in the A2 design (after: 2009-spring wheat; 2008-potato), 51.85 t/ha for B3 (preceding crop: 2009-spring wheat; 2008-temporary grassland 1st Year), 72.55 t/ha for option C4 (preceding crop: 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year). In the case of C4, a positive influence of the meadow on the production of forage turnip is observed, with a production increase of 39.92 % compared to option B3 and a production increase of 6.53 % compared to A2.

In 2012 (a dry year), the production of forage turnip was 28.50 t/ha in B2 (preceding crop: 2011-temporary grassland 1st Year; 2010-spring wheat; 2009-potato; 2008-temporary grassland 1st Year), compared to 30.50 t/ha in C3 (preceding crop: 2011-temporary grassland 1st Year; 2010-spring wheat; 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year). In the case of option C3, a positive influence of the grassland on the production of forage turnip is observed, with an increase in production of 7.02 %.

In 2013 (a dry year), the production of forage turnip was 40.82 t/ha for A2 (preceding crop: 2012-temporary grassland 2nd Year; 2011-temporary grassland 1st Year; 2010-forage turnip; 2009-spring wheat; 2008-potato), compared to 40.07 t/ha MV in the B4 alternative (preceding crop: 2012-potato; 2011-temporary grassland 1st Year; 2010-silage maize; 2009-forage turnip; 2008-temporary grassland 1st Year) and respectively 35.85 t/ha for C4 (preceding crop: 2012-spring wheat; 2011-temporary grassland 1st Year; 2010-forage turnip; 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year). In A2, a positive

influence of the grassland (preceding crop: temporary grassland 2nd Year) on the production of forage turnip is observed, with a production increase of 2.00 % compared to B4 and respectively 13.86 % compared to C4.

In 2014 (a dry year), the production of forage turnip was 58.45 t/ha for A5 (preceding crop: 2013-silage maize; 2012-temporary grassland 2nd Year; 2011-temporary grassland 1st Year; 2010-potato; 2009-temporary grassland 1st Year; 2008-silage maize), compared to 43.50 t/ha in B1 (preceding crop: 2013-silage maize; 2012-spring wheat; 2011-temporary grassland 1st Year; 2010-potato; 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year) and respectively 50.08 t/ha for C5 (preceding crop: 2013-spring wheat; 2012-temporary grassland 2nd Year; 2011-temporary grassland 1st Year; 2010-silage maize; 2009-temporary grassland 2nd Year; 2008-temporary grassland 1st Year).

Hypotheses

This study aims to investigate the role of temporary grassland as a precursor in arable crop rotation using a multi-year plot-based experimental design. The overall main objective is to assess whether the duration of grassland preceding an arable crop can influence yield, and whether this effect varies across crops and annual climatic conditions.

H1: Grassland duration produces a general effect on crop yields across a multi-crop design.

H2: The effect of grassland duration differs among crop types.

H3: Inter-annual variability and climatic conditions have an effect on the relation between the variables in H1 and H2.

Data structure and empirical analyses

This study exhibits a plot-based crop rotation dataset (as previously referenced in Figure 1), followed across several consecutive years. The structure of the data collected over the years follows a longitudinal structure, with each row corresponding to a unique year and plot variant combination, including current crop, previous crop, and yield (t/ha). Statistical analyses were conducted using SPSS Version 26.

As exhibited in Figure 1, 2011 is a rest year, in which grassland was used to preserve crop rotation continuity and to compute grassland duration as a precursor for the next crops. This does not bias the statistical analyses, because the yield was a dependent variable measured only for the arable crops, therefore grassland yield is not an outcome in the present study.

Our variables of interest are:

-The independent variable (IV): grassland duration as a precursor, which was coded for statistical analyses into two categories, namely a) grass_consec_years, which represents the number of consecutive grassland years immediately preceding the current year, and b) grass_duration_cat, the categorical version for analysis (0- no grassland, 1- temporary grassland 1st Year, 2- temporary grassland 2nd Year, 3 and 3+ years- 3 or more years of consecutive grassland);

-The dependent variable (DV): yield, measured in tonnes per hectare (t/ha), analysed separately for each arable crop (potatoes, spring wheat, silage maize and forage turnips);

-Context variable: year, representing the inter-annual variability and the climatic context and year-specific management. 'NPK' (the complex mineral fertilizer applied on the plots of land) is collinear with 'year' because the annual dose is constant across crops within the same year.

Climatic conditions were classified into three categories, namely dry, normal or rainy, based on the aggregated annual rainfall patterns.

RESULTS

Given the small sample size per crop, factorial models with interactions (duration x year) could lead to unstable estimates, therefore, these analyses have been avoided. Also, due to the large inherent differences in absolute yield levels, direct comparison of raw yield figures would have been misleading. To address this and ensure accuracy, yields were standardized within each crop category using Z-scores. This statistical procedure preserves within-crop variability, while enabling a unified analysis across crops. This way, we were able to focus on relative yield performance rather than absolute magnitudes.

Factorial analysis of variance (ANOVA) models was applied using Type III sums of squares to account for unbalanced designs. The primary model included crop type, year, and grassland duration as fixed factors, along with the interaction between grassland and crop.

A secondary model examined the influence of climatic category in place of year, in order to avoid degrees-of-freedom limitations. Statistical significance was evaluated at $\alpha = 0.05$. Effect sizes were quantified using partial eta squared (ηp^2).

It appears that the overall model explained a substantial proportion of yield variability (R^2=0.587, adjusted R^2=0.443).

A significant main effect of year was observed (F=6.63, p<0.001, ηp^2=0.334), indicating a strong interannual variability in yield across the study period.

It has been noted that the main effect of grassland duration did not appear to reach conventional significance level (p=0.098) suggesting that grassland duration alone does not impose a uniform influence on yield across all crops.

In contrast the interaction between crop type and grassland duration was highly significant (F=4.90, p<0.001, ηp^2=0.450). This interaction accounted for a significant size of explained variance and demonstrating that the yield response to grassland duration differs significantly amongst crops.

As shown in Figure 2 and Table 3, mean standardized yields vary little across grassland duration categories, while variability increases noticeably for longer grassland phases.

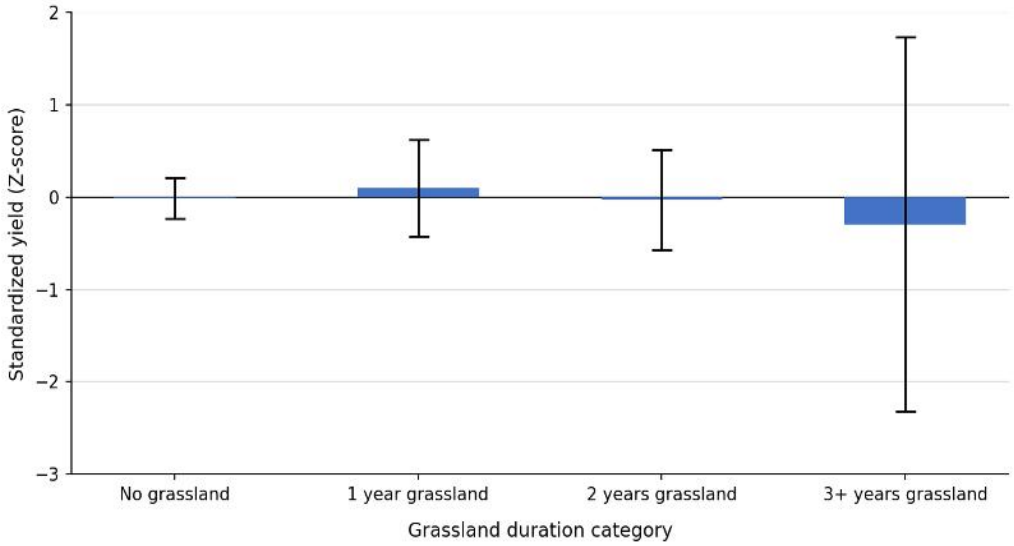

Fig. 2 - Mean standardized crop yield (Z-score) across grassland duration categories

Error bars represent 95 % confidence intervals. Yield values were standardized within crop types to account for inherent yield differences among crops. Short-term grassland phases (1–2 years) are associated with stable or slightly positive standardized yields, while the 3+ years category exhibits high variability due to limited sample size and should be interpreted with caution.

In addition, the main effect of the crop type itself was not significant once yields were standardized thus confirming that the study focus on interaction dynamics rather than crop level differences.

In the climate-based model, the climatic category showed a significant main effect on standardized yields (F=4.70, p=0.012, ηp^2=0.125) highlighting the importance of environmental conditions.

At the same time, the crop x grassland duration interaction remained highly significant (p<0.001) indicating that the crop specific nature of grassland effects carry-on across climatic context. The interaction between climate and grassland duration was not significant suggesting that the climate variates overall yield levels rather than fundamentally altering grassland response patterns.

Table 3

Mean standardized crop yield (Z-score) by grassland duration category

Z-score (yield)			
Grass_duration_cat	**N**	**Mean**	**Std. Deviation**
No grassland	47	-.0133900	.73873321
1 year grassland	25	.1001461	1.27145984
2 years grassland	13	-.0306740	.90286311
3+ years grassland	5	-.2951118	1.62858376
Total	90	.0000000	.97726976

CONCLUSIONS

The results provide insight on effects of temporary grassland on crop yields are not uniform across cropping system. Instead of depicting a universal yield enhancing factor, the grassland duration interacts strongly with specific crops by producing divergent responses depending on crop specific physiological and agronomic characteristics.

Yield values were standardized within crop types. The 3+ years category shows increased dispersion due to limited sample size and should be interpreted with caution.

The absence of a significant main effect of grassland duration should not be interpreted as proof of ineffectiveness. Instead, it reflects the ecological reality that the soil-mediated benefits of grasslands are context-dependent. Crops with higher nutrient demands or greater sensitivity to soil structure appear to benefit differently from grassland phases than crops with lower input requirements.

The strong year effect highlights the role of interannual variability, reinforcing the importance of a long-term observation for further evaluating rotational effects. Climatic conditions further influenced yields but did not negate the crop dependent nature of grassland impacts.

Overall, these findings support the interpretation of temporary grasslands as a stabilizing component within crop rotations. Their primary contribution appears to consolidate yield variability and enhancing system resilience rather than maximizing mean yields across all crops.

In terms of limitations, we noted the use of the aforementioned complex mineral fertilizer NPK whose effect cannot be separated from year effects as they are constant within year across all crops. Another limitation reflects the small sample size per crop and sparse duration categories, which limits inference strength. To address any analysis-related constraints, yields were standardized within crops and analysed collectively. This approach prioritizes the detection of interaction patterns and of system-level responses when it comes to mean differences for a crop. Results must be interpreted with caution, as this exploratory study should be replicated on more crops and repetitions, in order to gather a wider variety of data for ease of comparison. Future research should combine more numerous datasets with mixed-effects statistical modeling, to further identify crop variations in different environmental conditions.

Our study is explorative research which has opened up valuable avenues for future research, while also consolidating existing academic knowledge on crop variation. It investigated the role of temporary grassland as a precursor for arable crop rotation, with the main result indicating that grassland influence crop yields primarily through crop-specific interactions, rather than a uniform main effect on crops. Grassland duration strongly interacts with the crop type, generating yield stability across variable climatic conditions. These findings challenge simplistic assumptions of universal yield enhancement, following grassland phases and instead emphasize the role of grasslands in promoting resilience and functional diversity within agricultural systems. From both an agronomic and methodological perspective, evaluating interaction structures across crops provides a more realistic understanding of rotational benefits in sustainable agriculture.

ACKNOWLEDGEMENT

The authors have recognitions for researchers from National Research-Development Institute for Pedology, Agrochemistry and Environment Protection Bucharest, Romania for support during the research.

Keywords: *exergy analysis, two-temperature-level, refrigeration and freezing system, throttling process, exergy destruction, coefficient of performance, low-GWP refrigerants.*

ABSTRACT
This study compares energy and exergy performance of two vapour-compression refrigeration systems designed to provide simultaneous refrigeration and freezing at two distinct temperature levels for food-industry applications. The simulation results indicated that R1234yf provided the best overall performance for both configurations. The exergy analysis showed that the throttling processes in the first configuration had the fastest increase in exergy destruction with the variation of ambient temperature. The structural improvement of the second configuration led to an increase in overall system performance, confirming the importance of refrigerant selection and structural optimisation of the refrigeration system. For R1234yf, the energy coefficient of performance increased from 2.69 to 2.97 at an ambient temperature of 35 °C and from 1.98 to 2.24 at 45 °C when configuration (b) was used instead of configuration (a).

REZUMAT
Acest studiu compară performanța energetică și exergetică a două sisteme frigorifice cu comprimare mecanică de vapori, proiectate pentru a asigura simultan refrigerarea și congelarea la două niveluri distincte de temperatura, pentru aplicații din industria alimentara. Rezultatele simulărilor au indicat faptul ca R1234yf a oferit cea mai bună performanță globală pentru ambele configurații. Analiza exergetică a arătat ca procesele de laminare din prima configurație au prezentat cea mai rapida creștere a distrugerii de exergie odată cu variația temperaturii ambiante. Îmbunătățirea structurala a celei de-a doua configurații a condus la creșterea performantei globale a sistemului, confirmând importanta selecției agentului frigorific si a optimizării structurale a sistemului frigorific.

INTRODUCTION

In agri-food applications, temperature requirements vary according to the specific characteristics of each product and its intended technological use. Some products must be stored under refrigeration conditions, whereas others require freezing conditions. Two-temperature-level refrigeration systems are used in food storage facilities, commercial units and cold-chain applications where different thermal conditions must be provided simultaneously. These systems can provide one temperature level for refrigeration and another for freezing, either within the same installation or through interconnected refrigeration configurations, such as cascade systems or other forms of thermal coupling.

Refrigeration and freezing are essential technologies for the preservation of agri-food products, as low temperatures reduce microbial activity, slow down enzymatic reactions and limit quality losses. Horticultural and food products have a high water content and deteriorate rapidly during storage, transport and distribution. For this reason, the use of artificial cold through refrigeration or freezing represents one of the most effective methods for preserving perishable products (*Sorică et al., 2023*).

For fresh fruit, storage in climate-controlled rooms contributes to maintaining appearance, firmness and nutritional characteristics during storage (*Hou et al., 2023*). Low-temperature storage is also important for grain preservation, where accurate temperature control can limit biological deterioration and maintain storage conditions. *Han and Leng (2026)* investigated an intelligent control strategy for low-temperature grain storage, demonstrating the potential of precise thermal regulation for agricultural product preservation. For food products of animal origin, refrigeration, partial freezing, and controlled-atmosphere packaging have been investigated as solutions for maintaining quality and extending storage life (*Hou et al., 2024*). For fish and other frozen products, freezing time is a key parameter because it influences product structure, water loss and final quality. *Ren et al. (2026)* experimentally investigated an industrial horizontal plate freezer integrated into a CO_2 refrigeration system. Decreasing the mean evaporating temperature from (-36.1°C) to (-48.6°C) reduced the average freezing time by 35.3%. However, the authors showed that lowering the evaporating temperature reduced the coefficient of performance (COP), while the specific energy consumption remained nearly unchanged because the shorter freezing time partly compensated for the lower performance of the refrigeration cycle.

Another major issue in the agri-food industry is the energy consumption of refrigeration systems. The food chain has a high energy demand, and the choice of refrigeration technology can significantly influence operating costs and environmental impact. *Ferretto et al. (2025)* analysed refrigeration systems for commercial food refrigeration and showed that the refrigerant and system configuration should be selected according to the application and climatic conditions. At the same time, the performance of refrigeration systems is sensitive to ambient temperature, particularly in commercial applications where operation is continuous and the refrigeration load varies over time (*Ferretto et al., 2025; Tsimpoukis et al., 2024*).

The selection of the refrigerant is influenced by regulations aimed at reducing fluorinated greenhouse gas emissions. Refrigerants with a high global warming potential are being progressively restricted, while low-GWP working fluids are increasingly used in commercial and industrial refrigeration systems. *Regulation (EU) 2024/573* establishes the current framework for fluorinated greenhouse gases and replaces *Regulations (EU) No 517/2014*. In this context, R448A, R449A, R454C and R1234yf were considered as working fluids in relation to the requirements established by the aforementioned EU Regulation. R449A and R454C have been investigated in commercial refrigeration systems and food applications, whereas R448A is used in supermarket refrigeration installations (*Ferretto et al., 2025; Giménez-Prades et al., 2024; Tsimpoukis et al., 2024*). R1234yf has also been analysed as a low-GWP refrigerant in studies concerning the energy and exergy performance of vapour-compression refrigeration systems (*Aized et al., 2022*).

Energy analysis is used to assess the overall performance of refrigeration systems through the coefficient of performance. However, exergy analysis is used to evaluate individual processes, as it identifies exergy destruction in each component and highlights the main sources of irreversibility. *Altinkaynak (2021)* analysed R448A and R449A as alternatives to R404A and compared their coefficient of performance, exergy efficiency, and distribution of exergy destruction. *Aized et al. (2022)* applied energy and exergy analyses to several low-GWP refrigerants, including R1234yf. In industrial cold-storage applications, exergy analysis is used to identify components with high exergy destruction and to establish directions for the optimisation of refrigeration systems (*Aksoy and « erçi, 2026)*. In the same context, the development of IoT systems for refrigeration installations has shown that real-time data acquisition, thermodynamic calculations and control functions can support the transition from passive monitoring to the intelligent operation of refrigeration systems (*Bizdadea et al., 2025*).

Recent studies have applied exergy analysis to evaluate and optimise refrigeration systems and other thermal systems at both component and overall system levels (*Aized et al., 2022; Mamut and Sciubba, 2025; Roy and Mandal, 2023*). In the present study, exergy analysis was used to investigate the individual thermodynamic processes occurring within each refrigeration system. The distribution of exergy destruction was analysed to identify the components and processes that limit the performance of the two configurations and account for the differences in their overall performance. Building on the previous study by Ciobanu et al. [6], which compared several two-temperature-level refrigeration configurations mainly from an energy-performance perspective, the present work focuses on two selected configurations and extends the analysis by including a detailed exergy assessment, the distribution of exergy destruction among the main processes, and the influence of ambient temperature. The aim of this paper is therefore to compare the energy and exergy performance of these two vapour-compression refrigeration systems for simultaneous refrigeration and freezing applications in the food industry, using R448A, R449A, R454C and R1234yf as working fluids.

MATERIALS AND METHODS

Selection of Working Fluids

The refrigerants were preliminarily selected based on the literature review, current European Union requirements, environmental characteristics, safety classification and thermodynamic properties. Particular attention was given to the saturation pressure at the freezing-chamber evaporation temperature. Table 1 summarises the relevant characteristics of the candidate fluids at (-29°C) (*ASHRAE-UNEP, 2024; Danfoss Group, 2024*).

R448A, R449A, R454C and R1234yf were retained for the comparative analysis. By contrast, R1233zd(E) and R1234ze(E) were excluded because their saturation pressures at (−29°C) were below atmospheric pressure, which would require sub-atmospheric operation on the low-pressure side under the considered operating conditions. Unlike the previous study by *Ciobanu et al. (2025)*, where compression was assumed to be adiabatic and reversible, both compressors in the present study were modelled as adiabatic devices with a constant isentropic efficiency of 0.80, thereby accounting for compressor irreversibility. This value was selected based on the 0.80-0.90 range reported by *« engel et al. (2019)* for well-designed compressors and on the recent study by *Liu et al. (2026)*, in which compressor isentropic efficiencies between 0.65 and 0.85, including 0.80, were investigated for an R1234yf refrigeration system. Pressure losses in the refrigerant lines and heat exchangers were neglected. The intermediate pressure was defined as the saturation pressure corresponding to the evaporation temperature of the refrigeration chamber.

Table 1

Characteristics of the refrigerants considered in the study and saturation pressure at the freezing-chamber evaporation temperature

No.	Refrigerant	ODP	GWP	Safety class	Refrigerant type	Saturation pressure at −29 °C [bar]
1.	R448A	0	1387	A1	Zeotropic blend	1.68
2.	R449A	0	1397	A1	Zeotropic blend	1.68
3.	R454C	0	148	A2L	Zeotropic blend	1.50
4.	R1234yf	0	4	A2L	Pure fluid	1.03
5.	R1233zd(E)	0	4.5	A1	Pure fluid	0.11
6.	R1234ze(E)	0	7	A2L	Pure fluid	0.64

Description of the Refrigeration Systems

Two configurations of two-temperature-level vapour-compression refrigeration systems were analysed. Both configurations were designed to provide refrigeration and freezing simultaneously, under the same operating conditions. The main parameters used in the comparative energy and exergy analyses are presented in Table 2.

Table 2

Main operating parameters used in the analysis

No.	Parameter	Symbol	Value	UM
1.	Freezing-chamber temperature	t_f	-25	°C
2.	Refrigeration-chamber temperature	t_r	0	°C
3.	Ambient temperature, decision variable	t_0	35˜45	°C
4.	Minimum temperature difference in the heat exchangers	ΔT_{HE}	5	K
5.	Cooling capacity corresponding to the refrigeration load	$\dot{Q}_{\mathrm{ev},r}$	1	kW
6.	Cooling capacity corresponding to the freezing load	$\dot{Q}_{\mathrm{ev},f}$	0.421	kW

The schematic diagram of refrigeration system (a) and the corresponding thermodynamic cycle are shown in Fig. 1. Refrigeration system (a) comprises a refrigeration evaporator (Ev_r), a freezing evaporator (Ev_f), three throttling valves (Tv_1, Tv_2 *and* Tv_3), a high-stage compressor (C_{p1}), a low-stage compressor (C_{p2}), a condenser (Cd), and a liquid separator (*Sl*).

The refrigeration evaporator (Ev_r) provides the refrigeration load, whereas the freezing evaporator (Ev_f) provides the freezing load. The refrigerant from vapour leaving the freezing evaporator (Evf) is compressed by the low-stage compressor (C_{p2}), while the high-stage compressor (C_{p1}) raises the pressure of the combined refrigerant flow to the condensing pressure. Expansion valve (Tv_3) is installed upstream of the liquid separator (*Sl*) and reduces the pressure of part of the liquid refrigerant leaving the condenser to the intermediate-pressure level. The liquid separator connects the refrigerant branches operating at the two pressure levels.

C_{p1} – high-stage compressor; C_{p2} – low-stage compressor; Cd – condenser; Ev_r – refrigeration evaporator; Ev_f – freezing evaporator; Tv_1,Tv_2 and Tv_3 – throttling valves; Sl –liquid separator; $\dot{m}$,$\dot{m}_0$,$\dot{m}_1$ and $\dot{m}_2$– refrigerant mass flow rates; 1–7 – thermodynamic state points.; p – pressure; h – specific enthalpy. Source: adapted from Ciobanu et al. (2025).

Refrigeration system (b) includes the same main components as refrigeration system (a). However, the connection of the liquid separator (*Sl*) and the arrangement of the freezing branch differ from those of system (a). In system (b), the refrigerant discharged by the low-stage compressor (C_{p2}) enters the liquid separator, together with the two-phase refrigerant stream produced by throttling through expansion valve (Tv_3). Intercooling and phase separation occur in (*Sl*) at the intermediate-pressure level. The vapour leaving the liquid separator mixes with the refrigerant flow from the refrigeration evaporator (Ev_r) before entering the high-stage compressor (C_{p1}). The liquid phase leaving the separator is expanded through (Tv_2) and subsequently supplied to the freezing evaporator (Ev_f). The schematic diagram of refrigeration system (b) and the corresponding thermodynamic cycle are presented in Fig. 2.

Mathematical Model of Refrigeration System (a)

After establishing the refrigeration loads and the main operating parameters of the two systems according to the data presented in Table 2, the mathematical models were developed. Energy balances were used to evaluate the overall performance of the systems, whereas exergy analysis was applied to identify the processes associated with the highest exergy destruction. The mathematical models were implemented using Engineering Equation Solver (EES) software (F-Chart Software, n.d.).

Refrigeration system (a), presented in Fig. 1, provides the required cooling loads at two temperature levels, corresponding to refrigeration and freezing applications. Based on the overall energy balance derived from the first law of thermodynamics, the following relationship can be written *(Russell and Adebiyi, 1993)*:

$$\dot{Q}^a_{ev_f} + \dot{Q}^a_{ev_r} + \dot{W}^a_{cp_1} + \dot{W}^a_{cp_2} = \dot{Q}^a_{cd} \quad (1)$$

where: $\dot{Q}^a_{ev_f} and \dot{Q}^a_{ev_r}$ are the cooling capacities corresponding to the freezing and refrigeration loads, respectively, [kW]; $\dot{W}^a_{cp_1} and\ \dot{W}^a_{cp_2}$ are the power inputs of the high-stage and low-stage compressors, respectively, [kW]; $\dot{Q}^a_{cd}$ is the heat transfer rate from the refrigerant to the surroundings in the condenser, [kW]; and superscript a denotes refrigeration system (a).

The cooling capacity corresponding to the freezing load is calculated as:

$$\dot{Q}^a_{ev_f} = \dot{m}_2(h_1 - h_7) \quad (2)$$

The cooling capacity corresponding to the refrigeration load is calculated as:

$$\dot{Q}^a_{ev_r} = \dot{m}_1(h_3 - h_6) \quad (3)$$

where: $\dot{m}_1 and\ \dot{m}_2$ are the refrigerant mass flow rates through the refrigeration and freezing evaporators, respectively, [kg/s], while $h_1, h_3, h_6\ and\ h_7$ are the specific enthalpies at the corresponding thermodynamic state points, [kJ/kg].

The power input of the high-stage compressor is:

$$\dot{W}^a_{cp_1} = \dot{m}(h_4 - h_3) \quad (4)$$

The power input of the low-stage compressor is:

$$\dot{W}^a_{cp_2} = \dot{m}_2(h_2 - h_1) \quad (5)$$

where: $\dot{m}$ is the total refrigerant mass flow rate through the high-stage compressor, [kg/s], and $h_1, h_2, h_3\ and\ h_4$ are the specific enthalpies at the corresponding compressor inlet and outlet state points, [kJ/kg].

The heat transfer rate rejected by the condenser is:

$$\dot{Q}^a_{cd} = \dot{m}(h_5 - h_4) \quad (6)$$

where: h_5 is the specific enthalpy at the condenser outlet, [kJ/kg].

The overall energy coefficient of performance of refrigeration system (a) is defined as:

$$COP^a_{en} = \frac{\dot{Q}^a_{ev_f} + \dot{Q}^a_{ev_r}}{\dot{W}^a_{cp_1} + \dot{W}^a_{cp_2}} \quad (7)$$

Exergy analysis was applied to evaluate the thermodynamic performance of the individual processes. For the complete refrigeration system operating under steady-state conditions, the general exergy balance is written as follows (*Radcenco, 1977*).

$$\sum \dot{E}x^{T_i}_{Q_i} + \sum \dot{I}_i = \sum \dot{W}_i \quad (8)$$

where: $\dot{E}x^{T_i}_{Q_i}$ is the exergy transfer rate associated with heat transfer at temperature T_i, [kW]; $\dot{W}_i$ is the power transfer rate, [kW]; $\dot{I}_i$ is the exergy destruction rate of component or process i, [kW]; and T_i is the absolute temperature at which heat transfer occurs, [K].

Applying Equation (8) to refrigeration system (a) gives:

$$\dot{E}x^{T_{7-1}}_{Q^a_{ev_f}} + \dot{E}x^{T_{6-3}}_{Q^a_{ev_r}} + \dot{I}^a_{cp_1} + \dot{I}^a_{cp_2} + \dot{I}^a_{tv_1} + \dot{I}^a_{tv_2} + \dot{I}^a_{tv_3} + \dot{I}^a_{ls} + \dot{I}^a_{cd} = \dot{W}^a_{cp_1} + \dot{W}^a_{cp_2} \quad (9)$$

where: $\dot{E}x^{T_{7-1}}_{Q^a_{ev_f}}$ and $\dot{E}x^{T_{6-3}}_{Q^a_{ev_r}}$ are the exergy transfer rates associated with the heat absorbed in the freezing and refrigeration evaporators, respectively, [kW]; $\dot{I}^a_{cp_1}$ and $\dot{I}^a_{cp_2}$ are the exergy destruction rates in the high-stage and low-stage compressors, respectively, [kW]; $\dot{I}^a_{tv_1}, \dot{I}^a_{tv_2}$ and $\dot{I}^a_{tv_3}$ are the exergy destruction rates associated with the throttling processes, [kW]; $\dot{I}^a_{ls}$ is the exergy destruction rate in the liquid separator, [kW]; and $\dot{I}^a_{cd}$ is the exergy destruction rate in the condenser, [kW].

After identifying the exergy fuel and exergy product of the system, *Equation (9)* can be expressed in fuel-product form as follows:

$$\dot{W}^a_{cp_1} + \dot{W}^a_{cp_2} = \dot{E}x^{T_f}_{Q^a_{ev_f}} + \dot{E}x^{T_r}_{Q^a_{ev_r}} + \dot{I}^a_{cp_1} + \dot{I}^a_{cp_2} + \dot{I}^a_{ev_f} + \dot{I}^a_{ev_r} + \dot{I}^a_{tv_1} + \dot{I}^a_{tv_2} + \dot{I}^a_{tv_3} + \dot{I}^a_{ls} + \dot{I}^a_{cd} \quad (10)$$

The exergy coefficient of performance of refrigeration system (a) is calculated as:

$$\eta^a_{ex} = \frac{\dot{E}x^{T_f}_{Q^a_{ev_f}} + \dot{E}x^{T_r}_{Q^a_{ev_r}}}{\dot{W}^a_{cp_1} + \dot{W}^a_{cp_2}} \cdot 100 \quad (11)$$

where: η^a_{ex} is the exergy coefficient of performance of refrigeration system (a), [%].

Mathematical Model of Refrigeration System (b)

The configuration shown in Fig. 2 represents refrigeration system (b), which is also designed to meet refrigeration and freezing loads at two distinct temperature levels. The corresponding energy and exergy relations are developed below for this system arrangement.

The energy balance derived from the first law of thermodynamics and applied to refrigeration system (b) is written as follows:

$$\dot{Q}^b_{ev_f} + \dot{Q}^b_{ev_r} + \dot{W}^b_{cp_1} + \dot{W}^b_{cp_2} = \dot{Q}^b_{cd} \quad (12)$$

where: superscript b denotes refrigeration system (b), while the remaining terms have the same meanings and units as those defined for *Equation (1)*.

The overall energy coefficient of performance of refrigeration system (b) is calculated:

$$\mathrm{COP}^b_{en} = \frac{\dot{Q}^b_{ev_f} + \dot{Q}^b_{ev_r}}{\dot{W}^b_{cp_1} + \dot{W}^b_{cp_2}} \quad (13)$$

where: COP^b_{en} is the overall energy coefficient of performance of refrigeration system (b), [–].

The exergy balance of refrigeration system (b), expressed in terms of exergy fuel, exergy product and exergy destruction, is written as:

$$\dot{W}^b_{cp_1} + \dot{W}^b_{cp_2} = \dot{E}x^{T_f}_{Q^b_{ev_f}} + \dot{E}x^{T_r}_{Q^b_{ev_r}} + \dot{I}^b_{cp_1} + \dot{I}^b_{cp_2} + \dot{I}^b_{ev_f} + \dot{I}^b_{ev_r} + \dot{I}^b_{tv_1} + \dot{I}^b_{tv_2} + \dot{I}^b_{tv_3} + \dot{I}^b_{ls} + \dot{I}^b_{cd} \quad (14)$$

where: the exergy-transfer and exergy-destruction terms have the same meanings and units as those defined for refrigeration system (a), while superscript b indicates that the terms refer to refrigeration system (b).

The exergy efficiency of refrigeration system (b) is calculated as:

$$\eta^b_{ex} = \frac{\dot{E}x^{T_f}_{Q^b_{ev_f}} + \dot{E}x^{T_r}_{Q^b_{ev_r}}}{\dot{W}^b_{cp_1} + \dot{W}^b_{cp_2}} \cdot 100 \quad (15)$$

where: η^b_{ex} is the exergy efficiency of refrigeration system (b), [%].

The exergy transfer rate associated with heat transfer is calculated as:

$$\dot{E}x^{T_i}_{Q_i} = \dot{Q}_i \left(\frac{T_0}{T_i} - 1\right) \quad (16)$$

where: $\dot{E}x^{T_i}_{Q_i}$ is the exergy transfer rate associated with heat transfer in process i, [kW]; $\dot{Q}_i$ is the corresponding heat transfer rate, [kW]; T_0 is the ambient reference temperature, [K]; and T_i is the absolute temperature at which heat transfer occurs, [K].

The exergy destruction rate of each process is calculated as:

$$\dot{I}_i = T_0 \dot{S}_{gen_i} \quad (17)$$

where: $\dot{I}_i$ is the exergy destruction rate of process i, [kW], and $\dot{S}_{gen_i}$ is the entropy generation rate associated with the process, [kW/K].

The relative exergy destruction associated with each process, expressed with respect to the total compressor power input, is calculated as:

$$\psi_i = \frac{\dot{I}_i}{\sum_i \dot{W}_i} \cdot 100 \quad (18)$$

where: ψ_i is the relative exergy associated with each process i, [%], and $\sum_i \dot{W}_i$ is the total compressor power input, [kW].

RESULTS

To identify the working fluid providing the highest overall performance for the two investigated refrigeration systems, the overall energy and exergy coefficients of performance were evaluated for R448A, R449A, R454C and R1234yf. The ambient temperature, t_0, was varied from 35 °C to 45 °C and was used as the independent variable in the sensitivity analysis.

For refrigeration system (a), the overall energy coefficient of performance decreased with increasing ambient temperature for all the investigated refrigerants, as shown in Fig.3. R1234yf provided the highest values over the entire temperature range, followed by R448A, R449A and R454C. The energy coefficient of performance obtained with R1234yf decreased from approximately 2.69 at 35°C to approximately 1.98 at 45°C.

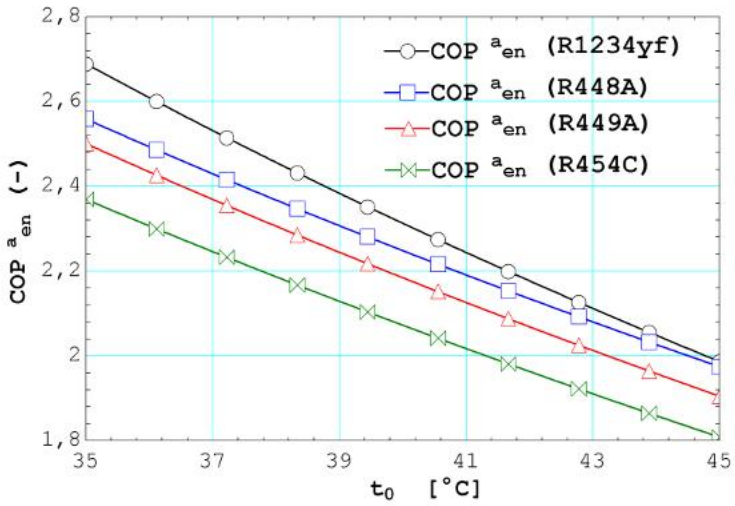

Fig. 3 - Variation of the overall energy coefficient of performance of refrigeration system (a) with ambient temperature for the investigated refrigerants

A similar tendency was obtained for the exergy coefficient of performance of refrigeration system (a), as presented in Fig. 4. The values decreased as the ambient temperature increased, while the ranking of the refrigerants remained unchanged. R1234yf provided the highest exergy coefficient of performance, which decreased from approximately 43.6% to 39.7% over the investigated temperature range. R454C showed the lowest values.

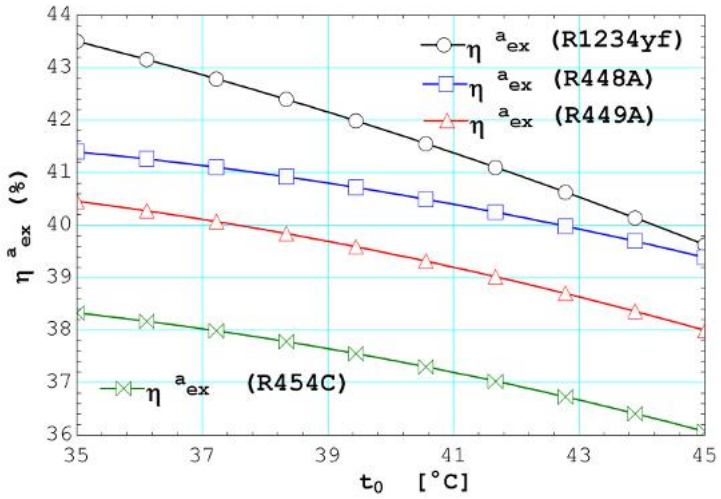

Fig. 4 - Variation of the exergy coefficient of performance of refrigeration system (a) with ambient temperature for the investigated refrigerants

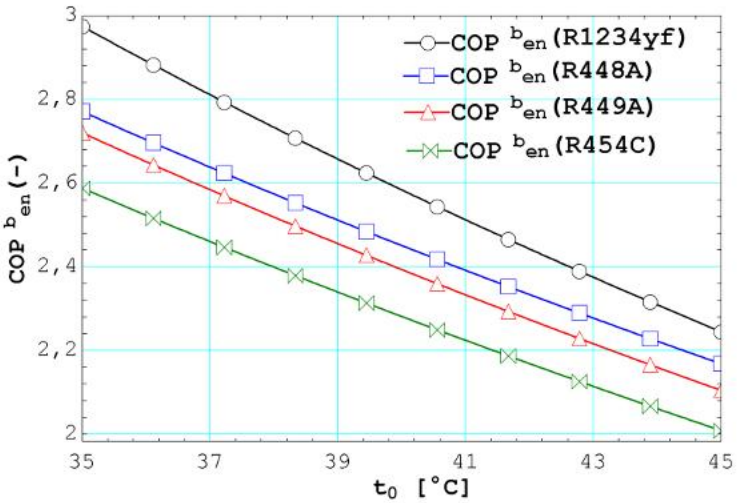

Fig. 5 - Variation of the overall energy coefficient of performance of refrigeration system (b) with ambient temperature for the investigated refrigerants

The results obtained for refrigeration system (b) are presented in Figs. 5 and 6. The overall energy coefficient of performance decreased with increasing ambient temperature for all four refrigerants. R1234yf again provided the highest values, followed by R448A, R449A and R454C. For R1234yf, the energy coefficient of performance decreased from approximately 2.97 at 35 °*C* to approximately 2.24 at 45 °*C*.

The exergy coefficient of performance of refrigeration system (b) followed the same decreasing tendency, as shown in Fig. 6. R1234yf provided the highest values, ranging from approximately 48.0% at 35 °*C* to approximately 44.7% at 45 °*C*. R454C presented the lowest exergy performance throughout the investigated range.

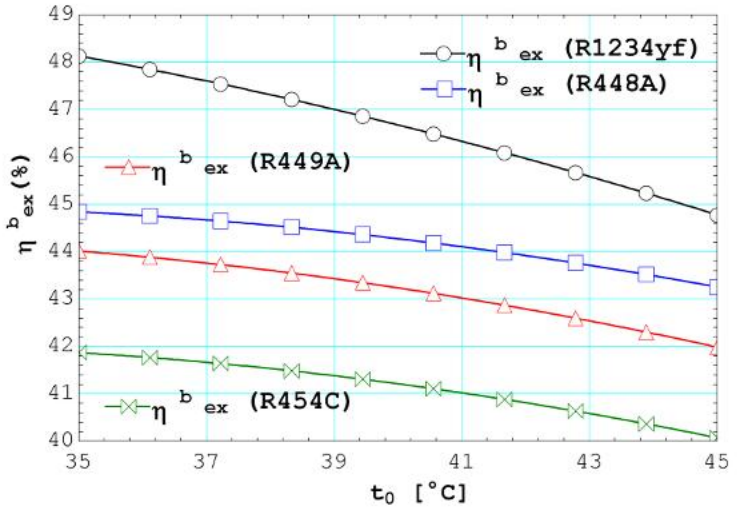

Fig. 6 - Variation of the exergy coefficient of performance of refrigeration system (b) with ambient temperature for the investigated refrigerants

The comparison of the results presented in Figs. 3–6 showed that refrigeration system (b) achieved higher energy and exergy performance than refrigeration system (a) under the same operating conditions. The influence of the system configuration was observed for all the investigated refrigerants. Based on the overall results, R1234yf was selected for the component-level exergy analysis of the two refrigeration systems.

The relative exergy destruction associated with the individual processes of refrigeration system (a) is presented in Fig. 7. The relative exergy destruction associated with the first and second throttling processes increased considerably with ambient temperature. The contribution of the high-stage compressor remained almost constant, whereas the relative contributions of the condenser, low-stage compressor and evaporators generally decreased over the investigated temperature range.

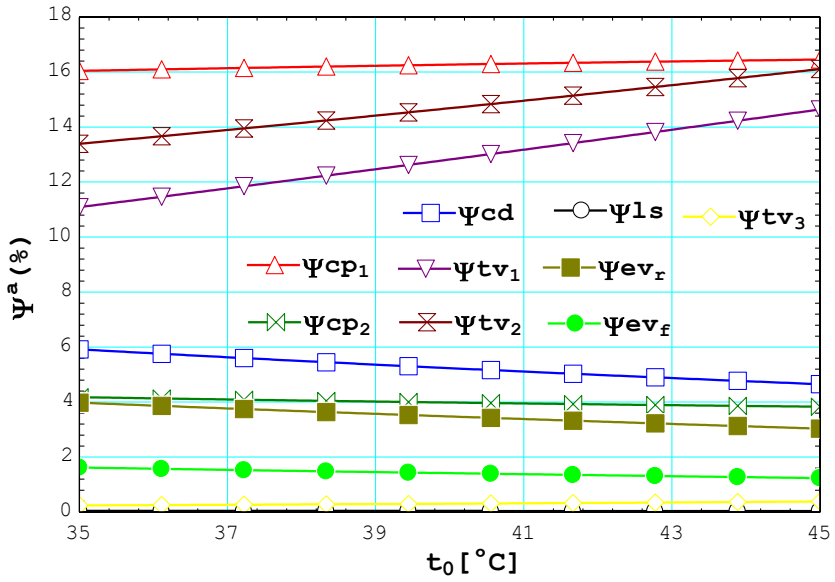

Fig. 7 - Relative exergy destruction associated with the individual processes of refrigeration system (a) using R1234yf

ψ^a– relative exergy destruction associated with system a

For refrigeration system (b), the distribution of relative exergy destruction is shown in Fig. 8. The contribution of the first throttling process increased with ambient temperature, while the third throttling process also showed an increasing tendency. The relative exergy destruction of the second throttling process remained comparatively low. The high-stage compressor represented one of the largest individual contributions, but its variation with ambient temperature is limited.

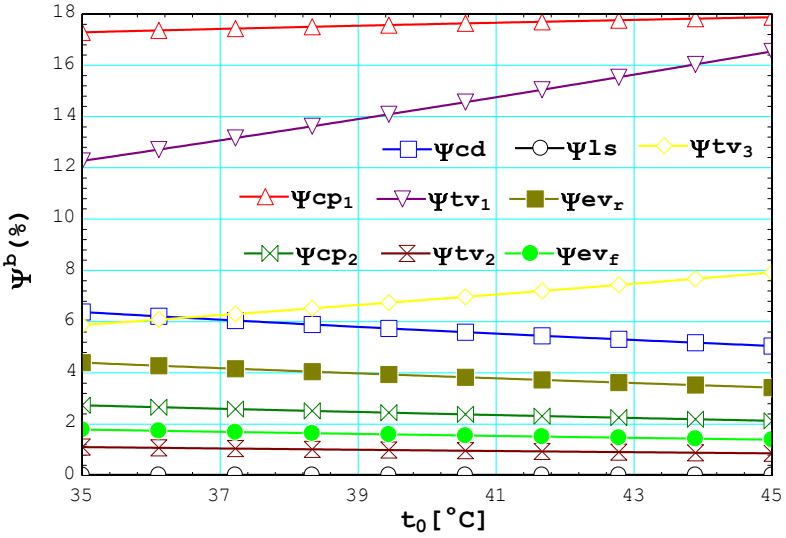

Fig. 8 - Relative exergy destruction associated with the individual processes of refrigeration system (b) using R1234yf

ψ^b– relative exergy destruction associated with system b

The total relative exergy destruction associated with the throttling processes of the two refrigeration systems is compared in Fig. 9. In both configurations, the total value increased with ambient temperature and followed a similar tendency. However, refrigeration system (b) maintained lower values throughout the investigated temperature range. For refrigeration system (a), the total relative exergy destruction of the throttling processes increased from approximately 24.6 % at 35 °C to approximately 31.1 % at 45°C. For refrigeration system (b), the corresponding values increased from approximately 19.1 % to approximately 25.2%.

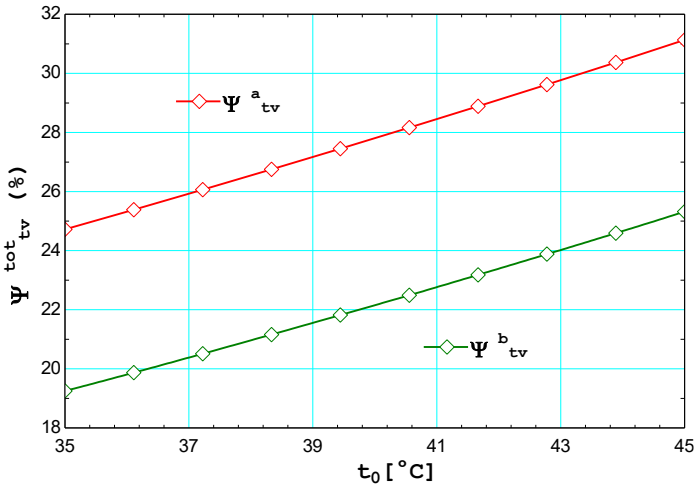

Fig. 9 - Total relative exergy destruction associated with the throttling processes of refrigeration systems (a) and (b) using R1234yf

ψ_{tv}^{tot} – total relative exergy destruction associated with the throttling processes; superscripts a and b denote refrigeration systems (a) and (b), respectively.

The comparison of Figs. 3–6 confirms the superior performance of refrigeration system (b) under the same operating conditions. For R1234yf, the COP of system (b) was approximately 10.4% higher than that of system (a) at 35 °C and 13.1% higher at 45 °C, while the corresponding improvements in exergy efficiency were approximately 10.1% and 12.6%, respectively. This performance advantage is consistent with the lower irreversibilities associated with the throttling processes in configuration (b), for which the total relative exergy destruction remained below that of configuration (a) over the entire investigated temperature range. These results indicate that the modified flow arrangement and intermediate-pressure separation in system (b) provide a thermodynamically more favourable distribution of irreversibilities.

CONCLUSIONS

An energy and exergy analysis was carried out for two refrigeration system configurations capable of simultaneously providing the temperature levels required for refrigeration and freezing. Their performances were evaluated using R448A, R449A, R454C and R1234yf under different ambient-temperature conditions.

The comparative analysis showed that the working fluid had a significant influence on the overall energy and exergy performance of both systems. Among the investigated refrigerants, R1234yf provided the highest energy and exergy coefficients of performance over the entire ambient-temperature range, while both indicators decreased as ambient temperature increased.

Although refrigeration systems (a) and (b) contained the same main components, their different structural arrangements led to different overall performances. Under the same operating conditions, system (b) provided higher energy and exergy coefficients of performance than system (a).

The process-level exergy analysis showed that the relative exergy destruction associated with the throttling processes presented the greatest sensitivity to ambient temperature. The staged throttling arrangement adopted in refrigeration system (b) reduced the total relative exergy destruction associated with these processes throughout the investigated temperature range. This reduction explained the improved overall performance of system (b).

Therefore, refrigerant selection and system configuration should be considered jointly when designing and optimising two-temperature-level refrigeration systems. Exergy analysis proved useful for identifying the main sources of irreversibility and supporting the development of more efficient systems for simultaneous refrigeration and freezing.

As a final conclusion, out of the two configurations investigated in the present paper, configuration (b) is the one recommended to be used in the food industry where both freezing and refrigeration are needed. Among the two configurations investigated, configuration (b) is recommended for food-industry applications requiring simultaneous refrigeration and freezing under the operating conditions and cooling capacities considered in this study. Further analysis is required before extending this conclusion to significantly larger-capacity refrigeration systems.

ABSTRACT

The quality inspection of sorghum grains after drying is critical for ensuring storage stability and processing quality. However, traditional manual inspection methods are inefficient, time-consuming, and prone to subjective biases. To address these challenges, this study proposes an improved YOLOv8s model, named YOLOv8s-GBD, for accurate sorghum grain classification and detection. The proposed model integrates three key enhancements. First, the DFC Attention-based bottleneck structure from GhostNetV2 is incorporated into the C2f module to enhance global context awareness and improve detection accuracy. Second, a bi-directional feature pyramid network (BiFPN) is introduced to optimize multi-scale feature fusion. Third, a dynamic head framework based on attention mechanisms is adopted to strengthen feature representation, further boosting the model's accuracy and robustness. Experimental results demonstrate that the YOLOv8-GBD model achieves 95.2% precision, 98.0% recall, 98.7% mAP1, 97.5% mAP2, and 96.6% F1-score. Compared to the original YOLOv8s model, these metrics show improvements of 3.1%, 1.7%, 1.2%, 1.0%, and 2.4%, respectively. Furthermore, the YOLOv8-GBD model outperforms other YOLO series models in sorghum grain classification and detection tasks. In conclusion, the YOLOv8s-GBD model meets the requirements for high accuracy in sorghum grain quality inspection, offering a robust solution for practical applications.

摘要

干燥后高粱籽粒的品质检测对保障仓储稳定性与加工品质至关重要。然而传统人工检测方式效率低下、耗时长，且容易存在主观偏差。针对上述问题，本文提出一种改进 YOLOv8s 模型 YOLOv8s-GBD，实现高粱籽粒精准分类与检测。该模型包含三项核心改进：第一，在 C2f 模块中嵌入 GhostNetV2 的 DFC 注意力瓶颈结构，增强模型全局上下文感知能力，提升检测精度；第二，引入双向特征金字塔网络（BiFPN）优化多尺度特征融合；第三，采用基于注意力机制的动态检测头框架强化特征表征能力，进一步提升模型精度与鲁棒性。实验结果表明：YOLOv8s-GBD 模型精确率 95.2%、召回率 98.0%、mAP1 为 98.7%、mAP2 为 97.5%、F1 分数 96.6%。相较于原始 YOLOv8s 模型，各项指标分别提升 3.1%、1.7%、1.2%、1.0%、2.4%。同时，在高粱籽粒分类检测任务中，YOLOv8s-GBD 模型性能优于其他 YOLO 系列模型。综上，YOLOv8s-GBD 模型能够满足高粱籽粒品质检测的高精度需求，可为实际工程应用提供可靠方案。

INTRODUCTION

Sorghum is one of the important food crops in China. In the processing, transportation, storage, acquisition, sales and other links, the quality of sorghum grains needs to be tested. Its quality directly affects food security and economic benefits. However, during the acquisition and drying process, the grain will inevitably be affected by environmental factors such as temperature, which will lead to a series of quality changes, such as mildew, lesions and mechanical damage (*Olgun M et al., 2016; Tsuzuki W et al., 2014*). Sorghum grains with defects or damage but still have use value are called imperfect grains. The national standard GB/T8231-2024 defines imperfect grains as: diseased, moth-eaten, damaged, sprouted, mouldy and heat-damaged.

During the harvesting process of sorghum, some sorghum seeds are wrapped with glume-protected and useful grains called shelled grains. Sorghum grading indicators such as moisture, capacity, and thousand grain weight need to be completed on-site before sorghum enters storage after the drying session. Some indicators such as imperfect grains and shelled grains cannot be completely eliminated. Small samples need to be tested to ensure grain quality, guide grain storage management and prevent economic losses. Therefore, research on sorghum quality evaluation methods and techniques is of great practical significance to meet the market demand and ensure sorghum storage safety.

The traditional classification of imperfect grains and shelled grains is mainly detected by manual visual inspection. This method is not only inefficient, but also easily affected by subjective factors, resulting in poor accuracy and reliability of the detection results (*Zhang W. et al., 2021; Wang L. et al., 2022; Ni C et al., 2019*). At present, many scholars use physical and chemical detection methods to study the imperfect particles (*Guo M. et al., 2019; Liu J. et al., 2024; Pearson et al., 2007; Yang et al., 2021*), such as analysing the time-domain characteristics of the acoustic wave, or studying the interaction between the acoustic wave and the medium to achieve the detection of imperfect particles (*Sun et al., 2021*). This method is fast, but highly dependent on the acoustic propagation medium, and is highly susceptible to the influence of noise. Chemical detection methods can achieve rapid screening of fungal contamination and mycotoxins in grain, but the repetition rate is very poor and prone to environmental pollution (*Gab-Allah et al., 2021*).

With the rapid development of modern information technology, such as machine vision technology, near-infrared spectroscopic detection technology, hyperspectral detection technology are more and more widely used in the field of agricultural products (*Na et al., 2019; Qi et al., 2024; Qin et al., 2017*). Meanwhile, target detection technology based on deep learning shows great potential in the field of agricultural product quality inspection.

The use of hyperspectral imaging and near-infrared spectroscopy can be used to directly measure the mould condition and disease spots of grain kernels (*Delwiche et al., 2019; He et al., 2021; Sendin et al., 2017*). *Liu Zhang et al., (2021),* proposed a data calibration model based on multi-angle near-infrared hyperspectral, using four sides of wheat grain images combined with machine learning models to detect wheat damaged by rice weevil, and the accuracy rate reached 97%. *Li et al., (2022),* proposed a method for identifying unsound wheat kernels based on a deep convolutional Generative Adversarial Network (DCGAN) and near-infrared hyper-spectral imaging to identify unsound wheat seeds. Experiments show that the recognition accuracy based on the joint model of DCGAN and CNN reaches up to 96.67%. *Fengshuang Liu et al. (2023)* proposed a new spectral-spatial feature extraction-enhanced fully-connected neural network (SSFE-FCNN) to achieve the detection of pixel-level mechanical dam-ages in glutinous maize, and the experiments show that the accuracy of this method reaches up to 98.09%. It can be achieved for the grading operation of maize. Although the use of hyperspectral imaging technology, near infrared spectroscopy technology can achieve the detection of grain defects, germination, etc., but its cost is high and the effect is limited for the detection of grain shape, disease spots and other appearance characteristics.

In recent years, many researchers have used machine vision methods to detect defective grains. The commonly used methods are traditional image processing methods and artificial neural network methods (*Chen Z. et al., 2022; Shen R. et al., 2023*). The traditional image pro-cessing method detects by extracting features such as colour and shape. This method has low accuracy and poor robustness. Therefore, there are more related researches on target detection using deep learning techniques. *Zhang et al., (2025),* proposed a method for identifying unsound wheat seeds based on multi-scale parallel convolutional neural networks. Experiments showed that the accuracy of this method reached 98.798 %. *Lin W. et al.,* (*2023*), proposed an online classification method for soybean seeds based on deep learning. This method can accurately classify normal, damaged, abnormal and unclassifiable soybeans. The accuracy rate reaches 95.63% on NVIDIA Jetson TX2, which lays the foundation for online soybean quality evaluation. *Gao et al., (2022),* studied the identification of wheat unsound kernels based on machine vision and deep learning network models. By comparing the advantages and disadvantages of GoogleNet, DenseNet, IX-Resnet, Res2Net and other networks, a Res24_D_CBAM_Atrous wheat imperfect kernel detection method was proposed, with an accuracy rate of 94 %.

In summary, the combination of machine vision and deep learning enables the detection of imperfect grains at a low cost. Currently, it is widely used in crops such as wheat, corn and soybean, but there are few literatures on the detection of imperfect grains and husked grains of sorghum. Therefore, identifying imperfect, perfect, and shelled grains in sorghum is of great practical importance, but the wide variety places higher demands on the generalisation ability of the model.

To address the aforementioned challenges, an improved model YOLOv8s-GBD (YOLOv8s-C2f_Ghostblockv2-BiFPN-DymiHead) based on YOLOv8s is proposed to achieve accurate recognition of sorghum seed categories. In this study, the C2f module in the YOLOv8s backbone feature extraction network is improved by incorporating the DFC Attention-based Bottleneck structure from GhostNetV2 into the C2f module. This modification strengthens the global context-awareness of feature representation and enhances the detection accuracy of the model. Additionally, a bidirectional feature pyramid network (BiFPN) is incorporated to enhance multi-scale feature fusion performance and thereby improve the accuracy of small-target detection. Finally, to further boost the model's feature expression capability, a target detection head framework based on the attention mechanism (Dynamic Head) is introduced. This not only improves the model's accuracy and robustness but also ensures accurate classification of sorghum seed categories.

MATERIALS AND METHODS

Sorghum grain dataset

The training of the YOLOv8s-GBD algorithm proposed in this study requires labelled sorghum grain datasets. However, existing open-source datasets lack a specific dataset for sorghum grain classification. Consequently, this study constructed a dedicated sorghum grain dataset by collecting images of sorghum grains. The dataset was systematically classified and labelled, with each grain individually enclosed in an independent bounding box.

Materials

Sorghum samples were provided by Bengbu Chuqian Trading Co., Ltd. Three different types of sorghum grains—perfect grains, imperfect grains, and shelled grains-from the Hongyingzi variety were used as research objects. Due to sample limitations, this study focused solely on three types of imperfect grains: lesion grains, damaged grains, and insect-damaged grains. Prior to the experiment, the seeds were dried to ensure that the moisture content of the sorghum grain samples was (13.5 ± 0.5)%. Subsequently, perfect grains, imperfect grains, and shelled grains were carefully selected from the samples.

Sorghum grain image acquisition

In this study, high-resolution industrial cameras were used to collect images of sorghum grains. The industrial camera is a colour camera with a resolution of 25 MP and a 25 mm focal length lens. The industrial camera is connected to the host computer through GigE to ensure the high speed and stability of data transmission.

In the process of image acquisition, the industrial camera is fixed on the array platform, which is 25 cm away from the sorghum grain. The image acquisition device is shown in Fig. 1. In order to reduce environmental interference, the collection site is in the laboratory, and the collection time is selected during the period of stable light (10 a.m. to 2 p.m.). The selected three different types of sorghum grains were randomly spread on a black worktable. Through the SDK software of the industrial camera, the parameters are reasonably set to obtain a colour image with a resolution of 5120 × 5120, which is stored in the jpg format, and a total of 167 colour images are collected.

Dataset construction

The images collected by industrial cameras contain multiple sorghum grains, making them difficult to label. Therefore, this study employs threshold segmentation, morphological processing and contour search algorithms to divide the images into several sub-images, as shown in Fig. 2. The image dataset consists of sub-images containing only one complete grain. Sorghum grains are classified based on their appearance, epidermal characteristics, and integrity, as illustrated in Fig. 3. The open-source LabelImg image annotation tool (https://github.com/tzutalin/labelImg) is utilized to annotate perfect grains, imperfect grains, and shelled grains within the images. The three types of sorghum grain images are described as follows:

(1) Perfect grain: complete and shiny sorghum grain.

(2) Imperfect grain: lesion grains, damaged grains and insect-damaged grains.

(3) Shelled grain: Sorghum grain with guard glumes (shells).

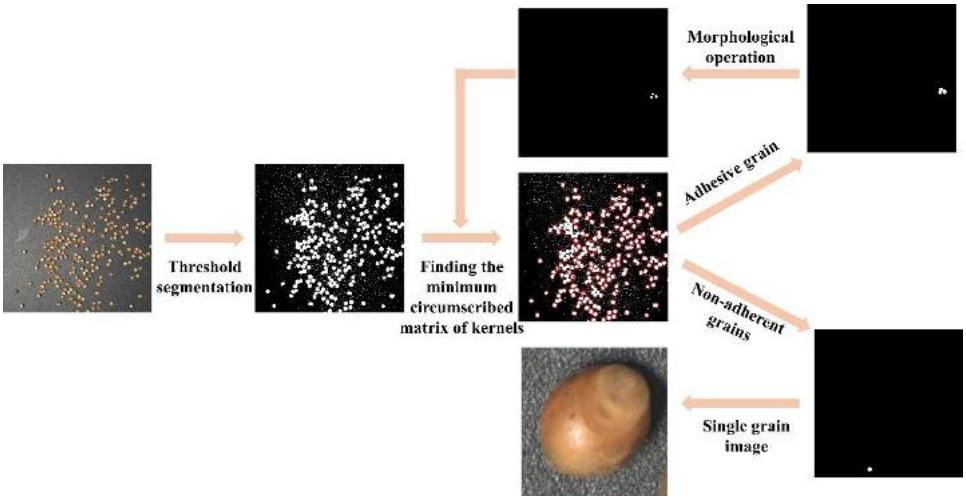

Fig. 2 - Image pre-processing

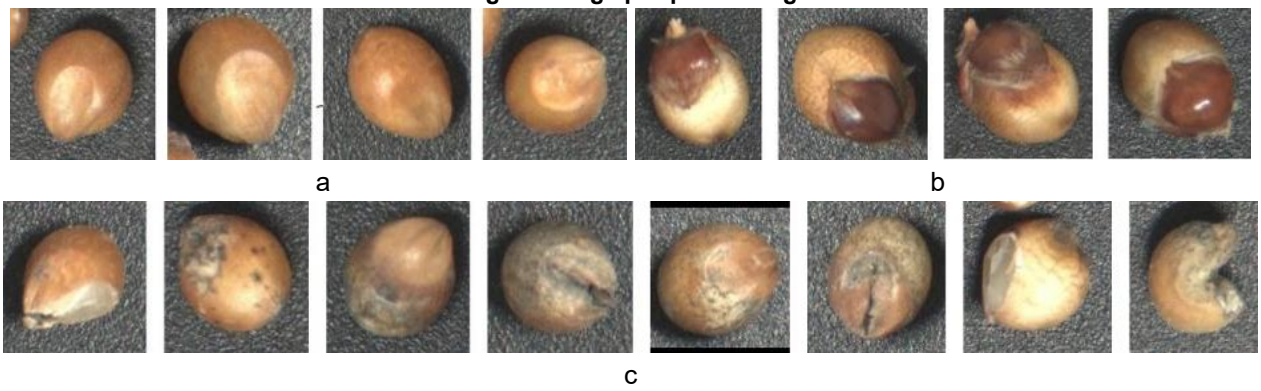

Fig. 3 - Sample of sorghum grain

a - Perfect grain; b - Shelled grain; c - Imperfect grains.

To improve the model's generalization ability and enhance detection performance. The dataset was augmented using preprocessing techniques such as random image rotation and brightness-contrast. The final dataset contained 6330 perfect grains, 7590 imperfect grains, and 5980 shelled grains. To train and validate the model, the three types of sorghum grain images were divided into training, validation and test sets in the ratio of 7:2:1, respectively.

Deep Learning Network Construction

YOLOv8

YOLOv8 is a state-of-the-art single-stage object detection model developed by Ultralytics. The model consists of four parts: Input, Backbone, Neck and Output (*Chitraningrum et al., 2024; Jiang, P et al., 2022*). In the backbone network and Neck section, the design concept of YOLOv7 is referenced. The backbone network employs the C2f module to extract multi-scale features. In the Head section, a decoupled head structure is adopted to separate the classification and detection tasks. Meanwhile, YOLOv8 adopts Task-Aligned Assigner positive-negative sample matching and introduces Distribution Focal Loss (DFL) to improve the training stability and generalisation performance. In addition, the operation of disabling Mosaic augmentation during

the last 10 epochs of YOLOX training is introduced in the data augmentation phase, which effectively enhances the model's accuracy. These changes make YOLOv8 perform well in the classification recognition task. By comparing the model training results of different scales of YOLOv8, as shown in Table 1. Although YOLOv8n has the fewest model parameters, its small number of residual structures results in relatively low detection accuracy. However, YOLOv8m, YOLOv8l, and YOLOv8x have a larger number of parameters, making it difficult to meet the requirements for lightweight and real-time performance. Therefore, this study selected YOLOv8s as the basis for designing a new sorghum grain classification and detection model algorithm, as shown in Fig. 4.

Table 1

Comparison of the performance of different versions of YOLOv8

Model	Size	mAP50	mAP 50-95	Parameters/×106 M	Weight size/MB
Yolov8n	640	0.694	0.653	3.2	5.9
Yolov8s	640	0.707	0.759	11.7	21.4
Yolov8m	640	0.712	0.734	26.0	49.5
Yolov8l	640	0.708	0.721	43.7	83.5
Yolov8x	640	0.703	0.719	68.2	130

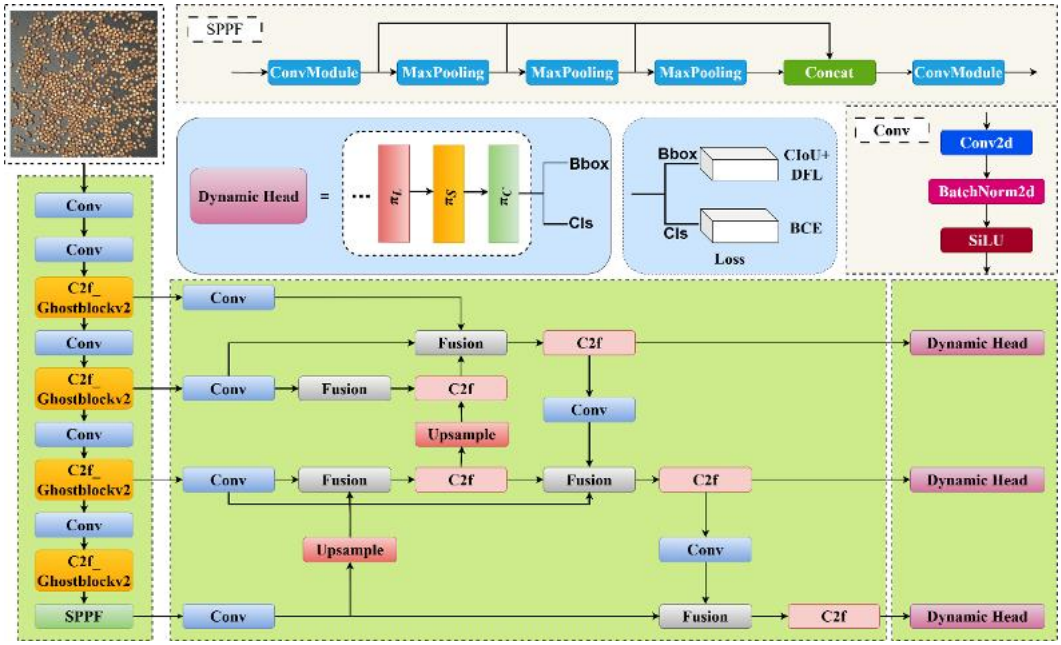

Fig. 4 - Improved YOLOv8 model

C2f_Ghostblockv2

The backbone feature extraction network of the model has the greatest impact on the model accuracy. GhostNetV2 proposed by *Tang et al., (2022),* is a lightweight model, which reduces the number of parameters while ensuring a certain accuracy. In this study, the Bottleneck structure of GhostNetV2 is introduced into the C2f network structure to replace the original convolution layer to form a new network structure C2f_Ghostblockv2, as shown in Fig. 5. This structure solves the problem of recognition accuracy of the model.

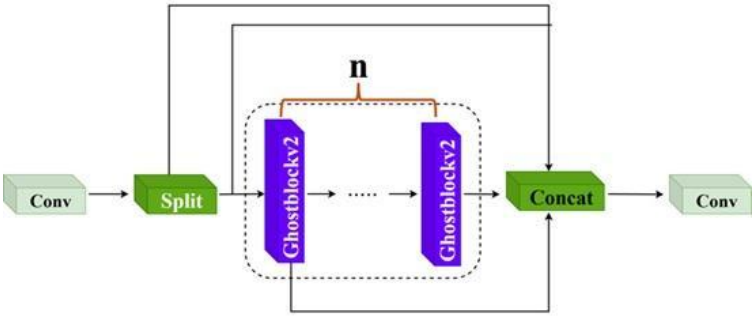

Fig. 5 - Structure of C2f _ Ghostblockv2

The Bottleneck structure of GhostNetV2 consists of two Inverted Residual Bottle-neck structures based on the Ghost Module, as shown in Fig. 6. Specifically, the first Ghost module expands the number of output channels via an extension layer to generate extended features, while the second Ghost module reduces the number of channels to align with the shortcut path's output. To enhance the model's representational capacity, GhostNetV2 integrates the DFC (Decoupled Fully Connected) attention mechanism within the first Ghost module. The DFC attention operates in parallel with the first Ghost module to produce an attention map, which is element-wise multiplied with the extended features to strengthen their representational power. These enhanced features are then passed through the second Ghost module to generate the final output features. The DFC attention captures long-range spatial dependencies by decomposing a fully connected layer into two separate fully connected layers along the horizontal and vertical directions, aggregating pixel information in both dimensions independently. When identifying different types of sorghum grains, this mechanism allows the model to maximize its performance, thereby improving the recognition accuracy of the improved model.

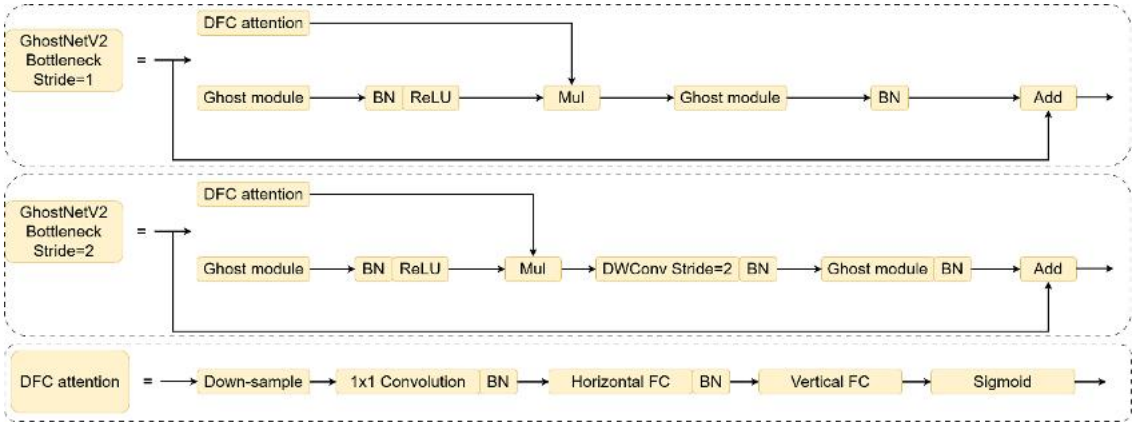

Fig. 6 - Bottleneck structure of GhostNetV2

Feature Fusion Network (BiFPN)

In the original YOLOv8s network, the multi-scale feature maps extracted by the backbone network are input into the PANet structure for feature fusion, the structure of which is shown in Fig. 7(a). The PANet structure uses the summation of different features to achieve the fusion of different feature layers. However, there are many types of sorghum grains, and the sizes of damaged grains and shelled grains in perfect grains and imperfect grains are different. If only simple feature-layer summation is performed, it will result in uneven contributions of different input features to the fused output features. To avoid this problem and make the network better capture multi-scale feature information, this study introduces BiFPN (*Li N. et al., 2024*) to improve the YOLOv8s network, as illustrated in Fig. 7(b).

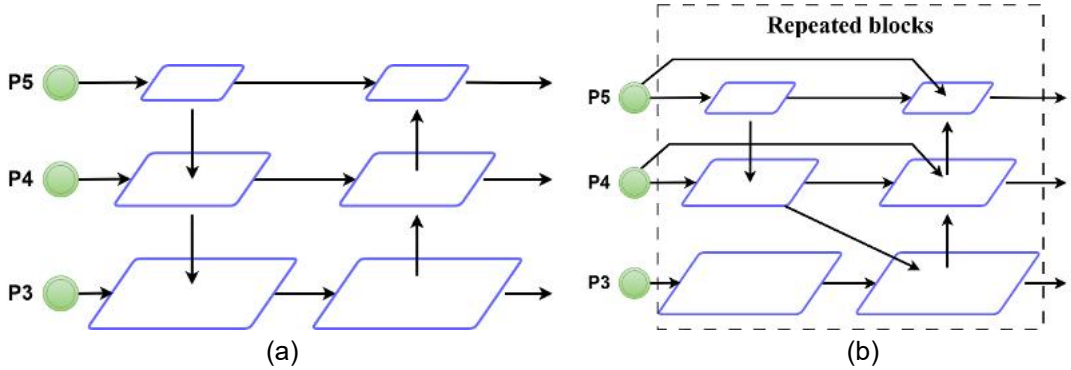

Fig. 7 - Structure of PANet, BiFPN

BiFPN introduces a bi-directional fusion mechanism, where features are fused through bi-directional paths (top-down and bottom-up). In the top-down path, high-level features are fused with low-level features by upsampling. In the bottom-up path, low-level features are fused with high-level features through downsampling. This bi-directional flow enhances the expressive power of the features and allows the different scale features to complement each other. The structure automatically adjusts the importance of different scale features through a weighted fusion mechanism to achieve more accurate feature fusion and improve target detection performance. Meanwhile, the BiFPN module can be repeatedly stacked to enhance information fusion.

By replacing the Neck structure in the YOLOv8s network with the BiFPN network, the model integrates the local and global features of different types of sorghum grains. This approach retains shallower semantic information while preserving deeper location information. Consequently, accurate detection of different types of sorghum seeds at different scales is achieved.

DymiHead

The Head part of the YOLOv8 network architecture receives multi-scale feature maps from the Backbone and Neck networks. These feature maps have different resolutions and are used to detect targets of different sizes. However, the difference of grain size in sorghum grain images is small, only some damaged grains are significantly different from other grain sizes, and other types of grain sizes are relatively close. Therefore, this study introduces a dynamic head framework based on attention mechanism to enhance the feature expression ability of the model.

Dynamic Head consists of Scale-aware Attention, Spatial-aware Attention and Task-aware Attention, and its structure is shown in Fig. 8. The Scale-aware Attention module (π_L) consists of Mean Pooling, 1×1 Convolution, ReLU Activation function and Hard Sigmoid function. This module adaptively enhances important features and suppresses redundant information by computing the spatial and channel attention of the feature map, enabling the model to better capture multi-scale targets. The spatial-aware attention module (π_S) consists of offset learning and 3× 3 convolution. This module focuses on the spatial location information of the feature map and uses the global context information to enhance the response of the target region. The task-aware attention module (π_C) is implemented by global average pooling, two fully connected layers, a normalisation layer, and a shifted sigmoid function. This module exploits task-specific attention mechanisms to enhance the performance of the model in multi-task learning.

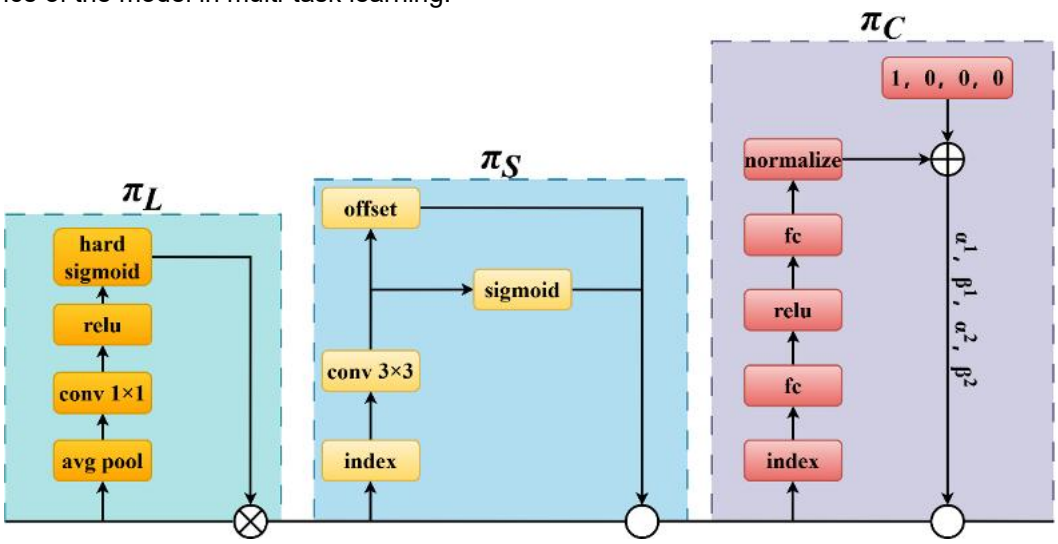

Fig. 8 - Dynamic Head structure

The multi-scale feature maps of sorghum grains extracted by the backbone net-work and Neck network were input into Dynamic Head. Different attention mechanisms operate in different dimensions, complement each other, and collectively enhance the representation ability of the target detection head. By dynamically adjusting the feature weights, the accuracy and robustness of sorghum seed target detection are significantly improved.

Loss calculation

In sorghum kernel classification and detection, the trained model predicts the class of each detected kernel. The prediction results can include both correct and incorrect classifications; therefore, it is essential to evaluate whether the predicted kernel class matches the ground-truth label. The final classification result is determined based on this comparison, enabling the identification of different sorghum kernel types.

This study uses the loss function in the original YOLOv8s network structure, which consists of two parts: category classification loss and border regression loss. Classification Loss uses cross entropy loss. This method measures the performance of the model by calculating the cross entropy of the probability distribution predicted by the model and the probability distribution of the real label. The YOLOv8s target detection model uses CIOU as the regression loss function, which is defined as:

$$CIoU = IoU - \left(\frac{\rho^2(b,b^{gt})}{d^2} + \alpha v\right) \quad (1)$$

$$v = \frac{4}{\pi^2}(arctan\frac{w^{gt}}{h^{gt}} - arctan\frac{w}{h})^2 \quad (2)$$

$$\alpha = \frac{v}{(1-IoU)+v} \quad (3)$$

where ρ is the Euclidean distance, d is the diagonal of the minimum bounding box, v is the trade-off parameter, and α is the corresponding trade-off parameter.

The boundary loss is then in the form of CIoU (Complete Iou) Loss+DFL. Both the distance and overlap rate between the detection frame and the target frame are considered, as well as the influence of the length ratio of the detection frame on regression.

RESULTS

Experimental environment and parameters

The experiments were conducted on a Windows 10 system equipped with an Intel Core i5-12600KF CPU operating at 3.70 GHz, an NVIDIA GeForce RTX 4060 Ti GPU with 16 GB of video memory, and 32 GB of system RAM. The PyTorch deep learning framework (version 1.12.1) was used, with PyCharm 2020.2.1 as the development environment. GPU acceleration was configured using CUDA 11.6 and cuDNN 8.9.7. Python 3.8.5 was used together with torchvision 0.13.1 and torchaudio 0.12.1.

Table 2

Hyperparameters used for deep learning training

Parameter	Parameter Value
Initial learning rate	0.01
Final learning rate	0.01
Weight decay factor	0.0005
IoU threshold	0.7
Momentum	0.9
Learning Rate Adjustment Strategy	steps
Image size	160pixel × 160pixel
Batch-size	32
Number of epochs	200

Before training, the hyperparameters were optimized, with particular attention to key settings such as the input image size and batch size. Examination of the loss curve showed that, when the number of training epochs was set to 200, the model loss gradually stabilized, indicating that the model had reached convergence. Therefore, the number of training epochs was set to 200 in this study. The detailed experimental hyperparameters are presented in Table 2.

Evaluation indicators

In machine learning and deep learning, the prediction results of classification tasks are classified into the following four categories:

(1) *True Positive (TP)*: the prediction is positive, the label value is also positive, and the prediction is correct.

(2) *False Negative (FN)*: Predicted as a negative case, labelled as a positive case, wrong prediction

(3) *False Positive (FP):* the prediction is positive, the label value is negative, the prediction is wrong

(4) *True Negative (TN):* predicted as a negative case, the label value is negative, the prediction is correct

In this study, *P (Precision, %), R (Recall, %), mAP1 (mAP50), mAP2 (mAP50-95)* and *F1* were used to evaluate the performance of the network model. The corresponding equations for these five metrics are as follows:

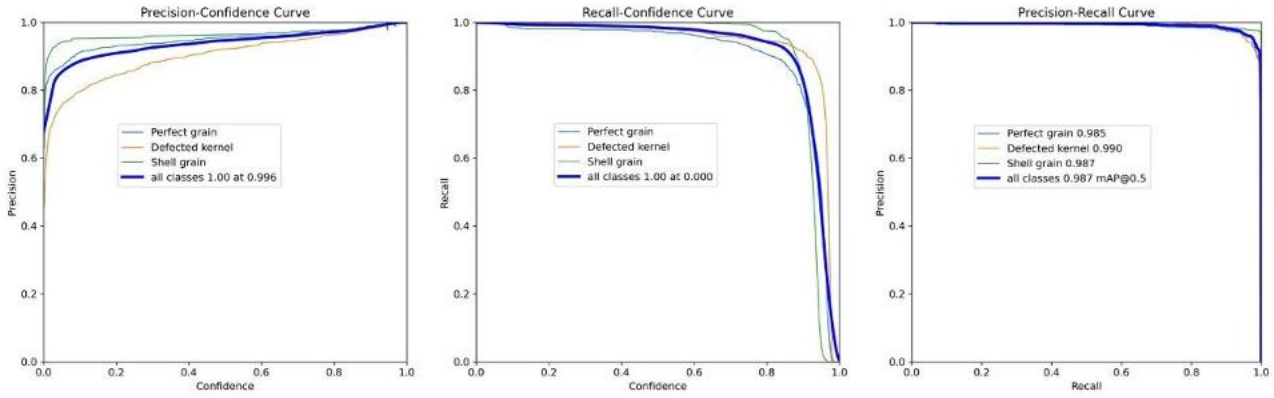
$$P = \frac{TP}{TP+FP} \times 100\% \quad (4)$$

$$R = \frac{TP}{TP+FN} \times 100\% \quad (5)$$

$$F1 = \frac{P*R*2}{P+R} \quad (6)$$

$$AP = \int_0^1 P(R)dR \quad (7)$$

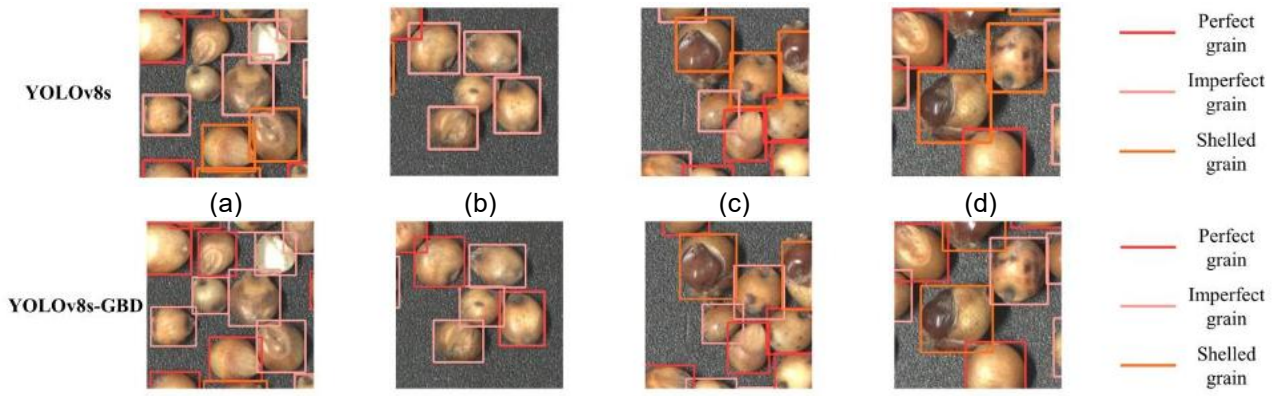
$$mAP = \frac{1}{M}\sum_{k=1}^{M} AP(k) \times 100\% \quad (8)$$



As indicated by the above equations, a higher P corresponds to fewer false positives (FP), meaning that fewer samples from other classes are incorrectly predicted as the target class. A higher $Recall$ corresponds to fewer false negatives (FN), indicating fewer missed detections of positive samples. Because a model may

achieve high P but relatively low $Recall$, or vice versa, the $F1$-score was used to provide a balanced evaluation of P and $Recall$. As the harmonic mean of P and $Recall$, the $F1$-score is strongly influenced by the lower of the two values and therefore helps prevent model selection based on only one favourable metric. The mean average precision (mAP) provides an overall measure of object detection performance across classes and IoU thresholds, depending on the specific mAP definition used.

Improved detection performance of the YOLOv8 algorithm



The YOLOv8s-GBD sorghum kernel classification and detection model proposed in this study was trained using transfer learning. The precision P, R, and PR curves obtained during training are shown in Fig.9.

As shown in Fig. 9, the precision values for the Perfect grain, Defected kernel, and Shell grain categories were 0.985, 0.990, and 0.987, respectively. Furthermore, the mean $Average\ Precision\ (mAP1)$ achieves a value of 0.987. These results indicate that the proposed model achieved high classification and detection performance for different sorghum kernel categories.

(a) (b) (c)

Fig. 9 - P, R, PR curves

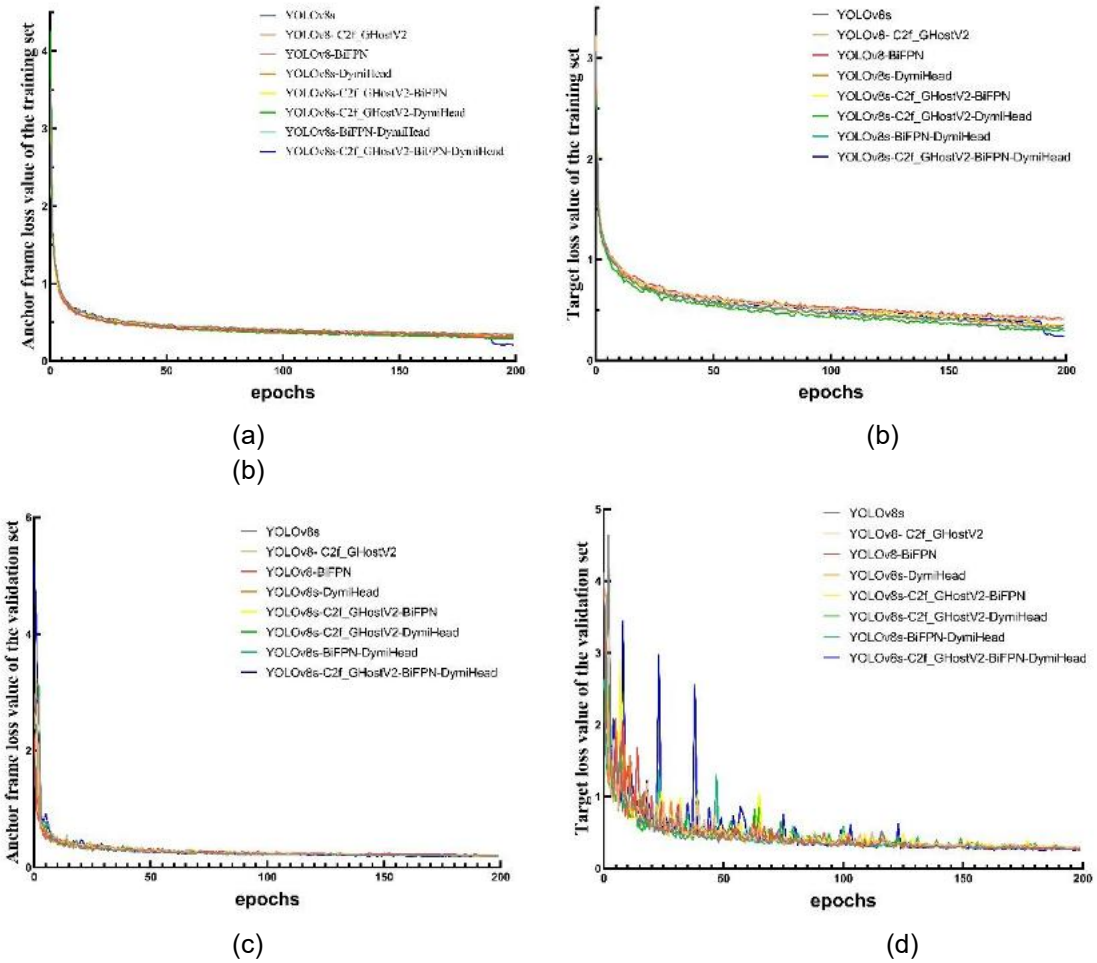
(a) (b) (c) (d)

(e) (f) (g) (h)

Fig. 10 - Image details of different models

a - Leak detection 2, False detection; b - Leak detection, False detection 1; c - False detection 1, Inaccurate bounding box; d - False detection 1, Inaccurate bounding box 1; e - No leak detection, No false detection; f - No leak detection, No false detection; g - No false detection, Bounding box accuracy; h - No false detection, Bounding box accuracy

The model outputs in this study identify different types of sorghum kernels using rectangular bounding boxes overlaid on the images. For clearer visualization, representative regions of the sorghum kernel detection images were cropped and enlarged. YOLOv8s was used as the baseline model for comparison, as shown in Fig. 10. The comparison results show that dense kernel distributions can lead to severe overlap and adhesion between adjacent kernels. Under these conditions, although YOLOv8s can detect some targets, it is more prone to false detections, missed detections, and inaccurate bounding-box localization. In contrast, the YOLOv8-GBD model detects densely distributed kernels more reliably and provides more accurate classification of kernel types.



Ablation study

Using the same training, validation, and test sets, ablation experiments were conducted to evaluate the contribution and effectiveness of the different optimization strategies. Based on the YOLOv8s architecture, the Backbone, Neck, and Head components were modified separately. In the Backbone, the GhostNetV2 bottleneck was introduced into the C2f structure to incorporate a long-range attention mechanism and improve feature extraction accuracy. In the Neck, a BiFPN structure was employed for multi-scale feature fusion. In the Head, the original detection head was replaced with a Dynamic Head to enhance feature representation capability. Each modified model was trained for 200 epochs, and the best-performing model was selected for evaluation. The performance metrics of the different models are presented in Table 3.

Table 3

Performance metrics of different models

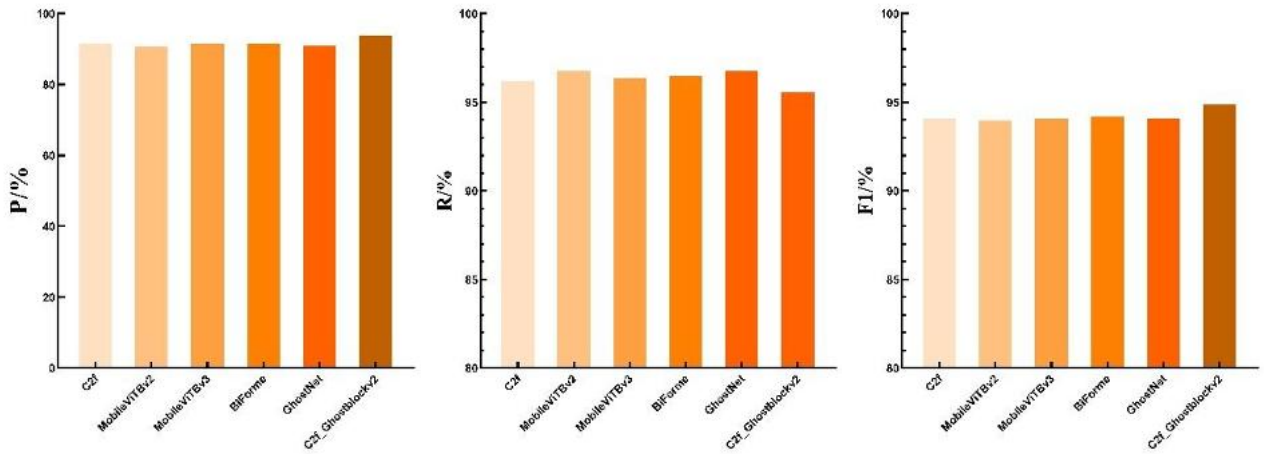
Model	P/%	R/%	mAP1/ %	mAP2/ %	F1/%
YOLOv8s	92.1	96.3	97.5	96.5	94.2
YOLOv8- C2f_Ghostblockv2	94.4	95.7	98.1	96.6	95.0
YOLOv8-BiFPN	93.3	96.9	98.2	96.7	95.4
YOLOv8-DymiHead	93.7	95.9	98.5	97.2	94.8
YOLOv8- C2f_Ghostblockv2-BiFPN	93.9	96.9	98.1	96.8	95.4
YOLOv8-C2f_Ghostblockv2-DymiHead	94.3	96.3	98.4	97.4	94.8
YOLOv8-BiFPN-DymiHead	93.9	96.5	98.4	97.4	95.2
YOLOv8s-C2f_Ghostblockv2-BiFPN-DymiHead	95.2	98.0	98.7	97.5	96.6

(a) (b)

(c) (d)

Fig. 11 - Training and validation loss curves of different models

As shown in Table 3, introducing C2f_GhostBlockV2, BiFPN, and DymiHead individually resulted in varying improvements in model precision, recall, and mean average precision. The baseline YOLOv8s model achieved a precision of 92.1% for sorghum kernel classification and detection. After introducing C2f_GhostBlockV2, BiFPN, and DynamicHead separately, the precision increased to 94.4%, 93.3%, and 93.7%, respectively, corresponding to improvements of 2.3, 1.2, and 1.6 percentage points relative to the baseline model. Among the individual modifications, C2f_GhostBlockV2 produced the largest improvement in precision. However, only BiFPN improved recall compared with the baseline model. These results indicate that optimizing a single network component provides only limited overall performance gains.



When two optimization strategies were combined, the detection model generally achieved further improvements in precision, recall, and mean average precision, with no obvious deterioration in overall performance. Among the tested combinations, BiFPN combined with DymiHead provided the best overall performance. Compared with the baseline YOLOv8s model, this combination improved precision, recall, mAP1, and mAP2 by 1.8, 0.2, 0.9, and 0.9 percentage points, respectively.

The above experiments show that optimizing the Backbone, Neck, and Head components of YOLOv8s can improve model performance for sorghum kernel classification and detection. Accordingly, the three optimization strategies described above were integrated to develop the proposed YOLOv8s-GBD sorghum kernel classification and detection model. Compared with the baseline YOLOv8s model, YOLOv8s-GBD improved P, R, mAP1, mAP2 and F1 by 3.1, 1.7, 1.2, 1.0, and 2.4 percentage points, respectively. Fig. 11 shows the loss curves for the different model configurations. As shown in the figure, the YOLOv8s-GBD model exhibited relatively high initial training and validation loss values. The losses decreased rapidly during the first 50 epochs and gradually stabilized after approximately 100 epochs, indicating that the model approached convergence.

Comparison experiment of different feature extraction networks

To evaluate the performance of the improved feature extraction network, this study replaces the original C2f module of yolov8s with mainstream network structures such as MobileViTBv2, MobileViTBv3, BiFormer, and GhostNet. The training set, validation set and test set used in this study are used for training, and the training effect is compared with that of C2f_Ghostblockv2 as shown in Fig. 12.

In this study, there are many categories of sorghum grains, especially imperfect grains, with large differences in appearance size, and high requirements for the accuracy and F1 value of the model. From Fig. 12, it can be seen that the C2f _ Ghost-blockv2 structure has the largest gain in the accuracy and F1 value of sorghum grain classification and recognition. Compared with other structures, C2f _ Ghostblockv2 has a small difference in accuracy and recall rate, which can effectively avoid the short board effect and is more suitable for the needs of this study.

(a) (b) (c)

Fig. 12 - Accuracy, recall and F1 value for different feature extraction networks

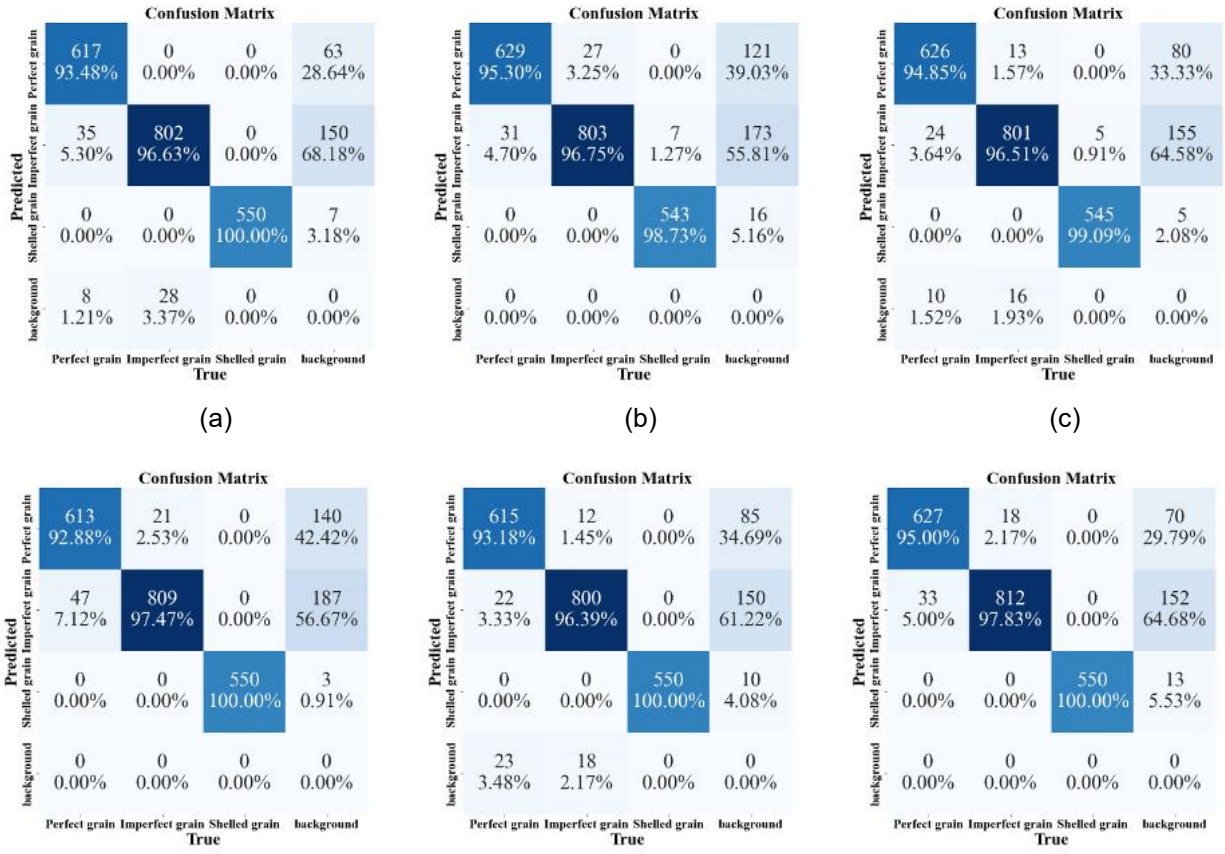


Fig. 13 - Confusion matrix of test effects of different feature extraction networks

As illustrated in Fig. 13, C2f_Ghostblockv2 has the highest classification accuracy for imperfect grains among the six models. Although the classification accuracy of C2f_Ghostblockv2 perfect grains is slightly lower than that of MobileViTBv2, it is still higher than the other network structures. Among the six models, the classification accuracy of C2f_Ghostblockv2 perfect grains is not the best, but its overall classification accuracy is the highest among all models. It shows that C2f_Ghostblockv2 has superior performance in sorghum grain classification.

Comparison of different models

To further evaluate the effectiveness of the YOLOv8s-GBD algorithm for sorghum grain classification and recognition, model training was performed on different versions of the YOLO target detection algorithm using the same training, validation and test sets. The participating comparison detection networks are YOLOv5, YOLOv7-tiny, YOLOv9, YOLOv10, and YOLOv11, and the test results are shown in Table 4.

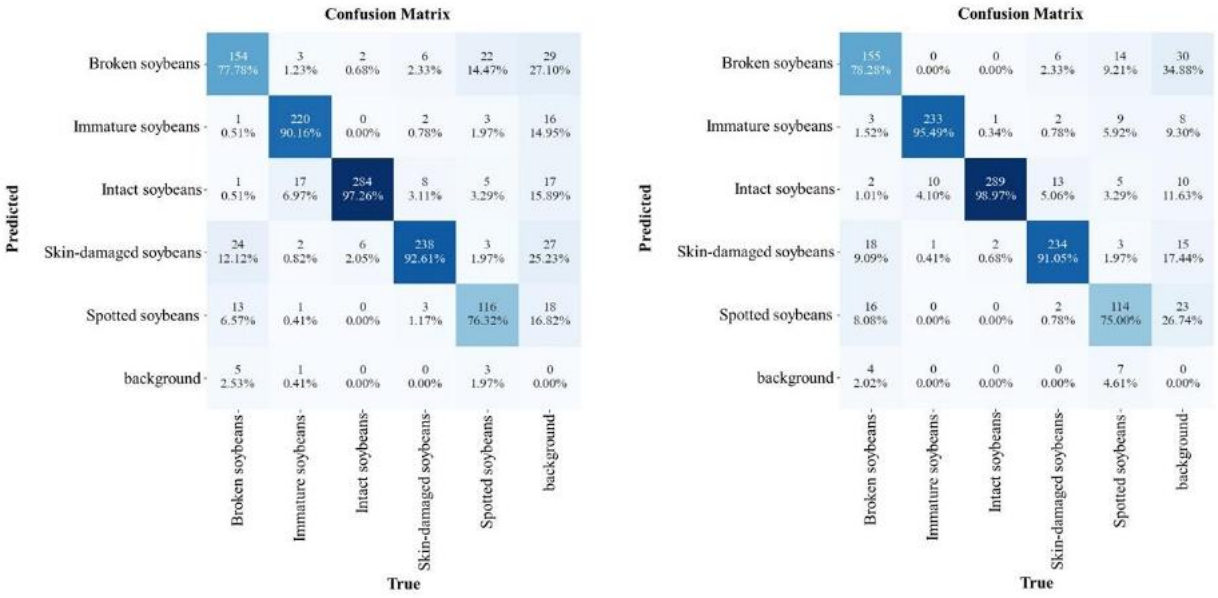
As shown in Table 4, the YOLOv8s-GBD algorithm achieves 95.2%, 98.0%, 98.7% and 97.5% in P, R, mAP1 and mAP2 values, respectively. It is superior to other YOLO models in terms of P and mAP1, and only the R value and mAP2 value are slightly lower than YOLOv11, and much higher than other YOLO models. Therefore, the com-prehensive recognition performance of YOLOv8s-GBD algorithm is better than other YOLO models. The algorithm proposed in this study can realize the recognition of sorghum grain classification.

Table 4

Parameters of performance indicators for different models

Model	P/%	R/%	mAP1/ %	mAP2/ %	F1/%
YOLOv5	90.1	97.9	96.4	93.7	93.8
YOLOv7-tiny	87.2	92.9	92.7	90.4	90.0
YOLOv9	91.2	96.0	98.6	96.1	93.5
YOLOv10	92.7	96.1	97.7	95.1	94.4
YOLOv11	93.1	98.7	98.5	97.9	95.8
YOLOv8s-C2f_Ghostblockv2-BiFPN-DymiHead	95.2	98.0	98.7	97.5	96.6

Generalization experiment



In order to verify the generalization of the algorithm proposed in this study, YOLOv8s-GBD and YOLOv8s were compared on other data sets. The soybean seed dataset purchased from CSDN platform was used in this experiment. The dataset contains five categories of soybean seed images such as intact, speckled, immature, broken and lost, which are very similar to the sorghum seed classification in this study. In this study, 5513 soybean seed images were screened and divided into training, validation, and test sets according to the ratio of 7:2:1.

Table 5

Soybean data set comparison test

Model	P/%	R/%	mAP1/%	mAP2/%	F1/%
YOLOv8s	84.2	86.0	92.3	79.8	93.8
YOLOv8s-GBD	87.2	92.9	92.7	90.4	90.0

The test environment and parameter configurations were kept consistent with the sorghum seed classification test, and the test results are shown in Table 5. Compared with YOLOv8s, YOLOv8s-GBD improves the accuracy and recall by 3 and 6.9 per-centage points, which effectively reduces the problem of misdetection and omission of soybean seeds; and improves the mAP1 and mA2 by 0.4 and 10.6 percentage points, which indicates that YOLOv8s-GBD has a higher detection precision. The detection effect of the two models on the soybean seed data set is shown in Fig. 14. It can be seen from Fig. 14 that the comprehensive detection accuracy of YOLOv8s-GBD on soybean seed test set is high, which proves the generalization of this research method.

(a) (b)

Fig. 14 - Confusion matrix of YOLOv8s and YOLOv8s-GBD test results

CONCLUSIONS

(1) To address the low efficiency and time-consuming nature of conventional quality inspection methods for dried sorghum kernels, an improved YOLOv8s-GBD model was developed based on YOLOv8s. In the Backbone, the C2f module was enhanced by incorporating a GhostNetV2 bottleneck with DFC attention to strengthen feature extraction. BiFPN was introduced in the Neck to improve multi-scale feature fusion, while a Dynamic Head attention mechanism was adopted to enhance feature representation and improve model accuracy and robustness.

(2) The different optimization strategies were trained using the same training and validation sets and evaluated on a common test set. The proposed YOLOv8s-GBD model achieved P, R, mAP1, mAP2 and F1-score values of 95.2%, 98.0%, 98.7%, 97.5%, and 96.6%, respectively. Compared with the baseline YOLOv8s model, these metrics increased by 3.1, 1.7, 1.2, 1.0, and 2.4 percentage points, respectively. The results indicate that YOLOv8s-GBD provides improved performance for sorghum kernel classification and detection and satisfies the accuracy requirements of dried sorghum quality inspection.

(3) Future research should expand both the number of samples and the range of defective-kernel categories. The present study considered only lesion-damaged, mechanically damaged, and insect-damaged kernels among the defective classes. Future work should include additional types of defective kernels to improve the comprehensiveness and accuracy of sorghum kernel classification and detection.

ACKNOWLEDGEMENT

This work was funded by the Key R&D Program of Shandong Province, China (2024CXGC010901) and the integrated pilot project of agricultural machinery Research and Development, Manufacturing and Application in Shandong Province (NJYTHSD−202311). We also sincerely appreciate the editors and anonymous reviewers for their valuable comments and constructive suggestions to improve the quality of this paper.

Keywords: *Crop row recognition; Maize seedlings; Deep learning model; Centreline extraction*

ABSTRACT
The seedling stage is a relatively short but critical period in the maize growth cycle, during which rapid weeding, pesticide application, and fertilization are required. Crop row centreline extraction technology based on computer vision can assist agricultural machinery in performing automated field operations, thereby improving work efficiency. Therefore, improving the accuracy of crop row centreline extraction imposes higher requirements on existing models and algorithms. In this study, a model named Synergistic Attention YOLO (SA-YOLO) was proposed. The feature extraction capability for crop rows was enhanced by introducing the spatial and channel synergistic attention module and designing the A2C2f module integrated with switchable atrous convolution. In addition, a crop topological skeleton feature point extraction strategy and a collaborative fitting method combining principal component analysis and least squares was integrated to accurately extract crop row centrelines from the skeleton feature points of crop pixels within the segmented region of interest. Comparative experiments showed that the SA-YOLO model achieved competitive performance, with an average precision at IoU threshold 0.5 (AP_{50}) of 99.1%, and a mask Intersection over Union (IoU_{mask}) of 83.8%, while maintaining a lightweight architecture with only 3.72 M parameters. The mean angle error (A_{mean}) of crop row centerline extraction was 0.590°, and the mean normalized lateral error (L_{mean}^{norm}) was 0.357%. This study provides a new approach for exploring crop row centerline extraction in agriculture and can further enrich the theoretical and technical foundation for visual navigation of agricultural robots.

摘要
苗期是玉米生长周期中相对较短但关键的时期，需要快速完成除草、施药、施肥等工作。基于计算机视觉的作物行中心线提取技术可以辅助农业机械进行自动化田间作业提高工作效率。因此，作物行中心线提取精度的提升对现有模型与算法提出了更高的要求。本研究提出了一种名为 SA-YOLO 的模型，通过引入 SCSA 注意力模块和设计的 A2C2f_SAConv 模块增强了对作物行特征的提取能力。此外，还集成了作物拓扑骨架特征点提取策略与 PCA-LSM 协同拟合方法，通过分割输出的 ROI 区域内作物像素的骨架特征点来精确提取作物行中心线。对比实验表明，SA-YOLO 模型实现了具有竞争力的性能，其 AP_{50} 为 99.1％，IoU_{mask} 为 83.8％，同时保持轻量级架构，参数仅为 3.72M。作物行中心线提取产生的平均角度误差为 0.590°，归一化横向误差为 0.357%。该研究为探索农业作物行中心线提取提供了新的思路，可以进一步丰富农业机器人视觉导航的理论和技术基础。

1. INTRODUCTION
As one of the most important food crops worldwide, maize plays a key role in global food security. Achieving efficient and intelligent maize production is an important pathway to ensure food supply capacity. In field management during the maize seedling stage *(Shahid et al., 2024)*, rapid and accurate recognition of maize row centrelines is an important foundation for autonomous navigation of agricultural machinery *(Liu et al., 2023; Liu et al., 2024b)*, precision agricultural operations *(Chamara et al., 2023; Huang et al., 2020)*, and crop phenotyping analysis.

Therefore, constructing an accurate and efficient maize row centreline recognition method through intelligent means is of great significance for improving maize production efficiency and sustainable development capability.

With the gradual introduction of sensor technology and agricultural Internet of Things technology into modern agriculture, the methods for crop row centreline extraction have become increasingly diversified. Current research mainly focuses on extracting centrelines from two types of data: crop images *(Song et al., 2023)* and point clouds *(Jiang et al., 2025)*. Among these, crop point cloud data are often acquired using sensors such as light detection and ranging (LiDAR) *(Liu et al., 2024a)* and ultrasonic sensors *(Bronson et al., 2021)*. Point clouds can directly reflect the row structure of crops in three-dimensional space, but the high complexity of acquisition and processing limits their widespread application in field operations requiring high real-time performance *(Luo et al., 2021; Fan et al., 2023)*. In contrast, RGB image-based methods have become the most commonly used data source for field row extraction due to their low acquisition cost and fast processing speed. However, relying solely on colour information makes it difficult to stably distinguish crops from soil under complex conditions such as illumination changes and weed interference, necessitating enhanced crop feature representation. Traditional methods enhance crop row features through operations such as excess green segmentation *(Ban et al., 2024)* and morphological operations *(Cai et al., 2026)* on RGB images. However, these methods are susceptible to field illumination, weeds, and other factors. In complex field environments, maize seedlings are short and sparse, occupy few pixels in the image, and lack sufficient morphological and textural information, making it difficult to effectively distinguish them from soil, residual film, and early-stage weeds *(Kim et al., 2023)*.

Recently, with the continuous development of deep learning technologies, many studies have improved the accuracy of crop row centrelines by continuously refining deep learning networks and post-processing fitting methods. In terms of deep learning networks, multi-scale feature extraction modules, attention mechanisms, or lightweight convolutions have been designed to improve segmentation accuracy while maintaining real-time performance *(Wang et al., 2023)*.

Lv et al. (2026) proposed a DAC feature fusion architecture based on YOLOv11s and adopted LAMP pruning optimization. The resulting YOLO-DP network achieved 93.8% mAP_{50} in complex orchard environments. In the post-processing fitting stage, depending on different annotation strategies, feature point extraction methods also vary. Existing annotation strategies are mainly divided into two categories: annotating specific parts of each crop plant and annotating each entire crop row as a whole. Current research on annotating specific parts of each crop plant has gradually refined from the whole plant to more morphologically stable parts such as plant cores or stems *(Diao et al., 2023; Li et al., 2023)*. This method, however, incurs high annotation cost and may lead to large errors in crop row centrelines due to missed or false detections. In contrast, the method of annotating an entire crop row as a connected region can directly guide the network to learn the row structure features of crops and significantly reduce annotation cost.

Some researchers have extracted feature points by methods such as vertical cutting of pixel strips to obtain centroids or centre points *(Han et al., 2026)*. Yet, this feature point extraction method requires high segmentation accuracy. Because the row spacing of maize seedlings is narrow, adjacent rows are prone to visual adhesion, and uneven emergence or high planting density may cause local staggered interruptions *(Gao et al., 2023)*, all of which can lead to deviation of the fitted centreline. Other researchers have combined deep learning algorithms with traditional feature enhancement methods to extract feature points.

For example, the Excess Green operator and Otsu method are used to segment crops and soil background in the region of interest (ROI), and then Features from Accelerated Segment Test (FAST) corner detection is used to extract crop feature points *(Yang et al., 2023)*. Nevertheless, the FAST corner detection method *(Chen et al., 2021)* mainly targets edges and texture-rich areas and does not act on the crop main stem, which may eventually cause deviation and instability in feature point extraction. In the stage of centreline fitting based on extracted feature points, studies have used fitting algorithms such as the Least Squares Method (LSM) *(Luo et al., 2025)*, Hough Transform (HT) *(Chen et al., 2020)*, and Random Sample Consensus (RANSAC) *(Jin et al., 2025)* to extract crop centrelines. However, the LSM algorithm is sensitive to outliers; the HT algorithm has high computational complexity and introduces errors due to discretization of the parameter space; and the RANSAC algorithm suffers from fluctuating fitting results due to the instability of iterative random sampling and high computational overhead, with centreline errors mostly exceeding 3°, making it difficult to meet the high accuracy requirements of agricultural machinery navigation.

Therefore, the specific contributions of this study to address the above main problems are summarized as follows:

(a) This study provides an open-source Corn Seedling Row (CSR) dataset, which offers a data foundation for related agricultural navigation research. The dataset can be publicly accessed at https://github.com/Possibility007/Corn-Seedling-Row.

(b) This study develops an open-source deep learning model, Synergistic Attention YOLO (SA-YOLO), which can accurately and efficiently segment crop rows, providing a lightweight perception solution for autonomous visual navigation of agricultural robots.

(c) This study proposes a principal component analysis and least squares method (PCA-LSM) collaborative optimization method based on crop topological skeleton feature points for crop row centreline extraction.

(d) The code is publicly available at https://github.com/yyyyyyu-git/SA-YOLO.

2. MATERIALS AND METHODS

The proposed method consists of five main processes. First, an RGB camera was used to collect maize seedling images. The rows were annotated to establish a maize seedling row dataset. Maize seedling rows were segmented based on the SA-YOLO model. ROI extraction and Jet mapping were used to enhance maize seedling features. Finally, based on the extracted skeleton feature points, principal component analysis (PCA) was used to determine the main direction, and then LSM was used to recognize the row centrelines. A schematic overview of the method is shown in Fig. 1.

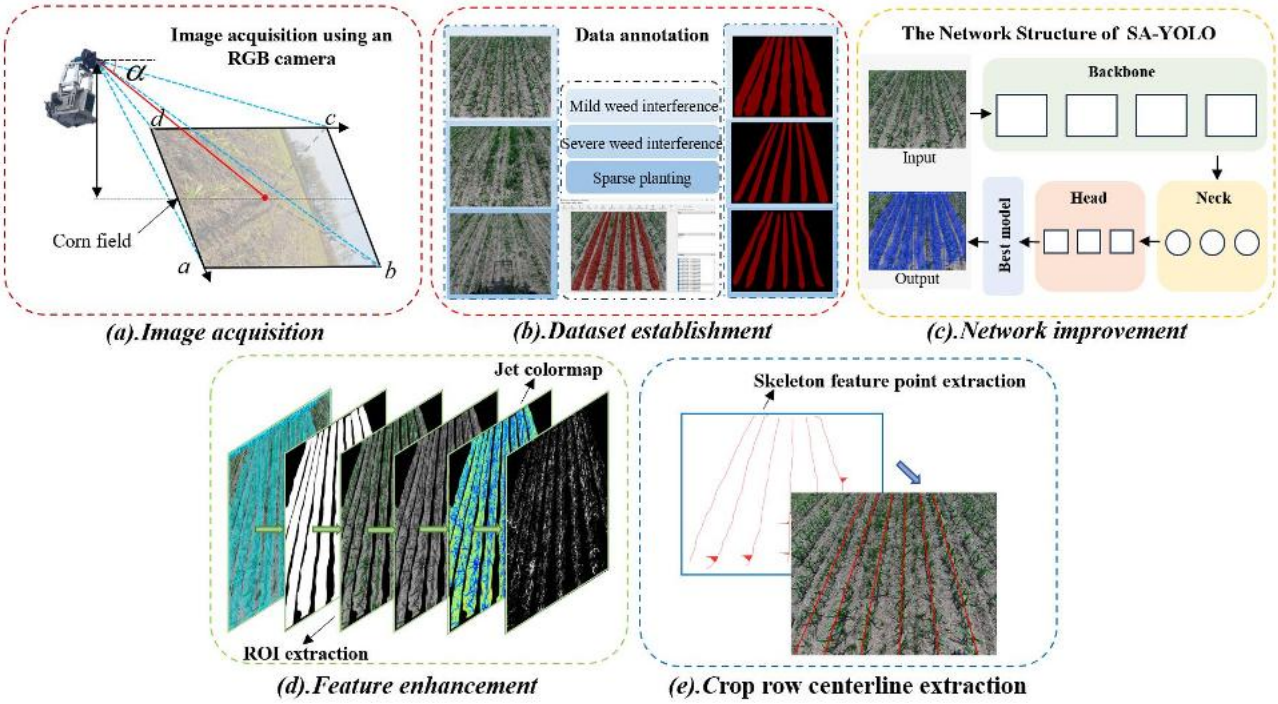

Fig. 1 - Schematic diagram of the overall workflow

2.1 Field image acquisition of maize seedlings

The maize seedling images used in this study were captured at the WanDong Comprehensive Experimental Station of Anhui Agricultural University in Mingguang County, Chuzhou City, Anhui Province (latitude 32°45′20.6″ N, longitude 118°6′55.9″ E, altitude 46 m), from July 5 to July 10, 2025. The image acquisition device was an Ailiguang ALI2312-SCH-SABA-IP67 monocular RGB camera, capturing images at 1920×1536 pixels. The camera was installed at a vertical height of 2.5 m above the ground, with a tilt angle of 50°. A total of 941 original images were collected, all saved in JPG format. The image acquisition scene and method are shown in Fig. 2.

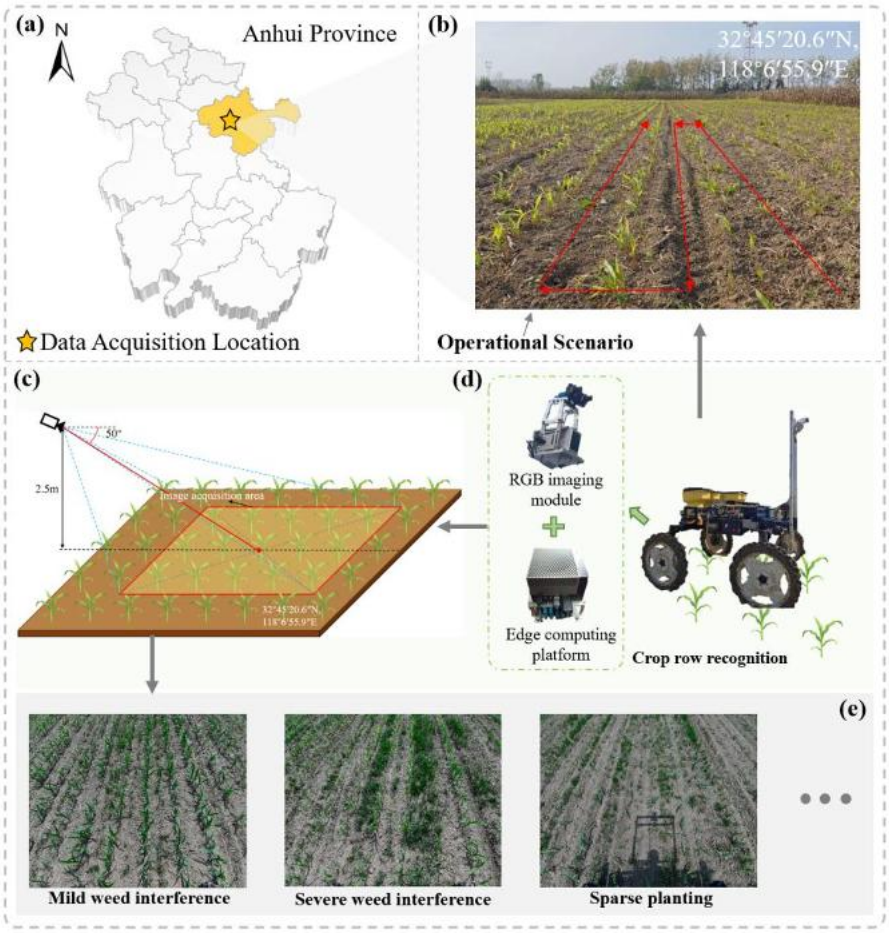

Fig. 2 - Schematic diagram of image acquisition location and method

(a) Data acquisition location; (b) Data acquisition scene; (c) Data acquisition method; (d) Data acquisition device; (b) (e) Example of acquired image.

2.2 Image Annotation and Data Preprocessing

The model in this study is an instance segmentation model for maize seedling rows. Labelme was used for image annotation, and each maize row was annotated separately. Each maize row was annotated as an independent instance, with its mask covering an entire row of maize seedlings, forming a continuous management unit. The generated .json files were converted into .txt files required for model training. After annotation, the image dataset was split for better model training. The image dataset contained a total of 941 images, which were divided into training, validation, and test sets at a ratio of 7:1:2. An annotation example for the seedling maize dataset is shown in Fig. 3, including multiple scenes such as mild weed interference, severe weed interference, and sparse planting.

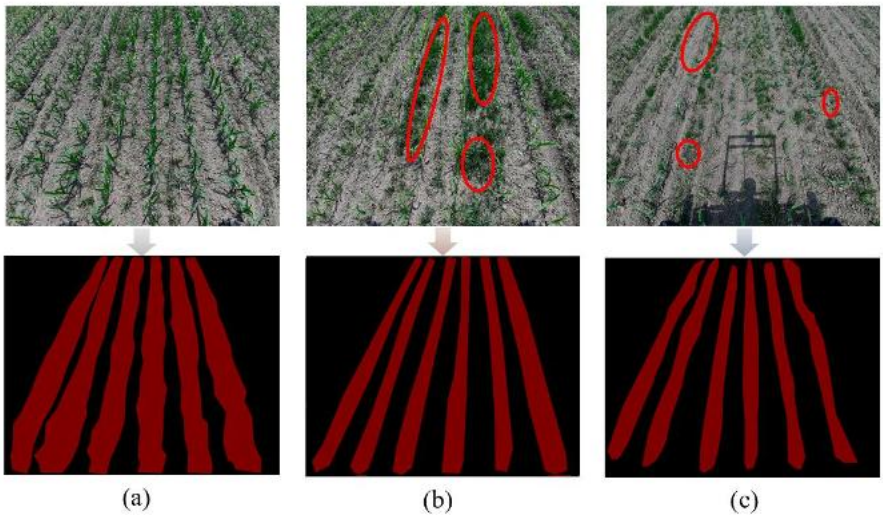

Fig. 3 - Example of dataset annotation

(a) Mild weed interference scene; (b) Severe weed interference scene; (c) Sparse planting scene.

2.3 SA-YOLO model

To address the problems of small plants, inter-row adhesion, and complex background in maize seedling row segmentation, an improved model named SA-YOLO was proposed based on YOLOv12n-seg. The SCSA attention module was introduced into the fast pooling layer of the backbone network to enhance the perception of row structure, and the designed A2C2f_SAConv module was introduced into the neck network to improve feature extraction capability, thereby improving segmentation accuracy while maintaining lightweight characteristics. The structure of the improved SA-YOLO is shown in Fig. 4.

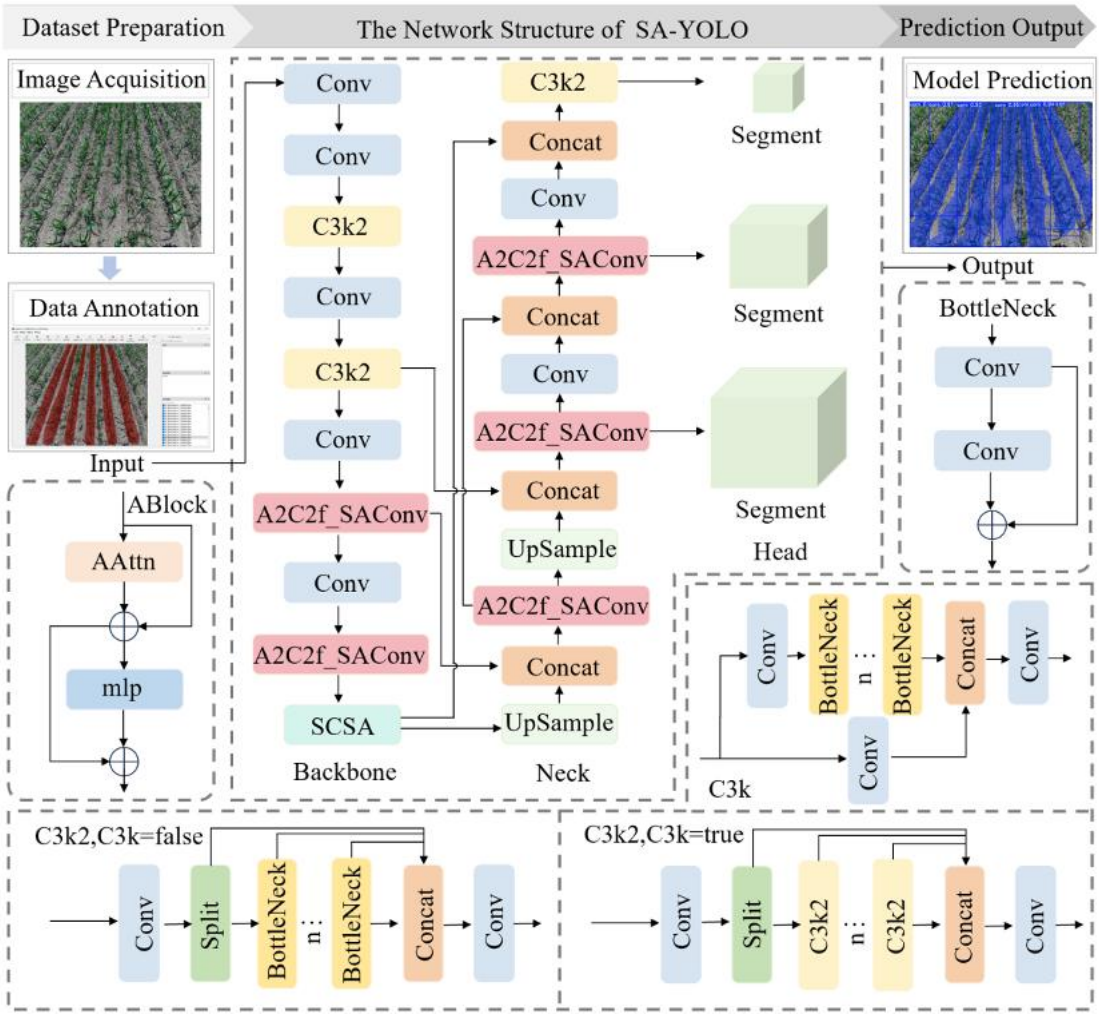

Fig. 4 - Structure of the SA-YOLO model

2.3.1 YOLOv12n-seg model

YOLOv12n-seg is a lightweight instance segmentation version of the YOLOv12 series. Its structure mainly consists of four parts: the input layer, attention-enhanced backbone, multi-scale fusion neck, and segmentation detection head. The input layer preprocesses the image to improve model robustness to different sizes and lighting conditions. The backbone network adopts the region attention module (A^2) and the residual efficient layer aggregation network (R-ELAN), reducing computational complexity while enhancing feature extraction capability. The neck network fuses multi-scale semantic and detail information through a bidirectional feature pyramid structure, improving model convergence and feature representation. The segmentation detection head integrates object localization, classification, and pixel-level segmentation to output instance bounding boxes and precise masks. Although this baseline model performs well in general scenes, in complex field environments, maize seedling row segmentation still faces challenges such as detail loss and mis-segmentation in adhesive regions, necessitating targeted improvements.

2.3.2 SCSA attention module

To enhance the model's perception of the spatial layout and key features of seedling rows, the Spatial and Channel Synergistic Attention (SCSA) module *(Si et al.,2025)* was introduced after the fast pooling layer of the YOLOv12n-seg backbone network. SCSA consists of a Shared Multi-Semantic Spatial Attention (SMSA) module and a Progressive Channel-wise Self-Attention (PCSA) module connected in series. Its structure is shown in Fig. 5.

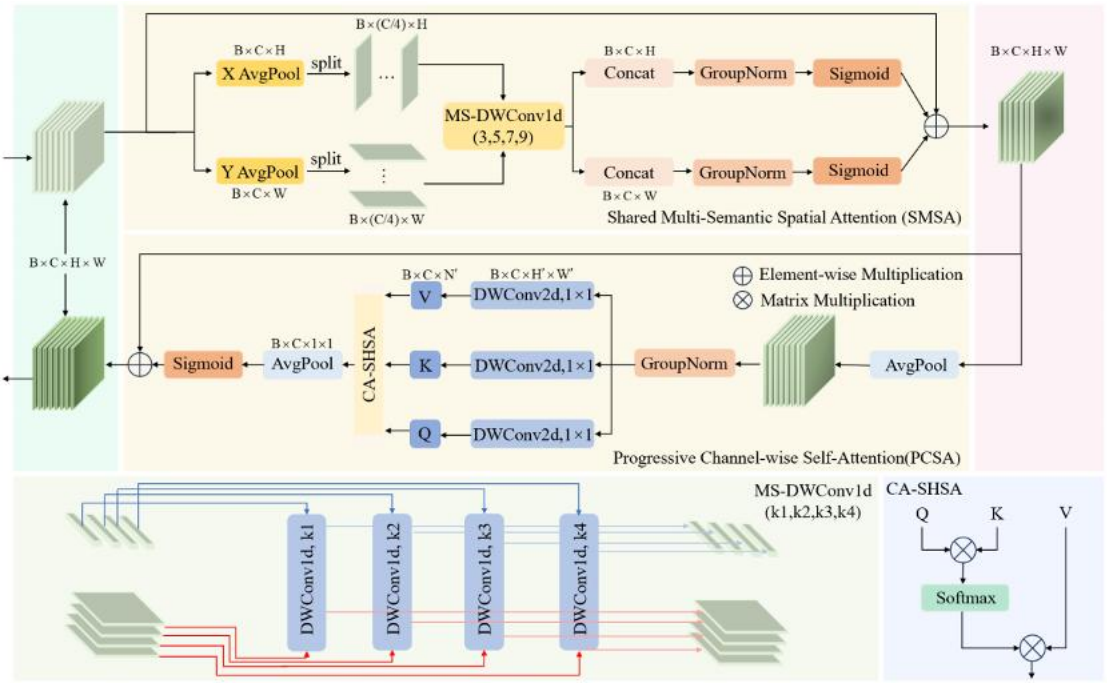

Fig. 5 - Structure of the SCSA attention mechanism module

The SMSA module first performs global average pooling on the input feature map along the height and width dimensions, obtaining two one-dimensional feature sequences. Each sequence is then evenly divided into K sub-features to extract spatial information at different semantic levels in parallel. For each sub-feature, one-dimensional depthwise separable convolutions with kernel sizes of 3, 5, 7, and 9 are used to capture multi-scale spatial context. The height and width dimension features are then aligned through shared convolution, and after concatenating the sub-features, group normalization and Sigmoid activation are applied to generate spatial attention weights. The calculation formulas are shown in (1)~(3).

$$\mathrm{Attn_H}=\sigma\left(\mathrm{GH_K^N}\left(\mathrm{Concat}\left(\mathrm{H_1^{\tilde{X}}},\mathrm{H_2^{\tilde{X}}},\cdots,\mathrm{H_K^{\tilde{X}}}\right)\right)\right) \tag{1}$$

$$\mathrm{Attn_W}=\sigma\left(\mathrm{GW_K^N}\left(\mathrm{Concat}\left(\mathrm{W_1^{\tilde{X}}},\mathrm{W_2^{\tilde{X}}},\cdots,\mathrm{W_K^{\tilde{X}}}\right)\right)\right) \tag{2}$$

$$\mathrm{SWSA(X)=X_s=Attn_H\times Attn_W\times X} \tag{3}$$

where:

$\sigma(\cdot)$ denotes Sigmoid normalization, and $GH_K^N(\cdot)$ and $GW_K^N(\cdot)$ denote group normalization along the H and W dimensions with K groups, respectively.

The PCSA module further performs channel-wise self-attention enhancement on the spatial features output by SMSA. First, progressive average pooling is applied to X_S to reduce resolution while preserving key spatial structure. Then, three independent two-dimensional depthwise convolutions are used to generate Query (Q), Key (K), and Value (V). Single-head self-attention is performed in the channel domain to model inter-channel dependencies. Finally, global pooling and Sigmoid activation are applied to generate channel attention weights, which are multiplied by X_S to obtain the final output. The calculation formulas are shown in (4)~(7).

$$\mathrm{X_p=Pool_{(7,7)}^{(H,W)\to(H',W')}(X_s)} \tag{4}$$

$$\mathrm{Q=F_{proj}^{Q}(X_p),K=F_{proj}^{K}(X_p),V=F_{proj}^{V}(X_p)} \tag{5}$$

$$\mathrm{X_{attn}=Attn(Q,K,V)=Softmax}\left(\frac{\mathrm{QK^T}}{\sqrt{C}}\right)\mathrm{V} \tag{6}$$

$$\mathrm{PCSA(X_s)=X_c=X_s\times\sigma}\left(\mathrm{Pool_{(H',W')}^{(H',W')\to(1,1)}(X_{attn})}\right) \tag{7}$$

where: $Pool_{(k,k)}^{(H,W)\to(H',W')}(\cdot)$ denotes a pooling operation with kernel size $k\times k$ that resizes the resolution from (H,W) to (H',W'). $Fproj(\cdot)$ denotes the linear projections for generating query, key, and value.

SMSA effectively captures multi-semantic spatial information of seedlings in complex field environments through multi-scale convolution, while PCSA enhances feature consistency and suppresses redundancy through progressive channel interaction. The SCSA module significantly improves the model's representation ability of fine seedling features and their spatial row distribution while maintaining low computational overhead, providing more robust feature input for subsequent segmentation tasks.

2.3.3 A2C2f_SAConv module

To address the limitation of standard convolution with a fixed receptive field that cannot adaptively match features at different scales, the A2C2f module in the network was replaced with an improved module incorporating Switchable Atrous Convolution (SAConv) *(Qiao et al.,2021)*, named A2C2f with Switchable Atrous Convolution (A2C2f_SAConv). Its structure is shown in Fig. 6b. SAConv dynamically adjusts the dilation rate and incorporates a context-aware mechanism, enabling the network to optimize multi-scale feature fusion.

The core idea of SAConv is to extend the traditional static atrous convolution into a dynamic, spatially adaptive feature extraction mechanism. Its structure is shown in Fig. 6a. It employs multiple convolution branches with different dilation rates in parallel and dynamically fuses the outputs of each branch through a lightweight, pixel-wise learned switch function, allowing each spatial position to autonomously select the most suitable receptive field based on local context. In addition, SAConv integrates global context preprocessing and postprocessing modules, which perform global average pooling and convolution to calibrate features globally, further improving feature consistency and discriminability. The calculation formulas are shown in (8) and (9).

$$S(x)=\sigma\left(Conv_{1\times1}\left(AvgPool_{5\times5}(x)\right)\right) \tag{8}$$

$$y=S(x)\cdot Conv(x,w,1)+\left(1-S(x)\right)\cdot Conv(x,w+\Delta w,r) \tag{9}$$

where:

The switch function *S(x)* is generated by a 5×5 average pooling layer followed by a 1×1 convolutional layer and normalized by the activation function σ. Conv(x,w,r) denotes the convolution operation with weight *w*, hyperparameter *r*, and trainable weight Δw.

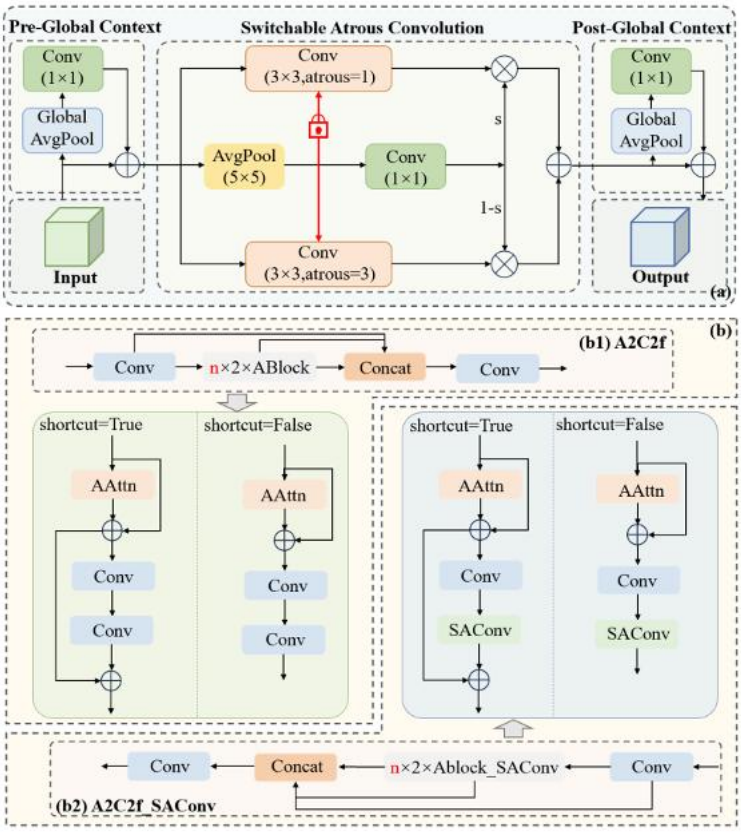

Fig. 6 - Structure of the SAConv module

(a) SAConv structure; (b) Difference between the A2C2f module and the A2C2f_SAConv module.

2.4 Crop row centreline fitting

In the crop row centreline fitting process, contour detection is a key factor affecting the accuracy of the fitted centreline. In this study, the segmentation results were used to extract the ROI region, and the skeleton feature points were extracted from the binary image of crops within the ROI region. Finally, PCA was used to determine the main direction, and LSM was used to fit these skeleton feature points to obtain the centrelines of maize seedling rows.

2.4.1 Crop row skeleton feature point extraction

The improved SA-YOLO model was used to infer the positions of maize seedling rows through instance segmentation. Masks were generated from the inferred segmentation regions, and bitwise operations were performed with the original image to extract the ROI region *(Luz et al.,2024)*, which eliminated a large amount of interference information and saved computational cost. The extraction process is shown in Fig. 7. After the ROI region was extracted, grayscale processing was applied to the image *(Rodríguez et al., 2021)*. However, because the colour features of maize seedlings and ground soil are similar in grayscale images, direct binarization made it difficult to effectively segment maize. Pseudo-colour processing technology *(Bayareh et al.,2021)* significantly enhances image distinguishability by assigning different colour maps to different gray values; this method has been widely used in fields such as medical imaging and meteorological analysis. Among them, the Jet mapping, as a typical pseudo-colour algorithm, is often used to highlight detailed features in images due to its high colour contrast. After Jet mapping, the visual features of the maize seedling regions were significantly enhanced, creating favourable conditions for subsequent processing. After maize seedling feature enhancement, binarization was applied to the image *(Surulivelu et al.,2026)*. Skeleton feature points were extracted from the binarized image. A morphological skeletonization method was used to iteratively delete edge pixels while preserving region connectivity, gradually thinning the crop rows into a single-pixel-wide topological skeleton. This process not only extracted the central feature points of the crop rows but also fully preserved their overall directional trend. The resulting skeleton feature point set was continuous, dense, and geometrically meaningful, faithfully reflecting the morphological characteristics of the crop rows.

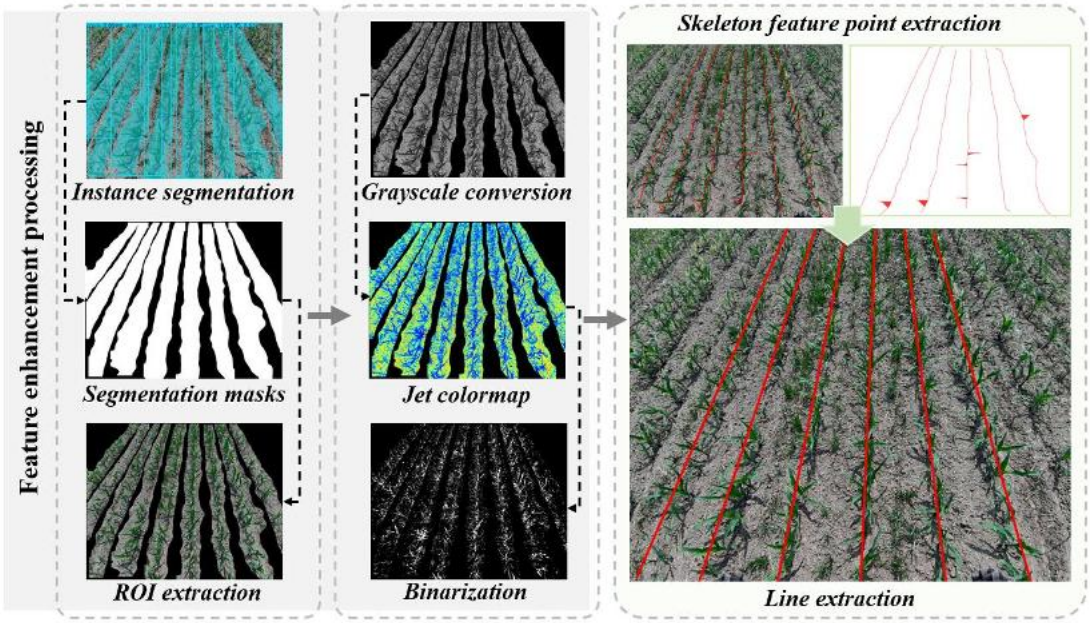

Fig. 7 - Flowchart of crop row centreline fitting

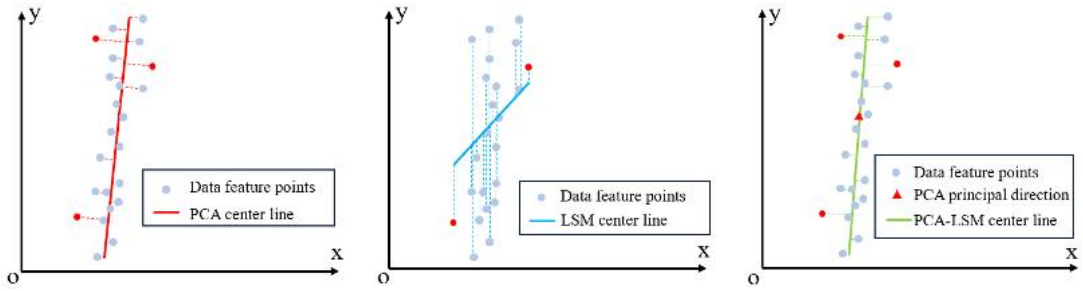
2.4.2 Crop row centreline fitting

PCA robustly estimates the dominant direction of a point set, which corresponds to the eigenvector associated with the largest eigenvalue. However, because the fitted straight line is determined only by the direction of the first principal component without optimizing errors in specific directions, it remains sensitive to outliers. Using LSM alone, although it minimizes the error along a preset independent variable direction, if that direction does not match the actual deviation direction of interest, the resulting line fails to accurately reflect the geometric characteristics of the data. Moreover, its robustness to outliers is poor, and a few outliers can cause the fitting result to deviate significantly from the true trend.

Therefore, this study proposed a collaborative PCA-LSM method. The skeleton feature points were used to fit a straight line that best represents the crop rows. First, PCA was used to determine the main direction of the point set. Then, based on the relative inclination angle between this main direction and the coordinate axes, an appropriate LSM form was selected. This method combines the directional robustness of PCA with the precise fitting capability of LSM, providing better tolerance to outliers and enabling extraction of crop row centrelines that conform to the overall distribution of the data. A schematic comparison of the three methods is shown in Fig. 8.



The calculation formula for the PCA principal direction is shown in Equation (10):

$$C=\frac{1}{N-1}\sum_{i=1}^{N}(p_i-\bar{p})(p_i-\bar{p})^T \tag{10}$$

where: $\bar{P}$ is the centroid of the point set, $P_i=(x_i,y_i)$, and the principal direction vector is denoted as $v=(v_x,v_y)$.

The method for selecting the appropriate least squares form is shown in Equation (11):

$$S_{\epsilon}^2=\begin{cases}\min\limits_{k,b}\sum_{i=1}^{N}\left(x_i-(ky_i+b)\right)^2, & \text{if } |v_y|>|v_x|\\ \min\limits_{m,b}\sum_{i=1}^{N}\left(y_i-(mx_i+b)\right)^2, & \text{if } |v_y|<|v_x|\end{cases} \tag{11}$$

(a) (b) (c)

3. RESULTS AND DISCUSSION

3.1 Training environment and evaluation metrics

3.1.1 Parameter settings and model training

The model training platform in this experiment used an NVIDIA GeForce RTX 4050 GPU, a 13th Gen Intel(R) Core(TM) i7-13620H processor, 6 GB of video memory, and the Windows 11 operating system. The programming language was Python 3.12, the software platform was PyCharm 2023.2.4, the PyTorch framework version was 2.0.0, and the CUDA version was 11.8. Stochastic gradient descent was used for training. The image resolution was set to 640×640 pixels, the momentum was 0.937, and the weight decay coefficient was 0.0005. The initial learning rate was set to 0.01, and the number of training epochs was 100.

3.1.2 Segmentation evaluation

To evaluate the performance of the improved network for maize seedling row segmentation in field scenes, metrics at the mask level, including Precision (*P*), Recall (*R*), Average Precision (AP_{50}), and mask Intersection over Union (IoU_{mask}), were adopted to assess model performance. Among them, AP_{50} is the area under the precision-recall curve, which comprehensively measures the model's detection capability for a single class and serves as the core metric for evaluating overall network performance. The calculation formulas for the specific parameters are shown in Equations (12)~(15).

$$P=\frac{TP}{TP+FP} \tag{12}$$

$$R=\frac{TP}{TP+FN} \tag{13}$$

$$AP_i=\int_0^1 P_i(R_i)dR_i \tag{14}$$

$$IoU_{mask}=\frac{Area(Mask_{predicted}\cap Mask_{ground\_truth})}{Area(Mask_{predicted}\cup Mask_{ground\_truth})} \tag{15}$$

where:

TP (True Positive), FP (False Positive), and FN (False Negative) in Equations (12)~(14) are defined at the instance level: TP is the number of correctly segmented maize seedling row instances, FP is the number of incorrectly segmented instances, and FN is the number of missed instances. Equation (15) computes the pixel-level mask IoU for a single matched instance using mask areas.

3.1.3 Centreline extraction evaluation

To quantify the accuracy of the extracted crop row centrelines, evaluation metrics based on the lateral error and angle error between the predicted centreline and the ground truth centreline were constructed. The test image set was defined as S_{images}, the total number of images was $k = |S_{images}|$, i=1, 2, …, k. The mean normalized lateral error (L_{mean}^{norm}), the standard deviation of lateral error (L_{std}^{norm}), the mean angle error (A_{mean}), and the standard deviation of angle error (A_{std}) were used to reflect the average deviation level of the predicted navigation line relative to the ground truth centerline across all images. Smaller values indicate higher overall fitting accuracy. The calculation principle of this method is shown in Fig. 9. The formulas for comprehensive evaluation of navigation line accuracy and stability are shown in Equations (16)~(19).

$$L_{mean}^{norm} = \frac{1}{k} \sum_{s \in S_{images}} L_s^{norm} \tag{16}$$

$$L_{std}^{norm} = \sqrt{\frac{1}{k} \sum_{s \in S_{images}} (L_S^{norm} - L_{mean}^{norm})^2} \tag{17}$$

$$A_{mean} = \frac{1}{k} \sum_{i=1}^{k} \theta_i \tag{18}$$

$$A_{std} = \sqrt{\frac{1}{k-1} \sum_{i=1}^{k} (\theta_i - A_{mean})^2} \tag{19}$$

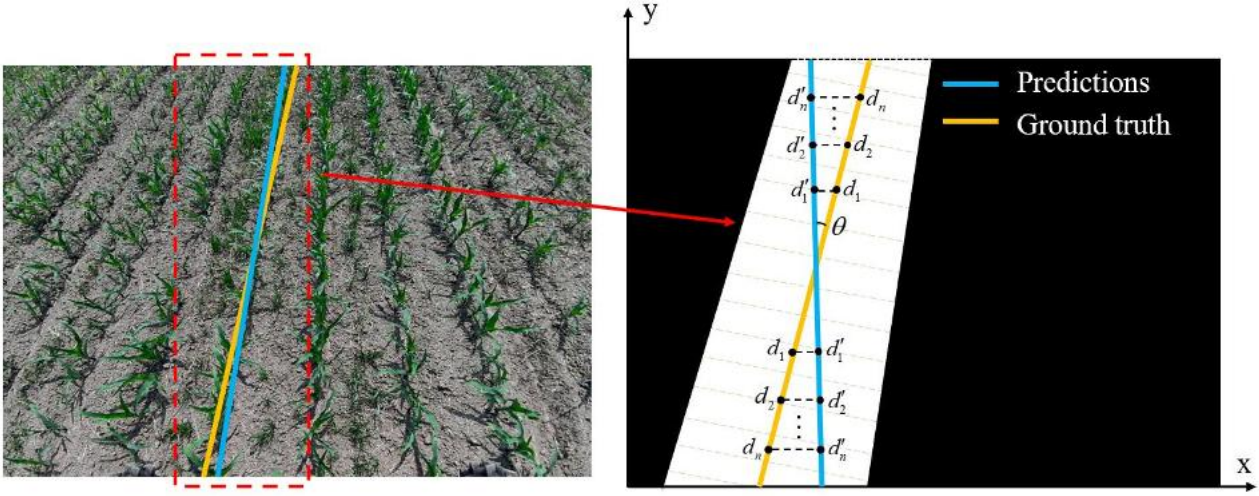

Fig. 9 - Schematic diagram of centreline extraction accuracy evaluation

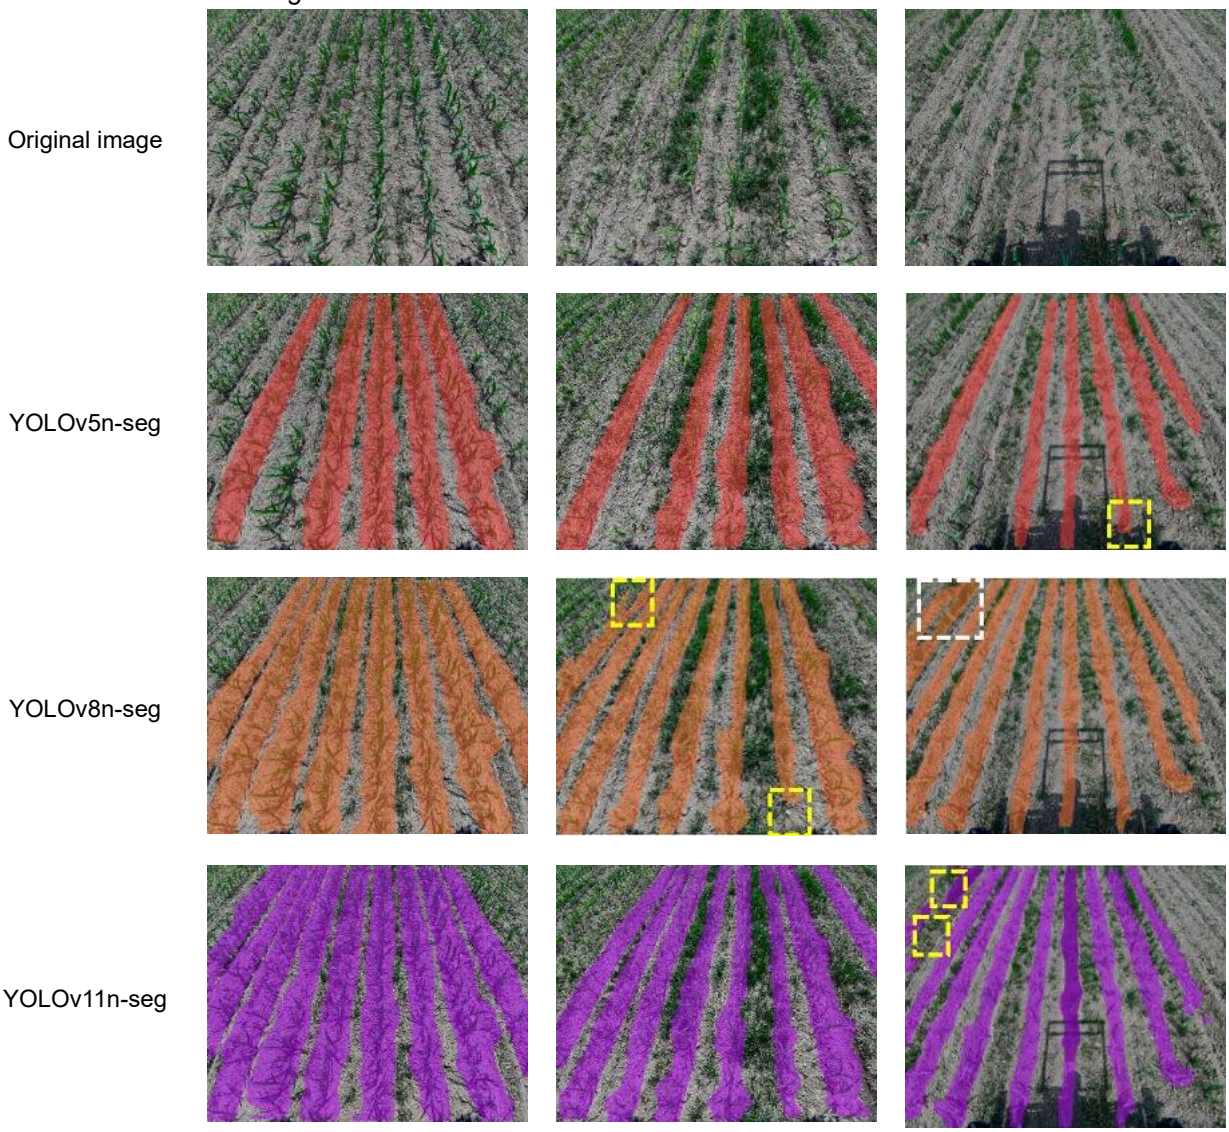
3.2 Comparison of different segmentation models



To validate the performance of the SA-YOLO model, comparative experiments were conducted against YOLOv5n-seg, YOLOv8n-seg, YOLOv11n-seg, and the baseline YOLOv12n-seg in a complex maize field environment at the seedling stage. The results are shown in Table 1. The SA-YOLO model achieved the best segmentation accuracy, with an AP_{50} of 99.1% and an IoU_{mask} of 83.8%, which was 1.5% higher than the suboptimal YOLOv8n-seg model. It also maintained leading performance in both precision and recall, indicating that the model can more completely and accurately identify maize row regions. From a lightweight perspective, although YOLOv5n-seg had the smallest number of parameters, its AP_{50} was relatively low. The YOLOv11n-seg model achieves the same P and AP_{50} as the SA-YOLO model, but its IoU_{mask} is 2.0 percentage points lower. Under a lightweight configuration with only 3.72 M parameters and 8.9 Giga Floating Point Operations (GFLOPs) of computation, SA-YOLO achieved an inference speed of 161.29 Frames Per Second (FPS), which was an improvement over the baseline YOLOv12n-seg's 153.85 FPS. Compared with the baseline YOLOv12n-seg, SA-YOLO increased AP_{50} by 0.3 percentage points and IoU_{mask} by 5.0 percentage points, validating the effectiveness of the proposed improved modules in enhancing feature extraction capability and segmentation accuracy.

Table 1

Comparison of detection performance of different network models

Model	P (%)	R (%)	AP_{50} (%)	AP_{50-95} (%)	IoU_{mask} (%)	FPS	Inference Times (ms)	Parameters (M)	GFLOPs	Model size (MB)
YOLOv5n-seg	96.5	94.7	98.5	65.2	82.2	117.65	8.5	**1.88**	**6.7**	**4.1**
YOLOv8n-seg	**96.6**	98.0	98.9	**66.8**	82.3	**232.56**	**4.3**	3.26	12.0	6.8
YOLOv11n-seg	96.5	**98.4**	**99.1**	65.2	81.8	185.19	5.4	2.83	10.2	6.0
YOLOv12n-seg	95.6	97.4	98.8	64.2	78.8	153.85	6.5	2.81	10.2	6.1
SA-YOLO	96.5	98.0	**99.1**	64.0	**83.8**	161.29	6.2	3.72	8.9	7.8

Maize seedling row images from different scenes, including mild weed interference, severe weed interference, and sparse planting, were randomly selected from the dataset for recognition experiments. As shown in Fig. 10, under the mild weed interference scene, the SA-YOLO model successfully segments 9 rows of maize seedlings, while other models all suffered from missed segmentation. Under the severe weed interference scene, YOLOv8n-seg had incomplete segmentation boundaries within the yellow box, affecting row continuity, and YOLOv12n-seg had false detection of weeds as maize rows within the red box. Under the sparse planting scene, the models exhibited blurred boundaries. YOLOv8n-seg and SA-YOLO showed some adhesion between rows within the white box. Across the three scenes, SA-YOLO successfully segmented the most rows of maize seedlings.

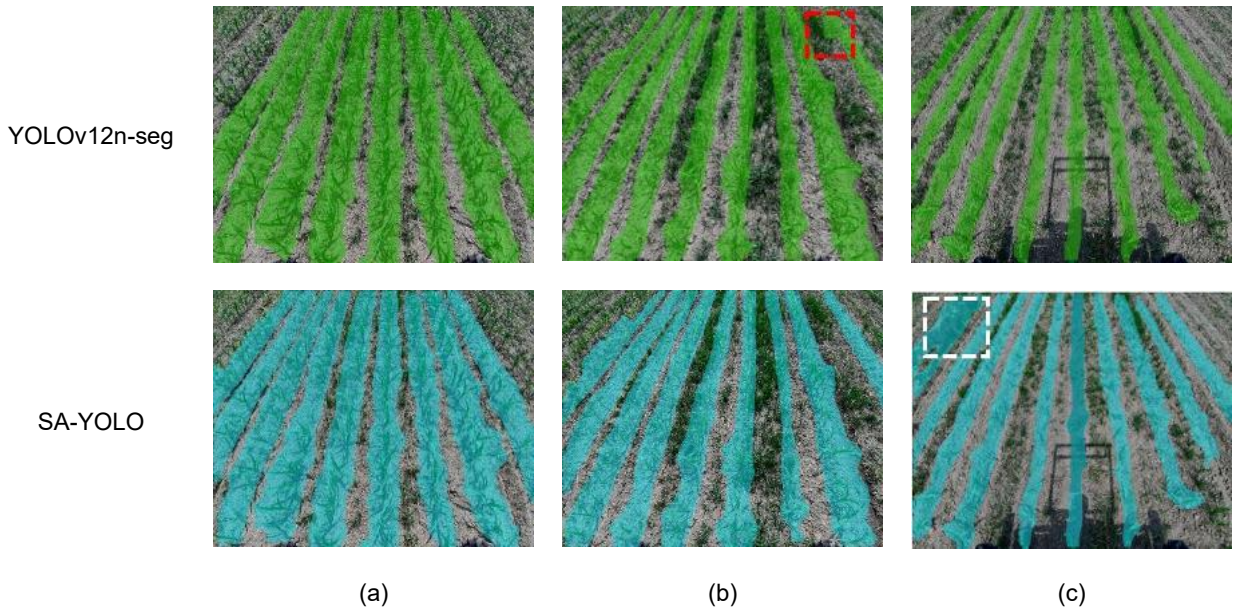


Fig. 10 - Segmentation results of five models under different scenes

(a) Segmentation results in mild weed interference scene; (b) Segmentation results in severe weed interference scene; (c) Segmentation results in sparse planting scene. The yellow boxes indicate incomplete segmentation regions, the white boxes indicate inter-row adhesion regions, and the red boxes indicate false segmentation of weeds.

Based on the above data, the improved SA-YOLO model in this study can accurately segment maize seedling rows in the above scenes, demonstrating that the introduction of the SCSA attention mechanism and the designed A2C2f_SAConv module can achieve better maize row segmentation accuracy in complex field environments, providing theoretical and technical support for the application of agricultural navigation systems *(Lopes et al., 2025)*.

3.3 Ablation experiments

To validate the effectiveness of each improved module, ablation experiments were conducted by sequentially introducing A2C2f_SAConv, SCSA and CBAM modules into the YOLOv12n-seg baseline model. The results are shown in Table 2. The baseline model achieved AP_{50}, AP_{50-95}, and IoU_{mask} of 98.8%, 64.2%, and 78.8%, respectively, on the test set. After introducing only the A2C2f_SAConv module, AP_{50} increased to 99.1%, IoU_{mask} increased by 5.0 percentage points to 83.8%, and the parameter count increased by only 0.91 M, indicating that this module effectively enhances multi-scale feature extraction capability through switchable atrous convolution while maintaining lightweight advantages *(Hu et al., 2025)*. Adding only the SCSA attention module achieved an AP_{50} of 98.9% and an IoU_{mask} of 81.6% with no increase in parameter count, validating the effectiveness of the SCSA spatial and channel synergistic attention mechanism. In contrast, introducing only the Convolutional Block Attention Module (CBAM) module gave an AP_{50} of 98.9% and an IoU_{mask} of 82.5%, with a slight increase in parameters *(Arthur et al., 2025; Guo et al., 2023)*.

Table 2

Ablation experiment results of YOLOv12n-seg

A2C2f_SA Conv	SCSA	CBAM	P (%)	R (%)	AP_{50} (%)	AP_{50-95} (%)	IoU_{mask} (%)	FPS	Inference Times (ms)	Parameters (M)	GFLOPs	Model size (MB)
×	×	×	95.6	97.4	98.8	64.2	78.8	153.85	6.5	**2.81**	10.2	**6.1**
√	×	×	96.3	**98.3**	**99.1**	64.6	**83.8**	178.57	5.6	3.72	8.9	7.7
×	√	×	95.9	98.1	98.9	64.6	81.6	163.93	6.1	**2.81**	10.2	**6.1**
×	×	√	95.6	98.0	98.9	**65.4**	82.5	**196.08**	**5.1**	2.83	9.6	**6.1**
√	√	×	96.5	98.0	**99.1**	64.0	**83.8**	161.29	6.2	3.72	8.9	7.8
√	×	√	**97.2**	96.8	99.0	64.9	83.5	181.82	5.5	3.73	**8.3**	7.8

Although optimization with a single module can improve model performance, more significant breakthroughs rely on synergy and combination among modules *(Liu et al.,2022; Shao et al., 2026; Gao et al., 2024; Meng et al., 2024)*. When both A2C2f_SAConv and SCSA were introduced, the model achieved the best performance, with AP_{50} of 99.1%, IoU_{mask} of 83.8%, *P* and *R* of 96.5% and 98.0%, respectively, and an inference speed of 161.29 FPS. However, introducing both A2C2f_SAConv and CBAM did not bring gains and reduced recall by 1.2 percentage points. Fig. 11 shows the performance curves of the ablation experiments, intuitively demonstrating the improvement in segmentation performance before and after the improvements.

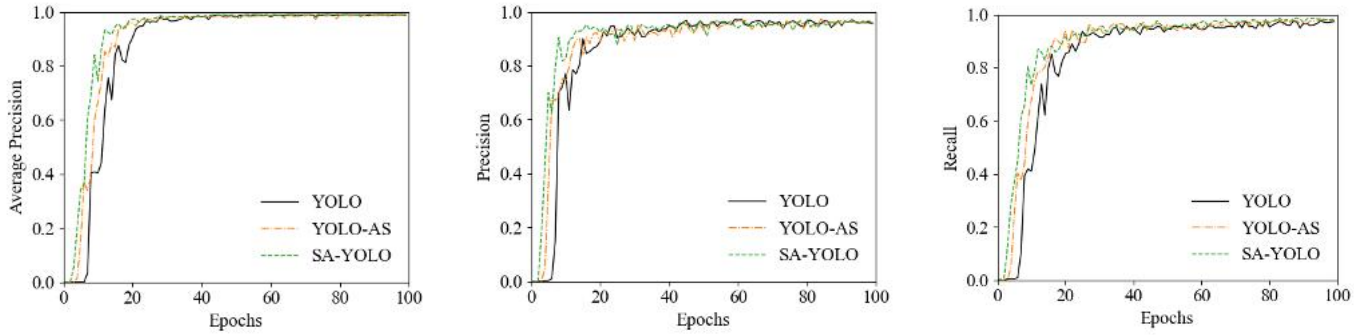

Fig. 11 - Performance curve comparison of improved algorithms

(a) Comparison of average precision curves of YOLOv12; (b) Comparison of precision curves of YOLOv12; (c) Comparison of recall curves of YOLOv12. YOLO refers to the YOLOv12n-seg model, and YOLO-AS refers to YOLOv12n-seg with the A2C2f_SAConv module.

To further visually compare and evaluate segmentation accuracy and understand the model's decision basis, heatmaps of maize seedling row image detection were used, as shown in Fig. 12. It can be seen that the heatmap of the SA-YOLO model is closer to the actual maize seedling row regions. In Fig. 12a, the boundaries indicated by the two straight lines are the boundaries that the model should accurately segment. Fig. 12b shows the heatmap of the YOLOv12n-seg baseline model, where the soil regions between adjacent crop rows exhibited weak boundary discrimination ability, leading to blurred boundaries between rows and incomplete segmentation at farther distances. Fig. 12c and Fig. 12d are heatmaps of the models with the A2C2f_SAConv convolution module and the SCSA attention mechanism module, respectively. The introduction of the A2C2f_SAConv module provided more complete activation of long maize seedling rows by expanding the receptive field, and the heatmap values at the far right were higher than those of the baseline model. The introduction of the SCSA attention mechanism module helped the model better distinguish the difference between maize seedling rows and the background, resulting in higher heatmap values at the maize seedling rows and clearer differentiation at the boundaries. Fig.12e shows the heatmap of the SA-YOLO model. Compared with the YOLOv12n-seg baseline model, the boundaries are clearer and the activation of maize seedling rows is more complete.

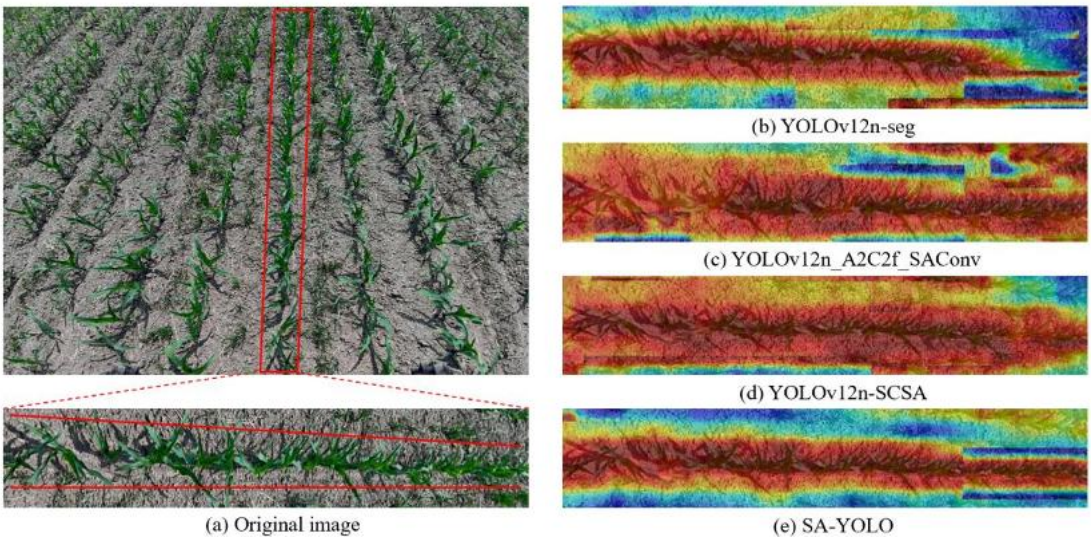

Fig. 12 - Heatmaps of maize seedling row image detection

The red regions represent the areas of greatest focus for the model, the yellow regions represent areas of secondary importance, and the blue regions represent areas with the least influence, typically representing redundant information.

3.4 Crop row centreline detection experiments

3.4.1 Crop row centreline detection using different methods

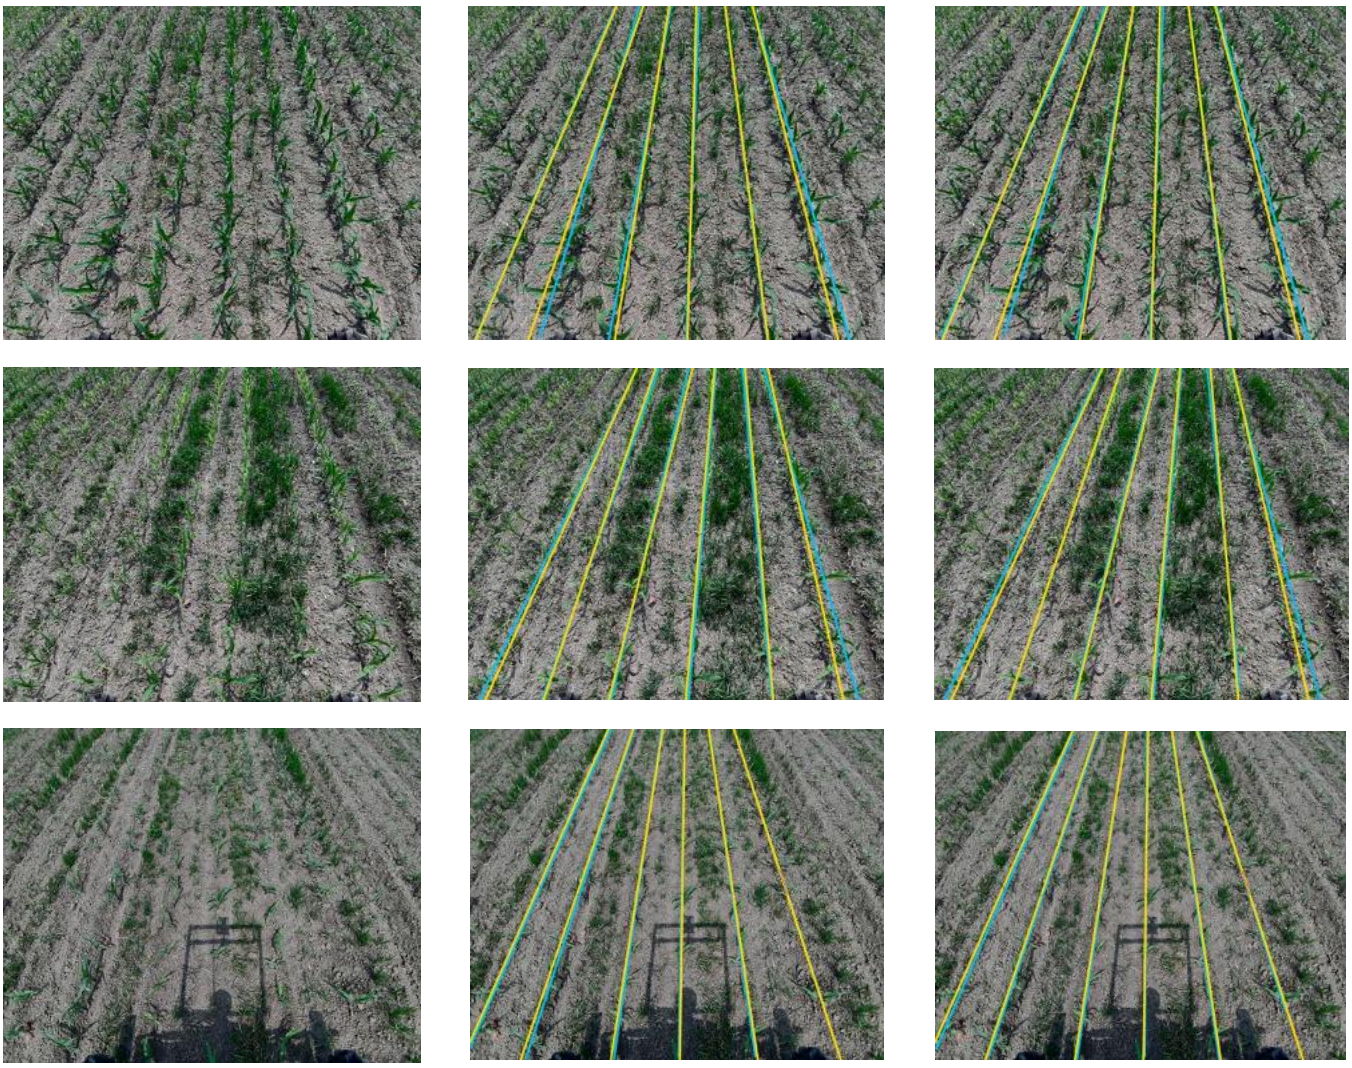
From a test dataset of 189 maize seedling row images, crop row centrelines were extracted using PCA *(Zhang et al.,2024a)*, LSM *(Ju et al.,2024)*, and the proposed PCA-LSM method, and were also compared with the traditional HT method *(Chen et al.,2025)* and the RANSAC method *(Zhang et al.,2024b)*. The quantitative results are shown in Table 3. As shown in the table, the PCA method achieved a A_{mean} of 0.613°, a L_{mean}^{norm} of 0.359%, and a mean pixel lateral error of 6.90 pixels. The LSM method achieved a A_{mean} of 0.590°, a L_{mean}^{norm} of 0.357%, and a mean pixel lateral error of 6.85 pixels. The results of the PCA-LSM method were exactly the same as those of the LSM method, with all metrics identical. The reason for this is that the maize rows in the test images were approximately vertical, causing PCA-LSM to always select the vertical fitting form, which is mathematically equivalent to LSM. Although PCA was slightly better in stability, LSM had a slight advantage in mean values. Overall, all three methods could effectively extract crop row centrelines, with angle errors all below 0.7° and pixel errors below 7 pixels, meeting the basic accuracy requirements for visual navigation of agricultural robots. The PCA-LSM method automatically degenerated to LSM on the vertical row dataset, verifying the correctness of its adaptive selection.

Table 3 Comparison of crop row centreline detection results using different methods

Fitting method	Scene	Mean angle error (°)	Mean normalized lateral error (%)	Mean pixel lateral error (px)
HT *(Chen et al.,2025)*	Maize seedling	2.600	-	10.78
RANSAC *(Zhang et al.,2024b)*	Rice transplanting	0.776	0.730	4.69
PCA	Maize seedling	0.613	0.359	6.90
LSM	Maize seedling	0.590	0.357	6.85
This study	Maize seedling	0.590	0.357	6.85

Compared with the RANSAC method, its A_{mean} of 0.776° and L_{mean}^{norm} of 0.730% were both higher than those of the proposed algorithm, while its mean pixel lateral error of 4.69 pixels was better than that of our method because of the different image resolutions. The image size in this study was 1920×1536 pixels, while the image size in that study was 1280×1024 pixels. Under the same maize seedling scene, the HT method achieved a A_{mean} of 2.600°, far higher than that of the PCA-LSM method used in this study. The reason for this is discussed as follows. Most fitting algorithms are based on object detection methods, using the center point or bottom midpoint of the detection box as feature points, which may introduce fitting errors due to discrete or missing plants. Alternatively, instance segmentation or semantic segmentation methods obtain feature points by calculating the centroids of connected regions or directly extract the skeleton of inter-row regions, both of which can cause overall deviation of the navigation line due to segmentation breaks or mis-segmentation. Centreline extraction methods that directly act on the crop itself usually use corner detection algorithms such as FAST to extract feature points. The feature points extracted by such methods are mainly from the leaf regions of the crop rather than the main stem regions of the crop rows, ultimately resulting in fitted centrelines that deviate from the crop main stem and are unstable. Compared with existing mainstream methods, the row-unit instance segmentation annotation adopted in this study provides a more structurally consistent learning target for the model. Meanwhile, the skeleton feature point extraction method proposed in this study directly acts on the crop itself, using an image thinning algorithm to extract the topological midline of the crop. This method not only preserves the complete geometric orientation information of the crop rows but also has a natural ability to suppress noise at segmentation edges. Traditional methods require high segmentation accuracy, whereas this study only uses segmentation to extract the ROI region to reduce noise interference, avoiding overall deviation of the navigation line due to segmentation breaks or mis-segmentation, and providing a feature point set with more uniform spatial distribution and higher geometric fidelity for subsequent navigation line fitting.

3.4.2 Crop row centreline detection of different models in complex scenes



To validate the effectiveness of the proposed SA-YOLO model in crop row centreline extraction, comparative experiments were conducted against the baseline YOLOv12n-seg model. The error statistics of the two models are shown in Table 4.

Table 4

Comparison of crop row centreline detection results of different models

Model	Angle error (°)		Normalized lateral error (%)	
	Mean	Std	Mean	Std
YOLOv12n-seg	0.622	0.530	0.379	0.433
SA-YOLO	0.590	0.498	0.357	0.428

The proposed SA-YOLO model outperformed the baseline YOLOv12n-seg model in all metrics. In terms of angle error, the mean of SA-YOLO decreased from 0.622° to 0.590°, a relative reduction of 5.1%; the standard deviation decreased from 0.530° to 0.498°, a relative reduction of 6.0%. This indicates that the row lines extracted by SA-YOLO are closer to the ground truth rows, with better stability across different scenes. In terms of normalized lateral error, the mean of SA-YOLO decreased from 0.379% to 0.357%, a relative reduction of 5.8%. The standard deviation remained essentially unchanged, indicating that SA-YOLO improved accuracy while maintaining stability. The introduction and design of the SCSA attention module and the A2C2f_SAConv module enriched contextual information and preserved shallow details, enabling the model to more accurately locate crop row centres. Fig. 13 shows the crop row centreline detection performance of YOLOv12n-seg and SA-YOLO in mild weed interference, severe weed interference, and sparse planting scenes, respectively.

(a) (b) (c)

Fig. 13 - Crop row centreline detection results under different scenes

(a) Detection scenes; (b) Detection results of YOLOv12n-seg model; (c) Detection results of SA-YOLO model.

3.4.3 Comparison with related studies

To further evaluate the superiority of the proposed navigation method, our method was compared with other related studies. As shown in Table 5, under field crop environments, our method achieved lower mean angle error and mean normalized lateral error than other state-of-the-art deep learning methods. In addition, it is worth noting that the mean pixel errors of the navigation line generation methods using YOLOX-Nano and Faster R-CNN architectures in jujube orchard and kiwifruit orchard environments, respectively *(Zheng et al., 2023; Ma et al., 2021)*, were slightly lower than our mean lateral pixel error in the maize seedling field. This phenomenon can be explained by the fact that the field scene is more complex than orchards, with weaker illumination, more occlusion, and unstructured environments. The main reason is also the larger image width in this study compared with those studies. Compared with other advanced methods *(Lai et al., 2026)*, the proposed method has stronger robustness and generalization ability and can meet the navigation requirements of maize seedling fields.

Table 5

Performance comparison of different crop row line extraction methods

Reference	Scene	Network	Mean angle error (°)	Mean normalized lateral error (%)	Mean pixel lateral error (px)
(Kong et al., 2025)	Heading rice	SEU-Enet	1.910	-	-
(Lai et al., 2026)	Multiple seedling crops	YOLO-SSR	-	0.720	-
(Zheng et al., 2023)	Jujube orchard	YOLOX-Nano	2.550	0.700	4.49
(Ma et al., 2021)	Kiwifruit orchard	Faster R-CNN	3.200	0.340	5.10
This study	Maize seedling	SA-YOLO	0.590	0.357	6.85

Although the proposed method has clear advantages in accuracy, there are still some limitations. The parameter count of the model is 3.72 M, which is higher than that of the SEU-Enet model of *Kong et al. (2025)* (approximately 0.094 M), leaving room for optimization in extreme lightweight scenarios. This study mainly focused on the accuracy analysis of navigation line extraction and has not yet performed end-to-end real-time testing on actual agricultural machinery platforms.

4. CONCLUSIONS

In this study, to address the problem of crop row centreline extraction for visual navigation of agricultural robots, the SA-YOLO model was constructed, and a crop-based skeleton feature point extraction method and a corresponding crop row centreline extraction method were designed. The model enhanced feature extraction capability by introducing the SCSA attention module and replacing the original A2C2f module with the designed A2C2f_SAConv module, achieving accurate segmentation of crop row regions. In the crop row centreline extraction stage, the constructed skeleton feature point extraction and PCA-LSM joint optimization method effectively improved the accuracy of crop row centrelines. The experimental results showed that the IoU_{mask}, AP_{50}, P, and R scores of the SA-YOLO model were 83.8%, 99.1%, 96.5%, and 98.0%, respectively. Compared with the other four models, it exhibited higher recognition accuracy while maintaining faster segmentation speed. Second, regarding the proposed algorithm, the A_{mean} is reduced to 0.590° and its A_{std} to 0.498°, while the L_{mean}^{norm} is reduced to 0.357% and its L_{std}^{norm} to 0.428%. All the above metrics satisfy the precision requirements of autonomous agricultural machinery. However, several aspects of the proposed model require further improvement. The validation of the model was mainly focused on the crop seedling stage, and its applicability in other growth stage scenes needs further verification. Therefore, future work will include more crop species, more growth stages, and more samples from complex environments to promote the practical application of the algorithm.

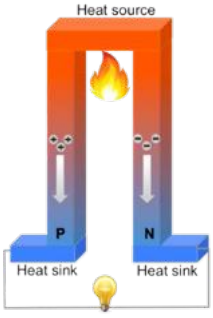
Keywords: *energy harvesting, thermoelectric generator, waste heat recovery, carbon-neutral energy, biochar pyrolysis, Seebeck effect*

ABSTRACT

This study explores the potential of harvesting and utilizing thermoelectric energy generated during biochar production. Biochar, a carbon-rich material produced from biomass pyrolysis, offers a sustainable pathway for waste management and soil improvement. However, the biochar production process also generates significant heat, much of which remains underutilized. This research investigates the integration of thermoelectric generators (TEGs) into biochar production equipment to convert waste heat into electricity. The system's design and optimization aim to enhance energy efficiency while supporting renewable energy goals, by using the harvested energy to power up small devices, such as sensors. Experimental results demonstrate the feasibility of capturing thermal energy and converting it into usable electrical power, contributing to the overall sustainability of the process. The experimental results revealed a maximum output voltage of 1.226 V, recorded at a temperature gradient of approximately 42.0 °C, a peak power output of approximately 37.6 mW, an overall maximum temperature gradient of approximately 42.8 °C reached slightly before the voltage peak, and a cumulative harvested energy of 288.92 J. The findings also highlight key factors influencing thermoelectric conversion efficiency, including temperature gradients, TEG material properties, and system integration challenges. This approach not only mitigates energy losses but also aligns with global efforts toward carbon neutrality and resource optimization. The study underscores the dual benefit of biochar production: providing agricultural benefits while supporting energy sustainability.

REZUMAT

Acest studiu explorează potențialul de captare și utilizare a energiei termoelectrice generate în timpul producției de biochar. Biocharul, un material bogat în carbon obținut prin piroliza biomasei, oferă o cale sustenabilă pentru gestionarea deșeurilor și îmbunătățirea solului. Totuși, procesul de producere a biocharului generează, de asemenea, cantități semnificative de căldură, mare parte din aceasta rămânând nevalorificată. Această cercetare investighează integrarea generatoarelor termoelectrice (TEG) în echipamentele de producere a biocharului, pentru a transforma căldura reziduală în energie electrică. Proiectarea și optimizarea sistemului urmăresc creșterea eficienței energetice și susținerea obiectivelor de energie regenerabilă, prin utilizarea energiei recuperate pentru alimentarea unor dispozitive de mici dimensiuni, cum ar fi senzorii. Rezultatele experimentale demonstrează fezabilitatea captării energiei termice și conversiei acesteia în energie electrică utilizabilă, contribuind la sustenabilitatea generală a procesului. Rezultatele experimentale au evidențiat o tensiune maximă de ieșire de 1,226 V, înregistrată la un gradient de temperatură de aproximativ 42,0 °C, o putere maximă de aproximativ 37,6 mW, un gradient maxim general de temperatură de aproximativ 42,8 °C, atins cu puțin timp înaintea vârfului de tensiune, și o energie totală recoltată de 288,92 J. Constatările evidențiază, de asemenea, factorii cheie care influențează eficiența conversiei termoelectrice, inclusiv gradientele de temperatură, proprietățile materialelor TEG și provocările legate de integrarea sistemului. Această abordare nu doar reduce pierderile de energie, ci se aliniază și eforturilor globale pentru neutralitate carbonică și optimizarea resurselor. Studiul subliniază beneficiul dublu al producției de biochar: oferirea de avantaje agricole și susținerea sustenabilității energetice.



INTRODUCTION

In the context of increasing global energy demand and the need to reduce greenhouse gas emissions, the efficient use of available energy resources has become a critical research priority (*Cui X. et al., 2024; Moriarty P. & Honnery, D., 2016*). A significant share of the energy generated in industrial, agricultural, and biomass-processing systems is dissipated as residual heat, often without being valorized (*Jiang, Y. et al., 2024*), a situation particularly evident in processes such as biomass pyrolysis and biochar production, where high operating temperatures coexist with relatively low overall energy efficiency (*Champier D., 2017*); Seebeck-based recovery from biomass carbonization heat has recently been explored in simulation (*Badaka H. K. & Morega A. M., 2024*). In power stations, for example, approximately two-thirds of the energy produced is lost as waste heat, mainly discharged through cooling towers, since most electricity generation relies on gas- or steam-powered turbine systems in which fuel combustion is first converted into mechanical energy and only subsequently into electricity (*Sanin-Villa D., 2022*). As a result, only about one-third of the energy released from the fuel reaches the power lines leaving the plant.

Several technologies exist for recovering this thermal energy, including Organic Rankine Cycles (ORC), turbo-compounding, and thermoelectric generators (TEGs). Among these, TEGs are a promising solution for the direct conversion of waste heat into electricity. Based on the Seebeck effect, they enable solid-state energy conversion without moving parts, offering high reliability, low maintenance requirements, and scalability (*Ridwan M., 2025*), and have been increasingly investigated for waste-heat recovery from internal combustion engines, industrial processes, and biomass-based systems (*Williams, N. P. et al., 2022*), including automotive exhaust-heat recovery, where structural design and optimization remain active research topics (*Wang Y. et al., 2025*). Thermoelectric recovery from such systems typically relies on arrays of thermoelectric modules (TEMs) applied to surfaces with non-uniform temperature distributions, reducing fuel consumption and pollutant emissions in the process (*Săvescu C. et al., 2025*).

The Seebeck effect arises from the diffusion of charge carriers along a temperature gradient in a conductor or semiconductor, generating a potential difference between the hot and cold sides; the sign of this potential- and of the corresponding Seebeck coefficient identifies the material as p-type (positive) or n-type (negative) (*Quan R. et al., 2020*). The Seebeck coefficient quantifies the ratio between the induced voltage and the applied temperature gradient, and is obtained using a thermoelectric circuit formed of two dissimilar materials, typically two semiconductors with opposite-sign coefficients, joined at junctions held at different temperatures (*Deng Y. et al., 2022*). Materials with a high Seebeck coefficient are the most efficient at converting thermal energy into electricity; the effect underlies applications ranging from thermoelectric generators and thermocouple temperature sensors to wearable devices that harvest body heat.

Despite these advantages, wider adoption of thermoelectric systems remains limited by relatively low conversion efficiencies and by challenges related to thermal integration (*Liu Z. et al., 2023*). TEG performance depends not only on the intrinsic properties of the thermoelectric materials but also on external factors such as the temperature gradient, heat-transfer conditions, and the quality of thermal contact between the heat source and the modules (*Ciupercă R. et al., 2022*). Surface-mounted configurations are particularly sensitive to heat-transfer effectiveness across multiple interfaces, where thermal resistances and contact imperfections can substantially reduce the achievable temperature difference (ΔT) and, consequently, the electrical output (*Mastrullo R. et al., 2019*). The complementary Peltier effect, in which an electric current passed through the junction of two dissimilar materials causes heat to be absorbed at one junction and released at the other, governs the reverse operating mode of the same devices, used for active cooling, and reflects the same carrier-transport mechanism that underlies Seebeck-based power generation (*Chelladorai P. et al., 2024; Maican E., 2015*).

MATERIALS AND METHODS

Thermoelectric generators (TEG)

A thermoelectric generator (TEG) directly converts heat into electrical energy through the Seebeck effect: when a temperature difference is applied across a conductive or semiconductive material, charge carriers diffuse from the hot end to the cold end, producing an electric current. A practical TEG is built from multiple thermocouples, each an n-type and a p-type semiconductor pair, connected electrically in series and thermally in parallel; the conversion efficiency depends on the thermoelectric material used and is quantified by the dimensionless figure of merit (ZT), which combines electrical conductivity, the Seebeck coefficient, absolute temperature and thermal conductivity (*Ridwan M., 2025*).

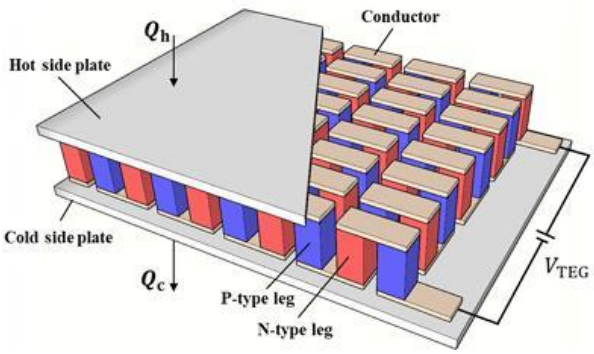

Fig. 3 - Graphic representation of a thermoelectric generator *(Yaman K., et al., 2025)*

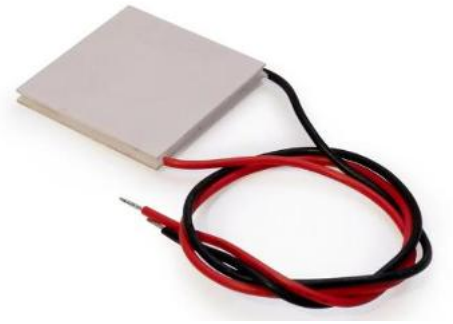

Fig. 4 - Thermoelectric generator module *(Iavnic T., et al., 2024)*

Bismuth telluride (Bi_2Te_3), the active material in the TEC1-12706 Peltier modules used in this study, is among the most widely used thermoelectric materials for near-room-temperature applications (typically 200-300 °C), owing to its favorable electrical conductivity and Seebeck coefficient and its correspondingly high figure of merit (ZT) at low-to-medium temperatures; it is likewise the basis for the reverse (cooling) operating mode of the same devices in thermoelectric refrigeration.

- **Heat source**

The biochar production equipment (Fig. 7) generates high temperatures during the pyrolysis process. The external surfaces of the equipment have been identified as a consistent source of residual heat, making them ideal for mounting Peltier modules.

Although thermally insulated, the heat generated by the six 2000 W heating elements is sufficient for four series-connected Peltier modules to generate a significant electric potential.

Fig. 5 - Bismuth telluride in natural form *(Hqgraphene.com)*

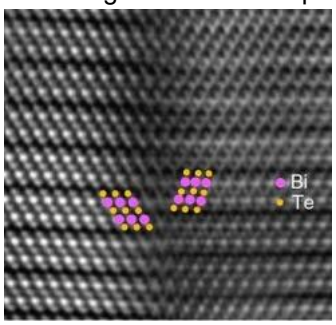

Fig. 6 - Bismuth telluride under microscope *(Hqgraphene.com)*

Fig. 7 - Biochar production equipment

- **TEG modules**

The core of the system comprises four TEC1-12706 modules. While these are primarily designed as Peltier modules for thermoelectric cooling and heating, they can be repurposed as thermoelectric generators (TEGs) when subjected to a temperature gradient. In this configuration, they convert heat into electrical energy through the Seebeck effect. To maximize the voltage output from the TEGs, the four modules are connected in series. This configuration ensures that the voltage generated by each module adds up, resulting in a combined output equal to the sum of individual module voltages. This is particularly advantageous when the application requires higher voltages to power downstream electronics or charge batteries.

For a better cooling distribution on the cold side of the generator, a heat sink was mounted on each of the four modules with thermal paste. (Fig. 8)

Being a low-powered application, it is important to minimize the voltage drop as much as possible. The voltage drop across conductive materials is governed by Ohm's law:

$$U = I \cdot R \quad (1)$$

where U is the voltage drop, I is the current, and R is the resistance of the wire. The resistance (R) of a wire is proportional to its length (L) and resistivity (ρ) and inversely proportional to its cross-sectional area (S):

$$R = \rho \cdot \frac{L}{S} \quad (2)$$

To minimize the resistance of the wiring used with thermoelectric generator (TEG) modules and consequently reduce the voltage drop, the wire length (L) was minimized in this design. This approach ensures that the electrical energy generated by the TEG modules is efficiently transferred to the load or storage system. Shortening the wire length not only reduces resistive losses but also minimizes the thermal resistance introduced by longer wires, which can interfere with the thermal gradient for TEG operation. This optimization step is particularly critical in low-voltage systems, where even minor losses can significantly impact overall performance.

Before conducting the actual experiments, preliminary tests were performed to determine the correct polarity of the thermoelectric generator (TEG) modules and to confirm their functionality based on the Seebeck effect. These tests involved applying a temperature gradient across the module surfaces.

To simulate a temperature differential, heat was applied to the hot side of the TEG module using a handheld lighter, while ice was placed on the cold side. This setup ensured a significant thermal gradient necessary to generate an electromotive force. Using a multimeter, the output voltage and polarity were measured to verify the module's orientation and ensure proper connectivity for subsequent testing. The results confirmed the expected behavior, with the TEG generating a voltage consistent with the Seebeck effect and the designated polarity. This step was a qualitative orientation check preceding the formal experimental campaign described in the following sections, and is reported here only as such, not as part of the formal measurement procedure.

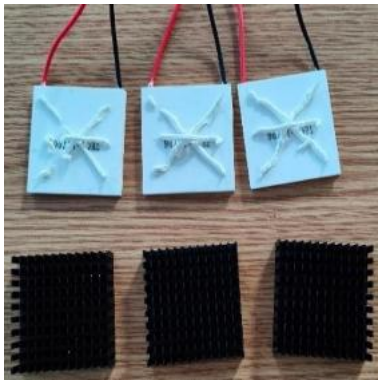

Fig. 8 - Heat-sink mounting using thermal paste

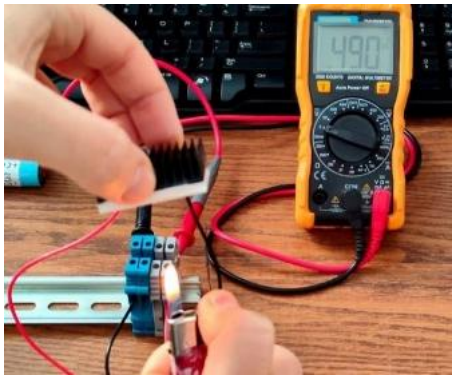
Fig. 9 - Applying ice on the cold side



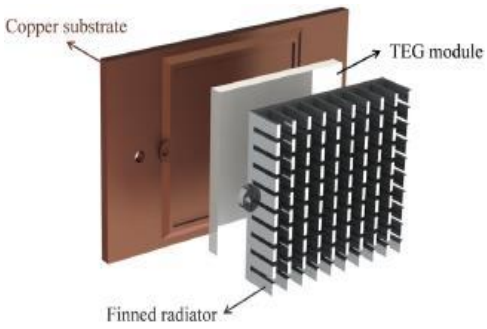


Fig. 10 - Applying high temperature on hot side

For ensuring an efficient and uniform heat distribution across the hot-side surfaces of the Peltier modules, they were mounted on a copper plate, due to its superior thermal conductivity properties. Subsequently, the assembled structure was attached to the equipment using a thermally conductive double-sided adhesive tape, providing both mechanical stability and adequate thermal contact. In order to enhance thermal dissipation and reduce the temperature at the cold junction, the setup utilized four heat sinks, each with dimensions of 40x40 mm.

(Jiang, Y. et. al., 2024)

Figure 12. TEG modules setup

Other instrumentation used

The output voltage and current supplied to the resistive load (Fig. 16) were measured with a PANCONTROL PAN Profimeter digital multimeter (CAT III 600 V), with a DC voltage range of 0.1 mV–600 V and a manufacturer- specified accuracy of 0.7%–4.0% depending on range and function.

Thermal measurements were performed using a UNI-T UTi32 thermal imaging camera. The device operates over a temperature measurement range of −20 °C to 1000 °C and features an infrared (IR) resolution of 32 × 32 pixels. The thermal images were displayed on a 2.4-inch IPS screen with a resolution of 480 × 320 pixels. In addition, the integrated digital camera provides visible-light images at a resolution of 640 × 480 pixels. The camera supports three visualization modes: thermal, visible, and fusion, allowing thermal data to be analyzed alongside conventional imagery. According to the manufacturer's specifications, the instrument has a stated temperature-measurement accuracy of ±2 °C or ±2%, whichever is greater, and a thermal sensitivity (NETD) of 0.15 °C.

Temperature regulation was performed using a Gefran 650 PID temperature controller, a compact 1/16 DIN process controller designed for accurate and stable thermal regulation in industrial applications. The controller has a 48 × 48 mm front-panel format and an approximate depth of 80 mm. Its universal main input can be configured for different temperature sensors, including J, K, R, S, T, C and D thermocouples, as well as PT100 and JPT100 resistance temperature detectors (RTDs). Linear input signals of 0–60 mV, 0–1 V, 0–5 V, 0–10 V and 0/4–20 mA are also supported.

Temperature at the module hot side was sensed with a Gefran TC8-D-1-K thermocouple (Type K), connected to the Gefran 650 controller, with a manufacturer-stated tolerance of IEC 60584-2 Class 2: ±2.5 °C for −40...+333 °C, or ±0.0075×|t| for t > 333 °C (i.e., approximately ±3 °C at the ~400 °C internal operating temperature reached in this study).

The 10 Ω load resistor was a general-purpose commercial resistor with a typical tolerance of ±5%, as manufacturer-specific tolerance data were not available for this component.

Methodology

The measurements were conducted in Bucharest on December 11, 2025. Ambient temperature data were obtained from the website weatherspark.com. The measurements were carried out over a period of 335 minutes, from 9:00 a.m. to approximately 3:30 p.m., with ambient temperatures ranging between 3°C and 12°C. In addition, temperature and output voltage measurements were recorded at 5-minute intervals throughout the duration of the experiment.

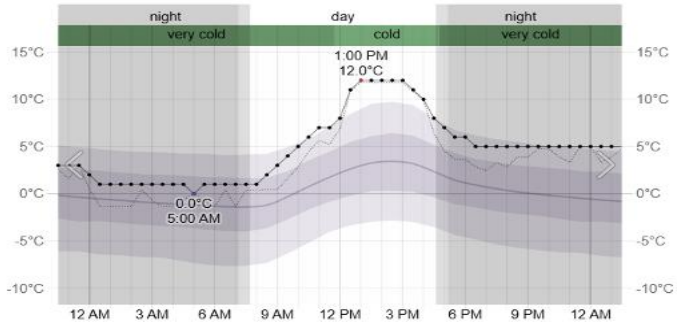

Fig. 13 - Ambient temperatures in Bucharest, 11 Dec 2025 *(Weatherspark.com)*

For the experimental determination of the electrical parameters (current, and output power), a resistive load of 10 Ω was connected across the terminals of the thermoelectric modules. The selection of this load value was based on the maximum power transfer principle, which states that the power delivered to the load is maximized when the load resistance is approximately equal to the internal resistance of the source.

Each thermoelectric module exhibits an internal electrical resistance of approximately 2.5 Ω. With the four modules connected in series, as described above, the equivalent internal resistance of the source is 4 × 2.5 Ω = 10 Ω, which matches the selected load resistance exactly. Therefore, the use of a 10 Ω load closely satisfies the impedance matching condition, enabling an accurate experimental assessment of the maximum extractable power from the system; this equivalence between the source and load resistance is also what justifies halving the total output voltage in Eq. (3) below.

$$V_{load} = \frac{V_{out}}{2} \quad (3)$$

$$I = \frac{V_{load}}{R_L} \quad (4)$$

$$P = V_{load} \cdot I = \frac{V_{load}^2}{R_L} \quad (5)$$

$$\eta = \frac{P}{Q} \quad (6)$$

where:

V_{load} – voltage measured across the load resistor [V]

I – electrical current flowing through the circuit [A]

P – electrical power delivered to the load [W]

P_{avg} – average electrical power delivered to the load [W]

η – yield, expressed here as a conversion ratio relative to the fixed reference power Q_{ref} = 180 W (see Results), rather than a directly measured thermoelectric conversion efficiency [%]

The average electrical power obtained during the experimental campaign was 14.37432 mW. The total duration of the experiment was 335 minutes, corresponding to 20,100 seconds. Based on these values, the total electrical energy generated by the system was calculated as the product of average power and time.

$$E \approx P_{avg} \cdot t \approx 0.01437432 \cdot 20100 \approx 288.92 \text{ [J]} \quad (7)$$

where:

E – electrical energy produced by the system [J]

Theoretical model

The electrical voltage generated by the thermoelectric modules is governed by the Seebeck effect, which establishes a direct proportionality between the generated voltage and the temperature difference across the module.

$$V = \alpha \cdot \Delta T + b \quad (8)$$

where:

V - output voltage [V];

α - Seebeck coefficient [V/K];

ΔT - temperature difference across the module [K].

The thermoelectric modules were mounted on the external surface of the biochar production equipment. Therefore, the temperature difference was defined as:

$$\Delta T = T_{hot} - T_{cold} \quad (9)$$

To determine the temperatures at the ceramic surfaces of the TEGs (Thot and Tcold), it had to be accounted the fact that heat doesn't transfer perfectly from the heat source to the modules as there is thermal friction (thermal resistance) in the copper plate and especially in the thermally conductive tape used.

When heat flows through any material, it loses "pressure" (temperature). The temperature at the actual Peltier junction is always lower than the source and higher than the ambient air.

$$T_{hot} = T_{ext} - (Q \cdot R_{hot}) \quad (10)$$

$$T_{cold} = T_{amb} + (Q \cdot R_{cold}) \quad (11)$$

$$Q = \frac{T_{top} - T_{bottom}}{R_{th}} \quad (12)$$

where:

Q - heat flow [W]

R - thermal resistance [K/W]

T_{top} – temperature on the top of a material [°C]

T_{bottom} – temperature on the bottom of a material [°C]

- **Hot side thermal resistance model**

To determine the temperature drop between the measured external temperature, *T*ext, and the actual hot-side surface temperature of the TEG, *T*hot, Fourier's law of heat conduction and a thermal-resistance model were applied.

$$R_{th} = \frac{L}{k \cdot A} \quad (13)$$

where:

L – thickness of the material (m)

k – thermal conductivity (W/mK)

A – surface area (m²)

$$T_{drop} = Q \cdot R_{th} \quad (14)$$

where:

T_{drop} – Temperature drop across a layer [°C]

The thickness of the copper plate is 1mm, while the other dimensions are 40x40 mm, it results:

$$R_{copper} = \frac{L_{copper}}{k_{copper} \cdot A_{copper}} = \frac{0.001}{401 \cdot 0.0064} \approx 0.00039 \text{ [K/W]} \quad (15)$$

It means that the thermal resistance of the copper plate is negligible, the copper plate itself barely causing any temperature drop (less than 0.1°C).

As for the thermally conductive tape, its thickness was measured as 0.2 mm, while the dimensions are 40x40 mm. Therefore:

$$R_{band} = \frac{L_{band}}{k_{band} \cdot A_{band}} = \frac{0.0002}{1.5 \cdot 0.0064} \approx 0.02083 \text{ [K/W]} \quad (16)$$

- **Cold side thermal resistance model**

Although copper has high thermal conductivity, air has much lower thermal conductivity. As a result, heat dissipation from the heat sinks to the surrounding air is limited, causing the cold side of the TEG module to remain warmer than the ambient temperature.

The effective cold side temperature T_{cold} is calculated by adding the temperature loss factors to the ambient air temperature:

$$T_{cold} = T_{amb} + T_{convective} + T_{conduction} \quad (17)$$

The total cold side resistance (R_{cold}), consists of three components:

- Interface Resistance (R_{int}) - thermal resistance at the contact interface between the TEG module and the heat sink.
- Conduction Resistance ($R_{conduction}$) - thermal resistance associated with heat conduction through the aluminum base of the heat sink.
- Convective Resistance ($R_{convective}$) - thermal resistance associated with heat transfer from the heat-sink fins to the surrounding air; this component typically accounts for the largest temperature drop.

$$R_{convective} = \frac{1}{h \cdot A} = \frac{1}{50 \cdot 0.0064} \approx 3.125 \text{ [K/W]} \quad (18)$$

The convective heat-transfer coefficient adopted in Eq.(18) (h = 50 W/(m²K)) reflects a natural-convection regime for the finned heat sinks used, since no forced-air cooling (fan or blower) was applied during testing.

The other two terms in Eq. (19) — the interface resistance between the TEG module and the heat sink, associated with the thin layer of thermal paste, and the conduction resistance through the thin aluminum base of the heat sink — are, by the same reasoning applied to the copper plate on the hot side in Eq. (15), several orders of magnitude smaller than the convective resistance calculated in Eq. (18). They were therefore neglected. Consequently, the cold-side temperature rise is dominated by the convective resistance, with $R_{convective} \approx 3.125$ K/W.

The heat flow, Q, rejected at the cold side consists of the heat transferred from the hot side together with the internally generated Joule heat:

$$T_{rise} = Q_{total} \cdot (R_{int} + R_{conduction} + R_{convection}) \quad (19)$$

Because the convective thermal resistance of the heat sink $R_{convection}$ is determined primarily by the heat-sink geometry and airflow conditions, a higher heat flow results in a larger temperature difference across the cold-side thermal resistance.

The Seebeck coefficient was determined using linear regression applied to the experimental dataset, according to the relation:

$$\alpha = \frac{V_{out}}{\Delta T} \quad (20)$$

Since the experiment was conducted using 4 modules mounted in series:

$$V_{out} = 4 \cdot \alpha \cdot \Delta T \quad (21)$$

The linear regression fitted to the full V_{out} versus ΔT dataset (Figure 21) gives a slope of 0.0293 V/°C for the four-module series, corresponding to a per-module Seebeck coefficient of:

$$\alpha_{module} = \frac{0.0293}{4} = 0.00733 \text{ [V/K]} \quad (22)$$

As a consistency check, the Seebeck coefficient was also estimated from a single stable data point near the plateau, where the open-circuit output voltage was V_{out} = 1.226 V and ΔT ≈ 42.0 °C.

$$\alpha_{module} = \frac{V_{out}}{4 \cdot \Delta T} = \frac{1.226}{4 \cdot 42.0} = 0.00729 \text{ [V/K]} \quad (23)$$

where: α - the effective Seebeck coefficient of the thermoelectric module under real operating conditions [V/K]

ΔT - temperature difference between the hot and cold side of the module [°C]

V_{out} - voltage measured at the corresponding temperature difference ΔT [V]

The close agreement between the regression-based estimate (0.00733 V/K) and the single-point value (0.00729 V/K) confirms the consistency of the Seebeck coefficient obtained under real operating conditions, and both are in line with the expected performance of commercial thermoelectric modules operating under non-ideal thermal conditions. As shown in Figures 21 and 23, the heating and cooling phases form two visibly distinct branches around this regression line, a hysteresis attributable to the thermal inertia of the system discussed above; the reported slope represents an average across both branches rather than a single-valued instantaneous relationship.

RESULTS

The biochar production unit, acting as the thermal source, reached the target internal temperature of 400 °C in approximately one hour. This temperature was maintained for a duration of about two hours, after which a gradual decrease was observed.

A pronounced thermal inertia of the system was identified. While the internal temperature attained its maximum value within the first hour, the external surface temperature exhibited a delayed response, reaching a peak of 71 °C after approximately three hours from the start of the process. This behavior highlights the transient heat transfer dynamics and the thermal buffering capacity of the system.

Fig. 14 - Measurement of the equipment surface temperature

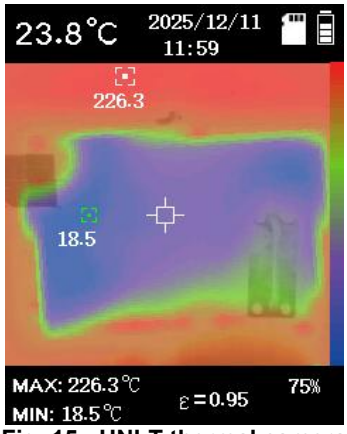

Fig. 15 - UNI-T thermal camera screenshot

Fig. 16 - Measuring the output voltage

Although the theoretical model predicts a linear relationship between output voltage and temperature difference, the experimental results show deviations from ideal linearity. These deviations may be attributed to several factors, including thermal contact resistance between the module and the equipment surface, insufficient heat dissipation from the cold side, transient thermal conditions during measurement, and nonuniform temperature distribution within the module. These values indicate that the system is suitable for low-power applications such as environmental monitoring or autonomous sensing systems.

The experimental measurements performed over a total duration of 335 minutes highlight the temporal evolution of the thermal regime of the biochar reactor and its direct influence on thermoelectric energy generation.

- **Thermal evolution of the system**

The internal temperature of the heat source exhibited a rapid increase during the initial phase, rising from near-ambient values to approximately 400 °C within the first 60–65 minutes. After reaching this peak, the system maintained a quasi-steady thermal plateau at ~400 °C for a significant duration (approximately 65 to 190 minutes), followed by a gradual cooling phase.

In contrast, the external temperature of the heat source and the temperatures measured at the thermoelectric module interfaces (hot and cold sides) showed a delayed and attenuated response. The hot-side temperature increased progressively from ~5.8 °C to a maximum of approximately 62.4 °C, while the cold-

side temperature rose from ~3.5 °C to about 20.6 °C. This resulted in a maximum recorded temperature difference (ΔT) of approximately 42.8 °C.

The data clearly indicate the presence of thermal gradients and heat transfer limitations between the reactor core and the thermoelectric modules, as the external and interface temperatures remained significantly lower than the internal reactor temperature throughout the experiment.

- **Voltage generation and correlation with temperature gradient**

The electrical output of the thermoelectric modules followed the evolution of the temperature gradient across their surfaces. At low ΔT values (approximately 2–3 °C), the generated voltage was minimal (~0.02 V). As ΔT increased, the output voltage rose steadily, reaching a maximum value of 1.226 V at ΔT ≈ 42 °C.

During the steady-state thermal regime (approximately 160–190 minutes), both ΔT and voltage output stabilized, with voltage values consistently around 1.20–1.22 V. This indicates a strong correlation between thermal stability and consistent electrical generation.

Following the decline in reactor temperature, both ΔT and output voltage decreased proportionally, confirming the direct dependence of thermoelectric performance on the available temperature gradient.

- **Electrical performance under load**

The electrical characterization of the system using a 10 Ω resistive load provided insight into the practical energy harvesting capability. The measured current increased with ΔT, ranging from approximately 1 mA at low temperature differences to 61.3 mA at peak conditions.

The corresponding electrical power output reached a maximum value of approximately 37.6 mW at ΔT ≈ 42 °C. At intermediate conditions (ΔT ≈ 26.3 °C), the system produced around 10.8 mW, while at low ΔT values (~2–3 °C), the power output was negligible (~0.01 mW).

These results confirm that the usable electrical power is highly sensitive to the temperature gradient and increases nonlinearly with ΔT.

- **Energy conversion efficiency**

The calculated P/Q_{ref} conversion ratio (yield) remained low throughout the experiment, with values ranging from 0.0001% at minimal ΔT to a maximum of approximately 0.021% at peak operating conditions. Even under stable high-temperature conditions, this ratio did not exceed that value; as explained above, it is referred to the fixed reference power Q_{ref} = 180 W rather than to a per-point modelled heat flow, so it should not be interpreted as a directly measured thermoelectric conversion efficiency.

This limited efficiency reflects both the inherent constraints of thermoelectric conversion at relatively low temperature gradients and the thermal losses occurring within the system.

- **Observed thermal effects influencing performance**

The experimental data reveal several important physical phenomena affecting system performance:

- ✓ A temperature lag between the internal reactor temperature and the thermoelectric module temperatures, indicating significant thermal inertia.
- ✓ A reduced effective ΔT across the modules compared to the available thermal potential, suggesting heat transfer limitations.
- ✓ A gradual rather than instantaneous response of voltage output to temperature changes, further supporting the presence of thermal inertia in the system.

Additionally, the relatively low hot-side temperatures compared to the reactor interior suggest the presence of thermal resistance along the heat transfer path, which limits the effective utilization of the available heat.

Table 1

Summary of key operating points across the thermal cycle

Time point	T_ext (°C)	T_int (°C)	T_hot (°C)	T_cold (°C)	ΔT (°C)	V_out (V)	I (mA)	P (mW)	η (%)	Qref (W)
Start (t = 5 min)	6.3	8.3	5.8	3.5	2.3	0.020	1.0	0.010	0.0000056	180
Plateau onset (t = 65 min)	27.5	401.0	24.1	8.4	15.8	0.359	17.95	3.222	0.00179	180

Table 1 consolidates the recorded and derived quantities at five representative points of the thermal cycle, read directly from the logged dataset underlying Figures 17–24.

The heat flow used as the denominator in Eq. (6), Q_{ref} = 180 W, is a fixed reference power adopted for all five operating points, not a per-point value measured or derived from the thermal-resistance model developed in Materials and Methods; as discussed below, the hot-side and cold-side branches of that model imply markedly different per-point heat flows that cannot yet be reconciled into a single value, so a fixed reference was preferred for this comparison. Accordingly, the derived quantity reported in the η (%) column throughout this study is a conversion ratio referred to this fixed reference power, and should not be read as a directly measured thermoelectric conversion efficiency.

- **Uncertainty analysis**

A brief propagation-of-uncertainty estimate was performed for the peak operating point (Plateau end, t = 185 min). The temperature-gradient uncertainty is dominated by the thermal camera's manufacturer-stated accuracy (±2 °C or ±2%, whichever is greater). Since $\Delta T = T_{hot} - T_{cold}$ is derived from two such independent readings, the combined uncertainty is $\Delta(\Delta T) = \sqrt{(\Delta T_{hot}^2 + \Delta T_{cold}^2)} \approx \pm 2.8$ °C, i.e., approximately ±7% of the peak $\Delta T \approx 42.0$ °C. The output voltage and current were measured with a manufacturer-stated accuracy of 0.7-4.0%, taking a representative mid-range value of ≈2%, the corresponding uncertainty at the peak point is $\Delta V_{out} \approx \pm 0.02$ V and $\Delta I \approx \pm 1.2$ mA. Propagating these through $P = V \cdot I$ gives $\Delta P/P = \sqrt{((\Delta V/V)^2 + (\Delta I/I)^2)} \approx \pm 2.8\%$, i.e., $\Delta P \approx \pm 1.1$ mW on the peak power of 37.6 mW. These figures should be read as indicative rather than a full metrological budget, since the campaign consisted of a single run and repeatability could not be independently assessed; a repeated campaign under similar conditions would be needed to establish the run-to-run (Type A) component of the uncertainty.

- **Extrapolating the results**

Based on the experimental results obtained using a limited number of thermoelectric modules, a theoretical scaling of the system was performed to estimate the potential electrical output when utilizing the entire available heated surface of the reactor door. The total surface area of the door is approximately 2178.75 cm², and excluding the handle area, it remains with a usable area of 2128.75 cm². Assuming the use of standard thermoelectric modules with approximate dimensions of 4 × 4 cm (16 cm² per module), the maximum number of modules that can be mounted is 133 modules. By extrapolation, the total theoretical electrical power becomes approximately 1.25 W. Such power levels are sufficient for several agricultural and autonomous applications, including powering wireless sensor nodes (soil moisture, temperature, humidity), supplying microcontrollers and data logging systems, charging small batteries or supercapacitors for intermittent operation and supporting low-power IoT communication modules, such as LoRa-based systems.

This extrapolated value of 1.25 W should be read as an upper-bound estimate rather than an expected operating point. It assumes a uniform temperature gradient across the entire 2128.75 cm² usable door surface, equal to the $\Delta T \approx 42$ °C measured at the single, most favorably located four-module array in the present setup, and a linear scaling of the cooling capacity of the cold-side heat sinks with the number of modules. In a real 133-module array, both assumptions would degrade: the temperature gradient is expected to be non-uniform across such a large surface, and the shared ambient air volume would reduce the effective convective heat-transfer coefficient per module as module density increases, so the true achievable output at that scale is expected to fall below this estimate.

DISCUSSION AND PERSPECTIVES

Despite the successful generation of electrical power, the overall P/Qref conversion ratio (yield) remained low, with a maximum value of approximately 0.021%. This limited value can be attributed to several factors, including:

- the relatively small temperature gradient across the modules compared to the high source temperature;
- thermal losses due to insufficient heat exchanger optimization;
- the intrinsic limitations of commercially available Peltier modules when used as thermoelectric generators.

Another significant limiting factor identified is the imperfect thermal contact between the heat source and the thermoelectric modules. This interface-related issue represents one of the primary causes of temperature loss in the system. Due to surface irregularities, non-uniform pressure distribution, and microscopic air gaps, a portion of the available thermal energy is not effectively transferred to the hot side of the Peltier modules. This phenomenon is inherently difficult to quantify experimentally, as it depends on contact quality at a micro-scale level, which cannot be directly measured with conventional instrumentation. As a result, it introduces uncertainty in the effective temperature gradient and reduces the overall system performance.

Furthermore, the data suggest that the external temperature of the heat source increased significantly more slowly than the internal temperature, indicating thermal resistance between the reactor core and the module interface. This highlights a critical design limitation and suggests that improved thermal coupling mechanisms, for example enhanced heat sinks, conductive interfaces, or forced cooling on the cold side could substantially increase ΔT and, consequently, electrical output.

One of the primary perspectives for improving system performance lies in the optimization of thermal coupling between the heat source and the thermoelectric modules. As identified in the present study, imperfect contact surfaces and intermediate layers introduce significant thermal resistance.

Future work should focus on:

- the use of advanced thermal interface materials with higher conductivity,
- improved mechanical fixation methods to ensure uniform pressure distribution,
- surface treatment techniques for example polishing or machining to reduce micro-scale air gaps; and the integration of phase-change materials to buffer transient thermal loads and stabilize the temperature gradient across the modules, as recently demonstrated for other TEG configurations (*Karadirek G. et al., 2025*).

The experimental results demonstrate that thermoelectric energy recovery from a biochar production system is feasible, albeit currently limited by low conversion efficiency and thermal losses. However, the obtained data also provide a solid basis for extrapolating the system performance under improved design and scaling conditions.

A key perspective for enhancing the overall electrical output lies in the geometric scalability of the thermoelectric system. In the present configuration, only a limited number of Peltier modules were installed. Considering the available surface of the reactor door, approximately 52.5 × 41.5 cm, excluding a 5 × 10 cm area occupied by the handle, a significantly larger number of modules could be mounted in a dense arrangement.

From a theoretical standpoint, increasing the number of modules proportionally increases the total electrical output, provided that similar thermal conditions (ΔT) are maintained. Under such conditions, the system could transition from milliwatt-level generation, tens of mW measured experimentally with four modules, toward the sub-2 W range estimated in this study for a full-door array of 133 modules (see the extrapolation above); reaching higher power levels would require a larger heated surface, a higher module density, or thermal management improvements beyond the present door-mounted geometry.

This scaling potential enables the consideration of practical applications within the agricultural sector, particularly for low-power and distributed systems. The generated energy could be used for:

- powering wireless environmental sensors, such as soil moisture, temperature, humidity;
- supplying data acquisition and transmission modules in precision agriculture systems;
- charging low-power batteries or supercapacitors for autonomous field devices;
- supporting IoT-based monitoring platforms integrated into biochar or biomass processing units.

Such applications are especially relevant in remote or off-grid agricultural environments, where energy autonomy and sustainability are critical.

An additional promising aspect identified in this study is the presence of secondary heated surfaces within the biochar equipment, reaching temperatures of up to approximately 250 °C. These areas represent an untapped thermal resource that could be exploited using specialized high-temperature thermoelectric modules (e.g., modules based on materials optimized for medium-to-high temperature gradients).

The integration of such modules could significantly increase the overall energy recovery potential of the system by:

- expanding the effective heat exchange surface,
- utilizing multiple thermal zones with different temperature levels,
- enabling a more efficient distribution of thermoelectric conversion across the equipment.

In a combined configuration—where both the reactor door and secondary heated surfaces are utilized—the system could evolve into a multi-source thermoelectric harvesting platform, substantially improving total electrical output and system viability.

Nevertheless, achieving these improvements requires addressing the limitations identified in the current study, particularly:

- reducing thermal contact resistance;
- optimizing heat transfer pathways;
- improving cold-side cooling efficiency.

Overall, while the present experimental setup yields relatively low electrical efficiency, the results clearly indicate that through scaling, improved thermal integration, and the use of advanced thermoelectric materials, biochar production systems have the potential to power low-consumption auxiliary electronics — such as wireless sensor nodes, data loggers, and IoT communication modules — rather than to serve as a primary energy source, given the very low P/Qref conversion ratio (~0.021%) obtained in this study. In this targeted, auxiliary-power role, the approach can still contribute to energy self-sufficiency and sustainability in agricultural applications.

CONCLUSIONS

This research demonstrates that thermoelectric energy recovery from a biochar production system is technically feasible: the surface-mounted TEG array reached a maximum output voltage of 1.226 V, a peak power of 37.6 mW, and a maximum temperature gradient of 42.8 °C over a 335-minute heating cycle, consistent with the expected Seebeck-effect behavior.

The overall P/Q_{ref} conversion ratio, referred to the fixed reference power $Q_{ref} = 180$ W rather than to a per-point modelled heat flow (see Results), nonetheless remained very low (maximum ≈ 0.021%), driven primarily by imperfect thermal contact between the heat source and the module hot side and by the intrinsic limitations of Peltier modules repurposed as generators, as discussed above.

Scaling to the full reactor-door surface indicates that a multi-module array could reach power levels sufficient for low-consumption auxiliary electronics — wireless sensor nodes, data loggers, and IoT communication modules — though not for primary power generation.

Taken together, these results position TEG-based waste heat recovery from biochar production as a viable auxiliary-power source for agricultural monitoring applications, contributing to energy self-sufficiency in a targeted, realistic role rather than as a primary generation method.

Keywords: *orchard fruit-bag collection; air suction; airflow field analysis; orchard field test*

ABSTRACT
To address the environmental pollution caused by discarded non-biodegradable fruit bags in orchards, an air-suction orchard fruit-bag collection machine was developed. First, theoretical calculations and analyses were conducted on the key machine components to determine the main operating parameters. Kinematic analysis was then performed using ADAMS, and the airflow field was simulated using Fluent. Next, a prototype was manufactured. Based on multivariable response surface analysis conducted in Design-Expert, the optimal parameter combination was identified as a travel speed of 2 km/h, a suction-inlet air velocity of 15.5 m/s, and a helical-conveyor rotational speed of 66 r/min. Orchard field tests showed that, under the optimal operating conditions, the actual collection rate reached 82.5%, confirming that the machine met the intended design requirements.

摘要
针对果园废弃套袋纸不易降解、污染环境等问题，提出了气吸式果园套袋纸回收机的设计。首先对关键装置进行理论计算与分析，确定影响作业效果的关键因素，以此为基础进行ADAMS运动学分析和Fluent气流场仿真分析。然后进行样机研制，通过 Design-Expert 进行多因素响应面分析，确定整机的工作参数最佳组合为：行进速度为2 km/h、吸入口风速为15.5 m/s、螺旋输送装置转速为66 r/min。果园试验表明，在最佳工作参数下，样机试验回收率为82.5%, 验证本设计能够实现预期的工作效果。

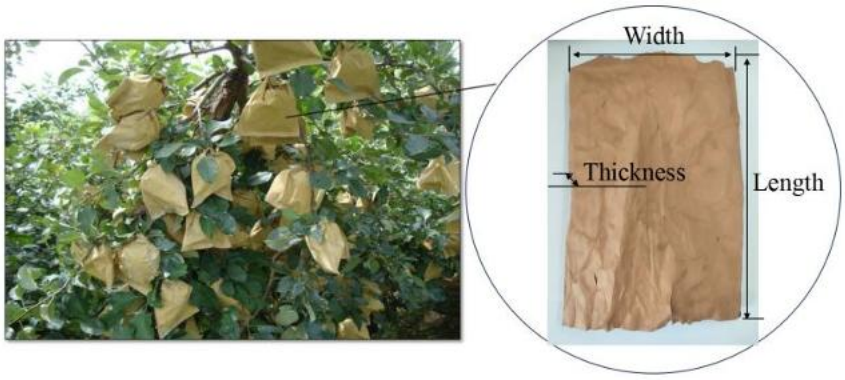
INTRODUCTION
The bagging of young fruit on trees has been widely adopted in orchards for crops such as apples, pears, and peaches. Taking apple orchards as an example, fruit bags not only help reduce pest and disease incidence and limit pesticide exposure but also significantly improve fruit appearance and quality *(Liu et al., 2024; Yu et al., 2022)*. To promote uniform coloration, the bags are generally removed approximately two weeks before harvest, after which they are often discarded in the orchard *(Hong et al., 2020; Kim et al., 2013)*. Because these fruit bags are primarily made from wood pulp with a high fiber content and also contain wet-strength agents and other additives, their natural degradation is limited *(Chen et al., 2024)*. Therefore, collecting the discarded fruit bags can reduce resource waste and help protect the orchard production environment *(Luo et al., 2011; Zhang et al., 2014)*.

Currently, waste fruit bags are collected primarily by hand, a process characterized by high labor requirements, high costs, and low efficiency. These limitations reduce orchard growers' willingness to participate in collection activities *(He et al., 2022; Cao et al., 2019)*. The lack of efficient mechanical collection equipment has therefore become a major constraint on the sustainable development of the fruit industry *(Cai et al., 2024; Bishnoi et al., 2023)*. Research on machinery specifically designed to collect discarded fruit bags in orchards remains limited both in China and internationally; however, relevant studies have been conducted on related collection equipment.

For example, Guo Wensong of China Agricultural University developed a brush-tooth mechanically driven film-separation device for collecting residual plastic film *(Guo et al., 2020; Wang et al., 2019)*. The brush teeth dislodged the residual film, after which negative-pressure airflow at the suction inlet lifted the film.

The collected material was then discharged by a centrifugal fan and separated using a mesh screen. In addition, Liu Enshui and colleagues at Tarim University used Fluent to simulate a gravity settling chamber and determine the optimal operating parameters of the collection device *(Liu et al., 2021; Wang et al., 2012)*.

Existing studies have focused mainly on residual-film collection machinery *(Peng et al., 2020; Hou et al., 2023; Wang et al., 2024)*, whereas research specifically addressing air-suction machines for collecting discarded fruit bags remains limited *(Ken et al., 2024; Ma et al., 2024)*. Although several machines based on relatively simple operating principles have been investigated, innovation in their collection mechanisms has been insufficient, limiting their ability to meet the practical requirements of large-scale discarded fruit-bag collection.



To address these challenges, an air-suction orchard fruit-bag collection machine was developed. The key components were analyzed theoretically to determine the main operating parameters. Kinematic simulations were then conducted in ADAMS, and computational fluid dynamics simulations were performed in Fluent to evaluate the mechanical and aerodynamic performance of the machine. A prototype was subsequently manufactured based on the theoretical analysis and simulation results. Response surface methodology was used to determine the optimal combination of operating parameters, with the collection rate selected as the response variable. Experimental results confirmed that the machine met the intended design requirements.

MATERIALS AND METHODS

Physical Characteristics of Discarded Fruit Bags

The physical characteristics of discarded fruit bags from apple orchards were determined through systematic sampling. A total of 100 discarded fruit bags were randomly collected and divided equally into 10 groups for statistical analysis. Their main physical properties were as follows: the mean length was 180 mm, the mean width was 147 mm, and the mean thickness was 2.2 mm. The coefficient of friction and the mean mass of a single bag were 0.52 and 5.6 × 10^{-3} kg, respectively. Representative fruit bags are shown in Fig. 1.

The terminal velocities of the fruit bags ranged from 2.9 to 5.6 m/s, whereas those of soil-clod impurities ranged from 11.5 to 15.0 m/s.

Fig. 1- Fruit bags and their dimensional characteristics

Overall Structure and Operating Principle

The air-suction fruit-bag collection machine mainly consists of a centrifugal fan, an air duct, a settling chamber, a helical conveyor, a direction-changing mechanism, a vertical scraper, a filter screen, a compression device, an engine, and a transmission system. The overall structure of the machine is shown in Fig. 2.

Power is transmitted from the power take-off shaft to the centrifugal fan through a belt-and-pulley drive, while the helical conveyor and vertical scraper are driven by chain-and-sprocket mechanisms. The rotating blades on both sides of the vertical scraper move the fruit bags toward the center, after which the helical conveyor further conveys them to the central collection area. A filter screen mounted at the bottom provides preliminary removal of impurities. The negative-pressure airflow generated by the centrifugal fan then draws the concentrated fruit bags into the settling chamber, where larger impurities are separated.

The cleaned fruit bags are subsequently conveyed through the air duct to the collection bin. Finally, the compression device compacts the bags, thereby completing the collection process.

The vertical scraper, helical conveyor, and settling chamber are the key components of the air-suction fruit-bag collection machine. Accordingly, the design and analysis of these components constitute the main focus of this study.

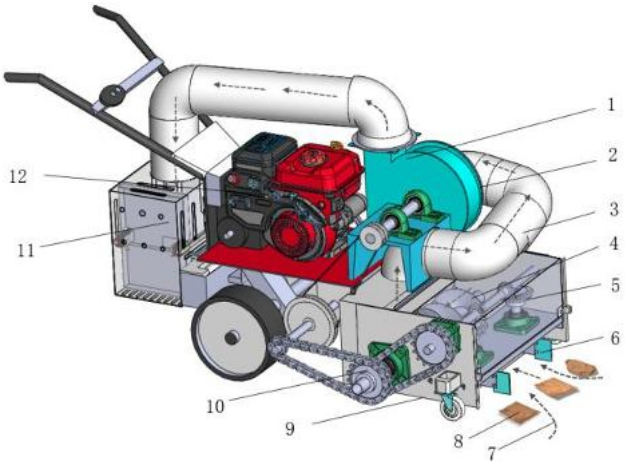

Fig. 2 - Structure of the air-suction fruit-bag collection machine

Design of the Vertical Scraper Collection Mechanism

The vertical scraper collection mechanism mainly consists of a horizontal drive shaft, two vertical rotating shafts, an adjustment plate, bearing housings, and two symmetrically arranged vertical scraper blades connected through a reversing mechanism. Power is supplied by the engine, and the rotational speed is reduced through belt, chain, and bevel-gear transmissions. The two meshing bevel-gear pairs rotate in opposite directions, ensuring that the left and right scraper blades move the fruit bags toward the center.

The operating principle of the vertical scraper collection mechanism is shown in Fig. 3. Power is transmitted to the horizontal drive shaft through a chain drive, causing the shaft to rotate clockwise. A small bevel gear mounted on the drive shaft engages with a large bevel gear, thereby driving the scraper blades on both sides to rotate inward and move the fruit bags toward the center. To ensure stable fruit-bag collection, an appropriate rotational speed of the scraper blades must be determined.

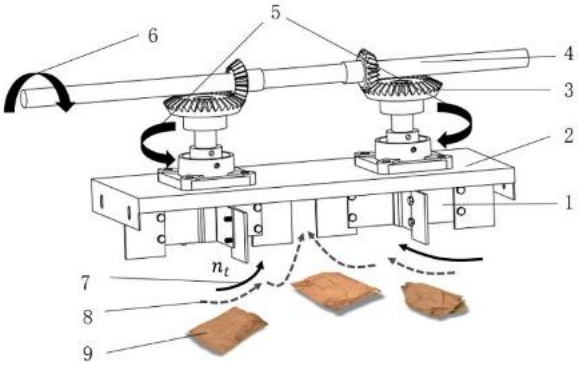

Fig. 3 - Operating principle of the vertical scraper collection mechanism

1. Scraper blades; 2. Adjustment plate; 3. Direction-changing mechanism; 4. Horizontal drive shaft; 5. Rotation direction of the vertical shafts; 6. Rotation direction of the drive shaft; 7. Rotation direction of the scraper blades; 8. Fruit-bag trajectory; 9. Fruit bag.

During operation, the vertical scraper collection mechanism relies primarily on the centrifugal force generated by the rotating scraper blades to move the fruit bags toward the center. A force analysis was conducted for the scraper blade, fruit bag, and bottom plate, and a rectangular coordinate system was established, as shown in Fig. 4. At the position illustrated, the fruit bag is subjected to the centrifugal force exerted by the scraper blade, the friction force acting along the bottom plate, the normal support force from the bottom plate, and its own weight.

Force equilibrium along the bottom plate indicates that the fruit bag can be conveyed into the collection mechanism only when the component of centrifugal force in the conveying direction exceeds the sum of the friction force and the component of gravity acting along the bottom plate.

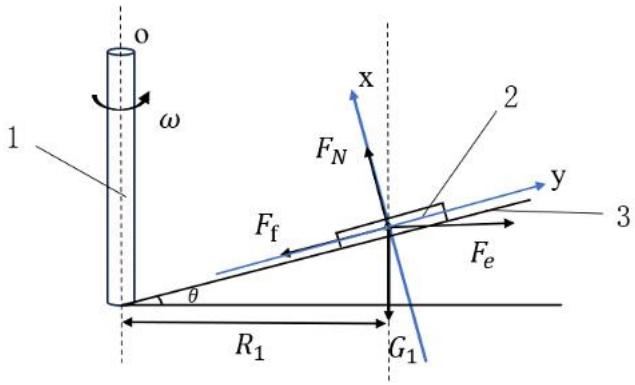

Fig. 4 - Force analysis of a fruit bag on the bottom plate

1. Vertical rotating shaft; 2. Fruit bag; 3. Bottom plate.

Force analysis:

$$\begin{cases} F_f + G_1 \sin\theta \le F_e \cos\theta \\ F_N = G_1 \cos\theta + F_e \sin\theta \end{cases} \quad (1)$$

where:

$$G_1 = m_l g \quad (2)$$

$$F_f = \mu F_N = \mu(m_l g \cos\theta + F_e \sin\theta) \quad (3)$$

where, F_e is the centrifugal force acting on the fruit bag, N; F_f is the friction force acting on the fruit bag, N; G_1 is the weight of the fruit bag, N; F_N is the normal support force exerted by the bottom plate, N; m_l is the mass of a single fruit bag, kg ; θ is the inclination angle of the bottom plate, set to 7°; μ is the coefficient of friction between the fruit bag and the bottom plate, set to 0.52.

Based on the measured physical characteristics, the mass of a single fruit bag was 5.6×10^{-3} kg. Substitution of the relevant parameters into Eqs. (1)–(3) showed that the centrifugal force acting on the fruit bag must exceed 3.77×10^{-2} N for the bag to be conveyed smoothly along the bottom plate and into the collection mechanism.

The centrifugal force generated during blade rotation is related to the blade rotational speed as follows:

$$F_e = m_l \omega_t^2 R_1 \quad (4)$$

$$\omega_t = \frac{\pi n_t}{30} \quad (5)$$

where, ω_t is the angular velocity of the scraper blades, rad·s^{-1}; R_l is the radial distance from the axis of rotation to the fruit bag, m; n_t is the rotational speed of the scraper blades, r·min^{-1}.

The minimum centrifugal force required for successful collection by the vertical scraper mechanism was calculated to be 3.77×10^{-2} N. According to Eqs. (4) and (5), when the blade radius was 0.18 m, the corresponding rotational speed of the scraper blades was 58.39 r·min^{-1}. Therefore, the vertical scraper mechanism can collect the fruit bags smoothly when the blade rotational speed exceeds 58.39 r·min^{-1}.

Design of the Helical Conveyor

To convey the fruit bags toward the center of the machine, a helical conveyor was designed. Helical blades were welded symmetrically to both sides of a hollow shaft, with equal numbers of blades arranged in opposite helical directions. Arc-shaped baffles closely followed the curvature of the rotating blades, thereby helping to prevent fruit-bag accumulation. A filter screen mounted at the bottom removed impurities such as weeds and soil clods. As shown in Fig. 5, the helical conveyor mainly consists of a hollow shaft, helical blades, arc-shaped baffles, a filter screen, and shock-absorbing wheels.

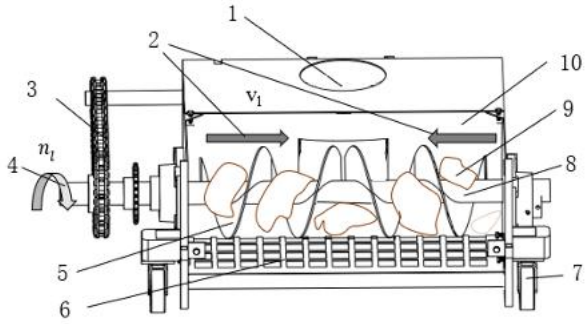

Fig. 5 - Structure and operating principle of the helical conveyor

1. Fruit-bag inlet; 2. Direction of fruit-bag movement; 3. Chain. 4. Rotation direction of the hollow shaft; 5. Helical blades; 6. Filter screen. 7. Shock-absorbing wheel. 8. Hollow shaft. 9. Fruit bag. 10. Arc-shaped baffle.

Based on the operating requirements of the collection machine, the principal geometric parameters of the helical blades were designed, including the outer diameter D_l, shaft diameter d_l, and pitch S_l.

To ensure that the fruit bags entered the helical conveyor smoothly and were conveyed from both sides toward the center, the helical-blade dimensions were selected according to the measured dimensions of the fruit bags. The structural parameters of the conveyor were determined with reference to the fruit-bag characteristics and the *Agricultural Machinery Design Manual*. Considering the physical properties of the fruit bags and the orchard operating environment, the blade outer diameter D_l, pitch S_l, and shaft diameter d_l were set to 160, 160, and 40 mm, respectively, to improve conveying efficiency.

During operation, an excessively low rotational speed of the helical blades may prevent the fruit bags from being conveyed promptly toward the center, resulting in accumulation on both sides. Conversely, an excessively high rotational speed may cause the blades to strike the bags, making them bounce and disrupting their movement toward the center. This may cause the bags to fall out of the conveying area. Therefore, the critical rotational speed of the helical conveyor must be determined.

To prevent accumulation and bouncing, the rotational speed of the helical conveyor should be maintained between the minimum speed required for effective conveying and the critical speed at which the fruit bags begin to lose stable contact with the conveyor. The critical condition was determined by comparing the centrifugal force acting on a fruit bag with its weight:

$$\frac{m_l \omega_l^2 D_l}{2} \leq m_l g \tag{6}$$

where:

$$\omega_l = \frac{\pi n_l}{30} \tag{7}$$

where, m_l is the mass of a single fruit bag, kg; ω_l is the angular velocity of the helical conveyor, rad·s^{-1}; g is the gravitational acceleration, m·s^{-2}; n_l is the rotational speed of the helical blades, r·min^{-1}.

Substituting Eq. (6) into Eq. (7) gives:

$$n_l \leq \frac{30}{\pi}\sqrt{\frac{2g}{D_l}} \tag{8}$$

The calculated critical rotational speed of the helical blades was 106.76 r·min^{-1}. Therefore, considering the previously determined minimum operating speed, the helical conveyor should operate within the range of 58.39–106.76 r·min^{-1}. Within this range, the conveyor can meet the requirements for stable fruit-bag conveying and collection while reducing the risks of blockage and bag bouncing.

Kinematic Simulation of the Helical Conveyor

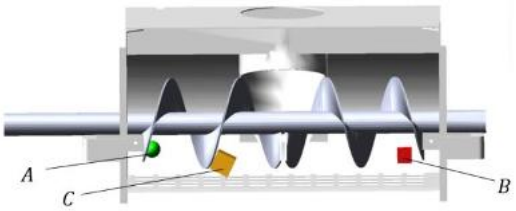
To evaluate the conveying performance of fruit bags in the helical conveyor, a kinematic simulation was conducted using ADAMS. Before analyzing the motion of the conveyor, kinematic constraints between the components and contact constraints between the fruit bags and the relevant machine parts were defined in the model. The simulation duration was set to 8 s, with 500 calculation steps. The constraint relationships are

listed in Table 1. Because the shape of the fruit bags varied, three representative bag shapes were included in the simulation, as shown in Fig. 6.

Table 1

Constraint relationships in the helical conveyor model

No.	Constraint type	Constrained components
1	Fixed joint	Frame–ground
2	Fixed joint	Helical blades–auger shaft
3	Revolute joint	Auger shaft–frame
4	contact	Fruit bag–frame
5	contact	Fruit bag–helical blades
6	contact	Fruit bag–auger shaft



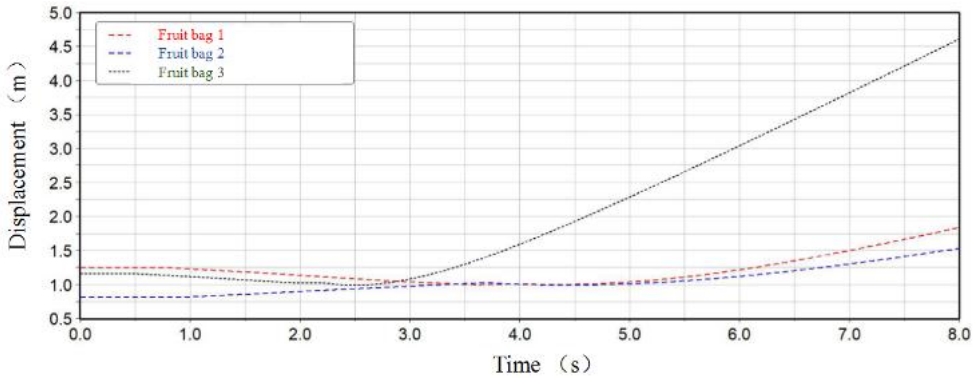


Fig. 6 - ADAMS model of the helical conveyor and representative fruit-bag shapes

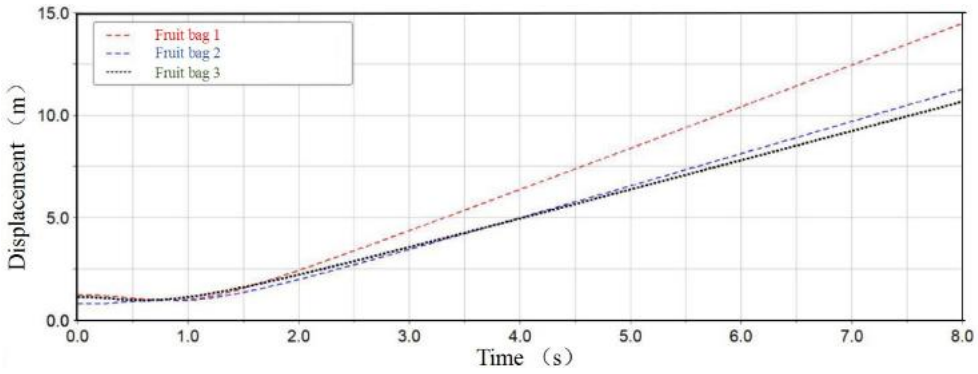

A, fruit bag 1, B, fruit bag 2, C, fruit bag 3.

Based on the simulation results, the displacement curves of the fruit bags at different helical-blade rotational speeds are shown in Fig. 7.

(a) Helical-blade rotational speed of 58.39 r·min⁻¹

(b)

(b) Helical-blade rotational speed of 106.76 r·min⁻¹

Fig. 7 - Displacement curves of the fruit bags at different helical-blade rotational speeds

As shown in Fig. 7, comparison of the displacement curves at helical-blade rotational speeds of 58.39 and 106.76 r·min⁻¹ indicates that a higher rotational speed produced greater fruit-bag displacement over the same period. All three representative fruit bags exhibited stable and smooth motion. These results demonstrate that the helical conveyor can reliably convey the fruit bags toward the center of the machine.

Design of the Settling Chamber

The settling chamber uses gravity-induced settling to separate fruit bags from impurities. It plays an important role in both fruit-bag recovery and impurity removal. The chamber mainly consists of a settling section, an inlet, and an outlet. Its structure and operating principle are shown in Fig. 8.

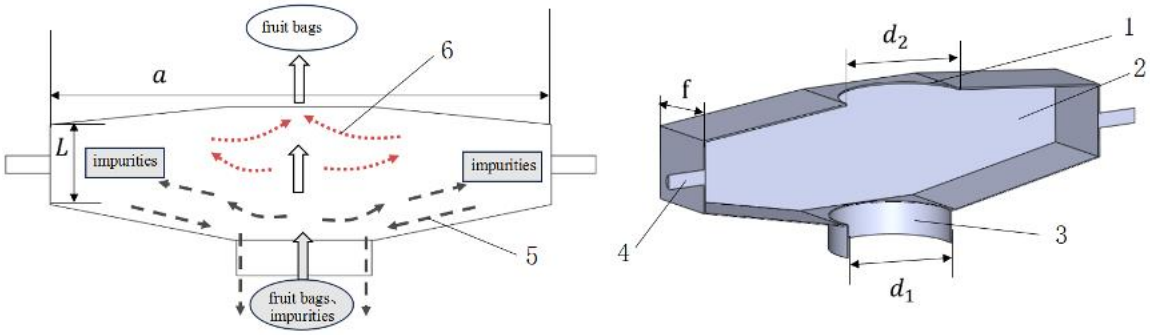

Fig. 8 - Structure and operating principle of the settling chamber

1. Air outlet; 2. Settling section; 3. Inlet; 4. Fixed shaft; 5. Impurity trajectory; 6. Fruit-bag trajectory. a, length of the settling chamber; f, half-width of the settling chamber; L, height of the settling chamber; d_1 is the inlet diameter; d_2, air-duct diameter.

Field investigations showed that, during fruit-bag collection, brittle weed residues were broken into smaller fragments by the vertical scraper and helical conveyor and were subsequently removed through the bottom filter screen. Only a small amount of large weed material entered the settling chamber. Therefore, the impurities reaching the settling chamber consisted mainly of small soil clods. To achieve effective separation of the fruit bags from the soil clods, the airflow velocity in the settling chamber had to be higher than the terminal velocity of the fruit bags but lower than that of the soil clods.

Assuming a constant volumetric airflow rate through the system, different airflow velocities can be obtained by designing the inlet and settling section with different cross-sectional areas. The corresponding airflow velocities were calculated using Eq. (9):

$$Q = v_1 A_1 = v_2 ab \tag{9}$$

where, Q is the volumetric airflow rate supplied by the centrifugal fan, m³·s⁻¹; v_1 is the airflow velocity at the inlet, m·s⁻¹; A_1 is the cross-sectional area of the inlet, m²; is the airflow velocity in the settling section, m·s⁻¹; *a* and *b* are the length and width of the settling section, respectively, m.

Considering that the mean fruit-bag length was 180 mm and that sufficient clearance was required for pneumatic conveying, both the air-duct diameter and the inlet diameter were set to 200 mm. Based on the measured terminal velocities of the fruit bags and soil clods, the airflow velocity in the settling chamber was set to 5.6 m·s⁻¹ to facilitate impurity separation. The settling-chamber length was set to 500 mm so that it was compatible with the overall dimensions of the collection mechanism. According to Eq. (9), the required settling-chamber width was calculated to be 224 mm.

Because the cross-sectional area gradually increased from the suction inlet to the settling chamber, the airflow velocity decreased through this transition region, thereby reducing the aerodynamic force acting on both the fruit bags and the soil clods. Effective separation occurred when the aerodynamic lifting force was sufficient to entrain the fruit bags but insufficient to carry the soil clods. Under these conditions, the fruit bags were conveyed upward by the airflow, whereas the soil clods settled under gravity and were discharged through the bottom screen rather than entering the collection bin. The resultant force acting on a soil clod is expressed by Eq. (10):

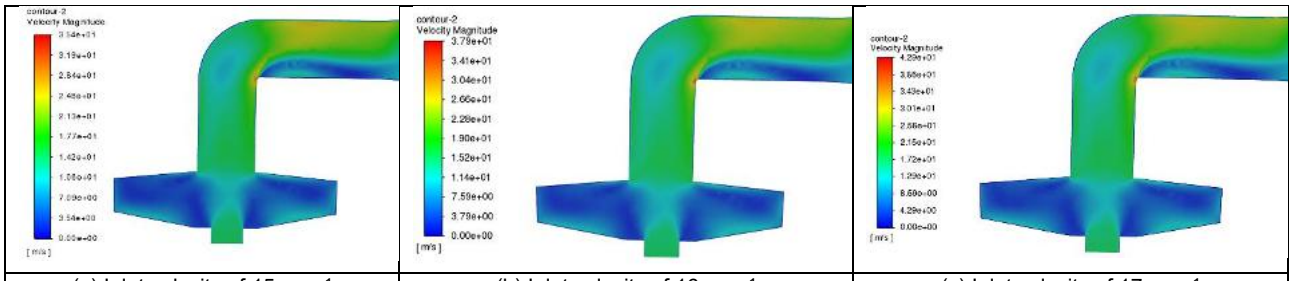
$$F = Kmv_2^{\,2} - mg = Kmv_2^{\,2} - Kmv_t^{\,2} = ma_1 \tag{10}$$

where, F is the resultant force acting on the soil clod, N; m is the mass of the soil clod, in kilograms，kg; g is the gravitational acceleration, taken as 9.8 m·s⁻²; K is the aerodynamic or buoyancy coefficient of the soil clod; v_t is the terminal velocity of the soil clod, m·s⁻¹; a_1 is the acceleration of the soil clod, m·s⁻².

As the aerodynamic lifting force gradually decreased, the soil clods moved upward under deceleration until their velocity decreased to zero, with the resultant acceleration being non-positive.

The upward travel distance of the soil clods was used to determine the required height of the settling chamber. This distance is expressed by Eq. (11):

$$-v_3^2 = 2a_1 h \tag{11}$$



where, h is the upward travel distance of the soil clod, m; v_3 is the initial upward velocity of the soil clod at the bottom of the settling chamber, m·s⁻¹.

Based on the structural requirements of the machine, the initial velocity of the soil clod at the bottom of the settling chamber was set to 5.6 m·s⁻¹. Substitution of the relevant parameters into Eq. (11) yielded a required settling-chamber height of 123 mm.

Airflow-Field Simulation Analysis of the Settling Chamber

The airflow field in the fruit-bag conveying system is highly complex. To characterize the airflow behavior, simulation analysis was conducted using Fluent. Velocity distributions were analyzed on cross-sections of both the settling chamber and the conveying duct, allowing the transport behavior of the fruit bags to be observed visually.

The measured terminal velocity of the fruit bags ranged from 2.9 to 5.6 m·s⁻¹. According to the empirical coefficient, the conveying airflow velocity should be 2.6-5.0 times the terminal velocity of the fruit bags. Considering the practical operating conditions and the need for impurity removal, the inlet airflow velocity should not be set excessively high. Based on a comprehensive assessment, inlet velocities of 15, 16, and 17 m·s⁻¹ were selected. The simulated airflow-velocity contours under these three inlet conditions are shown in Fig. 9.

(a) Inlet velocity of 15 m·s⁻¹ (b) Inlet velocity of 16 m·s⁻¹ (c) Inlet velocity of 17 m·s⁻¹

Fig. 9 - Airflow-velocity contours at different inlet velocities

As shown in Fig. 9(a), at an inlet velocity of 15 m·s⁻¹, the airflow velocity near the lower section of the settling chamber reached approximately 17 m·s⁻¹, allowing the fruit bags and impurities to be rapidly drawn into the chamber. As the cross-sectional area of the settling chamber increased, the airflow velocity gradually decreased from the central region toward both ends. The velocity at both ends was approximately 5.6 m·s⁻¹, which facilitated separation of the fruit bags from the impurities. In the upper section of the settling chamber, the cross-sectional area decreased abruptly, causing the airflow velocity to increase to approximately 18 m·s⁻¹ and enabling the fruit bags to be conveyed smoothly through the outlet.

As shown in Fig. 9(b), the conveying performance at an inlet velocity of 16 m·s⁻¹ was similar to that observed at 15 m·s⁻¹. Under this condition, the fruit bags were effectively separated from the impurities and conveyed smoothly through the outlet.

As shown in Fig. 9(c), when the inlet velocity was set to 17 m·s⁻¹, the airflow velocity near the lower section of the settling chamber reached approximately 21 m·s⁻¹, allowing both the fruit bags and impurities to enter the chamber. However, the airflow velocity in the middle section ranged from 8.59 to 12.9 m·s⁻¹. This range exceeded the terminal velocity of the soil-clod impurities, resulting in incomplete separation of the impurities from the fruit bags.

Based on these results, the inlet airflow velocity should be maintained between 15 and 16 m·s⁻¹ to ensure effective separation of the fruit bags from impurities and stable conveying through the system.

RESULTS

Orchard Field Test

Based on the preceding design and simulation analyses, a prototype was manufactured and tested in an apple orchard. The tree-row spacing ranged from 1,400 to 2,000 mm, while the within-row tree spacing ranged from 1,100 to 1,400 mm. The machine travel speed was varied from 1 to 3 km·h⁻¹. The orchard field test is shown in Fig. 10.

Fig. 10 - Orchard field test of the prototype

Experimental Design and Parameter Optimization

To determine the optimal combination of operating parameters, a three-factor, three-level response surface experiment was designed using Design-Expert. The selected test factors were machine travel speed (1~3 km·h⁻¹), inlet airflow velocity (15~16 m·s⁻¹), and *helical-conveyor* rotational speed (62~68 r·min⁻¹). The coded levels of these factors are presented in Table 2. The fruit-bag collection rate was selected as the response variable and was calculated as follows:

$$Y_1 = (1 - \frac{M_2}{M_1}) \times 100\% \quad (12)$$

where, Y_1 is the fruit-bag collection rate, %; M_2 is the mass of fruit bags remaining in the field after operation, kg; M_1 is the initial mass of fruit bags in the field before operation, kg.

Table 2

Coded levels of the experimental factors

Coded level	Factors		
	Travel speed (km·h⁻¹)	Inlet airflow velocity (m·s⁻¹)	Helical-conveyor rotational speed (r·min⁻¹)
-1	1	15	62
0	2	15.5	65
1	3	16	68

According to the experimental design, 17 experimental runs were conducted. The experimental design matrix and corresponding results are presented in Table 3. In the table, X_1, X_2, and X_3 represent the coded values of the three factors, while Y_1 denotes the fruit-bag collection rate.

Table 3

Experimental design matrix and collection-rate results

Run	Factors			Fruit-bag collection rate Y_1/%
	Travel speed X_1	Inlet airflow velocity X_2	Helical-conveyor rotational speed X_3	
1	1	1	0	74.8
2	0	0	0	83.5

Run	Factors			Fruit-bag collection rate Y_1/%
	Travel speed X_1	Inlet airflow velocity X_2	Helical-conveyor rotational speed X_3	
3	0	0	0	82
4	0	1	-1	78.1
5	1	-1	0	72.7
6	-1	-1	0	74.5
7	-1	0	1	80
8	0	-1	1	82.1
9	0	-1	-1	78.9
10	0	0	0	83.1
11	-1	1	0	71
12	1	0	1	78.5
13	0	0	0	82.7
14	0	0	0	83
15	1	0	-1	75.2
16	0	1	1	80.7
17	-1	0	-1	78.4

Multiple regression analysis was performed on the experimental data, and the analysis of variance (ANOVA) results are presented in Table 4. The overall regression model was highly significant ($P < 0.05$), whereas the lack of fit was not significant ($P > 0.05$), indicating that the model adequately described the experimental data. The terms X_3, X_1^2, and X_2^2 had highly significant effects on the fruit-bag collection rate. According to the reported *P*-values, X_1, X_2, and the interaction term X_1X_2 also had significant effects, whereas the remaining terms were not significant. Based on the reported main-effect results, the factors were ranked in descending order of their influence on the collection rate, Y_1, as follows: helical-conveyor rotational speed (X_3), inlet airflow velocity (X_2), and machine travel speed (X_1).

Table 4

Analysis of variance for the regression model of fruit-bag collection rate

Source	Collection rate				
	Sum of squares	df	Mean Square	*F*-value	*P*-value
model	238.81	9	26.53	26.37	< 0.0001**

Pure error	1.25	4	0.313		
Total	245.85	16			

Note: * Significant at ($0.01 \leq P \leq 0.05$); ** highly significant at ($P<0.01$).

To provide a more intuitive representation of the interaction effects of the factors on the fruit-bag collection rate, the response surface was generated from the experimental results and the regression model, as shown in Fig. 11. When the machine travel speed was held constant, the collection rate first increased and then decreased as the inlet airflow velocity increased, reaching a maximum when the inlet airflow velocity

ranged from 15.2 to 15.8 m·s⁻¹. In addition, the collection rate reached its highest value when the machine travel speed ranged from 1.5 to 2.5 km·h⁻¹.

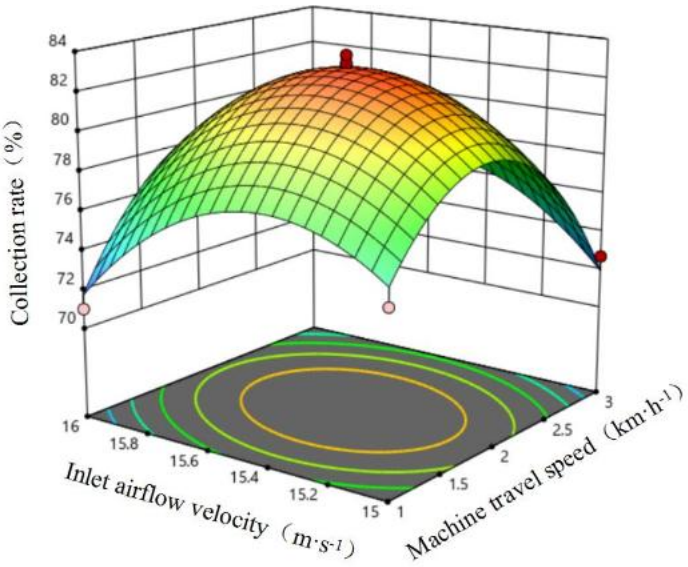

Fig. 11 - Effects of travel speed and inlet airflow velocity on the fruit-bag collection rate

Based on the ANOVA and response surface analyses, the regression equation for the fruit-bag collection rate, Y_1, was obtained as follows:

$$Y_1 = 82.86 - 0.3375X_1 - 0.45X_2 + 1.34X_3 + 1.4X_1X_2 - 5.77X_1^2 - 3.84X_2^2 \quad (13)$$

Considering the operating requirements of the air-suction fruit-bag collection machine, Design-Expert was used to optimize Eq. (13). The optimal parameter combination was a machine travel speed of 1.895 km·h⁻¹, an inlet airflow velocity of 15.509 m·s⁻¹, and a helical-conveyor rotational speed of 66.22 r·min⁻¹. Under these conditions, the model predicted a collection rate of 83.5%.

Experimental Results

The optimized parameters were rounded to practical operating values of 2 km·h⁻¹ for machine travel speed, 15.5 m·s⁻¹ for inlet airflow velocity, and 66 r·min⁻¹ for helical-conveyor rotational speed. Ten orchard field-test runs were conducted under these conditions. The mean collection rate was 82.5%, and the relative error between the predicted and measured values was 1.21%. The close agreement between the two values confirmed the reliability of the optimization model.

CONCLUSIONS

This study systematically investigated the environmental pollution caused by discarded fruit bags in orchards and their potential for recovery. An air-suction fruit-bag collection machine was designed, simulated, manufactured, and experimentally validated. The main conclusions are as follows:

(1) Based on the structural design and theoretical calculations, kinematic simulations of the helical conveyor were conducted using ADAMS, and airflow-field simulations of the settling chamber were performed using Fluent. The results showed that when the inlet airflow velocity ranged from 15 to 16 m·s⁻¹, the fruit bags could be effectively separated from the impurities and conveyed smoothly through the collection system.

(2) A prototype was manufactured based on the theoretical calculations and simulation results, and orchard field tests were conducted. Design-Expert was used to determine the optimal operating parameters. Under the optimized conditions, the measured collection rate was 82.5%. The field-test results confirmed that the machine met the intended design requirements.

Keywords: *high-moisture fields; rice-stubble wheat; seeding machinery; field tests*

ABSTRACT
To address the low quality of mechanized wheat seeding in rice-stubble fields in the middle and lower reaches of the Yangtze River, caused by high soil moisture content and heavy straw coverage, a press-groove uniform seeding machine was designed. Key mechanisms for rotary tillage, precision seedbed preparation, depth-controlled furrow formation, and banded soil covering were developed, and the overall transmission system and blade-roller arrangement were designed to create a wheat seeder suitable for high-moisture rice-stubble fields. Field tests showed that the vegetation coverage rate after operation was 94.2%, the qualified rate of seeding depth was 98.0%, and the coefficient of variation of seeding uniformity was 18.1%. The machine effectively reduced seed skips and exposed seeds during mechanized seeding in high-moisture fields.

摘要
针对长江中下游水旱轮作区稻茬农田土壤含水率高，秸秆覆盖量大等导致小麦机械化播种质量低的问题，本文设计一种压沟匀播机，研发了旋耕、种床精整、定深种沟成型、带状覆土等关键机构，完成了整机传动、刀辊排列等设计，创制一种适用于高湿稻茬农田的小麦播种机，田间试验表明，机具作业植被覆盖率为 94.2%，播深合格率达 98%，播种均匀性变异系数为 18.1%，有效解决了湿烂田机械化播种的“漏播”“露籽”等问题。

INTRODUCTION
The rice-wheat cropping system is the predominant agricultural production system in the paddy-upland rotation regions of the middle and lower reaches of the Yangtze River in China and represents the principal cropping pattern for these two staple grain crops in Jiangsu Province. With an annual planting area of approximately 2.7 million ha, Jiangsu accounts for about 35% of the national rice–wheat rotation area, making it the largest rice-wheat double-cropping region in China (*Gao, 2023; Zhang et al., 2021*). As of 2024, Jiangsu Province had more than 90,000 family farms engaged in grain production, with an average operating area exceeding 170 ha per farm. The continuing expansion of production scale has increased the demand for mechanized field operations, creating a need for further improvements in both the quality and technological level of agricultural mechanization (*Guan et al., 2022; Zhang et al., 2023*).

Because of the abundant seasonal rainfall during the wheat planting period, the soil is often heavy and cloddy, with large amounts of crop residue remaining on the field surface. Existing methods, such as shallow rotary tillage seeding and no-till strip seeding in residue-free fields, are poorly suited to these high-moisture operating conditions. Consequently, the uniformity of seeding depth and seed distribution during mechanized wheat seeding in rice-stubble fields often fails to meet agronomic requirements. Problems such as exposed seeds, seed clustering, seedling gaps, and broken ridges are particularly severe (*Chen et al., 2022*). To ensure an adequate field seed population, the seeding rate must be increased by two- to threefold, substantially increasing production costs (*Sun et al., 2024*). In addition, tractor traffic leaves deep wheel ruts, causing considerable disturbance to the field surface. The resulting seedbed is markedly uneven, which adversely affects subsequent rotary tillage and seeding operations.

Because of differences in cropping systems among countries, research on wheat seeding machinery for rice-stubble fields has been more extensive in China, whereas relatively few similar studies have been reported elsewhere. The main research objectives have been to reduce operating power consumption and improve seeding quality (*Aladdin et al., 2021*).

To address poor operating quality and low efficiency caused by soil adhesion and blockage of the rotary tiller during tillage in rice-stubble fields, *Liu Guoyang et al.* established constitutive and contact models for rice-stubble soil, investigated the soil detachment behavior from rotary tiller components, designed an anti-adhesion rotary tiller, and developed an intelligent vibration-assisted anti-adhesion rotary tiller (*Liu, 2024*).

Li Hongwen et al. designed a wide-width precision reduced-rate seeder for rice-stubble fields based on drainage and seeding requirements. The qualified rate of seeding depth was 86.7%, and that of fertilizer placement depth was 93.3% (*Hong Hu, et al., 2016*). To reduce power consumption during tillage, *Hao Jianjun et al.* designed a wedge-shaped drag-reducing rotary tiller. The results showed that, compared with a rotary tiller conforming to the national standard, the new machine was 8.3% lighter and reduced operating power consumption by 9.29% (*Hao Jianjun, et al., 2019*).

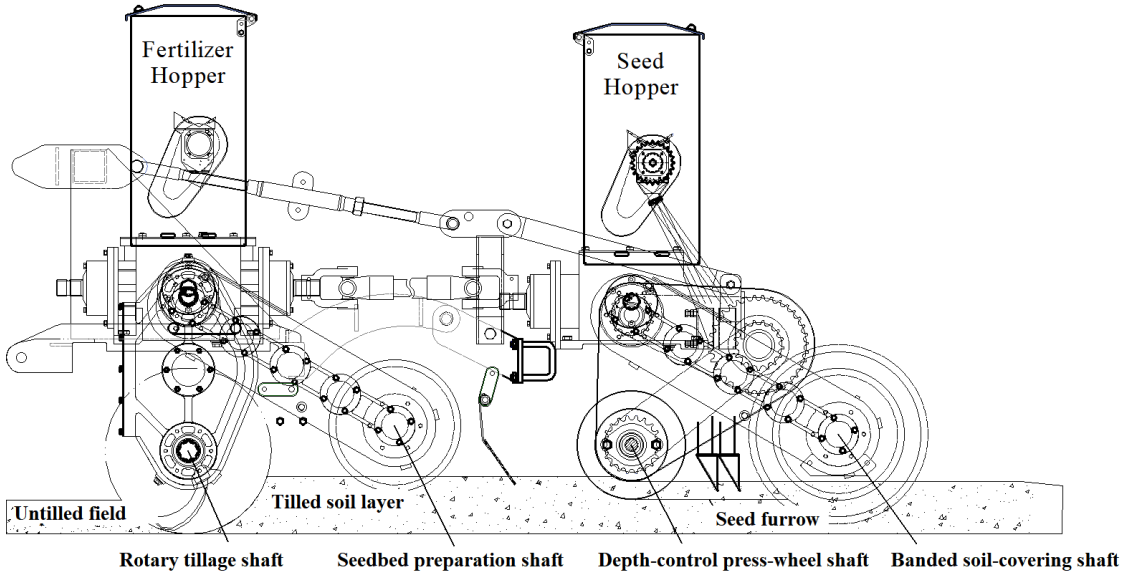
Matin et al. addressed the problem of poor seeding quality in paddy-upland rotation areas of Southeast Asia by designing a blade-roller structure equipped with a single row of six rotary tillage blades. Field tests showed that the new blade roller significantly improved seeding quality (*Matin M.A. et al., 2021*). Behera et al. compared the field performance of a rotary tiller and a combined tillage machine. The results showed that the torque requirement of the rotary tiller was 28% higher than that of the combined tillage machine, whereas its draft resistance and total power consumption were lower (*Behera et al., 2021*).

To address problems such as inconsistent seeding depth and poor seeding uniformity in wheat seeding in rice-stubble fields, the present study investigated a press-groove, depth-controlled uniform seeding technology for wheat in high-moisture rice-stubble fields. The proposed technology integrates rotary tillage and seeding, seedbed preparation under high-moisture conditions, and seeding-depth control. It is intended to improve seeding quality, reduce production costs, enhance operating efficiency and crop yield, and support high-quality, efficient, environmentally sustainable wheat production.

MATERIALS AND METHODS

Overall Design of the Seeding Machine

To meet the requirements for wheat seeding in high-moisture rice-stubble fields, the machine developed in this study integrates seedbed preparation and seeding-depth control functions. The corresponding mechanisms are arranged sequentially according to the operating process of fertilization, seedbed preparation (primary and secondary tillage), seed-furrow formation, in-furrow seeding, and banded soil covering. The machine consists of front and rear sections (Fig.1). The primary tillage unit, seedbed preparation unit, rear depth-control press wheel, and banded soil-covering shaft all use side-drive transmission. The two sections are connected by a three-point hitch, and power is introduced through the intermediate gearbox of the front section. The fertilizer-metering shaft and seed-metering shaft are both motor-driven and controlled by a synchronous control system to improve the field uniformity of seeding and fertilization.



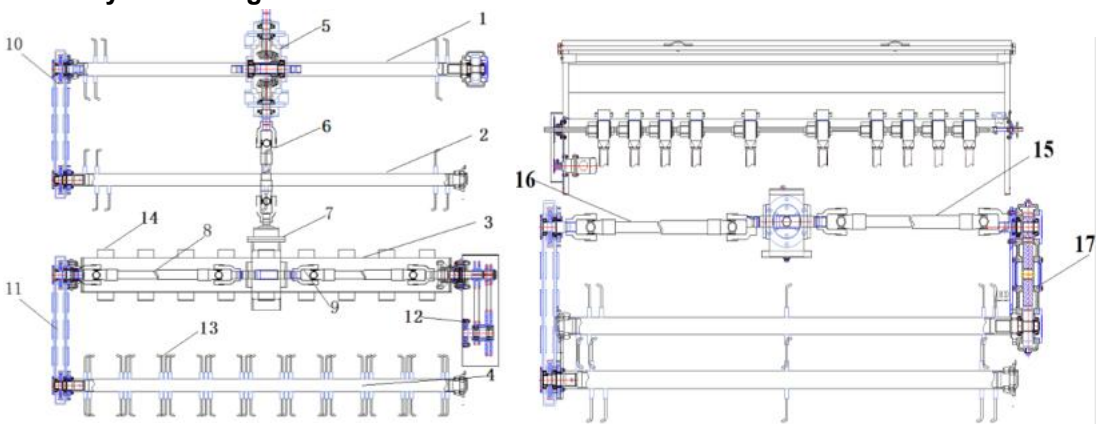


Fig. 1 - Overall schematic design of the seeding machine

The seeder is equipped with four working shafts and therefore has a relatively complex transmission system. Figures 2(a) and 2(b) show the top and front views, respectively, of the overall transmission layout. The transmission process is as follows. The tractor PTO is connected to intermediate gearbox *5*. Power is transmitted through universal-joint drive shaft *15* to side gearbox *17* and then to rotary tillage shaft *1*. Power is also transmitted through universal-joint drive shaft *16* to side gearbox *10* and then to seedbed-finishing shaft *2*. Meanwhile, intermediate gearbox *5* transmits power through universal drive shaft *6* to gearbox *7*, which distributes power to the seed-furrow-forming shaft and gearbox *11*. Gearbox *11* then drives soil-covering shaft *4* to complete the soil-covering operation. The transmission schematic is shown in Fig. 4.

Transmission System Design

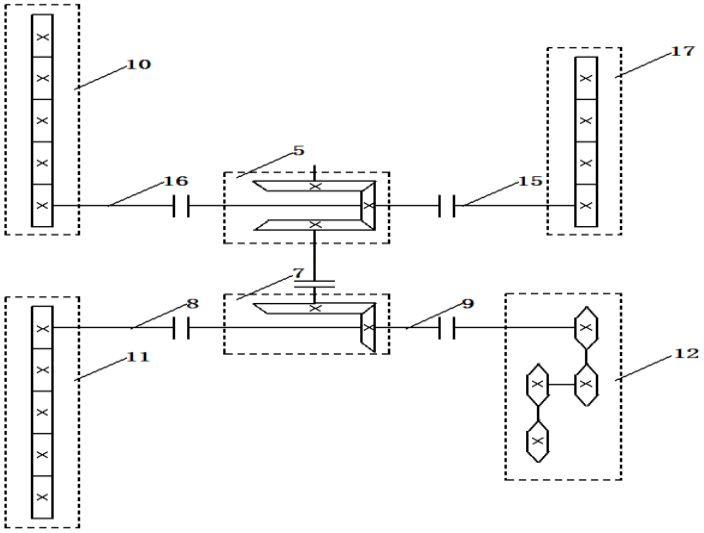

Fig. 3 - Schematic diagram of the transmission mechanism

The rotational speed of the blade shaft was determined using Eq. (1), which accounts for the machine forward speed, blade-shaft rotational speed, and soil-cutting pitch. Because rotary tillage requires a relatively high degree of soil fragmentation, the soil-cutting pitch should not be excessively large; a range of 60–90 mm was considered appropriate.

$$\frac{60V_m}{ZS_{max}} \leq n \leq \frac{60V_m}{ZS_{min}} \quad (1)$$

where: n is the blade-shaft rotational speed, rpm; V_m is the forward speed, m/s; Z is the number of cutting edges. The cutting pitch S was set to 80mm, the forward speed V_m to 1.3m/s, and Z to 2. Based on these values, the rotational speed of the rotary tillage shaft was determined to be 295 rpm, while that of the seedbed preparation shaft was 350 rpm.

Design of key working components

Rotary tiller shaft

The rotary tillage shaft is the main soil-engaging component during tillage and is also a major source of power consumption for the entire machine. Its design should account for force balance, reduced soil blockage, and minimized repeated cutting. In this study, the blades on the rotary tillage shaft were arranged primarily in a helical pattern to ensure balanced loading on both sides. The shaft had a total length of 2304 mm and was equipped with 72 blades, comprising left- and right-curved blades. Two blades were mounted on each cutting plane. The specific arrangement is shown in Fig. 5.

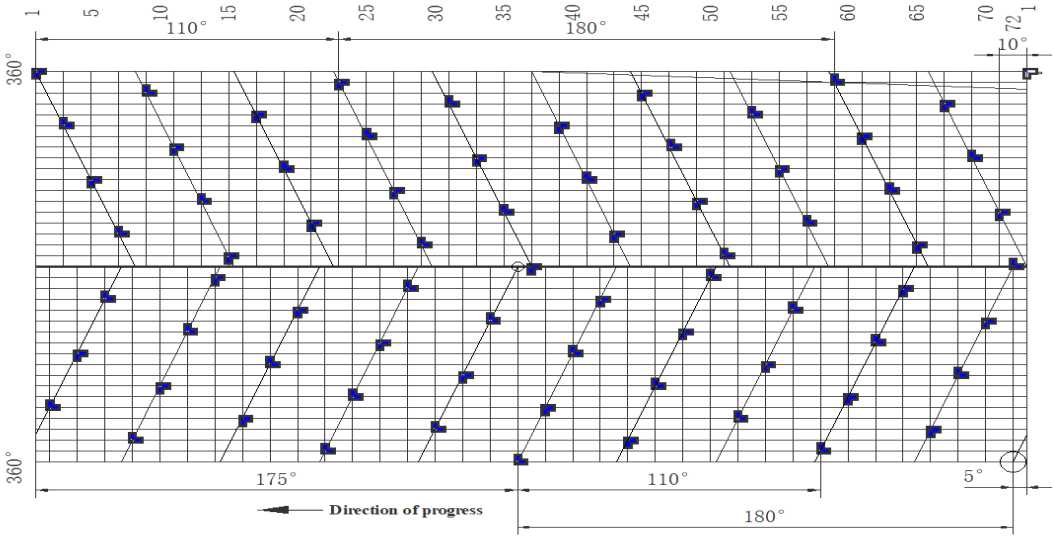

Fig. 4 - Blade arrangement on the rotary tillage shaft

Seedbed preparation shaft

The seedbed soil should be finely tilled and leveled before seeding to facilitate the seeding operation and improve seeding quality. The seedbed preparation shaft is a key component for seedbed preparation. In this study, a high rotational speed and a small rotation radius were adopted based on commonly used blade configurations. The blade rotation radius was set to 175 mm, and the blades were arranged primarily in a helical pattern. The shaft had a total length of 2310 mm and was equipped with 60 blades, comprising left- and right-curved blades. Two blades were mounted on each cutting plane. The specific blade arrangement is shown in Fig. 5.

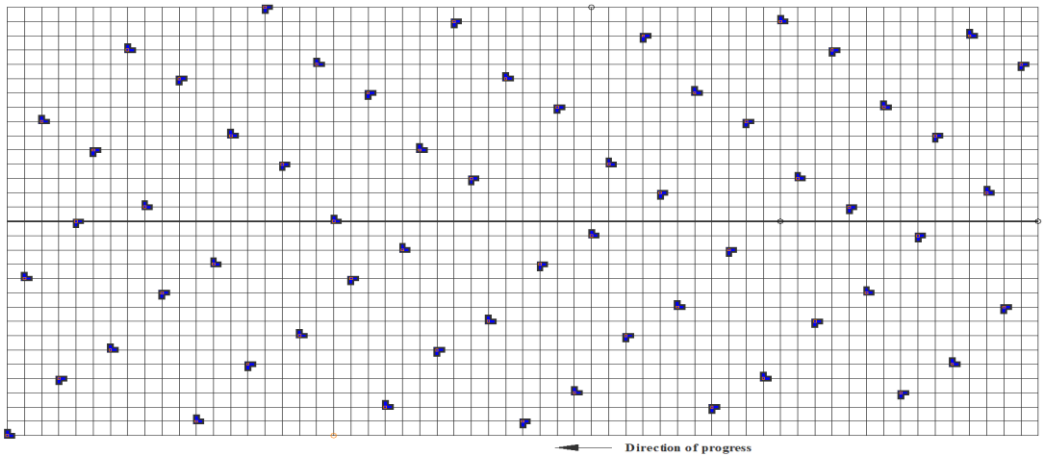

Fig. 5 - Blade arrangement on the seedbed preparation shaft

Depth-limiting press wheel shaft

Seed depth control was one of the technical difficulties in the sowing operation of high-land paddy fields with stubble. This paper aimed to improve the consistency of seed depth and reduce the "exposed seeds" phenomenon. A seed depth forming roller for sowing furrows had been designed. The width of the forming device could be determined according to the width of the seed band, as shown in Figure 6.

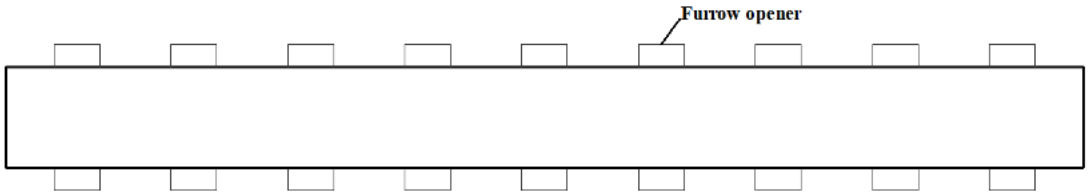

Fig. 6 - Schematic design of the depth-control press-wheel shaft

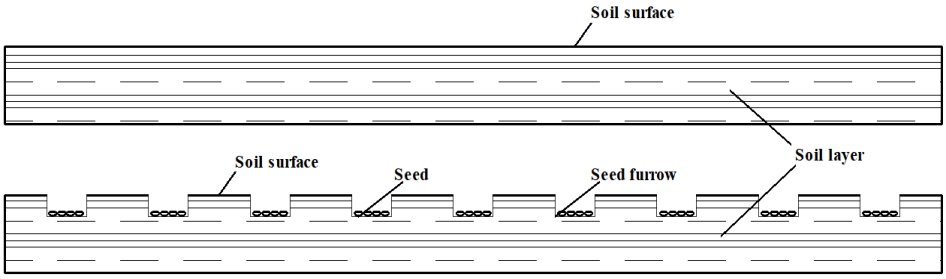

Fig. 7 - Schematic of the seeding operation

Banded soil-covering shaft

Determining the seeding depth is the first step in controlling seed placement depth, while the second step is to achieve a controlled amount of soil covering. Based on the principle of rotary soil covering, a banded soil-covering mechanism was designed, as shown in Fig. 8. The banded soil-covering shaft had a total length of 2304 mm. Nine soil-covering units were arranged in a helical pattern, with six rotary tillage blades in each unit, including four blades at each end, as shown in Fig. 9.

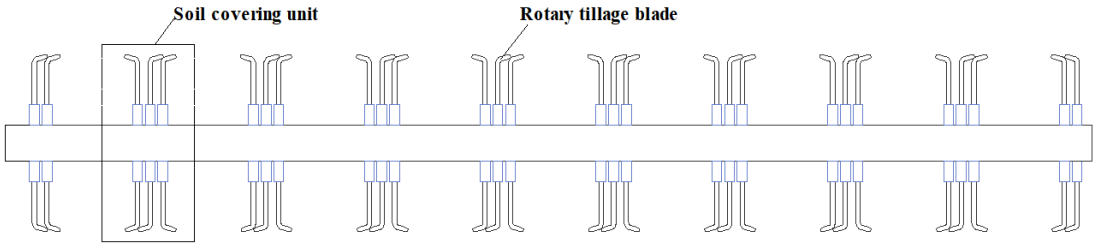

Fig. 8 - Soil-covering unit and rotary tillage blade

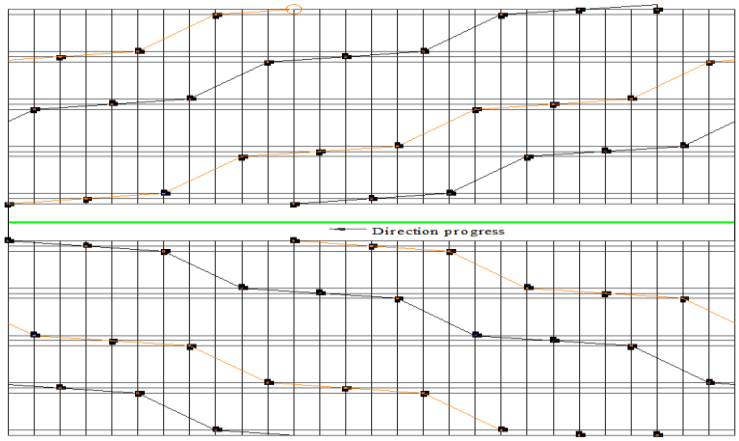

Fig. 9 - Blade arrangement on the banded soil-covering shaft

Experiment and results analysis

Experimental conditions

In October 2024, field tests of the rotary tillage, fertilization, furrow-pressing, and wide-row seeding machine for high-moisture rice-stubble fields were conducted at the Sihong Modern Agricultural Park in Shiji Town, Sihong County, Jiangsu Province. The wheat cultivar used in the tests was ‘Xumai 45’, with a thousand-grain weight of 46.1 g and a bulk density of 803 g/L.

The experimental field was 100 m long and 50 m wide. The rice row spacing was 14 cm, and the stubble height was 22.1 cm. The operating speed was set to 1.3 m/s, and a CFJ2004 tractor was used. The measured soil properties are presented in Table 1, and the field seeding test is shown in Fig. 10. The main instruments used in the tests included a soil moisture meter, soil firmness meter, stopwatch, and measuring tape.

Table 1

Soil properties

Soil depth [cm]	Moisture content	Bulk density [g/cm³]	Soil firmness [MPa]
0 ~ 10	31.2%	1.08	0.59
10 ~ 20	25.3%	1.32	1.68
20 ~ 30	20.5%	1.57	2.48

Fig. 10 - Field seeding operation

Evaluation indicators and methods

To evaluate the operating quality of the machine under high-moisture field conditions, the qualified rate of seeding depth, seeding uniformity, and vegetation coverage rate were selected as the main performance indicators. The specific evaluation methods were as follows.

Vegetation coverage rate

A large amount of straw residue remained on the field surface, which can adversely affect seeding quality and subsequent seedling emergence. Therefore, the vegetation coverage rate was evaluated. The test method followed the national standard GB/T 5668-2017, *Rotary Tiller*. Before and after operation, five sampling points were selected along the diagonal of the test area. At each sampling point, all stubble and straw lying on the soil surface within a 1 m² area were collected and weighed. The mean values before and after operation were then calculated (*Aqsiq et al., 2018*). The vegetation coverage rate was calculated using Eq. (2):

$$F_b = \frac{W_q - W_h}{W_q} \times 100 \quad (2)$$

where: F_b is the vegetation coverage rate, [%]; W_q is the mean mass of vegetation before operation, [g]; W_h is the mean mass of vegetation after operation, [g].

Qualified rate of seeding depth

According to the agricultural machinery evaluation guideline DG/T 027-2024, *Rotary Tiller and Seeder*, five test plots were selected in advance within three operating cycles. Thirty measurement points were established in each plot. After seeding and soil covering, the covering soil was carefully removed, and the thickness of the soil layer above the seeds was measured.

The proportion of measurement points with a seeding depth within (h ± 0.5) cm, where *h* is the locally specified agronomic seeding depth, was calculated as the qualified rate of seeding depth (*Agricultural Mechanization Station, 2024*).

Seeding uniformity

According to the agricultural machinery evaluation guideline DG/T 027-2024, the seeding operation was simulated in an open field at the specified operating speed. Seeds were deposited on a horizontal, straw-free surface. Three test plots were selected in advance. In each plot, six rows were measured, and 10 consecutive measurement sections were selected from each row. The coefficient of variation of seeding uniformity was calculated using Eqs. (3)–(6) (*Agricultural Mechanization Station, 2024*).

$$D = \sum_{i=1}^{3} D_i \quad (3)$$

$$X = \frac{1}{3}\sum_{i=1}^{3} X_i \quad (4)$$

$$G = \sqrt{\frac{1}{D}\sum(x - X)^2} \quad (5)$$

$$V = \frac{G}{X} \times 100\% \quad (6)$$

where:

D is the total number of measurement sections; D_i is the number of measurement sections in each test plot; X is the overall mean number of seeds per section; X_i is the mean number of seeds per section in each test plot; x is the number of seeds in an individual measurement section; G is the overall standard deviation; n is the number of measured rows; V is the coefficient of variation of seeding uniformity.

RESULTS AND ANALYSIS

Straw residue removal rate

Table 2

Straw residue mass before and after seeding

Pre-seeding residue mass		Post-seeding residue mass	
Measurement point	**Residue mass [g/m²]**	**Measurement point**	**Residue mass [g/m²]**
1	330.3	1	28.3
2	413.2	2	18.5
3	351.5	3	17.6
4	345.6	4	20.3
5	326.3	5	18.6
Mean	353.4	**Mean**	20.7
Residue removal rate [%]	94.2		

As shown in Table 2, the mean surface residue mass decreased from 353.4 g/m² before seeding to 20.7 g/m² after seeding, corresponding to a residue removal rate of 94.2%. This substantial reduction in surface residue provided favorable conditions for subsequent seed placement and seedling emergence.

Seeding depth

Table 3

Qualified rate of seeding depth

Indicator	Value
Total number of measurement points	150
Number of qualified points	147
Qualified rate of seeding depth [%]	98

As shown in Table 3, a total of 150 measurement points were evaluated, of which 147 met the specified seeding-depth requirement, resulting in a qualified rate of 98.0%. These results indicate that the machine achieved a high degree of seeding-depth consistency in high-moisture rice-stubble fields.

Seeding uniformity

Table 4

Seeding uniformity indicators

Indicator	Value
D	900
D_0	0
A	0
X	10.6
S	1.91
V [%]	18.1

As shown in Table 4, no empty measurement sections occurred during the seeding operation. The mean number of seeds per section was 10.6, with a standard deviation of 1.91. The coefficient of variation of seeding uniformity was 18.1%, indicating that the seeding performance remained within the acceptable range. The relatively high coefficient of variation may be attributed to the soft and slippery field surface, which could have affected machine travel stability and, consequently, seed distribution.

CONCLUSIONS

Based on the characteristics of the rice-wheat rotation system in the middle and lower reaches of the Yangtze River and the difficulty of controlling seeding depth in high-moisture fields, the following conclusions were drawn:

(1) A press-groove uniform seeding machine was designed, incorporating key mechanisms for seedbed preparation and precise seeding-depth control. The machine was developed to reduce seed skips and exposed seeds during mechanized wheat seeding in high-moisture rice-stubble fields.

(2) The machine incorporated a rotary tillage shaft with a helical blade arrangement, a seedbed preparation shaft, and a banded soil-covering shaft. The overall transmission system was designed and integrated into a complete seeding machine suitable for high-moisture rice-stubble fields. Field tests showed a straw residue removal rate of 94.2%.

(3) Compared with similar machines, it significantly improved the sowing quality. A depth-controlled furrow-pressing seeding method was developed. Field tests showed that the qualified rate of seeding depth reached 98.0%, while the coefficient of variation of seeding uniformity was 18.1%, indicating good seeding-depth consistency and acceptable seeding uniformity under the tested field conditions.

WRITING INSTRUCTIONS

Article Types

Three types of manuscripts may be submitted:

1. **Regular articles:** should describe new and carefully confirmed findings, and experimental procedures should be given in sufficient detail for others to verify the work. The length of a full paper should be the minimum required to describe and interpret the work clearly (recommended max.10 pages);
2. **Reviews:** must contain at least three basic elements: an introduction or background information section; the body of the review containing the discussion of sources; and, finally, a conclusion and/or recommendations section to end the paper. The length of a full paper should be the max. 20 pages (if the number of references is 80-100) and max. 45 pages (if the number of references is over 300).

Manuscripts should be written in English (American or British usage is accepted, but not a mixture of these) and submitted directly on the journal website. The 2nd, 3rd and the next versions can be sent by e-mail, ***inmatehjournal@gmail.com*** mentioning the registration number (N…).
Please be sure to include your full affiliation and e-mail address (see Sample manuscript)
The authors are responsible for the accuracy of the whole paper and references.
There are allowed 2 papers by each first author.
The text layout should be in single-column format. To avoid unnecessary errors it is strongly advised to use the "spell-check" and "grammar check" functions of your word processor.

Review Process

All manuscripts are reviewed by 2 members of the Scientifically Review Office. Decisions will be made as rapidly as possible and the journal strives to return reviewers' comments to authors in approx.3 weeks.
The editorial board will re-review manuscripts that are accepted pending revision.

NOTE:

Submission of a manuscript implies: that the work described has not been published before (excepting as an abstract or as part of a published lecture or thesis) that it is not under consideration for publication elsewhere.

1. REGULAR ARTICLES

- Manuscripts should be concise, in ***1.15 line spacing***, and should have 2 cm all over margins. The font should be ***Arial 10 pt.*** Ensure that each new paragraph is clearly indicated, using **TAB at 1 cm**.
- Title will be ***Arial 12 pt***. and explicit figures will be ***Arial 9 pt***.
- Text will be written in English.
- Chapters' titles are written by ***Arial 10 pt, Bold, Uppercase*** (e.g. **INTRODUCTION, MATERIALS AND METHODS**), between chapters is left a space for 10 pt. At the beginning of each paragraph, TAB of 1 cm.
- The paper body will be written in ***Arial 10 pt., Justify alignment***.

TITLE ***Arial 12 pt., Uppercase, Bold, Center*** *(in English language)* and ***Bold Italic*** *(in native language)*.
Should be a brief phrase describing the contents of the paper. Avoid long titles; a running title of no more than 100 characters is encouraged (without spaces).

AUTHORS ***ARIAL 9, Bold, Centre alignment***
Under the paper's title, after a space (enter) 9 pt., write ***authors' names*** and ***affiliations (Arial 8 pt.-Regular)***
When the paper has more than one author, their name will be followed by a mark (Arabic numeral) as superscript if their affiliation is different. Less than 6 authors.
Corresponding author's name (next row), ***(Arial 8 pt.)***. Should be added also: phone, fax and e-mail information, for the paper corresponding author (***font: 8 pt., Italic***).

KEYWORDS ***(In English)*** about 4 to 7 words that will provide indexing references should be listed (title: ***Arial 10pt, bold italic,*** text ***Arial 10 pt., italic***).
A list of non-standard *Abbreviations* should be added. In general, non-standard abbreviations should be used only when the full term is very long and used often. Each abbreviation should be spelled out and introduced in parentheses the first time it is used in the text. Standard abbreviations (such as ATP and DNA) need not to be defined.

ABSTRACT ***(in English and Native language, Arial 10 pt.)***, the title *bold*; the text of abstract: *italic*) should be informative and completely self-explanatory, briefly present the topic, state the scope of the experiments, indicate significant data, and point out major findings and conclusions. The Abstract should be max.250 words. Complete sentences, active verbs, and the third person should be used, and the abstract should be written in the past tense. Standard nomenclature should be used and abbreviations should be avoided. No literature should be cited.

INTRODUCTION (*Arial 10 pt.*) should provide a clear statement of the problem, the relevant literature on the subject, and the proposed approach or solution. It should be understandable to colleagues from a broad range of scientific subjects. We should refer to the current stage of researches performed in the field of the paper to be published, by quoting up-to-date specialty studies, preferably published after 2006, excepting certain referential specialty books/studies, especially papers issued in magazines/journals/conferences/ISI quoted symposia or in other international data bases, which are well known and available.

MATERIALS AND METHODS (*Arial 10 pt.*) should be complete enough to allow experiments to be reproduced. However, only truly new procedures should be described in detail; previously published procedures should be cited, and important modifications of published procedures should be mentioned briefly. Methods in general use need not be described in detail.

RESULTS (*Arial 10 pt.*) should be clarity presented. The results should be written in the past tense when describing findings in the authors' experiments. Results should be explained, but largely, without referring to the literature. Discussion, speculation and detailed interpretation of data should not be included in the Results, but should be put into the Conclusions section.

CONCLUSIONS (*Arial 10 pt.*) The main conclusions drawn from results should be presented in a short Conclusions section. Do not include citations in this section.

Formulae, symbols and abbreviations: Formulae will be typeset in Italics (preferable with the Equation Editor of Microsoft Office 2003) and should be written or marked as such in the manuscript, unless they require a different styling. They should be referred to in the text as Equation (4) or e.g. (4). The formulae should be numbered on the right side, between brackets *(Arial 10 pt.)*:

$$P = F \cdot v \tag{1}$$

Terms of the equation and the unit measure should be explained, e.g.

P is the power, [W];
F – force, [N];
v – speed, [m/s]

SI units must be used throughout.

Tables should be self-explanatory without reference to the text. The details of the methods used in the experiments should preferably be described in the legend instead of in the text. The same data should not be presented both in table and graph form or repeated in the text.
Table's title will be typed ***Arial 9 pt, Bold, Centered***
In the table, each row will be written Arial 9 pt, single-spaced throughout, including headings and footnotes.
The table should be numbered on the right side, ***Arial 10 pt.***

Figures ***(Arial 9 pt., Bold, Center)*** should be typed in numerical order (Arabic numerals). Graphics should be high resolution (e.g.JPEG). Figure number is followed by what represent the figure or graph e.g.:

Fig. 1 – Test stand

Legend: ***Arial 8 pt, Italic, Center,*** e.g.:
1 - plansifter compartments; 2- break rolls; 3 – semolina machines; 4 – reduction rolls; 5 – flour

ACKNOWLEDGMENTS (*Arial 10 pt.*) of people, grants, funds etc should be brief (*if necessarily*).

REFERENCES (*Arial 10 pt.*)
(In alphabetical order, in English and in the original publication language).
Minimum 10 references, last 10 years, minimum 3 references from the last 2 years

It can be used "*References*" tool from the *Word Editor*. **APA Style (American Psychological Association)**

Citations style

Text: All citations in the text may be made directly (or parenthetically) as bellow.

- ***single author:*** the author's name (without initials, unless there is ambiguity) and the year of publication:

"as previously demonstrated *(Brown, 2010)*".

- ***two authors:*** both authors' names and the year of publication: *(Adam and Brown, 2008; Smith and Hansel, 2006; Stern and Lars, 2009)*
- ***three or more authors:*** first author's name followed by "et al." and the year of publication: "As has recently been shown *(Werner et al., 2005; Kramer et al., 2000)* have recently shown ...."

Citations of groups of references should be listed first alphabetically, then chronologically.

Units, Abbreviations, Acronyms

- Units should be metric, generally SI, and expressed in standard abbreviated form.
- Acronyms may be acceptable, but must be defined at first usage.

2. REVIEWS

Reviews and perspectives covering topics of current interest in the field, are encouraged and accepted for publication. A review must have at least 80 references. It might give a new interpretation of old material or combine new with old interpretations. Or it might trace the intellectual progression of the field, including major debates. And depending on the situation, the literature review may evaluate the sources and advise the reader on the most pertinent or relevant.

Literature reviews must contain at least three basic elements: an introduction or background information section; the body of the review containing the discussion of sources; and, finally, a conclusion and/or recommendations section to end the paper.

The following provides a brief description of the content of each: Introduction: Gives a quick idea of the topic of the literature review, such as the central theme or organizational pattern. Body: Contains your discussion of sources and is organized either chronologically, thematically, or methodologically. Conclusions / Recommendations: Discuss what you have drawn from reviewing literature so far.
