	CONTENT Vol.79	Pag.
1.	**DESIGN AND SIMULATION OF A COMBINED SEED AGITATION PLATE FOR AN AIR-SUCTION PRECISION SEED METERING DEVICE WITH MULTIPLE-SEED-PER-HILL BASED ON DEM / *基于离散元的一穴多粒气吸式精密排种器组合型搅种盘设计与仿真*** **Zhiwei WANG[1)], Deyi ZHANG[1)], Sugirbay ADILET[2)], Naishuo WEI[1)], Yanwu JIANG[1)], Jianguo ZHOU[1)], Jun CHEN[1*)]** [1)] College of Mechanical and Electronic Engineering, Northwest A&F University, Yangling, Shaanxi, China; [2)] Research School of Veterinary Medicine and Agriculture, Shakarim University, Semey, Kazakhstan	**15**
2.	**SIMULATION AND OPTIMIZATION OF THE SEED METERING PLATE FOR AN AIR-SUCTION PRECISION SEED METERING DEVICE WITH MULTIPLE-SEED-PER-HILL BASED ON CFD / *基于CFD的一穴多粒气吸式精密排种器排种盘仿真与优化*** **Zhiwei WANG[1)], Yanwu JIANG[1)], Deyi ZHANG[1)], Sugirbay ADILET[2)], Naishuo WEI[1)], Jianguo ZHOU[1)], Jun CHEN[1*)]** [1)] College of Mechanical and Electronic Engineering, Northwest A&F University, Yangling, Shaanxi, China [2)] Research School of Veterinary Medicine and Agriculture, Shakarim University, Semey, Kazakhstan	**28**
3.	**DESIGN AND OPTIMIZATION OF A HUMAN–MACHINE COLLABORATIVE VIBRATION HARVESTING SYSTEM FOR LYCIUM BARBARUM L. / *枸杞人机协同振动采收系统设计与优化*** **Yahao GE[1)], Zeyu WANG[1)], Min WANG [1)], Yifan ZHANG [1)], Jun CHEN[1*)], Ming ZHANG [2)]** [1)] College of Mechanical and Electronic Engineering, Northwest A&F University, Yangling, Shaanxi, China [2)] Ningxia Zhengqi Hong Lycium barbarum L. Industrial Development Co., Ltd， Guyuan, China	**40**
4.	**STUDY ON NON-PARAMETRIC EXTRAPOLATION METHOD OF TRACTOR PTO LOAD BASED ON DBSCAN / *基于DBSCAN对拖拉机PTO的载荷非参数外推方法研究*** **Yin TANG, Shuaijie MA, Fuxi SHI*** College of Mechanical and Electronic Engineering, Northwest A&F University, Yangling /China	**51**
5.	**GRIPPING FORCE ESTIMATION FOR AN ROV ROBOTIC ARM IN INTENSIVE AQUACULTURE *ESTIMAREA FORȚEI DE PRINDERE PENTRU UN BRAȚ ROBOTIC ROV ÎN ACVACULTURĂ INTENSIVĂ*** **Dan CUJBESCU[1)], Iulian VOICEA[*1)], Cătălin PERSU[1)], Iuliana GĂGEANU[1)], Carmen Bălțatu[1)], Viorel FĂTU[2)], Vlad ARSENOAIA[3)]** [1)] National Institute of Research – Development for Machines and Installations Designed to Agriculture and Food Industry, Romania; [2)] Research Development Institute for Plant Protection (ICDPP); [3)] Faculty of Agriculture, Ion Ionescu de la Brad University of Agricultural Sciences and Veterinary Medicine, Iasi / Romania	**61**
6.	**DESIGN AND EXPERIMENTAL RESEARCH OF SELF-PROPELLED TOBACCO STEM HARVESTER / *自走式烟杆收获机设计与试验研究*** **Liquan YANG[1,2)], Guangyu YIN[1,2)], Rui FENG[1)], Junya HUANG[1)], Xiaodong LIU[1)], Jianbo WANG[1)], Dongwei YAN[1)], Qingqing L、[1, *)], Guangxi LI[1, *)]** [1)] Henan Province Engineering Research Centre of Ultrasonic Technology Application, [2)] Pingdingshan University, Pingdingshan, Henan, China; [2)] Pingdingshan Company, Henan Tobacco Company, Pingdingshan, Henan, China	**70**
7.	**DESIGN AND EXPERIMENTAL STUDY OF A RESIDUAL FILM BALING DEVICE / *残膜打包装置的设计与试验研究*** **Guan WANG[1)], Haolin WANG[2)], Zhihong TIAN[1)], Qi Wang[1)], Dong JI[1)], Fengbo LIU[1)*]** [1)] Liaoning Agricultural Vocational and Technical College, 76 Yucai Road, Yingkou, China; [2)] Design Department of Liaoning liaotuo Dayi Agricultural Machinery Co., Ltd, Fushun, China	**83**
8.	**APP-ENABLED WIRELESS LOOP RESISTANCE TESTING FOR EFFICIENT EVALUATION OF AGRICULTURAL POWER SYSTEM EQUIPMENT / *基于APP的无线回路电阻测试实现农业电力系统设备的高效评估*** **Yue YAO, Yanquan HOU*, Wei LI, Juntao ZHAO, Chen HUANG, Cen LI** State Grid Heilongjiang Electric Power Co., Ltd. Qitaihe Power Supply Company / P.R.China	**93**
9.	**DESIGN AND EXPERIMENT OF IWOA-OPTIMIZED FUZZY PID VARIABLE FERTILIZATION CONTROL SYSTEM FOR RICE BASED ON N-P-K HYBRID PRESCRIPTION GRAPH / *基于 N-P-K 融合处方图的 IWOA 优化模糊 PID 水稻变量施肥控制系统设计与试验*** **Kun ZHANG[1)], Lin WAN[*1,2)], Gang CHE[1,2)], Chun-sheng WU[3)], Xi-lu LI[*3)]** [1)] College of Engineering, Heilongjiang Bayi Agricultural University, Daqing, China [2)] Key Laboratory of Intelligent Agricultural Machinery Equipment in Heilongjiang Province, Daqing, China; [3)] Heilongjiang Province Agricultural Machinery Science Research Institute - Jiamusi Branch, Jiamusi China	**104**
10.	**THE BEHAVIOR OF VEGETABLE SEED PICK-UP USING A VACUUM SEED-METERING UNIT (VSMU) / *سلوك التقاط بذور الخضروات باستخدام وحدة تلقيم البذور بالشفط*** **Mohamed ABO-HABAGA[1)], Zakaria ISMAIL[1)], Mohamed SHALABY[1)], Mahmoud OKASHA[*2,3)]** [1)]Agricultural Engineering Department, Faculty of Agriculture, Mansoura University / Egypt [2)]Agricultural Engineering Research Institute (AEnRI), Agricultural Research Center (ARC), Giza / Egypt [3)]Department of Agricultural, Food, Environmental and Animal Sciences (DI4A), University of Udine, Udine / Italy	**115**

11.	**APPLICATION OF LLM + ZERO-SHOT LARGE MODELS FOR FRUIT OBJECT DETECTION /** *应用LLM + Zero-Shot大模型实现水果目标检测* **Yingdong QIN [1,2,3,*], Haoyu SONG [1,2,3], Jingyi LI [4], Keyao WEN [1]** [1] College of Artificial Intelligence and Low-Altitude Technology, South China Agricultural University, Guangzhou, China; [2] National Center for International Collaboration Research on Precision Agricultural Aviation Pesticides Spraying Technology (NPAAC), South China Agricultural University, Guangzhou, China; [3] Center for International Cooperation and Disciplinary Innovation of Precision Agricultural Aviation Applied Technology ('111 Center'), South China Agricultural University, Guangzhou, China; [4] School of Statistics and Data Science, Guangdong University of Finance & Economics, Guangzhou, China	**125**
12.	**A LIGHTWEIGHT TEA BUD DETECTION METHOD FOR ONLINE GRADING OF FRESH TEA LEAVES BASED ON IMPROVED YOLOV11N /** *一种基于改进YOLOv11n的面向茶鲜叶在线分级的轻量化茶芽检测方法* **Wenguang ZHENG *), Xinyong SHI, Rongyang WANG** School of Mechanical Engineering & Automation, University of Science and Technology Liaoning, Anshan, China School of Intelligent Manufacturing and Elevator Mechanics, Huzhou Vocational and Technical College, Huzhou, China	**134**
13.	**PRECISION INTEGRATED DECISION-MAKING AND CONTROL SYSTEM FOR WATER AND FERTILIZER MANAGEMENT IN ORCHARDS BASED ON THE INTERNET OF THINGS AND CLOUD PLATFORM /** *基于物联网与云平台的果园水肥一体化精准决策控制系统设计* **Kang NIU*, Hongze GUO, Weipeng ZHANG, Bo ZHAO, Guopeng ZHANG, Liming ZHOU** State Key Laboratory of Agricultural Equipment Technology, Chinese Academy of Agricultural Mechanization Sciences Group Co., Ltd., Beijing, China	**149**
14.	**THERMAL ENVIRONMENT IMPROVEMENT AND PARAMETER OPTIMIZATION OF WET CURTAIN FAN VENTILATION IN A GREENHOUSE: A CFD STUDY WITH EXPERIMENTAL VALIDATION /** *温室湿帘风机通风热环境改善与参数优化：CFD研究与实验验证* **Huanran SUN[1, 2], Binguang JIA[*3], Ziye SONG[4]** [1]Shandong Huayu University of Technology, Dezhou, China; [2]Shandong Engineering Research Center of Low-Carbon Energy Internet of Things Technology, Dezhou, China; [3]Department of Mechanical and Electrical Engineering, Jinan Engineering Polytechnic, Jinan, China; [4]Civil and Transportation Engineering College, Weifang University, Weifang, China	**163**
15.	**A REVIEW ON THE DEVELOPMENT STATUS AND TRENDS OF KEY TECHNOLOGIES FOR HYBRID TRACTORS /** *混合动力拖拉机关键技术发展现状及趋势综述* **Zhaoyue LIU[1], Jikang XU※[1], Xiaodong LV[1], Jinliang LI[2]** [1] Qingdao Agricultural University/ China; [2] Lingong Agricultural Equipment Co., Ltd. / China	**175**
16.	**EXPERIMENTAL STUDY AND ANALYSIS ON MECHANICAL PROPERTIES OF CASSAVA ROOTS AT HARVESTING STAGE /** *收获期木薯块根力学特性试验研究与分析* **Guanghao XU[1], Wenwen LI[1,3], Jiannong SONG[2], Binfeng SUN[1], Zhongsheng CAO[1], Junbao HUANG[1], Xinyi PENG[1], Yanda LI[1*]** [1] Institute of Agricultural Engineering, Jiangxi Academy of Agricultural Sciences, Nanchang / China; [2] College of Engineering, China Agricultural University, Beijing / China [3] College of Engineering, Jiangxi Agricultural University, Nanchang / China	**204**
17.	**RESEARCH AND ANALYSIS ON THE OPERATING PERFORMANCE OF RIDGE ROLLERS UNDER DIFFERENT OPERATING MODES /** *起垄机不同作业模式下作业性能研究与分析* **Xin ZHANG[1], Yucheng LIANG[1*], Lu GAN[1], Yanliang ZHANG[1], Yiwen YUAN[2]** [1] Heilongjiang Academy of Agricultural Machinery Engineering Sciences, Harbin, China [2] College of Mechanical and Electrical Engineering, Heilongjiang University, Harbin, China	**216**
18.	**REAL-TIME AND PRECISE DETECTION OF FIELD SOYBEAN RUST AND BACTERIAL SPOT BASED ON IMPROVED YOLOV11N /** *基于改进 YOLOv11n 的田间大豆豆锈病与细菌性斑点病实时精准检测* **Tianhao WU, Yongcai MA*, Hanyang WANG** College of Engineering, Heilongjiang Bayi Agricultural University, Daqing / China	**229**
19.	**DESIGN AND IMPLEMENTATION OF A VISUAL MONITORING SYSTEM FOR PADDY FLOW INSTABILITY IN INTELLIGENT HUSKERS /** *面向智能砻谷机的稻谷料流失稳视觉监测系统设计与实现* **Min CHENG[*1], Shihao ZHOU[1], Yong PAN[2], Xingchuang WANG[1]** [1] School of Mechanical and Electrical Engineering, Henan University of Technology, Zhengzhou / China; [2] School of Intelligent Engineering, Henan Mechanical and Electrical Vocational College, Zhengzhou / China	**239**

20.	**LENGTH OF CLOSED FISHTAIL-SHAPED TURNS AND HEADLAND WIDTH WHEN PLOUGHING WITH A REVERSIBLE PLOUGH IN AN IRREGULARLY SHAPED FIELD / *ДЪЛЖИНА НА ЗАТВОРЕНИ ГЪБОВИДНИ ЗАВОИ И ШИРОЧИНА НА ИВИЦАТА ЗА ЗАВИВАНЕ ПРИ ОРАН С ОБРЪЩАТЕЛЕН ПЛУГ В ПОЛЕ С НЕПРАВИЛНА ФОРМА*** **Krasimir TRENDAFILOV** Trakia University – Stara Zagora, Faculty of Technics and Technologies – Yambol, Department of Mechanical Engineering/ Bulgaria	**249**
21.	**ENAS-BASED YOLOv8 IMPROVEMENT WITH JOINT STRUCTURE AND LOSS SEARCH FOR CORN SEEDLING AND WEED DETECTION /** ***基于ENAS的YOLOv8改进方法：结合结构与损失函数搜索实现玉米幼苗与杂草检测*** **Junnan HU [1)], Hanyang WANG *[11)], Yongcai MA [1)], Dan LIU [2)]** [1)] College of Engineering, Heilongjiang Bayi Agricultural University, Daqing, Heilongjiang/ China [2)] College of Civil Engineering and Water Conservancy, Heilongjiang Bayi Agricultural University, Daqing, Heilongjiang / China	**259**
22.	**RESEARCH ON MULTI-OBJECT TRACKING OF PIGS BASED ON IMPROVED BYTE TRACK / *基于改进ByteTrack的多目标生猪跟踪研究*** **Jinhang MU[1,2)] , Yiran LIU[1)] , Lingqing FENG*[,1)]** [1)] College of Information Science and Engineering, Shanxi Agricultural University, Taigu, China [2)] School of Computer Science and Technology, North University of China, Taiyuan, China	**269**
23.	**EXPERIMENTAL INVESTIGATION OF A MACHINE FOR LOCAL STRIP APPLICATION (MLSA) OF SAPROPEL-BASED ORGANIC FERTILIZER MIXTURES / *ЕКСПЕРИМЕНТАЛЬНІ ДОСЛІДЖЕННЯ МАШИНИ ДЛЯ ЛОКАЛЬНОГО СМУГОВОГО ВНЕСЕННЯ (МЛСВ) ОРГАНІЧНИХ ДОБРИВ НА ОСНОВІ САПРОПЕЛЮ*** **Igor TSIZ, Volodymyr DIDUKH, Serhiy KHOMYCH, Victor TARASYUK, Roman KHLOPETSKYI** Lutsk National Technical University / Ukraine	**278**
24.	**STUDY ON THE EFFECTS OF MOISTURE CONTENT ON THE COMPRESSIVE MECHANICAL PROPERTIES OF SWEET POTATO ROOTS / *含水率对甘薯块根压缩力学特性的影响研究*** **Shuai GAO, Yuecheng WU, Kaiyan XIN, Ping ZHAO[*)]** College of Engineering, Shenyang Agricultural University, Shenyang, Liaoning, China	**288**
25.	**FROM HARVEST TO PACKAGE: AN AUTONOMOUS ROBOT FOR INTEGRATED TOMATO PICKING AND BAGGING / *用于番茄一体化采摘与包装的自主机器人*** **Yanhua YING, Dongya LI *, Jiahui HU, Yujie ZHOU, Yubo LI** College of Engineering, Applied Technology College of Soochow University, Suzhou, China	**299**
26.	**STRUCTURAL DESIGN AND VISION-BASED TARGET DETECTION AND LOCALIZATION OF A DESERT SHRUB STUBBLE-CUTTING MACHINE / *沙生灌木平茬机的结构设计与基于视觉的目标检测与定位*** **Weiqi WU[1)], Haitang CEN*[1)], Wang GUO[2)], Wei ZHANG[1)]** [1)] School of Mechanical Engineering, Inner Mongolia University of Technology, Hohhot / China; [2)] Inner Mongolia Academy of Science and Technology, Hohhot / China	**311**
27.	**SMOOTH-PLANNER: A ROBUST GRADIENT-BASED LOCAL TRAJECTORY PLANNING METHOD FOR NON-HOLONOMIC ORCHARD ROBOTS/** ***SMOOTH-PLANNER：一种面向非完整约束果园机器人基于梯度的鲁棒局部轨迹规划方法*** **Fanjun MENG, Fa SUN, Mengmeng NI, Zhisheng ZHAO, Lili YI*** School of Agricultural Engineering and Food Science, Shandong University of Technology, Zibo / China	**323**
28.	**RECENT ADVANCES SURVEY IN COMPUTER VISION AND ARTIFICIAL INTELLIGENCE FOR FRUIT DETECTION / *TINJAUAN KEMAJUAN TERKINI TEKNOLOGI PENGLIHATAN KOMPUTER DAN KECERDASAN BUATAN DALAM PENGESANAN BUAH*** **Qi LIU[1)], Puteri Suhaiza binti SULAIMAN[1*)], Mas Rina binti MUSTAFFA[1)], Zainal bin Abdul KAHAR[1)], Lian BAI[2)], Huicai XU[1)]** [1)] Faculty of Computer Science and Information Technology, Universiti Putra Malaysia, Serdang, Selangor, Malaysia [2)] College of Software, Shanxi Agricultural University, Taigu, Shanxi, China	**332**
29.	**DESIGN AND PERFORMANCE TESTING OF AN AUTOMATIC ORIENTATION AND CONVEYING DEVICE FOR POSTHARVEST CABBAGE TRIMMING BASED ON A CONICAL TREAD / *基于圆锥踏面的采后甘蓝自动定向输送装置设计及试验*** **Gongpei CUI [1)], Yu ZHANG [1)], Huanhuan CHEN [1)], Yongjie CUI [2,3,4)], Jing ZHANG [1)], Dongdong LI [1)], He LI [1)], Wanzhang WANG [*1)]** [1)] College of Mechanical and Electronic Engineering, Henan Agricultural University, Zhengzhou, China; [2)] College of Mechanical and Electronic Engineering, Northwest A&F University, Yangling, China; [3)] Key Laboratory of Agricultural Internet of Things, Ministry of Agriculture and Rural Affairs, Yangling, China; [4)] Shaanxi Key Laboratory of Agricultural Information Perception and Intelligent Service, Yangling, China	**351**

30.	**KINEMATIC ANALYSIS AND OPTIMAL DESIGN OF THE SEPARATION CONVEYOR DEVICE FOR *PANAX NOTOGINSENG* COMBINE HARVESTER** **Ibrahim Issa Mohamed ISSA[1,3*)], Zhaoguo ZHANG[1,2,3*)], Faan WANG[2,3)], Altyeb Ali Abaker OMER[4)], Wael EL-KOLALY[5)]** [1)] Faculty of Mechanical and Electrical Engineering, Kunming University of Science and Technology, Kunming, China; [2)] Faculty of Modern Agricultural Engineering, Kunming University of Science and Technology, Kunming, China; [3)] Research Center on Mechanization Engineering of Chinese Medicinal Materials in Yunnan Universities, Kunming, China; [4)] School of Tea and Coffee, Puer University, Puer, China; [5)] Agricultural Engineering Research Institute (AEnRI), Agricultural Research Center (ARC), Ministry of Agriculture, 256 Dokki, Giza, Egypt	**365**
31.	**DESIGN AND EXPERIMENT OF A SPOON-CLAMP TYPE GARLIC SEED METERING DEVICE / *勺夹式大蒜排种器设计与试验*** **Xinyan ZHANG, Lin LUO, Dongming ZHANG, Shu-juan YI *)** College of Engineering, Heilongjiang Bayi Agricultural University, Daqing / P. R. China	**387**
32.	**MECHANIZED DETASSELING TECHNOLOGY FOR CORN SEED PRODUCTION: GLOBAL PROGRESS, KEY CHALLENGES, AND OPTIMIZATION STRATEGIES / *制种玉米机械化去雄技术：全球进展、核心挑战与优化策略*** **Yang LI [1,2)], Yiteng LEI [*1)], Luochuan XU[1)], Wei DONG [1)]** [1)] College of Electronic Engineering, Yili Normal University, Yining, China; [2)] Key Laboratory of Micro Nano Electric Sensing Technology and Bionic Instruments, Yili Normal University, Yining, China.	**404**
33.	**DEVELOPMENT AND PERFORMANCE EVALUATION OF A ROTARY POWER WEEDER FOR PADDY CULTIVATION / रोटरी पावर वीडर का विकास एवं धान की खेती में मूल्यांकन** **Subhash CHANDRA, Sanjay KUMAR, Sanjay Kumar PATEL, Adityanshu TRIPATHI, Shreesh Sanjay AMIN, Priyanshu KUMAR*** Department of Farm machinery and Power Engineering, College of Agricultural Engineering and Technology, Dr. Rajendra Prasad Central Agricultural University, Pusa (Samastipur)-848125, Bihar, India	**421**
34.	**EXPERIMENTAL STUDY ON THRESHING POWER CONSUMPTION OF AN AXIAL-FLOW THRESHING DEVICE WITH ADJUSTABLE THRESHING INTENSITY / *脱粒力度可调式轴流脱粒装置脱粒功耗试验研究*** **Yuejiang TENG[1,2)], Chengqian JIN[*3)], Fuxiang XIE[1,2)], Jian SONG[1,2)]** [1)] School of Machinery and Power Engineering, Weifang University, Weifang / China; [2)] Shandong Key Laboratory of Intelligent Manufacturing Technology for Advanced Power Equipment, Weifang/China; [3)] Nanjing Institute of Agricultural Mechanization, Ministry of Agriculture and Rural Affairs, Nanjing / China	**432**
35.	**DESIGN AND EXPERIMENT OF AUTOMATIC STRIP-ZONING PESTICIDE APPLICATION CONTROL SYSTEM FOR SOYBEAN-MAIZE STRIP INTERCROPPING BASED ON MACHINE VISION / *基于机器视觉的大豆玉米带状复合种植自动分带施药控制系统设计与试验*** **Gongpei CUI, Huanhuan CHEN, Yu ZHANG, Zishang YANG, Lele WANG, He LI *)** College of Mechanical and Electrical Engineering, Henan Agricultural University, Zhengzhou, Henan, China	**444**
36.	**OPTIMISATION AND EXPERIMENTAL RESEARCH OF FURROWING TOOL BASED ON EDEM/ *基于EDEM的开沟刀具优化与试验研究*** **Jian YAN[1)], Jing MI[2*)], Fei XIA[3)], Guangwen YANG[2)], Chenjun HU[2)], Bin YANG[2)], Yan ZHOU[2)], Bo ZHANG[4)], Po NIU[5*)]** [1)] Chongqing Three Gorges Vocational College, School of Automotive Engineering, People's Republic of China; [2)]Yibin Academy of Agricultural Sciences, People's Republic of China; [3)]Chongqing Kaizhou District Agriculture Service Centre, Chongqing, People's Republic of China; [4)]Chongqing Wanzhou District Agricultural Technology and Machinery Promotion Centre, People's Republic of China; [5)]College of Mechanical Engineering, Chongqing Three Gorges University, People's Republic of China	**461**
37.	**PARAMETER CALIBRATION OF THE BONDING MODEL FOR ASTRAGALUS ROOT BASED ON DISCRETE ELEMENTS / *基于离散元的黄芪根BONDING模型参数标定*** **Jun YOU, Xin DU *), Qi-xin SUN, Shu-fa CHEN, Jing-yi MAO** Jiangsu Ocean University, Lianyungang / China	**472**
38.	**DETECTION OF COMBINE-HARVESTER FEED QUANTITY BASED ON MULTI-SOURCE INFORMATION FUSION / *基于多信息融合的联合收割机喂入量检测方法研究*** **Jizhong WANG[1)*], Wei DONG[1)], Yong WU[2)], Yangchun LIU[3)], Hongze GUO[3)]** [1)] Weifang University, Weifang, China [2)] Shandong Maritime Vocational College. Weifang, China [3)] State Key Laboratory of Agricultural Equipment Technology, China Academy of Agricultural Mechanization Science Group Co., Ltd. Beijing, China	**484**

39.	**YOLO11-RCSP: CHERRY TOMATO FLOWER POLLINATION STATUS RECOGNITION BASED ON MULTI-SCALE FEATURE FUSION /** *YOLO11-RCSP：融合多尺度特征的圣女果花授粉状态识别* **Jianhua CUI, XinYU LI, FuZhun LI, XiaoYing ZHANG** College of Software, Shanxi Agricultural University, Taigu, Shanxi / China	**497**
40.	**RESEARCH ON GRAPE DISEASE DETECTION METHOD BASED ON PWE-YOLO /** *基于PWE-YOLO的葡萄病害检测方法* **Haoyue LIU [1], Benzhi YANG [1], Mingyang Gao [1], Dong WANG [1], Yuepeng SONG[1,2,*], Longlong REN[1,2,*]** [1] Shandong Agricultural University, College of Mechanical and Electrical Engineering/ China; [2] Shandong Provincial Engineering Laboratory of Agricultural Equipment Intelligence/ China	**501**
41.	**DESIGN AND EXPERIMENTAL STUDY OF A SELF-PROPELLED ELECTRIC TRACKED CHASSIS FOR *PANAX NOTOGINSENG* TRANSPLANTER IN HILLY AND MOUNTAINOUS REGIONS /** *丘陵山区自走式三七移栽机电动履带底盘设计与试验研究* **Wei SU[1], Congcong LIAO[1], Qingxu YU*[2], Yi ZENG[1], Qinghui LAI[1], Cantong SU[1]** [1]University of Science and Technology Kunming, Kunming, China; [2]Nanjing Institute of Agricultural Mechanization, Ministry of Agriculture and Rural Affairs, Nanjing, China	**514**
42.	**IMPROVED DBO ALGORITHM FOR FIXED-WING UAV MOUNTAIN CROP IRRIGATION PATH PLANNING /** *改进的DBO算法用于固定翼无人机山地作物灌溉路径规划* **Shengfu WU[1], Peng ZHOU[1,2*], Jin LUO[1], Linjia CHUAN[1], Jing LIU[1], Fugui ZHANG[1,2*]** [1] School of Mechanical Engineering, Guizhou University, Guiyang, Guizhou/ China [2] Guizhou Provincial Key Laboratory of Mountainous Intelligent Agricultural Machinery, Guiyang, Guizhou/ China	**534**
43.	**HOW CAN SMARTPHONE DEVICES BE INTEGRATED WITH SPECTRAL SIGNATURES TO DETECT MATAG HYBRID? /** ***BAGAIMANAKAH PERANTI TELEFON PINTAR DAPAT DIINTEGRASIKAN DENGAN TANDA TANGAN SPEKTRAL UNTUK MENGESAN HIBRID MATAG?*** **Nur Adibah MOHIDEM[1], Nik Norasma CHE'YA[2,3,4*], Mohammadmehdi SABERIOON[5], Mohamad Syukri TAN SHILAN[6], Nur Annisa MAT NORDIN[2]** [1]Public Health Unit, Department of Primary Health Care, Faculty of Medicine and Health Sciences, University Sains Islam Malaysia, Bandar Baru Nilai, Nilai, Negeri Sembilan, Malaysia. ABSTRACT

To improve the seed-filling performance of pneumatic precision seed metering devices for small-seeded crops, a U-shaped seed agitation plate and a combined-type agitation plate were developed. The agitation performance of cylindrical, U-shaped, and combined-type agitation plates was evaluated using the average and maximum velocities of the seed population as quantitative indicators. A three-factor, three-level simulation experiment based on the Discrete Element Method (DEM) was conducted, with agitation plate type, rotational speed, and knob height as the main factors. The optimal parameter combinations were determined as follows: for millet, a combined-type agitation plate with a rotational speed of 24.85 r/min and a knob height of 8.36 mm; for broomcorn millet, 24.17 r/min and 7.96 mm; and for rapeseed, 22.93 r/min and 8.57 mm. Bench experiments were carried out to validate the optimized combined-type agitation plate. The seed-filling rates reached 99.3%, 100%, and 99.7% for millet, broomcorn millet, and rapeseed, respectively. The results indicate that the combined-type agitation plate significantly improves seed mobility and filling performance, providing an effective solution for precision seeding of small-seeded crops.

摘要

针对小籽粒气吸式排种器搅种效果不佳而使得排种盘充种效果差的问题，本研究设计了一种 U 型搅种钮和组合型搅种钮。为了对比和验证圆柱型、U 型、组合型三种搅种盘的搅种质量，以种群在搅种过程中的平均速度和最大速度为评价指标，选取搅种盘类型、搅种盘转速、搅种钮高度为试验因素利用 EDEM 离散元仿真软件对其进行了三因素三水平正交仿真试验，得到了谷子最佳参数组合为组合型搅种盘、作业速度 24.85r/min、搅种钮高度 8.36 mm，糜子最佳参数组合为组合型搅种盘、作业速度 24.17 r/min、搅种钮高度 7.96mm，油菜籽最佳参数组合为组合型搅种盘、作业速度 22.93 r/min、搅种钮高度 8.57 mm。通过台架试验对谷子，糜子，油菜籽种群搅种钮高度分别为 8.4 mm、8.0 mm、8.6 mm 时在最低工作速度 10r/min 时的搅种效果进行验证，组合型搅种盘对应三类种子的充种率分别为 99.3%、100%和 99.7%，优于圆柱形和 U 型搅种盘。试验证明组合型搅种盘具有良好的搅种效果，能够满足小籽粒种子的搅种需求。

INTRODUCTION

Millet, broomcorn millet, and rapeseed are important grain and economic crops in Northwest China. Due to the region's arid climate, limited precipitation, and relatively low temperatures, plastic film mulching is widely adopted in crop production *(Bai et al., 2025)*. In addition, because of the low emergence rate of small-seeded crops, hill-drop sowing with multiple seeds per hole is commonly used *(Tan et al., 2025)*.

To improve the seeding quality and efficiency of small seeds, pneumatic precision seed metering devices capable of multi-grain seeding per hole have been increasingly developed *(Gaikwad et al., 2008; Zhang et al., 2015; Rezaei et al., 2019; Yu et al., 2024)*. However, the small size, low mass, and impurity content of these seeds often result in poor flowability within the seed chamber. This leads to insufficient seed filling or seed leakage at the suction holes of the metering plate, thereby reducing seeding stability. To address this issue, seed agitation devices are introduced to enhance seed flowability and improve seed-filling performance. During operation, agitation knobs interact with seeds through contact, extrusion, and collision, promoting particle mobility within the seed chamber *(Yazgi et al., 2007; Onal et al., 2012; Ibrahim et al., 2018; Wang et al., 2023; Li et al., 2025; Li et al., 2026)*.

Previous studies have proposed various methods to improve seed flowability and filling performance. For example, *Shi et al. (2020)* designed a pneumatic combined-hole precision seed metering device with an integrated agitation mechanism, which enhanced seed filling through shaped holes and guided airflow. *Cong et al. (2014)* developed a dual-purpose pneumatic seed metering device with embedded guiding strips to improve seed distribution. *Ren et al. (2024)* improved seed flowability by arranging curved grooves and shaped holes in a staggered configuration. *Lei et al. (2016)* proposed a cylindrical double-helix agitation device to enhance wheat seed mobility, while *Wang et al. (2019)* designed a wedge-shaped agitation structure to improve seeding accuracy in rice seeders. *Li et al. (2019)* and *Li et al. (2024)* further optimized agitation structures to improve seed filling and reduce seed damage under high-speed conditions. International studies have likewise shown that the operating parameters and auxiliary filling structures of pneumatic seed metering devices strongly affect metering performance and crop adaptability *(Singh et al., 2005; Karayel et al., 2022)*, and a recent review further highlighted the growing importance of coupled numerical and experimental approaches in the development of pneumatic seed-metering devices *(Bustos-Gaytán et al., 2025)*.

Although these studies have demonstrated the importance of agitation devices in improving seed flowability and filling performance, most designs focus on specific crops or operating conditions. Systematic research on universal agitation devices suitable for multiple small-seeded crops remains limited. The novelty of this paper lies in the design of a combined-type agitation plate, the DEM-based mechanistic comparison of three knob configurations, and the parameter optimization of a single structure applicable to three representative small-seeded crops.

Preliminary experiments in this study revealed that, for millet, broomcorn millet, and rapeseed, insufficient agitation leads to seed leakage and blockage of suction holes by impurities. Therefore, a U-shaped and a combined-type seed agitation plate were designed to improve seed flowability and stability. Based on DEM simulations using EDEM, the key factors affecting agitation performance were analyzed. A three-factor, three-level experimental design was then conducted to determine the optimal parameter combination of the agitation plate. The results provide a theoretical and technical basis for the design of universal pneumatic precision seed metering systems for small-seeded crops.

MATERIAL AND METHODS

Design and working principle of the seed agitation plate

As shown in Fig. 1, three agitation-knob configurations were designed for the seed agitation plate: cylindrical, U-shaped, and combined types (a combination of cylindrical and U-shaped structures). The agitation plate was designed to be positioned close to the circumferential region of the suction holes on the seed metering plate, while avoiding interference with the seed-cleaning mechanism. In addition, the height of the agitation knobs was optimized to ensure effective seed disturbance without interfering with surrounding components such as the seed chamber housing.

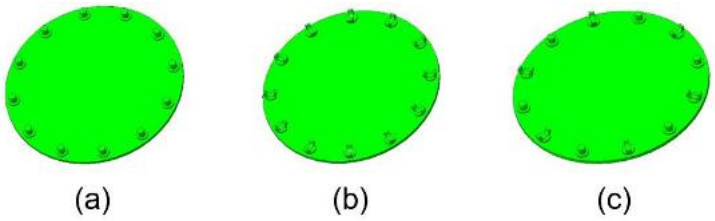

Fig. 1 - Agitation-knob configurations of the seed agitation plate

(a) Cylindrical type; (b) U-shaped type; (c) Combined type

As shown in Fig. 2, the geometric parameters of the seed agitation plate and agitation knobs are illustrated. To ensure effective interaction between the agitation knobs and the seed population, while maintaining sufficient clearance for the seed-cleaning mechanism, the diameter of the agitation plate (D) and the spacing between symmetrically arranged knobs (d_1) were designed according to the dimensions of the seed metering plate. Simulation-based pre-experiments demonstrated that many factors have negligible effects on the seed-agitating performance. Therefore, considering the matching compatibility with the seed metering plate, the parameters were set as follows: D = 160 mm, d_1 = 140 mm, h_{12} = 2 mm, k_{12} = 10 mm, k_{21} = 3 mm, and d_2 = 10 mm.

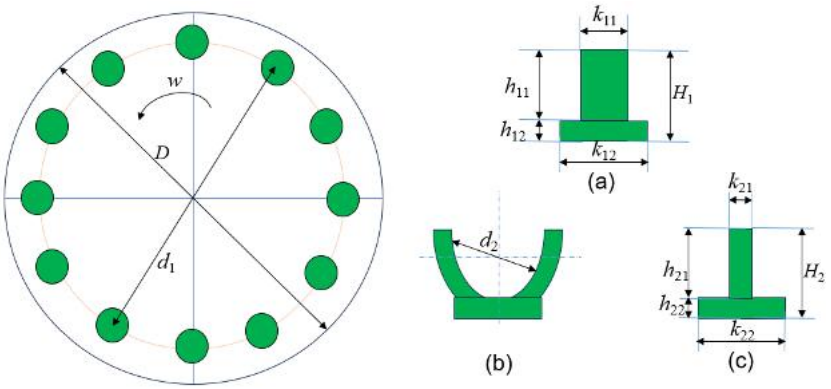

Fig. 2 - Geometric configuration of the seed agitation

(a) Front view of cylindrical type; (b) Front view of U-shaped type; (c) Front view of combined type

A pedestal structure was first introduced on the metering plate, on which the cylindrical and U-shaped agitation knobs were mounted. The number and arrangement of the knobs were determined based on uniform circumferential distribution and sufficient interaction coverage with the seed population. In this study, twelve agitation knobs were evenly distributed along the circumference of the agitation plate.

Considering key factors such as knob geometry, rotational speed of the metering plate, and knob height, the agitation performance was further analyzed using DEM simulations.

DEM-based simulation and analysis of the seed agitation process

Seed particle modeling

Statistical analysis indicated low variability among the effective seed samples. Therefore, one representative seed from each type (millet, broomcorn millet, and rapeseed) was selected for three-dimensional (3D) reconstruction.

Each selected seed was scanned using a portable 3D scanner (EinScan, accuracy ≤ 0.02 mm, Shenzhen Xinlin 3D Co., Ltd., China) to obtain its geometric morphology. The scanned data were processed in VxElements software, including calibration, alignment, mesh generation, and surface reconstruction. The resulting 3D models were exported in STL format.

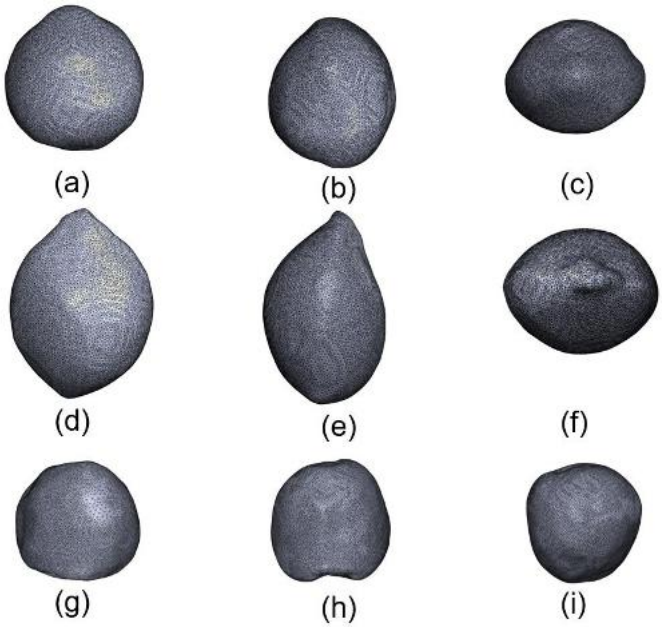

Fig. 3 - 3D reconstructed models of seeds

(a–c) Millet; (d–f) Broomcorn millet; (g–i) Rapeseed

The STL models were subsequently imported into SolidWorks 2021 for visualization, and the corresponding views of the three seed types are shown in Fig. 3.

For DEM simulation in EDEM, the Hertz–Mindlin (no-slip) contact model was used in this simulation, the seed particles were constructed using a multi-sphere approximation method based on the scanned 3D geometries. The millet, broomcorn millet, and rapeseed models were composed of six, eight, and seven spheres, respectively, to balance computational efficiency and shape accuracy.

Because the effective seed samples exhibited relatively small dimensional variation, one representative seed from each crop was used to establish the multi-sphere model. This strategy is suitable for comparative analysis of knob configuration and operating parameters, but it cannot fully represent seed-size dispersion, broken seeds, or impurity particles in real seed lots. Therefore, the present DEM model should be regarded as a simplified but representative model, and its engineering validity was further checked through bench experiments.

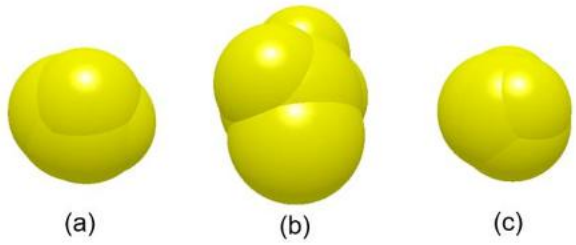

Fig. 4 - Multi-sphere particle models used in EDEM

(a) Millet; (b) Broomcorn millet; (c) Rapeseed

The material and contact parameters used in the simulation were defined based on experimental measurements and literature values *(Yazgi et al., 2007; Onal et al., 2012; Ibrahim et al., 2018; Cui et al., 2025; He et al., 2025; Wang et al., 2025; Zhang et al., 2025)*, as summarized in Table 1.

Table 1

Static friction coefficient (seed–housing)	0.577/0.467/0.517

Construction of DEM model and simulation setup

The three-dimensional model of the seed metering device was developed in SolidWorks 2021, exported in STL format, and imported into EDEM for simulation. The material properties and contact parameters were assigned according to the values listed in Table 1.

A particle generation region was defined at the seed inlet to simulate seed feeding. The particle generation rate of 10,000 particles/s and the total particle number of 40,000 were determined through preliminary simulation trials to ensure rapid chamber filling, continuous particle coverage in the working region around the agitation plate, and stable response values without excessive computational cost. The initial falling velocity of 2 m/s was assigned to allow the particles generated at the inlet to enter the seed chamber smoothly and to avoid artificial accumulation near the particle factory.

Particle generation lasted for 4 s to complete chamber filling, followed by a settling period of approximately 2 s. When the particle velocity decreased below 0.01 m/s, the seed bed was considered to reach a quasi-static state, after which the rotational simulation was initiated.

The metering plate and agitation plate were then assigned rotational motion. Taking a rotational speed of 20 r/min as an example, the angular velocity was set to 120°/s, with rotation about the central axis of the metering plate. The simulation time step was set to 20% of the Rayleigh time step, and the total simulation time was 3 s so that a sufficiently long stable agitation interval could be captured for statistical analysis.

Post-processing and evaluation indices

In the EDEM post-processing module, the velocity distribution of seed particles was visualized using a color scale, where red indicates high velocity and blue indicates low velocity (Fig. 5). The velocity field reflects the agitation intensity induced by the agitation plate.

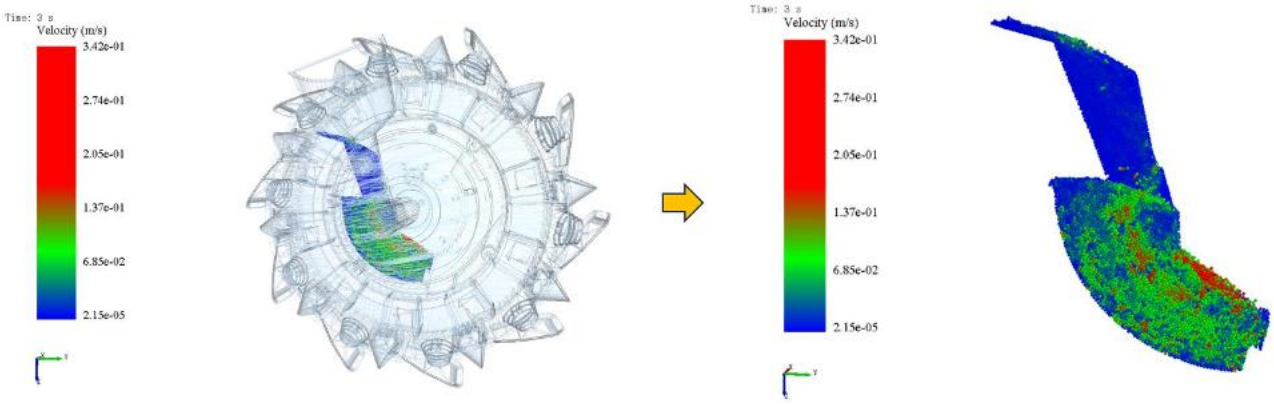

Fig. 5 - Velocity distribution of seed particles during agitation

To quantitatively evaluate the agitation performance, the average velocity and maximum velocity of the seed population were selected as the primary DEM indicators. These two indices reflect the overall particle mobility and the local disturbance intensity in the filling zone, respectively, and are therefore closely related to the seed replenishment capacity near the suction-hole circumferential region. In addition, the seed-filling rate obtained from the bench test was used as an engineering validation index. Because the present DEM model was simplified to facilitate comparative structural optimization, contact frequency and spatial uniformity of particles were not extracted in this study and are discussed as limitations.

Preliminary simulation results

As shown in Fig. 6, the temporal variations of average and maximum velocities for different agitation plate configurations are presented. During the initial stage (0–0.3 s), the velocity curves fluctuate due to startup effects. After 0.3 s, the system reaches a relatively stable state. Therefore, the interval of 0.3–3.0 s was selected for statistical analysis.

Under a rotational speed of 20 r/min and an agitation knob height of 8.0 mm, the average velocities of the seed population for the cylindrical, U-shaped, and combined-type agitation plates were 0.0148 m/s, 0.0153 m/s, and 0.0167 m/s, respectively. The corresponding maximum velocities were 0.3593 m/s, 0.3641 m/s, and 0.4086 m/s.

These results indicate that the geometry and configuration of agitation knobs significantly influence seed agitation performance. The combined-type agitation plate exhibited superior performance compared with the other configurations. Therefore, further analysis considering additional factors is necessary.

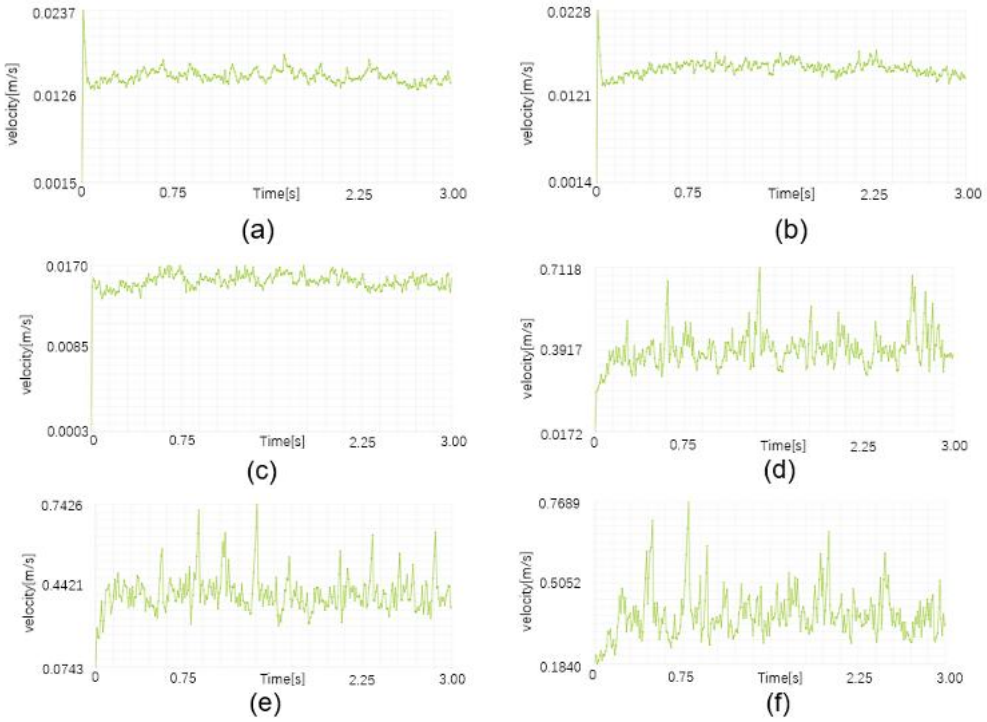

Fig. 6 - Time-dependent velocity curves of seed particles

(a–c) Average velocity each for millet, broomcorn millet, rapeseed;
(d–f) Maximum velocity each for millet, broomcorn millet, rapeseed

Response surface design

Based on the simulation results and preliminary analysis, the agitation knob type, rotational speed of the agitation plate, and agitation knob height were identified as the primary factors influencing seed agitation performance.

Three types of agitation knobs—cylindrical, U-shaped, and combined—were selected as factor X_1. According to the typical operating speed range of seed metering devices (2.0–5.0 km/h), the corresponding rotational speed of the metering plate ranges from 10 to 27 r/min. Therefore, three representative levels (15, 20, and 25 r/min) were selected for factor X_2. Considering the structural constraints and clearance between the agitation knobs and adjacent components (e.g., seed chamber housing and seed-cleaning mechanism), the feasible range of knob height was determined to be 0–15 mm. Accordingly, three levels (6.0, 8.0, and 10.0 mm) were selected for factor X_3 *(Han et al., 2018; Liu et al., 2022; Gao et al., 2023; Ding et al., 2024)*.

A three-factor, three-level response surface design generated in Design-Expert 8.0.6 was adopted, resulting in 17 simulation runs with five center-point replications. Quadratic regression models were then established for the two response variables, and the coded levels of the factors are listed in Table 2.

Table 2

Factor levels used in the experimental design

Code	Agitation knob type (X_1)	Rotational speed (X_2) [r/min]	Agitation knob height (X_3) [mm]
-1	A: Cylindrical	15	6.0
0	B: U-shaped	20	8.0
1	C: Combined	25	10.0

Bench validation of seed-filling performance

Because low rotational speed provides the weakest particle disturbance and therefore the most stringent condition for maintaining seed filling, bench experiments were conducted at the minimum operating condition of the seed metering device (10 r/min, corresponding to a forward speed of 2.0 km/h). Validation under this condition was used to verify whether the optimized structure could still ensure adequate seed replenishment under the least favorable agitation state. The agitation knob height was set according to the optimized simulation results.

However, the present validation was limited to low-speed bench conditions, and further experiments over the full operating-speed range are still required.

The experiments were carried out using a JPS-12 seed metering performance test bench (Heilongjiang Provincial Agricultural Machinery Research Institute, China). The system mainly consists of a seedbed belt, a metering device mounting frame, a hydraulic system, and a high-speed imaging system. The bench has a total length of 9.5 m, a belt width of 0.7 m, and an adjustable forward speed range of 1.5–12.0 km/h. The high-speed camera was operated at 300 frames per second (fps), and the recorded images were processed using i-SPEED Control Software.

Due to the difficulty in directly quantifying seed agitation through visual observation, the seed-filling rate was selected as the engineering validation index of agitation performance. Improved agitation enhances seed mobility in the filling zone, weakens local seed crowding, and reduces the probability of insufficient filling at the suction holes.

For each seed type (millet, broomcorn millet, and rapeseed), corresponding to three different types of seed agitating plates (cylindrical, U-shaped, and combined), 300 consecutive seeding events were recorded for each treatment. The filling and missing conditions of seeds in each hill were captured through a transparent seed chamber using both a high-speed camera and a mobile camera. The average seed-filling rate was calculated based on the recorded data.

RESULTS AND DISCUSSION

Results and analysis of the experimental design

A three-factor, three-level response surface experiment was conducted using Design-Expert software, resulting in 17 simulation runs. The average velocity (Y_1) and maximum velocity (Y_2) of the seed population were selected as response variables to evaluate agitation performance. The experimental design and corresponding results are summarized in Table 3.

Table 3

Regression modeling and ANOVA

The experimental results were analyzed to obtain polynomial regression equations, in which the average population velocity and the maximum population velocity were taken as the response variables, and the coded values of the factors were used as independent variables, as follows:

$$Y_1 = 0.016 + 0.000275X_1 + 0.0004375X_2 + 0.0003625X_3 + 0.000175X_1X_2 + 0.000125X_1X_3 + 0.00015X_2X_3 - 0.00022X_1^2 - 0.000095X_2^2 - 0.000395X_3^2 \quad (1)$$

$$Y_2 = 0.38 + 0.005675X_1 + 0.012X_2 + 0.007388X_3 + 0.005725X_1X_2 + 0.001675X_1X_3 + 0.00535X_2X_3 - 0.00465X_1^2 - 0.002275X_2^2 - 0.007225X_3^2 \quad (2)$$

Quadratic regression models were developed for both response variables (Y_1 and Y_2) based on the coded factors. Analysis of variance (ANOVA) results (Tables 4 and 5) indicate that both models are statistically significant ($p < 0.05$), with no significant lack-of-fit ($p > 0.05$), confirming the adequacy of the regression models.

For both response variables, the main factors X_1 (agitation knob type), X_2 (rotational speed), and X_3 (knob height) significantly affected the results ($p < 0.05$), while interaction terms were generally insignificant. The quadratic term X_3^2 also showed a significant effect, indicating a nonlinear relationship between knob height and agitation performance.

Effect of factors on average velocity (Y_1)

The response surfaces for the average velocity are shown in Fig. 8. Among the three factors, rotational speed (X_2) exhibited the most significant influence, followed by knob height (X_3), while knob type (X_1) had a relatively smaller effect.

As the knob configuration changed from cylindrical to U-shaped and then to the combined type, the average velocity of the seed population increased. The cylindrical part mainly breaks the compact seed layer and promotes upward and radial displacement, whereas the U-shaped part provides a temporary guiding and holding space for particles. Their combination extends the particle-structure interaction path, increases the disturbance depth, and reduces the low-mobility region near the chamber wall, thereby improving continuous seed replenishment around the suction-hole zone.

With increasing rotational speed, the average velocity increased monotonically because more kinetic energy was transferred from the rotating structure to the seed population per unit time. In contrast, knob height exhibited a quadratic effect. When the height was too small, the disturbance depth was insufficient and only the superficial seed layer was mobilized. When the height became excessive, particles were overly squeezed toward the chamber wall, leading to local congestion and a reduction in overall particle circulation.

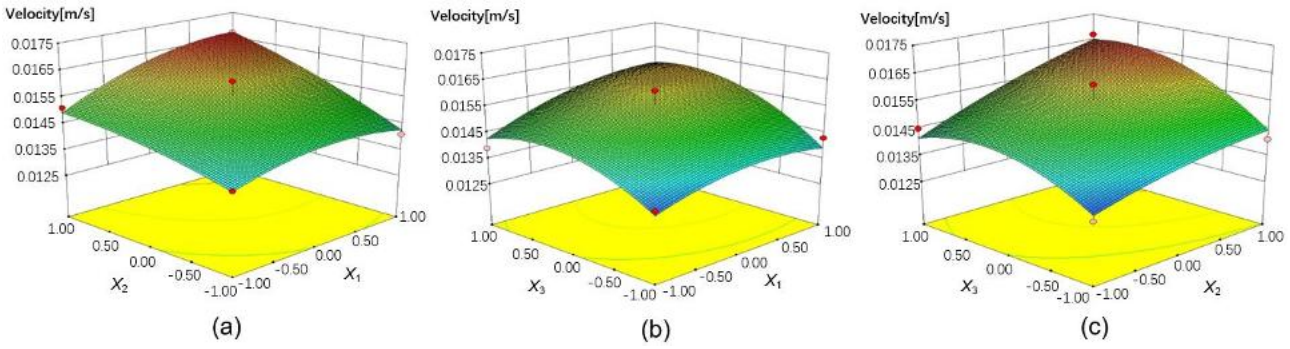

Fig. 8 - Response surfaces to influences of different factors on the seed population average speed

(a) X_1 and X_2; (b) X_1 and X_3; (c) X_2 and X_3

Effect of factors on maximum velocity (Y_2)

The response surfaces for maximum velocity are presented in Fig. 9. Similar trends were observed for Y_2 as for Y_1. Rotational speed remained the most influential factor, followed by knob height, while knob type had the least effect. Compared with the average velocity, the maximum velocity responds more sensitively to local strong interactions between the knob and nearby particles.

Increasing rotational speed significantly enhanced the maximum velocity of seed particles because the instantaneous particle-structure interaction became stronger. The influence of knob height also exhibited a nonlinear effect. An excessively large knob height reduced the free-movement space of particles and converted part of the agitation effect into compressive crowding rather than effective acceleration.

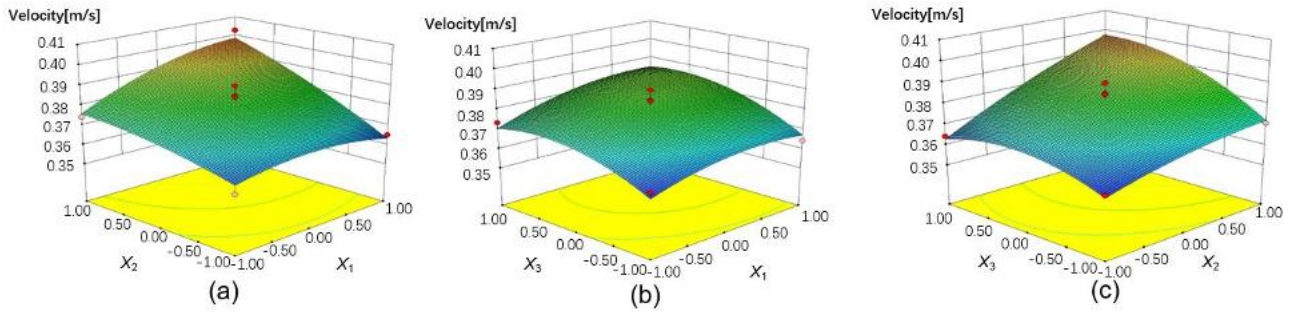

Fig. 9 - Response surfaces to influences of different factors on the seed population maximum speed
(a) X_1 and X_2; (b) X_1 and X_3; (c) X_2 and X_3

The consistent trends observed for both response variables confirm the reliability of the simulation results. From an engineering perspective, the superior performance of the combined-type agitation plate indicates that a moderate increase in particle mobility is beneficial to low-speed seed filling. Because the agitation mechanism is mounted on the existing rotating plate and operates within a relatively low speed range, its additional energy demand is expected to be limited. Moreover, the disturbance mode is dominated by pushing and rolling rather than high-energy impact, so obvious seed damage is not expected. However, direct seed-damage and germination tests were not conducted in this study, and these aspects should be included in future work. The proposed structure can also be extended to other small-seeded crops by re-matching the knob height, chamber clearance, and rotational speed according to seed size and flowability.

Optimization of parameters

Based on the regression models, the optimal parameter combinations were obtained for each seed type. For millet, the optimal configuration was a combined-type agitation plate with a rotational speed of 24.85 r/min and a knob height of 8.36 mm. For broomcorn millet, the optimal parameters were 24.17 r/min and 7.96 mm, while for rapeseed, the optimal values were 22.93 r/min and 8.57 mm.

The results indicate that the combined-type agitation plate consistently provides superior agitation performance across all seed types.

The simulation results demonstrate that agitation performance improves with increasing rotational speed. However, to ensure practical applicability, the optimized design must also perform effectively under low-speed conditions. Therefore, validation experiments were conducted at the minimum operating speed (10 r/min) using the optimized knob heights for each seed type. This choice represents the most unfavorable agitation condition for the device; nevertheless, the present experimental verification is still limited to low-speed bench conditions, and future studies should extend the validation to the full operating-speed range and integrated field conditions.

Bench test validation results

As shown in Fig. 10, the seed-filling performance of the seed holes on the seed plate after the agitation process is presented.

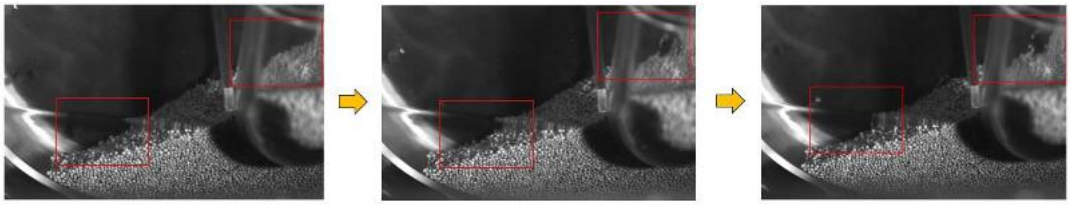

Fig. 10 - Variation of the millet population under the action of the combined agitation plate

The filling condition was analyzed and statistically evaluated on a hole-by-hole basis using recordings from a high-speed camera and a mobile phone. Under the conditions where multiple-seed adsorption was neglected and the seed-cleaning device was not activated, the results indicate that at an operating speed of 10 r/min, for the combined agitation plate, the seed-filling rates of millet, broomcorn millet, and rapeseed were 99.3%, 100%, and 99.7%, respectively; for the cylindrical seed agitation plate, the corresponding seed-filling rates were 94.3%, 97.0%, and 96.3%, respectively; and for the U-shaped seed agitation plate, the corresponding values were 97.3%, 98.7%, and 98.0%, respectively. These results demonstrate that the combined seed agitation plate exhibits superior agitation performance compared with the other two types, thereby satisfying the design requirements of the seed agitation mechanism of the seed metering device.

CONCLUSIONS

This study developed U-shaped and combined-type agitation plates to improve the agitation performance of pneumatic seed metering devices for small-seeded crops. Based on DEM simulations and bench validation experiments, the following conclusions were obtained.

(1) The agitation performance of cylindrical, U-shaped, and combined-type configurations was systematically evaluated using the average and maximum velocities of seed particles as response variables. The combined-type agitation plate exhibited superior performance compared with the other two configurations.

(2) A three-factor, three-level experimental design was conducted to analyze the effects of agitation plate type, rotational speed, and knob height. The optimal parameter combinations were identified as follows: for millet, 24.85 r/min and 8.36 mm; for broomcorn millet, 24.17 r/min and 7.96 mm; and for rapeseed, 22.93 r/min and 8.57 mm, all with the combined-type agitation plate.

(3) Bench validation experiments confirmed that, under the minimum operating speed of 10 r/min, the optimized agitation configurations achieved high seed-filling rates of 99.3%, 100%, and 99.7% for millet, broomcorn millet, and rapeseed, respectively. These results demonstrate that the proposed agitation plate effectively enhances seed-filling performance and meets the operational requirements of precision seeding under the least favorable agitation condition.

The proposed design provides a practical structural option for improving the low-speed filling stability of pneumatic precision seed metering devices for millet, broomcorn millet, and rapeseed. Future studies should incorporate seed-size distributions and impurity particles into the DEM model and carry out seed-damage, germination, full-speed bench, and integrated field validations.

ABSTRACT

To enhance the seeding accuracy of multi-seed-per-hole operations for small-seed crops, a combined experimental-CFD optimization method for an air-suction seed metering plate was developed. Single-factor tests established that the suitable suction-hole diameter was 0.4-0.6 times the equivalent seed diameter, and threshold-based negative-pressure tests were used to define the acceptable suction-hole negative-pressure range for millet, broomcorn millet, and rapeseed. CFD pressure-tracing analysis was then performed to quantify the mapping between suction-hole pressure and air-chamber inlet negative pressure. On this basis, a three-factor, three-level optimization test was conducted using inlet negative pressure, suction-hole diameter, and suction-hole thickness as variables, with the qualification rate of suction-hole pressure as the response. The optimized parameter combinations were 2.51 kPa, 0.88 mm, and 0.31 mm for millet; 2.97 kPa, 1.12 mm, and 0.35 mm for broomcorn millet; and 2.35 kPa, 0.93 mm, and 0.32 mm for rapeseed. Bench validation showed seed-filling rates of 93%, 97%, and 96%, respectively. The results demonstrate that the proposed method can effectively reduce empirical trial workload and provide a practical basis for the design of pneumatic precision seed metering plates for small-seed crops.

摘要

为提高小籽粒作物一穴多粒作业的播种精度，本文提出了一种针对气吸式排种盘的 CFD 仿真试验联合优化方法。通过单因素试验确定，适宜的吸孔直径应为种子当量直径的 0.4～0.6 倍；同时，基于基准压力试验界定了谷子、糜子和油菜籽适宜的吸孔负压范围。随后，采用 CFD 压力追踪分析方法，定量建立了吸孔负压与气室入口负压之间的映射关系。在此基础上，以入口负压、吸孔直径和吸孔厚度为试验因素，以吸孔负压合格率为响应指标，开展了三因素三水平优化试验。优化结果表明：谷子的最优参数组合为 2.51 kPa、0.88 mm 和 0.31 mm；糜子的最优参数组合为 2.97 kPa、1.12 mm 和 0.35 mm；油菜籽的最优参数组合为 2.35 kPa、0.93 mm 和 0.32 mm。台架验证结果显示，三者的充种率分别达到 93%、97%和 96%。结果表明，所提出的方法能够有效减少经验试验工作量，并可为小籽粒作物气力式精密排种盘的设计提供实用依据。

INTRODUCTION

Millet, broomcorn millet, and rapeseed are important economic crops in Northwest China, where sowing practices include manual broadcasting, drill sowing, and hill-drop sowing, while the level of mechanization in some mountainous and hilly areas remains relatively low *(Cong et al., 2014; Gao et al., 2022; Cao et al., 2026)*. The regional climate is characterized by low temperature, aridity, and limited precipitation, which are unfavorable for seed germination and early growth. Consequently, plastic-film mulching and multi-seed-per-hole sowing are commonly adopted to improve seedling establishment. Under these agronomic conditions, single-seed precision sowing is generally unsuitable for small-seed crops.

Precision sowing technology can significantly improve sowing quality by placing a controlled number of seeds at specified row spacing, plant spacing, and sowing depth, while simultaneously completing operations such as fertilization, soil compaction, and mulching *(Gao et al., 2026; Wei et al., 2026)*. The seed metering device is the core component of precision sowing systems and can be broadly classified into mechanical and pneumatic types *(Gaikwad and Sirohi, 2008; Karayel et al., 2022; Bustos-Gaytán et al., 2025)*.

Among them, pneumatic seed metering devices are widely used because of their strong adaptability to seed-size variation, low mechanical damage, and suitability for relatively high-speed operation *(Wang et al., 2017; Li et al., 2023; Yang et al., 2026)*.

Previous studies have shown that vacuum pressure, hole geometry, plate speed, and seed delivery conditions jointly determine the performance of precision seeders *(Ibrahim et al., 2018; Rezaei Asl et al., 2019)*. *Karayel et al. (2004)* mathematically analyzed the vacuum-pressure requirement of a precision seeder, *Yazgi and Degirmencioglu (2007)* optimized seed-spacing uniformity through response surface methodology, *Panning et al. (2000)* evaluated laboratory and field methods for planter spacing assessment, and *Onal et al. (2012)* examined the theoretical and experimental accuracy of a vacuum-type precision metering unit. In China, related studies have further improved seed filling by using dual-chamber structures, grooved-tooth disturbance, wedge-shaped agitation, and protrusion-assisted seed plates *(Ding et al., 2018; Li et al., 2019; Wang et al., 2019; Xing et al., 2020)*. However, most available studies focus on single-seed precision sowing or general spacing performance, whereas the coupled pressure-matching problem of small seeds under multi-seed-per-hole conditions remains insufficiently clarified.

Accordingly, the novelty of this study lies in three aspects: (1) an engineering matching rule between seed size and suction-hole diameter was established for small-seed multi-seed-per-hole sowing; (2) the mapping between suction-hole pressure and air-chamber inlet pressure was quantified through CFD-assisted pressure tracing; and (3) the coupled effects of inlet negative pressure, suction-hole diameter, and suction-hole thickness were optimized and validated experimentally for three representative small-seed crops. These results provide a more directly applicable design route for pneumatic seed metering plates than empirical parameter selection alone.

MATERIAL AND METHODS

Selection of suction hole diameter range

The geometry of suction holes, including shape, diameter, and thickness, plays a critical role in the performance of seed metering plates *(Dun et al., 2019; Gao et al., 2022; Ren et al., 2024)*. Considering the seed cleaning and unloading mechanisms employed in this study, concave–convex hole structures were excluded due to their incompatibility with the operational requirements.

To determine the appropriate suction hole diameter range, three types of seeds—millet, broomcorn millet, and rapeseed—were matched with a series of hole diameters ranging from 0.3 mm to 2.0 mm at intervals of 0.1 mm. The holes were fabricated using laser cutting on a steel plate with a thickness of 0.5 mm.

To ensure stable seed adsorption and transport while avoiding excessive cleaning and seed damage during release, a geometric matching method was adopted. Seeds were placed on suction holes of varying diameters, and the interaction between seed geometry and hole size was evaluated. The criterion for suitable matching was defined as the condition at which the seed just began to enter the suction hole without falling through.

Based on repeated observations and statistical screening, the relationship between suction-hole diameter and equivalent seed diameter was expressed as:

$$d_k = (0.4-0.6)\ d_z \quad (1)$$

where: d_k – the diameter of the seed metering plate suction hole, mm; d_z - the equivalent diameter of small-seed crops, mm.

Table 1

Range of suction hole diameters for different seed types

Item	Millet	Broomcorn millet	Rapeseed
Equivalent diameter [mm]	1.5717	2.5290	2.1331
Suction hole diameter [mm]	0.629-0.943	1.012-1.517	0.853-1.280
Median suction hole diameter [mm]	0.786	1.265	1.067

This empirical relationship is consistent with the geometric compatibility requirements between seed size and suction hole diameter, ensuring stable adsorption without multiple seed pickup. Accordingly, the suitable ranges of suction hole diameters for each seed type were determined, as summarized in Table 1. It can be observed that the suction hole diameter increases proportionally with seed size, which is consistent with the relationship d_k = (0.4–0.6)d_z.

Selection of negative pressure range

The negative pressure at the suction hole is a key parameter governing seed adsorption, transport, and release in pneumatic seed metering devices *(Hu et al., 2025; Shi et al., 2025)*. An appropriate negative pressure range should ensure stable seed pickup, prevent excessive seed removal during cleaning, and allow reliable seed release.

To determine the feasible range of suction hole negative pressure, a threshold-based experimental method was employed. Two types of brushes were used to simulate external disturbances during the seed cleaning process: a soft nylon brush (bristle diameter 0.09 mm) and a stiff bristle brush (diameter 0.20 mm). The lower limit of negative pressure was defined as the minimum pressure at which the seed remained attached to the suction hole when lightly contacted by the soft brush. The upper limit was defined as the pressure at which the seed was just removed when subjected to the stiff brush. Each measurement was repeated 20 times, and the average values were used to reduce experimental uncertainty. The difference between these two thresholds was taken as the effective negative pressure range for seed adsorption. This range ensures sufficient holding force during seed transport while avoiding excessive adhesion that may hinder seed release.

The experimental setup is shown in Fig. 1 and mainly consisted of a fixed frame, a PVC suction tube with a diameter of 6 mm, a vacuum pump (OL 750 AD, rated suction capacity 125 L/min), a pressure-regulating device (IRV 20-C06, adjustment range -0.5 to -100.0 kPa), and the corresponding power supplies. During the experiment, the suction tube was sealed to the back side of a single suction hole to eliminate air leakage, and the negative pressure was increased stepwise by 0.1 kPa from an initial value of -0.1 kPa until the defined threshold conditions were reached.

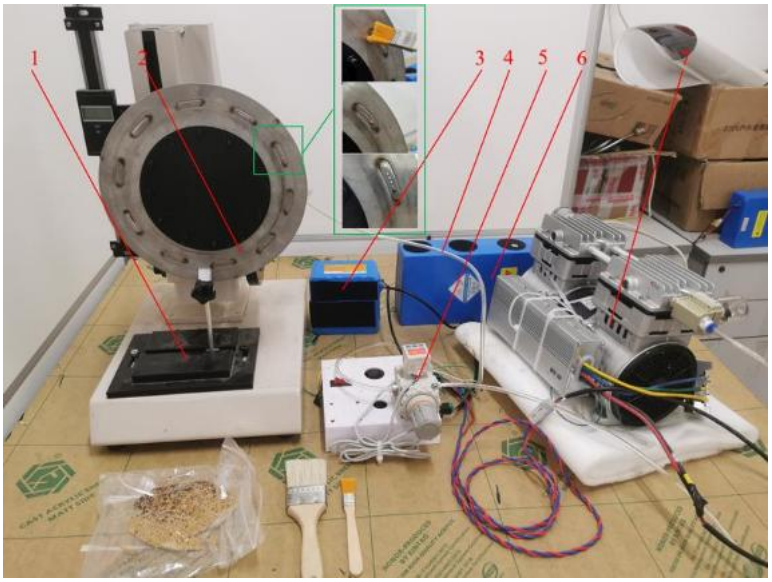

Fig. 1 - Experimental setup for the single-factor test of the seed metering plate

1. seed plate support frame; 2. seed metering plate; 3. 24V power supply for the pressure regulator; 4. suction tube; 5. pressure regulating device; 6. 36V power supply for the vacuum pump; 7. vacuum pump

As shown in Table 2, the effective negative-pressure ranges for millet, broomcorn millet, and rapeseed were 0.77-2.67 kPa, 0.97-3.25 kPa, and 0.92-2.81 kPa, respectively. Although only 0.22, 0.31, and 0.27 kPa were sufficient for the initial adsorption of the three seeds at the median suction-hole diameters, these values were below the engineering working range defined by the brushing-threshold criterion and therefore were not used for subsequent optimization.

Table 2

Range of suction hole negative pressure for different seed types

Item	Millet	Broomcorn millet	Rapeseed
Median suction hole diameter [mm]	0.8	1.2	1.0
Suction hole negative pressure range [kPa]	0.77-2.67	0.97-3.25	0.92-2.81
Median suction hole negative pressure [kPa]	1.72	2.11	1.87

Potential sources of experimental variation in the negative-pressure tests included seed-size dispersion after grading, manual differences during brush contact, the 0.1 kPa pressure-setting resolution, and local sealing variability between the suction tube and the plate. These effects were reduced by seed grading, repeated measurements, and the use of averaged values in all subsequent analyses. The obtained pressure ranges therefore provide a practical basis for balancing seed retention and release during pneumatic metering.

Simulation-based determination of air chamber suction inlet pressure range

To establish the relationship between the air-chamber inlet negative pressure and the suction-hole pressure of the seed metering plate, CFD simulations were conducted on the airflow field within the chamber.

As shown in Fig. 2, a three-dimensional model of the air chamber was developed in SolidWorks and imported into ANSYS Fluent for numerical simulation. Considering the circumferential symmetry of the chamber around the central axis of the suction inlet, a symmetric cross-sectional model was used to reduce computational cost while retaining the dominant pressure-transfer characteristics relevant to the present study *(Zhang et al., 2022; Zhao et al., 2023; Zhong et al., 2024)*.

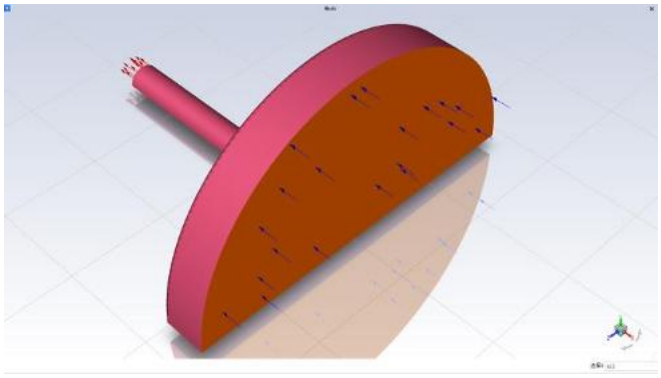

Fig. 2 - 3D model of air chamber flow field

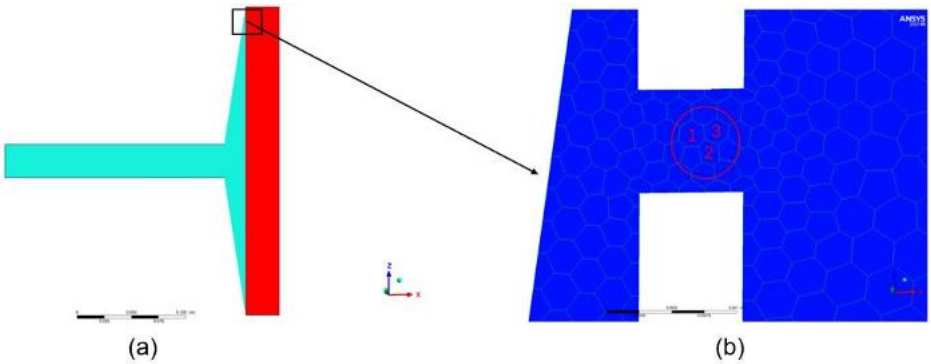
As shown in Fig. 3, a two-dimensional symmetric cross-sectional model extracted from the 3D geometry was used for the CFD calculations. To improve the accuracy of pressure extraction, the cross-sectional model shown in Fig. 3(b) was discretized using a hexagonal-dominant cell, with local refinement applied in the suction inlet passage and suction-hole region, where the pressure gradient changed markedly. The global mesh size was approximately 0.20 mm, while the local mesh size in the refined region was reduced to 0.05 mm. Three mesh schemes were tested for mesh-independence analysis, containing approximately 28,436, 46,912, and 71,385 cells, respectively. The average pressure at three monitoring points near the suction-hole outlet was used as the mesh-independence criterion. When the number of cells increased from 46,912 to 71,385, the relative deviation of the monitored pressure was only 0.84%, indicating that further mesh refinement had a negligible effect on the simulation results. Therefore, considering both computational cost and numerical accuracy, the mesh with 46,912 cells was adopted for the subsequent simulations.

Millet was selected as the representative case for the pressure-tracing analysis. The suction inlet diameter was 30 mm, the suction-hole diameter was 0.8 mm, and the hole thickness was 0.5 mm. Three monitoring points were arranged near the suction-hole outlet, three monitoring points were arranged symmetrically near the suction-hole outlet, and their average pressure was used as the evaluation index. The inlet negative pressure was increased stepwise by 0.1 kPa.

In the simulations, air was treated as an incompressible fluid under steady turbulent flow conditions. Because the airflow inside the chamber was mainly characterized by internal negative-pressure flow, and the objective of this study was to determine the pressure-transfer relationship between the chamber inlet and the suction hole rather than to capture transient vortex evolution, the standard k–ε turbulence model was selected. Compared with more complex turbulence models, the standard k–ε model provides better numerical robustness and computational efficiency for steady engineering flows, and it has been widely used in airflow simulations of pneumatic seed-metering devices to achieve stable predictions of chamber pressure fields. The ambient conditions were set at 25 °C and 101 kPa *(Yu et al., 2014; Zhang et al., 2022; Tang et al., 2023; Wang et al., 2023; Zhong et al., 2024)*.



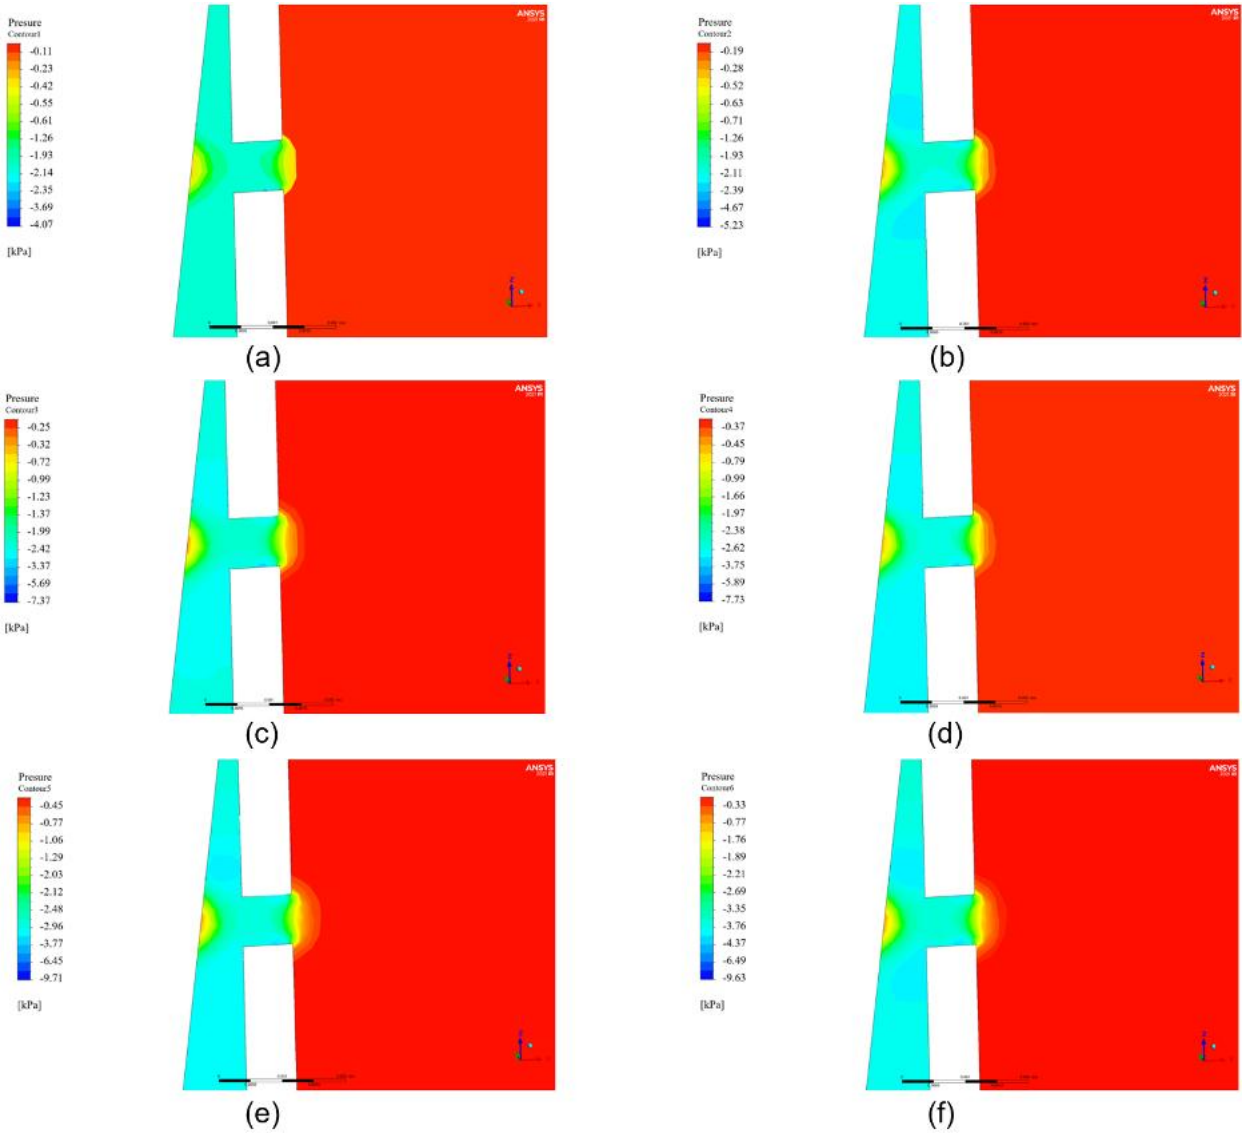


Fig. 3 - Computational domain and mesh of the airflow field

(a) Geometry of the air chamber; (b) Mesh of the cross-sectional plane.

Pressure–velocity coupling was handled using the SIMPLE algorithm, and second-order discretization schemes were applied to the pressure and momentum equations. The solution was considered converged when the residuals of the continuity and momentum equations were reduced below 1×10^{-5}, and the monitored suction-hole pressure remained stable with no further noticeable variation.

Eight representative inlet-pressure conditions, namely 1.9, 2.1, 2.4, 2.7, 3.1, 3.5, 3.9, and 4.1 kPa, were extracted from the stepwise simulation process. The corresponding suction-hole pressures were 0.62, 0.74, 1.24, 1.67, 2.06, 2.25, 2.61, and 2.73 kPa, respectively.

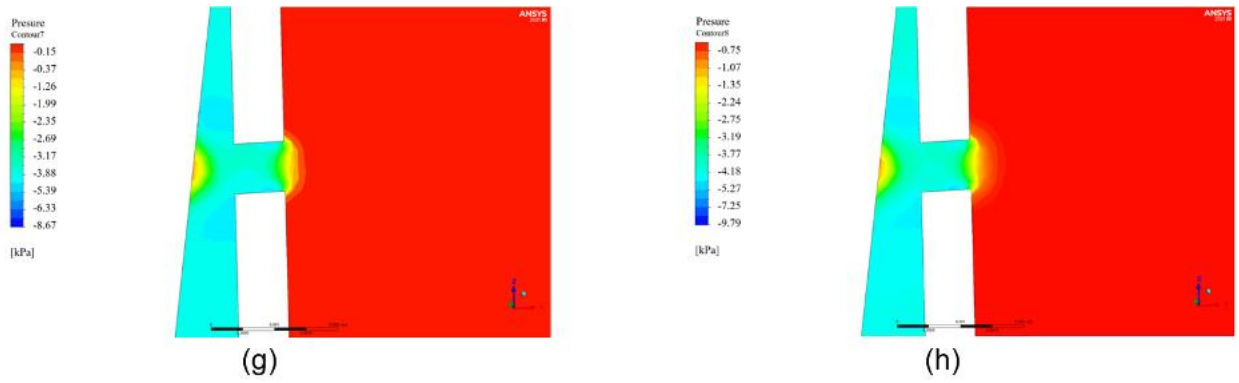

Fig. 4 - Pressure contours at suction holes under different air chamber inlet pressures

(a) 1.9 kPa; (b) 2.1 kPa; (c) 2.4 kPa; (d) 2.7 kPa; (e) 3.1 kPa; (f) 3.5 kPa; (g) 3.9 kPa; (h) 4.1 kPa

As shown in Fig. 4, the pressure contours at the suction hole changed regularly with increasing inlet negative pressure. When the chamber inlet pressure was lower than about 2.1 kPa, the suction-hole pressure was below the experimentally acceptable lower limit for millet. When the chamber inlet pressure exceeded about 3.9-4.1 kPa, the suction-hole pressure approached or exceeded the upper limit of the qualified range, indicating a risk of over-adsorption. Therefore, the corresponding inlet pressure range for millet was determined to be 2.11-3.95 kPa, which matches the experimentally defined suction-hole pressure range of 0.77-2.67 kPa.

Using the same tracing method, the inlet pressure ranges for broomcorn millet and rapeseed were obtained as 2.37-4.22 kPa and 2.23-4.16 kPa, respectively. These results establish a quantitative mapping between chamber inlet pressure and suction-hole pressure, thereby providing a direct basis for subsequent optimization of the seed metering plate.

Table 3

Relationship between air chamber inlet pressure and suction hole pressure

Item	Millet	Broomcorn millet	Rapeseed
Median suction hole diameter [mm]	0.8	1.2	1.0
Suction hole negative pressure range [kPa]	0.77-2.67	0.97-3.25	0.92-2.81
Air chamber suction inlet negative pressure range [kPa]	2.11-3.95	2.37-4.22	2.23-4.16

Experimental design for seed metering plate optimization

To determine the appropriate combination of suction hole diameter, suction hole thickness, and air chamber inlet negative pressure for different seed types, the factor ranges were defined based on the preliminary single-factor experiments and CFD simulation results. Using millet as an example, the selected ranges were 2.0–4.0 kPa for inlet negative pressure, 0.6–1.0 mm for suction hole diameter, and 0.3–0.7 mm for suction hole thickness.

A three-factor, three-level Box–Behnken response-surface design was employed, and the coded factor levels are listed in Table 4. The experimental design matrix and corresponding results are presented in Table 5. The design with 17 runs was employed, including five center-point replicates to estimate pure error. For each parameter combination, pressure values were extracted at 100 suction-hole positions along the metering plate, and the percentage of qualified pressure values was calculated as the response.

Table 4

Factor levels used in the experimental design

Code	Inlet negative pressure (X_1) [kPa]	Suction hole diameter (X_2) [mm]	Suction hole thickness (X_3) [mm]
-1	2	0.6	0.3
0	3	0.8	0.5
1	4	1.0	0.7

The qualification rate of suction-hole pressure was selected as the response variable. For millet, the acceptable suction-hole pressure range was defined as 0.8-2.7 kPa. Analysis of variance and response-surface optimization were performed in Design-Expert 8.0.6. In the statistical interpretation, the main sources of experimental error considered were seed-size variability after grading, pressure-setting resolution, and repeated positioning differences during testing.

Table 5

Experimental design matrix and results

No.	X_1	X_2	X_3	Y_1 [%]
1	-1	-1	0	74
2	1	-1	0	92

RESULTS AND DISCUSSION

Regression modeling and analysis of variance

Based on the experimental results, a quadratic regression model was established using Design-Expert 8.0.6, with the pressure qualification rate at the suction hole (Y_1) as the response variable and the coded factors (X_1, X_2, X_3) as independent variables:

$$Y_1 = 93 + 5.5X_1 - 5.12X_2 - 3.88X_3 - 3X_1X_2 - X_1X_3 + 0.25X_2X_3 - 9.38X_1^2 - 5.63X_2^2 - 2.12X_3^2 \quad (2)$$

Analysis of variance (ANOVA) was performed to evaluate the significance of the regression model, as summarized in Table 6. The results indicate that the model is statistically significant ($p < 0.05$), while the lack-of-fit term is not significant ($p > 0.05$), confirming that the model adequately describes the experimental data.

Table 6

Analysis of variance (ANOVA) for the regression model

Sources	Sum of squares	Degree of freedom	Mean square	*F*	*p*
Model	1177.69	9	130.85	13.23	0.0013
X_1	242.00	1	242.00	24.46	0.0017
X_2	210.13	1	210.13	21.24	0.0025
X_3	120.13	1	120.13	12.14	0.0102
X_1X_2	36.0000	1	36.0000	3.6390	0.0981
X_1X_3	4.0000	1	4.0000	0.4043	0.5451

Sources	Sum of squares	Degree of freedom	Mean square	*F*	*p*
X_2X_3	0.2500	1	0.2500	0.0253	0.8782
X_1^2	370.0658	1	370.0658	37.4074	0.0005
X_2^2	133.2237	1	133.2237	13.4667	0.0080
X_3^2	19.0132	1	19.0132	1.9219	0.2082
Lack of fit	23.25	3	7.75	0.67	0.6116
Pure error	46	4	11.50		
Total	1246.94	16			

Among the factors, X_1 (inlet negative pressure), X_2 (suction hole diameter), X_3 (suction hole thickness), as well as the quadratic terms X_1^2 and X_2^2, show significant effects on the response ($p < 0.05$). In contrast, the interaction terms are not significant, indicating weak coupling effects among the factors.

Effect of factors and response surface analysis

The effects of the factors on the pressure qualification rate are illustrated in Fig. 5. Among the three variables, inlet negative pressure exerted the strongest influence on the response, followed by suction-hole diameter, whereas suction-hole thickness showed a smaller but still significant main effect. The curved surface in Fig. 5(a) indicates that the qualified rate can be maximized only within a moderate pressure-diameter window; excessively low inlet pressure leads to insufficient suction-hole pressure, whereas excessive inlet pressure increases the risk of over-adsorption.

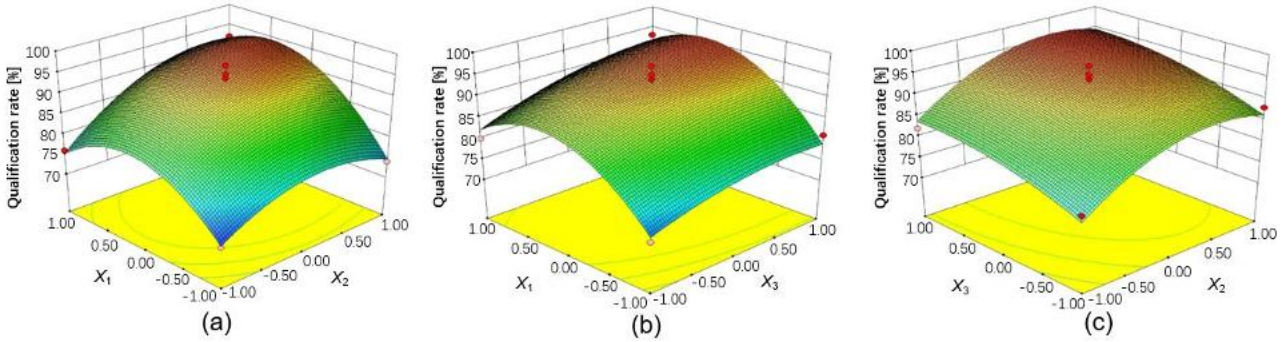

Fig. 5 - Response surfaces to influences of different factors on qualified rate of pressure at the suction hole

(a) X_1 and X_2; (b) X_1 and X_3; (c) X_2 and X_3

As shown in Fig. 5, the qualified rate first increased and then decreased with increasing inlet negative pressure. This trend reflects the transition from insufficient adsorption to an over-strong pressure field. A similar non-monotonic pattern was observed for suction-hole diameter: when the hole was too small, pressure transfer was insufficient, whereas an excessively large hole caused the local pressure to move outside the qualified range. By contrast, increasing suction-hole thickness tended to reduce the qualified rate because the longer flow passage increased local pressure loss and weakened effective pressure transmission near the hole exit.

Parameter optimization and engineering interpretation

Based on the regression model, the optimal parameter combination for millet was an inlet negative pressure of 2.51 kPa, a suction-hole diameter of 0.88 mm, and a suction-hole thickness of 0.31 mm.

Separate Box–Behnken designs were conducted for the three seed types, and only the millet design matrix is shown here as a representative example due to space limitations; the optimized results for the other two seed types are summarized in Table 7. Using the same methodology, the optimal combinations for broomcorn millet and rapeseed were determined to be 2.97 kPa, 1.12 mm, and 0.35 mm, and 2.35 kPa, 0.93 mm, and 0.32 mm, respectively.

The results further confirm that the empirical relationship between seed size and suction-hole diameter, namely that the hole diameter should be approximately 0.4-0.6 times the equivalent seed diameter, is applicable to the present metering system.

Table 7

Optimal parameter combinations for different seed types

Seed type	Inlet negative pressure [kPa]	Suction hole diameter [mm]	Suction hole thickness [mm]
Millet	2.51	0.88	0.31
Broomcorn millet	2.97	1.12	0.35
Rapeseed	2.35	0.93	0.32

Test bench validation experiment

To verify the rationality of the optimized parameter combinations and reduce the influence of random experimental error, a validation bench was established, as shown in Fig. 6. The test bench mainly consisted of a negative-pressure fan, the seed metering device, a high-speed camera, a seed bed belt, and an oil pump. The validation was carried out without seed-cleaning operations so that the filling performance of the seed metering plate itself could be evaluated independently.

According to the optimal simulation results, the parameter combination for millet was a negative pressure of 2.5 kPa, a suction hole diameter of 0.9 mm, and a suction hole thickness of 0.3 mm; for broomcorn millet, the optimal parameters were 3.0 kPa, 1.1 mm, and 0.4 mm, respectively; and for rapeseed, they were 2.4 kPa, 0.9 mm, and 0.3 mm, respectively.

Under the optimized parameter combinations, 100-hole validation tests were conducted for millet, broomcorn millet, and rapeseed. The seed-filling rates reached 93.0 ± 1.4%, 97.0 ± 0.9%, and 96.0 ± 1.1%, respectively. These results indicate that the CFD-based pressure tracing and response-surface optimization provided parameter combinations sufficiently close to the experimental optimum, and therefore can be used as an efficient preselection method for subsequent metering-plate design.

CONCLUSIONS

This study systematically investigated the key parameters affecting the performance of a pneumatic seed metering plate for small-seed crops through a combination of experiments, CFD simulation, and optimization analysis. The main conclusions are as follows:

(1) Single-factor tests established the engineering matching relationship between suction-hole diameter and seed size for the present metering system, namely that the suitable suction-hole diameter was 0.4-0.6 times the equivalent seed diameter.

(2) Brushing-threshold experiments and the dedicated adsorption test platform determined the acceptable suction-hole negative-pressure ranges for millet, broomcorn millet, and rapeseed as 0.77-2.67 kPa, 0.97-3.25 kPa, and 0.92-2.81 kPa, respectively.

(3) CFD pressure-tracing analysis clarified the mapping between suction-hole pressure and chamber inlet negative pressure, thereby converting the experimentally defined adsorption range into a directly usable chamber-pressure range for design and adjustment.

(4) Response-surface optimization identified the optimal parameter combinations for the three seed types, and bench validation produced seed-filling rates of 93%, 97%, and 96%, confirming the reliability of the optimized results.

From an engineering perspective, the proposed workflow can be used to narrow the parameter-search space of pneumatic seed metering plates for small-seed crops and reduce repeated physical trials. However, the CFD model was based on a steady and symmetric airflow field and did not explicitly account for transient leakage, plate rotation, or gas-solid coupling with moving seeds. These factors should be incorporated in future transient CFD-DEM studies to further improve predictive accuracy.

Keywords: *Lycium barbarum L., Human–Machine Collaboration, Vibration Harvesting, Selective t Harvesting, Performance Optimization*

ABSTRACT

To address the challenges of labor-intensive and inefficient manual harvesting of Lycium barbarum L. grown on a double-layer trellis, this study proposes a human–robot collaborative system. The system consists of a hand-held high-frequency rocker-oscillator harvester and an electric receiving cart. Mechanical property measurements of fruits and branches revealed detachment forces of 1.2 to 1.8 N for mature fruits and 2.5 to 3.0 N for immature fruits, with an average bending elastic modulus of 548.9 MPa for fruit-bearing branches, providing a basis for selective harvesting. A Box–Behnken design was employed to optimize vibration frequency, harvesting duration, and inter-rod spacing, and response surface analysis identified the optimal parameters as 18 Hz, 4.5 s, and 26 mm. Next, a central composite design optimized the receiving cloth tilt angle and radius to maximize collection efficiency, defined as the ratio of fruits collected by the cart to the total number of detached fruits. Field validation demonstrated a mature fruit harvesting rate of 96.2%, a mis-harvesting rate of 4.3%, a damage rate of 3.7%, and a collection efficiency of 96.1%, with relative errors below 0.5% compared to model predictions. These results confirm the system's effectiveness and provide technical support for standardized, low-damage mechanized fruit harvesting of Lycium barbarum L..

摘要

为解决双层篱架栽培枸杞人工采摘劳动强度大、效率低下的问题，本研究提出了一种人机协作采摘系统。该系统由手持高频摇摆振动采摘机与电动接果车组成。对果实及枝条力学特性的测定结果显示，成熟果实的脱离力为 1.2 至 1.8 N，未成熟果实为 2.5 至 3.0 N，果枝的平均弯曲弹性模量为 548.9 Mpa，为实现选择性采摘提供了理论依据。研究采用 Box–Behnken 试验设计对振动频率、采摘时长及振动杆间距进行了优化，并通过响应面分析确定最佳参数为振动频率 18 Hz、采摘时长 4.5 s 以及振动杆间距 26 mm。随后，利用中心复合试验设计对接果布的倾角与半径进行了优化，以最大化接果效率，接果效率定义为接果车收集到的果实数量占脱落果实总量的比例。田间验证结果显示，成熟果实采摘率达到 96.2%，误采率为 4.3%，损伤率为 3.7%，接果效率为 96.1%，各项指标实测值与模型预测值的相对误差均低于 0.5%。上述结果表明该系统具有高效、低损伤的应用潜力，为双层篱架栽培枸杞的标准化机械化果实采摘提供了技术支撑。

INTRODUCTION

The transition toward mechanization and intelligent technologies is of great significance for improving the production efficiency of *Lycium barbarum* L. *(Torregrosa et al., 2014)*. Owing to its indeterminate inflorescences and continuous multi-cropping fruiting, harvesting operations are frequent and labor-intensive *(Chen et al., 2025)*. At present, high-cost and low-efficiency manual harvesting remains predominant, constituting a major bottleneck for high-quality development of the industry. Therefore, the development of efficient and low-damage mechanized harvesting equipment is imperative.

Vibrational harvesting is the principal method for mechanized harvesting of *L. barbarum*, with notable progress in both hardware and operational strategies. The impact of shaker design, shaking position, and duration on fruit detachment efficiency has been experimentally tested in stone fruits such as apricots *(Erdogan et al., 2003)*. Canopy shaker systems for late-season oranges have also been studied to evaluate the effect of vibration parameters on fruit motion and detachment *(Castro-García et al., 2018)*, and the application of arrayed excitation units further enhances operational efficiency *(Mei et al., 2024)*.

Additionally, a variable-pitch combing brush device has been developed to achieve effective fruit detachment with reduced damage *(Zhang et al., 2018)*. Modifications to excitation methods can effectively increase harvesting efficiency *(Chen et al., 2025)*, while batch-specific parameter optimization improves overall yield *(Liu et al., 2025)*. Simulation and field trials have validated optimal parameter combinations *(Wang et al., 2025; Wang et al., 2026)*, and studies on energy transmission have revealed optimal excitation positions and resonance frequency for vibrational harvesting of *L. barbarum (Deng et al., 2025; Su et al., 2025; Zhao et al., 2021)*.

However, existing studies have mainly focused on fruit detachment, with limited attention to the receiving system. Portable harvesters typically rely on manually spread collection mats, resulting in high labor demands and significant fruit loss. Research on blueberries has shown that soft receiving surfaces can effectively reduce impact damage *(Yu et al., 2014)*, and rigid–flexible coupled collision models further optimize harvesting parameters *(Takeda et al., 2017; Wang et al., 2022)*. Additionally, proper selection of excitation frequency can improve picking rate *(Yu et al., 2024)*. Recent studies on mechanical harvesting systems in olives provide insights for power requirements and trunk shaker optimization *(Ghonimy et al., 2023)*, and analysis of coffee fruit-peduncle systems reveals vibration transmissibility and energy transfer for efficient harvesting *(Villibor et al., 2023)*. Studies on other small berry crops indicate that integrating harvesting and receiving functions can enhance efficiency and minimize fruit damage; multiple excitations improve fruit detachment, whereas mechanical analysis and transport optimization further reduce damage *(Sim et al., 2024; Komarnicki, 2025; Lyu et al., 2024)*. Nevertheless, systematic integration studies for *L. barbarum* remain lacking.

To address this gap, the present study proposes a human–machine collaborative harvesting approach with a portable vibrational harvester and an electric receiving cart. By integrating agronomic measurement, mechanical analysis, simulation, and field trials, key operational parameters are optimized to improve efficiency and reduce fruit damage, providing systematic support for mechanized harvesting of *L. barbarum*.

MATERIALS AND METHODS

Agronomic Parameter Measurement

Key agronomic parameters of goji berries, including plant height, row spacing, layer height, and layer width, were measured and are summarized in Table 1. These data serve as a reference for the design of subsequent harvesting equipment.

Table 1

Agronomic Parameters of Standard Double-Layer Trellis Cultivation

Agronomic Parameter	Description	Mean ± SD
Plant height (m)	Height from ground to the top of the plant	1.71 ± 0.12
Plant spacing (m)	Distance between centers of adjacent plants in a row	1.32 ± 0.10
Layer 1 height (m)	Height of first fruit-bearing branch layer from ground	0.73 ± 0.06
Layer 2 height (m)	Height of second fruit-bearing layer from ground	1.51 ± 0.30
Layer 1 width (m)	Horizontal width of the first layer fruit crown	1.27 ± 0.16
Layer 2 width (m)	Horizontal width of the second layer fruit crown	1.15 ± 0.23
Row spacing (m)	Distance between centers of adjacent rows	3.19 ± 0.35

The field study was conducted on goji plants cultivated by Ningxia Zhengqi Hong Industrial Development Co., Ltd. in Guyuan City, Ningxia, China. A standard double-layer trellis system was employed, with branches pruned to droop naturally, thereby minimizing inter-branch entanglement and facilitating mechanized harvesting (Fig. 1). The overall cultivation environment is depicted in Fig. 2.

Fig. 1 - Single Goji Plant Model

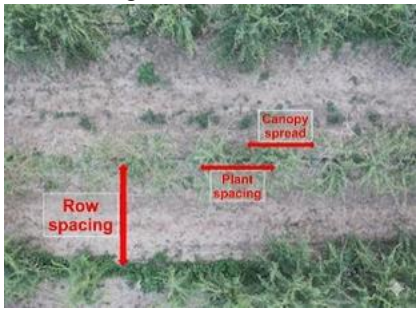

Fig. 2 - Cultivation Environment

Fruit Detachment Mechanical Parameters

The mechanical properties of goji berries at different physiological stages are crucial for designing vibration-based harvesting devices. Structural and compositional changes during maturation influence how easily the fruit detaches. The relationship between detachment force and moisture content is therefore critical for developing effective harvesting strategies.

To measure detachment force, a tensile load was applied along the peduncle at a constant speed, and the peak force at fracture was recorded. Mature fruits with 85–90% moisture content show peduncle shear forces of 1.2–1.8 N, whereas immature green fruits, despite sometimes exceeding 90% moisture, have more lignified peduncles and require higher detachment forces of 2.5–3.0 N.

As shown in Fig. 3, detachment force is negatively correlated with moisture content across all maturity stages. When moisture rises from 75% to 90%, mature fruits' detachment force decreases by ~30% to 1.2–1.8 N, while immature fruits decrease by only ~15%, remaining 2.5–3.0 N. This difference underlies the harvest-ripe, leave-unripe strategy, essential for selective mechanical harvesting and preventing damage to developing fruits.

Based on this relationship, vibration parameters can be adjusted in real time. For mature fruits with moisture above 85%, 15–20 Hz efficiently detaches them without stressing branches. Green fruits below 80% moisture require higher energy, naturally remaining attached under tuned excitation. These findings provide a theoretical basis for precise vibration control and intelligent, adaptive harvesting systems.

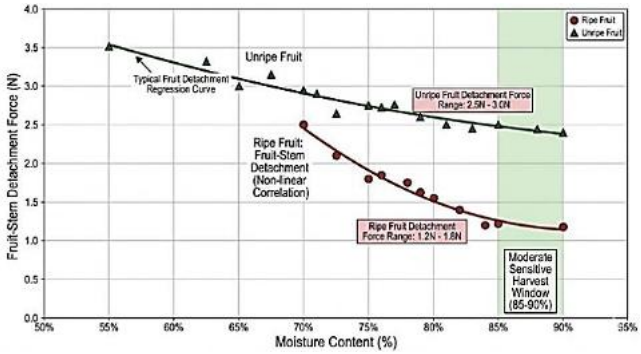

Fig. 3 - Hematic Illustration of the Relationship Between *Lycium barbarum L.* Detachment Force and Moisture Content

Analysis of Vibration Mechanisms

During operation of the portable goji harvester, the excitation rod induces forced vibrations in the "fruit–peduncle–branch" system. Statistical analysis identified three detachment modes: tensile break, fling-off, and impact detachment, with tensile break being predominant. The sequential stages of this process are illustrated in Fig. 4.

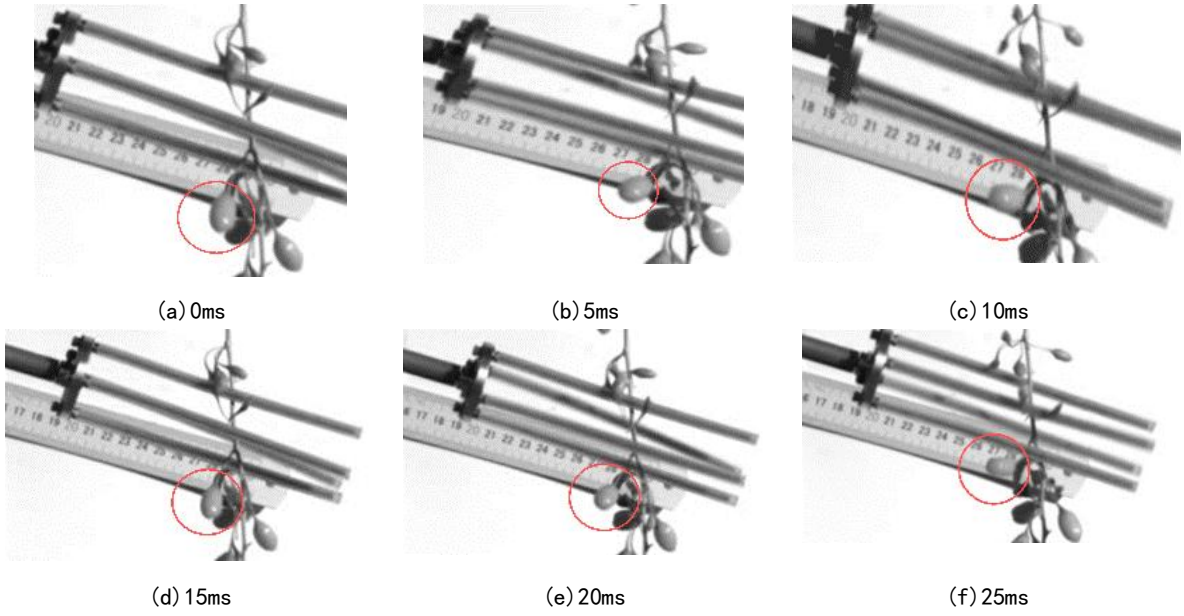

Fig. 4 - Sequence Diagram of Fruit Detachment During Vibration Harvesting

In the tensile break mode, vibration-induced tension in the peduncle generates a velocity difference between the branch and the fruit, while branch acceleration produces an inertial force exceeding the fruit–peduncle adhesion, causing detachment. As shown in Fig. 4a–f, the process follows six stages: (a) initial excitation and peduncle tensioning; (b) inertial sliding of the fruit after branch acceleration; (c) reverse branch motion and impact interaction; (d) secondary sliding after collision; (e) repeated peduncle tensioning during cyclic vibration; and (f) final fruit detachment. This sequence reveals that mature fruit removal is primarily driven by the accumulation of vibration-induced inertial force exceeding fruit–peduncle adhesion, which is essential for understanding the mechanism of selective harvesting. Notably, the repeated tensioning during cyclic vibration progressively weakens the peduncle connection, making final detachment more efficient.

A staged dynamic analysis of this vibration-induced detachment is summarized in Fig. 5, which illustrates the key mechanical interactions involved. During vibration harvesting, the fruit-bearing branch is regarded as an excitation carrier, and the fruit–peduncle system is simplified as a forced vibration system. The inertial force generated by vibration can be expressed as:

$$F_i = ma = m\omega^2 r \tag{1}$$

where F_i is the inertial force acting on the fruit (N), m is the fruit mass (kg), a is the vibration acceleration $(m \bullet s^{-2})$, ω is the angular velocity of vibration $(rad \bullet s^{-1})$, and r is the equivalent vibration radius (m).

Considering the combined effects of inertial force and gravity, the resultant tensile force acting along the fruit–peduncle connection can be described as:

$$F = \sqrt{(I\sin\theta + m\omega^2 r)^2 + (I\cos\theta - G)^2} \tag{2}$$

where F is the resultant tensile force acting on the fruit–peduncle connection (N), G is the fruit gravity (N), and θ is the angle between the peduncle and the vibration direction $(°)$. Fruit detachment occurs when $F > F_d$, where F_d is the measured fruit detachment force (N). Therefore, under appropriate vibration conditions, mature fruits with lower detachment force can be detached preferentially, while immature fruits with higher detachment force remain attached, thereby providing a clear mechanical basis for selective vibration harvesting. This principle ensures that only ripe fruits are removed during operation, leaving unripe fruits to continue maturing for subsequent harvests.

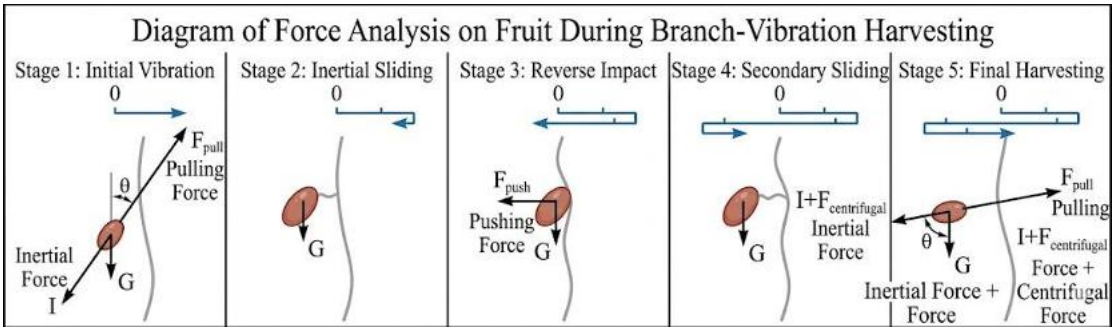

Fig. 5 - Schematic Diagram of the Dynamic Analysis of Fruit Detachment During Vibration Harvesting

During harvesting, the excitation rod applies direct vibration to fruit-bearing branches, inducing forced vibrations in the "fruit–peduncle–branch" system. Detachment forces differ among tissues: mature fruits require the least force, followed by flowers, while immature fruits and leaves require higher forces, with some overlap.

Vibration-based harvesting relies on inertial forces, and controlling vibration intensity is critical. By adjusting acceleration appropriately, mature fruits can be detached selectively while minimizing unintended detachment of other tissues. Calculated detachment accelerations rank in the order: mature fruits, immature fruits, leaves, and flowers, with minimal overlap, supporting effective selective harvesting.

Harvesting System Platform

A coordinated system was developed for mechanized Lycium barbarum L. harvesting, comprising a portable hand-held harvester and an electric fruit-collecting cart. During operation, the harvester is guided by an operator to detach fruits using the excitation rod, while the cart positions a receiving cloth beneath the branches to collect the detached fruits. The platform is mounted on a mobile chassis, manually navigated along orchard rows, with a fixed frame supporting all components.

Design of the Harvesting Device

The portable harvester improves *Lycium barbarum L.* harvesting efficiency and reduces labor through mechanized vibration. Its rocker-oscillator mechanism ensures smooth, continuous oscillation, and the harvesting head is adjustable. The oscillating rod length can be varied to control vibration amplitude and angle, enabling precise excitation at the fruit–peduncle junction (Fig. 6). Goji berries of different maturity often coexist on the same branch, requiring selective harvesting. During operation, the excitation rod acts on fruit-bearing branches, transmitting high-frequency torsional torque. Mature fruits detach when inertial force exceeds peduncle adhesion, while immature fruits remain attached, achieving selective harvesting of ripe fruits (Fig. 7).

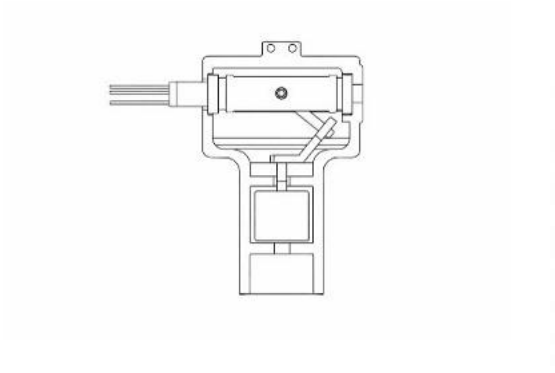

Fig. 6 - Schematic Diagram of the Hand-Held Harvesting Device Structure

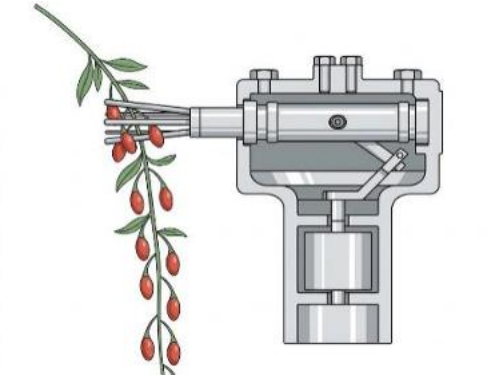

Fig. 7 - Operation Diagram of the Portable Harvesting Device

Design of the Receiving Device

A coordinated system combines a hand-held harvester with an electric collection cart. The operator vibrates fruit-bearing branches while the cart deploys a cloth to collect detached fruits, improving efficiency and reducing labor. The cart chassis fits the standardized double-layer trellis, with row spacing 3.19 m, canopy width 1.27 m, and inter-row corridor 1.92 m. Its width is 0.6 m, height 0.4 m, and length 1.6 m, allowing side-by-side operation and clearance under lower branches (first-layer branches average 0.73 m, lower traction line 0.61 m). The design lowers the center of gravity to enhance stability while accommodating 1.32 m plant spacing.

Based on its chassis dimensions, the receiving cart's structure and workflow were designed to reduce fruit loss and labor intensity. The operator guides the cart along orchard rows using a push handle, while an electric-driven, manually assisted mechanism deploys flexible side cloths to form a semi-enclosed collection surface. The low-center-of-gravity chassis with wide wheel track ensures stability, and the worm-gear motor maintains position under impact. The canopy, tilted 20° downward with a cushioning layer, absorbs shocks and directs detached fruits into the storage basket. Fruits are collected as branches are vibrated by the hand-held harvester, and the canopy is retracted after harvesting (Fig. 9).

Fig. 9 - Field Operation Diagram of the Receiving Cart

RESULTS

Experimental Design

To investigate the effects of vibration frequency X_1, harvesting duration X_2, and inter-rod spacing X_3 on harvesting performance, a Box–Behnken design was employed. The factor coding is summarized in Table 2.

Table 2

Factor Coding for the Portable Harvesting Device

Code	Vibration frequency X1 (Hz)	Harvesting duration X2 (s)	Inter-rod spacing X3 (mm)
1	20	5	40
0	15	3	30
-1	10	1	20

The mature fruit harvesting rate Y_1, mis-harvesting rate of immature fruits Y_2, and damage rate of mature fruits Y_3 were calculated as follows:

$$Y_1 = \frac{N_{hm}}{N_{hm} + N_{rm}} \times 100\% \quad (3)$$

$$Y_2 = \frac{N_{hi}}{N_{hi} + N_{ri}} \times 100\% \quad (4)$$

$$Y_3 = \frac{N_{dm}}{N_{hm}} \times 100\% \quad (5)$$

where N_{hm} is the number of harvested mature fruits, N_{rm} is the number of residual mature fruits, N_{hi} is the number of harvested immature fruits, N_{ri} is the number of residual immature fruits, and N_{dm} is the number of damaged mature fruits.

During each trial, the receiving device was carefully positioned precisely beneath the canopy, and the collection surface was fully deployed to ensure complete coverage of the target area and to maximize fruit capture efficiency (Fig. 10). The collection surface consists of a fixed central cloth and two motor-driven lateral arms that together envelop the trunk, forming a fully enclosed annular collection area around the base of the plant, effectively capturing all detached fruits and preventing losses. The harvester then applied controlled high-frequency excitation to fruit-bearing branches via the vibrating rods (Fig. 11), with vibration carefully tuned to avoid excessive stress. Detached fruits fell directly onto the tilted collection surface, rolled smoothly downward along the 20° slope, and gradually accumulated into the storage basket located at the lowest point. This carefully designed gravity-driven flow completely eliminates the need for manual fruit collection, minimizes handling, and effectively reduces impact damage by controlling both the distance and speed at which fruits fall before contacting the soft, cushioned collection surface.

Fig. 10 - Field Positioning of the Receiving Device

Fig. 11 - Vibration Harvesting Operation

Data Analysis

Using vibration frequency X_1, harvesting duration X_2, and inter-rod spacing X_3 as independent variables, and the harvesting rate of mature fruits Y_1, mis-harvesting rate of immature fruits Y_2, and damage rate of mature fruits Y_3 as dependent variables, trials were conducted sequentially for each treatment combination. The data are summarized in Table 3.

Table 3

Statistical Data of *Lycium barbarum L.* Vibration Harvesting Experiments

Index	X1	X2	X3	Y1/%	Y2/%	Y3/%
1	-1	-1	0	73.62	1.85	8.97
2	1	-1	0	69.34	5.2	6.5
3	-1	1	0	85.97	3.31	3.99
4	1	1	0	99.74	6.13	3.07
5	-1	0	-1	71.55	0.83	9.91
6	1	0	-1	90.16	1.77	6.6
7	-1	0	1	87.2	6.12	4.87
8	1	0	1	98.4	10.87	1.89
9	0	-1	-1	69.01	0.73	11.38
10	0	1	-1	85.88	2.6	7.12
11	0	-1	1	85.47	4.2	4.78
12	0	1	1	94.88	10.07	3.48
13	0	0	0	87.96	3.3	2.68
14	0	0	0	85.2	5.85	3.84
15	0	0	0	94.6	2.26	4.08
16	0	0	0	94.55	4.72	1.2
17	0	0	0	93.6	4.8	4.28

The experimental data were fitted using a second-order polynomial regression model, expressed as:

$$Y = \beta_0 + \sum \beta_i X_i + \sum \beta_{ii} X_i^2 + \sum \beta_{ij} X_i X_j \quad (6)$$

Where Y represents the response variable, β_0 is the intercept coefficient, β_i, β_{ii} and β_{ij} are the linear, quadratic, and interaction coefficients, respectively, and X_i and X_j are the coded independent variables.

Based on the definitions of Y_1, Y_2 and Y_3 (Eq.3 – Eq.5), a second-order polynomial regression was applied to obtain models for each evaluation indicator, as given in Eq. 7 – Eq. 9:

$$Y_1 = 91.18 + 4.91X_1 + 8.63X_2 + 6.17X_3 - 6.02X_2^2 \quad (7)$$

$$Y_2 = 4.19 + 1.48X_1 + 1.27X_2 + 3.17X_3 \quad (8)$$

$$Y_3 = 3.22 - 1.21X_1 - 1.75X_2 - 2.50X_3 + 1.64X_2^2 + 1.83X_3^2 \quad (9)$$

Analysis of variance (ANOVA) showed that the regression model for the harvesting rate of mature fruits Y_1 was significant $(P = 0.0095)$, with a non-significant lack-of-fit $(P = 0.3376)$ and $R^2 = 0.8980$. The model for the mis-harvesting rate of immature fruits Y_2 was highly significant $(P = 0.0083)$, with a non-significant lack-of-fit $(P = 0.5318)$ and $R^2 = 0.9020$. The model for the damage rate of mature fruits Y_3 was also highly significant $(P = 0.0025)$, with a non-significant lack-of-fit $(P = 0.7476)$ and $R^2 = 0.9321$. All three models showed good fit and high predictive reliability.

Parameter Optimization

The response surface analysis is shown in Fig. 12. Figs. 12(a–c) show the effects of harvesting duration, vibration frequency, and inter-rod spacing on the mature fruit harvest rate. Both duration and frequency initially increase the harvest rate, but saturation occurs beyond a certain threshold, indicating that most easily detached fruits have already been removed. Inter-rod spacing further improves overall harvest efficiency by reducing excitation blind zones, enhancing detachment from inner branches, and ensuring more uniform fruit removal across the canopy.

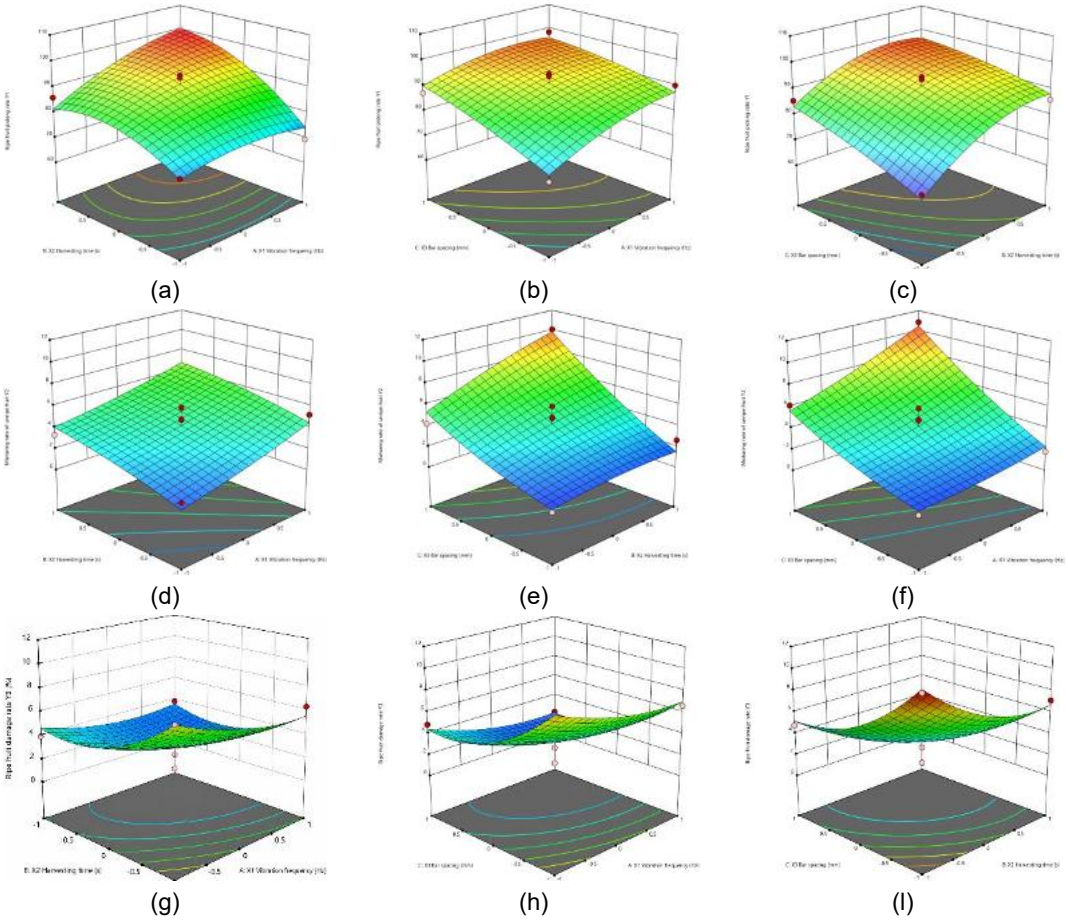

Fig. 12 - Response Surface Analysis

Figs 12(d–f) show the effects on mis-harvesting of immature fruits. Inter-rod spacing has the strongest influence, as wider spacing allows deeper penetration into the canopy, increasing unintended detachment. Vibration frequency and harvesting duration also contribute, with high-frequency, long-duration excitation potentially inducing peduncle fatigue.

Figs 12(g–i) illustrate effects on mature fruit damage, which exhibits a U-shaped trend. Narrow spacing leads to surface bruising, moderate spacing minimizes damage, and excessive spacing or duration causes secondary collisions, increasing peel rupture.

Multi-objective optimization identified the optimal combination as 18 Hz vibration frequency, 4.5 s harvesting duration, and 26 mm inter-rod spacing, predicting 96.47% harvest, 4.18% mis-harvesting, and 3.59% damage, balancing efficiency and fruit quality.

Based on the harvesting parameter optimization, the performance of the receiving device was further optimized. A central composite design (CCD) was used, with the receiving cloth tilt angle (20–40°) and radius (70–100 cm) as independent variables. The factor coding is summarized in Table 4.

Table 4

Factor Coding for the Lycium barbarum L. Receiving Device

Index	Tilt Angle of Receiving Cloth A_1 (°)	Radius of Receiving Cloth A_2 (cm)
1	40	100
0	30	85
-1	20	70

The collection efficiency of the receiving device Y_4 was used as the evaluation indicator, as expressed in Eq.10:

$$\eta = \frac{m_1}{m_2} \times 100\% \tag{10}$$

where m_1 is the number of fruits collected by the receiving device, and m_2 is the total number of detached fruits. Upon completion of the trials, the results are summarized in Table 5.

Table 5

Statistical Data of Lycium barbarum L. Receiving Experiments

Index	Tilt Angle of Receiving Cloth A1 (°)	Radius of Receiving Cloth A2 (cm)	Collection Efficiency B (%)
1	20	70	88.4
2	40	70	88.9
3	20	100	67.1
4	40	100	67.6
5	20	85	85.7
6	40	85	86.2
7	30	70	95.5
8	30	100	74.5
9	30	85	92.8
10	30	85	93.1
11	30	85	92.6
12	30	85	93.2
13	30	85	92.9

A second-order polynomial regression was applied to the experimental data to obtain the regression model for the collection efficiency of the receiving device Y4, as expressed in Eq.11:

$$\eta = 92.92 + 0.25A_1 - 10.60A_2 - 6.98A_1^2 - 7.93A_2^2 \tag{11}$$

The regression model was highly significant $(P < 0.0001)$ with a coefficient of determination $R^2 = 0.9998$, indicating an excellent fit. Response surface analysis showed that collection efficiency increased and then decreased with both tilt angle and cloth radius, revealing a single optimum within the experimental range. Optimization to maximize collection efficiency yielded a tilt angle of 29.72° and a cloth radius of 76.83 cm, corresponding to a predicted efficiency of 96.33%. For practical control, these parameters were rounded to 30° and 77 cm.

Validation experiments under these conditions produced a harvesting rate of mature fruits of 96.2%, a mis-harvesting rate of 4.3%, a damage rate of 3.7%, and a collection efficiency of 96.1%. The relative errors compared to model predictions (96.47%, 4.18%, 3.59%, and 96.33%, respectively) were all below 0.5%, confirming the reliability of the optimization and the accuracy of the model.

CONCLUSIONS

This study developed a human–machine collaborative harvesting system for double-layer trellis-cultivated goji berries, integrating a hand-held high-frequency rocker-oscillator harvester and an electric receiving cart. Mature fruits had detachment forces of 1.2–1.8 N and immature fruits 2.5–3.0 N, with the average bending elastic modulus of fruit-bearing branches being 548.9 MPa, providing a basis for selective harvesting and simulation. The harvester, equipped with a flexible silicone-coated comb head and Hall-effect speed monitoring, delivered precise excitation at 15–20 Hz. The receiving cart, with a 1.6 × 0.6 × 0.4 m chassis and side-mounted cantilever canopy, formed a ring-shaped collection area of 50–180 cm diameter with a 20° downward tilt. Response surface optimization identified operational parameters of 18 Hz vibration frequency, 4.5 s harvesting duration, 26 mm inter-rod spacing, 30° cloth tilt, and 77 cm radius. Field validation achieved a mature fruit harvesting rate of 96.2%, mis-harvesting rate of 4.3%, damage rate of 3.7%, and collection efficiency of 96.1%, with relative errors below 0.5%, demonstrating the platform's effectiveness for high-efficiency, low-damage harvesting.

ACKNOWLEDGEMENT

ABSTRACT

The power take-off (PTO) shaft of a tractor is subjected to complex and variable random loads during field operations, and the accuracy of the resulting load spectrum directly affects the reliability of fatigue life prediction. To address the limitations of traditional parametric extrapolation methods, particularly their inadequate fitting performance, a non-parametric extrapolation method based on DBSCAN clustering is proposed. Field test validation demonstrates that the proposed method effectively captures the multi-modal distribution characteristics of the load. The extrapolated results show good agreement with the measured data in terms of cycle count distribution and pseudo-damage indicators. Compared with the fixed-bandwidth method, the proposed approach increases the coefficient of determination by 3.401% and reduces the mean squared error (MSE) by 39.154%, while yielding pseudo-damage values closer to 1. These findings provide a novel technical approach for the construction of load spectra under complex operating conditions of agricultural machinery.

摘要

拖拉机动力输出轴在田间作业过程中承受复杂多变的随机载荷，其载荷谱编制的准确性直接影响疲劳寿命预测的可信度。针对传统参数化外推方法难以精确拟合的问题，提出一种基于 DBSCAN 聚类的非参数外推方法。田间实测数据验证表明，该方法能有效刻画载荷的多模态分布特征，外推结果在循环计数分布与伪损伤等指标上与实测数据具有良好的一致性。结果表明本文提出的方法决定系数相比于固定带宽提高了 3.401%，均方误差降低了 39.154%，伪损伤值更接近 1。研究结果为农业装备复杂工况下载荷谱编制提供了新的技术途径。

INTRODUCTION

In the development of modern agriculture, tractors are widely used and play a crucial role in agricultural mechanization and efficiency improvement *(Yu et al., 2023; Yang et al., 2018)*. The tractor power take-off (PTO) shaft is an important component of the tractor transmission system and a key part affecting the durability and reliability of the entire tractor. The tractor load spectrum can reflect the load history experienced by the whole tractor or its key components, serving as the foundation for tractor fatigue analysis and reliability assessment *(Liu et al., 2011)*. Load extrapolation is a critical step in load spectrum compilation, and its effectiveness directly affects the accuracy of the compiled load spectrum. Therefore, researching load extrapolation methods suitable for the tractor PTO shaft is of great significance for improving the credibility of tractor durability and reliability tests, as well as enhancing the operational performance of the tractor *(Wang et al., 2022)*.

In recent years, the combination of clustering algorithms and kernel density estimation has provided new ideas for load extrapolation (*Chen et al., 2017*). Kernel density estimation is a statistical method that directly infers the population probability density surface based on the sample data itself without any prior theoretical distribution assumptions. Research has shown that grouping load data using the Density-Based Spatial Clustering of Applications with Noise (DBSCAN) algorithm allows for the calculation of optimal bandwidths for different clusters of data, thereby effectively addressing the limitations of a global fixed-bandwidth. The DBSCAN algorithm can identify clusters of arbitrary shapes and automatically exclude noise points, which aligns naturally with the multi-operating condition and multi-modal distribution characteristics commonly found in load data *(He et al., 2018; Wang et al., 2016)*.

Based on the above analysis, this paper proposes a non-parametric extrapolation method for tractor PTO loads based on DBSCAN clustering *(Li et al., 2025)*. First, the PTO torque time history under typical operating conditions is collected through field tests. Second, the rain-flow counting method is used to extract the mean and amplitude of load cycles, and the DBSCAN algorithm is applied to perform cluster analysis on the mean-amplitude data. The rain-flow counting method is a counting method for calculating the amplitude and mean of load cycles, which conforms to the inherent characteristics of fatigue loads and is widely used in the statistical analysis of load time history. Then, based on the clustering results, bandwidth-optimized kernel density estimation is performed for the data of each cluster to establish a load probability distribution model. Finally, extrapolation is carried out through Monte Carlo simulation to obtain a PTO load spectrum covering the full life cycle. The research results can provide more accurate load input for tractor PTO fatigue strength design and bench durability tests, while also offering a methodological reference for load spectrum compilation under complex operating conditions in the field of agricultural equipment.

MATERIALS AND METHODS

Testing System Setup

The tractor wireless torque measurement system is mainly composed of a torque sensor, a data acquisition module, a wireless transmission module, and host computer software. The wireless torque sensor, model TQ201, primarily consists of a strain measurement circuit, a data processing unit, a wireless communication unit, and a power supply unit. The strain gauges and the sensor are fixed on the output shaft, forming the basic sensor. When the output shaft rotates, the resistance of the strain bridge changes, causing the voltage at the measurement terminal to change. The voltage signal is transmitted to the data processing unit, where it passes through the node's built-in high-precision resistive bridge circuit and amplification conditioning circuit. Subsequently, the signal is transmitted to the wireless receiving module via the wireless communication unit. Throughout the entire process, the power supply unit provides power to all components.

A schematic diagram of the ultimately constructed wireless torque testing system is shown in Figure 1 below.

Fig. 1 – Schematic diagram of wireless torque testing system

Field Test Load Collection

From May 20 to 25, 2025, a field test of tractor power take-off (PTO) shaft torque was conducted in the suburbs of Yangling District, Xianyang City, Shaanxi Province. The test prototype was a YCX504D tractor, and the operating condition was rotary tillage using a 1GQN-180Z rotary tiller. Based on the tractor wireless torque testing system, the PTO shaft torque load is displayed and recorded in real time.

Load Signal Preprocessing

During the real-vehicle testing of tractor PTO torque, the original load signal is often contaminated with singular points that do not represent true loads due to the harsh field environment, electrical system interference, and occasional instability of the sensor. These abnormal data can severely distort the statistical characteristics of the load distribution, thereby affecting the accuracy of fatigue damage calculations. Therefore, this study adopts a strategy combining the amplitude threshold method and the gradient threshold method to eliminate and smooth the original load signal.

The amplitude threshold method is primarily used to identify and eliminate outliers that significantly exceed the extreme values of the physical system or violate statistical laws. For load signals with stationary or pseudo-stationary random characteristics, such as tractor PTO torque, this study employs the classic criterion as the basis for determination.

$$\mu = \frac{1}{N}\sum_{i=1}^{N} x_i \quad (1)$$

$$\sigma = \sqrt{\frac{1}{N-1}\sum_{i=1}^{N}(x_i - \mu)^2} \quad (2)$$

According to statistical principles, if the data obey or approximately obey a normal distribution, the probability of abnormal points is extremely small. The discrimination criterion of the amplitude threshold method is as follows.

$$|x_i - \mu| > K\sigma \quad (3)$$

Among them, x_i is the load amplitude at the sampling point, μ is the mean of the load signal sequence, σ is the standard deviation of the load signal sequence, and K is the threshold coefficient, typically taken as 3.

When the signal point satisfies the above condition, it is determined as a gross error. To maintain the continuity of the time series, the point is usually not directly removed; instead, it is replaced by linear interpolation using adjacent valid data points, i.e.

$$x_i^* = \frac{x_{i-1}+x_{i+1}}{2} \quad (4)$$

Although the amplitude threshold method can effectively eliminate global extreme outliers, it cannot identify local abrupt signals where the amplitude does not exceed the limit but unreasonable mutations occur between adjacent sampling points. When a tractor encounters gravel or experiences sudden implement jamming, certain impacts may occur; however, limited by the inertia of the mechanical system, the instantaneous rate of change of the load has a physical upper bound. Therefore, the gradient threshold method is introduced to eliminate high-frequency abnormal sudden-change signals.

The gradient threshold method determines anomalies by calculating the difference between two adjacent sampling points (i.e., the local gradient) and comparing it with a set critical threshold. Its discrimination criterion can be expressed as:

$$|\Delta x_i| = |x_i - x_{i-1}| > \varepsilon \quad (5)$$

To avoid misidentifying actual transient impact loads as outliers, it is usually necessary to perform bidirectional gradient verification in conjunction with adjacent points. That is, a data point is determined as an outlier only when the gradients between it and both the previous and subsequent points are greater than the set threshold and are in opposite directions.

The improved discrimination criterion is as follows:

$$\begin{gathered} |x_i - x_{i-1}| > \varepsilon \\ |x_i - x_{i+1}| > \varepsilon \\ (x_i - x_{i-1})(x_i - x_{i+1}) > 0 \end{gathered} \quad (6)$$

In the formula, x_i is the current load signal point to be detected; x_{i-1} is the previous valid load signal point; x_{i+1} is the next load signal point; and ε is the gradient threshold. This threshold is typically determined based on the physical characteristics (maximum stiffness and response frequency) of the tractor's power transmission system or suspension system.

When a data point is identified as a gradient anomaly, polynomial interpolation is similarly employed for smoothing correction to restore the true physical profile of the signal, ensuring the accuracy of cycle amplitude extraction during subsequent rain-flow counting.

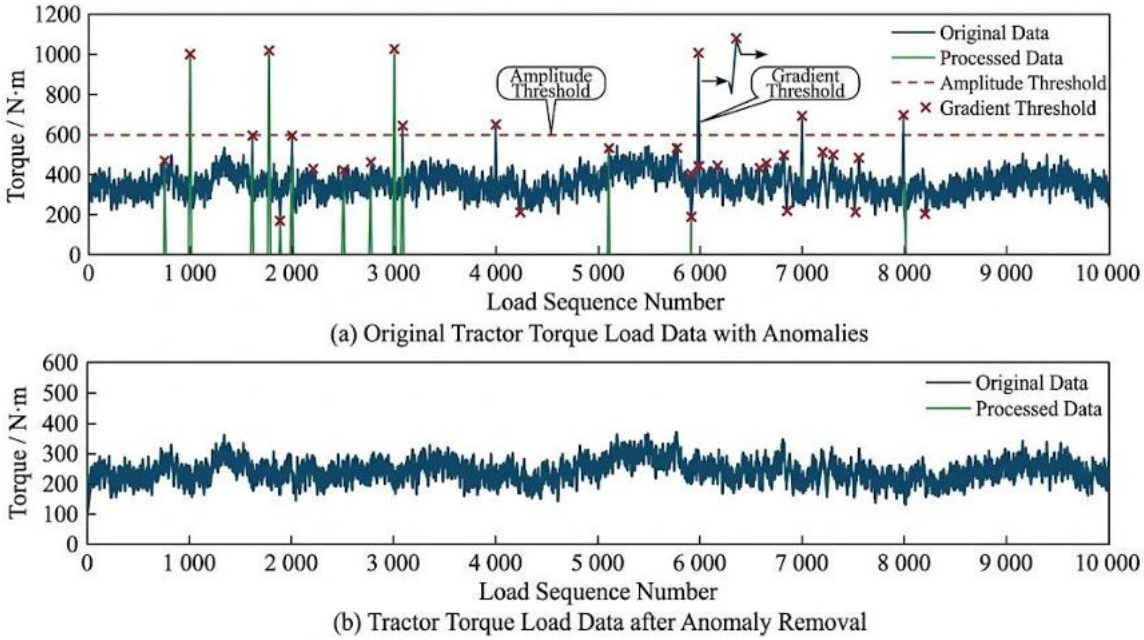

Fig. 2 – Comparison chart for removing singular points

After removing singular points from the load signal, the signal often still contains random high-frequency interference caused by tractor engine vibration, high-frequency excitation from the transmission system, and the inherent thermal noise of the sensor. To ensure that the subsequent rain-flow counting method can accurately extract the true load amplitudes that affect fatigue life, further smoothing and noise reduction of the signal are required.

For load spectrum compilation, traditional moving average filtering tends to flatten the peaks and valleys of the signal, thereby underestimating the true fatigue damage. Therefore, this paper adopts the S-G polynomial smoothing filter method for signal noise reduction. The core advantage of the S-G filter lies in its ability to filter out high-frequency noise while preserving the local extreme characteristics and waveform width of the original load signal to the greatest extent.

The S-G filter is essentially a sliding window filtering method based on local polynomial least squares fitting. Let the width of the smoothing sliding window be 2m+1; the set of data points within the window is denoted as $\{(ti,xi)|i=-m, \ldots, 0, \ldots, m\}$, where the center point corresponds to i=0. Within each sliding window, a k-order polynomial is used to fit the data points in the window.

The fitting polynomial can be expressed as:

$$p(j) = \sum_{r=0}^{k} a_r \, j^r \tag{7}$$

In order to solve for the coefficients of the polynomial, the principle of the least squares method is applied to minimize the sum of squared residuals between the fitted values and the actual observed values within the window.

$$E = \sum_{j=-m}^{m} \left(\sum_{r=0}^{k} a_r \, j^r - x_{i+j} \right)^2 \tag{8}$$

In order to minimize the error function, the partial derivatives with respect to each coefficient are taken and set to zero, allowing the coefficient matrix to be solved. In practical applications, through complex matrix operations and derivations, the smoothed fitting value at the center point is actually equivalent to the linearly weighted combination of the data points within the window. Therefore, the final smoothed output of the S-G filter can be expressed in the form of a convolution sum.

$$x_i^* = \sum_{j=-m}^{m} C_j \, x_{i+j} \tag{9}$$

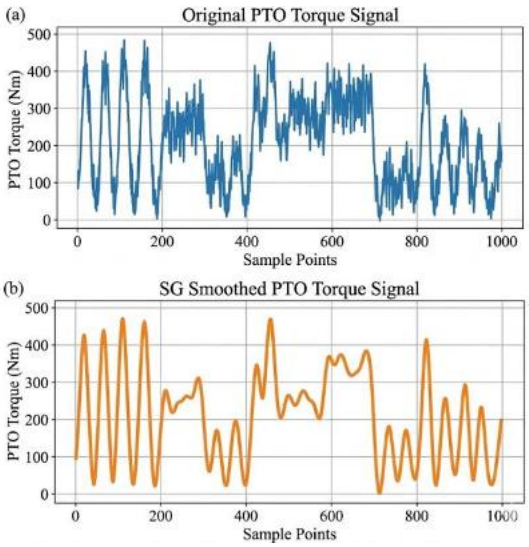

Fig. 3 – Comparison chart before and after noise reduction treatment

RESULTS

Load Counting Statistical Processing

After preprocessing, the data can be further screened and streamlined to improve analysis efficiency. The rain-flow counting method is a widely used statistical counting technique for measured load time histories, which extracts information on the amplitude and mean of load cycles, aligning with the inherent characteristics of fatigue loads. For the preprocessed load signal, the four-point rain-flow counting method is employed to perform statistical counting processing on the measured load, resulting in a mean-amplitude matrix of load cycles.

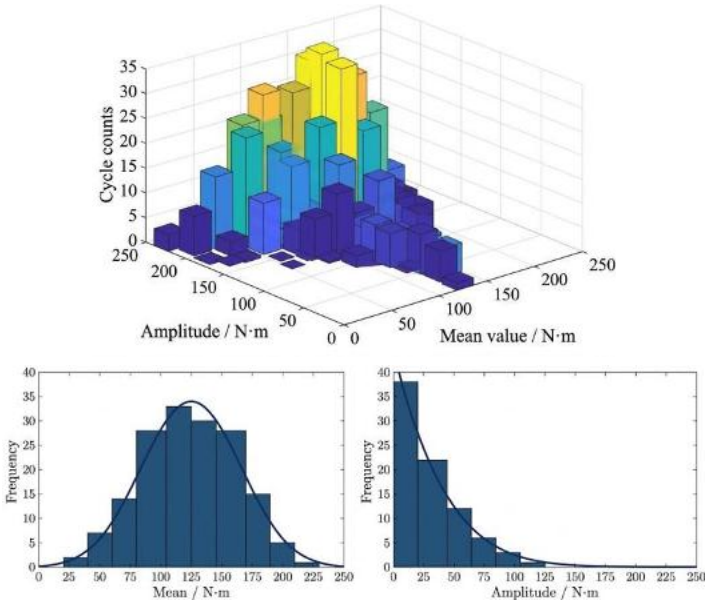

Fig. 4 – Schematic diagram of rainflow matrix

Kernel Density Extrapolation Based on DBSCAN Clustering

After completing the preprocessing of the tractor PTO load signal, the rain-flow counting method is used to extract load cycles from the torque time history, transforming the random load into a series of complete mean-amplitude cycles to form a sample set.

$$X = \{(m_i, a_i) \mid i = 1,2, \ldots, N\} \quad (10)$$

Among them, m_i is the mean value of the cycle, and a_i is the amplitude. This two-dimensional feature space serves as the foundation for subsequent clustering and probabilistic modeling. Due to the complex operating conditions of tractors, PTO loads often exhibit multi-modal distribution characteristics. Therefore, the DBSCAN density clustering algorithm is introduced to partition the sample set. DBSCAN identifies clusters of arbitrary shapes based on density reach-ability and automatically eliminates noise points.

The ε of a sample point x_i is defined as:

$$N_\varepsilon(x_i) = \{x_j \in X \mid d(x_i, x_j) \leq \varepsilon\} \quad (11)$$

The Euclidean distance is usually used as the distance metric d(·). If the number of sample points within the neighborhood satisfies

$$|N_\varepsilon(x_i)| \geq MinPts \quad (12)$$

Then x_i is a core point. Clusters are continuously expanded through direct density-reachability and density-reachability relationships, ultimately partitioning the samples into K clusters C_1, C_2, …, C_K and several noise points. The selection of the parameters ε and $MinPts$ is crucial: the k-distance graph method is used to determine ε (taking k=$MinPts$), that is, the distance from each sample to its nearest neighbor is calculated and sorted in descending order, and the distance corresponding to the inflection point of the curve is taken as ε; $MinPts$ is empirically tuned between 4 and 10. The clustering algorithm is shown in the figure.

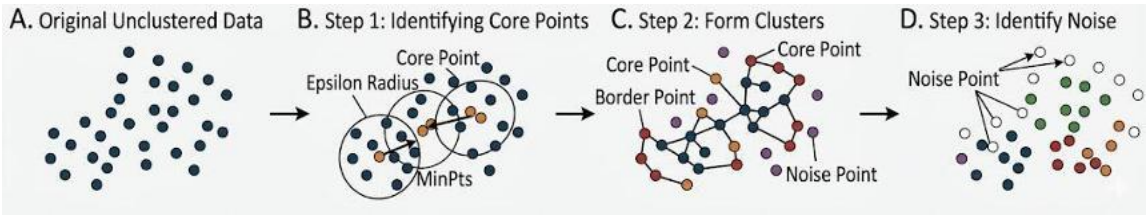

Fig. 5 – DBSCAN algorithm schematic diagram

After clustering is completed, a two-dimensional probability density function is established for each cluster C_j (with sample sizen_j), and kernel density estimation is used to describe its distribution. For the cluster, the probability density estimate is given by:

$$\hat{f}_j(m, a) = \frac{1}{n_j}\sum_{i=1}^{n_j} K_{H_j}(m - m_{ji}, a - a_{ji}) \quad (13)$$

where $K_{H_j}(\cdot)$ is the two-dimensional Gaussian kernel function.

$$K_{H_j}(u) = \frac{1}{2\pi|H_j|^{1/2}} exp\left(-\frac{1}{2}u^T H_j^{-1} u\right) \quad (14)$$

H_j is the bandwidth matrix. The selection of bandwidth directly affects the estimation accuracy, and the traditional global fixed-bandwidth struggles to accommodate the differences in data distribution across clusters. Therefore, the optimal bandwidth is calculated separately based on the characteristics of each cluster. The Rule-of-Thumb method is used to determine the bandwidth matrix. For two-dimensional data, n rule can be adopted:

$$.H_j = n_j^{-1/6}\hat{\Sigma}_j^{1/2} \quad (15)$$

where $\hat{\Sigma}_j$ is the sample covariance matrix of the cluster, estimated by the following formula:

$$\hat{\Sigma}_j = \frac{1}{n_j - 1}\sum_{i=1}^{n_j}\begin{bmatrix} (m_{ji} - \bar{m}_j)^2 & (m_{ji} - \bar{m}_j)(a_{ji} - \bar{a}_j) \\ (m_{ji} - \bar{m}_j)(a_{ji} - \bar{a}_j) & (a_{ji} - \bar{a}_j)^2 \end{bmatrix} \quad (16)$$

In the formula, $\bar{m}_j$ and $\bar{a}_j$ are the sample means of the mean and amplitude for that cluster, respectively. This adaptive bandwidth method preserves details in data-dense regions while providing smooth estimation in sparse regions, thereby improving the goodness of fit. After obtaining the probability density functions for each cluster, Monte Carlo simulation is used for load extrapolation. First, the sampling weights for each cluster are calculated:

$$w_j = \frac{n_j}{\sum_{j=1}^{K} n_j} \quad (17)$$

Noise points are not involved in modeling. The extrapolation factor is determined based on the operating time T_0 corresponding to the measured data and the design life T_{target}:

$$\lambda = \frac{T_{target}}{T_0} \quad (18)$$

The total number of extrapolated cycles is approximately:

$$N_{target} = \lambda N \quad (19)$$

The sampling process is as follows: a cluster is randomly selected according to the weight w_jj, and then a sample point is drawn from the kernel density mixture distribution of that cluster.

Specifically, a sample (m_{ji},a_{ji}) within the cluster is first randomly selected as the kernel center, and then a new sample $(m_{\text{new}i},a_{\text{new}i})$ is drawn from a two-dimensional Gaussian distribution with the center as the mean and a covariance matrix of H_{j2}. This process is repeated until N_{target} samples are obtained. To ensure the physical rationality of the extrapolated loads, boundary constraints are applied to the sampling results. Samples that exceed the boundaries are discarded and resampled. Finally, the extrapolated load cycle set is obtained:

$$X_{ext} = \{(m_k, a_k) \mid k = 1,2, \ldots, N_{target}\} \quad (20)$$

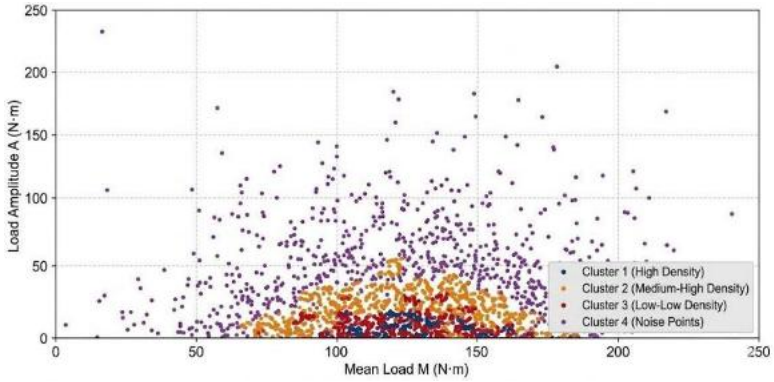

Fig. 6 – DBSCAN clustering effect diagram

Figure 6 shows the identification of load distribution based on DBSCAN clustering. Combined with adaptive bandwidth kernel density estimation and Monte Carlo sampling, it enables high-precision non-parametric extrapolation of complex tractor PTO loads.

Extrapolated Load Verification

To verify the effectiveness and accuracy of the proposed method, a comparison is made with the traditional load extrapolation based on fixed-bandwidth kernel density estimation. The evaluation is conducted in terms of two aspects, namely goodness of fit and pseudo-damage.

The fixed-bandwidth method and the DBSCAN clustering method proposed in this paper were both used to extrapolate to five times the original load. The coefficient of determination and mean square error were introduced as two parameters to compare the extrapolation effects, and the results are shown in Table1. The results indicate that, compared with the fixed-bandwidth method, the coefficient of determination of the proposed method increased by 3.401%, while the mean square error decreased by 39.154%. It can be concluded that the clustering-based load extrapolation with clustered data significantly improves the extrapolation performance, verifying the feasibility and effectiveness of the proposed method.

Table 1

Comparison of Extrapolation Effects

Extrapolation model	Coefficient of determination	Mean square error
Fixed-bandwidth	0.941	8.745
DBSCAN clustering	0.973	5.321

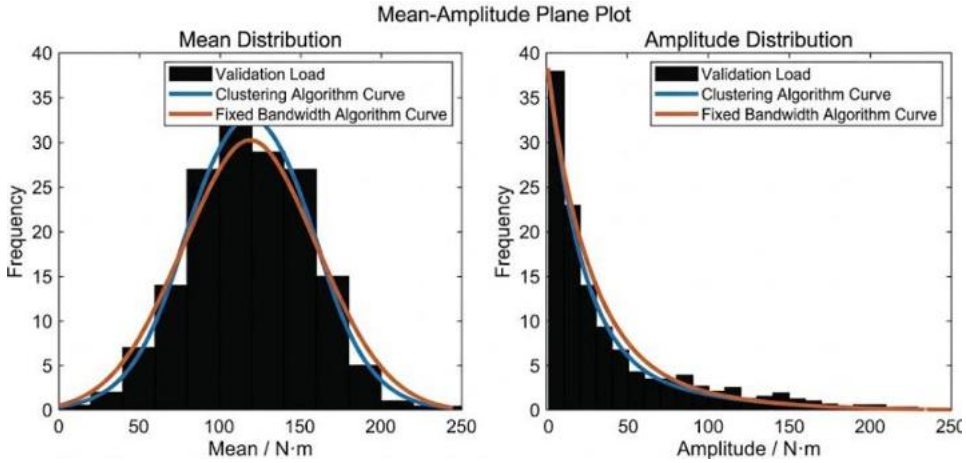

Fig. 7 – Mean amplitude probability fitting curve

To verify the accuracy of the extrapolated load spectrum generated by the DBSCAN based non-parametric estimation method, this paper introduces the pseudo-damage theory for equivalence testing. Pseudo-damage is an engineering indicator used to evaluate the severity of a load spectrum from the perspective of fatigue damage, comprehensively reflecting the influence of load amplitude distribution and cycle count on the fatigue life of components. The calculation of pseudo-damage is based on Miner's linear cumulative damage criterion and the S-N curve.

$$D_p = \sum_{i=1}^{k} n_i S_{ai}^m \quad (21)$$

In the formula, D_p represents the total pseudo-damage of the load spectrum; k is the total number of load levels after rain flow counting and two-dimensional grid division of the load spectrum; S_{ai}^m is the torque amplitude of the load level; $n_i$is the cycle count corresponding to the load level; and m is taken as 6.

The pseudo-damage ratio R_d is defined as the ratio of the pseudo-damage of the extrapolated load spectrum to the pseudo-damage of the proportionally scaled original load spectrum.

$$R_d = \frac{D_{p,ext}}{D_{p,ori} \times E_f} \quad (22)$$

In the formula, R_d is the pseudo-damage ratio, $D_{p,ext}$ is the pseudo-damage value of the full-life load spectrum generated by two-dimensional non-parametric extrapolation, $D_{p,ori}$ is the pseudo-damage value of the original measured load, and E_f is the extrapolation factor.

Table 2

Pseudo-damage ratio at different multiples

Different multiples	Fixed-bandwidth	The proposed method
10	1.098	1.032
20	1.112	1.038
30	1.103	1.041
40	1.113	1.043
50	1.121	1.045

Based on the comparison data of pseudo-damage ratios under different extrapolation factors, the adaptive bandwidth method based on DBSCAN clustering proposed in this paper demonstrates significantly superior performance compared to the traditional fixed-bandwidth method at all extrapolation factors. The pseudo-damage ratio of the fixed-bandwidth method fluctuates between 1.098 and 1.121, showing a clear upward trend as the extrapolation factor increases. In contrast, the pseudo-damage ratio of the proposed method remains stable between 1.032 and 1.045, not only closer to the ideal value of 1, but also exhibiting an increase of only 1.260% as the extrapolation factor rises, demonstrating excellent accuracy retention and factor insensitivity.

From a quantitative perspective, the method proposed in this paper reduces the deviation of the pseudo-damage ratio by an average of approximately 6.512% compared to the fixed-bandwidth method. The fundamental reason for this difference lies in the fact that the fixed-bandwidth kernel density estimation adopts a globally uniform smoothing parameter, which makes it difficult to simultaneously achieve fitting accuracy in both dense and sparse regions when dealing with the multi-modal distribution characteristics of tractor PTO loads, leading to distortion of the distribution tail features that is amplified with increasing extrapolation factors. In contrast, the DBSCAN clustering method effectively identifies natural clusters corresponding to different operating conditions through density-based clustering, and computes adaptive bandwidths based on the sample covariance of each cluster, thereby more accurately preserving the original load distribution morphology and fatigue damage characteristics.

The results indicate that the proposed method can more accurately replicate the fatigue damage potential of loads under different extrapolation requirements, exhibiting higher accuracy and robustness, and is suitable for load spectrum compilation throughout the full life cycle of tractor PTO.

CONCLUSIONS

（1）The clustering effectiveness of the DBSCAN algorithm is highly dependent on the selection of the neighborhood radius ε and the minimum number of samples MinPts. The current approach based on the k-distance graph combined with empirical tuning has a certain degree of subjectivity.

Future research can explore automatic parameter optimization methods based on clustering validity indices or introduce adaptive DBSCAN variants to achieve full adaptability in the clustering process, further enhancing the robustness and generality of the method. In non-parametric rain-flow extrapolation based on kernel density estimation, the kernel bandwidth is the most critical factor affecting the extrapolation performance. More accurate and effective selection algorithms can be introduced for the choice of kernel bandwidth.

（2）This study only considered the load characteristics in the two dimensions of mean and amplitude, whereas actual fatigue damage is also influenced by factors such as load sequence and frequency components. Subsequent research could attempt to incorporate additional features such as load duration and rise/fall rates into the analysis dimension to construct a higher-dimensional probability model. At the same time, methods for reconstructing time series with realistic temporal characteristics from extrapolated cycle distributions can be explored to meet the requirements of bench tests that demand full time-domain signals.

（3）The method proposed in this paper was validated based on PTO load data from a specific tractor model. Future work should extend the validation to load data from more tractor models and a wider range of operation types (such as plowing, rotary tillage, transportation, etc.) to verify the scalability of the method. More importantly, indoor bench durability tests using the extrapolated load spectrum should be conducted. By comparing the actual fatigue life of components with the life predicted by the extrapolated spectrum, a quantitative evaluation system for method accuracy can be established, providing a more solid foundation for engineering applications.

ABSTRACT

This paper presents a theoretical framework for estimating the gripping force of a three-degree-of-freedom robotic arm mounted on a remotely operated underwater vehicle, intended for sampling operations in intensive aquaculture systems. Using the static relationship based on the Jacobian transpose, the proposed method reconstructs the force and moment vectors acting at the end-effector from the estimated joint torques. The gripping force is determined by projecting the Cartesian force onto the normal directions of a two-finger gripper. Transmission efficiency and joint friction are incorporated into the model through the definition of an effective torque. The influence of hydrodynamic forces is treated as an external disturbance during quasi-static manipulation. The internal consistency of the model is evaluated through a numerical validation based on representative design parameters for compact underwater manipulators. The analysis indicates that a gripping force of approximately 150–200 N satisfies the friction-based stability condition for typical sampling loads of approximately 100 N. Furthermore, the resulting joint torques remain within the realistic operating limits of actuators commonly used in ROV-mounted manipulators. The findings confirm the dimensional consistency and physical plausibility of the proposed estimation framework, which may be applied to assisted underwater force estimation in aquaculture applications.

REZUMAT

Lucrarea dezvoltă un cadru teoretic pentru estimarea forței de prindere a unui braț robotic cu trei grade de libertate montat pe un vehicul subacvatic acționat de la distanță, care va fi utilizat în operațiunile de eșantionare într-un sistem intensiv de acvacultură. Folosind relația statică bazată pe transpunerea iacobiană, metoda reconstruiește vectorul forțelor și vectorul momentelor care apar la efectorul final de la cuplurile estimate în articulații. Forța de prindere este determinată prin proiectarea unei forțe carteziene pe direcțiile normale ale unui dispozitiv de prindere cu două degete. Eficiența transmisiei și frecarea articulară sunt încorporate în model printr-un cuplu efectiv. Efectul forțelor hidrodinamice este tratat ca forțe perturbatoare în timpul manipulării cvasi-statice. Consistența internă a modelului este evaluată prin intermediul unei validări numerice bazate pe parametri de proiectare reprezentativi pentru manipulatoare subacvatice compacte. Conform analizei, o forță de prindere de aproximativ 150–200 N îndeplinește condiția de stabilitate bazată pe frecare pentru sarcini tipice de eșantionare de aproximativ 100 N. Cuplurile articulare rezultate se încadrează în limitele realiste ale actuatoarelor utilizate în mod obișnuit în manipulatoarele montate pe ROV. Rezultatele analizei numerice confirmă coeziunea dimensională și plauzibilitatea fizică a cadrului de estimare sugerat, care poate fi utilizat în determinarea forței de manipulare subacvatică asistată în acvacultură.

INTRODUCTION

Recent developments in precision aquaculture have created a growing need to identify reliable solutions for underwater inspection and intervention, driven by the rapid expansion of intensive aquaculture (*Akram et al., 2022; Akram et al., 2025*).

Recent experimental studies have demonstrated the increasing use of remotely operated underwater vehicles for the inspection and monitoring of aquaculture nets, since these systems can operate efficiently in confined underwater environments and can integrate vision and control systems suitable for fish farm monitoring (*Cai et al., 2025*). In addition, the continuous evolution of autonomous and semi-autonomous strategies for the inspection of large fish cages has been observed. This trend has encouraged the integration of robust robotic manipulators on underwater platforms. The practical deployment of underwater robotic arms confirms the usefulness of these systems for maintenance, inspection, and intervention operations (*Vasileiou et al., 2025*).

For performing sampling operations, a robotic arm mounted on an ROV must be able to generate sufficient gripping force to prevent the manipulated object from slipping and, at the same time, limit contact loads to avoid damage to fragile or deformable samples. In current practice, direct force measurement at the end effector is frequently influenced by various factors such as operating costs, sealing requirements, space available for sensor integration, as well as long-term operational reliability. Thus, especially when the manipulation is performed slowly and the process is dominated by contact mechanics rather than fast dynamic effects, force estimation based on actuator signals and mathematical model relationships becomes a practical solution (*Bicchi, 1995; Yoshikawa, 1985*). The feasibility of coordinated vehicle–manipulator operation in complex environments has been validated through multibody models and control architectures in realistic underwater scenarios (*Di Vito et al., 2021*). Motion planning and coordinated control strategies have been proposed and implemented to deal with inertial effects and coupling between vehicle and manipulator (*Han et al., 2020*). Also, experiments have been performed to increase the robustness of the system to external disturbances through hybrid controllers and methods based on disturbance observers (*Li et al., 2019*). Studies on unmanned systems for aquaculture monitoring emphasized the growing integration of underwater robotic platforms, sensor technologies, and intelligent monitoring approaches for improving operational efficiency and environmental supervision in fish farming systems (*Ganie et al., 2025; Ubina and Cheng, 2022*). Recent experiments highlight adaptive approaches and model-free methods for interacting with unknown environments, highlighting the importance of robust force and motion control in underwater manipulation (*Yang et al., 2024*).

Since the robot must simultaneously manage model uncertainties, hydrodynamic perturbations, and contacts with deformable elements, its control plays a critical role in its underwater manipulation. Experimental research has been conducted to address this challenge, which has developed complex interaction control schemes for underwater vehicle–manipulator systems that ensure stable behavior during contact operations (*Heshmati-Alamdari et al., 2018*). Recent data-driven control studies for autonomous underwater vehicles have also demonstrated the potential of robust Koopman operator-based approaches for improving system stability and dynamic response under uncertain underwater operating conditions (*Liu et al., 2026; Rahmani and Redkar, 2024*). Studies have also been conducted that highlight the rapid development of underwater robots and the essential technologies required for their operational control, including dynamic modeling, sensor systems, and environmental interaction strategies, which have highlighted that interaction forces are essential for achieving safe and efficient underwater operations (*Sun et al., 2024*).

Classical robot modeling provides the mathematical foundation for relating joint variables to forces acting on the end effector, with standard kinematic and static relationships using the Jacobian matrix to transform joint torques into Cartesian vectors of forces and moments, which allows for force estimation when joint torques can be directly measured or inferred from motor currents (*Craig, 2005; Siciliano et al., 2009*). Experimental research has shown that underwater vehicle–manipulator systems introduce additional effects that influence the balance between torques and forces, including buoyancy, hydrodynamic drag, added mass, and coupling between vehicle motion and manipulator action (*Antonelli, 2014; Fossen, 2011*). Studies dedicated to underwater manipulators also show that real underwater systems are limited by joint friction, structural compliance, and sensor constraints, factors that directly affect interaction control and force reconstruction (*Sivčev et al., 2018*). Experiments on force and interaction control methods for underwater vehicle–manipulator systems have also been carried out, highlighting the need for high robustness against model uncertainties and deformable contacts, important aspects for gripping and sampling operations in aquaculture applications (*Heshmati-Alamdari et al., 2018*).

The novelty of this work consists in the development of an integrated theoretical framework that combines actuator signal interpretation, Jacobian-based static force reconstruction, transmission loss compensation, and gripper contact modeling for gripping force estimation in ROV-mounted underwater

manipulators dedicated to aquaculture sampling operations. The proposed approach provides a physically consistent and modular methodology suitable for underwater environments where direct force sensing is difficult due to sealing, space, and reliability constraints.

MATERIALS AND METHODS

1. System Overview and Assumptions

In order to carry out the experimental research, a system was analyzed that includes: a remotely operated underwater vehicle (ROV that ensures positioning and coarse movements) equipped with a serial robotic manipulator and a parallel gripper with two fingers, intended for sampling operations in intensive aquaculture environments that performs fine positioning and gripping operations. The present paper focuses on the manipulator-gripper subsystem and treats the vehicle as a rigid base, whose movement is slow in relation to the handling load, and for the theoretical development the following hypotheses are adopted:

1. The handling load is quasi-static, and inertial effects are negligible in relation to the contact forces.
2. The gripper applies symmetric normal forces on the object.
3. The torques in the joints can be estimated based on the actuator signals.
4. Hydrodynamic effects are treated as external perturbations and are not included in the main static model.
5. The manipulated object is rigid or weakly deformable, and the contact occurs at well-defined points.

These assumptions are consistent with standard approaches used in robotic manipulation and in the analysis of underwater vehicle–manipulator systems (*Craig, 2005; Siciliano et al., 2009; Antonelli, 2014*).

2. Kinematic Model of the Manipulator

The manipulator is modeled as a serial kinematic chain with n revolute or prismatic joints. The joint coordinate vector is defined as:

$$q = [q_1, q_2, \dots, q_n]^T \tag{1}$$

where:

q – the joint coordinate vector of the manipulator, [rad] or [m];

$q_1, q_2, \dots q_n$– the individual joint coordinates, and each term represents either a rotation angle for a revolute joint [rad] or a linear displacement for a prismatic joint, [m];

n – the total number of degrees of freedom of the manipulator, equal to the number of independently actuated joints, [-];

$[\,]^T$ – the transpose operator, which indicates that q is written as a column vector of size n x 1.

The kinematic structure of the ROV-mounted manipulator is illustrated in Fig. 1. The scheme defines the joint coordinates q_1, q_2, q_3, the end-effector frame, and the wrench F applied at the gripper, together with the joint torques τ_1, τ_2, τ_3. This representation provides the geometric basis for the derivation of the Jacobian matrix and for the static force mapping used.

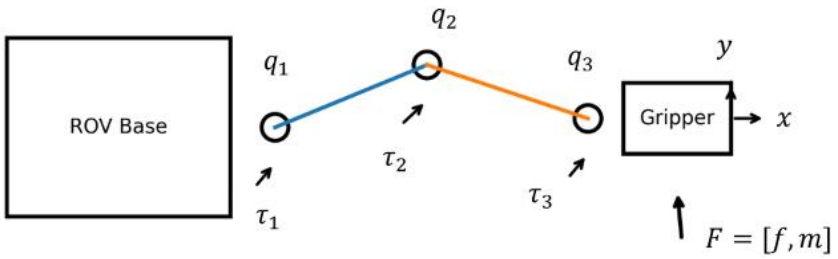

Fig. 1 – Kinematic scheme of the ROV-mounted manipulator and definition of joint variables and end-effector wrench

The pose of the end-effector is described by the vector:

$$x = [p^T, \varphi^T]^T \tag{2}$$

where:

p– the position, [m];

φ– the orientation, [rad].

The forward kinematics is expressed as:

$$x = f(q) \tag{3}$$

The differential kinematics is obtained by differentiation with respect to time:

$$\dot{x} = J(q)\dot{q} \tag{4}$$

where:

$J(q)$ – the manipulator Jacobian matrix.

The Jacobian relates joint velocities to end-effector linear and angular velocities and is computed using standard methods based on the chosen kinematic representation (*Craig, 2005; Siciliano et al., 2009*).

3. Static Force Relationship

Under quasi-static conditions, the relationship between joint torques τ and the wrench applied at the end-effector F is given by the principle of virtual work:

$$\tau = J^T(q)F \tag{5}$$

Here, F is defined as:

$$F = [f^T,\ m^T]^T \tag{6}$$

where:

f– force vector [N],

m – moment vector at the end-effector [N·m].

If the Jacobian transpose is full rank, or if a suitable pseudoinverse is used, the end-effector wrench can be estimated as:

$$F = (J^T(q))^{\dagger}\tau \tag{7}$$

where:

† represents the Moore–Penrose pseudoinverse operator.

From a dimensional point of view, the proposed formulation is coherent, with the electric current being expressed in amperes, the joint torques expressed in newton-meters, and the Cartesian forces expressed in newtons, and the Jacobian matrix and its transpose provide a physically meaningful correspondence between the joint space and the Cartesian space. This dimensional consistency allowed the estimated grip force to be directly correlated with the grip stability conditions, determined by friction and external loads. This relationship forms the basis for force estimation based on information on joint torques, a standard approach used in force control and interaction modeling in robotics (*Siciliano et al., 2009*).

4. Joint Torque Estimation from Actuator Signals

For electrically actuated joints, the motor torque τ_m is proportional to the motor current I

$$\tau_m = k_t I \tag{8}$$

where:

τ_m– the torque generated by the electric motor at its shaft, [N·m];

k_t– motor torque constant. It expresses the proportionality between the motor current and the produced torque, [N·m/A];

I– motor current supplied to the actuator, [A].

The joint torque τ is obtained by considering the transmission ratio r and the mechanical efficiency η:

$$\tau = \eta r \tau_m \tag{9}$$

where:

τ– the torque available at the robot joint after the transmission, [N·m];

η– mechanical efficiency of the transmission, it accounts for losses due to friction and other dissipative effects, [-];

r– transmission ratio (gear ratio), it relates the motor shaft torque to the joint torque, [-].

This relation shows how the motor torque is transformed into joint torque through the transmission mechanism, taking into account the gear ratio and the mechanical losses (*Craig, 2005; Siciliano et al., 2009*).

Friction and other parasitic effects can be represented by an additional torque term τ_f, leading to:

$$\tau_{eff} = \tau - \tau_f \tag{10}$$

where:

τ_{eff}– the torque actually available for producing motion or for balancing external forces at the joint, after subtracting losses, [N·m];

τ_f– the torque loss due to joint friction, seals, and other dissipative effects in the transmission, [N·m].

In this theoretical framework, τ_f is treated as an uncertainty term or as a parameter that can be compensated using standard friction models.

5. Gripper Contact Model and Gripping Force Definition

The gripper is modeled as a two-finger parallel mechanism applying normal forces F_n on opposite sides of the object. The total gripping force F_g is defined as:

$$F_g = 2F_n \tag{11}$$

where:

F_g– total gripping force applied by the gripper on the object, [N];

F_n– normal contact force applied by one gripper finger on the object surface, it is the force perpendicular to the contact surface at one finger, [N].

For static equilibrium, the gripping force must be sufficient to resist the external load W acting on the object. Assuming Coulomb friction with coefficient μ, the no-slip condition can be written as:

$$F_n \geq \frac{W}{2\mu} \tag{12}$$

where:

W– external load acting on the object (in practice, it represents the effective weight of the object, corrected by buoyancy in underwater conditions), [N];

μ– coefficient of friction between the gripper finger and the object surface, [-].

This relation is derived from basic grasp mechanics and is widely used for preliminary grasp force estimation (*Cutkosky, 1989; Salisbury and Mason, 1985*). In underwater conditions, the effective load W is corrected by buoyancy, but the same equilibrium principle applies (*Fossen, 2011*).

6. Extraction of Gripping Force from End-Effector Wrench

The estimated end-effector force vector $f$contains the interaction forces between the gripper and the object. The gripping force is obtained by projecting this force onto the normal directions of the gripper fingers. Let n_1 and n_2 be the unit normal vectors at the two contact points. The normal contact forces are:

$$F_{n1} = fn_1, \quad F_{n2} = fn_2 \tag{13}$$

where:

f– the resultant interaction force between the gripper and the object, expressed in Cartesian coordinates (the end-effector force vector acting at the gripper), [N].

Under symmetric grasp conditions:

$$F_{n1} \approx F_{n2} \approx F_n \tag{14}$$

and the gripping force is estimated as:

$$F_g = F_{n1} + F_{n2} \tag{15}$$

This procedure links the joint-level measurements to a physically meaningful gripping force value at the gripper-object interface.

7. Treatment of Underwater Effects

Hydrodynamic forces such as drag and added mass introduce additional torques at the joints and additional forces at the end-effector. For slow manipulation tasks, these effects are assumed to be small compared to contact forces and are treated as disturbances, following common practice in underwater manipulation modeling (*Antonelli, 2014; Fossen, 2011*).

The estimated force can therefore be expressed as:

$$F_{est} = F_{contact} + F_{dist} \tag{16}$$

where:

F_{est}– the force vector obtained from the model-based estimation process, which includes both the contact interaction force and additional disturbance effects, [N];

$F_{contact}$– the actual contact interaction force at the gripper–object interface, [N];

F_{dist}– disturbance force vector (it groups the contributions of unmodeled or parasitic effects, such as hydrodynamic drag, added mass effects, structural compliance, and measurement noise), [N].

This relation states that the force obtained from estimation is the sum of the actual contact force and additional disturbance-related force components.

RESULTS

This section presents the theoretical and numerical validation of the proposed gripping force estimation framework for a three-degree-of-freedom (3-DoF) serial manipulator mounted on an ROV, as illustrated in Fig. 1. The analysis focuses on the internal consistency of the mathematical formulation and on verifying whether the predicted force and torque levels are realistic for underwater sampling operations performed with compact robotic manipulators.

1. Logical workflow of the force estimation method

The estimation procedure follows the sequence illustrated in Fig. 2.

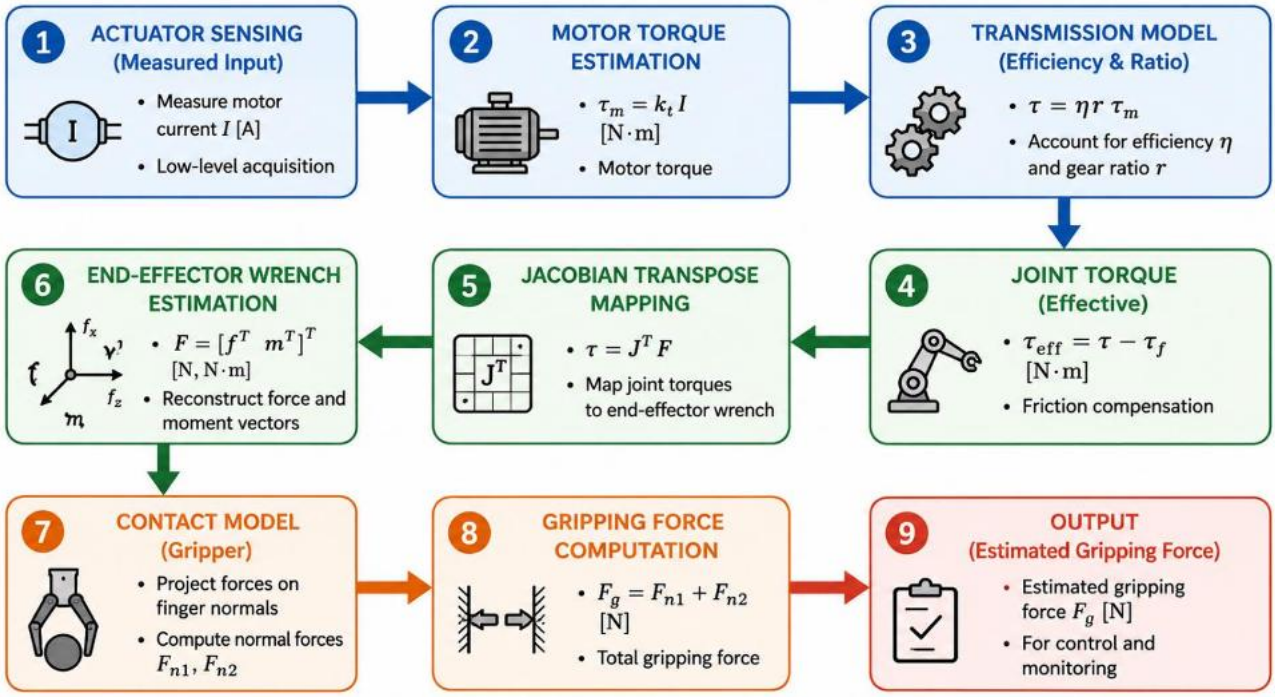

Fig. 2 – Logical block diagram for gripping force estimation

The process begins with actuator measurements, where the electric motor current is used to estimate motor torque. The transmission model converts the motor torque into joint torque, while mechanical losses are accounted for through an effective torque term.

2. Validation of gripping force requirements

To evaluate the physical plausibility of the model, representative design values typical for compact underwater manipulators were considered. Parallel grippers used for sampling tasks usually provide a nominal clamping capability in the range of 150–200 N. A representative external load associated with pulling or detaching a biological sample from a structure was assumed as:

$$W = 100 \text{ N} \tag{17}$$

From equations (12), (14), (15):

$$F_g \geq \frac{W}{\mu} \tag{18}$$

The minimum gripping force becomes:

$$F_{g,min} = \frac{100}{\mu} \tag{19}$$

The required gripping force therefore depends directly on the contact friction conditions:

- For $\mu = 0.5$

$$F_{g,min} = 200 \text{ N} \tag{20}$$

which corresponds to the upper bound of the considered gripper capability.

- For $\mu = 0.6$

$$F_{g,min} \approx 167 \text{ N} \tag{21}$$

which lies within the nominal operating range of compact parallel grippers.

- For a mid-range gripping force of approximately $F_{min} = 147$ N, the friction coefficient required to prevent slip becomes:

$$\mu_{min} = \frac{W}{F_g} = \frac{100}{147} \approx 0.68 \tag{22}$$

This result shows that grasp stability strongly depends on the contact interface. High-friction pads or textured surfaces significantly improve the safety margin of the grasp.

3. Joint torque validation for a 3-DoF manipulator

To validate the model, the external force was propagated through the kinematic chain of a 3-DoF planar manipulator corresponding to the structure shown in Fig. 1. The relationship between the Cartesian force and the joint torques is given by Eq. (5).

For a planar 3R manipulator, the end-effector position can be written as:

$$x = l_1 \cos q_1 + l_2 \cos(q_1 + q_2) + l_3 \cos(q_1 + q_2 + q_3) \tag{23}$$

$$y = l_1 \sin q_1 + l_2 \sin(q_1 + q_2) + l_3 \sin(q_1 + q_2 + q_3) \tag{24}$$

Hence, the Jacobian matrix associated with the planar force components is:

$$J(q) = \begin{bmatrix} -l_1 \sin q_1 - l_2 \sin(q_1 + q_2) - l_3 \sin(q_1 + q_2 + q_3) & -l_2 \sin(q_1 + q_2) - l_3 \sin(q_1 + q_2 + q_3) & -l_3 \sin(q_1 + q_2 + q_3) \\ l_1 \cos q_1 + l_2 \cos(q_1 + q_2) + l_3 \cos(q_1 + q_2 + q_3) & l_2 \cos(q_1 + q_2) + l_3 \cos(q_1 + q_2 + q_3) & l_3 \cos(q_1 + q_2 + q_3) \end{bmatrix} \tag{25}$$

For the considered case, the external force is purely vertical,

$$f = [0, -100]^T \quad \text{N} \tag{26}$$

Therefore:

$$\tau = J^T(q) f \tag{27}$$

reduces to: $\tau_i = J_{y,i} F_y$ (28)

where $J_{y,i}$ represents the element on row y, column i of the Jacobian matrix. Using l_1 = 0.20 m, l_2 = 0.18 m, l_3 = 0.156 m and $q_1 = 30°$, $q_2 = -45°$, $q_3 = 20°$, the following values are obtained:

$$J_{y,1} = 0.5025 \text{ m}; \; J_{y,2} = 0.3293 \text{ m}; \; J_{y,3} = 0.1554 \text{ m} \tag{29}$$

which yield the following joint torques

$$\tau_1 = -50.25 \text{ N} \cdot \text{m}; \; \tau_2 = -32.93 \text{ N} \cdot \text{m}; \; \tau_3 = -15.54 \text{ N} \cdot \text{m} \tag{30}$$

It is observed that the obtained torque values decrease from the base joint to the distal joint, which is consistent with the mechanical advantage of the serial manipulator. It is also found that the first joint supports the cumulative moment generated by all downstream segments, while the distal joint is mainly influenced by the local lever arm of the end effector, this evolution confirming the physical plausibility of the static relationship based on Jacobian used in the proposed model.

The value obtained for the third joint is practically identical to the direct moment balance around the wrist:

$$M = W \cdot l = 100 \cdot 0.156 = 15.6 \text{ N} \cdot \text{m} \tag{31}$$

This correspondence indicates that the Jacobian transpose mapping correctly captures the relationship between the external force applied at the gripper and the torques generated in the manipulator joints for the configuration illustrated in Fig. 1.

4. Interpretation of the validation results

The estimated gripping force lies inside the typical capability band of small parallel grippers, while the corresponding joint torques remain compatible with actuator sizes commonly employed in ROV-mounted robotic arms. In particular, the torque levels derived from the Jacobian-based mapping are consistent with those obtained from a direct mechanical moment balance, reinforcing the physical credibility of the model. The method can serve as a practical tool for monitoring and regulating gripping forces during underwater manipulation tasks, especially in situations where integrating dedicated force sensors at the end-effector is impractical due to sealing constraints, limited space, or cost considerations.

CONCLUSIONS

The paper presented a theoretical framework for estimating the gripping force of an ROV-mounted robotic arm intended for sampling operations in intensive aquaculture systems. The proposed approach combines actuator signal interpretation, transmission modeling, Jacobian-based force reconstruction, and gripper contact analysis to estimate the interaction force at the gripper-object interface.

The numerical validation demonstrated that the estimated gripping forces and joint torques remain within realistic operating ranges for compact underwater manipulators. The obtained torque distribution was consistent with the mechanical behavior of serial robotic structures, confirming the physical plausibility of the proposed model.

The modular structure of the method allows independent improvement of actuator, friction, hydrodynamic, and contact models, making the framework suitable for future extensions and experimental implementation in underwater manipulation applications.

Future research will focus on experimental validation under real operating conditions and on the integration of dynamic and hydrodynamic effects into the estimation process.

ABSTRACT

To promote the mechanization of the tobacco industry, a self-propelled tobacco stem harvester was designed in this study. To improve harvesting efficiency under varying terrain and planting conditions, the machine integrates key functional components, including a chain-clamp conveyor and a loosening shovel with optimized structural parameters. The performance of these core components was analysed using 3D modelling and finite element simulations conducted in ANSYS. Field experiment optimization indicated that the optimal operating parameters were a clamping chain speed of 0.7 m/s, a forward travel speed of 0.4 m/s, and a clamping chain gap of 12 mm. Experimental results showed that the harvester achieved a leakage rate of 3% and a breakage rate of 7%. Overall, the machine demonstrated reliable performance and satisfied practical operational requirements. This study provides an effective technical solution for the mechanization of tobacco stem harvesting, contributing to reduced production costs and the advancement of agricultural modernization.

摘要

为推进烟草产业机械化发展，解决烟杆后处理机械化清理的难题，设计了一种自走式烟杆收获机，针对不同地形及种植条件，旨在提升烟杆收获效率。采用 SolidWorks 三维建模、Ansys 有限元仿真和 Adams 运动分析软件，设计并优化了松土铲、链夹式夹持输送链、粉碎刀辊等核心零部件。为验证烟杆收获机的作业性能，以烟杆漏拔率和拔断率为试验目标，设计了单因素试验和正交试验进行了田间测试，综合分析结果表明夹持链运动速度 0.7m/s、机器前进速度 0.4 m/s、夹持链间隙 12 mm 时综合作业效果最佳，收获漏拔率 3%、拔断率 7%，烟杆粉碎后颗粒长度主要集中在 40-50mm，作业性能优良，满足使用需求。本研究为烟杆收获机械化提供了可行的技术方案，对降低生产成本、促进农业现代化具有重要意义。

INTRODUCTION

Tobacco is one of the world's most important cash crops *(Zeng et al., 2024; Mo, 2023; Wu, 2007)*, particularly in Asia, Africa, and South America, where many countries' economies rely heavily on the tobacco industry *(Zhang, 2016)*. As the world's largest producer and consumer of tobacco, China plays a significant role in generating farmers' income and local economic development through tobacco cultivation. Tobacco stems and roots are the residues left after tobacco leaf harvesting *(Yang et al., 2015)*. Due to their high lignin and cellulose content, they provide an ideal overwintering site for harmful microorganisms, such as bacteria and viruses, serving as hosts for various pathogens *(Li et al., 1999)*. They cannot be used as fertilizers for on-site application *(Zhang, 2007)*; therefore, they must be promptly removed from tobacco fields. Tobacco roots are large in volume and tightly bound to the rhizosphere soil, making them difficult to remove completely *(Li et al.,2010)*. After tobacco leaf harvesting each year, many tobacco stems and roots are discarded in fields, ditches, or riverbanks, forming agricultural waste that pollutes the soil and severely impacts the development and growth of the next crop season *(Zhang, 2007; Li, 2009; Reynaldo et al., 2000; Jin et al.,1999)*. Manual collection of tobacco stems and roots faces issues such as high labour intensity and low collection efficiency. Existing tobacco stem removal machinery primarily uses counter-rotating blades to remove stems and roots, which can cause root system fractures and severe residue problems. Therefore, an efficient tobacco field root removal mechanism is urgently required to address these issues *(Tu, 2006)*.

Some developed countries, such as the United States, France, and Japan, have been at the forefront of research into tobacco stem cleaning machinery, with advanced technology and rapid development *(Guo et al., 2023)*. These machines are characterized by multi-functionality, high power, and high levels of integration. However, their large size and working width render them unsuitable for the small-scale cultivation practices of Chinese tobacco farmers. Domestic machinery in China is mostly single-function, primarily designed for stem removal, with few machines capable of integrating functions such as stem removal, transportation, crushing, and collection.

Therefore, this study designed a self-propelled tobacco stem harvester capable of simultaneously completing tobacco stem pulling, root removal, transportation, and crushing operations, effectively addressing the issues of single functionality and low mechanization levels in existing tobacco stem cleaning equipment. Kinematic and dynamic analyses, finite element simulations, and field trials were conducted on the mechanism.

MATERIALS AND METHODS

1. Overall structural design of the self-propelled tobacco stem harvester

The self-propelled tobacco stem harvester completes the tasks of deep loosening of tobacco roots, pulling up tobacco stems, conveying, crushing, and collecting in a single operation. The main transmission system of the machine primarily uses a chain drive and gear meshing transmission. Power is provided by two 74-horsepower engines, one for machine movement and the other for the pulling stem operation. Based on the overall structural and functional requirements, the lifting arm assembly was designed at a 45° angle to the horizontal ground, with the initial clamping position set at 60° to enhance contact between the tobacco stems and conveyor chain and reduce the risk of missed lifting. Twelve bearing mounting sleeves were symmetrical welded to the outer side of the conveyor chain, providing stable pulling power through the gear transmission system. The integrated soil-loosening blade structure at the front significantly reduced the pulling force required to lift the tobacco stems. Additionally, the inner side of the clamping chain is equipped with a spring-loaded clamping mechanism that dynamically adjusts the gap between the two chains through elastic deformation, ensuring reliable clamping of the tobacco stems during lifting and effectively preventing slippage. The overall structural design is illustrated in Fig. 1.

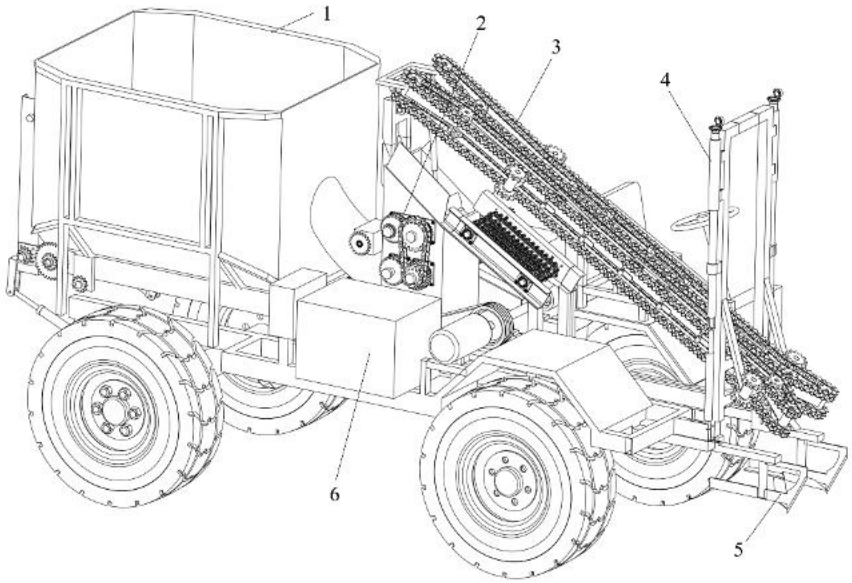

Fig. 1 – Structural diagram of a self-propelled tobacco pole harvester

1.1. Overall design of clamping conveyor chain

The clamping stem mechanism *(Gao et al., 2025)* rotates counterclockwise under the drive of the drive wheel, conveying the clamped tobacco stems to the crusher for crushing them. Although the clamping-type conveying method uses elastic components to secure tobacco stems, they may slip or shift during conveying, leading to blockages. Considering that tobacco stems ultimately need to be shredded and returned to the field, there is no need to maintain their original shape. After a comprehensive comparison and analysis, this study selected a chain-clamping stem device as the core conveying structure to ensure the stability of tobacco stem conveyance and operational continuity.

To ensure that the clamping chain maintains a stable clamping force and efficient transmission performance during tobacco stem conveying, an internal tensioning wheel staggered layout design was adopted, with external tensioning wheels installed to effectively avoid clamping force reduction and derailment risks caused by chain elongation. By welding U-shaped brackets to the top of both side supports, the structural integrity was enhanced to prevent component separation. To address the complex terrain of tobacco fields, bearings were installed in the bearing brackets, and a hydraulic cylinder was integrated at the front end of the clamping mechanism. These two components work in tandem to achieve dynamic height adjustment of the lifting stem assembly, thereby enhancing the environmental adaptability of the equipment. The power transmission mechanism is as follows: the universal joint driveshaft transmits power to the drive sprocket, driving the driven sprocket to rotate in the counterclockwise direction. After the tobacco stems are loosened by the soil loosening blade, they are fed into the clamping and pulling stem device inlet, immediately clamped by the clamping chain, and pulled out of the soil. Under the coordinated action of the tensioning wheels, the tobacco stems were smoothly conveyed to the shredding device inlet, as shown in Fig. 2.

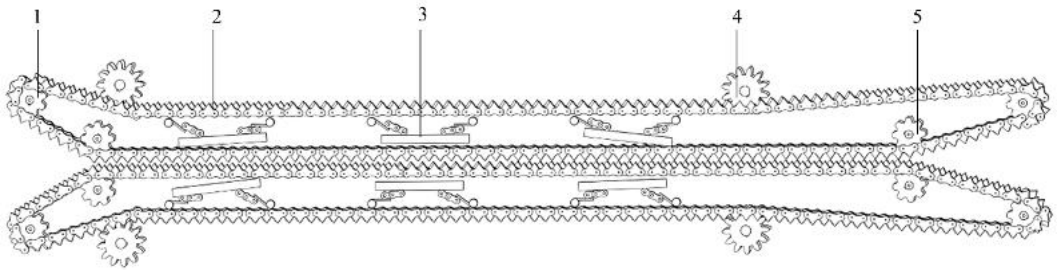

Fig. 2 – Clamping chain structure

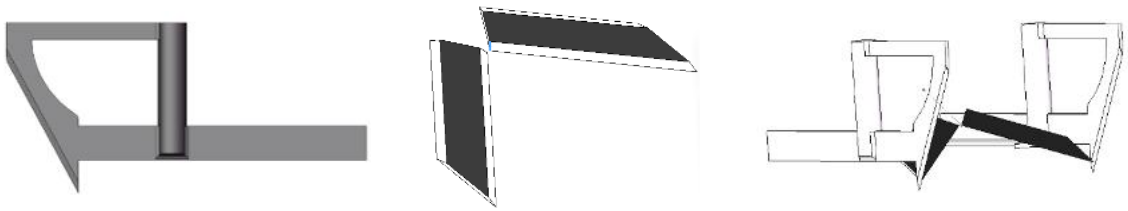
1. Drive sprocket 2. Clamping chain 3. Clamping plate 4. External tension sprocket 5. Gap adjusting sprocket

1.2. Loosening Shovel Design

Loosening shovels can be classified into chisel-, arrow-, and wing-shaped shovels *(Fan, 2022)*, duck-foot shovels, vibrating loosening shovels, and combination shovels. Based on the soil type of the tobacco field, a combination shovel type was selected to adapt to different working environments. According to the research findings in *Yu et al., (2007), and Tong et al., (2005)*, the operational resistance of a soil loosening shovel is primarily influenced by factors such as shovel type, operational speed, operational depth, and angle of penetration. Because the shovel structure and operational speed were already finalized in this study, the research focus was on determining the operational depth and angle of penetration parameters of the soil loosening shovel.



(1) Working depth

The appropriate selection of working depth is crucial for reducing working resistance, protecting the soil structure, and ensuring operational effectiveness. Excessively deep working depths increase the working resistance, leading to higher energy consumption, component wear, and damage to the soil's original aggregate structure. Conversely, excessively shallow depths do not meet the operational requirements for effectively loosening tobacco stems. According to relevant research *(Guo, 2023),* when the working depth is between 200 and 300 mm, effective loosening can be ensured while balancing energy consumption and soil protection. After careful consideration, this study selected 250 mm as the working depth of the loosening blade to achieve a balanced optimization of the working performance and energy consumption.

(2) Angle of Entry

The size of the angle of entry directly affects the ease of entry of the loosening blade *(Zhang 2014)*. An excessively small angle makes penetration difficult and reduces work efficiency, whereas an excessively large angle increases resistance and accelerates tool wear. According to the literature *(Wang et al., 2007)*, the optimal penetration angle is 60°–70°; therefore, 60° was selected.

After determining the parameters, the tillage blade was modelled, as shown in Fig. 3.

(a) Shovel frame (b) Shovel blade (c) Assembly

Fig. 3 – General assembly drawing of ripper shovel

1.3. Analysis of the dimensions of the crushing roller

The tobacco stem *(Chen et al., 2025)* was crushed using a multi-roller crusher *(Jiang et al., 2019)*, and the model and spatial arrangement of the roller are shown in Fig. 4.

(a) Knife roller model (b) Four knife roller arrangement configurations

Fig. 4 – Knife roller model and its arrangement

According to *Yang et al., (2024)*, the cutting speed of tobacco stems is generally between 16 and 30 m/s. The diameter of the cutting roller was 240 mm, and the minimum cutting speed of the cutting roller was:

$$n_{\min} = \frac{30v}{\pi R} = \frac{30 \times 14}{\pi \times 0.24} = 557 \text{ r} \cdot \text{min}^{-1} \quad (1)$$

where: $n_{\min}$ is the minimum cutting speed of the cutting roller, r·min^{-1}; v is minimum linear velocity, m·s^{-1}.

Maximum cutting speed:

$$n_{\max} = \frac{30v}{\pi R} = \frac{30 \times 30}{\pi \times 0.24} = 1193.7 \text{ r} \cdot \text{min}^{-1} \quad (2)$$

where: $n_{\max}$ is the maximum cutting speed of the cutting roller, r·min^{-1}; v is maximum linear velocity, m·s^{-1}.

The rotational speed of the cutting roller was selected as 800 r·min^{-1}.

According to the Agricultural Machinery Design Manual *(Wang et al., 2007)*, the relationship is expressed as follows:

$$H = d + \frac{rv_m}{v_d} \quad (3)$$

where: H is the distance between the knife holder and the centre of the spindle, mm; d is the diameter of the tobacco stem, mm; r is the rotation radius of the cutting roller blade, mm; v_m is the conveying speed of the conveyor chain, m·s^{-1}; v_d is the linear speed of the cutting roller blade, m·s^{-1}.

1.4. Design of the Transmission System for the Tobacco Stem Harvester

The self-propelled tobacco stem harvester's transmission system uses a combination of chain and belt drives. The output shaft of the main motor transmits power to the transfer case, which is then distributed by gear z1 to the symmetrically arranged bevel gears z2 and z3 on both sides. The bevel gears drive the clamping chains at equal speeds in opposite directions, thereby providing the required power for tobacco stem clamping. Auxiliary motor 2 transmits power via a belt drive to gear z8, which subsequently drives z10, z11, and z12. These four gears operate in coordination to realize the synchronous counter-rotation of the four cutting rollers, as shown in Fig. 5.

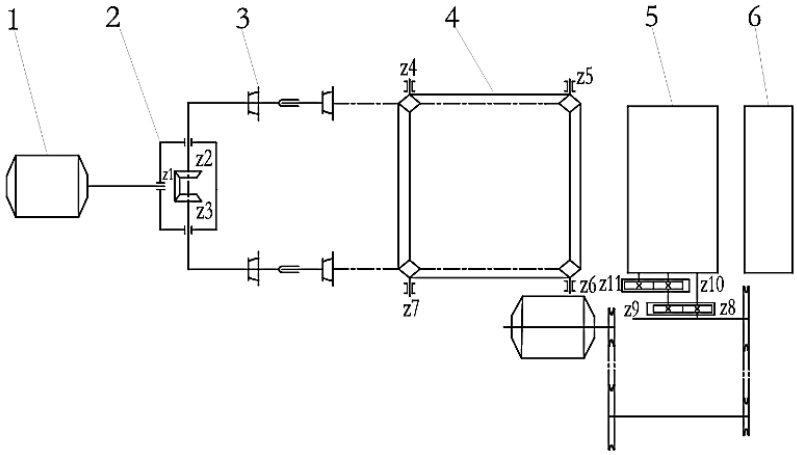


Fig. 5 – Transmission system of the tobacco harvester

1. Motor 2. Transfer case 3. Universal drive shaft 4. Clamping chain 5. Crushing device 6. Collection bin

1.5. Design of the Hydraulic System for the Tobacco Stem Harvester

To enable the tobacco stem harvester to adapt to varying field terrain conditions, two hydraulic cylinders were installed on both sides of the clamping chain. When operating on elevated terrain, the clamping chain can be raised, whereas on lower terrain it can be lowered accordingly, ensuring efficient and accurate tobacco stem harvesting. The hydraulic system mainly consists of a hydraulic pump, a relief valve, a three-position four-way directional control valve, and a check valve, as shown in Fig. 6.

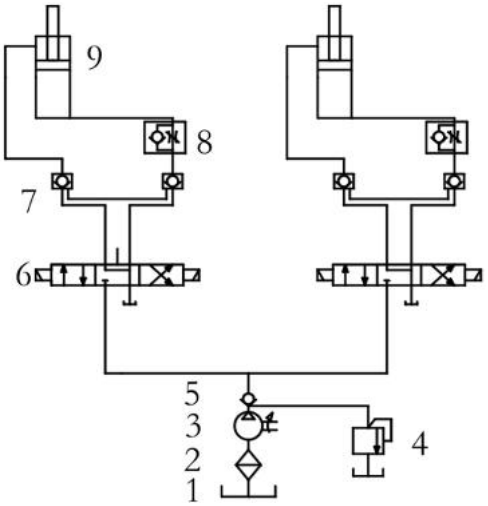

Fig. 6 – Hydraulic system of tobacco stem harvester

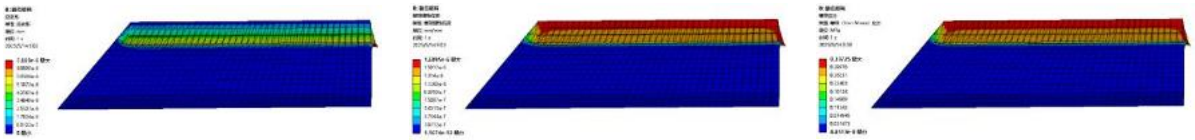
1. Oil tank; 2. Filter; 3. Hydraulic pump; 4. Relief valve; 5. Check valve; 6. Three-position, four-way directional control valve; 7. Pilot-operated check valve; 8. Throttle check valve; 9. Hydraulic cylinder

Hydraulic pump *3* serves as the power source of the system, supplying pressurized hydraulic oil and constituting the core of the hydraulic system. Hydraulic cylinder *9* acts as the actuator, converting hydraulic energy into mechanical energy to drive the movement of the working components. Relief valve *4*, check valve *5*, control check valve *7*, throttle check valve *8*, and the three-position four-way directional control valve *6* function as control and regulating components, governing the pressure, flow rate, and flow direction of the hydraulic oil. Oil tank 1 and filter *2* are auxiliary components that ensure reliable and stable system operation. During operation, hydraulic oil stored in oil tank *1* is filtered by filter *2* and then drawn in and pressurized by hydraulic pump *3*. The pressurized oil passes through check valve *5*, which prevents reverse flow, and enters the directional control valve *6*. By switching positions, the directional control valve controls the flow direction of the hydraulic oil. When the valve is set to the corresponding working position, the pressurized oil flows through its internal passages, passes through control check valve *7*, and enters either the rodless chamber or the rod chamber of hydraulic cylinder *9*. The piston extends when oil enters the rodless chamber and retracts when oil enters the rod chamber. The throttle check valve *8* regulates the flow rate of the hydraulic oil entering and leaving the hydraulic cylinder, thereby controlling the piston movement speed. Relief valve *4* limits the system pressure; when the pressure exceeds the preset value, the valve opens to return oil to the tank, ensuring system safety.

2. Stress Analysis and Motion Simulation of Key Components



2.1. Force analysis of deep loosening plough

An Ansys finite element simulation was used to determine the material properties and mesh division for the loosening plough model, and a constraint force of 500 N was applied. The equivalent stress and total deformation cloud diagrams are shown in Fig. 7 and 8, respectively.

(a) Total deformation (b) Equivalent elastic strain (c) Equivalent stress

Fig. 7 – Stress contour diagram of ripper shovel 1

(a) Total deformation (b) Equivalent elastic strain (c) Equivalent stress

Fig. 8 – Stress contour diagram of soil loosening shovel 2

The maximum stress on the soil loosening blade frame during operation was 39.91 MPa, primarily concentrated in the middle and lower sections of the blade edge. This value is significantly below the allowable stress of the material, ensuring structural safety and reliability. Under the influence of operational bending moments, the maximum deformation of the soil loosening blade was 0.13322 mm, which is an imperceptible micro-deformation not visible to the naked eye and does not affect harvesting operations, indicating that the soil loosening blade design meets the requirements. The maximum stress on the soil loosening blade was 0.33725 MPa, and the maximum deformation was 7.661×10^{-6} mm. The maximum stress on the soil loosening blade was far below the material yield strength of 250 MPa, and the deformation was small. Therefore, the design is safe, reliable, and meets operational requirements.

2.2. Simulation of the clamping and pulling stem mechanism

2.2.1. Modelling of the clamping process

The tobacco stem is the main test object, and its parameters significantly affect the final test results. Through research on the physical characteristics of the tobacco stem, it was determined that the length, diameter, and mass of the tobacco stem were approximately 1200 mm, 25 mm, and 695 g, respectively.

The volume of the tobacco stem can be obtained from Equation (4)

$$V=\pi r^2 h=\frac{\pi D^2 h}{4}=\frac{3.14\times25^2\times1200}{4}=588.75\ \text{cm}^3 \tag{4}$$

where: V is the volume of the tobacco stem, cm³; D is tobacco diameter, cm; h is tobacco length, mm.

Using the density formula $\rho = m/v$, the density of the tobacco stem was approximately 1.18 g/cm³. According to *Wang et al., (2007)*, the elastic modulus of the tobacco stem is 1147 MPa, and the Poisson's ratio is 0.33.

During the clamping and pulling processes, owing to the complexity of the simulation process, most components did not significantly affect the simulation results. Therefore, simplifying the model not only provides a more intuitive representation of the motion process but also significantly reduces simulation complexity.

In SolidWorks, components such as the frame, clamping chain, and bearings were simplified, parameters were set, and the model was saved in the '*.xt' file format before being imported into Adams for simulation analysis. The simplified model is illustrated in Fig. 9.

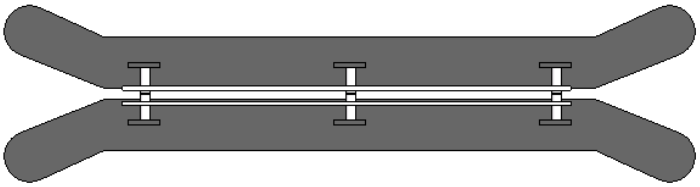


Fig. 9 – Simplified model of the clamping mechanism

The clamping device operates through the coordinated action of various mechanisms, and simulating its motion requires constraints between the mechanisms. Specifically, the operational state of the mechanisms is equivalent to the linear motion of the model, the spring tension state when the tobacco holder is clamped is equivalent to the linear motion of the stopper plate, and the tobacco holder clamping process is equivalent to the linear motion of the tobacco holder. When the tobacco stem is clamped, it comes into contact with the clamping link, thereby generating a contact force. According to reference *(Pu, 2005),* the contact force between the tobacco stem and clamping link is continuous. In the Adams software, the formula for calculating the contact stiffness coefficient K of the object contact system is shown in Equation (5).

$$K=\sqrt{\frac{16RE^2}{9}}=\frac{4}{3}E\sqrt{R} \tag{5}$$

where: R is the contact radius，mm; E is the moment of inertia, MPa.

$$\frac{1}{R}=\frac{1}{R_1}+\frac{1}{R_2} \tag{6}$$

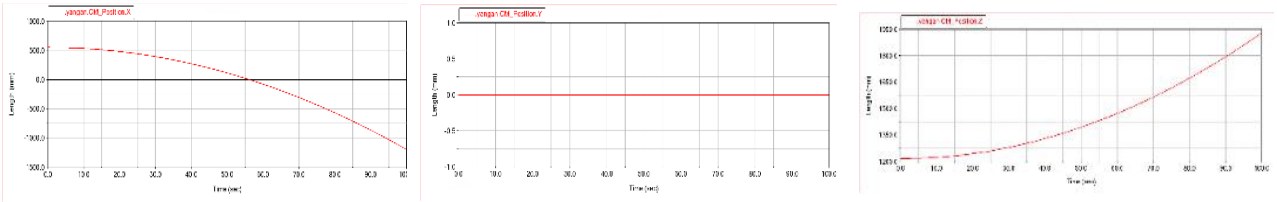
where: R_1 and R_2 represent the contact radius of the object during the contact process. If the contact surface is flat, the contact radius becomes infinite.

$$\frac{1}{E}=\frac{(1-\mu_1^{\ 2})}{E_1}+\frac{(1-\mu_2^{\ 2})}{E_2} \tag{7}$$

where: E_1 and E_2 are the Young's moduli between the two contacting objects，MPa, and μ_1 and μ_2 are the Poisson's ratios between the two contacting objects.

During the simulation process, the material selected for the clamping chain was 45 steel, with a Young's modulus of 2.09 × 10⁵ MPa and Poisson's ratio of 0.269. The Young's modulus of the tobacco stem was 1147 MPa, and the Poisson's ratio was 0.33. The simulated motion of the tobacco stem in Adams is the contact between the tobacco stem and guard plate, which can be regarded as the contact between a cylindrical surface and plane. Based on the modelling of the tobacco stem, the contact radius of the tobacco stem was set to 12.5 mm. Substituting the data into Equations (8) and (9) yields:

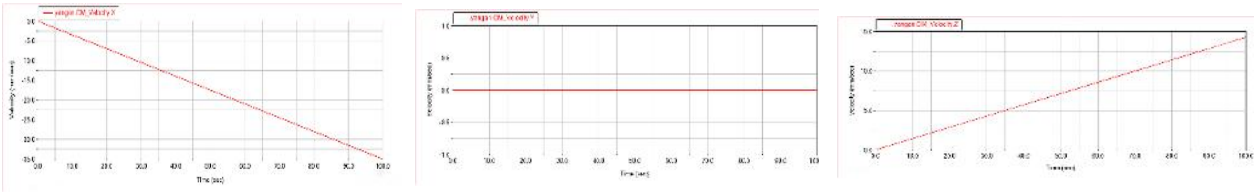
$$\frac{1}{R}=\frac{1}{12.5}+\frac{1}{\infty} \tag{8}$$



$$\frac{1}{E}=\frac{(1-0.3^2)}{2.05\times10^5}+\frac{(1-0.33^2)}{1147} \tag{9}$$

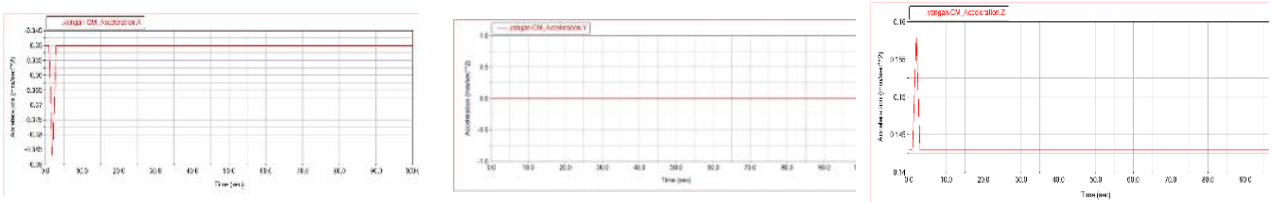
Substituting the data into Equation (2) yields the contact stiffness coefficient K:

$$K=\frac{4}{3}E\sqrt{R}=\frac{4}{3}\times1279.9\times\sqrt{12.5}=6033.6 \tag{10}$$



2.2.2. Simulation analysis of the clamping process motion

The simulation analysis of the clamping process motion mainly analyses the displacement, velocity, and acceleration of the tobacco stem as it moves from the lower to the upper end of the clamping chain. The simulation results obtained using Adams software are shown in Figs. 10–12.



(a) Displacement in the X direction (b) Displacement in the Y direction (c) Displacement in the Z direction

Fig. 10 – Displacement curve of the tobacco holder clamping point

(a) Displacement in the X direction (b) Displacement in the Y direction (c) Displacement in the Z direction

Fig. 11 – Speed curve of the tobacco holder clamping point

(a) Displacement in the X direction (b) Displacement in the Y direction (c) Displacement in the Z direction

Fig. 12 – Acceleration curve of the tobacco holder clamping point

By analysing the displacement curve shown in Fig. 10, it can be seen that tobacco stem 1 exhibits a negative displacement trend along the X-axis, as the displacement direction is opposite to the positive direction of the coordinate axis, effectively increasing the displacement magnitude; the displacement along the Y-axis remains constant, while the displacement along the Z-axis continues to increase. This result directly reflects the actual operating conditions of the tobacco stem moving backward along the longitudinal (Z-axis) direction under the influence of the conveyor chain after being clamped and pulled out, which is consistent with the theoretical expectations.

Fig. 11 shows that the velocity of the tobacco stem along the X and Z axes increased in opposite directions in a synchronized manner, whereas the velocity along the Y axis remained zero throughout, further validating the directional conveying characteristics of the tobacco stem within a two-dimensional plane.

Fig. 12 indicates that the acceleration along the Y-axis is zero, whereas the acceleration along the X- and Z-axes remains relatively stable during motion, although significant fluctuations occur between 0 and 5 s. The analysis indicates that this fluctuation is caused by an instantaneous change in acceleration due to inertial forces when the smoke stem is lifted. As the smoke stem entered the stable conveying phase, the acceleration gradually returned to a steady state.

Based on the analysis results of the displacement, velocity, and acceleration, the clamping and lifting stem mechanism operated smoothly, and its dynamic performance met the design specifications.

3. Field Trial of Tobacco Stem Harvester

The trial site was selected in the tobacco fields of the Yilong Machinery Factory in Henan Province, using tobacco stems from the current season. The tobacco stems used in the trial were those remaining after tobacco leaf harvesting, with an average height of approximately 1200 mm, an average diameter of 30.6 mm, and plant spacing of 60 mm. The tobacco field ridges were 50 cm wide, 30 cm high, and spaced 80 cm apart from each other. The trial site had no recent rainfall, with clear weather and moderate soil moisture content, which made it suitable for the trial operations.

Typically, mechanical operations require that the rate of harvest omission and the rate of tobacco stem breaking (the roots are not pulled out, but the stems are broken) should both be below 10%. The formulas for calculating the rate of harvest omission (Y_1) and the rate of stem breaking (Y_2) are as follows:

Stem removal performance indicators

$$\text{Harvest omission rate: } Y_1=W_1/W \tag{11}$$

$$\text{Stem breaking rate: } Y_2=W_2/W \tag{12}$$

where: Y_1 represents the rate of tobacco harvest omission, Y_2 represents the rate of tobacco stem breaking, W_1 represents the number of tobacco harvest omissions, W_2 represents the number of broken tobacco stems, and W represents the total number of tobacco stems tested.

The primary operational parameters affecting the tobacco harvest omission and stem breaking rates were the clamping chain transmission speed, harvester forward speed, and clamping chain clearance. These parameters were tested to determine their influence on the tobacco harvest omission and stem breaking rates. The field trial process is illustrated in Fig. 13.

(a) Test process (b) Condition of tobacco fields after testing

Fig. 13 – Field experiments

3.1. Single-factor field test

3.1.1. Effect of clamping chain transmission speed on tobacco harvest omission rate and stem breaking rate

The forward speed of the tobacco-stem harvester can be adjusted using a transmission gearbox. The transmission speed of the dual-row clamping chain was controlled by the drive system, whereas the clamping chain gap was finely adjusted using nuts on the compression springs. In the first field trial, the forward speed of the harvester was set to 0.6 m/s, and the clamping gap was set to 9 mm. Five gradient clamping chain transmission speeds of 0.6, 0.8, 1.2, 1.5, and 1.8 m/s were selected for testing. During the trial, 100 tobacco stems were pulled for each parameter set. The results of the field trials are shown in Fig. 14.

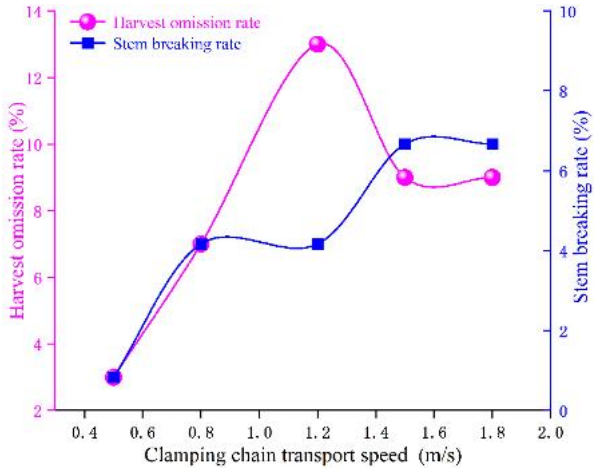


Fig. 14 – The harvest omission rate and stem breaking rate of tobacco stems under different speeds of clamping chain

Fig. 14 shows that when the conveying speed of the clamping chain is within the range of 0.6–1.2 m/s, the leakage rate increases linearly with the speed. However, when the speed increased to 1.2–1.5 m/s, the harvest omission rate decreased slightly and stabilized at 1.5 m/s. The stem breaking rate continued to increase with increasing conveying speed, reaching a peak near 1.5 m/s before stabilizing. Considering the dual optimization requirements of the harvest omission and stem breaking rates, the overall performance of tobacco stem removal was optimal when the conveying speed of the clamping chain was controlled between 0.6 and 0.8 m/s.

3.1.2. Effect of harvester forward speed on tobacco harvest omission rate and stem breaking rate

The conveying speed of the clamping chain was set to 0.7 m/s, and the forward speeds of the tobacco stem harvester were set to 0.4, 0.5, 0.6, and 0.7 m/s, respectively, while maintaining a constant chain gap of 9 mm. A total of 100 tobacco stems were pulled, and the harvest omission and stem breaking rates were recorded. The test results are presented in Fig. 15.

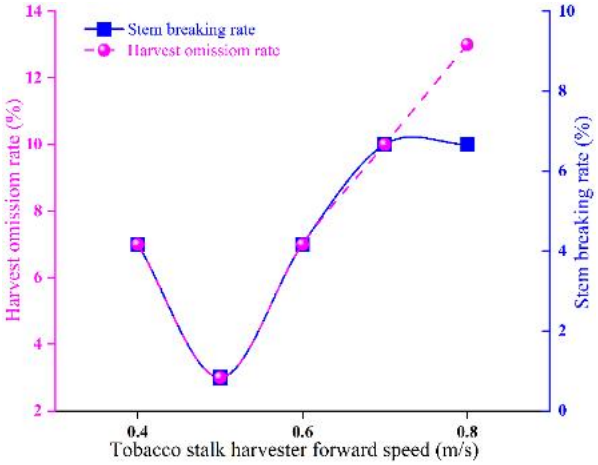

Fig. 15 –The harvest omission rate and stem breaking rate of tobacco stems under different harvester forward speeds

According to the experimental data in Fig. 15, when the forward speed of the tobacco stem harvester was within the range of 0.4–0.5 m/s, the harvest omission rate decreased as the speed decreased.

However, within the range of 0.5–0.7 m/s, the stem breaking rate increased with speed, reaching a peak at 0.7 m/s and then stabilizing. Combining the harvest omission rate and stem breaking rate change curve, within the 0.4–0.5 m/s speed range, the stem breaking rate decreased as speed increased, and within the 0.4–0.6 m/s range, the stem breaking rate showed an upward trend. Through a comprehensive dual-indicator optimization analysis of the harvest omission and stem breaking rates, when the forward speed of the tobacco stem harvester was controlled between 0.4 and 0.6 m/s, the overall operational performance of the equipment reached its optimal level. This parameter effectively reduces the risk of harvest omission and stem breakage while ensuring operational efficiency of the harvester.

3.1.3. Effect of clamping chain spacing on tobacco harvest omission rate and stem breaking rate

The clamping chain conveying speed was set to 0.7 m/s, and the tobacco stem harvester forward speed was set to 0.5 m/s. Clamping chain gaps of 7, 9, 12, 15, and 18 mm were selected. Under these conditions, 100 tobacco stems were pulled, and the harvest omission and stem breaking rates were recorded. The test results are presented in Fig. 16.

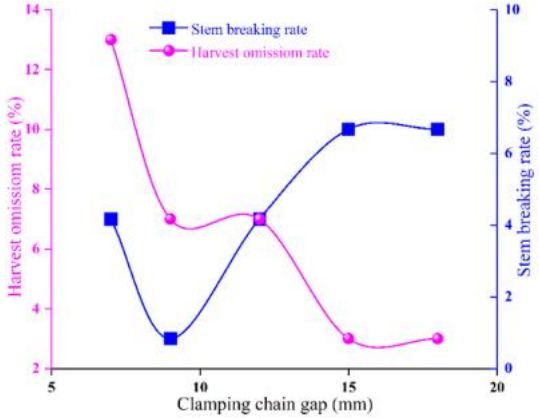

Fig. 16 – The harvest omission rate and stem breaking rate of tobacco stems under different clamping chain gaps

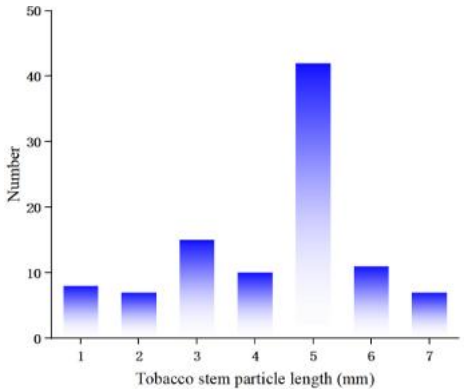

As shown in Fig. 16, when the clamping chain gap was between 7 and 9 mm, the harvest omission rate decreased as the clamping chain gap increased. When the clamping chain gap was between 9 and 15 mm, the harvest omission rate increased as the clamping chain gap increased, reaching a maximum at 15 mm and then stabilizing. The stem-breaking rate decreased as the clamping chain gap increased. Therefore, the optimal clamping chain gap for the removal efficiency was 9–15 mm.

3.1.4. Analysis of Tobacco Stem Crushing Performance

The primary factors affecting tobacco stem crushing efficiency are the conveyor chain transmission speed and the cutting roller rotational speed *(Guo et al., 2023)*. The conveyor chain speed was set to 0.7 m/s, and the cutting roller rotational speed was set to 800 r·min^{-1}. For each test, a random sample of 100 crushed tobacco stems was selected for length measurement. The experiment was repeated three times, and the average value of the three measurements was calculated. The experimental test setup is shown in Fig. 17(a).

(a) Automatic unloading process of crushed tobacco stems

(b) Statistical distribution of tobacco stem crushing effectiveness

Fig. 17 – Tobacco stem crushing effectiveness

As shown in Fig. 17(b), the number of crushed tobacco stem particles was primarily concentrated in the 40–50 mm range, followed by the 20–40 mm and 50–70 mm ranges. No particles larger than 70 mm were observed, which generally aligns with a normal distribution. The crushing results met the design expectations.

3.2. Multi-factor orthogonal experiment

3.2.1. Experimental design

To analyse the interactive effects between the clamping chain speed, harvester forward speed, and clamping chain gap, a multi-factor orthogonal experimental design was developed based on single-factor experiments. The clamping chain transport speed was set to 0.6, 0.7, and 0.8 m/s, the forward speed of the tobacco stem harvester was set to 0.4, 0.5, and 0.6 m/s, and the clamping chain gap was set to 9, 12, and 15 mm. An $L_9(3^3)$ orthogonal array was employed, consisting of nine experimental runs, with the experimental scheme presented in Table 1.

Table 1

Table of orthogonal test protocols

Number	Forward speed (m/s)	Clamping chain transport speed (m/s)	Clamping chain gap (mm)
1	0.4	0.6	9
2	0.4	0.7	12
3	0.4	0.8	15
4	0.5	0.6	12
5	0.5	0.7	15
6	0.5	0.8	9
7	0.6	0.6	15
8	0.6	0.7	9
9	0.6	0.8	12

3.2.2. Test Results and Analysis

In each test group, 100 tobacco stems were pulled out, and the number of stems that were not pulled out and the number of broken stems were counted. The harvest omission and stem-breaking rates for each group were calculated, and the test results are presented in Table 2.

Table 2

Orthogonal test results

No.	Forward Speed (m/s)	Clamping Chain Transport Speed (m/s)	Clamping Chain Gap (mm)	Harvest Omission Rate (%)	Stem Breaking Rate (%)
1	0.4	0.6	9	6	10
2	0.4	0.7	12	4	2
3	0.4	0.8	15	12	2
4	0.5	0.6	12	8	6
5	0.5	0.7	15	14	2
6	0.5	0.8	9	10	16
7	0.6	0.6	15	12	4
8	0.6	0.7	9	8	18
9	0.6	0.8	12	10	6

Although orthogonal experiments can determine the optimal combination of working parameters for equipment field operations, it is difficult to intuitively quantify the extent to which travel speed, clamping chain speed, and clamp gap affect the harvest omission and stem breakage rates. Therefore, to accurately identify the significant differences between each factor and their impact on operational performance, it is necessary to further use the range analysis method to conduct an in-depth analysis of the experimental data. The results of the range analysis for the rate of harvest omission and stem breaking are shown in Tables 3 and Table 4.

Table 3

Range analysis of the harvest omission rate

Value	Forward Speed (m/s)	Clamping Chain Speed (m/s)	Clamping Chain Gap (mm)
K1	7.333	8.667	8.000
K2	10.667	8.667	7.333
K2	10.000	0.667	12.667.
Extreme Difference	3.334	2.000	5.334

Table 4

Range analysis of the stem breaking rate

Value	Forward speed (m/s)	Clamping chain speed (m/s)	Clamping chain gap (mm)
K1	4.667	6.667	14.667
K2	8.000	7.333	4.667
K2	9.333	8.000	2.667
Extreme difference	4.666	1.333	12.000

Different factors, levels, and response indicators yield varying effects, and a larger range value indicates a greater influence of a factor on the experimental results. As shown in Table 3, the order of influence of the factors on the harvest omission rate was clamping chain gap > forward speed > clamping chain speed. Similarly, as shown in Table 4, the order of influence of the factors on the stem breakage rate was clamping chain gap > forward speed > clamping chain speed.

Based on the analysis of the above experimental results, when the forward speed is 0.4 m/s, the clamping chain speed is 0.7 m/s, and the clamping chain gap is 12 mm, the comprehensive operational performance of the tobacco stem harvester is optimal.

4. CONCLUSIONS

This study focuses on the design and experimental research of a self-propelled tobacco stem harvester. The main design parameters of the self-propelled tobacco stem harvester were established through field testing of tobacco stems and soil physical properties, combined with literature analysis to determine key component parameters, and validated through simulation and field trials. The main conclusions are as follows.

(1) A chain-clamp-holding and transport device was designed, which integrated a spring-loaded clamping mechanism and hydraulic adjustment system to achieve a dynamic adaptive adjustment of the clamping gap. This effectively addresses issues such as slippage and missed extraction during tobacco stem transportation, significantly enhancing the harvesting reliability.

(2) Based on the Ansys static simulation analysis, the maximum stress of the soil loosening blade structure under operational conditions was 22.35 MPa, and the maximum deformation was 0.0125 mm, both of which were below the material's allowable strain value, thus verifying the structural strength and stability. Based on Adams' dynamic simulation results, the entire machine operated smoothly and met the design performance requirements.

(3) Through field single-factor experiments, the optimal parameter ranges were determined as follows: clamping chain transmission speed of 0.6–0.8 m/s, clamping gap of 9–15 mm, and harvester forward speed of 0.4–0.6 m/s. Further optimization through multi-factor orthogonal experiments yielded the optimal parameter combination: forward speed of 0.4 m/s, clamping chain transport speed of 0.7 m/s, and clamping chain gap of 12 mm. Crushing performance tests showed that the particle size of crushed tobacco stems was primarily distributed between 40 and 50 mm, with a size distribution conforming to a normal distribution pattern, achieving the design-expected crushing effect.

ABSTRACT
To address the problems of low bale-forming rate and loose compaction during the mechanized recovery of residual plastic film in farmland, a three-stage residual film baling device was developed. Based on the discrete element method (DEM), a flexible thin-shell model of the residual film was established, and dynamic simulation and parameter optimization of the baling process were carried out using Rocky DEM software. Combined with single-factor experiments and response surface methodology, the effects of baling chamber inclination angle, belt type, belt linear speed, and upper belt inclination angle on bale integrity and compaction were analyzed. The results showed that the bale-forming rate of the three-stage device reached 99.13%, and the bale density reached 83.75 kg/m³ under the optimal conditions: baling chamber inclination angle of 30°, upper belt inclination angle of 30°, belt linear speed of 2.3 m/s, and the use of a rough-surface belt. Field validation tests showed that the average density of the residual film bales was 91.4 kg/m³, with a prediction error of only 2.23 kg/m³ compared with the simulation results. The device operated stably and reliably. This study presents a high-efficiency residual film baling device with improved bale-forming rate and compaction performance through structural optimization and parameter tuning, providing technical support for efficient recovery and pollution control of residual plastic film in farmland.

摘要
针对机械化农田残膜回收过程中出现的袋装率低和薄膜包装松散的问题，本研究开发了一种三阶段残膜包装装置。基于离散元方法，建立了残膜的柔性薄壳模型，并使用 rockydem 完成了残膜包装过程的动态模拟和参数优化。结合单因素实验和响应面分析，探讨了包装腔角度、包装带类型、线速度和上带安装角度对包装完整性和紧凑性的影响规律。结果表明，三阶段装置的包装率达到了 99.13%，薄膜密度为 83.75 千克/立方米，当包装腔方位角为 30°、上带安装倾斜度为 30°、线速度为 2.3 米/秒且使用粗糙带时。现场验证显示，残膜袋的平均密度为 91.4 千克/立方米，与模拟预测的误差仅为 2.23 千克/立方米。该装置的运行稳定可靠。在本研究中，通过结构创新和参数优化，开发出了一种高回收率且结构紧凑的残膜包装装置，为农田残膜的高效回收和污染控制提供了技术支持。

INTRODUCTION
The extensive use of plastic films in agriculture has significantly enhanced crop productivity and efficiency in modern farming residual film. However, the improper disposal of agricultural plastic waste, particularly plastic films used for mulching, poses substantial environmental threats, contributing to soil pollution and microplastic contamination in agroecosystems (*Li et al., 2021; Zhang et al., 2020*). As the agricultural sector strives for sustainability, the development of effective residual film recovery technologies has become paramount (*Wang et al., 2021; Liu et al 2019*).

Recent advancements in machine design and technology have led to the emergence of residual film recovery machines, which facilitate the collection, recycling, and reprocessing of used plastic films (*Chen et al., 2020; Torres et al., 2022*). These machines not only streamline the waste recovery process but also significantly reduce labor costs and enhance recovery efficiency, thereby promoting sustainable agricultural practices (*Xu et al., 2023; Gao et al., 2022*).

Studies have demonstrated that implementing residual film recovery systems can result in considerable economic benefits for farmers (*Smith et al., 2019; Kim et al., 2021*). For instance, the recovery of used films allows for the recycling of valuable polymers back into the production cycle, reducing raw material dependency and lowering overall production costs (*Mao et al., 2022; Huang et al., 2020*). Moreover, these technologies contribute to closing the loop in agricultural plastics management, aligning with circular economy principles (*Anderson et al., 2021; Roberts et al., 2022*).

Despite significant strides in technology, challenges remain in achieving widespread adoption of residual film recovery machines (*Yuan et al., 2023; Deng et al., 2022*). Factors such as initial costs, maintenance, and the need for farmer education on proper usage significantly influence their implementation (*Liu et al., 2022; Choi et al., 2021*).

In conclusion, residual film recovery machines play a crucial role in mitigating the environmental impact of plastic films used in agriculture. Ongoing research and development efforts should focus on overcoming existing barriers, optimizing machine efficiency, and enhancing the circular economy in agriculture to ensure sustainable development. During the compression stage of the belt-type baling device, the residual film is still prone to probabilistic scattering and the movement trajectory is difficult to control, which is not conducive to the formation of high-density and stable formed residual film bales. Therefore, based on an in-depth analysis of the forming mechanism of the residual film in the baling chamber, structural constraints and parameter optimization are used to suppress the scattering and winding behaviors and improve the forming quality of the residual film package (*Xie et al., 2020; Tan et al., 2022*).

To address key problems such as the low bale-forming rate and loose baling during the mechanized recovery of residual plastic film in farmland, a three-stage belt-type residual film baling device was developed based on DEM and flexible thin-shell modeling technology *(Potyondy et al., 2004; Roessler et al., 2018)*. By establishing a dynamic model of residual film behavior in the baling chamber and performing three-dimensional simulations and parameter optimization using Rocky DEM software, the effects of key factors—including the inclination angle of the baling chamber, the type and linear speed of the baling belt, and the installation angle of the upper baling belt—on the integrity and compaction density of the residual film bales were systematically analyzed. The performance of the optimized parameter combination was further verified through field experiments.

MATERIALS AND METHODS

Overall structure and working principle

The residual film baling device mainly consists of a lower baling belt, a rear baling belt, and two side plates. Compared with conventional steel-roller-type baling systems, the belt-type baling structure reduces the overall machine weight and prevents film leakage between the rollers. Driven by the rear belt, the residual film rotates within the baling chamber and is gradually compacted to form a residual film bale. The overall structure of the device is shown in Fig. 1.

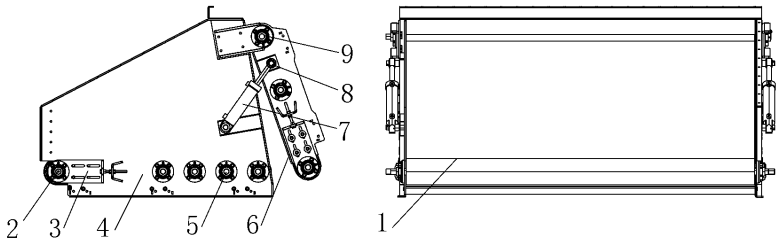

Fig. 1 - Basic structure of the residual film baling device

1. Discharge belt; 2. Lower belt drive roller; 3. Tension adjustment mechanism; 4. Side plates; 5. Support roller; 6. Rear baling belt; 7 Hydraulic cylinder; 8. Rear belt drive roller 9. Drive roller.

The lower baling belt is tensioned over the drive roller by means of a tension adjustment mechanism. The drive roller is fixed to the two side plates by bolted connections. For unloading, the rear baling mechanism can be lifted by a hydraulic cylinder to form a discharge channel. During operation, the lower belt captures the residual film discharged from the upstream collection device and conveys it toward the rear baling belt. After contacting the lower belt, the residual film is lifted and then falls back onto the accumulated film layer, forming an initial core through a winding process. As material continues to be supplied, the core grows progressively into a compact residual film bale. The formed bale is finally discharged from the rear of the device under the combined action of gravity and belt motion.

Baling Mechanism Design

The baling mechanism mainly consists of a lower baling mechanism and a rear baling mechanism. The lower baling mechanism includes a lower baling belt, a front drive roller, a rear drive roller, and support rollers. The rear baling mechanism consists of a rear baling belt, an upper drive roller, a lower drive roller, and support rollers. The two baling mechanisms are arranged symmetrically in a V-shaped configuration. Based on theoretical analysis and considering potential interference with the residual film recovery machine, the optimal angle between the two mechanisms was determined to be 70°.

The V-shaped space forms the baling chamber of the device, in which the residual plastic film is effectively compressed to form a residual film bale. To facilitate field operation and transportation, and to ensure that the bales can be discharged in a single operation, positioning blocks are installed on both sides of the belts to prevent lateral deviation caused by uneven tension during the baling process.

Due to the complex spatial structure of the baling chamber and the difficulty of precise analytical calculation, an estimation method based on the bale diameter is proposed to determine the appropriate size of the baling chamber. The calculation method is given as follows:

$$m = \rho \frac{\pi d^2}{4} l > \lambda LWX \quad (1)$$

In the formula, m represents the mass of a single residual film bale (kilograms), ρ is the density of the bale at discharge (kg/m^3), d is the diameter of the bale (m), l is the length of the bale (m), L is the maximum length of the field working row (m), W is the working width of the front-end residual film recovery machine (m), X is the mass of residual film per unit area (kg/m^2) and λ is the impurity coefficient of the bale.

The derivation of Equation (1) is based on the mass-volume equivalence principle. The mass of a single residual film bale (m) can be expressed as the product of the bale volume (V) and the mixture density (ρ) at the moment of discharge. Assuming that the bale is approximately cylindrical, with diameter (d) and length (l), its volume can be expressed as: $V = \frac{\pi d^2}{4} l$. Meanwhile, the total mass of residual film collected during a single operation can be expressed as the product of the working width (W), operation row length (L), residual film mass per unit area (X), and impurity coefficient (λ). By equating the two expressions and solving for (d) Equation (1) can be obtained.

To determine the impurity content of residual film per unit area in the experimental field, the following method was adopted. Random sampling was conducted in the test field, and five operation rows were selected. For each row, a standard sampling area of 8 m × 2.1 m was defined. The sampling process is illustrated in Fig. 2.

After the residual film within the sampling area was collected into the collection box using the residual film recovery machine, the data were analyzed. The corresponding measurement results are presented in Table 1.

Fig. 2 - Sampling and measurement of residual film during mechanical recovery

(1) Experimental field *(2) Residual film collection by the machine*

Table 1

Residual film mass in the experimental field

No.	Residual film mass / g	Residual film mass per unit area / kg/m ²
1	180.63	11.15×10-3
2	178.55	11.02×10-3
3	181.32	11.19×10-3
4	177.48	10.95×10-3
5	181.29	11.19×10-3
Average value	**179.85**	**11.10×10-3**

According to Table 1, the residual film mass per unit area (*X*) was taken as 9.46×10-3kg/m². Considering that the working width (*W*) of the residual film recovery machine is 2.1 m, the operating width of the proposed device was designed to match that of the 11CM-2100 residual film recovery machine; therefore, *W* was set to 2.1 m. The maximum measured operation row length (*L*) in the test field was 1000 m. The density of the residual film bale (ρ) was taken as 122.7 kg/m³ based on test results obtained from a roll-type residual film baling machine.

Eight groups of samples were randomly collected from the residual film mixture recovered by the machine. The analysis showed that the average volume ratio of residual film to impurities was 2.18:1.

Considering regional and crop-dependent variations in impurity content, and to ensure a sufficient design margin, the impurity coefficient (λ) was finally set to 2. Substituting these values into Equation (1) yields a minimum bale diameter of $d \geq 0.45\text{m}$. Taking into account the structural dimensions of the 11CM-2100 residual film recovery machine and avoiding interference with the baling device, a diameter of $d = 0.5\text{m}$ was selected as the design parameter. According to Equation (1), the corresponding bale mass (*m*) was calculated to be 57.33 kg. The designed residual film baling system is suitable for both manual handling and mechanized operation and meets ergonomic requirements.

Discrete element modelling of residual film

The residual film was modeled in Rocky DEM using the “flexible membrane” contact model, which allows for large deformation and bending behavior. Each film element was represented by a triangular mesh with assigned elastic properties: Young’s modulus of 0.2 GPa, Poisson’s ratio of 0.4, and a thickness of 0.05 mm. The contact interaction between film elements and the baling belts was defined using a linear spring-dashpot model, with a coefficient of restitution of 0.45, a static friction coefficient of 0.6, and a rolling friction coefficient of 0.15. These parameters were calibrated by comparing the simulated film stacking behavior with results from physical drop tests. The calibration process involved adjusting the friction coefficients until the simulated angle of repose matched the experimentally measured value of 38° for field-collected residual film samples. The simulation time step was set to 20% of the Rayleigh time step, and the total simulation time corresponded to 15 s of real operating conditions.

Establishment of the three-stage baling device model

During the simulation, observation of the dynamic behavior of the residual film revealed a stochastic scattering phenomenon, as shown in Fig. 3.

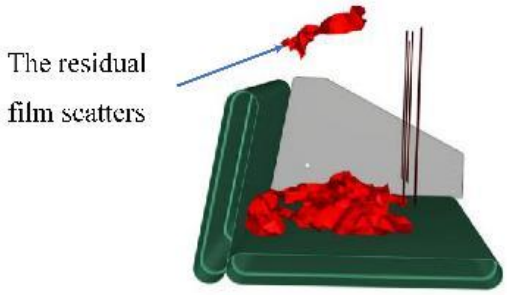

Fig. 3 - Residual film scattering phenomenon

When the residual film comes into contact with the rear baling belt, its relatively rough surface produces a hooking effect, leading to a sudden increase in frictional resistance. As a result, the residual film tends to scatter along the direction of belt motion. In actual operation, scattered film is prone to entanglement with transmission components or accumulation in structural gaps, which reduces operational efficiency and may cause blockage or mechanical failure. To address this issue, a third (upper) baling belt was introduced above the original lower and rear belts, forming a three-stage constraint system. This configuration significantly improves control over the motion trajectory of the residual film and effectively suppresses scattering

The upper belt serves two main functions. First, it intercepts residual film that deviates from the intended trajectory and redirects its motion through frictional interaction. Second, during bale formation, it works in coordination with the lower and rear belts to apply multi-directional compressive forces, resulting in improved compaction uniformity, higher bale density, and enhanced forming stability. The optimized three-stage structure is shown in Fig. 4.

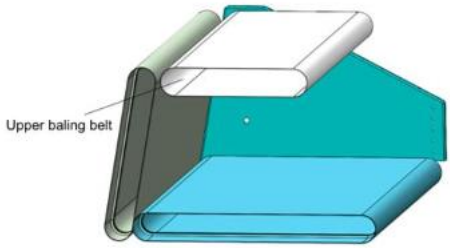

Fig. 4 - Three-stage residual film baling device

To investigate the influence of installation parameters on the baling performance, the installation inclination angle of the baling belt, the inclination angle of the baling chamber, and the belt linear speed were selected as experimental factors. The bale-forming rate and bale density were used as evaluation indicators, and single-factor experiments were conducted on the three-stage baling device.

The effect of the installation inclination angle on the device performance is shown in Fig. 5.

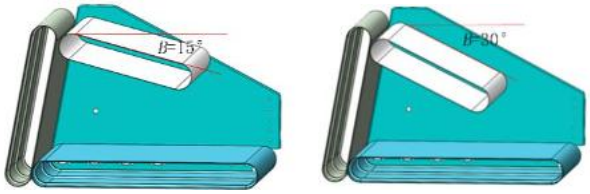

Fig. 5 - Installation inclination angle of the upper baling belt

The baling belt was selected as a rough-surface belt. The inclination angle of the baling chamber was set to 0°, the belt linear speed was fixed at 1.5 m/s, and the installation inclination angle of the upper belt was varied at 0°, 5°, 10°, 15°, 20°, 25°, and 30°. Each experiment was repeated five times, and the average values were used for analysis. The results are presented in Fig. 6.

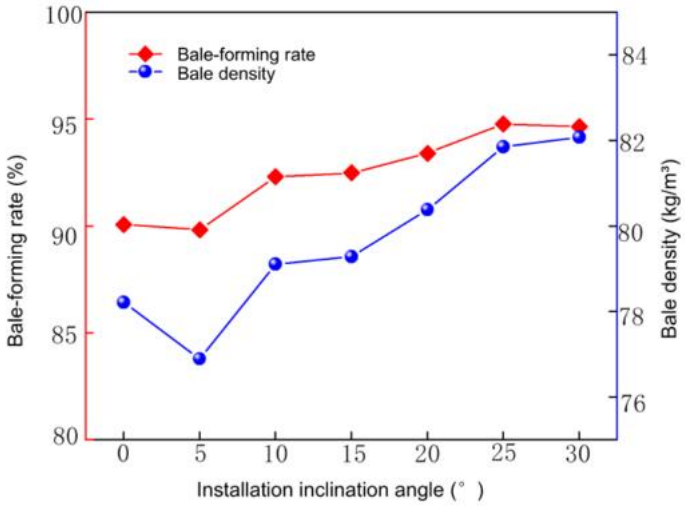

Fig. 6 - Effect of installation inclination angle on baling performance

It can be seen from Fig. 6 that the installation inclination angle of the upper baling belt has a significant influence on the forming quality of the residual film bales. As the inclination angle increases, both the bale-forming rate and bale density show an increasing trend, reaching optimal values at 30°. This behavior can be attributed to the fact that a larger inclination angle enhances the wrapping and normal constraint effects of the belt on the residual film. As a result, scattering during the compaction process is effectively suppressed, and the motion trajectory of the film becomes more stable, leading to improved bale formation and higher density.

A single-factor experiment was further conducted to investigate the effect of belt linear speed on the performance of the three-stage baling device. The installation inclination angle was fixed at 30°, and the inclination angle of the baling chamber was set to 0°. The belt linear speed was varied at 0.5 m/s, 1.0 m/s, 1.5 m/s, 2.0 m/s, and 2.5 m/s. Each experiment was repeated five times, and the average values were used for analysis. The results are shown in Fig. 7.

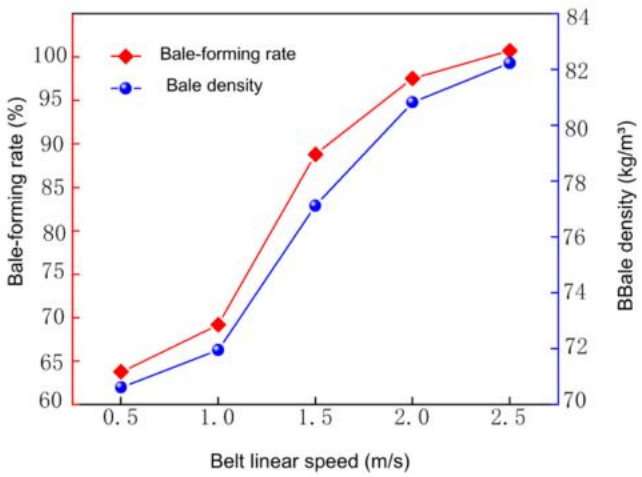

Fig. 7 - Effect of belt linear speed on baling performance

As shown in Fig. 7, compared with the conventional two-stage structure, the three-stage device exhibits clear advantages in terms of bale-forming rate and bale density. As the belt linear speed increases, both indicators show a continuous upward trend, reaching optimal values at 2.5 m/s. This behavior can be explained by the enhanced compaction effect provided by the third-stage belt. When the volume of the residual film bale reaches a certain level, the upper belt applies additional compressive force. By increasing the normal pressure and contact area, the overall frictional interaction and constraint on the residual film are significantly enhanced, resulting in improved bale integrity and higher density.

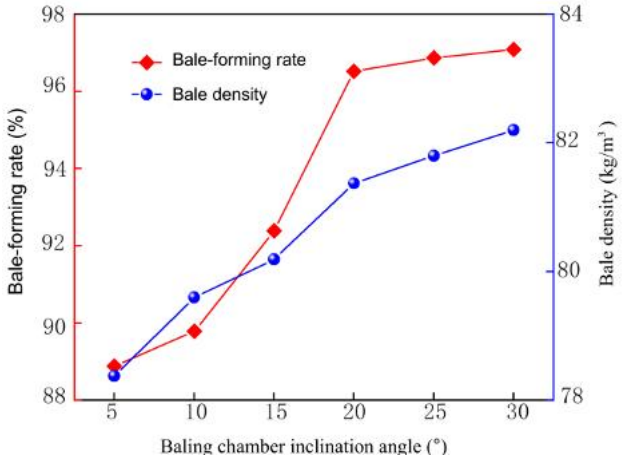

Fig. 8 - Effect of baling chamber inclination angle on baling performance

A single-factor experiment was conducted to investigate the effect of the baling chamber inclination angle on the performance of the three-stage baling device. The installation inclination angle of the upper belt was fixed at 30°, and the belt linear speed was set to 1.5 m/s. The results are presented in Fig. 8. As the baling chamber inclination angle increases, both the bale-forming rate and bale density exhibit an increasing trend. This is because a larger inclination angle enhances the spatial constraint during the compaction process. In combination with the three-stage belt system, a multi-directional constraint is formed, which effectively controls the motion trajectory of the residual film, improves material aggregation, enhances compaction, and reduces scattering.

RESULTS

Simulation performance test of three-stage baling device

To investigate the performance variation of the three-stage residual film baling device under multi-factor conditions, and to identify the key variables affecting bale density and bale-forming rate, an orthogonal experimental design was adopted to determine the optimal operating parameter combination. The belt linear speed, the installation inclination angle of the upper belt, and the inclination angle of the baling chamber were selected as experimental factors. The corresponding factor levels are presented in Table 2.

Table 2

Factor levels of the three-stage baling device

Level	Baling chamber inclination angle A/°	Upper belt inclination angle B/°	Belt linear speed C/m·s^{-1}
-1	20	20	2.1
0	25	25	2.3
1	30	30	2.5

Analysis of experimental data

A simulation experiment was designed using the Box–Behnken method. A total of 17 experimental runs were conducted, including five replications at the center point. The experiments were designed to investigate the interaction effects between the bale-forming rate, bale density, and three key factors.

Regression model for bale-forming rate

Analysis of variance (ANOVA) and significance tests of the regression coefficients were performed for the regression model of the residual film bale-forming rate (Y_1). The regression equation for Y_1 is given as follows:

$$\hat{Y}_1 = 97.38 + 0.635A + 0.8345B + 0.6162C + 0.0075AB - 0.1042AC + 0.11BC + 0.3117A^2 - 0.1008B^2 - 1.52C^2 \quad (2)$$

Taking the bale-forming rate as the response variable, the regression model established for the baling chamber inclination angle (A), the upper belt inclination angle (B), and the belt linear speed (C) was found to be highly significant (F = 402.8). The linear terms (A, B, C), interaction terms (AC, BC), and quadratic terms (A^2, B^2, C^2) were all statistically significant. The lack-of-fit term was not significant (F = 2.0, p = 0.2565), indicating good model adequacy. The coefficient of determination was R^2 = 0.9981, with an adjusted R^2 of 0.9956 and a predicted R^2 of 0.9803, demonstrating excellent model fit and strong predictive capability.

Based on response surface methodology (RSM), the experimental data were analyzed to investigate the interaction effects between the bale-forming rate and its key influencing factors, as shown in Fig. 9.

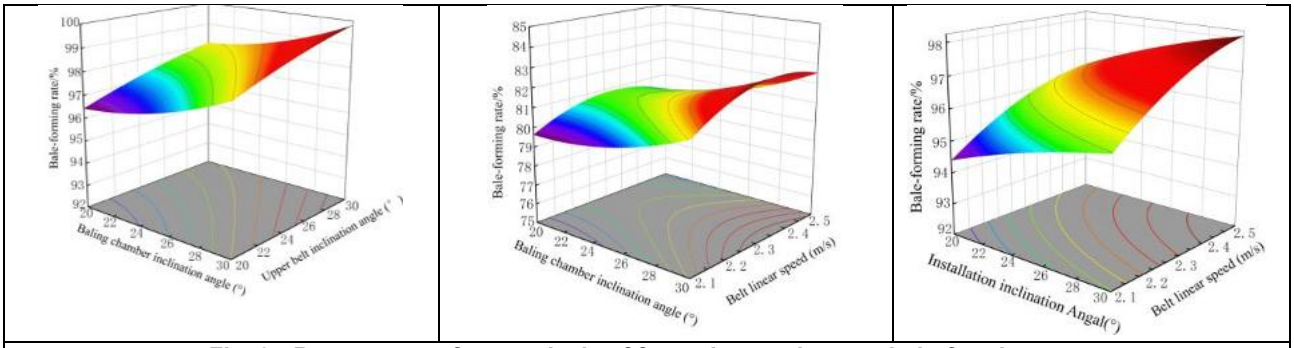

Fig. 9 - Response surface analysis of factor interactions on bale-forming rate

(a) Interaction between baling chamber inclination angle and upper belt inclination angle

(b) Interaction between baling chamber inclination angle and belt linear speed

(c) Interaction between upper belt inclination angle and belt linear speed

Figure 9(a) shows that the bale-forming rate increases with the increase in the upper belt inclination angle, and its influence is more significant than that of the baling chamber inclination angle. This trend can be explained by the change in force components acting on the residual film. As the inclination angle increases, the normal force component exerted by the upper belt becomes more effective in constraining the film, while the tangential (conveying) component also increases, improving both compaction and motion control. Consequently, the probability of film scattering is reduced.

Figure 9(b) indicates that, under the interaction between belt linear speed and baling chamber inclination angle, the bale-forming rate initially increases and then decreases with increasing belt speed, reaching a peak value (approximately 81.5%) at around 2.3 m/s. The influence of belt linear speed is more pronounced than that of the baling chamber inclination angle.

Figure 9(c) shows that the response surface for the interaction between belt linear speed and upper belt inclination angle is convex, indicating the presence of an optimal parameter region. The effect of the upper belt inclination angle on the bale-forming rate is more significant than that of belt linear speed.

The variation in bale density follows a similar trend. The maximum density is also achieved at approximately 2.3 m/s, as optimal compaction requires both sufficient compressive force and adequate residence time for interlayer bonding of the residual film. At excessively high belt speeds, the residence time in the compression zone is reduced, limiting effective compaction.

According to the response surface analysis, the order of influence of each factor on the bale-forming rate is: upper belt inclination angle > baling chamber inclination angle > belt linear speed

Regression model for bale density

The regression model for residual film bale density (Y_2) was analyzed using ANOVA and significance tests of the regression coefficients. The regression equation for Y_2 is given as follows:

$$\hat{Y}_2 = 81.35 + 1.03A + 1.21B + 0.4217C - 0.0075AB - 0.055AC + 0.11BC + 0.5051A^2 - 0.3983B^2 - 0.9424C^2 \quad (3)$$

The developed regression model for bale density was found to be highly significant (F = 875.1). The linear terms (A, B, C), interaction terms (AC, BC), and quadratic terms (A^2, B^2, C^2) were all statistically significant. The lack-of-fit term was not significant (F = 4.73, p = 0.0838), indicating good model adequacy. The coefficient of determination was R^2 = 0.9988, with an adjusted R^2 of 0.9973 and a predicted R^2 of 0.9849, demonstrating excellent agreement between the model and experimental data, as well as strong predictive capability.

Based on response surface methodology, the interaction effects of each factor on bale density were analyzed, and the corresponding response surface plots are shown in Fig. 10.

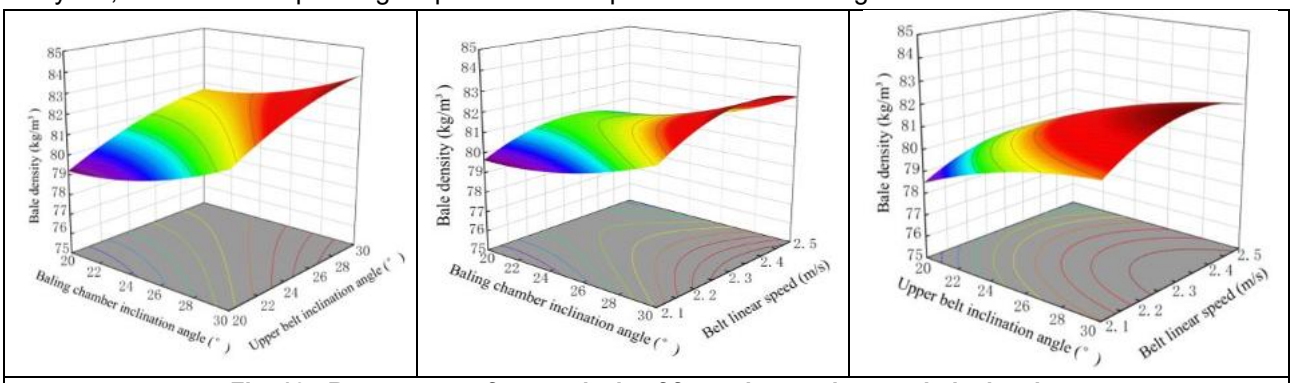

Fig. 10 - Response surface analysis of factor interactions on bale density

(a) Interaction between baling chamber inclination angle and upper belt inclination angle	*(b) Interaction between baling chamber inclination angle and belt linear speed*	*(c) Interaction between upper belt inclination angle and belt linear speed*

Figure 10(a) shows that bale density increases with increasing upper belt inclination angle, and its influence is more significant than that of the baling chamber inclination angle. Figure 10(b) indicates that, under the interaction between belt linear speed and baling chamber inclination angle, bale density initially increases and then decreases with increasing belt speed, reaching a peak value of approximately 81.2 kg/m³ at around 2.3 m/s. The interaction between these two factors is significant. Figure 10(c) shows that, under the interaction between belt linear speed and upper belt inclination angle, the influence of the upper belt inclination angle on bale density is more pronounced than that of belt linear speed.

To determine the optimal operating parameters, the regression models were optimized using Design-Expert software. The constraints were set as follows: baling chamber inclination angle of 25°–30°, upper belt inclination angle of 20°–30°, and belt linear speed of 2.1–2.5 m/s. The optimization results indicate that the maximum bale density (83.75 kg/m³) is achieved at a baling chamber inclination angle of 29.92°, an upper belt inclination angle of 29.64°, and a belt linear speed of 2.3 m/s. Meanwhile, the maximum bale-forming rate (99.13%) is obtained at a baling chamber inclination angle of 29.96°, an upper belt inclination angle of 30.11°, and a belt linear speed of 2.33 m/s.

Considering manufacturing feasibility and operational convenience, the final selected parameter combination was a baling chamber inclination angle of 30°, an upper belt inclination angle of 30°, and a belt linear speed of 2.3 m/s.

Performance tests of the residual film baling device were then conducted. Based on the average of 10 trials, the results (Table 6) show that the measured bale density was 91.4 kg/m³, and the bale-forming rate reached 100%. The experimental results are in good agreement with the simulation predictions, demonstrating the feasibility and accuracy of the proposed simulation model. The operational performance of the machine is shown in Fig. 11.

CONCLUSIONS

(1) The proposed three-stage baling structure significantly improved baling performance. By introducing an upper baling belt to the conventional two-stage configuration, a three-dimensional constraint system was formed. This effectively suppressed residual film scattering and enhanced bale compactness. Both the bale-forming rate and bale density were significantly improved compared with the traditional two-stage structure.

(2) The optimal combination of operating parameters was determined using response surface methodology. For the three-stage baling device, the optimal conditions were a baling chamber inclination angle of 30°, an upper belt inclination angle of 30°, a belt linear speed of 2.3 m/s, and the use of a rough-surface belt. Under these conditions, the maximum bale-forming rate reached 99.13%, and the bale density reached 83.75 kg/m³, indicating optimal operational performance.

(3) Field tests verified the reliability of the simulation results and the practicality of the device. Under the optimized parameters, the measured average bale density was 91.4 kg/m³. The experimental results were in good agreement with the simulation predictions, demonstrating the high predictive accuracy of the developed model. The device operated stably and reliably, meeting the requirements for residual film recovery in farmland conditions.

(4) This study provides a feasible technical solution for efficient residual film recovery and pollution control. Through structural innovation and systematic parameter optimization, the device achieved high bale-forming rates and high-density compaction. This contributes to improved recovery efficiency and reduced post-processing costs, with positive implications for mitigating residual film pollution in agricultural fields.

Although the DEM model captures the main flexible behavior of residual film, it simplifies the material as a homogeneous elastic shell and does not account for tear propagation or variable impurity adhesion. The model parameters were calibrated under dry, low-impurity conditions; their applicability to wet or high-impurity environments requires further validation. In addition, the scalability of the optimal parameters to different crop types (e.g., maize vs. cotton) and field conditions has not been systematically investigated. The long-term durability of the three-stage belt system (e.g., belt wear and tension stability) will be evaluated in future multi-season field trials.

ABSTRACT

Agricultural power networks accelerate contact wear and reduce the accuracy of conventional loop resistance testing. This study presents an APP-based wireless three-phase synchronous measurement system integrating UC3854-driven multi-stage power factor correction (0–100 A, 82–83.17% efficiency, PF 0.99) and a supercapacitor pulse module (16 V trigger, 230 V charge). The system achieves 0.01 μΩ resolution and >10,000 MΩ insulation resistance. Field validation on 110 kV GIS reduced wiring and testing times by 67% (≤1% deviation), while 500 kV GIL measurements improved efficiency by 80%. The platform enables high-current stability, strong interference immunity, and digitalized operation.

摘要

农业配电网运行于潮湿、多尘、腐蚀性环境，加速接触磨损并降低传统回路电阻测试仪的精度。本研究开发了一种基于 APP 的无线三相同步回路电阻测试系统，采用基于 UC3854 的多级功率因数校正架构（0–100 A 恒流输出，效率 82–83.17%，功率因数 0.99）和超级电容脉冲放电模块（16 V 触发，230 V 充电）。系统实现 0.01 μΩ 测量分辨率和>10,000 MΩ 绝缘电阻，优于商用回路电阻测试仪典型的 0.1 μΩ 分辨率。现场测试表明：110 kV GIS 设备接线时间由 30 min 缩短至 10 min，测量时间由 3 min 缩短至 1 min（效率提升 67%，偏差 ≤1%）；500 kV GIL 区段（1.2 km）将传统五段测试整合为单次连续测量（效率提升 80%）。该系统为高电流稳定输出、强抗干扰、快速接线和数字化管理的农业配电网提供了高效可靠的测试解决方案。

INTRODUCTION

The rural power distribution network is a critical infrastructure in modern agriculture, supporting not only livestock production, irrigation systems, and primary processing, but also the integration of distributed energy and agricultural IoT. Consequently, the reliability of high-voltage switchgear—responsible for circuit control and protection—has become a key determinant of grid security (*Li, 2022*). Compared with urban systems, rural equipment is more exposed to humidity, dust, corrosive gases, and temperature fluctuations, which accelerate contact degradation and increase the risk of abnormal loop resistance, potentially leading to overheating, protection failure, and system outages (*Li et al, 2022*). Loop resistance measurement is widely used to evaluate the operational condition of GIS and GIL switchgear. According to standards such as GB 50150 and DL/T 596, resistance values should not exceed 120% of factory references, and significant phase deviations indicate potential faults. However, conventional testers face substantial limitations in rural applications. Fixed-spacing clamps often fail to meet GB/T 3048.4–2007 requirements, especially for large or irregular conductors, resulting in poor measurement reliability (*Ma et al., 2022; Deng, 2021*). Temperature variations introduce resistance drift and reduce testing efficiency due to thermal stabilization requirements *(Zhang et al., 2021*). In addition, strong electromagnetic interference in substations distorts measurement signals (*Fang, 2020; Fang, 2020b*), while traditional instruments lack real-time data transmission capabilities, hindering digital management (*Wu & Zhang, 2020*). Condition-based maintenance (CBM) has been extensively studied worldwide.

Early work by EPRI in the 1970s introduced reliability-centered maintenance concepts (*Yuan et al., 2020*), followed by developments in Japan and Europe emphasizing online monitoring and integrated diagnostic systems (*Wang et al., 2018; Ban et al., 2018*). In contrast, existing loop resistance testing technologies in China still rely on single-phase sequential measurement and wired control, limiting efficiency and data reliability (*Xiao et al., 2014*).

To address these challenges, this study develops a three-phase synchronous loop resistance testing system tailored for rural environments. The system integrates wireless APP-based control, a high power-factor constant-current source, supercapacitor-assisted pulse discharge, enhanced electromagnetic compatibility design, and optimized Bluetooth communication. It enables rapid deployment, high-precision measurement, and automated data management, thereby facilitating the transition toward condition-based and digitalized operation of agricultural power distribution systems.

MATERIALS AND METHODS

System Architecture of the Tester

Within this system, the overall topology presents a hierarchical structure composed sequentially of the front-end power equipment, sensor unit, data acquisition and processing module, signal-processing chain, and fault-diagnosis module. During operation, the power equipment generates current, voltage, and loop-impedance states that are first captured in real time by high-sensitivity sensors. After entering the data acquisition unit, the sensing signals are quantized and preprocessed according to the required sampling accuracy and bandwidth, followed by preliminary data structuring and anomaly elimination performed by an embedded processor. The signal-processing module applies filtering, denoising, feature decomposition, and parameter modeling to the acquired signals, enabling the dynamic characteristics and state parameters of the electrical circuit to be presented with an enhanced signal-to-noise ratio. The fault-diagnosis module identifies abnormal conditions—such as loop-resistance deviation, contact erosion, and poor contact—based on the extracted key features, and transmits the diagnostic results to the App interface via a wireless communication link, allowing maintenance personnel to monitor equipment health in real time and perform remote control and decision support.

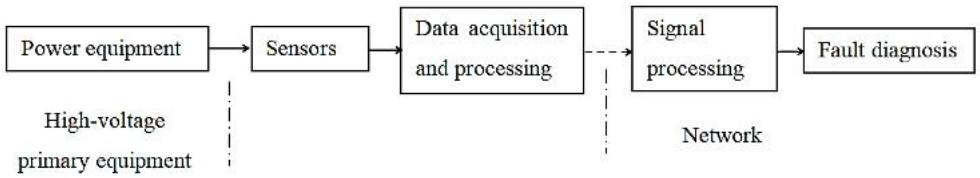

Fig. 1 – Topology of an App-Wireless-Controlled Loop-Resistance Tester for Switchgear

To eliminate the influence of temperature on the measurement results, an automatic temperature-compensation technique is employed. The ambient temperature is continuously monitored using a DHT11 temperature–humidity sensor, and the measured resistance is corrected to its equivalent value at the standard reference temperature of 20°C using the resistance–temperature conversion formula $R_t=R_o(1+\alpha t)$ (*Lai et al., 2019*). In this equation, R_o denotes the standard resistance at 20℃, R_t is the measured resistance under the current ambient temperature, and α represents the temperature coefficient of the conductor material. This correction ensures the comparability of measurement data across different environments and seasons. The main controller adopts the STM32F103C8T6, a 32-bit microcontroller operating at a clock frequency of 72 MHz, integrating a 12-bit ADC, DMA controller, and multiple communication interfaces. These features meet the requirements of three-phase data acquisition and Bluetooth communication, while its low-power operation mode supports long-duration field testing (*Chen et al., 2016*). The design schematic is shown in Figure 2.

Interference suppression is achieved through power-supply filtering, Bluetooth AFH frequency hopping, and electromagnetic-compatibility design. For GIS/GIL applications, a dedicated wireless auxiliary short-circuiting module is integrated, enabling long-distance testing within 3 km via LoRa communication. After the system is powered on, the main program performs initialization, defining system variables and assigning initial values, configuring the I/O modules, and setting parameters for the display, serial ports, and other functional modules. Once initialization is completed, the program enters a keypad-scanning routine (i.e., scanning touch-keys on the display) and responds to user operations.

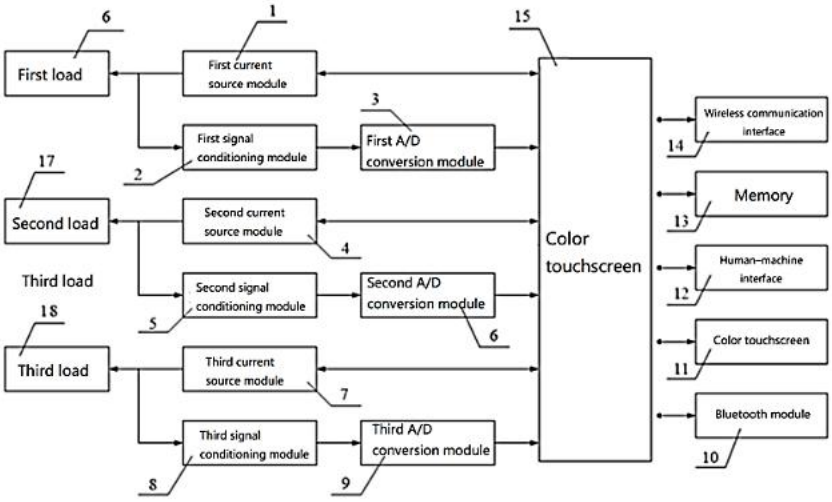

Fig. 2 – The structural schematic diagram of the tester

The GC7135B A/D converter synchronously samples three-phase current, voltage, and temperature; the STM32 computes resistance, resistivity, and temperature-corrected values transmitted to a mobile APP. The APP supports Bluetooth pairing, time sync, parameter configuration, command execution, real-time data reception, validity assessment (inter-phase deviation ≤5% as qualified), WORD report generation, and PMS interface reservation. To counter 2.4-GHz ISM band EMI (*Kusuma Neerugatti & Pakala, 2025*), a hierarchical anti-interference architecture integrates FEC, ARQ, AFH, and packet-length adaptation (*Golaghazadeh et al., 2022; Labiod et al., 2014*). Bluetooth uses 1/3-rate repetition and 2/3-rate shortened Hamming coding; ARQ with CRC enables fast retransmission via ACK/NACK (Type-I Hybrid ARQ). AFH dynamically excludes interfered channels, while variable packet lengths mitigate high-interference transmission risks. A two-tier validation framework (laboratory and field) evaluates functionality, stability, communication reliability, and applicability. Laboratory tests assess Bluetooth communication, data-display sync, constant-current output (0–100 A), measurement range/resolution, HMI, insulation, and EMC using standard resistors, calibrators, and EMI injection. Field tests on 110-kV GIS and 500-kV GIL systems (*Chen et al., 2025*) verify three-phase synchronous measurement, long-distance wireless triggering, and integrated operation; the 1.2 km GIL test validates coordinated main/remote module operation under practical grid conditions.

Development and Testing of the High-Power-Factor Power Supply

The design of the current source employs the UC3854 as the core controller to realize active power-factor correction. Based on the preset current value, the controller automatically adjusts the PWM duty ratio and regulates the switching frequency of the MOSFETs, ensuring that the output current remains stable at the specified level.

Fig. 3 – Photograph of the power supply unit

This study employs a multi-stage AC/DC/AC/DC topology with active power correction and PWM modulation for a high-power, high-power-factor intelligent DC supply (Figure 4). Module (1): rectification; (2): BOOST step-up; (3): half-bridge conversion; (4): high-frequency transformer; (5): secondary rectification; (6): temperature sensor; (7): protection unit; (8): PWM modulator; (9): UC3854-based PFC controller; (10): control interface.

Working process: Mains AC is rectified by (1) to DC bus voltage, then conditioned via the PFC loop (2, 9) to improve power factor. PWM modulator (8) drives half-bridge converter (3) to invert DC to high-frequency AC; transformer (4) provides isolation and step-down; module (5) rectifies and filters to final DC output. Temperature sensor (6) monitors power semiconductors, feeding protection unit (7) to adjust PWM (8) or activate cooling. Control interface (10) manages current setting and display. UC3854-based PFC (9) regulates BOOST input current in-phase with voltage, pushing power factor >0.95; PFC auto-activates under heavy load and disables under light load. PWM modulator (8) serves as the core control unit, adjusting duty cycle and switching frequency per preset current from (10) to stabilize output. The multi-stage structure delivers 100 A at 10 V, exceeding 500 A at 5 V.

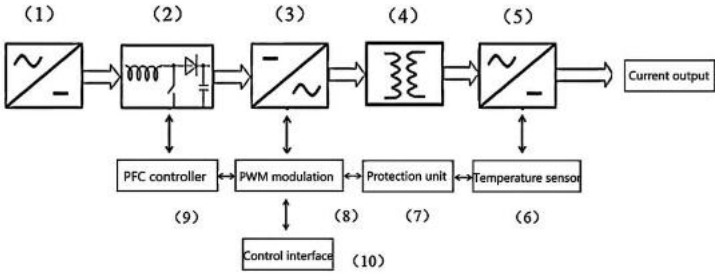

Fig. 4 – Block diagram of the current source principle

In this design, the UC3854 integrated circuit, produced by Texas Instruments for active power factor correction (APFC), is adopted. By incorporating input-voltage feed-forward technology together with the internal multiplier and divider, the loop gain of the control circuitry becomes independent of input-voltage fluctuations. This enables stable operation across the full input-voltage range while ensuring excellent dynamic response and load-regulation performance. The application schematic of the UC3854 is shown in Figure 5.

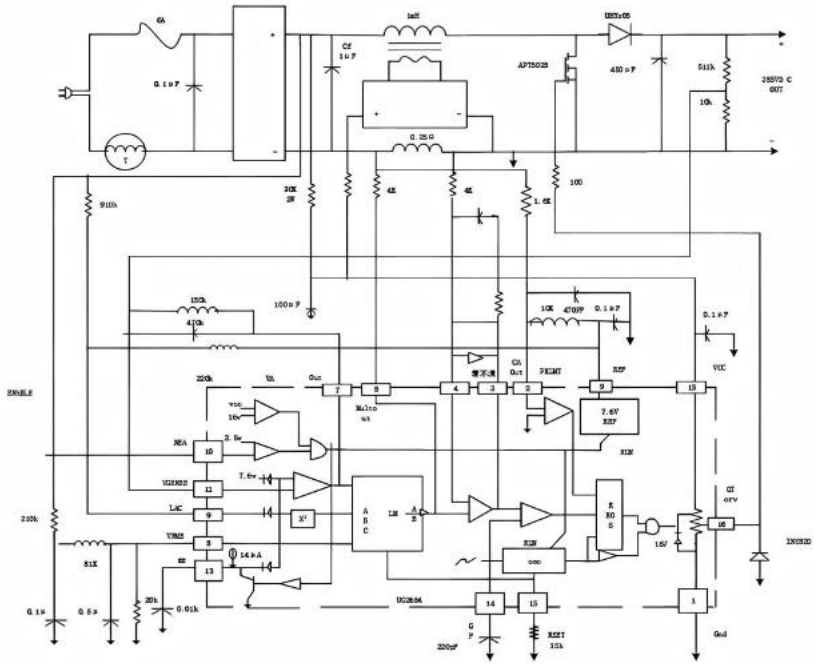

Fig. 5 – Schematic diagram of the UC3854 application circuit

Although the AC/DC and DC/AC stages provide sufficient power, the output voltage remains excessive and current capacity inadequate. A step-down transformer with rectification is therefore introduced to obtain a stable high-current DC output (*Yuan et al., 2020*). Performance evaluation focuses on efficiency, harmonics, waveform quality, thermal behavior, and electromagnetic compatibility under controlled conditions (20 ± 5 ℃, 30%–70% RH). The input is connected to a calibrated power analyzer, and the output to a programmable electronic load. Efficiency is measured from 10% to 100% load with 60 s stabilization per point. Harmonic spectra and total harmonic distortion (THD) are measured under full-load conditions, while waveform distortion, ripple characteristics, and dynamic response are evaluated using high-bandwidth oscilloscopic measurements.

Thermal performance is assessed 60 min full-load operation using thermocouples or infrared imaging to determine steady-state distribution. Electromagnetic compatibility is verified through EFT, surge, and ESD tests applied to power and signal ports, with continuous monitoring of system stability. This framework enables systematic validation of key metrics and supports subsequent system optimization.

Design of the Test Power Supply Based on Supercapacitors

Supercapacitors provide rapid charge–discharge, high power density, long cycle life (>500,000), and wide-temperature operation (−40 to 70 °C). Compared with batteries and electrolytic capacitors, they offer 30–40× higher capacitance at equal volume, faster charging (~95% within 10 s), lower ESR, and significantly enhanced instantaneous power capability. These properties enable high-current pulse generation for loop-resistance measurement. Peak current and duration depend on initial voltage U, capacitance C, inductance L, and resistance R. Large parasitic inductance induces voltage spikes, mitigated by series inductance (validated by simulation). Peak current scales with voltage, exceeding kA levels above 16 V (~2200 A at 32 V), while higher voltage or capacitance extends pulse duration. The discharge path is modeled as a series RLC circuit. Based on the zero-input response of a second-order system, pulse current generation is realized. The 220 V AC input is isolated and half-wave rectified. A microcontroller controls relay-based charging and SCR-based discharging, with a diode preventing reverse current. Charging and discharging are coordinated via optocoupler-driven switching. Experimental validation employs C=1500μF, L=15mH, shunt 100 A/45 mV, and R=0.5Ω, confirming feasibility of the proposed design.

Research on Anti-Strong-Electric-Field and Anti-Strong-Magnetic-Field Interference Techniques

Testing equipment relies on microelectronic components (ICs, digital circuits) for control, signal transmission, measurement, monitoring, and diagnostics, making it highly sensitive to transient disturbances and substation electromagnetic environments. EMC tests are essential to ensure sufficient immunity and reliable operation of intelligent high-voltage devices (*Zhang et al., 2021*). Laboratory analysis of electromagnetic environments guides controlled EMC testing to guarantee field reliability under complex scenarios. This study incorporates strong electric and magnetic field interference considerations into enclosure, high-current power source, functional/signal/communication port designs for robust field usability. For the high-current power source, differential-mode (L1) and common-mode (L3, C2, C3) filters mitigate interference from switching operations, pump start/stop transients, and transformer excitation in agricultural grids. X-class capacitor C1 (phase-neutral) provides high-frequency discharge during voltage spikes to suppress differential-mode noise coupling. Common-mode choke L3 with symmetrically arranged Y-class capacitors C2 and C3 attenuates common-mode interference from lightning, capacitor switching, and long-line transients. The combined filters ensure stable input under weak grids, long transmission lines, and strong interference, providing clean front-end power for subsequent rectification and constant-current output.

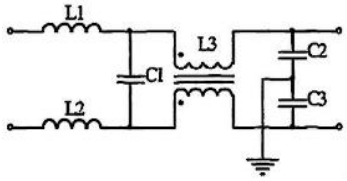

Fig. 6 – Input-End Filter Circuit of the Power Supply

An active PFC circuit at the front-end rectification stage synchronizes input current with grid voltage, maintaining near-sinusoidal waveforms to suppress harmonic injection and high-frequency distortion—critical in rural/agricultural grids where complex loads, voltage fluctuations, and high line impedance cause low-order harmonics, current distortion, sampling noise, ADC instability, and control-loop oscillations. The PFC stage stabilizes energy input, reduces conducted interference, and prevents high-frequency noise from propagating into the filter network and constant-current module. RC snubber networks across MOSFETs and IGBTs attenuate high dv/dt transients and voltage spikes, mitigating reverse voltage ringing and parasitic oscillations in inductive agricultural grid environments. This reduces radiated and conducted EMI while protecting sensors, amplifiers, and microcontrollers. A hybrid single-point and low-impedance grounding strategy minimizes grounding inductance/impedance, rapidly diverting high-frequency currents during transients to limit internal noise propagation. Critical components (drivers, communication modules, ADC units) are protected via localized shielding combined with low-impedance grounding, ensuring interference currents discharge preferentially through the shielding structure—enhancing system robustness against electromagnetic disturbances in harsh agricultural conditions.

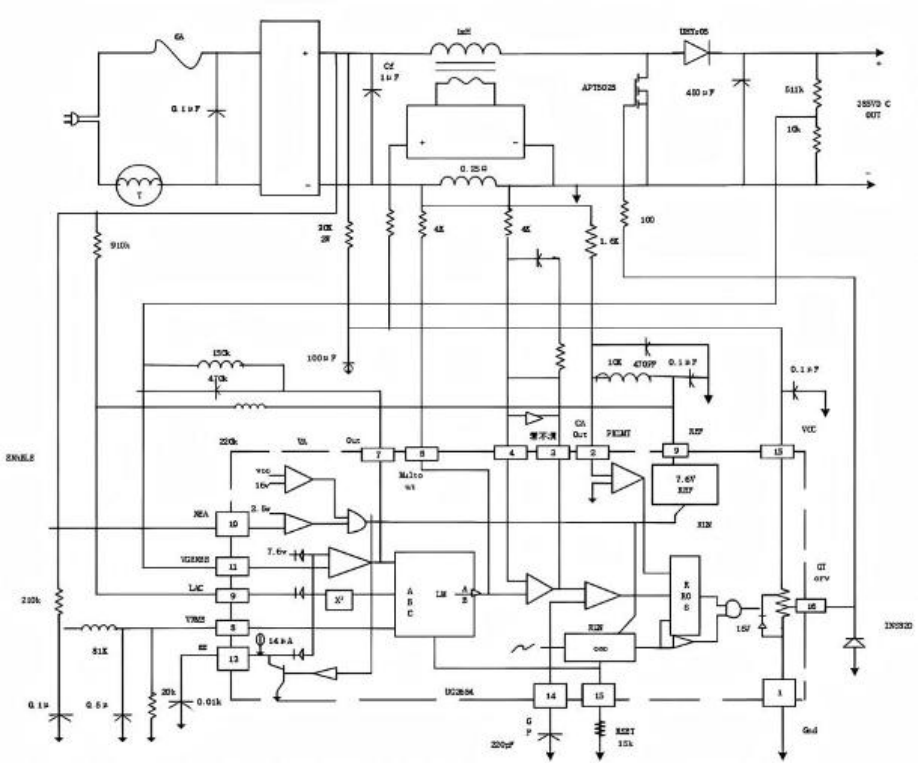

Fig. 7 – Schematic diagram of the UC3854 application circuit

Following the initial design, the AC/DC–DC/AC stages provide sufficient power but yield excessively high voltage and insufficient current capacity. To meet system requirements, a step-down transformer combined with rectification is introduced to generate a stable high-current DC output. Performance evaluation of the high-power-factor supply targets five key metrics: efficiency, harmonic characteristics, waveform quality, thermal behavior, and electromagnetic compatibility, all conducted under controlled conditions (20 ± 5 ℃, 30%–70% RH) using calibrated instrumentation. Efficiency is assessed across 10%–100% load with 60 s steady-state measurements to derive efficiency curves, while harmonic performance is evaluated at full load to obtain spectral distribution and total harmonic distortion. Waveform characteristics are captured via high-bandwidth oscilloscopic sampling to analyze distortion, ripple, and dynamic response. Thermal performance is determined through a 60 min full-load test, with temperature evolution monitored at critical components to establish steady-state distribution. Electromagnetic compatibility is verified by applying EFT, surge, and ESD disturbances to power, enclosure, and signal ports, while continuously tracking system stability and measurement integrity. This unified framework ensures systematic validation of electrical, thermal, and anti-interference performance, providing a robust basis for subsequent optimization and system integration.

RESULTS

Performance Testing of the High Power Factor Power Supply

To satisfy on-site testing requirements in rural grids, the high power factor DC supply was experimentally validated across 10%–100% load conditions. The efficiency curve demonstrates that, despite minor fluctuations at low load due to unstable grid quality, efficiency stabilizes beyond 40% load and exceeds 82% at full load, with a peak of 83.17%. This ensures stable current delivery under intermittent agricultural loads and enhances the consistency of loop resistance measurements. Harmonic analysis under full-load conditions shows low total harmonic distortion with a dominant fundamental component, confirming that the PFC design effectively suppresses harmonic amplification in weak rural distribution networks, thereby preventing measurement instability caused by harmonic interference. Thermal testing indicates that after 60 min full-load operation, key components stabilize at 113 °C (transformer) and 117–118 °C (rectifier), remaining within safe limits under a 23°C ambient environment and demonstrating suitability for prolonged field operation. Electromagnetic compatibility results further reveal that, under EFT, ESD, and RF disturbances typical of rural grids, the system maintains stable output without data interruption or fluctuation. Overall, the proposed power module exhibits high efficiency, thermal reliability, and strong anti-interference capability, providing a robust energy foundation for three-phase high-current loop resistance testing.

Table 1

Values under different load conditions

	Efficiency test value 220 Vac -50 Hz	Target efficiency value	Conclusion
Efficiency at 20% load	93.20%	>82%	Through
Efficiency at 50% load	94.30%	>85%	
Efficiency at 100% load	92.80%	>82%	
Power factor at 100% load	0.991	>0.9

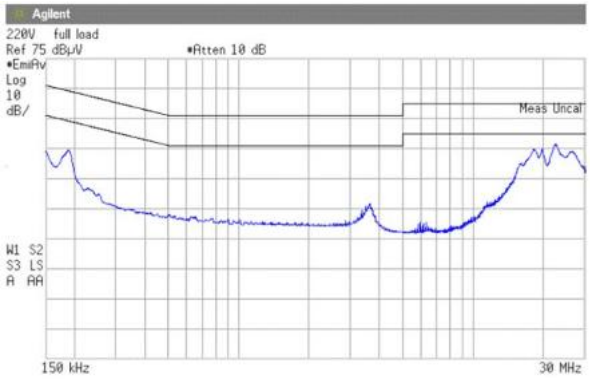

Fig. 12 – Electromagnetic compatibility (EMC) testing under full-load conditions

Supercapacitor Performance Testing

Figure 13 presents the supercapacitor discharge waveform at (U=16\text{ V}), where the current rapidly reaches its peak with a smooth rising edge and no observable spike interference, confirming that the current-limiting inductor and conduction control effectively suppress inductive transient distortion typical of rural grids. When the capacitor bank is charged to 230 V, the output current stabilizes at 100 A and remains steady throughout discharge without collapse induced by line inductance, contact instability, or humidity variations, demonstrating its capability to provide a reliable pulse source for high-impedance test circuits.

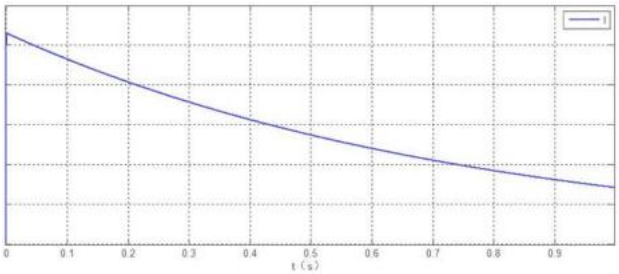

Fig. 13 – Discharge Current Waveform of the Supercapacitor at a Charging Voltage of U = 16

Figure 14 further exhibits an underdamped RLC response with low oscillation amplitude and smooth decay, indicating proper impedance matching. Compared with conventional capacitor discharge, which often produces voltage spikes and abrupt current transitions under humid and variable-temperature conditions, the proposed design suppresses initial peaks via series inductance, ensuring stable loop current and preventing false triggering of protection mechanisms. These results collectively confirm that the supercapacitor-based power supply offers high stability, reliability, and environmental adaptability, making it well-suited for deployment in rural distributed power testing scenarios.

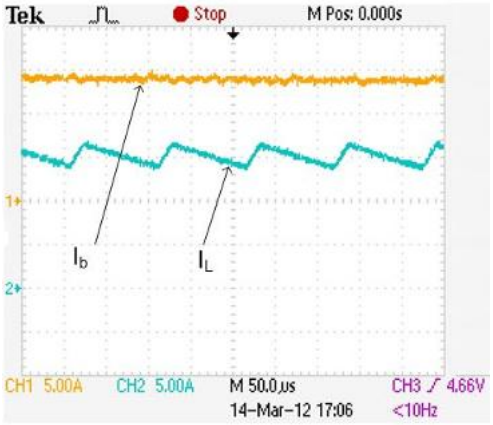

Fig. 14 – Discharge Current Waveform of the RLC Circuit

Performance Testing of the Tester

Comprehensive performance evaluation, conducted in accordance with technical specifications, confirms that the system fulfills all critical functional and operational requirements. Stable Bluetooth communication and WORD-format report export compatible with PMS platforms are achieved. The system provides real-time display of resistance, voltage, current, resistivity, and temperature-corrected values with design-level precision. The DC constant current source operates within 0–100 A, ensuring smooth regulation without overshoot. Measurement range covers 0–19,999 μΩ with 0.01 μΩ resolution, meeting micro-ohm accuracy demands. The human–machine interface integrates a 7-inch 800×480 touchscreen and high-speed thermal printing for rapid reporting. Insulation resistance exceeds 10,000 MΩ, far above the ≥0.5 MΩ requirement. Under full-load conditions (100 A), stable multi-module operation is maintained, with power conversion efficiency ≥82% and power factor up to 0.99 (GB/T14549-93 compliant). Electromagnetic compatibility testing further verifies that all ports satisfy immunity requirements, with no functional degradation or data distortion observed.

Table 2

Test Report Indicators

Testing Item	Technical Requirement	Test Result
Bluetooth Functionality	Must be able to upload data, export data documents, control data acquisition, and generate documents; meet PMS system requirements for document format and data.	Successfully uploads data, exports documents, allows control and generation of documents, meeting PMS system format and data requirements.
Data Display	Must display resistance, voltage, current, resistivity, and resistance values at standard temperature.	Successfully displays resistance, voltage, current, resistivity, and resistance values at standard temperature.

Testing Item	Technical Requirement	Test Result
DC Constant Current Source	Must output 0–100 A test current, with built-in stepwise current increase function.	Outputs 0–100 A test current with stable stepwise increase.
Measurement Range & Resolution	Range: 0–19,999 μΩ; Resolution: 0.01 μΩ	Range: 0–19,999 μΩ; Resolution: 0.01 μΩ
Human–Machine Interface	Equipped with 800×480 HD color 7-inch touchscreen for user interaction.	Equipped with 800×480 HD color 7-inch touchscreen, fully operational.
Insulation Performance	Insulation resistance between instrument casing or panel and ground must be ≥0.5 MΩ.	Measured >10,000 MΩ, far exceeding requirement.

Field tests were conducted on 110 kV GIS equipment at a 220 kV substation in Liaoning Province. The results demonstrate the following advantages of the proposed method:

Connection Efficiency: Simultaneous three-phase connection reduced the setup time from 30 min, required for conventional sequential single-phase connection, to 10 min, representing a 67% improvement.

Testing Duration: Simultaneous three-phase testing completed the full testing procedure within 1 min, compared with 3 min for conventional sequential testing, resulting in a further 67% reduction in testing time.

Data Reliability: The measured phase resistances were 35.95 μΩ (phase A), 36.04 μΩ (phase B), and 35.61 μΩ (phase C). The inter-phase deviation was less than 1%, satisfying the qualification criteria, while the deviation from laboratory-calibrated reference values remained within 0.5%, demonstrating higher accuracy than conventional testing instruments.

For 500 kV GIL testing over a distance of 1.2 km, a wireless auxiliary short-circuit device was coordinated with the main testing unit. Conventional segmented measurement, requiring five segments and approximately 5 min of total testing time, was replaced by single-connection testing completed within 1 min, corresponding to an 80% improvement in testing efficiency. The measured loop resistance was 72.5 μΩ, with a deviation of less than 1% compared with the conventional measurement result of 73.1 μΩ, thereby verifying the accuracy of long-distance testing.

Fig. 15 – Field measurement image of the loop resistance tester

CONCLUSIONS

This study develops a high-power constant-current source based on an AC/DC/AC/DC multi-stage architecture integrated with a UC3854 PFC circuit, achieving a power factor of 0.99 and efficiency above 82% under full load, while maintaining stable output in rural grid conditions characterized by voltage fluctuation and harmonic disturbance. Coupled with an RLC-optimized supercapacitor pulse module, the system delivers smooth, controllable high-current waveforms, ensuring stable excitation even in high-impedance and high-inductance loops, thereby overcoming current collapse issues and improving measurement repeatability. To ensure operational reliability, a comprehensive electromagnetic compatibility framework is established, incorporating differential/common-mode filtering, PFC shaping, RC snubber circuits, single-point grounding, and shielding structures. Experimental validation confirms stable performance in communication, data acquisition, and micro-ohm-level measurement without data drift under EFT, ESD, and RF interference, demonstrating strong anti-interference capability. Field applications further verify system effectiveness.

In 110 kV GIS testing, connection and measurement times are reduced by 67%, while in 500 kV GIL systems, integrated wireless testing improves efficiency by 80%. Across all scenarios, phase deviation remains below 1% and measurement error within 0.5%, confirming high consistency and reliability. Overall, the proposed APP-based wireless three-phase synchronous loop resistance testing system integrates high-efficiency power supply, supercapacitor pulse discharge, and robust EMC design to achieve accurate, efficient, and reliable testing in rural power grids, providing a practical solution for condition monitoring and digitalized operation of agricultural distribution systems.

ABSTRACT

Traditional uniform fertilization in rice paddy fields is associated with low fertilizer-use efficiency and severe agricultural non-point source pollution. Existing variable-rate fertilization equipment commonly presents limitations such as reliance on single-source prescription information and insufficient control precision. To address these issues, this study uses an impeller-type fertilizer applicator as the working platform and, considering the characteristics of cold-region rice cultivation in Heilongjiang Province, constructs an integrated ternary nitrogen-phosphorus-potassium fertilization prescription map. A mapping model between fertilizer application rate and motor speed is established, and a fuzzy PID controller optimized using an improved whale optimization algorithm (IWOA) is designed. Fertilizer-discharge calibration tests and field trials were conducted. The results showed that the coefficient of determination (R^2) between fertilizer discharge rate and motor speed reached 0.9912. The IWOA-fuzzy PID algorithm achieved a step-response overshoot of only 3.3% and a settling time of 1.55 s, while the relative error of field fertilization was controlled within ±5%.

摘要

水稻格田传统均匀施肥模式存在肥料利用率低、农业面源污染突出等问题，现有变量施肥装备普遍存在处方信息单一和控制精度不足等缺陷。针对上述问题，本文以叶轮式施肥装置为作业载体，结合黑龙江寒地水稻种植特点，构建氮磷钾三元融合施肥处方图。建立施肥量 - 电机转速映射模型，设计基于改进鲸鱼算法（IWOA）优化的模糊 PID 控制器。开展排肥标定试验，以及田间试验。试验结果表明：排肥量与电机转速拟合决定系数 R^2=0.9912，IWOA - 模糊 PID 算法阶跃响应超调量仅 3.3%，调节时间 1.55 s，田间施肥相对误差控制在 ±5% 以内。

INTRODUCTION

The area of rice cultivation in our country is vast, and it is a pillar industry for ensuring national food security. The traditional fertilization model has led to increasingly prominent issues of resource waste and ecological problems (*Wang et al., 2024; Ren et al., 2023*). In the scenario of large-scale production of rice fields, the extensive and uniform fertilization method causes a decline in fertilizer utilization rate and an increase in agricultural non-point source pollution (*Li et al., 2022; Liu et al., 2012*). With the rapid iteration of smart agriculture and precise agricultural machinery technology, variable fertilization control in rice fields has become the mainstream direction of industry development. However, during the implementation of this technology, there are always two major challenges: the complex operation environment of paddy fields and the limited computing power of edge terminals of agricultural machinery (*Hu et al., 2023; Hu et al., 2021*).

The rice field operation environment is complex and variable, and the movement of machinery is prone to skidding and jolting. Coupled with the continuous fluctuations in field humidity and soil moisture content, it not only changes the load state of the impeller fertilizer distribution mechanism but also causes problems such as fertilizer deliquescence, caking, and blockage (*Wang et al., 2024; Ding et al., 2025*).

Various interference factors in the field can mask the operation characteristics of the fertilization mechanism, making it difficult for traditional fertilization control methods to accurately identify changes in working conditions and dynamically match the fertilizer demand in the field. This is also an important cause for the current low control accuracy of variable fertilization equipment (*Bai et al., 2022; Wang et al., 2023*).

At present, variable fertilization for rice is mainly divided into two technical routes: real-time sensing and prescription map. Both schemes have their own advantages and inherent defects (*Wang et al., 2024*). Real-time sensing fertilization relies on dynamic collection of nutrient data by field sensors, with fast decision response speed, but the sensors are prone to interference from paddy mud water and dust, resulting in poor long-term operational stability and high equipment modification costs (*Li et al., 2024*). Prescription map fertilization relies on the pre-mapped nutrient layers in the field for operations, with clear decision logic and lower hardware costs, and is also the mainstream choice in domestic rice-growing areas. However, the existing prescription maps are mostly single nutrient layers and cannot meet the agronomic requirements for coordinated fertilization of nitrogen, phosphorus, and potassium (*Ding et al., 2025; Qin et al., 2025*).

In recent years, domestic and foreign research institutions and agricultural machinery enterprises have conducted a large number of research projects on variable fertilization equipment for rice, prescription map technology, and intelligent control algorithms. The team from Huazhong Agricultural University in China developed an electrically driven side-drip fertilization device for rice, optimizing the synchronization of fertilization points (*Li et al., 2024*). Northeast Agricultural University based on Kriging interpolation method constructed a fertilization prescription map for rice, combined with neural network to optimize control parameters. Xi'an University of Science and Technology used Kalman filtering to optimize sensor data, reducing fertilization control error to 2.7% (*Li et al., 2024*). Guizhou University based on the GIS platform built a fertilization decision system to achieve spatial analysis of field nutrients (*Mou et al., 2017*). Foreign enterprises such as John Deere, Kubota, and Igus have launched complete sets of intelligent fertilization agricultural machinery, relying on high-precision positioning technology to achieve dynamic variable operations (*Abdalla & Nafchi, 2024*); several domestic agricultural technology enterprises have also introduced mass-produced variable fertilization equipment, achieving certain fertilizer-saving effects in large-field operations (*Wang et al., 2004; Chen Li et al., 2008*). These studies have advanced variable fertilization technology from different dimensions such as equipment structure, data processing, and algorithm optimization, providing a solid theoretical and practical foundation for subsequent research.

PID and fuzzy PID algorithms are the most widely used mainstream technologies in the field of agricultural mechanical control (*Wang et al., 2023*). The traditional PID algorithm has a simple structure and is easy to implement in engineering, but its parameters are fixed and have poor control effect when facing nonlinear loads of the impeller fertilizer distribution mechanism and system time delays (*Chen et al., 2008*); the basic fuzzy PID can achieve online self-adaptive adjustment of parameters, but the fuzzy rules and initial parameters are mostly set based on manual experience, which is prone to fall into local optimal solutions and easily causes excessive overshoot and lag in dynamic working conditions such as sudden changes in vehicle speed and load disturbances (*Qin et al., 2025; Bai et al., 2022*). The limitations of existing algorithms further restrict the operational accuracy and working condition adaptability of variable fertilization equipment.

MATERIALS AND METHODS

Fertilizer application device structure and working principle

The wheeled fertilizer distributor uses the separated blades of the impeller to form independent fertilizer chambers for fertilizer filling and discharge. Since the fertilizer is not forcibly squeezed during operation, problems such as particle breakage, deliquescence, adhesion, and blockage in compound fertilizers can be effectively avoided. At the same time, the continuous and smooth fertilizer-discharge process during impeller rotation ensures a good linear relationship between discharge amount and impeller speed, thereby meeting the dynamic regulation requirements of prescription-chart-based variable-rate fertilization.

The device adopts a centrifugal fertilizer application device, which consists of a fertilizer box, a centrifugal fertilizer discharger, a fertilizer discharging motor, a fan, etc. The discharge port at the bottom of the fertilizer box is connected to the fertilizer inlet of the discharger. After receiving the control instructions, the motor drives the centrifugal fertilizer wheel to rotate. Under the influence of gravity, the fertilizer particles fall into the Venturi tube. The stable air pressure output by the air system transports the fertilizer along the fertilizer guiding pipe outward. At the same time, under the action of the high-speed airflow, the fertilizer enters the mud ditch to complete the variable fertilizer application for rice.

Overall structure and working principle of the fertilization system

A closed-loop control architecture of upper-level computer decision-making and lower-level machine execution is adopted. During the operation process, the upper-level computer matches the pre-established grid prescription map with the real-time obtained GNSS-RTK positioning information, completes spatial grid addressing based on the current position, and further calculates the target fertilization amount corresponding to the current operation position. The lower-level machine uses the ESP32 controller as the control unit. After receiving the fertilization instructions issued by the upper-level computer, it combines the real-time operation vehicle speed and converts the target fertilization amount into the theoretical rotational speed command for the fertilizer distribution motor. The lower-level machine introduces a fuzzy PID control strategy optimized based on the improved whale optimization algorithm (IWOA) to adjust the rotational speed of the fertilizer distribution motor in real time, and outputs pulse signals to drive the TB6600 stepper motor driver, thereby controlling the 57 stepper motors to complete the fertilizer distribution operation. At the same time, a Hall sensor is installed at the fertilizer distribution shaft end to collect the actual rotational speed of the motor in real time, and the feedback signal is transmitted back to the microcontroller, together with the control instructions, to form the bottom-level rotational speed closed-loop.

CONSTRUCTION OF INTEGRATED FERTILIZATION PRESCRIPTION MAP

Nutrient spatial interpolation and rasterization

Converting the scattered and point-like vector data in the database into continuous planar control maps that the system can read is the key step in establishing the prescription map. In the ArcGIS software, rasterization processing is carried out using the ordinary Kriging spatial interpolation algorithm. Ordinary Kriging is an unbiased optimal linear estimation method and its mathematical model is shown in Eq. (1):

$$\hat{Z}(x_0)=\sum_{i=1}^{n}\lambda_i Z(x_i) \quad (1)$$

where:

$\hat{Z}(x_0)$ is the estimated nutrient value at the grid point x_0 that needs to be predicted, $Z(x_i)$ is the is the measured value at the known sampling point x_i, n is the number of adjacent measured points involved in the interpolation, λ_i is the weight coefficient of the i-th measured point for the predicted point.

The determination of the weight coefficient λ_i relies on the fitting of the semi-variance function, which is used to measure the spatial autocorrelation degree of soil nutrients in a certain direction and distance. The formula is expressed as follows:

$$\gamma(h)=\frac{1}{2N(h)}\sum_{i=1}^{N(h)}[Z(x_i)-Z(x_i+h)]^2 \quad (2)$$

where:

$\gamma(h)$ is the half-mutation value for a step size of h, $N(h)$ is the number of sample point pairs with a spatial distance of h.

The conventional interpolation results in a continuous gradient surface, while the actual fertilization operation is carried out based on discrete units and requires a rasterization reconstruction. Considering the 2.1-meter working width of the transplanting machine used in the experiment, the nearest neighbor method is selected for spatial resampling. The pixel scale of the prescription map is divided into 2.1m × 2.1m squares, and from a logical perspective, the geographic information is mapped into a two-dimensional control array that the microcontroller can directly read.

Calculation of target fertilizer application rate

Based on the actual operation requirements of the fertilizer application machine, practical modifications were made to the classic model. The modified model uses the absolute nutrient gap as the base, removes the low utilization compensation term that is prone to causing data fluctuations, and adds the base application ratio coefficient R.

For any grid i within the operation area, the formula for calculating the target amount of compound fertilizer to be applied based on the single-nutrient balance is as shown in Eqs. (3), (4), and (5):

$$W_{Ni}=\frac{Y\times(U_N/100)-C_{Ni}\times K_s\times E_{sN}}{F_N}\times R_N \quad (3)$$

$$W_{Fi}=\frac{Y\times(U_P/100)-C_{Pi}\times K_s\times E_{sP}}{F_P}\times R_P \quad (4)$$

$$W_{Ki}=\frac{Y\times(U_K/100)-C_{Ki}\times K_s\times E_{sK}}{F_K}\times R_K \quad (5)$$

where:

W_{Ni},W_{Fi},W_{Ki} is the theoretical amount of compound fertilizer base fertilizer calculated based on the individual requirements of nitrogen, phosphorus and potassium at grid point i for the target yield of the experimental field rice, (kg/hm^2); Y is the target yield of the rice in the experimental field, (kg/hm^2); UN, UP, UK is the amount of pure nutrients required for each 100 kilograms of rice to be formed, (kg); C_{Ni},C_{Pi},C_{Ki} is the background contents of available nitrogen, available phosphorus and available potassium obtained through kriging interpolation at grid point i, (mg/kg); K_s is the conversion constant for converting soil nutrient measurement values to the actual total nutrient content of the topsoil per hectare; E_{sN},E_{sP},E_{sK} is the seasonal utilization rate of the soil's own nutrients; F_N,F_P,F_K is the mass fraction of the corresponding effective components in the compound fertilizer; R_N,R_P,R_K is the proportion coefficients for the application of base fertilizers with different nutrient compositions.

The sampling depth for the experiment was set at the standard plough layer, which is 20 cm deep. Considering that the average bulk density of the soil in this area is approximately 1.15 g/cm^3, the total weight of the plough layer soil is approximately 2.3 × 10^6 kg. Therefore, when the soil nutrient concentration is 1 mg/kg, its equivalent absolute nutrient quantity per hectare is 2.3 kg, so the constant K_s is set as 2.3.

The selected fertilizer is a controlled-release compound fertilizer. The specific N-P205-K2O ratio is 21-15-16. By dividing the formula denominator by this mass fraction, the actual nutrient requirements can be converted into the total weight of the compound fertilizer. This fertilizer contains more than 8% controlled-release fertilizer, which can effectively delay the release of nitrogen.

Table 1

Target fertilization amount calculation parameters table

Symbol	Numerical value	Units
Y	9500	kg/hm²
U_N	2.1	kg
U_P	1.1	kg
U_K	2.5	kg
F_N	0.21	%
F_P	0.15	%
F_K	0.16	%
E_{sN}	0.35	%
E_{sP}	0.4	%
E_{sK}	0.5	%
R_N	0.75	%
R_P	0.45	%
R_K	0.35	%
K_s	2.3	%

Generation of diversified and integrated prescription diagrams

The fusion weight ratio of N, P, and K was set as 0.6 : 0.3 : 0.1. On the ArcGIS software platform, the weighted overlay operation of three independent raster maps was carried out using the map algebra module. The mathematical fusion model is expressed as Eq. (6):

$$W_f(i,j)=\omega_N \cdot W_N(i,j)+\omega_P \cdot W_P(i,j)+\omega_K \cdot W_K(i,j) \quad (6)$$

where: $W_f(i,j)$ is the Integrated coordinates; Y is the target yield of the rice in the experimental field,(kg/hm²); (i,j) is the final target amount of fertilizer application at the plot level; ω_N, ω_P, ω_K are the decision weights for nitrogen, phosphorus, and potassium; W_N, W_P, W_K calculated theoretical target quantity of the single-factor compound fertilizer.

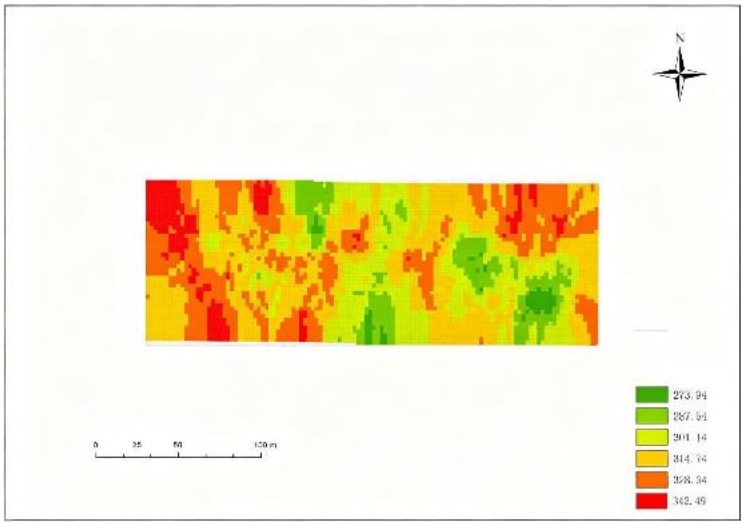

Fig. 4 - Variable fertilization integration prescription chart

IWOA - FUZZY PID ALGORITHM DESIGN

Design of fuzzy PID controller

Proportional-Integral-Derivative, abbreviated as PID, is the most widely used and mature classic algorithm in mechanical and electrical control engineering. It achieves precise regulation of the controlled object by linearly combining the error signal. The expression of PID control in continuous time is as follows:

$$u(t)=K_p\left[e(t)+\frac{1}{T_i}\int_0^t e(\tau)d\tau+T_d\frac{de(t)}{dt}\right] \quad (7)$$

where:

$u(t)$ is the controller output; $E(t)$ is the system error; Kp is the final target amount of fertilizer application at the plot level; T_i *is the integral time constant, (s);* T_d is the differentiating time constant, (s); $e(t)$ is the speed error.

If the traditional position-based PID algorithm is used directly, the program must continuously accumulate all historical rotational speed errors throughout the entire operation cycle. This not only excessively consumes the limited memory resources of the microcontroller, but the more fatal risk lies in the fact that when field operations cross the prescription map grid and the target fertilization amount instructions undergo a step-like sudden change, the accumulated massive errors will instantly trigger the integral saturation effect. Therefore, the bottom-level fertilizer application control selects the incremental digital PID control algorithm. Instead of directly outputting the absolute value of the control quantity, it outputs the incremental $\Delta u(k)$ of the control variable frequency pulse frequency. The core difference equation derivation formula is:

$$\Delta u(k)=u(k)-u(k-1) \quad (8)$$

Discretizing Eq. (7) yields the underlying running formula for the incremental PID on the microcontroller:

$$\Delta u(k)=K_p[e(k)-e(k-1)]+K_i e(k)+K_d[e(k)-2e(k-1)+e(k-2)] \quad (9)$$

where:

$K_i = K_p\frac{T}{T_i}$ is the discrete integral coefficients, $K_d=K_p\frac{T_d}{T}$ is the discrete differential coefficient.

The above incremental PID algorithm has solved the engineering implementation problems of the underlying control. However, the fixed PID parameters are difficult to adapt to complex working conditions such as load fluctuations and sudden changes in target fertilization amounts during field operations, and may lead to large control overshoot and lag in response. Therefore, this paper introduces the fuzzy control algorithm to perform online dynamic tuning of the three parameters of the PID controller. The equation is as follows:

$$\begin{cases} K_p(k)=K_{p0}+E_p\cdot\Delta K_p(k) \\ K_i(k)=K_{i0}+E_i\cdot\Delta K_i(k) \\ K_d(k)=K_{d0}+E_d\cdot\Delta K_d(k) \end{cases} \quad (10)$$

The fuzzy basic domains of the input variables e, ec and the output variables ΔK_p, ΔK_i, ΔK_d are uniformly set to the range [-3, 3]. The fuzzy domain is divided into 7 fuzzy linguistic levels, which are defined as: NB (very large negative), NM (moderately negative), NS (small negative), ZO (zero), PS (small positive), PM (moderately positive), and PB (very large positive).

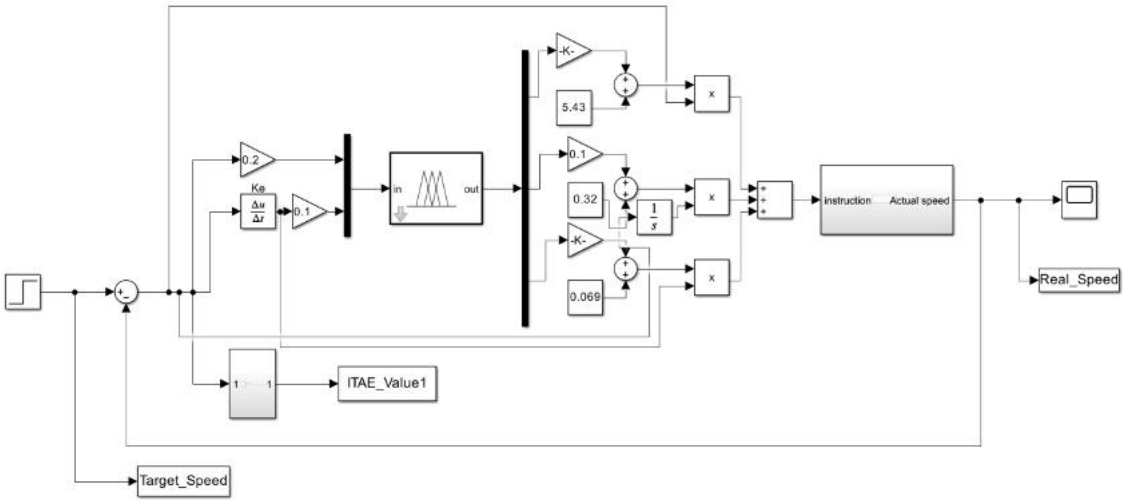

Fig. 5 - Architecture diagram of the fuzzy PID control system

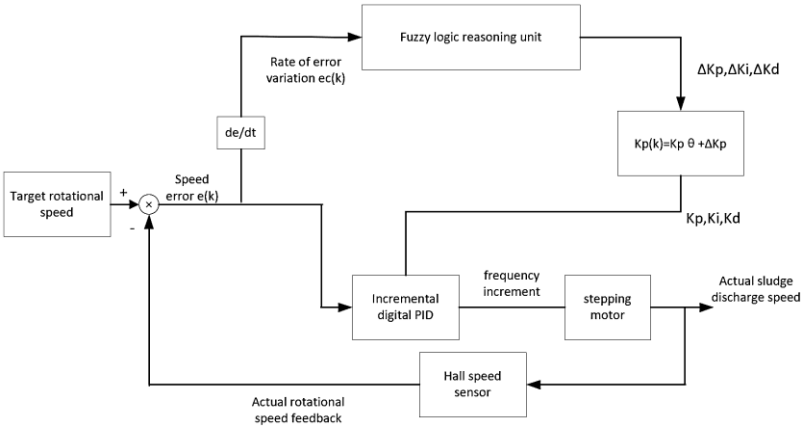

Fig. 6 - Fuzzy PID simulation model

Improvement of population initialization with tent mapping introduction

The standard WOA uses pseudo-random numbers to generate the initial population, which may cause individuals to cluster within the optimization space, thereby reducing the search efficiency of the algorithm in the early stage. The Tent mapping has a strict uniform probability density distribution and pure chaotic characteristics within the [0,1] interval. Its mathematical expression is:

$$z_{i+1} = z_i/\alpha, \quad 0 \le z_i < \alpha \tag{11}$$

$$z_{i+1}(1 - z_i)/(1 - \alpha), \quad \alpha \le z_i \le 1 \tag{12}$$

The value of α is set to the typical value of 0.499. A chaotic sequence is generated using the Tent mapping, and then it is transformed into the initial positions of the fuzzy PID parameters through the inverse mapping. This enables the initial population of pilot whales to evenly cover the entire parameter domain, thereby improving the global optimization starting point of the algorithm from the very beginning.

Nonlinear convergence factor strategy based on cosine function

The linearly decreasing approach results in less global exploration time in the initial stage of the algorithm, and too rapid attenuation in the local development stage later on, which makes it easy to miss the optimal solution. The actual parameter optimization process is a highly complex nonlinear dynamic process. Therefore, this paper proposes a nonlinear convergence factor update strategy based on the cosine function, and the mathematical model is modified as:

$$a = 2 \cdot \cos\left(\frac{\pi}{2} \cdot \frac{t}{T_{max}}\right) \tag{13}$$

The improved α value maintains a relatively slow decay rate in the early stage of iteration, providing the population with more ample time for global and extensive search, thus avoiding premature convergence of the algorithm. In the later stage of iteration, as the slope of the cosine function increases, the α value rapidly decays to 0, prompting the algorithm to converge quickly to the high-precision local extremum point.

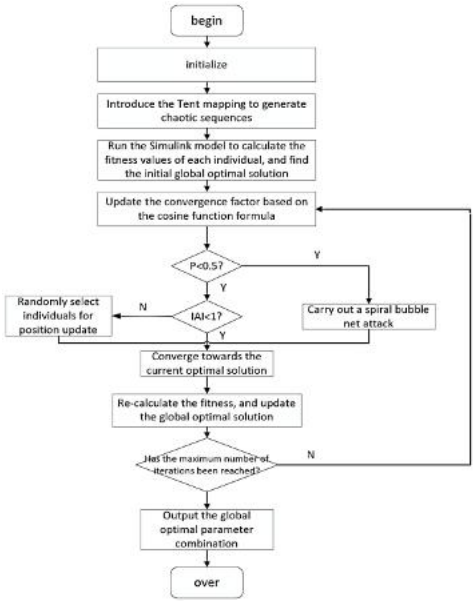

Fig. 7 - Fuzzy PID simulation model

Algorithm simulation analysis

A simulation model was built on the MATLAB/Simulink platform, and step response simulations were conducted for the traditional PID, basic fuzzy PID, and IWOA-fuzzy PID. The optimal physical operating range of the system is 10 to 60 r/min. Therefore, in this section, the target rotational speed command of the system is set to the median value within this range, which is 30 r/min.

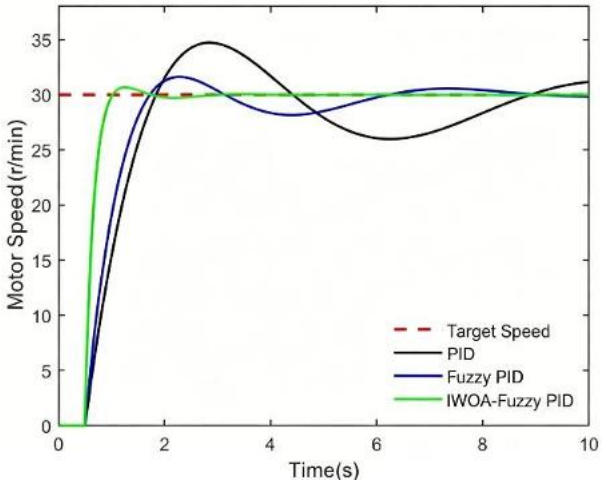

Fig. 8 - Fuzzy PID simulation model

Table 2

Comparison of step response performance indicators

Control algorithm	Rise time [s]	Overshoot [%]	Accommodation time[s]
PID	2.45	16.7	8.8
Fuzzy PID	1.68	6.7	6.02
IWOA - Fuzzy PID	0.92	3.3	1.55

In the PID algorithm, the initial parameters are K_p = 1.23, K_i = 0.84, and K_d = 0.05. Due to the presence of a 0.485-second pure lag in the motor speed response, the relatively large integral coefficient accumulated a huge error energy within the starting dead zone, resulting in a severe integral saturation phenomenon. The weak differential damping was unable to effectively restrain it, directly causing the response curve to soar to around 35 r/min, with a severe overshoot and long-term oscillation. In the fuzzy PID algorithm, the system introduced error and error rate change K_e = 0.2 and Kec = 0.1, and the three compensation quantities ΔK_p, ΔK_i, and ΔK_d were 0.57, 0.1, and 0.05 respectively. Due to the limitation of manual experience setting, the system could not fully exert its potential. Eventually, after 50 generations of deep evolution using the IWOA algorithm, the system successfully escaped from the local optimal trap and locked onto the global optimal parameters K_p = 5.43, K_i = 0.32, and K_d = 0.069. After generating only 1.8% overshoot and a brief real mechanical micro-vibration, it quickly stabilized and precisely matched the target rotational speed command of 30 r/min.

Calibration test of the relationship between fertilizer discharge amount and rotational speed

In this experiment, the calibration speed range of the fertilizer discharge shaft was set at 10 to 60 r/min, and the step size of the test speed was set at 10 r/min. All these were strictly repeated for 6 independent sampling measurements. When calculating the data later, the average values of each group were extracted as the actual fertilizer discharge amount at that speed.

Table 3

Test data on fertilizer discharge amount at different rotational speeds

Rotate speed [r/min]	Measure-ment 1 [g]	Measure-ment 2 [g]	Measure-ment3 [g]	Measure-ment 4 [g]	Measure-ment 5 [g]	Measure-Ment 6 [g]	Average fertilizer application rate [g/min]
10	1121.2	1135.4	1128.5	1119.8	1138.1	1129.2	1128.7
20	2650.3	2681.2	2658.5	2675.9	2645.1	2679.6	2665.1

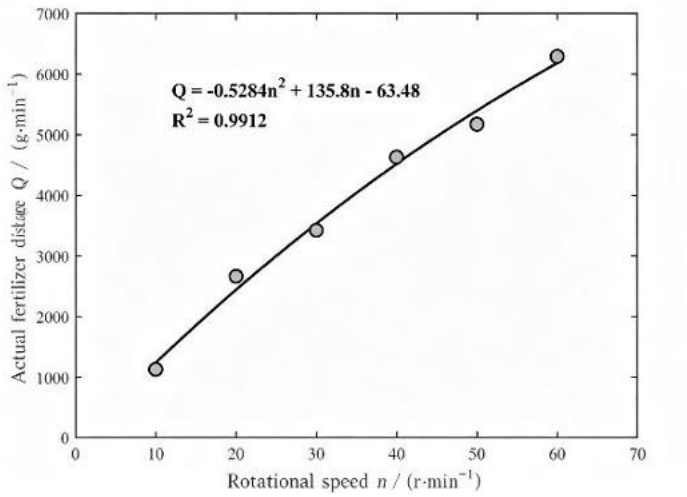

Fig. 9 - Speed and fertilizer discharge rate calibration curve

The coefficient of determination R^2 of the fitted equation is 0.9912. In the system's global closed-loop, this equation is used to convert the fertilizer application rate specified by the prescription map into a dynamic rotational speed executable by the hardware. After the controller obtains the local target displacement Q issued by the prescription chart, it needs to perform real-time reverse optimization calculation to convert it into the target rotational speed n_t of the stepper motor. The underlying control relationship is expressed as Eq. (14):

$$n_t = \frac{-135.8 + \sqrt{135.8^2 - 4 \times (-0.5284) \times (-63.48 - Q)}}{2 \times (-0.5284)} \tag{14}$$

Field trial

The experiment adopted the IWOA-fuzzy PID algorithm as the core driving strategy. The experiment was conducted at the Erliuhe Farm. The experimental equipment was a Jinjiang riding-type rice transplanting machine with a working width of 2.1 meters and equipped with a fan-type fertilizer distributor.

The test equipment includes an ESP32 microcontroller, a GNSS-RTK positioning receiver, a TB6600 stepper motor driver, a 24V power supply, a high-precision electronic balance, and a measuring tape.

The actual fertilizer discharge amount was measured using the box difference weighing method. Before starting the experiment, an adequate initial fertilizer mass W_1 was placed in the fertilizer box and weighed. After the transplanting machine completed the experiment, the remaining fertilizer mass W_2 in the box was weighed again. By calculating the difference between the two measurements ($\Delta W = W1 - W2$), the actual fertilizer discharge amount was obtained. The initial fertilizer mass in the box was 15 kg.

Fig. 10 - Field trial

The travel speed of the transplanting machine was fixed at 1 m/s. Six paths corresponding to different prescription grades were planned in the field, with each path having a length of 20 m. A fertilizer collection bag was attached to the fertilizer discharge outlet, and the fertilizer discharge system was started at the beginning of each path. The motor pulse signal was stopped at the end of the 20 m path. The remaining fertilizer mass in the fertilizer box was then weighed using an electronic balance. The actual fertilizer application rate was calculated using Eq. (15), and the relative error δ was calculated using Eq. (16):

$$M_a = \frac{10000 \times m_a}{L \times W} \quad (15)$$

$$\delta = \frac{M_a - M_t}{M_t} \times 100\% \quad (16)$$

where:

M_a is the actual fertilizer application rate per unit area, (kg/hm^2); m_a is the total mass of discharged fertilizer, (kg); L is the working length, (m); W is the working width, (m); δ is the fertilizer application error; M_t is the target fertilizer application rate, (kg/hm^2).

RESULTS

The fertilizer mass measured for each prescription level was substituted into the formula for calculation, and the results of the constant-rate fertilizer application test are shown in Table 4.

Table 4

The results of the fertilizer application test

Prescription chart level	Target fertilizer application rate [kg/hm^2]	Total discharged fertilizer mass [ma/kg]	Actual fertilizer application rate [kg/hm^2]	Relative error [%]
1	273.94	1.167	277.86	1.43
2	287.54	1.176	280	-2.62
3	301.14	1.317	313.57	4.13
4	314.74	1.31	311.9	-0.9
5	328.34	1.409	335.48	2.17
6	342.49	1.384	329.52	-3.79

CONCLUSIONS

This study addressed the key challenges of fertilization operations in cold-region paddy fields and developed an intelligent variable-rate fertilization system driven by integrated prescription maps. Based on measured field soil data, the study completed the integration and rasterization of multiple nutrient prescriptions for nitrogen, phosphorus, and potassium, thereby solving the problem that traditional single-nutrient prescriptions cannot meet the coordinated fertilizer-supply requirements of rice cultivation. Based on the impeller-type fertilizer discharge device, a mechanism analysis was conducted, and a correlation model between fertilizer application rate and motor speed was established. In addition, a spatiotemporal delay compensation strategy was introduced to effectively correct fertilizer placement deviations caused by machine travel and fertilizer transport. The improved whale optimization algorithm was used to optimize the parameters of the fuzzy PID controller, significantly enhancing the dynamic control capability of the system. The test results showed a strong linear correlation between fertilizer application rate and motor speed, with a coefficient of determination of 0.9912. The optimized control algorithm achieved a step-response overshoot of 3.3% and a settling time of only 1.55 s, while the fertilizer application errors under different field operating conditions were controlled within ±5%, meeting the field agronomic requirements of rice cultivation.

ABSTRACT

This study aimed to evaluate the performance of a vacuum seed-metering unit (VSMU) developed for sowing vegetable seeds in trays under different vacuum pressures. Laboratory experiments were conducted using three seed types with markedly different physical and geometric properties: pepper, Armenian cucumber, and okra. Metering performance was evaluated in terms of the accuracy, miss, and multiple indices. The results showed that seed physical and geometric properties affected the optimal vacuum pressure, which was 1.52, 7.5, and 8.5 kPa for pepper, Armenian cucumber, and okra seeds, respectively. The corresponding accuracy indices were 93.54%, 91.25%, and 96.04%. Seeds with a relatively large mass, such as okra seeds, or low sphericity, such as Armenian cucumber seeds, required higher vacuum pressures than the flat, approximately circular pepper seeds. The developed VSMU therefore demonstrated its ability to handle seeds with diverse physical and geometric characteristics and achieve accurate seed metering.

الملخص

تهدف هذه الدراسة إلى تقييم وحدة شفط البذور المُصمَّمة لزراعة بذور الخضراوات بدقةٍ عالية، عند مستويات مختلفة من ضغط الشفط. تم إجراء التجارب المعملية على ثلاثة أصناف من البذور المختلفة في الخصائص الفيزيائية والهندسية: بذور الفلفل، القثاء الأرمني والبامية. تم تقييم الأداء باستخدام مؤشر جودة البذر، ومؤشر الفقد، ومؤشر المتعدد. وأظهرت النتائج أن الخصائص الفيزيائية للبذور تُؤثِّر بدرجة كبيرة على قيم ضغط الشفط المثلى، والتي بلغت 1.52، و7.5، و8.5 كيلو باسكال لبذور الفلفل، والقثاء الأرمني، والبامية على التوالي. وبلغت نسبة دقة البذر 93.54% و91.25% و96.04% على التوالي. تؤكد هذه النتائج أن البذور ذات الكتلة الكبيرة، كالبامية، أو ذات الكروية القليلة، كالقثاء الأرمني، تحتاج إلى ضغوط شفط أعلى مما تحتاجه بذور الفلفل الدائرية المُسطَّحة. وهكذا أظهرت وحدة الشفط المُطوَّرة القدرةَ على التعامل بدقة مع أشكال البذور المختلفة، وتطوير تقنيات الزراعة الدقيقة لمحاصيل الخضروات المتعددة.

INTRODUCTION

The Egyptian agricultural sector requires numerous physically demanding tasks and a large workforce. However, the sector faces several challenges: a shortage of skilled labor, high wages, and a lack of interest among young people in pursuing agricultural careers (*Abo-Habaga et al., 2024 a, b*). Meanwhile, vegetables are the most economical source of vitamins and minerals vital for a healthy lifestyle and are widely recognized as a fundamental element of food and nutrition security. To maintain an adequate supply of vegetables, further investment in agricultural output, post-harvest management, food safety, and market accessibility is necessary (*Zamuco et al., 2023*). Many agricultural operations, including sowing, transplanting, harvesting, and packaging, still require considerable manual labor. It leads to higher overall production costs (*Arteaga et al., 2020*). Sowing is the first critical operation in commercial vegetable seedling production. Depositing a single seed in each cell of a plug tray is essential because multiple seeds per cell result in excess seedlings, whereas missed seeds leave empty cells. These faults increase the labor required to add or remove seedlings later in the production process. Therefore, precision single-seed sowing is important for high-quality, efficient seedling production (*Xia et al., 2021*). Nevertheless, the overall mechanization level for vegetables is currently approximately 20%, much lower than that for food crops. Given the growing scale of vegetable cultivation, adopting mechanization for seeding is essential (*Li et al., 2025*). Sowing seeds is a crucial step after soil preparation. Among the many cultivation methods, tray planting is one of the most important, efficient, and reliable. This ensures increased productivity, uniform growth and seedling quality, and independent development of each seedling (*Lin and Lee, 2023*).

[1] *Mohamed Abo-habaga, Associate Professor; Zakaria Ismail, Professor; Mohamed Shalaby, M.Sc. Student; Mahmoud Okasha, Researcher*

However, manual sowing in trays is inaccurate and time-consuming, especially with small seeds, as one worker can sow 100 trays in 8 hours, producing approximately 9800 seedlings (*Gaikwad and Sirohi 2008*). It limits production accuracy and capacity due to fatigue and human error. Thus, solutions are moving towards the use of machinery for sowing, which can be complex at times due to variations in seed physical and geometrical properties (*Arteaga et al., 2020*). Tray planting systems require continuous preparation and filling of the soil before sowing. The seed placement process is crucial, as it directly affects the accuracy of placing seeds at the appropriate depth and location (*López et al., 2018*). Numerous machines and technologies were designed and developed for sowing, including mechanical and electrical components and intelligent robots, to improve plant production. Among these, pneumatic seeders have proven to be the most effective, enhancing plant uniformity and offering several other advantages (*Liu et al., 2024*; *Pradhan et al., 2024*). Several studies on vacuum seed meters emphasize the impact of the physical dimensions of the seed pick-up mechanism, including negative pressure, forward speed, and various operational variables, on measurement performance (*Liu et al., 2021*). *Karayel et al. (2004)* reported optimal suction levels for several vegetable seeds and emphasized the high accuracy of air suction in precision agriculture. Other research has discussed the mechanics of seed suction as a combination of differential pressure and pressure-gradient forces (*Shi et al., 2020*; *Li et al., 2021*). *Gaikwad and Sirohi (2008)* developed an inexpensive machine that pneumatically sows trays and found that suction pressure is the primary determinant of sowing accuracy, followed by nozzle diameter. Results under ideal seeding conditions were over 90% for both pepper and tomato seeds.

Similarly, *Li et al*. (2025) developed a precision seeding machine with a vacuum cylinder for irregularly shaped vegetable seeds. They applied computational fluid dynamics (CFD) modeling to study airflow distribution and the relationships among suction pressure, vibration frequency, and key seeding indices. *Ding et al*. (2024) developed a seed-planting machine for seedling trays and noted that seeds with different morphological characteristics require specific planting criteria. Failure to dynamically consider these criteria results in reduced accuracy and increased planting errors.

Zamuco et al. (2023) reported that the accuracy of their planting machine for seedling trays was significantly affected by pressure and seed surface area, with both factors strongly influencing machine performance. The vacuum seed-metering unit (VSMU) uses vacuum as its primary operating mechanism to achieve single, stable seed separation. Suction level is the primary operational factor affecting the efficiency of the capture and individualization process. The main purpose of this study is to evaluate the behavior of vegetable seed pick-up with various physical and geometric properties (pepper, Armenian cucumber, and okra) using a vacuum seed-metering unit (VSMU).

MATERIALS AND METHODS

The VSMU system (Fig. 1) was developed, and the research work was carried out at the AGRI-TRONICS laboratory, Department of Agricultural Engineering, Faculty of Agriculture, Mansoura University, Mansoura, Egypt, during the period January-May 2026.

The VSMU system

VSMU was developed for precision seed sowing, using a pneumatic mechanism that changes vacuum pressure based on seed physical and geometric parameters. The unit is composed of two basic components: the suction unit and the electrical control unit. The combination enabled precision single-seed pick-up with minimal seed misses and enhanced sowing accuracy across a range of seed types.

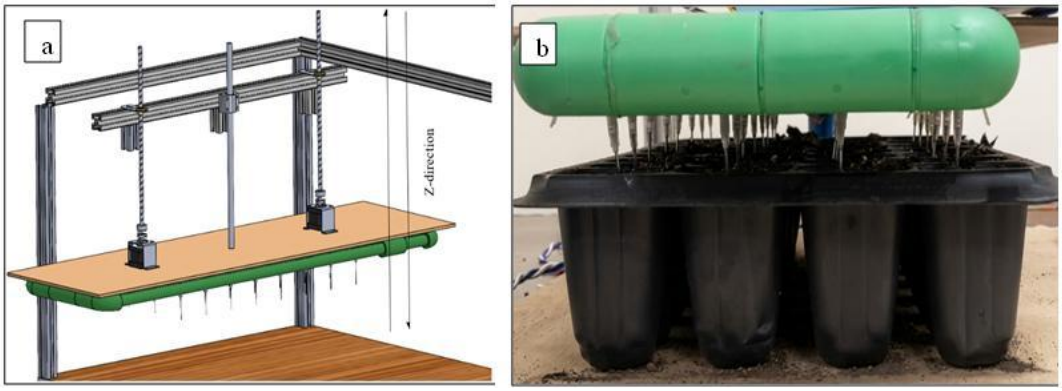

Fig. 1 – The VSMU system: (a) 3D design showing the direction of the z-axis, (b) photo of the VSMU during seed placement into the tray

Suction unit:

The suction unit picks up the seeds using needles with suction nozzles, driven by a suction motor connected to a flexible hose and PPR plastic pipes. The nozzle's picking surface was made flat by smoothing the needle's pointed nose to avoid seed damage, and its length was kept at 30 mm to facilitate picking seeds even as the seed level in the seed box declined (Fig. 2).

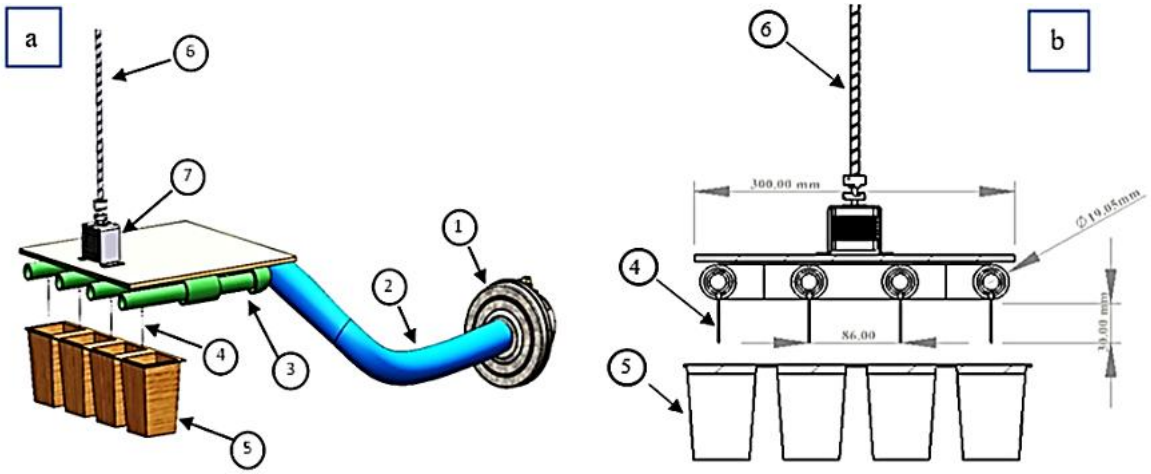

Fig. 2 – VSMU (a) Conceptual drawing and (b) Line diagram (Dim. in mm)

1 – Suction motor; 2 – Flexible vacuum hose; 3 – PPR plastic pipes; 4 – Nozzles; 5 – Seeds box; 6 – Lead Screw; 7 – Stepper motor

Seed box

A wooden seed box was designed measuring 550 × 270 mm with a depth of 30 mm, featuring cells with inward-inclined hive walls to centralize the seeds, thereby enhancing seed extraction during the unit's continuous operation.

Suction pipes and manifold

The VSMU's airflow system was designed using PPR plastic pipes of two different diameters. A 1-inch pipe was connected directly to the flexible hose supplying the suction motor, while 3/4-inch parallel pipes—matched to the cell arrangement in the tray—distributed airflow to the suction needles mounted on them.

Suction motor

A 2200 W suction motor, functioning at 220 V and 50 Hz, was incorporated to generate the pneumatic suction necessary for seed collection. This assembly facilitates the secure attachment of seeds from the seed box and prevents them from being ejected from the nozzle until they reach the tray.

Vacuum intensity adjustment mechanism

Servo motor

The SG90 servo motor served as a precise actuator, connecting the digital control system to the analogue AC dimmer. The servo was mechanically connected to the AC dimmer mechanism to adjust its displacement, enabling indirect control of suction strength via the user interface. It converted PWM control signals into accurate rotational velocities, enabling modulation of the suction operation level. The SG90 functions within a voltage range of 4.8 to 6.0 V. It provides a stall torque of 1.8 kg·cm (0.176 N·m) at 4.8 V and 2.0 to 2.2 kg·cm (0.196 to 0.215 N·m) at 6.0 V. It is compatible with PWM signals and possesses a rotational range of 0° to 180°. The no-load speed is approximately 0.12 seconds per 60 degrees.

AC dimmer

The SCR Voltage Regulator Module is a 2200 W, 220 VAC-type SCR control device for the smooth, continuous control of the effective voltage to the suction motor. It allows for accurate speed control of the suction motor to match the suction it produces. The SCR VC module phase angle controls AC for the SCR. Using phase-control technology, the SCR operates at an angle that reduces the effective load voltage relative to the RMS load voltage. The module simultaneously controls the motor's effective speed and the output voltage to the load, with no discrete switching. The module requires a 220VAC power source. It has a maximum capacity of 2200 Watts, making it suitable for controlling many high-wattage AC load motors, including Universal and AC motor types. The SCR VC module can be used as a VR for motor speed control and, in some applications, as a standard PID-compatible power modulation module. The SCR module's output voltage is modulated to provide adjustable suction, depending on system requirements, allowing precise control of suction pressure in the VSMU system to accommodate differences in seed properties. Based on initial experiments conducted on the studied seeds, the appropriate suction levels for sowing ranged from 1 to 9 kPa.

Operational pressures were measured at the flexible hose interface near the vacuum source using a calibrated pressure gauge. To guarantee experimental consistency and pressure stability, measurements were verified and stabilized before each trial run.

Seed release mechanism

After picking the seeds, the suction unit moves to the tray where the seeds will be placed, down into the soil. The needles penetrate the soil to a depth predetermined by the user, depending on the type of seed. When the specified depth is reached. Experimentally, the dimmer automatically pauses the suction motor for 10 seconds to ensure that the negative pressure is fully discharged, leaving the seeds for the needle nozzle. The suction unit then moves, leaving the seeds inside the soil.

Electrical and control components:

Arduino Mega

The Arduino Mega 2560 served as the principal microcontroller for system control and the integration of all electronic components. The system analyzed input signals from the user interface and sensors to produce control outputs that operated the servo motor and managed the AC voltage controller. It is predicated on the ATmega2560 microcontroller. It possesses a clock speed of 16 MHz. It functions at 5 volts. The device features 54 digital input/output pins, 15 of which support PWM output, 16 analogue input pins, and several serial communication interfaces, including 4 UARTs, facilitating simultaneous connections to multiple devices. The system comprises 256 KB of flash memory (8 KB allocated to the bootloader), 8 KB of SRAM, and 4 KB of EEPROM. The Mega 2560 was deemed suitable for overseeing the multi-component control architecture of the developed system owing to its superior I/O capacity and greater memory than smaller Arduino boards.

RAMPS 1.6 expansion control board

The RAMPS 1.6 extension control board was used to interface with and coordinate the system's motion-control components. It is based on a multi-axis control architecture using an Arduino-compatible shield. It supports up to 5 stepper motor drivers and modular connectors for end stops, heaters, and sensors and is normally run at 12–24 V DC. It has MOSFET power outputs for controlled loads and a heatsink assembly for optimized thermal dissipation at high current.

User interface – UI

The LCD2004 module was used as a human-machine interface (HMI) to monitor the system and select parameters. It consists of a 20 × 4-character LCD, an integrated rotary encoder, and an SD card interface. It runs on 5V direct current and communicates with the main controller over a standard parallel or I2C link. With this setup, the embedded firmware is in charge and can autonomously tune the system.

Power supply

A regulated 12 V DC switching-mode power supply (SMPS) powered the control and actuation subsystems. The SMPS accepts a wide input voltage range of 100-240 VAC, provides a stable 12 V DC output, and has a maximum current rating of 15 A, for a total rated output power of 180 W. The SMPS has built-in protections against overload, overvoltage, short circuits, and other hazards, helping extend its lifespan and ensuring normal operation with a wide variety of loads.

Stepper motor

The NEMA 17 stepper motor provides accurate positional control of the mechanical actuation components. The NEMA 17 stepper motor is a bipolar hybrid model with a standard step angle of 1.8° (200 steps per revolution). The electrical specification of the NEMA 17 stepper motor is a phase current rating of 1.2 to 2.0 A and a holding torque rating of 30-70 N·cm. The NEMA 17 stepper motor can be interfaced with drivers that use either pulse-width modulation (PWM) or step/direction control signals to provide accurate open-loop positioning. The general geometric specifications of the NEMA 17 stepper motor include a standard 42 × 42 mm frame size with a variety of different shaft combinations.

Stepper motor driver module

The DRV8825 driver was used to control the stepper motor, leveraging its high precision microstepping capabilities. In addition, the module provides a motor supply voltage range of 8.2 to 45 V and a maximum of 2.2 A per phase with sufficient thermal management. It supports microstepping resolutions up to 1/32 step, driven by STEP and DIR logic signals. Moreover, the driver includes built-in protection circuitry, including overcurrent, thermal shutdown, and under-voltage lockout (UVLO).

Studied factors

The developed VSMU was evaluated under various working conditions. The key elements assessed were seed morphology and vacuum intensity, as these factors directly affect seed pick-up efficiency and deposition accuracy.

1. Morphology: Three types of seeds were chosen to determine the performance of the metering unit for a variety of seed sizes, shapes, surface textures, and masses (Table 1): pepper *(Capsicum annuum L.)*, Armenian cucumber *(Cucumis melo var. flexuosus)*, and okra *(Abelmoschus esculentus L.)* seeds. For each type, length (L), width (W), and thickness (T) were measured on 30 seeds using a digital caliper (accuracy 0.01 mm), and thousand-seed mass (M) was determined with a digital balance. Sphericity (φ) and aspect ratio (R_a) were determined by Eqs. (1) and (2), according to *Mohsenin (1970).*

$$\phi = \frac{(L \times W \times T)^{1/3}}{L} \times 100 \quad (1)$$

$$R_a = \frac{W}{L} \times 100 \quad (2)$$

Table 1

The physical and geometrical properties of the studied seeds

Seed type	Parameter	L (mm)	W (mm)	T (mm)	φ (%)	Ra (%)	M (g/1000 seeds)
Pepper	Mean	3.71	3.87	0.89	62.96	104.31	3.5
	±SD	0.50	0.19	0.16			
	CV (%)	13.47	4.91	17.98			
Armenian cucumber	Mean	5.21	2.22	1.59	50.61	42.61	30.2
	±SD	0.60	0.22	0.49			
	CV (%)	11.52	9.91	30.82			
Okra	Mean	4.71	4.02	3.59	86.64	85.35	81.4
	±SD	0.30	0.24	0.36			
	CV (%)	6.37	5.97	10.02			

The data in Table 1 demonstrate significant differences in physical attributes among the three seed varieties evaluated. Okra seeds exhibited the largest dimensions (L = 4.71, W = 4.02, T = 3.59 mm), highest φ (86.64%) and R_a (85.35%), and greatest thousand-seed mass (81.4 g), suggesting a compact, near-spherical form. On the other hand, the Armenian cucumber seeds exhibited the largest elongation, the lowest φ (50.61%) and *Ra* (42.61%), and an intermediate thousand-seed mass of 30.2 g. The pepper seeds had a considerably low T of 0.89 mm, which resulted in a flat morphology, a moderate φ of 62.96%, and the smallest thousand-seed mass of 3.5 g. Such diversity in seed geometry and mass among the three varieties is likely to result in different pick-up reactions at varying suction pressures.

2. Vacuum pressure levels: The stability of pick-up and reliability of singulation were examined across different suction levels. The control system regulated the vacuum motor speed to generate the required pneumatic pressure, and the suction strength was electronically controlled. The experiment was performed at pressure levels ranging from 1 to 9 kPa.

Operation of the suction unit

Each seed type and suction pressure level had 15 trial replications for that specific combination. In each replication, 32 tray cells/nozzles were tested; therefore, the total sample size was 480 cells per treatment. The suction pressure was adjusted to the target value before each trial, allowed to stabilize, and verified with the vacuum gauge before beginning the seed pick-up cycle. After the user determines the required suction power variables, the suction unit moves to the seed box. The servo motor then automatically adjusts the dimmer to the specified suction level. At that time, the seeds are drawn toward the needle nozzle by the suction. Then the suction unit moves to the tray to be planted, and the seeds are placed inside the soil. The servo moves to close the suction motor for 10 seconds as a rest time to ensure all seeds fall and remain in the soil. Then, the suction unit returns to its position to start a new circuit, and the process repeats until the user-specified number of circuits is completed. The workflow procedure is shown in Fig. 3.

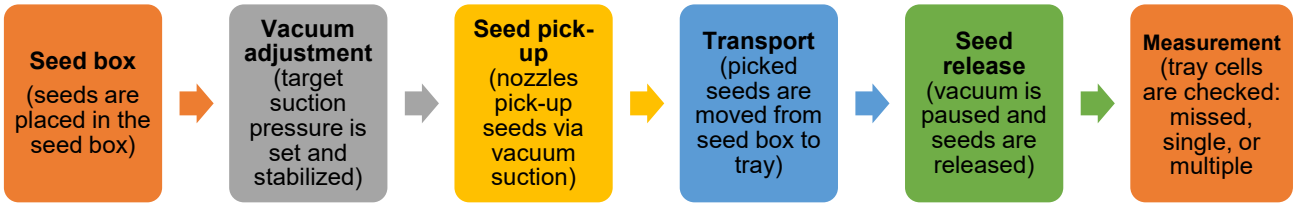

Fig. 3 – Workflow procedure of VSMU

Measurements

The total miss index (I_m), total multiple index (I_d), and accuracy percentage (S) were calculated according to Eqs. (3-5), respectively, according to *Kachman and Smith* (1995) and *Ismail et al. (2023).*

$$I_m = \frac{N_m}{N_t} \times 100 \quad (3)$$

$$I_d = \frac{N_d}{N_t} \times 100 \quad (4)$$

$$S = \frac{N_{success}}{N_t} \times 100 \quad (5)$$

where: S is the accuracy percentage, [%]; N_m is the number of cells that were "lost", and no seeds were sown; N_d is the number of cells in which "two seeds" (Doubles) descended; N_t is the total number of cells; $N_{success}$ is the number of successful cells.

Instruments:

1) A digital caliper was used to measure the seeds' dimensions. The digital caliper has a measurement range of 0 to 150 mm with an accuracy of 0.01 mm.
2) A digital balance was used to measure the mass of the seeds. It has a maximum capacity of 200 g with an accuracy of 0.001 g.
3) The vacuum pressure inside the system was measured by a vacuum gauge. The device's measuring range is -1 to 0 bar (0 to -30 inHg), and its accuracy class is 1.6 (±1.6% full scale).

RESULTS AND DISCUSSION

The VSMU system was evaluated using three parameters: the accuracy percentage index (S), the missing index (I_m), and the multiple index (I_d). In experimental trials, for each seed type, the S of vacuum seed placement was determined at different theoretical suction levels using these indicators. I_m shows a seed not captured due to insufficient suction pressure. I_d occurs when more than one seed is picked up at once, which can be caused by excessive vacuum pressure or by seeds clumping together around the nozzle. The accuracy index was calculated as the ratio of successful single-seed pickup events to the total number of pickup attempts, with both missed and multiple-seed pickups classified as unsuccessful events. Tests were conducted to determine the effects of different vacuum pressures on seed-pickup performance and singulation efficiency.

The experimental results were used to determine the optimal suction level for each seed type, defined as the level at which the accuracy percentage was maximized and the missing- and multiple-seed indices were minimized. For each seed type, 15 replications were conducted at each suction pressure level. The tested pressure levels ranged from 1 to 9 kPa (Figs. 4-7).

1. Pepper

Increasing the vacuum pressure from 1 to 9 kPa, the total miss index (I_m) changed slightly from 3% to 2%; the total multiple index (I_d) rose from 4% to 21%, while the accuracy percentage (S) decreased from 93% to 77%. As vacuum pressure increased, metering accuracy declined, mainly because (I_d) increased rather than (I_m) decreased (Fig. 4).

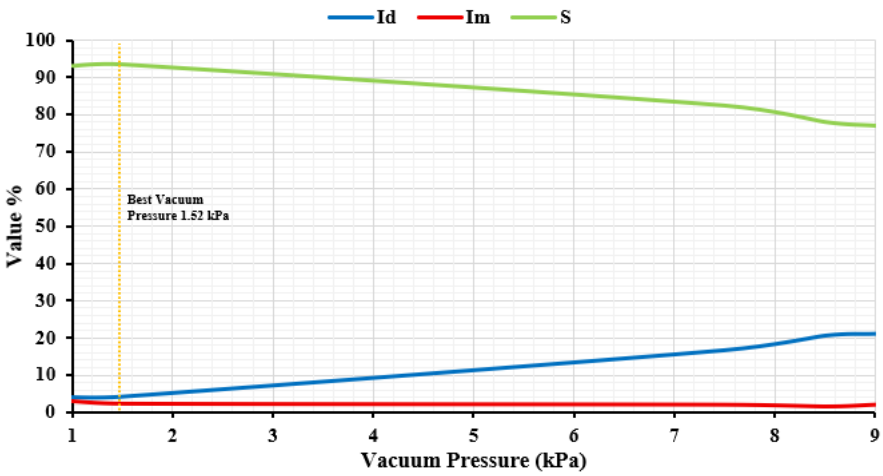

Fig. 4 – Effect of suction pressure on I_d, I_m, and S for pepper seeds

2. Armenian cucumber

Increasing vacuum pressure from 1 to 9 kPa, the total miss (I_m) index decreased from 14% to 2.3%; the total multiple index rose from 2% to 10.2%; and then the accuracy percentage (S) continued to rise from 84% to 91.25% at 7.5 kPa -Best Vacuum Pressure- and then decreased again to 87.5% at 9 kPa. As vacuum pressure increased, the reduction in the total miss index (I_m) was the dominant effect at lower pressures, while the rise in the total multiple index (I_d) became more pronounced at higher pressures (Fig. 5).

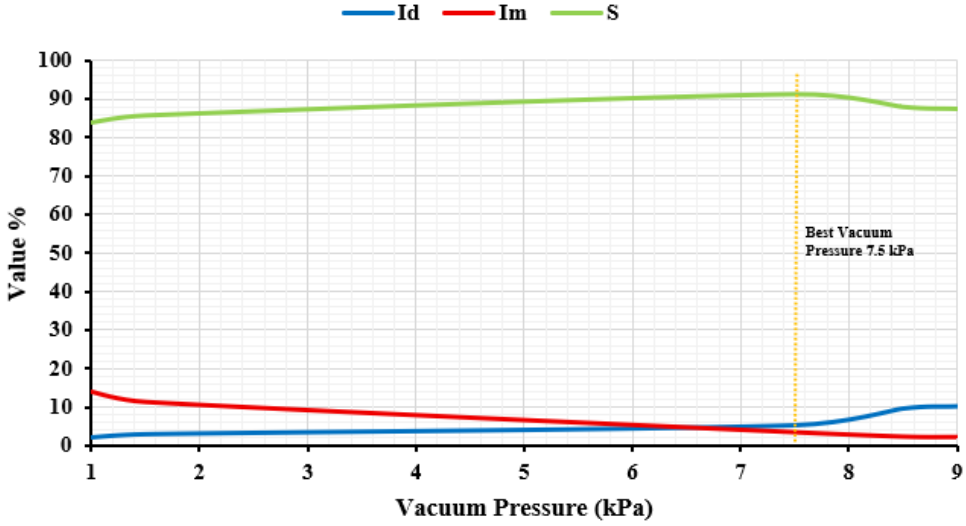

Fig. 5 – Effect of suction pressure on I_m, I_d, and S for Armenian cucumber seeds

3. Okra

Increasing vacuum pressure from 1 to 9 kPa, the total miss index (I_m) decreased from 15% to 2.4%; the total multiple index (I_d) rose from 0.1% to 2% and then the accuracy percentage (S) continued to rise from 84.9% to 96.04% at 8.5 kPa -Best Vacuum Pressure- and then decreased again to 95.6% at 9 kPa. As vacuum pressure increased, the reduction in the total miss index (I_m) was the dominant effect at lower pressures. In comparison, the rise in the total multiple index (I_d) became more pronounced at higher pressures (Fig. 6).

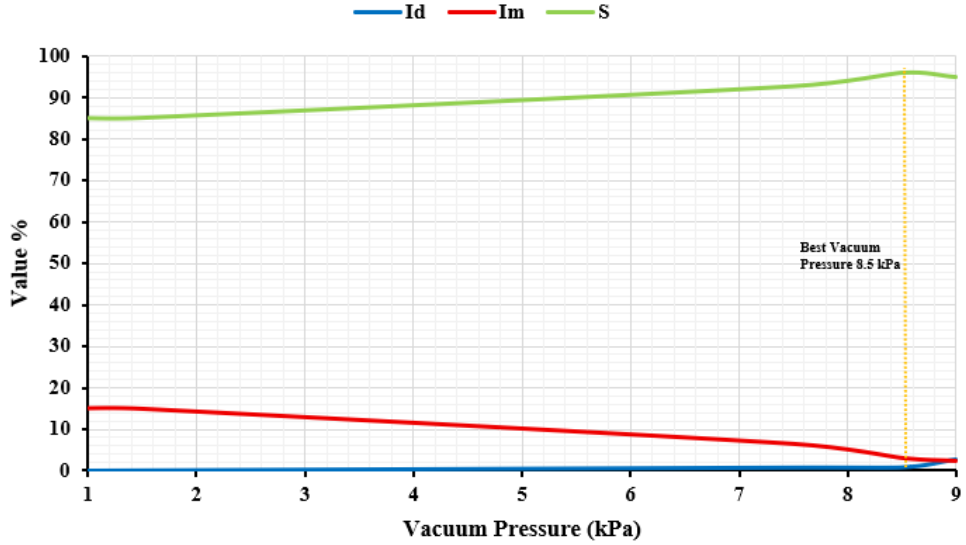

Fig. 6 – Effect of suction pressure on I_m, I_d, and S for *okra* seeds

Comparative seed singulation performance across crop types

The VSMU accuracy percentage varied across seed types at their respective optimum suction settings. For each crop, the best operating condition was selected based on the maximum accuracy percentage index (S) and minimum missing (I_m) and double (I_d) indices. The best suction pressures were 1.52, 7.5, and 8.5 kPa for pepper, Armenian cucumber, and okra seeds. Values of missing and multiple-seeds are expressed as mean ± standard deviation based on 15 replications. At the optimum suction pressures, pepper seeds at 1.52 kPa recorded 1.20 ± 1.01 missing events and 2.07 ± 1.22 multiple-seed events.

Armenian cucumber seeds at 7.5 kPa recorded 1.27 ± 0.70 missing events and 3.27 ± 1.03 multiple-seed events. Meanwhile, okra seeds at 8.5 kPa recorded 1.00 ± 0.65 missing events and 0.27 ± 0.46 multiple-seed events. These results indicate that the selected suction pressure for each seed type yielded stable seed pick-up performance, with acceptable variation across replications. The values obtained for *S*, I_m, and I_d for pepper seeds under these conditions were 93.54%, 2.29%, and 4.16%, respectively. Armenian cucumber seeds were recorded at 91.25%, 3.54%, and 5.2%, respectively. Okra seeds performed best overall with an *S* value of 96.04% and I_m and I_d values of 3.12% and 0.83%, respectively. The variation in singulation performance was attributed to differences in seed size, shape, and surface contact characteristics under pneumatic suction conditions.

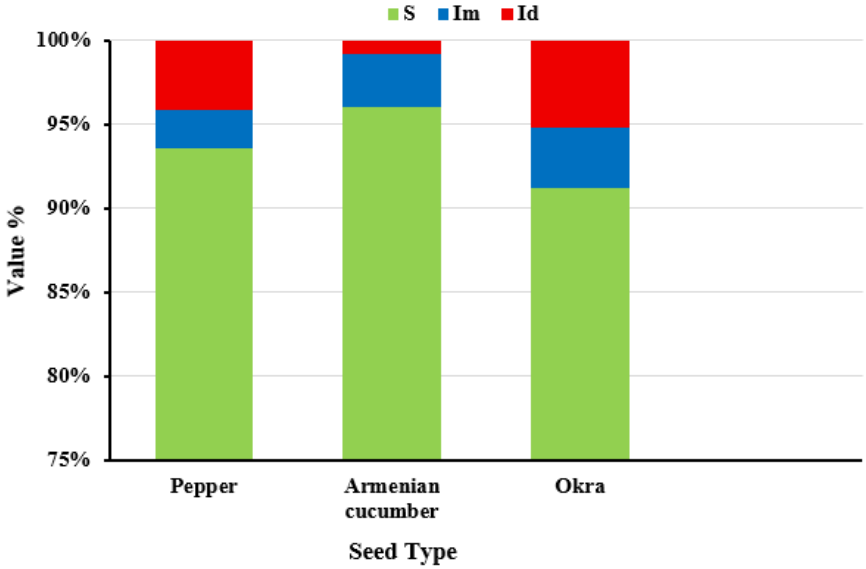

Fig. 7 – Seed singulation performance

Pepper seeds have a lower optimum vacuum pressure primarily because of their low seed weight and flat shape. This setup provides enough suction force to lift the pepper seeds at very low vacuum pressures. In contrast, the low sphericity and length of Armenian cucumber seeds would inhibit stable contact with the nozzle, thereby requiring higher vacuum levels to pick up the seeds reliably. Okra seeds, while highly spherical, have the highest seed weight and thus require more suction force to maintain stable attachment during transport than either of the other two seed types. Thus, the optimum vacuum pressure depends on the interaction between the seed's physical characteristics and the nozzle design, rather than on the seed's size alone. The results are in agreement with those of *Karayel et al.* (2022), determined in laboratory experiments conducted under controlled conditions, that the optimum vacuum pressure of the air-suction seed-metering device changed depending on the seed type and was 3.0 kPa for soybean, 4.0 kPa for maize, 2.5 kPa for melon and watermelon, 2.0 kPa for sugar beet, and 1.5 kPa for onion seeds. In the present investigation, a similar trend was observed, with pepper seeds requiring the lowest optimum vacuum pressure (1.52 kPa). This value closely matches that of onion seeds, due to their similar small seed size and reduced mass. In contrast, cucumber and okra seeds required much greater vacuum pressures, 7.5 kPa and 8.5 kPa, respectively. This trend is reconcilable with the higher vacuum pressure level observed for larger seeds such as melon, watermelon, soybean, and maize. This shows that the different morpho-physical properties of the seeds also determine the optimal vacuum pressure, with seed size and weight being the most significant factors. VSMU's success in providing accurate, repeatable seed singulation across all seed types confirmed prior theories that vacuum pressure depends on both seed type and the system employed. The findings that are used to assign optimum vacuum pressures (1.52 kPa for pepper, 7.5 kPa for Armenian cucumber and 8.5 kPa for okra) are consistent with previous research of pneumatic seeding systems in which small seeds typically require less suction (1.5-4.0 kPa) in controlled lab conditions (*Karayel et al., 2004*; *Karayel et al., 2022*). The findings are also similar to those for other small vegetable seeds, such as onion and sugar beet. The interaction between the physical properties of the seeds and the operational characteristics of the VSMU led to higher vacuum requirements for okra and Armenian cucumbers due to their irregular shapes and low sphericity. Because of these properties, the effective contact area between the seed and the suction area of the orifices is reduced; therefore, pick-up stability is reduced, which increases the amount of vacuum necessary to achieve proper seed singulation.

Higher suction demand during steady-state operation can result from operating modes and measured conditions that differ from those in the laboratory. Seed metering studies using vacuum systems have established that both seed characteristics and operational conditions can affect vacuum requirements, and that many observed deviations from ideal values can be attributed to seed–orifice interactions rather than to defects in the vacuum system (*Karayel et al., 2004; Jabir and Alfadil, 2022*). Therefore, it can be concluded that the optimal vacuum pressure arises from the interaction between the seed and the system, rather than being determined solely by the seed's characteristics.

CONCLUSIONS

The VSMU provided highly repeatable seed pick-up performance at a range of vacuum pressures and seed physical characteristics. Seed capture performance was influenced by vacuum pressure, as indicated by the single-seed pick-up accuracy percentage (S), miss index (I_m), and multiple index (I_d). The test results indicated that the vacuum pressure providing the best performance depends upon the seed characteristics, including seed shape/size, mass, and surface. The vacuum pressure at which the best pick-up performance for pepper seeds occurred was 1.52 kPa, corresponding to a single-seed pick-up (S) of 93.54%, a miss index of 2.29%, and a multiple index of 4.16%. The pick-up pressure for okra seed pick-up performance was 8.5 kPa, resulting in a single-seed pick-up accuracy percentage (S) of 96.04%, a miss index of 3.12%, and a multiple index of 0.83%. The pick-up performance for Armenian cucumber seeds was 7.5 kPa, yielding a single-seed pick-up accuracy percentage (S) of 91.25%, a miss index (I_m) of 3.54%, and a multiple index (I_d) of 5.20%. Overall, optimizing vacuum pressure improved single-seed capture efficiency and reduced missed and multiple-seed pick-ups, thereby minimizing erroneous seed placement by the vacuum pick-up system. Thus, the VSMU can be regarded as an efficient and versatile mechanism for precision sowing applications of seeds with different physical properties. Nevertheless, this study was conducted under controlled laboratory conditions and was limited to only three types of vegetable seeds. Future work should include other seed types and nozzles with different geometries, be tested across a wider range of operating conditions, and include nursery-scale validation.

Keywords: Fruit Recognition, LLM, Vision Transformer, Zero-Shot, Smart Agriculture

ABSTRACT

Efficient and flexible agricultural image annotation is crucial for intelligent crop monitoring in smart agriculture, yet conventional detection models are limited by fixed class labels and require extensive manual annotations. This study presents a zero-shot annotation framework that integrates OWLv2, Google's second-generation open-vocabulary vision model, with large language models (e.g., GPT-3.5, DeepSeek V1) to enable multilingual, natural language-driven fruit recognition in smart agriculture. A user-friendly interface was developed to support individual or batch image annotation with adjustable sensitivity to meet diverse field requirements. Experimental evaluations demonstrated the framework's strong generalizability and semantic understanding capabilities, allowing recognition of unseen fruit categories and attributes such as ripeness or color. The system significantly reduces annotation time and labor costs, while enhancing accessibility through natural language interaction. To ensure a robust evaluation of generalizability, a cross-domain protocol was employed using a novel dataset from 2025. Results showed that OWLv2 achieved an F1-score of 0.80 and an mAP of 0.8301, significantly outperforming the pre-trained YOLO11 (F1: 0.74, mAP: 0.60) in zero-shot scenarios. OWLv2 exhibited superior flexibility and required no task-specific dataset retraining, although its computational demands remain higher than lightweight models like YOLO11. Notably, while the LLM (DeepSeek) introduced a total one-time API latency of 598.3 ms (called only once for processing multiple images). the actual core computational latency of OWLv2 was only 257.7 ms per image. Despite a total processing time of 891.9 ms (including visualization output), the framework demonstrates superior recall (0.9080) and semantic flexibility without retraining. These results verify the enormous application potential of OWLv2 and similar zero-shot models in agriculture, providing scalable solutions for automated annotation, real-time monitoring, and large-scale data collection.

摘要

在智慧农业领域，传统农业领域图像目标检测模型受限于固定的类别标签，并依赖大量人工标注。本研究提出了一种可以语言交互的零样本（zero-shot）标注框架，将 Google 第二代开放词汇视觉模型 OWLv2 与大语言模型（GPT-3.5、DeepSeek V1）相结合，以实现面向智慧农业的多语言、自然语言驱动的果实识别。为此，我们开发了一个交互界面，支持单张或批量图像标注，并可根据实际田间需求调节检测灵敏度。实验评估结果表明，该框架具备优异的泛化能力与语义理解能力，能够识别未曾在训练集中出现的果品类别及其属性（如成熟度、颜色等）。基于 2025 年果园数据集的跨域评估表明，OWLv2 的 F1 分数（0.80）与 mAP（0.8301）显著优于零样本场景下的预训练 YOLO11（F1: 0.74, mAP: 0.60）。相较于传统模型，OWLv2 展现出更强的灵活性，且无需针对特定任务重新训练数据集；时延分析显示，LLM（DeepSeek）仅引入 598.3 ms 的单次调用延迟（多张图只调一次），OWLv2 的核心计算耗时仅为 257.7 ms/幅。尽管包含图像输出的总处理时间为 891.9 ms，但该框架在无需重训的情况下展现了极高的召回率（0.9080）与语义灵活性。上述结果验证了 OWLv2 及同类零样本模型在农业领域具有为自动化标注、实时监测及大规模数据采的巨大潜力。

INTRODUCTION

In recent years, the emergence of transformer-based architectures has significantly advanced the field of computer vision, with growing implications in agricultural automation and precision farming. One notable breakthrough was Google's Vision Transformer (ViT), which introduced the concept of dividing images into fixed-size patches (e.g., 16×16) and treating them as sequential data, similar to words in natural language processing (*Dosovitskiy et al., 2020*). This approach enabled visual models to benefit from the scalability and learning efficiency of transformer networks, paving the way for a wide range of vision tasks with reduced reliance on task-specific architectures.

Following ViT, transformer-based vision models have evolved rapidly. Notably, OpenAI's CLIP model (*Radford et al., 2021*) demonstrated that joint vision-language pretraining on web-scale data can result in powerful zero-shot capabilities. Similarly, research from institutions such as Google and NVIDIA (*Xu J. et al., 2023*) has explored large-scale multimodal models for open-vocabulary learning, where systems are trained not on fixed class labels but on flexible language prompts. These developments are highly relevant to agriculture, where the diversity of crops, growing conditions, and field scenarios presents a challenge to traditional classification-based systems.

To address the need for more adaptable models, Google introduced the Open-Vocabulary Learner (OWL) framework. The first generation, OWL-ViT (*Minderer et al., 2022*), combined ViT backbones with vision-language pretraining in the style of CLIP, enabling zero-shot object detection based on textual input. However, it still relied heavily on annotated data for downstream adaptation. In response, OWLv2 was released in 2023 (*Minderer et al., 2023*), introducing a self-labelling mechanism called OWL-self. This technique allows the model to automatically generate pseudo-annotations via bounding box proposals, which are then refined through loss computation and further model updates. The concept aligns with the iterative self-supervision loop proposed by Meta AI in its Segment Anything (SA) model (*Kirillov et al., 2023*), which reduces dependence on manual labels by enabling scalable training on unlabeled image datasets.

Compared to chemical methods for fruit detection, image-based methods are more intuitive (*Qin et al., 2023*). *Wei et al. (2023)* verified that imaging techniques enhance the accuracy of conventional sensing methods for food detection. In smart agriculture, open-vocabulary models excel in dynamic environments like orchards or greenhouses, enabling tasks such as fruit recognition, disease monitoring, and crop growth assessment (*Espinoza et al., 2023; Mimma et al., 2022; Zhang et al., 2025*). *Li et al. (2025)* developed an improved YOLOv8n model for strawberry detection, which achieved high precision and lightweight deployment but still relied on labeled fruit datasets and fixed class definitions. *Tang et al. (2025)* proposed an enhanced YOLOv11n model for kiwifruit flower detection under occlusion, demonstrating strong performance in complex orchard environments but requiring task-specific training data. Their work underscores the value of open-vocabulary zero-shot models that support flexible, unannotated fruit and flower recognition. *Tan et al. (2021)* early explored the zero-shot paradigm but were hindered by limited datasets, methods, and computational resources, resulting in unsatisfactory performance.

In this study, the application of OWLv2 to agricultural image segmentation is investigated, with particular emphasis on fruit recognition and annotation under diverse field conditions. OWLv2 was locally deployed using Google's open-source implementation and integrated with the ChatGPT 3.5 API to enhance natural language interaction capabilities. Systems incorporating large language models (LLMs), such as ChatGPT, generally exhibit improved usability and broader user acceptance in practical applications (*Qing et al., 2023*). The proposed system enables users to submit free-form agricultural queries, ranging from crop names to complex descriptions such as "ripe citrus under leaves", and generates corresponding segmentation masks in a zero-shot manner. In addition, a user-friendly interface with configurable parameters was developed to support both single-image and batch annotation workflows.

MATERIALS AND METHODS

Experimental Environment and Hardware

The proposed framework was implemented using Python 3.7 on an Ubuntu 22.04 LTS workstation. To ensure reproducibility, all visual inference tasks were executed on a consistent hardware setup: an Intel Core i7-10700K CPU, 32 GB of DDR4 RAM, and an NVIDIA GeForce RTX 3060 GPU with 12GB of VRAM. The OWLv2 model (google/owlv2-base-patch16) was deployed via the Hugging Face Transformers library.

Logic Architecture and Feature Matching Mechanism

This section describes the deployment of OWLv2 in combination with GPT-3.5 or DeepSeek V1 for open-vocabulary fruit image annotation in an agricultural context. The method involves four key stages: (1) environment setup and model loading, (2) query preprocessing via GPT-3.5 or DeepSeek V1, (3) image inference and prediction using OWLv2, and (4) postprocessing and visualization. The technical schematic of the developed zero-shot annotation framework with language interaction capability is shown in **Fig. 1**.

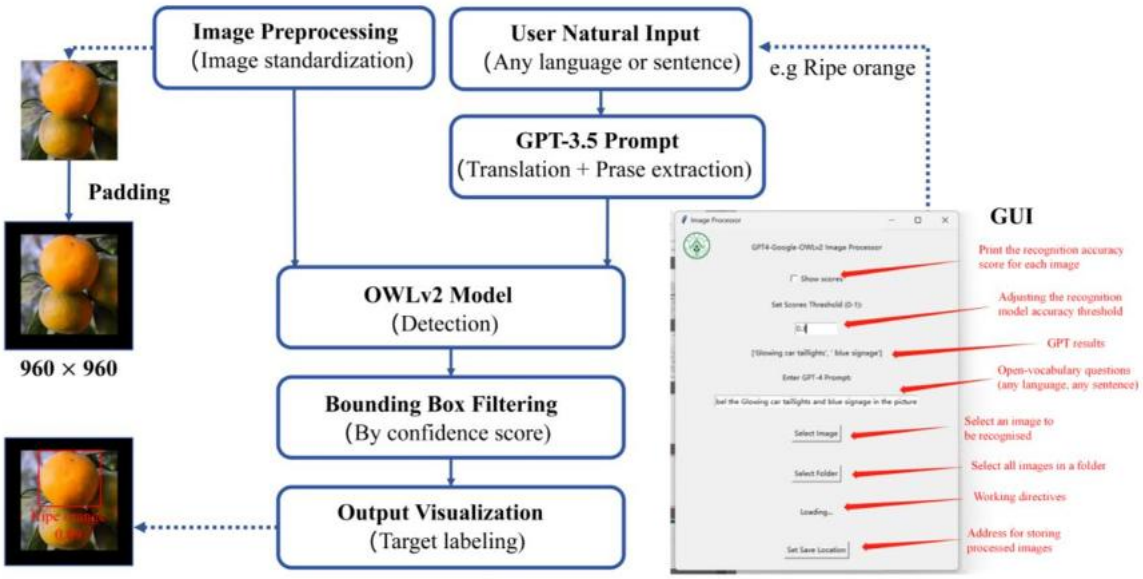

Fig. 1 - Zero-Shot Models for Fruit Object Detection Steps

Since it is based on Transformer architecture, the library is housed in the public repository NielsRogge/Transformers-Tutorials on GitHub*, where the OWLv2 model can be located. Additionally, the SAM model is available for those interested, despite its distinct functionality, exhibiting similar characteristics during application. First and foremost, the installation of the library is crucial.

Subsequently, the workflow involves loading the OWLv2 model, processor, and input image. After completing these steps, a query vocabulary must be defined for object retrieval. In the original OWLv2 framework, queries are required to be provided as comma-separated vocabulary terms in string format, which limits usability and flexibility. To improve user interaction, the proposed system directly integrates the outputs of ChatGPT 3.5 or DeepSeek V1 through a predefined system prompt. First, the user input is translated into English and converted into concise noun phrases representing the target objects. Several examples are included in the prompt design to facilitate few-shot learning by the large language model (LLM). During inference, the user input is first processed by ChatGPT or DeepSeek, and the generated output is subsequently used as the query input for OWLv2. This strategy enables the system to accept arbitrary sentence structures and multilingual inputs while maintaining compatibility with the OWLv2 query format. To ensure deterministic keyword extraction, the LLM API temperature was fixed at 0.0, and the prompt design followed a strict JSON-like few-shot template, as illustrated in **Tab. 1**.

The core of the zero-shot detection lies in the similarity matching between image tokens and text queries. To eliminate mathematical redundancy, the similarity score $S_{i,j}$ is calculated as the normalized dot product (cosine similarity) between the visual and textual embeddings:

$$S_{i,j} = \frac{f_{image}(x_i) \cdot f_{text}(q_j)}{\|f_{image}(x_i)\| \|f_{text}(q_j)\|} \quad (1)$$

where: x_i denotes the i-th visual token, q_j is the j-th text query embedding, f_{image} and f_{text} represent the respective encoders. This score determines the confidence level for each bounding box proposal.

Subsequent steps involve the local deployment of OWLv2, including image standardization through padding to achieve a fixed shape and size (torch size of 960 x 960). After the forward pass, the model's output is obtained. Finally, coordinate annotation and visualization are carried out based on the model's output, accompanied by the labeling of their similarities for later adjustments to the model's sensitivity.

Table 1

System prompt used for keyword extraction

Prompt
You are a keyword extraction machine. Your main responsibility is to extract key target words and determine the action objects of the questioner. For instance, when statements like 'I want to find an apple', 'Search for bananas', or 'Where is the watermelon' are given, the targets for the questioner are the apple, bananas, and watermelon, respectively. Only output the object, including object phrases. If there are multiple objects, separate them with commas. If the input is in another language, it is considered to be English. Use English output only. Cannot output the word 'picture'. Regardless of the syntax used by the questioner, your answer can only be an object (a noun or noun phrase with modifying qualifiers, if there are no modifiers only nouns are output). Preferably output modified nouns, e.g., 'girl in a skirt' instead of 'skirt' and 'girl'

Evaluation Protocol and Metrics

To rigorously validate the system's performance beyond a simple demonstration, a cross-domain evaluation protocol was established.

Baseline Model Dataset (YOLO11): To provide a robust benchmark, the YOLO11 model (Released in late 2024) was pre-trained on a specific agricultural dataset consisting of 1,217 RGB images of oranges (1,017 for training and 200 for validation). These images were captured between 2024 and 2025 across various locations in Guangdong, China, covering diverse environmental challenges such as standard lighting, minor occlusions, and fruit clustering.

Test Dataset Definition: A test set of 50 high-resolution images was independently collected in 2025 at a citrus orchard in Sihui, Guangdong. These images include complex variables such as heavy occlusion, variable lighting (noon vs. evening), and fruit clustering.

Quantitative Metrics: The detection performance is quantified using standard computer vision metrics:

1. Precision and Recall: To evaluate accuracy and coverage.
2. F1-Score: The harmonic mean of precision and recall.
3. mAP (mean Average Precision): Calculated at an IoU (Intersection over Union) threshold of 0.5.
4. Inference Latency: Measured in milliseconds (ms) to assess real-time potential.

Ground Truth: Manual annotation was performed by two researchers using the LabelImg tool to provide the benchmark for Comparison with the OWLv2 outputs.

RESULTS

Q&A-annotation Tool

A graphical user interface (GUI) for annotation was developed using Tkinter, a lightweight Python library. The tool supports common image formats, including *.jpg* and *.png*, and allows users to process either individual images or image folders in batch mode. User input is provided through a simple text input box, while the corresponding output information is displayed directly within the interface, as shown in **Fig. 1**. The main functional parameters of the tool are summarized in **Tab. 2**.

Table 2

Q&A-Semantic Annotation Tool Parameters

Performance indicators	parameter
Single Operation Time	1~2 s
Batch Operation Time (30 sheets)	~25 s per sheet
Startup Time	~20 s
Supported File Formats	.jpg, .png, etc.
Interaction Languages	English, Chinese, French, German, Spanish, etc.
Semantic Conversion Tools	ChatGPT, DeepSeek
LLM API Latency	~1 s

The batch processing capability of our program is demonstrated in **Fig. 2**. This function enables rapid and efficient annotation of large image datasets with high accuracy, significantly reducing the time and labor costs associated with manual labeling.

As noted in Google's documentation, such automated annotation avoids errors caused by fatigue during repetitive labeling tasks. The source code of the program is publicly available in the supplementary materials.

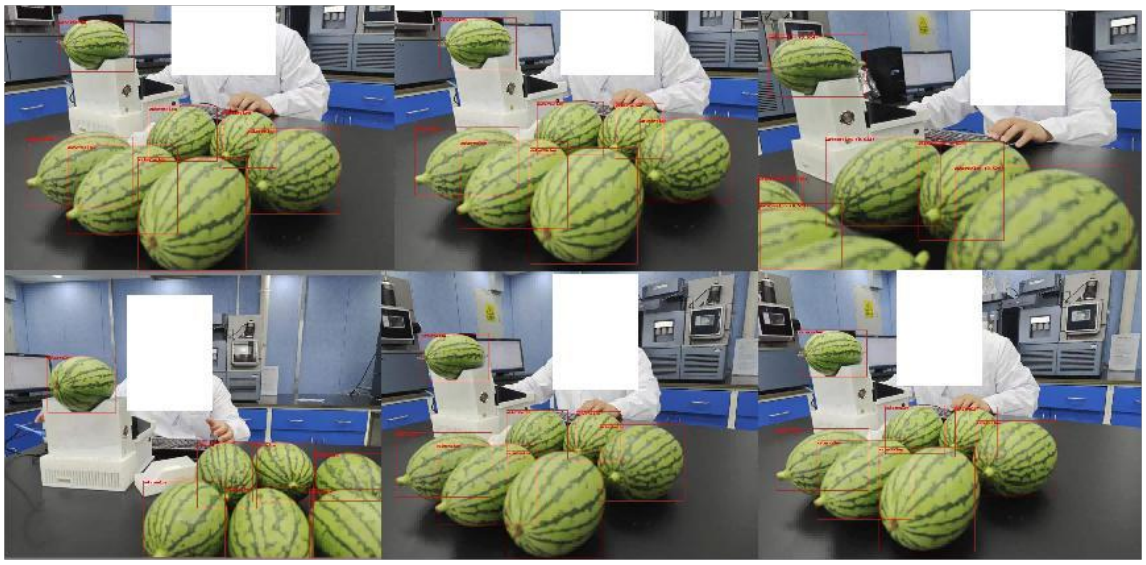

Fig. 2 - Batch Labeling of Watermelon Targets

Understanding of Word Semantics and Generalizability

Compared to traditional object detection models, OWLv2 demonstrates the ability to interpret semantic descriptors, enabling it to analyze attributes such as fruit ripeness without additional fine-tuning. As shown in **Fig. 3**, the model correctly inferred the "ripe" status of Shatangju mandarins produced in Sihui, Guangdong, China. In **Fig. 3b**, the AI-generated maturity scores are visually presented and align closely with human perception, although some misclassifications remain. These can be filtered out using thresholding strategies as demonstrated in **Fig. 3c**.

It is hypothesized that such human-like image-semantic understanding arises from the model's interpretation of not only color features (e.g., the word "yellow" used as a prompt did not strictly correspond to the model's assigned maturity scores) but also more comprehensive features such as orange, red, or green hues, as well as texture information, as indicated in the model's official documentation. Moreover, the proposed open-ended, natural language querying approach facilitates voice-based usage by farmers and enhances accessibility for farmers speaking different languages worldwide. Apart from maturity assessment, citrus images also hold significant potential for semantic applications in pest and disease monitoring (*Zongyin et al., 2025*).

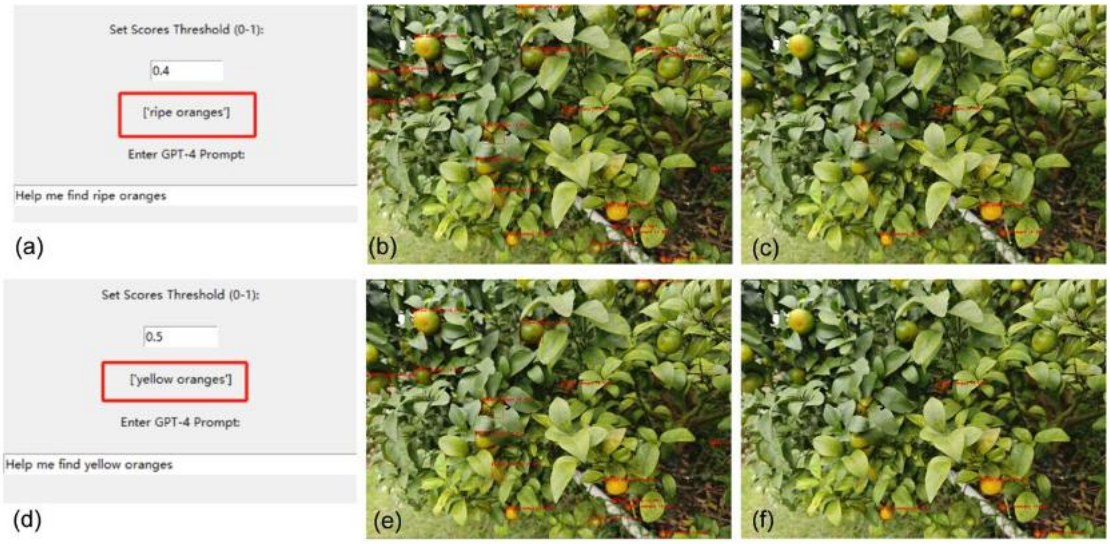

Fig. 3 - Semantic understanding ability.

(a) Questioning and extracting vocabulary (the meaning of ripe fruit); (b) The threshold score is 0.25; (c) The threshold score is 0.4; (d) Questioning and extracting vocabulary (the meaning of fruit color); (e) The threshold score is 0.35; (f) The threshold score is 0.5.

Differences from other model applications

Fig. 4 compares OWLv2 with two widely used publicly available models on Hugging Face, using both network resource images and our own dataset. Targets with a screening score greater than 0.5 were marked for evaluation. OWLv2 was more aggressive in detecting oranges and identified a greater number of fruits overall, though it also produced some misclassifications. It is important to note that these comparison models are not zero-shot models; they require training with annotated datasets. Despite this, OWLv2, trained on a billion-level text-image dataset with strong computational support, demonstrated comparable or even superior performance in certain tasks. While general-purpose models remain effective for simple detection tasks, integrating OWLv2 with APIs such as GPT or DeepSeek further lowers the barrier to its practical application.

(a) Google/owlv2 (network diagram); (b) Facebook/detr-resnet-50 (network diagram); (c) Hustvl/yolos-tiny (network diagram); (d) Google/owlv2 (real-world image); (e) Facebook/detr-resnet-50 (real-world image).

Comparative Evaluation of Zero-shot Foundation Model and YOLO11 for Cross-Domain Object Detection

To benchmark local deployment, zero-shot OWLv2 was compared with a pre-trained YOLO11 model. To prioritize generalization, a cross-domain evaluation was conducted using a novel, independent dataset. This protocol ensures a fair comparison by testing YOLO11 on unseen, heterogeneous data rather than its original training distribution, matching the zero-shot conditions of OWLv2. On its internal validation set, the pre-trained YOLO11 achieved a Precision of 0.9250, a Recall of 0.8333, an F1-score of 0.88, and an mAP of 0.9199. For the comparative test, 50 representative images were selected as the common test set for both the zero-shot OWLv2 and the pre-trained YOLO11 models.

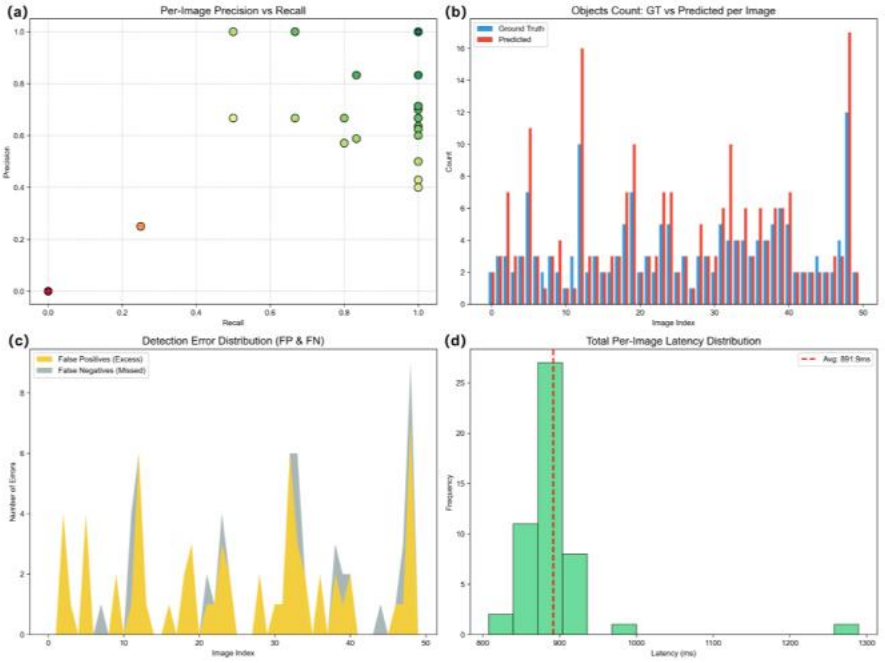

Fig. 5 - Comprehensive performance evaluation of the zero-shot OWLv2 model

(a) PR scatter plot showing per-image precision and recall distribution; (b) Object count consistency between GT and predicted labels; (c) Error distribution identifying fluctuations in FP and FN; (d) Latency distribution with a mean processing time of 891.9 ms.

Table 3

Performance comparison between zero-shot OWLv2 and YOLO11 on the orange dataset

Method	TP	FP	FN	Precision	Recall	F1-Score	mIoU	mAP	Avg. Computation Latency (ms)
OWLv2	158	63	16	0.7149	0.908	0.8000	0.8482	0.8301	257.7
YOLO11	120	27	54	0.8163	0.6897	0.7477	0.8438	0.6055	116.2

The performance of OWLv2 is evaluated from four dimensions **(Fig. 5)**. As illustrated in the Per-Image Precision vs. Recall plot, a significant majority of the data points are clustered in the high-recall and high-precision region (upper right), demonstrating the model's robustness. The Objects Count comparison reveals a high degree of consistency between the Ground Truth (GT) and predicted labels across varying object densities. Regarding error analysis, the Detection Error Distribution suggests that False Positives (FP) constitute the primary source of error compared to False Negatives (FN), indicating a slight tendency towards over-detection in cluttered environments. Furthermore, the Latency Distribution analysis confirms the model's computational efficiency; the total per-image latency follows a near-normal distribution with an average of 891.9 ms. In fact, this is because the program additionally outputs annotated images, while the actual computation latency is only 257.7 ms (**Tab. 3**) and Average DeepSeek latency (Run once before the computational procedure) is only 598.3 ms.

Although the original YOLO validation set achieved a Precision of 0.9250 and an F1-score of 0.88, validation performance typically exceeds that of the test set. Upon switching to the specific test dataset, YOLO11 yielded a Precision of 0.8163 and an F1-score of 0.74, which are considered reasonable within this context. However, owing to a more aggressive detection strategy, OWLv2 significantly outperformed YOLO in terms of Recall (0.9080 vs. 0.6897) while maintaining a respectable Precision of 0.7149. Consequently, OWLv2 achieved a superior F1-score of 0.80. While both models exhibited comparable Mean Intersection over Union (mIoU) values (0.8482 and 0.8438, respectively), OWLv2 demonstrated superior robustness with a substantially higher mAP (0.8301 vs. 0.6055), making it more suitable for detection tasks in complex environments.

Error Analysis of Zero-Shot Foundation Model Annotation via Local Deployment

A comparative review of the OWLv2 outputs against the manually annotated dataset reveals that human annotators often overlook small or partially concealed targets due to visual fatigue or resolution constraints. Consequently, traditional supervised training sets may not fully encompass all ground-truth oranges present in a scene. The zero-shot foundation model consistently identifies minute targets that are only discernible upon magnification, highlighting its significant utility for pre-annotation workflows. This suggests a paradigm shift where foundation models perform automated labeling, leaving humans to act solely as verifiers to mitigate the experiential errors commonly introduced during manual dataset construction.

Detailed manual verification of the detection errors indicates that false positives are primarily driven by extreme texture variations resulting from lighting and shadow fluctuations. Specifically, overexposure (pure white) and deep shadows (black) can lead the model to fragment a single fruit into 2 or 3 separate detections (e.g., as shown on the **Fig. 6** left, where one orange is misidentified as two).

Fig. 6 - Comparison of Zero-Shot OWLv2 and Manual Annotation

(a) Annotations generated by the foundation model under zero-shot conditions;
(b) Standard manual annotations derived from the laboratory's existing dataset.

Discussion

The performance of the zero-shot model demonstrates a "detect-at-all-costs" strategy, prioritizing comprehensive recall over strict precision. This "detect-all" capability is effective not only for close-range operations but also for long-distance path planning by identifying distant fruits in advance. *Jin (2020)* applied visual servo control to agricultural picking robots, emphasizing accurate target positioning as critical for automated harvesting but limited by conventional image detection pipelines. In practice, orange localization was also achieved to assist grasping using traditional object recognition schemes in the previous work, but the factor that most significantly affected operational efficiency was unrelated to fruit coordinate positioning *(Lan et al., 2026).* In this study, switching the detection framework from YOLO11 to OWLv2 only increased the average inference time by approximately 140 ms.

Beyond validating its basic feasibility, the primary advantage of such foundation models lies in their rich semantic information. For instance, the model can theoretically analyze crop growth stages based on prompts like "ripe oranges". However, since the foundation model is pre-encapsulated, the exact semantic threshold for concepts like "maturity" remains a "black box" during API calls. Because both semantic prompts and image features are likely abstracted into high-dimensional vectors, the internal understanding of these concepts can only be calibrated through iterative adjustments of the confidence scores.

In this study, the integration of the Segment Anything Model (SAM) was investigated, as illustrated in **Fig. 7**. SAM offers general image segmentation based on object boundaries, complementing OWLv2's semantic recognition. While SAM does not always outperform OWLv2, their combination could enable instance detection and area measurement for applications such as yield estimation and disease monitoring. Future versions like SAM2 may also support video stream segmentation for real-time use in agricultural machinery or UAVs.

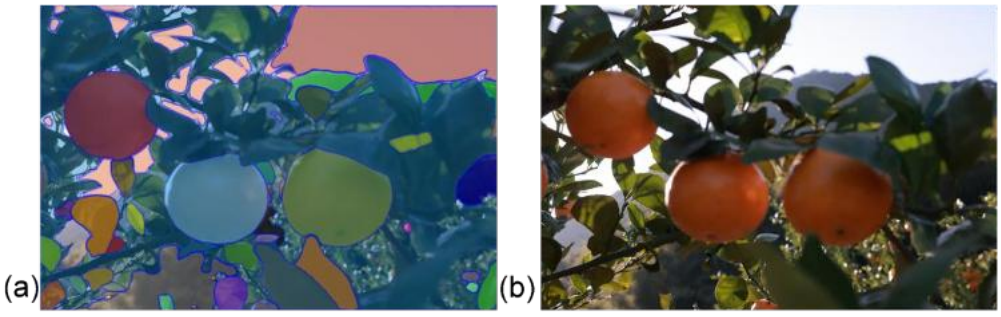

Fig. 7 - Using the SAM model to segment oranges
(a) segmentation image; (b) visible light image.

Moreover, OWLv2 shows certain advantages over models like YOLO, as it requires no annotated datasets or retraining to recognize new classes or descriptive attributes. This makes it suitable for backend decision-making, semantic analysis, and rapid dataset annotation. Its ability to interpret terms like "ripe" or color variations via natural language is valuable in diverse crop scenarios. However, for real-time orchard operations requiring high-speed and lightweight models, YOLO remains more appropriate due to its faster inference and computational efficiency.

CONCLUSIONS

This work presented a zero-shot fruit recognition and annotation tool by integrating OWLv2 with GPT or DeepSeek to support multilingual, natural language queries. The system showed strong generalizability and semantic understanding, allowing recognition of unseen fruit categories and descriptive attributes without retraining. Its ability to interpret complex human language inputs makes it practical for deployment in diverse agricultural environments. Cross-domain experimental results verified that the framework possesses superior generalization capabilities compared to traditional supervised models like YOLO11 when encountering unseen environments. Future work will focus on integrating segmentation models and optimizing inference speed to meet the real-time requirements of smart agriculture.

ABSTRACT

To address the limitations of computational resources and the stringent real-time stability requirements in post-harvest online grading of fresh tea leaves, this study proposes a lightweight object detection method oriented toward efficient deployment. The YOLOv11n network was selected as the baseline model. A StarNet backbone was introduced to enhance nonlinear inter-channel interactions while reducing the complexity of feature extraction. In addition, a DySample dynamic upsampling module was employed to predict content-adaptive sampling locations, thereby improving multi-scale feature reconstruction under lightweight constraints. Furthermore, a wavelet-based pooling structure was designed to perform structure-aware frequency-domain decomposition, preserving critical edge and texture information while reducing redundant computation. The Inner-MPDIoU loss function was also adopted to calculate overlap consistency within a compact core region, thereby improving bounding-box localization stability for fine-grained structures. Based on these integrated improvements, the lightweight YOLOv11-SDWI detection model was developed. Experimental results demonstrated that the proposed model achieved an accuracy of 89.5%, with only 4.9 GFLOPs and 1.89 M parameters. To further verify its engineering applicability, the algorithm was encapsulated into a complete visual software system specifically designed for fresh tea leaf sorting. The developed system provides a functional interface for real-time detection, effectively bridging theoretical algorithm design and practical agricultural applications, and establishing a solid software foundation for future deployment on physical sorting equipment.

摘要

为了解决采后鲜茶在线分级中计算资源有限以及对高实时稳定性的严格要求，本文研究了一种面向高效部署的轻量化目标检测方法。以 YOLOv11n 网络为基线模型。引入 StarNet 主干网络以增强非线性通道间交互并降低特征提取复杂度。采用 DySample 动态上采样模块来预测内容自适应的采样位置，从而在轻量化约束下改善多尺度特征重建。进一步设计了基于小波的池化结构来执行结构感知的频域分解，在保留关键边缘和纹理信息的同时减少冗余计算。此外采用 Inner MPDIoU 损失在紧凑的核心区域上计算重叠一致性，增强了细粒度结构的边界框定位稳定性。基于这些系统性改进，构建了 YOLOv11 SDWI 轻量化检测模型。实验结果表明，所提模型实现了 89.5%的精度，同时仅需 4.9 G 浮点运算数和 1.89 M 参数量。为了验证其工程应用潜力，该算法被封装成专为鲜茶分拣量身定制的完整视觉软件系统。这种系统级实现为实时检测提供了功能性界面，成功弥合了理论算法设计与实际农业应用之间的差距，并为未来在物理分拣设备上的部署奠定了坚实的软件基础。

INTRODUCTION

Tea grading has become a crucial process in modern tea production, as stable and efficient quality classification directly affects product value, consumer acceptance, and processing efficiency.

In practical production, fresh tea leaves are typically graded according to external characteristics such as bud–leaf morphology, tenderness, integrity, and size. Common grading categories include single bud, one bud with one leaf, one bud with two leaves, and broken leaves. Early studies on tea quality analysis and classification mainly relied on traditional image processing and machine learning methods.

Wenguang Zheng, Assoc. Prof. Ph.D. Eng; Xinyong Shi, M.S. Stud. Eng.; Rongyang Wang, Prof. Ph.D. Eng.

For example, multispectral features were extracted using wavelet transforms, and Chinese famous tea classification was achieved via a multi-class least square support vector machine *(Li X. et al., 2011)*. Hyperspectral imaging was employed to model and quantitatively characterize the evolution of color and category during the tea drying process *(Xie C. et al., 2014)*. In addition, tea image classification was achieved based on handcrafted texture features, such as local binary patterns *(Tang Z. et al., 2015)*. These methods typically depend on manually designed features combined with shallow classifiers, and can achieve reasonable performance under controlled experimental conditions. However, due to the lack of end-to-end learning capability, their generalization ability is limited, making it difficult to meet the comprehensive requirements for robustness, accuracy, and scalability in practical applications.

With the rapid development of computer vision and deep learning technologies, convolutional neural network (CNN)–based object detection methods have demonstrated significant advantages in target recognition and localization under complex backgrounds by automatically learning hierarchical feature representations from large-scale data. The Faster R-CNN framework was applied to tea bud recognition and detection, demonstrating significant effectiveness in handling complex poses, occlusions, and background interference *(Xu G. et al., 2020; Zhu H. et al., 2022)*. In addition, a variety of deep learning paradigms have been explored for tea-related visual perception tasks. These include discriminative pyramid networks for semantic segmentation *(Hu G. et al., 2021)*, Mask R-CNN for joint detection and picking-point localization *(Wang T. et al., 2023)*, SSD-based feature fusion models for enhanced bud detection *(Chen B., Yan J., 2021)*, and Transformer-based frameworks such as RT-DETR-Tea to strengthen global feature modeling and multi-scale semantic fusion in complex environments *(Chen Y. et al., 2024)*. These studies indicate that, compared with traditional approaches, deep learning–based object detection algorithms achieve higher detection accuracy and better efficiency in complex environments.

The YOLO family of models represents a typical class of single-stage object detection methods. Through continuous optimization of network architectures and feature fusion strategies, these models have achieved a favorable balance between detection accuracy and computational efficiency and have gradually been introduced into complex agricultural vision scenarios. In tea bud detection research, existing studies have mainly focused on suppressing background interference and modelling scale variation. A two-level fusion framework, combining YOLOv3-based detection with DenseNet201-based classification, was constructed to improve the recognition accuracy of tea bud targets *(Xu W. et al., 2022)*. In addition, a refined TBC-YOLOv7 algorithm was developed by integrating Transformer modules, a bidirectional feature pyramid, and coordinate attention mechanisms, while employing the SIOU loss function to accelerate convergence and enhance detection accuracy *(Wang S. et al., 2023)*. Regarding the YOLOv8 framework, various optimization strategies have been explored. For instance, an occlusion-aware dual-attention mechanism was introduced to enhance model robustness under complex backgrounds and partial occlusions for tea pest and disease detection *(Wu Y. et al., 2025)*. Furthermore, YOLOv8-based models have been improved through attention mechanisms, multi-scale feature fusion, enhanced convolutional structures, Transformer modeling, and regression loss optimization, effectively increasing tea leaf detection and grading accuracy under leaf stacking conditions in complex environments *(Tang X. et al., 2025; Xia Y. et al., 2024; Zhao X. et al., 2024)*. In summary, existing studies indicate that YOLO-series models are capable of effectively handling target scale variation and complex background interference while maintaining real-time performance, thereby providing a solid technical foundation for the development of online tea leaf detection and grading systems.

Although the YOLO family has demonstrated strong performance in real-time object detection, there remains considerable room for optimization in specific application scenarios. In recent years, lightweight optimization of YOLO-based models has become an active research topic, with improvements explored in backbone design, feature fusion, sampling strategies, and training objectives. For instance, the YOLO-PEFL model was developed by replacing the YOLOv4 backbone with ShuffleNetV2 and adjusting anchor sizes, reducing model size by approximately 80% while maintaining 96.71% accuracy for efficient pear flower detection *(Wang C. et al., 2022)*. Similarly, the PAG-YOLO architecture was introduced, incorporating spatial and channel attention mechanisms with a specialized loss function to improve small-ship detection accuracy with negligible computational overhead *(Hu J. et al., 2021)*. To further reduce complexity, the GhostNet-YOLOv5 framework was proposed by integrating a GhostNet backbone, achieving 76.31% accuracy with only 5.94 million parameters and a 10 MB weight size *(Cao M. et al., 2022)*. Another approach involved adopting ShuffleNetV2 as the YOLOv5 backbone combined with channel pruning in the neck and detection head, compressing the model to 27% of its original size *(Zhang S. et al., 2023)*.

Additionally, a lightweight tea bud detection model was constructed by introducing GhostConv, bottleneck attention modules, and weighted feature fusion into YOLOv5, which increased mAP by 9.66% while significantly reducing FLOPs and parameters *(Gui Z. et al., 2023)*. Recent studies have also focused on optimizing bounding box regression loss functions to enhance training stability and performance under constrained model capacities.

However, existing studies have mainly focused on object detection during tea garden picking or in complex natural scenes, while relatively less attention has been paid to post-harvest grading, which is a critical stage in the processing pipeline. Therefore, this paper focuses on the research scenario of post-harvest fresh tea leaf grading equipment. Under this operating condition, fresh tea leaves, after mechanical pre-screening, are fed into intelligent sorting equipment, within which multi-stage single-row conveying devices are used to orderly transport and spread the tea leaves, so that they present a low-occlusion and relatively regular arrangement during the visual detection stage. Therefore, under this application background, how to construct a lightweight detection model that balances computational efficiency, detection accuracy, and engineering deplorability remains an urgent problem to be solved. Based on this, this paper proposes an improved lightweight object detection framework, YOLOv11-SDWI. The proposed method performs coordinated optimization from both the network architecture and training strategy levels, enhancing feature representation capability and regression stability while maintaining a compact model structure. At the same time, a fresh tea leaf dataset oriented toward post-harvest online grading scenarios is constructed to provide data support for subsequent model training and evaluation. Experimental results show that the proposed method can maintain competitive detection performance while significantly reducing computational complexity and parameter scale, verifying its engineering application potential in practical tea sorting systems.

MATERIALS AND METHODS

YOLOv11 network improvements

The YOLO family has continuously evolved in the field of object detection, becoming a representative technical framework with significant influence and broad practical adoption *(Ge Z. et al., 2021; Redmon J., Farhadi A., 2017)*. Multi-scale feature representation and extraction capabilities have been further enhanced in YOLOv11 through improved backbone and neck architectures, as well as the introduction of modules such as C3K2, SPPF, and C2PSA, demonstrating superior performance for small-object detection in complex scenes *(Khanam R., Hussain M., 2024)*. Given that tea buds are small targets and traditional methods often suffer from insufficient accuracy or excessive computational overhead, YOLOv11n was selected as the baseline model for further design and optimization in this study.

To address the real-time requirements and computational constraints in fresh tea leaf sorting, this study develops the YOLOv11-SDWI model based on the YOLOv11n baseline. This architecture integrates the StarNet backbone, the DySample dynamic upsampling module, the Wavelet Pooling downsampling module, and the Inner-MPDIoU bounding box regression loss function. The structural details of the proposed YOLOv11-SDWI network are illustrated in Figure 1.

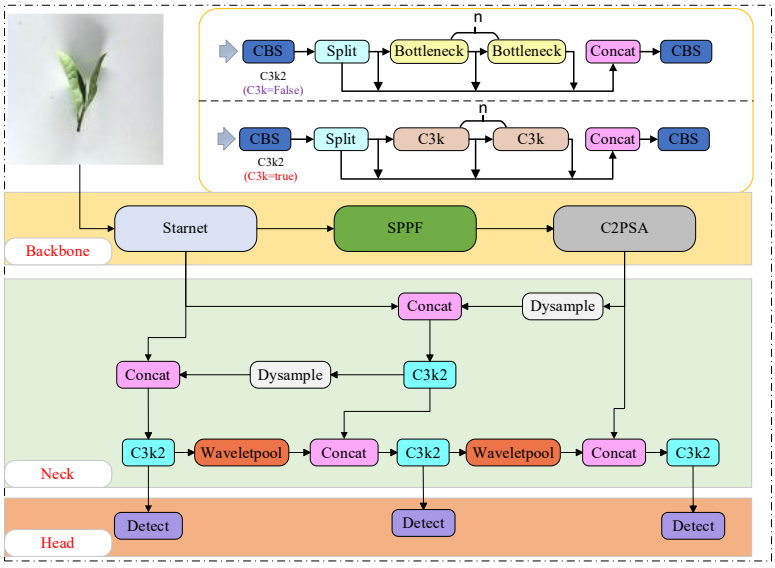

Fig. 1 - Architecture of the proposed YOLOv11-SDWI lightweight fresh tea leaf detection network

Lightweight Backbone Optimization Using StarNet

In post-harvest fresh tea leaf online grading scenarios, detection models are typically deployed on edge devices, where computational and storage resources are limited and long-term stable real-time operation is required. Therefore, the backbone network must maintain sufficient feature representation capability under low computational cost and a small parameter budget. Traditional convolutional backbones usually enhance representation by increasing network depth or channel width, which significantly increases computational and storage overhead, while channel interactions are mainly modelled through linear aggregation, limiting their ability to capture complex feature combinations. To address these issues, this study introduces StarNet into the YOLOv11n backbone *(Ma X. et al., 2024)***Error! Reference source not found.**, leveraging star-shaped operations to enhance nonlinear inter-channel interactions. This design improves the effective feature output per unit of computation while preserving a compact architecture, thereby enabling a more efficient lightweight feature extraction backbone.

As illustrated in Fig. 2, StarNet adopts a stage-wise hierarchical architecture. After the initial convolutional stem, feature maps are progressively processed by multiple stages (Stage1–Stage4). Each stage consists of a down-sampling convolution followed by several stacked StarBlocks, enabling multi-scale semantic feature extraction with gradually increasing receptive fields. StarBlock is the fundamental building unit of StarNet, and its internal data flow is explicitly shown in the figure. Given an input feature with channel dimension d, the feature is first processed by a depth wise convolution (DW-Conv) to extract spatial information with low computational overhead. The resulting feature is then fed into two parallel fully connected (FC) branches that expand the channel dimension to 4d.One branch is activated by ReLU6, and the outputs of the two branches are fused through an element-wise multiplication operation. This operation introduces nonlinear inter-channel interactions without explicitly increasing the output channel dimension. The fused feature is subsequently projected back to dimension d through an FC layer and further refined by a DW-Conv. A residual connection is finally applied to combine the block input and output, ensuring stable feature propagation across stacked StarBlocks.

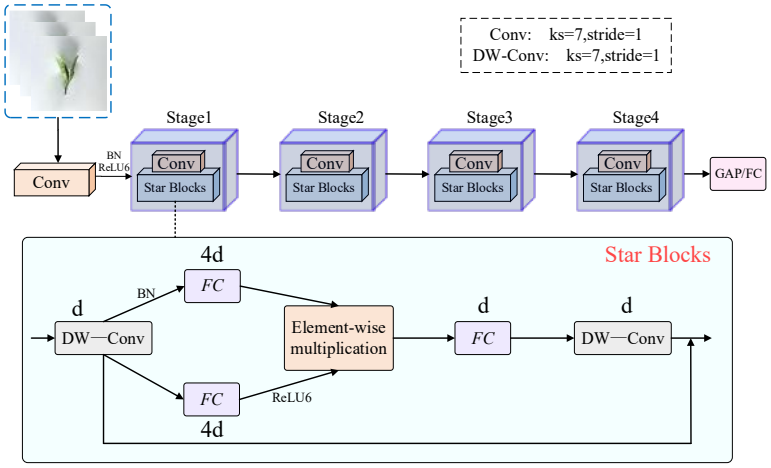

Fig. 2 - Schematic diagram of the StarNet backbone architecture

By stacking multiple StarBlocks within each stage, StarNet progressively enhances feature representation from low-level details to high-level semantics while maintaining a compact structure. When integrated into the YOLOv11 backbone, the input tea leaf image is sequentially processed by the stem convolution, StarNet backbone stages, and the subsequent neck for multi-scale feature fusion. This design provides compact yet discriminative feature representations for the detection head, which is particularly beneficial for lightweight deployment under resource-constrained edge environments.

DySample Upsampling Module

During multi-scale feature fusion, the upsampling module directly determines the spatial reconstruction quality of high-level semantic features. Conventional nearest-neighbor or bilinear interpolation relies on fixed sampling over regular grids that is independent of feature content; while computationally efficient, such methods often fail to accurately recover spatial structures near object boundaries, fine-grained textures, or regions with significant structural variation. To address this limitation, this paper introduces the DySample *(Liu W. et al., 2023)* upsampling module into the Neck of YOLOv11.

By predicting content-adaptive sampling locations, DySample enables learnable feature reconstruction, thereby enhancing the representation capability of multi-scale feature fusion under lightweight constraints.

As illustrated in Fig. 3, the overall workflow of DySample consists of two components: sampling coordinate construction and feature resampling. Given an input feature map $X \in \mathrm{R}^{C \times H \times W}$, the module first predicts a set of two-dimensional offset information through a lightweight linear mapping, and constructs a high-resolution sampling coordinate set S based on a regular initial grid. Subsequently, differentiable bilinear resampling is performed on the input feature X according to S, generating an output feature X' whose spatial resolution is increased to $sH \times sW$. Since the resampling process is differentiable with respect to the sampling coordinates, the prediction of sampling locations can be jointly optimized with the detection objectives during training, thereby enabling end-to-end adaptive upsampling.

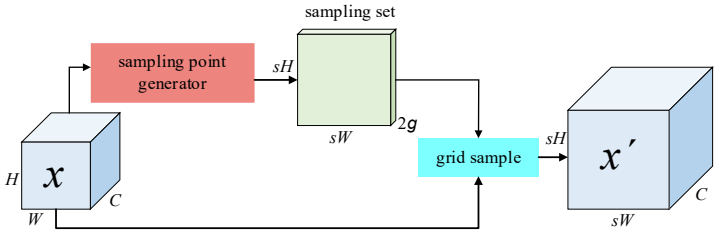

Fig. 3 - Overall workflow of the DySample upsampling module

During the construction of sampling coordinates, DySample achieves a balance between representation capability and computational complexity by adopting a grouped sampling + scope control strategy. As shown in the upper part of Fig. 4, under the static scope control mode, the module predicts an offset map O in the low-resolution feature domain via a linear mapping and applies a fixed scaling factor to constrain its magnitude, so that the initial sampling points are distributed around a regular grid. The offsets are then mapped to the high-resolution sampling grid through a spatial–channel rearrangement operation and added to the regular initial grid to obtain the final sampling coordinate set S. By constraining the maximum displacement of sampling points with a fixed scope, this strategy ensures structural stability of the sampling pattern while avoiding severe resampling instability caused by excessive offsets, making it suitable for regions with relatively smooth structural variations.

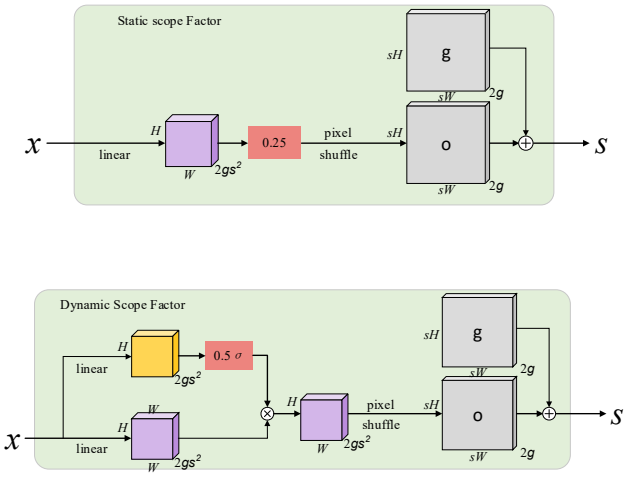

Fig. 4 - Static and dynamic scope control mechanisms in DySample

As illustrated in the lower part of Fig. 4, under the dynamic scope control mode, DySample further introduces an input-adaptive scale modulation factor on top of offset prediction. This factor is jointly applied with the predicted offsets to dynamically adjust the sampling displacement magnitude at each spatial location. Specifically, in flat regions or structurally simple areas, the displacement magnitude is automatically suppressed, causing sampling positions to remain close to the regular grid; in contrast, in edge regions or areas with significant structural variations, the displacement magnitude is adaptively amplified, thereby enhancing the sensitivity of sampling locations to spatial structure changes. Through this mechanism, DySample enables region-aware adaptive sampling without introducing a significant increase in computational cost, effectively accommodating spatial heterogeneity across different regions of the feature map.

As shown in Fig. 5, DySample provides the LP (Low-resolution to Pixel Shuffle) and PL (Pixel Shuffle to Low-resolution) offset prediction schemes. The LP structure predicts offsets directly in the low-resolution feature domain and maps them to the high-resolution sampling grid via spatial-channel rearrangement. The PL structure projects features into the high-resolution domain first to predict offsets, which are then reshaped to match the sampling coordinates. Both structures ultimately generate a sampling coordinate set *S* for the subsequent differentiable resampling process.

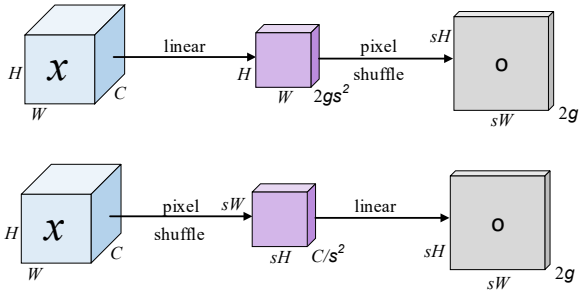

Fig. 5 - Offset prediction structures of DySample: LP and PL schemes

In summary, DySample reformulates the traditional rule-based upsampling process into a learning framework that integrates regular priors with content-adaptive offsets, enabling the upsampling module to actively adapt to object structures and scale variations during end-to-end training. In this work, simply replacing the original fixed-interpolation upsampling module in the YOLOv11 neck with DySample can significantly improve feature reconstruction quality with almost no increase in computational complexity.

Structure-Aware Downsampling Method Based on Wavelet Transform

In convolutional neural networks, downsampling operations are commonly employed to enlarge the receptive field and reduce feature resolution. However, traditional downsampling methods based on strided convolution or pooling essentially perform direct spatial subsampling, which easily introduces aliasing effects during resolution reduction and leads to irreversible loss of high-frequency structural information such as edges and textures. For post-harvest fresh tea leaf grading tasks, bud contours, leaf-edge morphology, and local structural variations constitute critical discriminative cues; degradation of such structural information at the downsampling stage can directly impair subsequent feature fusion and detection accuracy. To address this issue, this study introduces the WaveletPool downsampling module *(Williams T., Li R., 2018)*, which replaces conventional spatial downsampling with a structure-aware frequency-domain decomposition mechanism.

As shown in Fig. 6, WaveletPool applies a two-dimensional Discrete Wavelet Transform (DWT) to the input feature map. Given an input feature map *X*, WaveletPool does not perform spatial downsampling directly; instead, it first applies fixed wavelet filtering operations independently to each channel. Specifically, the module employs four fixed two-dimensional Haar wavelet kernels to convolve the input features in parallel, thereby decomposing the original feature representation into four sub-band components with clear physical interpretations: LL, LH, HL, and HH. Among them, LL represents the low-frequency approximation component, which mainly preserves global structure and contour information, while LH, HL, and HH correspond to high-frequency detail components in different directions, characterizing edges, textures, and local structural variations, respectively.

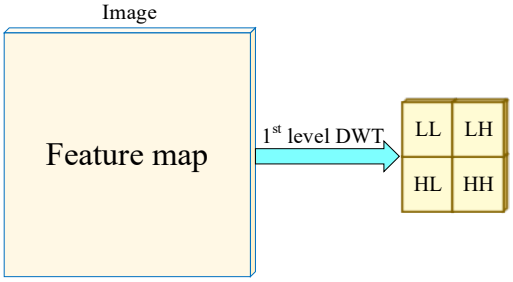

Fig. 6 - Schematic diagram of WaveletPool-based feature downsampling

This frequency-domain reorganization ensures structural integrity across scales. By preserving essential discriminative cues, WaveletPool facilitates precise feature reconstruction and target localization, effectively mitigating the information loss common in conventional lightweight designs.

Bounding Box Regression Constraint Based on Internal Region Consistency

In the post-harvest fresh tea leaf detection task, bud–leaf targets are often slender, small in scale, and subject to pronounced boundary variations. When bounding box regression is optimized solely by global overlap, it may suffer from boundary deviations that are difficult to further converge once the predicted and ground-truth boxes enter a high-overlap regime. To address this issue, this work introduces an Inner-IoU *(Wang D. et al., 2025)* based regression strategy: it computes overlap consistency on a more compact core region defined inside both boxes, and incorporates key geometric position offset constraints to strengthen the joint alignment of the target body and boundary structure under a lightweight setting.

As illustrated in Fig. 7, let the spatial resolution of the input feature map be $h \times w$. The predicted bounding box width and height in the feature space are denoted as w_{pred} and h_{pred}, respectively, while the corresponding ground-truth width and height are denoted as w_{gt} and h_{gt}. The top-left and bottom-right coordinates of the predicted bounding box are (x_1^{pred}, y_1^{pred}) and (x_2^{pred}, y_2^{pred}), respectively, and the corresponding ground-truth coordinates are (x_1^{gt}, y_1^{gt}) and (x_2^{gt}, y_2^{gt}).

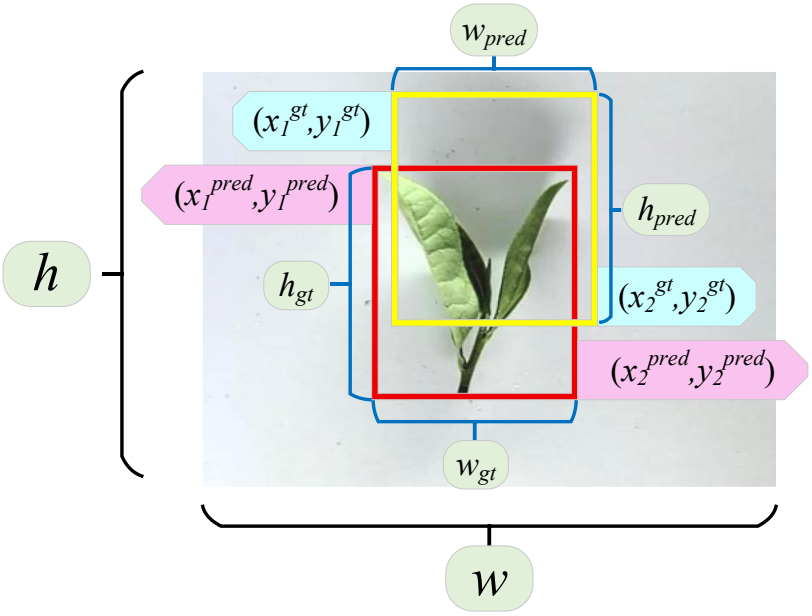

Fig. 7 - Illustration of Bounding Box Regression under Inner-IoU Constraint

At the level of region constraint, the regression supervision is not directly imposed on the complete predicted box and ground-truth box. Instead, a more compact core region is constructed inside both boxes, focusing exclusively on the effective area covered by the target body. This internal region is spatially constrained jointly by the predicted box and the ground-truth box, such that the overlap computation is concentrated on the target itself. As a result, interference from background regions and boundary redundancy is effectively reduced during the regression process. Under scenarios where the target size is small or the two boxes already exhibit a high degree of overlap, this constraint strategy can still maintain stable optimization signals, thereby improving the continuity and convergence of the regression process.

At the level of geometric position constraint, explicit modelling of the positional offsets between the predicted box and the ground-truth box is further introduced. As illustrated in Fig. 7, the spatial discrepancies at both the top-left and bottom-right corners of the predicted and ground-truth boxes are jointly incorporated into the regression constraint, enabling coordinated correction of boundary geometry across position, width, and height dimensions. To prevent imbalance in optimization strength across targets of different scales during regression, these positional offsets are normalized using the minimum enclosing region jointly formed by the two boxes. This normalization ensures that targets of varying sizes are subject to a consistent geometric constraint scale during training.

Through the combined effect of internal region consistency constraints and key positional distance awareness, the regression process no longer focuses solely on whether the predicted box covers the target, but further strengthens fine-grained alignment in terms of boundary geometry and spatial structure. Without introducing additional inference overhead, this strategy effectively improves the localization accuracy and stability of detection boxes in scenarios involving fine-grained structural details.

Intelligent Sorting Software System Design

To apply the proposed YOLOv11 SDWI model to actual fresh tea leaf sorting scenarios, a visual software system is designed in this study. The complete operational workflow of the software system is illustrated in Figure 8.

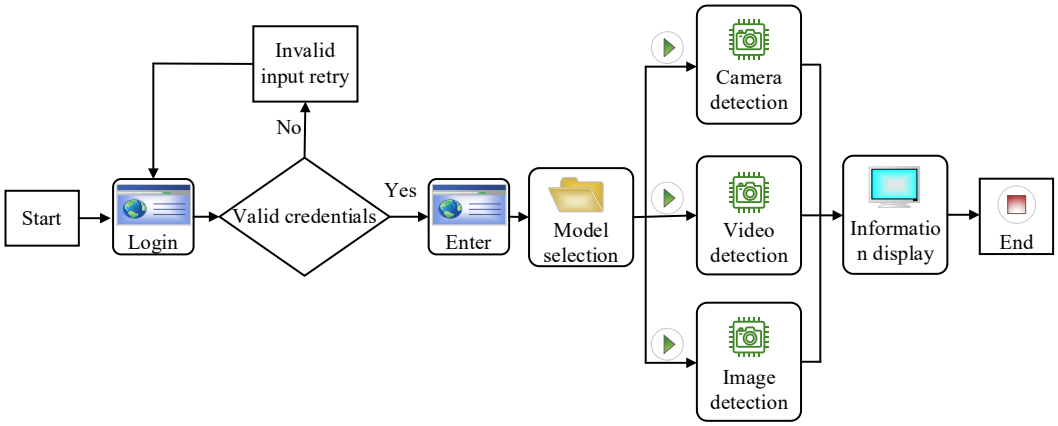

Fig. 8 - Operational workflow of the visual software system for fresh tea leaf sorting

The process begins with a user authentication stage where users input their account and password to log in. If the credentials are incorrect, the system prompts an error and requires re login. Upon successful authentication, the user enters the main interface and proceeds to the model selection module. Here the core inference engine loads the trained lightweight model weights. To accommodate diverse practical needs, the system offers 3 distinct detection modes including camera detection, video detection, and image detection. Once a specific mode is selected and visual data is input, the backend immediately executes feature extraction and bounding box regression. The system then continuously outputs target categories and confidence scores and bounding box coordinates to the front end information display module before ending the process. This logic ensures a seamless transition from data input to result visualization. The initial login interface of the developed intelligent system is presented in Figure 9, demonstrating a user friendly design tailored for practical agricultural applications.

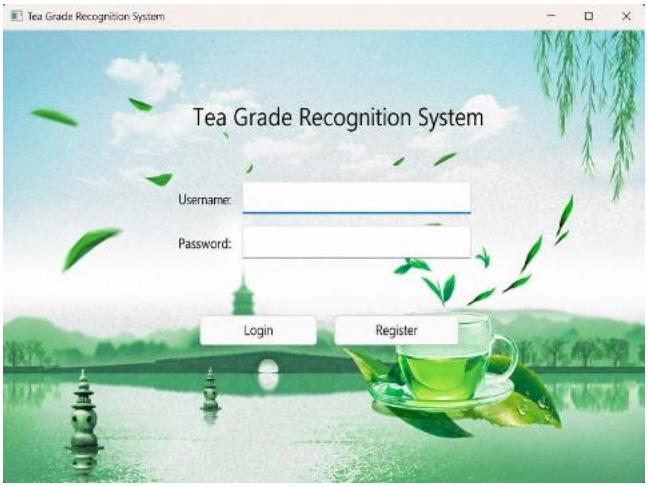

Fig. 9 - Initial graphical user interface of the developed intelligent sorting software

Image Acquisition and Dataset Construction

This study constructs an image dataset of post-screened fresh tea leaves for tea grade recognition and online grading. To address the stacking and occlusion that can occur during conveyance in intelligent sorting equipment and consequently degrade visual recognition, the multi-stage single-file conveying unit of the sorting system is used to spread and separate the leaves, so that they present a low-occlusion and relatively orderly arrangement on the conveyor belt, enabling the acquisition of image samples with clearer contours and texture details. Images are captured frame by frame using a Canon 6D II camera at a fixed viewpoint, covering diverse poses, scales, and local detail variations of fresh tea leaves during conveyance to enhance data diversity and representativeness.

During dataset construction, the raw images are first screened and organized, and samples with obvious blur, abnormal exposure, missing targets, or severe occlusion are removed. Ultimately, 1,563 valid images of fresh tea leaves of different grades are obtained to build the grading dataset. To ensure objective and reproducible training and evaluation, all images are randomly split into training, validation, and test sets at a ratio of 7:2:1.

Data Screening and Image Annotation

In this study, the collected fresh tea leaf images were manually annotated using the bounding-box labelling tool Labellmg to obtain object category labels and spatial localization information. According to the main picking morphology, fresh tea leaves were divided into four classes: one bud and one leaf, one bud and two leaves, one bud and three leaves, and one bud with multiple leaves, encoded as 0, 1, 2, and 3, respectively. To ensure a comprehensive dataset representation, a total of 8,267 instances were annotated across 1,563 images. According to the picking morphology, the instances were categorized into four classes: one bud with one leaf (1,923 instances), one bud with two leaves (2,196 instances), one bud with three leaves (1,747 instances), and one bud with multiple leaves (2,401 instances). The class definitions and index mapping are listed in Table 1.

Table 1

Categories of fresh tea leaves and corresponding codes

Category	Code
One bud with one leaf	0
One bud with two leaves	1
One bud with three leaves	2
One bud with multiple leaves	3

After annotation, labels were saved as XML files in the PASCAL VOC format. Each bounding box corresponds to a target instance, and a single image may contain multiple instances; the number of boxes varies with the number of fresh tea leaf targets in the image. Representative appearances and poses of the four classes are shown in Figure 10.

To support subsequent YOLO-based training and inference, a Python script was further used to convert the annotations from the VOC format to the YOLO format. After conversion, each image is associated with a TXT label file, where each target is represented as n, x, y, w, h. Here, n denotes the class index, x and y are the normalized horizontal and vertical coordinates of the bounding-box center, and w and h are the normalized width and height of the bounding box. To enhance the generalization ability of the model, data augmentation is applied to the training set during training to increase sample diversity.

Fig. 10 - Examples of fresh tea leaf samples from different grade categories

RESULTS

Experimental Environment and Training Strategy

The experimental platform in this study is based on the Ubuntu 20.04 operating system with Python 3.8. The deep learning framework used is PyTorch 1.10.0, with CUDA 11.3 configured to enable GPU-accelerated computation. In terms of hardware, the platform is equipped with a single NVIDIA GeForce RTX 3090 GPU with 24 GB of memory, an AMD EPYC 7642 48-Core Processor (20 vCPU), and 90 GB of system memory.

To ensure a rigorous and fair comparison, all models evaluated in this study, including the proposed YOLOv11-SDWI and various baseline architectures, were trained from scratch for 300 epochs without utilizing any pre-trained weights. Furthermore, a uniform input resolution was maintained across all experiments, and the standard data augmentation strategies provided by YOLOv11 were adopted. No individual hyperparameter tuning was performed for any specific model, as all hyperparameters were kept strictly consistent with the default configurations of the baseline YOLOv11 model.

Evaluation Metrics

This study evaluates model performance from two aspects: detection accuracy and computational efficiency. Commonly used metrics in object detection are adopted, including *Precision (P), Recall (R), and Mean Average Precision (mAP)*, as well as indicators reflecting model complexity and inference cost, such as the number of parameters (Params), floating-point operations (FLOPs), real-time inference speed measured in Frames Per Second (FPS), and model weight file size. These metrics are used to comprehensively and quantitatively assess the performance of the proposed improved model, and their definitions and meanings are described as follows.

$$P = \frac{TP}{TP + FP} \tag{1}$$

$$R = \frac{TP}{TP + FN} \tag{2}$$

$$AP = \int_0^1 (P \times R) dx \tag{3}$$

$$mAP = \frac{1}{N} \sum_{i=1}^{N} AP(i) \tag{4}$$

In the above definitions:

True Positives (TP) denote the number of actual positive samples that are correctly predicted as positive, that is, the number of targets correctly detected by the model;

False Negatives (FN) denote the number of actual positive samples that are incorrectly predicted as negative, that is, the number of targets missed by the model;

False Positives (FP) denote the number of actual negative samples that are incorrectly predicted as positive, that is, the number of background regions mistakenly detected as targets.

Ablation Experiments

To verify the effectiveness of the proposed lightweight improvement strategies, YOLOv11 is adopted as the baseline model, and multiple modifications are introduced from both network architecture and training strategy perspectives. Ablation experiments are conducted to analyze the impact of different module combinations on model performance. At the network architecture level, improvements are applied to the backbone network, feature fusion process, and downsampling strategy; at the training strategy level, the bounding box regression loss function is optimized. For clarity in ablation analysis, the symbols a, b, c, and d are used to denote the four modules StarNet, DySample, Wavelet Pooling, and Inner-MPDIoU, respectively, with their corresponding relationships listed in Table 2.

Table 2

Module Notation Used in Ablation Experiments

Module	StarNet	DySample	Wavelet Pooling	Inner-MPDIoU
Symbol	a	b	c	d

The ablation results are shown in Table 3. Introducing StarNet (a) effectively reduces the model parameters from 2.58 M to 1.95 M and the FLOPs from 6.3 G to 5.2 G, while improving the detection accuracy to 87.9%, demonstrating efficient model compression with stable performance. Further incorporating DySample (a+b) or Wavelet Pooling (a+c) leads to additional accuracy gains and reduced computational cost, indicating that these lightweight modules contribute positively when combined with an optimized backbone. When StarNet, DySample, and Wavelet Pooling are jointly integrated (a+b+c), the FLOPs and parameter count are reduced to 4.9 G and 1.89 M, corresponding to reductions of 22.2% and 26.7% compared with the baseline,

while achieving an accuracy of 89.1%. By further introducing Inner-MPDIoU to form the complete YOLOv11-SDWI model, the detection accuracy is increased to 89.5% without additional computational overhead, demonstrating effective synergy among the proposed components.

Table 3

Results of network ablation experiments

Model	Mean Average Precision mAP@0.5(%)	Floating Point Operations (FLOPs)/G	Number of Parameters (Params)(×10⁶)
YOLOv11	87.0	6.3	2.58
YOLOv11-SDWI	89.5	4.9	1.89
YOLOv11+a	87.9	5.2	1.95
YOLOv11+a+b	88.5	5.0	1.94
YOLOv11+a+c	88.1	5.2	2.11
YOLOv11+a+d	88.5	5.0	1.94
YOLOv11+b+c	88.7	6.3	2.53
YOLOv11+a+b+c	89.1	4.9	1.89

Backbone Network Comparison

To verify the applicability and advantages of the selected backbone network in lightweight object detection tasks, comparative experiments were conducted on several mainstream lightweight backbones under the same detection framework and unified training strategy. The compared backbones include StarNet, EfficientViT, FasterNet, MobileNetV4, and UniRepLKNet. The performance of different backbone networks was comprehensively evaluated from three aspects: detection accuracy, floating-point operations (FLOPs), and parameter scale. The corresponding results are presented in Table 4. Among these metrics, detection accuracy is measured using the mean average precision at an IoU threshold of 0.5.

Table 4

Performance Comparison of Different Lightweight Backbone Networks

Module	Mean Average Precision mAP@0.5(%)	Floating Point Operations (FLOPs)/G	Number of Parameters (Params)(×10⁶)
Starnet	87.9	5.2	1.95
efficientViT	87.3	7.9	3.73
Fasternet	86.8	9.2	3.90
Mobilenetv4	85.7	21.0	5.43
unireplknet	86.4	14.1	5.80

As shown in Table 4, StarNet achieves a mean average precision of 87.9% at an IoU threshold of 0.5, which is comparable to EfficientViT (87.3%) and higher than FasterNet, UniRepLKNet, and MobileNetv4. Despite similar detection accuracy, StarNet exhibits significantly lower computational complexity, requiring only 5.2G FLOPs, which is markedly less than EfficientViT (7.9G), FasterNet (9.2G), UniRepLKNet (14.1G), and MobileNetv4 (21.0G). In addition, StarNet contains only 1.95M parameters, approximately half of those in EfficientViT and FasterNet, and substantially fewer than UniRepLKNet and MobileNetv4.

Overall, these results indicate that while some backbone networks achieve competitive accuracy, they do so at the cost of increased computation or model size. In contrast, StarNet provides a more favorable balance between detection performance and efficiency, making it better suited for real-time, resource-constrained tea leaf sorting applications. Accordingly, StarNet is selected as the backbone network of the proposed lightweight detection framework.

Comparative Experiments with Different Detection Models

To comprehensively evaluate the potential and efficiency of the proposed YOLOv11-SDWI model for intelligent post-harvest tea leaf sorting, an extensive comparative analysis is conducted against a diverse range of mainstream object detection baselines. These baselines encompass classic two-stage detectors, conventional single-stage architectures, and multiple representative iterations within the YOLO series, thereby ensuring a thorough evaluation across different network paradigms. To guarantee fairness, all models are trained and validated on the identical dataset using strictly unified evaluation protocols. The assessment

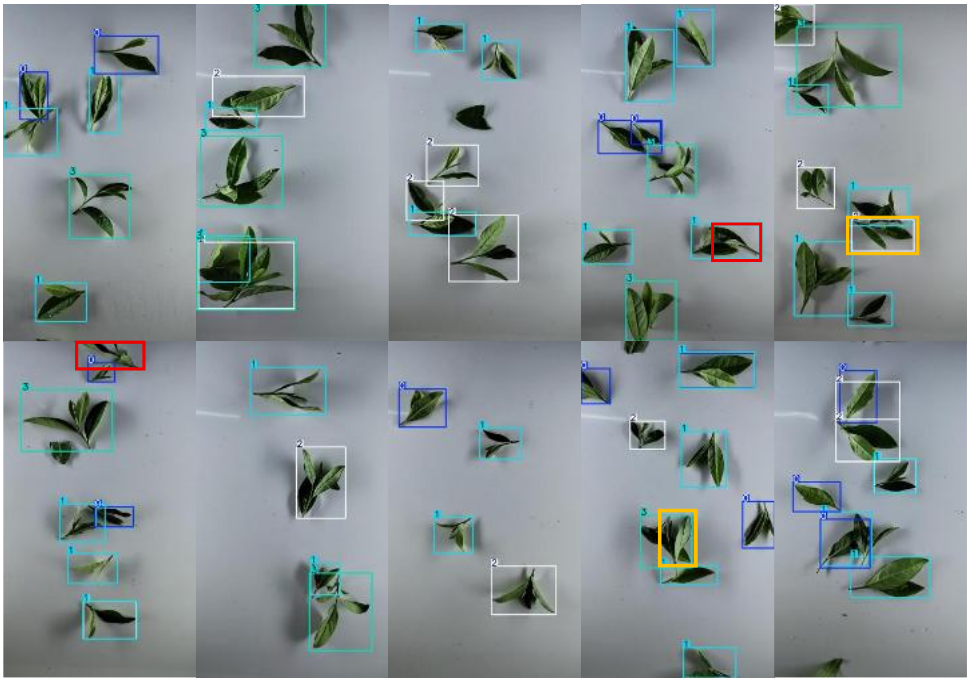
focuses on the critical trade-off between detection accuracy and computational complexity, which is a key consideration for agricultural equipment with limited computing resources: the mean Average Precision at an IoU threshold of 0.5 (mAP@0.5) is utilized to quantify detection precision, while the parameter scale (Params) and floating-point operations (FLOPs) are simultaneously reported to gauge the lightweight characteristics and theoretical deployment feasibility. The detailed quantitative results are summarized in Table 5.

Table 5

Comparative evaluation of mainstream object detection models.

Model	Mean Average Precision mAP@0.5(%)	Floating Point Operations (FLOPs)/G	Precision *P*	Recall *R*	Number of Parameters (Params)(×10⁶)	MB
YOLOv5	83.5	4.1	77.4	78.3	1.76	77.3
YOLOv7-tiny	86.3	13.0	81.9	85.4	6.01	44.6
YOLOv8n	86.3	8.1	82.2	80.4	3.06	39.5
YOLOv9t	86.9	11.0	80.8	79.3	2.66	90.5
YOLOv10n	85.6	8.2	78.4	78.8	2.67	71.2
YOLOv11n	87.0	6.3	82.1	81.2	2.58	23.8
YOLOv12n	84.9	6.5	76.9	77.4	2.50	25.2
YOLOv13n	83.1	5.9	76.6	75.8	2.64	16.4
Fast RCNN	87.7	370.3	81.3	80.9	13.7	241.5
SSD	84.3	62.7	80.2	80.7	26.4	76.4
RTDETR	78.5	100.6	73.8	72.6	28.4	113.6
Ours	89.5	4.9	85.4	84.9	1.89	19.3

Based on the detailed data in Table 5, the proposed YOLOv11-SDWI model significantly outperforms mainstream detection networks across multiple core performance indicators. Compared to the baseline YOLOv11n model, our network not only reduces the parameter count from 2.58M to 1.89M but also increases the mean average precision from 87.0% to 89.5%, achieving a dual optimization of performance and computational complexity. This leading position remains robust during horizontal comparisons with other lightweight versions. For instance, YOLOv12n has a computational overhead of 6.5G floating point operations with a precision of only 84.9%, meaning our model delivers a detection capability 4.6% higher while maintaining a lower computational cost. Similarly, YOLOv13n exhibits a higher computational cost of 5.9G but only achieves a mean average precision of 83.1%. When compared with heavy two stage networks like Fast RCNN, the latter reaches an accuracy of 87.7% but imposes a computational burden over 75 times that of our model, making it entirely unsuitable for real-time processing in hardware restricted environments. On the other end of the spectrum, YOLOv5 possesses a slightly smaller calculation volume leading by 0.8G, yet its detection precision is 6.0% lower than our model. This substantial precision gap renders it inadequate for fresh tea processing tasks that demand high sorting quality.



Synthesizing the experimental results above, the YOLOv11-SDWI model discovers an ideal balance between detection accuracy and lightweight design. It provides a high mean average precision of 89.5% and a precision rate of 85.4% using a minimal storage space of 19.3 MB. The data fully validate that the model effectively eliminates redundant computations and strengthens the recognition ability for tiny tea bud targets without sacrificing feature representation. This architecture combining high efficiency and accuracy demonstrates strong competitiveness in the specific agricultural application of intelligent fresh tea sorting. It offers solid technical support for portable agricultural equipment with limited computing resources, presenting significant theoretical value and practical deployment potential.

Model Visualization Analysis

Beyond computational efficiency, the proposed YOLOv11-SDWI demonstrates enhanced localization stability in complex backgrounds. Figure 11 presents a comparative visualization of 10 randomly selected representative test samples. Quantitative observation of these specific images reveals that the baseline model produced 4 false negatives (missed detections) and 3 false positives (misclassifying background leaves as buds). Following the structural optimizations, YOLOv11-SDWI successfully reduced the false negatives to 2 and the false positives to 2. This targeted reduction in visual detection errors confirms that the lightweight modifications effectively preserve critical structural features, minimizing both target omission under occlusion and background interference in practical grading scenarios.

Intelligent Sorting System Visualization and Functional Testing

Based on the preliminary software architecture design, this study successfully developed the fresh tea grade recognition system. The actual operational interface is illustrated in Figure 12. After importing the test image or video stream, the built in lightweight core inference engine executes target feature extraction and classification localization. The right information statistics panel is designed to monitor operational metrics including processing time and target count. This functional layout ensures that operators can intuitively observe the working status of the detection algorithm.

Fig. 12 - Main detection interface of the fresh tea grade recognition system

In the central main display area, the system precisely marks the spatial position of each tea bud through visualized colored bounding boxes and overlays the corresponding confidence scores above the targets. The detection results and location information data table at the bottom synchronously records the specific attributes of all tracked targets including categories and precise bounding box coordinate ranges. These structured coordinate and category output data are formatted to be directly transmittable as control commands to downstream mechanical sorting execution mechanisms in future applications. The overall software implementation proves that the lightweight model constructed in this study can be effectively packaged into an independent application with comprehensive visualization features. This development provides a necessary and reliable software foundation for the future physical integration of post-harvest fresh tea online grading equipment.

CONCLUSIONS

This paper proposes a lightweight object detection framework YOLOv11 SDWI for post-harvest fresh tea leaf online grading. By systematically optimizing the network architecture and training strategy of the baseline YOLOv11n model the proposed method achieves a comprehensive enhancement in both detection accuracy and computational efficiency. Experimental results demonstrate that the YOLOv11 SDWI model outperforms the baseline model across all accuracy metrics. The mean average precision increases from 87.0 % to 89.5 %. The precision rises from 82.1 % to 85.4 %. The recall also improves from 81.2 % to 84.9 %. Simultaneously the proposed model significantly reduces computational costs. The floating point operations are decreased from 6.3 G to 4.9 G. The parameter count is reduced from 2.58 M to 1.89 M. The model weight size is compressed from 23.8 MB to 19.3 MB. This proves that the improved model successfully strikes an optimal balance between high performance and lightweight design.

Overall, the proposed method exhibits strong potential for practical deployment in post-harvest tea sorting systems. Building upon the visual software system developed in this study future work will focus on expanding the dataset to include multiple tea varieties and further improving detection accuracy. Most importantly the plan is to integrate the proposed software architecture with mechanical sorting hardware to conduct real world physical deployment and joint debugging on actual production lines ultimately achieving the complete engineering application of the intelligent tea grading equipment.

ABSTRACT

Addressing the issues of severe resource wastage, low automation levels, and insufficient control precision in traditional orchard water and fertiliser management, this paper proposes a multi-dimensional, collaborative integrated water and fertiliser management system for orchards. This system combines IoT sensing technology, wireless communication technology, cloud platform computing, and intelligent control algorithms. Through a layered architecture design, this system innovatively enhances the perception layer, transmission layer, data layer, and application layer. It integrates diverse communication protocols such as ZigBee, LoRa and NB-IoT, combines sensors for irrigation, fertilisation, and other aspects, and merges intelligent algorithms including PID closed-loop control and fuzzy neural networks. This enables precise water-fertiliser ratio formulation, remote real-time monitoring, and adaptive regulation. Field validation at a demonstration orchard in Guangdong demonstrated water savings of 30%–65%, fertiliser reductions of 40%–50%, and crop yield increases of 20%–135%. Research findings indicate that the deep integration of IoT and cloud platforms significantly enhances water and fertiliser utilisation efficiency in orchards while reducing labour costs. This provides technical support for standardised orchard cultivation, aligning with the demands for precision and intelligent development in modern agriculture.

摘要

针对传统果园水肥管理中资源浪费严重、自动化程度低、管控精度不足等问题，结合物联网感知技术、无线通信技术、云平台计算与智能控制算法，提出一套多维度协同的果园水肥一体化管控体系。该体系通过分层架构设计，分别对感知层、传输层、数据层与应用层进行了改良创新，整合 ZigBee、LoRa 等多元通信协议，集成灌溉，施肥等多方面传感器，融合 PID 闭环控制、模糊神经网络等智能算法，实现水肥精准配比、远程实时监控与自适应调控。通过广东示范果园田间验证，系统可节水 30%~65%、节肥 40%~50%，作物增产 20%~135%，研究结果表明，物联网与云平台的深度融合可显著提升果园水肥利用效率、降低人工成本，为果园标准化栽培提供技术支撑，符合现代农业精细化、智能化发展需求。

INTRODUCTION

China ranks as the world's foremost fruit producer, with orchard cultivation spanning 19.33 million hectares and total fruit output exceeding 261 million tonnes *(Lu et al., 2022).* However, traditional orchard water and fertiliser management predominantly relies on flood irrigation, furrow irrigation combined with manual fertiliser application *(Singh et al., 2025; Kun et al., 2021; Yang et al., 2025),* presenting three significant challenges. Firstly, resource utilisation efficiency is low, with an irrigation water use coefficient of merely 0.536 and chemical fertiliser utilisation rates below 40%, significantly trailing developed nations' standards *(Zhang et al., 2025)*. Secondly, labour intensity is high, as manual irrigation and fertilisation in large-scale orchards are time-consuming and labour-intensive, exacerbated by an ageing workforce and labour shortages *(Lin et al., 2020; Zheng et al., 2024; Zhao et al, 2025; Ji et al, 2023; Liu et al, 2025).* Thirdly, there are pronounced ecological risks, with excessive water and fertiliser leading to environmental issues such as soil acidification, salinisation, nitrate leaching, and groundwater contamination *(Jian et al, 2021; Li et al, 2024; Song et al, 2025)*.

As agricultural supply-side reforms advance, the "one control, two reductions" strategy has become a core objective for green agricultural development, rendering traditional water and fertiliser management models inadequate for meeting the demands of high-quality industrial development *(Zhu et al, 2023; Tran et al, 2023)*.

As a core precision agriculture technology, water-fertiliser integration delivers water and nutrients directly to root zones in precise, crop-specific ratios. This significantly enhances water and fertiliser utilisation rates, reduces environmental pollution, and improves crop yield and quality *(Fu et al., 2021; Wongchai et al., 2022; Adamo et al., 2025)*.

Overseas adoption of water-fertiliser integration commenced earlier, with Israel, the United States, and the Netherlands achieving large-scale implementation. Over 90% of Israeli agricultural production employs integrated water-fertiliser management (*Meng et al., 2022*); 33% of American fruit tree cultivation utilises this technology, forming a variable fertilisation system based on GPS navigation and prescription maps; while the Netherlands has achieved synergistic optimisation of water-fertiliser coupling and environmental control in protected orchards *(Nie et al., 2023; An et al., 2022; Sun et al., 2025)*. These systems exhibit high water and fertiliser utilisation rates, significantly reducing labour intensity for farmers. However, their limitations—including weak system integration, single-dimensional control, limited communication range, and lack of cloud-based coordination—make direct application to China's diverse topographical orchards challenging *(Sheng et al., 2023)*.

The emergence of IoT and cloud platform technologies offers novel solutions to these challenges *(Xu et al., 2025)*. Through multi-sensor collaborative sensing, wireless data transmission, and cloud-based data analysis, remote, automated, and precision water and fertiliser management becomes feasible. Moreover, cloud platforms enable unified multi-region control, substantially enhancing large-scale management efficiency *(Xing et al., 2024)*.

This study aims to construct an integrated IoT-cloud platform system for water-fertiliser management tailored to complex orchard environments. It addresses challenges including multi-parameter precision sensing with stable long-distance transmission, intelligent decision-making and adaptive regulation of water-fertiliser ratios, and cloud-based collaborative control with multi-terminal user-friendly operation. Adaptable to diverse orchard scenarios—mountainous, protected, and large-scale contiguous plots—this system provides a comprehensive technical solution for intelligent water-fertiliser management, holding significant potential for widespread application. The proposed orchard water-fertiliser integration control system design integrates IoT and cloud platform technologies, achieving precision, remote operation, and automation in water-fertiliser management. Research findings indicate that this system significantly enhances water-fertiliser utilisation efficiency, reduces labour costs, increases crop yield and quality, and is adaptable to diverse complex orchard environments. It holds considerable significance for advancing the intelligent and green development of modern agriculture.

MATERIALS AND METHODS

Precision decision control system

System design proposal

Design of a precision decision control system for water and fertiliser application in field crops this system employs a dual-layer architecture comprising a local head-end control system and a remote intelligent cloud platform. The head-end control system serves as the central hub managing multiple devices, undertaking tasks including water extraction, filtration, fertiliser injection, water distribution, and associated controls. It enables real-time control and operational status monitoring of critical components such as water sources, pumps, filters, motors, and electrical control cabinets. It continuously monitors and alerts on critical metrics such as outlet pressure and flow rate of the main pipeline network, filter differential pressure, and three-phase electrical parameters of pump motors. This ensures equipment safety by protecting pumps, motors, filters, and pipelines during system malfunctions.

Addressing the varying water and fertiliser requirements of different fruit tree varieties and growth stages throughout their lifecycle, the orchard water and fertiliser precision control system employs a closed-loop control method combining servo drive with state feedback. It receives prescription data issued by the remote cloud platform in real time, parses it, and transmits valve start/stop control signals to the valve control system. By executing actions such as valve opening, closing, or partial opening, it achieves automated management for the precise application of water, fertiliser, and pesticides. The variable irrigation and fertilisation ratio decision model, constructed based on knowledge engineering theory, is embedded within the integrated water

and fertiliser system to achieve intelligent dynamic adjustment of water and fertiliser ratios. The system dynamically adjusts pump group operation based on real-time orchard conditions, comprehensively optimising field moisture ratios and enhancing water resource utilisation efficiency through refined management. Closed-loop control automatically activates solenoid valve operation triggered by prescription decisions from the cloud platform, establishing a precision decision-making framework based on prescription map data and real-time field parameters. This ensures irrigation operations automatically cease at the time points specified in the prescription map.

Primary controller

As the control core of the entire water-fertiliser integration system, the head controller possesses bidirectional data interaction and control capabilities. Downstream, it connects wirelessly via IoT to various monitoring nodes including valve controllers, pump station controllers, and data loggers. Through these nodes, it collects data such as pipeline valve status, pipe pressure, and pump operating parameters. Based on this collected data, it executes control commands including solenoid valve opening/closing, pump start/stop, and variable frequency regulation to achieve precise application of water, fertiliser, and pesticides. Upstream, it communicates with the cloud platform for data storage, processing, and remote intelligent control.

The head unit serves as the operational vehicle for the water-fertiliser integration system. It comprises core components including an irrigation tank, chemical application tank, fertiliser tank, pipeline booster pump, filter, integrated water-fertiliser tank assembly, automatic water-fertiliser application controller, differential pressure butterfly valve, solenoid valves, and flow meters. Its fundamental structure is illustrated in Figure 1.

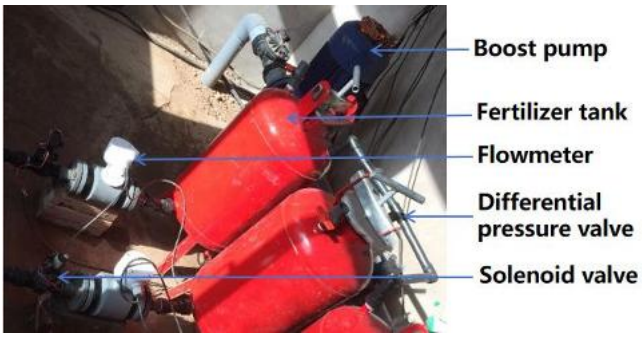

Fig. 1 - Primary equipment configuration plan

The primary controller also incorporates intelligent gateway functionality, establishing communication links between the control system and remote cloud servers via its RTU communication module. This facilitates bidirectional data exchange and control command transmission between the control system and precision management platform, ensuring effective remote command execution and real-time field data uploads. It employs IoT communication protocols such as ZigBee, LoRa, or custom 433 MHz for field monitoring nodes, delivering stable IoT connectivity. Whether utilising broadcast or polling communication mechanisms, it ensures uninterrupted communication links and reliable data transmission. Through each monitoring node, it manages the entire process of sensor data collection, transmission, storage, local display, and cloud uploading for parameters including pressure, flow rate, valve status, and pump operation.

The master controller visually presents the communication status of IoT nodes within the control system, core operational parameters, and the working status of actuators such as valves and pump stations through diverse formats including data lists, trend curves, and graphical representations. This provides maintenance personnel with a clear, comprehensive overview of system operations. It features automatic control parameter configuration, enabling manual/automatic mode switching based on preset requirements to flexibly adapt to varying management scenarios. Users may remotely access the precision crop management platform via smartphones, computers, or other smart terminals to operate various control systems.

On-site controller

The on-site controller serves as an IoT node within the control system. It comprises a power management module, IoT communication module, sensor data acquisition module, relay output module, node enclosure, solar panel array, storage battery, and high-gain communication antenna, and is mounted on field node poles.

The controller's input interface employs an RS-485 serial port for connecting various sensors to gather field data. Its output interface utilises relay outputs capable of driving actuators such as solenoid valves and pump station motors, with a pulse voltage of ±12 V when interfacing with solenoid valves.

On-site controllers perform dual functions of data acquisition and control signal output. Depending on monitored objects and control tasks, they are categorised as integrated monitoring controllers, valve controllers, pump station controllers, and various signal acquisition units. When integrated with corresponding control objects, on-site controllers form intelligent terminal devices such as wireless smart electrically controlled valves, wireless smart pump controllers, wireless smart soil moisture monitors, wireless pipeline pressure measurement and control units, and wireless flow monitors.

Variable rate fertiliser application system

Overall technical approach

The variable fertiliser application control system, serving as the core execution module for precision water-fertiliser integration control, comprises five functional units: the host computer control system, microcontroller system, fertiliser hopper detection module, discharge port fertiliser weighing module, and fertiliser discharge motor control module, as illustrated in Figure 2. Its core operational mechanism functions as follows: the microcontroller, serving as the heart of the micro-control system, simultaneously acquires two critical signals—fertiliser weight within the hopper and discharge chute—via an AD acquisition card. This data is then transmitted to the host computer through an RS-232 serial communication link. The host computer integrates the preset prescription chart information with the two feedback signals. Through algorithmic analysis, it derives precise fertiliser blending ratios and application rate parameters. Control commands are then issued to the microcontroller system, which executes the instructions. This system implements coordinated position and speed control of the fertiliser discharge chute motor. By adjusting the chute wheel speed, variable regulation of the fertiliser blending and application process is ultimately achieved.

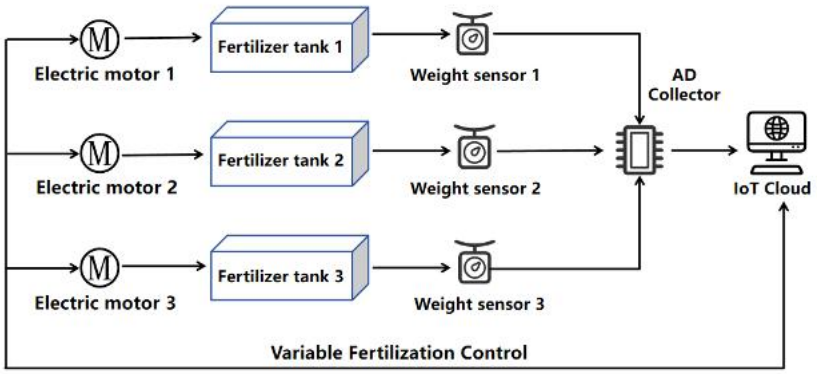

Fig. 2 - Schematic diagram of variable-rate fertiliser application control system

Specific functions of each unit

(1) Host computer control system: Real-time acquisition of fertiliser weight variations within the hopper and feedback signals from the discharge chute via RS-232 serial communication. Integrates prescription maps to precisely match target area fertiliser requirements and blending ratios, generating tailored control commands transmitted to the microcontroller system. This enables coordinated decision-making for variable-rate fertiliser blending and application.

(2) Microcontroller system: Undertakes dual core functions. Firstly, it acquires and pre-processes weight signals from both the hopper and discharge chute, transmitting these via RS-232 serial bus to the host computer. Secondly, based on prescription parameters and vehicle speed signals received from the host, it employs servo control technology to regulate variable fertiliser application throughout the mixing and dispensing process.

(3) Fertiliser hopper detection module: Utilises pressure sensors for real-time monitoring of hopper contents. The process involves: changes in hopper weight causing fluctuations in sensor output signals; the microcontroller system acquiring these voltage variations via an AD acquisition card; signal conditioning followed by transmission to the host computer via RS-232 interface; the host computer calibrating and converting the voltage signals to derive real-time hopper weight changes, representing actual fertiliser application monitoring data.

(4) Discharge outlet fertiliser weighing module: Employing a suspended pressure sensor to perform real-time verification of fertiliser application rates at the discharge outlet. The specific process is as follows: Fertiliser falling from the hopper into the discharge outlet hopper triggers signal changes in the suspended pressure sensor. The microcontroller system acquires this voltage signal via an AD acquisition card and transmits it to the host computer. The host computer processes the data, converting it into the actual weight value of fertiliser at the discharge outlet, thereby forming a closed-loop feedback verification of the fertiliser application rate.

Irrigation control system design

Facility composition

The orchard intelligent irrigation system, serving as a crucial operational component of the precision decision-making control system for water and fertiliser application, comprises core hardware including remote pressure transmitters, remote electromagnetic flow meters, intelligent irrigation controllers, pulse solenoid valves, intelligent irrigation gateways, and a cloud-based decision platform.

The remote pressure gauge collects pipeline pressure signals from the irrigation system, transmitting them via 5G communication to the cloud decision platform. Based on pipeline pressure conditions, the platform assesses system functionality, identifies faults such as leaks, and feeds this information back to the decision control platform. Alarm devices then alert farmers to faults, ensuring timely maintenance. Remote electromagnetic flow meters capture dynamic flow data from orchard irrigation pipelines, transmitting this via 5G to the cloud platform. The platform analyses instantaneous flow rates to assess pipeline operational status and detect leaks, while accumulating flow statistics to quantify water consumption per irrigation cycle across zones. This provides data-driven support for scientific decision-making within the orchard irrigation system.

The cloud decision platform serves as the central brain of the orchard's intelligent drip irrigation system. It collects and stores parameter information transmitted by field irrigation controllers, processes this data to generate precise control commands, and supports the expansion of orchard zone controller units according to user requirements. Concurrently, the cloud decision platform provides 24/7 real-time monitoring, parameter querying, data storage, and analytical capabilities. Its web interface displays orchard, pipeline, and environmental parameters, enabling users to remotely regulate zone solenoid valves via control buttons. All historical parameter data is archived in the server database for user retrieval and download, providing traceability support for irrigation system maintenance and optimisation. Furthermore, the system continuously monitors pump parameters including power consumption, flow rate, and pressure, enabling remote metering control and management of water usage. Through intelligent control technology, pump operation can be regulated to achieve precise flow regulation, thereby conserving water resources.

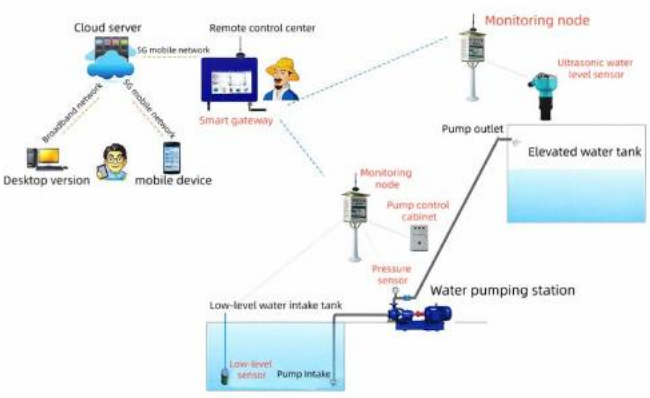

Fig. 3 - Pump station control for irrigation systems

First wireless gateway

The primary wireless gateway serves as the core communication convergence node for the system, primarily facilitating data aggregation and remote transmission for intelligent devices such as pump controllers, wireless valve controllers, and wireless water level sensors, as illustrated in Figure 4. This gateway accesses the internet via GPRS/CDMA/5G mobile communication technology (utilising an IoT SIM card), establishing a direct data exchange link with the cloud-based irrigation management platform. Field intelligent nodes—including pump controllers, valve controllers, soil moisture sensors, and pressure sensors—support two communication access modes: firstly, integrating gateway communication functionality to connect directly with the cloud platform; secondly, forming internal node networking via IoT wireless protocols such as LoRa, with

aggregated data subsequently transmitted to the cloud platform via the master gateway. Furthermore, the master gateway may be integrated with the head controller to form an intelligent head controller with gateway functionality. This enables remote real-time monitoring and control of the precision application system for water, fertiliser and pesticides in the field, while reducing system operation and communication costs. The wireless head gateway offers precise, efficient, secure and stable long-range information transmission, alongside advantages of operational simplicity and high signal recognition rates, ensuring the reliability of the system's communication links.

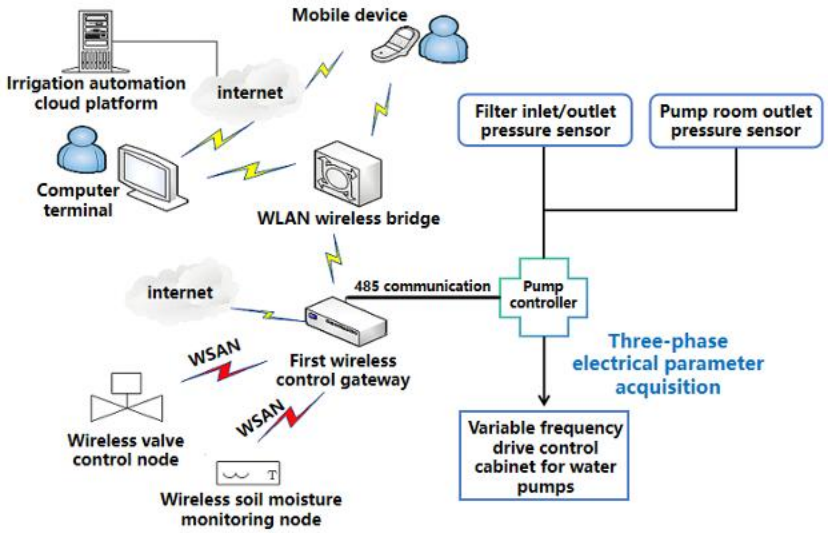

Fig. 4 - First control system architecture diagram

Automated monitoring management

Based on the aforementioned communication architecture, the system enables remote centralised management of pump stations alongside granular monitoring of irrigation water usage and energy efficiency. Total irrigation water consumption is controlled through real-time monitoring and statistical analysis, implementing an authorised water withdrawal control mechanism to provide technical support for managing irrigation water volume within prescribed limits. Real-time energy efficiency monitoring automatically collects electrical parameters such as pump station voltage, current, and power consumption. Combined with operational data including pressure, flow rate, and filter operational status, this enables multi-dimensional statistical analysis. It accurately assesses the rationality of field irrigation patterns, providing foundational data support for optimising water resource allocation and power dispatch.

Users can access comprehensive remote monitoring of pump station operations via cloud-based servers, overcoming spatial (any internet-covered area), temporal (all-hour), and device (compatible with PCs, mobiles, tablets, and other terminals) constraints. Specific monitoring functions include: real-time monitoring of outlet pressure and flow rate, monitoring of variable frequency drive cabinet operational status, and dynamic monitoring of well water levels. The system also features low water level alarms for wells, enabling timely alerts for abnormal water levels to ensure pump station operational safety and continuity of irrigation operations.

Multi-protocol converged communications technology

Internet of Things information transmission

By leveraging a multi-protocol converged communication scheme, perception data collected from the orchard environment is transmitted to the cloud platform with high throughput via 5G cellular networks, where an adaptive protocol selection mechanism is implemented based on the topographical complexity of the orchard: specifically, ZigBee technology is deployed in flat orchard scenarios, which delivers a transmission range of 50-300 m with ultra-low power consumption characteristics and thus is suitable for large-scale sensor node deployment in low-relief terrain, whereas LoRa technology is adopted for mountainous orchard environments featuring complex terrain and long communication distances, enabling an extended communication range of up to 8 km with robust anti-interference capability to mitigate signal attenuation caused by obstacles such as fruit tree canopies and undulating terrain, and the specific configuration and selection criteria of wireless communication modules are elaborated in Table 1.

Table 1

Communication module selection guide

Communication protocol	Core parameters	Suitable scenarios	Model selection
ZigBee	Transmission distance: 50–300 m; Operating current ≤30 mA; Frequency band: 2.4 GHz	Facility orchard/greenhouse	When node spacing is small (< 100 m) and the number of nodes is large (≥50)
LoRa	Transmission distance: 1–8 km; Operating current ≤100mA; Frequency bands: 433/868/915MHz	Mountain orchards/sloping land	Transmission distance > 500 m, complex terrain with numerous obstructions
NB-IoT	Transmission distance: 1–10 km; Operating current ≤20mA; Carriers: China Mobile/China Unicom/China Telecom	Wide-area dispersed orchards (multi-parcel, cross-regional)	When there is no self-built gateway and nodes are dispersed (across townships)

Remote communication mechanism

The remote decision-making control system necessitates the establishment of an effective and reliable remote wireless transmission network. The GSM network's short message service data transmission method has inherent limitations: it suffers from poor real-time performance, is prone to peak congestion during holidays, imposes byte-count restrictions on communication traffic, and carries high tariff costs, rendering it ill-suited for large-volume data transmission requirements. By contrast, GPRS offers distinct advantages: higher data transmission reliability and throughput rates, built upon the Internet Protocol to enable global internet access, permanent connectivity, and pay-as-you-go pricing. This platform utilises the GPRS network as its transmission medium, specifically employing the Transmission Control Protocol within the IP suite for remote data transfer.

The data communication service programme employs multithreading technology to achieve real-time monitoring, reception, and processing of requests sent by the remote data transmission module. This service continuously monitors a predefined port. Upon detecting a request signal from the remote data transmission module, it creates a dedicated thread to process the request. The thread first parses the function code within the request packet, directing it to the appropriate processing workflow based on the function code's specificity. Subsequently, the workflow parses the request data according to predefined communication protocol specifications and completes data persistence by writing it to the database. The communication interaction flow and data transmission link between the server and client are illustrated in Figure 5.

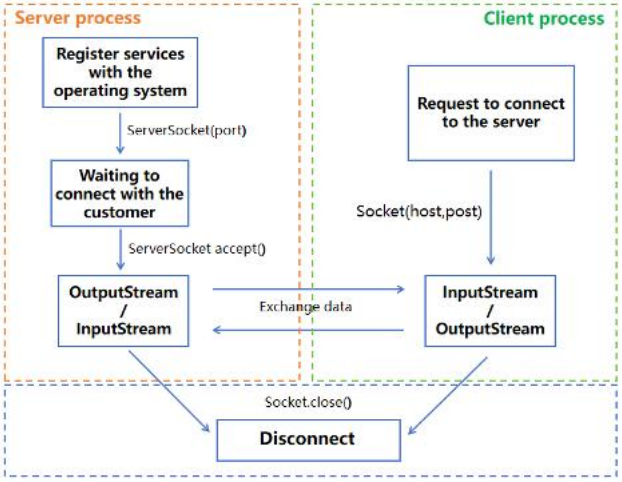

Fig. 5 - Server-client communication process

Cloud platform collaborative control technology

Core architecture of the cloud platform

The cloud platform is built upon the Spring 3.0 MVC framework, employing a MySQL+Redis database architecture to deliver data storage, intelligent decision-making, and remote management capabilities. It provides multi-dimensional analytical reports covering water and fertiliser utilisation efficiency, crop growth trends, and cost-benefit assessments, generating regional water and fertiliser management plans. This enables unified oversight across multiple orchards, with support for data export and visualisation.

Parameters and selection

When selecting hardware for cloud platforms, compatibility should be prioritised to ensure protocol alignment across all component layers. Consideration must also be given to the protection of outdoor components and their environmental adaptability to temperature variations. Wide-temperature models should be selected for cold regions, while anti-condensation models are required for high-humidity areas. Finally, cost and provisions for future scalability must be factored in. Specific selection parameters are detailed in Table 2.

Table 2

Selection criteria for modules of the cloud platform

Core parameters	Technical specifications	Suitable scenarios	Model selection
Data storage	Real-time data storage: ≥100,000 entries; Historical data storage: ≥1 billion entries; Storage type: Relational	Large-scale orchards (≥5 sites)	For long-term data analysis, select "Cloud Server + Local Backup"; For small orchards, consider "Lightweight Cloud" (low cost).
Concurrent access	Supported concurrent users: ≥100; Device connections: ≥1000; Response time: ≤2 seconds	Multi-team collaboration (e.g. growers + technicians)	Cooperatives / Enterprise users should select the “High Concurrency' model”; Individual orchards may opt for the “Basic Edition”.
Security level	Permission Management: Data Encryption for Transmission and Storage; Automatic Backup Frequency: daily	Sensitive data (such as output/cost)	Cross-regional management supports multi-tenant independent administration.
Functional module	Core functions: data monitoring, remote control, alarm management, etc; Extended functions: water-fertiliser models, yield forecasting, energy consumption analysis, etc.	High demand for intelligent solutions	For orchards requiring only basic management controls, the Standard Edition without extended features is available.

Software and system interface design

Control and execution system software

The system software comprises two components: the host computer control software and the microcontroller execution software. The host computer control software reads weight data from the microcontroller and, in conjunction with pre-stored fertiliser application rates for specific plot locations and implement points, calculates the servo motor's rotational speed. It then transmits commands to the microcontroller. Figure 6 illustrates the operational interface of the host computer control software.

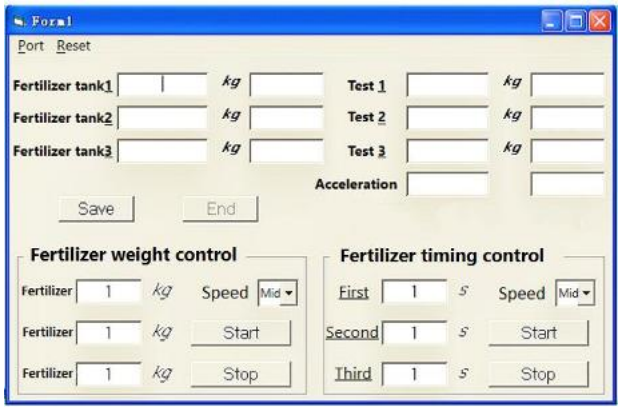

Fig. 6 - Host computer control software operating interface

The specific operational procedure is as follows: click the Port button to access the serial port parameter configuration interface, which includes settings for port number, baud rate, parity bit, data bits, and stop bits. Clicking Reset will clear the fertiliser hopper weight data. Upon system power-up, the host computer software displays real-time weighing values for all three fertiliser hoppers and flow measurements for all three feeders.

Within the fertiliser control panel, pre-set fertiliser quantities for each hopper may be manually input according to operational requirements, or automatically retrieved from the prescription chart by the software. Fertiliser application rate dynamically adjusts in direct correlation with the implement's forward speed: increased forward speed synchronously accelerates fertiliser application, while reduced forward speed correspondingly decelerates it. After completing the above parameter presets, click the "Start" button to initiate fertilisation operations. Data from detection results is saved by clicking the "Save" button. If data saving is unnecessary, clicking the "Cancel" button will prompt a warning dialogue box alerting to the risk of unsaved data. Table 3 summarises the control equipment selection.

Table 3

Control equipment selection table

Controller type	Core technical parameters	Suitable scenarios	Model selection
Edge controller	Interfaces: ≥8 channels; Protection rating: IP65; Power supply: DC 24V	Large-scale orchards (≥10 hectares)	Requirement for basic functionality to be maintained when offline
Local PLC controller	Interfaces: ≥4 channels; Protection rating: IP30; Power supply: AC 220V	Small to medium-sized orchards (≤5 hectares)	When on-site operational requirements are numerous
Industrial touchscreen	Screen size: 7–10 inches; Communication: RS485 / Ethernet; Protection rating: IP65	Local operational requirements (e.g., campus control room)	Supports one-touch start/stop quick operation
Mobile terminal (app)	Functionality: Remote control, data viewing, alert notifications; Communication: 4G/5G/Wi-Fi; Response time: ≤3 seconds	Remote inspection / Multi-orchard management	Multi-site manager selection

The core software module of the microcontroller comprises AD data acquisition and pulse signal output. Upon system power-up or AD7706 reset, the initialisation configuration of the microcontroller's SPI interface is completed first. Data exchange between the microcontroller and AD7706 employs a bidirectional synchronous serial communication method. The AD7706's DIN pin receives control commands issued by the microcontroller, while the converted digital signal is returned to the microcontroller via the DOUT pin. The DRDY register is set to low to receive information from the microcontroller, with the communication frequency set to 2 Mbps. The AD7706 is configured with an update frequency of 50 Hz, yielding a -3 dB cutoff frequency of 13.1 Hz and a gain amplification factor of 1. The microcontroller can output pulses of varying frequencies by configuring the registers of its PWM module. The detailed execution flow of the microcontroller software is illustrated in Figure 7.

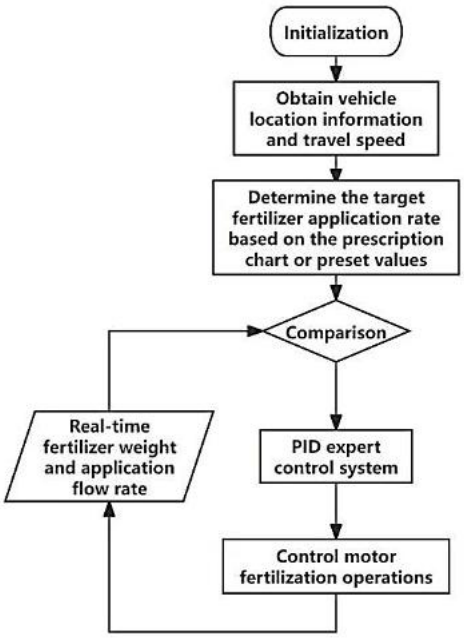

Fig. 7 - Software flowchart

Web application development

The application platform is built upon the Spring MVC framework, with its technical architecture illustrated in Figure 8.

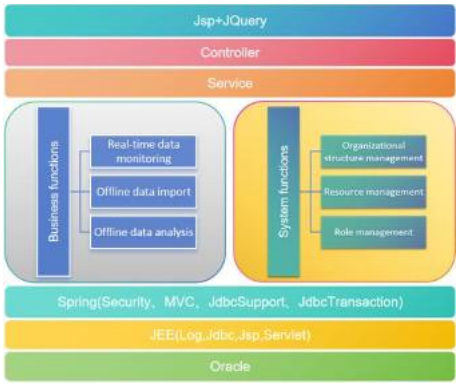

Fig. 8 - Application platform technical architecture

The system employs a Browser/Server architecture for web application development, deployed on cloud server nodes. It supports dual-platform access via mini-programs and mobile applications (Apps), utilising responsive design for multi-device compatibility. The human-machine interface adheres to ergonomic design standards, ensuring excellent usability. Users may monitor core hydrological parameters—including irrigation pressure and flow rates across demonstration zone sub-sections—alongside valve operational statuses in real-time via web browsers or mobile terminals at any location. Concurrently, remote irrigation and fertilisation control commands may be issued to implement time-segmented, zone-specific, and scheduled precision application of water, fertilisers, and pesticides. Historical monitoring data and operational logs can be queried, enabling data-driven analysis for optimising crop irrigation and fertilisation parameters. This design achieves full-process visualised control over irrigation and fertilisation operations, providing data-driven technical support for precision agricultural management decisions. Figure 9 illustrates the zone control interface and display screens for spray flow rates and pipeline pressure within the remote intelligent monitoring system application.

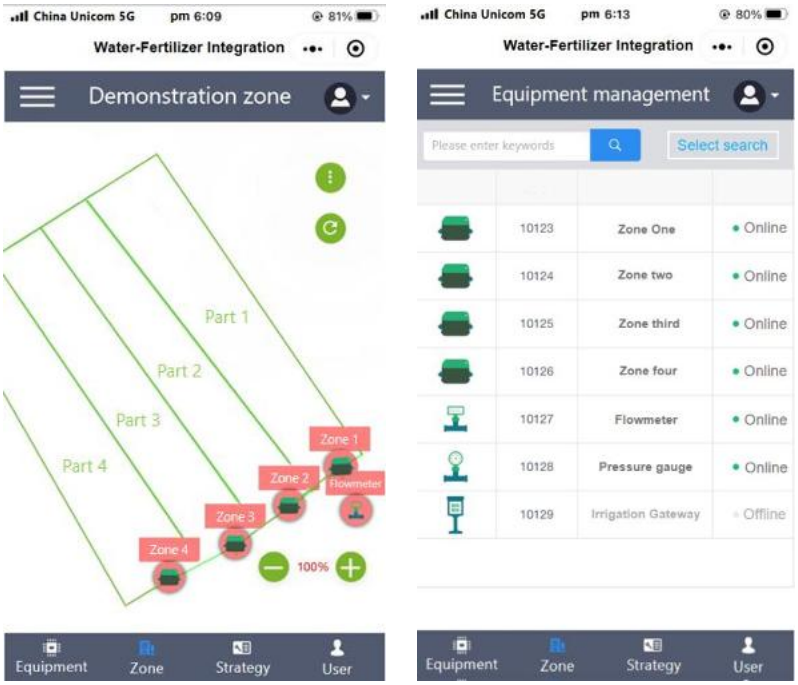

Fig. 9 - Remote intelligent monitoring system App interface

Database selection analysis

As the core repository for system information storage, databases underpin the entire process of data operations including insertion, deletion, modification, and retrieval. Their performance directly determines the overall operational efficiency of the system. Therefore, selecting a suitable database tailored to specific system requirements is crucial for reducing response latency and enhancing overall system performance.

Different database types possess distinct technical characteristics and applicable scenarios, necessitating targeted selection based on the specific application requirements of the monitoring system, as illustrated in Table 4. From the perspective of current market applications, relational databases have long held a dominant position. This category organises data using a two-dimensional tabular structure, achieving efficient CRUD operations through standardised data models and mature algorithmic mechanisms.

Table 4

Database selection comparison

Name	Type	Core features	Applicable scenarios
Oracle Database	Relational	Comprehensive data management capabilities, robust transaction processing power, and a rich product ecosystem	Large-scale enterprise applications
MySQL	Relational	Open-source and free of charge, with outstanding performance, compact size, and cross-platform compatibility	Website development for small and medium-sized enterprises, lightweight applications
SQL Server	Relational	SQL-based, easy to operate, user-friendly management interface, low operational costs	Development of various web projects
NoSQL	Non-relational	Supports dynamic mode, capable of storing semi-structured data, predominantly key-value storage.	High-concurrency, massive-scale data storage scenarios

Taking into account the operational requirements and technical compatibility of this monitoring system, the final configuration has been determined as follows: MySQL 1.8 will be employed to store harvester operational data, whilst Redis will be utilised as a caching database for frequently accessed data. This approach ensures an optimal balance between storage performance and operational demands.

RESULTS

The field trial scene at the citrus orchard demonstration base in Huizhou, Guangdong Province is depicted in Figure 10. Key indicators including citrus fruit growth status and yield were recorded both before and after implementing this water-fertiliser integrated control system. The relevant statistical results are presented in Table 6.

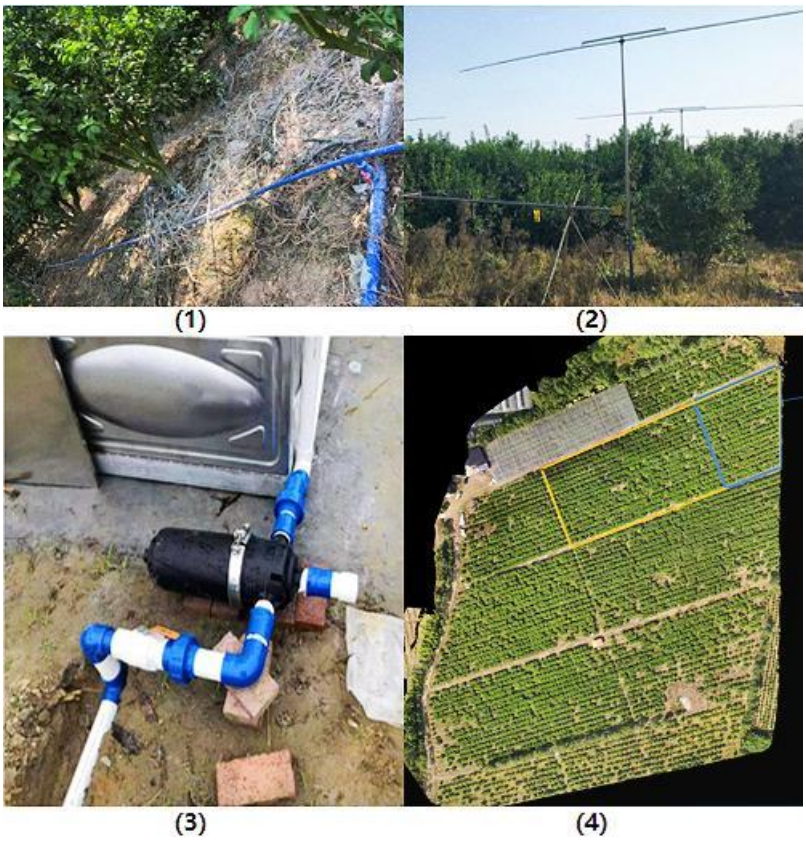

Fig. 9 - Field trial scenario

(1) Drip irrigation pipeline; (2) Dribble board; (3) Fertiliser pipeline; (4) Citrus orchard plot

Table 6

Comparison of citrus growth and yield indicators

Indicator	Experimental group	Control group	Increase rate
Number of fruits per individual tree	445	334	33.2%
Single fruit weight	0.23 kg	0.16 kg	43.8%
High-quality fruit yield	89.1%	70.0%	19.1%
Total output	3180 kg/hm²	2050 kg/hm²	55.1%

The field trial established a precision management system utilising IoT and cloud platforms as the experimental group, with a conventional manual management area serving as the control group. The trial period spanned one year, monitoring indicators including: water and fertiliser use efficiency, crop growth metrics, and system operational stability.

Experimental results demonstrated superior crop growth metrics in the experimental group compared to the control group, indicating that this orchard's integrated water and fertiliser control system effectively enhances fruit quality and yields.

CONCLUSIONS

(1) The system employs irrigation-fertilisation coupling technology, enabling full-growth-cycle requirement design tailored to crop needs. Water and nutrients are delivered directly to crops in precise quantities, at scheduled times, and in proportioned ratios. Statistical analysis and evaluation have been conducted on the selection of all necessary hardware and software components for this process.

(2) The precision control decision system remotely regulates the timing and volume of water and fertiliser application based on crop growth monitoring and detailed prescription information from decision models. It automatically activates and deactivates solenoid valves for unattended operation. Alternatively, by configuring application modes on the controller, the system dynamically applies water, fertiliser, and pesticides according to input instructions.

(3) The precision water and fertiliser decision-making employs the following management methods: operational condition monitoring, closed-loop control, zone management, time-division multiplexing, and platform-based decision-making. This study incorporates a tailored system interface design and optimises the communication network and cloud platform architecture, enabling real-time display of field water and fertiliser status on the remote monitoring interface. Future applications may incorporate multi-source sensor fusion technology combined with machine vision for crop growth monitoring, establishing specialised water and fertiliser models for multiple crops. This would extend applicability to field crops and protected horticulture. Continuous refinement of intelligent algorithms, alongside integration of big data analytics and machine learning, could enable predictive regulation of water and fertiliser requirements, further enhancing the system's adaptability and control precision.

ACKNOWLEDGEMENT

This research was supported by National Key Research and Development Program Project (Grant No. 2023YFD2001103).

Keywords: *Greenhouse, Wet curtain, Temperature, Velocity*

ABSTRACT

Effective cooling is crucial for maintaining suitable thermal environments in greenhouses during hot summers. This study developed a coupled numerical model to investigate the cooling performance of a wet curtain system in a multi-span plastic greenhouse in Weifang, China. Relative deviations were less than 5.88% for wet curtain outlet temperature and below 7% for average greenhouse temperature. Results indicated that the wet curtain reduced the average greenhouse temperature by 2.33 ~ 4.20 ℃, with the maximum reduction of 4.20 ℃ occurring at 12:00. The cooling capacity increased with rising solar radiation in the morning and then diminished in the afternoon. The cooled air entered as a floor-level jet, accumulated near the crop zone, and subsequently rose due to buoyancy, forming two large recirculation vortices that enhanced vertical mixing and improved temperature uniformity. Consequently, the average indoor air velocity increased by 8.38% ~ 22.40% compared to ventilation without the wet curtain. Parametric analysis revealed that the average greenhouse temperature decreased nonlinearly with increasing inlet velocity, and the marginal cooling benefit dropped significantly when the inlet velocity exceeded 0.75 m/s. An optimal inlet velocity range of 0.75 ~ 1.0 m/s is recommended. The model accurately captured the thermal performance and airflow patterns of the greenhouse with wet curtain cooling.

摘要

在炎热的夏季，有效的降温对维持温室适宜的热环境至关重要。本研究建立了一个耦合数值模型，用于研究山东潍坊一座连栋塑料温室中湿帘系统的降温性能。湿帘出口温度的相对偏差小于 5.88%，温室平均温度的相对偏差小于 7%。结果表明，湿帘使温室平均温度降低了 2.33 ~ 4.20 ℃，其中 12:00 时降幅最大，达 4.20 ℃。上午降温能力随太阳辐射增强而提高，午后则逐渐减弱。冷却后的空气以贴地射流形式进入温室，在作物区附近积聚，随后因浮力作用上升，形成两个大型回流涡，增强了垂直混合，改善了温度均匀性。因此，与无湿帘的通风相比，室内平均风速提高了 8.38% ~ 22.40%。参数分析显示，温室平均温度随入口风速的增加呈非线性下降，当入口风速超过 0.75 m/s 时，边际降温效益显著降低。推荐的最佳入口风速范围为 0.75 ~ 1.0 m/s。该模型准确捕捉了湿帘降温温室的热工性能和气流流型。

INTRODUCTION

With the global population projected to reach 8.5 billion by 2030 (*Abedrabboh et al., 2024*), the demand for food is explosive growth, with an estimated increase of 50% (*Bergman et al., 2011*), thereby placing greater pressure on water resources and arable land. Consequently, enhancing food yield has become a critical issue in addressing food security.

Greenhouse is a facility that utilize solar energy to enable off-season crop cultivation (*Dietz et al., 2011*). Greenhouses transmit shortwave solar radiation while blocking longwave radiative loss, thus maintaining a favorable thermal environment for off-season cultivation (*Zhang et al., 2025*).

Huanran Sun, M.S. Eng.; Binguang Jia, Prof. Ph.D.; Ziye Song, Prof. Ph.D.

Compared with open-field cultivation, the greenhouse contributes to a notable increase in overall crop yield, as greenhouse can monitor and regulate growing conditions (*Garcia et al., 2026*). At the same land area, tomato production in greenhouse can achieve yields approximately 15 times higher than those obtained in open-field systems (*Abedrabboh et al., 2024*). Furthermore, off-season crop marketing can significantly elevate market prices, which contributes to enhance the economic profitability of agricultural production (*Lei et al., 2023*). Although greenhouses can maintain suitable internal conditions for the growth for horticultural products in winter, the greenhouse effect intensifies internal temperatures during summer, leading to increased pest and disease incidence and, in severe cases, dehydration and crop mortality (*Rahman et al., 2021*). Therefore, effectively providing an optimal growing environment under high-temperature summer conditions has become a prominent research focus in the horticulture (*Krishna et al., 2024*).

Based on cooling strategies, summer greenhouse cooling can be categorized into passive and active approaches (*Zhang et al., 2022*). Passive cooling relies on natural ventilation driven by indoor–outdoor temperature gradients. Although optimizing vent configurations can improve airflow and temperature distribution (*Park et al., 2022*). Some researchers (*Moreno-Teruel et al., 2022*) noted that the increase in the greenhouse width could enhance crop radiation interception and elevate internal CO_2 concentrations for the passive cooling strategy. The greenhouse designed by Yang et al. demonstrated superior performance over front roof and side vent configurations under both sunny and overcast conditions, resulting in improved crop growing environments and a 7.9% increase in tomato yield (*Yang and Liu, 2024*). Despite extensive research on passive cooling techniques, the limited temperature gradient between the interior and exterior renders passive cooling insufficient to ensure adequate crop growth conditions during summer.

Active cooling techniques employ fans to forcibly introduce outdoor air or cold air generated by mechanical cooling systems into the greenhouse (*Peng et al., 2023*). Depending on the cold source, active cooling can be divided into artificial cooling and natural cooling. Compared with natural ventilation, forced ventilation can provide the required airflow rates in summer but may still induce spatial temperature heterogeneity (*Jerszurki et al., 2021*; *Yoon et al., 2024*).

When the environment temperature was greater than the suitable temperature for crop growth in summer, wet curtain systems, which relied on the core mechanism of evaporative cooling, could produce air cooler than ambient conditions, emerging as a critical solution for summer greenhouse cooling (*Shen et al., 2026*). As wet curtain achieved temperature reductions of 5 to 15 °C while consuming only one-quarter to one-third of the energy required by conventional air conditioning, wet curtain greenhouse cooling systems have attracted considerable research interest (*Chen et al., 2023*).

However, a critical shortcoming persists in most CFD studies on wet curtain greenhouses. To simplify computation, the cooling effect of the wet curtain is typically predefined as a fixed temperature drop or a fixed cooling efficiency based on empirical correlations. Although this empirical boundary treatment is computationally efficient, it neglects the dynamic interactions among the incoming air velocity, the heat and mass transfer within the water film, and the fluctuating outdoor climatic conditions (solar radiation and air humidity). Consequently, such simplifications cannot capture the transient response of the cooling system, and under highly variable solar radiation loads, they may cause significant deviations in the predicted spatial distributions of airflow and temperature. This study proposes a mechanistic-coupling modeling approach. Unlike conventional empirical methods, the heat and mass transfer equations of the wet curtain are embedded into the greenhouse mathematical model via user-defined functions (UDFs). This integration enables the inlet boundary conditions at the wet curtain to dynamically respond to real-time outdoor environmental parameters, rather than being prescribed in advance.

MATERIALS AND METHODS

Description of experimental greenhouse

The experimental facility employed in this study was a large-scale multi-span plastic greenhouse in Weifang City, China (118°32′E, 36°41′N). As illustrated in **Fig. 1**, the greenhouse were 36 m in length, 16 m in width and 4.5 m in height. Along the longitudinal direction, the structure was divided into four identical modules, each with a length of 9 m. Each module was equipped with an air inlet and an outlet, both measuring 4 m in width and 1.5 m in height. A wet curtain pad matching the inlet dimensions was installed at the air intake, with a fan positioned downstream of the pad. The roof adopted an arched configuration, reaching a maximum height of 4.5 m, while the surrounding sidewalls, which connect to the arched roof, have a height of 3 m.

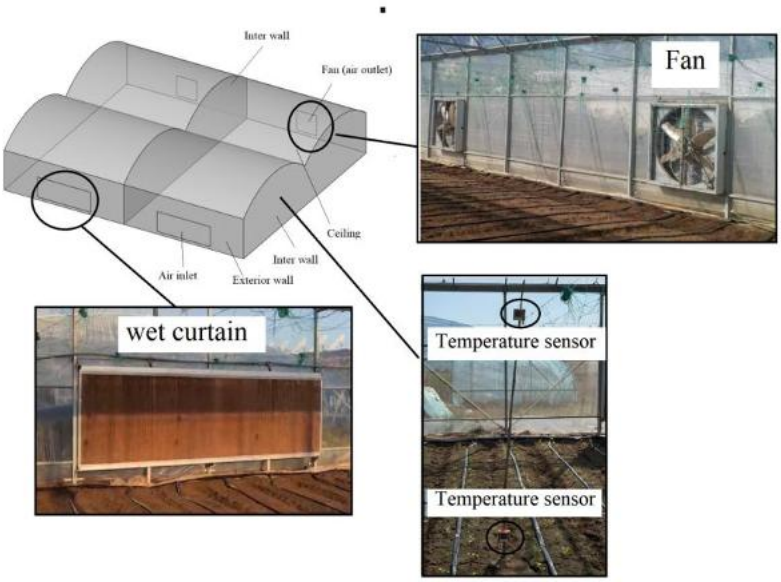

Fig. 1 - Experimental greenhouse structure and location of observation points

Cooling experiments were conducted on September 17, 2025, between 8:00 and 17:00. This date was deliberately chosen to avoid interfering with the ongoing crop production cycle, as the greenhouse is a commercial cultivation facility. Measurements were therefore scheduled during a non-planting window while the house was empty, and the day itself was a typical clear, hot day representative of the late-summer climatic conditions requiring cooling. The ambient temperature ranged from 18.8 ℃ to 28.2 ℃, and the relative humidity varied between 39.4% and 58.8%. The wet curtain pad was supplied with recirculating water maintained at a controlled temperature of 18–20 ℃. The water flow rate was set according to the pad manufacturer's specification to ensure complete wetting of the pad surface, approximately 30 L·min-¹. The evaporative cooling efficiency of the pad under these operating conditions is approximately 80%. A total of 10 temperature monitoring points were arranged inside the greenhouse, distributed between the upper and lower regions to capture vertical temperature variations. Temperature measurements were performed using Testo 174H data loggers (operating range: -20 ~ 70 ℃; accuracy: ±0.5 ℃). Solar radiation, which was mounted above the west side of the greenhouse roof, was recorded using a TBQ-2 pyranometer (measurement range: 0 ~ 2000 W/m; accuracy: 5 %; sensitivity: 8.963 μV·W/m²; spectral range: 0.3 ~ 3.0 μm). Ambient wind speed was monitored using a YGC-FS anemometer (measurement range: 0 ~ 45 m/s; resolution: 0.1 m/s; accuracy: ± (0.3 + 0.03 V) m/s) positioned on the western side of the greenhouse.

Physical model and mesh generation

The physical model of the greenhouse was established and meshed by Gambit software. As illustrated in **Fig. 2**, the experimental greenhouse could be divided into several geometrically identical modules; therefore, to reduce computational expense, only one module was selected for physical modeling. After the model construction, mesh generation was performed. The mesh configuration of the greenhouse was depicted in **Fig. 2**. Mesh quality assessment revealed a maximum skewness of 0.82, with 93.8% of grid elements exhibiting a skewness below 0.6, indicating satisfactory mesh quality suitable for subsequent simulations.

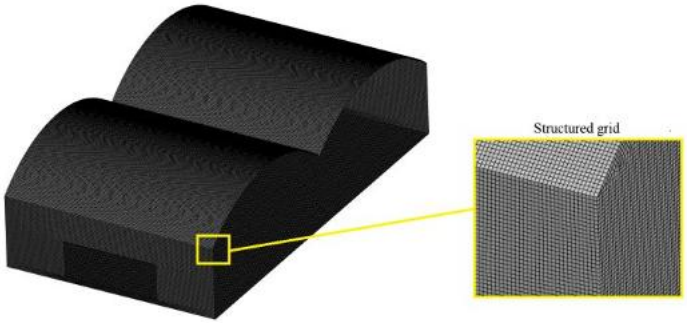

Fig. 2 – Grid generated in greenhouse computational domain

To achieve a balance between computational speed and accuracy, a grid independence test was performed using seven systematically refined meshes under conditions without wet curtain ventilation. The resulting average temperatures were plotted in **Fig. 3**. As the mesh was refined, the predicted average temperature decreased monotonically and the variation became negligible beyond 3.49 × 10⁶ elements. To quantitatively assess the discretization error, the Grid Convergence Index (GCI) was calculated. GCI for the fine-grid solution was determined to be 1.36%, confirming that the discretization uncertainty is sufficiently small. Consequently, the mesh with 3.49 × 10⁶ elements was selected as an appropriate compromise between accuracy and computational cost.

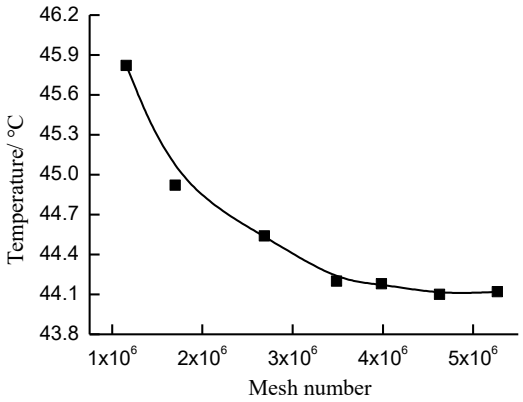

Fig. 3 - Average temperature with respect to mesh number

Governing equations

Computational fluid dynamics simulation techniques could discretize the system of partial differential equations governing fluid flow in both space and time, and obtain physical quantities (e.g., velocity, pressure, temperature) at discrete points through iterative solution of the resulting algebraic equations. This approach provided a convenient and effective means for parametric investigations of greenhouse cooling using wet curtain systems.

Prior to conducting the numerical simulations, the following assumptions were adopted (*Jiao et al., 2024*):

(1) The effects of crop respiration and transpiration on the temperature and velocity distributions of air inside the greenhouse are neglected;

(2) The Boussinesq approximation is employed to account for the influence of buoyancy forces on airflow;

(3) Infiltration of cold air into the greenhouse is disregarded.

(4) There are no crops being cultivated in the greenhouse.

The continuity, momentum, and energy equations for the air region within the greenhouse are expressed as follows (*Fu et al., 2023*):

$$\frac{\partial \rho}{\partial t} + \nabla\left(\rho \vec{v}\right) = 0 \tag{1}$$

$$\frac{\partial}{\partial t}\left(\rho \vec{v}\right) + \nabla\left(\rho \vec{v}\vec{v}\right) = -\nabla P + \nabla \cdot \left(\bar{\bar{\tau}}\right) + \rho \vec{g} \tag{2}$$

$$\frac{\partial}{\partial t}\left(\rho E\right) + \nabla \cdot \left(\vec{v}\left(\rho E + P\right)\right) = \nabla \cdot \left(k_{eff}\nabla T - \sum_j h_j \vec{J}_j + \left(\bar{\bar{\tau}}_{eff} \cdot \vec{v}\right)\right) \tag{3}$$

where: ρ was the air density (kg/m³); t was time (s); v was velocity vector (m/s); P was the pressure (Pa); τ was the stress tensor (Pa); g was the gravitational acceleration vector (m/s²); E was the total energy per unit mass (J/kg); k_{eff} was the effective thermal conductivity (W/(m·K)); T was Temperature (K); h_j was the enthalpy of species (J/kg); J_j was diffusion flux of species (kg/(m²·s)); τ_{eff} was the effective stress tensor (Pa).

Given that the airflow in a greenhouse typically exhibits complex turbulent characteristics, specifically manifested as high-strain-rate flow formed when cold air jets impinge on the ground, and large-scale recirculation vortices driven by buoyancy after heating (*Allali et al. 2024*). To more accurately predict the velocity and temperature distributions inside the greenhouse, this study adopts the RNG *k-ε* turbulence model

based on renormalization group theory. Compared with the standard k-ε model, the RNG *k-ε* model introduces an additional source term into the ε equation and modifies the calculation formula for turbulent viscosity, thereby enabling more effective handling of high strain rates, streamline curvature, and the nonlinear effects of buoyancy on the turbulent structure (*Chen, 2015*). This model has been widely applied in CFD simulations of greenhouse environments and similar building ventilation, and can reasonably resolve the temperature stratification and vortex structures of interest in this study.

$$\frac{\partial(\rho k)}{\partial t}+\frac{\partial(\rho k u_i)}{\partial x_i}=\frac{\partial}{\partial x_j}\left[\alpha_k \mu_{eff}\frac{\partial k}{\partial x_j}\right]+G_k+\rho\varepsilon \tag{4}$$

$$\frac{\partial(\rho \varepsilon)}{\partial t}+\frac{\partial(\rho \varepsilon u_i)}{\partial x_i}=\frac{\partial}{\partial x_j}\left[\alpha_\varepsilon \mu_{eff}\frac{\partial \varepsilon}{\partial x_j}\right]+\frac{C_{1\varepsilon}^{*}}{k}G_k-C_{2\varepsilon}\frac{\beta\varepsilon^2}{k} \tag{5}$$

where: G_k was the generation term of turbulent kinetic energy; k caused by the average velocity gradient; $C_{1\varepsilon}$ and $C_{2\varepsilon}$ were empirical constants; $C_{1\varepsilon}$=1.42, $C_{2\varepsilon}$ = 1.68.

The discrete ordinates (DO) radiation model implemented in the CFD framework enables the incorporation of solar radiation as a function of longitude and latitude. The DO radiation model was selected for calculating solar radiation, with the relevant governing equations provided below (*Jiao et al., 2024*).

$$\nabla\left(I_\lambda\left(\vec{r},\vec{s}\right)\vec{s}\right)+\left(\alpha_\lambda+\sigma_s\right)I_\lambda\left(\vec{r},\vec{s}\right)=\alpha_\lambda n^2\frac{\sigma T^4}{\pi}+\frac{\sigma_s}{4\pi}\int_0^{4\pi}I_\lambda\left(\vec{r},\vec{s}\right)\Phi\left(\vec{s}\cdot\vec{s}'\right)d\Omega' \tag{6}$$

The physical properties employed in the governing equations are summarized in Table 1.

Where: $\vec{r}$ was the position vector; $\vec{s}$ was the direction vector, *a* was the absorption coefficient, n was the refractive index, σs was the scattering coefficient, σ was the Stefan-Boltzmann constant (5.672×10^{-8} W·m^{-2}·K^{-4}); *I* was the radiation intensity (W·m^{-2}), Φ was the phase function, Ω' was the solid angle.

The physical properties employed in the governing equations are summarized in Table 1 (*He et al., 2018*).

Table 1

Physical property parameters in mathematical model

Name	Density/ Kg/m^3	Specific heat capacity/ J/(kg·K)	Thermal conductivity/ W/(m·K)	Absorptivity	Transmittance	Viscosity/ Pa·s	Coefficient of thermal expansion/ 1/K
Air	0.91	1006.4	0.0242	0	1	1.79×10^{-5}	3.34×10^{-3}
Soil	1300	800	1.3	0.4	0	-	-
Polycarbonate	920	2300	0.4	0.3	0.7	-	-

Boundary conditions

Near-wall regions were treated using the standard wall function approach. The roof, sidewalls, and ground surface of the greenhouse were all configured as wall boundary conditions. For these boundaries, the free-stream temperature was set to the ambient temperature, and the convective heat transfer coefficient was assigned a value of 15 W/ (m²·K). At the greenhouse inlet, fans were installed to force outdoor air through the wet curtain, where it was cooled before being delivered into the greenhouse interior. A velocity inlet boundary condition was prescribed at the inlet. The corresponding inlet velocities were set as 0.25 ~ 1.50 m/s. The temperature variation of the incoming air was determined by solving the heat and mass transfer processes within the wet curtain. The outlet air temperature was calculated using the following expression (*Jiang et al., 2021*):

$$T_{wc,out}=T_{wb,in}+\left[\frac{T_{w,in}+T_{wc,out}}{2}+\left(T_e-T_{wb,in}\right)e^{-NTU}\right] \tag{7}$$

where: $T_{wc,out}$ was the air temperature at the outlet of the wet curtain, ℃; $T_{wb,in}$ was the temperature of the water in the wet curtain, ℃; T_e was the environment temperature, ℃; *NTU* was the number of heat transfer units.

The number of heat transfer units (NTU) was defined as (*Bergman et al., 2011*):

$$NTU=\frac{A_{total}}{\dot{m}_a C_{p,eff}}\frac{k_{da}}{I}\left[0.1\left(\frac{I}{b}\right)^{0.12}\left(\frac{u_a I}{\nu_a}\right)^{0.8}Pr^{0.33}\right] \tag{8}$$

where: I was the specific surface area of the wet curtain, m^2/m^3; b was the thickness of the wet curtain, m; u_a was the velocity at which air passes through the wet curtain, m/s; Pr was Prandtl number; v_{da} was the kinematic viscosity of air, m^2/s.

The parameters employed in the mathematical model and boundary conditions were summarized in Table 2.

Table 2

Parameters of boundary conditions

Time	Environment temperature/℃	External radiation temperature/℃	Solar radiation/ W/m^2
8:00:00	27.00	13.83	522.90

17:00:00	31.50	20.31	491.56

RESULTS AND DISCUSSION

Validation

The experimental data (*Al-Ismaili, 2009*) were employed to validate the wet curtain model. The results in **Fig. 4** indicated that the relative deviation of the temperature values model ranged from 3.96% to 5.88%. In summary, the proposed mathematical model could effectively predict the heat transfer performance wet curtain in greenhouse.

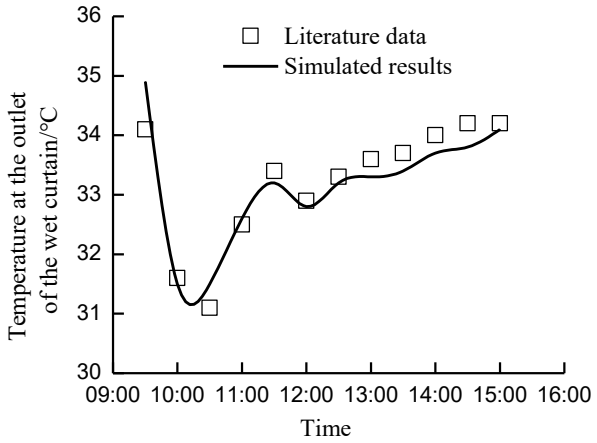

Fig. 4 - Comparison of the predicted and the measured temperature at the outlet of the wet curtain

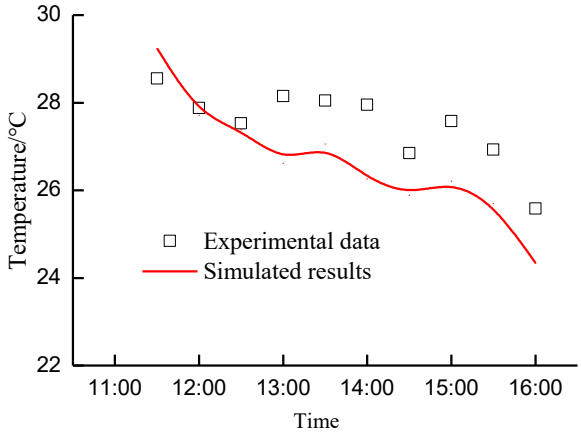

Fig. 5 - The average temperature of the greenhouse

To further substantiate the accuracy of the developed mathematical model, a comparison was conducted between the experimentally measured and numerically simulated average temperatures in the greenhouse. As illustrated in **Fig. 5**, the experimentally obtained average greenhouse temperatures were in strong agreement with the predicted results, exhibiting a relative deviation of less than 7%. The relative deviation between the experimental and simulated results might be attributed to the fact that the numerical simulation employed hourly average values of ambient temperature and solar radiation, whereas during the experimental process, these parameters exhibited fluctuations within the given hour. Based on the analyses presented in **Fig. 4** and **Fig. 5**, it could be concluded that the established mathematical model not only accurately predicted the operational performance of the wet curtain but also effectively characterized the temperature distribution within the greenhouse.

Comparison between greenhouse and wet curtain

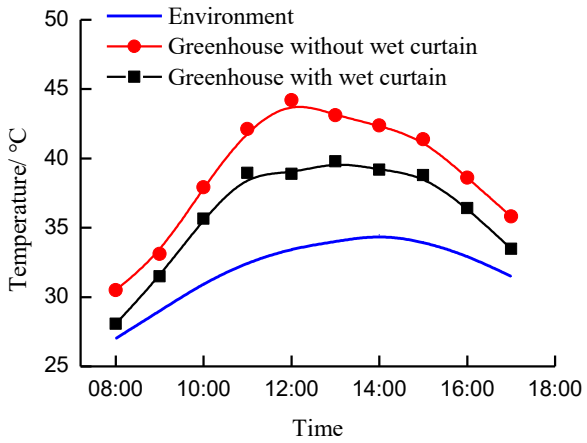

Fig. 6 - Averages temperature in greenhouse with and without wet curtain

Fig. 6 illustrated the average temperature in greenhouse with and without wet curtain on a typical day. Starting from 8:00, the initial temperatures were recorded at 30.49 °C (without wet curtain) and 28.07 °C (with wet curtain); then, given the rising ambient temperature and solar radiation, the indoor temperature progressively increased, peaking between 12:00 and 13:00 at 44.20 °C (without wet curtain) and 39.79 °C (with wet curtain); finally, temperatures gradually declining as solar radiation intensity diminished. A comparative analysis of the cooling effect of the wet curtain revealed that, during the period from 8:00 to 17:00, the wet curtain effectively reduced the ambient temperature within the greenhouse, with its cooling efficacy initially increasing and then decreasing throughout the day. At 8:00, wet curtain achieved an additional temperature reduction of 2.42 ℃ in the average greenhouse temperature, whereas at 12:00, the reduction attributable to the wet curtain reached 4.20 ℃. Subsequently, as solar radiation increased, the cooling effect of the wet curtain gradually weakened, diminishing to 2.33 °C by 17:00. The cooling capacity of the wet curtain was directly governed by its evaporation efficiency. From 8:00 to 12:00, as solar radiation intensified, the temperature difference between the outdoor air and the water in the wet curtain progressively increased, promoting the water evaporation and enhancing the actual cooling capacity of the wet curtain. After 12:00, the decrease in the solar radiation and air temperature, and the increase in the relative humidity resulted in the fact that the differences in both water vapor partial pressure and temperature between the air and the wet curtain water diminished, ultimately leading to a gradual attenuation of the cooling performance of the wet curtain.

Fig. 7 presented the temperature distribution within the greenhouse at 12:00.

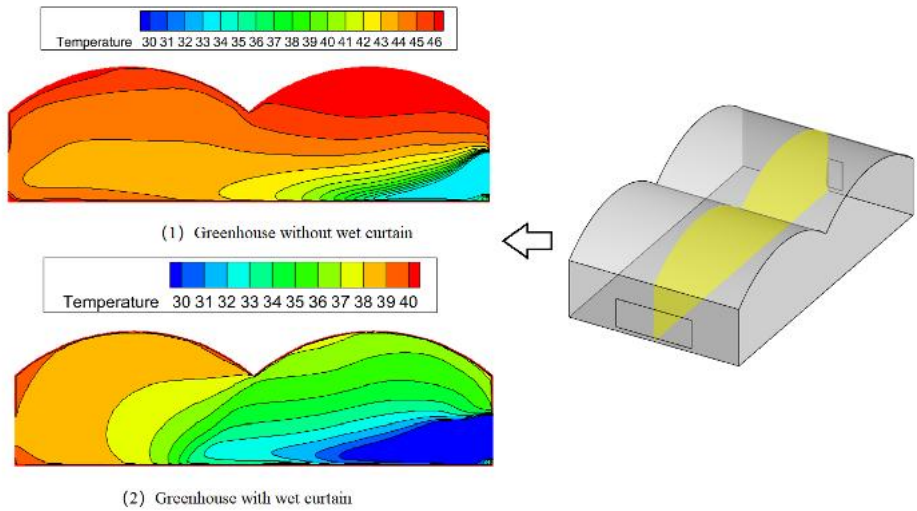

Fig. 7 - Temperature distributions in greenhouse

As illustrated in **Fig. 7**, two distinct temperature gradients appeared in the greenhouse, oriented horizontally and vertically. Owing to the transparent covering material, a substantial portion of solar radiation penetrated the greenhouse, resulting in indoor temperatures considerably higher than ambient levels.

The incoming air, either ambient or pre-cooled by the wet curtain, mixed with the warmer indoor air, thereby reducing the greenhouse temperature. The gradual intermingling of warm and cool air generated a temperature gradient along the direction of airflow. The vertical temperature gradient was influenced by two primary factors. First, because the air inlet was located at the lower portion of the greenhouse, the relatively cool air tended to accumulate near the floor under gravitational forces. Second, the polycarbonate material at the greenhouse ceiling directly absorbed a portion of the solar radiation, raising its own temperature and consequently creating a high-temperature zone near the roof.

A comparison between **Fig. 7** (1) and (2) revealed that the implementation of wet curtain substantially lowered the temperature in the crop-growing zone near the greenhouse floor. This phenomenon could be attributed to two key factors: (1) As outdoor air flowed through the wet curtain, the evaporation of water could absorb heat from the air, reducing the inlet air temperature below ambient levels. As a result, the air entering the greenhouse possessed an enhanced capacity to extract heat from the interior. (2) As depicted in **Fig. 7** (2), the cool air generated by the wet curtain gradually warmed upon entering the greenhouse. The heated air, driven by buoyancy forces, induced the natural convection beneath the greenhouse arch, as illustrated in **Fig. 9**. Such natural convection accelerates the mixing between the lower and upper regions of the greenhouse, thereby improving the uniformity of the indoor temperature distribution.

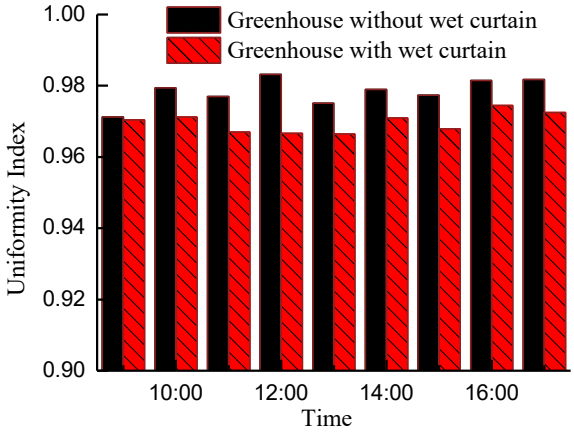

Fig. 8 - Uniformity Index of temperature with times

To better quantify the temperature distribution inside the greenhouse, **Fig. 8** presented the variation of the Uniformity Index of temperature over time.

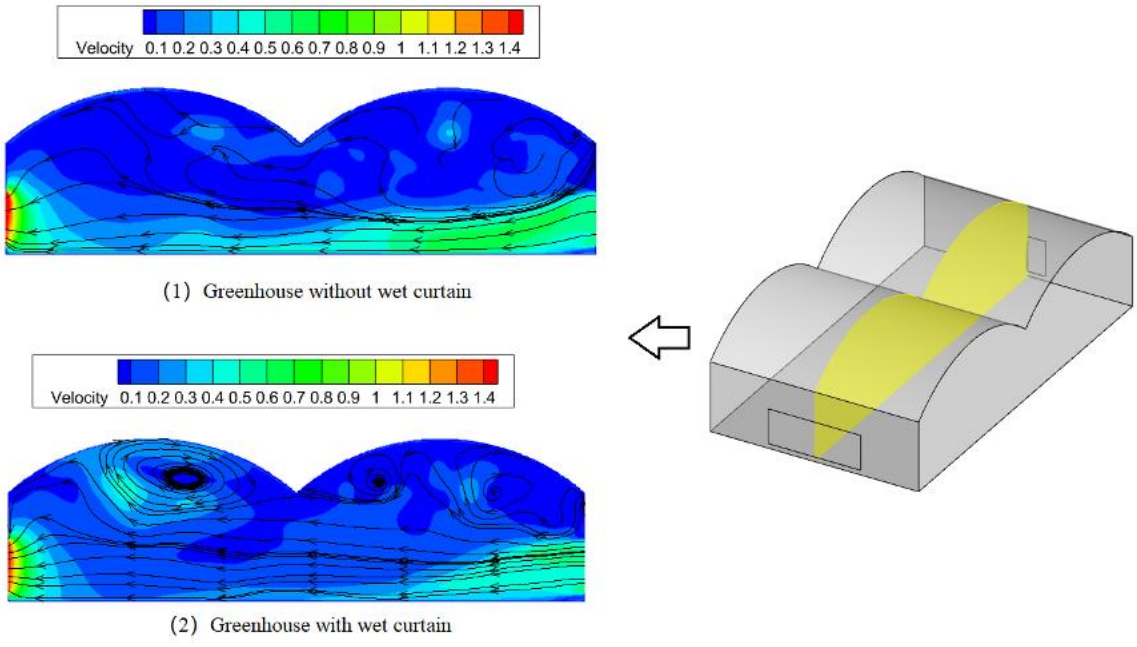

Fig. 9 - Velocity distributions in greenhouse

It could be seen from **Fig. 8**, the uniformity index under both conditions remained above 0.96 between 9:00 and 17:00, with relatively small overall fluctuations. It should be noted, however, that the uniformity index in the greenhouse without a wet curtain was slightly higher than that in the greenhouse with a wet curtain at most time points. Combined with the preceding analysis of temperature gradients, this can be explained by the fact that after the wet curtain system introduces cool air into the greenhouse, a distinct cold–hot interface forms in the horizontal airflow direction, causing a slight statistical decline in the uniformity index that measures the overall spatial distribution. Nevertheless, it is precisely this pronounced horizontal temperature difference that acts as the key driving force for the natural convection described earlier. As pointed out in the text, the cool air gradually warms after entering the greenhouse and rises under buoyancy, effectively accelerating the mixing between the cooler lower zone and the warmer upper zone of the greenhouse.

It could be found from **Fig. 9** (1) and (2) that, introducing wet curtain in greenhouse, the low-temperature air cooled by the wet curtain entered through the air inlet at a relatively high velocity, forming a stable cold air jet. This jet advanced along the ground while tending to accumulate near the greenhouse floor due to its lower temperature and higher density. As the flow developed, the cold air mixed with the warm air within the greenhouse, resulting in the decrease in its density. Under the effect of buoyancy, the warmed air gradually raised, eventually forming an updraft near the greenhouse arch. After reaching the top of the greenhouse, the ascending airflow was redirected by the enclosure. Part of the airflow moved forward and the others reversed, thereby generating two relatively regular large-scale recirculating vortices across the greenhouse cross-section. In contrast, if the greenhouse did not introduce wet curtain, the air inlet temperature was equal to the ambient temperature, resulting in a negligible density difference and weak buoyancy effects. The airflow advanced primarily in the horizontal direction, failing to establish effective vertical stratification or uplift.

Fig. 10 illustrated the temporal variation of the average air velocity in the two greenhouses. It could be seen from Fig. 10 that from 8:00 to 12:00, the average air velocity gradually increased with times, and reached maximum values of 0.16 m/s (without wet curtain) and 0.18 m/s (with wet curtain) at 12:00, respectively. After 12:00, the average air velocity decreased. During the 8:00 ~ 12:00 period, the intensifying solar radiation raised the temperature in the greenhouse, thereby increasing the vertical temperature gradient within the greenhouse and promoting fluid mixing.

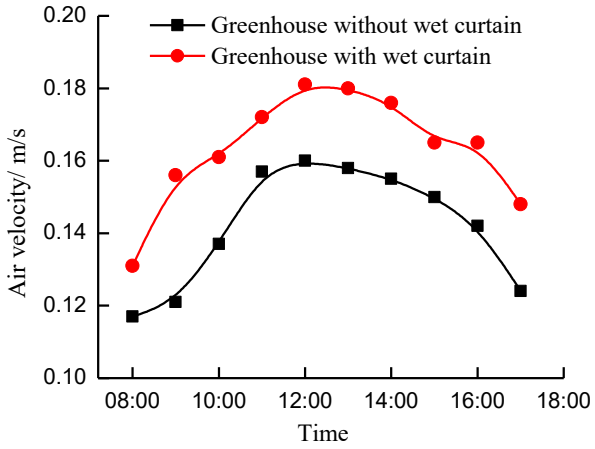

Fig. 10 - Average velocity with times

As also shown in **Fig. 10**, the implementation of pad ventilation enhances indoor air velocity, achieving an increase ranging from 8.38% to 22.40% during the 8:00 ~ 17:00 period.

The effect of the inlet velocity

Fig. 11 illustrated the average temperature in greenhouse for different inlet air velocity at 12:00. As depicted in **Fig. 11**, an increase in inlet velocity led to a gradual decline in the average greenhouse temperature, albeit with a decreasing rate of reduction. When the inlet velocity increased from 0.25 m/s to 0.5 m/s, the average greenhouse temperature decreased from 41.44 ℃ to 37.88 ℃, representing a cooling

rate of 8.59%. In contrast, when the inlet velocity rose from 1.25 m/s to 1.5 m/s, the temperature reduction rate was merely 0.64%.

At low inlet velocities, the residence time of air within the wet curtain was relatively prolonged, allowing sufficient heat and moisture exchange between the air and the water in the wet curtain, thereby enabling substantial cooling. Consequently, an increase in inlet velocity effectively augmented the influx of cooled air into the greenhouse, significantly reducing the average indoor temperature.

However, as the inlet velocity continued to increase, the residence time shortened, and the heat and mass transfer between the water film and the airstream became incomplete, resulting in a diminished decline in outlet air temperature. Moreover, high inlet velocities enhanced the inertial dominance of the cold jet, causing the low-temperature air to traverse the crop zone rapidly without adequate mixing with the warm air in the greenhouse before advancing toward the outlet, thereby compromising the effectiveness of heat exchange. Hence, the reduction in average greenhouse temperature exhibited a nonlinear pattern. A comprehensive analysis of the average greenhouse temperature trends presented in **Fig. 11** indicated that once the inlet velocity exceeded 0.75 m/s, the temperature decline slowed markedly, and the marginal cooling benefit diminished. Accordingly, this study identified an inlet velocity range of 0.75 ~ 1.0 m/s as optimal for pad operation.

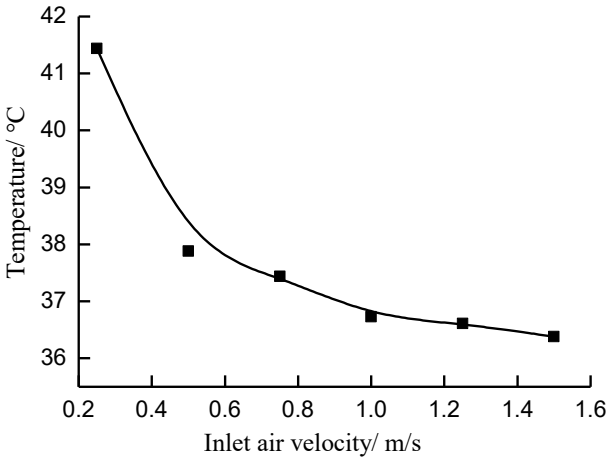

Fig. 11 - Average temperature in greenhouse for different inlet air velocity

CONCLUSIONS

A coupled numerical model of the wet curtain and greenhouse was developed and validated to investigate the mechanisms governing the influence of the wet curtain cooling system on the greenhouse thermal environment in summer. The main conclusions were as follows:

(1) The established mathematical model could accurately describe its cooling processes. The air cold by wet curtain implemented as a boundary condition for greenhouse simulations, the relative deviation between the simulated and measured average greenhouse temperatures was less than 7%, indicating that the established model effectively predicted the thermal performance of the greenhouse with wet curtain.

(2) The cooling performance of the wet curtain pronounced diurnal variation. During the period from 8:00 to 12:00, the temperature difference between the outdoor air and the water in wet curtain increased with intensifying solar radiation, enhancing the driving force for water evaporation and progressively improving cooling efficacy. After 12:00, as solar radiation weakened, the cooling capacity gradually declined. Over a typical day, the pad reduces the average greenhouse temperature by 2.33 ℃ to 4.20 ℃, with the maximum cooling effect occurring at 12:00.

(3) The cold air produced wet curtain could modify the airflow pattern within the greenhouse. Low-temperature air entered through the lower inlet as a jet, accumulated near the crop zone under gravitational forces, and subsequently rose upon heating due to buoyancy, forming two large-scale recirculating vortices across the greenhouse cross-section. This configuration effectively promoted mixing between the upper and lower air layers, resulting in a more uniform temperature distribution. Compared with forced ventilation without pad operation, the pad increased the average air velocity within the greenhouse by 8.38% to 22.40%.

(4) Parametric analysis of inlet velocity revealed that the average greenhouse temperature decreases nonlinearly with increasing inlet velocity, with the rate of reduction gradually slowing. Once the inlet velocity

exceeded 0.75 m/s, the marginal cooling benefit declined significantly. An inlet velocity in the range of 0.75 ~ 1.0 m/s was recommended.

ABSTRACT

Driven by global agricultural mechanization and green low-carbon transformation, hybrid tractors have become a key focus in agricultural machinery competition due to fuel economy and operational adaptability. Using literature review and comparative analysis, this paper summarizes global and domestic technological development and characteristics of typical models. It analyzes three core power topological structures, compares energy configurations and management strategies, clarifies applicable scenarios and pros and cons of different routes, and points out bottlenecks in power coupling, energy storage and control, as well as industrial dilemmas like high costs and poor supporting facilities.

摘要

在全球农业机械化与绿色低碳转型的双重驱动下，混合动力拖拉机凭借其燃油经济性与作业适应性优势，成为全球农机技术竞争的焦点。为厘清混合动力拖拉机关键技术的发展现状与现存问题，为该领域技术的进一步优化和规模化推广提供参考，本文采用文献梳理与对比分析的方法，系统归纳了该领域国内外技术发展格局与代表机型技术特征，深入剖析了三类核心动力拓扑结构的工作原理与性能差异，对比了不同能量源配置方案、能量管理策略的应用效果与验证方法。研究明确了各类技术路线的适用场景与优劣势，指出了当前该领域在动力耦合、储能系统、控制策略方面的研发瓶颈，以及成本、配套设施等产业化应用难题。

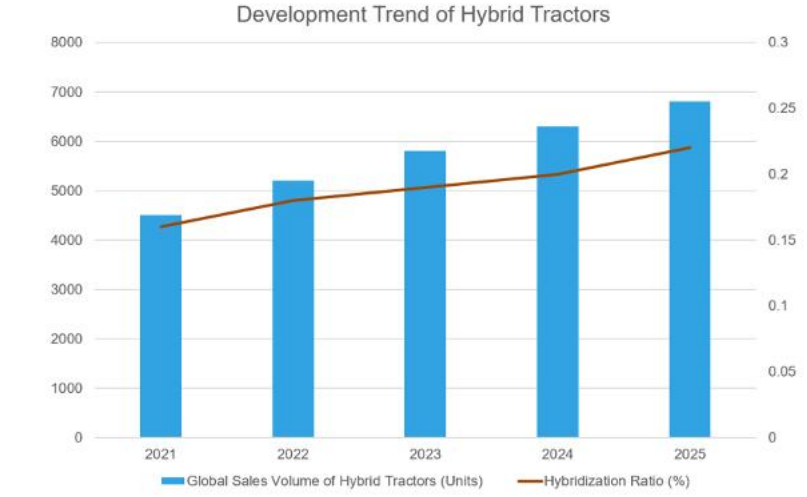
INTRODUCTION

Currently, global agriculture is transforming toward industrial model upgrading and sustainable development, and the problems of high emissions and high energy consumption commonly existing in traditional agricultural machinery have become increasingly prominent. As the core power equipment in agricultural production, the energy consumption control and emission management of tractors have become critical to industrial development. Pure electric tractors are limited by shortcomings such as insufficient horsepower, short endurance and operating time, and poor environmental adaptability, and it will take time to overcome these problems. Against this background, hybrid tractors, which integrate traditional fuel power and electric power and realize collaborative energy distribution through a power coupling system, have become a key transitional technology. With remarkable effects on energy conservation and emission reduction as well as great potential for improving operational efficiency, they also represent an important direction for the iterative upgrading of agricultural machinery and equipment. Policies from various countries have gradually increased support. China's 14th Five-Year Plan clearly includes high-end intelligent and new energy agricultural machinery in key supported areas, creating a favorable environment for the technical research and development and industrialization of hybrid tractors (*Yin et al., 2025*).

At present, the technology of hybrid tractors has formed a diversified pattern with three mainstream technical routes, namely series hybrid, parallel hybrid and series-parallel hybrid, developing in parallel. Meanwhile, energy management strategies have gradually evolved from rule-based control to optimization algorithms and intelligent strategies, which has become a current research hotspot. Nevertheless, this field still faces core controversial issues and technical bottlenecks as follows: the low collaborative efficiency of the power coupling system restricts the performance improvement of the whole machine.

The excessively high cost of power batteries leads to the high price of the complete machine, affecting its market promotion; energy management strategies are highly complex and difficult to adapt to diverse operating scenarios, and their stability and reliability need to be further enhanced. These problems jointly hinder the industrialization process of hybrid tractors, and further exploration in technological breakthroughs and path optimization is required to realize their large-scale application (*Li, 2026*). Current reviews of hybrid tractors only discuss individual technologies (topology or energy management) without systematic comparisons across the full technical chain: topology, coupling, components, strategies and configurations. Most reviews focus on regional research rather than establishing a global framework covering European, North American and Asian technical routes, and seldom summarize core debates and industrial limitations from practical engineering cases.

This paper reviews global advances in hybrid tractor technologies, compares three typical topologies and various energy management schemes, identifies industrialization barriers and technical disputes, and predicts future trends to offer systematic support for further research and engineering implementation.



The objective of this review is to systematically analyze the technical routes, key bottlenecks, and development trends of hybrid tractors, aiming to provide a reference for their performance optimization and industrial promotion.

Development Background and Driving Forces

Agricultural machinery, as an important part of non-road mobile machinery, has attracted increasing attention concerning its emission problems. Traditional agricultural tractors are usually equipped with oversized diesel engines and emit large quantities of pollutants and carbon dioxide during field operation. Studies have shown that agricultural machinery and equipment are among the major contributors to emissions in the agricultural sector. This situation runs counter to the trend of global sustainable development, prompting various countries to pursue more environmentally friendly power solutions for agricultural applications **Error! Reference source not found.**.

Policy-driven support serves as a critical impetus for the development of hybrid tractors. The key special project on Key Technologies for Factory Agriculture and Intelligent Agricultural Machinery Equipment implemented under China's 14th Five-Year Plan has accelerated the research, development and industrial application of high-end intelligent agricultural power equipment. The Agricultural Mechanization Station of the Ministry of Agriculture and Rural Affairs has provided clear directional guidance for the industry by organizing technical seminars on the test and appraisal of power machinery, focusing on technological innovation and test certification of new energy agricultural machinery and equipment. The field trials and verification of new energy and high-end intelligent tractors carried out in Tacheng, Xinjiang in 2025 systematically assessed key indicators including product reliability and operating efficiency, providing an important basis for technological optimization and industrialization of such equipment **Error! Reference source not found.**.

Market demand is also a key factor in the development of hybrid tractors. With the increase in the number of large-scale farms, the demand for hybrid tractors—agricultural machinery featuring high efficiency and low operating costs—is growing steadily, as shown in Figure 1 and Figure 2.

Data sources: Market reports on hybrid tractors from 2021 to 2025 by authoritative institutions such as Global Info Research, Market Research Future, and QYResearch, compiled through cross-validation.

Fig. 1 - Development Trends of Hybrid Tractors

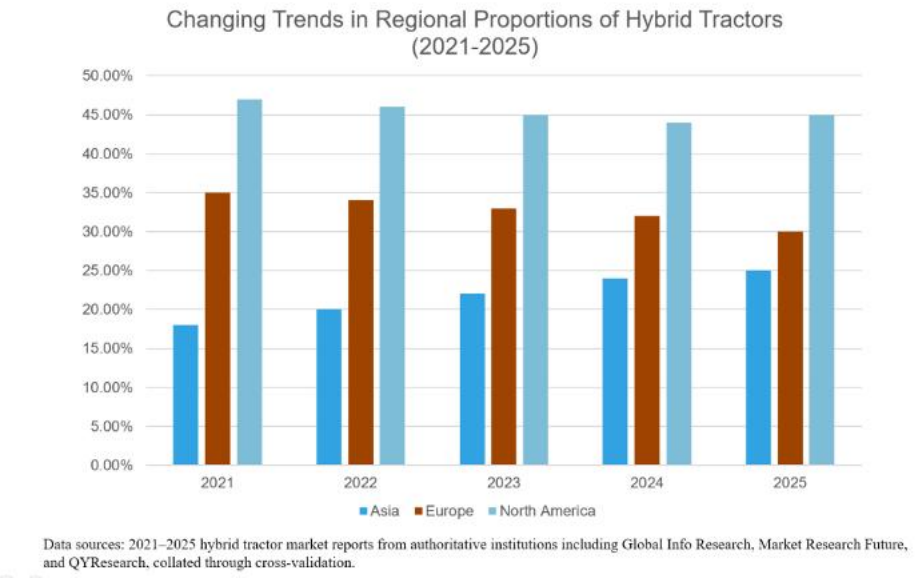


Fig. 2 - Trend of Regional Proportion Change of Hybrid Tractors

Taking the world's largest hybrid wheeled tractor launched by Zoomlion as an example, it is specially designed for high-intensity and high-efficiency operations in ultra-large-scale farms. It can achieve a continuous operating area of 7,200 mu within 12 hours, with a 15% improvement in operating efficiency and a 10% reduction in fuel consumption. Such remarkable performance advantages endow it with strong competitiveness in the international market. This high-quality agricultural machinery equipped with cutting-edge technology can effectively solve the pain points of modern agriculture (*Han, 2023*).

Development History

Since the 19th century, the development of hybrid tractors has gradually realized the leap from conceptual prototype to commercial explosion, as shown in Table 1. From the hybrid system combining steam and internal combustion engines, to the research and development of modern hybrid technologies, and then to the formation of a multi-architecture product matrix, it indicates that hybrid power technology has become increasingly mature (*Niu, 2025; Wen et al., 2025*).

Table 1

The Development History of Hybrid Tractors

Stage	Time Range	Core Progress	Representative Events
Technical Embryonic Stage	1970s–1999	Integration of steam and internal combustion engines, accumulation of hydraulic transmission technology.	1970s: US initiated research on hybrid power for construction and agricultural machinery; 1997: John Deere launched the world's first hybrid tractor prototype.
Exploration Stage	2000-2016	European and American enterprises launched research and development of modern hybrid power technology.	India's ITL launched commercial prototypes.
Independent Innovation Stage	2017-2024	Domestic enterprises broke through core technologies and broke the foreign monopoly.	Yuchai IE-POWER powertrain was implemented; LiuGong 350 hp-class hybrid models were mass-produced.
Commercial Explosion Stage	From 2025	Formation of a multi-architecture product matrix and implementation of policy subsidies.	Zoomlion series-parallel hybrid models were mass-produced; special subsidies were implemented in Jiangsu and other regions.

Stage Achievements

A number of iconic prototype models have emerged in the field of hybrid tractors at present, with major breakthroughs achieved in core performance. A collaborative development pattern of multiple configurations has been formed, and a complete industrial ecosystem centered on "configuration innovation — control optimization — independent component development — standard support" has been gradually built, driving the industry to achieve leapfrog development.

Hybrid configurations have become the mainstream direction for heavy-duty hybrid tractor models. The hydraulic-electric hybrid configuration based on HMCVT (Hydromechanical Continuously Variable Transmission) enables efficient power transmission. HMCVT transmits power in parallel through dual flows, namely the hydraulic branch and the mechanical branch, and its overall efficiency depends on the synergistic cooperation between the two branches. The hydraulic branch, i.e., the pump-motor system, features relatively low efficiency (generally 60% to 80%), while the mechanical branch boasts high efficiency (up to over 95%). The overall transmission efficiency of the system is improved by optimizing the power split ratio between the two branches *(Wang, 2018; Xu et al., 2012*).

Currently, a virtuous cycle has taken shape among policy subsidies, technological R&D, production and manufacturing, and market application, laying a solid foundation for the sustainable development of the hybrid tractor industry. It has driven the sector to achieve leapfrog development, gradually shifting from "foreign technological monopoly" to "domestic independent innovation" and from "single-point demonstration application" to "full scenario coverage".

Research Progress Abroad

Research progress on hybrid tractors varies in different regions abroad, with characteristic technical routes formed in accordance with local farming scenarios, accompanied by high technical maturity and industrialization levels.

North America focuses on high-horsepower models, with power-split hybrid technology as the core, featuring mature commercialization and comprehensive experimental data, which are suitable for large-scale farming. As shown in Figure 3(a), studies on the American John Deere 8R 410 Hybrid series-parallel power-split tractor demonstrate that control strategies such as MPC are adopted to improve energy efficiency. The Case NH Puma Hybrid series has a rated power of 250 kW and a comprehensive fuel-saving rate of 24%, and has been put into large-scale batch production (*Zhou et al., 2024; Wang et al., 2025*).

In Europe, plug-in hybrid technology serves as the core, with emphasis on multi-energy coupling to adapt to diverse low-carbon operating scenarios. As shown in Figure 3(b), the Italian Antonio Carraro SRX Hybrid, a parallel-torque-coupled hybrid tractor, integrates a 55 kW Stage 5 internal combustion engine and a 20 kW electric motor. It supports multiple operating modes including pure electric, hybrid, energy recovery, and power assist, and features a compact articulated narrow body for flexible orchard operations. It combines the advantages of fuel saving and low emissions, and is also integrated with an Industry 4.0 intelligent control system to achieve high efficiency, environmental protection, and operational stability. In 2019, Germany's Fendt launched the X concept series, a series hybrid tractor without energy storage devices, as illustrated in Figure 3(c). Figure 3(d) presents the series-parallel hybrid topology adopted by Austria's STEYR, with a peak power of 250 kW. This model achieves a maximum gradeability of 35° and a fuel saving rate of 25% in tests conducted in the Alpine region. Relevant studies also indicate that control strategies such as MPC are employed (*Wang, 2024; Varlese et al., 2025*).

Relying on their technological advantages in small and medium-horsepower models, Japan and South Korea focus on research and development in this field, promoting the integration of electrification and intelligence to adapt to small-scale and refined farming operations. Some scholars have carried out relevant experimental verifications, laying a foundation for industrialization (*Xu, 2021*).

Research Progress in China

In recent years, the hybrid tractor industry in China has developed rapidly. A number of leading enterprises, including China YTO Group Corporation, Yuchai Group and Zoomlion Heavy Industry, have launched a variety of innovative products suitable for different scenarios, achieving breakthroughs in high-horsepower models, small and medium-sized facility horticulture models and other fields. For example, more than 20 types of power equipment were displayed at the on-site demonstration of high-end intelligent agricultural power equipment held in Yangling, Shaanxi Province in 2025, highlighting the progress of China in this field.

As a leading enterprise in China's agricultural machinery industry, China YTO Group launched the Dongfanghong HB 2204 series hybrid tractor in 2022, which is equipped with a 161.7 kW China IV diesel engine and an Electric Continuously Variable Transmission (E-CVT) system, with a localization rate of over 85%. Field tests conducted in the corn planting area of Zhoukou, Henan Province show that this model has a plowing fuel consumption of 15.2 L/h, which is 23% lower than that of traditional tractors, an operating efficiency of 6.5 hectares per hour, and a brake energy recovery efficiency of 18% (Anon., 2023). Yuchai Group boasts mature powertrain technology. As shown in Figure 3(e), the IE-POWER series hybrid powertrain released in 2021 consists of an engine, a generator, a drive motor and an electric-shift gearbox, suitable for tractors with 200–260 horsepower. Applications in the sugarcane planting areas of Guangxi show that this powertrain reduces the comprehensive fuel consumption of tractors by 10%-30%, and decreases the failure rate by 5%-30% compared with traditional transmission systems (*Anonymous, 2022*).

(i) ZOOMLION Hybrid Wheeled Tractor (Series-Parallel Hybrid Configuration, 2025)

Fig. 3 - Typical hybrid electric tractor products worldwide

SDLG Agricultural Machinery adopts the power-split technical route. Studies have shown that power-split technology transmits power through the parallel combination of hydraulic and mechanical systems, which can significantly improve transmission efficiency. Especially under medium and low-speed working conditions such as plowing, the hydraulic power split ratio can be lower than 20%, with a high proportion of mechanical transmission, and the efficiency is close to that of pure mechanical transmission (*Li et al., 2026*). In vegetable greenhouse operations in Shouguang, Shandong Province, this model features a turning radius of only 1.8 m, a gradeability of 25°, reduces comprehensive fuel consumption by 28% compared with conventional models, and is equipped with an electric output function to adapt to various agricultural implements. Zoomlion focuses on small and medium-sized hybrid tractors.

The CA504ET distributed drive model launched in 2023 has a power of 74.6 kW, adopts wheel motor differential steering with a turning radius of less than 1.5 m, and supports 1-hour fast charging. In tea planting operations in the hilly areas of Hunan Province, this model achieves a pure electric driving range of 80 km and a comprehensive energy-saving rate of 22%, making it the first facility horticulture hybrid tractor practically promoted in China (*Zhang et al., 2003*).

In addition, as shown in Figure 3(f), the 300-horsepower "Honghu" T300 pure electric intelligent tractor launched by the Chinese Academy of Sciences in 2022 is customized for black soil farmland. It adopts a pure electric drive configuration without internal combustion engine and hybrid energy storage system, achieving high efficiency and stability in power output. This design optimizes energy utilization through the hybrid power system and significantly improves continuous operation capacity, with a single operation duration of up to 10 hours and an operation efficiency of 12 hectares per hour, representing an efficiency improvement of approximately 30% compared with traditional models. This indicates that China has joined the ranks of international advanced levels in the field of high-power pure electric intelligent tractors (*Ren et al., 2022*).

Notably, although some domestic models have achieved a high localization rate, China still has weak independent research and development capabilities for high-end core components, whose performance indicators lag behind international advanced levels, leading to high import dependence. This has become the primary bottleneck restricting the development of the industry. The constraints are mainly concentrated in core modules of high-end Electric Continuously Variable Transmission (E-CVT), high-performance motor controllers, special sensors and other fields (*Mocera, 2020*). Compared with the independently developed CVT gearboxes of international brands with a transmission efficiency of over 95%, domestically produced E-CVT gearboxes in China still have gaps in transmission efficiency, load-bearing capacity and service life. Problems such as wear and shift shock are more likely to occur under long-term high-load operation. For high-horsepower models, the permanent magnet synchronous motors independently developed in China are inferior to international counterparts in terms of power density and heat dissipation performance. In addition, the insufficient precision manufacturing level of core components and the poor quality stability of basic parts such as high-end bearings and seals also contribute to the performance gaps (*Wu, 2019; Huang et al., 2025*).

On the other hand, compared with the intelligent optimization algorithms widely adopted internationally, such as Model Predictive Control (MPC) and Equivalent Consumption Minimization Strategy (ECMS), most enterprises in China still apply simple logic threshold control strategies, which can only realize basic power mode switching and fail to optimize energy flow distribution in real time according to load fluctuations and varying operating scenarios in field farming (*Qiu, 2026*). For example, although the Zoomlion CA504ET model has achieved breakthroughs in pure electric range and comprehensive energy-saving rate during tea planting operations in the hilly areas of Hunan Province, the energy switching response lags under sudden load changes, resulting in partial energy waste.

Horizontal Comparison of Technical Routes for Hybrid Tractors Worldwide

As shown in Table 2, the differences in the technological development of hybrid tractors worldwide are not prominent, and several key distinctions mainly originate from variations in technological accumulation, industrial foundations, and market demands. Foreign manufacturers focus on the optimization of power-split series-parallel hybrid technology, which is adaptable to multiple horsepower ranges and operating scenarios with mature industrialization. Series, parallel, and series-parallel configurations each have their own emphases and are suitable for regional application scenarios, among which the series-parallel configuration acts as the core technology with extensive coverage of application scenarios.

The domestic technical route emphasizes practicality and presents a diversified development trend. Series and extended-range configurations represent the mainstream, parallel configurations have achieved gradual breakthroughs, and series-parallel configurations remain in the research and development (R&D) and pilot stage. Series configurations are widely applied, parallel configurations are dedicated to refined agricultural operations, and the core technologies of series-parallel configurations rely on imports, failing to realize large-scale industrialization.

In terms of energy sources, foreign countries feature a diversified pattern, with lithium-ion batteries as the primary energy source and composite energy storage as the auxiliary; new energy sources such as hydrogen fuel have already been industrialized. In China, lithium-ion batteries are the absolute mainstream, composite energy storage is in pilot application, and hydrogen fuel is still in the R&D and demonstration stage (*Hu et al., 2025*).

In terms of intelligence, foreign countries have formed a complete intelligent operation system. Combined with technologies such as intelligent algorithms and autonomous navigation, adaptive operating conditions and full life cycle management have been realized. In contrast, China is still in the basic stage, with core focus on navigation and simple operating condition switching, poor system coordination, and lack of full life cycle management functions.

At the supply chain level, foreign countries have an extremely high localization rate of core components and a complete supply chain. In China, the localization of medium and low-end components is mature, while high-end components rely on imports, resulting in polarized cost control. Overall, foreign countries focus on high-end and diversified intelligence, while China emphasizes practicality and economy. With technological breakthroughs and the improvement of the industrial chain in the future, the gap is gradually narrowing (*Yu, 2022*).

Table 2

Horizontal Comparison of Technical Routes for Hybrid Tractors Worldwide

Comparison Dimension	Foreign Status	Domestic Status	Core Differences
Topology Configuration	Dominated by series-parallel (power-split) configuration;	Dominated by series/extended-range configuration; series-parallel configuration is in pilot stage	Foreign countries focus on high-end development; China focuses on practicality
Energy Source	Mature industrialization application of Lithium-ion battery + hybrid energy storage + hydrogen fuel	Lithium-ion battery as the main energy source, hybrid energy storage in pilot application; hydrogen fuel in R&D stage	Diversified energy sources abroad; single energy type in China
Intelligence Level	MPC/ECMS algorithms + autonomous navigation + remote diagnosis	Basic navigation + logic threshold control	Mature system collaboration abroad; domestic intelligence at basic stage
Localization Rate of Core Components	Localization rate of core components ≥ 95%	Independent production for medium and low-end components; 15%–30% of high-end components imported	Complete supply chain abroad; domestic high-end components rely on imports

Multi-Energy Coupling Mechanism

The multi-energy coupling mechanism serves as the foundation of a hybrid power system. Its core function is to coordinate, superpose, or distribute the power from different sources such as the engine and drive motor. Through three core coupling modes, it adapts to the varying load demands of tractors in different operations, ensuring smooth and efficient power output while maximizing energy utilization. The three coupling modes have clear divisions of labor and different applicable scenarios. There is no absolute superiority or inferiority among them, as all are designed to balance the overall power performance and energy efficiency of the tractor.

Power coupling is the most commonly used coupling mode. Its core logic is to superpose or distribute the output power of the engine and the drive motor, and dynamically allocate the power proportion of the two power sources according to the operating load, so as to avoid overload or inefficient operation of a single power source. The core equation is as follows:

$$P_{total} = P_{engine} \pm P_{motor} \text{ or } \tau_{output} = \tau_1 + \tau_2 \quad (1)$$

where: P_{total} is the total output power of the hybrid power system [kW];P_{engine} is the output power of the internal combustion engine [kW]; P_{motor} is the output power of the drive motor [kW]; τ_{output} is the total output torque of the hybrid power system [N·m]; τ_1 is the output torque of the internal combustion engine [N·m]; τ_2 is the output torque of the drive motor [N·m].

Its working process does not require strict synchronization of the rotational speed and torque of the power sources; power coordination is only realized through the coupling device, making it suitable for scenarios with large load fluctuations (*Wang et al., 2026*).

Speed coupling mechanisms typically employ planetary gears, differentials, or dedicated transmission devices to synthesize the speeds of the engine and motor in a fixed ratio, enabling continuously variable transmission or power splitting. In a study by Zuo Tiantian et al., Lagrange equations and dynamic models were established to analyze the differential transmission characteristics of the power coupling device for hybrid

tractors, verifying the effectiveness of speed coupling mechanisms in coordinating the speeds of different power sources (*Zuo et al., 2013*). Deng Xiaoting (*Deng, 2012; Deng et al., 2026*) and his colleagues designed a test bench for parallel hybrid electric tractors. Torque and speed sensors were used to monitor the speed difference between the engine and the motor in real time, and the coupling device was adopted to realize dynamic matching, which significantly improved the transmission efficiency.

Torque coupling directly superimposes the output torque of the engine and the drive motor and transmits it to the drive wheels through a coupling device. Its core advantage is fast dynamic response, making it suitable for scenarios requiring instant high torque such as slope climbing and heavy-load starting (*Wang et al., 2026*). Its working principle is that the torques of the two power sources are directly superimposed through gear meshing, clutches and other structures, without complicated speed coordination, enabling rapid output of high torque and improving the overall power performance. Torque coupling technology resolves the contradiction between instantaneous high-torque demand and system energy efficiency through efficient coordination of multiple power sources. Future research can further explore the dynamic response optimization of electromagnetic couplers, torque distribution strategies for hybrid energy systems, and thermal management schemes for high-power-density motors (*Dong, 2026*).

Power Mode Switching Logic

Power mode switching logic serves as the control center of a hybrid power system. Its core function is to automatically or manually switch among the four primary power modes based on real-time parameters such as tractor operating conditions, load magnitude, and energy storage status, so as to realize “on-demand energy supply” and maximize energy-saving effects and operational efficiency. The switching process is smooth without power interruption, adapting to the complex operating environment in farmland. Currently, the four core power modes are: pure electric drive mode; hybrid drive mode; regenerative braking mode; and idle stop mode. The specific trigger conditions and operating states are shown in Figure 4.

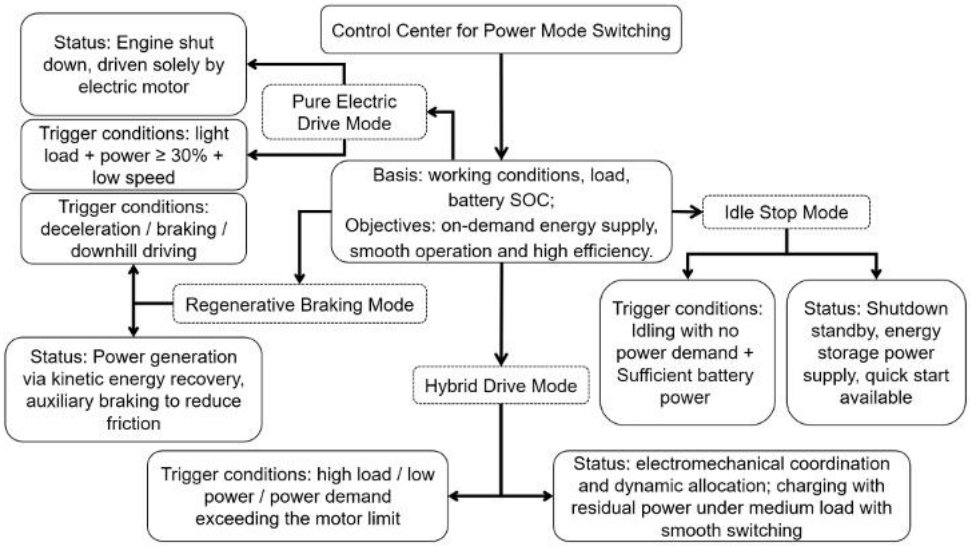

Fig. 4 - Block Diagram of Power Mode Switching Conditions and Operating States

Dynamic Regulation Principle of Energy Flow

The dynamic regulation principle of energy flow is the core of energy saving in hybrid power systems. It focuses on establishing a closed-loop mechanism of "energy recovery–storage–reuse". Through an intelligent control system, it monitors the generation, consumption and storage status of energy in real time, recovers and stores otherwise wasted energy, and redistributes it according to operational requirements, thus maximizing energy utilization efficiency.

Energy recovery marks the starting point of the closed-loop mechanism. Its core is to capture redundant energy generated during tractor operation and convert it into storable and utilizable electric energy, which mainly includes two types of recovery scenarios. The first is braking energy recovery, corresponding to the regenerative braking mode mentioned earlier. When the tractor decelerates, brakes or travels downhill, the motor operates in reverse, converting the kinetic energy of the whole machine into electric energy. The energy flow path is: Kinetic energy → Motor (generator mode) → Electric energy → Energy storage device. This is the primary scenario for energy recovery (*Wang et al., 2023*). The second is excess engine power recovery.

When the tractor operates under medium load, the engine maintains a high-efficiency speed range, and the part of output power exceeding the operational demand drives the generator to produce electricity, recovering the excess power and avoiding energy waste.

Energy storage acts as the core hub of the closed-loop mechanism. Its key lies in classified storage via different energy storage devices according to energy characteristics, balancing the requirements of "short-term rapid storage" and "long-term stable power supply". The mainstream storage scheme adopts a hybrid energy storage system of "hydraulic accumulator + power battery", and some high-end models are equipped with supercapacitors. Among them, hydraulic accumulators focus on short-term rapid energy storage and release, mainly storing the instantaneous large amount of energy generated during braking with fast response speed, which can quickly provide auxiliary power for high-load operations (*Wang et al., 2026*). Power batteries focus on long-term stable storage, storing electric energy recovered from excess engine power and braking, ensuring power supply for pure electric drive mode and auxiliary equipment. Supercapacitors are used for supplementary storage to improve the response speed of energy recovery and release, adapting to scenarios with frequent load fluctuations (*Ren et al., 2018*).

Energy reuse is the final stage of the closed-loop mechanism. Its core lies in rationally distributing the stored electric energy to various power components through an intelligent energy regulation system according to the real-time operational demands of the tractor, thereby achieving efficient energy utilization. It specifically includes three application scenarios:

First, driving energy supply. The stored electric energy is converted into power via the drive motor to assist the engine or independently provide power for the tractor's travel and operation, adapting to pure electric drive and hybrid drive modes.

Second, auxiliary energy supply. It supplies power to auxiliary components such as the whole-machine control system, hydraulic system, and navigation equipment, reducing energy loss caused by the engine driving the generator for power supply.

Third, emergency energy supply. When the engine malfunctions or the energy storage device has sufficient power, the pure electric drive mode can be used to complete emergency operations or field transfer, avoiding delays to the work progress (*Li et al., 2024*).

In summary, the core operating logic of a hybrid power system is as follows: it achieves power coordination through the multi-energy coupling mechanism, adapts to different operating scenarios relying on flexible power mode switching logic, and maximizes energy utilization efficiency via the closed-loop energy regulation of "recovery-storage-reuse". This ultimately fulfills the dual goals of energy conservation, consumption reduction and power performance enhancement, meeting the diverse and complex field operation demands of hybrid tractors.

Typical Structures and Extensions

The series hybrid topology, also known as the electrically coupled hybrid system, is characterized as shown in Figure 5.

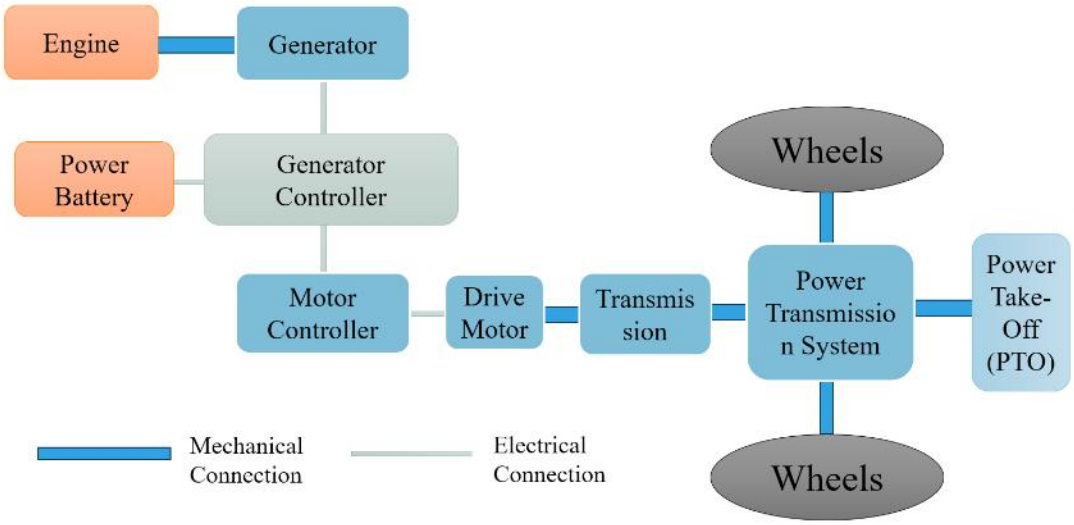

Fig. 5 - Topology Diagram of Series Hybrid Tractor Power System

There is no mechanical connection between the engine and the drive wheels; the engine directly drives the generator to produce electricity, and the electric energy is converted into mechanical energy by the motor to drive the wheels. The advantage of this structure is that the engine can always operate in its high-efficiency range regardless of actual driving conditions, thus significantly improving fuel economy. Another merit of the series configuration is the simplified transmission system. However, since energy undergoes two conversions (mechanical energy → electric energy → mechanical energy), efficiency losses may occur under certain operating conditions. Therefore, this structure is particularly suitable for working scenarios with large load fluctuations and frequent start-stop operations (*Wen et al., 2025; Luo, 2025; Lu et al., 2017*).

The parallel hybrid topology is characterized by the fact that both the engine and the motor can directly drive the wheels, with a mechanical coupling relationship between them. This structure offers the advantage of a more direct energy transfer path, avoiding losses caused by multiple conversions, resulting in higher energy efficiency especially under high-speed and steady working conditions. Parallel hybrid tractors show significant potential in energy optimal control (*Wang et al., 2020*).

Figure 6 shows a torque-coupled parallel hybrid configuration. Mechanical power from the diesel engine and power from the electric motor supplied by the power battery are combined via a torque coupler, then transmitted to the rear wheels through the transmission and final drive. Meanwhile, the transmission is also connected to the PTO, enabling independent output of working power to realize coordinated power supply for both driving and field operations.

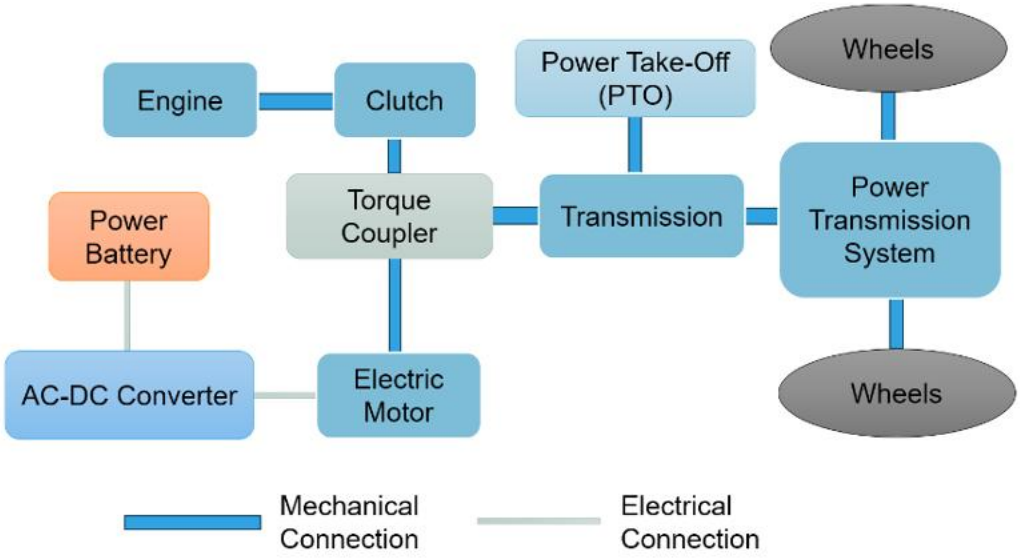

Fig. 6 - Schematic Diagram of Torque-Coupling Parallel Hybrid Powertrain Configuration

Figure 8 shows the power-split series-parallel hybrid topology, which combines the characteristics of series and parallel configurations. It can not only decouple the engine from the drive wheels, but also retain a direct mechanical drive path, enabling more flexible energy flow. This structure typically realizes power splitting via a planetary gear mechanism or complex transmission device, yet also introduces challenges of structural complexity and higher cost. Among series-parallel layouts, the planetary gear-based electric continuously variable transmission (ECVT) has become a research focus due to its multi-node and multi-power-source arrangement. ECVT often adopts a dual or triple planetary row configuration, and realizes multiple operating modes through the combination of actuators such as clutches and brakes.

For instance, in Tan Mengqi's research on the energy management strategy of a dual planetary row hybrid system, the dual planetary row hybrid powertrain was systematically designed using the equivalent tree graph method. Its tree graph representation is shown in Figure 7(a).

The configuration mainly consists of an engine (E), two motors (MG1, MG2), two planetary gear sets (S1, C1, R1) and (S2, C2, R2), two brakes (B1, B2), and three clutches (CL1, CL2, CL3), with its structural diagram shown in Figure 7(b) (*Tan, 2025*).

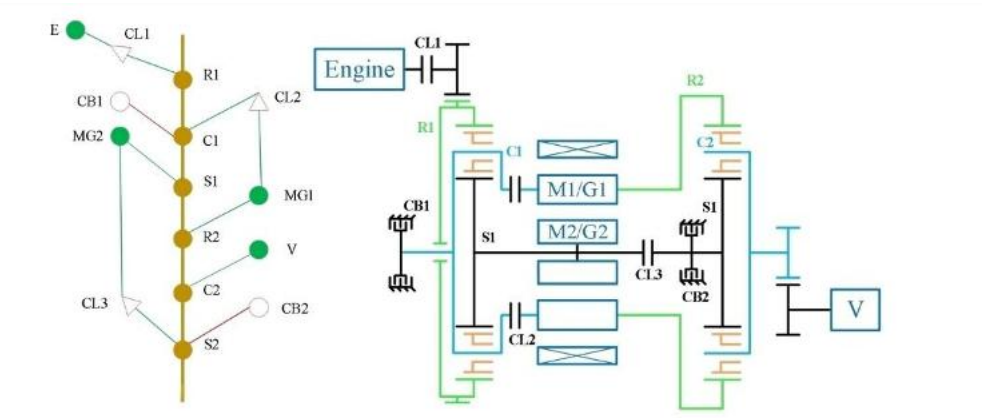

Fig. 7 - Schematic of Dual Planetary Gear Hybrid Powertrain (*Tan, 2025*)

The advantage of the series-parallel hybrid structure lies in its ability to intelligently select the optimal operating mode according to different working conditions. Under low-speed and heavy-load conditions, the system can adopt series mode to ensure the engine operates in its high-efficiency range. Under high-speed and steady working conditions, it can switch to parallel mode or direct mechanical drive mode to reduce the number of energy conversions. Under heavy-load conditions such as rapid acceleration or climbing, the engine and motor can output power simultaneously to provide maximum driving capability *(Yan, 2023)*.

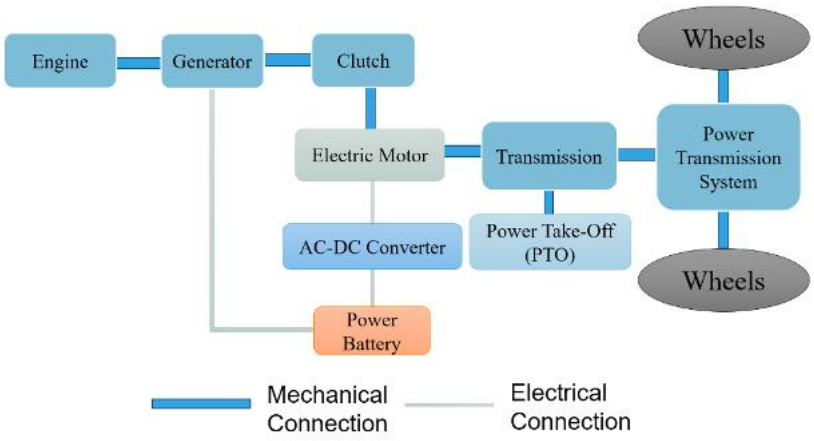

Fig. 8 - Series-Parallel Hybrid Drive Schematic

Extended topologies are optimized and extended hybrid forms based on series, parallel and series-parallel basic configurations, combined with the requirements of operating scenarios and energy-saving goals. They mainly fall into two categories: range-extended hybrid and plug-in hybrid. Both adopt the principle of "electric drive as the main, fuel as the auxiliary", but differ significantly in power transmission, energy replenishment methods and scenario adaptability. They are the mainstream extended directions for the industrial promotion of current hybrid tractors, suitable for farming conditions and infrastructure levels in different regions (*Zhao et al., 2018*).

The configuration innovation and technological extension of hybrid tractors mainly center on three core objectives, namely energy conservation and efficiency enhancement, scenario adaptability, and cost optimization. On the basis of basic topologies and extended topologies, and in combination with emerging energy storage technologies, intelligent technologies and actual field operation demands, the diversified upgrading of power configurations and cross-border extension of core technologies are realized. Meanwhile, such innovation and extension make up for the inherent shortcomings of conventional configurations, promoting the development of hybrid power systems toward high-end, diversified and adaptive trends while balancing technological advancement and engineering feasibility. Furthermore, technological extension should cover the independent localization of core components. Domestic enterprises have gradually broken through the technical bottlenecks of key components such as high-end CVT gearboxes and high-performance motor controllers, promoted the collaborative matching between core components and hybrid power configurations, and continuously reduced the dependence on imported key parts.

Performance Comparison

Based on relevant domestic and international research data, field test results of benchmark models and simulation analysis conclusions, three typical hybrid power topologies, namely the power-split type, series type and series-parallel type, present significant differences in four core dimensions: power performance, fuel economy, emission characteristics, and reliability and maintainability, making them adaptable to different operating scenarios and application demands. The performance differences, main advantages and disadvantages of the three topologies are shown in Table 3 and Table 4. In terms of comprehensive performance comparison, different hybrid power technical routes show distinct characteristics. For fuel economy, the power-split topology achieves the optimal performance, with a fuel consumption rate as low as 10.8 L/h during tillage operations and an energy-saving rate of 32%; the series topology has prominent advantages in low-speed operations, with a fuel consumption rate of 15.2 L/h during seeding operations and an energy-saving rate of 23%; the series-parallel topology features excellent multi-condition adaptability, with a comprehensive energy-saving rate of up to 28%. In terms of power performance, the series-parallel topology holds remarkable advantages: the maximum gradeability of series-parallel models can reach 35°, and the power response time is only 0.2 s, making it particularly suitable for complex hilly terrains; the power-split topology ranks second, with a power split efficiency exceeding 90% in some models and a 15% improvement in acceleration performance; while the power output of the series topology is 10% to 15% lower than that of the series-parallel topology under high-load operations. In terms of cost and reliability, the assembly price of the series topology is about 30% lower than that of the series-parallel topology, and the failure rate is reduced by 40%; the power-split topology has a 20% lower maintenance cost than the series-parallel topology due to its moderate structural complexity; the series-parallel topology has a relatively high control system failure rate owing to multi-mode switching requirements, and the failure probability of the coupling device reaches 8% after 1000 hours of continuous operation (*Tong, 2025; Liu et al., 2018; Liu et al., 2025*). Hybrid tractor schemes rely on industry, supply chains and markets instead of mere performance. Series topology suits domestic mass production for low R&D costs. Power-split series-parallel types excel in Western high-power tractors. For hilly and greenhouse farms, simple series/parallel structures are more cost-effective.

Table 3

Comparison of Performance Indicators for Different Hybrid Powertrain Configurations

Performance Indicators	Series Type	Power-Split Type	Series-Parallel Type
Fuel consumption rate (L/h, plowing condition)	15.2~18.0	10.5~12.8	12.0~14.5
Energy-saving rate (compared with conventional models)	20%~30%	25%~35%	22%~32%
Power response time (s)	0.2~0.4	0.1~0.2	0.15~0.3
Maximum gradeability (°)	25~30	30~35	32~38
Structural complexity	Low	Medium	High
Manufacturing cost (relative value)	1.0	1.3~1.5	1.4~1.6
Battery capacity requirement (kWh)	20~40	15~25	25~50
Applicable operating conditions	Long-term operation at low speeds	Continuous operation at medium and high speeds	Operation under complex working conditions

Data source: Original Strength Document "What Are the Respective Characteristics of Series and Parallel Hybrid Electric Vehicles?"

Table 4

Comparison of Characteristics for Hybrid Tractors with Different Powertrain Configurations

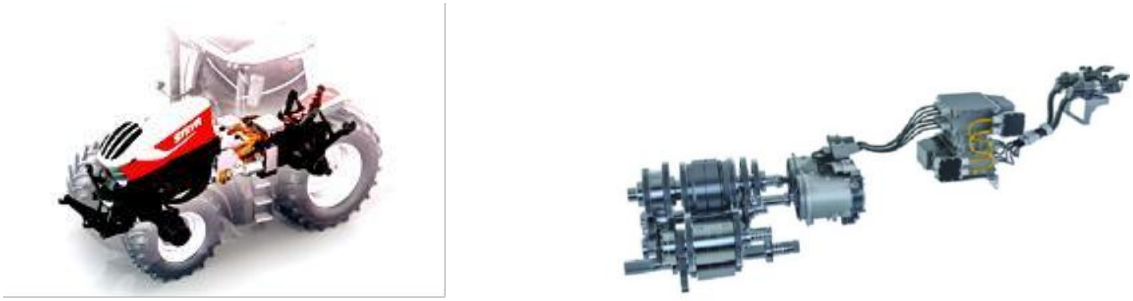
Drive Configu-ration	Sub - Configu-ration	Core Characteristics	Key Advantages	Main Disadvantages
Series Type	Range-extended type / General type	Load decoupling; range-extended type is dominated by pure electric drive, while the general type mainly relies on the engine-generator set.	Continuously variable transmission; simplified transmission system.	High energy conversion loss; relatively large system weight.
Parallel Type	Torque / speed / traction coupling type	Torque/speed/traction coupling; adaptable to time-varying loads and complex terrains.	Efficient engine operation; satisfactory load response; simplified transmission system.	Dependence on large-capacity batteries; high control complexity; high development cost.

Drive Configu-ration	Sub - Configu-ration	Core Characteristics	Key Advantages	Main Disadvantages
Series-Parallel Type	Series-parallel type / Power-split type	A power generation system is added on the basis of the coupling system, supporting the switching of multiple driving modes.	Multi-mode drive; maximized energy efficiency.	Complex power system; high development cost; difficult control.

Analysis of Key Component Technologies

The performance, reliability and domestic localization level of hybrid tractors mainly depend on the technical maturity of four key components: power source, energy storage system, power coupling device and electronic control system. Combined with the current industry technology status, authoritative test data and domestic localization progress, this paper systematically analyzes the detailed technical points of each component, identifies the technical bottlenecks and development directions, and explains the root causes of the performance differences among the three topologies mentioned above.

The power source is the core driving unit of hybrid tractors, which is divided into two major categories: diesel engines and new energy motors. The cooperative operation of the two determines the power output and energy-saving effect of the topology, and its technical level directly affects the operation adaptability of tractors. At present, mainstream hybrid tractors are equipped with China IV emission diesel engines, and some high-end models have been upgraded to China V emission standards. The core of the upgrade focuses on three goals: reducing emissions, improving efficiency, and adapting to hybrid collaboration. Currently, domestic diesel engines for agricultural machinery have achieved domestic localization of China IV emission technologies, but some core aftertreatment components for China V emission standards still rely on imports (*Liu, 2023*).



New energy motors constitute the core of the electric drive for hybrid tractors. The performance differences among the three mainstream motor types determine their adaptability to different topological structures and operating scenarios, as detailed below.

(1) Permanent magnet synchronous motors feature high power density, high operating efficiency, excellent speed regulation performance, and stable low-speed torque output. They are suitable for the high-frequency mode switching requirements of series-parallel and power-split topologies, and can accurately match the load fluctuations in complex hilly terrains, making them the mainstream choice for high-end hybrid tractors at present. Their shortcomings lie in the relatively high cost and the tendency of permanent magnets to demagnetize under high temperature and vibration. Additional protective structures are required when adapting to the high-dust and high-temperature field operating environment of tractors, resulting in slightly higher maintenance costs (*Lu, 2023; Zhu, 2025; Zhao et al., 2021*).

(2) Asynchronous motors feature a simple structure, high reliability, and moderate cost, with outstanding high-temperature resistance and anti-vibration performance. They are suitable for the “engine generation + motor drive” mode of series topology and can meet the continuous power output demand of long-term low-speed operation. Their shortcomings include low power density, poor low-speed efficiency, and relatively slow dynamic response, making them unsuitable for series-parallel topologies with high-frequency load fluctuations and rapid mode switching (*Gui, 2026*).

(3) Switched reluctance motors have relatively high power density, robust structure, low cost, and large starting torque, making them suitable for high-load operating scenarios. Furthermore, they have no risk of permanent magnet demagnetization and feature low maintenance costs. However, their shortcomings include complex control logic, significant noise and vibration during operation, and poor low-speed running smoothness. At present, they are mainly applied in low-end series hybrid tractors for light and medium-load operations, and have not been widely used in high-end models (*Li, 2026*).

In conventional tractors, continuously variable transmission (CVT) refers to a technology that realizes uninterrupted speed regulation of the whole machine by continuously adjusting the transmission ratio between the input and output shafts of the transmission system without changing the engine speed. In the field of hybrid tractors, this technology has been further extended to the smooth and continuous control of the whole machine’s operating speed. The current mainstream technical routes include the centralized electric-drive CVT system shown in Figure 3(c), the distributed electric-drive CVT system shown in Figure 9, and the electromechanical coupling CVT system. Their technical characteristics and typical products are presented in (*Wen et al., 2025*).

Fig. 9 - Main Technical Characteristics and Typical Products of CVT Power System and Engine

The energy storage system serves as the core carrier for energy recovery and power compensation of hybrid tractors. It is responsible for storing energy generated by the engine and recovered via braking, and supplementing energy to the drive system under high-load conditions. Its performance directly affects the energy-saving rate and power response speed of the topology, and is mainly divided into three categories: power batteries, supercapacitors, and fuel cells.

Power battery technology functions to store surplus engine energy and braking recovery energy, providing high-energy-density supplementary energy support for electric motors. Most hybrid tractors adopt lithium-ion batteries, which feature high energy density but relatively low power density. In the single-motor drive hybrid system proposed by Wang Zhiguo et al., efficient collaboration between the internal combustion engine and the electric motor was achieved through optimized control strategies, raising the charge-discharge efficiency of power batteries to over 90%. However, the core problems of power battery technology lie in low-temperature performance attenuation and limited cycle life *(Scolaro et al., 2021, Troncon et al., 2019)*.

Supercapacitor technology is designed to compensate for the low power density of batteries and quickly respond to instantaneous load demands (e.g., tractor startup or climbing). It has a power density of 5–10 kW/kg and a charge-discharge efficiency exceeding 95%, making it suitable for frequent start-stop operating conditions. Yue Dongpeng et al. pointed out that supercapacitors in hybrid systems can realize short-term energy buffering, reduce peak current pressure on batteries, and extend their service life (*Sunil et al., 2026*). Their limitation is low energy density, requiring combined use with batteries (*Wang et al., 2026; Wang, 2015*).

Fuel cell technology, as an auxiliary power source, provides continuous electric energy output through hydrogen energy conversion, but has not yet been promoted or piloted.

The power coupling device is the core of power distribution for hybrid tractors, responsible for coupling and splitting the power of diesel engines and new energy motors to realize the switching of different power modes. Its technical bottlenecks and domestic localization progress directly restrict the performance and cost control of hybrid topologies, and are mainly divided into three categories: clutches, planetary gear sets, and electronic control couplers.

The electronic control system is responsible for the overall coordinated control of the power source, energy storage system, and power coupling device. It mainly consists of an Engine Control Unit (ECU), Vehicle Control Unit (VCU), and Battery Management System (BMS). The coordinated control capability, as well as the technical level of chips and algorithms, directly determines the performance and reliability of the hybrid topology.

For the coordinated control architecture of ECU/VCU/BMS, the three units form a "hierarchical control and collaborative linkage" architecture, which is the core of power mode switching and optimal energy distribution for hybrid tractors. As the main control unit, the VCU receives real-time data from the ECU, BMS, and field operation sensors, formulates optimal control strategies according to operating conditions, sends control commands for engine speed and fuel injection volume to the ECU, charge-discharge control commands to the BMS, and power distribution and mode switching commands to the power coupling device (*Sunil et al., 2026*) ; the ECU executes VCU commands, optimizes the engine operating state to ensure the engine maintains a high-efficiency speed range, and feeds back real-time engine operating data; the BMS monitors the real-time status of power batteries and supercapacitors, controls charge-discharge speed and current to prevent overcharging and over-discharging, extends the service life of energy storage components, and feeds back the energy status of the energy storage system.

At present, the coordinated control architecture of domestic hybrid tractors has achieved initial maturity and can meet basic power distribution and mode switching requirements. However, high-end models lack sufficient coordinated control accuracy and slow response speed, and the data interaction efficiency of the three units still needs to be optimized. Chips and algorithms are the core of the electronic control system and also the main technical bottleneck of domestic hybrid tractors (*Zhang, 2024; Cheng et al., 2026*).

In terms of chips, high-computing-power Microcontroller Unit (MCU) chips and power chips required for high-end ECU/VCU/BMS mainly rely on imports. Although domestic chip enterprises have launched mid-end chips, their computing power, high-temperature resistance, and vibration resistance are insufficient to meet the high-frequency control demands of high-end hybrid tractors, and they also suffer from poor stability and high failure rates. Domestic substitution of chips is currently the core development direction (*Zhang, 2024; Jing et al., 2020*).

In terms of algorithms, the core challenge lies in adaptive control algorithms for operating conditions. The field operating conditions of tractors are complex, and traditional logic threshold control algorithms can no longer meet precise control demands. Intelligent algorithms such as Model Predictive Control (MPC) and reinforcement learning are required to realize condition-adaptive power distribution and mode switching. At present, domestic enterprises are still in the research and development and testing stage of intelligent algorithms. The adaptability and stability of the algorithms are insufficient to accurately match complex field conditions, and the compatibility between algorithms, topologies, and key components is poor, resulting in the failure to fully exert the performance of some high-end hybrid tractors *(Xie et al., 2018*).

In summary, the technical maturity and domestic localization level of the four key components directly determine the performance, cost, and reliability of hybrid tractors. At present, domestic hybrid tractors have realized the localization of mid-to-low-end components, and core shortcomings are concentrated in high-end motors, electronic control chips, high-end electronic control couplers, hydrogen fuel cells and other fields. In the future, it is necessary to carry out industry-university-research collaborative research to break through core technical bottlenecks, promote the domestic substitution of key components, and optimize the collaborative compatibility of each component to support the high-quality development of the hybrid tractor industry (*Chen, 2024*).

Energy Source Configuration and Matching Strategy

The core of energy source configuration for hybrid tractors lies in the type selection and parameter matching of diesel engines and energy storage devices. Its primary objective is to adapt to complex field operating conditions and achieve a balance between dynamic performance, energy-saving efficiency and service life. Combined with industrial research and practical applications of tractor models, three mainstream technical routes have been formed at present. The following section systematically analyzes the configuration by focusing on three core aspects: the comparison between single and composite energy source configurations, parameter matching methods, and case studies of 300-horsepower-class models, in conjunction with the technical characteristics of energy storage systems *(Paciolla et al., 2024, Sayed et al., 2024)*.

Comparative Study on Single Energy Source and Composite Energy Source Configurations

The energy source configuration of hybrid tractors can be divided into two categories: the engine plus single energy storage device configuration and the hybrid energy storage configuration. Based on different theoretical foundations, they show significant differences in performance, applicable scenarios and cost control (*Zhu et al., 2025*).

The single energy source configuration, centered on "matching a single energy storage device with the engine", features a simple structure and low development difficulty, making it the mainstream basic configuration for current hybrid tractors. Most engines adopt China IV/Euro V emission diesel engines, and lithium iron phosphate batteries are preferred as power batteries, which adapt to the high-temperature and vibratory field operating environment of agricultural machinery. With a thermal runaway temperature ≥ 600 ℃, their safety performance is superior to that of ternary lithium batteries, and the battery capacity is matched to 15–50 kWh according to the horsepower class (*Liu et al., 2025*). The IE-POWER electric continuously variable transmission powertrain released by Yuchai Group adopts a series hybrid architecture, which collaborates a single energy storage device (battery) with the engine, achieving a 10%–30% improvement in operating efficiency and a 10%–30% increase in fuel saving rate (*Huang, 2021*). This configuration simplifies the transmission system layout and reduces development complexity, and is especially suitable for 200–260 HP

heavy-duty tractors (*Wang, 2024*). Its core advantages include simple structure and moderate cost, adapting to light and medium-load long-term operation scenarios. The main limitation is that battery life is significantly affected by the agricultural machinery operating environment; continuous high temperature and high-frequency vibration in the field accelerate battery degradation, resulting in a short actual service life. In addition, the peak power output is limited, making it difficult to adapt to high-load scenarios such as deep tillage and heavy-load transfer.

The composite energy source configuration is an optimized upgrade based on the single configuration, with the core logic of "integrating the high energy density of power batteries and the high power density of supercapacitors". Its theoretical foundation is "energy-power dual complementarity": power batteries undertake continuous energy supply, while supercapacitors provide instantaneous power compensation and rapid energy recovery. The two cooperate to match the engine power output and achieve optimal comprehensive performance *(Song et al., 2019*). Its core advantage is balanced comprehensive performance, which not only solves the problems of insufficient peak power and short service life of the single battery configuration, but also makes up for the shortcomings of low energy density of single supercapacitors and inability to operate in pure electric mode for a long time (*Liu et al., 2019*). The main limitation is the complex structure and high cost. A special energy cooperative control strategy needs to be designed, and the parameter matching of multiple energy storage devices is difficult. The manufacturing cost is 30%–40% higher than that of the single battery configuration. At present, it is mainly used in high-end high-horsepower hybrid tractors to adapt to complex operating conditions (*Li et al., 2026, Mocera, 2021*).

In summary, the single energy source configuration focuses on "low cost and adaptation to basic working conditions", with the core advantages of simple structure and convenient maintenance, but limited comprehensive performance. The composite energy source configuration focuses on "high performance and adaptation to complex working conditions", with the core advantages of balanced power and energy saving as well as longer component service life, but suffers from high cost and complex control. The choice between the two mainly depends on the operating scenarios, horsepower requirements and cost budget. The single energy source configuration is preferred for small and medium-horsepower tractors in basic operations, while the composite energy source configuration is prioritized for high-horsepower tractors in complex working conditions.

Energy Source Parameter Matching Method

The core of energy source parameter matching lies in optimizing the parameter combination of engine power and energy storage devices (capacity and power) according to the operating condition requirements of the typical operating cycles of hybrid tractors, so as to achieve the optimization objectives of "meeting power demand, minimizing energy consumption and maximizing service life". Its core process is "operating condition modeling - target setting - parameter optimization - verification and iteration" *(Mocera et al., 2022, Pascuzzi et al., 2024, Paciolla et al., 2024)*.

Operating condition modeling is the foundation of parameter matching, which focuses on quantifying key parameters such as load characteristics, speed variations and braking frequency of the typical operating cycles of hybrid tractors through field tests and simulation analysis, and constructing an operating condition model that conforms to actual operations. At present, the mainstream modeling method in the industry is "field tests + MATLAB/Simulink simulation". Firstly, real-time data including load power, travel speed, braking time and slope variations of tractors under typical operating conditions such as plowing, rotary tillage, sowing, transfer and braking are collected by sensors, and the proportion of different operating conditions is determined based on accumulated field operation data of more than 1000 hours. Subsequently, based on the collected data, an operating condition load spectrum model is constructed to clarify the basic power demand of the engine, as well as the peak power and energy storage requirements of the energy storage device, and a power demand time series $P_{req}(t)$ is established. Key parameters include average power P_{avg}, peak power P_{max}, load factor $\eta_L = \frac{P_{avg}}{P_{max}}$, and cycle period T, which provide data support for parameter matching. During the modeling process, the particularities of agricultural machinery operations—such as large fluctuations in field loads and complex operating environments—must be emphatically considered. Therefore, environmental impact factors should be integrated into the model to avoid the disconnection between theoretical modeling and practical applications. For example, battery capacity degradation must be considered in high-temperature environments, and power redundancy should be reserved under vibratory conditions to ensure the rationality

of parameter matching. Parameter matching optimization takes "maximum energy-saving rate, satisfactory power performance, longest service life, and minimum cost" as the multi-objective optimization objective. Combined with the operating data, intelligent optimization algorithms are adopted to collaboratively optimize the engine power and parameters of the energy storage device. The details are as follows:

A multi-objective optimization framework is constructed, and the objective function is established as follows:

$$\min\left\{w_1\frac{f_1}{f_{1,ref}}+w_2\frac{f_2}{f_{2,ref}}+w_3\frac{f_3}{f_{3,ref}}\right\} \quad (2)$$

where:

f_1 is the energy consumption [kwh/m]; f_2 is the battery degradation rate [%/1000 h]; f_3 is the proportion of time with insufficient power [%]; $f_{i,ref}$ are the respective reference benchmark values of the three indicators; division is performed to normalize indicators with different dimensions and magnitudes for summation. w_i is the weight coefficient, which needs to be determined using the Analytic Hierarchy Process.

Constraint conditions are set as follows:

Power constraint:

$$P_{eng}+P_{bat}\geq P_{req}(t)+\Delta P_{margin} \quad (3)$$

where:

P_{eng} is the engine output power [W], P_{bat} is the battery output/input power [W]; P_{req} is the vehicle total required power at time t (varies in real time with driving conditions) [W], ΔP_{margin} is the reserved power margin [W].

SOC boundary:

$$SOC_{min}\leq SOC(t)\leq SOC_{max} \quad (4)$$

where:

SOC is the State of Charge [%].

Engine operating range:

$$\omega_{eng}\in[\omega_{idle},\omega_{rated}] \quad (5)$$

where:

ω_{eng} is the engine rotational speed [r/min]; ω_{idle} is the minimum idle rotational speed [r/min]; ω_{rated} is the rated maximum operating rotational speed [r/min].

In terms of optimization algorithm applications, the industry currently mainly adopts intelligent optimization algorithms such as genetic algorithm and particle swarm optimization. Combined with Simulink simulation models, multi-objective optimization is performed on the parameters of engines and energy storage devices, and parameter combinations are iteratively optimized to finally determine the optimal matching scheme (*Liu et al., 2017; Li et al., 2025; Zhang et al., 2025*).

In summary, the core of energy source configuration for hybrid tractors lies in "operating condition adaptation, parameter optimization, and type matching". The single energy source configuration is suitable for basic operations and cost control, while the composite energy source configuration adapts to complex working conditions and improves comprehensive performance. The parameter matching method based on operating condition modeling and intelligent optimization algorithms can achieve the optimal balance of energy source configuration. Case studies of 300-horsepower-class models show that the hybrid energy storage configuration represents the development trend of high-end models, but the bottlenecks of cost and control complexity need to be broken through. Meanwhile, the technical characteristics of the energy storage system directly affect the selection and performance of energy source configuration. In the future, it is necessary to further optimize the performance of energy storage devices, promote the collaborative upgrading of energy source configuration with topological structures and electronic control systems, and support the high-end development of the hybrid tractor industry.

Research Progress of Typical Energy Management Strategies

For hybrid electric vehicles, there are generally two or more power sources. Therefore, it is necessary to design reasonable energy management strategies according to the power demand under different road conditions and rationally distribute the output power of each power source to achieve the optimal control objectives. At present, domestic and foreign research on energy management strategies for hybrid power systems mainly focuses on the fields of automobiles and buses. Existing multi-energy energy management strategies can be mainly divided into three categories (*Gao, 2024*), as shown in Figure 10.

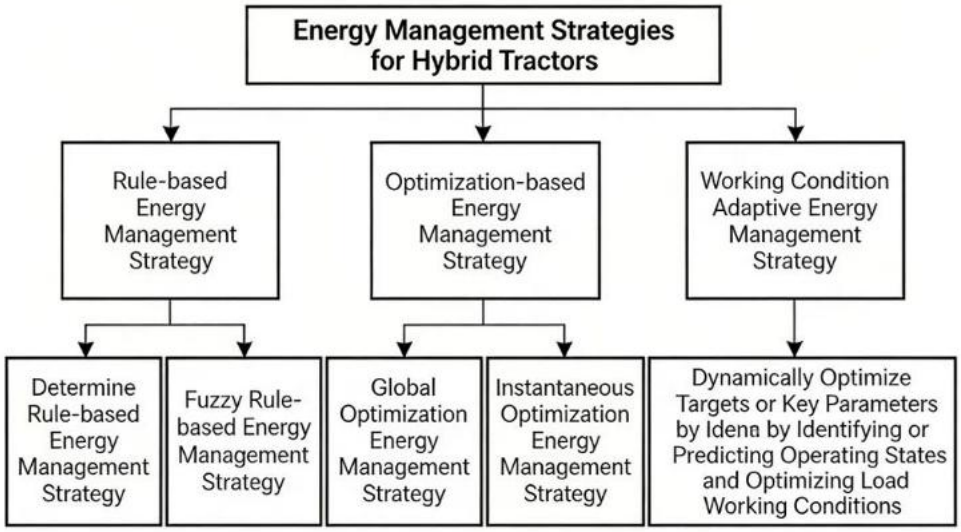

Fig. 10 - Classification of EMS for Hybrid Tractors

Rule-based energy management strategies can be divided into deterministic rule-based strategies and fuzzy rule-based strategies. Deterministic rule-based strategies predefine control rules based on engineering experience or expert knowledge to realize power distribution among multiple power sources. They are simple, practical and highly implementable, with representative ones including state machine strategy, power-following control rules and thermostat control rules. Unlike the simple switching thresholds of deterministic rule-based strategies, fuzzy rule-based strategies are a nonlinear control technology formed by combining fuzzy mathematics and mathematical logic. They can predict future driving states through fuzzy logic inference based on known driving states, exhibiting strong robustness (*Yao et al., 2023;*).

Ding Axin et al. (*2021*) used dynamic programming energy management strategy to obtain the optimal energy distribution results for a fuel cell/battery hybrid power system, and on this basis, designed an improved state machine energy management strategy. Simulation results showed that the strategy can realize real-time control and effectively reduce the system hydrogen consumption.

Chen X.R. et al. (2022) proposed an external energy efficiency maximization strategy based on power decoupling for the fuel cell + battery architecture, and compared it with traditional control strategies. The results showed that the proposed strategy can meet the power demand of ships under typical working conditions, effectively reduce hydrogen fuel consumption, improve battery utilization, and enable efficient operation of the entire system.

Fei Peng et al. (2017) further proposed a processing compensation strategy based on fuzzy logic hysteresis state machine and differential power strategy, which improved the dynamic coordination efficiency of the hybrid system and increased fuel efficiency by 7%.

Optimization-based management strategies achieve optimal system control under preset constraints, and can be mainly divided into global optimization control and instantaneous optimization control. The former takes a given driving cycle as the premise and conducts global search optimization analysis combined with modern optimization algorithms and control theory, mainly including dynamic programming control, stochastic dynamic programming, etc. The latter takes a certain working condition and driving state as the optimization interval, establishes an objective function to minimize fuel consumption in this interval, and optimizes the system energy distribution in real time online. Compared with the former, it can realize real-time dynamic optimization, mainly including Pontryagin's Minimum Principle, Equivalent Consumption Minimization Strategy, etc. (*Wang et al., 2022*).

Dima Fares et al. (2015) proposed an offline optimization algorithm based on weighted improved dynamic programming, combined with online optimization using a PID controller. The results showed that the algorithm converges faster than the ordinary dynamic programming algorithm and achieves higher fuel economy compared with rule-based algorithms. *Peng et al. (2021)* proposed an offline optimal energy management strategy combining Pontryagin's Minimum Principle and dynamic programming, and introduced a damping coefficient into the cost function, which effectively reduced the dynamic fluctuation of fuel cell output power. The feasibility of the strategy was verified through experiments.

Ding Chenguang et al. (2026) innovatively proposed an energy management strategy based on frequency division decoupling. The strategy aims to design a low-pass filtering algorithm, enabling the fuel cell to provide the main power output and low-frequency fluctuating power, while the lithium battery recovers braking energy and provides high-frequency fluctuating power. The effectiveness of the strategy was verified under Chinese urban bus driving cycles and actual bus operating conditions. In addition, with the rapid development of the automotive manufacturing industry, some control strategies based on intelligent algorithms have been applied to the energy management of hybrid power systems, typically including machine learning, artificial neural networks and model predictive control. Such strategies are relatively complex and difficult to implement, but are of far-reaching significance for in-depth research and innovation in the automotive field. *Chen Zeyu et al.* (*2022*) proposed an energy management strategy based on deep reinforcement learning, which determines the optimal variable power through the deep deterministic policy gradient algorithm. The effectiveness of the strategy was verified by real-vehicle tests and comparison with the particle swarm optimization strategy (*Kebriaei et al., 2015*).

Huang Zhenzhen et al. (*2021*) designed an online multi-objective energy management strategy for fuel cell vehicles based on BP neural network. The strategy trained simulation datasets obtained based on Pontryagin's Minimum Principle to establish neural network sub-models, and combined the obtained sub-models into a multi-neural network model. Finally, the feasibility of the strategy was verified through online software simulation and hardware-in-the-loop simulation tests respectively.

Li X. et al. (2019) proposed an energy management strategy based on explicit model predictive control, formulated the optimal control problem as a multi-parameter quadratic programming optimization problem, and realized real-time control by solving the multi-parameter quadratic programming problem offline, which effectively improved fuel economy and reduced online computation time.

Gao Zhi et al. (2024) conducted research on the energy management strategy of a fuel cell tractor hybrid power system. Taking a hydrogen fuel cell hybrid tractor as the research object, they determined the fuel cell/lithium battery/supercapacitor three-power-source topology, completed component selection and matching, and built a simulation model. The EEMS strategy was designed and compared with SMC and ECMS. Hardware-in-the-loop test verification showed that EEMS can ensure stable system operation, significantly reduce hydrogen consumption, and alleviate power impact on the fuel cell.

Through the analysis of existing literature, it can be found that although rule-based energy management strategies are simple, effective and easy to implement, they rely on given expert experience or rules, are difficult to adapt to real-time dynamic working conditions, and cannot guarantee optimal control of the hybrid system. Although optimization-based control strategies have outstanding theoretical performance, can maximize the optimization of hybrid systems and improve system performance and fuel economy, they have high requirements for hardware and control accuracy, and require long computation time, resulting in high production costs and difficulty in practical application. Some literatures also fail to consider field interference factors, leading to limitations in test results. Future development directions need to expand multi-field working conditions, optimize the real-time performance of EEMS to promote engineering application, improve system reliability with intelligent algorithms, and perfect the test system to adapt to actual field scenarios. Hybrid tractor energy management strategies mostly adopt road vehicle frameworks, poorly adapting to violent, irregular field operation loads. Dynamic programming is hard to engineer; MPC faces high hardware cost barriers; widely used rule-based strategies have limited energy-saving potential. Balancing accuracy, cost and adaptability is the core challenge (*Brudeli G et al.,2026*).

Research Review on Strategy Optimization Directions

The core of the energy management strategy for hybrid tractors is to dynamically allocate the power output of the engine and motor, and maintain the stability of the battery State of Charge (SOC) to achieve optimal fuel economy (*Wang et al., 2015*).

Strategies that allocate power based on preset logical rules mainly include the thermostat strategy and the power-following strategy. Among them, the thermostat strategy sets an SOC threshold range of 30%-70%: the engine starts to generate electricity when the SOC is below the threshold, and the system switches to pure electric drive when the SOC exceeds the threshold. The power-following strategy dynamically adjusts the engine output according to the real-time power demand of the tractor, enabling the engine to match real-time load fluctuations (*Dobretsov et al., 2024*).

Optimization strategies with minimum fuel consumption as the objective function optimize power distribution through algorithms, including dynamic programming (which solves the optimal solution based on global operating condition information and serves as an offline optimization benchmark), model predictive control (which realizes real-time control relying on receding horizon optimization), and nonlinear programming genetic algorithm (which optimizes key parameters via genetic algorithm to improve control accuracy) (*Wang et al., 2015*).

Intelligent algorithm strategies integrating machine learning, reinforcement learning and other technologies include fuzzy PID control, which combines fuzzy logic and PID algorithm to optimize the response characteristics of the power generation system, and deep reinforcement learning, which learns the optimal strategy through the interaction between agents and the operating environment to adapt to complex and variable field working conditions.

The selection of technical routes for hybrid tractors is restricted by three core factors: operating scenarios, power level and cost budget.

(1) Operating scenarios: Large-area plain field operations are suitable for series configuration and engine-battery energy source layout and rule-based strategy, highlighting the advantages of endurance and cost control; complex hilly field operations are suitable for series-parallel configuration and engine-battery-supercapacitor energy source layout and model predictive control strategy, emphasizing dynamic performance and environmental adaptability; facility horticulture operations are suitable for power-split configuration and engine-supercapacitor energy source layout and fuzzy PID strategy, focusing on operational flexibility and low noise.

(2) Power level: Small-horsepower tractors with a power rating lower than 50kW mainly adopt series configuration and engine-battery energy source layout; high-horsepower tractors with a power rating higher than 150kW tend to use series-parallel configuration and engine-battery-supercapacitor energy source layout.

(3) Cost budget: Economical users such as individual farmers choose series configuration and engine-battery energy source layout and rule-based strategy, with the complete machine price 10%~15% higher than that of conventional tractors; large-scale farms prefer series-parallel configuration and engine-battery-supercapacitor energy source layout and optimization-based strategy. Although the initial investment is 30%~40% higher, the annual operating cost is reduced by 24%~30%, with an investment payback period of about 3~4 years (*Zhou, 2026*).

Review on Verification Methods of Energy Management Strategies

Verification of energy management strategies for hybrid tractors is the key to their transformation from theoretical models to engineering applications. Combined with the characteristics of field operating conditions, there are four core verification methods:

(1) As a low-cost and efficient preliminary method, simulation verification builds powertrain system and strategy models relying on platforms such as MATLAB/Simulink, and completes preliminary iterations combined with field operating condition load spectra. It has the advantages of low cost, short cycle and the ability to simulate extreme working conditions, but is limited by dependence on model accuracy and detachment from the actual environment, which is suitable for the initial stage of strategy research and development (*Wang et al., 2021*);

(2) As a bridge between simulation and real-vehicle tests, bench test verification simulates field operating conditions in a controllable environment through powertrain system or complete vehicle benches to realize semi-physical verification. It features accurate data and high safety, but is difficult to simulate the complex interaction among soil, farm implements and tractors, which is suitable for the strategy optimization stage (*Li et al., 2026*);

(3) Field real-vehicle test verification is the final standard for engineering implementation, which verifie s the adaptability, reliability and economy of strategies in real field scenarios. It has high result credibility, but is restricted by long cycle, high cost and great interference from natural factors, which is suitable for the strat egy application stage (*Wu et al., 2014*);

(4) As a high-end intelligent development trend, Hardware-in-the-loop (HIL) test verification integrates virtual models and physical hardware with strong real-time performance, making it suitable for the verification of intelligent strategies. However, it has high equipment cost and technical threshold, which is applicable to t he research and development of high-end intelligent strategies (*Qiao et al., 2022*).

In practical applications, a full-process integrated system of "simulation verification→HIL test verification→bench test verification→field real-vehicle test verification" is generally adopted. In the future, it will develop towards the standardization of operating condition load spectra, the integration of digital twin and HIL, and the improvement of multi-objective verification systems.

Technical R&D Bottlenecks

In terms of power coupling and transmission efficiency, the series configuration suffers from large energy conversion losses, and the conversion efficiency of the "engine-generator-motor" chain needs to be improved; its energy consumption under high-speed operating conditions is higher than that of the series-parallel configuration. The power-split configuration has high requirements for the machining accuracy of planetary gear mechanisms, and the gear meshing efficiency of domestic enterprises is 5%~8% lower than the international advanced level. The mode switching shock problem of the series-parallel configuration has not been completely solved, and the switching shock of some models reaches 0.3g, which affects operation comfort and component service life.

In terms of energy storage system performance, batteries account for 20%~30% of the complete machine cost, and the service life of batteries in agricultural machinery operating environments is only 1/2~2/3 of that in electric vehicles. Supercapacitors have low energy density and must be matched with large-capacity batteries to meet long-time operation requirements, which increases system complexity and cost. The energy distribution strategy of hybrid energy storage systems is not yet mature, and the cooperative control accuracy between batteries and supercapacitors needs to be enhanced.

In terms of control strategies, optimization-based and intelligent algorithm strategies rely on accurate operating condition prediction models. However, agricultural operating conditions are greatly affected by soil, climate and crops with strong uncertainty, leading to reduced control accuracy. The weight distribution of multi-objective optimization strategies lacks a unified standard and requires recalibration in different operating scenarios, increasing R&D difficulty. The synergy between the control system and the operation system is insufficient, failing to achieve integrated power-operation optimization. The above shortcomings in technical R&D have led to divergences in the technical route selection of hybrid tractors.

Research Focuses and Controversies

Research and development of hybrid tractor technologies center on three core links: power coupling, energy storage system, and control strategy. Clear research focuses have been formed for key technological breakthroughs, while significant academic and industrial controversies exist due to differences in technical route selection and performance priority setting. Such controversies mainly involve three aspects: research focuses and divergences of power coupling and transmission efficiency, energy storage system performance, and control strategy.

The research focus of power coupling and transmission efficiency lies in breaking through the performance shortcomings of three topological structures:

- Firstly, optimizing the energy conversion loss of the series topology, reducing the multi-stage conversion loss of the "engine-generator-motor" chain by improving the matching parameters of generators and motors and enhancing the energy distribution accuracy of the electronic control system;
- Secondly, upgrading the processing technology of core components for the power-split topology, conquering the high-precision processing technology of planetary gear mechanisms, and narrowing the meshing efficiency gap with the international advanced level;
- Thirdly, suppressing the mode switching shock of the series-parallel topology, developing adaptive buffer control algorithms to reduce the impact load in the process of multi-mode switching. The divergences are reflected in the priority of technical routes. Some studies argue that priority should be given to the low-cost optimization of the series topology to meet the demand for large-scale promotion; other studies advocate tackling the mode switching technology of the series-parallel topology to seize the high-end market with its comprehensive performance advantages. The two sides hold different views on the route selection between "cost priority" and "performance priority".

In terms of research focuses and divergences of energy storage system performance, they mainly focus on three core issues:

- Firstly, cost control and service life extension of power batteries, improving battery reliability in agricultural machinery operating environments by developing special battery PACK technologies with vibration resistance and high temperature resistance, and exploring battery recycling and echelon utilization paths to reduce costs;
- Secondly, optimizing the collaborative mechanism of hybrid energy storage composed of supercapacitors and batteries, breaking through the precise control technology of energy distribution strategies, and balancing the advantages of high power density of supercapacitors and high energy density of batteries.

Thirdly, simplifying the structure of the hybrid energy storage system, reducing system complexity and complete machine layout difficulty through integrated design.

The divergences mainly concentrate on the selection of energy storage technical routes. For the research focuses and divergences of control strategies, they mainly focus on the precision and integration of strategies:

- Firstly, constructing a high-precision prediction model suitable for agricultural operating conditions, integrating multi-source data such as soil, climate and crops to improve the adaptability of intelligent algorithms to complex operating conditions;
- Secondly, establishing a dynamic weight adjustment mechanism for multi-objective optimization strategies to achieve balanced optimization of fuel economy, power performance and component service life;
- Thirdly, promoting the collaborative integration of control system and operation system, developing an integrated algorithm of "power control-farm implement control-navigation control" to realize optimal energy distribution in the whole operation process.

The divergences are mainly reflected in the technical implementation path, with differences in the route selection between "adaptive algorithm optimization" and "systematic standardized research and development".

Industrialization Application Bottlenecks

Hybrid tractors face multiple challenges in popularization and application, especially in terms of cost and cost performance. Their selling price is 30%~60% higher than that of traditional tractor models. For instance, the Dongfanghong HB2204 is 250,000 yuan more expensive than traditional models with the same horsepower, and the price of imported hybrid tractors is even higher. Although their operating cost can be reduced by 24%~30%, the investment payback period is relatively long. In terms of infrastructure and after-sales service, there are also prominent problems including a rural charging pile coverage rate of less than 5%, which restricts the application of pure electric mode, as well as a high technical threshold and high cost for hybrid system maintenance.

Core Technology Development Trends

(1) Develop integrated power coupling devices to reduce structural complexity and improve transmission efficiency; explore novel transmission technologies such as electromagnetic coupling transmission and the integration of Hydro-mechanical Continuously Variable Transmission (HMCVT) with electric drive, breaking through the limitations of traditional mechanical transmission. For high-horsepower models, focus on the optimization of series-parallel topology, and develop lightweight and highly reliable multi-mode coupling devices to reduce manufacturing costs by 15~20%.

(2) Develop special high-power-density batteries for agricultural machinery, such as solid-state batteries, to extend endurance and reduce costs; optimize hybrid energy storage systems and dynamically adjust the energy distribution ratio between batteries and supercapacitors based on operating conditions; develop battery thermal management and vibration protection technologies to extend battery life to 5–6 years, close to the level of electric vehicle batteries.

(3) Integrate multi-source sensor technology to construct adaptive operating condition prediction models and improve the real-time performance and accuracy of optimization strategies; develop intelligent algorithms combining deep learning and reinforcement learning to realize self-learning and self-optimization of control strategies, adapting to complex and variable agricultural operating environments; develop an integrated "power-operation" control platform to collaboratively optimize energy management with implement control and path planning, improving overall operating efficiency.

Innovation of Research Methods and Verification Systems

(1) Reduce costs through large-scale production to approach the level of traditional high-end tractor models; adopt modular design to realize the standardization and generalization of powertrain, energy storage system and control system, so as to lower research and development and manufacturing costs.

(2) Build an "agricultural machinery cooperatives and charging piles" model, and deploy fast charging piles in major agricultural production areas to solve the charging difficulty; establish a professional after-sales service network, carry out technical training for maintenance personnel to shorten the fault maintenance cycle; build a remote diagnosis and operation and maintenance platform, and realize predictive maintenance via big data analysis to reduce the failure rate.

(3) Improve the technical standard system, and formulate national standards for hybrid tractors covering energy saving rate test methods, safety requirements and electromagnetic compatibility; strengthen policy support, increase the proportion of purchase subsidies, set up special research and development funds, and encourage collaborative innovation between enterprises and universities; promote the "combination of lease and purchase" and "trade-in for new" models to reduce users' initial investment proportion and accelerate the popularization and application.

CONCLUSIONS

(1) Hybrid tractors have become the core development direction under the background of global agricultural mechanization and green low-carbon transformation, forming a diversified technological pattern and industrialization promotion trend. Driven by policy support, market demand and technological innovation, this field has achieved leapfrog development from conceptual prototype to commercial explosion, and distinctive technical routes adapted to local farming scenarios have been formed both domestically and internationally. Foreign countries are represented by high-horsepower power-split hybrid tractors in North America, plug-in multi-energy coupling hybrid tractors in Europe, and small and medium-horsepower refined hybrid tractors in Japan and South Korea, with high industrialization maturity and complete core technology and supply chain systems. China has made remarkable breakthroughs in the period of independent innovation, with leading enterprises such as YTO Group Corporation, Yuchai Group and Zoomlion emerging, forming a gradient product layout covering 200~320 horsepower heavy-duty models and light and small facility agricultural models. Core indicators such as fuel saving rate and operation efficiency have reached the international advanced level. For example, the plowing fuel consumption of Dongfanghong HB2204 is 23% lower than that of traditional models with the same horsepower, and the operation efficiency of the "Honghu" T300 developed by the Chinese Academy of Sciences is increased by 30%. However, the whole industry is still in the transition stage from "domestic independent substitution" to "high-end breakthrough".

(2) The topological structure and technical level of key components determine the upper limit of the complete machine performance, and different technical routes present distinct differentiated adaptation characteristics. The three core topological structures of series, parallel and series-parallel have their own advantages and disadvantages. The series structure has become the mainstream choice for light and medium load and long-time operation scenarios due to its simple structure and moderate cost, but its energy conversion loss and energy consumption under high-speed working conditions are relatively high. The power-split structure, with a plowing fuel consumption rate of 10.5~12.8L/h and a fuel saving rate of 25%~35%, is the technical route with optimal fuel economy, suitable for medium and high-speed continuous operation. The series-parallel structure realizes adaptive operation under complex working conditions through multi-mode switching, with a maximum climbing gradient of 32~38° and a power response time of only 0.15~0.3s, making it suitable for complex terrains such as hills and mountains, but it has the shortcomings of complex structure and high manufacturing cost. In terms of key components, China has achieved domestic production of National Stage IV diesel engines and medium and low-end power batteries, but core components such as high-end E-CVT gearboxes, high-performance permanent magnet synchronous motors and high-computing power electronic control chips still rely on imports. There is a 5~8% gap in transmission efficiency, power density and other indicators compared with the international advanced level, and the lack of precision manufacturing and collaborative adaptation capabilities of core components has become the primary technical bottleneck restricting the improvement of complete machine performance.

(3) The optimization of energy management strategies and energy source configuration is the core to improve system energy efficiency, and currently faces dual challenges of working condition adaptability and real-time performance. Two routes have been formed for energy source configuration: single energy storage and hybrid energy storage. The single energy storage configuration, centered on lithium iron phosphate

batteries, is suitable for small and medium-horsepower basic operations with significant cost advantages. The hybrid energy storage configuration integrates the "energy-power dual complementarity" advantages of power batteries and supercapacitors, becoming the first choice for 300-horsepower high-end models, but its control complexity and manufacturing cost are 30~40% higher than those of the single configuration. Energy management strategies have evolved from traditional rule-based strategies to optimization algorithms and intelligent algorithms. However, most domestic enterprises still rely on logic threshold control, which is difficult to adapt to field load fluctuations and scenario changes. Although intelligent algorithms such as MPC and ECMS, which are mainstream applications abroad, can maximize energy efficiency, they have high requirements for hardware computing power and the accuracy of working condition prediction models, making large-scale engineering application difficult. In terms of verification system, the full-process integrated verification of "simulation-bench-field-hardware-in-the-loop" has become a trend, but problems such as insufficient standardization of working condition load spectra and shallow application of digital twin technology lead to deviations between strategy verification and actual operation scenarios.

(4) Multiple bottlenecks still exist in technological research and development and industrialization promotion, and core controversies focus on the priority of technical routes and performance balance. At the technological R&D level, three prominent problems are insufficient power coupling efficiency (energy conversion loss of series structure and mode switching shock of series-parallel structure up to 0.3g), limited performance of energy storage system (batteries account for 20~30% of the complete machine cost, and the service life is only 1/2~2/3 of that of electric vehicle batteries), and poor coordination of control strategies (lack of integrated "power-operation" optimization). Academic and industrial controversies are reflected in the choice between "cost priority" and "performance priority" routes, the adaptation of energy storage technical routes, and the trade-off between algorithm optimization and system standardization. At the industrialization level, the selling price of complete machines is 30~60% higher than that of traditional models, with a long investment payback period; the coverage rate of rural charging piles is less than 5%, restricting the application of pure electric mode; the high technical threshold for hybrid system maintenance and imperfect after-sales service network jointly restrict large-scale promotion.

(5) Future development needs to focus on core technological breakthroughs, improvement of industrialization ecology and innovation of policy mechanisms to promote the transformation of hybrid tractors towards high-end, intelligent and low-cost development. At the technical level, focus should be placed on developing integrated power coupling devices, special high-power-density solid-state batteries for agricultural machinery, thermal management and vibration protection technologies to extend battery life to 5~6 years; integrate multi-source sensors and deep learning algorithms to build a working condition adaptive prediction model, and develop an integrated "power-operation-navigation" control platform. At the industrialization level, realize the standardization and generalization of core components through modular design, and reduce manufacturing costs through large-scale production; build an infrastructure network of "agricultural machinery cooperatives and charging piles" and establish a professional after-sales service and remote diagnosis system; improve technical standards such as energy saving rate testing and safety requirements, increase support for purchase subsidies and special R&D funds, and promote the "combination of lease and purchase" and "trade-in for new" models to reduce users' initial investment. With the breakthrough of core technical bottlenecks and the maturity of the industrial ecology, hybrid tractors will gradually transform from "transitional technology" to "mainstream equipment", providing core power support for the sustainable development of global agriculture.

Keywords: *harvesting stage, cassava roots, mechanical properties, mechanical damage, experimental study*

ABSTRACT

During mechanized harvesting operations, including excavation, root–soil separation, collection, and transportation, cassava roots are susceptible to multiple mechanical loads such as shear, compression, and impact, which easily induce mechanical damage and seriously deteriorate the processing quality and storage performance of cassava roots. To reveal the mechanical variation characteristics and damage thresholds of cassava roots under primary mechanical damage modes during harvesting and transportation, this study took harvest-stage cassava roots as the research object and conducted systematic mechanical property tests. Three typical mechanical tests, including compression, shear, and bending tests, were performed to explore the mechanical response rules of cassava roots under typical loads, obtain key mechanical parameters and damage thresholds, and clarify the failure characteristics and mechanical mechanisms under different loading modes. The research results clarify the internal relationship between mechanical properties and mechanical damage of cassava roots at the harvesting stage. This study provides reliable basic data and theoretical support for the parameter optimization of key working components, operational parameter matching of specialized cassava harvesters, and the optimal selection of tool edge angles for cassava slicing machinery, and possesses practical engineering significance for reducing mechanical harvesting damage and improving the post-harvest commodity rate and processing performance of cassava roots.

摘要

木薯块根在机械化收获的挖掘、薯土分离、收集及转运作业中，易受到剪切、挤压、撞击等多种机械载荷作用而产生损伤，严重影响块根加工品质与存储期。为揭示收获与运输过程中木薯块根主要机械损伤形式下的受力变化特性及阈值，本研究以收获期木薯块根为研究对象，系统开展了力学特性试验研究。通过开展压缩、剪切、弯曲三项力学性能试验，测定收获期木薯块根在典型载荷作用下的力学响应规律，获取其关键力学参数与损伤阈值，明确不同受力形式下的破坏特征与力学机制。研究结果阐明了收获期木薯块根的力学特性与机械损伤的内在关联，为专用木薯收获机关键工作部件参数优化、作业参数匹配以及木薯切片机械刀具刃角的合理选取提供可靠的基础数据与理论支撑。在降低木薯机械化收获损伤、提升产后商品率与加工性能方面具有重要的应用价值。

INTRODUCTION

Cassava, a species of the genus Manihot in the *Euphorbiaceae* family, is ranked among the world's three major tuber crops together with potato and sweet potato *(FAO., 2001)*. Having a cultivation history of more than 200 years in China, cassava is mainly grown in tropical and subtropical provinces including Guangxi, Guangdong, Hainan, Yunnan, Fujian, Hunan and Jiangxi *(Fu et al., 2018; Li et al., 2024; Xu et al., 2025)*. Notably, Guangxi Zhuang Autonomous Region accounts for over 60% of China's total cassava planting area and fresh tuber yield *(Feng et al., 2022)*.

Guanghao Xu, Assistant Researcher Ph.D. Eng.; Wenwen Li, M.S. Eng. Stud.; Jiannong Song, Prof. Ph.D. Eng.; Binfeng Sun, Associate Researcher Ph.D.; Zhongsheng Cao, Associate Researcher Ph.D.; Junbao Huang, Assistant Researcher Ph.D.; Xinyi Peng, Assistant Researcher M.S. Eng.; Yanda Li, Senior Researcher Ph.D.

Restricted by the limited area of tropical and subtropical zones in China, as well as the high labor intensity and low mechanization level of cassava cultivation, domestic cassava output has long failed to meet the demand of national industrial production *(Liang et al., 2016; Li et al., 2025)*.

According to the latest statistics released by the Food and Agriculture Organization of the United Nations (FAO), China's cassava planting area reached approximately 3.42×10^5 hectares and the fresh tuber yield was about 7.92×10^6 tons in 2024 *(FAO., 2026)*. Since 2009, China's imports of dried cassava chips have consistently made up more than 80% of the global trade volume of this product *(Tan et al., 2018; FAO., 2026)*.

During mechanized harvesting, cassava roots sustain various types of mechanical damage in the processes of digging, root-soil separation, collection and transportation *(Yang et al., 2026)*. Common damage forms include shearing by the cutting edge of digging blades, compression from digging and separating components, and impact between roots or between roots and container walls during collection and conveying. Such mechanical damage severely impairs the subsequent processing quality and thus reduces the commercial value of cassava roots *(Li et al., 2023; Dankwa et al., 2025; Sreekumar et al., 2026)*.

After harvesting, cassava roots are first sliced, followed by natural or mechanical drying to reduce the moisture content of slices for the production of dried cassava chips *(Simo-Tagne et al., 2021; Gao et al., 2022; Krishnakumar et al., 2022)*. Therefore, investigating the mechanical properties of fresh cassava roots at the harvesting stage is of great significance for the structural design, parameter optimization and operational parameter selection of cassava harvesters and dedicated cassava slicers. To date, numerous experimental studies have been conducted worldwide on the mechanical properties of common crop materials, mainly focusing on crop rhizomes, fruits, stems and leaves *(Fan et al., 2022; Hostetler et al., 2022; Jin et al., 2024; Zhang et al., 2025)*.

Yang Wang et al. prepared cylindrical and polyhedral specimens from cassava roots and measured their tensile, compressive and shear strengths as well as elastic modulus via physical tests *(Yang et al., 2011)*.

Yan Mei et al. adopted cuboid specimens of cassava roots to investigate their compressive and shear mechanical characteristics *(Yan et al., 2013; Yan et al., 2013)*. Nevertheless, these studies only tested partial tissues of cassava roots rather than the whole root. Cassava roots at the harvesting stage have a complex structure, with distinct mechanical performances among the outer cortex, inner cortex, parenchyma and pith. Mechanical parameters obtained from partial tissues fail to reflect the actual mechanical properties of intact cassava roots.

In this study, intact fresh cassava roots at the harvesting stage were selected as test materials. Combined with the main damage characteristics during harvesting and the subsequent slicing process, physical experiments were carried out to investigate the effects of major test factors on the compressive, shear and bending mechanical properties of cassava roots. Based on the analysis of experimental results, the variation laws of mechanical properties affected by each factor were summarized. The findings can provide fundamental data and theoretical support for the structural design of key components and the selection of operational parameters of low-damage and high-efficiency cassava harvesters and slicers.

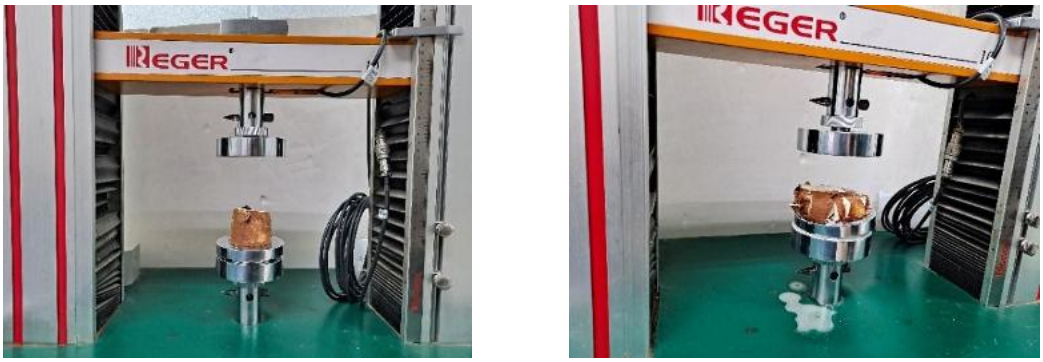
MATERIALS AND METHODS

Compression mechanical property test

Preparation of compression specimens

The test materials were collected from the full mechanization demonstration base for cassava and pineapple production at the Agricultural Machinery Research Institute, Chinese Academy of Tropical Agricultural Sciences, Zhanjiang City, Guangdong Province.

The cassava variety used was *Nanzhi 199*. Intact cassava roots with uniform shape, free from diseases, pests and mechanical damage were selected and cleaned to remove surface soil for standby.



Shear specimens with a length of 50 mm were prepared from the head, middle and tail parts of the cassava roots, and the average diameter at the middle of each specimen was recorded. Both cut ends of the finished specimens were immediately sealed with paraffin to mitigate test errors caused by water loss.

Fig. 1 - Compressive specimens

Test apparatus

The testing device adopted was the RGM-4005 microcomputer-controlled fully digital electronic universal material testing machine manufactured by Reger Instruments. This equipment is mainly used to determine the mechanical properties and related physical parameters of various materials under tension, compression, bending and shear conditions. Equipped with different fixtures, it can also perform tests such as tearing, peeling and puncture. A disc-type compression fixture was used in this experiment. The structural appearance and technical parameters of the testing machine are presented below. Other auxiliary tools included a vernier caliper, paraffin, utility knife and steel ruler.

a. Universal material testing machine **b. Post-compression state of samples**

Fig. 2 - Reer RGM-4005 electronic universal testing machine

Table 1

Nameplate parameters of electronic universal testing machine

Item	Parameter value
Tester model	RGM-4005
Maximum load capacity	5 kN
Test speed range	0.001–500 mm/min
Relative error of test force	Within ±1% of indicated value
Relative error of speed	Within ±1% of indicated value
Relative error of displacement	Within ±1% of indicated value
Tensile test stroke	800 mm
Effective test width	400 mm
Motor power	0.4 kW
Overall dimension of main machine	975 × 460 × 2170 mm
Weight of main machine	Approx. 200 kg

Experimental design and methods

Cassava roots are generally quasi-cylindrical, conical, or spindle-shaped, and their compressive mechanical properties differ among the head, middle, and tail regions *(Yang et al., 2011)*. Based on the structural characteristics of cassava roots and previous literature *(Yang et al., 2022; Dai et al., 2026)*, three experimental factors were selected for this study, namely loading direction, loading speed, and root position. The experimental factors and corresponding levels are listed in Table 2.

Table 2

Factors and levels for compression test

Level	Loading direction (A)	Loading speed (B) / (mm/min)	Root position (C)
1	Axial	50	Head
2	Major radial	100	Middle
3	Minor radial	150	Tail

According to the selected experimental factors and levels, an $L_9(3^4)$ orthogonal array was adopted for the compression mechanical property test of cassava tuberous roots. A total of 9 groups of tests were conducted in each run, and all tests were repeated once, resulting in 18 test groups in total. The compression fixture was correctly mounted on the electronic universal testing machine. A cassava tuberous root sample was placed at the center of the lower platen of the compression fixture, and the upper platen was adjusted until its bottom surface just contacted the sample. After setting the operating parameters of the testing machine, the test was initiated by clicking the "Run" button. The compressive load increased gradually. When the compression deformation reached the maximum value, the cassava tuberous root fractured, accompanied by a sharp drop in load reading, and the test was terminated. All experimental data were automatically recorded by the computer.

The compressive stress calculation formula for cassava roots is expressed as:

$$\sigma_y = \frac{F_y}{A} \quad (1)$$

In equation:

σ_y- Maximum compressive stress of specimen, [MPa];

F_y- Maximum compressive load in compression test, [N];

A - Cross-sectional area of specimen, [mm^2].

The calculation formula for the cross-sectional area under axial compression is expressed as:

$$A_y = \pi \left(\frac{D_b + D_s}{4}\right)^2 \quad (2)$$

In equation:

A_y- Axial cross-sectional area of specimen, [mm^2];

D_b- Maximum outer diameter at the middle of specimen, [mm];

D_s- Minimum outer diameter at the middle of specimen, [mm].

The calculation formula for cross-sectional area under radial compression is expressed as:

$$A_{y1} = 50 D_b \quad (3)$$

$$A_{y2} = 50 D_s \quad (4)$$

In equation:

A_{y1}- Cross-sectional area of specimen at major diameter, [mm^2];

A_{y2}- Cross-sectional area of specimen at minor diameter, [mm^2].

Shear mechanical property test

Preparation of shear specimens

Test materials were sourced from the same batch used in the compressive mechanical property test. Specimens with a length of 50 mm were prepared from the head, middle and tail portions of cassava roots, and the average diameter at the middle position of each specimen was recorded. After preparation, the cut ends of specimens were immediately sealed with paraffin to minimize experimental errors induced by moisture loss.

Test apparatus

A computer-controlled fully digital universal material testing machine (Model RGM-4005, Reger Instrument, Shenzhen, China) was adopted for the test. A self-designed shear fixture dedicated to cassava roots was equipped in this experiment. The fixture consists of two components: a blade clamping seat and a specimen supporting base, wherein the supporting base enables adjustment of the angle between the blade and the axial line of cassava root specimens. Additional experimental accessories include shear blades, vernier calipers, paraffin, utility knives and steel rulers. The operation mode of shear test and fixture structure are shown in figure 3.

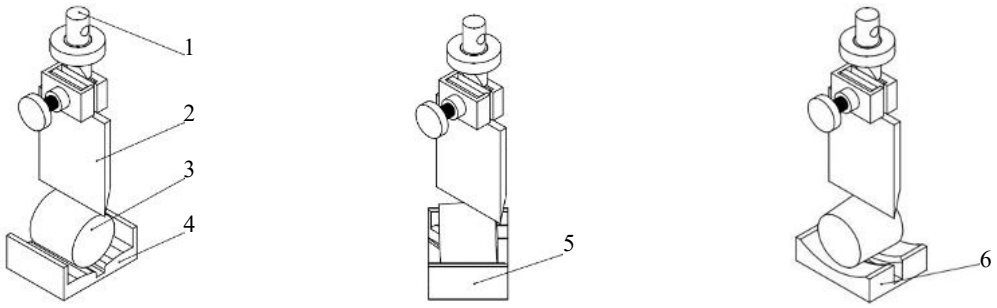


Fig. 3 - Shear mode and fixture

1. Blade clamping seat; 2. Shear blade; 3. Shear specimen; 4. Axial shear supporting base; 5. Lateral 45° shear supporting base; 6. Radial shear supporting base

Experimental design and methods

Based on previous studies on shear mechanical properties of rhizome crops and the actual slicing operation of cassava roots *(Yan et al., 2013; Chen et al., 2024)*, four experimental factors including shear angle (D), blade cutting edge angle (E), root position (F) and loading speed (G) were selected to investigate the shear mechanical characteristics of cassava roots. The shear angle is defined as the included angle between the cutting edge of the blade and the central axis of specimens, with three levels of 0°, 45° and 90°. A single-edge cutter was adopted in this test, and the blade cutting edge angles were set as 15°, 30° and 45°. Three root positions (head, middle and tail of cassava roots) were chosen, and loading speeds were designed at 50 mm/min, 100 mm/min and 150 mm/min. The experimental factors and corresponding levels are listed in Table 3.

Table 3

Factors and levels for shear test

Level	Shear angle (D)	Blade cutting edge angle (E)	Root position (F)	Loading speed (G) / (mm/min)
1	0°	15°	Head	50
2	45°	30°	Middle	100
3	90°	45°	Tail	150

According to the selected experimental factors and levels, an orthogonal array test $L_9(3^4)$ was adopted for the shear mechanical property test of cassava roots. Nine groups of tests were conducted per trial, and each test was replicated once, resulting in a total of 18 experimental groups. A tension-compression load cell was mounted on the sensor holder of the universal material testing machine. Subsequently, the blade fixture and specimen supporting base of the self-made cassava root shear fixture were connected to the upper and lower fixture joints of the testing machine, respectively, to complete the assembly of the load cell, fixture and testing equipment. The shear specimen was placed on the specimen supporting base. The moving crosshead of the universal testing machine was adjusted to make the cutting edge tangent to the outer cylindrical surface of the specimen. The specimen base of the fixture was further adjusted to set a specified included angle between the central axis of cassava root and the blade cutting edge. After parameter configuration on the testing machine, the test was initiated by clicking the “Run” button and terminated once the specimen was completely cut off by the blade. All test data were automatically recorded by the supporting software of the universal material testing system.

The shear stress calculation formula of cassava roots is expressed as:

$$\sigma_j = \frac{F_j}{A_j} \tag{5}$$

where:

σ_j- Maximum shear stress of specimen, [MPa];

F_j- Maximum shear load during shear test, [N];

A_j- Shear cross-sectional area of specimen, [mm^2].

The calculation formula for cross-sectional area under axial shear is given as:

$$A_j = 50D_j \tag{6}$$

where:

D_j- Average outer diameter of specimen, [mm].

The calculation formula for cross-sectional area under both axial 45° and 90° shear is defined as:

$$A_j = {\pi\left(\frac{D_j}{2}\right)^2}\Big/{\sin\alpha} \quad (7)$$

where: α- Included angle between blade cutting edge and specimen central axis, [rad].

Bending mechanical property test

Preparation of bending specimens

Test materials were consistent with those used for the compression mechanical property test. Referring to relevant literatures *(Yan et al., 2013; Chen et al., 2024)*, ten bending specimens with a length of 200 mm were prepared. In the preparation process, the head and tail of cassava roots were cut off and only the middle nearly cylindrical part was reserved. The outer diameters at the front, middle and rear positions of each specimen were measured and recorded by a vernier caliper, and the average value was regarded as the specimen diameter. After specimen fabrication, both end cross-sections were sealed with paraffin wax, and the bending test was conducted immediately.

Test apparatus

A computer-controlled fully digital universal material testing machine (Model RGM-4005, Reger Instrument, Shenzhen, China) was adopted for the test. The fixture consisted of the original indenter matched with the tester and self-fabricated lower supports, as shown in Figure 4. Other experimental tools included a vernier caliper, paraffin wax, utility knife and steel ruler.

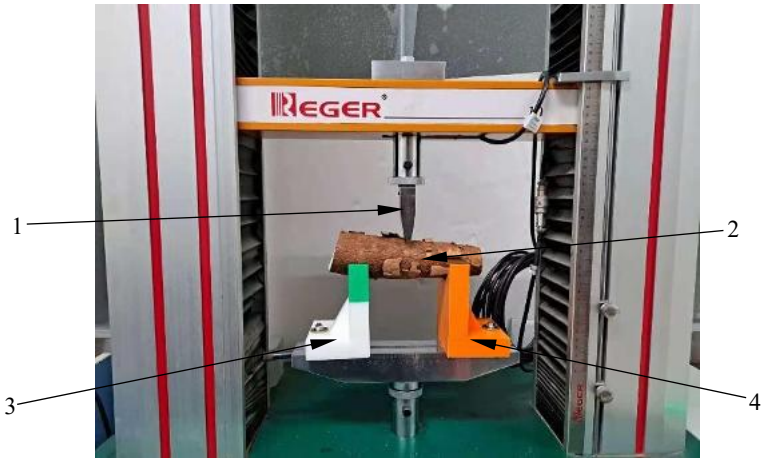

Fig. 4 - Bending test of cassava roots

1. Upper indenter; 2. Compression specimen; 3. Left lower support; 4. Right lower support

Experimental design and methods

The three-point bending method was adopted for the bending mechanical property test. The span of the three-point bending fixture on the universal testing machine was adjusted to 100 mm, with the midpoint of the span set as the indentation position of the upper indenter. The prepared cassava root specimen was placed on the supports, and the test was performed at a loading speed of 2 mm/min until complete fracture of the specimen. The double-layer peel of cassava root is approximately 2 mm thick and tightly bonded to the flesh; thus, cassava roots are simplified as cylindrical materials. Based on the load data recorded by the testing machine, the flexural modulus of elasticity and flexural strength of cassava roots can be calculated.

The bending moment equation for three-point bending test of cylindrical specimens is given as *(Liu., 2004)*:

$$M_w = \frac{F_w L}{4} \quad (8)$$

In equation:

M_w- Bending moment of specimen, [N·mm];

F_w - Maximum bending load of specimen, [N];

L - Bending span of specimen, [mm].

The moment of inertia and flexural section modulus of cylindrical specimens are expressed as *(Liu., 2004)*:

$$I_w = \frac{\pi d_w^4}{64} \quad (9)$$

$$W_w = \frac{\pi d_w^3}{4} \quad (10)$$

where:

I_w- Moment of inertia of specimen, [mm^4];

d_w- Diameter of specimen, [mm];

W_w- Flexural section modulus of specimen, [mm^3].

The calculation formula for flexural elastic modulus of the specimen is as follows:

$$E_w = \frac{F_w L^3}{48 y_w I_w} \quad (11)$$

where:

E_w- Flexural elastic modulus of specimen, [MPa];

y_w- Bending deflection of specimen, [mm].

The calculation formula for flexural strength of the specimen is as follows *(Liu., 2004)*:

$$\sigma_w = \frac{M_w}{W_w} \quad (12)$$

where: σ_w- Flexural strength of specimen, [MPa].

RESULTS AND ANALYSIS

Compression mechanical property test results and analysis

Test results

Loading direction, loading speed and root position were selected as influencing factors for compression tests of cassava roots at harvest stage, while compressive stress and compression deformation were taken as evaluation indices. After data calculation and screening, the measured values of compressive stress and compression deformation are listed in Table 4.

Table 4

Compression test results of harvest-stage cassava roots

Test No.	Level combination	Compressive stress (MPa)		Compression deformation (mm)	
		I	II	I	II
1	$A_1B_1C_1$	1.12	1.00	15.94	12.42
2	$A_1B_2C_2$	1.09	1.73	15.05	15.18
3	$A_1B_3C_3$	1.28	1.56	14.38	13.98
4	$A_2B_1C_2$	0.32	0.30	8.29	7.66
5	$A_2B_2C_3$	0.45	0.56	5.79	11.85
6	$A_2B_3C_1$	0.40	0.21	7.29	9.49
7	$A_3B_1C_3$	0.70	0.34	15.84	8.99
8	$A_3B_2C_1$	0.40	0.35	10.25	6.66
9	$A_3B_3C_2$	0.26	0.38	10.69	7.99

Results analysis

ANOVA of compression test data for cassava roots was conducted with SPSS, and the results are shown in Tables 5 and 6.

Error	50.530	9	5.614	—	—
Total	2435.170	18	—	—	—
Corrected Total	219.250	17	—	—	—

Note: R^2 = 0.770 (Adjusted R^2 = 0.565)

Loading direction (A) exerted an extremely significant effect on both compressive stress and compression deformation of cassava roots (P < 0.001 and P = 0.003, respectively). Loading speed (B) significantly affected compressive stress (P = 0.047) but showed insignificant influence on compression deformation (P > 0.05), while root position (C) had no significant impact on the two indicators (P > 0.05). The factor influence order was loading direction > loading speed > root position, and the determination coefficients indicated satisfactory fitting of the two ANOVA models.

As shown in the experimental data in Table 4, the average axial compressive stress is 3.45 times and 3.24 times the average compressive stress under large radial and small radial compression, respectively. The compressive stress varies from 0.21 MPa to 1.73 MPa with an overall average of 0.69 MPa. Loading direction exerts the most significant influence on the compressive stress of cassava roots, and the axial compressive strength is higher than the radial compressive strength.

Shear mechanical property test results and analysis

Test results

The load-displacement curves automatically recorded by the software of an electronic universal testing machine during shear tests on harvest-stage cassava roots were processed to obtain the maximum shear force of each sample. Combined with the premeasured root diameter of each replicate group, the maximum shear stress was calculated in accordance with the specified data processing method, and the calculated results are listed in Table 7.

Table 7

Shear test results of harvest-stage cassava roots

Test No.	Level combination	Maximum shear stress (kPa)

9	$D_3E_3F_2G_1$	112.28	78.96

Results analysis

ANOVA of shear test data for cassava roots was conducted with SPSS, and the results are shown in Tables 8.

Table 8

ANOVA for maximum shear stress results

Source	Type III Sum of Squares	df	Mean Square	f	Sig.
Corrected Model	8449.965[a]	8	1056.246	2.508	0.096
Intercept	7919.111	1	7919.111	18.806	0.002

Source	Type III Sum of Squares	df	Mean Square	f	Sig.
Shear angle (D)	1121.622	2	560.811	1.332	0.311
Blade cutting edge angle (E)	5487.648	2	2743.824	6.516	0.018
Root position (F)	523.623	2	261.812	0.622	0.559
Loading speed (G)	1317.072	2	658.536	1.564	0.261
Error	3789.928	9	421.103	—	—
Total	150744.510	18	—	—	—
Corrected Total	12239.893	17	—	—	—

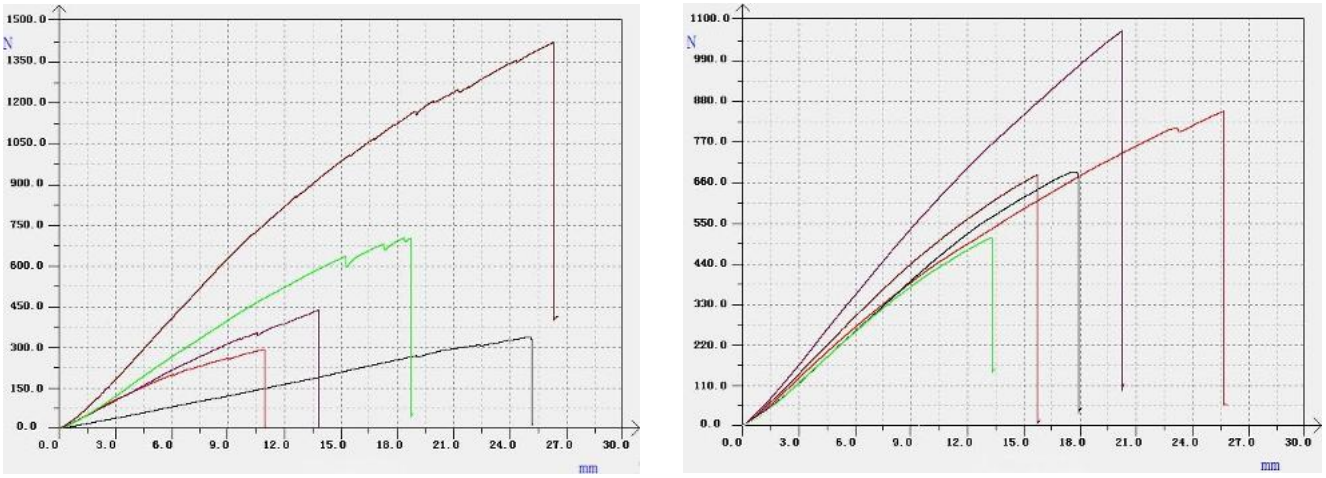
Note: R^2 = 0.690 (Adjusted R^2 = 0.415)

ANOVA results indicated that blade cutting edge angle (E) exerted a significant effect on the maximum shear stress of cassava roots (P < 0.05), which was the dominant factor governing the shear mechanical properties of cassava roots. Shear angle (D), root position (F) and loading speed (G) had no statistically significant influence on maximum shear stress (P > 0.05). The priority of factor influence followed the order: blade cutting edge angle (E) > loading speed (G) > shear angle (D) > root position (F). The determination coefficient R^2 = 0.690 and adjusted R^2 = 0.415 indicated that the regression model had acceptable fitting performance for experimental analysis.

Cassava roots consist of epidermis, endodermis and flesh, with respective mass proportions of 1.0% – 2.0%, 10.0% – 14.0% and 80.0% – 90.0%, showing relatively uniform internal composition. At the initial cutting stage, shear load increases nearly linearly with rising displacement, and the load-displacement curve approximates a straight line. After the shear load reaches its peak value, further increase of cutting displacement leads to two distinct load-falling patterns: sharp cliff-type drop and fluctuating stepwise decline. The difference originates from specimen dimension, loading speed and blade cutting edge angle. Larger outer diameter, loading speed or blade cutting edge angle causes wedge-induced fracture inside cassava roots during cutting, resulting in abrupt cliff-like load reduction; in contrast, wedge-induced fracture disappears when any of the three parameters is set at a low level. According to shear test data, the maximum shear stress of harvest-stage cassava roots ranges from 37.99 kPa to 154.22 kPa with an average value of 87.72 kPa. ANOVA confirms that blade cutting edge angle imposes a statistically significant effect on the shear strength of cassava roots.

Bending mechanical property test results and analysis

Test results



In the bending test of harvest-stage cassava roots, the maximum bending load F_w and bending deflection y_w for each specimen were obtained from load–displacement curves automatically recorded by the electronic universal testing machine. The bending elastic modulus E_w and flexural strength σ_w were calculated according to Eqs. (8) – (12), and the results are summarized in Table 9.

Table 9

Bending test results of harvest-stage cassava roots

Test No.	Specimen diameter d_w (mm)	Bending deflection y_w (mm)	Maximum bending load F_w (N)	Bending elastic modulus E_w (MPa)	Flexural strength σ_w (MPa)
1	37.33	9.40	227.04	5.28	1.11
2	39.35	10.95	290.92	4.70	1.22

Figure 5 shows the load-displacement curves obtained from three-point bending tests of harvest-stage cassava root specimens.

a. Test 1 b. Test 2

Fig. 5 - Bending load–deformation curves

Results analysis

As listed in Table 9, the maximum bending load of cassava roots specimens increases gradually with rising specimen diameter. Quadratic regression fitting was conducted between measured maximum bending load and specimen diameter, and the fitted equation is expressed as $F_w = 1.56d_w^2 - 112.3d_w + 2311$ with a determination coefficient R^2 = 0.9429, revealing that the ultimate bearing bending load has a positive quadratic correlation with root diameter. The bending elastic modulus generally declines as specimen diameter increases, while bending strength fluctuates slightly within the range of 1.05 - 1.53 MPa with an average value of 1.19 MPa. Owing to the high moisture content inside cassava roots, a great deal of sap exudes from loading and supporting positions during bending test, which imposes a certain influence on the measured bending strength. As illustrated in Figure 5, the whole bending process of harvest-stage cassava roots can be divided into two stages: quasi-elastic deformation stage and brittle fracture stage. At the initial loading phase, bending deformation is approximately proportional to the applied load. Once the load reaches the critical yield point, the specimens rupture instantly without apparent plastic deformation accompanied by crisp cracking sound, meanwhile the bending load drops sharply in cliff-type form, which demonstrates obvious brittle fracture property of cassava roots.

CONCLUSIONS

In this study, mechanical tests including compression, shear and bending were carried out on intact cassava roots at the harvesting stage. Based on systematic experimental analysis, the main research conclusions are summarized as follows:

(1) The compression test results show that the loading direction has a significant influence on the compressive stress of cassava roots, while the loading speed and root position have no significant effect. All three experimental factors (loading direction, loading speed and root position) exhibit insignificant effects on the compressive deformation of cassava roots. The compressive stress of harvest-stage cassava roots ranges from 0.21 MPa to 1.73 MPa, with an average value of 0.69 MPa, and the axial compressive strength is generally higher than the radial compressive strength.

(2) The shear test results indicate that the influencing order of each factor on the maximum shear stress of cassava roots is blade cutting edge angle (E) > loading speed (G) > shear angle (D) > root position (F). Only the blade cutting edge angle presents a significant effect on the shear mechanical properties, while the other factors have no significant influence. The shear stress of harvest-stage cassava roots varies from 37.99 kPa to 154.22 kPa, with an average value of 87.72 kPa.

(3) The bending test results demonstrate that the bending elastic modulus decreases gradually with the increase of cassava root diameter, while the bending strength fluctuates slightly in the range of 1.05–1.53 MPa, with an average of 1.19 MPa. Quadratic regression fitting was conducted between the maximum bending load and root diameter, and the coefficient of determination (R^2) reaches 94.29%, which indicates high fitting accuracy and verifies the reliability of the test data and the applicability of the regression model.

(4) By comparing the average failure stress obtained from compression, shear and bending tests, the damage priority of cassava roots under mechanical load is determined as shear damage, compressive damage and bending damage. This study systematically clarifies the basic mechanical response rules and mechanical damage characteristics of harvest-stage cassava roots. The research results can provide reliable theoretical support and basic test data for the structural parameter optimization of key components of dedicated cassava harvesters, the matching of field operation parameters, and the optimal selection of tool edge angles for cassava slicing machinery.

Keywords: *ridge roller, operating mode, resistance, ridge formation, experiment*

ABSTRACT
To explore the operational performance of a ridge roller under two different working modes, namely, linear arrangement (LA) and interleaved arrangement (IA) of adjacent ridging shovels, firstly, theoretical analysis was conducted to conclude that the operational resistance of IA is greater than that of LA. Secondly, a discrete element simulation method was employed to establish a discrete element simulation model. The extracted data verified the conclusions of the theoretical analysis. Qualitative analysis was conducted based on the formed ridge profile, indicating that LA has a better ridge forming effect than IA. Finally, field experiments were conducted, with the operating speed of the ridge roller (1.5 km/h, 3 km/h, 4.5 km/h) and different installation distances between adjacent ridging shovels (0, 240 mm, 480 mm) as experimental factors. The average operational resistance, the distance between adjacent ridge tops, and the height difference at the bottom of the ridge furrow were used as indicators for a full-factor experiment. It was concluded that under the same conditions, LA has the best ridge forming effect but requires the greatest resistance, while IA can effectively reduce resistance but has a poorer ridge forming effect. This study provides a theoretical basis and guidance for tillage and soil preparation operations.

摘要
为探究起垄机两种不同作业模式，即相邻起垄铲直线排布（LA）和交错排布（IA）下的作业性能，首先通过理论分析得出 IA 的作业阻力大于 LA；其次采用离散元仿真模拟方法，建立离散元仿真模型，通过提取数据验证了理论分析的结论，并通过形成的垄体断面轮廓进行定性分析，得出 LA 的垄体成型效果优于 IA；最后通过田间试验，以起垄机作业速度（1.5 km/h、3 km/h、4.5 km/h）和相邻起垄铲不同前后安装距离（0、240 mm、480 mm）为试验因素，以平均作业阻力和相邻垄体垄顶距离和垄沟最底端高度差为指标进行全因素试验，得出其他条件相同情况下，LA 的垄体成型效果最好，但是所需阻力最大，IA 阻力能有效降低但是垄体成型效果较差。本研究可为耕整地作业过程提供一定的理论依据和指导作用。

INTRODUCTION

The Northeast region is China's foremost grain production base, predominantly utilizing the ridge tillage method. This approach facilitates increasing soil temperature, enhancing water infiltration, and creating an optimal environment for crop root growth *(Zhao et al., 2025; Zhang et al., 2022; Yuan et al., 2019).* Therefore, rotary tillage and ridging operations are crucial components of agricultural mechanized production *(Shen et al., 2020; Guan et al., 2021).*

A large amount of research has been conducted both domestically and internationally on the issues of operational resistance and ridge formation effectiveness during rotary tillage and ridging operations. Scholars from the Nanjing Research Institute of Agricultural Mechanization under the Ministry of Agriculture have designed a sweet potato double-row ridging machine. The plow body primarily serves the function of furrowing, with a large amount of backfill soil *(Wang et al., 2025).* Researchers from Hunan Agricultural University have designed a plow-rotating combined rapeseed ditching and ridging machine. Compared to traditional ridging machines, it significantly improves soil fallback and achieves better ridging results (*Bao et al., 2017*). Some foreign researchers have also conducted comparisons on the ditching performance and fuel consumption of different ditching implements (*Kumar Sahu et al., 2018*).

Researchers from Henan Agricultural University optimized key components of the tobacco ridger and conducted experiments, resulting in reduced operational resistance and better consistency in ridge formation *(Song et al., 2024; Chen et al., 2022).* Scientific researchers and others have developed hillside land-leveling machines, but their functions are relatively limited, and the ridging effect is poor *(Zheng et al., 2021).*

Overall, current research on the operational resistance and ridge formation effectiveness of ridging machines primarily revolves around optimizing key components, with almost no theoretical research conducted on the most basic operational modes. Therefore, this paper focuses on two different operational modes of ridging machines, LA and IA, to study the factors affecting the operational resistance and ridge formation of ridging machines, aiming to provide theoretical support for rotary tillage and ridging operations.

MATERIALS AND METHODS

Ridge tiller operating mode

The ridger operates in two modes during its working process, and the top views of these two modes are illustrated in Fig. 1. The first mode involves the ridging shovels being aligned in a straight line. This ridging method ensures high uniformity and consistency in the ridges. However, on deeply plowed or rototilled soil, where there are numerous stems and stubble, and if the soil viscosity is high, the operational resistance increases, potentially leading to blockages and affecting the working efficiency, as depicted in Fig. 1(a). To address the blockage issue and reduce operational resistance, the second mode was developed, where adjacent ridging shovels are arranged in a staggered manner, maintaining a certain installation distance in the forward direction. This mode significantly reduces the likelihood of blockages, but it suffers from poor consistency in the shape of the ridges, as shown in Fig. 1(b).

(a) Linear arrangement (LA) *(b) Interleaved arrangement (IA)*

Fig. 1 – Two ridge-forming modes

1. ridge shovel; 2. soil

Regardless of which operation mode the ridger adopts, the operation process will encounter significant resistance, requiring a power machine to provide substantial energy. To understand the force conditions on the ridging shovel under the two operation modes, a force analysis was conducted on one side plate of a single ridging shovel.

Force analysis of LA

When the ridging shovel is arranged in a straight line, the squeezing action between the inner plates of two adjacent ridging shovels will push the soil from a width of a_1 to a ridge width of b_1, thereby directly forming a ridge. At this time, the two side plates that help form the ridge platform are subjected to the force of the soil. In this operation mode, both sides of the ridge are squeezed by the side plates, and the soil can only move in a limited space, being completely constrained. In soil mechanics, this situation is referred to as the presence of infinite soil complete constraint on both sides of the ridge, assuming that the soil has a low moisture content or is dry and loose soil. A force analysis is conducted on any mass point O with a depth of h embedded in the soil on the side plate as it moves forward at a constant speed, as shown in Fig. 2.

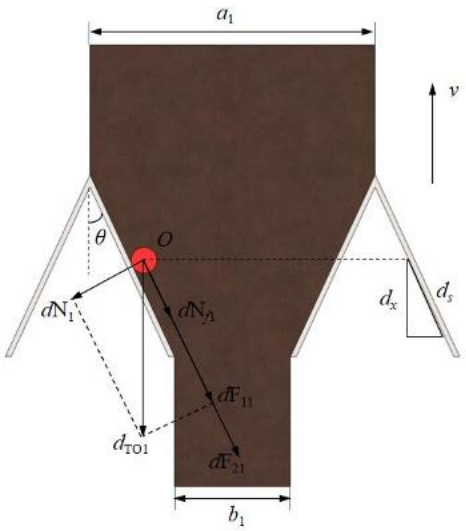

Fig. 2 – Force analysis of LA

In the figure, v represents the advancing direction of the ridging shovel, θ denotes the half-apex angle of the ridging shovel, dx signifies the displacement of particle O along the advancing direction, and ds indicates the displacement of particle O along the side plate. Calculations are performed based on Rankine's theory and assuming uniform normal pressure distribution on the side plate *(Waldron L.J., 1977*; *Waldron L.J. et al., 1981).*

$$\begin{cases} dA = hds \\ ds = \dfrac{dx}{\cos\theta} \\ dN_1 = pdA \\ dN_{f1} = \mu dN_1 \\ dF_{11} = \dfrac{dN_1}{\tan\theta} \\ dF_{21} = dN_{f1} + dF_{11} \\ p_1 = \xi\left(K_p\gamma h + 2c\sqrt{K_p}\right) \\ K_p = \dfrac{1+\sin\phi}{1-\sin\phi} \\ \xi = 1+\left(K_p - 1\right)\dfrac{\tan\theta}{\tan\phi} \end{cases} \quad (1)$$

where:

dA—when the displacement in the forward direction is x, the area swept by the side plate in a small unit, m^2;

dN_1—normal pressure acting on a micro-unit area, N;

p_1—normal pressure per unit area, N;

dN_{f1}—friction force, N;

μ—coefficient of friction;

d_{F11}—the component of the total resistance of soil to the side plate in the direction of the side plate, N ;

d_{F21}—total resistance in the direction of the side plate, N;

K_p—soil resistance coefficient under the condition of complete constraint on both sides of the side plate;

γ—soil bulk density;

β—the angle between the soil failure surface and the horizontal plane, （°）;

Φ—Soil internal friction angle, (°) ;

c—Soil cohesion, typically ranging from 5 to 100 kPa for cohesive soil;

ξ—For the three-dimensional shape factor, when there is complete constraint from infinite soil on both sides of the ridge, based on Coulomb's passive earth pressure theory, this parameter needs to be introduced for three-dimensional correction.

By processing Eq. (1), the total drag force of the micro-unit in the direction of the side plate is obtained:

$$dF_{21}=\left[1+\left(\frac{1+\sin\phi}{1-\sin\phi}-1\right)\frac{\tan\theta}{\tan\phi}\right]\left[\frac{1+\sin\phi}{1-\sin\phi}\gamma h^2+2hc\sqrt{\frac{1+\sin\phi}{1-\sin\phi}}\right]\left(\mu\frac{dx}{\cos\theta}+\frac{dx}{\sin\theta}\right) \quad (2)$$

Force analysis of IA

When the ridging shovels are arranged in a staggered manner, during operation, the two adjacent ridging shovels at the front will first extrude soil from a width of a_2 to a ridge width of b_2, forming a large ridge. Subsequently, the middle ridging shovel located behind them will divide the ridge width b_2 into two ridges with a width of c_2. Unlike the analysis in the previous section, when two ridges with a width of c_2 are formed, there are no other ridging shovels on either side of the rear ridging shovel to press against its side plates. The two sides of the formed ridge are in free constraints, which is referred to as the absence of infinite soil body complete constraints on both sides of the ridge. A force analysis is conducted on any mass point O with a depth of h into the soil on the side plate, as shown in Fig. 3.

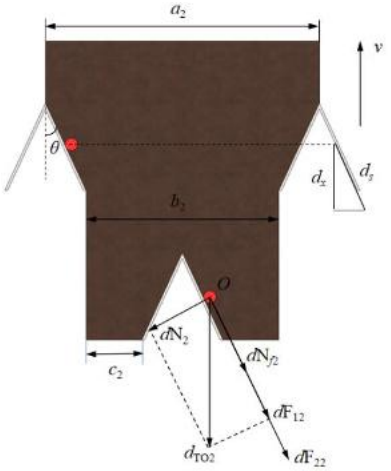

Fig. 3 – Force analysis of IA

Similar to the analysis in the previous section, there are:

$$\begin{cases} dA=hds \\ ds=\dfrac{dx}{\cos\theta} \\ dN_2=pdA \\ dN_{f2}=\mu dN_2 \\ dF_{12}=\dfrac{dN_2}{\tan\theta} \\ dF_{22}=dN_{f2}+dF_{12} \\ p=K_f\gamma h \\ K_f=\dfrac{\tan\beta+\cot(\beta+\theta)}{\tan\beta+\cot(\beta+\theta+\delta)}\dfrac{\sin\beta}{\sin\theta}\cos(\beta+\theta+\delta) \end{cases} \quad (3)$$

where: dN_2—normal pressure acting on a micro-unit area, N;

P_1—normal pressure per unit area, N;

dN_{f2}—friction force, N;

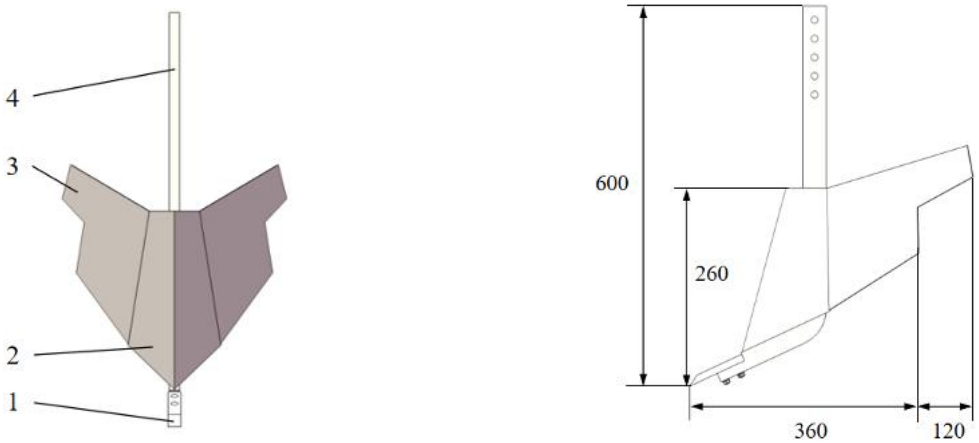
d_{F12}—the component of the total resistance of soil to the side plate in the direction of the side plate, N;

d_{F22}—total resistance in the direction of the side plate, N;

K_f—Soil resistance coefficient under free constraints on both sides of the side plate;

δ—The friction angle between the side plate and the soil, (°).

By processing Eq. (2), the total drag force of the micro-unit in the direction of the side plate is obtained:



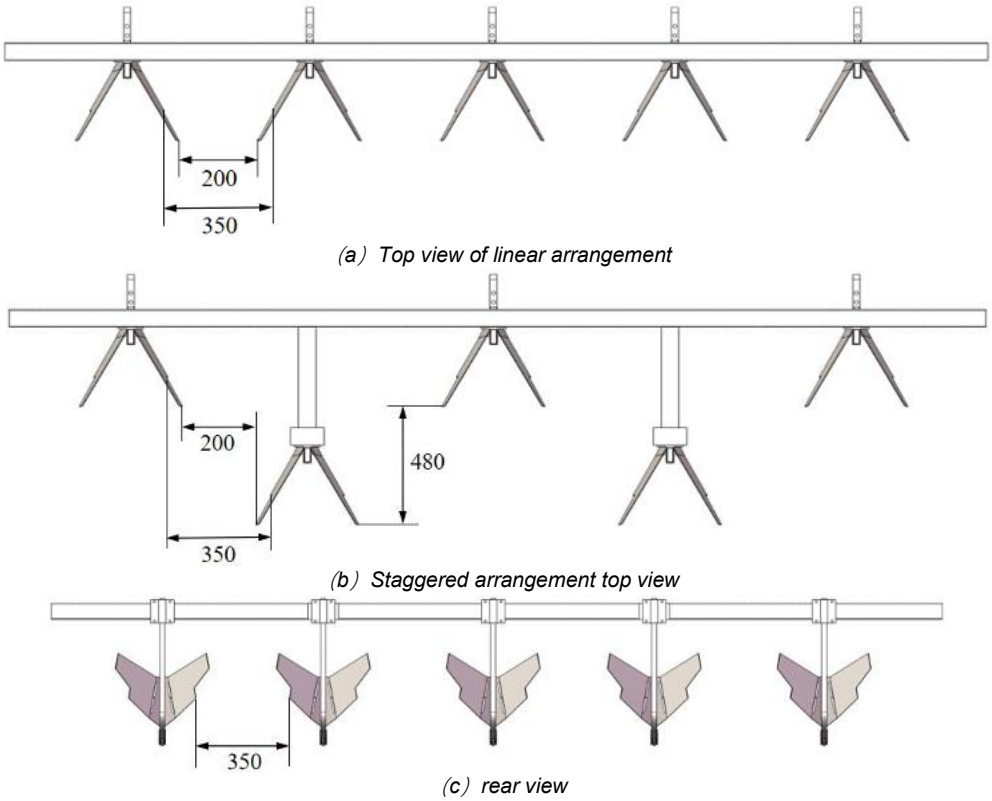
$$dF_{22} = \frac{\tan\beta + \cot(\beta+\theta)}{\tan\beta + \cot(\beta+\theta+\delta)} \frac{\sin\beta}{\sin\theta} \cos(\beta+\theta+\delta)\gamma h^2 \left(\mu \frac{dx}{\cos\theta} + \frac{dx}{\sin\theta} \right) \quad (4)$$

Based on the above analysis, it can be concluded that when the ridger operates in two different modes, the force conditions on the ridging shovel are completely different. When the friction force on the side plate of the ridging shovel is large, the corresponding power consumption of the entire machine is also high, and the wear on the side plate is also faster. Therefore, in order to reduce fuel consumption and extend the service life of the side plate of the ridging shovel, discrete element simulation analysis is conducted on the ridging shovel under the two operating modes, with the aim of qualitatively analyzing the force conditions on the ridging shovel and the consistency of the ridges in the two operating modes.

Ridge roller model establishment

The agricultural practice for corn cultivation in Northeast China primarily involves standard ridges with a ridge spacing of 650 mm. Therefore, the ridge spacing of the ridge roller model used in the simulation is set to 650 mm. To more clearly observe the simulated resistance of the two ridge-forming operation modes, the number of ridges is appropriately increased. Taking the example of forming four ridges with five ridge shovels, the simulation is conducted.

As the core component of the ridger, the ridging shovel bears almost all the operational resistance of the entire machine. Due to variations in ridging agronomic requirements across different regions, and considering only the differences in operational resistance of the ridging shovel under different arrangement modes and the consistency of ridge formation in this paper, the model is simplified. The digging shovel tip adopts a chisel-type tip and is installed at the bottom of the shovel handle using countersunk square root bolts. The soil divider plate is mounted on the lifting plate through a hinged shaft and can rotate at the hinged shaft to adjust the opening and closing angle. The three-dimensional diagram and key dimensions of the ridging shovel are shown in Fig. 4.



(a) Front view of ridging shovel
1.blade tip; 2.lifting board; 3.partition board; 4.shovel handle

(b) Side view of ridging shovel

Fig. 4 – Structural diagram of ridging shovel

During the simulation, based on agronomic requirements, the ridge top width is set at 250 mm. Using the 3D software SolidWorks 2020 (Dassault systems France, originally developed in USA), a model of the ridger is created according to the ridge forming conditions. The 3D models and key operational parameters of the ridger for two ridging modes are shown in Fig. 5. Since the ridge platform is formed by the contour created after the ridging process and subsequent compaction by the compaction wheel, this simulation analysis does not consider the factor of the compaction wheel. Therefore, the design specifies a distance of 200 mm between the ends of two adjacent soil divider plates (which is less than the top width of the ridge platform, which is 250 mm), a distance of 350 mm between the bottom ends of two soil divider plates, and a distance of 480 mm between the front and rear of two adjacent ridging shovels in the staggered arrangement mode.

Establishment of discrete element simulation model

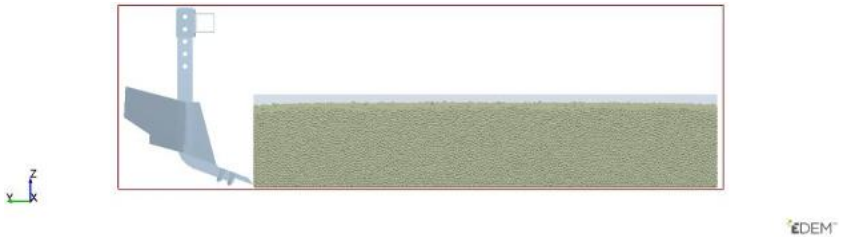
This study takes black soil in Northeast China as the research object. Based on the physical characteristics of Northeast black soil, a soil model is established using the discrete element software EDEM 2018 (USA). The simulation parameters are shown in Table 1 *(Zhao et al., 2021; Zeng et al., 2020; Ucgul M. et al., 2015; Zhang et al., 2023; Kojo A.et al., 2021; Hadi Z. et al., 2022)*.

Table 1

Parameters of Soil Model

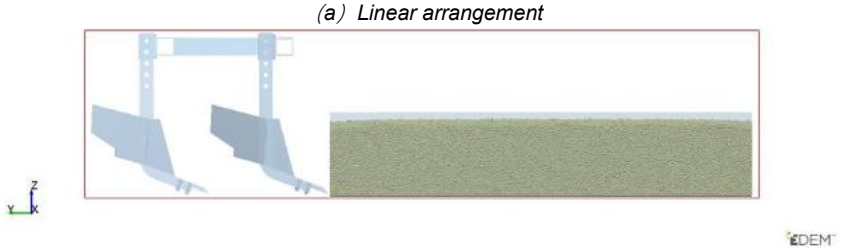
Parameters	Values
Poisson's ratio	0.41
Shear modulus / MPa	1.24
Density / (kg·m^{-3})	2150
Coefficient of restitution between soil particles	0.6
Static friction coefficient between soil particles	0.3
Rolling friction coefficient between soil particles	0.2
Normal contact bonding stiffness between soil particles / (N·m^{-3})	3.4×10^{8}
Shear contact bonding stiffness between soil particles / (N·m^{-3})	1.5×10^{8}
Critical normal stress / Pa	2×10^{5}
Critical shear stress / Pa	6.8×10^{4}
Bond radius / mm	5.5

Assuming that the field has undergone rotary tillage before ridging, resulting in fine and uniform soil, the external dimensions of the soil bin are determined based on the overall dimensions of the ridger, the ridging depth, the ridge-platform dimensions, and the ability of the ridger to form a distinct ridge in the simulation. Accordingly, the external dimensions of the soil bin are set to 3500 mm × 1500 mm × 300 mm (length × width × height). Due to the large volume of this soil bin, to shorten simulation time, the soil particle radius is set to 5 mm, and the soil particle generation type is selected with no limit on quantity, with a generation rate of 50,000 particles per second, and particle positions are randomly generated. The particles generated by the particle factory fill the soil bin under gravity. To make the bonding force between soil particles more consistent with field conditions, the soil bin is settled after being filled, and then continues to be filled until it is completely filled.



Save the overall model of the ridger in .stp format and import it into the EDEM soil bin model. The material is selected as 65 Mn, the depth of the ridging plate into the soil is 190 mm, and the forward speed is set to 3 km/h *(Liao et al., 2022)*. The simulation parameters of the ridger are shown in Table 2 *(Wang, 2019)*.

Table 2



Parameters of soil model

Parameters	Values
Poisson's ratio	0.3
Shear modulus / MPa	7.9×10^4
Density / (kg·m^{-3})	7865
Coefficient of restitution between the subsoiler and soil	0.6
Static friction coefficient between the subsoiler and soil	0.6
Rolling friction coefficient between the subsoiler and soil	0.05

The overall model under the two operating modes is shown in Fig. 6.

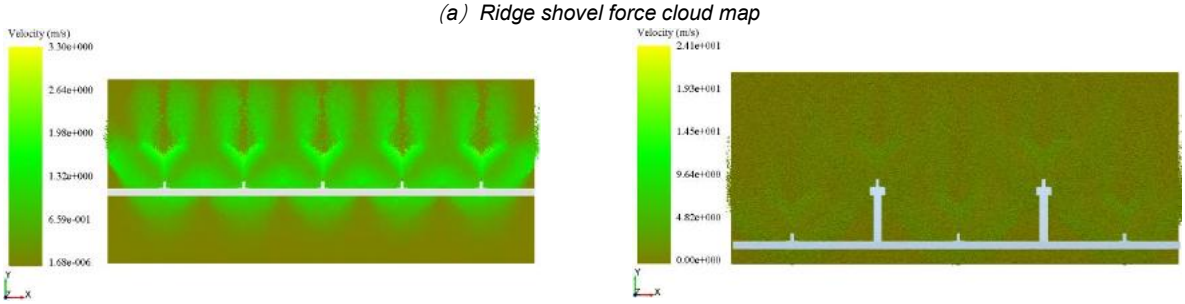
(b) Interleaved arrangement

Fig. 6 – Overall Model Construction

RESULTS



Simulation result of force analysis

The force and soil-velocity nephograms of the ridging shovel under the two operating modes of the ridger at the same time point are shown in Fig. 7.

LA *IA*

(a) Ridge shovel force cloud map

LA *IA*

(b) Soil velocity nephogram

Fig. 7 – Cloud Map Display

By extracting the force data at multiple identical time points after the ridging shovel is fully buried in soil under the two modes, and plotting the curves by Excel 2020, the results are shown in Fig. 8.

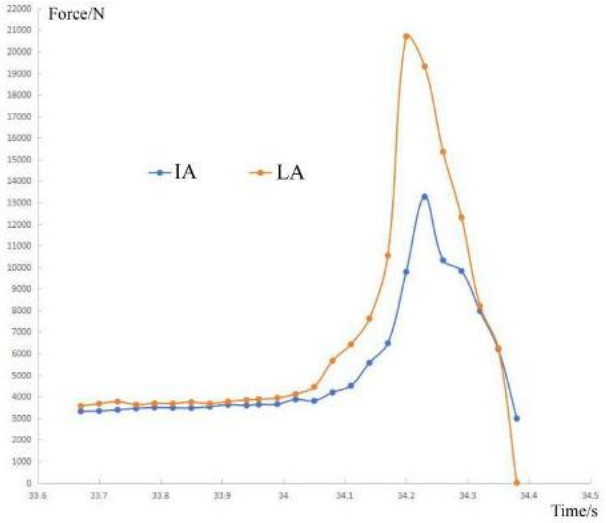


Fig. 8 – Force Line Graph of Ridging Shovel

Based on the analysis of the force cloud diagram and force polygonal line diagram of the ridging shovel, it can be concluded that the force exerted on the straight-line arrangement is greater than that on the staggered arrangement. According to the analysis of the soil particle velocity cloud diagram, the disturbance to soil particles caused by the straight-line arrangement is more pronounced than that caused by the staggered arrangement. This indicates that the closer the distance between two adjacent soil boards, the more pronounced the squeezing effect on soil particles during operation, and the greater the frictional force exerted on the adjacent soil boards. Consequently, the straight-line arrangement results in greater operational resistance and soil particle disturbance compared to the staggered arrangement.

Simulation result of ridge formation analysis

After the simulation of the ridging shovel is completed and the state of the soil particles in the soil bin has stabilized, cross-sections are taken at the same position on the ridge. The screenshots of the cross-sections under the two operating states are shown in Fig. 9.

（a）LA （b）IA

Fig. 9 – Cross-sectional View of the Ridge

Through observation and comparison, it can be seen that the shape of ridges formed by the straight arrangement is more consistent, with the depth of furrows being basically uniform. The bottom ends of the furrows are generally on the same straight line, and the distances l_1 and l_2 between the ridges of two adjacent ridges are basically consistent, as shown in Fig. 9(a). However, in the staggered arrangement, after the two ridging shovels located at the rear operate, the separated soil will move to both sides, causing soil to slide off the side of the ridge that is farther from the soil divider plate. This results in a height difference h_1 at the bottom end of the furrow, leading to poor consistency in the ridges, making the depth of the ridge platforms and furrows inconsistent, and there is a certain gap in the distance between the ridges of two adjacent ridges, with l_3 being slightly smaller than l_4, as shown in Fig. 9(b).

Based on the above analysis, it is preliminarily concluded that the linear arrangement mode results in greater resistance for the ridging machine but produces ridges with better consistency, while the staggered arrangement mode results in less resistance for the ridging machine but produces ridges with poorer consistency.

Field performance test

In the previous force analysis, it was conducted from a microscopic perspective, assuming low soil moisture content or dry soil, aiming to theoretically analyze the different forces exerted on the ridging shovel under two operating modes. According to relevant literature, the forward speed during operation also affects the force exerted on the ridging machine *(Tong et al., 2013; Jia et al., 2018).*

To explore the impact of different operating modes of the ridger on anti-blocking effect and ridge formation effect during actual operation, this chapter conducts a full-factor experiment based on the same structural parameters of the ridging shovel, using forward speed and the installation distance between adjacent ridging shovels as experimental factors, and taking operating resistance, the distance between the ridges of two adjacent ridges, and the height difference at the bottom of the furrow as indicators *(Wu, 2021).*

Test conditions and preparation

The field experiment was conducted at the experimental base of the Heilongjiang Academy of Agricultural Mechanization Engineering and Science in May 2025. The average stubble height of corn stalks was 103 mm, with soil hardnesses of 487 kPa (100 mm) and 1235 kPa (200 mm). The average soil moisture content was 16.2%, and the average root stubble moisture content was 38.6%. The experiment utilized a 1GZL-2 rotary tillage and ridging machine, which features rotary tilling at the front, three ridging shovels attached at the back, and an intermediate ridging shovel with an extension rod that allows for adjustment of the distance between adjacent shovels. This machine can form two ridges in a single operation. A photo of the rotary tillage and ridging machine is shown in Fig. 10.

Fig. 10 – Picture of rotary tillage and ridging machine

The equipment required for the experiment includes a Lovol 604 tractor (Shan dong, China), a GPS-10A multi-function testing device (Huade Soil Instrument Manufacturing Co., Ltd., Nanjing, China) for motor vehicles, a level ruler (Ningbo Deli Tools Co., Ltd., Zhejaing, China), a tape measure (Ningbo Deli Tools Co., Ltd., Zhejaing, China), a soil hardness meter (Huade Soil Instrument Manufacturing Co., Ltd., Nanjing, China), and a cutting ring assembly (Huade Soil Instrument Manufacturing Co., Ltd., Nanjing, China). The testing system is shown in Fig. 11.

Fig. 11 – Field experiment

The forward speeds were selected as 1.5 km/h, 3 km/h, and 4.5 km/h. As shown in Fig. 5(b), considering the front-to-rear dimension of the ridging shovel is 480 mm, the installation distances were chosen as 0, 240 mm, and 480 mm. To ensure a noticeable difference in resistance during each test, the forward distance for each test was set at 110 m, which includes a 10 m buffer zone and a 100 m effective working length. Each test was repeated three times. During the test, the forward speed was controlled by the tractor's electronic throttle, and the installation distance of the ridging shovel was adjusted by changing extension rods of different lengths. The coding of experimental factors is shown in Table 3.

Table 3

Experimental Factors and Levels

Level	Factors	
	Forward speed (km/h)	Front-to-rear installation distance (mm)
1	1.5	0
2	3	240
3	4.5	480

The operational resistance is represented by the average resistance within an effective operational length of 100 meters. The data acquisition method for the distance between the top of adjacent ridges and the height difference at the bottom of the furrow is as follows: within the experimental group corresponding to the effective operational length of 100 meters, three sets of data are randomly collected every 10 meters for recording.

The average operational resistance results are presented in Table 4.

Table 4

Analysis of Average Operational Resistance

Forward speed / (km·h^{-1})	Operating resistance of adjacent ridging shovels under different installation distances / N		
	0	240	480
1.5	1542	1346	1295
	1608	1377	1230
	1588	1285	1192
3	1830	1602	1452
	1857	1588	1389
	1760	1590	1490
4.5	1944	1750	1633
	2013	1681	1584
	2036	1684	1592

Analysis of the results in Table 4 reveals that when the forward speed remains constant, the operating resistance gradually decreases as the installation distance between adjacent ridging shovels increases. This trend aligns with the results of the theoretical analysis mentioned earlier, and the operating resistance is at its maximum when the installation distance between adjacent ridging shovels is zero. When the installation distance between adjacent ridging shovels remains constant, the operating resistance gradually increases as the forward speed increases.

The distance between the ridges of adjacent furrows is shown in Table 5.

Table 5

Distance Between the Tops of Adjacent Ridges

Forward speed / (km·h^{-1})	Distance between the ridges of adjacent furrows under different installation distances of adjacent ridge shovels / mm		
	0	240	480
1.5	203	205	206
	202	205	203
	203	204	206
3	202	208	209
	202	205	209
	201	207	208
4.5	203	213	215
	201	210	214
	203	211	217

Based on the analysis of the results in Table 5, it can be seen that when the forward speed remains constant, the distance between the ridges of adjacent furrows increases with the increase in the installation distance between adjacent furrowing shovels. When the installation distance between adjacent furrowing shovels is 0, the distance between the ridges of adjacent furrows is almost unaffected by speed. As the installation distance between adjacent furrowing shovels increases, the distance between the ridges of adjacent furrows is more significantly affected by speed, and the increase is more pronounced.

The height difference at the lowest end of adjacent ridges and furrows is presented in Table 6.

Table 6

Height difference at the lowest end of adjacent ridges and furrows

Forward speed / (km·h^{-1})	The height difference at the bottom of adjacent ridges and furrows under different installation distances between adjacent ridge shovels / mm		
	0	240	480
1.5	3	8	9
	2	8	8
	3	6	8
3	2	10	15
	1	11	18
	2	13	14
4.5	4	17	30
	3	20	41
	1	23	36

Based on the analysis of the results in Table 6, it can be seen that when the forward speed is constant, the height difference at the bottom of adjacent ridges and furrows increases with the increase of the installation distance between adjacent ridging shovels. When the installation distance between adjacent ridging shovels is 0, the height difference at the bottom of adjacent ridges and furrows is almost unaffected by speed. As the installation distance between adjacent ridging shovels increases, the height difference at the bottom of adjacent ridges and furrows is more significantly affected by speed, and the increase is more pronounced.

In all experimental groups, no blockage occurred, and it did not reach the level that required stopping the machine for cleaning. However, as the installation distance between adjacent ridging shovels increased, the accumulation of soil, straw, and stubble at the ridging shovel during operation was significantly alleviated.

CONCLUSIONS

(1) This article conducts a force analysis of the ridging shovel under two operating modes of the ridging machine (i.e., whether there is a front-to-back installation distance between two adjacent ridging shovels). Through theoretical analysis, it is concluded that the operating mode where the front-to-back installation distance between two adjacent ridging shovels is 0 results in a greater force on the ridging machine than the other mode.

(2) Using the discrete element simulation method, a discrete element model of the tiller-soil system was established. Under the condition of consistent other parameters, discrete element simulation tests were conducted for two operating modes with installation distances of 0 and 400 mm between adjacent tilling blades. This not only verified the previous conclusion, but also observed through the simulated ridges that the consistency of the ridges was also affected.

(3) A full-factorial field experiment was conducted, considering the forward speed of the ridger (1.5 km/h, 3 km/h, 4.5 km/h) and the installation distance between adjacent ridging shovels (0, 240 mm, 480 mm) as experimental factors. The experiment evaluated the ridger force, the distance between the ridges, and the height difference at the bottom of adjacent ridges as indicators. The results indicated that when the installation distance between adjacent ridging shovels was 0, the operational resistance was the highest, but the ridge formation effect was the best. As the forward speed and the installation distance between adjacent ridging shovels increased, the ridge formation effect gradually deteriorated. No blockage occurred during the experiment, but there was accumulation of soil, stems, and stubble at the ridging shovel, which could be effectively alleviated by increasing the installation distance between adjacent ridging shovels.

ACKNOWLEDGEMENT

This study was Supported by the Project of Laboratory of Advanced Agricultural Sciences, Heilongjiang Province (ZY04JD05-013); Heilongjiang province key research and development plan project (2024ZXDXB35) funding.

Keywords: *Soybean Disease Detection, YOLOv11, Lightweight Model, Real-time Detection*

ABSTRACT

To overcome YOLOv11's limitations in complex field environments, this paper proposed SDD-YOLOv11n, a lightweight real-time detector for soybean diseases. The model reconstructed the backbone using GhostConv to minimize redundancy and integrates a C3k2_Star module to enhance small lesion detection against background noise. Additionally, a Detect Efficient (DE) head further compressed the architecture. Experimental results verified the model's efficiency, achieving a parameter count of 1.88 M and a weight size of 3.9 MB—reductions of 27.3% and 25% compared to YOLOv11n, respectively. Furthermore, the model maintained high detection performance with a Mean Average Precision (mAP50) of 75.6% and an F1-score of 69.3%, demonstrating its effectiveness in balancing architectural efficiency and accuracy in complex field environments.

摘要

针对 YOLOv11 在复杂田间环境下存在的局限性，本文提出了一种轻量化的大豆病害实时检测模型——SDD-YOLOv11n。该模型利用 GhostConv 重构主干网络以最大限度地降低特征冗余，并引入 C3k2_Star 模块，旨在抑制背景噪声干扰的同时增强对微小病斑的检测能力。此外，设计了 Detect Efficient (DE) 检测头以进一步压缩模型架构。试验结果验证了该模型的高效性，其参数量仅为 1.88 M，权重文件大小为 3.9 MB，较 YOLOv11n 分别降低了 27.3%和 25%。同时，该模型在 mAP50 和 F1-Score 上分别达到了 75.6%和 69.3%，证明了其在检测精度和架构效率之间的良好平衡，能够有效应对复杂田间环境下的检测任务。

INTRODUCTION

As a vital oil and protein source, soybean production in China is integral to the national economy. However, prevalent diseases like soybean rust and bacterial spot can cause yield losses of 10%–80% or even total failure (*Liu et al., 2014*). Since traditional manual identification is inefficient and subjective, developing rapid, accurate detection technologies is essential for precision agriculture and food security (*Xiao et al., 2024*).

In recent years, to address issues regarding the accuracy and efficiency of crop disease identification, numerous scholars have focused on improving deep learning algorithms (*Xu et al., 2025*). *Zhu* proposed the CBF-YOLO algorithm, incorporating CSE-ELAN, Bi-PAN, and FFE modules, to detect common soybean pests in complex environments, significantly enhancing the model's detection capabilities (*Zhu et al., 2024*). *Korade* utilized YOLO for leaf extraction and applied various deep learning models to predict disease status. Their findings indicated that ResNet-50 was superior in capturing images from farms for soybean condition prediction, achieving the highest accuracy across all metrics; furthermore, they generated a confusion matrix to evaluate classification accuracy, verifying the model's robustness *(Korade et al., 2025)*. Using the public RiceDisease dataset, *Gan* proposed the G-YOLO model to improve rice leaf disease detection. By combining a lightweight efficient detection head with a multi-scale pyramid pooling layer, the model increased detection speed while maintaining considerable accuracy, making it highly suitable for deployment on resource-constrained edge devices (*Gan et al., 2025*). Similarly, to facilitate edge deployment for peanut disease identification, Sun developed YOLO-PLNet, a lightweight real-time detector specifically optimized for resource-constrained hardware *(Sun et al., 2025*).

To improve localization capabilities for tiny lesion features on cucumbers, Liu proposed the DCNSE-YOLOv7 algorithm, which introduced deformable convolutions and the SENet attention mechanism to strengthen effective target extraction, employed the K-means++ algorithm for anchor box reclustering, and replaced the loss function with Focal-EIOU (Liu *et al., 2023*). To enhance the identification accuracy of ginger leaf pests and diseases in natural environments, *Lan* introduced the GhostNet network and CA attention mechanism to propose Ginger-YOLOv5s, an improved model based on YOLOv5s that met real-time detection requirements while reducing missed and false detections (*Lan et al.,2024*). *Yang* proposed a lightweight tomato leaf pest and disease model based on YOLOv8n (*Yang et al., 2025*).

By reconstructing the original C2f with the StarBlock module and introducing the MLCA attention mechanism to reduce features along the channel dimension, further lightweighting of the original model was achieved. However, despite these advancements, existing studies generally encounter difficulties in balancing detection efficiency with accuracy. Common issues include excessive model parameters, high memory footprint, and a lack of universality in experimental data.

In summary, although deep learning is widely applied in agriculture, existing high-performance models (e.g., ResNet-50, Faster R-CNN) possess large parameter counts, making them difficult to deploy on agricultural drones and edge devices with limited computing power. While attempts have been made to lightweight the YOLO series, there remains a critical deficiency in maintaining a balance between extreme lightweighting (<4 MB) and performance preservation. Furthermore, optimizations targeting the YOLOv11 architecture for this context are currently insufficient. Consequently, this paper proposes SDD-YOLOv11n. By introducing GhostConv to reconstruct the backbone, integrating the C3k2_Star module, and designing a Detect Efficient (DE) head, this study aims to resolve the aforementioned challenges.

MATERIALS AND METHODS

IMAGE ACQUISITION AND DATASET CONSTRUCTION

The soybean disease dataset utilized in this study was collected at Jianshan Farm in Nenjiang, Heihe City, Heilongjiang Province. The dataset comprises three categories of leaf conditions: Healthy, Bean Rust, and Angular Leaf Spot (as shown in Fig. 1). To enhance image diversity and improve the algorithm's generalization capability, original images were acquired using a Redmi K60 smartphone under varying lighting conditions, weather scenarios, and growth backgrounds. Subsequently, the captured images underwent a manual screening process to select high-quality samples. All selected images were standardized to JPEG format, resulting in a total of 6,523 images.

To ensure the diversity of training samples and mitigate model overfitting, data augmentation techniques were applied to the existing dataset. Common augmentation methods employed include rotation, cropping, brightness adjustment, translation, background masking, and Gaussian noise injection. Specifically, noise injection was utilized to simulate environmental uncertainties encountered in real-world scenarios, thereby enhancing the model's robustness and generalization in complex field conditions (*Sulaiman et al., 2022*). Following data augmentation, the expanded dataset was manually annotated using LabelImg. The class labels were defined as "Healthy," "Bean_Rust," and "Angular_Leaf_spot." Finally, the dataset was randomly partitioned into training, validation, and test sets in a ratio of 8:1:1.

Despite the application of various data augmentation techniques to simulate complex field environments, the current dataset presents certain limitations. The images were exclusively acquired from a single geographic location (Jianshan Farm) using a specific capture device (Redmi K60), and encompass only three primary leaf conditions (Healthy, Bean Rust, and Angular Leaf Spot). Consequently, this restricted range of geographic, climatic, and disease category variations may inherently constrain the model's generalization capability when deployed across more diverse real-world agricultural scenarios. Acknowledging this, future data collection efforts will prioritize expanding the dataset across varied regions, diverse lighting scenarios, and encompassing a broader spectrum of soybean diseases to further enhance model robustness.

As a significant evolution in the series, YOLOv11 integrates novel feature extraction modules to maintain high speed and accuracy (*Khanam et al.,2024*). Its backbone, optimized from YOLOv9's GELAN architecture, features the C3k2 module. Compared to the C2f module in YOLOv8, C3k2 offers superior feature extraction with reduced parameter count and complexity, facilitating deployment across diverse environments (*Wu et al., 2025*). Among the five variants, this study selects YOLOv11n as the baseline. Its minimal computational footprint makes it particularly suitable for resource-constrained agricultural IoT devices (*Wang et al., 2025*).

a. Healthy b. Bean_Rust c. Angular_Leaf_spot

Fig. 1 - H (healthy) vs D (diseased) leaves of soybean

To further optimize the trade-off between detection accuracy and efficiency in YOLOv11n, this study proposes three structural enhancements. First, GhostConv substitutes standard convolutions to minimize computational redundancy and parameter volume. Second, a novel C3k2_Star module is introduced to refine the original C3k2 structure, offering a lighter and more flexible solution for resource-constrained field environments. Finally, a Detect Efficient (DE) head is implemented to replace the standard detection head, significantly reducing computational load while maintaining detection performance. The architecture of the improved SDD-YOLOv11n is illustrated in Figure 2.

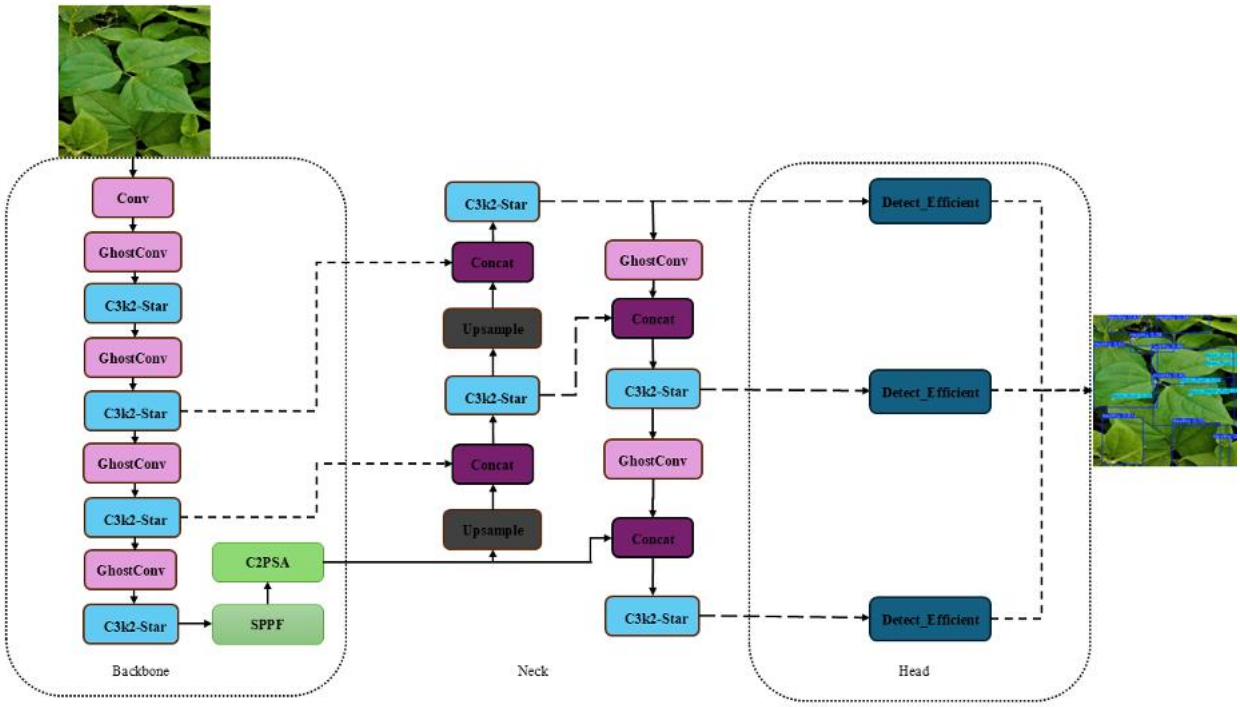

Fig. 2 - The architecture of the SDD-YOLOv11n network

Ghostconv Module

To accommodate resource-constrained edge devices in field applications, the substantial computational overhead caused by redundant feature maps in YOLOv11's standard convolutions presents a challenge (*Han et al., 2020*). Consequently, this study integrates the GhostNet architecture into YOLOv11n by substituting standard convolutions (excluding the initial layer) with GhostConv modules. By leveraging "cheap linear operations" to generate feature maps, this approach significantly compresses parameter volume while preserving critical spatial information. GhostConv achieves efficient feature learning by decoupling primary feature extraction from "ghost" feature generation.

The specific process is as follows:

1) Primary Feature Generation:

A small subset of convolution kernels is selected to extract core primary features. Assuming the input feature map is $X \in \mathbb{R}^{H\times W\times C}$, the number of primary feature channels is m (where $m \ll N$), and the number of

convolution kernels is m, the calculation for the primary feature map $Y^{'}$ is defined as shown in Equation (1):

$$Y^{'} = X * f^{'} \quad (1)$$

where $f^{'}$ represents the primary convolution kernels, and the computational cost is approximately $\frac{1}{s}$ of that of standard convolution.

2) Ghost Feature Generation:

For each primary feature, $s-1$ ghost features are generated via cost-effective linear operations, where s represents the generation ratio controlling the total number of features $N = m \times s$. Letting the i-th primary feature be $y_i^{'}$, its corresponding ghost feature generator is $\Phi_{i,j}$. The calculation for the ghost features is defined as shown in Equation (2):

$$y_{i,j} = \Phi_{i,j}(y_i^{'}),\ \forall i = 1,\ldots,m,\ \ j = 1,\ldots,s-1 \quad (2)$$

Upon completion of these two steps, the primary features and ghost features are concatenated to obtain the final output feature map Y.

In contrast to the full-channel operations in YOLOv11, GhostConv executes standard convolution on a subset of channels and generates the remainder via linear transformations. This mechanism significantly reduces computational complexity and parameter volume while preserving robust feature expression, thereby achieving model lightweighting without compromising detection accuracy.

C3k2_star Module

Derived from the Cross Stage Partial (CSP) architecture, the C3k2 module optimizes gradient flow and reduces redundancy through feature partitioning and fusion. However, to address the strict computational constraints of field environments, further lightweight optimization is required. Consequently, this study introduces the C3k2_Star module to replace the standard C3k2 in both the backbone and neck networks, thereby enhancing deployment efficiency.

The core of the C3k2_Star module lies in the stacking of n Star_Block instances. Derived from StarNet (*Ma et al., 2024*), the Star_Block employs element-wise multiplication for feature modulation. Inputs are processed via two parallel branches to generate a gating signal and a feature stream, respectively, which are then fused through element-wise multiplication to enhance feature representation (*Li et al., 2020)*.

Letting the input feature be X, this core interaction process is defined by Equation (3):

$$Y = (W_1 X) * f(W_2 X) \quad (3)$$

Where W_1 and W_2 represent the weight matrices of the two branches, respectively; f denotes the non-linear activation function; and $*$ represents element-wise multiplication. The structure of the StarBlock module is illustrated in Figure 3.

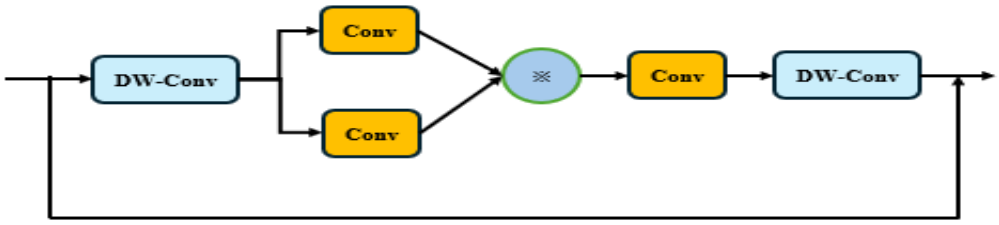

Fig. 3 - Structure of the StarBlock Module

Through element-wise multiplication, the module achieves dynamic channel re-weighting, effectively isolating minute disease symptoms from complex backgrounds by suppressing noise and amplifying relevant features. This "Star operation" significantly enhances representational capability via high-dimensional mapping Figure 3: Structure of the StarBlock Module maintaining a low parameter count, avoiding the substantial computational overhead associated with global attention mechanisms.

The final output undergoes a linear mapping to restore the channel dimensions, incorporating a residual connection as defined in Equation (4):

$$Y_{out} = W_3(Y_{star}) + X \quad (4)$$

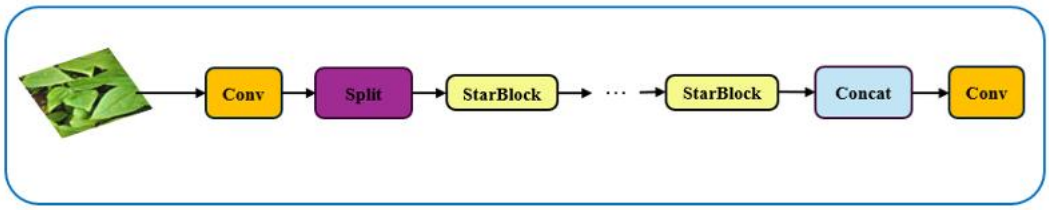

Fig. 4 - Structure of the C3k2_Star Module

Where W_3 represents the output projection matrix, and the addition operation denotes the residual connection. The structure of the C3k2_Star module is illustrated in Figure 4.

Detect_Efficient Module

To address parameter redundancy in YOLOv11n's decoupled head and enhance inference efficiency, this study introduces the DE module. While retaining Distribution Focal Loss (DFL) and Anchor-free strategies to ensure localization precision and multi-scale adaptability, the design implements lightweight optimizations to mitigate the high computational overhead associated with standard dense convolutional layers. The core principle of DFL is defined in Equation (5):

$$\hat{y} = \sum_{i=0}^{n} P\,(y_i) y_i \tag{5}$$

Where $\hat{y}$ represents the predicted bounding box coordinate, and $P(y_i)$ denotes the predicted probability density function. During the discretization process, the continuous regression range is discretized into the interval $[y_0, y_n]$, where $\sum P\,(y_i) = 1$.

To mitigate the high computational cost of dense convolutions, the DE module substitutes standard layers with stacked 3×3 Grouped Convolutions at the input of each branch. This design significantly lowers parameter count and complexity via independent channel processing, achieving an optimal speed-accuracy trade-off suitable for agricultural deployment.

RESULTS

Training Environment and Experimental Setup

Experiments were conducted on a Linux platform featuring an NVIDIA RTX 4090D (24GB) GPU and an 18-core 2.6GHz CPU, utilizing PyTorch 2.2.0 (CUDA 12.1). Training employed the SGD optimizer (momentum=0.937, initial $lr = 0.01$) with an input resolution of 640×640, a batch size of 64, and a duration of 300 epochs. Performance was evaluated via Precision(P), Recall(R), mAP, Parameters, GFLOPs, FPS, and Model Size(M-S).

Model Performance Evaluation

Upon evaluation on the test set, the computational complexity and inference efficiency of the optimized SDD-YOLOv11n model are presented in Table 1.

Table 1

The computational complexity and inference efficiency of the optimized SDD-YOLOv11n

GFLOPs	Parameters	FPS（Inference）	FPS(Comprehensive)	M-S/MB
4.4	1877017	503.59	285.05	3.9

Experimental results demonstrate that SDD-YOLOv11n exhibits significant lightweight efficiency, characterized by 1.88 M parameters, 4.4 GFLOPs, and a 3.9 MB file size, rendering it ideal for edge deployment. Furthermore, the model achieves exceptional speed—503.59 FPS for pure inference and 285.05 FPS for comprehensive processing—fully satisfying the stringent real-time requirements of agricultural disease detection.

The quantitative evaluation results for the SDD-YOLOv11n model are detailed in Table 2.

Table 2

Quantitative Evaluation Results of the SDD-YOLOv11n Model

P / %	R / %	F1-Score / %	mAP50 / %	mAP50-95 /%
68.9	70.3	69.3	75.6	54.2

Results indicate that the model demonstrates robustness with an mAP of 75.6% and a high-threshold mAP of 54.2%. Furthermore, an overall F1-score of 69.3% signifies a well-balanced trade-off between precision and recall.

Ablation Studies of Proposed Improvements

To validate the efficacy of the proposed improvements, a comprehensive ablation study was conducted on the YOLOv11n baseline. By incrementally integrating GhostConv, C3k2_Star, and the DE Head, the specific quantitative results are presented in Table 3.

Table 3

Ablation experiment

Model	Parameters	GFOLPs	M-S/MB	FPS	P%	R/%	mAP50)/%
Base	2582737	6.3	5.2	290.56	68.9	72.0	76.9
Base+a	2257041	5.5	4.6	298.38	69.3	69.9	76.3
Base+b	2472393	6.4	5.1	267.92	69.7	71.1	76.4
Base+c	2313041	5.1	4.7	290.47	68.9	71.5	76.9
Base+a+b	2146713	5.6	4.5	302.05	70.1	69.6	76.1
Base+a+b+c	1877017	4.4	3.9	285.05	68.9	70.3	75.6

Note: "Base" refers to the YOLOv11n model; "a", "b", and "c" denote the GhostConv module, the C3k2_Star module, and the DE module, respectively.

Combining all three modules yielded the best performance, validating the effectiveness of each component and their synergy.

Comparative Analysis of Different Detection Models

To benchmark SDD-YOLOv11n, quantitative comparisons were conducted against mainstream detectors—including Faster R-CNN(F-R) (*Ren et al., 2016*), SSD (*Liu et al., 2024*), and recent YOLO iterations (*Tian et al., 2025, Lei et al., 2025*)—under identical experimental conditions. Performance was evaluated via mAP, Parameters, GFLOPs, FPS, Recall, and Memory Size, with specific results detailed in Table 4.

Table 4

Contrast test

Model	Parameters	GFOLPs	M-S/MB	FPS	P/%	R/%	mAP50)/%
YOLOv11n	2582737	6.3	5.2	290.56	68.9	72.0	76.9
YOLOv12n	2508929	5.8	5.2	266.42	70.2	70.3	76.7
YOLOv13n	2448480	6.1	5.2	250.64	70.1	69.6	76.1
SSD	24103280	30.5	12.5	55.20	61.5	64.0	68.5
F-R	41350110	180.2	25.4	18.50	71.0	68.5	74.5
Ours	1877017	4.4	3.9	285.05	68.9	70.3	75.6

Comparative analysis reveals that while Faster R-CNN achieved the highest Precision (71%), its extensive computational overhead (41.3 M parameters, 18.5 FPS) and SSD's sub-optimal performance limit their practical utility. This aligns with the findings of *Korade*, whose international study demonstrated that while heavy architectures like ResNet-50 can achieve superior accuracy in soybean disease prediction, they often pose significant challenges for real-time farm deployment due to their complexity. In contrast, SDD-YOLOv11n surpasses these traditional models in comprehensive efficiency, demonstrating superior feature fusion in complex farmland environments. Against state-of-the-art YOLO variants (v12n, v13n), the proposed model reduces parameters and GFLOPs by approximately 25% while enhancing inference speed by 18–34 FPS. Achieving this lightweight design with negligible accuracy loss, SDD-YOLOv11n strikes a critical balance for energy-constrained drone applications.

Ultimately, SDD-YOLOv11n addresses the hardware constraints of smart agriculture. With only 1.87 M parameters (approx. 1/22 of Faster R-CNN) and the lowest computational load (4.4 GFLOPs), its minimal memory footprint (3.9 MB) facilitates cost-effective deployment on embedded systems like Raspberry Pi and Jetson Nano. The model's exceptional inference speed (285.05 FPS) not only extends operational endurance but also reserves ample computational margin for real-time decision-making systems.

Visualization of Detection Results

In this section, the detection results obtained from the trained YOLOv11n, YOLOv12n, YOLOv13n, and SDD-YOLOv11n models are visualized. The resulting comparison is illustrated in Figure 5, where bounding boxes are color-coded as follows: dark blue denotes “Healthy” leaves, sky blue indicates “Bean Rust,” and white represents “Angular Leaf Spot.”

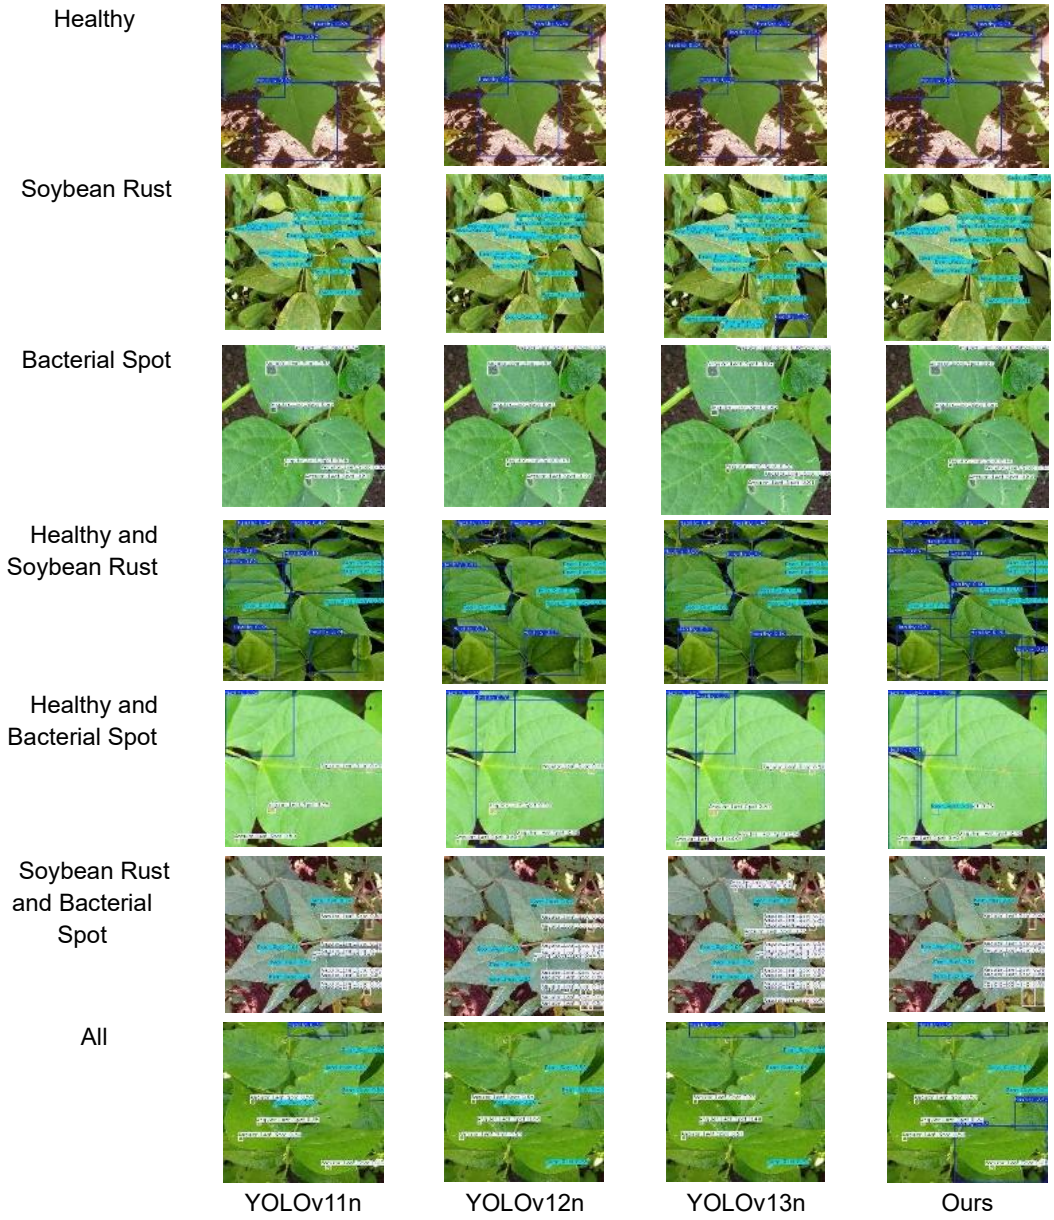

Fig. 5 – Visual Comparison of Detection Results Across Different Models

As illustrated, SDD-YOLOv11n achieves detection accuracy comparable to state-of-the-art benchmarks (YOLOv11n, v12n, v13n). Notably, it demonstrates superior robustness in classifying “bean rust,” avoiding the misclassifications observed in YOLOv12n and v13n. The results confirm the model’s efficacy in distinguishing between healthy, rust-infected, and angular leaf spot samples. Furthermore, by maintaining high detection speeds with minimal resource consumption, SDD-YOLOv11n is highly conducive to real-time deployment on edge devices.

Error Analysis and Robustness Evaluation

Figure 6 illustrates the confusion matrix of SDD-YOLOv11n on the test set, demonstrating exceptional classification consistency within complex field environments. Specifically, the “Healthy” category achieves near-perfect recognition. Misclassifications between the visually similar “Bean Rust” and “Angular Leaf Spot” (104 and 187 instances, respectively) are negligible relative to their vast true positive baselines. This confirms the robust discriminative feature extraction capability of the proposed GhostConv backbone and C3k2_Star module.

Fig. 6 – Confusion matrix of the SDD-YOLOv11n model on the test set

However, the matrix's background row and column reveal the primary error source: false negatives and false positives induced by background interference, with "Angular Leaf Spot" exhibiting a notably higher missed detection rate. To further interpret these error mechanisms and validate the model's decision-making process, Grad-CAM visualizations (Fig. 7) were evaluated on representative scenarios. This interpretability approach follows the recent advancements by Alhammad, who utilized deep learning combined with explainable AI (XAI) to ensure the transparency and reliability of disease classification in plant pathology *(Alhammad et al., 2025)*. As shown in Fig. 7(a), the model demonstrates exceptional feature focusing capabilities; even under severe leaf overlapping, the high-response regions (dark red) precisely localize on minute, early-stage bean rust lesions, visually confirming the efficacy of the proposed modules. Conversely, Fig. 7(b) and 7(c) expose the model's limitations under severe background noise. Fig. 7(b) illustrates a typical missed detection where a diseased leaf is ignored because the model's attention is erroneously drawn to surrounding weeds, resulting in a low feature response (cold tones) on the actual lesion. Furthermore, Fig. 7(c) presents a false-positive case where a non-target weed is misclassified as a "Healthy" leaf. Crucially, this uncovers an attention defocusing mechanism: the high-response areas are severely scattered across the background soil. This hallucination-like misclassification indicates that homologous green backgrounds and extreme lighting remain the main bottlenecks for the lightweight model's spatial attention allocation. Future work will integrate multi-scale feature fusion strategies to enlarge the global receptive field and optimize detection performance in such challenging scenarios.

(a) Accurate feature focusing on early-stage bean rust

(b) A false-negative case caused by severe background distraction

(c) A false-positive case showing attention defocus caused by complex background noise

CONCLUSIONS

To address the requirements for field-based soybean disease detection, this study successfully constructed a high-quality soybean disease image dataset. Based on this dataset and the YOLOv11n architecture, an efficient detection model for soybean rust and bacterial spot—SDD-YOLOv11n—was designed and implemented. The proposed model significantly reduces parameter count, GFLOPs, and model size while maintaining commendable accuracy, thereby providing a theoretical foundation for subsequent applications in actual field environments. The specific conclusions are as follows:

1. Structural Improvements: This study introduced structural optimizations to the YOLOv11n baseline. Specifically, standard convolutional layers were replaced with Ghost modules from the GhostNet architecture. Furthermore, the C3k2_Star module, inspired by StarNet principles, was proposed to supersede the original C3k2 module. Finally, a highly efficient detection head, Detect_Efficient, was developed. Experimental results indicate that, at the cost of a marginal decrease of approximately 1% in Mean Average Precision (mAP), the model achieved reductions of roughly 27.3% in parameter count, 30.1% in floating-point operations, and 25% in model size, while simultaneously increasing the frame rate by 5.5 FPS. This demonstrates a substantial reduction in computational demand while maintaining robust accuracy, thereby satisfying the conditions required for practical detection.
2. Comparative Advantage: Compared to current mainstream detection models, SDD-YOLOv11n exhibits significant advantages in terms of lightweight characteristics. While ensuring high accuracy, the model volume is merely 3.9 MB, and the floating-point operations are limited to 4.4 GFLOPs. In conclusion, SDD-YOLOv11n demonstrates superior performance regarding parameter count, model size, and computational complexity.

Although the SDD-YOLOv11n model proposed in this study achieved promising detection results on the self-constructed soybean leaf disease dataset, there remains room for improvement. Limitations exist regarding the diversity of disease types and the environmental complexity within the dataset due to the challenging nature of data acquisition. Future research will focus on expanding the scale and diversity of the data. Additionally, model compression techniques such as pruning and knowledge distillation will be applied to further lightweight the model, thereby continuing to reduce computational resource consumption and hardware dependency. Future work will also prioritize deployment experiments on edge devices to evaluate the model's real-time performance and stability in actual field environments.

ABSTRACT

To achieve precise prevention and control of rubber roll wear in huskers, this study established a complete experimental platform integrating mechanical transmission, feeding control, and visual acquisition units, and subsequently developed a real-time monitoring system for paddy flow instability based on machine vision. An image acquisition system composed of a CMOS camera and a customized light source was built to construct a dedicated dataset for paddy flow states. Based on the lightweight YOLOv8n detection model, Python programming was adopted in the PyCharm environment with the Ultralytics library integrated, realizing real-time recognition and quantitative analysis of paddy flow states. The results demonstrated that the system realized a real-time detection efficiency of 14 FPS on a local workstation, and the YOLOv8n model achieved a recognition accuracy of 90.8% in terms of mean Average Precision at IoU threshold 0.5 (mAP@0.5) for sparse and overlapping grain states. The system could effectively capture key abnormal states, including inclined paddy grains entering the rolling zone, sparse paddy flow lasting more than 5 seconds, and overlapping paddy flow density exceeding 10 grains/cm². This study transformed the mechanical characteristics of paddy flow instability into pixel-level quantitative indicators and established an integrated visual monitoring paradigm of "perception-analysis-decision", providing effective technical support for the intelligent management and control of huskers.

摘要

为实现砻谷机胶辊磨损的精准防控，本研究搭建了集成机械传动、喂料控制与视觉采集单元的完整实验平台，开发了基于机器视觉的稻谷料流失稳实时监测系统。采用 CMOS 相机与定制光源构建图像采集系统，构建稻谷料流状态专用数据集；基于 YOLOv8n 轻量化检测模型，在 PyCharm 环境中采用 Python 编程集成 ultralytics 库，实现料流状态的实时识别与量化解析。结果表明，该系统在本地工作站可实现 14FPS 的实时检测效率，YOLOv8n 模型对颗粒稀疏与堆叠状态的识别精度（交并比 0.5 阈值下的平均精度均值，mAP@0.5）达到 90.8%，可有效捕捉稻谷颗粒入轧倾斜、料流稀疏持续时间大于 5 秒、料流堆叠密度超过 10 粒/cm²等关键异常状态。本研究将料流失稳的力学特征转化为像素级量化指标，构建"感知-解析-决策"一体化视觉监测范式，为砻谷机智能管控提供了有效的技术支撑。

INTRODUCTION

During the operation of a rubber roll husker, the uniform wear condition of rubber rolls is crucial for maintaining a stable hulling process (*Prabhakaran et al., 2017*). Studies indicate that the dynamic imbalance in paddy flow distribution is the fundamental cause of uneven rubber roll wear (*Yehia & Katab, 2018*). However, constrained by the complex environment of the rolling zone, existing industrial sensors struggle to accurately monitor dynamic paddy flow conditions. To address this, there is an urgent need to develop a machine vision-based monitoring system. By enabling online recognition and analysis of the paddy flow before it enters the rolling zone, the system can accurately capture unstable flow patterns and provide real-time data support for subsequent control. The technology enables the prevention of rubber roll wear from the source and offers a new paradigm for the intelligent upgrading of grain processing equipment.

Early monitoring technologies primarily focused on mechanical parameters. For instance, Zhancheng Grain Machinery Factory in Zhejiang developed a real-time roll pressure monitoring system that uses sensors to provide immediate feedback on pressure data, offering visual guidance for manual operation (*Xiang and Ruan, 2009; Zhou et al., 2025*).

Wang et al. (2013) introduced a PLC control system into the rubber roll husker, integrating functions such as equipment start-stop, flow regulation, and fault alarm, thereby preliminarily achieving automated management of the hulling process. *Wang (2016)* designed a real-time monitoring system that breaks through single-dimensional limitations by simultaneously collecting parameters such as rubber roll speed, roll pressure, and flow rate, enabling intelligent management of operational parameters. Furthermore, uneven feeding during rubber roll husker operation leads to uneven wear of the rubber rolls, which can cause vibration and noise. *Wu et al. (2024)* conducted real-time detection and identification of abnormal wear conditions on the rubber rollers of a husker based on point cloud data, effectively addressing the challenge of accurately monitoring the wear state of rubber rollers. *Zhu (1979)* pointed out that rubber roll eccentricity is caused by vibration during the hulling process. To address this issue, *Liu (2020)* applied a multi-link vibration isolation concept within the rolls and designed an impact isolator, which mitigated shock vibration transmission and acoustic radiation in the rubber roll husker. Future studies should further investigate the influence of uneven rubber roll wear on rotor dynamic characteristics to mitigate vibration and noise.

In the field of material flow monitoring, although existing bulk material monitoring technologies are quite diverse, specialized research on paddy flow remains scarce. Current achievements mainly focus on belt conveyor scenarios in industries such as coal, while the physical and chemical characteristics of paddy differ significantly from other materials, imposing higher requirements on monitoring technology. For material flow monitoring on belt conveyors, *Wen et al. (2023),* integrated line laser and binocular vision techniques to detect coal flow on the conveyor belt, and achieved high-precision volumetric flow calculation through host computer processing. The method exhibits limited adaptability to complex conditions in paddy flow, such as overlapping and inclination. *Xu et al. (2022)* integrated RFID technology with point cloud data processing methods to achieve real-time measurement of the mass flow rate of bulk materials on a conveyor belt, obtaining high-precision results on fine sand materials, which can provide a reference for similar applications in paddy flow monitoring. *Yan et al. (2023)* employed a dual-array capacitive sensor combined with the BP-Adaboost algorithm to realize multi-parameter measurement of gas–solid two-phase flow, effectively improving the identification capability for complex flow conditions such as sparse or stacked particles. *Zhu et al. (2024)* evaluated the measurement performance of an array capacitive sensor for particle concentration in gas–solid two-phase flow through a CFD-DEM coupling method, thereby laying a theoretical foundation for precise monitoring of particle flow. However, this method requires adaptive optimization for the specific characteristics of paddy flow to enhance the accuracy and stability of the monitoring system.

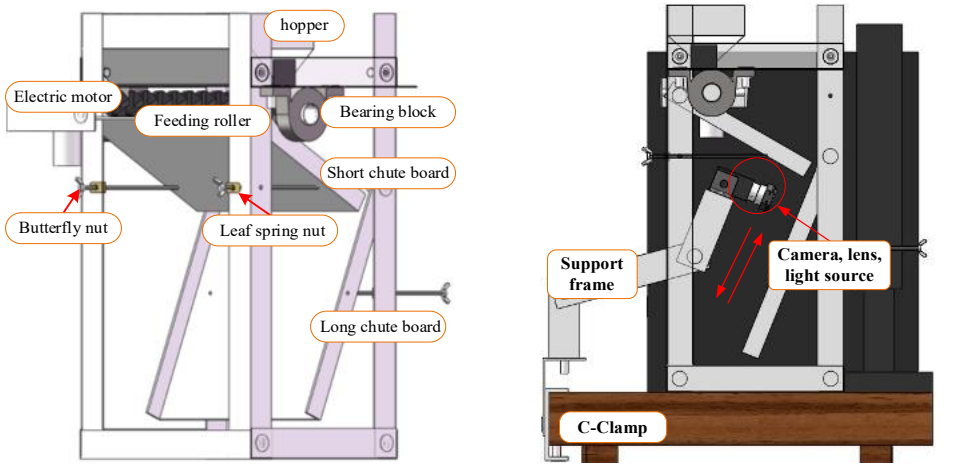
Current paddy flow monitoring faces three challenges: the difficulty in balancing accuracy with adaptability, the insufficient reliability of low-cost sensors, and the disconnection between monitoring and control processes. Therefore, this paper proposes an integrated visual monitoring paradigm of "perception-analysis-decision". By converting the mechanical characteristics of paddy flow instability into pixel-level quantitative indicators, it establishes a closed-loop feedback channel for the full-cycle intelligent management of rubber rolls.

MATERIALS AND METHODS

The feeding device and the visual acquisition unit form the hardware core of the system, working in coordination with the host computer to establish a comprehensive paddy flow status monitoring framework.

Mechanical system structure and functional implementation

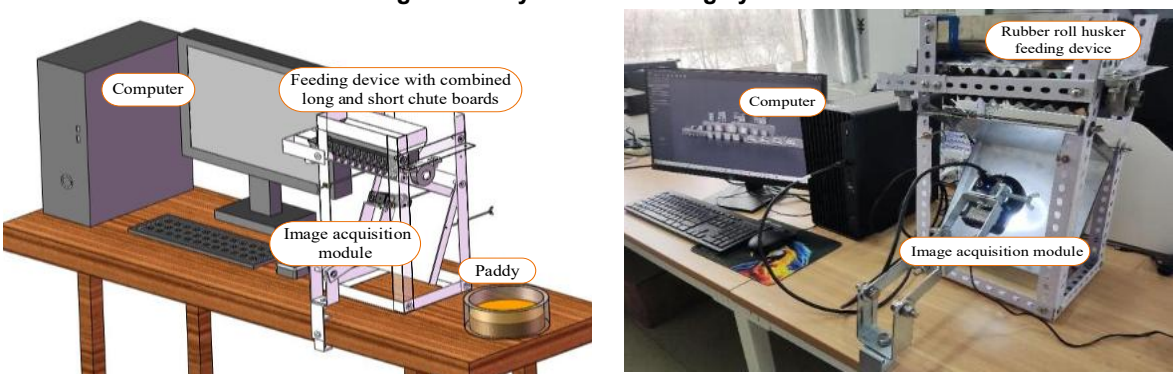
The structure and control performance of the feeding device directly determine the data reliability of the monitoring system. This apparatus adopts a combined long and short chute board structure and employs modular design to achieve precise simulation and regulation of paddy flow conditions. As shown in Fig. 1(a), the device consists of a hopper, feeding roller, electric motor, long and short chute boards, chute adjustment mechanism, and support frame.



The electric motor drives the feeding roller at a constant speed, ensuring continuous and stable material conveyance. The long and short chute boards facilitate uniform material distribution and guided flow through their uniquely designed inclination angles. The integrated Q312B leaf spring nut and butterfly bolt assembly enables stepless adjustment of the chute inclination, thereby allowing precise control over paddy flow velocity and density distribution. The support frame employs a rigid connection design to effectively suppress mechanical vibration interference with the paddy flow state. Through coordinated mechatronic control, the entire setup provides stable and reliable experimental conditions for the visual monitoring system.

Software architecture and data processing flow

The vision acquisition system establishes a comprehensive technical framework for paddy flow monitoring through the integration of hardware and software algorithms. As shown in Fig. 1(b), the vision acquisition unit adopts a modular design incorporating a Hikvision MV-CU013-A0UC CMOS industrial camera, MVL-HF0628M-6MPE 6mm fixed-focus lens, and ring LED light source (*Yu, 2024*).



The system utilizes a C-mount interface and USB 3.0 protocol to establish a high-speed data transmission channel. The camera ensures complete capture of dynamic paddy flow characteristics through its high-frame-rate acquisition capability. The lens maintains geometric imaging accuracy with a low distortion rate of -0.103%. The ring light source effectively suppresses localized shadows and enhances grain texture features through multi-angle uniform illumination. Under the centralized management of MVS V4.4.0 professional software, the unit achieves unified control of parameters including acquisition frequency, resolution, and image format. All hardware components operate in coordination with the computer-based main control system through standard communication protocols, collectively forming a stable and reliable visual perception foundation. Feeding device with combined long and short chute boards (*Zhang et al., 2024*).

The system software employs a multi-threaded architecture developed in a Python-OpenCV environment, implementing three core functional modules. The image acquisition module captures 640×640 resolution video streams at 168 FPS through the VideoCapture interface, performing color space conversion and image preprocessing. The model inference module utilizes the Ultralytics library to load an optimized YOLOv8 model, executing object detection with preset confidence and IoU thresholds to output particle localization and classification data. The visualization module integrates functions for rendering detection bounding boxes, annotating categories, and counting particles, supporting real-time display and result storage. Each module exchanges data through asynchronous message queues, working in conjunction with MVS professional software to manage device control and parameter configuration, thereby establishing a complete "acquisition-analysis-display" processing pipeline. By integrating the computer, image acquisition module, and feeding device, an efficient and stable image acquisition platform was established. The structural model diagram of this platform is shown in Fig. 2, providing a foundation for subsequent object detection and analysis.

Fig. 2 - 3D structural design and physical experimental platform for the flow monitoring system

Paddy flow dataset construction

YOLOv8 is an object detection algorithm based on convolutional neural networks. Building upon the YOLO series, it enhances detection performance by incorporating novel features and architectural improvements (*Ma et al., 2024; Paul et al., 2024; Tian., 2024*). The algorithm requires a large volume of image data with corresponding annotations as training samples. Through learning from these samples, it extracts features such as shape and color of paddy, thereby establishing a mapping relationship between input images and target detection results. To accurately identify paddy flow conditions, this study constructed a dedicated image dataset *(Ma et al., 2024)*. The dataset comprises a total of 530 images, including 220 static scenes and 310 dynamic scenes, divided into training and validation sets in an 8:2 ratio. Due to limitations in dataset size and annotation cost, only a training set and a validation set have been currently divided, with no separate test set established. Model performance evaluation is primarily conducted based on the validation set, while the model's generalization capability is further verified through dynamic real-time monitoring experiments. Future work will expand the dataset and introduce an independent test set to refine the evaluation framework. Using the LabelImg tool, manual annotations were performed in YOLO format, generating label files containing target bounding box coordinates and category labels. During annotation, sparse and overlapping paddy flow conditions were labeled as Sparse Grains (SG) and Pile-up Scenes (PS) tags respectively (*Song, 2025*). As shown in Fig. 3, for sparsely distributed grains, each grain was individually annotated with SG tags; for overlapping regions, whether single-layer or multi-layer distribution, they were uniformly labeled as PS tags to ensure the model can effectively learn morphological features of grains under different density conditions.

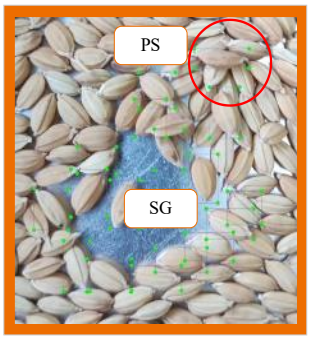

Fig. 3 - Labeling of paddy condition data

Model training via comparative experiments

During the model training phase, the YOLOv8 training parameters were configured within the PyCharm development environment. The yolov8n.pt, yolov8s.pt, and yolov8m.pt pre-trained models were selected for a comparative experiment to evaluate their performance on the paddy flow dataset. For data configuration, the dataset path was explicitly specified via a configuration file, with "SG" and "PS" defined as the two target categories. In the hyperparameter settings, the number of training epochs was set to 100, the batch size was set to 4, the initial learning rate (lr0) was 0.01, and the final learning rate (lrf) was 0.01, using a cosine annealing scheduling strategy. All models were trained under identical experimental settings to ensure comparability of the results (*Ma, 2021*). The complete algorithm workflow is shown in Fig. 4.

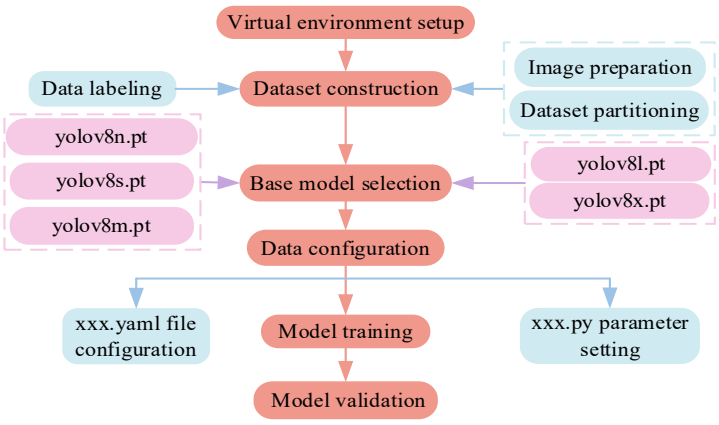

Fig. 4 - YOLOv8 application flowchart

RESULTS

Comprehensive model performance evaluation

Based on the YOLOv8 architecture, a comparative experiment was conducted using three model specifications named yolov8n.pt, yolov8s.pt and yolov8m.pt on a self-built paddy flow dataset. Through comprehensive evaluation using metrics including mAP@0.5, FPS and model size, the most suitable model architecture for dynamic monitoring scenarios was successfully identified (*Ma et al., 2025*).

Table 1

Performance metrics of different model specifications on the paddy flow dataset

Method	mAP0.5(%)	mAP0.5:0.95(%)	Frame Rate (FPS)	Model Size(MB)
YOLOv8n	90.8	73.1	14	6.3
YOLOv8s	89.5	74.2	9	22.5
YOLOv8m	92.4	77.2	3	52

Experimental results demonstrate notable performance disparities among the YOLOv8 series models in paddy flow detection tasks. As shown in Table 1, the nano model YOLOv8n achieves the optimal balance between accuracy and speed, attaining 90.8% mAP@0.5 with a compact model size of 6.3MB and an inference speed of 14 FPS. This demonstrates its strong capability in identifying sparse paddy flow conditions, making it suitable for deployment in computationally constrained small-scale rubber roll huskers. However, its mAP@0.5:0.95 of 73.1% falls below that of the medium model, indicating insufficient precision in target localization at lower IoU thresholds. The small model YOLOv8s shows suboptimal performance in both detection accuracy (89.5%) and processing speed (9 FPS), primarily attributable to increased network depth causing loss of shallow features. In contrast, YOLOv8m demonstrates comprehensive leadership in detection accuracy, achieving 92.4% mAP@0.5 and 77.2% mAP@0.5:0.95. Its deep feature pyramid effectively integrates multi-scale information, successfully addressing occlusion problems caused by paddy flow accumulation. Nevertheless, its practical application remains constrained by an inference speed of 3 FPS and a substantial model size of 52MB. Additionally, setting the training batch size to 4 may theoretically have a slight impact on model generalization performance. As shown in Table 1, all three models completed effective training in the paddy flow detection task, yielding stable and reliable detection results. The core focus of this study is to verify the monitoring feasibility of lightweight models, and the negative impact of this parameter setting on the final detection performance is within an acceptable range.

Table 2

Comparative analysis of performance metrics for different model variants on the paddy flow dataset

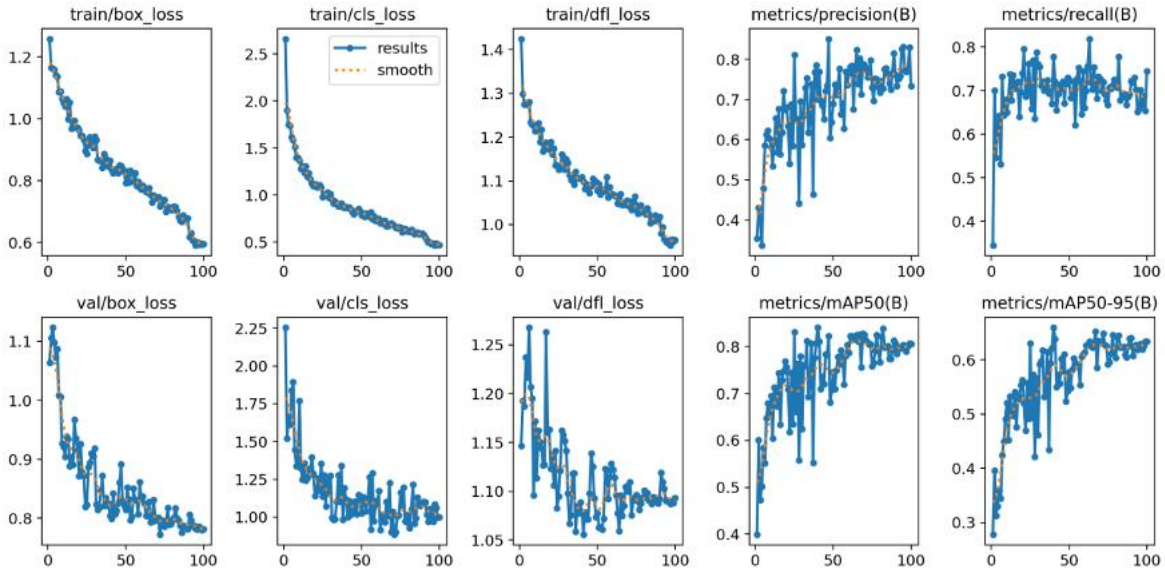
Parameter	YOLOv8n	YOLOv8s	YOLOv8m
Detection accuracy	Strong in sparse scenes Weak in overlapping scenes	Lowest overall performance	Optimal for all scenarios
Inference speed	14 FPS (Excellent real-time performance)	9 FPS (Suboptimal efficiency)	3 FPS (Severe delay)
Hardware compatibility	Embedded device friendly	Cost-ineffective	Requires GPU server support
Data dependency	Sensitive to low-resolution input	Sensitive to feature distribution	Requires high-quality training data

As shown in Table 2, comparative analysis of performance metrics from different model specifications on the paddy flow dataset demonstrates that although YOLOv8m achieves optimal detection accuracy, the final selection was determined to be YOLOv8n as the core model for paddy flow monitoring, considering the system's stringent requirements for real-time performance and embedded deployment. This model achieves the best balance between accuracy and speed, with its compact 6.3MB size and 14 FPS inference speed better aligning with practical engineering applications, thereby establishing a reliable technical foundation for real-time monitoring of paddy flow states in rubber roll huskers.

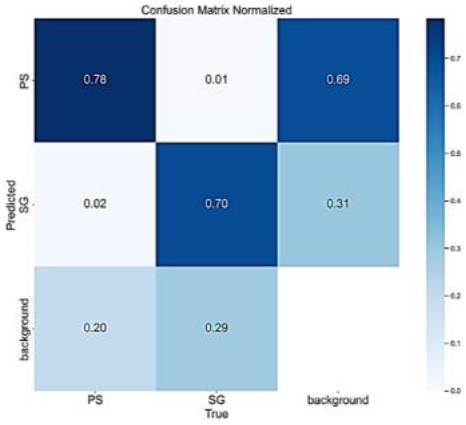
Evaluation of model prediction results

During the training of the YOLOv8 model, the convergence curve serves as a critical indicator for evaluating training effectiveness.

As shown in Fig. 5(a), the YOLOv8n model demonstrates favorable convergence characteristics on the paddy flow dataset. The bounding box regression loss decreases from 1.2 to 0.6, while the classification loss on the validation set exceeds that of the training set by 0.1, suggesting mild overfitting. Fluctuations in the object confidence loss within the validation set indicate that the model's adaptability to complex scenarios requires further improvement. Performance metrics reveal a precision of 0.8 and a recall of 0.75, with mAP50 reaching 0.82.



However, mAP50-95 plateaus at 0.68, indicating a performance bottleneck in detection under high IoU thresholds. After 50 training epochs, the model stabilizes, with the performance gap between the training and validation sets controlled within 5%, demonstrating robust generalization capability.



Analysis of convergence curves for YOLOv8s and YOLOv8m on the paddy flow dataset reveals distinct training patterns. YOLOv8s shows a decrease in bounding box loss from 1.2 to 0.6, with the validation set converging at 0.8, demonstrating progressive improvement in localization capability. However, the model displays noticeable overfitting as evidenced by a validation classification loss of 1.0 significantly exceeding the training loss of 0.5. Additionally, fluctuations in objectness loss reaching 1.2 on the validation set indicate limited generalization capability. The performance metrics show precision and recall values of 0.8 and 0.7, respectively, on the validation set, with mAP50 reaching 0.8, while mAP50–95 plateaus at 0.6 and shows slower growth.

Similarly, YOLOv8m exhibits a decline in bounding box regression loss from 1.2 to 0.6 in training and 0.8 in validation, confirming continuous localization improvement. Nevertheless, the model demonstrates pronounced overfitting with a validation classification loss of 1.0 compared to the training loss of 0.5. Objectness loss fluctuations up to 1.2 in validation further reveal inadequate generalization capacity. Performance metrics indicate validation precision of 0.8, recall of 0.7, and mAP50 of 0.8, while mAP50-95 stabilizes at 0.6 with decelerated growth. Both architectures consequently face limitations in high-threshold detection performance despite their steady progress in localization accuracy.

Convergence curve analysis reveals that YOLOv8s exhibits elevated validation loss with overfitting tendencies, while YOLOv8m demonstrates rapid initial convergence but subsequent instability. In contrast, YOLOv8n delivers optimal performance on the paddy flow dataset, characterized by synchronized and stable decline in both training and validation losses, demonstrating superior generalization capability that best aligns with the requirements of this monitoring task.

Classification accuracy is regarded as a vital metric for evaluating the classification capability of YOLOv8 models. When a model maintains high accuracy on both training and validation sets, it indicates effective fitting while possessing strong generalization capability. As shown in Fig. 5(b), the confusion matrix analysis of YOLOv8n demonstrates 78% recognition accuracy for overlapping paddy flow and 70% accuracy for sparse paddy flow, with cross-misclassification rates between both categories remaining below 3%. However, the background misclassification rates reach 20% for overlapping flow and 29% for sparse paddy flow, indicating the current model's capability to distinguish complex backgrounds requires further enhancement.

(a) Convergence curve of Yolov8n on the paddy flow dataset (b) Confusion matrix of YOLOv8n

Fig. 5 - Training dynamics and classification performance of YOLOv8n

Confusion matrix analysis of YOLOv8s indicates 65% recognition accuracy for overlapping paddy flow and 68% for sparse conditions, with a cross-misclassification rate of merely 2% between these two categories. However, the background misclassification rates reach critically high levels of 34% and 32% respectively, suggesting inadequate learning of background features and heightened susceptibility to interference from target characteristics. For YOLOv8m, the recognition accuracy for SG reaches 86%, while its predictive accuracy for PS remains notably low at 55%, demonstrating strong SG identification capability but significant errors in PS detection. The absence of cross-misclassification between categories confirms high accuracy in single-target recognition. Additionally, PS and SG instances are misclassified as background at substantial rates of 45% and 14% respectively, indicating prevalent background misclassification issues.

Classification accuracy analysis demonstrates that YOLOv8n achieves optimal overall performance in paddy flow detection, with recognition accuracies of 78% for overlapping paddy flow and 70% for sparse paddy flow, while maintaining cross-misclassification rates below 3% between categories. Despite background misclassification rates ranging from 20% to 29%, it still exhibits superior performance compared to other models. Both YOLOv8m and YOLOv8s exhibit specific limitations, either in particular scenario recognition capabilities or overall performance deficiency, accompanied by notably high background misclassification rates. Comprehensive evaluation confirms YOLOv8n as the preferred solution for achieving simultaneous accurate identification of both sparse and overlapping states in paddy flow.

Validation of the paddy flow monitoring system

To verify the practical performance of the material flow monitoring system, this study conducted system validation based on a dynamic material flow simulation platform in a local workstation environment equipped with a 12th-generation Intel Core i7 processor, 32 GB of RAM, and no GPU acceleration. A graded quantitative characterization system was proposed to systematically describe sparse and overlapping unstable states of paddy flow by defining grain density levels within a unit area. For sparse paddy flow conditions, three severity levels were established based on grain count per unit area: mild (10~20 grains), moderate (25~40 grains), and severe (45~60 grains). For overlapping paddy flow conditions, both single-layer and multi-layer structures were uniformly annotated as overlapping regions using the same grain quantity classification criteria. The system implements dynamic visualization of detection results through Python programming, enabling real-time display of distributed sparse and overlapping paddy flow regions at different severity levels.

The system achieves deep integration with the CMOS camera SDK through Python-OpenCV. Within the PyCharm development environment, it utilizes the Ultralytics library to load the trained YOLOv8n model weights and employs a multi-threaded architecture for synchronous processing of image acquisition and model inference tasks. For the dynamic and non-stationary monitoring scenario of paddy flow, the system must achieve real-time image sensing, instant processing, and fast inference. It should synchronously perform acquisition, detection, and recognition during transient changes in the flow state, ensuring high synchronization between the output results and the actual flow state, thereby meeting the timeliness and real-time decision-making requirements of online dynamic material flow monitoring (*He et al., 2025*). The system achieves real-time monitoring of dynamic paddy flow parameters via an asynchronous message queue mechanism, stably outputting key state information such as sparse and overlapping grain distributions. The real-time monitoring performance is illustrated in Fig. 6.

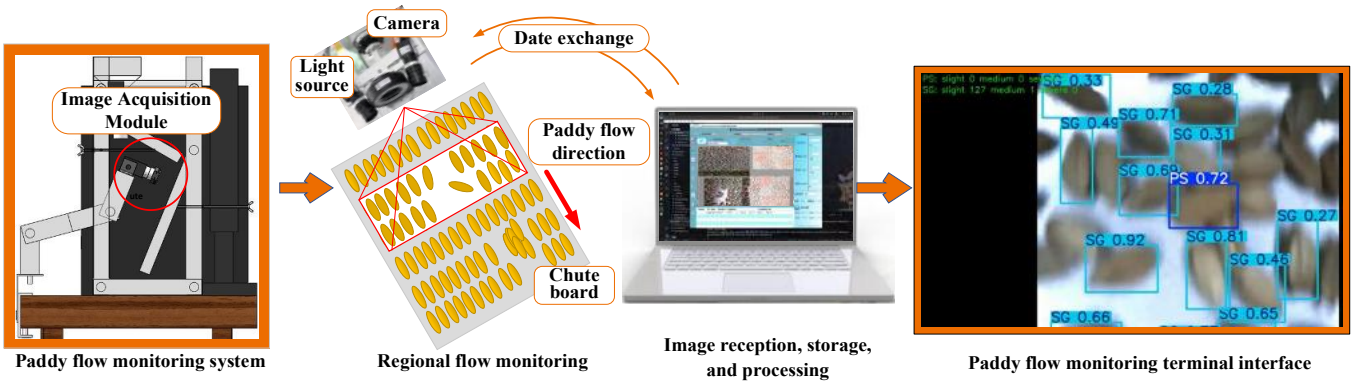


Fig. 6 - Real-time monitoring of sparse and overlapping paddy flow

Validation results demonstrate that the system maintains a stable frame rate of 14 FPS when processing 640×640 resolution video streams, meeting the real-time monitoring requirements. *Chen et al. (2020)* developed a real-time vision-based detection system for dynamic grain flow monitoring in rice combine harvesters and showed that a frame rate of 10~20 FPS is sufficient to capture transient changes in agricultural material flow and fulfill the engineering requirements for online detection. The comprehensive recognition accuracy for sparse and overlapping paddy flow states reaches 89.7%, enabling synchronous output of critical information including sparse and overlapping paddy flow conditions. The asynchronous message queue mechanism ensures stable data exchange, with memory usage remaining stable at approximately 1.8 GB during testing. The system demonstrates excellent engineering applicability and robustness, providing effective technical support for intelligent control of rubber roll huskers.

CONCLUSIONS

Addressing the issue of uneven wear in rubber roll huskers caused by unstable paddy flow, this paper systematically investigates machine vision-based monitoring methods for paddy flow conditions.

By constructing a dedicated image dataset, developing an optimized lightweight detection model, and integrating hardware-software systems, the feasibility and effectiveness of this technical approach in engineering applications have been verified.

The main conclusions are as follows:

(1) A comprehensive technical solution for paddy flow status monitoring has been proposed. This solution systematically establishes a technical framework encompassing image acquisition platform construction, multi-scenario data collection, specialized dataset development, and monitoring system integration, providing a reusable methodological foundation for dynamic paddy flow monitoring.

(2) Comparative experiments based on the YOLOv8 architecture demonstrate that the YOLOv8n nano model achieves the best balance between accuracy and speed. Although its mAP@0.5 of 90.8% is lower than that of YOLOv8m, its inference speed and model size are superior to the latter, while maintaining a real-time processing speed of 14 FPS, thereby fully meeting the real-time requirements of the husker operation scenario.

(3) The real-time paddy flow monitoring system exhibits significant engineering application value. Through coordinated hardware-software design, the system accurately identifies unstable paddy flow conditions including sparse and overlapping states in dynamic paddy flow, providing effective technical support for wear control in rubber roll huskers.

This research validates the application potential of machine vision technology based on lightweight deep learning models in agricultural mechanization. The proposed monitoring solution not only offers a novel approach for quality control in rice processing but also serves as a technical reference for real-time monitoring of other agricultural materials. Future research may further explore the model's adaptability under more complex working conditions and its integration with data from other sensors.

Keywords: *headland, closed fishtail turn, turning, headland width, length of turn*

ABSTRACT
The efficiency of agricultural operations depends on the length of non-working passes in the headlands. Therefore, the aim is to minimize both turn length and headland width. Various methods are used to construct turn trajectories, allowing them to be compared under specific conditions and enabling the most efficient movement pattern to be selected. This article examines closed fishtail-shaped turns composed of arcs with a given radius and straight-line segments. Analytical relationships were derived to determine the headland width and the length of closed fishtail-shaped turns for different travel directions of a machine-tractor unit equipped with a mounted reversible plough in an irregularly shaped field. It was found that, at a positive angle between the travel direction of the unit and the field boundary, movement of the unit across the field from right to left results in shorter closed fishtail-shaped turns and requires a narrower headland than movement from left to right.

РЕЗЮМЕ
Ефективността на извършване на земеделските операции зависи от дължината на неработните ходове в ивиците за завиване. Стремежът е дължината на завоите и широчината на ивицата за завиване да бъдат минимални. За построяване на траекторията на завоите се използват различни методи, които позволяват те да бъдат сравнявани при определени условия и да бъде избиран най-ефективният начин на движение. В настоящата статия са разгледани затворени гъбовидни завои изградени от дъги с определен радиус и прави линии. Изведени са аналитични зависимости за определяне на широчината на ивицата за завиване и дължината на гъбовидни затворени завои при различни направления на движение на машинно-тракторен агрегат с навесен обръщателен плуг в поле с неправилна форма. Установено е, че при положителен ъгъл между посоката на движение на агрегата и границата на полето и движение на агрегата по полето отдясно наляво гъбовидните затворени завои са с по-малка дължина и изискват по-тясна ивица за завиване в сравнение с движението отляво надясно.

INTRODUCTION

To increase the efficiency of the movement of autonomous machine-tractor units in the field, it is necessary to determine the most suitable trajectories of movement not only inside the field, but also in the headlands. If when moving in the field, efficiency is determined mainly by the direction and sequence of work movements, then when moving in the headlands, a choice must be made between different types of turns. The goal is to reduce the time for making turns, their length and the headland width. This, in turn, will lead to an increase in the productivity of the units and a decrease in soil compaction in the headlands. Ward et al. divided the headland into three zones – transition area, turning area and area located near to the field edge. The authors found that yields in these zones were lower than yields in the field. The main characteristic of the turning area was traffic, and this zone consistently reported worse yields than those in the field area. The outer zone also yielded significantly less, indicating that there were factors other than traffic that had an impact (*Ward et al., 2020*).

To select the most effective way of turning, the authors compare different types of turns, using the following approaches to build the turns:

1. The turns consist of primitives – straight lines and arcs with a certain radius. This allows the turns to be compared without considering factors such as driving speed and wheel turning speed.

Jeon et al. consider a stretched turn and a closed fishtail turn, which are created from arcs with the minimum turning radius of the tractor and straight lines. When performing a closed fishtail turn, the shape of the turn does not change depending on the angle between the direction of the working move and the field boundary, which leads to an additional path when entering or leaving the headland, depending on this angle (*Jeon et al., 2021*). In another study, the turns were built in the same way and again the shape of the turns was not adjusted to the angle between the working move and the field boundary. This results in a larger headland width *(Wang et al., 2025*). The authors point out that the length of the non-working move decreases by 18%, which is due to the different way of moving in the field.

Han et al. conducted a simulation study of three types of turns in the headland. In the proposed algorithm, the turns are built from curves with a certain turning radius of the tractor and straight sections. The highest field efficiency is achieved when performing a fishtail turn (X-shaped) due to the shorter path in the headland, which leads to less total field processing time. The authors recommend this turn for fields with a larger width, while for small widths (30 m) the efficiency is higher when performing a stretched turn (C-shaped) (*Han et al., 2019*).

An algorithm for performing a closed fishtail turn with an arcuate reverse is presented in (*Wang and Noguchi, 2018*). Unlike other algorithms, the turning radii in the two directions are different. The authors indicate that compared to a fishtail turn with a straight reverse movement, their proposed movement algorithm provides a smaller lateral deviation (3.9 cm), and the time and trajectory of the turn are reduced by 17% and 21%, respectively. The headland width is also smaller.

Chen et al. derived relationships for the turn length and turning time in the headland for four types of turns, but the type of turn depends on the angle between the travel direction and the field boundary, as well as on the direction in which the turn is performed. According to the authors, the largest reduction in turn length, the turning time and the headland width is achieved for the semicircular turn to the left (*Chen et al., 2023*).

2. The turns are made up of straight lines, arcs with a certain radius and connecting curves with a variable radius

When the turns are made up of arcs with a minimum radius and straight lines, it is necessary for the unit to stop or the turning of the wheels to be done very quickly, which leads to a large jerk of the machine. Therefore, Boryga proposes to use trigonometric transition curves to perform turns in the headland. They have a gradually changing curvature, which provides a smooth transition between the segments of the trajectory. This reduces sudden changes in direction and improves the dynamics of movement (*Boryga et al., 2025*).

Sabelhaus et al. analysed three forward turns in which clothoids were used to connect straight-line segments and circular arcs *(Sabelhaus et al., 2015)*. A clothoid has a curvature that varies progressively up to the reciprocal of the minimum turning radius, thereby providing a smooth transition between the other elements of the trajectory. Sabelhaus et al. also examined seven different headland turns constructed using clothoids. The authors indicated that the headland width is smallest in the fishtail turn, and the turn length and the time of its execution depend on the distance between the working moves. At a short distance of 3 m, the fishtail turn has the shortest turn length and the shortest driving time. While at 10 m the values of these indicators are lower in the Ω-turn (*Sabelhaus et al., 2013*).

Koc presents an analytical approach to modeling the curvature of the connecting curve using differential equations. The method can be applied to identify various types of transition curves. The author gives examples of solving the problem involving linear change of curvature and the curvature in polynomial and trigonometric form (*Koc, 2014*).

3. Turns involve curves with variable radius and follow a guiding curve that usually copies the field boundary

An algorithm is used to determine the field boundary based on images, then a reference line for turning is generated at a certain distance from the field boundary, and the turning trajectory is designed based on Bezier curves. The authors found that when turning at a lower speed, there is less lateral deviation and better trajectory tracking effect, but the turning time is longer (*Gao et al., 2023*).

Another study presented a field boundary detection algorithm based on DeepLabv3+, which also uses Bezier curves to calculate the turning trajectory. It was found that the robot can successfully perform a turn with a maximum deviation of 0.09 m, demonstrating precise navigation control in complex agricultural environments (*Wu et al., 2025*).

A similar algorithm is described in the patent (*Kakkar et al., 2021*). The turn is made along a guide line, which has the shape of the field boundary. A different turn trajectory can be selected, which can be displayed on the screen. The algorithm can select a trajectory according to various optimization criteria - road length, fuel economy, etc.

4. The turns are composed of two symmetrical curves described by polynomials

Boryga et al. propose an algorithm for planning a trajectory in which the movement proceeds along two transitional curves, constituting the so-called transition bi-curve. The authors consider turns of 90, 180, 270 and 360 degrees. According to them, the trajectories, the curvature of which is described by a polynomial of the third degree are the most favourable. They are characterized by the smallest absolute values of maximal acceleration and jerk and to lack jerk discontinuity (*Boryga, et al., 2020*).

Since the low efficiency of turning (turn length, time for its execution, headland width) is caused by the large turning radius of the tractor, a headland turning system has been created, including a steering auxiliary wheel in front of the tractor. This provides a large turning angle of ± 180º. This way of turning reduces the time for turning by about 50%, the turn length by about 80%, and the headland width by an average of about 50% for different types of turns (*Yang et al., 2022*). Such a turning system is more effective for units with a small and medium working width - up to 9 – 11 m (*Trendafilov and Delchev, 2018*). Systems with a fifth wheel on the tractor have not yet gained popularity.

The steering system built into the tractor can be supplemented with control of the breaking force of the wheels when turning. This will result in a reduction in the turning radius by about 15% to 35% compared to a manually operated vehicle without breaking (*Bharadwa, et al., 2021*).

Fishtail turns usually have the smallest length and width of headland. Therefore, they are preferred when making turns by implements with mounted machines. The aim of this study is to determine the headland width and the length of fishtail closed turns performed by a reversible plough in different directions of movement in an irregularly shaped field.

MATERIALS AND METHODS

Previous publications examined the movement of trailed and semi-mounted reversible ploughs in the headlands of an irregularly shaped field (*Trendafilov, 2010; Trendafilov, 2017*). In these cases, the turns were performed in forward motion. Trendafilov derived relationships for determining the turn length and headland width when performing open fishtail-shaped turns with reverse movement *(Trendafilov, 2025)*. The same methodology is used in the present article and is described again for the reader's convenience.

Fig. 1 shows a diagram of the machine-tractor unit. Its designations are:

- α is the angle between the direction of movement of the unit and the headland. It varies between 0º and 90º. It is assumed that the angle is positive when it is on the right side of the unit when moving towards the headland (Fig. 1a), and negative – on the left side of the unit (Fig. 1b);
- B – the working width of the unit;
- l_a– the kinematic length of the unit;
- l_n – the distance from the center of the unit (the middle of the rear axle of the tractor) to the top of the share of the first plough body;
- g – the distance from the axis of symmetry of the tractor to the top of the share of the last plough body;
- y – the distance from the tractor's axis of symmetry to the end of the share of the first plough body (or to the inner edge of the wheel of the tractor, which moves in the furrow left during the previous working stroke);
- R – the turning radius of the unit;
- M – the distance between the outer edges of the rear wheels of the tractor;
- H – the longitudinal base (distance between the front and rear axles) of the tractor;
- E – the headland width.

A closed fishtail turn is considered with two directions of movement of the machine-tractor unit in the field – from left to right and from right to left. The turn is made up of three circular segments with a radius equal to the minimum turning radius of the unit. The turn length in the headland includes the length of the circular segments and the length of the rectilinear path travelled by the unit until reaching the inner border of the headland. The headland width is determined by summing straight segments, the length of which can be determined from the parameters of the unit. The headland width and the turn length are determined for an interval of change of angle α from 10º to 90º, since below 10º a headland is not needed.

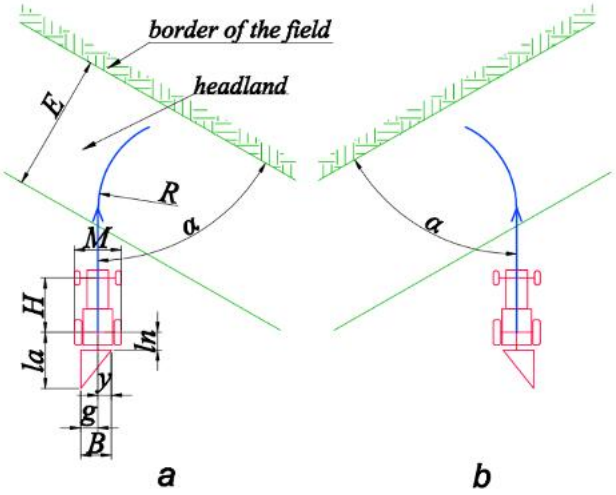

Fig.1 - Scheme of the machine-tractor unit and angle between its direction of movement and the field boundary (*Trendafilov, 2025*)

a – positive angle; b – negative angle

Only the case in which angle α is positive is considered, since a symmetric image is obtained at a negative angle. As indicated by *Trendafilov (2010)*, the relationships are the same, but their positions are interchanged. Thus, the relationships for movement across the field from left to right at a positive angle apply to movement across the field from right to left at a negative angle, while the relationships for movement from right to left at a positive angle α apply to movement from left to right at a negative angle.

Using the obtained relationships, the headland width and turn length were determined for a ploughing unit with the following parameters: $H = 2\ m$; $M = 1.8\ m$; $R = 3.2\ m$; $B = 1.2\ m$; $l_a = 2\ m$; $l_n = 0.6\ m$; $y = 0.5\ m$; $g = 0.7\ m$. The results are presented graphically and analysed.

RESULTS

Closed fishtail turn - movement from left to right

As shown in Fig. 2a, the turn is composed of three circular arcs, whose central angles satisfy the following relationship:

$$\beta_1 + \beta_2 + \beta_3 = 180° \quad (1)$$

Hence, the turn length is obtained as:

$$l_T = \pi R \quad (2)$$

The width of headland E can be determined by summing the segments of known length:

$$x = l_a.\sin\alpha + (R - g)\cos\alpha - R\cos(\alpha + \beta_1) \quad (3)$$

$$y = H.\sin(\alpha + \beta_1) \quad (4)$$

$$z = -0.5M.\cos(\alpha + \beta_1) \quad (5)$$

Therefore, the headland width is obtained as:

$$E = x + y + z = l_a \sin\alpha + (R - g)\cos\alpha + H.\sin(\alpha + \beta_1) - (R + 0{,}5M)\cos(\alpha + \beta_1) \quad (6)$$

Angle β_1 is determined from triangles O_1CO_2 and O_2DO_3. The following equations are used:

$$2R\cos\beta_1 + 2R\cos\beta_3 = 2R - B \quad (7)$$

$$2R\sin\beta_1 + l_a + l_n = 2R\sin\beta_3 \quad (8)$$

Thus angle β_1 is obtained as:

$$\beta_1 = \cos^{-1}\left[\frac{2R-B}{4R\cos\left[\tan^{-1}\left(\frac{l_a+l_n}{2R-B}\right)\right]}\right] - \tan^{-1}\left(\frac{l_a+l_n}{2R-B}\right) \quad (9)$$

When angle α decreases without changing angles β, the headland is bounded by the front left wheel of the tractor, which reaches the field boundary, and by the rear plough body. At a certain value of the angle α, the headland is additionally bounded, besides the last plough body, by the rear right wheel of the tractor at the end of its reverse movement (Fig. 2b). This condition is necessary to prevent the tractor from entering the already worked part of the field. In this case, the segments used to determine the headland width have the following lengths: y – determined using Eq. (4); z – determined using Eq. (5); and

$$e = (R + 0{,}5M)\cos(\beta_3 - \alpha) \tag{10}$$

$$d = R\cos(\alpha + \beta_1) \tag{11}$$

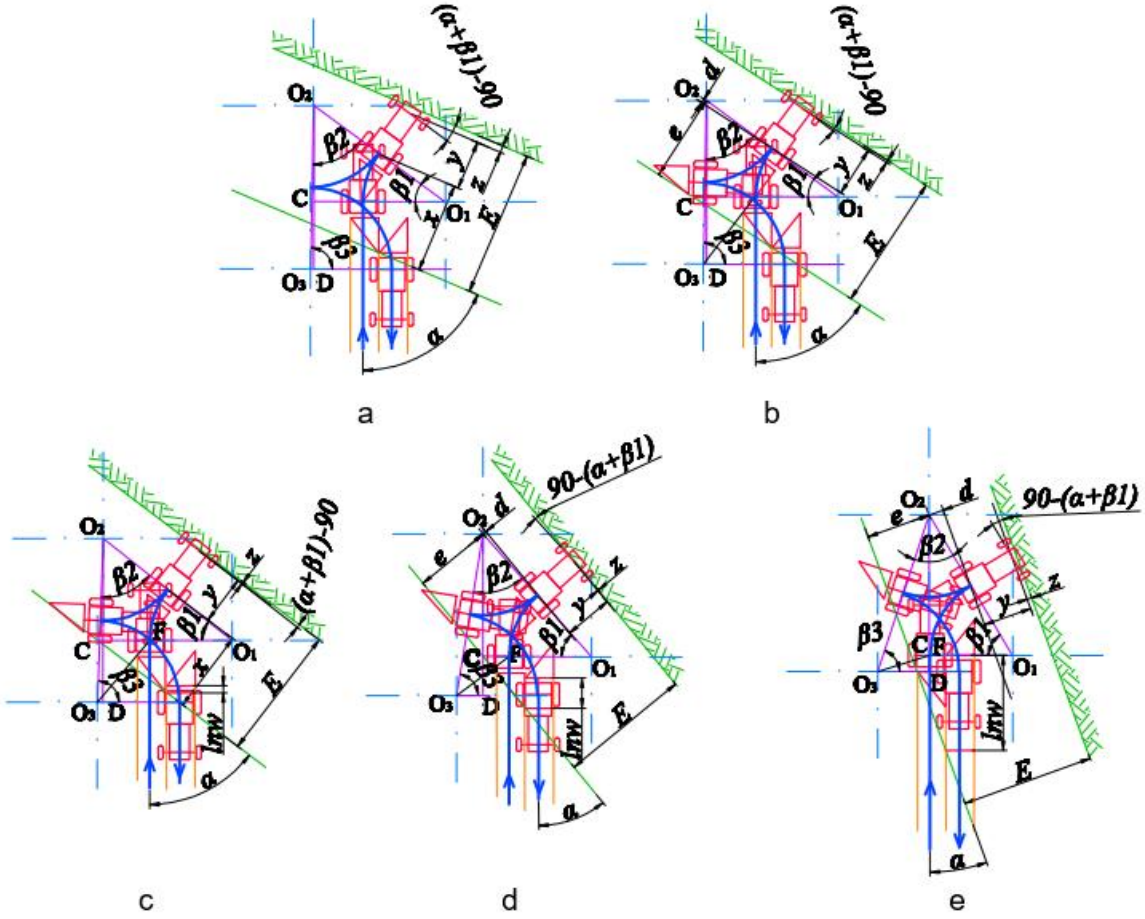

Fig. 2 - Scheme of a closed fishtail turn when moving from left to right

The headland width is given by:

$$E = e - d + y + z = (R - 0{,}5M)\cos(\alpha + \beta_1) + H.\sin(\alpha + \beta_1) + (R + 0{,}5M)\cos(\beta_3 - \alpha) \tag{12}$$

From Eqs. (7) and (8), angle β_3 is determined as follows:

$$\beta_3 = \tan^{-1}\left(\frac{l_a + l_n}{2R - B}\right) + \cos^{-1}\left[\frac{2R - B}{4R\cos\left[\tan^{-1}\left(\frac{l_a + l_n}{2R - B}\right)\right]}\right] \tag{13}$$

After equating Eqs. (6) and (12), the value of angle α at which the transition between the two equations occurs is determined as follows:

$$\alpha = \tan^{-1}\left[\frac{(R+0{,}5M)\cos\beta_3 - (R-g) + 2R\cos\beta_1}{l_a + 2R\sin\beta_1 - (R+0{,}5M)\sin\beta_3}\right] \tag{14}$$

Both front wheels of the tractor reach the end of the field simultaneously when:

$$\alpha + \beta_1 = 90 \tag{15}$$

For values of angle α lower than:

$$\alpha = \tan^{-1}\left(\frac{l_a + l_n}{R - B}\right) \tag{16}$$

the values of angles β change. The boundary of the headland passes through the last plough body and the rear right wheel of the tractor (Fig. 2c).

After completing the turn, the tractor must perform a straight-line non-working pass of length l_{nw} until the front plough body reaches the headland boundary. The headland width is determined using Eq. (12). The straight-line non-working pass is given by:

$$l_{nw} = l_a + l_n - (R - B)\tan\alpha \quad (17)$$

The turn length is given by:

$$l_T = \pi R + l_{nw} = \pi R + l_a + l_n - (R - B)\tan\alpha \quad (18)$$

The values of angles β are determined from triangles O_1CO_2 and O_2DO_3 using Eq. (7) and the following equation:

$$2R\sin\beta_1 + (R - B)\tan\alpha = 2R\sin\beta_3 \quad (19)$$

In this expression, angle α is used for simplification, since angle DO_3F is approximately equal to α. Thus, the angles β are obtained as follows:

$$\beta_1 = \cos^{-1}\left[\frac{2R-B}{4R\cos\left[\tan^{-1}\left(\frac{(R-B)\tan\alpha}{2R-B}\right)\right]}\right] - \tan^{-1}\left(\frac{(R-B)\tan\alpha}{2R-B}\right) \quad (20)$$

$$\beta_3 = \tan^{-1}\left(\frac{(R-B)\tan\alpha}{2R-B}\right) + \cos^{-1}\left[\frac{2R-B}{4R\cos\left[\tan^{-1}\left(\frac{(R-B)\tan\alpha}{2R-B}\right)\right]}\right] \quad (21)$$

When angle α decreases and reaches the value

$$\alpha = \tan^{-1}\left(\frac{B}{l_a - l_n}\right) \quad (22)$$

the headland boundary becomes parallel to the beam carrying the plough bodies (Fig. 2d). At a smaller angle, the headland boundary is no longer determined by the last plough body, but by the first plough body when the unit enters the headland and by the rear right wheel of the tractor (Fig. 2e). The front right wheel of the tractor reaches the field boundary. The lengths of the segments used to determine the headland width are as follows: e, determined using Eq. (10); d, determined using Eq. (11); y, determined using Eq. (4); and

$$z = 0{,}5M.\cos(\alpha + \beta_1) \quad (23)$$

For the headland width, the following expression is obtained:

$$E = e + d + y + z = (R + 0{,}5M)\cos(\alpha + \beta_1) + H.\sin(\alpha + \beta_1) + (R + 0{,}5M)\cos(\beta_3 - \alpha) \quad (24)$$

By equating Eqs. (12) and (24), it can be seen that they are equal when condition (15) is satisfied. This corresponds to the transition between the variants shown in Fig. 2c and Fig. 2e.

The length of the straight-line non-working pass in the headland after the turn increases as angle α decreases. It is determined as follows:

$$l_{nw} = \frac{B}{\tan\alpha} + l_n - (R - B)\tan\alpha \quad (25)$$

The turn length is:

$$l_T = \pi R + l_{nw} = \pi R + \frac{B}{\tan\alpha} + l_n - (R - B)\tan\alpha \quad (26)$$

By equating Eqs. (18) and (26), the angle at which the turn lengths for the two variants are equal is obtained:

$$\alpha = \tan^{-1}\left(\frac{B}{l_a}\right) \quad (27)$$

Closed fishtail turns - movement from right to left

At a large angle α, the front right wheel of the tractor reaches the field boundary (Fig. 3 a). During reverse movement, the tractor does not reach the field boundary. The turn length is also determined using Eqs. (1) and (2). The lengths of the segments used to determine the headland width are as follows:

$$x = l_a\sin\alpha + (g - R)\cos\alpha + R\cos(\alpha - \beta_1) \quad (28)$$

$$y = H.\sin(\alpha - \beta_1) \quad (29)$$

$$z = 0{,}5M.\cos(\alpha - \beta_1) \quad (30)$$

The headland width is:

$$E = x + y + z = l_a\sin\alpha + (g - R)\cos\alpha + H\sin(\alpha - \beta_1) + (R + 0{,}5M)\cos(\alpha - \beta_1) \quad (31)$$

Angles β_1 and β_3 are determined using equations (9) and (13) respectively. When angle α decreases and reaches a certain value, the rear wheels of the tractor also reach the field boundary during reverse movement (Fig. 3 b). The figure shows the limiting case in which the front and rear wheels of the tractor reach the field boundary. In this case, the headland width can be determined using Eq. (31) or by using the following segments:

$$m = -(R + 0{,}5M)\cos(\alpha + \beta_3) \quad (32)$$

$$n = (R - y)\cos\alpha \quad (33)$$

$$q = l_n \sin\alpha \tag{34}$$

$$E = m + n - q = -(R + 0{,}5M)\cos(\alpha + \beta_3) + (R - y)\cos\alpha - l_n \sin\alpha \tag{35}$$

After equating Eqs. (31) and (35), angle α is obtained as follows:

$$\alpha = \tan^{-1}\left[\frac{H\sin\beta_1 - (R+0{,}5M)(\cos\beta_3 + \cos\beta_1) - (B-2R)}{H\cos\beta_1 + (R+0{,}5M)(\sin\beta_1 - \sin\beta_3) + l_a + l_n}\right] \tag{36}$$

At smaller values of angle α the headland width is determined using Eq. (35). At the angle α determined using Eq. (22), the line of all plough bodies becomes parallel to the headland boundary.

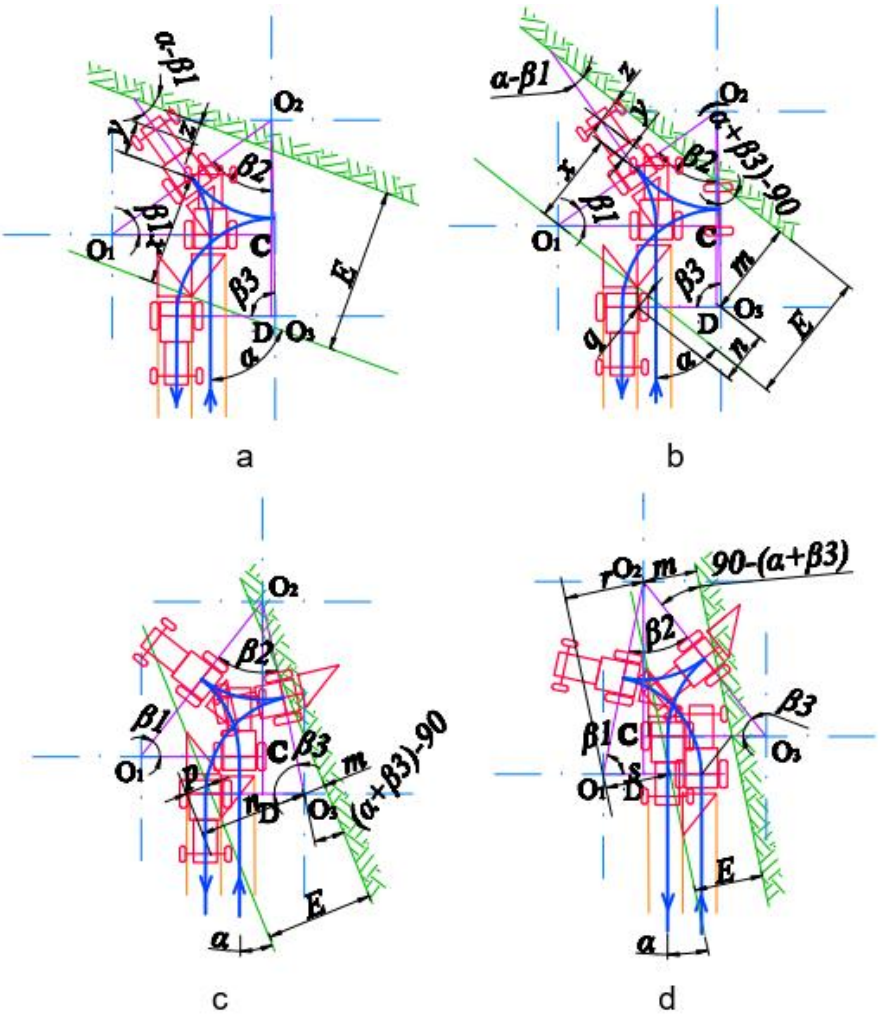

Fig. 3 - Scheme of a closed fishtail turn when moving from right to left

For values of angle α smaller than that determined by Eq. (22), the headland boundary is determined by the last plough body when the unit enters and leaves the headland (Fig. 3c). It can be seen that the front left wheel of the tractor enters the field; however, this is permissible because this part of the field has not yet been processed.

The relationships used to determine the headland width are as follows: (m), determined using Eq. (32), and:

$$p = l_a \sin\alpha \tag{37}$$

$$n = (R + g)\cos\alpha \tag{38}$$

$$E = m + n - p = -(R + 0{,}5M)\cos(\alpha + \beta_3) + (R + g)\cos\alpha - l_a \sin\alpha \tag{39}$$

Angles β vary depending on angle α and are determined using Eq. (7) and the following equation:

$$2R\sin\beta_3 - 2R\sin\beta_1 = 2l_a - \frac{B}{\tan\alpha} \tag{40}$$

The equations for determining angles β are as follows:

$$\beta_1 = \cos^{-1}\left[\frac{2R-B}{4R\cos\left[\tan^{-1}\left(\frac{2l_a-\frac{B}{\tan\alpha}}{2R-B}\right)\right]}\right] - \tan^{-1}\left(\frac{2l_a-\frac{B}{\tan\alpha}}{2R-B}\right) \quad (41)$$

$$\beta_3 = \tan^{-1}\left(\frac{2l_a-\frac{B}{\tan\alpha}}{2R-B}\right) + \cos^{-1}\left[\frac{2R-B}{4R\cos\left[\tan^{-1}\left(\frac{2l_a-\frac{B}{\tan\alpha}}{2R-B}\right)\right]}\right] \quad (42)$$

The rear axle of the tractor becomes parallel to the field boundary when:

$$\alpha + \beta_3 = 90 \quad (43)$$

As angle α decreases further, the rear right wheel reaches the field boundary (Fig. 3 d). In this case, the following relationships are used to determine the headland width:

$$m = (R + 0{,}5M)\cos(\alpha + \beta_3) \quad (44)$$

$$r = 2R\cos(\beta_1 - \alpha) \quad (45)$$

$$s = (R - g)\cos\alpha - l_a\sin\alpha \quad (46)$$

$$E = m + r - s = (R + 0{,}5M)\cos(\alpha + \beta_3) + 2R\cos(\beta_1 - \alpha) - (R - g)\cos\alpha + l_a\sin\alpha \quad (47)$$

The variants shown in Fig. 3c and Fig. 3d are equivalent at the angle:

$$\alpha = \tan^{-1}\left(\frac{(R+0{,}5M)\cos\beta_3 + R\cos\beta_1 - R}{(R+0{,}5M)\sin\beta_3 - R\sin\beta_1 - l_a}\right) \quad (48)$$

At an angle α smaller than that determined by

$$\alpha = \tan^{-1}\left(\frac{B}{2l_a}\right) \quad (49)$$

angles β are determined using Eq. (7) and the following equation:

$$2R\sin\beta_1 - 2R\sin\beta_3 = \frac{B}{\tan\alpha} - 2l_a \quad (50)$$

Their values are obtained as follows:

$$\beta_1 = \tan^{-1}\left(\frac{\frac{B}{\tan\alpha}-2l_a}{2R-B}\right) + \cos^{-1}\left[\frac{2R-B}{4R\cos\left[\tan^{-1}\left(\frac{\frac{B}{\tan\alpha}-2l_a}{2R-B}\right)\right]}\right] \quad (51)$$

$$\beta_3 = \cos^{-1}\left[\frac{2R-B}{4R\cos\left[\tan^{-1}\left(\frac{\frac{B}{\tan\alpha}-2l_a}{2R-B}\right)\right]}\right] - \tan^{-1}\left(\frac{\frac{B}{\tan\alpha}-2l_a}{2R-B}\right) \quad (52)$$

Fig. 4 shows the variation in headland width depending on the angle between the direction of the working pass and the field boundary for a specific machine-tractor unit. It can be seen that when the turn is performed from right to left, a narrower headland is required. Its width decreases as angle α decreases. When the unit moves across the field from left to right, the headland width changes only slightly and remains constant at angles below 50°.

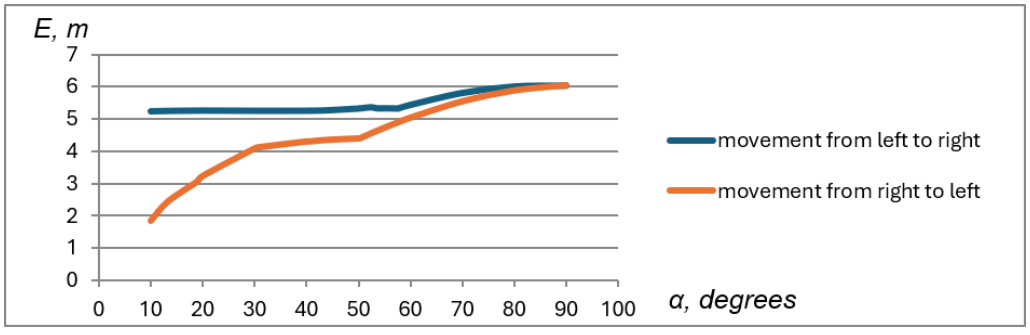

Fig. 4 - Headland width when making fishtail closed turns in different directions of movement depending on the angle α

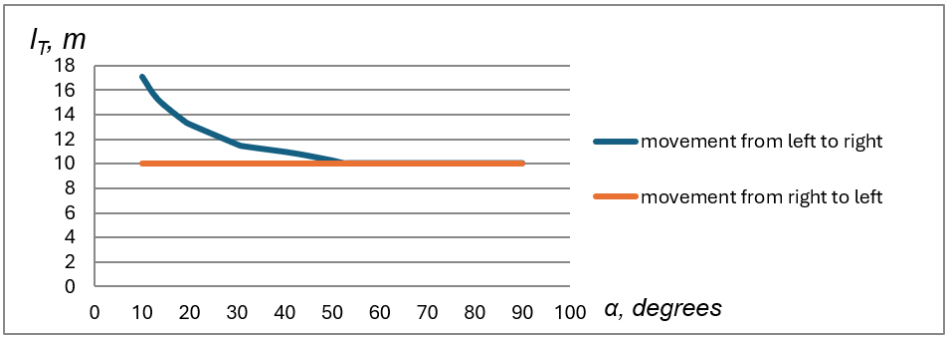

Fig. 5 - Turn length in the headland when performing fishtail closed turns in different directions of movement depending on the angle α

Fig. 5 shows the turn length for different travel directions. The turn length remains constant when the unit moves from right to left, whereas it increases significantly at smaller values of angle α when the unit moves from left to right. This is due to the presence of an additional straight-line path in the headland under this movement mode, which occurs at small values of angle α.

CONCLUSIONS

Analytical relationships were derived for determining the headland width and the length of closed fishtail-shaped turns during the movement of a machine-tractor unit equipped with a mounted reversible plough in an irregularly shaped field. It was established that, at a positive angle between the travel direction of the unit and the field boundary, movement of the unit across the field from right to left results in shorter closed fishtail-shaped turns and requires a narrower headland compared with movement from left to right. Future research should include a comparative analysis of open and closed fishtail-shaped turns in terms of turn length and headland width, and should provide relevant practical recommendations.

ABSTRACT

Corn seedling and weed detection during the 2–5-leaf stage is essential for precision weeding, but similar morphology, field background interference, and the accuracy-efficiency trade-off limit the practical use of lightweight detectors. To address these problems, this study proposes Corn-Weed-ENAS, an improved YOLOv8-based detection model with joint structure and loss-function search. A differentiated ENAS search space was constructed for the backbone, neck, detection head, and loss function to automatically identify a compact architecture suitable for corn seedling-weed detection. A field image dataset of 2–5-leaf corn seedlings and weeds were collected in Heilongjiang Province, and comparative and ablation experiments were conducted against mainstream detectors. The proposed model achieved 97.3% mAP@0.5 with 2.5M parameters and 6.7 GFLOPs, showing a favorable balance between detection accuracy and lightweight deployment. To further verify its agricultural engineering applicability, an indoor simulated operation test was conducted on a Jetson Orin Nano Super platform using 20 pots of corn seedlings and weeds and a moving test vehicle at 1.2 m/s. In the virtual spraying signal verification, YOLOv8n produced five missed detections and one false detection, whereas Corn-Weed-ENAS produced three missed detections and no false detection. These results indicate that Corn-Weed-ENAS can provide more reliable weed localization and virtual trigger outputs for selective spraying decision support.

摘要

玉米 2~5 叶期苗草识别是精准除草的重要基础，但玉米幼苗与杂草形态相近、田间背景干扰复杂，且轻量化检测模型常存在精度与效率难以兼顾的问题。针对上述问题，本文提出一种结合结构搜索与损失函数搜索的 YOLOv8 改进模型 Corn-Weed-ENAS。该方法面向骨干网络、颈部网络、检测头和损失函数构建差异化 ENAS 搜索空间，自动获得适用于玉米苗草检测任务的紧凑型网络结构。本文采集黑龙江省 2~5 叶期玉米幼苗与杂草图像数据集，并与主流目标检测模型开展对比和消融试验。结果表明，所提出模型在 2.5M 参数量和 6.7 GFLOPs 条件下取得 97.3% mAP@0.5，实现了检测精度与轻量化部署之间的较好平衡。为进一步验证其农业工程应用适应性，本文基于 Jetson Orin Nano Super 平台开展了室内模拟作业试验，采用 20 盆玉米苗与杂草盆栽以及 1.2 m/s 移动试验车进行虚拟喷药信号验证。结果显示，YOLOv8n 出现 5 次漏检和 1 次误检，而 Corn-Weed-ENAS 仅出现 3 次漏检且无误检。结果说明，Corn-Weed-ENAS 能够为选择性喷药决策支持提供更可靠的杂草定位与虚拟触发输出。

INTRODUCTION

Weeds compete with crops for water, nutrients, and sunlight, suppressing crop growth and reducing yield and quality (*Hamuda et al., 2016; Islam et al., 2021*). Effective weed control during critical growth stages is thus essential for agricultural productivity (*Knezevic and Datta, 2015; Ramesh et al., 2021*). Current weed management relies on manual, mechanical, biological, and chemical methods (*Bajwa et al., 2015; Christensen et al., 2009; Wang et al., 2013*), with chemical control dominating globally due to its efficiency (*Harker and O'Donovan, 2013; Wei et al., 2010*). The 2–5-leaf stage is a critical weeding window for corn, where seedlings and weeds exhibit minimal morphological differences.

While targeted herbicide application can reduce weed damage, mechanical weeding is inefficient and labor-intensive, and chemical weeding causes pesticide waste and soil pollution, conflicting with green agriculture principles. Developing precise seedling-weed detection algorithms therefore holds significant academic and practical value for modernizing corn production and advancing sustainable agriculture (*Zhang, 2021*).

Driven by the growth of smart agriculture, machine vision and deep learning have become mainstream for agricultural target detection. The YOLO series of single-stage detectors is widely adopted for its balanced speed and accuracy (*Miao et al., 2025; Tang et al., 2025*). Among these, YOLOv8, with superior feature extraction, inference efficiency, and edge-deployment suitability, has been applied to corn seedling and weed detection (*Chu et al., 2025; Wang et al., 2026*). However, standard YOLOv8 faces notable limitations in real agricultural scenarios, including lighting variations, soil interference, seedling-weed occlusion, and morphological similarity at the 2–5-leaf stage. Existing studies have improved accuracy and lightweighting via complex dataset collection and module optimization, laying a foundation for seedling-stage weed detection (*Liu et al., 2022; Wang et al., 2026; Zhao et al., 2026*).

Recent studies have explored deep-learning-based crop and weed detection under natural field conditions. For example, MSRCR-YOLOv4-tiny was used to improve field corn weed detection under complex illumination, while improved YOLO-based models have been developed for corn-field weed detection and target spraying system design. These studies demonstrate the feasibility of lightweight object detection for agricultural weed control. However, most existing methods mainly focus on image-level detection accuracy and module-level network improvement. The connection between detection outputs and agricultural machinery decision signals, such as weed target-point localization and selective spraying triggering, is still insufficiently discussed.

Most current improvements rely on manually adding attention mechanisms and optimizing feature fusion modules, which depend heavily on researcher experience and consume substantial computational resources and time (*Ghosh et al., 2025; Jin et al., 2023; Yang et al., 2021*). Neural Architecture Search (NAS) addresses the limitations of manual network design; in particular, Efficient Neural Architecture Search (ENAS) drastically reduces search time and cost via parameter sharing, enabling automatic discovery of task-specific lightweight, high-performance networks, and has been widely used in computer vision (*Pham et al., 2018*). Currently, ENAS applications in object detection are limited to single-module local optimization, with scarce research in agriculture.

To meet the precision weed control needs of intelligent agricultural machinery, this study constructs a seedling-weed dataset for realistic corn seedling scenarios, focusing on 2–5-leaf corn and common weeds. A full-module ENAS-based joint optimization strategy is implemented for the YOLOv8 network, including fine-grained search of the backbone, neck, detection head, and loss function. Compared with manual module design, the proposed search strategy aims to obtain a compact architecture with better task adaptability. In addition to offline comparative and ablation experiments, this study further conducts an indoor simulated deployment experiment on a Jetson Orin Nano Super platform. The detection outputs are converted into weed center points and software-level virtual spraying trigger signals, thereby evaluating the potential of the proposed model as a perception and decision-support module for selective spraying or intelligent weeding equipment.

MATERIALS AND METHODS

Data collection

Data for this study were collected in Longfeng Town, Longfeng District, Daqing City, Heilongjiang Province. The corn varieties planted were Xianyu 696 and Xianyu 335. The collection environment and growth conditions are shown in Fig 1. The corn was planted in single rows on ridges, with a row spacing of 65 cm. Sampling took place from May to June 2025, when the corn was in the 2–5-leaf stage. Images were captured using a D435i stereo depth camera positioned 40-70 cm above the ground, with the camera's downward angle set between 60°and 90°. The dataset includes various lighting conditions (sunny, cloudy, overcast, etc., as well as early morning, morning, noon, afternoon, evening), different weed growth stages and species (such as Chenopodium, Apium, and Kochia), as well as varying levels of occlusion and weed density to ensure the dataset's generalizability. The dataset exhibits sufficient diversity, aiming to ensure its robustness in real-world application scenarios (*Le et al., 2021; Yang et al. 2025*).

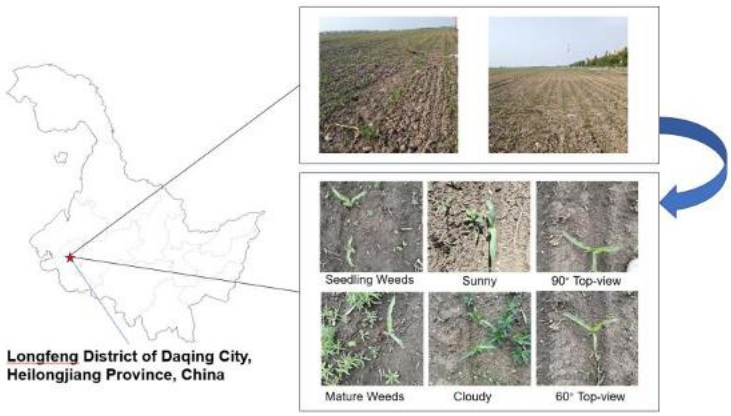

Fig. 1 - Data collection environment and dataset details

The data was manually screened to remove low-quality images with exposure issues (overexposure or underexposure) or blurriness, resulting in a total of 4,000 images, all saved in JPG format. During the preprocessing stage, a differentiated preprocessing strategy was employed to enhance the model's robustness in complex real-world scenarios. Specifically, while ensuring that the main content of the images remains recognizable, some images with slight blurring and uneven lighting were selectively retained with the aim of enabling the model to learn to perform recognition under suboptimal conditions. At the same time, all images were cropped to a uniform size to establish a standard input format. To further enhance the model's generalization ability and stability, this study implemented systematic data augmentation techniques to expand the training dataset by simulating a wider range of imaging variations. During the data augmentation phase, to enhance the model's robustness and generalization capabilities for corn seedling-weed detection recognition in complex field environments, a comprehensive augmentation strategy that included rotation, resizing, noise addition, and brightness adjustment was employed. The images were then annotated using the LabelImg tool and classified into two categories: corn and weeds. The dataset was randomly divided into training, validation, and test sets in an 8:1:1 ratio, ensuring that each set contained images from different environments (*Li et al., 2023*).

Development of the ENAS framework

This study builds upon the ENAS framework proposed by Pham et al. in 2018, retaining its core modules—the controller, hypernetwork, and reward signal—to construct a fine-grained search space covering all components of YOLOv8. An optimized ENAS network is proposed to achieve end-to-end automatic optimization of YOLOv8. Unlike traditional methods, this study focuses on the four key components of YOLOv8—the Backbone, Neck, Head, and loss function—to design differentiated, fine-grained search spaces and strategies that balance detection accuracy with model lightweighting, thereby improving search efficiency and convergence stability. The search process is as follows: the controller makes decisions regarding the architecture, the sub-architectures evaluate composite metrics on the hypernetwork validation set, and the controller updates the reinforcement learning policy based on these results, guiding the search toward a lightweight, high-performance solution. This framework integrates both global and local features required for identifying corn seedlings and weeds during the 2–5-leaf stage, striking a balance between accuracy and efficiency. The optimized, lightweight architecture selected is used for real-time, high-precision detection of corn seedlings and weeds in the field, achieving a Pareto optimal balance of accuracy, size, and speed.

Corn-Weed-ENAS searchable object detection model architecture

This study proposes the Corn-Weed-ENAS searchable object detection model, which centers on a weight-sharing supernetwork that integrates the ENASChoice module. It natively supports end-to-end architecture search and is tailored to meet the deployment requirements of agricultural embedded scenarios. The hypernetwork is designed according to the principle of layer-by-layer reconfigurability, which enables the construction of a fine-grained search space covering the entire network pipeline, including the core network components and supervisory signals. The search space consists of two main levels. First, fine-grained end-to-end search is performed across the Backbone, Neck, and Head. The backbone, neck, and detection head layers are encapsulated in ENASChoice modules, each integrating more than ten types of operation primitives, including standard convolutions, ghost convolutions, depthwise separable convolutions, attention mechanisms, and lightweight modules.

During the search process, the controller selects the optimal operation for each ENASChoice module, enabling end-to-end customization of the microarchitecture, from backbone feature extraction and multi-scale feature fusion to detection output. Second, flexible loss-function configuration is introduced. By incorporating multiple loss functions into the search space, the proposed method enables the joint optimization of the network architecture and the supervisory signal.

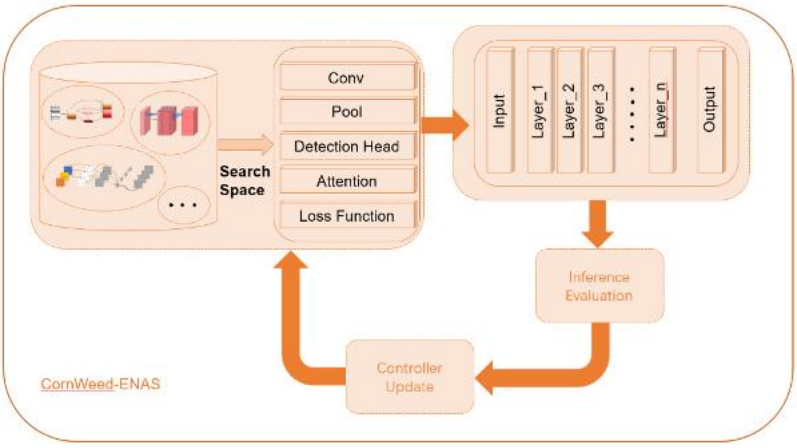

Fig. 2 – Corn-weed-ENAS Workflow

Cooperative optimization algorithms and architecture mapping mechanisms

Most traditional NAS algorithms are limited to optimizing the backbone network. To address this inherent limitation, this study proposes an improved Corn-Weed-ENAS co-optimization algorithm. Within the weight-sharing framework, the algorithm simultaneously performs joint optimization of architectural parameters and network weights, fully expanding the search space to encompass all critical dimensions that determine the model's final performance, covering the four core modules: Backbone, Neck, Head, and loss function. Throughout the architecture exploration process, the controller can dynamically balance multiple sets of interdependent key metrics. These metrics include model accuracy, computational complexity, and on-device inference speed. The ultimate goal of an algorithm is not the extreme optimization of a single metric. Its goal is to collaboratively identify the globally optimal architecture across multiple metrics, thereby achieving a paradigm shift from local component optimization to global system-level coordination. To achieve an efficient mapping from architectural decisions to an executable network topology, this study introduces a layer-by-layer mapping mechanism. The controller outputs a discrete selection index for each searchable unit. Using a prebuilt lookup dictionary, the system precisely maps indices to predefined operation keys or module instances, establishing a direct and stable link between high-level architectural decisions and low-level network implementation. Once the search is complete, the system instantiates a deterministic subnetwork from the hypernetwork based on the optimal selection sequence sampled by the controller. The subnet retains only the selected operations and modules. It also fully inherits the pre-trained weights from the hypernetwork, ultimately enabling a seamless transition from architecture search to a deployable model.

Automatic search algorithms and implementation

In the Corn-Weed-ENAS framework proposed in this study, the hyperparameters of the controller design and search process are set as follows. Architectural decisions are made using independent classification controllers, with each ENASChoice module and configurable component corresponding to a separate classification distribution. The maximum number of search rounds is set to 300. In each round, the controller samples a complete architectural configuration, corresponding to a specific subnet instance within the predefined full-stack search space. The key hyperparameters for policy-gradient updating include a baseline decay rate of 0.9 and an entropy regularization coefficient of 0.01.

After initializing the controller and the weight-sharing hypernetwork, the search iteration process is started. In each iteration, the current controller policy is evaluated as follows. First, the controller samples an architectural configuration, which is represented as a sequence of choice indices. Then, using a predefined lookup dictionary, this index sequence is mapped to specific operations and modules. Next, the selected subnet is activated in the hypernetwork, and 10% of the full dataset is selected for training to enable efficient subnet evaluation.

Finally, a reward value is calculated using a multi-objective function that balances detection accuracy and inference efficiency, thereby guiding the direction of the architecture search. The reward function is defined as follows:

$$R = R_{gating} + R_{main} + R_{bonus\_all} + R_{bonus\_pareto} \quad (1)$$

wherein: R_{gating} is the gating penalty:

$$R_{gating} = -base_{penalty} - \alpha \times \max(0, map_{[0.5]min} - map_{[0.5]}) - \beta \times \max(0, map_{[0.5-0.95]min} - map_{[0.5-0.95]}) \quad (2)$$

where $base_{penalty} = 2.0, \alpha = 50.0, \beta = 30.0, map_{[0.5]min}$ and $map_{[0.5-0.95]min}$ are the minimum acceptable $map_{[0.5]}$ and $map_{[0.5-0.95]}$ values;

$R_{main} = \sum w_i \times gain_i + \sum w_j + save_j$, where $gain_i$ denotes the relative improvement of metrics (precision, recall, $map_{[0.5]}$, $map_{[0.5-0.95]}$) over the baseline (normalized via tanh function with $s_{metric} = 0.01$, and $save_j$ denotes the relative reduction of resources (parameters, FLOPs, weight size) compared to the baseline (normalized via tanh function with $s_{cost=0.05}$.

R_{bonus_all} is the "all-improve" bonus: a fixed value if the architecture outperforms the baseline in all metrics and underperforms in all resource indicators (zero if identical to the baseline);

R_{bonus_pareto} is the Pareto front bonus: scaled by the number of dominated architectures when the candidate is added to the Pareto front (Pareto tolerance tol= $1e-12$).

After receiving the reward, the algorithm executes the policy update step. The advantage function is computed as Advantage = Reward - Baseline, where Baseline refers to the exponential moving average of historical rewards. The controller's loss function is defined as follows:

$$L_{controller} = -log\pi_\theta(a) \cdot A - \lambda H(\pi_\theta) \quad (3)$$

Specifically, $\pi_\theta(a)$ denotes the joint probability that the IndependentCategoricalController samples the architectural configuration a under the current policy θ (product of independent categorical distribution probabilities for each configurable component). The negative logarithm of this probability, $-log\pi_\theta(a)$, corresponds to '-log_prob' in the code and serves as the core component of policy gradient computation. A denotes the advantage function, computed as $A = R - B$; here, R is the multi-objective reward calculated via Formula (1), and B is the global exponential moving average baseline (independent of search state). This advantage value quantifies the relative quality of the current architectural configuration against the average performance. $H(\pi_\theta)$ represents the average entropy of the controller's categorical distributions (across all configurable components), weighted by the coefficient λ to encourage architectural exploration.

The aforementioned iterative process proceeds cyclically until any of the following termination conditions is satisfied: (1) The preset maximum number of epochs is reached; (2) Algorithm performance converges, i.e., the improvement in the best fitness reward obtained over N consecutive generations falls below a preset threshold ε. Upon termination of the search, the architectural decision individual with the highest historical fitness is selected as the optimal solution. Subsequently, the system instantiates the corresponding operations and modules via the two-stage mapping process based on this optimal decision, directly extracts the corresponding weights from the pre-trained supernetwork, and assembles them into the final deployable lightweight detection model, thus completing the entire workflow from automated architecture search to efficient model derivation.

Edge deployment and indoor simulated virtual spraying signal verification

To further evaluate the practical applicability of the proposed Corn-Weed-ENAS model in agricultural machinery scenarios, an indoor simulated operation experiment was conducted using a Jetson Orin Nano Super development board. The development board was equipped with 8 GB memory and a 1024-core NVIDIA Ampere architecture GPU. A driver-free USB camera with a resolution of 0.3 megapixels was used as the image acquisition device. During the experiment, the camera center was installed 60 cm above the ground, and the optical axis of the camera was set at a downward angle of 60° relative to the horizontal plane. This configuration was used to simulate the visual perception condition of a small selective spraying or intelligent weeding platform.

Twenty pots of potted plants were arranged to construct the indoor simulated operation scene. Each pot contained 1–5 corn seedlings and weeds, forming different crop-weed distributions and partial occlusion conditions. During the experiment, the test vehicle moved along the horizontal line of the potted plants at a speed of 1.2 m/s.

The trained YOLOv8n and Corn-Weed-ENAS models were deployed on the Jetson Orin Nano Super platform for real-time detection. For each detected weed target, the center point of the bounding box was calculated and regarded as the potential spraying target point. A virtual spraying trigger signal was generated when the detected weed target satisfied the predefined trigger condition. Since no actual herbicide spraying device was connected in this experiment, the generated signal was used as a software-level virtual spraying signal to evaluate whether the model could provide usable perception outputs for subsequent selective spraying control.

This verification focused on the transformation from visual detection results to application-oriented decision signals. Missed detection was recorded when a weed target requiring a trigger signal was not detected by the model. False detection was recorded when a non-weed object or background region was incorrectly detected as a weed target and could lead to an unnecessary virtual spraying signal. The number of missed detections and false detections was compared between YOLOv8n and Corn-Weed-ENAS to evaluate the reliability of the proposed model in the simulated selective spraying scenario.

RESULTS

Evaluation metrics and parameter settings

To comprehensively and objectively evaluate the detection accuracy and target-recognition robustness of the detection models identified by the Corn-Weed-ENAS framework for corn seedling and weed detection, as well as their engineering deployment efficiency and lightweight characteristics when adapted to agricultural edge devices, this study combines conventional accuracy metrics from object detection with engineering-oriented deployment metrics to construct a multidimensional evaluation framework. The names, physical meanings, and descriptions of each evaluation metric are presented in Table 1. All subsequent calculations of these metrics follow the standard conventions used in the field of object detection.

Table 1

Evaluation metrics

Index	Description
IoU=0.5	The ratio of the intersection to the union between the model-predicted bounding box and the actual bounding box
AP	Average Accuracy at Different Recall Rates
mAP@0.5	Mean Average Precision for corn seedling and weed detection at an IOU threshold of 0.5
F1 score	Harmonic Mean of Precision and Recall
FPS	Number of images the model can process per second
Precision（P）	The ratio of accurately detected corn seedlings and weeds in the image to the total number of detected corn seedlings and weeds
Recall(R)	The proportion of correctly identified corn seedlings and weeds in the image relative to the total number of corn seedlings and weeds in the dataset
Weights	Weight Size(MB)
Parameters	Number of parameters in a model(M)

Among these, IoU, AP, mAP@0.5, precision, recall and F1 score are accuracy metrics for quantifying the target localization and classification performance of corn seedling and weed detection models; FPS, model weight and parameter count are deployment metrics to evaluate inference speed and compactness, meeting the demands of agricultural edge computing applications. All tests were conducted on a Windows 11 system with an Intel Core i7-13700KF CPU and NVIDIA GeForce RTX 4070 Ti Super GPU, with PyCharm as the IDE and the core software stack: Python 3.10.19, PyTorch 2.7.1 and CUDA 12.6. For fair and comparable experimental results across all models, a unified set of hyperparameters was adopted: 640×640 input resolution, stochastic gradient descent (SGD) as the optimization algorithm, and 300 training epochs.

Comparative study

Comparison models are categorized into three types covering object detectors of different generations and architectural paradigms: (1) YOLO baseline models (YOLOv5s, YOLOv7-tiny, and YOLOv8n, the search benchmark in this study); (2) the latest lightweight YOLO models (YOLOv11n, YOLOv12) representing state-of-the-art advances in lightweight visual recognition; (3) the classic two-stage detector Faster R-CNN, selected as the accuracy-oriented baseline. Detailed comparison results are presented in Fig. 3.

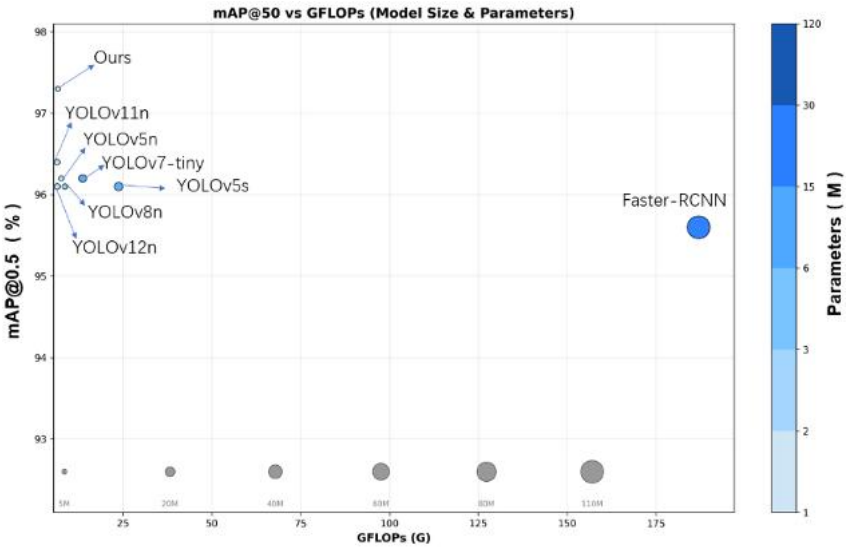

Fig. 3 - Performance Comparison of Different Object Detectors on a Dataset of Corn Seedlings and Weeds

Table2

Other indicators not included in Fig 2

Indicator	YOLOv5s	YOLOv5n	YOLOv7	YOLOv8n	YOLOV11n	YOLOV12n	Faster-RCNN	Ours
P	93.9	93.6	93.7	92.7	93.6	93.6	77.9	94.6
R	92.1	93.0	93.3	93.2	92.6	93.2	96.1	96
FPS	66	204	119	180	241	240	8	234

The results show that the model identified by the Corn-Weed-ENAS framework achieved a 97.3% accuracy rate (mAP@0.5), with precision, recall, and F1 scores all outperforming the comparison algorithms, demonstrating the highest recognition accuracy. At the same time, with 5.2 million model weights, 2.5 million parameters, and only 6.7 billion FLOPs, it achieves improved performance while remaining lightweight.

Results of edge deployment and virtual spraying signal verification

The indoor simulated deployment experiment showed that both YOLOv8n and Corn-Weed-ENAS could be deployed on the Jetson Orin Nano Super platform and could output weed detection results and virtual spraying trigger signals under the moving operation condition. The test was conducted using 20 pots of potted corn seedlings and weeds. The camera was mounted 60 cm above the ground with a 60° downward viewing angle, and the test vehicle moved along the potted plants at a speed of 1.2 m/s.

Under the same deployment platform, camera configuration, operation speed, and virtual trigger strategy, YOLOv8n produced five missed detections and one false detection, whereas Corn-Weed-ENAS produced three missed detections and no false detection. Compared with YOLOv8n, Corn-Weed-ENAS reduced the number of missed detections by 40.0% and reduced the number of false detections from one to zero. This result indicates that the proposed Corn-Weed-ENAS model had more stable weed localization performance and lower risk of unnecessary virtual spraying signals in the simulated operation scenario.

Although this experiment did not involve actual herbicide spraying, it provided a software-level verification of the transformation from detection results to spraying decision signals. The results demonstrate that Corn-Weed-ENAS can not only achieve high detection accuracy in offline image evaluation, but also generate target-point outputs and virtual trigger signals on an edge device. Therefore, the proposed model has potential as a perception and decision-support module for selective spraying or intelligent weeding equipment.

Table3

Edge deployment and virtual spraying signal verification results under the indoor simulated operation scenario

Model	Platform	Test scene	Missed detections	False detections	Relative change
YOLOv8n	Jetson Orin Nano Super	Indoor potted-plant simulated operation	5	1	Baseline

Model	Platform	Test scene	Missed detections	False detections	Relative change
Corn-Weed-ENAS	Jetson Orin Nano Super	Indoor potted-plant simulated operation	3	0	Missed detections reduced by 40.0%; false detections reduced to 0

Ablation experiment

To validate the effectiveness of each structural module in the model and demonstrate the performance advantages of the Corn-Weed-ENAS model proposed in this paper, this section presents a systematic set of ablation experiments. The experiment uses the YOLOv8n model as the baseline and systematically decomposes it into four core search modules: the backbone network, the neck structure, the detection heads, and the loss function. It compares the detection accuracy and computational cost of the model under different combinations of these modules. Additionally, the experiment compares the final optimized model with the baseline model and the step-by-step search models to comprehensively evaluate the effectiveness of the model optimization. The evaluation metrics used in this experiment are the same as those in the comparative experiments. The experimental results are shown in Table 4.

Table 4

Results of the ablation experiment

Model configuration	mAP@0.5 (%)	Precision (%)	Recall (%)	Weights (M)	Parameters (M)	FLOPs (G)
YOLOv8n (Baseline)	96.1	92.7	93.2	6.3	3.0	8.1
Only Backbone	96.7	93.7	93.4	5.8	2.9	7.6
Previous + Neck	96.8	94.4	94.0	5.4	2.7	7.1
Previous + Detection Head	97.1	94.9	94.4	5.2	2.5	6.7
Corn-Weed-ENAS	97.3	95.1	94.6	5.2	2.5	6.7

Ablation experiments show that each module has a significant impact on model performance: Experiments show that the selection of the backbone, neck, head, and loss function all have a significant impact on model performance. The model offers notable advantages in terms of compactness, with 5.2 million weights, 2.5 million parameters, and 6.7 billion FLOPs. Its mAP@0.5 reached 97.3%, with the best performance across all accuracy metrics. It effectively addresses the challenge of balancing accuracy with lightweight design, outperforms both the baseline model and stepwise improvement models in overall performance, and offers significant practical value.

CONCLUSIONS

Comparative and ablation experiments validated the effectiveness of the proposed Corn-Weed-ENAS model for corn seedling and weed detection. Compared with mainstream detectors including YOLO series models and Faster R-CNN, Corn-Weed-ENAS achieved 97.3% mAP@0.5 with 2.5M parameters and 6.7 GFLOPs, showing a favorable balance between detection accuracy, compactness, and deployment efficiency.

The ablation results further confirmed that the searched backbone, neck, detection head, and loss-function configuration jointly contributed to the final model performance.

To strengthen the agricultural engineering application of the study, an indoor simulated deployment experiment was conducted on a Jetson Orin Nano Super platform. Under a simulated moving operation condition with 20 pots of corn seedlings and weeds, YOLOv8n produced five missed detections and one false detection, whereas Corn-Weed-ENAS produced three missed detections and no false detection. The proposed model reduced missed detections by 40.0% and eliminated false detections compared with YOLOv8n. These results indicate that Corn-Weed-ENAS can provide more reliable weed localization and virtual spraying trigger outputs on an edge device.

Overall, Corn-Weed-ENAS can serve as a lightweight perception and decision-support module for selective spraying or intelligent weeding equipment. However, the deployment experiment in this study was a software-level virtual signal verification under an indoor simulated potted-plant scenario, and actual herbicide spraying and field weeding performance were not evaluated. Future work will connect the model with physical spraying or mechanical weeding actuators and conduct field-level operational tests to further verify its engineering applicability.

ABSTRACT

As the pig farming industry evolves towards intelligence and large-scale operations, multi-object tracking technology plays a pivotal role in enhancing farming efficiency and optimizing health management. Addressing the issues of trajectory interruption and jitter caused by frequent occlusion of targets, significant scale variations, rapid motion, and sudden turns in large-scale breeding scenarios, an improved ByteTrack method is presented. This method employs YOLOv8 as the detector and enhanced the ByteTrack framework. By incorporating an Exponential Moving Average (EMA) trajectory smoothing module, it optimizes the trajectory jitter issues encountered by traditional Kalman filtering in fast-moving or sudden turning scenarios, resulting in smoother and more continuous tracking trajectories. Experimental results on a real-world livestock farm video dataset demonstrate that the proposed method achieves improvements across several key evaluation metrics. Specifically, the Multi-Object Tracking Accuracy (MOTA) increased by 1.61%, Identification F1 Score (IDF1) improved by 2.55%, and the Recall rose by 9.68%. The results demonstrate that the proposed method can effectively track pigs in complex farming environments with frequent occlusions, large scale variations, and abrupt motion, providing reliable underlying data support for downstream applications, such as abnormal behavior identification and automated physical activity statistics in intelligent pig farming systems.

摘要

随着养猪业向智能化与规模化发展，多目标跟踪技术对提升养殖效率与优化健康管理具有关键作用。针对规模化养殖场景中目标频繁遮挡、尺度变化显著、快速运动及突然转向导致的轨迹中断与抖动问题，本文提出一种基于改进 ByteTrack 算法的生猪多目标追踪方法，旨在应对规模化养殖场景中目标频繁遮挡、尺度变化显著及轨迹中断等挑战，以提升养殖智能化管理效率。该方法以 YOLOv8 作为目标检测器，并在 ByteTrack 多目标追踪框架基础上，引入指数移动平均（EMA）轨迹平滑模块，有效缓解了传统卡尔曼滤波在目标快速运动或突然转向时出现的轨迹抖动问题，从而获得更为平滑、连续的追踪轨迹。在实际养殖场视频数据集上的实验结果表明，本方法在多项关键评价指标上均有显著提升，其中多目标跟踪准确率（MOTA）提升 1.61%，身份一致性（IDF1）提升 2.55%，召回率提升 9.68%。该方法能够有效应对复杂场景下的目标追踪任务，通过缓解遮挡与尺度变化对追踪精度的影响，能够为后续生猪异常行为识别、运动量自动化统计等实际生产应用提供稳定的底层数据支撑。

INTRODUCTION

The pig farming industry occupies a crucial position in the agricultural economic system, and its development directly affects the stability of meat supply in the market as well as farmers income. With the increasing scale and intensification of pig farming, high labor costs, difficulties in disease prevention, and environmental pollution have become bottlenecks for healthy pig farming (*Reza et al., 2025*). In this context, smart farming has become an important development trend in the pig farming industry (*Trabachini et al., 2025*). Monitoring the health status of pigs is a key aspect of pig production and an important step in achieving intelligent monitoring.

Traditional group pig monitoring mainly relies on manual inspection, which is inefficient, labor-intensive, and unable to provide continuous monitoring. Although sensor-based methods can achieve effective monitoring, they require expensive equipment and may cause stress responses in pigs. In contrast, vision-based multi-object tracking enables continuous and non-contact monitoring by providing identity and location information for each pig, thereby supporting timely abnormal behavior detection and disease prevention.

Monitoring the health status of pigs is a critical component of pig production and a key step in achieving intelligent farming (*Devi et al., 2024*). Traditional manual inspection methods are inefficient, costly, and cannot provide continuous monitoring. Sensor-based approaches are expensive and may induce stress in pigs, negatively impacting their health (*Pandey et al., 2021*). Utilizing multi-object tracking technology, farm staff can monitor pigs' locations, movements, and behavior patterns continuously and without contact, enabling timely detection of diseases, stress, and other abnormalities, and allowing for prompt intervention, thereby effectively preventing disease spread (*Jaoukaew et al., 2024*).

In recent years, methods for multi-object tracking of pigs have shifted from approaches based on handcrafted features to those based on deep learning. Deep learning-based multi-object tracking methods for pigs can be broadly categorized into key-point recognition-based methods, image segmentation-based methods, and object detection-based methods (*Lu et al., 2024*). Key-point recognition methods track targets by detecting their key skeletal points (such as the snout, base of the tail, and four hooves in pigs) (*Psota et al., 2020*). These methods can estimate target poses or behaviors during tracking but rely heavily on key-point visibility, making them unsuitable for densely populated or highly obstructed environments (*Yin et al., 2025*). Methods based on image segmentation precisely extract the target from the background through pixel-level segmentation and then track the mask (*Compte et al., 2025*). However, pixel-level processing is very computationally intensive (*Liang et al., 2025*). The object detection-based approach is currently the mainstream method. It first obtains the bounding boxes of objects through a detector and then matches these boxes between frames to acquire object identities and trajectories (*Li et al., 2025*).

To address challenges in pig farming scenarios, including frequent occlusions, large target scale variations, and abrupt target motion, this paper proposes an improved ByteTrack-based multi-pig tracking framework for achieving more stable and continuous trajectory association in complex breeding environments. The main contributions of this paper are as follows:

(1) YOLOv8 is adopted as the object detector to improve bounding box regression accuracy and enhance detection robustness under complex backgrounds, scale variations, and mutual occlusions;

(2) An Exponential Moving Average (EMA)-based trajectory smoothing module is introduced to improve the ByteTrack framework. By computing a weighted average of historical trajectory positions, this module compensates for the limitations of Kalman filtering during abrupt changes in the target motion state, thereby significantly reducing tracking-box jitter and ensuring the continuity of target trajectories. This makes it particularly suitable for practical applications in complex dynamic scenarios.

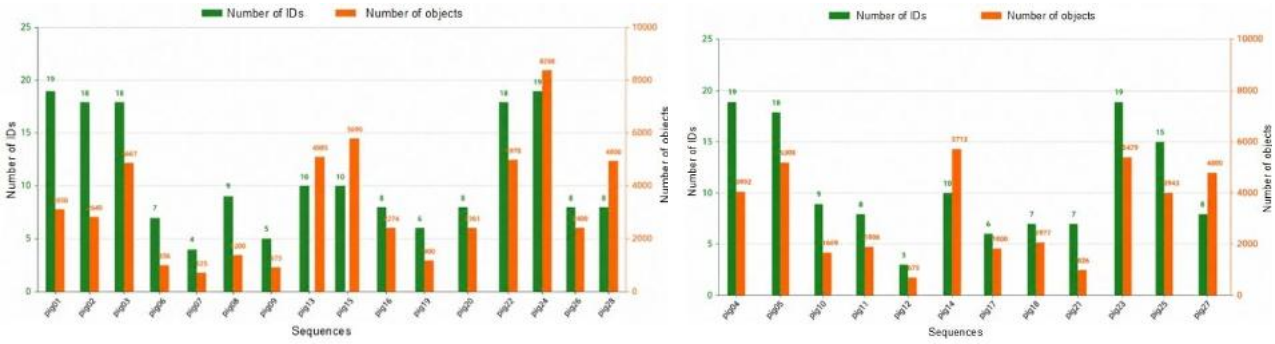
(3) A real-world multi-pig tracking dataset covering multiple scenes and camera viewpoints is constructed, and extensive experiments are conducted to validate the effectiveness of the proposed method.

MATERIALS AND METHODS

Dataset construction

In order to ensure the diversity of data scenarios, videos were collected from different farms, with some videos coming from a farm in Taiyuan, Shanxi (Pig Farm 1), some from a farm in Yuncheng, Shanxi (Pig Farm 2), and some from publicly available online datasets. Figure 1 shows samples from the dataset.

As shown in Figure 1, (a) and (c) are taken from an oblique angle, capturing a more comprehensive view of the pigs' bodies, with the main challenge being mutual occlusion. The individuals in (c) have a very high similarity, making identity recognition difficult. (b) is taken from a side view, which is severely obstructed by the pen bars and is also more prone to mutual occlusion. (d) is taken from a top-down view, which reduces occlusion but limits the coverage area and the information that can be collected about the pigs.



In order to train a multi-object tracking model for pigs, long videos were divided into clips ranging from 150 to 600 frames, and the collected videos were annotated in the MOT format. A total of 28 videos were annotated, with 16 used as the training set, containing 4,980 frames, and 12 used as the test set, containing 4,050 frames. The detailed information of the videos is shown in Figure 2. The entire dataset includes a total of 9,030 frames, 304 IDs, and 88,067 annotated objects.

Overall architecture

Many online tracking methods rely on Kalman filtering for trajectory prediction (*Stanojevic et al., 2024*). Although Kalman filtering can predict the positions of targets, its predictions are susceptible to noise, resulting in unsmooth trajectories. This is manifested as jumps or jitters in the tracking boxes, which in turn affect the stability of tracking. The workflow of the improved ByteTrack method is shown in Figure 3.

In pig farming scenarios, the movement trajectories of pigs are usually irregular, often accompanied by rapid movements, sudden turns, or body tremors. Based on this, this study introduces the Exponential Moving Average (EMA) algorithm (*Haynes et al., 2012*), which smooths prediction results by performing a weighted average on historical trajectory positions. Unlike Kalman filtering, which assumes relatively smooth linear motion, EMA smoothing is more tolerant to abrupt short-term motion fluctuations commonly observed in pig movement behaviors. This characteristic makes EMA particularly suitable for livestock tracking scenarios with frequent irregular motion patterns.

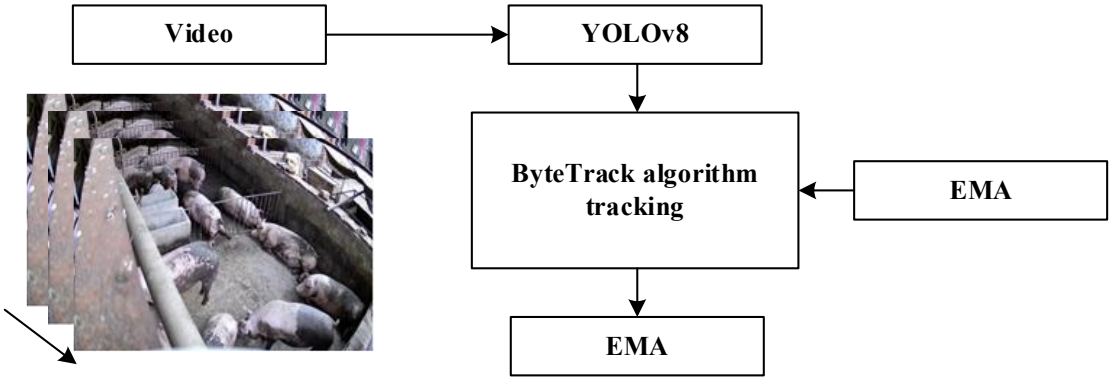

Fig. 3 - Overall architecture of the improved ByteTrack multi-object tracking method

Furthermore, the performance of ByteTrack strongly depends on the stability of object detections, since its association process relies on confidence scores and IoU similarity across consecutive frames. In pig farming scenarios, frequent occlusions, abrupt motion, and similar appearances often lead to unstable detections when conventional detectors are used.

To address these challenges, YOLOv8 is adopted for its stronger feature extraction and localization capability, especially for small-scale and partially occluded targets. Meanwhile, the EMA-based trajectory smoothing module further reduces trajectory jitter caused by sudden motion and detector noise.

ByteTrack Tracking Method

ByteTrack is a lightweight and efficient multi-object tracking algorithm that does not require the integration of a Re-ID module or depend on additional training processes (*Zhang et al., 2022*). When an object undergoes significant occlusion, the confidence of the detection boxes generated by the detection algorithm typically decreases. The most notable improvement of this system is the reasonable reuse of low-confidence detection boxes, which effectively suppresses object loss in occlusion scenarios.

The tracking process of the ByteTrack is shown in Figure 4.

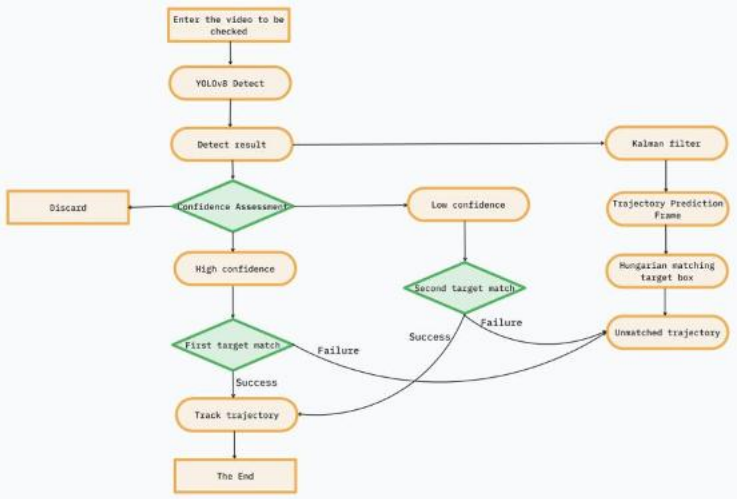

Fig. 4 – Flowchart of ByteTrack

Specifically, the system first divides the detection boxes based on a confidence threshold. In the initial matching stage, the trajectory boxes predicted by the Kalman filter are associated with high-confidence detection boxes through the IoU matrix and the Hungarian algorithm; subsequently, the remaining unmatched trajectories are matched with low-confidence detection boxes in a secondary matching stage. Ultimately, only unmatched detection boxes are discarded, while successfully matched targets are used to update trajectories or initialize new trajectories.

YOLOv8 Detection Method

YOLOv8 is a mature detector widely used in multiple real-world scenarios. These successful applications fully validate YOLOv8's strong adaptability and high performance in various contexts, providing a reliable technical foundation for the pig detection tasks in this study (*Sohan et al., 2024*). The network architecture of YOLOv8 is shown in Figure 5.

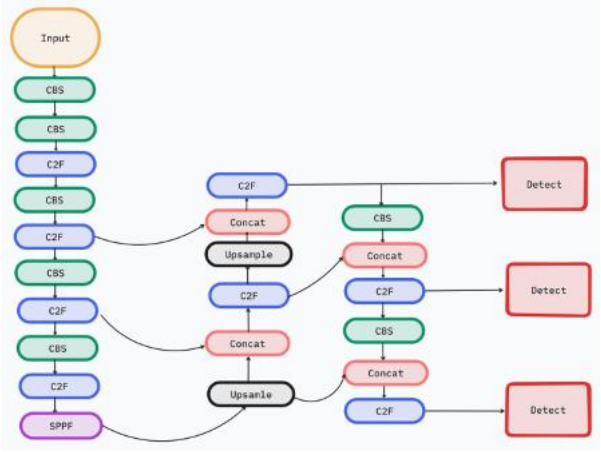

Fig. 5 - YOLOv8 network structure diagram

In Figure 5, the overall architecture of the YOLOv8 model mainly consists of four parts: Input, Backbone, Neck, and Head.

The Input end is responsible for performing data augmentation on the input images to improve the model's generalization ability. The Backbone is used to extract multi-level features from the images and mainly consists of modules such as CBS (*Conv BN SiLU*), C2f (lightweight residual module), and SPPF (spatial pyramid pooling). Through multiple downsampling and feature refinement steps, the Backbone gradually compresses the feature map size while enhancing semantic information.

The Neck section is designed to integrate feature information at different scales to enhance detection performance. This section draws on the design concepts of FPN and PANet, effectively combining shallow and deep features, significantly improving the detection of small targets.

The Head outputs multi-scale feature maps and generates feature maps of three different sizes. Each scale network outputs the target's bounding box, confidence score, and class label.

Evaluation Method

The model evaluation metrics include: $MOTA$, $IDF1$, IDP, MT, ML, IDS, FP(False Positives), FN(False Negatives), precision, and recall (*Dendorfer et al., 2020*).

MOTA is as shown in formula (1):

$$MOTA = 1 - \frac{\sum_t (FN_t + FP_t + IDSW_t)}{\sum_t GT_t} \quad (1)$$

It measures the overall accuracy of the entire tracking system, taking into account missed detections, false positives, and ID switches. IDS is the number of times a target's identity changes. GT is the total number of targets in the ground truth. FP is the false detected targets, and FN is the missed detections.

$IDF1$ is as shown in formula (2):

$$IDF1 = \frac{2 \times IDTP}{2 \times IDTP + IDFP + IDFN} \quad (2)$$

$IDF1$ is the harmonic mean of ID Precision and $ID\ Recall$, used to measure the consistency of identity preservation. $IDTP$ is the correctly predicted identities, $IDFP$ is the incorrectly assigned identities, and $IDFN$ is the missed identities that should have been detected.

The precision and recall is calculated as formula (3) and (4):

$$Precision = \frac{TP}{TP + FP} \quad (3)$$

$$Recall = \frac{TP}{TP + FN} \quad (4)$$

FN (False Negatives) refers to missed detections, meaning that the target in the ground truth was not detected. TP (True Positive) means the model successfully detected a target that actually exists.

RESULTS AND DISCUSSION

Experimental Setup

This experiment was conducted on a hardware platform equipped with an Intel® Core™ i5-11260H processor, 15.7GB of memory, and an NVIDIA GeForce RTX 3050 GPU, with Windows 11 as the operating system. The algorithm was implemented based on Python 3.10 and the PyTorch 2.6.0 framework, and accelerated using CUDA 11.8. The detection model is based on the YOLO architecture and was trained using YOLOv8s, with the training process consisting of 50 epochs.

During the model training phase, the batch size was set to 16, the initial learning rate was set to 0.001, and the weight decay coefficient was 0.0005. The loss function weight allocation was as follows: BoxLoss was 0.05, the classification loss weight was 0.3, and DflLoss was 1.5. To further improve the model's accuracy and recall, the experiment introduced a data augmentation strategy.

Model Training Results

As shown in Figure 6, the trends of key metrics during the model training process are displayed. After training converges, the model's accuracy remains above 0.95, and the recall stays above 0.87.

For each video sequence, the frame rate is maintained at 10 FPS, and the total inference time is approximately 5 minutes.

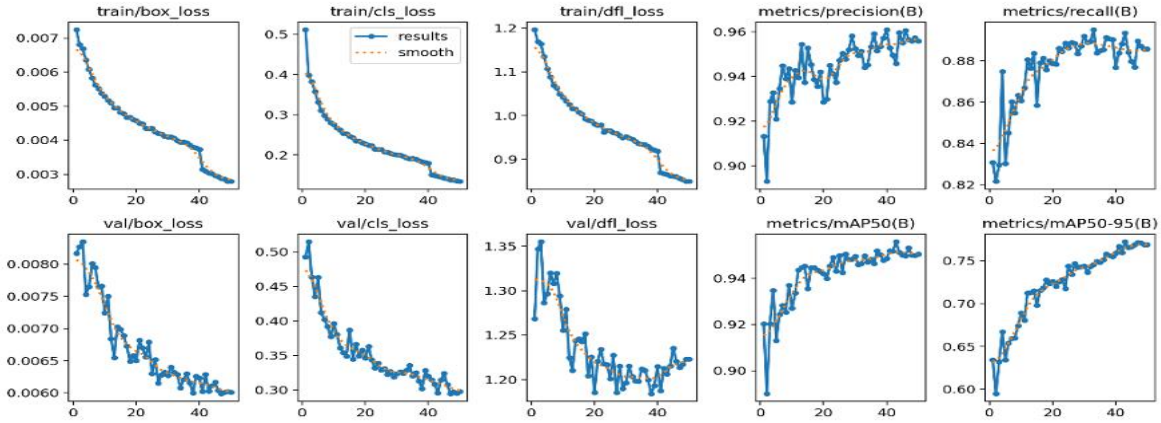

Fig. 6 - Training Results of YOLOv8 Model

Muti-Target Tracking Results Of Live Pigs

The results of multi-pig tracking using the improved ByteTrack algorithm are shown in Table 1.

The improved ByteTrack algorithm performs well in the task of tracking pigs. Although the MOTA metric is relatively low in some specific scenarios (pig12), overall, this improvement is significantly effective.

Table 1

Experimental Results of Multi-object Tracking of Pigs

Video	MOTA	IDF1	IDP	IDR	FP	FN	IDS	precision	recall
pig04	92.84%	92.95%	92.79%	93.11%	145	131	10	96.38%	96.72%
pig05	94.10%	89.66%	89.07%	90.26%	187	116	10	96.52%	97.81%
pig10	72.98%	78.29%	76.50%	80.17%	259	179	13	85.19%	89.28%
pig11	81.34%	67.20%	69.49%	65.06%	104	219	14	93.85%	87.87%
pig12	30.81%	83.52%	72.17%	99.11%	357	105	5	61.49%	84.44%
pig14	84.09%	71.41%	67.63%	75.63%	781	105	23	87.78%	98.16%
pig17	81.00%	91.32%	84.50%	99.33%	328	12	2	84.50%	99.33%
pig18	83.21%	92.05%	91.25%	92.87%	182	147	3	90.95%	92.56%
pig21	79.66%	87.05%	84.34%	89.95%	111	56	1	87.40%	93.22%
pig23	93.63%	83.75%	83.07%	84.45%	210	119	20	96.23%	97.83%
pig25	86.63%	89.52%	84.93%	94.62%	482	32	13	89.03%	99.19%
pig27	99.08%	99.83%	100.00%	99.67%	14	30	0	99.71%	99.38%

Ablation Experiment Results

To evaluate the impact of the improved module on the tracking system, an ablation experiment was conducted on the video pairs in the test set, and the results are shown in Table 2.

Table 2

Ablation Experiment Results

Ablation module	Evaluation metrics								
EMA	MOTA	IDF1	IDP	IDR	IDS	FP	FN	precision	recall
×	80.00%	83.00%	87.79%	79.21%	79	1225	4857	94.58%	84.97%
√	81.61%	85.55%	82.98%	88.69%	114	3160	1251	89.09%	94.65%

Figure 7 shows a comparison of the effects before and after adding the EMA module. (a) and (b) are consecutive video frames without using the EMA module, while (c) and (d) show the results of processing the same two video frames after adding the EMA module. As shown in Figure 6, by introducing the EMA trajectory smoothing algorithm, the consistency between the size of the tracking box and the actual size of the pig's body has been significantly improved.

Comparative Experiment

To verify the effectiveness of the improved ByteTrack algorithm, the experiment compared it with two multi-object tracking algorithms, OCSORT and DeepSORT (*Wojke et al., 2017; Cao et al., 2023*). All three algorithms follow the Tracking-by-Detection paradigm, which first uses an object detector to obtain targets in each frame and then matches the detected boxes with existing trajectories through an association strategy. To ensure a fair comparison, all three used YOLOv8s as the base detection model and conducted multi-object tracking tests on the same video sequences. Table 4 shows the results of the comparative experiment.

(a) Frame 1 without EMA module added (b) Frame 2 without EMA module added (c) Add EMA module frame 1 (d) Add EMA module to frame 2

Fig. 7 - Comparison of effects with or without the EMA module

Table 3

Comparison of Experimental Results

Algorithm Name	Evaluation metrics								
	MOTA	IDF1	IDP	IDR	IDS	FP	FN	precision	recall
DeepSORT	81.10%	85.55%	82..98%	88.69%	114	263	104	89.09%	94.65%
OCSORT	84.10%	85.52%	89.25%	81.89%	149	374	3651	96.90%	87.59%
Improved ByteTrack	81.61%	85.55%	82.98%	88.69%	114	3160	1251	89.09%	94.65%

As shown in Table 3, among the three trackers, DeepSORT performed the worst overall. This is because in complex scenarios, DeepSORT is prone to higher ID switches and missed detections. OC-SORT has relatively high multi-object tracking accuracy, but it also has a high false detection rate, indicating that it often loses track, resulting in poor trajectory continuity. In contrast, the improved ByteTrack algorithm performs well overall, although its accuracy and stability are slightly inferior to OC-SORT. It can be seen that the improved ByteTrack achieves the best overall performance.

Practical Application Discussion

The data from Pig Farm 1 were collected in Taiyuan, Shanxi Province, from April 19 to April 30, 2019. The pigsty consisted of 10 pens (6 m × 5 m × 1.2 m), each housing 5–6 sows. A Hikvision DS-2CD3T86FWDV2-I3S high-definition network camera was installed on the side wall and ceiling (approximately 2 m height) of each pen for video collection.

Multi-object tracking technology enables continuous and non-contact monitoring of pigs by providing stable identity and trajectory information for each individual. Based on this advantage, the proposed improved ByteTrack method can continuously analyze pig movement trajectories and behavioral patterns, offering reliable data support for abnormal behavior detection, activity analysis, and livestock health management. In practical deployment, the system requires only standard HD cameras and GPU-based edge computing devices. By integrating YOLOv8 with the ByteTrack+EMA framework, the system enables real-time pig tracking and trajectory smoothing while remaining compatible with existing farm management systems.

CONCLUSIONS

This study focuses on the challenges in multi-object tracking of pigs, such as variable target scales, mutual occlusion, and complex scenes, and proposes a pig multi-object tracking method based on an improved ByteTrack. By introducing the EMA trajectory smoothing algorithm, the method performs weighted averaging of the targets' historical position information, effectively suppressing the jitter of detection boxes.

Experimental results show that the proposed improved method achieves significant performance gains in real-world applications. Compared with the baseline model ByteTrack, MOTA increased by 1.61%, IDF1 increased by 2.55%, Recall improved by 9.68%, and the FN was greatly reduced. The results indicate that the improved ByteTrack performs stably in complex scenarios with high pig density, frequent occlusions, and highly similar appearances, demonstrating strong practical application potential.

Keywords: *sapropel, organic fertilizer mixture, local strip application, applicator machine, torque, mass flow rate*

ABSTRACT

An alternative approach to the utilization of lake sapropel is its mixing with available organic sorbents, such as chopped cereal straw. The application of such mixtures in strips into the soil ensures the formation of a moisture-holding nutrient layer during crop cultivation. To form these strips, an experimental prototype of a single-row machine was developed. Under laboratory conditions, the torque M required to drive the machine and the mixture mass flow rate Q were investigated. The variable parameters included the rotational speed of the metering beater shaft n, the blade inclination angle ξ, the width of the hopper outlet opening a, and the opening position of the metering beater housing gate Δ. To obtain mathematical models of the machine drive torque $M(a,\Delta,\xi,n)$ and the mixture mass flow rate $Q(a,\Delta,\xi,n)$ in the form of regression equations, a statistical design of experiments method for a four-factor experiment based on the Box–Behnken design was applied. Analysis of the obtained regression equations showed that, in order to reduce the energy consumption of the machine drive, it is advisable to maintain the beater rotational speed within the range of $n = 550$–600 rpm, the blade inclination angle at $\zeta = 45 - 50^0$, and the maximum opening of the metering beater housing gate $\Delta = 0.06$ m. A nomogram was developed for regulating the mixture feeding rate of the machine by changing the width of the hopper gate opening a. It was also established that, at the maximum mass flow rate of $Q = 3.5$ kg/s, the torque required for the machine drive M ranged from 6.9 to 7.2 N·m.

РЕЗЮМЕ

Альтернативним способом використання озерного сапропелю є його змішування із доступними органічними сорбентами, наприклад, січкою соломи злакових культур. Внесення таких сумішей смугами у ґрунт забезпечує формування вологоутримуючого поживного шару під час вирощування сільськогосподарських культур. Для формування таких смуг розроблено експериментальний зразок однорядної машини. В умовах лабораторії досліджували крутний момент M, необхідний на привід машини та продуктивність подачі суміші Q. Змінними параметрами були частота обертання вала дозуючого бітера n, кут нахилу лопаті ξ, ширина вихідного отвору бункера a машини та положення заслінки дозуючого бітера Δ. Для отримання математичних моделей крутного моменту приводу машини $M(a,\Delta,\xi,n)$ та продуктивності подачі суміші $Q(a,\Delta,\xi,n)$ у вигляді рівняння регресії було використано математичний метод планування для чотирифакторного експерименту, який базувався на плані Бокса-Бенкіна. Аналізуючи отримані рівняння регресії встановили, що для зменшення енергетичних затрат на привід машини доцільно забезпечувати частоту обертання бітера у межах $n = 550$-600 об/хв., кут нахилу лопаті - $\zeta = 45 - 50^0$ та максимальну величину відкривання заслінки корпусу дозуючого бітера $\Delta = 0.06$ м. Отримано номограму для регулювання продуктивності подачі суміші машиною шляхом зміни ширини відкривання заслінки бункера a. Також встановлено, що під час досягнення максимальної продуктивності у $Q = 3.5$ кг/с значення крутного момент на привід машини M знаходиться у межах 6.9 до 7.2 Н·м.

INTRODUCTION

A distinctive feature of lake sapropels is their complex influence on all factors determining soil fertility. In particular, numerous studies have reported a positive effect of sapropel and sapropel-based fertilizers on the soil water–air regime and thermal conditions. When sapropel is applied to the soil, an increase in total and capillary water capacity, water-holding capacity, and moisture content of the upper soil horizon is observed (*Baksiene et al., 2015; Edesi et al., 2020; Shevchuk, 1996; Skrylnyk et al., 2021*). It has also been established that the extent of improvement in the water–physical properties of soil depends both on the application rate of sapropel fertilizers and on their quality, particularly their chemical and mechanical composition.

At the same time, the commonly known methods of using sapropel as a fertilizer involve its dewatering from the natural moisture content of deposits, typically ranging from 92–98%, down to approximately 60% *(Booth et al., 2007; Bulgakov et al., 2017; Zarina et al., 2023*). Dewatering sapropel to such a moisture level is associated with significant energy consumption and financial costs, which in turn increases the cost of fertilizers produced on its basis.

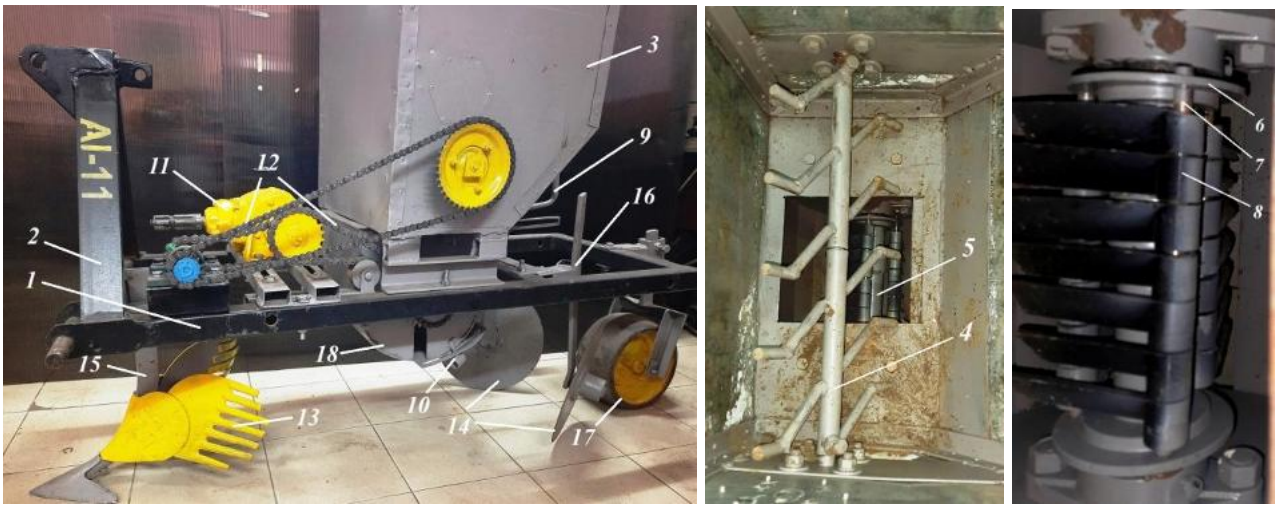
It is also well known that achieving high yields of agricultural crops is largely constrained by climate change in general and, in particular, by the catastrophic depletion of soil moisture reserves. Recent studies (*Didukh et al., 2024*) have demonstrated the possibility of forming a nutrient, moisture-holding layer from sapropel and sapropel-based mixtures capable of accumulating water and, when necessary, releasing it to the surrounding soil layers and plants.

Climate change, the energy crisis, and ongoing soil degradation processes are forcing farmers to move away from conventional farming systems and to adopt energy- and resource-saving technologies, such as Mini-till, No-till, Strip-till, and Verti-till (*Jaskulska et al., 2020; Kargwal et al., 2022; Kosolap and Krotinov, 2011*). Among these systems, Strip-till technology has become increasingly widespread. This approach replaces traditional row cultivation with strip cultivation, typically characterized by inter-row spacings ranging from 30 to 75 cm.

These trends create favorable conditions for the local application of fertilizers based on sapropel of natural moisture content for crops grown using wide-row planting systems. This solution is particularly relevant for soils with a light mechanical composition that are located in close proximity to sapropel deposits. Such fertilizers may consist of sapropel mixtures with readily available organic sorbents, for example, chopped cereal straw (*Didukh et al., 2024*).

Existing designs and studies of equipment for the local strip application of organic fertilizers in orchards and for row crops (*Glancey and Adams, 1996; LaguÎ et al., 2006; Popa et al., 2025; manufacturer data: Renmark*) are generally based on conventional manure spreaders additionally equipped with transverse belt or screw conveyors, or with horizontal spreading discs. These machines enable the placement of organic fertilizer strips on the soil surface near tree trunks, berry bushes, vineyards, or within the inter-rows of row crops. For the local strip application of liquid organic fertilizers into the soil, tank units equipped with cultivators have been developed. Such systems perform soil tillage according to the Strip-till concept and typically form from 4 to 12 fertilizer strips, with inter-row spacings varying from 45 to 75 cm *(manufacturer data: Vogelsang*). For the subsurface strip application of solid organic fertilizers, machines employing flexible screw-type distribution devices have also been developed and tested (*Landry et al., 2011*). However, the aforementioned machines are not suitable for the application of sapropel-based mixtures or for the formation of a moisture-holding nutrient layer due to specific design features that prevent their working elements from handling materials with increased stickiness and viscosity. Taking into account the advantages and limitations of the existing machine designs, a modernized organic fertilizer spreader was developed to enable the formation of subsurface strips of high-moisture solid organic fertilizers for the cultivation of wide-row crops (*Didukh et al., 2024*).

The primary quality parameter of machines designed for uniform surface application of organic fertilizers is the uniformity of distribution. Consequently, numerous experimental and theoretical studies have been devoted to determining the influence of spreading unit parameters on the uniformity of fertilizer distribution over the field surface (*Duhovnik et al., 2004; Cârdei et al., 2019; Ştefan (Popa) et al., 2015; Stefan et al., 2021*).



Well-known theoretical and experimental studies of organic fertilizer application machines have also focused on evaluating the influence of hopper geometry and conveying system parameters on machine energy consumption and on the characteristics of the outgoing fertilizer flow (*Landry et al., 2005; Ştefan et al., 2017*).

For machines performing strip application of organic fertilizers, experimental investigations have established specific energy consumption values and deviations in application rates for individual strips (*LaguÎ et al., 2006; Landry et al., 2011*). In recent years, there has also been a widespread implementation of advanced computer-aided design and simulation tools for the development and modeling of organic fertilizer spreaders and their working elements (*Sengottaian et al., 2019; Stefan et al., 2025*).

The aim of this study is to investigate the influence of the main design and technological parameters of the working elements of a modernized organic fertilizer spreader (*Didukh et al., 2024*) on the drive torque and the mixture mass flow rate of the machine.

MATERIALS AND METHODS

To investigate the developed design of the modernized organic fertilizer spreader (*Didukh et al., 2024*), an experimental prototype of a single-row machine for the local strip application (MLSA) of sapropel-based mixtures was manufactured (Fig. 1a). The machine is based on a frame *1*, on which the hitch mechanism *2* and the fertilizer hopper *3* are mounted. An agitator *4* is installed inside the hopper (Fig. 1b), while a metering beater *5* is located beneath the hopper within its own housing. The metering beater 5 (Fig. 1c) consists of a central shaft fitted with two flanges *6*, each carrying three shafts *7*. Blades 8 are pivotally mounted on the shafts *7*. Regulation of the fertilizer flow supplied from the hopper *3* to the metering beater *5* is performed using a gate *9*, whereas the overall fertilizer application rate is controlled by a gate *10* of the metering beater housing *18*.

a b c

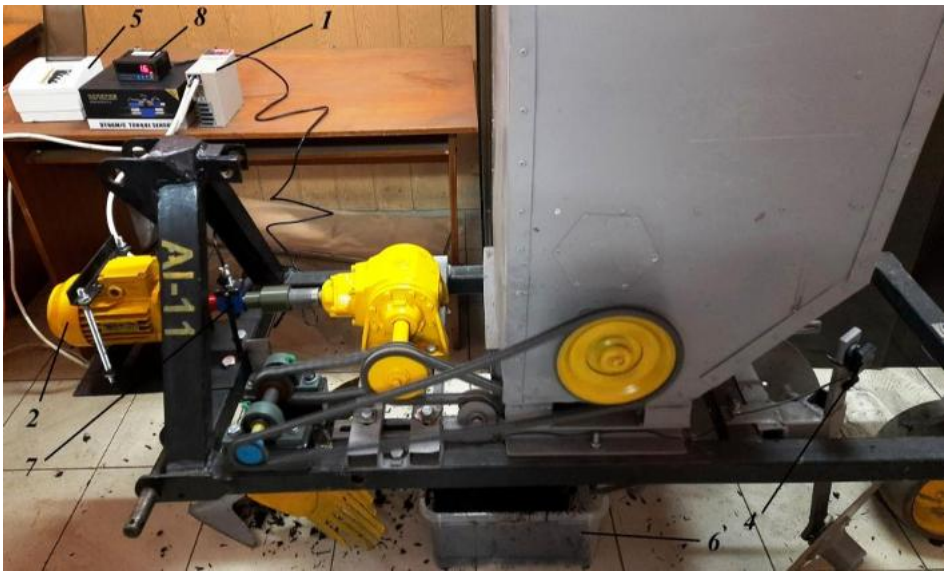


Fig. 1 - Experimental prototype of the MLSA machine for sapropel and sapropel-based mixtures
***(a)** general view; **(b)** internal part of the hopper; **(c)** metering beater*

To form the furrow, the machine is equipped with a furrow opener *13*, while furrow covering is performed by disc closers *14*. The furrow depth and the ridge height formed during furrow covering are adjusted by the mechanisms controlling the working depth of the opener *15* and the position of the disc closers *16*, respectively. To ensure a horizontal operating position of the machine, a support wheel *17* is provided, which simultaneously performs the function of soil compaction above the applied fertilizers.

Based on theoretical analysis and literature sources (*Didukh et al., 2024; LaguÎ et al., 2006*), it was established that the drive torque and the mixture mass flow rate are significantly influenced by the following design and technological parameters: the rotational speed of the metering beater shaft, the angle between the working surface of the blade and the axis of rotation of the metering beater (hereinafter referred to as the blade inclination angle), the width of the machine hopper outlet opening (determined by the position of the hopper gate), and the opening angle of the metering beater housing gate (determined by the position of the metering beater gate).

To investigate the influence of these factors on the torque required to drive the machine M and on the mixture mass flow rate Q, laboratory tests were conducted. For this purpose, the experimental machine prototype was additionally equipped with an asynchronous motor *2*, an electronic rotational speed controller *1*, and a torque sensor *7* with a monitoring unit *8* (Fig. 2). To obtain mathematical models describing the

variation of the machine drive torque M and the mixture mass flow rate Q in the form of regression equations, a design of experiments approach for a four-factor experiment based on a second-order, symmetric, non-composite Box–Behnken design, originally proposed by *Box and Behnken, (1960)*, was applied. The factors investigated in the experiment are presented in Table 1. The ranges of variation in the rotational speed of the metering beater shaft and the blade inclination angle were selected based on the results reported by *Didukh et al., (2024)*.

(a) general view; (b) installation of the Hall-effect sensor; (c) rotational speed monitor.

Table 1

Investigated factors and their variation ranges

Variation level	Factors			
	Width of the hopper outlet opening, *a*	**Opening of the metering beater housing gate, *Δ* (m)**	**Blade inclination angle, *ζ***	**Rotational speed of the metering beater shaft, *n***
	[m]	**[m]**	**[deg.]**	**[rpm]**
	x_1	x_2	x_3	x_4
Upper (+1)	0.14	0.08	50	850
Central (0)	0.10	0.06	45	700
Lower (-1)	0.06	0.04	40	550

The investigated factors were fixed at the specified levels as follows. To vary the rotational speed of the metering beater shaft n, a frequency inverter Veichi AC01-T3-1R5G-B (1) was used to control the rotational speed of the asynchronous drive motor (2) (Fig. 2).

The achieved rotational speed of the metering beater shaft was monitored using a Hall-effect sensor (3) and recorded based on the readings of the monitor (4). To vary the blade inclination angle ζ, three sets of blades were manufactured from PLA plastic using 3D printing, with each set consisting of 21 blades (Fig. 3) and corresponding to the angle values listed in Table 1. The suitability of using plastic for blade manufacturing was substantiated in *Tsiz et al., (2026)*. The blade length from the mounting axis was 100 mm, while the width and thickness of the working part were 30 mm and 5 mm, respectively.

a) b)

Fig. 3 – Photograph of the blade manufacturing process with an inclination angle of $\zeta = 45^0$ by 3D printing (a) and the manufactured blades with inclination angles of $\zeta = 40^0$ and $\zeta = 50^0$ (b).

The experiments were carried out using a mixture consisting of 87% sapropel with a moisture content of $W = 92.2$ %, and 11% chopped winter wheat straw with a moisture content of $W = 13.6$ % and a cutting length of 5–20 mm. The moisture content of the mixture was $W = 81.7$ %. The stickiness characteristics of this and other sapropel-based mixtures are presented in *Tsiz et al., (2026).*

After setting the factor values specified by the experimental design in the form of parameters of the experimental setup, the hopper was filled with the above-described mixture, and the power supply of the frequency inverter Veichi AC01-T3-1R5G-B (1) was switched on using the control panel (5). Subsequently, the electric current frequency corresponding to the rotational speed of the beater shaft required by the experimental plan was set on the inverter display, and the power supply of the electric motor (2) was switched on. During the experiment, the mixture delivered by the metering beater was collected in a container (6) (Fig. 2). Each experimental run involved operating the machine for 20 s, after which the drive was switched off. During the experiment, between the 15th and 20th second of machine operation, the torque value measured by the sensor (7) was recorded based on the readings of the monitor (8).

The mixture mass flow rate of the machine, expressed in kg/s, was determined by dividing the mass of the mixture collected in the container (6) (Fig. 2) during one experimental run by the duration of the experiment (20 s). All experiments aimed at determining the drive torque and the mixture mass flow rate at the factor levels specified by the experimental design were performed in three replicates.

RESULTS

To process the experimental data obtained for the drive torque and the mixture mass flow rate, the methodology described in *Box and Behnken, (1960)* and *Tsiz and Homich, (2013)* for a four-factor experimental design was applied. The calculations were performed using Mathcad software. The reproducibility of the experiment was confirmed using Cochran's test. For the drive torque, the calculated value of the Cochran criterion satisfied the condition $G^{calc} = 0.110 < G^{tab}(0.05;27;2) = 0.318$ and for the mixture mass flow rate of the machine, the corresponding condition – $G^{calc} = 0.213 < G^{tab}(0.05;27;2) = 0.318$ was also fulfilled. The maximum standard deviation of the experimental torque values was $S = 0.49$ N·m, whereas the corresponding value for the mixture mass flow rate was $S = 0.22$ kg/s.

The significance of the regression coefficients was evaluated using confidence intervals determined according to Student's *t*-test. The tabulated value of this criterion at a 5% significance level and with the corresponding number of degrees of freedom of the reproducibility variance $f_1 = 2$ was $t = 4.3$.

After excluding the terms with statistically insignificant coefficients, the regression equations took the following form:

– for the drive torque

$$y_1 = 4.7 + 1.467 \cdot x_1 - 0.233 \cdot x_2 - 0.133 \cdot x_3 + 1.017 \cdot x_4 + \\ +0.275 \cdot x_1 \cdot x_4 + 0.188 \cdot x_1^2 - 0.388 \cdot x_2^2 + 0.187 \cdot x_4^2 \quad (1)$$

– for the mixture mass flow rate

$$y_2 = 1.29 + 1.007 \cdot x_1 + 0.101 \cdot x_2 + 0.455 \cdot x_4 + 0.156 \cdot x_1 \cdot x_4 + 0.436 \cdot x_1^2 + 0.262 \cdot x_4^2 \quad (2)$$

where: x_1, x_2, x_3, x_4 - are the coded values corresponding to the following factors: the width of the hopper outlet opening a, the opening of the metering beater housing gate Δ, e blade inclination angle ζ, and the rotational speed of the metering beater shaft n, respectively.

The adequacy of the regression equations was verified using Fisher's test. The calculated value of this criterion for the drive torque, with the variance of inadequacy $S_{n.}^2 = 0.00502$ and the variance of experimental reproducibility $S_y^2 = 0.01$ was $F^{calc} = 5.02$. The tabulated value of Fisher's criterion at the adopted 5% significance level was:

$$F^{tab}(0.05; f_2; f_1) = 19.43 \quad (3)$$

where: $f_2 = 18$ - is the number of degrees of freedom of the inadequacy variance;

$f_1 = 2$ - is the number of degrees of freedom of the experimental reproducibility variance.

Since

$$F^{calc.} = 5.02 < F^{tab}(0.05; f_2; f_1) = 19.43 \quad (4)$$

the hypothesis of adequacy of the regression equation, for which the response function is the drive torque required for machine operation, is confirmed.

The calculated value of Fisher's criterion for the mixture mass flow rate, with the inadequacy variance $S_{n.}^2 = 0.011$ and the experimental reproducibility variance $S_y^2 = 3.612 \times 10^{-3}$ was equal to $F^{calc} = 3.011$. The tabulated value of Fisher's criterion at the adopted 5% significance level was:

$$F^{tab}(0.05; f_2; f_1) = 19.44 \quad (5)$$

where: $f_2 = 20$ - is the number of degrees of freedom of the inadequacy variance;

$f_1 = 2$ - is the number of degrees of freedom of the experimental reproducibility variance.

Since

$$F^{calc.} = 3.011 < F^{tab}(0.05; f_2; f_1) = 19.44 \quad (6)$$

the hypothesis of adequacy of the regression equation, for which the response function is the mixture mass flow rate, is confirmed.

After converting the factors to their natural values, the regression equations (7) for the drive torque and (8) for the mixture mass flow rate of the machine were obtained. The reported precision of the regression coefficients was required to ensure the adequacy of the developed regression equations. Based on equation (7), response surfaces were constructed (Fig. 3a–c), whereas two-dimensional cross-sections of the response surface were generated based on equation (8) (Fig. 3d).

$$M = 3.14627778 - 18.90833333 \cdot a + 104.75 \cdot \Delta - 0.0266 \cdot \xi - 0.00943889 \cdot n + \\ +0.04583333 \cdot a \cdot n + 117.5 \cdot a^2 - 970.0 \cdot \Delta^2 + 8.31 \cdot 10^{-6} \cdot n^2; \quad (7)$$

$$Q = 6.59694444 - 47.525 \cdot a + 5.05 \cdot \Delta + 0.01586889 \cdot n + \\ +0.026 \cdot a \cdot n + 272.5 \cdot a^2 + 1.164 \cdot 10^{-5} \cdot n^2, \quad (8)$$

where: M - the drive torque required for machine operation [N·m];

Q - the mixture mass flow rate of the machine [kg/s].

The analysis of the regression equation for the drive torque required for machine operation (1) and the corresponding response surfaces (Fig. 4a–c) indicates a significant influence of all the investigated factors on this parameter. An increase in the drive torque is caused by an increase in the hopper outlet width a and the rotational speed of the metering beater shaft n. For factor a, this effect is associated with an increase in the mass of the mixture supplied by the metering beater per unit time, whereas for factor n, it is explained by the increased aerodynamic resistance acting on the rotating rotor blades.

In turn, an increase in the blade inclination angle ζ leads to a reduction in the projected area of the blade surface onto the plane perpendicular to the direction of rotation, which results in a decrease in aerodynamic resistance. The reduction in the drive torque with increasing opening of the metering beater housing gate Δ is evidently caused by a decrease in resistance during the discharge of the mixture from the rotor blades through the outlet opening of the housing.

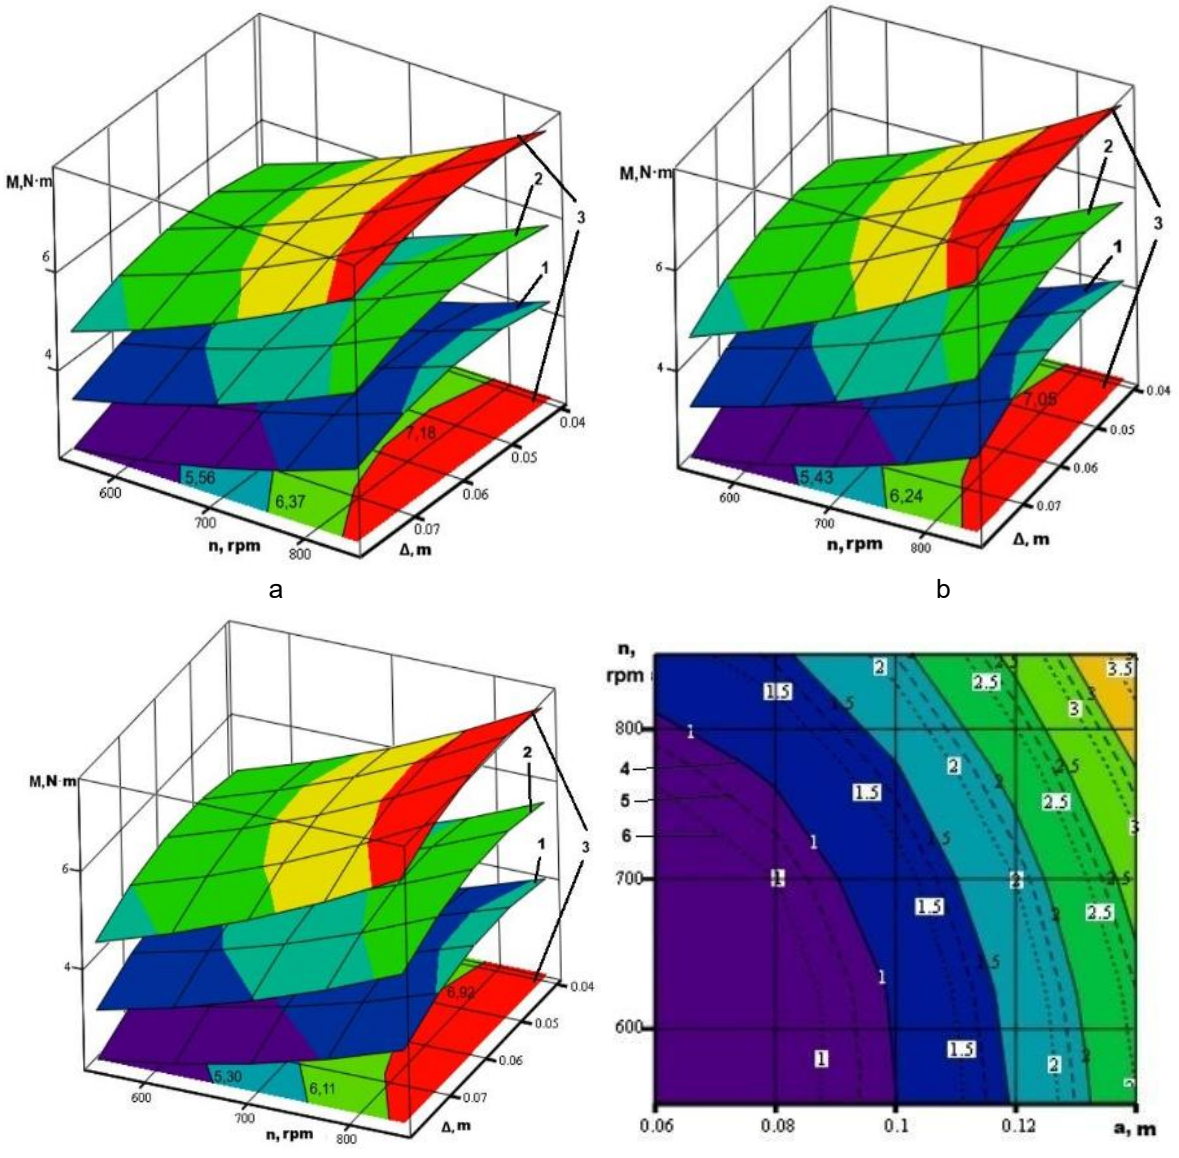

Fig 4 – Response surfaces constructed using equation (7) (a–c) and contour plots generated based on equation (8) (d).

a - $\zeta = 40^0$; b - $\zeta = 45^0$, c - $\zeta = 50^0$; 1 - $a = 0.06$ m; 2 - $a = 0.10$ m; 3 - $a = 0.14$ m; 4 - $\Delta = 0.04$ m; 5 - $\Delta = 0.06$ m; 6 - $\Delta = 0.08$ m

At the same time, the analysis of Equation (2) and the corresponding plots (Fig. 4d) indicates that the blade inclination angle ζ has no significant effect on the mixture mass flow rate. An increase in the mixture mass flow rate is observed with increasing rotor rotational speed n and hopper outlet width a.

Based on a comparison of the plots for the drive torque M (Fig 4, a-c) and the mixture mass flow rate Q (Fig 4, d) it was established that an increase in productivity Q is accompanied by an increase in the drive torque required for machine operation M. In order to achieve the maximum productivity $Q = 3.5$ kg/s the maximum drive torque values M in the range of 6.9–7.2 N·m are required.

Visual observations of the MLSA operation demonstrated stable performance without adhesion of the moist mixture to the working surfaces of the beater blades over the entire investigated range of factor variation (Table 1).

Therefore, in order to reduce energy consumption for machine operation, it is advisable to maintain the beater rotational speed within the range of $n = 550–600$ rpm, a blade inclination angle of $\zeta = 45 – 50^0$, and the maximum opening of the metering beater housing gate $\Delta = 0.06$ m.

Under these conditions, the required fertilizer application rate should be adjusted by selecting the hopper outlet width a using the plot shown in Fig. 4d as a regulating nomogram.

To compare the experimentally obtained values of drive torque M and productivity Q with the results obtained in studies of similar machines mentioned above, it is necessary to test the MLSA under field conditions. Laboratory investigations confirmed the operability of the developed design and the correctness of the adopted design solutions, which ensure self-cleaning of the blades when working with mixtures of increased stickiness.

A further development of the conducted research is the design of a multi-row machine capable of forming strips of a moisture-holding nutrient fertilizer layer during the cultivation of crops with different inter-row spacings. The design of such a machine can be developed by modernizing existing organic fertilizer spreaders using the proposals described in *Didukh et al., (2024)*.

CONCLUSIONS

Based on previous studies and existing designs of machines for organic fertilizer application, an experimental prototype of a single-row MLSA was developed. Equipping the MLSA with an electric drive, a frequency controller, and a torque sensor enabled experimental investigations of its operation under laboratory conditions.

The conducted MLSA studies, using a mathematical design of experiments approach, made it possible to obtain regression-based mathematical models describing the dependence of the drive torque $M(a,\Delta,\xi,n)$ and the mixture mass flow rate $Q(a,\Delta,n)$ on the investigated factors.

It was established that achieving the maximum productivity $Q = 3.5$ kg/s requires the maximum drive torque M values in the range from 6.9 to 7.2 N·m. In order to reduce energy consumption during machine operation, it is advisable to maintain the beater rotational speed within the range of $n = 550$-600 rpm, the blade inclination angle $\zeta = 45 – 50^0$ and the maximum opening of the metering beater housing gate $\Delta = 0.06$ m. Under these operating conditions, the required fertilizer application rate should be set by selecting the hopper outlet width a, using the plot shown in Fig. 4d as a regulating nomogram.

Future research will focus on field testing of the MLSA and on the development of a multi-row machine capable of forming strips of a moisture-retaining nutrient fertilizer layer for crops grown with different row spacings.

Keywords: *Sweet potato, Compressive mechanical properties, Moisture content, Elastic modulus, Maximum rupture force.*

ABSTRACT
To investigate the effects of moisture content on the compressive mechanical properties of sweet potato roots, this study used three sweet potato varieties (Zishu, Hongyao, and Xiguahong) cultivated in the Tianjin region as experimental materials. Experiments were conducted between October 8, 2025, and January 8, 2026, in a laboratory environment maintained at 20°C ± 2°C and 50% ± 5% relative humidity. The test employed a moisture content measurement method based on storage duration, measuring moisture content every 10 days. Simultaneously, compressive mechanical property tests were performed using an INSTRON 3344 series universal material testing machine under conditions of a 10 mm/min loading speed and a maximum pressure of 1500 N. The maximum rupture force, maximum deformation, and elastic modulus of sweet potatoes at different moisture contents were determined. Data analysis was conducted using Design-Expert 13 software. The results indicated that the variation patterns of moisture content were similar across the different sweet potato varieties. The moisture content decreased rapidly during the initial storage period, showed a brief increase in the middle stage, and then continued to decline at a slower rate in the later stage. Moisture content significantly affected the compressive mechanical properties of sweet potatoes. As the moisture content decreased, the elastic modulus and maximum rupture force increased, while the maximum deformation decreased.

摘 要
为探究水分含量对甘薯块根压缩力学特性的影响，本研究以天津地区种植的紫薯、红瑶、西瓜红三个甘薯品种为试验材料，于 2025 年 10 月 8 日至 2026 年 1 月 8 日，在温度保持为 20℃±2℃、相对湿度保持为 50%±5%的实验室环境中开展试验。本试验采用基于贮藏时长的水分含量测定方法，每 10 天测定一次甘薯水分含量；同时使用英斯特朗 3344 系列万能材料试验机，在加载速率 10 毫米 / 分钟、最大压力 1500 牛的试验条件下开展压缩力学特性测试，测定不同水分含量下甘薯的最大断裂力、最大变形量及弹性模量，并采用 Design-Expert 13 软件对试验数据进行分析。试验结果表明，不同甘薯品种的水分含量变化规律具有一致性：贮藏初期水分含量快速下降，贮藏中期出现短暂上升，贮藏后期则以较慢速率持续降低。水分含量对甘薯的压缩力学特性存在显著影响，随着水分含量的降低，甘薯的弹性模量和最大断裂力呈上升趋势，而最大变形量呈下降趋势。

INTRODUCTION

Sweet potato is an important food crop, rich in nutrients such as protein, carotenoids, flavonoids, anthocyanins, various vitamins, and minerals (*Alam M.K., 2020; Khatun T., 2025*). The physical and mechanical property parameters of sweet potato roots serve as crucial theoretical basis for the design of related machinery and are essential parameters for establishing models when studying the interaction mechanisms between sweet potatoes, soil, and machinery using numerical simulation methods (*Zhao Ping, 2024*). Furthermore, the compressive characteristics of sweet potatoes are also a theoretical guide for designing machinery used in storage, transportation, and processing. Since moisture content significantly influences compressive mechanical properties, studying the compressive mechanical properties of sweet potatoes at different moisture levels is of great importance. Additionally, the deep processing methods for sweet potatoes are closely related to their moisture content.

Different moisture levels determine the most suitable processing techniques; for instance, slicing, juicing, and mashing are more appropriate at high moisture content, while baking, frying, and grinding into flour are better suited for lower moisture content. Therefore, investigating the variation pattern of sweet potato moisture content during storage is particularly important, providing references for selecting preservation methods, processing techniques, and optimal timing.

Currently, researchers domestically and internationally have conducted studies on the relationship between the compressive mechanical properties of root and tuber crops and moisture content. Foreign scholar studied the relationship between the mechanical properties and moisture content of cassava roots, measuring the mechanical response of cassava roots under compression and other loads at different moisture contents and analyzing the effect of moisture content on mechanical indicators such as hardness and elastic modulus (*Bo M.W. et al, 2016*). *Agboola et al, (2024*), experimentally studied the mechanical properties of sugarcane stalks, analyzing compressive strength, Young's modulus, and other mechanical performance indicators based on compression tests conducted at different growth stages and among different varieties. *Bulan R et al, (2020),* investigated the relationship between moisture content and mechanical properties of arecanut fruits by measuring various engineering properties of fresh arecanut fruits at three different moisture levels. Their findings revealed that a reduction in moisture content led to increases in most dimensional, frictional and compressive indicators, while sphericity, thousand-fruit mass and bulk density decreased. *Teshome A et al, (2025),* measured grain size, thousand-kernel weight, bulk density, angle of repose, friction coefficient and other indicators under multiple moisture contents and conducted statistical analyses. The results demonstrated that rising moisture content enlarged grain dimensions, thousand-kernel weight, angle of repose and friction coefficient yet lowered bulk density, with significant disparities in grain properties across treatments, indicating that differentiated seeding equipment should be matched for wheat varieties with varying cultivars and moisture contents. Domestic researcher conducted tests on the mechanical physical characteristics of sweet potato tubers at harvest, demonstrating that sweet potato tubers can be considered isotropic materials (*Shen Haiyang, 2020*). An overview of these studies reveals that relatively little attention has been paid to the patterns of moisture content variation and its specific effects on compressive mechanical properties. *Zhang Lingzhi et al, (2025)*, explored the variation laws of moisture content in various plant organs, grain starch content, and membrane puncture properties at different grain positions during ripening. They verified that the grain dehydration rate had an extremely significant positive correlation with the moisture contents of stalks and cobs. When the grain moisture content fell below 25%, the yield load and elastic modulus at the side and top positions of grains in the desiccant treatment group were superior to those in the natural dehydration group. *Cui Qingliang et al, (2022),* measured the tensile, bending, shear and dynamic cutting mechanical properties of buckwheat stalks, analyzed the influences of moisture content, stalk height above ground and cutting parameters. The results revealed that buckwheat stalks with higher moisture content exhibited greater tensile and cutting-related indicators yet weaker bending performance; the overall mechanical strength of stalks declined with the increase of height above ground. Cutting speed and blade bevel angle had significant effects on cutting stress and cutting energy consumption, and the optimal ranges of cutting parameters were put forward.

However, reviewing literature on crops similar to sweet potatoes, conducted block experiments on cassava stems and determined stem mechanical parameters, finding that the moisture content at different growth locations significantly affected the maximum compression load, indicating a significant influence of moisture content on compressive mechanical properties (*Wang Wei, 2017*). *Wang Juxia, (2024*), through completely randomized compression mechanical property tests on mung bean seeds, found that under the same loading speed, seed moisture content significantly affected the yield load and apparent elastic modulus of the seeds. Based on the above analysis, this paper aims to study the effect of moisture content on the compressive mechanical properties of sweet potato roots.

MATERIALS AND METHODS

Test Materials

This experiment was conducted in a sweet potato test field established through cooperation between Shenyang Agricultural University and Yuelong Town, Tianjin. Three cultivated sweet potato varieties, namely Zishu, Hongyao, and Xiguahong, were used as experimental materials. Manual harvesting took place on October 8, 2024 (*Liao J., 2025*).

Thirty tubers of each variety were selected based on uniform size, absence of damage, pests, and diseases, ensuring consistent maturity. After harvest, The length, width, and thickness of the fresh sweet potatoes for each variety were measured using a vernier caliper, and tubers of similar size and shape were selected, labeled, and stored, as shown in Figure 1. All test sweet potatoes were stored in the Agricultural Product Processing and Storage Laboratory of Shenyang Agricultural University from October 8, 2025, to January 8, 2026, totaling 3 months.

Fig. 1 - Sweet potato samples used for the experiment

Test Equipment and Instruments

The test equipment included a 101-type electric drum drying oven (Tianjin Tonglixinda Instrument Factory), an INSTRON 3344 series universal material testing machine (INSTRON, USA), an electronic balance (precision 0.01 g), a vernier caliper (measurement range 0-300 mm, accuracy 0.02 mm), plastic bags, and labels. The universal testing machine was used to test the compressive mechanical properties of sweet potatoes at different moisture contents. It can display compression load, displacement, speed, and test curves in real-time. The electronic balance and the 101 electric drum drying oven were used to determine the moisture content of the sweet potatoes. The vernier caliper was used to measure the diameter and thickness of the sweet potato samples.

Experimental Procedure

Detailed elaboration of the adopted test method and its advantages over conventional laboratory testing methods

The integrated storage-stage moisture monitoring combined with uniaxial compression test adopted in this work is a customized composite testing scheme for fresh tuber crops. Conventional single standard laboratory analysis methods are divided into two independent tests: one-time destructive drying for moisture measurement and separated compression tests on randomly sampled tuber blocks, which have two obvious defects: first, the moisture sample and mechanical sample are taken from different sweet potato individuals, leading to inconsistent actual moisture levels between mechanical test specimens and measured moisture data; second, traditional instant dehydration treatment will destroy the original internal tissue structure of fresh sweet potatoes and cannot reflect the natural tissue state of tubers during actual storage.

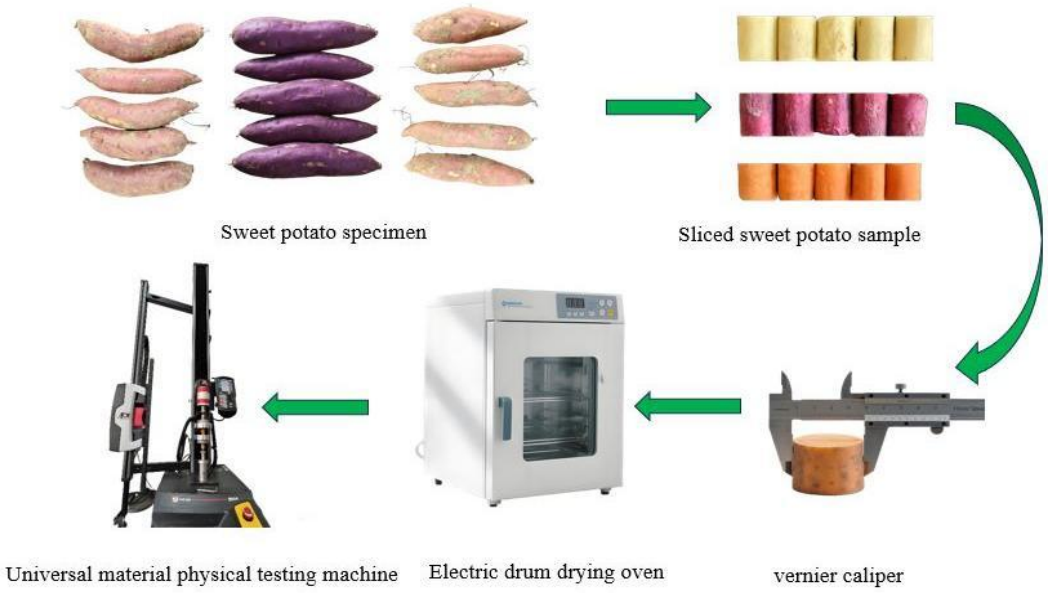

Fig. 4 - Test Procedure

The present testing method synchronously completes moisture tracking and compression measurement on the same batch of sweet potato tubers under natural storage environment, without artificial forced dehydration before mechanical testing. Cylindrical samples are cut from the same intact tuber for moisture detection and compression loading respectively, which ensures the complete consistency of tissue state and moisture background of test specimens. Besides, continuous 90-day periodic sampling avoids the error caused by discrete single-point sampling in short-term static tests. Compared with vacuum drying independent mechanical test and rapid oven drying mechanical test, this method can truly restore the natural water migration and tissue hardening law of sweet potato during postharvest storage, and the data correlation between moisture and mechanical indicators is higher, which is more suitable for exploring the continuous variation law of mechanical properties of fresh root crops with moisture content.

Sample repetition setting for guaranteeing test accuracy

Sweet potatoes were cut into cylindrical pieces approximately 15 mm thick using a sampling tool. The slices were made flat, avoiding cracks or unevenness, as shown in Figure 4. The universal testing machine was turned on and preheated for 10-15 minutes to ensure instrument stability. Test machine parameters were set: loading speed at 10 mm/min, maximum pressure set to 1500 N based on expected compression degree. The cut sweet potato sample was placed on the compression platform of the testing machine, ensuring it was centered, as shown in Figure 5. The testing machine was started, applying pressure to the sample at the set loading speed, and the deformation under different pressures was recorded. The deformation of the sample was observed, and any anomalies were recorded. Changes in the moisture content of sweet potatoes during storage are affected by temperature and humidity (*Guo Lianghu, 2020*). Therefore, environmental temperature and humidity were kept stable to avoid affecting the experimental results. Experiments were conducted in a laboratory environment maintained at 20°C ± 2°C and 50% ± 5% relative humidity. For each sweet potato variety under every single storage time/moisture level, 5 parallel tuber individuals were selected, and 3 cylindrical specimens were cut from each tuber for repeated compression tests; a total of 15 replicate compression samples were measured per treatment group. Meanwhile, 5 parallel thin slice samples were prepared for moisture content measurement at each test node. Multi-layer repetition design (individual tuber repetition + specimen repetition) can eliminate random errors caused by individual differences of sweet potato tubers, cutting thickness deviation and instrument micro-fluctuation, effectively improving the stability and reproducibility of test data.

The above steps were repeated for multiple sweet potato samples to ensure the repeatability and accuracy of the results. Based on the recorded pressure and deformation data, the elastic modulus of the sweet potato samples was calculated. The elastic modulus is an indicator reflecting the material's ability to resist deformation (*Long Che, 2024*).

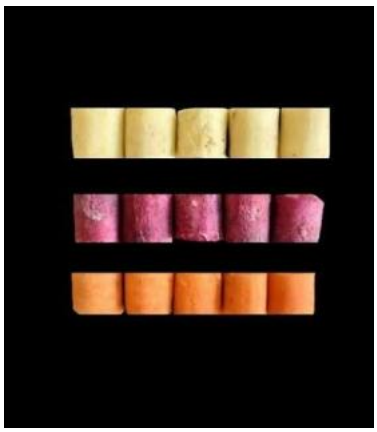

Fig. 6 - Cylindrical samples of sliced sweet potatoes

Test Design and Methods

To study the effect of moisture content on the compressive mechanical properties of sweet potatoes, this test adopted a moisture content testing method based on storage time. After harvest, the first moisture content determination and compression mechanical test were conducted; the second test was performed after 10 days; the third after 20 days; the fourth after 30 days; the fifth after 40 days; continuing this pattern, moisture content was tested every 10 days, resulting in 10 measurements over a total of 90 days. Through these tests, the variation patterns of moisture content with storage time for the three sweet potato varieties were obtained.

There are many methods for measuring moisture content; currently, internationally common methods include vacuum drying and convection oven drying (*Ge Naijun, 2025; Chen Siyu, 2025*). Based on available laboratory conditions and referencing GB/T 12078-2008, the convection oven drying method and mass weighing method were used to determine the moisture content of sweet potatoes. First, 10 samples were prepared for each sweet potato variety, cut into thin slices of similar thickness, and numbered separately. The weight of the samples was measured and the initial weight recorded. They were evenly placed on trays and in a convection oven at 100°C, dried for 0, 1, 2, 3, and 4 hours respectively. During the drying process, at specified times, samples of the three varieties were taken out, weighed, and the data recorded. If the weight no longer changed, it signified the end of drying; samples not meeting the specified drying standard were returned to the convection oven for continued drying.

$$x = \frac{m_1 + m_2}{m_1} \quad (1)$$

where: x is the moisture content of the crop, m_1 is the mass of the sample in grams, m_2 is the mass of the sample dried to constant weight in grams.

The procedure for testing the compressive properties of sweet potatoes was as follows: the loading speed was fixed at 10 mm/min, and the loading direction was vertical (*Ruan B., 2024*). Samples from the three sweet potato varieties were compressed at their natural moisture content levels after different storage periods to obtain the maximum rupture force, maximum deformation, and elastic modulus. The influence of moisture content on compressive mechanical properties was then studied through static load mechanical performance analysis. For each of the three sweet potato varieties tested, five replicate tests were conducted at the same moisture content level. For each of the three sweet potato varieties tested, five independent intact tubers were selected at the same moisture content level, and three cylindrical test pieces were cut from each tuber for compression test, forming 15 repeated test replicates for one treatment to reduce random test error. Data were statistically analyzed, and the mean and variance were calculated. During the test, a rigid plate was used as the loading device (*Barnett M.R., 2004*). The test sweet potato sample was placed in the center of the platen, and the upper platen was adjusted so that it did not contact the sweet potato. Entering the test program control interface, the control parameters were selected in the method settings, including a loading rate of 10 mm/min, an upper load limit of 1500 N, an upper displacement limit of 25 mm, an upper load drop percentage of 20%, and an upper load drop value of 10 N. In the test interface, the steps were followed by clicking load zero, reset extensometer, start, and finish sequentially. To reduce test error, each test was repeated five times under the same conditions, and the average value was taken finally.

This paper selected sweet potato moisture content as the experimental factor. The maximum rupture force at sample fracture, maximum deformation, and elastic modulus were used as test indicators. A three-factor, three-level experimental design was implemented, and response surface analysis was conducted to explore the interaction between these three factors and their effect on moisture content. The factor levels are shown in Table 1:

Table 1

Factor level table

Factor	level		
	-1	0	1
A（N）	300	390	480
B（mm）	5	7.5	10
C（MPa）	3	4.5	6

Note: A denotes maximum breaking force, B denotes maximum deformation, and C denotes elastic modulus.

To explore the interactive effects of the three factors on moisture content, simulation analyses were performed for each model sequentially. The data obtained from the simulation process were integrated, and the monitoring results are shown in Table 2.

Table 2

Orthogonal experimental design of moisture content

Test Number	A Maximum breaking force / N	B Maximum deformation / mm	C Modulus of elasticity / MPa	Y_1- Moisture content （%）
1	390	5	3	71.5
2	390	10	6	72.5
3	390	7.5	4.5	75.3
4	390	10	3	74.2
5	390	5	6	74.1

13	300	7.5	6	73.1
14	300	10	4.5	73.8
15	300	7.5	3	73.2
16	480	5	4.5	74.0
17	390	7.5	4.5	75.2

Based on Design-Expert 13 software, data were analyzed to perform significance tests and analysis of variance (ANOVA) for the mean Y_1 moisture content regression equation.

RESULTS AND DISCUSSION

Variation Pattern of Moisture Content in Different Varieties

The moisture content measurement results for the three varieties from 0 to 3 months after harvest were collected and analyzed, as shown in Figure 6. It can be observed that the moisture content of the three sweet potato varieties at harvest reached 74%-76%, but as storage time increased, the moisture content showed a decreasing trend: during the first 0-30 days of storage, the moisture content decreased rapidly; around 45 days, the decreasing trend slowed down further, reaching about 72%-74%. At 60 days of storage, the Zishu variety had the lowest moisture content and tended to stabilize. Starting from day 50, the moisture content of the Hongyao, Xiguahong, and Zishu varieties also slightly increased. Taking Xiguahong as an example, the moisture content of freshly harvested tubers initially reached 74.8%; after 20 days, it decreased to 74.3%, a drop of about 0.5%. The moisture content on day 90 was 72.7%, and the data stabilized. For different sweet potato varieties, their moisture content also differed. Overall, despite the different varieties, the variation pattern of moisture content in sweet potato tubers was similar. In the initial storage period, the moisture content decreased relatively quickly.

This is because physiological activities within the sweet potato continue after harvest, and respiration consumes a certain amount of water. The moisture content showed a brief increasing trend in the middle stage, possibly due to high humidity in the storage environment and poor ventilation, causing the sweet potato surface to absorb moisture from the air, leading to an increase in its moisture content. Microbial metabolic activities can also produce water, causing local increases in moisture content. However, this increase is temporary. As storage time increases, the moisture content of sweet potatoes continues to decrease, but the rate of decrease gradually slows down. Considering that sweet potatoes contain starch, sugars, and other carbohydrates besides water, it is certain that the tubers are not fully mature immediately after harvest, the skin is still tender, the cork layer has not formed, the water content is high, and they are prone to peeling. At this stage, sweet potatoes have sufficient moisture and a relatively soft texture, making them suitable for direct processing into mashed or pulped sweet potato for fillings in pastries. They can also be used to make sweet potato beverages or processed into ready-to-eat products such as steamed or roasted fresh sweet potato products.

Through compression mechanical tests, the compressive mechanical properties of different sweet potato varieties at various moisture contents were obtained (Table 3).

Table 3

The values of compressive mechanical properties under different moisture contents

Variety	Moisture content /%	Maximum breaking force / N	Maximum deformation / mm	Modulus of elasticity / MPa
Xiguahong	74.8	302.45	6.10	4.85
	74.3	389.54	9.45	4.11
	73.8	460.75	7.35	5.70
	73.3	487.68	10.45	5.33
	73.1	517.68	7.40	5.25
	72.8	562.25	17.50	3.92
	72.9	540.59	8.30	5.81
	73.0	506.61	13.05	3.26
	72.8	480.55	7.25	5.01
	72.7	473.50	8.52	4.71
Hongyao	75.3	299.85	6.32	4.19
	74.6	370.57	5.90	5.04
	74.0	424.75	10.21	4.15
	73.5	484.65	8.25	4.82
	73.4	494.35	7.45	5.68
	73.5	477.28	8.85	5.08
	73.7	457.92	6.54	5.42
	73.6	436.05	7.25	4.35
	73.5	427.52	8.65	4.11
	73.5	415.28	8.14	4.48
Zishu	74.3	344.69	4.85	5.44
	73.8	408.45	7.65	4.71
	73.4	464.15	6.35	6.22
	73.1	514.74	8.71	5.32
	72.9	542.72	6.45	7.04
	73.1	560.31	5.32	7.87
	73.2	542.56	5.21	7.18
	73.1	521.15	6.23	7.89
	73.0	506.45	7.15	6.38
	73.0	495.51	6.45	6.11

The rupture force of sweet potato primarily refers to the maximum value of the external load sustained by the sweet potato at the point of rupture. From Table 3, it can be seen that as the moisture content decreases, the compressive load that the sweet potato can withstand increases. The moisture content of all varieties was above 70% at the initial harvest stage. During the first 20 days of natural storage, the moisture content decreased rapidly. For example, for Hongyao, the maximum rupture force increased from 299.85 N to 370.57 N. Then, after about 50 days of storage, the change in maximum rupture force tended to stabilize. With further increase in storage time, around 90 days, when the moisture content was lower, the rupture force showed a subsequent decrease in some cases.

The elastic modulus of sweet potato is a measure of its resistance to deformation. A larger elastic modulus indicates that a greater external load pressure is required to cause elastic deformation. From the experimental data in Table 3, it can be observed that the modulus for the three varieties increased as the moisture content decreased. However, after 50 days, the trend of change in the elastic modulus was similar for the three varieties, with Zishu having the highest elastic modulus, followed by Xiguahong, and Hongyao having the smallest. A higher elastic modulus value indicates better firmness of the tuber. Analysis suggests that after the moisture content decreases, the elastic viscosity of the sweet potato decreases, and the density increases. The sweet potato becomes closer to a rigid body, is less prone to deformation under pressure, and possesses a certain load-bearing capacity.

The compressive deformation of sweet potato refers to its deformation under external compressive load, specifically the maximum displacement at the fracture point. From the experimental data in Table 3, it can be seen that as the moisture content decreases, the deformation tends to decrease, and the trend of change is consistent across different varieties. For example, for the Hongyao variety, the change in sweet potato deformation with moisture content is shown in Figure 7 (Note: Referenced but not provided in original text).

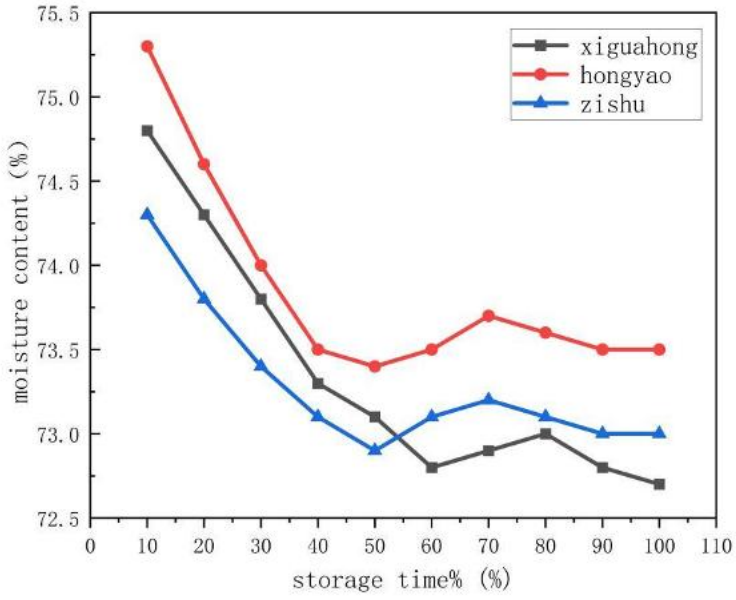

Fig. 7 - The variation law of moisture content of sweet potatoes with storage time

When the moisture content decreased from 75.3% to 73.5%, the deformation showed a decreasing trend, but overall, the decrease was relatively slow. After 50 days of storage, when the moisture content dropped to around 73.4%, the change in deformation was small. Other varieties exhibited their own characteristics, but the overall trend was consistent. As storage time increases and moisture content gradually decreases, the internal tissue of the sweet potato becomes more compact. Additionally, increased maturity and hardness enhance its ability to resist external loads, resulting in reduced deformation. At this stage, the moisture content is moderate, and the texture has a certain toughness, making it suitable for producing sweet potato dried strips by natural air-drying or oven-drying to remove some moisture while retaining flavor. They can also be processed into sweet potato flour through dehydration and grinding, which can be used for thickening or making pastries.

Based on Design-Expert 13 software, the significance of the regression equation and the analysis of variance for the mean Y_1 moisture content are shown in Table 4. Due to space limitations, this paper only presents the analysis for one sweet potato variety, Hongyao.

Table 4

Significance and analysis of variance of mean regression equation

Source	Sum of Squared Deviations	degree of freedom	Mean Square	F-value	p-value	Significance
Model	20.83	9	2.31	70.28	＜0.0001	**
A	1.53	1	1.53	46.50	0.0002	**
B	1.05	1	1.05	31.92	0.0008	**
C	0.41	1	0.40	12.30	0.009	**
AB	0.64	1	0.64	19.44	0.003	**
AC	0.30	1	0.30	9.19	0.019	*
BC	4.62	1	4.62	140.386	＜0.0001	**
A2	1.72	1	1.72	52.37	0.0002	**
B2	4.55	1	4.55	138.30	＜0.0001	**
C2	4.77	1	4.78	145.03	＜0.0001	**
residual	0.2305	7	0.03			
Missing item	0.1625	3	0.05	3.186	0.146	ns
Pure error	0.0680	4	0.02			
total	21.05	16				

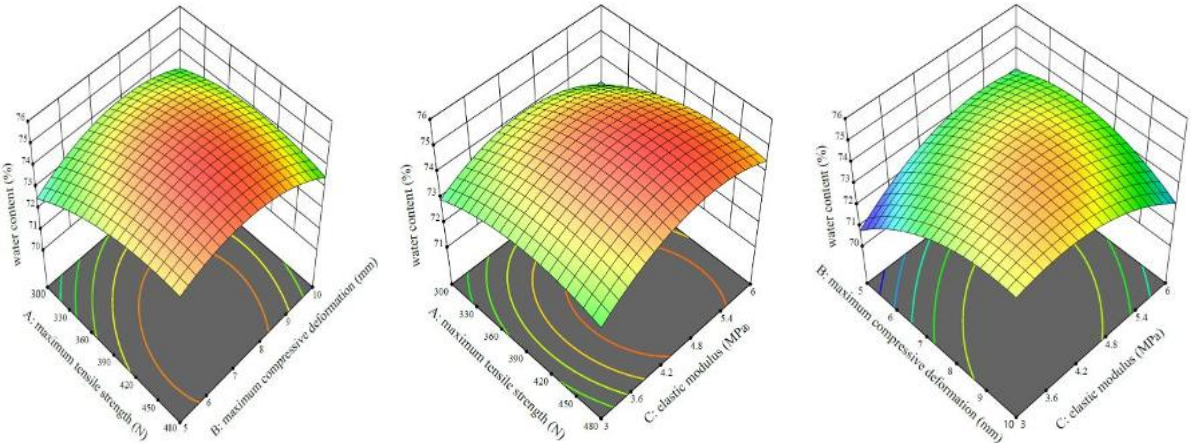
Note: P < 0.01 indicates highly significant results, denoted by **; P < 0.05 indicates significant results, denoted by *; P > 0.05 indicates non-significant results, denoted by ns.

According to the table data, the significance test result for the model (p-value less than 0.0001) indicates that the model is statistically highly significant. Simultaneously, the p-value for the lack of fit is 0.146, indicating that the lack of fit is not significant. The fit statistic $R_1^2 = 0.9891$, indicating a high degree of fit for the regression model. The regression equation for moisture content is given by Equation 2:

$$Y_1=75.18+0.4375^*A+0.3625^*B+0.225^*C-0.4^*AB+0.275^*\mathrm{AC}-1.07^*\mathrm{BC}-0.64^*\mathrm{A}^2-1.04^*\mathrm{B}^2-1.06^*\mathrm{C}^2 \quad (2)$$

where: Y_1: Moisture content of crop. A: Maximum rupture force. B: Maximum deformation. C: Elastic modulus. AB, AC, BC: Interaction terms of two factors. A^2, B^2, C^2: Quadratic terms of each single factor.

The response surfaces showing the interactive effects of the three factors on Y_1 moisture content are shown in Figure 8:



(a) Response surface of maximum rupture force (A) and maximum deformation (B) on sweet potato moisture content;

(b) Response surface of maximum rupture force (A) and elastic modulus (C) on sweet potato moisture content;

(c) Response surface of maximum deformation (B) and elastic modulus (C) on sweet potato moisture content.

Fig. 8 - Three-dimensional response surface plots showing the interactive effects between every two mechanical indicators (maximum rupture force, maximum deformation, elastic modulus) on the moisture content of Hongyao sweet potato tubers. Each subfigure corresponds to the coupling effect of two independent mechanical factors on the moisture content response value, while the third factor is fixed at the zero central level (A =390 N, B =7.5 mm, C =4.5 MPa). The vertical axis of each 3D surface represents the predicted moisture content; the two horizontal axes represent the two selected mechanical indicators respectively. The gradient change of surface height intuitively reflects the changing trend of moisture content under different factor combinations. The curved shape of the response surface demonstrates that there exists obvious nonlinear interaction between every pair of mechanical indicators, consistent with the significance results of AB, AC and BC interaction terms in ANOVA table. The surface shows an overall rising trend first and then falling, which is caused by the negative quadratic terms of A, B and C in the regression equation. The BC coupling surface has the steepest curvature, indicating that the interaction between maximum deformation and

elastic modulus exerts the most prominent influence on sweet potato moisture content, which matches the extremely significant p-value of BC item ($p<0.0001$) in the analysis of variance.

CONCLUSIONS

Through moisture content tests and mechanical property tests on different sweet potato varieties from the Tianjin region, this study investigated the effect of moisture content on the mechanical properties of sweet potato roots and their variation patterns. The influence of moisture content on the maximum rupture force, maximum deformation, and elastic modulus for three sweet potato varieties was analyzed. The main conclusions are as follows:

The moisture content of three sweet potato varieties was studied over 3 months post-harvest. The variation pattern of moisture content was similar across different sweet potato varieties. During the initial storage period, the moisture content decreased rapidly, showed a brief increase in the middle stage, and continued to decrease in the later period.

Moisture content had a highly significant effect on the mechanical properties of sweet potatoes, including the maximum rupture force, maximum deformation, and elastic modulus. The elastic modulus and maximum rupture force increased with decreasing moisture content, while the maximum deformation decreased with decreasing moisture content.

In the early storage period, when sweet potatoes have high moisture content, they are suitable for direct processing into mash or pulp for use as fillings in pastries. They can also be used to make sweet potato beverages or processed into ready-to-eat products like steamed or roasted fresh sweet potatoes. In the later storage period, when the moisture content is moderate and the texture has a certain toughness, they are suitable for making sweet potato dried strips by natural air-drying or oven-drying to remove partial moisture while retaining flavor. They can also be processed into sweet potato flour through dehydration and grinding, which can be used for thickening or making pastries.

ABSTRACT
In addressing the high labor costs and low operational efficiency of greenhouse tomato harvesting and separate packaging workflows, this study develops an integrated tomato harvesting robotic system embedded with RGB-D machine vision, 5-degree-of-freedom manipulator and vertical heat-sealing net bag packaging mechanism. The YOLOv8s lightweight detection model trained on self-built multi-light greenhouse tomato dataset (1260 annotated images covering unobstructed, semi-occluded and heavily occluded fruits) is adopted to identify ripe tomatoes with a recognition accuracy of 95.2%, and ImageJ software is introduced to conduct secondary maturity screening via RGB chromatographic analysis. A global path planning combined with TEB local trajectory optimization realizes autonomous obstacle avoidance navigation of the wheeled mobile platform, while RRT-Connect bidirectional random tree algorithm is applied for obstacle-free grasping trajectory planning inside dense tomato canopies. A total of 120 valid cyclic tests are carried out in simulated greenhouse environment to verify the full-chain automation including fruit detection, in-situ picking and instant bagging. Experimental results show that the average single-fruit processing cycle is 12.1 s, with a picking success rate of 90.8% and bagging success rate of 98.3%. Compared with skilled manual picking and packaging, the overall working efficiency is improved by approximately 30%. This system firstly realizes continuous integrated harvesting and commercial packaging operation for greenhouse tomatoes, providing a feasible technical solution for full-process intelligent protected agriculture.*

摘要
针对温室番茄采摘、包装分离作业带来的高人力成本与低效问题，本文研发一套集成 RGB-D 机器视觉、五自由度机械臂与立式热封网袋包装机构的一体化番茄采收机器人。系统采用 YOLOv8s 轻量化检测模型，基于自建多光照温室番茄数据集（1260 张标注图像，覆盖无遮挡、半遮挡、重度遮挡样本）实现成熟番茄识别，识别精度 95.2%；配套 ImageJ 软件通过 RGB 色谱分析完成果实成熟度二次校验。采用 A 全局路径规划结合 TEB 局部轨迹优化实现轮式移动底盘自主避障导航，RRT-Connect 双向随机树算法完成密植冠层内无碰撞抓取轨迹规划。在模拟温室环境完成 120 组完整循环试验，验证识别、就地采摘、即时套袋全流程自动化。试验结果表明，机器人单果平均处理周期 12.1 秒，采摘成功率 90.8%，套袋成功率 98.3%；相较熟练人工采摘包装综合效率提升约 30%。本系统首次实现温室番茄采收与商品化包装连续一体化作业，为设施农业全程智能化提供可行技术方案。*

INTRODUCTION
Facility agriculture, through controlled-environment production, is crucial for ensuring stable and efficient food supply. As a primary protected-field crop, tomatoes face significant harvesting challenges: concentrated fruit ripening leads to a surge in labor demand, resulting in tight operation cycles, high-intensity work, and rising costs. The aging workforce and global labor shortage trends further exacerbate this issue, making large-scale manual harvesting increasingly economically unsustainable. Consequently, developing autonomous harvesting robot systems has become an imperative for agricultural sustainability.

[1] *Yanhua Ying, Undergraduate student; Dongya Li, Professor; Jiahui Hu, Undergraduate student; Yyjie Zhou, Undergraduate student; Yubo Li, Undergraduate student.*

To this end, extensive research has been conducted in the field of agricultural harvesting robots. International projects, such as the EU's CROPS *(Goulart, 2023)* have developed modular multi-crop operation platforms integrating perception and manipulation. Research on crops like cucumbers and grapes has also advanced solutions combining machine vision, flexible end effectors, and motion planning. While these systems have made significant strides in fruit recognition and separation, their functionality largely remains confined to the "identify-harvest" stage. Harvested fruits typically require separate manual processes for sorting and packaging, adding handling steps and increasing damage risks, thereby hindering the realization of continuous automation from plant to packaged product. Particularly, the technology for immediate online automated commercial packaging (such as protective netting bags) post-harvest remains a critical bottleneck for achieving end-to-end automation *(Marin et al., 2025).*

To advance full automation of the "harvesting-packaging" process for greenhouse tomatoes, this study designed and validated a multi-sensor fusion robotic system. This system integrates a highly compact mechanical platform (incorporating an end-effector, vertical heat-sealing bagging mechanism, and buffer collection bin) with collaborative intelligent algorithms (YOLO-based visual detection, A*/TEB and RRT-Connect/visual servo hierarchical planning, and behavior tree scheduling). It combines ripe fruit identification, precise picking, on-site bagging, and collection into a single continuous operational cycle. Simulated greenhouse experiments demonstrated a 90.8% picking success rate, 98.3% bagging success rate, and an average processing cycle of approximately 12 seconds per fruit. Overall efficiency significantly surpassed manual labor, providing a highly efficient and feasible solution for automated greenhouse tomato production *(Liu et al., 2025)*.

Matache et al. (2026) developed an AI greenhouse tomato harvesting robot that only supports fruit picking without on-site packaging, requiring repeated manual fruit transfer and causing peel damage, which fails to realize end-to-end production. Current tomato harvesting robots have three core research gaps:

Most platforms lack integrated heat-sealing bagging actuators, separating harvesting and packaging procedures. Visual systems rarely combine YOLO detection with image-based maturity grading, and few reports fully disclose YOLO version, dataset and occlusion detection performance;

No unified collaborative scheduling system exists for mobile chassis, manipulator and bagging module.

To address the above bottlenecks, this study proposes a multi-sensor fusion robot integrated with 5-axis manipulator and vertical bagging mechanism. YOLOv8s combined with ImageJ chromatographic analysis realizes precise fruit screening, while A*/TEB navigation and RRT-Connect arm planning support lossless canopy picking. The system achieves continuous identification-picking-bagging-collection operation to fill the gap of integrated post-harvest packaging.

MATERIALS AND METHODS

OVERALL DESIGN AND INTEGRATION OF THE HARVESTING ROBOT SYSTEM

System Architecture and Workflow

To achieve full automation of tomato picking, bagging, and collection, this system employs a layered, collaborative hardware-software architecture Fig. 1 *(Adochiei et al., 2025)*, thereby enabling a closed-loop operational workflow Fig. 2.

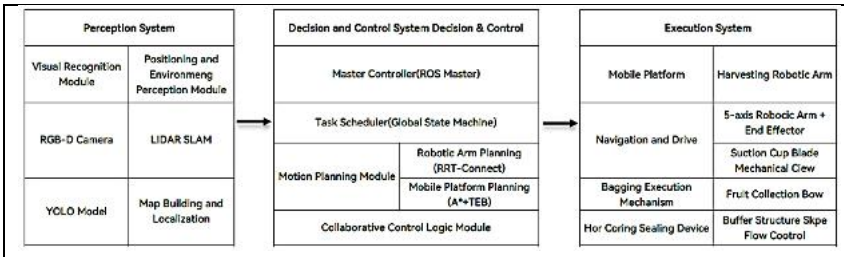

Fig. 1 - Overall System Architecture

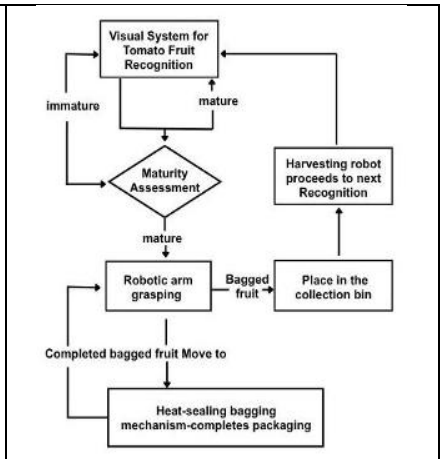

Fig. 2 - Workflow

Key Technical Parameters of the Harvesting Robot

Key design parameters are shown in Table 1.

Table 1

Summary of Key Performance Indicators for Tomato Harvesting Robots

Parameter	Technical Index
Overall Dimensions	Length 1200 mm × Width 880 mm × Height 960 mm
Whole Machine Weight	6 kg
Maximum Working Radius (Range)	2–5 m
Battery Endurance Time	2-5 h
Harvest Success Rate	85%-93 %
Bagging success rate	88%-95 %
Ripe Tomato Recognition Accuracy	95.2 %
Single Fruit Processing Cycle	10-15 s
Hourly Processing Capacity	249-400 fruits/h

In mechanical and structural design, overall dimensions must strictly comply with relevant specification constraints *(He et al., 2025)*. Concurrently, the vision system must operate stably under complex lighting conditions and identify partially obscured or overlapping fruits, achieving millimeter-level positioning accuracy to ensure precise grasping *(Wang & Liu, 2025)*.

DESIGN AND IMPLEMENTATION OF ROBOTIC MECHANICAL SYSTEMS

1. Overview of mobile platforms

A front-wheel-drive wheeled chassis with long wheelbase is adopted to enhance driving stability. The picking manipulator, heat-sealing bagging unit and fruit bin are arranged sequentially along the travel direction to match the picking-bagging-collection workflow *(Luo et al., 2017).*

After grasping, the fruit is transferred to the bagging mechanism and slides down a 20° inclined chute into the rear buffer bin. This integrated layout shortens fruit conveying paths and forms the mechanical foundation for continuous automatic operation (Fig. 3).

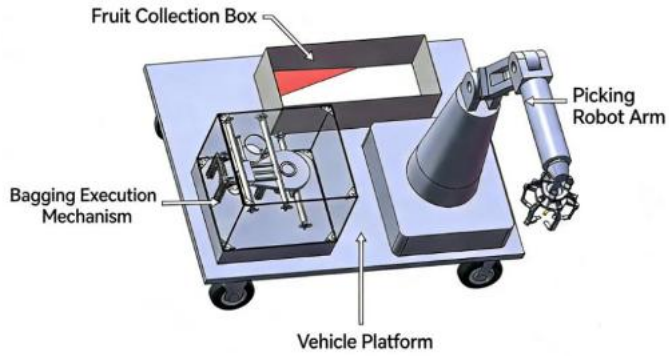

Fig. 3 - Mobile Platform

2. Design of harvesting robotic arm and end-effector

A 5-axis manipulator is equipped with 360° rotating base and wrist joints, plus a 270° elbow joint. The gripper integrates flexible protective sleeves, retractable vacuum cups and cable-driven cutting blades *(Bu et al., 2025)*. Three parallel cylinders' control gripper opening and closing for 50-100 mm diameter tomatoes. Vacuum assistance realizes gentle fruit transfer before bagging (Figs. 4-6).

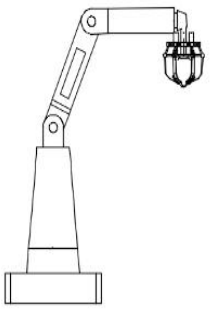

Fig. 4 - Manipulator

Fig. 5 - Gripper

Fig. 6 - Gripper Finger

3. Bagging actuator design

A vertical hot-cut net bagging device is proposed to replace inefficient manual packaging. Its three core modules work sequentially: net bag feeding, conical expansion, and thermal sealing & cutting.

Dual friction rollers deliver mesh bags; the tapered guide expands bag openings to fit variable fruit sizes. A cam-driven hot blade completes simultaneous cutting and sealing, with adjustable speed and temperature controlled by PLC (Figs. 7-8).

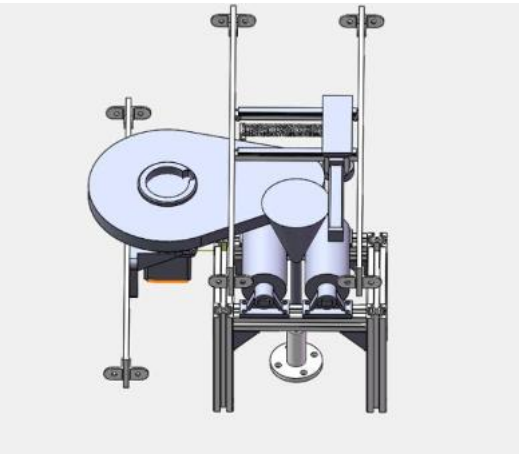

Fig. 7 - Structural Diagram of the Bagging Mechanism

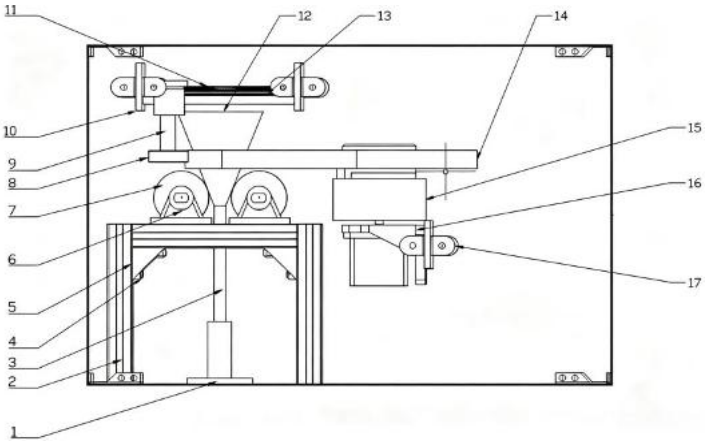

Fig. 8 - Schematic of the Bagging Mechanism

1-External Threaded Flange; 2-Support Profile; 3-Support Steel Pipe; 4-Nuts and Bolts; 5-Angle Bracket; 6-Support Frame; 7-Dual Active Friction Wheel Mechanism; 8-Rollers; 9-Connectors; 10-Support Plate; 11-Tension spring; 12-Guide cone; 13-Linear slide rail; 14-Cam mechanism; 15-Coupling; 16-Drive motor; 17-Triangular iron

4. Fruit collection bin design

The storage bin is fitted with foam anti-collision cushions and a 20°- 30° slope connecting the bagging device. Adjustable flexible partitions separate fruits by size to reduce extrusion damage while maintaining storage density (Fig. 9).

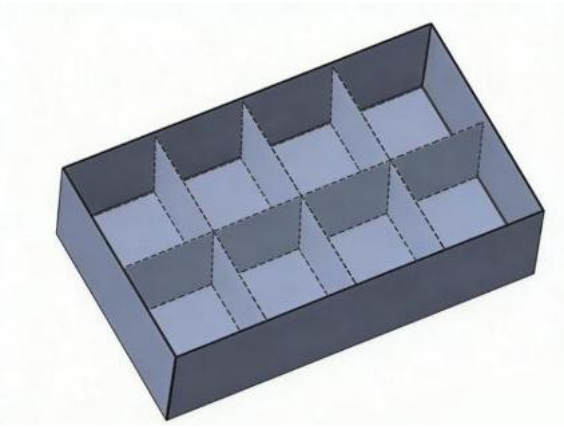

Fig. 9 - Fruit Collection Bin

MACHINE VISION-BASED TOMATO IDENTIFICATION AND HARVESTING LOCALISATION

1. Visual system hardware configuration

As shown in Fig. 10, the visual system hardware primarily consists of an industrial control computer, power supply, depth camera, robotic arm with its controller, and an electric gripper. The system employs an MK-GEB013GC-M1 camera paired with an MK-FC23M35F28-10M-A lens to capture tomato fruit images *(Yuan et al., 2023)*, meeting requirements for color recognition and spatial perception. The Model K280L Industrial Control Computer runs the visual recognition model, performs deep learning inference, controls the electric gripper, and communicates with the robotic arm controller. The robotic arm control system employs a dedicated controller equipped with a teach pendant, enabling automatic planning of the shortest motion path based on the target coordinates of the end-effector.

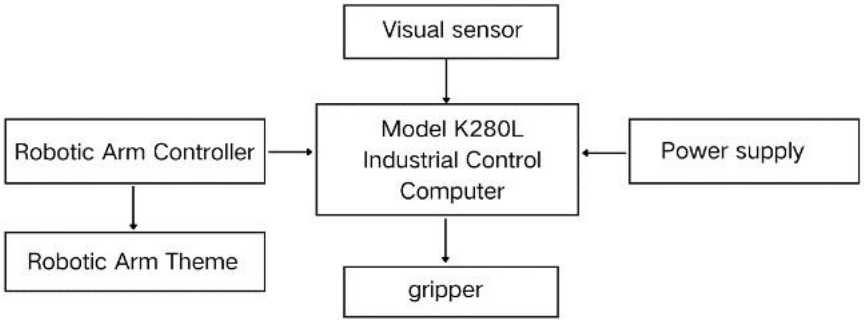

Fig. 10 - Block Diagram of the Vision System

2. Tomato recognition and localization algorithm

First, calibrate the robot to establish three Cartesian coordinate systems: the flange coordinate system, the gripper coordinate system, and the camera coordinate system *(El-sheikha et al., 2024).* As this robot employs an 'eye-on-hand' mounting configuration, measurements reveal the X, Y, and Z deviation values between the camera coordinate system origin and the gripper coordinate system origin: X=20, Y=0, Z=30 (mm).

The coordinate transformation relationship between a point P in space within the flange coordinate system and the gripper coordinate system is as follows:

If a point P in space is represented as P_b in the flange coordinate system and P_g in the gripper coordinate system, then:

$$P_b = {}^{b}R_g P_g + {}^{b}t_g \quad (1)$$

$${}^{b}R_g = R_z R_y R_x \quad (2)$$

represents the rotation matrix, and ${}^{b}t_g$ denotes the translation vector calculated from the X, Y, Z offsets. When expressed in homogeneous coordinates, the transformation matrix takes the form:

$$\begin{bmatrix} X_b \\ Y_b \\ Z_b \\ 1 \end{bmatrix} = \begin{bmatrix} {}^{b}R_g & {}^{b}t_g \\ O^T & 1 \end{bmatrix} \begin{bmatrix} X_g \\ Y_g \\ Z_g \\ 1 \end{bmatrix} = {}^{b}T_g \begin{bmatrix} X_g \\ Y_g \\ Z_g \\ 1 \end{bmatrix} \quad (3)$$

Here, ${}^{b}T_g$ represents a 4×4 homogeneous transformation matrix. After image acquisition, the computer performs feature extraction (including edge detection and corner operations), classifying features into three categories: fruit stalks, leaves, and fruits. Subsequently, path planning is conducted using the RRT algorithm to navigate around stem and leaf obstacles during harvesting *(Meng et al., 2025).*

3. Determining fruit maturity and harvest readiness

Tomatoes with diameters of 30-50 mm were selected, and fruit size was determined from the images captured by the camera. As illustrated in Fig. 11, ImageJ software was used to extract the RGB intensity values of the tomato fruit images. These values were then compared with reference color characteristics to evaluate fruit ripeness, as shown in Fig. 12 *(Sep˙ lveda et al., 2020).*

Fig. 11 - Representative image of a tomato fruit

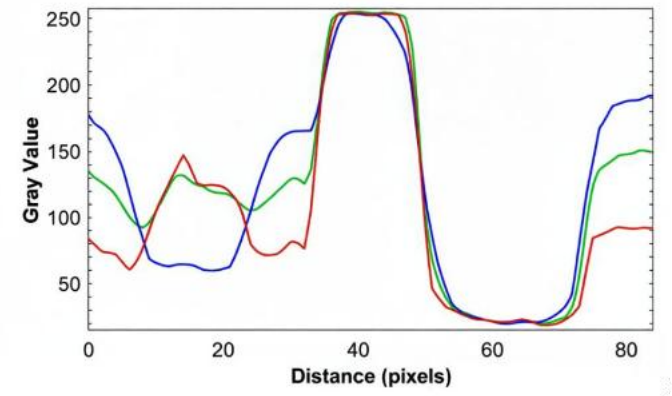

Fig. 12 - Chromatographic Range

YOLO VISUAL DETECTION MODEL AND TRAINING DATASET

This work adopts lightweight YOLOv8s for tomato recognition, leveraging C2f multi-scale backbone and decoupled detection heads to enhance detection of occluded fruits and reduce ripeness misclassification.

1. Self-Built Tomato Dataset

RGB-D images were captured under morning weak light, midday strong light and evening diffuse light, totaling 1260 samples categorized by occlusion: 520 unobstructed, 460 semi-occluded (10%-50% leaf coverage), 280 heavily occluded (>50% leaf coverage). Four labels (ripe_tomato, unripe_tomato, leaf, branch) were annotated via LabelImg. The dataset was split 7:2:1 for training, validation and testing, with random cropping, brightness jitter, flip and blur augmentation applied during training.

2. Model Training Parameters and Evaluation Metrics

Training ran on Model K280L PC with RTX 3060 GPU; BatchSize=16, initial lr=0.001, cosine annealing decay, total 150 epochs. Loss combines CIoU and cross-entropy. Evaluation metrics include mAP@0.5, Precision, Recall and single-frame inference latency, analyzed in Results.

3. Data Flow Between YOLO and ImageJ Software

The ROS vision node feeds frames into YOLOv8s to extract bounding boxes of ripe tomatoes;

Target regions are auto-cropped and batch-exported for ImageJ analysis.

ImageJ extracts RGB gray curves to match standard ripeness thresholds.

Only qualified fruit coordinates are transmitted to the manipulator planning module; underripe targets are discarded.

This two-stage screening reduces mis-harvest caused by contour-only YOLO judgment.

ROBOT MOTION PLANNING AND COLLABORATIVE CONTROL

Mobile Platform Path Planning

Equation (4) is the heuristic cost function of A* algorithm, used to search the shortest collision-free global path in greenhouse crop rows.

The A* algorithm employs a heuristic function *(Shao, 2025)*:

$$f(n) = g(n) + h(n) \tag{4}$$

to guide the search, ensuring the shortest path while enhancing efficiency.

The TEB (Timed Elastic Band) algorithm models the robot's future trajectory as a timestamped sequence of poses:

$$B = \{Q_i\}_{i=0}^{n},\ Q_i = [x_i, y_i, \theta_i, \Delta t_i]^T \tag{5}$$

and achieves smooth, safe local motion by minimizing the total cost function:

$$F(B) = \sum_k \omega k \cdot f_k(B) \tag{6}$$

to achieve smooth and safe local motion *(Li, 2025)*.

Equations (5) and (6) model robot pose sequence and overall trajectory cost, realizing real-time local obstacle avoidance based on LiDAR point cloud data.

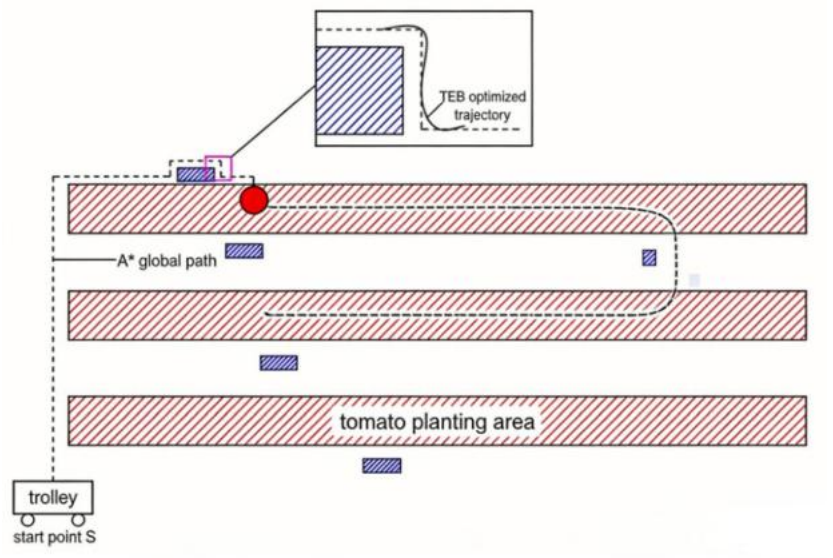

Fig. 13 - Tomato Planting Area and Mobile Platform Path

The system adopts a two-layer planning architecture of “global guidance—local optimization”. The flowchart of the A* algorithm Fig. 14 and the complete operational flowchart of A* working in tandem with TEB are shown in Fig. 15. *(Ji et al., 2023).*

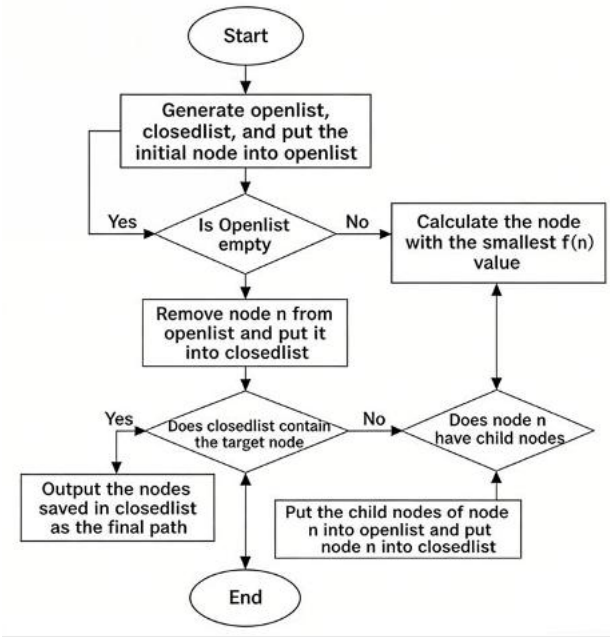

Fig. 14 - A* Algorithm Flowchart

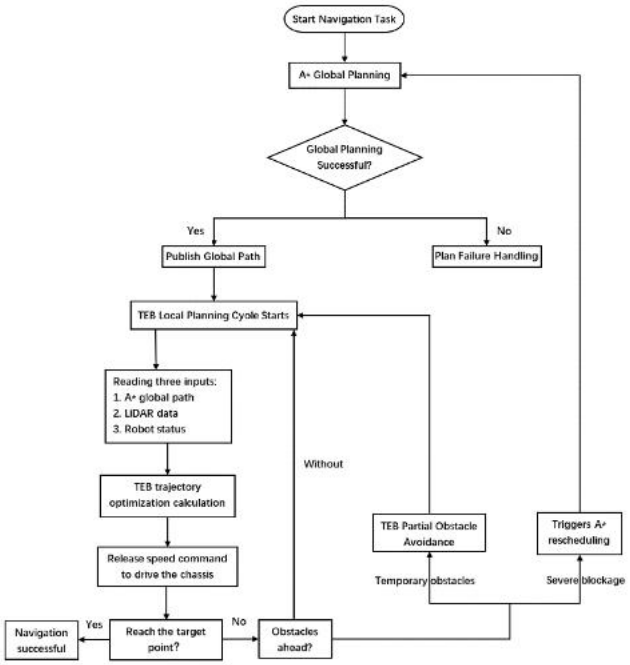

Fig. 15 - Collaborative Workflow Diagram

Robotic Arm Picking Motion Path Planning

The picking robotic arm must operate within dense, unstructured canopy structures, presenting challenges of high-dimensional configuration space search and dynamic obstacle avoidance *(Yuan & Shen, 2017)*. To address this, the system employs a comprehensive strategy combining ‘Global Sampling Planning (RRT-Connect) *(Yu et al., 2017)* + Local Visual Servoing Fine-Tuning + Semantic Layered Obstacle Avoidance’.

Global Path Planning: Employing the RRT-Connect bidirectional random tree algorithm, random trees are simultaneously grown from the start point q_{start} and the goal point q_{goal}. Through random sampling, node expansion, and collision detection, it rapidly searches for feasible paths in high-dimensional spaces with probabilistic completeness.

The node-expansion rule is defined as follows:

$$q_{new} = q_{near} + \varepsilon \cdot \frac{q_{rand} - q_{near}}{\|q_{rand} - q_{near}\|} \quad (7)$$

Equation (7) defines the node-expansion rule used in the bidirectional RRT-Connect algorithm, enabling rapid collision-free path planning within a dense tomato canopy.

Semantics-Based Hierarchical Obstacle Avoidance Strategy: See Table 2 below for details:

Table 2

Parameter Table for Stratified Obstacle Avoidance Strategy

Grade	Obstacle type	Safe distance	Constraint nature		Handling principles
Level 1	Such as greenhouse skeleton, support columns, etc.	70 mm	Hard constraint		Touching is strictly prohibited, and intrusion is regarded as a collision
Level 2	Tomato branches, leaves, vines	1 mm	Soft constraints (continuous costs)		Allow slight contact to guide the detour with a continuous penalty function
Level 3	Other fruits to be protected	3 mm	Strong repulsion constraint		Active protection gives a very high cost of repulsion to avoid collisions

System Collaborative Control and Communication Framework

To ensure the coordinated and orderly operation of the mobile platform, robotic arm, and bagging device, the system manages the temporal dependencies, spatial conflicts, and exception-handling requirements associated with the different tasks, as illustrated in Fig. 16.

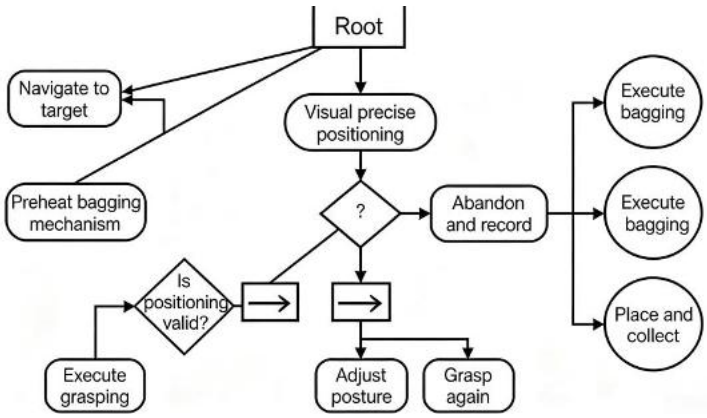

Fig. 16 - Multi-Task Coordinated Control System

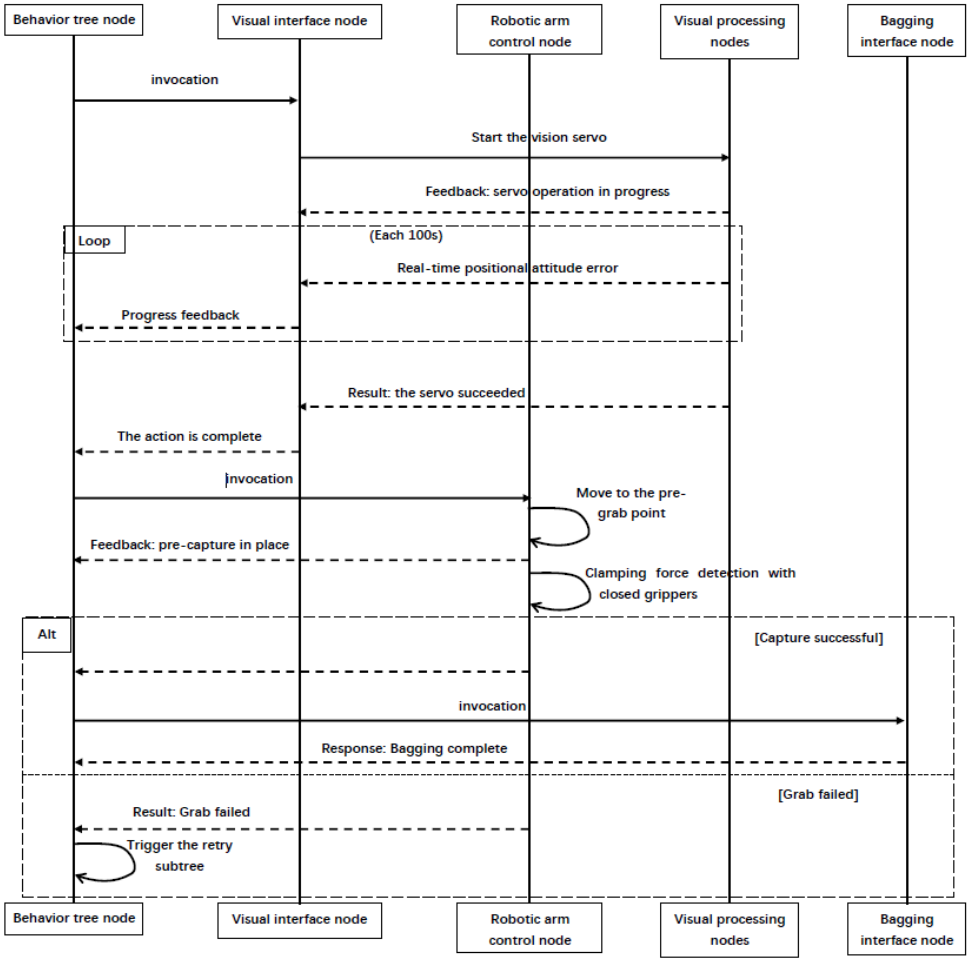

Fig. 17 - Internal Execution Logic and Multi-System Coordination Mechanism

To clearly illustrate the internal execution logic of critical action nodes within the behavior tree and the multi-system coordination mechanism, the 'Execute Harvesting Action' node serves as an example. Internally, it invokes sub-services such as visual servo, grasping, and bagging to achieve a seamless sequence from visual fine positioning to fruit grasping and bagging. Fig. 17 details this node's execution flow and the invocation relationships between its modules.

The system employs a ROS-based modular communication network, where functional nodes exchange data and execute tasks via Topics, Services, and Actions. A TF tree manages coordinate transformations, enabling real-time coordination and synchronization among the mobile platform, robotic arm, and packaging device under behavior tree scheduling.

RESULTS

System Integration and Experimental Analysis

Quantitative Performance Analysis of YOLOv8s Visual Detection Model

Detection performance under three occlusion grades is tested on the test set, as listed in Table 3.

Table 3

YOLOv8s detection performance under different fruit occlusion conditions

Occlusion Level	mAP@0.5	Precision /%	Recall /%	Single-frame Inference Time /ms
Unobstructed ripe tomato	98.6	97.3	96.8	28.6
Semi-occluded ripe tomato	94.1	94.5	93.2	29.1
Heavily occluded ripe tomato	87.3	88.1	86.5	30.2

The mAP declines with increased leaf coverage but still meets picking requirements. Combined with ImageJ secondary screening, the overall maturity discrimination accuracy reaches 93.5%. The average 29 ms inference time ensures real-time grasping response on the K280L industrial computer.

Navigation Experiment of Mobile Platform Based on A and TEB Algorithm*

A* global + TEB local dual planning is verified in simulated greenhouse ridges with static and dynamic obstacles, 20 repeated trials for each group. Comparative results are shown in Table 4.

Table 4

Comparative navigation results of A* single planning and A*+TEB dual planning

Evaluation Index	A* + TEB Dual Planning	Single A* Global Planning	Performance Improvement Rate
Global path length of standard ridge / m	18.62	18.62	-
Average single navigation time / s	22.4	28.7	22.0%
Maximum lateral deviation during obstacle avoidance / mm	36.2	94.7	-
Total collision times within 20 groups of tests	0	12	-
Average terminal positioning error / mm	±8.3	±15.6	46.8%

TEB optimizes local trajectories based on LiDAR data, eliminating collision risks and improving docking precision for manipulator picking.

Classification Statistical Test of Independent Net Bagging Operation

The robot completes single-fruit independent heat-sealed packaging. Special bagging tests are carried out for tomatoes with diameters ranging from 50 mm to 100 mm. 120 valid experimental samples are grouped by fruit size to count bagging success rate and fault distribution, as shown in Table 5.

Table 5

Bagging performance statistics of tomatoes with different diameters

Tomato Diameter Range / mm	Number of Test Samples	Successful Bagging Cases	Bagging Success Rate / %	Main Fault Types
50–70 (small fruit)	42	41	97.6	Slight net bag offset (1 case)
70–85 (medium fruit)	50	49	98.0	Thermal sealing adhesion (1 case)
85–100 (large fruit)	28	27	96.4	Fruit jamming on guide cone (1 case)
Total Summary	120	118	98.3	Total faults: 2 cases

Overall bagging reliability meets commercial standards; large-fruit jamming can be mitigated by optimizing the conical guide stroke in future work.

Efficiency Quantitative Comparison Between Robotic System and Manual Operation

120 continuous robotic cycles yield an average single-fruit runtime of 12.1 ± 1.5 s. Three skilled workers achieved 17.3 ± 2.8 s per fruit under identical operations.

Hourly throughput: Robot ≈ 298 fruits/h; Manual ≈ 208 fruits/h, corresponding to ~30% efficiency improvement, consistent with Abstract claims.

Manual efficiency drops 23% after 4 h due to fatigue, while the robot maintains stable output without labor attenuation and extra transfer steps.

Experiments and Results

To validate system performance, testing was conducted in a simulated greenhouse environment. The experiment utilized tomato plants at varying stages of maturity, requiring the system to perform continuous integrated operations on ripe fruit *(Wu and Miao, 2025).* Through over 120 effective cycles, the system's performance metrics were evaluated and compared with manual operations, with results shown in Table 6.

Table 6

System Key Performance Indicator Test Results

Experimental Parameters	Experimental Parameters Average Value/Success Rate	Note
Total number of experiments (fruit)	120 times	Includes tests under different lighting conditions (morning/afternoon)
Average total time required per fruit	12.1 ± 1.5 s	The entire process time from identification to completion of bagged recycling
Accuracy rate for identifying ripe fruit	95.2%	The proportion of mature fruit correctly identified as “ready for harvest”
Comprehensive Accuracy Rate for Maturity Assessment	93.5%	Overall classification accuracy for green-ripe, color-changing, and fully ripe fruit stages
Harvest Success Rate	90.8%	The percentage of fruit stems successfully gripped and severed without causing damage to the fruit
Accuracy of Harvest Location Positioning	96.7%	Precision of the robotic arm's end effector reaching the predetermined fruit stalk cutting point
Bagging success rate	98.3%	Percentage of successful bagging operations
Average time required for manual operations (for comparison)	17.3 ± 2.8 seconds per fruit	The average time required for skilled workers to complete picking and bagging

Table 6 summarizes all key comprehensive indicators of the integrated robot prototype under simulated greenhouse tests.

System Comparison Analysis and Summary of Advantages

To objectively evaluate the comprehensive performance and innovative value of this design, this section compares it with three representative studies from recent years: a greenhouse tomato harvesting robot focused on sequence optimization *(Li, 2024)*, a strawberry harvesting robot investigating dual-arm coordination *(Liu et al., 2026),* and the latest row-planted strawberry harvesting robot designed for narrow ridge-edge environments *(Wang et al., 2025)*. Key systematic comparisons are presented in the table below.

Table 7

Systematic Comparative Analysis Chart

Comparison Dimensions	This Design: Tomato Harvesting Robot	Greenhouse Tomato Harvesting Robot	Dual-Arm Strawberry Picking Robot	Row-planted strawberry picking robot
Perception System Solution	Multi-source Fusion Perception: Integration of RGB-D cameras (target recognition/localization) and LiDAR (SLAM navigation).	Visual Perception: Utilizes an enhanced Ghost-CAE YOLOv5 model with a depth camera (D435).	Visual and 3D Reconstruction: Employs YOLOv8-segment for instance segmentation, combined with COLMAP for scene modeling.	Visual and End-Point Sensing: YOLOv5-based picking point localization combined with end-point fiber optic sensors for trigger detection.
Planning and Control Strategy	Hierarchical Collaborative Planning: A* (global path planning), TEB (local obstacle avoidance), RRT-Connect (robot arm path planning) integrated with vision servo closed-loop control.	Harvest Sequence Optimization: We propose the “K-G method,” which integrates K-means clustering with a Gaussian kernel function to optimize sequences.	Dual-Arm Task Planning: Proposes a coordinated algorithm integrating genetic and cheetah optimization (GCO), with path planning employing RRT*.	Task Decision Model: Priority-Based Harvesting Strategy Based on Fruit Spatial Relationships; Four-Degree-of-Freedom “PRPR” Configuration Manipulator.
Key Performance Indicators	Recognition success rate: 95.2%; Picking success rate: 90.8%; Bagging success rate: 98.3%; Single fruit full cycle: ~12.1 s.	mAP Recognition Rate: 95.12%; Picking Success Rate: 95.56%; Average Picking Cycle: ~6.7 s per fruit.	(Algorithm Performance) Reduces total job time by up to 34.5% and reduces dual-arm idle time by 81.9%.	Single-arm picking cycle: 5.0 s; Average dual-arm cycle: 4.57 s; Damage-free picking success rate: 59.56%.

Mechanical and Actuator Systems	Dedicated bagging mechanism (integrated heat sealing), flexible cushioning collection bin, vacuum-assisted end-effector for transfer.	Universal Six-Axis Robotic Arm (AUBO-i5) with Adaptive Flexible Four-Finger Gripper.	A composite end effector integrating active obstacle clearance (low-voltage blower) with passive obstacle avoidance (soft gripper).	Non-destructive mechanical gripper employing a spatial cam and spring steel plate for rapid gripping and shearing.
System Autonomy and Collaboration	Based on ROS and behavior trees, achieve adaptive coordination and task scheduling among the mobile platform, robotic arm, and bagging unit.	Achieved a closed-loop autonomous picking system for a single arm, without involving complex multi-motor unit coordination.	Establish a “dual cargo bay-dual workstation” model to optimize temporal and spatial conflicts between dual arms within overlapping work zones.	Features a distributed four-wheel independent drive/steering chassis with multiple steering modes to accommodate narrow aisle navigation.

CONCLUSIONS

This study designs and validates a fully integrated tomato harvest-and-packaging robot. The 12.1 s single-fruit cycle delivers ~30% higher efficiency than manual labor, with 95.2% fruit recognition, 90.8% picking and 98.3% bagging success rates.

The system’s performance relies on four coordinated technologies: YOLOv8s+ImageJ dual ripeness detection, A*/TEB inter-row navigation, RRT-Connect canopy obstacle avoidance and behavior tree multi-unit scheduling.

Different from single-function harvesting robots, the built-in vertical heat-sealing bagger realizes on-site commercial packaging to reduce fruit damage. This prototype provides a complete hardware and algorithm reference for full-process intelligent greenhouse agriculture.

Keywords: *desert shrubs, machine vision, structural design, stubble cutting machine*

ABSTRACT
Current research on shrub stubble cutting machines primarily focuses on mechanical structure design and operational performance, whereas shrub localization and cutting status still rely on manual judgment. To address this issue, an intelligent desert shrub stubble cutting machine integrating structural design with vision-assisted operation was developed. The overall structure and key component parameters were determined through theoretical analysis, and the disc cutting process was validated via Workbench simulation. The YOLOv5s model incorporating a Focal-CIoU loss function was adopted to enhance shrub detection under complex background conditions. Image processing and binocular vision were employed to obtain the three-dimensional coordinates of shrub roots. Experimental results demonstrate that the cutting device meets the operational requirements; the improved model achieves an accuracy of 91.9%, a recall of 96.5%, and a mAP of 98.3%; and the maximum relative errors for root depth and height measurements are 3.19% and 6.51%, respectively, satisfying the detection and localization requirements for shrub stubble cutting.

摘要
当前灌木平茬机的研究主要集中于机械结构设计与作业性能，而灌木定位和切割状态仍依赖人工判断。针对该问题，本文研制了一种将结构设计与视觉辅助作业相结合的智能荒漠灌木割茬机。通过理论分析确定了整机结构和关键部件参数，并利用Workbench仿真验证了圆盘切割过程。采用引入Focal-CIoU损失函数的YOLOv5s模型，以增强复杂背景条件下的灌木检测能力。利用图像处理和双目视觉获取了灌木根部的三维坐标。实验结果表明：切割装置满足作业要求；改进模型的准确率达到91.9%，召回率为96.5%，mAP为98.3%；根部深度和高度测量的最大相对误差分别为3.19%和6.51%，满足灌木平茬检测与定位要求。

INTRODUCTION
Land desertification represents a major obstacle to ecological restoration and sustainable development. As of 2024, desertified land in China accounts for approximately 26.8% of the country's total terrestrial area. Xerophytic shrubs, such as *Salix psammophila* and *Haloxylon ammodendron*, are widely used for windbreak and sand fixation as well as ecological restoration due to their pronounced drought tolerance and significant sand-binding capacity (*Gao S. et al., 2022*). These shrubs exhibit a growth characteristic known as "rejuvenation after pruning": prolonged absence of pruning leads to gradual branch senescence and even whole-plant mortality, which may in turn induce secondary desertification (*Pei et al., 2019*). Therefore, regular pruning is an essential measure to maintain the long-term vitality of these shrubs. At present, pruning of xerophytic shrubs in China relies predominantly on manual labor and semi-automatic backpack pruning machines, which suffer from low operational efficiency and high labor intensity. Moreover, prolonged use is associated with occupational health risks, including vibration-induced disorders and noise-induced hearing loss (*Tian, 2013*).

Existing research on pruning machines has primarily focused on mechanical structures and operational parameters. *Ma et al., (2015),* developed a tracked, self-propelled shrub pruning machine that improved adaptability to sandy terrain through a floating cutting mechanism. *Wang et al., (2025),* designed a hydraulic scissor-type Caragana pruning machine and reduced both branch breakage rate and cutting power consumption via parameter optimization. Although these studies have enhanced the operational performance of the equipment, the pruning process remains largely manual, with limited perception of shrub distribution and ground surface variations.

Regarding intelligent pruning operations, *Ren (2021)* integrated machine vision into Caragana pruning tasks, enabling the identification of root collar positions and supporting adaptive adjustment of the cutting platform height. However, this work focused on visual recognition in isolation and lacked full integration with the machine's structural design and practical operational workflows. In agricultural machinery research, machine vision has been successfully applied to identification and localization tasks in field operations—for example, *Fan et al., (2025),* achieved cotton row detection for spraying robots in cotton fields. Nevertheless, these studies targeted regularly spaced row crops, whose spatial distribution differs markedly from the sparse, irregular, and clustered arrangement of desert shrubs, rendering the direct transfer of such methods impractical for shrub pruning applications.

To address the aforementioned challenges, this paper proposes the design of an intelligent pruning machine for xerophytic shrubs. The machine is built upon a tracked mobile platform and integrates cutting and baling functions. It incorporates a visual recognition system based on an improved YOLOv5s model, synergistically combining image processing with binocular stereo vision measurement. Simulation analyses and prototype experiments were conducted to validate the machine's capabilities in accurate shrub identification, three-dimensional localization, and adaptive cutting. The findings provide a technical reference for the development of intelligent pruning equipment for xerophytic shrubs.

MATERIALS AND METHODS

Machine structure design

The intelligent shrub-topping machine developed in this study consists of a cutting unit, a baling unit, a binocular stereo camera, a tracked locomotion system, a conveying mechanism, a header lifting mechanism, a motor, and a battery. The overall configuration and key design parameters are illustrated in Fig. 1 and listed in Table 1, respectively (*Zhang B. et al., 2022; Georges R. et al., 2014*).

Table 1

Technical parameters of the shrub trimmer for sandy land

Parameter	Value
Overall machine weight (kg)	<500
Overall dimensions (length × width × height) (mm)	1450×1342×1000
Diameter of coppiced shrubs (mm)	0~20
Working width (mm)	700
Pruning height (mm)	10-100
Power of a single travelling motor (kW)	2

Operating principles

During operation, the rubber-tracked chassis propels the machine toward the target shrub stand. The cutting platform height is adjusted to a preset cutting position via an electric linear actuator (*Johnson P.C. et al., 2012*), after which the cutting motor is activated.

As the machine advances, the V-shaped guide plate mounted at the front end aligns and directs the shrubs, facilitating smooth entry into the cutting zone and enabling precise severance. The cut shrubs are continuously conveyed into the baling unit by a conveyor chain and progressively compacted under the compressive force exerted by the baling tines. Once the diameter of the shrub bundle within the baling unit reaches a preset threshold, the baling clutch engages automatically; the rope feed needle then delivers twine to the knotting mechanism to complete the binding process. Subsequently, the bound shrub bundle is ejected laterally from the machine. The clutch then disengages, and the baling unit ceases operation, thereby completing one full pruning cycle.

Main structure design of the cutting device

The cutting unit is one of the most critical components of the brush cutter designed for xerophytic shrubs. In this study, a disc-type cutting unit is adopted, as illustrated in Fig. 2. The cutting platform is connected to the frame via a four-bar linkage and secured with bolts. Power from the cutting motor is transmitted to the main shaft, and the ground clearance of the cutting unit is regulated by the extension and retraction of electric linear actuators mounted on both sides of the frame.

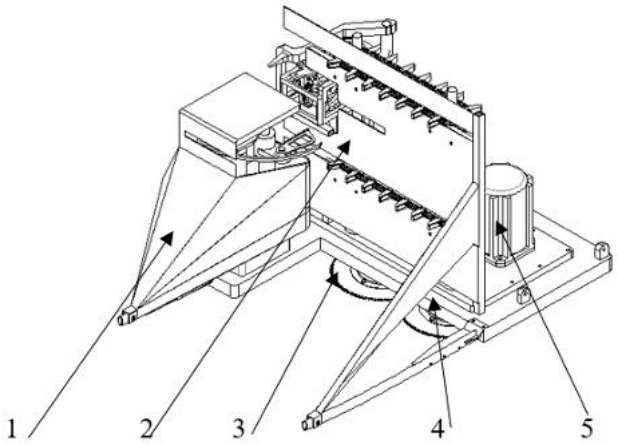

Fig. 2 - Schematic diagram of the cutting unit

1 – Branch gathering frame; 2 – Cutting baffle; 3 – Cutting component; 4 – Bottom plate drive; 5 – Cutting motor

Design and calculations of the cutting unit

1) Transmission system design

The transmission system of the cutting unit consists of gears, sprockets, and transmission shafts. Power from the motor is transmitted to cutting spindles I and II via gear trains. Spindle I additionally transmits power to the conveying unit and the baling unit to facilitate transport and compaction of the severed shrubs. The corresponding schematic diagram is presented in Fig. 3. At the lower end of the extended shaft of spindle I, the cutter head is attached, while the upper end is coupled to the gearbox via a keyway, enabling power transmission to the conveying unit.

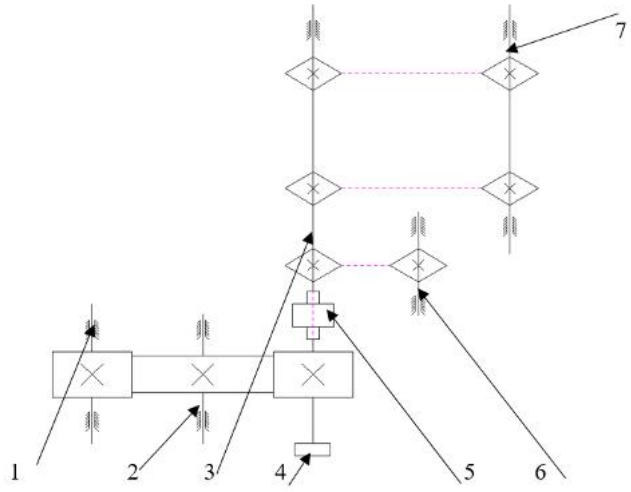

Fig. 3 - Schematic diagram of the transmission system

1 – Power input shaft; 2 – Intermediate shaft; 3 – Drive shaft of transmission chain; 4 – Cutting component; 5 – Planetary reducer; 6 – Power input shaft of baling mechanism; 7 – Transmission shaft of transmission chain

2) Circular saw blade selection

The principal parameters of the saw blade include the outer diameter D, thickness S, number of teeth T, rake angle γ_1, and clearance angle α_1. Based on the diameter of the shrub roots and in accordance with circular saw blade standards, the blade diameter is selected as D = 350 mm. The thickness of the blade is determined by Equation (1):

$$S = \eta_1 K \sqrt{D} \tag{1}$$

where:

η_1 is the safety factor, taken as 1.68; K is the thickness safety coefficient, taken as 0.075. After calculation, the thickness S of the circular saw blade is determined to be 2.3 mm. The number of teeth T is 100, the rake angle γ_1 is 20°, and the clearance angle α_1 is 15°.

3) Calculation of cutting power

The total power P_Z consumed during shrub cutting consists of the no-load rotational power P_K of the saw blade and the cutting power P_L. The corresponding formulas for calculating these three power components are given in Equations (2) - (4):

$$P_k = \frac{mv_c^2 + J\omega^2}{2} \tag{2}$$

$$P_L = \frac{v_f Al}{102} \tag{3}$$

$$P_Z = P_K + P_L \tag{4}$$

where:

m is the mass of the circular saw blade, 1.625 kg; v_c is the peripheral speed of the saw blade, 26 m/s; J is the moment of inertia of the saw blade, 0.49 kg·m^2; ω is the angular speed of the saw blade, rad/s; v_f is the feed velocity of the brush cutter, 0.5 m/s; A is the cutting width, m; l is the specific cutting energy required for shrubs, 490 J/m^2. Finally, P_K is 0.82 kW, P_L is 0.84 kW, and P_Z is 1.66 kW.

Main structure and working principle of the baling unit

This study adopts a side-baling configuration. The baling unit consists of a knotter, a power input chain, the knotter main shaft, a rope feed rocker, a rope feed rocker transmission shaft, and a stem compression rod. The power input shaft of the baling unit is connected to the conveyor chain main shaft via a chain drive. When the clutch lever is actuated—i.e., depressed and rotated by a specified angle—the power input shaft engages with the knotter main shaft, thereby initiating knotter operation. The rope feed rocker main shaft and the knotter main shaft are interconnected by a chain drive. The transmission chain is housed within the baseplate, and the chain type selected is the C08A roller chain. A schematic diagram of the baling unit is presented in Fig. 4.

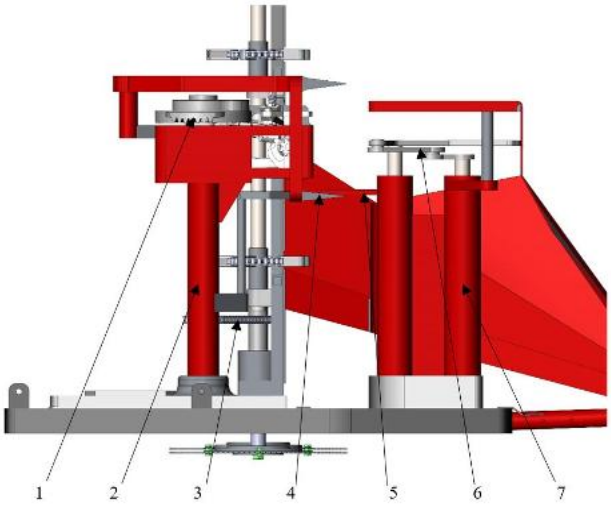

Fig. 4 - Structure of the baling mechanism

1 – Knotting device; 2 – Drive shaft sleeve I; 3 – Power input chain; 4 – Clutch control lever; 5 – Stem-pressing rod; 6 – Rope-feeding rocker; 7 – Drive shaft sleeve II

Design of the main components of the baling unit

1) Design of the knotter structure

The knotter consists of a conical gear disc, a rope-clamping device, and knotting pliers, as illustrated in Fig. 5. The phase difference between the inner and outer teeth of the conical gear disc is 58°, which governs the timing coordination between the rope-clamping device and the knotting pliers. The phase difference between the outer teeth and the cam's far stop point is 111°, which controls the timing coordination between the knotting pliers and the rope-cutting knife.

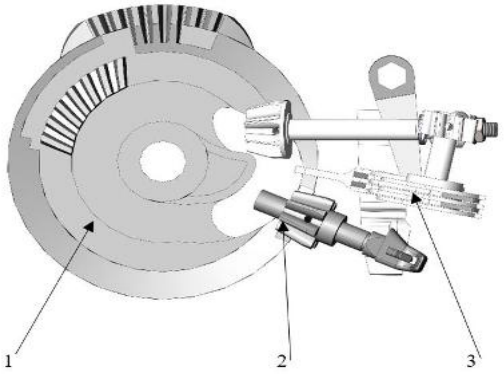

Fig. 5 - Structure of the knotting mechanism

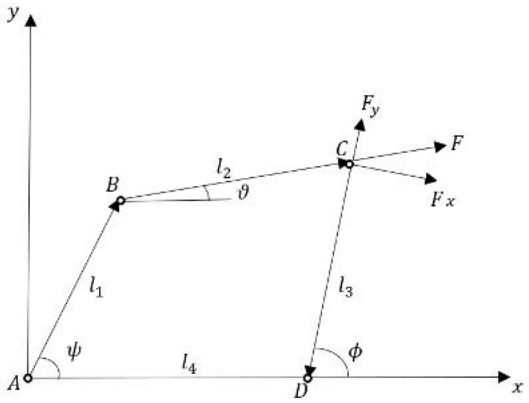
1 – Conical-toothed disc; 2 – Looping pliers; 3 – Rope clamp

2) Design of the rope-feeding rocker

The rope feed rocker, as the most critical auxiliary component of the baling unit, is designed to deliver rope accurately and rapidly to the knotter, thereby facilitating the baling operation. To minimize the time required for rope feeding and baling, a crank-rocker mechanism is adopted in the design of the rope feed rocker. A simplified motion analysis diagram is presented in Fig. 6 (*Mutlu H., 2021*). Based on this diagram, the motion parameters of the rocker can be determined. Through empirical design, the rotation radius of the driving crank l_1 is set to 63 mm. Using the crank-rocker mechanism calculation formulas, the lengths of the remaining three links—l_2, l_3, and l_4—are determined as 124 mm, 124 mm, and 134 mm, respectively.



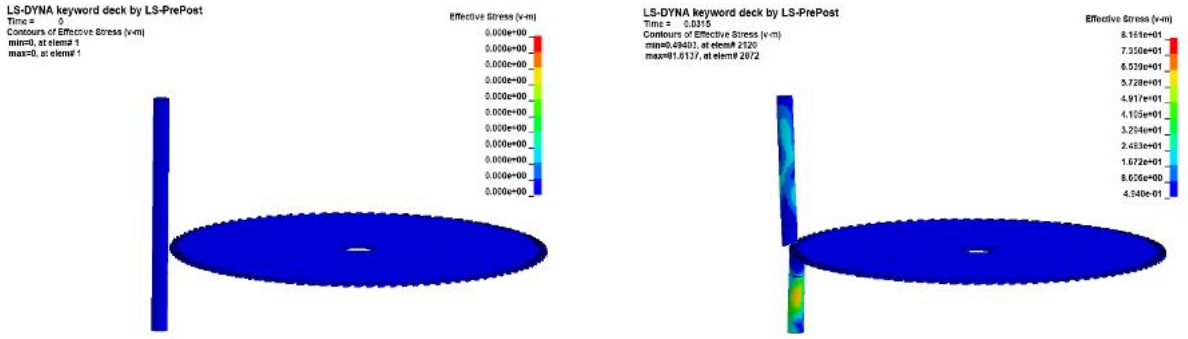


Fig. 6 - Force diagram of the crank-rocker mechanism

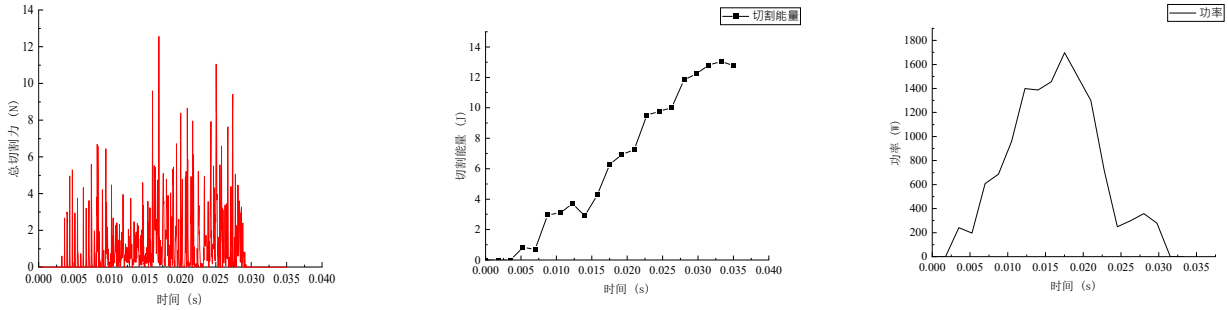
Simulation analysis on the stubble-cutting process of the cutting device

To ensure the accuracy of the simulation results while maintaining computational efficiency, the following simplifications were applied to the circular-disc cutting model: (1)The cross-section of the desert shrub was approximated as a circular profile; (2) The taper variation along the shrub stem was neglected, and the stem was modelled as a cylinder of uniform cross-sectional area; (3)The upper and lower clamping plates, transmission system, and bolts of the circular saw blade were omitted, and the bolt mounting holes were removed (*Wu G., Zhang D.D., 2022*).

Based on the aforementioned simplifications, the model was developed using SolidWorks. The saw blade was modelled with a diameter of 350 mm, a rake angle γ_1 = 20°, the clearance angle α_1 = 15°, and a tooth count T=100. As the primary target of cutting in this study was shrubs with a stem height of 0–20 mm, the shrub was simplified as a cylinder of 20 mm diameter and 200 mm height, with the cutting height set to 70 mm.



In Workbench, the material of the circular saw blade was defined as 65Mn steel, with a density of 7.85×10³ kg/m³, a Poisson's ratio of 0.3, and an elastic modulus of 210 GPa. Desert shrub stems are characterized as nonlinear, non-homogeneous, and anisotropic elastic materials (*Gangwar T., Schillinger D., 2019*). To reduce model complexity while satisfying the analysis requirements, the stem was simplified as an isotropic linear-elastic material. The corresponding material parameters were assigned from the Workbench material library as follows: density of 480 kg/m³, Poisson's ratio of 0.33, and elastic modulus of 5034 MPa. The stress distribution cloud diagram obtained from the simulation is presented in Fig. 7.

a. Initial moment of the simulation b. Moment of shrub cutting

Fig. 7 - Stress variation during the four stages of the simulated sawing process

The curves of total cutting force, required energy, and cutting power of the circular saw blade over time during shrub cutting are presented in Fig. 8. As shown in Fig. 8a, the maximum total cutting force acting on the shrub stem reaches 13 N at a simulation time of 0.175 s. From Fig. 8b, it can be observed that cutting initiates at 0.026 s; the shrub stem bends under load and accumulates strain energy. At 0.03 s, the stem releases all the stored energy due to elastic deformation. The maximum energy required for cutting the shrub is 13 J. As illustrated in Fig. 8c, the maximum power required for cutting is 1670 W, which is consistent with the power consumption obtained from the theoretical calculation presented earlier. These simulation results indicate that the cut-ting device designed in this study meets the operational requirements for shrub cutting.

a. Total cutting force b. Cutting energy c. Cutting power

Model training and evaluation of the visual recognition algorithm

Following the structural design of the pruning machine and the simulation analysis of the cutting components, this study investigates an image recognition algorithm for shrub detection during pruning operations. Model training and testing were conducted in a Windows 11 environment using a 12th Gen Intel(R) Core(TM) i5-12490F processor, an NVIDIA GeForce RTX 3060 Ti graphics card, 16 GB of RAM, and Python version 3.10.

In this experiment, 50 images were collected through online image retrieval and manual capture. The dataset was then augmented using techniques including horizontal flipping, brightness adjustment, rotation, scaling, cropping, high-frequency noise addition, Gaussian blurring, and histogram equalization. The final augmented shrub image dataset comprised 1,000 images and was randomly partitioned into training, validation, and test sets in an 8:1:1 ratio, corresponding to 80% for training, 10% for validation, and 10% for testing. During model training, the batch size was set to 8, the initial learning rate to 0.01, the weight decay coefficient to 0.0005, the momentum factor to 0.937, and the total number of epochs to 150.

Focal-CIoU-based improved loss function

In the original YOLOv5s network architecture, Complete Intersection over Union (CIoU) is employed as the bounding box regression loss function. CIoU quantifies the degree of matching between predicted and ground-truth bounding boxes by jointly considering the intersection over union (IoU), the Euclidean distance between their center points, and the consistency of their aspect ratios (*Li T. et al., 2023*). The corresponding formulas are given in Equations (5) - (7):

$$L_{CIoU} = 1 - \mathrm{IoU} + \frac{\rho^2\left(b, b^{gt}\right)}{c^2} + \alpha v = 1 - \frac{\left|B \cap B^{gt}\right|}{\left|B \cup B^{gt}\right|} + + \frac{\rho^2\left(b, b_{gt}\right)}{c^2} + \alpha v \quad (5)$$

$$v = \frac{4}{\pi}(\arctan\frac{w}{h} - \arctan\frac{w}{h}) \quad (6)$$

$$\alpha = \frac{v}{(1 - \mathrm{IoU}) + v} \quad (7)$$

where:

IoU is the intersection over union between the predicted box and the ground-truth box; B and B^{gt} are the predicted box and the ground-truth box, respectively; b and b^{gt} are the centers of B and B^{gt}, respectively; ρ^2 is the squared Euclidean distance between the two centers; c is the diagonal length of the smallest enclosing rectangle covering both boxes; α is the control parameter for the convergence speed of the loss; v is the measure of the aspect ratio difference.

In practical shrub detection, the sparse distribution of shrubs in desert environments results in some collected images where the shrubs occupy a significantly smaller proportion of the image area compared to the desert background. This imbalance hinders the model's ability to effectively learn discriminative shrub features, thereby reducing detection accuracy. To address this issue, this study adopts the computational principle of Focal Loss and integrates it with CIoU to formulate the Focal-CIoU loss function (*Peng H. et al., 2023*), as presented in Equation (8):

$$L_{Focal-CIoU} = IoU^{\gamma} L_{CIoU} \quad (8)$$

where:

γ represents the degree of outlier suppression.

By introducing the IoU modulation term, Focal-CIoU reduces the influence of samples with high IoU values in the loss computation, enabling the model to focus more on shrub targets with large localization errors during training—thereby improving localization accuracy and detection performance in complex backgrounds.

Experimental results and analysis of the visual recognition algorithm

To evaluate the shrub detection performance of the improved YOLOv5s network, comparative experiments were conducted using YOLOv5s, YOLOv7-Tiny, YOLOv8s, as well as the lightweight backbones MobileNetV3 and ShuffleNetV2 integrated into the YOLOv5 framework. All models were trained under identical conditions using the same dataset. The experimental results are presented in Table 2.

Table 2

Comparison of detection performance across different models

Models	Precision [%]	Recall [%]	mAP@0.5 [%]	Params [M]	FLOPs [G]
YOLOv5s	91.1	94.3	97.7	7.01	15.8
YOLOv7-Tiny	91.4	91.2	96.4	6.14	13.6
YOLOv8s	91.8	92.4	96.8	11.12	28.4
MobileNetV3	73.8	85.3	85.4	2.39	3.5
ShuffleNetV2	75.2	77.0	82.3	1.8	2.8
This paper	91.9	96.5	98.3	7.01	15.8

As shown in Table 2, YOLOv8s achieves the highest accuracy among all models evaluated; however, it also has the largest number of parameters and the highest computational cost, making it the most complex model.

Although MobileNetV3 and ShuffleNetV2 have fewer parameters and lower computational costs, their accuracy is insufficient to ensure reliable detection performance. The improved model achieves higher accuracy and recall than all other detection models in the experiment. Compared with YOLOv5, YOLOv7‑Tiny, and YOLOv8s, the improved model increases accuracy by 0.8, 0.5, and 0.1 percentage points, respectively, and recall by 2.2, 5.3, and 4.1 percentage points, respectively. Therefore, the proposed network model not only achieves higher accuracy and recall but also has fewer parameters and lower computational cost, making it more suitable for deployment on brush cutters for shrub detection.

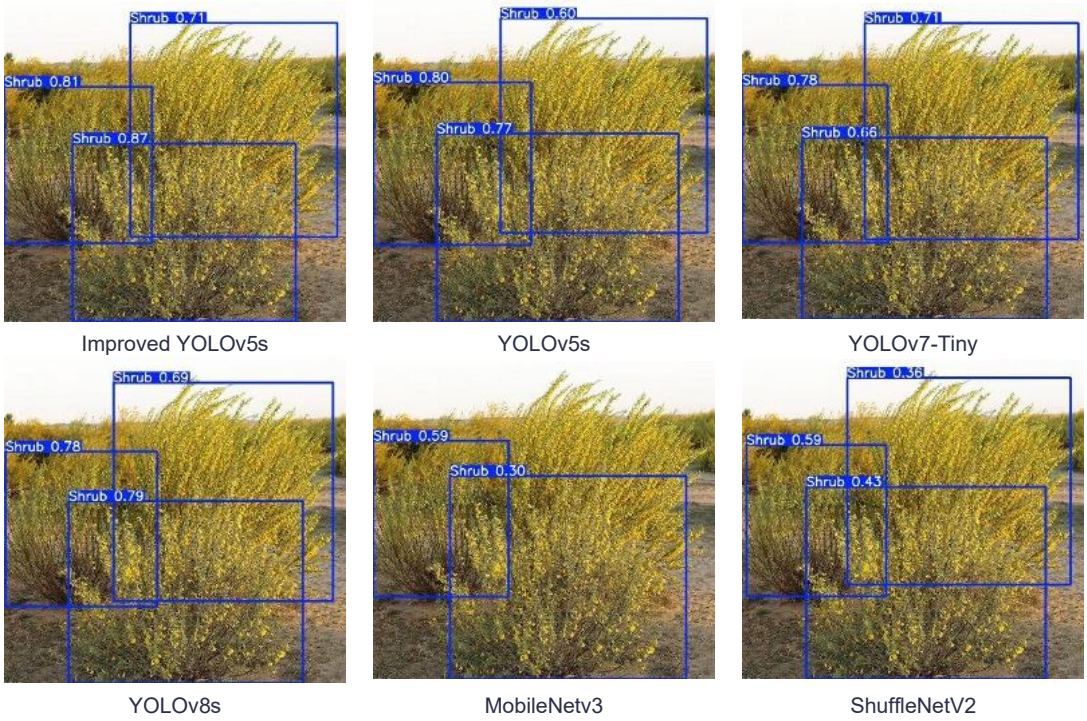

Fig. 9 - Shrub detection results across different network models

Figure 9 presents the shrub detection results of the six models. With the exception of ShuffleNetV2, which missed one shrub, all other models correctly detected three shrubs. Among them, the detection confidence of MobileNetV3 was significantly lower than that of the remaining four models, indicating weaker detection performance. Compared with the other network models, the improved YOLOv5s model achieves more accurate shrub localization and higher confidence scores, demonstrating superior detection performance.

Image processing-based shrub root detection and 3D measurement method

The shrub root image processing algorithm employs digital image processing techniques to isolate shrub root branches from complex backgrounds. To remove irrelevant information, the acquired image undergoes a series of preprocessing steps. First, the image is converted to grayscale using the maximum intensity method (*Chun P.J. et al., 2021*) to enhance the contrast between roots and background. Second, median filtering is applied for noise suppression (*Cao et al., 2024*). Third, Otsu's thresholding method (*Hu J. et al., 2024*) is used for segmentation, followed by intensity inversion to highlight root contours. Finally, a morphological closing operation (consisting of erosion followed by dilation) with a 10×10 structuring element (*Zhou R.G. et al., 2015*) is performed to suppress shadows and residual leaf fragments. The largest connected foreground region is then selected, and its contour is outlined in green to complete shrub root segmentation. The complete processing pipeline is illustrated in Fig. 10.

Experimental validation of shrub root localization accuracy

Using the parallax between the left and right cameras of the binocular stereo system and applying the principle of similar triangles, the distance from each three-dimensional scene point to the camera is computed (*Ren Z. et al., 2022; Hu W. et al., 2021; Zhai G. et al., 2020*). Camera calibration is then performed to estimate the intrinsic and extrinsic camera parameters and to correct lens distortion (*Wang Q. et al., 2022*). Finally, the Semi-Global Block Matching (SGBM) algorithm is employed for stereo correspondence, yielding the depth maps shown in Figs. 11a and 11b (*Almatrouk B. et al., 2024*).

The three-dimensional coordinate visualization of the shrub in the image is presented in Fig. 11c, where the y-axis represents the vertical height of the shrub relative to the camera plane, and the z-axis represents the depth (i.e., the distance along the optical axis) from the camera.

RESULTS

Construction and experimental validation of a simplified shrub stubble-cutting prototype

The simplified prototype of the pruning machine developed in this study is shown in Fig. 12a. Its main components include a gear reducer and a DC motor, a Raspberry Pi microcontroller unit, an STM32-based expansion board, a binocular stereo camera, an ultrasonic distance sensor, and a power supply unit.

Shrub detection experiment

In this experiment, an area with shrub vegetation on a university campus was selected as the test site, and the pruning machine prototype was deployed at the location shown in Fig. 12b. The prototype is equipped with YOLOv5s for real-time object detection, enabling the acquisition of image and spatial coordinate information. The shrub recognition results are presented in Fig. 12c, which demonstrates that the prototype achieves robust shrub detection performance.

Image processing-based shrub root detection experiment

To verify the effectiveness of the image processing algorithm, further processing was performed on the image containing the shrub with the largest bounding box area, thereby providing data support for shrub pruning. The shrub root detection results are presented in Fig. 13. As shown in the resulting images, the image preprocessing and morphological operations are effective, and the detection outcomes are accurate.

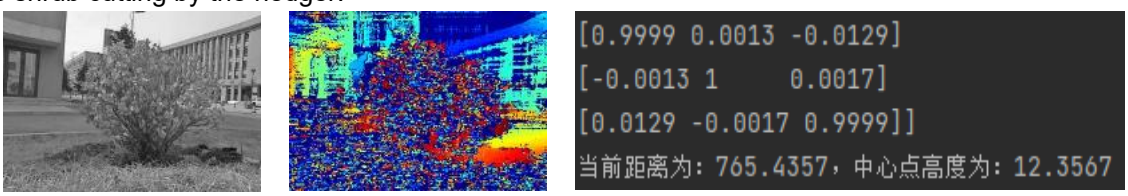

Fig. 13 - Results of the shrub root detection experiment

Experimental validation of shrub root localization accuracy

To verify the effectiveness of the proposed shrub root detection algorithm, images were captured using a binocular camera, and feature points were matched via the Semi-Global Block Matching (SGBM) algorithm. A depth map was then reconstructed based on binocular stereo vision principles. The experimental results are presented in Figs. 14a and 14b.

The depth image and the shrub root identification image were overlaid to integrate the root detection results into the shrub's depth map and to output the coordinates of the center point. The measured shrub root height and depth are shown in Fig. 14c, where the center point height corresponds to the vertical coordinate of the center of the shrub root bounding box relative to the camera plane. The relative errors in this trial were 2.51% for depth measurement and 5.59% for height measurement.

To evaluate the reliability of the algorithm for shrub depth and height estimation, 12 independent trials were conducted following the same procedure. The three-dimensional coordinates of each detected root center were extracted and compared against ground-truth distance and height measurements. The detailed results are listed in Table 3. The experimental results indicate that the maximum relative errors in depth and height estimation are 3.19% and 6.51%, respectively—both within the tooling alignment tolerance required for precise shrub cutting by the hedger.

CONCLUSIONS

Based on the operational requirements for pruning sand-dwelling shrubs, this study completed the overall structural design of the pruning machine and the selection of key component parameters. A simulation analysis of the circular-saw cutting process was also performed. The results demonstrate that the power demand during cutting is consistent with theoretical calculations, and that the designed cutting device meets both the power requirements and the operational specifications for shrub pruning.

This study introduced the Focal‑CIoU loss function into the YOLOv5s model and developed a shrub target detection model specifically tailored for desert environments with sparse backgrounds. The improved model achieves an accuracy of 91.9%, a recall of 96.5%, and an mAP@0.5 of 98.3%. While significantly enhancing detection performance, the model maintains a low parameter count, which is sufficient to meet the real‑time detection requirements of the shrub pruning machine.

Based on image processing and binocular stereo vision, this study achieved shrub root region segmentation and three-dimensional coordinate estimation. Experimental results demonstrate that under complex background conditions, the proposed shrub root detection method robustly extracts root contours. The maximum relative errors for depth and height measurements are 3.19% and 6.51%, respectively—both within the positioning accuracy tolerance required for shrub pruning operations.

Keywords: *Obstacle avoidance, trajectory optimization, B-spline, non-holonomic constraints*

ABSTRACT
This study proposes Smooth-Planner, a robust gradient-based local trajectory planning method for non-holonomic orchard robots operating in narrow row environments. The method employs a B-spline–based optimization framework that explicitly considers kinematic feasibility and collision avoidance without relying on dense global maps. Field experiments conducted in a standardized orchard demonstrate stable and repeatable performance, with lateral deviations effectively constrained and a minimum safety clearance of 0.90 m consistently maintained from crop rows. The results validate the practical safety and reliability of the proposed approach for autonomous agricultural operations.

摘要
本文提出了一种面向果园非完整约束移动机器人的稳健局部轨迹规划方法——Smooth-Planner。该方法基于 B 样条轨迹表示与梯度优化框架，在不依赖高精度全局地图的条件下，显式约束运动学可行性与避障安全性。标准化果园实地试验结果表明，该方法运行稳定、重复性良好，横向偏差得到有效控制，并始终保持不小于 0.90 m 的作物行安全间距。实验结果验证了该方法在自主农业作业中的安全性与实用性。

INTRODUCTION
With the rapid development of smart agriculture and digital orchard management, ground-based inspection robots are increasingly employed for tasks such as tree growth monitoring, precision spraying, and environmental data collection *(Dou et al., 2024; Hua et al., 2025)*. Unlike structured roads or open outdoor environments, orchard scenarios exhibit distinct spatial and perceptual characteristics, such as GNSS-denied canopy areas, narrow inter-row passages, and irregular branch protrusions *(Bayar et al., 2016)*. These features pose significant challenges to reliable autonomous navigation. Specifically, the complexity of the unstructured environment demands that the robot possesses high autonomy and strict safety awareness.

Local path planning is the core enabling technology for ensuring the safe and stable operation of these robots *(Cai et al., 2007)*. During routine inspection, robots must navigate continuously within confined corridors while coping with dynamic uncertainties, such as wind-blown branches and seasonal canopy variations. Crucially, the stability of local planning directly impacts operational efficiency and system safety. Frequent oscillations or abrupt stops caused by poor planning not only reduce task efficiency but also increase energy consumption and mechanical wear on the chassis *(Hu et al., 2015; Bai et al., 2019)*. Therefore, developing a local planner that satisfies requirements for real-time performance, robustness, and trajectory feasibility is of paramount importance.

A variety of local planning approaches have been applied in agricultural robotics. Classical sampling-based or search-based methods, such as the Dynamic Window Approach (DWA) *(Guo et al., 2024; Wang et al., 2024)* and Timed Elastic Band (TEB) *(Zai et al., 2023; Zheng et al., 2023)*, rely heavily on grid-based cost maps. In orchard environments characterized by sparse and noisy point clouds, maintaining a high-resolution grid map is computationally expensive, and discretization errors often lead to trajectory jitters or overly conservative behaviors *(Xie et al., 2018)*. More recently, gradient-based trajectory optimization methods *(Zhou et al., 2021)* have demonstrated superior smoothness and computational efficiency. However, most existing gradient-based planners are originally designed for holonomic aerial vehicles (UAVs). They often neglect the non-holonomic kinematic constraints of ground robots. Directly applying these methods to orchard robots typically results in infeasible trajectories that the vehicle hardware cannot execute, leading to tracking errors or collisions.

To address these challenges, this paper proposes a robust local trajectory planning method tailored for differential-drive orchard inspection robots, referred to as Smooth-Planner. The proposed approach adopts a gradient-based continuous trajectory optimization framework. Unlike traditional methods that depend on constructing explicit Euclidean Signed Distance Fields (ESDF) *(Han et al., 2019)* or grid maps *(Li et al., 2014)*, Smooth-Planner directly optimizes local trajectories by jointly considering smoothness, collision avoidance, and motion feasibility. By embedding geometry-aware obstacle avoidance constraints and non-holonomic motion limits into a continuously differentiable optimization formulation, the method generates high-quality executable trajectories even with incomplete perception.

The main contributions of this work are summarized as follows: (1) A map-free local trajectory optimization framework is established to handle the challenges of narrow orchard corridors and sparse perception, significantly reducing the dependency on high-precision environmental mapping. (2) A novel formulation of continuous collision and kinematic penalties is introduced, which strictly enforces non-holonomic constraints to ensure the generated trajectories are dynamically feasible for tracked ground robots. (3) Extensive field experiments in real orchard scenarios validate that the proposed method achieves high stability and maintains sufficient safety margins, proving its practical value for autonomous orchard inspection.

MATERIALS AND METHODS

System overview and problem formulation

The experimental platform used in this study is an electrically driven tracked robot designed for autonomous orchard inspection (Fig.1). To accurately account for collision risks in narrow inter-row environments, the robot geometry is abstracted as a bounding box with length L and width W. The perception system consists of an Ouster 3D LiDAR for local environment perception and a GNSS-RTK module for global pose estimation, while all planning algorithms are executed on an onboard NVIDIA AGX Orin computing platform. Under nominal operating conditions, the robot demonstrates high-precision trajectory tracking and reliable localization. This consistent baseline ensures that the deviations observed during obstacle avoidance are solely attributable to the proposed planning strategy rather than sensing noise or control instability.

Considering the differential steering mechanism, the robot is subject to non-holonomic kinematic *(Zhang et al., 2025)* constraints that prohibit instantaneous lateral motion. Under these constraints, the local trajectory planning problem is formulated as finding an optimal trajectory Φ within a receding horizon that minimizes a compound cost function J, while satisfying collision avoidance and kinematic feasibility requirements. Detailed formulations of the cost function and constraints are presented in the following sections.

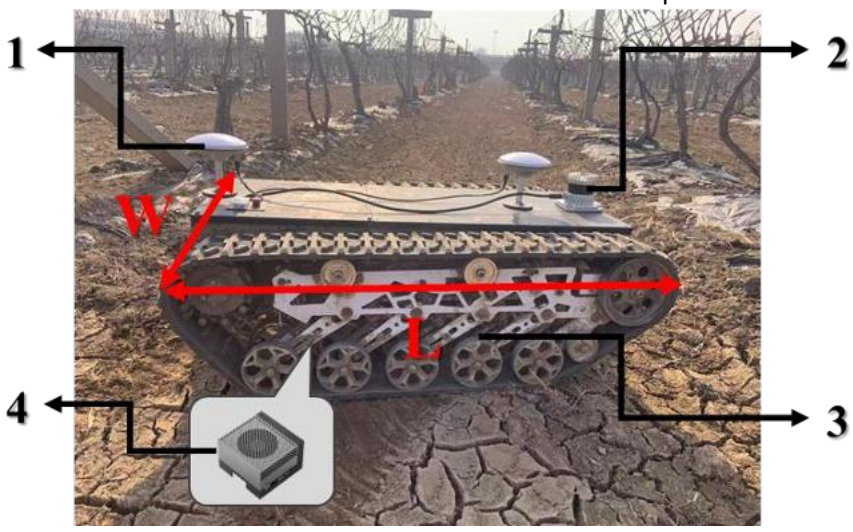

Fig. 1 -Tracked mobile platform for orchard robots

1. GNSS-RTK; 2. 3D LiDAR; 3. Crawler-Type Mobile Chassis; 4. Jetson AGX Orin.

Trajectory representation and motion modeling

To ensure smooth motion on uneven orchard terrain, the local trajectory is parameterized using a uniform B-spline curve *(Sun et al., 2024)*. The trajectory is uniquely defined by a set of control points $Q_i = \{Q_1, Q_2, \ldots, Q_{Nc}\}$, the spline degree P_b, and a uniform knot interval Δt, which enables direct adjustment of the trajectory during optimization.

Fig. 2 demonstrates the key geometric characteristics leveraged in this study **(1) Local Support**, which ensures that each trajectory segment is determined by only P_b+1 neighboring control points, allowing optimization constraints to be decoupled locally; **(2) Convex Hull**, implying that the continuous curve lies within the polygon formed by its control points, which simplifies collision checking; and **(3) Derivative Consistency**, allowing velocity and acceleration to be expressed as linear combinations of control points, enabling kinematic constraints to be enforced directly without explicit integration.

At low speed (< 1 m/s), lateral slip is neglected and the robot is modeled using a kinematic non-holonomic approximation *(Mínguez et al., 2002)*. Under this assumption, discrete velocity and acceleration associated with adjacent control points are approximated using finite differences with a constant time interval Δt as follows:

$$V_i = \frac{Q_{i+1}-Q_i}{\Delta t},\ A_i = \frac{V_{i+1}-V_i}{\Delta t} \tag{1}$$

where:

V_i and A_i denote the discrete velocity and acceleration, respectively; Q_i denotes the $i\text{-}th$ control point of the B-spline trajectory; Δt is the uniform time interval between adjacent control points.

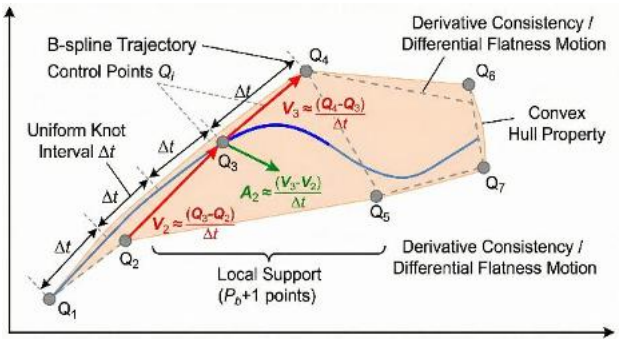

Fig. 2 - Illustration of B-spline trajectory properties

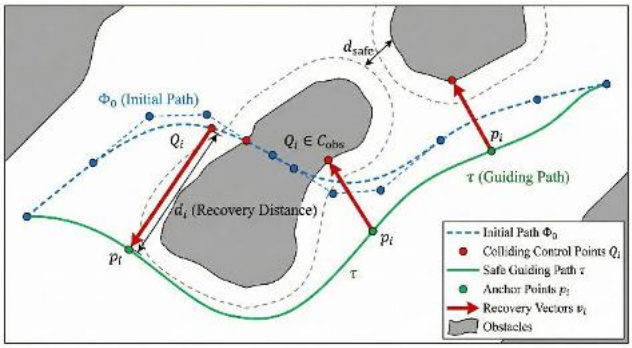

Fig. 3 --Front-end Logic - Optional

Collision-free Initial Trajectory Generator

To incorporate environmental awareness into the local planner, a collision-free initial trajectory generator is adopted as the front-end of the proposed method. Fig. 3 Schematic of the collision-free initial trajectory generation. The navigation layer initially outputs a globally smooth B-spline path Φ_0 that satisfies boundary constraints. When a colliding segment is detected, A^* search *(Hart et al., 1968)* is employed to generate a collision-free guiding path τ based on the topological structure of the environment. Unlike methods that rely on unstable gradients from irregular obstacle surfaces, τ serves as a safe topological attractor to guide the trajectory generation.

To precisely quantify collision risks, a safety threshold d_{safe} is first defined based on the robot's circumscribed radius *(Howell et al., 2022)*:

$$d_{safe} = \sqrt{\left(\frac{L}{2}\right)^2 + \left(\frac{W}{2}\right)^2} + \delta \tag{2}$$

where δ is a safety buffer.

For each control point Q_i, its distance to the nearest obstacle $d_{obs}(Q_i)$ is queried from the local obstacle cloud. Control points satisfying $d_{obs}(Q_i)<d_{safe}$ are identified as colliding points and grouped into a collision set C_{obs}.

For every colliding index i in C_{obs}, a unique anchor point p_i is assigned on the guiding path τ. Based on this correspondence, a collision recovery distance d_i and a recovery gradient vector $\boldsymbol{v_i}$ are defined as follows:

$$d_i = \|Q_i - p_i\| \tag{3}$$

$$\boldsymbol{v_i} = p_i - Q_i \tag{4}$$

where:

d_i denotes the Euclidean distance measuring the deviation of the colliding point from the safe path; $\boldsymbol{v_i}$ represents the gradient direction vector that pulls the control point Q_i back towards the safe anchor p_i.

Through this procedure, the feasible geometric references (p_i) and the associated recovery metrics (d_i, $\boldsymbol{v_i}$) are successfully generated, providing the essential collision-free initialization terms required for the subsequent gradient-based trajectory optimization.

Cost Function Formulation

To generate safe and executable trajectories, the local planning problem is formulated as a weighted multi-objective optimization (Fig. 4). The total cost function J is defined as:

$$\min_{Q} J = \lambda_s J_s + \lambda_c J_c + \lambda_k J_k \tag{5}$$

where:

J_s, J_c, and J_k represent smoothness, collision, and kinematic feasibility penalties, respectively. The coefficients λ_s, λ_c and λ_k are weighting factors that balance the trade-off between trajectory quality, safety, and feasibility.

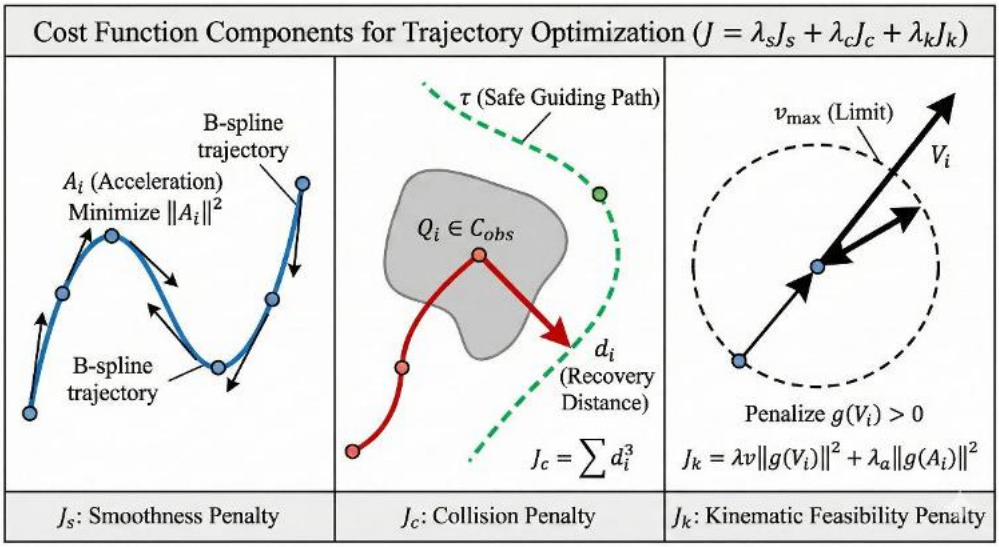

Fig. 4 - Cost function components

- Smoothness Penalty

Orchard environments are characterized by uneven terrain and varying soil conditions. Excessive acceleration can lead to chassis vibration, track slippage, or damage to onboard inspection sensors. To ensure trajectory smoothness and minimize control effort, a penalty on the control point acceleration is applied:

$$J_s = \sum_{i=1}^{N_c-2} \| A_i \|^2 \tag{6}$$

where:

N_c is the total number of control points in the B-spline trajectory, and A_i is the discrete acceleration vector derived in Equation (1).

The use of the squared L_2 norm serves two critical purposes. Mathematically, it provides a convex and continuously differentiable cost landscape, which facilitates rapid convergence for gradient-based optimization. Physically, the quadratic form heavily penalizes abrupt acceleration spikes, ensuring that the generated motion is gentle enough to prevent track slippage on soft orchard ground.

- Collision Penalty

The collision penalty strictly enforces the safety constraints. Unlike traditional methods that rely on computing gradients from irregular obstacle surfaces, this study leverages the recovery distance d_i derived from the safe guiding path. The penalty term J_c is formulated as:

$$J_c = \sum_{i \in C_{obs}} (d_i)^3 \tag{7}$$

This cubic formulation is applied exclusively to the set of colliding control points C_{obs} identified by the front-end. It ensures a continuous gradient that grows steeply as the control point deviates further from the safe anchor p_i, generating a strong restoring force that effectively pulls the trajectory back into the collision-free corridor defined by the guiding path.

- Kinematic Feasibility Penalty

To guarantee that the planned trajectory is executable by the hardware, dynamical limits are imposed as soft constraints. Velocities and accelerations exceeding the system limits (v_{max}, a_{max}) are penalized to ensure the generated commands remain within the robot's physical capabilities. The kinematic feasibility penalty J_k is formulated as:

$$J_{kinematic} = \sum_{i=1}^{N_c-1} \lambda_v \cdot g(V_i, v_{max}) + \sum_{i=1}^{N_c-2} \lambda_a \cdot g(A_i, a_{max}) \quad (8)$$

where:

$g(\cdot)$ is a squared penalty function activated only when constraints are violated:

$$g(x, x_{lim}) = \begin{cases} (\|x\|^2 - x_{lim}^2)^2 & \|x\| > x_{lim} \\ 0 & \|x\| \leq x_{lim} \end{cases} \quad (9)$$

where:

V_i and A_i are the discrete velocity and acceleration vectors, v_{max} and a_{max} denote the maximum linear velocity and acceleration allowed by the chassis, and λ_v and λ_a are the weighting coefficients.

This formulation provides a continuously differentiable gradient that grows quadratically with the violation magnitude, effectively pulling the trajectory back into the feasible state space without introducing unnecessary computational complexity.

Gradient-based Trajectory Optimization

Given the composite cost function J, the trajectory generation is resolved by finding the optimal control points Q_i that minimize this cost. To ensure rapid convergence and avoid infeasible local minima, the optimization is initialized using the collision-free geometric reference. This initialization strategy provides a high-quality initial guess that naturally lies within the safe topological corridor, allowing the gradient-based solver to focus on local smoothing and refinement rather than global search.

Let x denote the decision variable vector formed by flattening the control points Q_i. The optimization is solved using an iterative gradient update rule:

$$x_{k+1} = x_k - \alpha_k \mathrm{H}_k^{-1} \nabla \mathrm{J}(x_k) \quad (10)$$

where:

$\nabla J(x_k)$ is the gradient of the cost function, α_k is the step size determined by line search, and H_k^{-1} represents the inverse Hessian matrix. To solve this efficiently within the limited computing budget, the L-BFGS (Limited-memory Broyden–Fletcher–Goldfarb–Shanno) *(Liu et al., 1989)* algorithm is adopted. Unlike standard Newton methods, L-BFGS approximates H_k^{-1} using a limited history of past updates, significantly reducing memory consumption and computational complexity for the high-dimensional B-spline problem.

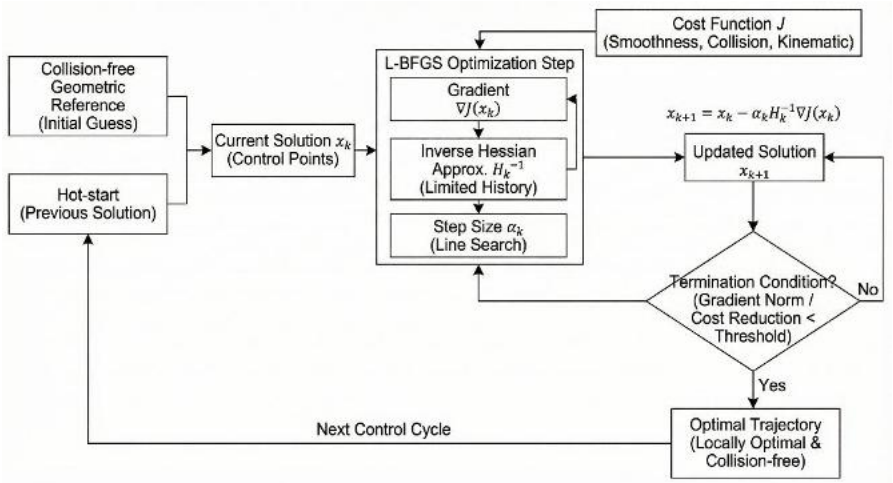

Fig. 5 - Flowchart of numerical optimization algorithm

In the dynamic context of orchard inspection, the optimizer employs a hot-start strategy, utilizing the solution from the previous control cycle as the initial guess for the current frame. The iteration terminates when either the gradient norm or the relative cost reduction falls below a predefined threshold, ensuring that a stable, locally optimal, and collision-free trajectory is regenerated in real-time.

RESULTS

Experimental Setup and Baseline Validation

Field experiments were conducted in a standard orchard environment in Shandong Province, China. The test site featured typical inter-row characteristics with an average row spacing of 4.5 m and a plant spacing of 1.5 m. The robot was tasked to follow predefined global paths, with all sensor data and trajectory logs recorded at 0.2 s intervals. throughout the trials, a constant forward speed of 0.6 m/s was maintained to ensure consistent motion dynamics.

Prior to the obstacle avoidance tests, the baseline path tracking accuracy was verified. The results showed that the robot maintained a lateral tracking error of less than 3.0 cm on straight paths. This high-precision baseline ensures that the significant deviations observed in subsequent experiments were solely driven by the active obstacle avoidance algorithm rather than control instability.

Local Obstacle Avoidance Performance

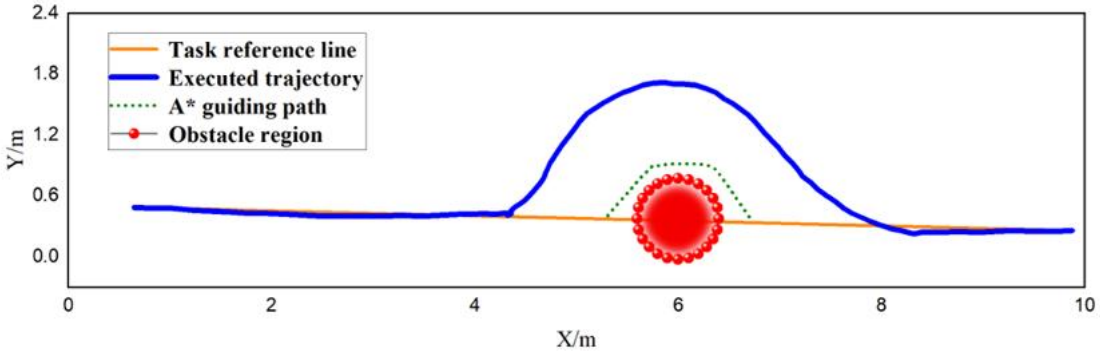

Fig. 6 -Obstacle avoidance trajectory

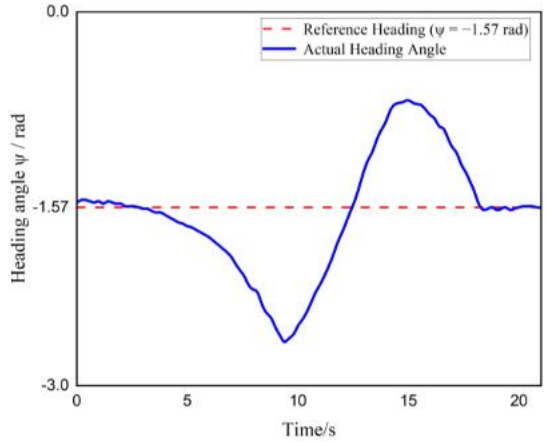

Fig. 7 - The curve of the heading angle over time

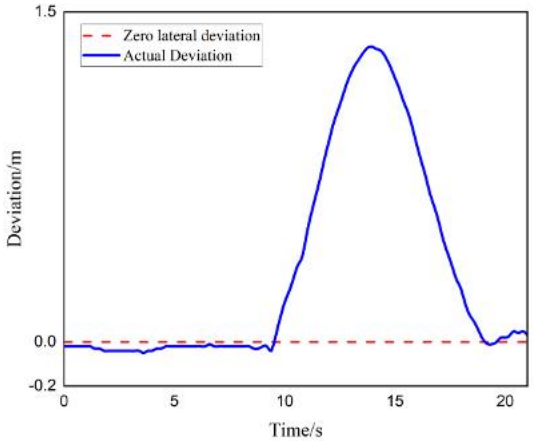

Fig. 8 - The curve of lateral deviation over time

Fig. 6 illustrates the spatial trajectory of the robot during a representative avoidance maneuver. The local avoidance process is initiated at approximately x = 4.35 m, where the robot smoothly deviates from the task path guided by the optimized B-spline trajectory. The maneuver is completed at around x = 8.32 m. Although a slight overshoot occurs immediately after obstacle clearance, it is rapidly attenuated by the feedback controller, allowing the trajectory to converge asymptotically back to the global reference path without persistent oscillations. The corresponding heading angle response is presented in Fig. 7. It is noteworthy that while the reference heading remains constant, the actual heading exhibits an anticipatory deviation as the robot perceives the obstacle, reaching a maximum difference of approximately 1.07 rad at t = 9.4 s. This heading-first response precedes significant lateral displacement, demonstrating the kinematic feasibility of the smooth transition into the avoidance maneuver. Fig. 8 quantifies the lateral deviation relative to the global path. The deviation profile exhibits a single-peak structure with a maximum amplitude of 1.34 m. Given the orchard row spacing of 4.5 m, the operational boundary lies at 2.25 m from the path centerline. Consequently, the maximum deviation of 1.34 m preserves a substantial safety margin of approximately 0.9 m from the vine rows. This result confirms that the proposed Smooth-Planner effectively utilizes the available free space to bypass obstacles while strictly adhering to the agronomic safety constraints of the orchard environment.

Stability and Robustness Validation

To further evaluate the practical applicability of the proposed method under realistic field conditions, additional experiments were conducted. Fig. 9 visualizes the onboard local point cloud perception during the obstacle avoidance maneuver, alongside corresponding real-world snapshots. As observed, despite the unstructured environmental noise typical of orchards, the obstacle geometry is distinctly captured by the LiDAR. The robot successfully executes a smooth bypass within the 4.5 m inter-row space. The strong consistency between the point cloud data and the physical environment confirms the reliability of the perception-planning pipeline.

To quantitatively assess the repeatability and stability of the system, the obstacle avoidance experiment was replicated in ten independent trials under identical conditions. Key performance indicators were extracted from each trial, and the statistical results are summarized in Table 1.

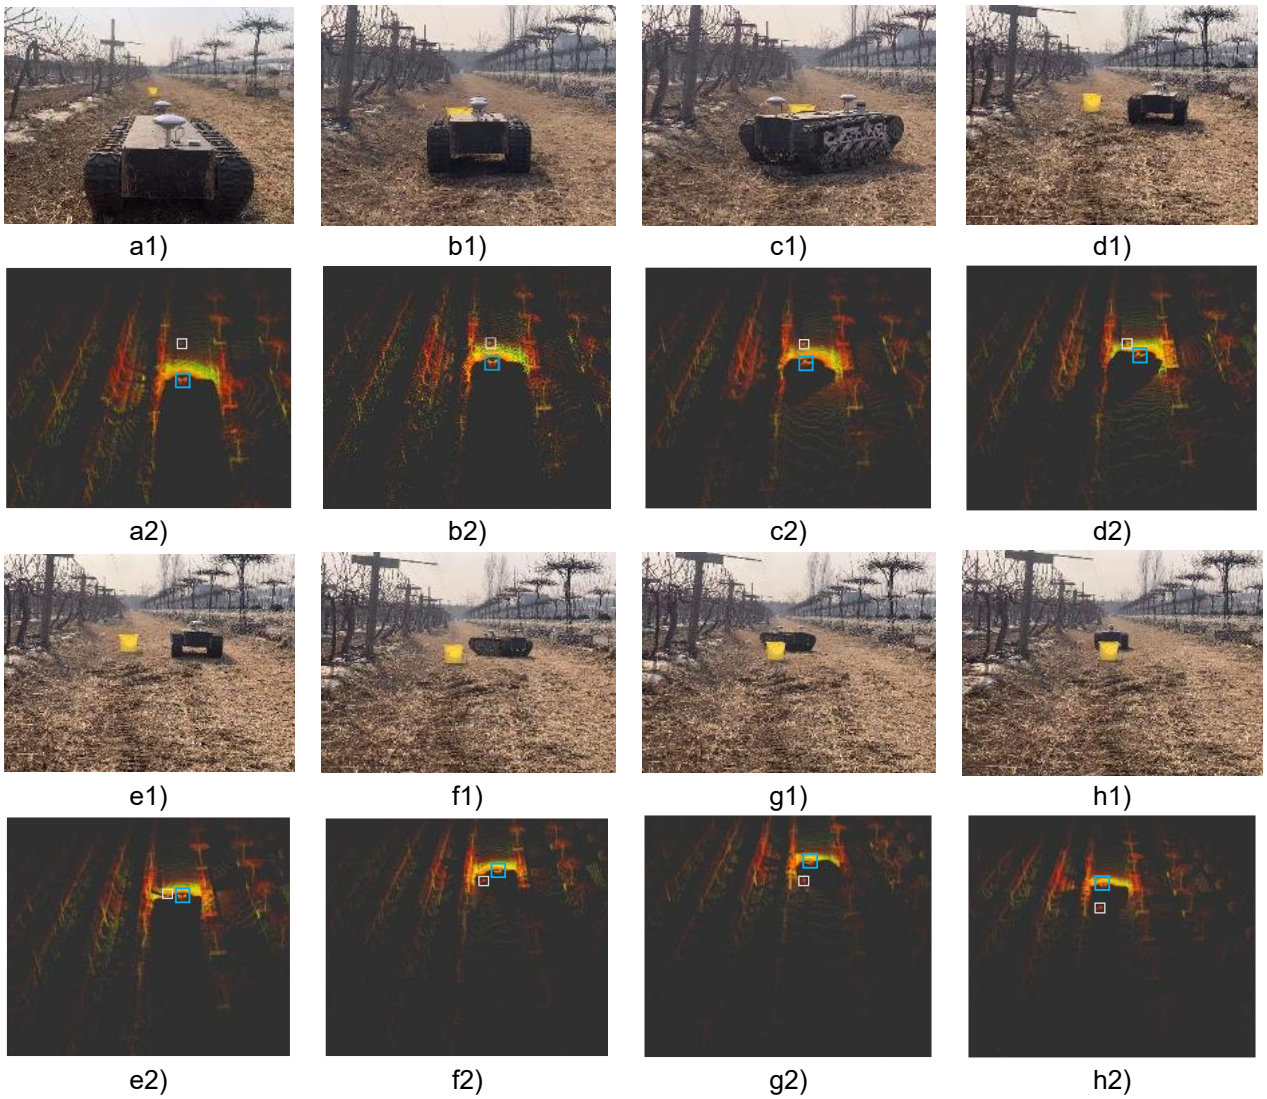

Fig. 9 – Real-world images and point cloud diagrams of obstacle avoidance operation

a1)–h1) – real-world images; a2)–h2) – LiDAR point cloud

Table 1

Statistical Metrics of Obstacle Avoidance Performance (N=10)

Performance Metric	Mean	Std. Dev.	Description
Max. Lateral Deviation(m)	1.32	0.08	Peak deviation from the global path
Min. Safety Margin(m)	0.9	0.07	Distance to the crop row boundary
Avoidance Duration(s)	9.65	0.15	Time elapsed during the maneuver
Total Path Length(m)	4.12	0.05	Length of the executed trajectory

As indicated in Table 1, the system demonstrates high repeatability. The Max. Lateral Deviation averaged 1.32 m with a standard deviation of only 0.08 m. This minimal variance is critical for agricultural automation, as it indicates that the robot's trajectory is highly predictable and robust against sensor noise across different runs.

Furthermore, by correlating these statistics with the 4.5 m row spacing, the Minimum Safety Margin is calculated to be approximately 0.9 m. Even accounting for the variance, the robot consistently maintains a sufficient buffer from the vine rows, thereby effectively mitigating collision risks with the crop canopy. The consistent values for Lateral Deviation RMSE and Avoidance Duration further validate that the proposed Smooth-Planner generates stable, feasible, and robust trajectories suitable for continuous orchard inspection tasks.

CONCLUSIONS

In this study, a robust local trajectory planning method, Smooth-Planner, was developed to address the challenges of autonomous navigation in narrow and unstructured orchard environments. By integrating a collision-free topological guiding path with a gradient-based continuous optimization framework, the proposed method generates smooth trajectories that strictly satisfy the non-holonomic kinematic constraints of differential-drive robots.

Field experiments conducted in a standardized orchard validated the effectiveness of the system. The results demonstrated that the robot could stably bypass obstacles with highly repeatable behavior, exhibiting an average maximum lateral deviation of 1.32 m with a minimal standard deviation of 0.08 m. Crucially, quantitative analysis confirmed that even during avoidance maneuvers, a minimum safety margin of approximately 0.93 m was maintained from the crop rows, ensuring agronomic safety. Overall, this work provides a reliable, map-free, and practical solution for the deployment of inspection robots in complex agricultural scenarios.

ABSTRACT

With the development of society and the advancement of science and technology, the object detection technology driven by Artificial Intelligence is also constantly innovating. As an important task in the field of agricultural Computer Vision, fruit detection in real environments faces many challenges. This paper reviews and analyzes the latest breakthroughs and representative studies in this field. Based on the existing research, the existing fruit detection algorithms are roughly divided into 5 categories: (1) the traditional fruit detection algorithm based on manual features; (2) the fruit detection algorithm based on two stages; (3) the fruit detection algorithm based on one stage; (4) the fruit detection algorithm based on anchor-free frame, and (5) the fruit detection algorithm based on transfer learning. This paper also discusses various application scenarios, such as multi-object detection, complex backgrounds, and edge computing. It also summarizes the classic and cutting-edge technical methods at the current time point, providing valuable insights for fruit detection in agricultural production.

ABSTRAK

Dengan perkembangan masyarakat dan kemajuan sains dan teknologi, teknologi pengesanan objek yang dipacu oleh kecerdasan buatan juga sentiasa berinovasi. Sebagai tugas penting dalam bidang penglihatan komputer pertanian, pengesanan buah-buahan dalam persekitaran sebenar menghadapi banyak cabaran. Kertas kerja ini mengulas dan menganalisis penemuan terkini dan kajian-kajian yang mewakili bidang ini. Berdasarkan kajian, algoritma pengesanan buah-buahan sedia ada secara kasarnya dibahagikan kepada lima kategori, iaitu: (1) algoritma pengesanan buah-buahan tradisional berdasarkan ciri manual; (2) algoritma pengesanan buah-buahan berdasarkan dua peringkat; (3) algoritma pengesanan buah-buahan berdasarkan satu peringkat; (4) algoritma pengesanan buah-buahan berdasarkan tanpa sauh; dan (5) algoritma pengesanan buah-buahan berdasarkan pembelajaran pemindahan. Kertas kerja ini juga membincangkan pelbagai senario aplikasi seperti pengesanan berbilang objek, latar belakang kompleks dan pengkomputeran tepi. Ia juga meringkaskan kaedah teknikal klasik dan canggih pada masa kini, memberikan pandangan berharga untuk pengesanan buah-buahan dalam pengeluaran pertanian.

INTRODUCTION

Agriculture is one of the most important sectors and plays a vital role in ensuring global food security, rural development, and economic growth. As agricultural technology advances and modernizes, several challenges need to be addressed, such as climate change, pests and diseases, labor shortages, and the need for sustainable resource management (*Devlet A., 2021*). The fusion of artificial intelligence (AI) and computer vision (CV) can alleviate these challenges and open up new opportunities to improve the efficiency, accuracy, and yield of agricultural processes. Object detection has become a key technology that helps to autonomously identify, locate, and classify objects such as leaves, fruits, pests, and diseases from images or video frames (*Gupta, S., &Tripathi, A.K., 2024*). There are a variety of technologies used for object detection in agriculture, including IoT sensors with cameras that can monitor leaves, fruits, vegetables, and crops in real time. Other technologies include drones and satellites for capturing large-scale crop images for analysis and pest detection, and robotic harvesters for automated sowing and harvesting of fruits and vegetables.

In addition, due to the advancement of deep learning (DL), object detection methods have shifted from feature-based models to data-driven methods, such as convolutional neural networks (CNNs) (*O'shea K. & Nash R., 2015*), YOLO (You Only Look Once) (*Redmon J. et al., 2016*), and region-based CNN (R-CNN) *(Girshick R. et al., 2015*), which are used to detect pests and diseases and growth stages. In addition, the recent developments of Vision Transformers (ViT) (*Dosovitskiy A. et al., 2020*), EfficientDet (*Tan M. et al., 2020*), and hybrid CNN-Transformer architectures have significantly improved the detection performance in harsh field environments.

In recent years, with the development of DL technology, the progress of AI has brought great development prospects to object detection. This paper sorts out the mainstream methods and their evolution in the current object detection field, summarizes their core features and application effects, reveals key influencing factors, and evaluates scalability and deployment feasibility, aiming to provide a reference for academia and engineering and help the digital upgrade of the industry.

Fruit Detection

As a core technology of CV, object detection aims to achieve dual perception of object location and classification in images. In the agricultural field, the goal of object detection is to use images or videos to identify and locate certain objects, such as fruits, leaves, vegetables, and pests on crops. This article focuses on the application of fruit-related aspects in agricultural planting and production. In the fruit detection scenario, its core task is to extract the feature representation of the object from complex farmland images, and then realize applications such as automatic picking, yield assessment, and quality grading. Figure 1 shows the evolution of the main technical methods for object detection.

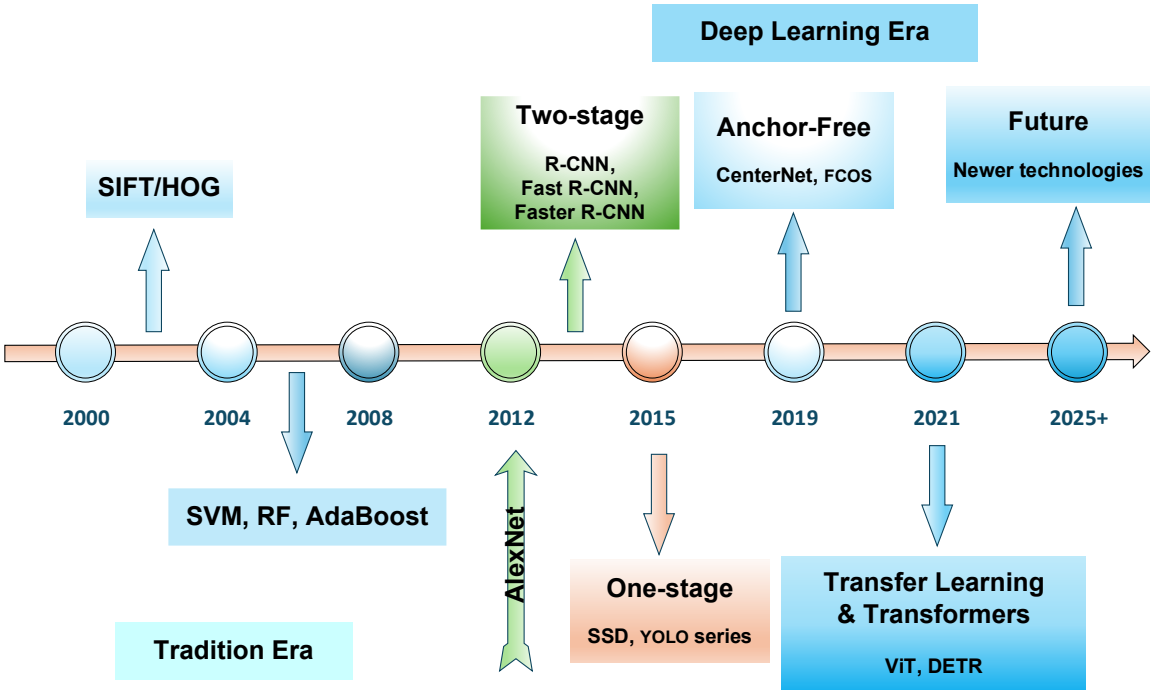

Fig. 1 - The evolution of the main technical methods for object detection

Traditional Methods

Traditional methods have been widely used in tasks such as fruit detection, counting, and grading. The core relies on the feature engineering technology route, and detection is mainly achieved through manual feature extraction and rule definition, such as color, shape, and texture. Its process usually includes four stages: image preprocessing, feature extraction, threshold setting, and classification rules. In image preprocessing, Gaussian or median filtering methods are often used for denoising, and color space conversion is used to enhance fruit features. Subsequently, the tomato area is extracted from the complex background through color segmentation (such as fixed threshold, Otsu method), and morphological operations (erosion, expansion, opening operations, and closing operations) are used to optimize the segmentation results. For the candidate area, edge detection and Hough transform are combined to fit the contour, and the real fruit is screened out using geometric features. At the same time, some fine-grained recognition tasks introduce texture analysis to improve accuracy.

The traditional algorithm is based on the image recognition model, and its detection process always consists of two parts. First, the image is feature extracted based on methods such as scale-invariant feature transform (SIFT) (*Lowe D.G., 2004*) and histogram of oriented gradient (HOG) (*Dalal N., &Triggs B., 2005*), and then the object in the image is classified using methods such as support vector machine (SVM) *(Burges C.J., 1998*) and adaptive boosting (Adaboost) *(Freund Y., & Schapire R.E., 1995*). *Ji et al. (2012)* proposed an apple recognition algorithm based on an SVM by extracting the color and shape features of the fruit in the image, and got good results on apple picking robots. However, the strategies for handling situations involving leaf shading and densely overlapping fruits are still not perfect and fall short compared to extreme conditions in real orchards. *Si et al. (2015)* proposed a fruit recognition algorithm based on color difference and its ratio, which determines the fruit by calculating the color difference and its ratio of pixels. It effectively eliminates the influence of shadows and soil in the natural environment, and achieves a recognition rate of 85%. However, the experiment used a small data scale, a single experimental scenario, and lacked systematic verification under complex conditions. *Mehra et al. (2016)* transformed images from RGB to Lab* color space, clustered pixels using k-means clustering, and then determined maturity based on color characteristics of these clusters. By integrating tomato maturity assessment with disease detection within a single CV framework, they demonstrated the practical value of multi-task recognition while validating the feasibility of image features for fruit quality monitoring and health evaluation. This approach exhibits significant systemic innovation and application significance. However, the feature extraction and classification methods employed exhibit insufficient robustness to lighting variations, fruit occlusion, and scenarios involving multiple concurrent diseases. Furthermore, the limited dataset size and diversity weaken the model's generalization capability, making it difficult to detect automated in real environments. *Al-Mashhadani et al. (2020)* used OpenCV combined with the HSV color space to estimate tomato ripeness and perform counting. They determined the colors of ripe and nearly ripe fruits through thresholding in the HSV color space. While this technique could identify fruits that were ripe and about to change color when grouped, it could not distinguish differences between them.

Traditional algorithms always rely on manually designed feature extraction methods, which are prone to false positives and false negatives when faced with complex scenarios such as changes in light, occlusion, and overlap. They also suffer from high computational complexity, low robustness, and poor adaptability. Although traditional image processing methods based on manual design have the advantages of simple implementation, low computational cost, and low hardware requirements, and have played an important role in early research, their limitations, such as slow processing speed and high computational complexity, have become increasingly apparent (*Bello R.-W. et al., 2025*).

Compared with traditional recognition methods, DL-based methods are self-learning directly from the image's own features and expression relationships. They have a strong ability to express fruit features, high generalization, and high accuracy, solving the problem that traditional methods cannot meet the real-time requirements. At the same time, with the improvement of computer computing power, more researchers have turned their attention to DL. *Girshick et al. (2014)* proposed the R-CNN algorithm, and the use of CNNs greatly improved the speed of object detection. AlexNet *(Krizhevsky A. et al., 2017*) defeated traditional object detection algorithms in the ImageNet Large-Scale Visual Recognition Challenge, and its speed and accuracy are far superior to traditional detection algorithms. So far, DL methods have begun to be widely used in various object detection and recognition algorithms. So, there are several main categories of commonly used methods for detecting fruits on plants based on DL. First is the Two-Stage-Based Algorithm, second is the One-Stage-Based Algorithm, third is the Anchor-Free-Based Algorithm, and the last is the Transformer-Based Algorithm.

Two-Stage-Based Detection Algorithm

The two-stage object detection algorithm is a classic paradigm for object detection in CV. Its core logic is to split the detection task into two stages: "candidate region generation" and "region fine detection" to achieve high-precision object positioning and classification. With their powerful feature learning and expression capabilities, CNNs have gradually replaced traditional image processing methods and become one of the mainstream technologies for detection. As an important representative of the two-stage detection framework, the R-CNN series algorithms have promoted the advancement of object detection technology.

Girshick et al. (2014) proposed the original R-CNN framework, which used a CNN to extract high-level features of candidate regions for the first time, significantly improving detection accuracy. The original R-CNN uses selective search to generate candidate regions, extracts features one by one through CNN, and combines SVM classification and bounding box regression to optimize the detection effect.

Although it improves accuracy, it still has a high computational cost and slow speed, making it difficult to meet real-time requirements. For this, Fast R-CNN (*Girshick R., 2015*) and Faster R-CNN (*Ren S. et al., 2015*) have been introduced. Fast R-CNN reduces redundant calculations and improves detection speed by sharing feature maps and ROIPooling. Faster R-CNN is later than Fast R-CNN. It introduces the region proposal network (RPN) to achieve end-to-end training of candidate region generation and detection, further improving efficiency and accuracy, realizing the integration of detection processes, and laying the foundation for a two-stage detection framework. Mask R-CNN (*He K. et al., 2017*) introduced an instance segmentation function based on Faster R-CNN, adds a mask branch, replaces ROIPooling with ROIAlign to eliminate quantization error, and realizes end-to-end training of object detection, classification, and instance segmentation. It has high accuracy and is extended to tasks such as panoramic segmentation, becoming the basic framework for multimodal vision tasks. It is particularly suitable for scenes with densely clustered fruits, and can effectively distinguish overlapping fruits and improve detection results. Figure 2 shows the basic principle of the two-stage-based detection algorithm.

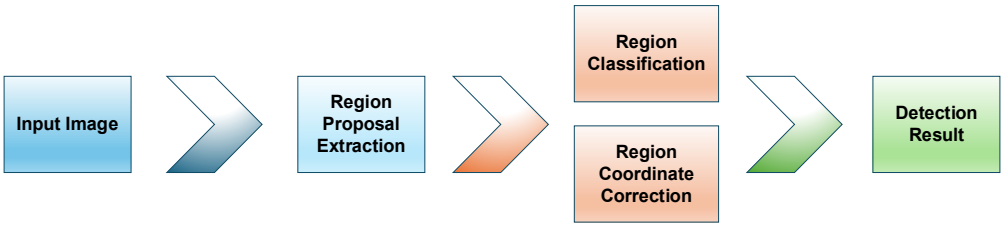

Fig. 2 - The basic principle of the two-stage-based detection algorithm

Ganesh et al. (2019) implement orange detection and instance segmentation based on Mask R-CNN. Its advantage lies in the use of a powerful two-stage segmentation framework, which enables the model to maintain high segmentation accuracy under complex backgrounds. However, Mask R-CNN itself has a large structure and slow inference speed, which makes it difficult to meet the application requirements of real-time picking or drone inspection. Furthermore, it doesn't conduct in-depth discussions on the model's cross-scene generalization, robustness, and data diversity. *Afonso et al. (2020)* proposed a tomato detection algorithm based on the Mask R-CNN approach. This algorithm detects objects and their corresponding pixels, utilizing RealSense cameras to capture tomato images from greenhouses for identifying four distinct stages of tomato ripeness. Results demonstrate the model's excellent performance in detecting and classifying tomatoes within the challenging greenhouse environment, indicating that Mask R-CNN can implicitly learn object depth—a critical factor for background elimination. However, the model exhibits strong dependence on the dataset and lacks validation for generalization. *Wang et al. (2021)* integrated an attention mechanism into the Faster R-CNN model to address the challenge of detecting young tomato against near-color backgrounds. Results show this method achieves a mAP of 98.46% with an average detection time of just 0.084 seconds per image. It enables real-time, accurate, and efficient detection of young tomato fruits, providing a robust solution for fruit detection under near-color backgrounds. But the more complex model structure increases hardware costs and deployment complexity. *Zu et al. (2021)* built a model using Mask R-CNN with a ResNet50-FPN backbone to detect and segment green tomatoes in greenhouses. The model uses ROIAlign bilinear interpolation to compute object regions generated from training feature maps. It achieves detection and segmentation of ripe green tomatoes through parallel operations of ROI object classification, bounding box regression, and mask generation. At an IOU threshold of 0.5, the model achieves an F1 score of 92.0%. And the model remains limited as experiments were conducted solely on green tomatoes, and performance degrades when fruits overlap. *Xu et al. (2022)* used a bimodal feature map and a balanced multi-task loss model, which improved stem segmentation accuracy during cherry tomato harvesting. Nevertheless, challenges persist regarding color and shape similarity, loss of stem features, and category differences. *Yan et al. (2024)* built a comprehensive recognition framework based on an improved Faster R-CNN, integrating apple detection, quantity statistics, localization, and quality estimation. Its advantage lies in unifying multiple tasks into a single model. Through feature pyramid optimization and region proposal modules, it improves detection accuracy and stability in complex orchard environments, effectively addressing real-world challenges such as occlusion and varying lighting conditions. However, while multi-task coupling enhances functionality, it also increases training complexity. Furthermore, the mechanisms of interaction between tasks have not been systematically analyzed, and the limited dataset size means that the demonstration of generalization ability remains insufficient.

Cong et al. (2025) proposed the TQVG Model based on Mask R-CNN for tomato quality grading. Results demonstrate that the model achieves higher mAP and faster inference speeds with fewer parameters. The model exhibits high dependence on training data, sensitivity to annotation quality, and lacks performance validation for real-time and mobile deployment. Furthermore, optimization is still needed in terms of inference efficiency.

While the R-CNN series offer high detection accuracy, they still have some significant limitations for widespread application in fruit detection. Their reliance on a two-stage process of "candidate region generation + classification and regression" results in high overall computational cost, slow inference speed, large file size, and cumbersome workflow, making edge deployment difficult and hindering real-time detection. Although improvements over the original R-CNN, independent steps such as candidate region generation still exist, leading to complex structures, high training costs, high computational resource requirements, and difficulties in end-to-end optimization. They also tend to miss information about dense, small objects, making them less effective against both small and dense objects.

Therefore, although they have significantly advanced object detection technology by optimizing feature extraction and candidate region generation, and perform well in high-accuracy detection and robustness against complex backgrounds, real-time deployment on mobile terminals and edge devices remains challenging due to limitations in detection speed and model size. So, it is necessary to combine lightweight design with efficient feature extraction strategies to further improve their practicality and versatility. Figure 3 shows the mAP values of some Two-stage detectors on the COCO dataset.

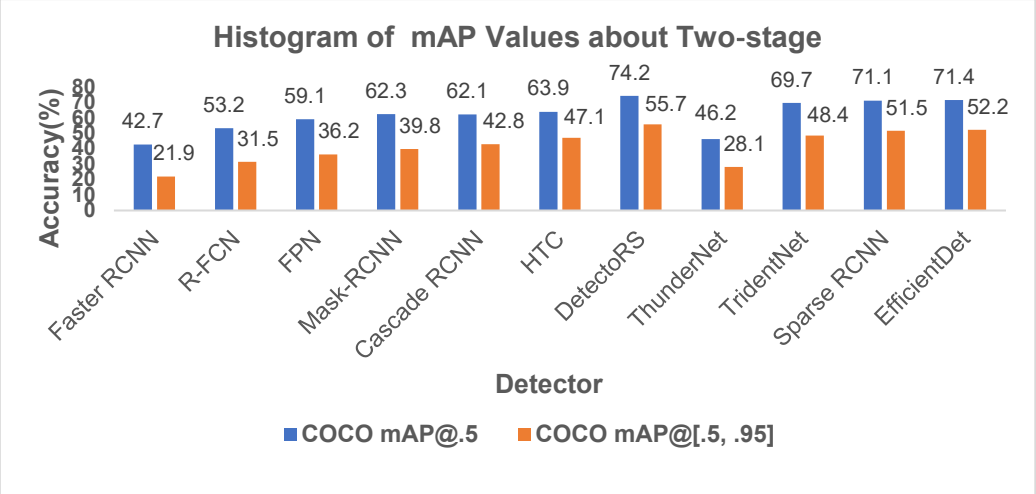

Fig. 3 - The mAP values of some Two-stage detectors on COCO dataset. There're Faster-RCNN *(Ren S. et al., 2015)*, R-FCN (*Dai J. et al., 2016*), FPN (*Lin T.-Y. et al., 2017*), Mask-RCNN (*He K. et al., 2017*), Cascade RCNN *(Cai Z., Vasconcelos, N., 2018*), HTC (*Chen K. et al., 2019*), DetectoRS (*Qiao S. et al., 2021*), ThunderNet *(Qin Z. et al., 2019*), TridentNet (*Li Y. et al., 2019*), Sparse RCNN (*Sun P. et al., 2021*), EfficientDet (*Tan M. et al., 2020*).

One-Stage-Based Detection Algorithm

The regression-based one-stage fruit detection and recognition method does not need to generate candidate regions, but directly obtains the category probability and position of the object, making its network structure simpler and sacrificing some accuracy, but the detection and recognition speed of the algorithm is improved.

YOLO *(Redmon, J. et al., 2016)* series are a typical representative of one-stage detection. With its end-to-end structure, fast speed, and high accuracy, it has become the mainstream technical route for fruit detection. Since YOLO was proposed, it has been iterated on many versions and widely used in agricultural visual inspection, especially in real-time and deployment flexibility scenarios. With the iteration, the YOLO series continues to optimize detection accuracy, efficiency, and generalization ability. YOLO9000 *(Redmon J., & Farhadi A., 2017*) adopted Darknet-19, anchor box and multi-scale training to improve the performance of small object detection; YOLOv3 *(Redmon J. & Farhadi A., 2018*) adopted a deeper Darknet-53 to enhance feature expression; YOLOv4 (*Bochkovskiy A. et al., 2020*) and YOLOv5 integrated CSPNet, Mish activation function, and Mosaic data enhancement, significantly improving speed and accuracy, and are widely used; YOLOv7 (*Wang C.-Y. et al., 2023*) proposed the ELAN (Efficient Layer Aggregation Network) architecture, which improves feature utilization through grouped convolution and residual connection, and performs expansion and compound scaling, supplemented by dynamic label allocation optimization, with strong robustness, and can adapt to complex lighting and occlusion scenes.

YOLOv8 adopts a unified framework for all tasks, enhanced features, and improved loss functions, and introduces adaptive strategies to achieve real-time deployment optimization. And YOLOX (*Ge Z. et al., 2021*) in the YOLO series is also a model based on an anchor-free architecture. YOLOX divides the input image into multiple smaller grids, so that predictions can be made quickly and grid by grid. YOLOX-PAI (*Wu Z. et al., 2022*) is an improved version of YOLOX. Its core part uses an adaptive spatial feature fusion strategy for feature enhancement and an attention mechanism to organize tasks. Figure 4 shows the basic principle of the one-stage-based detection algorithm.

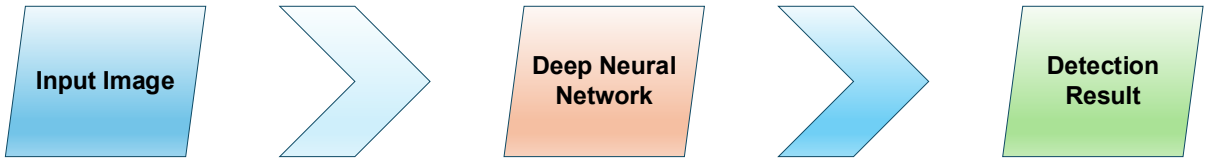

Fig. 4 - The basic principle of the one-stage-based detection algorithm

Mirhaji et al. (2021) utilize various YOLO models to detect and estimate fruit load in citrus orchards, and systematically evaluate the impact of different imaging methods and lighting conditions on detection performance. The results show that the model's precision, recall, F1 score, and mAP are 91.23%, 92.8%, 92%, and 90.8%, respectively, and the overall performance difference between nighttime and daytime imaging is not significant. But the model lacks specific optimization for orchard shading, dense fruit distribution, or strong light interference, and its robustness requires further verification.

Hernández et al. (2023) proposed a tomato ripeness detection model based on YOLOV3-tiny, achieving an F1 score of 90%. Although YOLOv3-tiny is sufficiently lightweight to significantly boost inference speed while maintaining detection accuracy, its overly simplified architecture limits feature extraction capabilities. This results in insufficient recognition accuracy under complex lighting, occlusion, and color transition conditions, necessitating further improvements in model robustness.

Zhang et al. (2023) employed YOLOv4-Tiny + FENB to detect tomatoes under occluded backgrounds during both daytime and nighttime. The nighttime mAP value reached 94.72%, with test results consistently outperforming both YOLOv4 and YOLOv4-Tiny, demonstrating the model's robust performance under nighttime and occluded conditions. However, the authors provided limited validation of the model's robustness and adaptability in complex backgrounds.

Li et al. (2023) proposed the YOLOv5s-Tomato model to identify four distinct tomato maturity stages. They enhanced small object detection performance using techniques like Mosaic data augmentation, the Focus module, and the CSPNet network architecture, while employing EIoU as the loss function. This approach yielded significant improvements in model size and detection speed. Results demonstrate that the model effectively meets greenhouse detection requirements while improving recognition accuracy for occluded and small tomatoes. Since all training images originated from a single greenhouse, further research is needed to evaluate its generalization in complex environments.

Zhang et al. (2024) proposed a cascaded DL network based on YOLOv5 for tomato detection and classification, achieving 82.4% accuracy and 90.9% recall in detecting unobstructed tomatoes. Additionally, the network achieved an average accuracy of 96.9% for tomato ripeness classification and a detection speed of 20 FPS. The validation dataset primarily relied on a single greenhouse scenario, leaving its generalization capability in complex backgrounds insufficiently validated. Furthermore, the analysis of trade-offs between accuracy, stability, and real-time performance for pose classification was inadequate.

Wang et al. (2024b) proposed the NVW-YOLOv8s model for real-time detection and segmentation of tomatoes at three distinct ripeness stages. This model addresses challenges such as sample imbalance, small object detection, and occlusion by introducing a foreground-foreground category balancing method and the C2f-N module, significantly enhancing detection and segmentation performance. The results show that both the mAP@0.5 and F1-Score outperform the baseline model YOLOv8s. However, this study lacks validation of the model's generalization ability across different geographical regions, growth conditions, or tomato varieties.

Wu et al. (2024) proposed a tomato ripeness recognition and stem detection model to address occlusion and overlap issues. The model incorporates CBAM attention and EfficientVMamba modules to enhance feature extraction from tomatoes at different maturity stages and improve small object detection. Experimental results demonstrate that the model achieves higher mAP, precision, recall, and F1 scores than the original YOLOv8n model when identifying tomatoes of varying ripeness in complex environments.

However, due to the limited diversity of scenarios, further validation of robustness and generalization capabilities is lacking.

Zhao et al. (2025) proposed a more lightweight and efficient ripeness detection algorithm, YOLO-DGS, to achieve precise detection of tomato fruit ripeness in natural environments. Experimental results demonstrate that the improved model achieves notable enhancements in inference speed, parameter count, F1 score, recall, and mAP. The study does not explore the lightweight nature or its application on edge devices.

Teng et al. (2025) propose a lightweight improved YOLOv8 model, DS-YOLO, for efficient strawberry fruit detection. By introducing depthwise separable convolutions and a lightweight feature fusion module, the model significantly reduces the number of parameters and computational cost, while maintaining or slightly improving detection accuracy and achieving higher real-time performance.

Experimental results show improvements in mAP@0.5, recall, and precision, while reducing the number of parameters and computational cost. Limited by the relatively small experimental dataset and limited scenarios, the model's generalization ability was not adequately validated. Furthermore, the model's robustness improvement was also limited for small strawberries, dense fruit clusters, and extreme lighting conditions.

The YOLO series are driving the development of detection technology towards real-time, lightweight, and industrial applications thanks to its excellent balance between speed and accuracy, flexible architecture, and complete ecosystem. However, due to its high downsampling and low feature map resolution, the YOLO series algorithms are prone to overlooking small objects or inaccurately locating them. Detection quality tends to degrade when objects are densely packed, overlapping, or when there is strong background interference. Since it relies primarily on manual resolution of class imbalances, its generalization ability is limited, and lightening the model significantly reduces its performance, making it difficult to achieve both accuracy and speed. In the future, it is hoped that solutions or approaches such as integrating Transformers, NAS optimization, and integrated detection-segmentation-tracking functions can further improve the performance of intelligent fruit detection models. Figure 5 shows the mAP of One-stage detectors on COCO dataset.

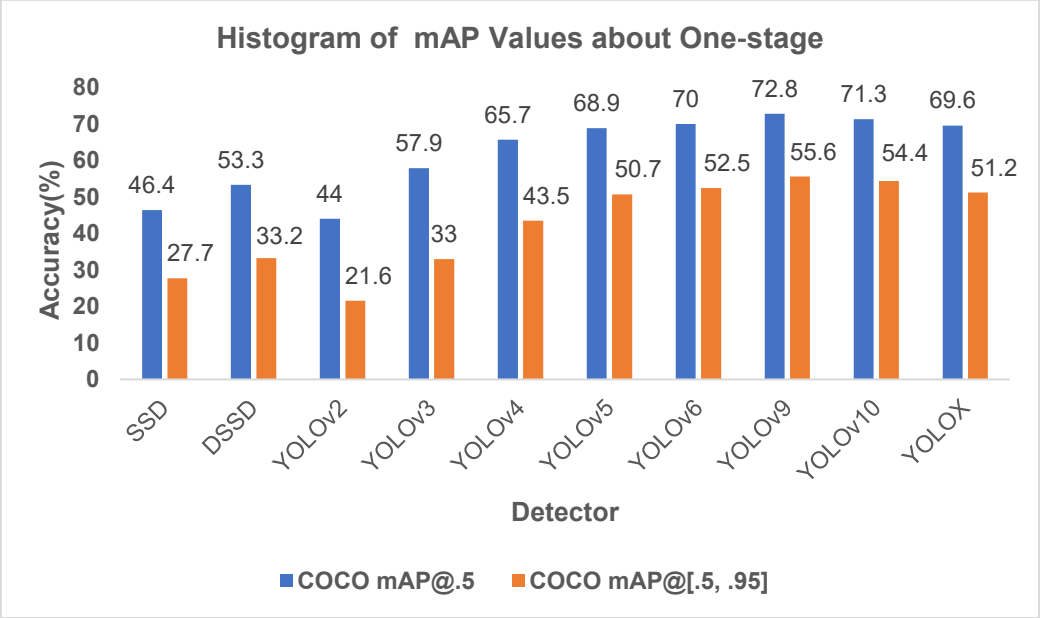

Fig. 5 - The *mAP* of One-stage detectors on *COCO* dataset.

Anchor-Free-Based Detection Algorithm

Although the anchor-free-based algorithm can select positive samples for box regression, it relies on pre-defined boxes and brings some obvious limitations. When too many negative samples are generated, there will be class imbalance; the anchor box of the object class also has the problem of object positioning; the hyperparameters introduced by the anchor box can only be adjusted based on experience, which may be a huge challenge when the workload is large. Based on the idea of eliminating the pre-defined anchor box, the anchor-free-based algorithm is proposed to solve these potential problems. The algorithms can be divided into key-point-based methods and anchor-point-based (also called center-point-based) methods.

Key-point-based detection algorithms use multiple preset keypoints to detect objects and make bounding box predictions based on grouping these keypoints. The first algorithm is CornerNet *(Law H., Deng, J., 2018*), which uses keypoint pairs at the top left and bottom right corners of the bounding box to detect objects and introduces a pooling layer to better locate the bounding box corners. And the CornerNet-Lite *(Law H. et al., 2019*) improves efficiency by introducing an attention mechanism to reduce the number of pixels processed. Then, Matrix networks (xNets) (*Rashwan A. et al., 2019*) provide a lightweight architecture based on scale and aspect ratio, making detection faster. Besides, CenterNet (*Duan K. et al., 2019*) addresses the limitations of CornerNet by adding a third keypoint in the bounding box.

Zhao & Yan (2021) selected the CenterNet framework as the model for solving the problem of fruit detection in digital images. It achieves end-to-end prediction in a single-stage detection process, omitting the candidate box generation step of the traditional two-step method and improving detection speed.

Experiments demonstrate that the model can maintain high detection accuracy even in complex backgrounds, reflecting the potential of CenterNet for small and dense objects. The experiments lack comparisons with more advanced or lightweight models, making it difficult to evaluate their practical advantages in current fruit detection research. Furthermore, the detection capability for multiple categories or fruits of different ripeness levels is not verified to validate the model's generalization ability, and its robustness in occluded, low-light, or multi-view scenarios is not validated. *Wang et al. (2024)* proposed a novel model called CenterNet-LW-SE based on CenterNet. Experimental results show that the model outperforms the original CenterNet in precision, recall, model size, and detection speed, achieving a 2.1% performance improvement while reducing model size by 16.69% and shortening average detection time by 30.40%. It enhances feature representation capabilities to address the challenges of small objects, strong camouflage, and complex backgrounds of camellia fruit in natural environments, particularly excelling in fine-grained feature enhancement. However, the overall model architecture still relies on CenterNet, and it lacks sufficient comparison with more advanced lightweight models (such as YOLOv8n, RT-DETR, and MobileOne), making it difficult to demonstrate its competitive advantage among current lightweight detection frameworks. Generalization validation is insufficient, lacking cross-regional, cross-seasonal, and cross-device dataset testing; model stability requires further verification. Although it claims to be lightweight, it does not provide a complete evaluation of inference time and hardware deployment, lacking edge performance metrics to support its deployment value. *Fan et al (2024)* employed the CenterNet neural network as the detection framework, which improved keypoint prediction accuracy while maintaining low computational cost and achieving a lightweight design. They also implemented structural reinforcement and feature enhancement for complex orchard environments, significantly improving the model's robustness in unstructured environments. Experimental results show that the model achieves an AP of 96.80% on the test set, with 18.91 FPS, a size of only 17.56 MB, and a RMSE of 4.405 mm for localization accuracy. Due to its relatively limited testing scenarios, its generalization and robustness under complex occlusion conditions are an important challenge.

Anchor-point-based detection algorithms use preset anchors and perform detection pixel by pixel. DenseBox (*Huang L. et al., 2015*) is an excellent anchor-point-based detection algorithm. And some years later, the fully convolutional single-stage (FCOS) (*Tian Z. et al., 2019*) model was proposed as a representative model, which uses FPN for multi-level prediction and forces classification of positive and negative anchors, and adds a prediction branch to the classification branch to eliminate the interference of anchors. The FCOS model is not only fast in calculation speed, but also can be customized to meet more requirements.

Liu et al. (2022) propose an accurate detection and segmentation method based on the FCOS object detection model for detecting and segmenting occluded green fruits. Results show that on the apple dataset, the detection and segmentation accuracies for green fruits reach 81.2% and 85.3%, respectively. On the Apple-ape dataset, the detection accuracy and segmentation accuracy reach 77.2% and 79.7%, respectively. The model has 39.7 M parameters and 169.8 G floating-point operations. The model addresses the problem of green fruits easily blending with the background leaves in natural scenes, resulting in weak contrast. An improved model is proposed to significantly enhance the distinguishability of fruits under the "occlusion + same-color background" condition. Combined with enhanced feature extraction and segmentation mechanisms (such as attention modules or multi-scale fusion), it effectively and robustly improves the segmentation boundary quality for fruits with weak texture and partial occlusion. But the model structure is relatively complex and computationally intensive, and the dataset coverage is still limited, so the bottlenecks in lightweight design and adaptability may still exist.

Zhao et al. (2023) propose a novel fruit detection model called FCOS-LSC based on FCOS to better address the challenge of identifying green fruits. This model can directly predict the object's center point and size, avoiding the complexity and parameter tuning issues of traditional anchor-box methods. It effectively enhances the ability to identify low-contrast fruits in complex backgrounds and efficiently identifies and locates green fruit images affected by overlapping occlusion, lighting conditions, and shooting angles. Experiments are insufficient to verify the model's generalization ability under different lighting conditions, different varieties, or multiple fruit categories, indicating room for improvement in robustness. Specific analysis of deployment efficiency, model parameter count, and computational cost is lacking, limiting its guidance for practical mobile or edge applications. Figure 6 shows the mAP of Anchor-free detectors on the COCO dataset.

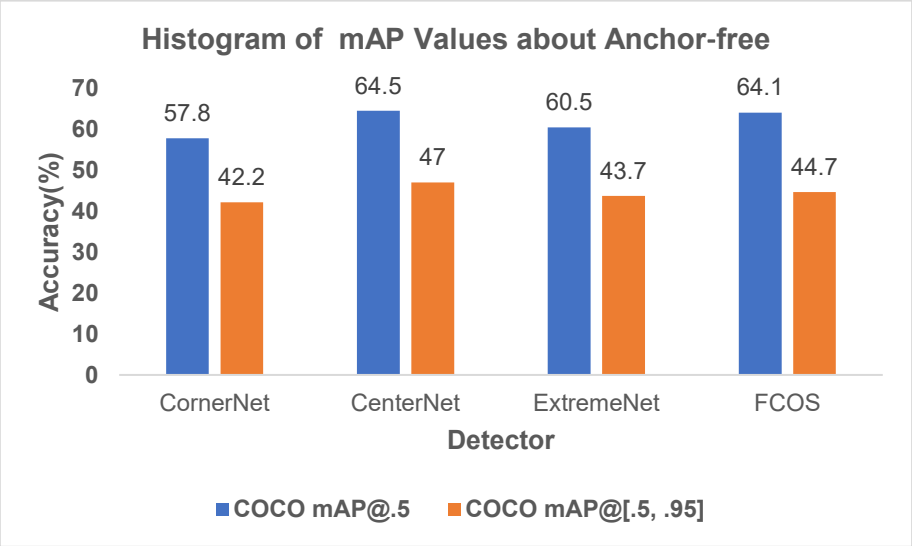

Figure 6. The mAP of Anchor-free detectors on the COCO dataset. There're CornerNet (*Law H., &Deng J., 2018*), CenterNet (*Zhou X. et al., 2019a*), ExtremeNet (*Zhou X. et al., 2019b*), FCOS (*Tian Z. et al., 2019*).

Transformer-Based Detection Algorithm

With the widespread application of the Transformer architecture in the field of CV, object detection technology has achieved a breakthrough. In 2020, the Facebook AI Research team proposed DETR (DEtection TRansformer) (*Carion N. et al., 2020*), which for the first time used a full Transformer structure to achieve end-to-end detection, eliminating traditional modules such as anchors and NMS. DETR has opened up a new path for object detection, especially in complex backgrounds and overlapping occlusions, showing good robustness and high accuracy, and has attracted attention in the field of intelligent agricultural monitoring.

DETR is the first end-to-end framework that introduces the Transformer into object detection. It eliminates NMS and anchor boxes through binary matching, directly outputs detection results, and simplifies the process. The first generation of DETR has high accuracy but slow training and limited small object detection capabilities, which affects the promotion of agricultural applications; the subsequent Deformable DETR *(Zhu X. et al., 2020*) proposed a deformable attention mechanism, introduced deformable convolution to strengthen local feature learning, and only focused on key sampling points, greatly improving small object detection performance and training efficiency; Conditional DETR *(Meng D. et al., 2021*) accelerated training convergence through the conditional cross-attention mechanism, which is faster than DETR; DN-DETR *(Li F. et al., 2022*) proposed a denoising training strategy, accelerated convergence by adding noise queries and reconstructing labels, and enhanced cross-scenario generalization capabilities through dynamic training strategies; DINO (*Zhang H. et al., 2022*) integrated DN-DETR's denoising training and conditional attention to achieve SOTA performance and support few-sample detection; RT-DETR (*Zhao Y. et al., 2024*) was improved based on DINO to achieve real-time end-to-end detection, balance accuracy and speed, and improve model performance; ViDT++ (*Song H. et al., 2021b*) combines visual Transformer and DETR to propose a sparse attention mechanism to achieve efficient detection on high-resolution images (*Zhu X. et al., 2020*). The DETR series is easy to integrate with multi-task learning, supports fruit detection, maturity grading, and size estimation, promotes the integrated development of intelligent monitoring, and is evolving towards lightweight and edge device adaptation, with good industrial application prospects. The Figure 11 shows the architecture of RT-DETR, and Figure 12 shows the mAP values of some classic transfer learning-based object detection models on the coco dataset.

Huang et al. (2024) designed a lightweight Transformer architecture-based pear detection model for natural environments, using the RT-DETR model. The improved model achieves accuracy, recall, and mean accuracy of 93.7%, 91.9%, and 98%, respectively. Compared with the original model, the number of parameters, computational cost, and weight memory are reduced by 48.47%, 56.2%, and 48.31%, respectively. This successfully combines the strong feature modeling capabilities of the Transformer with real-time requirements, alleviating the problems of large parameter count and high computational consumption in traditional ViT models. This research does not fully address the issue of insufficient training data, which may affect the model's generalization ability, and its adaptability to scenarios with extreme lighting changes and dense fruit occlusion is insufficient, requiring further strengthening of robustness. The model complexity is still higher than most lightweight CNNs, limiting its feasibility for deployment on low-power MCUs or edge devices with extremely low computing power. *Zhang (2025)* proposed PG-DETR based on DETR for detecting small, occluded early-stage pomegranate fruits in complex orchard environments. Experimental results show that PG-DETR requires only 6.7 million parameters and has a computational cost of 12.4 GFLOPs/s, achieving a mAP50 of 93.37%. Compared to the RT-DETR-R18 baseline model, our model reduces parameters by 66.2%, GFLOPs by 78.2%, and inference speed by 3.2 times, reaching 173.58 FPS. Despite its "lightweight" design, the DETR framework still incurs some computational overhead compared to YOLO-like frameworks, and its deployment advantage on truly low-power devices is not significant. Furthermore, the model's training is highly dependent on factors such as convergence speed and data size requirements, and its generalization ability may still be limited in small-sample agricultural scenarios. *Tang et al. (2025)* proposed a novel multi-scale lightweight DETR (ML-DETR) for the identification of ripe cherry tomatoes. The ML-DETR model achieves an accuracy of 91.36%, an mAP50 of 0.8875, a floating-point computation of 13.9 GFLOPs, and a frame rate of 81.2 FPS, outperforming the original RT-DETR model. This research primarily focuses on ripe fruit detection, with insufficient validation of its generalization ability to immature, occluded, and densely packed fruits, and incomplete coverage of real-world application scenarios. Furthermore, deployment experiments on real-world edge hardware are lacking, and the value of its lightweight design has not been fully validated in terms of actual device power consumption or real-time performance. *Liu et al. (2024)* proposed a green apple detection model based on an optimized deformable DETR. Experimental results show that the improved detection model significantly improves accuracy, with an overall AP of 54.1, an AP50 of 80.4, an AP75 of 58.0, an AP of 35.4 for small objects, an mAP of 60.2 for medium objects, and an AP of 85.0 for large objects. The model, based on a deformable DETR structure optimization, effectively enhances the detection capability for low-contrast, camouflaged objects like green apples, especially performing well in natural environments with leaf shading and complex lighting conditions. However, the experimental comparison range is relatively narrow, mainly focusing on green apples; cross-crop generalization ability was not tested, and scalability and universality are insufficient. Furthermore, the model's actual deployment performance is lacking, and the real-time harvesting or monitoring needs in agricultural scenarios have not been fully validated. Figure 7 shows the mAP values of some classic transfer learning-based object detection models on the coco dataset.

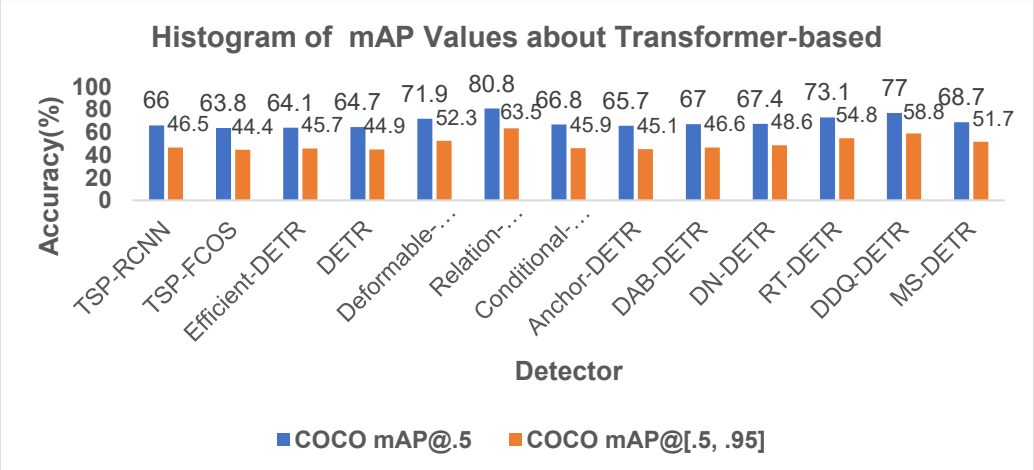

Fig. 7 - The mAP values of some classic Transformer-based detectors on the COCO dataset

They're TSP-RCNN (*Sun Z. et al., 2021*), TSP-FCOS (*Sun Z. et al., 2021*), Efficient-DETR *(Yao Z. et al., 2021*), DETR *(Carion N. et al., 2020*), Deformable-DETR (*Zhu X. et al., 2020*), Relation-DETR (*Hou X. et al., 2024*), Conditional-DETR *(Meng D. et al., 2021*), Anchor-DETR (*Wang Y. et al., 2022*), DAB-DETR (*Liu S. et al., 2022*), DN-DETR *(Li F. et al., 2022*), RT-DETR (*Zhao Y. et al., 2024*), DDQ-DETR (*Zhang S. et al., 2023*), MS-DETR (*Zhao C. et al., 2024*).

Key Challenges

Fruit detection technology can realize automatic fruit recognition, counting, and status analysis through DL algorithms, and is widely used in fields such as yield estimation, intelligent picking, and quality grading. Algorithms such as YOLOv8 and Faster R-CNN achieve a balance between detection accuracy and speed through multi-scale feature fusion and attention mechanism optimization. The Anchor-Free architecture is more adaptable to irregular fruits, and the introduction of the Transformer architecture improves the segmentation of overlapping and occluded objects. Current technology faces challenges such as missed detection of small objects, complex background interference, and insufficient real-time performance. Table 1 shows the main characteristics, advantages, and disadvantages of the backbone networks of some typical object detection models.

Table 1

The main characteristics, advantages, and disadvantages of the backbone networks of some typical object detection models.

Author	Net	Innovations	Advantages	Disadvantages
(Krizhevsky, A. et al., 2012)	AlexNet	The first employed a deep CNN, used sequential convolutional layers, and used a wide sensory field.	First pioneering DL for visual tasks; overall ease of understanding and implementation of the model; significant results for small datasets.	Although a deep network is used, the network has only 8 layers with limited depth; the computational cost of the model is high.
(Simonyan, K., & Zisserman, A., 2014)	VGGNets	Modeled with small convolutional filters (3×3); built a depth architecture; innovative use of miniature convolutional filters.	Strong model performance; performs well across datasets; good at capturing spatial hierarchies.	The model requires high computational power; the number of parameters in the model is large; the model is memory-intensive.
(He, K. et al., 2016)	ResNets	Innovative use of residual connectivity; first use of ultra-deep networks; enables batch normalization of applications.	Effectively mitigates the gradient vanishing problem; the model is highly scalable; it is faster and smaller compared to VGG.	The model requires more computational power; the model is too parameterized; the model is complex to train.
(Szegedy, C. et al., 2017)	Inception-ResNet	Used the Inception module with residual concatenation; established a multi-scale feature extraction mechanism; applied the residual Inception module	The model has more accuracy; the model is very efficient in extracting features; it effectively combines the advantages of Inception and ResNet.	Higher complexity of model architecture; high model requirements on computational resources; smaller range of applications
(Huang, G. et al., 2017)	DenseNets	The model has a compact architecture, and the input of the next layer comes from the output of the previous layer.	The model achieves efficient reuse of features, etc.; the model effectively mitigates the gradient vanishing problem.	Models are memory-intensive; internal connections are complex; memory consumption is high.
(Hu, J. et al., 2018)	SENet	Enables channel-level feature recalibration and lightweight modules	Improved channel interdependency and accuracy while enabling efficient integration with other architectures	Increases computational overhead and thus training time; slower than ResNets
(Tan, M., &Le, Q., 2019)	EfficientNets	A composite scaling method is used; depth separation of the convolution is achieved; and it is lightweight and efficient.	Higher precision and better efficiency with fewer parameters.	Requires tuning of scaling parameters; costly for computation and data movement; one-dimensional scaling only

Author	Net	Innovations	Advantages	Disadvantages
(Wang, C.-Y. et al., 2020)	CSPResNeXt	Implementing partial connectivity across stages, aggregating residual transforms; class does EfficientNet-like scaling	Reduced memory costs while not only maintaining accuracy but also obtaining better inference rates	Increased complexity, long training time, edges, and poor generalization
(Wang, C.-Y. et al., 2021)	CSPDarkNet	Partial connectivity enhancement across phases; available for YOLOv4; efficient feature extraction	Effectively balances speed and accuracy; reduces memory costs; can be used for real-time inspection programs.	Increased design complexity of the architecture leads to reduced ease of use and increased training time.
(Liu, Z. et al., 2022)	ConvNeXt	Simpler architecture with fewer activation and normalization layers	High performance; simple design; good generalization across different datasets	Requires more validation, high computational effort, and high computational power requirements
(Oquab, M. et al., 2023)	DINOv2	A self-supervised vision converter is employed to enable more efficient feature extraction.	Strong generalization ability and self-supervised learning without labeled data	It is data and computation-intensive, with high equipment requirements, while being less effective for small data sets.
(Matszangosz, K.K., &Wendt, M., 2024)	SAM	It's a base model created by the Facebook team that can be used in a wide range of applications.	Highly adaptable and can be used without adjustment or with fine-tuning	Extremely demanding on computing and storage resources, and real-time detection is not currently possible

Difficulty in Dense Detection of Small Objects

In the fruit detection task, “small object dense detection” is a key challenge, where the fruit size is often less than 2%-5% of the image resolution, and in the processing is easy to lose the features, resulting in a decline in the detection accuracy or even failure to detect the object. At the same time, the dense cluster distribution of fruits, accompanied by mutual overlap and branch and leaf occlusion, makes it difficult for the detection network to distinguish between neighboring small objects, and easy to miss detection and false detection. Researchers use multi-scale feature fusion, high-resolution input, attention mechanism, Deformable Convolution, and Transformer feature enhancement to improve the detection of dense small objects *(Bai Y. et al., 2024; Luo Q. et al., 2024; Song H. et al., 2021a*). However, the detection of dense small objects in complex environments is still a bottleneck (*Gong X., &Wu Q.*).

The Effects of Occlusion and Overlap

Fruits grow in the plant, are mostly obscured by leaves, or often grow in clusters and densely, which brings about seriousness between pairs of branches and leaves and fruits, resulting in blurred fruit outlines and making it difficult to distinguish the boundaries, which becomes a key challenge affecting the detection accuracy. Traditional detection methods and early CNN models are difficult to effectively deal with occluded or overlapping objects due to the limited local feature expression capability, and are prone to miss detection and false detection, while networks such as YOLO series and Faster R-CNN can hardly accurately distinguish overlapping objects (*Dalal M., Mittal P., 2025*).

To improve the detection performance, the researchers introduced the attention mechanism to enhance the attention of occlusion area, deformable convolution to improve the ability of local complex morphology perception, combined with instance segmentation to achieve pixel-level differentiation, and utilized the Transformer architecture to enhance the model's understanding of the complex spatial relationship between branches, leaves, and fruits (*Lin Y. et al., 2024; Singh P., Krishnamurthi R., 2024*). Despite these advancements, occlusion and object overlap remain significant challenges affecting detection robustness. Future work should focus on optimizing model architectures and data augmentation strategies to improve detection performance in complex environments.

The Impact of Light Variations

Light variations (e.g., sunlight intensity, shadows, high light reflections, backlighting, and low light) are the key challenges affecting the stability and generalization ability of the detection model, especially more

prominently in the open-air planting and greenhouse transparent coverage models, where the relationship between light and shadow is complex. Under strong sunlight, high light on the fruit surface leads to color distortion; low light or a cloudy environment reduces image contrast and blurs the boundary; under partial shade, the fruit is easily overwhelmed by shadows, which seriously affects the detection accuracy *(Jiang C. et al., 2022*). At the same time, the change of sunlight angle makes the fruit morphology and shadows constantly changing, which puts forward higher requirements on model robustness.

Although the mainstream algorithms have a certain degree of light invariance, there are still performance fluctuations under extreme environments. The researcher has enhanced the light change data, introduced light enhancement broadening, adaptive exposure compensation, attention mechanism, and global modeling ability of the Transformer to alleviate the light and shadow interference *(Dritsas E., 2025*). However, there is still room for improvement in detection performance under strong dynamic lighting scenarios.

The Interference of Complex Background

Different planting environments pose great challenges to the generalization ability and robustness of detection algorithms (*Dickinson S., 2009*). The greenhouse environment can be controlled, with stable light, clean background, the algorithm is easy to achieve high accuracy; while the open-air environment has a complex background, changing light, messy plant branches and leaves, and large differences in fruit morphology, which often leads to the same model in the two scenarios, resulting in performance fluctuations. In addition, the color and maturity of fruits in the open-air environment are greatly affected by natural factors, and the differences between different batches and plots are significant, which can easily lead to misdetection and omission; different planting management methods also increase the difficulty of the model in adapting to changes in spatial layout.

The generalization of the model can be improved to a certain extent through large-scale multi-scene datasets, cross-domain migration learning, style migration, scene adaptive mechanism, and fusion Transformer architecture. However, highly robust detection across scenes, regions, and species is still a challenge that needs to be broken (*Edozie E. et al., 2025*).

DISCUSSION

The Bright Future of Lightweight Networks

In the field of fruit object detection, lightweight networks are becoming an important direction to promote the scale application of smart agriculture. The demand for automated devices (e.g., drones, mobile robots, etc.) in agricultural production has increased, and there is an urgent need for “high-performance + low-computing power demand” detection models (*Zhang P. et al., 2022*). Although traditional high-precision networks have high accuracy, the models are large and energy-consuming, which are not suitable for low-power devices. Lightweight network design is accelerating, striving to balance detection accuracy and operational efficiency. MobileNet, ShuffleNet, SqueezeNet, and other CNN lightweight backbone networks significantly reduce model complexity by means of deep separable convolution, channel rearrangement, etc. MobileNetV3, combined with the optimized design of NAS, has been widely used in tomato detection and grading (*Tan Y. et al., 2025*).

The lightweight versions of the YOLO series (e.g., YOLOv4-Tiny, YOLOv5-Nano, YOLOv7-Tiny, etc.) can be efficiently deployed through pruning optimization and sparse training, with detection speeds up to 30-60 FPS, and are suitable for both embedded and mobile applications (*Li Z. et al., 2024*). Lightweight Transformer architectures (MobileViT) are gradually applied to crop detection, combining global modeling capability and high efficiency, showing good prospects.

The Potential of Transformer Architecture

As a breakthrough DL architecture, Transformer has been extended from NLP to CV by virtue of its powerful global feature modeling capability through the self-attention mechanism, and has been widely used in object detection, yield estimation, and ripening grading, etc. Compared with CNNs, Transformers can effectively capture long-range dependencies in images and improve the robustness and accuracy of detection and grading under complex backgrounds, dense fruit distribution, occlusion, and multi-scale changes. Compared with CNNs, Transformers can effectively capture long-range dependencies in images and improve the robustness and accuracy of detection and grading in complex backgrounds, dense fruit distribution, occlusion, and multi-scale change scenes *(Jackulin C., Murugavalli S., 2022; Zhao Z. et al., 2023*).

The DETR series simplifies the detection process and enhances the detection of small and occluded objects through the query matching mechanism without an anchor, and has already outperformed the traditional YOLO architecture in dense detection scenes.

The Importance of Dataset Construction

In the application of fruit detection, the construction of high-quality datasets is the core foundation to promote technological progress and industrialized applications. Despite the rapid development of DL and Transformer architecture, the lack of standardized data still restricts algorithm performance and generalization ability. Currently, tomato datasets are generally characterized by fragmented data, non-standardized annotations, and a lack of multimodal and multitasking data (*Chen L. et al., 2020*), leading the algorithms into the strange circle of "good results in the laboratory, but difficult to promote in the field".

The variable environment of agricultural scenarios and cultivation management measures leads to high costs and difficulty in data collection and labeling. Data enhancement and simulation data technology are becoming an important means to break through the data bottleneck and improve model robustness. Datasets with high-quality and uniform standards are an important factor in enhancing the generalization ability of models across cultivars and environments (*Akbar J.U.M. et al., 2024*).

The Prospects of Edge Computing

Edge computing has become an important trend as the demand for real-time, portability, and low cost in smart agriculture increases (*Dhiman P. et al., 2023*). Compared with traditional cloud computing, edge computing processes data directly on local devices such as cell phones, drones, and robots, reducing transmission latency, enhancing system real-time and stability, and adapting to complex and changing agricultural environments (*Sathyadhas G.N. et al., 2025*).

Smartphones have become mainstream edge computing terminals due to their powerful computing power (GPU/ NPU), convenience, and low cost. With lightweight models (e.g., MobileNet, YOLOv5-Nano, MobileViT) and AI frameworks (TF Lite, N-CNN), cell phone apps can realize real-time fruit detection and grading, and support intelligent management in the field (*Zheng H. et al., 2025*). With the help of high-performance edge equipment, lightweight Transformer, and NAS-optimized network, object detection technology will be available to everyone and everywhere, promoting smart agriculture to a new stage of universality and efficiency (*Liu H.I. et al., 2024*).

CONLCUSIONS

This paper systematically reviews the applications and significant advancements of CV and DL in fruit detection. Fruit detection technology has rapidly evolved from traditional algorithms to advanced architectures such as CNNs, YOLO, and DETR. However, this analysis shows that these technologies all face specific trade-offs in practical applications. While traditional CNNs provide reliable feature extraction benchmarks, their computational redundancy often fails to meet the real-time requirements of mobile devices. Single-stage detectors like YOLO, by sacrificing some fine-grained accuracy, greatly improve inference speed, making them the preferred choice for edge computing; however, their performance tends to bottleneck when dealing with densely clustered or severely occluded small target fruits. Conversely, Transformer-based models (such as DETR), with their global attention mechanism, have demonstrated breakthrough accuracy in solving complex occlusion problems, but their large number of parameters and high computational cost remain the biggest obstacles to their widespread deployment on low-power agricultural devices. Therefore, at this juncture, finding the optimal balance between computational efficiency and the ability to understand complex scenarios is the core challenge currently facing practical applications. To overcome the limitations of the aforementioned single model, experts and scholars are exploring and attempting to integrate lightweight architecture with the Transformer mechanism to reshape the research paradigm in this field. This hybrid network design not only addresses the low-cost requirement for easy deployment at the edge but also ensures high detection accuracy in complex environments, making it an inevitable trend for the true implementation of smart agriculture.

ABSTRACT

Automatic orientation and conveying are critical to enhancing the operational efficiency of postharvest cabbage commercial processing (e.g., trimming), reducing labor input costs, and boosting commodity added value. To address this demand, this study presents the optimal design of an automatic orientation and conveying device for postharvest cabbages based on conical treads, leveraging the moment of inertia principle. Through dynamic modeling and analysis, the key structural parameters governing orientation performance and their feasible ranges were quantified. Furthermore, the orientation reliability of the proposed structure was validated via ADAMS-based motion simulation. A prototype of the postharvest cabbage orientation and conveying device was fabricated, and parameter optimization experiments were conducted to determine the optimal operating conditions. The results indicate that the device achieves superior operational performance when the orientation roller angle is set to 20°, the axial clearance is 60 mm, and the conveying chain linear speed is 300 mm/s. Under these optimal parameters, the orientation success rate of postharvest cabbages reaches 98.67 ± 1.05%, with an orientation angle deviation of 5.18 ± 0.39°. This design remarkably improves the orientation and conveying precision of postharvest cabbages, laying a solid theoretical foundation and providing technical support for subsequent commercial processing operations such as root cutting.

摘 要

自动定向输送可有效提升采后甘蓝整修等商品化处理的作业效率，减少人工成本，提升其商品附加值。本文根据转动惯量原理优化设计了一种基于圆锥踏面的采后甘蓝自动定向输送装置，通过动力学分析确定了影响定向效果的关键结构参数及范围，并基于 ADAMS 运动仿真分析进一步验证了该结构的定向可行性。搭建采后甘蓝定向输送装置样机并进行参数优化试验，结果表明：定向辊锥度角度为 20°，轴向间隙为 60 mm，输送链条线速度为 300 mm/s 时作业效果最佳，采后甘蓝定向成功率为 98.67±1.05%，其夹角为 5.18±0.39°，进一步提升了采后甘蓝的定向输送性能，为后续根茎整修等商品化处理提供理论依据和技术支撑。

INTRODUCTION

Cabbage is one of the most widely cultivated and consumed vegetables in China. In 2024, its cultivation area amounted to 1.03×10^6 hectares with a total yield of 3.68×10^7 tons (*FAO, 2026*). Commercial processing represents an effective means to elevate the commodity added value of postharvest cabbage, and automatic orientation and conveying constitutes a pivotal procedural step in this workflow (*Du et al., 2019; Xiong et al., 2025*). Specifically, this process entails adjusting randomly arranged cabbages into a standardized posture via external force intervention, thereby facilitating subsequent postharvest operations including trimming, grading, packaging and storage (*Cui et al., 2023*).

Currently, scholars at home and abroad have conducted extensive relevant research in the field of automatic orientation and conveying for postharvest fruit and vegetable processing. Nevertheless, the majority of these studies focused on small and medium-sized spherical fruits and vegetables.

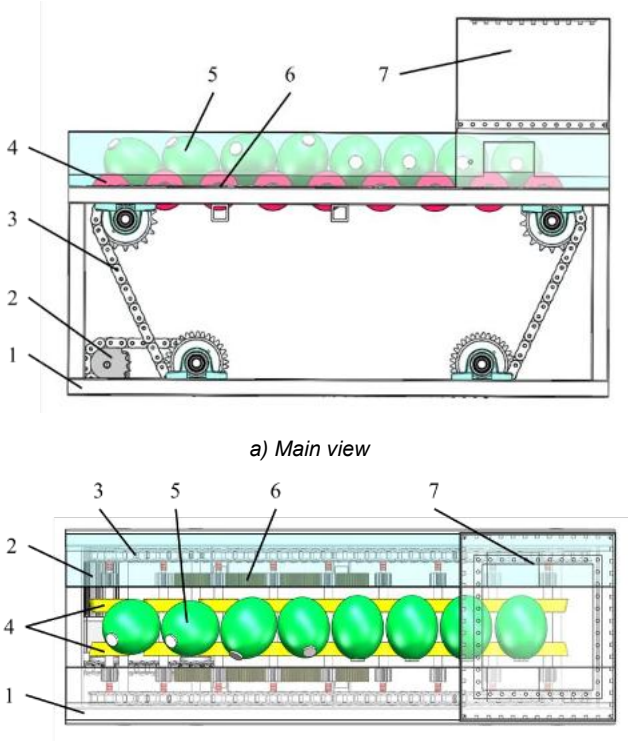
Bennedsen et al., (2005), developed an apple orientation and rotation device based on the differences in physical characteristics between apple stalks and calyxes. On this basis, *Li et al., (2009)*, added freely rotatable positioning wheels to adapt to apples of different diameters. Moreover, *Lefcourt et al., (2008, 2009)*, proposed an automatic apple orientation method based on two parallel tracks, which relies on the rotational inertia effect.

Mizushima and Lu., (2013), found that the orientation of apples could also be achieved using a double-cone roller structure. *Li et al., (2014)*, utilized the offset center-of-gravity position of lychees and the structural characteristics of curved rollers to realize automatic posture adjustment and single-row oriented conveying of lychees through counter-rotating rollers.

Kang et al., (2017, 2018), employed the rolling friction effect to keep jujubes in a stable state with minimum momentum during rotation, thereby gradually achieving sequential oriented arrangement of individual jujubes.

Zheng et al., (2015), adopted a pair of rollers with different diameters and a certain inclination angle to realize the oriented conveying of peppers. Considering the significant differences in the three-axis dimensions of fresh apricots and their symmetry along the suture plane, *Liu et al., (2012, 2016)*, proposed a differential belt-type dynamic orientation and conveying method based on the minimum action principle of space geometry.

Lin et al., (2017), optimized the design of a strawberry guiding roller with an hourglass-like geometric structure; strawberries completed the orientation process at the depressions between two adjacent rollers.



Wang et al., (2020), designed an oriented arrangement vertical and horizontal cutting machine suitable for large-scale processing of potato seed tubers, whose orientation arrangement device can effectively adjust the position and posture of seed tubers. However, unlike the aforementioned small and medium-sized quasi-spherical fruits and vegetables, cabbage presents structural characteristics of non-homogeneous mass distribution and axial offset of the mass center (*Cui et al., 2020*). Conventional cylindrical rollers fail to satisfy the automatic orientation requirements of cabbage. Hence, a novel orientation device is proposed, which can counteract the eccentric effect of cabbage's mass center through lateral friction torque.

To further enhance the orientation and conveying performance of postharvest cabbage, this study proposed an automatic orientation and conveying method for postharvest cabbage based on conical treads, building on previous research findings (*Cui et al., 2020; Zheng et al., 2021; Wang et al., 2021*). Conical rollers feature tapered surfaces with variable diameters. The constraint space formed by such rollers generates lateral friction torque on cabbages to counteract the influence induced by the axial offset of cabbage's mass center. Under the combined effect of the moment of inertia and the principle of minimum action, cabbages are guided to rotate stably around their minimum inertia axis, delivering superior automatic orientation performance. Through dynamic analysis, the key structural parameters and their feasible ranges affecting the orientation effect were determined, followed by the implementation of ADAMS motion simulation. Subsequently, a prototype of the postharvest cabbage orientation and conveying device was fabricated, and parameter optimization experiments were conducted to obtain the optimal combination of operating parameters. This research provides a solid theoretical basis and technical support for subsequent commercial processing operations of postharvest cabbage, such as root cutting.

MATERIALS AND METHODS

Automatic orientation and conveying device for postharvest cabbage based on conical treads

Automatic orientation and conveying device for postharvest cabbage based on conical treads was simplified as illustrated in Figure 1. It is composed of a frame, a drive motor, a chain transmission mechanism, a conical tread orientation roller group, a rack-and-pinion pair, an image detection mechanism, and other auxiliary components. Among these components, the conical tread orientation roller group comprises orientation rollers symmetrically fixed on the roller shaft. Gears engaged with the rack for transmission are symmetrically installed on the outer side of the roller shaft. Both ends of the roller shaft are connected to the chain transmission mechanism through couplings. Both the rack and the chain transmission mechanism are fixedly mounted on the frame.

Fig.1 - Schematic diagram of the structure of an automatic orientation conveying device for postharvest cabbage based on conical treads

1 – Rack; 2 – Drive motor; 3 – Chain transmission mechanism; 4 – Conical tread orientation roller group; 5 –Postharvest cabbage; 6 – Rack and pinion pair; 7 – Image detection mechanism.

Specifically, the drive motor drives the chain transmission mechanism to operate backward at a constant speed. Through the couplings, the conical tread orientation roller group is also driven to move backward at a constant speed. Meanwhile, under the drive of the rack-and-pinion pair, the conical tread orientation roller groups rotate passively, and adjacent conical tread orientation roller groups form a stable orientation space. According to the kinematic transmission relationship, a conversion relationship exists between the linear velocity of the conveying chain and the angular velocity of the rollers, as expressed in Eq. (1).

$$v = \omega r \tag{1}$$

where v is the linear velocity of the conveying chain, [m/s]; ω is the angular velocity of the rollers, [rad/s]; r is the pitch radius of the pinion in the rack-and-pinion pair, [m].

When postharvest cabbages fall into this orientation space, the conical tread orientation rollers exert forces on them, enabling the cabbages to achieve automatic orientation under the combined action of rotational inertia and the principle of minimum action, and then be conveyed backward under the drive of the chain transmission mechanism. When the gears leave the action area of the rack, no external force acts on the conical tread orientation rollers. Under the action of gravity and friction, the conical tread orientation rollers form a stable state with the oriented cabbages and continue to be conveyed backward. Finally, the cabbages reach the area of the image detection mechanism, where pose images are collected to evaluate the orientation effect, providing data support for subsequent commercial processing such as trimming.

Kinematics analysis of postharvest cabbage orientation

The conical tread possesses excellent self-centering and curve-guiding capabilities (*Zhong et al., 2016; Ren et al., 2010*). Furthermore, the orientation movement of postharvest cabbage on this structure conforms to the principles of moment of inertia and least action. Therefore, the orientation kinematics of postharvest cabbage was analyzed, as illustrated in Figure 2, and the structure was optimized to enhance the orientation and conveying performance of postharvest cabbage. At this point, the postharvest cabbage on the conical tread orientation roller group is subjected to the combined action of its own gravity, as well as the supporting force and frictional force from each conical tread orientation roller rotating in the same direction at the same speed. As a result, it gradually achieves stable rotational motion around its central axis, and the circumferences of the trajectories of the two contact points formed between the cabbage and the conical tread orientation rollers are equal.

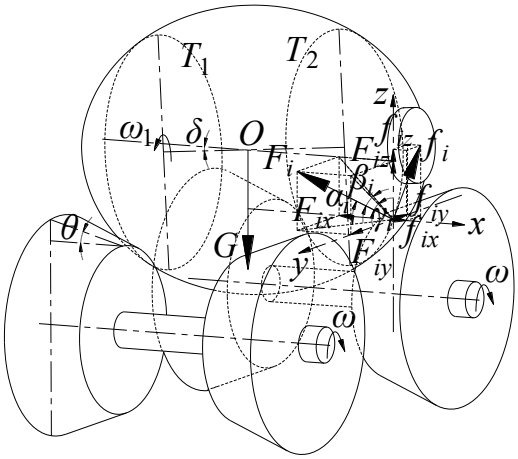

Fig. 2- Force analysis of postharvest cabbage movement on the conical tread orientation roller groups

Note: F_i denotes the support force exerted by the conical tread-oriented roller on postharvest cabbage, while f_i represents the frictional force exerted by the roller wheel on postharvest cabbage. F_{ix}, F_{iy}, and F_{iz} denote the component forces of the support force along the x, y, and z axes respectively, whereas f_{ix}, f_{iy}, and f_{iz} denote the component forces of the frictional force along the x, y, and z axes respectively. G denotes the gravitational force of the postharvest cabbage itself, ω represents the rotational angular velocity of the roller, ω_1 denotes the rotational angular velocity of the postharvest cabbage, α_i, β_i, γ_i denote the angles between the support force and the planes of the three coordinate axes respectively, θ denotes the taper angle of the roller, δ denotes the angle between the central axis of the postharvest cabbage and the roller axis, T_1 and T_2 denote the motion trajectories of contact points between the postharvest cabbage and the conical tread-oriented roller, and O represents the center of mass of the postharvest cabbage.

In this state, the postharvest cabbage moves dynamically and stably on the conical tread orientation rollers; that is, the force system within its rigid-body inertial force system reaches equilibrium. Therefore, it can be concluded that:

$$\sum M_x = \sum M_e + \sum M_{Ix} = 0 \tag{2}$$

where: M_x is the torque generated by postharvest cabbage rotating about the x-axis at angular velocity ω_x, [N·m]; M_e is the torque produced by external forces when postharvest cabbage rotates about its central axis, [N·m]; M_{Ix} is the principal moment of inertia of postharvest cabbage in the inertial coordinate system, [N·m].

As shown in Figure 2, the instantaneous forces acting on the postharvest cabbage in all directions have reached equilibrium. Furthermore, the angle between the support force exerted by the conical tread orientation roller on the postharvest cabbage and the component force at its point of contact is equal to the taper angle of the conical tread orientation roller. Therefore, when the postharvest cabbage rotates about its central axis, the torque generated by the external force is:

$$M_e = \sum \left| \vec{f}_{iy} + \vec{f}_{iz} \right| L_i = \mu_0 \sum F_i \cos\gamma_i L_i = \mu_0 \sum F_i \cos\theta L_i \tag{3}$$

where: f_{iy} and f_{iz} are the components of the friction force exerted by the conical tread-oriented roller on the postharvest cabbage along the y and z axes respectively, [N]; L_i is the perpendicular distance from the contact point between the postharvest cabbage and the roller to the rotational axis, [m]; μ_0 is the coefficient of friction between the roller and the postharvest cabbage; F_i is the support force exerted by the roller on the postharvest cabbage, [N]; γ_i is the angle between the support force and the component force at the contact point's cross-section, [°]; θ is the taper angle of the roller, [°].

Meanwhile, based on the theorem of motion of the center of mass and D'Alembert's principle in the center-of-mass frame, the rigid-body inertial force system of postharvest cabbage is simplified. The calculation methods for the principal vector of the inertial forces of the particle system and the principal moment of the inertial forces about the central axis are given in Eq. (4).

$$\begin{cases} \vec{F}_{IO} = \sum \vec{F}_{Ii} = -m\vec{a}_O \\ M_{Ix} = \sum M_x(F_{Ii}^{\mathrm{n}}) + \sum M_x(F_{Ii}^{\mathrm{t}}) \end{cases} \tag{4}$$

where: F_{I0} is the principal vector of the inertial force of the particle system, [N]; F_{Ii} is the inertial force of the center of mass of the postharvest cabbage, [N]; m is the mass of the postharvest cabbage, [kg]; a_O is the acceleration of the center of mass, [m/s]; F_{Ii}^{n} is the normal component of the inertial force of the center of mass

of the postharvest cabbage, [N]; F_{Ii}^{t} is the tangential component of the inertial force of the center of mass of the postharvest cabbage, [N].

Among these, the magnitudes of the various components of the inertial forces acting on the postharvest cabbage pith are as follows

$$\begin{cases} F_{Ii}^{\mathrm{t}} = m_i a_i^{\mathrm{t}} = m_i r_i \alpha \\ F_{Ii}^{\mathrm{n}} = m_i a_i^{\mathrm{n}} = m_i r_i \omega_1^2 \end{cases} \tag{5}$$

where: m_i is mass of any particle in the postharvest cabbage, [kg]; a_i^t is tangential component of acceleration for that particle, [m/s]; r_i is perpendicular distance from a given particle in the postharvest cabbage to the rotational axis, [m]; α is angular acceleration of the postharvest cabbage rotating about its central axis, [rad/s²]; a_i^n is normal acceleration component of the particle, [m/s]; ω_1 is angular velocity of the postharvest cabbage around the x-axis under slight disturbance, [rad/s].

As previously established, postharvest cabbage undergoes stable rotational motion about its central axis on the conical tread orientation roller group assembly, with its center of gravity positioned along the central axis. Therefore, it follows that:

$$\begin{cases} F_{IO} = 0 \\ \sum M_x(F_{Ii}^{\mathrm{n}}) = 0 \end{cases} \tag{6}$$

According to the simplified mathematical model of postharvest cabbage, the moments of inertia in the three directions of the x, y, and z axes can be calculated, and it can be obtained that:

$$\begin{cases} I_x = \dfrac{1}{5}\rho_2 V\left(b^2+c^2\right) + \dfrac{1}{2}V_1\left(\rho_1-\rho_2\right)r^2 \\ I_y = \dfrac{1}{5}\rho_2 V\left(a^2+c^2\right) + \dfrac{1}{2}V_1\left(\rho_1-\rho_2\right)\left(\dfrac{1}{6}\left(3r^2+h^2\right)+2\left(a-\dfrac{h}{2}\right)^2\right) \\ I_z = \dfrac{1}{5}\rho_2 V\left(a^2+b^2\right) + \dfrac{1}{2}V_1\left(\rho_1-\rho_2\right)\left(\dfrac{1}{6}\left(3r^2+h^2\right)+2\left(a-\dfrac{h}{2}\right)^2\right) \end{cases} \tag{7}$$

where: *Ix, Iy, and Iz* are moments of inertia of postharvest cabbage along the x, y, and z axes respectively, [kg·m²]; V is volume of postharvest cabbage, [m³]; V_1 is volume of the central column, [m³]; ρ_1 is density of the central column, [kg/m³]; ρ_2 is density of the head, [kg/m³]. The density of the above two tissue structures was calculated following the method proposed by *Zheng et al., 2021*, and their volumes were measured via the water displacement method; r is radius of the central column, [m]; h is length of the central column, [m]*; a, b* and c are radii of the postharvest cabbage along the x, y, and z axes, respectively, [m].

By combining Eqs. (4) to (7), the following expression is obtained:

$$M_{Ix} = \sum M_x(F_{Ii}^{\mathrm{t}}) = -\sum F_{Ii}^{\mathrm{t}} \cdot r_i = -\sum (m_i r_i^2)\alpha = -I_x\alpha = -\left[\frac{1}{5}\rho_2 V\left(b^2+c^2\right) + \frac{1}{2}V_1\left(\rho_1-\rho_2\right)r^2\right]\alpha \tag{8}$$

By combining Eqs. (2) to (8), the following expression is obtained:

$$\alpha = \frac{10\mu_0 \sum F_i \cos\theta L_i}{2\rho_2 V\left(b^2+c^2\right) + 5V_1\left(\rho_1-\rho_2\right)r^2} \tag{9}$$

In addition, for the conical tread orientation roller set to achieve orientation operation, it should meet the basic geometric position relationship and have no assembly interference. That is, postharvest cabbage in random orientations should not fall off during transport. Meanwhile, to ensure smooth execution of subsequent rhizome cutting, the rhizomes of postharvest cabbage must be positioned outside the conical tread orientation roller group. Therefore, the structural design and spatial arrangement of the conical tread orientation roller must meet these functional requirements:

$$\begin{cases} \min(D_x, D_y) > D_{\min} > D_A - D_R \\ \min(H) > C_A + 2T_R > \min(D_x, D_y) > C_A \\ D_A > D_R + 2T_R \tan\theta \end{cases} \tag{10}$$

where: D_x is the postharvest cabbage transverse diameter, [mm]; D_y is the postharvest cabbage longitudinal diameter, [mm]; D_{min} is the minimum diameter of the contact point trajectory between postharvest cabbage and roller, [mm]; D_A is center distance between axes of conical tread-oriented rollers, [mm]; D_R is Inner diameter of roller, [mm]; H is plant height of postharvest cabbage, [mm]; C_A is axial clearance of roller, [mm]; T_R is thickness of roller, [mm].

Calculated from Eq. (10):

$$\begin{cases} \theta < \arctan\left[\dfrac{\min(D_x, D_y)}{2T_R}\right] \\ \min(D_x, D_y) - 2T_R < C_A < \min(H) - 2T_R \end{cases} \tag{11}$$

Eqs. (9) and (11) demonstrate that during postharvest cabbage orientation on the conical tread orientation roller assembly, its motion state is influenced not only by the physical parameters of the cabbage itself but also by structural parameters such as the taper angle of the conical tread orientation roller and its positional relationship. This provides a theoretical basis for selecting factors in subsequent experiments aimed at optimizing the automatic orientation parameters for postharvest cabbage.

Simulation and Analysis of Orientation Movement of Postharvest Cabbage Based on ADAMS

Firstly, SolidWorks software was employed to establish a three-dimensional simulation model for the orientation motion of postharvest cabbage. By integrating the physical parameters of postharvest cabbage with the results of orientation kinematic analysis, the inner diameter of the conical tread orientation roller was determined to be 70 mm, with a taper angle of 20° and a thickness of 30 mm. The structural parameters of the roller were derived from the optimal parameter combinations reported in previous studies (*Cui et al., 2020; 2021*), with the radial and axial clearances set at 50 mm and 60 mm, respectively. Furthermore, postharvest cabbage was modeled as an isotropic elastic body (*Duet et al., 2019*) and simplified into two components: a central stem solid and a head solid. Both the physical parameters and material properties were kept consistent with the settings in *Cui et al., (2020),* to better verify the orientation performance of the conical tread orientation roller assembly. Subsequently, this three-dimensional model was converted into the universal IGS format and imported into ADAMS software. The simulation model for the orientation movement of postharvest cabbage is shown in Figure 3.

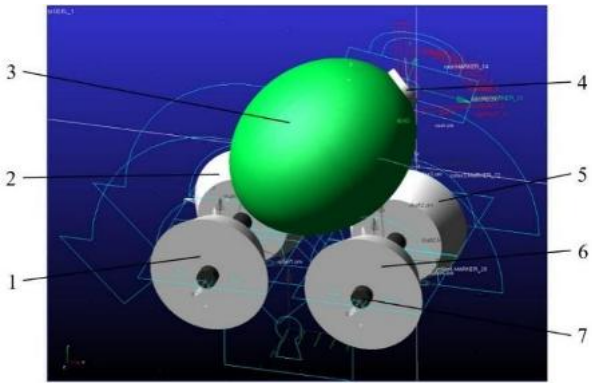

Fig. 3 - Postharvest cabbage automatic orientation simulation model

1 – Conical tread orientation roller 1; 2 – Conical tread orientation roller 2; 3 – Blade ball; 4 – Central column; 5 – Conical tread orientation roller 3; 6 – Conical tread orientation roller 4; 7 – Support shaft.

The simulation analysis workflow for postharvest cabbage orientation essentially followed that of *Cui et al.*, *2020*, with the specific steps outlined below:

(1) Material definition. The material properties of key components, including the orientation roller, leaf head, central stem, and support shaft, were set.

(2) Motion constraint conditions. Constraints were added to the conical tread orientation roller model, including fixed pairs, rotating pairs, drive mechanisms, and contact forces. The impact function method was adopted to define the contact forces between the central stem and head of postharvest cabbage and the roller.

The stiffness coefficient, collision index, maximum damping coefficient, static friction coefficient, and dynamic friction coefficient were set to 278 N/mm, 1.5, 0.3 N·s/mm, 0.5, and 0.48, respectively (*Zheng et al., 2021*).

(3) Marker point addition. One marker point was selected at the center of the base of the central stem and another at the center of the head, designated as point A (x_1, y_1, z_1) and point B (x_2, y_2, z_2), respectively. Both marker points are located along the central axis of postharvest cabbage.

(4) Motion parameter configuration. The initial pose of postharvest cabbage was divided into 26 distinct configurations (*Cui et al., 2020*) for simulation testing. The drive parameters were set to 12.00 rad/s, 15.00 rad/s, and 18.00 rad/s, respectively. The simulation duration was uniformly set to 10.0 seconds, with 500 simulation steps for each configuration.

(5) Orientation metric calculation method. In this study, orientation was analyzed solely based on the angle between the central axis of postharvest cabbage and the axis of the conical orientation roller, which was calculated according to Eq. (12).

$$\begin{cases} \delta = \arccos\left|\dfrac{l_{AB}^2 + l_{AC}^2 - l_{BC}^2}{2 l_{AC} l_{AB}}\right| \\ l_{BC} = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2 + (z_1 + k - z_2)^2} \\ l_{AC} = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2 + (z_1 + k - z_1)^2} = k \\ l_{AB} = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2 + (z_1 - z_2)^2} \end{cases} \quad (12)$$

where: δ is angle between the central axis of the postharvest cabbage and the roller axis, [°]; l_{BC}, l_{AC} *and* l_{AB} are lengths of line segments BC, AC, and AB respectively, [mm]; wherein the parameter *k* of the marked point *C* (x_1, y_1, $z_1 + k$) is a constant value set at 150 (*Cui et al., 2020).*

Automatic orientation performance optimization test based on conical treads

Based on the aforementioned kinematic and simulation analyses of the automatic orientation of postharvest cabbage using conical treads, a conical tread orientation conveying device for postharvest cabbage was designed and trial-manufactured, as illustrated in Figure 4. A total of 120 postharvest cabbages of the "Zhonggan 15" variety were selected as test samples. Their transverse diameters ranged from 114 to 128 mm, longitudinal diameters from 108 to 124 mm, plant heights from 132 to 155 mm, masses from 527 to 795 g, and sphericities from 87% to 94%.

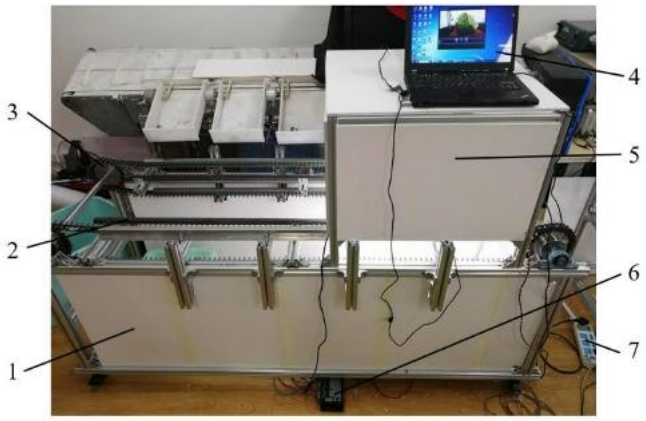

Fig. 4 - Prototype of a Postharvest Cabbage Cone-Tread Oriented Conveying Device

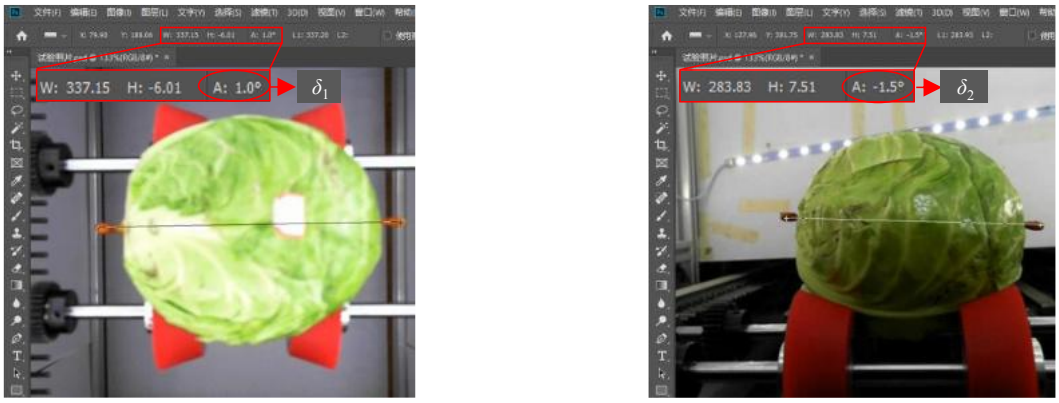
1 – Frame; 2 – Rack and pinion assembly; 3 – Chain drive mechanism; 4 – Laptop computer; 5 – Image acquisition system; 6 – Motor control system; 7 – Power supply.

In addition, the test equipment included a digital vernier caliper (accuracy: 0.01 mm, measuring range: 0–300 mm, manufactured by AIRAJ, Germany) and an AR926 laser tachometer (accuracy: ±0.05%, measuring range: 2.5–99999 r/min, manufactured by Dongguan Wanchuang Electronic Products Co., Ltd., China).

In this experiment, an orthogonal test was carried out with the taper angle of the conical tread orientation roller, the axial clearance, and the linear velocity of the conveyor chain as experimental factors, and the orientation angle of postharvest cabbage and the orientation success rate as experimental indicators, with details shown in Table 1.



The taper angle of the conical tread orientation roller was adjusted by replacing custom-made rollers with different taper angles, where the inner diameter and thickness of the rollers were fixed at 70 mm and 30 mm, respectively. The axial clearance was measured and adjusted using a digital vernier caliper, while the linear velocity of the conveyor chain was regulated by measuring the angular velocity of the sprocket with a laser tachometer. Each experimental group consisted of 30 cabbages, and each group was repeated three times; the average value was taken as the final experimental result.

Table 1

Orthogonal Test Factors and Levels for Conical Tread Orientation

Levels	Factors		
	Taper angle (°)	Axial clearance (mm)	Linear velocity of chain (mm/s)
1	10	40	225
2	20	50	300
3	30	60	375

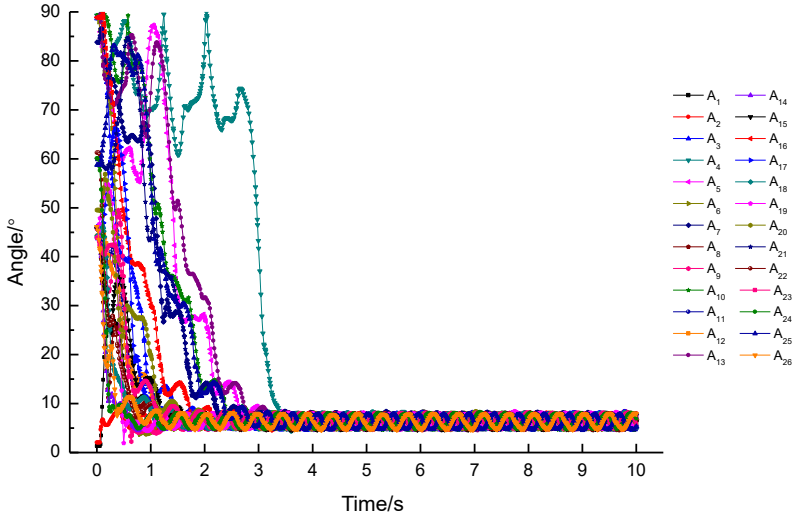
The experimental indicators, including the orientation angle and orientation success rate of postharvest cabbage, were calculated based on the calibration results of the angle between the central axis of postharvest cabbage and the axis of the rollers, which were obtained from the top-view and side-view images using Photoshop software. This measurement method was consistent with that reported by *Cui et al., (2020)*, as illustrated in Figure 5.

(a) Included angle from top-view δ_1 (b) Included angle from side-view δ_2

Fig. 5 - Method for determining the orientation angle of postharvest cabbage on a conical tread orientation roller

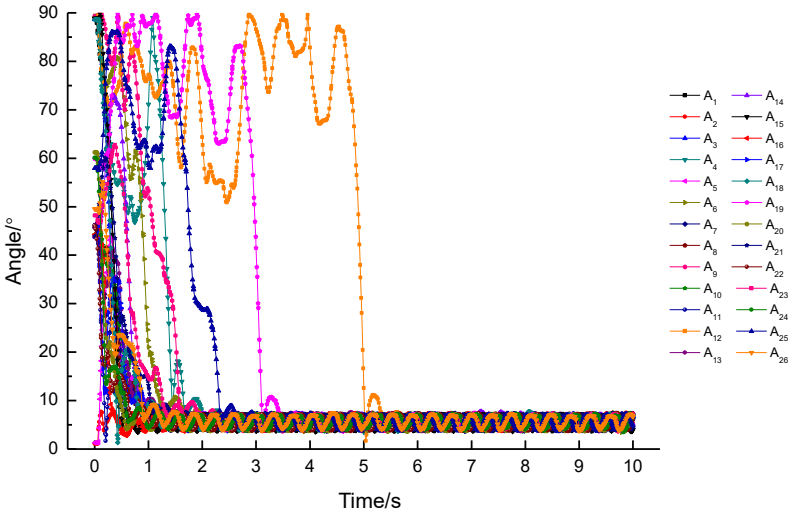
The calculation methods for the cabbage angle and orientation success rate are shown in Eqs. (13) and (14).

$$\delta = \arcsin\sqrt{\frac{\tan^2\delta_1 + \tan^2\delta_2}{1+\tan^2\delta_1 + \tan^2\delta_2}} \tag{13}$$



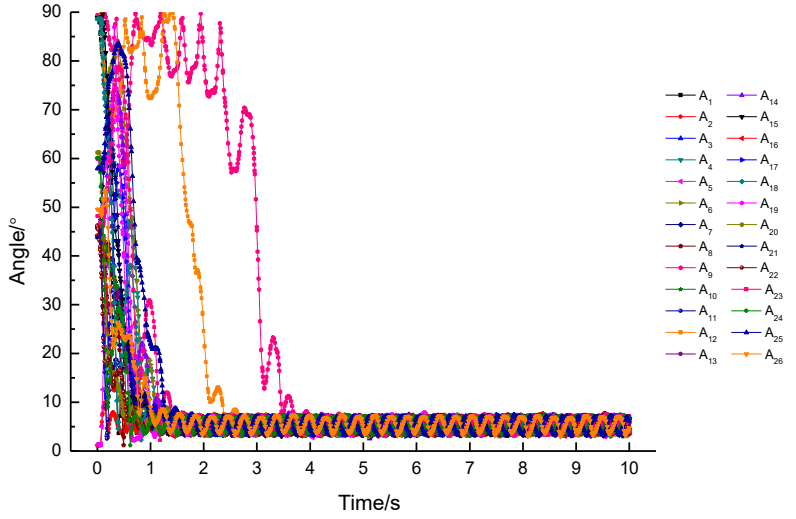
$$\eta_o = \frac{n_o}{N}\times 100\% \tag{14}$$

where: η_o is postharvest cabbage orientation success rate, [%]; n_o is number of postharvest cabbage achieving successful orientation (rotating around their central axis at a relatively small and stable angle), [heads]; N is total number of postharvest cabbage, [heads].



RESULTS

Analysis of the Simulation Results on the Orientation Movement of Postharvest Cabbage on Conical Tread Surfaces



The pattern of angular variation during the automatic orientation of postharvest cabbage on the conical tread orientation roller group is illustrated in Figure 6.

(a) Roller angular velocity: 12.00 rad/s.

(b) Roller angular velocity: 15.00 rad/s.

(c) Roller angular velocity: 18.00 rad/s

Fig. 6 - Pattern of Angular Movement Between the Central Axis of Postharvest Cabbage and the Axis of the Conical Orientation Roller

Specifically, as shown in Figure 6(a), the angle stabilizes at 6.62 ± 0.12° when the roller's angular velocity is 12.00 rad/s. The longest time required for angular stabilization is 3.52 seconds (for initial pose A_4). For initial poses A_{13} and A_5, the time required for angular stabilization decreases gradually, while the remaining postharvest cabbage poses take no more than 2.50 seconds to achieve angular stabilization.

Similarly, as shown in Fig. 6(b), the orientation angle of postharvest cabbages stabilized at 5.90 ± 0.07° when the angular velocity reached 15.00 rad/s. The maximum stabilization time was 5.42 s, which was observed for the initial pose A_{12}. For the initial poses A_{19} and A_3, the stabilization time decreased in turn, whereas the orientation angles for all other initial poses stabilized within 2.08 s. As depicted in Fig. 6(c), at an angular velocity of 18.00 rad/s for the conical tread orientation roller group, the orientation angle of postharvest cabbages stabilized at 5.74 ± 0.13°. The maximum stabilization time was 3.76 s for the initial pose A_9; the stabilization time for A_{12} was relatively shorter, and that for all other initial poses did not exceed 1.44 s.

It is worth noting that in the above cases, the initial poses of postharvest cabbages (A4, A12 and A9) that required the longest angular motion stabilization time all corresponded to rotational motion about a principal axis of inertia other than the central axis. Nevertheless, no orientation failure was observed, and all initial poses were successfully oriented. In comparison with the orientation accuracy of cylindrical orientation rollers (6.72 ± 1.23°; *Cui et al., 2020*), the conical tread-based automatic orientation and conveying structure for postharvest cabbages thus exhibits superior orientation performance and efficiency.

Analysis of the experimental results on the performance optimization of automatic orientation based on conical treads

As shown in Table 2, range analysis indicated that the experimental factors affecting the orientation angle of postharvest cabbages were ranked by significance as follows: axial clearance > taper angle > linear velocity of the conveyor chain. The optimal parameter combination for achieving the target orientation angle was determined as $A_2B_3C_3$. Similarly, for the orientation success rate, the factors were ranked by significance in the order of taper angle > axial clearance > linear velocity of the conveyor chain, with the optimal parameter combination identified as $A_2B_3C_2$.

Table 2

Results of Postharvest Cabbage Cone Tread Orientation Orthogonal Experiment

Test number	*A*	*B*	*C*	Orientation angle (°)	Orientation success rate (%)
1	1	1	1	8.39	80.00
2	1	2	2	7.54	81.11
3	1	3	3	5.51	87.78
4	2	1	2	6.63	94.44
5	2	2	3	6.78	90.00
6	2	3	1	6.17	96.67
7	3	1	3	7.72	82.22
8	3	2	1	7.07	90.00
9	3	3	2	5.88	92.22
$k_{\delta 1}$	7.15	7.58	7.21		
$k_{\delta 2}$	6.53	7.13	6.68		
$k_{\delta 3}$	6.89	5.85	6.67		
R_{δ}	0.62	1.72	0.54		
$k_{\eta 1}$	82.96	85.56	88.89		
$k_{\eta 2}$	93.70	87.04	89.26		
$k_{\eta 3}$	88.15	92.22	86.67		
R_{η}	10.74	6.67	2.59		

Note: A is the taper angle of conical roller, B is the axial clearance, C is the linear velocity of the chain.

A comparison of the optimal parameter combinations for the orientation angle and orientation success rate of postharvest cabbages shows consistency in the operational parameters for the taper angle and axial clearance of the conical orientation rollers: specifically, the taper angle at A_2 and axial clearance at B_3. In contrast, a variation was observed in the linear velocity of the conveyor chain.

Notably, the orientation success rate was relatively high at conveyor chain linear velocity C_2, and the orientation angle achieved at this velocity was essentially identical to that obtained at C_3. For this reason, conveyor chain linear velocity C_2 was selected, yielding the overall optimal parameter combination of $A_2B_3C_2$ for the conical orientation of postharvest cabbages.

Meanwhile, analysis of variance (ANOVA) was performed on the test results to judge whether the effect of each factor possessed statistical significance. Specifically, the ANOVA results for orientation deflection angle are listed in Table 3. The F-values of the three factors followed the order axial clearance > taper angle > linear velocity of the conveyor chain, which was entirely consistent with the factor sequence obtained from range analysis. Nevertheless, all F-values were far lower than the critical value at the significance level of 0.05. This indicated that within the parameter range selected for the test, none of the three factors induced statistically significant differences in the orientation angle. This phenomenon could be attributed to the compensation effect among different factor levels a smaller axial clearance can make up for the insufficient lateral friction torque for automatic orientation generated by rollers with a small taper angle, which restrains drastic fluctuations of cabbage orientation deflection angle as a whole and ultimately weakens the statistical discrimination ability of a single factor.

Table 3

ANOVA Results of Orientation Angle

Factors	Sum of squares	Freedom	*F* value
A	0.582	2	0.293
B	4.814	2	2.421
C	0.569	2	0.286
Error	5.965	6	

The ANOVA results for orientation success rate are presented in Table 4. The sequence of F-values follows taper angle > axial clearance > linear velocity of the conveyor chain, consistent with the ranking derived from range analysis. The surface structure of conical rollers directly determines the lateral friction torque for automatic orientation that corrects the posture of cabbages, so the roller taper angle always acts as the dominant control variable to achieve stable orientation. However, the F-values of all factors remain below the critical value corresponding to the significance level of 0.05. This implies that within the parameter range set in this study, none of the factors exhibited a significant regulatory effect. Subsequent research can appropriately expand the value interval of factor levels and add more gradient levels to further explore their underlying influence rules.

Table 4

ANOVA Results of Orientation Success Rate

Factors	Sum of squares	Freedom	F value
A	173.091	2	2.009
B	73.591	2	0.854
C	11.786	2	0.137
Error	258.468	6	

Optimal parameter combination trial validation

Sixty randomly selected Zhonggan 15 cabbages were used as experimental samples to verify the postharvest orientation performance of the conical tread orientation and conveying device for postharvest cabbages, which was operated at a taper angle of 20°, an axial clearance of 60 mm, and a linear velocity of 300 mm/s for the conveyor chain. The experimental results are summarized in Table 5.

Table 5

Postharvest Cabbage Cone Tread Orientation Validation Test Results

Test number	Number of cabbage successfully orientated (piece)	Orientation success rate (%)	Orientation angle (°)
1	59	98.33	5.37
2	59	98.33	5.14

Test number	Number of cabbage successfully orientated (piece)	Orientation success rate (%)	Orientation angle (°)
3	60	100	4.53
4	59	98.33	5.39
5	59	98.33	5.92
6	60	100	4.81
7	60	100	5.47
8	59	98.33	5.04
9	58	96.67	5.2
10	59	98.33	4.89
Standard	59.20	98.67	5.18
Deviation	0.63	1.05	0.39

The results demonstrate that under this optimal parameter combination, the orientation success rate of postharvest cabbages reaches 98.67±1.05%, with the orientation angle at 5.18±0.39°. Further analysis on the processing capacity of the prototype indicates that the rack length of the rack-and-pinion pair is 1 m, namely the actual effective length of the orientation section is 1 m. At the optimal chain linear velocity of 300 mm/s, the corresponding cabbage residence time for orientation section is approximately 3.33 s, which provides sufficient duration to complete automatic orientation. For individual cabbages with occasional orientation failure, they can be identified, rejected and circulated back into the orientation mechanism for secondary posture adjustment. Meanwhile, the uniform feeding spacing between adjacent cabbages is set to 150 mm, and the calculated theoretical hourly throughput reaches 7200 cabbages per hour, which satisfies the demand for large-scale commercial processing of cabbages. There exists a trade-off between orientation performance and processing capacity. If higher production efficiency is required in practical application, the conveying speed can be moderately increased at the cost of reduced orientation accuracy. For precision rhizome cutting scenarios with extremely strict requirements on trimming quality, the chain conveying speed can be reduced to extend the residence time for orientation, sacrificing partial throughput to acquire more stable orientation performance. These findings further enhance the orientation performance of postharvest cabbages and provide more favorable technical conditions for subsequent commercial processing operations, such as root and stem trimming.

CONCLUSIONS

(1) Based on the moment of inertia and the principle of minimum action, this study develops an automatic conveying and orientation device for postharvest cabbages equipped with conical tread rollers. The axially variable-diameter tread surfaces of conical rollers generate lateral friction torque acting on cabbages, counteracting orientation deviation caused by non-homogeneous mass distribution and axial offset of the mass center, and guiding cabbages to rotate steadily around their minimum inertia axis to achieve automatic orientation. Meanwhile, ADAMS dynamic simulation results reveal that cabbages with 26 types of initial poses can all complete automatic orientation on this device, with the maximum posture stabilization convergence time reaching 5.42 s, which further verifies the superiority and feasibility of the conical tread orientation mechanism.

(2) Range analysis and analysis of variance (ANOVA) of orthogonal tests indicate that the significance order of experimental factors affecting the orientation deflection angle of postharvest cabbages is axial clearance > taper angle > linear velocity of the conveying chain. The significance order of factors influencing orientation success rate is taper angle > axial clearance > linear velocity of the conveying chain. Within the parameter range set in this study, none of the experimental factors exerted a statistically significant regulatory effect on the orientation deflection angle or orientation success rate of postharvest cabbages. Future research can appropriately expand the value range of factor levels and add more gradient levels to further explore their underlying influence rules.

(3) The optimal combination of operating parameters was determined as follows: taper angle of 20°, axial clearance of 60 mm, and conveying chain linear velocity of 300 mm/s. Under this working condition, the orientation success rate reaches 98.67±1.05%, the average orientation deflection angle is 5.18±0.39°, and the theoretical processing throughput is 7200 cabbages per hour, which can basically meet the requirements of postharvest commercial treatment of cabbages. Nevertheless, all performance tests in this paper were only

carried out with the cabbage cultivar "Zhonggan No.15" as the research object, which brings certain limitations to this study. Follow-up research will investigate the automatic orientation adaptability of flatter, elongated and highly asymmetrical cabbage cultivars.

(4) Test results of the prototype performance reveal that occasional orientation failures are inevitable during long-term continuous orientation operation. Excluding failures caused by cabbage jamming due to oversized dimensions or cabbage slipping through roller gaps, all remaining failures stem from insufficient residence time for orientation. Cabbages rotating around non-central principal axes with large moments of inertia cannot complete automatic orientation within the limited available duration. To address the above problems, our research team plans to conduct follow-up studies on cabbage size grading and orientation posture recognition based on machine vision. Specifically, cabbages will be classified by size grading prior to orientation and delivered to dedicated orientation production lines matching their respective dimensions, so as to eliminate orientation failures induced by mismatches between cabbage size and structural parameters of the orientation device. After orientation, machine vision posture recognition will judge the orientation quality. Cabbages identified as orientation failures will be separated and recirculated into the orientation mechanism for secondary adjustment, thereby improving the orientation success rate for cabbages of various sizes.

ABSTRACT

Panax notoginseng is a high-value medicinal rhizome crop widely cultivated in the hilly and mountainous regions of southwest China, where traditional manual harvesting remains labor-intensive and inefficient. To address these challenges, this study focuses on the design, kinematic analysis, optimization, and validation of a separation conveyor device for a self-propelled Panax notoginseng combine harvester. The separation conveyor was developed based on the agronomic characteristics of Panax notoginseng and the mechanical requirements of soil-rhizome separation. A comprehensive methodology integrating theoretical modeling, kinematic and mechanical analysis, coupled discrete element-multibody dynamics (DEM-MBD) simulations using EDEM and RecurDyn, and laboratory experiments was employed. Key operational parameters, including conveyor speed, vibration frequency, and lifting angle, were systematically evaluated through quadratic regression and orthogonal experimental design. Simulation results indicated that effective soil separation could be achieved within 2.25 s, with fine soil particles separating earlier than larger aggregates. Laboratory tests identified optimal parameters of 0.8 m·s⁻¹ conveyor speed, 1.5 Hz vibration frequency, and a 20° lifting angle. Field validation experiments confirmed the reliability of the optimized design, achieving average separation and conveying rates of 96.87% and 96.42%, respectively, with a low rhizome damage rate of 1.88%. The results demonstrate that the proposed separation conveyor provides an effective solution for mechanized harvesting of Panax notoginseng and offers valuable reference for similar rhizome crop harvesters.

INTRODUCTION

Panax notoginseng is unique to southwest China, a well-known rhizome-based traditional Chinese medicine with excellent medicinal and economic value, which removes blood stasis and prevents cardiovascular and cerebrovascular diseases (*Issa et al., 2025c; Jiang et al., 2022; Lin et al., 2022*). Flowers, leaves, stems, and rhizomes can all be used as medicine. Modern medical research has found that *Panax Notoginseng* is rich in saponins, flavonoids, and various amino acids (*Zhou et al., 2010*). It is mainly cultivated in hilly and mountainous areas (*Zhang et al., 2016; Zhaoguo et al., 2023*). *Panax notoginseng* is mainly produced in mountainous and hilly areas such as Yunnan, Guangxi, and Sichuan *(Guiyun and Ying, 2012; Guo Jingjing et al., 2014*). Yunnan Province is located in the southwest of China and has mountainous plateau terrain. 87.21% of Yunnan Province's land area is located in the 1000~3000m medium altitude area. Mountains, hills, plains, and terraces account for 88.64%, 4.96%, 4.85% and 1.55% of Yunnan Province's area, respectively. Most of them are hilly and mountainous (*Thomas, 1992*). In recent years, the *Panax notoginseng* industry has entered a stage of large-scale, base-based, and standardized development *(Lihong et al., 2017*). However, *Panax notoginseng* is mainly harvested by traditional manual harvesting, which has low harvesting efficiency, high labor intensity, and is time-consuming and labor-intensive *(Zhenmeng et al., 2018*). Mechanized harvesting of *Panax notoginseng* can reduce farmers' work intensity and improve work efficiency *(Faan et al., 2024*).

Guo Siwei and others designed and developed a self-propelled *Panax notoginseng* combine harvester. The machine consists of an excavator, a primary conveying and separation device, a secondary conveying and separation device, a lifting device, a collection device, a hydraulic transmission system, a control system, and a crawler system. It integrates excavation, separation, conveying, and collection, achieving mechanized harvesting of *Panax notoginseng* and effectively reducing labor intensity (*Siwei, 2024*).

There is limited research on separation conveyor devices for rhizome crop harvesters from research institutes, while most research comes from agricultural machinery manufacturers (*Issa et al., 2025b*). For example, Johnson et al. applied the separation conveyor device to the technology of separation and loading conveyance using a hydraulic system to achieve highly controllable separation and conveying. The American Lockwood company developed a potato harvester that uses two-stage separation and conveying technology to load the harvester into the collection box, thereby improving separation and conveying efficiency *(Yitao et al., 2020*). The Japanese Matsuyama GSA600 harvester uses a rubber conveyor belt to improve durability without damaging rhizome and tuber tissue. The vibration device uses a three-speed adjustable setting to deliver different vibration frequencies for various crops and soil conditions (*Cheng et al., 2023*).

Recent research on conveying and separation devices for rhizome crop harvesters in China has primarily used DEM-MBD coupling simulations to design separation and conveying devices, study the movement of rhizomes and soil during the separation process, and assess the crushing effect *(Chen et al., 2024; Issa et al., 2025a; Wang et al., 2023b; Wang et al., 2023c*). For example, Wei Zhongcai from Shandong University of Science and Technology designed a wave-shaped conveyor suitable for potatoes *(Zhongcai et al., 2020*). To address the issue of high potato damage and skin breakage rates, he analyzed the key factors and structural parameters of the potato-soil separation process, utilizing a dual separation method that combines vibration and wave techniques to reduce these rates; additionally, Wang Feng from Gansu Agricultural University designed a double-layer separation conveyor for Pinellia Ternata, which employed a method of first conveying and then separating, while configuring the separation operation separately to enhance the rhizome-soil separation effect (*Feng, 2022*).

In summary, most rhizome and tuber harvesters in China, especially those for Chinese medicinal materials, have simple structures, small operating widths, and are mostly specialized harvesters for single medicinal materials. The conveying and separation components mainly include bar-type lifting chains, connecting-rod vibrating conveyors, roller conveyor chains, and cylindrical screens. In combination with previous research, the heavy soil in the *Panax notoginseng* planting area makes rhizome and soil separation more difficult, and the *Panax notoginseng* rhizome is rigid. It is challenging to break parameters during the conveying and separation process. Therefore, to ensure the separation of the rhizome and soil.

This study focused on the development and optimization of a separation conveyor for a self-propelled *Panax notoginseng* harvester to improve soil–rhizome separation efficiency. The separation conveyor was designed using computer-aided design tools and analyzed through coupled discrete element and multibody dynamics simulations. EDEM and RecurDyn software were used to simulate the conveying and separation processes and investigate the interactions among soil particles, rhizomes, and conveyor components. Key operating factors, including conveyor speed, vibration frequency, and lifting angle, were systematically evaluated using quadratic regression analysis to identify optimal parameter combinations. Field experiments were conducted to verify the simulation model and assess separation performance under practical operating conditions. The combined simulation and experimental approach provided a scientific basis for optimizing the structure and operating parameters of the separation conveyor system.

MATERIALS AND METHODS

Self-propelled combine harvester structure and working principle

Based on the agronomic conditions for *Panax notoginseng* cultivation in Yunnan and the basic physical parameters of *Panax notoginseng* and the soil, a self-propelled *Panax notoginseng* combine harvester was designed. *Panax notoginseng* is mainly planted in hilly and mountainous areas. Considering the influence of slopes, the entire machine should be smaller to meet the working requirements and deliver excellent performance. At the same time, it should meet the design requirements of relevant national and local standards. The strong adaptability and possibility of the crawler chassis, which can turn around at the end of fields, and adapt to different working conditions. Therefore, this study aims to design key components of a crawler self-propelled *Panax notoginseng* combined harvester to enable joint operations for *Panax notoginseng* excavation, separation, transportation, lifting, collection, and unloading, thereby adapting to small-plot operations in hilly and mountainous areas.

The *Panax notoginseng* combine harvester designed in this research comprises an excavation device, a separation conveyor device, a lifting device, a collection device, an engine, a hydraulic caterpillar chassis, and a wheelhouse, as shown in Figure 1. The entire vehicle utilizes hydraulic control. The engine drives the hydraulic pump, supplying power to the combine harvester. The hydraulic valve group then distributes this power to each system, moving the hydraulic motor and hydraulic cylinder to enable walking and harvesting operations.

When the *Panax notoginseng* combine harvester is operating, the excavation shovel is aligned with the *Panax notoginseng* ridge and the corresponding height is adjusted to meet the depth and angle of *Panax notoginseng* harvesting; the speed of the separation conveyor and the vibrating wheel are adjusted so that the excavated *Panax notoginseng* rhizome-soil complex can achieve a relatively ideal separation effect during the soil separating operation; the excavation shovel digs and crushes the *Panax notoginseng* rhizome-soil complex to facilitate the subsequent conveying and soil removal process; the separation conveyor is transported backward, and the *Panax notoginseng* rhizome-soil complex is shaken by the vibrating wheel to achieve soil removal; the *Panax notoginseng* after soil removal is thrown from the separation conveyor to the lifting device, and transported upward under the drive of the chain; after reaching the top, it is thrown into the aggregate box to complete the entire harvesting operation; after the collection is completed, the hydraulic cylinder flips it over to complete the unloading operation.

Design and analysis of the separation conveyor device

The separation conveyor is designed to separate soil from rhizomes and transport them. In contrast, the lifting device's primary role is transportation. During operation, the excavation device gathers the rhizome-soil mixture and delivers it to the separation conveyor. Here, soil is removed, and the *Panax notoginseng* rhizomes are conveyed onward. Finally, the cleaned rhizomes, along with any residual soil, are transferred to the lifting device for further transport.

Commonly used conveying devices can be divided into belt conveyor, roller push-type, chain-type lifting, bucket elevator, and throwing wheel type, according to structural form. Among them, the bar-type structure is more suitable for harvesting *Panax notoginseng* rhizome. It is simple to operate and has strong separation performance. It can ensure good conveying capacity at a large lifting angle (*Issa et al., 2020; Xiaohong, 2023*). It mainly includes guide wheels, plum blossom-shaped drive wheels, lifting chains, vibration wheels, driven wheels, and supporting wheels. After *Panax notoginseng* is excavated, it enters the separation conveyor device. During transport, fine impurities are directly deposited on the ridge through the bars. Part or all of the rhizome-soil complex, and large soil blocks, are further separated from the vibration wheel by vibration and then transported to the lifting device of the working components. The three-dimensional model of the separation conveyor components is shown in Figure 2. The primary power source is hydraulic transmission.

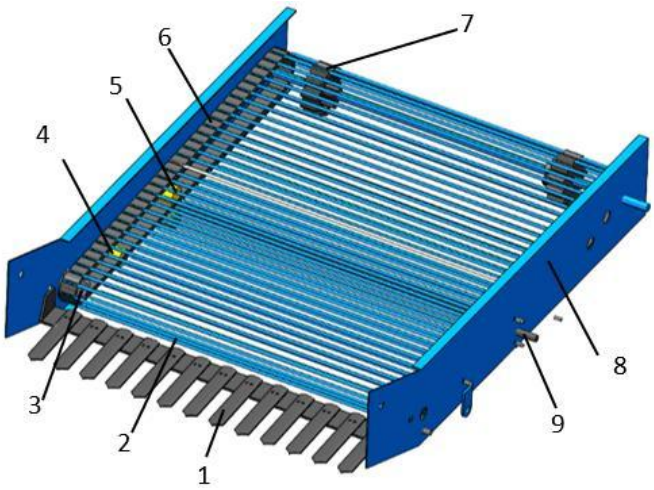

Fig. 2 - Structural diagram of the separation conveyor device

1. Excavation shovel; 2. Rod; 3. Driven wheel; 4. Supporting wheel 5. Vibration device; 6. Separation conveyor belt; 7. Drive wheels; 8. Separation conveyor frame; 9. Vibration device pillar

The working principle is that the excavation device removes the *Panax notoginseng* rhizome-soil complex, and the complex is transported to the separation conveyor device by friction and inertia. The soil is then broken, separated, and dropped by the vibration wheel. Finally, the *Panax notoginseng* is thrown to the lifting device at the rear end of the lifting chain. The main technical parameters are shown in Table 1.

Table 1

Main technical parameters of the separation conveyor device

Parameter	Numerical value
Device diameters (length × wide × Height)	1988×1540×1080 mm
Device weight	410 kg
Number of harvested ridges	1
Working width	1500 mm
Operating speed	≥0.4 m/s
Conveying speed	0.4 ~ 1.0 m/s

According to the previous planting site survey, the working width was determined to be 1500 mm. According to the design requirements of the bar elevator in the Agricultural Machinery Design Manual (*Hongwei, 2024*). The conveyor belt length should be 1200~1500 mm, and the selected length is 1400 mm. The bar gap was determined based on the minimum triaxial dimensions of the *Panax notoginseng* rhizome-soil complex. According to the previous research, the bar diameter was selected as 12 mm, the bar gap was 38 mm, and the bar center distance was 50 mm, as shown in Figure 3.

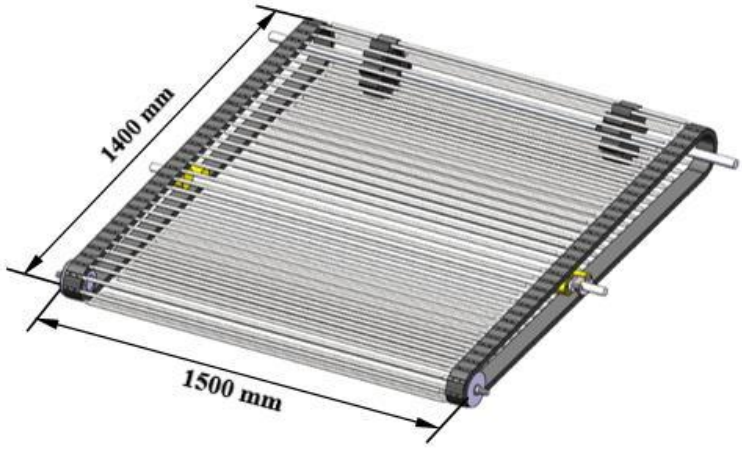

Fig. 3 - Separation conveyor size

On rhizome harvesters in many countries around the world, the distance between the harvester bars on the vibrating screen is 25~28 mm, 40~48 mm in the United States, and 30~40 mm in Japan and South Korea (*Wang et al., 2025; Zhaoguo et al., 2021*). The two-dimensional design scheme of the bar is shown in Fig. 4.

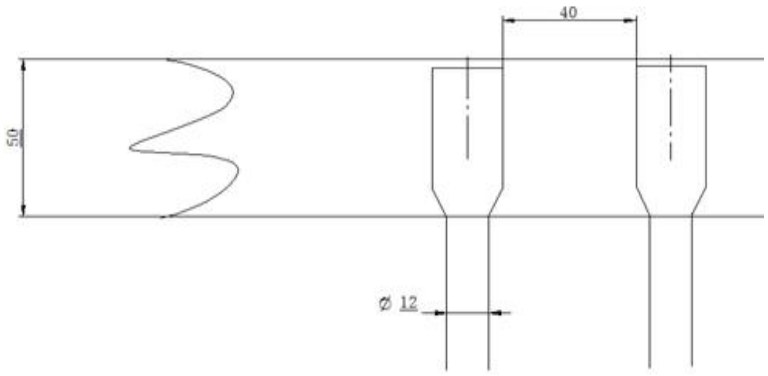

Fig. 4 - Design scheme of the bar

Determination of the drive wheel

The driving wheel is the main working part of the *Panax notoginseng* combined harvester movement transmission. It is also the main power-consumption component, driving the rotation of the entire conveyor belt and the movement of the vibration wheel, driven wheel, and supporting wheel. The actual production of the drive wheel is also complicated. The wheel hub is made of metal material and covered with plum blossom rubber. It is fixed on the drive shaft with a flange. The rotary shaft is first processed during manufacturing. Then the caster is matched with the conveyor belt to ensure the thick elastic rubber on the surface of the rotary shaft is matched. Through the driving wheel and the conveyor belt, the line contacts the flexible curved surface during movement, reducing rigid contact between the harvester parts and increasing overall harvester reliability. Due to the large span of the conveyor belt, four drive wheels are arranged symmetrically in pairs. The drive wheel is shown in Figure 5.

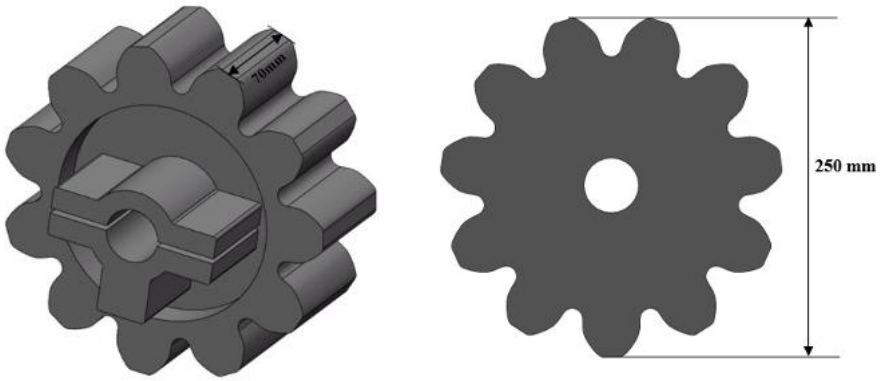

Fig. 5 - Drive wheel diagram

The separation conveyor speed is a key parameter of the separation conveyor device and is mainly controlled by the drive wheel. If the speed is too high, the vibration time of *Panax notoginseng* on the separation conveyor will be reduced, the rhizome-soil separation effect will be poor, the soil and impurities will not fall easily, and the excessive speed will also cause the tooth jump phenomenon; if the speed is too low, the soil will be piled up at the connection position between the excavation device and the separation conveyor device, reducing the harvesting efficiency. According to the supporting project's requirements, production efficiency should be ≥ 3 mu per hour. Combined with the operating width of the whole machine, it can be seen that the operating speed of the entire machine should be ≥ 0.38 $m \cdot s^{-1}$, so the speed of the separation conveyor should be greater than 0.38 $m \cdot s^{-1}$.

The drive wheel can be simplified as a polygonal rotating mechanism that drives the separation conveyor. By substituting the speed, number of teeth, and pitch into Eq. (1), the rotational speed *n* of the drive wheel can be obtained.

$$V_s = \frac{zpn}{60\times 1000} \quad (1)$$

where:

V_s is the separation conveyor speed [m·s^{-1}]; p is the pitch of the drive wheel [mm]; n is the drive wheel speed [r·min^{-1}]; z is the number of teeth of the drive wheel.

As shown in Figure 6, the velocity analysis of the separation conveyor indicates that the bar velocity can be decomposed into horizontal and vertical components.

$$\begin{cases} V_x = R\omega_1 cos\varphi' \\ V_y = R\omega_1 sin\varphi' \end{cases} \quad (2)$$

where:

R is the pitch radius of the drive wheel [mm]; ω_1 is the angular velocity of the drive wheel [rad·s^{-1}]; φ' is the phase angle [°], i.e. the angle between the line connecting the center of the bar with the center of the drive wheel and the vertical center line.

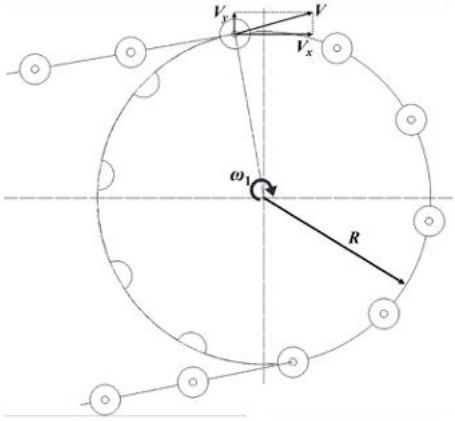

Fig. 6- Velocity analysis of the separation conveyor device

Based on the velocity analysis, the horizontal velocity component of the bar is responsible for conveying the material and therefore represents the conveying speed. Since the phase angle range is $-\frac{\pi}{2} \leq \varphi \leq \frac{\pi}{2}$, the following conclusions can be drawn.

$$\begin{cases} V_{\min} = R\omega_1 cos\frac{\pi}{2} = 0 \\ \varphi' = \pm\frac{\pi}{2} \end{cases} \quad (3)$$

When the phase angle is 90°, the separation conveyor bar and the drive wheel just come into contact and mesh, and the minimum lifting velocity is 0.

When the lifting velocity reaches its maximum value:

$$\begin{cases} V_{\max} = R\omega_1 \\ \varphi' = 0 \end{cases} \quad (4)$$

When the phase angle is 0, the bar coincides with the vertical centerline, and the velocity of the separation conveyor reaches its maximum value. At the next moment, the *Panax notoginseng* roots are thrown toward the lifting device. Therefore, to ensure smooth connection with the lifting-chain device, the radius and angular velocity of the drive wheel should be increased as much as possible. Accordingly, a drive wheel with 13 teeth, a diameter of 250 mm, and a width of 70 mm is selected and fixed to the drive shaft by means of a flange.

Determination of the vibration wheel

The vibration wheel is the main component of the separation conveyor device and the most critical component. The system realizes the rotation of the vibration wheel driven by the conveyor belt; the vibration wheel is an active double-roller vibration wheel (as shown in Figure 7). According to the overall configuration of the separation conveyor device and the transmission design requirements, the vibration wheel is installed between the front-driven wheel and the drive wheel. The upper part contacts the tight side of the conveyor belt. The single roller can rotate around its own fixed axis. The size is 70 mm in diameter and 75 mm in width. It is fixedly connected to the vibration shaft by a vibration wheel fixing plate.

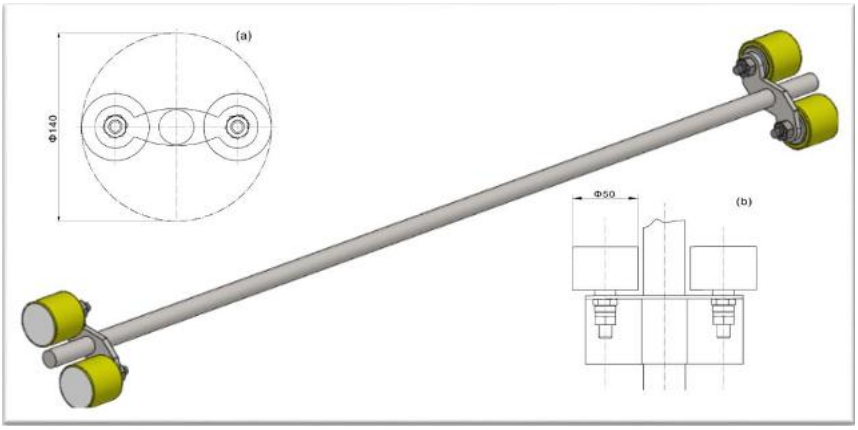

Fig. 7 - Structure diagram of the active vibration device

The active vibration device uses a hydraulic motor and is adjustable in speed. The vibration wheel shakes the separation conveyor twice for each rotation of the vibrating shaft. The vibration frequency is calculated as follows:

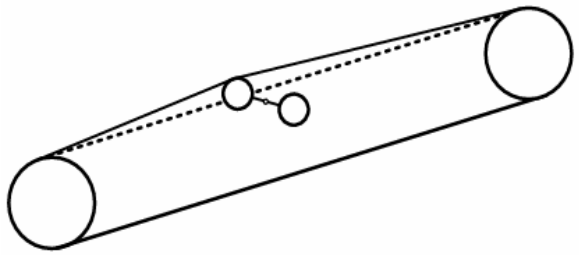

Fig. 8 - Vibration wheel working process diagram

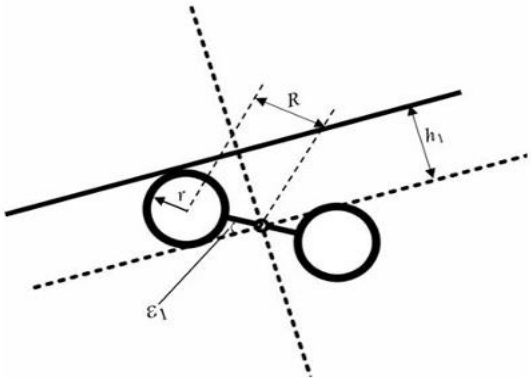

Fig. 9 - The vibration wheel lifts the separation conveyor

The calculation equation for the rotation angle of the vibration wheel is:

$$\varepsilon = \pm \arcsin\left(\frac{h_1 - r}{R}\right) + k\pi \quad (6)$$

where:

ε is the rotation angle of the vibration wheel [°]; h_1 is the distance between the vibration axis and the conveyor belt [mm]; r is the radius of the vibration wheel roller, [mm]; R is the distance from the origin to the center of the roller [mm]; k: natural number, k=0,1,2, …

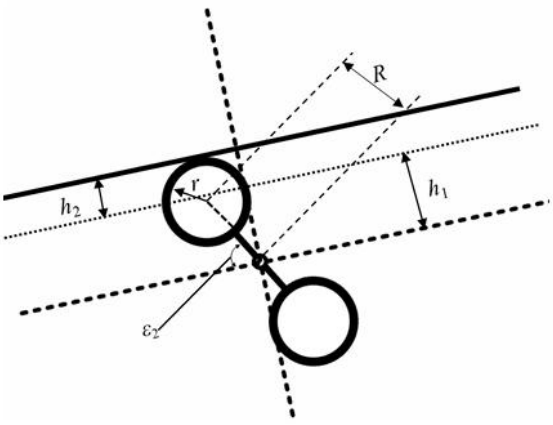

Fig. 10 - Schematic diagram of the conveyor belt lifted by the vibration wheel

As shown in Figure 10, when the vibration wheel lifts the conveyor belt, the contact point between the roller and the screen surface is displaced. The displacement can be divided into D_1 in the direction perpendicular to the conveyor belt and D_2 parallel to the conveyor belt. The displacement components are calculated using Eq. 7.

$$\begin{cases} D_1 = R|sin\varepsilon_2| + r - h_1 \\ D_2 = R|cos\varepsilon_1| - R|cos\varepsilon_1| \\ k\pi + \varepsilon_1 \geq \varepsilon_2 \geq (k+1)\pi - \varepsilon_1 \end{cases} \quad (7)$$

where:

ε_1 is the rotation angle before the vibration wheel lifts the screen surface [°]; ε_2 is the rotation angle after the vibration wheel lifts the screen surface [°].

The calculation equation for the rotation angle ε_2 after the vibration wheel lifts the screen surface is shown in equation 8.

$$\varepsilon_2 = \omega_2 t \quad (8)$$

where:

t is the rotation time of the vibration wheel (s).

Combining Eqs (7) and (8), the following equation can be obtained:

$$\begin{cases} D_1 = R|sin\omega_2 t| + r - h_1 \\ D_2 = R|cos\omega_2 t| - R|cos\varepsilon_1| \\ k\pi + \varepsilon_1 \geq \omega_2 t \geq (k+1)\pi - \varepsilon_1 \end{cases} \quad (9)$$

Taking the derivative of the above equation, the velocity of the screen contact point under the action of the vibration wheel can be obtained as follows:

$$\begin{cases} V_1 = \frac{Dd_1}{dt} = \omega_2 R\cos\omega_2 t \\ V_2 = \frac{Dd_2}{dt} = \omega_2 R sin\omega_2 t \end{cases} \quad (10)$$

The acceleration of the screen contact point under the action of the vibration wheel can then be obtained as follows:

$$\begin{cases} a_1 = \frac{dV_1}{dt} = {\omega_2}^2 R\sin\omega_2 t \\ a_2 = \frac{dV_2}{dt} = {\omega_2}^2 R\cos\omega_2 t \end{cases} \quad (11)$$

Mechanical analysis of the separation conveyor device

The movement of the *Panax notoginseng* rhizome on the separation conveyor device can be roughly divided into four stages (*Wang et al., 2023a*): from the front guide wheel to the front end of the vibration wheel, the vibration wheel action stage, from the rear end of the vibration wheel to the end of the drive wheel, and from the end of the drive wheel to the lifting chain device. Since the movement of the *Panax notoginseng* rhizome from the front guide wheel to the end of the drive wheel is similar, only the two movement conditions on the separation conveyor device, and when thrown out from the end of the drive wheel are discussed and analyzed.

The *Panax notoginseng* rhizome is transported along the inclined surface on the separation conveyor device. When the screen surface is approximated as a straight line, and the air resistance is not considered, the force analysis of the *Panax notoginseng* rhizome is performed, as shown in Figure 11. To ensure the smooth transportation of the *Panax notoginseng* rhizome and the separation of the rhizome and soil, the following conditions should be met:

$$\begin{cases} f_s - \mathrm{mgsin}\alpha_\mathrm{s} \geq \mathrm{ma_x} \\ F_\mathrm{N} - \mathrm{mgcos}\alpha_\mathrm{s} \geq \mathrm{ma_y} \end{cases} \quad (12)$$

where:

f_s is the friction between *Panax notoginseng* rhizome and screen surface, [N]; m is the mass of Panax notoginseng rhizome, [kg]; F_N is the support force of screen surface on *Panax notoginseng* rhizome, [N]; α_s is the angle between screen surface and horizontal plane, [N]; $\mathrm{a_x}$: tangential acceleration of *Panax notoginseng* rhizome along screen surface, m·s^{-2}; $\mathrm{a_y}$ is the normal acceleration of *Panax notoginseng* rhizome along screen surface, m·s^{-2}.

To ensure that the rhizome of *Panax notoginseng* is hit by the vibration wheel and thrown up, the following conditions should be met:

$$\begin{cases} \frac{mg}{z}\omega_2{}^2(R+r)cos\alpha_s > mg \\ \omega_2 = \frac{nb}{30} \end{cases} \quad (13)$$

where:

n is the vibration wheel speed, [r·min^{-1}]; b is constant, [b=π^2].

Simplifying equation (13), the vibration wheel speed should satisfy:

$$n > 30\sqrt{\frac{1}{(R+r)cos\alpha_s}} \quad (14)$$

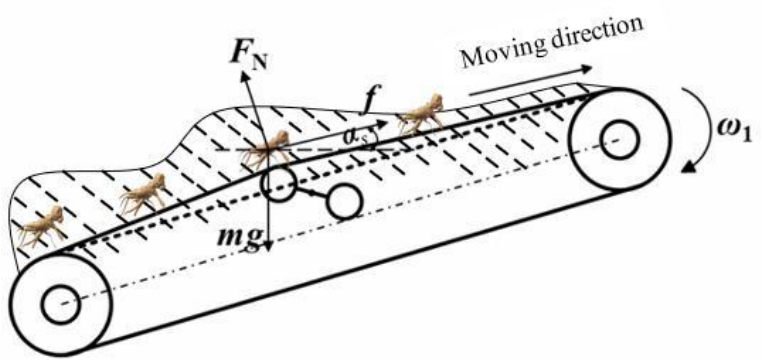

Fig. 11 - Mechanical analysis of the separation conveyor device

Analysis of the throwing motion at the end of the conveyor belt

After the rhizome of *Panax notoginseng* passes through the front end of the conveyor belt and the vibration wheel, it reaches the end and first does an oblique throwing motion, then a horizontal throwing motion, and finally goes to the lifting device. During the analysis, the screen surface is regarded as a plane, with the center of mass of the rhizome of *Panax notoginseng* as the origin, the horizontal right is the positive direction of the X-axis, and the vertical upward is the positive direction of the Y-axis. Without considering the air resistance, the displacement and velocity of the rhizome of *Panax notoginseng* are analyzed, as shown in Figure 12. Assume that the initial velocity of the rhizome of *Panax notoginseng* is v_a, which can be decomposed into the velocity vax in the X-axis direction and the velocity v_{ay} in the Y-axis direction, and satisfies the following relationship:

$$\begin{cases} v_{ax} = v_a cos\theta_s \\ v_{ay} = v_a sin\theta_s \end{cases} \quad (15)$$

where: θ_s: screen surface inclination [°]; v_{ax}: X-axis speed [m·s^{-1}]; v_{ay}: Y-axis speed [m·s^{-1}].

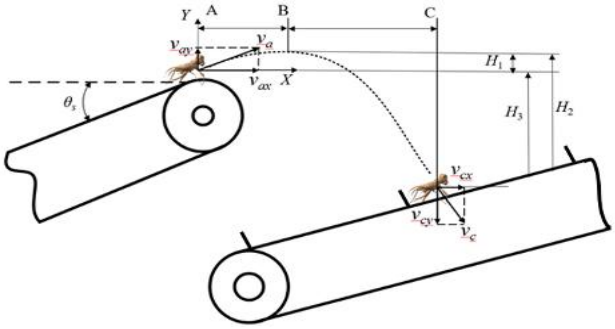

Fig. 12 - Throwing-motion analysis of *Panax notoginseng* rhizomes

The rhizome of *Panax notoginseng* performs oblique projectile motion in the AB section and horizontal projectile motion in the BC section. The displacement and velocity analyses of the two sections have been performed. The displacement analysis of the oblique projectile motion in the AB section is shown in equations (16), (17), and (18) since point B is the end point of the oblique projectile motion of the rhizome of *Panax notoginseng*, the vertical velocity v_{by} = 0 and the horizontal velocity v_{bx} = cosθ of the rhizome of *Panax notoginseng* at point B.

$$H_1 = \frac{v_{ay}{}^2}{2g} \quad (16)$$

$$X_1 = v_{\mathrm{ax}} t_1 \tag{17}$$

$$t_1 = \frac{v_{\mathrm{ay}}}{\mathrm{g}} \tag{18}$$

where:

H_1 is the vertical displacement of segment AB, [m]; X_1 is the horizontal displacement of segment AB, [m]; t_1 is the time taken for segment AB, [s]; g is the gravitational acceleration, [m·s^{-2}], g=9.8 m·s^{-2}.

The displacement analysis of the BC segment horizontal projection motion is shown in equations (19), (20), and (21):

$$H_2 = H_1 + H_3 \tag{19}$$

$$X_2 = v_{\mathrm{ax}} t_2 \tag{20}$$

$$t_2 = \sqrt{\frac{2H_2}{\mathrm{g}}} \tag{21}$$

where:

H_2 is the vertical displacement of BC segment, [m]; H_3 is the drop height of *Panax notoginseng* rhizome from the end of the separation conveyor to the lifting chain device, [m]; t_2 is the time taken for BC process, [s]. By combining and simplifying Eqs. (16)–(21), the displacement and time required for the *Panax notoginseng* rhizomes to be thrown from the end of the separation conveyor to the lifting-chain device can be obtained, as shown in the following equations:

$$H_2 = \frac{{v_{ay}}^2}{2\mathrm{g}} + H_3 \tag{22}$$

$$t = \frac{v_{\mathrm{ay}}}{\mathrm{g}} + \sqrt{\frac{2\left(\frac{{v_{ay}}^2}{2\mathrm{g}} + H_3\right)}{\mathrm{g}}} \tag{23}$$

$$t = v_{\mathrm{ax}}\left(\frac{v_{\mathrm{ay}}}{\mathrm{g}} + \sqrt{\frac{2\left(\frac{{v_{ay}}^2}{2\mathrm{g}} + H_3\right)}{\mathrm{g}}}\right) \tag{24}$$

Since point C is the end point of the horizontal motion, the horizontal velocity of point C $v_{\mathrm{cx}} = v_{\mathrm{a}}\cos\theta$, and the vertical velocity and the resultant velocity are shown in the following equation.

$$v_{\mathrm{cy}} = \mathrm{g}t_2 = \sqrt{{v_{ay}}^2 + 2gH_3} \tag{25}$$

$$v_{\mathrm{c}} = \sqrt{{v_{cx}}^2 + {v_{cy}}^2} = \sqrt{(v_a cos\theta)^2 + {v_{ay}}^2 + 2\mathrm{g}H_3} \tag{26}$$

In summary, the speed and displacement of *Panax notoginseng* rhizome from the end of the separation conveyor to the lifting device are primarily determined by the initial speed, screen surface inclination, and drop height. To ensure that the *Panax notoginseng* rhizomes can fall smoothly from the separation conveyor to the lifting device, the initial speed and drop height should be increased as much as possible, and the screen surface angle should be reduced. The conveying speed is taken as 0.6~1.4 m·s^{-1}, and the inclination angle is 15~35°.

Simulation analysis and test of the separation conveyor device

Establishing the separation conveyor simulation environment

Soil particle size and distribution data were measured, and the soil discrete element particle model was divided into three categories. The default spherical particles in EDEM were used. The soil particle shape, size, and proportions are shown in Table 2 and were added as the second category of bulk particles.

In RecurDyn, create a Wall file from the completed multibody dynamics model. Enable the RecurDyn-EDEM coupling interface and import the metal model's Wall file into EDEM's Geometry window, as shown in Figure 13. Create a solid thin plate at the bottom and end of the lifting chain to simulate the soil drop and the transition between the *Panax notoginseng* rhizome-soil complex and the next-level working component. Set the physical properties of the *Panax notoginseng* rhizome, soil particles, and metal model, enter the contact parameters, select the JKR contact model, and set the surface energy parameters for the contact.

Table 2

Soil discrete element particle model

Name	Model	Diameter / mm	Scale / %
Single spherical particles		1.6	33.9
Double-spherical particles		3.6	25.2
Triple-spherical particles		5.2	41.3

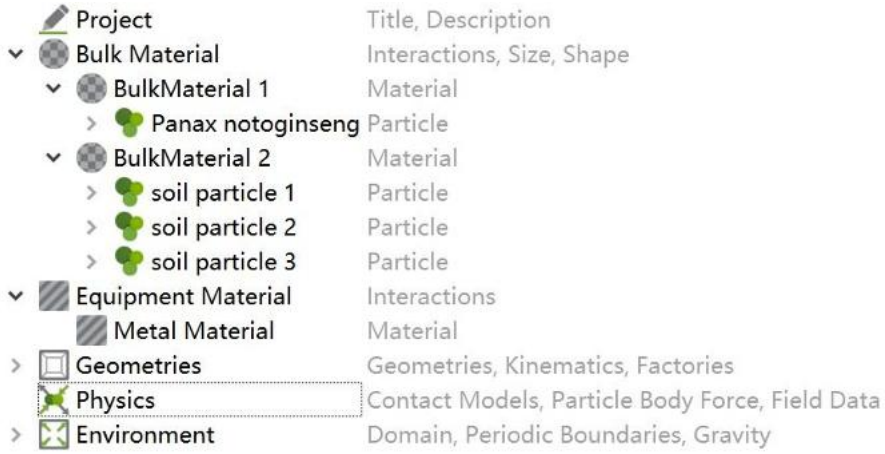

Fig. 13 - Establishment of granular and metallic materials

A virtual cube with an edge length of 0.2 m is generated at the front of the elevator chain. The Y-direction is defined as the gravity direction, and the acceleration is 0.98 m·s^{-2}, as shown in Figure 14.

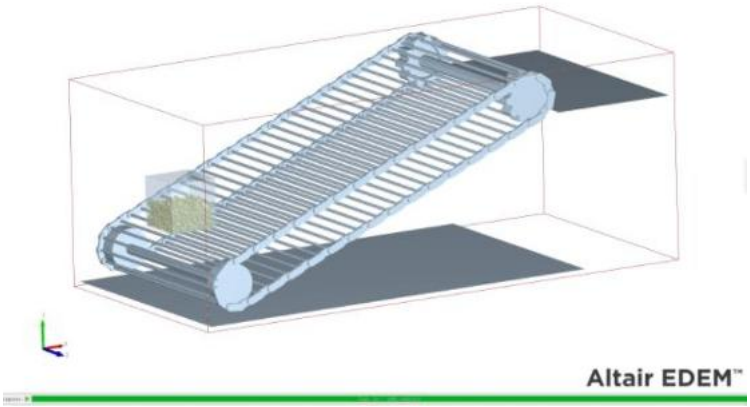

Fig. 14 - Establishment of coupled simulation environment

A discrete element model of the *Panax notoginseng* rhizome stem is generated within the box, enclosing a predetermined proportion of soil particles. This simulates the actual production process of the *Panax notoginseng* rhizome-soil complex as it is transported and separated by the elevator chain. At this point, the simulation environment is set up, and the coupled simulation can begin. Set the simulation time to 4 s and the step size to 0.01 s.

Simulation test results of the separation conveyor device

Overall movement of the *Panax notoginseng* rhizome-soil complex

The simulation results show that the rhizome-soil separation of the *Panax notoginseng* rhizome-soil complex was essentially complete within 2.25 seconds of simulation. Therefore, the main focus was on observing the conveying and separation movement characteristics of the *Panax Notoginseng* rhizome-soil complex during the period 0 to 2.2 seconds. The lifting velocity was 0.8 m·s^{-1} and the lifting angle was 25°, as shown in Figure 15.

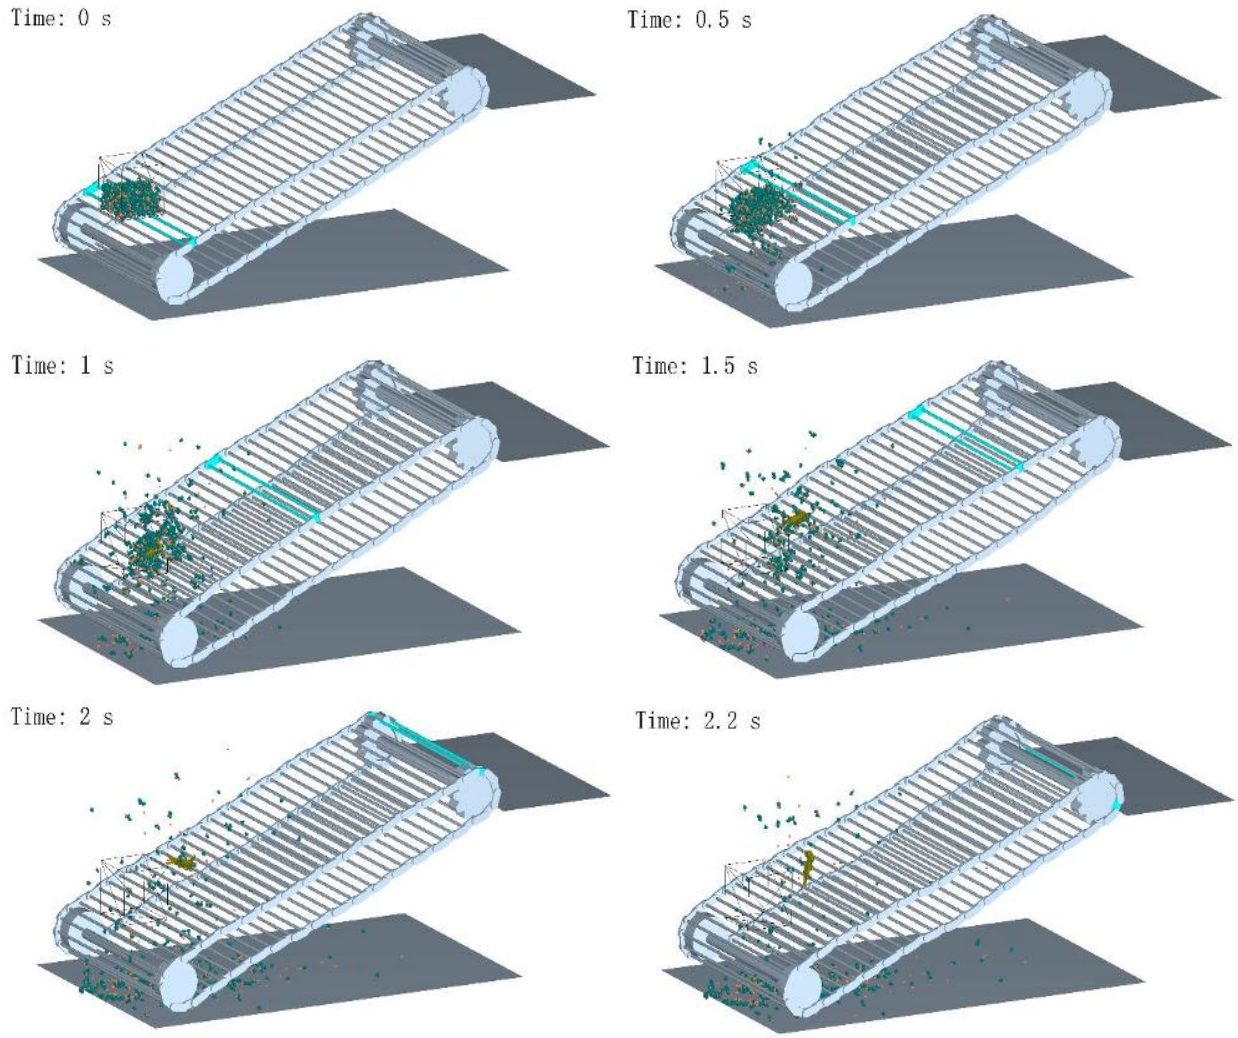

Fig. 15 - Movement trajectory of the *Panax notoginseng* rhizome-soil composite

To observe the relative motion of the *Panax notoginseng* rhizome soil complex and the lifting chain, use the blue bar below the virtual box as the observation point. The *Panax notoginseng* rhizome-soil complex freely falls onto the screen surface. Some loose, fine soil particles escape directly through the gaps between the bars, while the majority of the soil adheres to the surface of the *Panax notoginseng*. The relative friction between the *Panax notoginseng* rhizome-soil complex and the screen surface tends to transport the material diagonally upward. The vibration of the elevator chain gradually separates the *Panax notoginseng* roots from the soil particles, and the separation efficiency gradually increases as the amount of soil in the *Panax notoginseng* rhizome-soil complex decreases. Due to the low gravity, the soil particles are struck by the bars and scattered, resulting in significant variations in their velocities. However, the velocity of the *Panax notoginseng* rhizome on the screen surface does not change significantly, and the conveying speed is lower than the lifting speed. In EDEM post-processing, the *Panax notoginseng* particles were set to Steam mode. The *Panax notoginseng* rhizome exhibits "bouncing" and "backflowing" on the elevator chain. The degree of "bouncing" and "backflowing" becomes more pronounced as the number of soil particles attached to the rhizome decreases.

Rhizome-soil separation of Panax notoginseng rhizome-soil complex

To observe the effect of rhizome-soil separation in the coupled simulation of the *Panax notoginseng* rhizome-soil complex, the 3D Viewer-Setup Selections-Grid Bin Group function in the EDEM post-processing module was used to partition the particle computational domain. Three soil particle groups were selected for computational particle grouping. The dimensions and position of the Gind Bin Group were set, along with the number of bins. The computational domain was rotated along the Z-axis to an angle parallel to the elevator chain screen surface. Using a 0.4s time frame as an example, the soil particle computational domain partitioning is shown in Figure 16.

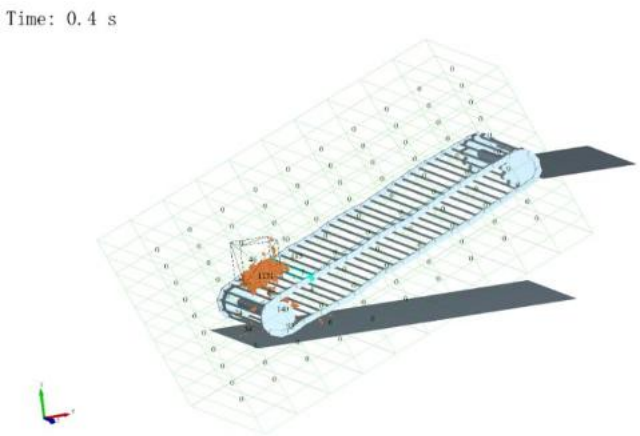

Fig. 16 - Gind Bin Group setting

The separation of the rhizome and soil in the *Panax notoginseng* rhizome-soil complex is expressed as the sieving rate. There are 1,800 soil particles of varying sizes and shapes. By counting the number of particles attached to the *Panax notoginseng* at each step, the sieving rate of the *Panax notoginseng* rhizome-soil complex can be calculated. The calculation equation is as follows:

$$Z_s = \frac{n_s}{N_s} \times 100\% \quad (27)$$

where: Z_s is the Simulated sieving efficiency of the *Panax notoginseng* root-soil complex, [%]; n_s is the Number of soil particles attached to the *Panax notoginseng*; T_s is the Total number of soil particles.

The sieving rate of the *Panax notoginseng* rhizome-soil composite was calculated for each step length, ranging from 0 to 2.20 seconds. The trajectory of soil particle motion is plotted in Figure 17. The sieving rate curve is plotted in Figure 18. Single spherical particles are purple, double spherical particles are orange, and triple spherical particles are green. The sieve clearance rate of the *Panax notoginseng* rhizome-soil complex increased rapidly within 0.25 s, then slowly increased until it approached 100%. This is because finely divided single-spherical particles separated preferentially; double-spherical particles separated in the middle section; and triple-spherical particles had strong adhesion to the *Panax notoginseng* rhizome, bouncing on the sieve surface with the *Panax notoginseng* and gradually separating.

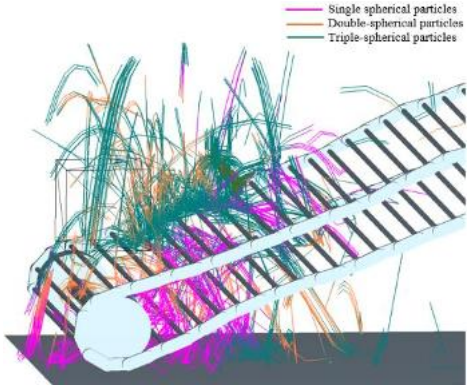

Fig. 17 - Soil particle motion trajectory

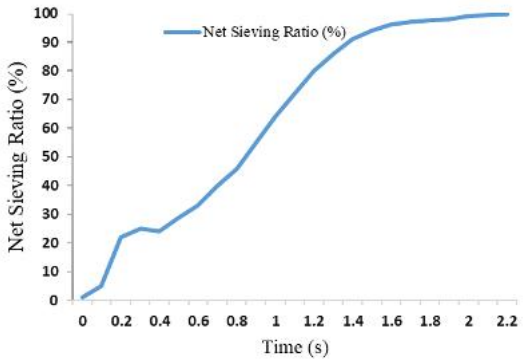

Fig. 18 - Sieve clearance rate curve

Dynamic analysis of Panax notoginseng rhizome

To investigate the motion and forces acting on *Panax notoginseng* rhizome on the separation conveyor, a triaxial force curve for *Panax Notoginseng* particles was plotted, as shown in Figure 19. At the front end of the separation conveyor, the *Panax Notoginseng* rhizome-soil complex exhibits high soil adhesion and is relatively heavy, making it difficult to lift. Therefore, from 0 to 0.75 s, the forces acting on the *Panax Notoginseng* rhizome are uneven and exhibit irregular variations. After 0.75 s, the forces acting on the *Panax Notoginseng* rhizome fluctuate dramatically at regular intervals, primarily due to the vibration of the separation conveyor. The moment the rod strikes the rhizome, the forces acting on the rhizome vary significantly. The *Panax notoginseng* rhizome is mainly subjected to the force in the X-axis and Y-axis directions on the inclined plane of the separation conveyor.

The friction between the *Panax notoginseng* rhizome-soil composite and the separation conveyor mainly provides the force on the X-axis. At the moment when the rod hits the *Panax notoginseng* rhizome, the *Panax notoginseng* rhizome is mainly subjected to the force in the normal direction of the separation conveyor, which is manifested as the force in the positive direction of the Y-axis and the force in the negative direction of the X-axis. After being thrown up, the force received by the *Panax notoginseng* is the gravity in the negative direction of the Y-axis, and the forces on the X-axis and Z-axis are close to zero.

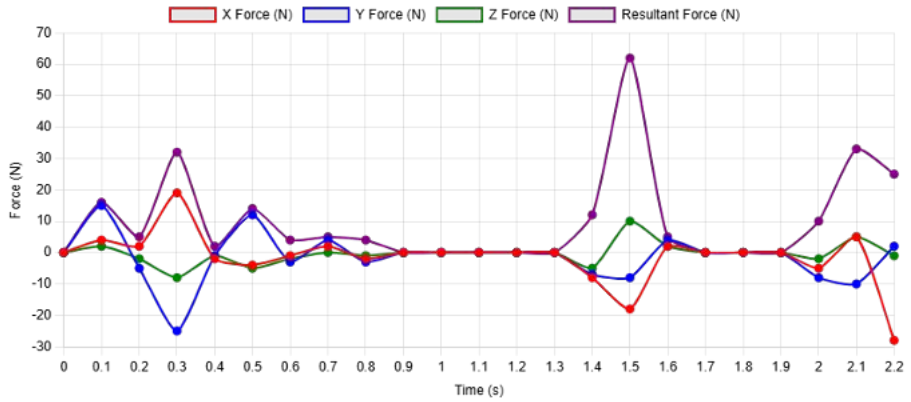

Fig. 19 - Force variation curve of Panax notoginseng rhizome

The forces acting on the three axes of the *Panax notoginseng* rhizome drive the changes in its velocity along these three axes, as shown in Figure 20. The velocity on the Z axis changes slightly, at around 0 $m \cdot s^{-1}$, indicating that the movement of the *Panax notoginseng* rhizome in the axial direction of the rod is not apparent; the velocity on the X axis is positive within 0-1.7 s, indicating that the *Panax notoginseng* lifting effect is significant; the velocity on the X axis is negative within 1.7-2.2 s, indicating that the movement direction of the *Panax notoginseng* rhizome is rolling downward along the separation conveyor, with "backflow" occurring; the velocity on the Y axis fluctuates regularly in the positive and negative directions, indicating that the *Panax notoginseng* rhizome vibrates significantly on the separation conveyor, and the greater the fluctuation amplitude, the greater the height to which the Panax notoginseng is thrown.

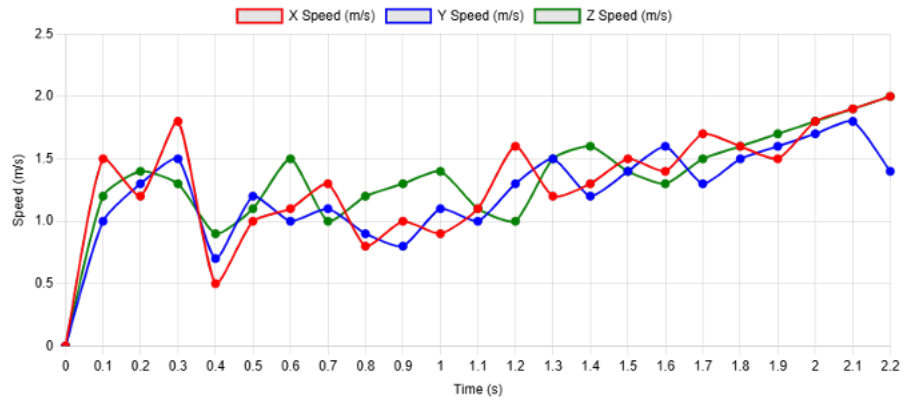

Fig. 20 - Speed variation curve of *Panax notoginseng* rhizome

Lab Test of the separation conveyor

To assess the performance of the separation conveyor device in the *Panax notoginseng* harvester, a bench test was conducted at the Research Center on Mechanization Engineering of Chinese Medicinal Materials in Yunnan. The lab test utilized a separation conveyor device capable of adjusting multiple operational parameters. The drive shaft's height, which influences the lifting angle, is adjustable via a two-link worm-gear lift, while vibration amplitude is controlled by varying the distance between the vibration shaft and the working surface. An inverter controls the conveyor's speed and vibration frequency by driving two three-phase asynchronous motors. The frame comprises a 6 mm-thick Q235 steel plate and a galvanized square tube, with adjustment mechanisms for inclination angle and vibration amplitude, facilitated by a drive shaft and laser-cut sliding grooves. Asynchronous motors power two turbine screw lifters synchronously to maintain the setup's stability. The primary *Panax notoginseng* harvester separation conveyor device is shown in Figure 21.

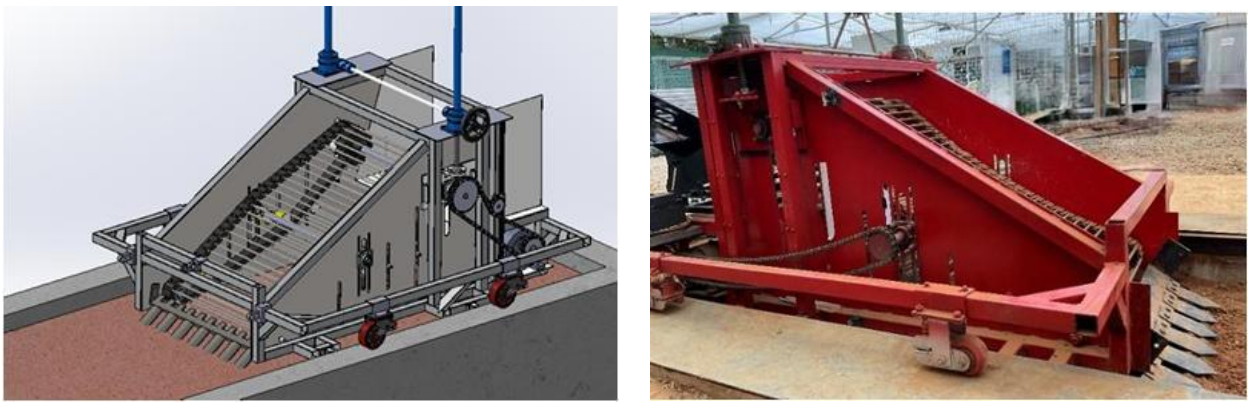

Fig. 21 - The separation conveyor device lab test prototype

Test plan and evaluation indicators

According to theoretical calculations and operational requirements, the main factors affecting the performance of the separation conveyor device are conveyor speed, conveyor inclination angle, and vibration frequency. Referring to the design and analysis of key component parameters, it is known that the conveyor inclination is changed by adjusting the platform separation conveyor device, and the preset range is 15°~35°; the YVR-1 digital tachometer of Yatai Optoelectronics is used to measure the conveying shaft speed of the two three-phase asynchronous motors under no-load conditions (Figure 22). The conveyor drive wheel ratio converts the drive wheel and vibration wheel speeds, and then the conveyor speed and vibration frequency are calculated. The preset conveyor speed is 0.6~1.4 m·s^{-1}, and the preset vibration frequency is 1~3 Hz.

Fig. 22 - Rotational speed measurement

Experiments were conducted to determine the optimal operating parameters of the separation conveyor device, using the separation and conveying rates as evaluation criteria. The conveying rate Y_1 refers to the ratio of the number of *Panax notoginseng* transported by the separation conveyor to the next stage of working components within a specific period to the number of *Panax notoginseng* entering the separation conveyor, and the calculation equation is:

$$Y_1 = \frac{N}{M} \times 100\% \tag{28}$$

where: Y_1 is the conveying rate, [%]; N is the number of particles passing through the separation conveyor; M is the number of particles entering the separation conveyor.

The separation rate Y_2 is the percentage of the actual mass of the separated material to the mass of the material that should be separated. The mass of soil and other impurities separated by the separation conveyor device per unit time, and the mass of impurities attached to the rhizome of *Panax notoginseng* after separation, are measured to facilitate detection of the separation process. The separating rate calculation equation is:

$$Y_2 = \frac{m_1}{m_1+m_2-m_3} \times 100\% \tag{29}$$

where: Y_2 is the separation rate, [%]; m_1 is the mass of impurities separated after separating, [g]; m_2 is the mass of *Panax notoginseng* rhizome and soil after separating, [g]; m_3 is the mass of *Panax notoginseng* rhizome, [g].

Orthogonal test design

To explore the influence of each experimental factor and its interaction on the quality of conveying and separation operation, the lifting speed X_1 is 0.6, 0.8, and 1.0 m·s^{-1}, the vibration frequency X_2 is 1 Hz, 1.5 Hz, and 2 Hz, and the lifting angle X_3 is selected as 15°, 20°, and 25°. The conveying and separating rates are used as experimental indicators in the orthogonal rotation combination test for quadratic regression (Figure 23). The level coding of the experimental factors is shown in Table 3.

Fig. 23 - Separation conveyor device lab test

Table 3

Experimental factors and codes

Code	Experimental factor		
	Lifting speed X_1/m·s^{-1}	Vibration frequency X_2/Hz	Lifting angle X_3 /°
1.682	1.14	2.34	28.40
1	1.0	2.0	25
0	8.0	1.5	20
-1	0.6	1.0	15
-1.682	0.46	0.66	11.60

Orthogonal Experimental results

The Experimental plan and results are shown in Table 4. A total of 23 test groups were conducted, and the test was repeated 3 times at each combination level. The arithmetic mean was taken as the test value of the conveying and separating rates.

$$Y_1 = 95.53866 + 2.20391X_1 - 1.65008X_2 + 1.21982X_3 + 1.74500X_1X_2 + 0.777500X_1X_3 + 1.25750X_2X_3 - 3.04412{X_1}^2 - 0.958665{X_2}^2 - 0.939224{X_3}^2 \quad (30)$$

$$Y_2 = 94.19028 + 0.455272X_1 + 0.775363X_2 - 0.314116X_3 - 0.462500X_1X_2 + 0.212500X_1X_3 + 0.462500X_2X_3 - 1.00566{X_1}^2 - 0.733492{X_2}^2 - 0.406535{X_3}^2 \quad (31)$$

Design-Expert 13 software was used to analyze the conveying and separation rates test results using variance ANOVA. The significance test results are shown in Table 5. The results in the table show that the experimental model is highly statistically significant ($p < 0.0001$), indicating that the designed test is reasonable and practical. The determination coefficient R^2 for Y_1 and Y_2 are 0.9589 and 0.9360, respectively, implying that the regression equation has a high degree of fitting; in summary, the models can be used for analysis and optimization. The experimental factors lifting speed X_1, vibration frequency X_2, and lifting angle X_3 all significantly affect the conveying rate Y_1 and the separation rate Y_2 ($p < 0.05$). The interaction term between lifting speed and vibration frequency ($X_1 X_2$), as well as the vibration frequency and lifting angle ($X_2 X_3$), has a significant influence on the conveying Y_1 and separation Y_2 rates ($p < 0.05$), the interaction term between lifting speed and lifting angle ($X_1 X_3$) had a non-significant effect on the conveying Y_1 and separation Y_2 rates ($P>0.05$). The squared terms X_1^2, X_2^2, and X_3^2 significantly affected the Y_1 and Y_2 ($p < 0.01$).

The *Panax Notoginseng* rhizome conveying rate constantly changes during operation, and the average value during the period of constant speed stability is the *Panax notoginseng* rhizome conveying rate. The changes in the conveying rate obtained are shown in Figure 24. Response surface plots were generated using Design-Expert 13 to visualize the effects of the factors above on the conveying rate. Figure 24a shows that the *Panax notoginseng* rhizome conveying rate Y_1 decreases slightly with increased vibration frequency X_2. With the increase in lifting speed X_1, the conveying rate Y_1 first increases and then decreases. Figure 24b shows that the conveying rate Y_1 increases with the lifting angle X_3, first and then decreases, as the ratio of lifting speed X_1 to lifting angle X_3 increases. Figure 24c shows that the conveying rate Y_1 decreases significantly with the increase in vibration frequency X_2, and the conveying rate Y_1 is not considerably affected by the lifting angle X_3 ratio to vibration frequency X_2.

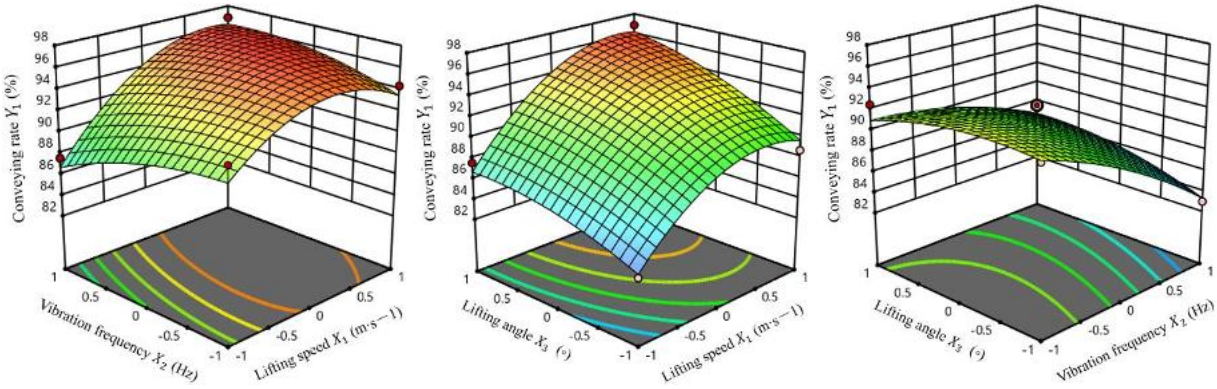

Fig. 24 - Response surface of interaction factors to the *Panax Notoginseng* rhizome conveying rate Y_1
(a) response surface under factors X_1 and X_2; (b) response surface under factors X_1 and X_3; and (c) response surface under factors X_2 and X_3

Figure 25 indicates the *Panax notoginseng* rhizome separation rate Y_2. Figure 25d shows that the separation rate Y_2 increases with an increasing lifting speed X_1 and vibration frequency X_2 from -1 to 1. Figure 25e shows that the conveying rate Y_2 increases slightly with increasing lifting speed X_1 and lifting angle X_3, and first increases and then decreases as X_1 increases from 0 to 1. The rhizome separation rate Y_2 gradually increases as the vibration frequency X_2 from -1 to 1 increases, and the separation rate Y_2 is not considerably affected by the lifting angle X_3 ratio to vibration frequency X_2, as shown in Figure 25f.

Field validation experiment

Experimental design

The machining and assembly of the whole machine were completed based on the structural parameters of the separation conveyor device. Field validation tests were conducted in November 2025 at the *Panax notoginseng* farm in Shilin County, Kunming City, Yunnan Province, to evaluate the practical applicability and reliability of the device under real-world agricultural conditions. The operation parameters of the separation conveyor device during the field harvesting experiment are shown in Table 6.

Figure 26 depicts the scenario for field harvesting operations. Test tools include a steel tape measure, an electronic stopwatch, an electronic balance, a temperature and humidity meter, a soil moisture tester, and a digital display soil hardness meter. The experiment design of the field during the harvest period of *Panax Notoginseng* is as follows: the average ridge width of *Panax Notoginseng* is 1400 mm, the average ridge height is 200 mm, the average thickness of the mixture of *Panax Notoginseng* and soil is 100-150 mm, and the average diameter of rhizome is 26.3 mm, soil moisture content 13.2%, the soil is soft and sticky, with moderate cohesion. The weather is sunny, and the average temperature at harvest is 24°, with a relative humidity of 71%.

Table 6

Operation parameters of the separation conveyor device

Parameter	Numerical value
Working inclination angle of separation conveyor (◦)	20
Working speed of separation conveyor (m·s^{-1})	0.8
Vibration frequency (Hz)	1.5

Fig. 26 - Field harvesting experiment

Test measurements

(1) *Panax Notoginseng* conveying rate:

The *Panax Notoginseng* conveying rate (T) was calculated to determine how the mass of the *Panax Notoginseng* remained unconveyed. It was defined as follows:

$$T = \frac{W_1}{W_1+W_2} \times 100\% \quad (32)$$

where W_1 is the total mass of harvested Panax Notoginseng (kg), and W_2 is the total mass of unharvested *Panax Notoginseng* (kg).

(2) *Panax Notoginseng* damage rate:

After *Panax Notoginseng* was harvested by machine, the harvested rhizomes were categorized into two groups: reasonable and damaged. The weight of each rhizome group was measured individually. The total damage rate (D) of the *Panax notoginseng* can be gained from the following equation:

$$D = \frac{W_4}{W_3+W_4} \times 100\% \quad (33)$$

where W_3 is the total mass of good *Panax Notoginseng* (kg); W_4 is the mass of damaged *Panax Notoginseng* by the harvester machine (kg).

(3) Separation rate:

$$S = \frac{m_1}{m_1+m_2-m_3} \times 100\% \quad (34)$$

where S is the separation rate, %; m_1 is the mass of impurities separated after separating, (kg); m_2 is mass of *Panax notoginseng* rhizome and soil after separating, (kg); m_3 is the mass of *Panax notoginseng* rhizome, (kg).

Field experiment results

The treatments were randomly distributed in the main subplot and sub-subplot; the sub-subplot area was 52.5 m² (35×1.5 m), with 1.5 m between sub-subplots and 10 m at the end of each sub-subplot. After each subplot of experiments is completed, the data collection is carried out within half an hour to ensure consistent rhizome moisture evaporation. The average value is then calculated using the test data from the sub-subplots. The average value of all measured data is used as the final evaluation indicator. The results of the field test are listed in Table 7.

Table 7

Experimental results

Serial Number	Separation rate/%	Conveying rate/%	Damage rate/%
1	96.45	95.25	2.07
2	97.16	95.44	1.86
3	96.38	96.85	2.18
4	96.67	97.13	1.55
5	97.11	96.71	1.93
6	95.92	96.83	1.28
7	97.23	97.14	2.05
8	98.06	95.94	2.13
Average	96.87	96.42	1.88

DISCUSSION

The average values for the efficiency of *Panax notoginseng*-soil separation, the conveying rate of *Panax notoginseng*, and the rhizome damage rate for the separation conveyor device are 96.87%, 96.42%, and 1.88%, respectively. The relative errors between the laboratory and field test results for the efficiency of *Panax notoginseng*-soil separation and the rhizome conveying rate are 0.97% and 1%, respectively. These values are consistent with the optimized parameters and meet the agronomic requirements for *Panax notoginseng* harvesting. The separation rate of *Panax notoginseng* increased by 0.10%, and the damage rate decreased by 0.99% compared to the reference (*Zhenmeng et al., 2018*). The results indicate that the separation conveyor device yields a higher harvest of *Panax notoginseng* in hilly areas.

CONCLUSIONS

(1) This study systematically investigated the design, analysis, and optimization of a separation conveyor device for a self-propelled *Panax notoginseng* combine harvester, addressing the challenges of harvesting in hilly and mountainous regions of southwest China. By integrating agronomic characteristics of *Panax notoginseng* with mechanical design principles, a crawler-type harvester capable of excavation, separation, conveying, lifting, and collection was successfully developed to improve harvesting efficiency and reduce labor intensity.

(2) Through detailed kinematic and mechanical analyses, the separation conveyor structure and key components such as the drive wheel, vibration wheel, and bar-type conveyor were theoretically modeled and optimized. Coupled DEM–MBD simulations using EDEM and RecurDyn provided insights into soil–rhizome interaction, particle separation behavior, and dynamic forces acting on *Panax notoginseng* rhizomes. Simulation results demonstrated that effective soil separation could be achieved within approximately 2.25 s, with finer soil particles separating earlier than larger aggregates.

(3) Laboratory experiments and quadratic regression orthogonal tests further validated the simulation outcomes. Conveyor speed, vibration frequency, and lifting angle were identified as significant factors influencing conveying and separation performance. Optimal parameters were determined as a conveyor speed of 0.8 $m \cdot s^{-1}$, vibration frequency of 1.5 Hz, and lifting angle of 20°, achieving separation and conveying rates exceeding 95% under laboratory conditions.

(4) Field validation experiments confirmed the reliability and applicability of the optimized design. The separation conveyor achieved an average separation rate of 96.87%, conveying rate of 96.42%, and a low rhizome damage rate of 1.88%, meeting agronomic and mechanization requirements. Overall, this research provides a solid theoretical and experimental foundation for advancing mechanized harvesting of *Panax notoginseng* and similar rhizome crops.

ACKNOWLEDGEMENT

We would like to express our sincere appreciation to all those who supported and contributed to this research. Special thanks to the Research Center on Mechanization Engineering of Chinese Medicinal Materials in Yunnan Universities for providing invaluable resources and support throughout this study, under project number 2022YFD2002004. We also extend our gratitude to the Faculty of Mechanical and Electrical Engineering and Faculty of Modern Agricultural Engineering, Kunming University of Science and Technology, Kunming, China, for their collaboration and valuable contributions, Additionally, we acknowledge the School of Tea and Coffee, Puer University, Puer, China. and the Agricultural Engineering Research Institute (AEnRI), Agricultural Research Center (ARC), 256 Dokki, Giza, Egypt.

Keywords: *precision seeding, single-clove metering, discrete element method, bench test, garlic mechanization*

ABSTRACT

To reduce miss-seeding and improve the stability of single-clove pickup in garlic seed metering devices, a spoon-clamp type garlic seed metering device was designed. The proposed mechanism combined spoon-type seed pickup with spring-assisted clamping, so garlic cloves with irregular surfaces could be picked up, carried, cleaned, and discharged more stably. Based on the geometric characteristics of three garlic varieties, the key parameters of the seed plate, seed pickup spoon, and opening-closing mechanism were determined by theoretical analysis. A three-dimensional model of the seed metering device and garlic-clove models were established using the discrete element method. Single-factor simulations were then performed to analyze the effects of seed plate speed and seed pickup spoon diameter on the qualified seeding index, reseeding index, and miss-seeding index. The suitable simulated operating range was 1–7 r/min for seed plate speed and 25–35 mm for seed pickup spoon diameter. Bench tests showed that the suitable parameter combination for "Acheng Purple Garlic" and "Nong'an Purple Garlic" was a seed plate speed of 4 r/min and a seed pickup spoon diameter of 32 mm. For "Zhaozhou White Garlic", the suitable combination was 5.5 r/min and 28 mm. These results showed that the spoon-clamp mechanism was feasible for improving single-clove garlic metering stability under controlled bench-test conditions.

摘要

针对大蒜蒜瓣形状不规则导致排种器漏播率高、单粒取种稳定性不足等问题，本文设计了一种勺夹式大蒜排种器。该装置将取种勺取种与弹簧辅助夹持相结合，使蒜瓣在取种、携种、清种和投种过程中保持较稳定的约束状态。基于三种大蒜蒜瓣的几何特性，通过理论分析确定排种盘、取种勺及开合机构等关键参数。采用离散元法建立排种器三维模型和蒜瓣颗粒模型，并通过单因素仿真分析排种盘转速和取种勺直径对合格指数、重播指数和漏播指数的影响。仿真结果表明，排种盘转速为 1–7 r/min、取种勺直径为 25–35 mm 时排种性能较优。台架试验结果表明，"阿城紫皮蒜"和"农安紫皮蒜"的适宜参数组合为排种盘转速 4 r/min、取种勺直径 32 mm；"肇州白皮蒜"的适宜参数组合为排种盘转速 5.5 r/min、取种勺直径 28 mm。研究结果说明，勺夹式取种机构在受控台架条件下具有提高大蒜单粒取种稳定性的可行性。

INTRODUCTION

Garlic is one of the main specialty cash crops in China. Precision garlic seeding technology is important for improving the quality and efficiency of mechanized garlic sowing *(Wei et al., 2022; Xie et al., 2015)*. Garlic cloves have irregular curved surfaces and differ greatly in variety, shape, and size. These characteristics can easily cause miss-seeding, reseeding, and unstable seed carrying during mechanical sowing. Improving the stability of single-clove pickup and transport is therefore an important issue in the development of garlic seed metering devices. Existing garlic seeding devices mainly include spoon-chain, spoon-belt, cell-type, and pneumatic seed metering devices *(Liu et al., 2019; Zhang et al., 2014)*. Reviews and recent studies have also emphasized the need for improved single-clove pickup, directional control, and adaptability *(Cui et al., 2018; Fang et al., 2024; Jiang, 2018; Shao et al., 2025)*. These devices can meet some agronomic requirements, but their performance is still limited by seed leakage, unstable single-clove pickup, high structural complexity, or poor adaptability to different garlic varieties.

Previous studies have improved garlic seed metering performance through different technical routes. *Li et al. (2020)* designed a wheel-spoon type single-clove seed picking device, but different spoon structures were needed for different garlic grades. *Li et al. (2017)* and *Geng et al. (2016)* designed seed-box delivery mechanisms, but manual replanting was still required when serious miss-seeding occurred. Other mechanical garlic planting devices were reported by *Choi et al. (2003)*, *Dong et al. (2015)*, *Han (2011)*, and *Kang (2000)*. *Bakhtiari et al. (2009)* developed a precision garlic seeder with good performance, although the sensors and control system increased the manufacturing cost. *Xie et al. (2022)* proposed a tooth-assisted pneumatic garlic seed metering device, and *Hou et al. (2024)* designed a multi-disturbance seed-cleaning device. These studies indicate that seed pickup stability, miss-seeding control, and structural adaptability remain important problems. Most spoon-type mechanisms mainly depend on passive seed filling or spoon carrying, and the clove is not actively constrained during transport. A clove may slip, fall, or be picked up together with other cloves under shape variation and collision disturbance. A metering mechanism that combines spoon pickup with controlled clamping is therefore needed to improve carrying stability while reducing seed damage.

Accordingly, this study aimed to: (1) design a spoon-clamp type garlic seed metering device that combines spoon pickup with spring-assisted clamping; (2) determine the key structural parameters of the seed plate, seed pickup spoon, and opening-closing mechanism based on garlic-clove dimensions and theoretical analysis; (3) analyze the effects of seed plate speed and seed pickup spoon diameter using DEM simulation; and (4) verify the suitable parameter combinations through bench tests with three garlic varieties. This study provides a basis for further optimization and field validation of garlic precision seeding devices.

MATERIALS AND METHODS

Dimensional Measurement

The geometric characteristics of garlic cloves are the basis for designing the key components and selecting the control parameters of the seed metering device. The axial dimension method is commonly used to measure seed materials *(Liu et al., 2018)*. In this study, clove morphology was described by length L, width W, thickness H, and tail length T. As shown in Fig. 1, a three-axis spatial coordinate system XYZ was established with the centroid of the garlic clove as the origin O. The length, width, and thickness directions were defined as the X-, Y-, and Z-axes, respectively. To keep the design parameters consistent, garlic cloves with similar moisture content and intact appearance were selected. Each dimension was measured using a Vernier caliper with an accuracy of 0.01 mm.

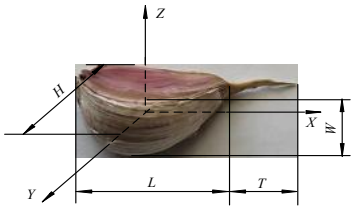

Fig. 1 – Determination of the geometric dimensions of garlic cloves

A total of 300 cloves were randomly selected from each variety, including “Acheng Purple Garlic”, “Zhaozhou White Garlic”, and “Nong’an Purple Garlic”. Each dimension was measured three times with equal precision. The probability density distribution of garlic dimensions was analyzed using Excel *(Tang, 2018)*, and the mean and standard deviation were calculated, as shown in Table 1.

Table 1

Geometrical dimensions of three garlic varieties

Tested varieties	Length [mm]		Width [mm]		Thickness [mm]		Tail Length [mm]	
	Mean	Standard Deviation	Mean	Standard Deviation	Mean	Standard Deviation	Mean	Standard Deviation
Acheng Purple Garlic	28.43	0.93	16.95	0.82	17.05	0.97	10.71	1.02
Zhaozhou White Garlic	32.80	2.94	14.34	1.31	10.13	0.70	12.04	0.99
Nong’an Purple Garlic	25.37	1.61	16.26	0.79	15.93	0.78	12.40	0.82

Table 1 shows clear differences in the geometric dimensions of the three garlic varieties. The average length, width, thickness, and tail length of “Acheng Purple Garlic” were 28.43, 16.95, 17.05, and 10.71 mm, respectively. The corresponding values for “Zhaozhou White Garlic” were 32.80, 14.34, 10.13, and 12.04 mm. For “Nong’an Purple Garlic”, the values were 25.37, 16.26, 15.93, and 12.40 mm. These data provide a basis for designing the seed pickup spoon parameters.

Overall Structure and Working Principle of the Seed Metering Device

The spoon-clamp garlic seed metering device mainly consists of seed pickup spoons, torsion springs, a seed plate, limit rods, and other components, as shown in Fig. 2. The working process of the device includes four zones: seed pickup, seed clamping, seed cleaning, and seed discharge.

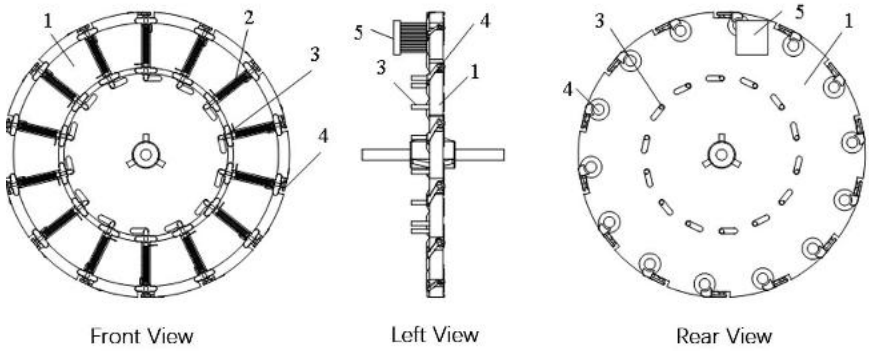

Fig. 2 – Overall structure of spoon-clamp garlic seed metering device

1 – Seed Plate; 2 – Torsion Spring; 3 – Limit Rod; 4 – Seed Pickup Spoon; 5 – Seed Cleaning Brush

During operation, the seed plate rotates around the main shaft and drives the seed pickup spoons, torsion springs, and clamping components. When a seed pickup spoon reaches the seed pickup zone, the limit rod opens the spoon through the torsion spring shaft. After the spoon passes the limit block, the elastic force of the torsion spring closes the spoon and clamps a garlic clove. The clamped clove then moves with the seed plate. When the spoon passes through the seed cleaning brush, excessive or unstable cloves are removed. At the seed discharge position, the second limit rod opens the spoon and releases the clove. This process integrates seed pickup, clamping, cleaning, and discharge. It is also the main structural difference between the proposed mechanism and ordinary spoon-type carrying devices.

Design of Key Components

Design of Seed Plate

The seed plate of the precision garlic seed metering device adopts a disc structure. Its main parameters include seed plate diameter, rotational speed, and the number of seed pickup spoons. A relationship among seed plate diameter, rotational speed, forward speed, and the number of seed pickup spoons was therefore established.

A larger seed plate diameter and more seed pickup spoons can reduce angular velocity and increase the curvature radius at the seed drop point, which helps stabilize seed pickup. Increasing the seed plate diameter can also increase spring deformation and improve control of the squeezing force during seed carrying. However, an excessive diameter increases the size, weight, and power consumption of the metering mechanism. Considering the relationship among seed plate radius, rotational speed, and forward speed, the seed plate diameter was set to 400 mm in the prototype design.

The linear speed of the seed plate refers to the linear speed at the seed pickup spoon. As the rotational speed increases, the time for the seed pickup spoon to pass through the seed area decreases. This may increase miss-seeding and cause picked cloves to fall under collision disturbance. Therefore, the linear speed of the seed pickup spoon should generally not exceed 0.35 m/s.

The maximum linear speed was set to 0.35 m/s, and the maximum rotational speed of the seed plate was calculated according to Equation (1).

$$\frac{d_p n_p \pi}{60} = 0.35 m/s \quad (1)$$

where d_p is the seed plate diameter, [m]; and n_p is the seed plate rotational speed, [r/min].

During operation, the garlic seeder mainly relies on ground-wheel transmission. According to the coordination between seed metering and forward movement, the time required for a garlic clove to rotate through the arc distance between adjacent seed pickup spoons should be equal to the time required for the seeder to move forward by one hill spacing. The relationship between seed pickup spoon spacing and garlic plant spacing is expressed as follows:

$$S_p = r\theta = \frac{n_p d_p \pi t}{60} \tag{2}$$

$$(1+\delta)\ \upsilon_c t = S_c \tag{3}$$

where S_p is the arc distance between adjacent seed pickup spoons on the seed plate, [m]; r is the seed plate radius, [m]; θ is the angular displacement, [rad]; n_p is the seed plate rotational speed, [r/min]; d_p is the seed plate diameter, [m]; t is the travel time, [s]; δ is the ground-wheel slip rate; υ_c is the forward speed of the machine, [m/s]; and S_c is the garlic plant spacing, [m].

By combining the above two formulas, the expression for the seed pickup spoon spacing can be obtained as follows:

$$S_p = \frac{S_c n_p d_p \pi}{(1+\delta)60\upsilon_c} \tag{4}$$

According to the agronomic requirements for garlic planting, the plant spacing S_c is 80–120 mm, the forward speed of the seeder υ_c is 0.2–0.4 km/h, and the ground-wheel slip rate δ is 0.05–0.12. When δ = 0.08, the calculated arc distance S_p between adjacent seed pickup spoons on the seed plate is 58–116 mm.

$$n_s = \frac{\pi d_p}{S_p} \tag{5}$$

where n_s is the number of seed pickup spoons, [pcs]; d_p is the seed plate diameter, [m]; and S_p is the arc distance between adjacent seed pickup spoons, [m].

The calculation showed that the arc distance between adjacent seed pickup spoons on the seed plate was 116 mm, and the number of seed pickup spoons was 14.

Design of Seed Pickup Spoon

A spoon-clamp seed pickup structure was proposed because garlic cloves differ greatly in three-dimensional morphology and have uneven curved surfaces. The seed pickup spoon is used for seed pickup and carrying. During seed plate rotation, the spoon should carry the garlic clove to the discharge position without damage or falling. A larger spoon can reduce miss-seeding, but an excessively large spoon may increase reseeding. The spoon size was therefore determined according to the external dimensions of the garlic cloves. The three-dimensional shape of garlic cloves was approximately regarded as an ellipsoid. The spoon opening was initially designed as a circular opening similar to a small hemisphere. To reduce miss-seeding and reseeding, the diameter of the spoon opening should be greater than the average clove width and smaller than the average clove length. The initial diameter was set to 30 mm. The minimum and maximum diameters were 16 mm and 36 mm, respectively, and the spoon depth was about 4 mm, which was about two-thirds of the maximum clove thickness. The structure of the seed pickup spoon is shown in Fig. 3.

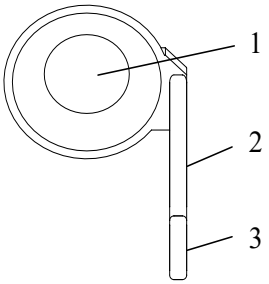

Fig. 3 – Structure diagram of seed pickup spoon
1 – Spoon Body; 2 – Spoon Handle; 3 – Fixing Hole

Design of Opening and Closing Mechanism

The seed pickup process of the precision garlic seed metering device mainly depends on the opening and closing mechanism. The fixed end contacts the limit rod and continuously opens the seed pickup spoon. As the seed plate rotates, the elastic potential energy of the torsion spring increases. When the fixed end is separated from the limit rod, the stored elastic potential energy is released, and the seed pickup spoon closes rapidly under the action of the torsion spring. The operating performance of this mechanism directly affects seed clamping, transport, and discharge. It is therefore an important component for precision seed pickup in garlic planting. The opening and closing mechanism are shown in Fig. 4.

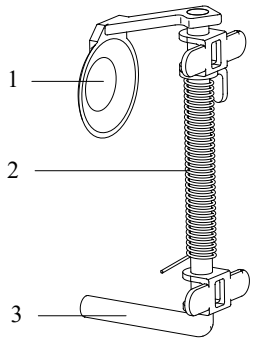

Fig. 4 – Opening and closing mechanism of the garlic seed metering device
1 – Seed Pickup Spoon; 2 – Torsion Spring; 3 – Limit Rod

The opening-closing mechanism realizes the opening and closing movement of the seed pickup spoon through the combined action of the torsion spring and limit rod. During opening, elastic potential energy is stored in the torsion spring and then released to generate the clamping force of the seed pickup spoon. The clamping force affects both seed pickup stability and clove damage. Because the clamping force is difficult to adjust directly during operation, different spring wire diameters were used as equivalent clamping force levels in the experiment. The relationship between spring wire diameter and clamping force is expressed by Eq. (6).

$$\begin{cases} P = k\Delta s \\ k = \dfrac{1000 d_w}{\left(\dfrac{d}{d_w}\right)^3} \end{cases} \quad (6)$$

where P is the clamping force of the seed pickup spoon, [N]; k is the spring stiffness coefficient, [N/mm]; Δs is the spring deformation, [mm]; d_w is the spring wire diameter, [mm]; and d is the mean spring diameter, [mm].

"Acheng Purple Garlic" was selected for the single-factor test on clamping force to clarify its effect on seed damage rate. The spring wire diameters were set to 0.5, 0.6, 0.7, 0.8, 0.9, and 1.0 mm. For each spring wire diameter, 300 garlic cloves were selected and evenly divided into three groups for repeated seed pickup tests. The seed damage rate was determined according to visible damage to the garlic body after the skin was peeled off. Considering the practical requirements of agricultural production and the adjustable range of the mechanism, the spring wire diameter was set within 0.5–1.0 mm. The number of damaged cloves among the effectively clamped cloves was counted, and the seed damage rate was used as the evaluation indicator. The test plan and results are shown in Table 2.

Table 2
Single-factor test scheme and results for spring wire diameter

Spring Wire Diameter [mm]	0.5	0.6	0.7	0.8	0.9	1.0
Seed Damage Rate [%]	0	0	0	5.33	6.66	8.00

The single-factor results showed that the seed damage rate was 0% when the spring wire diameter was 0.5–0.7 mm. Visible damage began to appear when the spring wire diameter exceeded 0.7 mm. The spring wire diameter was therefore set to 0.7 mm, corresponding to a clamping force of approximately 2.401 N. This value was selected to maintain clamping stability while reducing garlic-clove damage.

Determination of Seed Discharge Port Position

The position of the seed discharge port directly affects the falling height and initial state of the garlic clove, and is therefore an important parameter for device coordination.

Fig. 5 shows the seed pickup process and the falling process from the discharge port.

To determine the discharge port position, the seed pickup process was assumed to be uniform. The horizontal and vertical coordinates of the garlic clove during movement with the seed plate are denoted as x and y. When the garlic clove falls from the discharge port, its initial horizontal and vertical velocities are denoted as v_x and v_y. The horizontal and vertical displacements after falling are denoted as X and Y. The expressions for these variables are given in Equation (7).

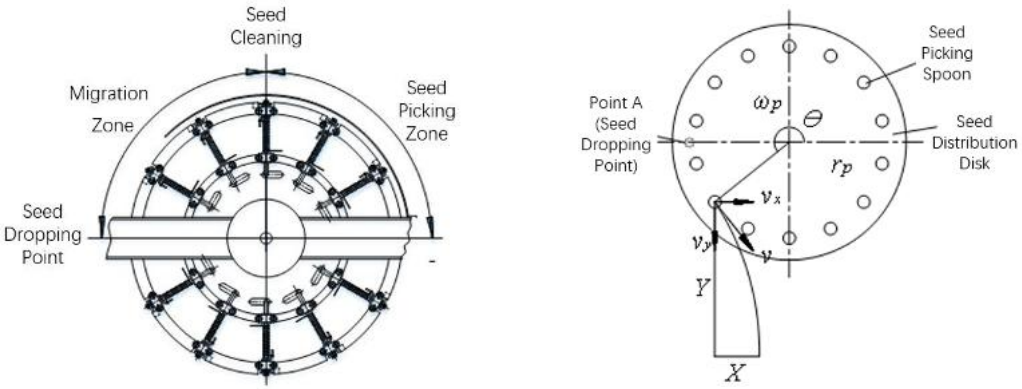

Fig. 5 – Motion analysis of seeding process

$$\begin{cases} x = r_p \cos\theta \\ y = r_p \sin\theta \\ \dot{x} = -r_p \sin\theta \\ \dot{y} = r_p \cos\theta \\ X = r_p \omega_p t \cos\theta \\ Y = r_p \omega_p t \sin\theta + \dfrac{gt^2}{2} \end{cases} \quad (7)$$

where x and y are the horizontal and vertical coordinates of the garlic clove, [m]; $\dot{x}$ and $\dot{y}$ are the corresponding velocity components, [m/s]; X and Y are the horizontal and vertical falling displacements, [m]; r_p is the seed plate radius, [m]; θ is the garlic-clove discharge angle, [rad]; ω_p is the angular velocity of the seed plate, [rad/s]; t is the falling time, [s]; and g is the gravitational acceleration, [m/s²].

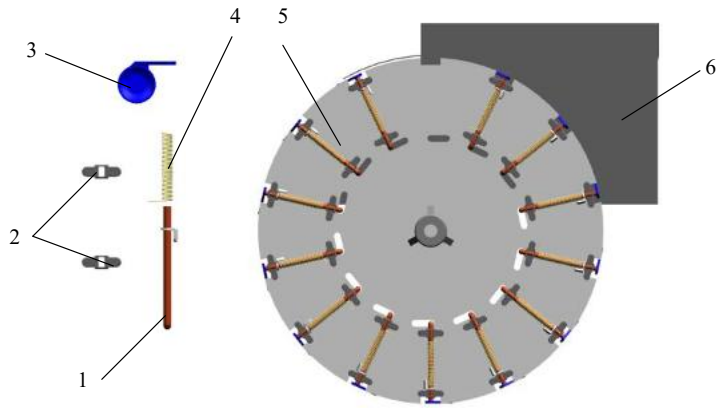
To reduce the horizontal velocity during discharge and obtain zero horizontal displacement after the garlic clove falls from the discharge port, the discharge position was determined according to the motion relationship in Equation (7). Among the solutions, −90° corresponds to the initial seed pickup position. Therefore, point A in Fig. 5 was selected as the seed discharge port position.

Discrete Element Simulation

A model of the precision garlic seed metering device and garlic-clove models were constructed using the discrete element method (DEM), and simulation experiments were then conducted *(Hu, 2010)*. The control-variable single-factor method was used to clarify the independent effects of seed plate speed and seed pickup spoon diameter at the prototype design stage. The qualified seeding index, reseeding index, and miss-seeding index were selected as evaluation indicators. EDEM software was used for the virtual simulation tests, which provided data support for structural improvement and operational parameter selection of the precision garlic seed metering device.

Establishment of Seed Metering Device Geometric Model

The geometric model of the seed metering device is an important factor affecting the accuracy of seed pickup simulation. The precision garlic seed metering device was modeled using NX/UG 3D software *(Bertrand et al., 2005; Cundall and Strack, 1979; Hou et al., 2019; Li et al., 2003; Qian, 2008; Sakaguchi et al., 2001; Sharma et al., 2011; Yang and Hsiau, 2000; Yu et al., 2005)*, as shown in Fig. 6. To improve calculation efficiency while preserving the main contact boundaries, small fillets, threaded holes, and other non-critical details were simplified before importing the model into EDEM.



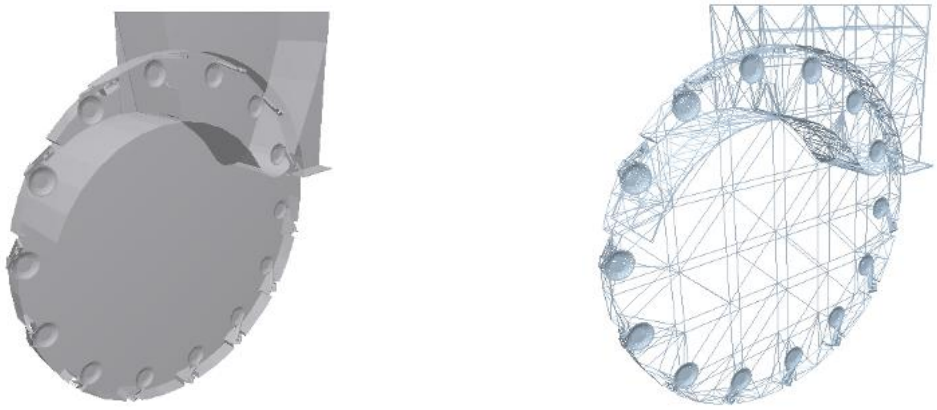


Fig. 6 – Three-dimensional model of garlic seed metering device
1 – Opening and Closing Limit Rod; 2 – Fixing Washer; 3 – Seed Pickup Spoon; 4 – Spring; 5 – Seed Plate; 6 – Seed Box

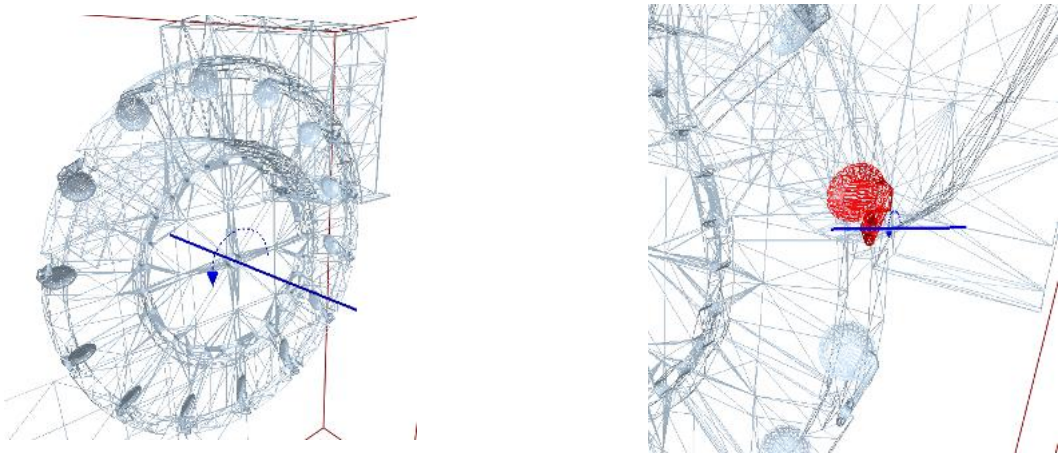
According to the requirements of prototype development and preliminary material property measurements, the seed pickup spoon was set as 65 Mn steel, with a Poisson's ratio of 0.40, a shear modulus of 7.85×10^9 Pa, and a density of 7800 kg/m^3. The seed plate and seed box were set as aluminum alloy, with a Poisson's ratio of 0.42, a shear modulus of 1.7×10^{10} Pa, and a density of 2700 kg/m^3.

a) Garlic seed metering device in filled format *b) Garlic seed metering device in mesh format*

Fig. 7 – Virtual simulation model of spoon-clamp garlic precision seed metering device

Establishment of Discrete Element Model for Garlic Cloves

The shape and size of garlic cloves are important factors affecting the seeding performance of the seed metering device. In this study, the seeding performance of three garlic varieties was analyzed. According to the morphological and dimensional characteristics of the three varieties, the clove shapes were divided into two categories. "Acheng Purple Garlic" and "Nong'an Purple Garlic" were classified as drum-shaped, while "Zhaozhou White Garlic" was classified as slender. Based on the parameters measured in previous material property studies, multi-sphere filling was carried out for the two clove shapes. The filled garlic-clove particles are shown in Fig. 8.



a) Drum-shaped *b) Slender*

Fig. 8 – Filling condition of two kinds of garlic cloves

Numerical Simulation Test of Seed Metering Device Performance

The seeding performance of the garlic seed metering device is affected by garlic variety and size, seed plate speed, and seed pickup spoon diameter. In this study, seed plate speed and seed pickup spoon diameter were selected as the main design variables. The qualified seeding index, reseeding index, and miss-seeding index were used as evaluation indicators. A single-factor control-variable simulation was adopted to determine the suitable parameter range before bench-test validation. The possible interaction between factors was not the focus of this prototype-stage study and should be further analyzed in later optimization work.

a) Rotation direction of the seed plate and seed pickup spoon *b) Self-rotation direction of the seed pickup spoon*

Fig. 9 – Simulation of component motion settings

Factors and Evaluation Indicators for Virtual Simulation Experiments

The rotational speed of the seed plate was matched with the revolution speed of the seed pickup spoons. A rotating model was used to set the rotational speed of the seed plate and each seed pickup spoon, and the self-rotation motion of the seed pickup spoons was also added. A factory model was used to establish a virtual particle factory above the seed box for dynamic particle generation. The operating parameters of the spring were set through the Application Programming Interface, as shown in Fig. 9.

Virtual simulation experiments were conducted using the same structural parameters of the spoon-clamp precision garlic seed metering device. The effects of seed plate speed and seed pickup spoon diameter on seeding performance and the suitable parameter range were analyzed for drum-shaped and slender garlic cloves. Based on theoretical analysis, preliminary tests, agronomic requirements, and actual operating conditions, the seed plate speed was set to 1–13 r/min, and the seed pickup spoon diameter was set to 15–45 mm. Single-factor virtual simulation experiments were conducted separately for the two garlic-clove types.

Referring to the national standards GB/T 6973–2005 “Test Methods for Single Seed (Precision) Planters” and NY/T 503–2015 “Quality of Single Seed (Precision) Planter Operations,” the qualified seeding index, reseeding index and miss-seeding index were selected to evaluate the operational performance, suitable parameter range and stability of the precision garlic seed metering device. Considering the differences between simulation and bench tests and the operability of the virtual statistics, the calculation formulas for each simulation indicator were defined as follows:

$$S_f = \frac{n_{0f}}{N_f} \times 100\% \tag{8}$$

$$D_f = \frac{n_{1f}}{N_f} \times 100\% \tag{9}$$

$$M_f = \frac{n_{2f}}{N_f} \times 100\% \tag{10}$$

where S_f is the simulation qualified seeding index, [%]; D_f is the simulation reseeding index, [%]; M_f is the simulation miss-seeding index, [%]; n_{0f} is the single-seed pickup count, [pcs]; n_{1f} is the count of two or more seeds picked up, [pcs]; n_{2f} is the no-seed pickup count, [pcs]; and N_f is the theoretical seed pickup count, [pcs].

Bench-Test Materials and Equipment

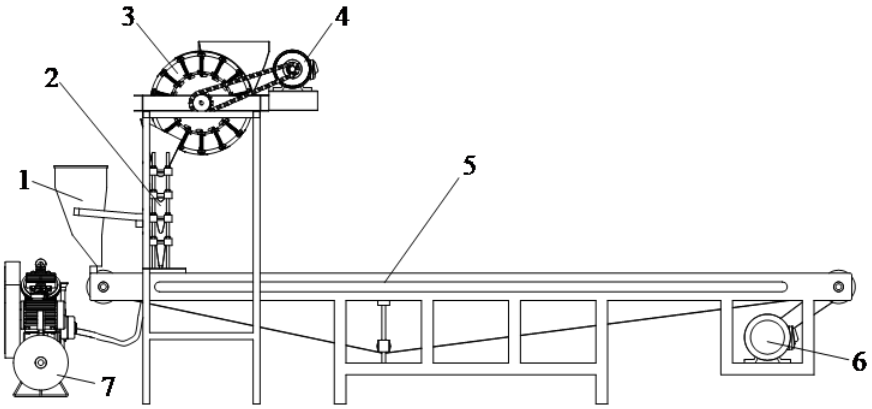


Fig. 10 – Test-bed of spoon-clamp garlic precision seeding device

1 – Soil Spreading Device; 2 – Three-stage Alignment Mechanism; 3 – Spoon-clamp Precision Garlic Seed Plate; 4 – Speed-regulating Motor for Seed Metering Device; 5 – Conveyor Belt; 6 – Speed-regulating Motor for Conveyor Belt; 7 – Air Pump

The test materials were three garlic varieties widely planted in the Heilongjiang region: “Acheng Purple Garlic”, “Zhaozhou White Garlic”, and “Nong’an Purple Garlic”. The cloves were manually graded and screened to ensure a moisture content of 55%–65%, plump and symmetrical shapes, and no scars, rot, or pest damage. Garlic cloves with similar specifications were selected for single-factor performance testing and validation of the seeding device.

A self-made spoon-clamp precision garlic seeding test bench was used, and its overall structure is shown in Fig. 10. The bench mainly consisted of a spoon-clamp precision garlic seed metering device, a seed alignment mechanism, a soil spreading device, a conveyor belt, and a speed-regulating motor. The seed metering device and alignment mechanism completed seed pickup and alignment. The positioning bowl in the alignment mechanism was opened and closed by an air pump. The soil spreading device mainly consisted of a soil box and adjustable baffles. It spread soil evenly on the conveyor belt, allowing the garlic cloves to fall into the soil on the conveyor belt after alignment.

The motors of the seed metering device and conveyor belt were controlled by frequency converters, which adjusted the working speeds and improved the operability of the test bench. The JPS-12 frequency converter was selected to ensure precise motor speed adjustment and stable bench operation. According to the agronomic requirements for garlic seeding spacing, a conversion relationship between the working speed of the seed metering device and the forward speed of the machine was needed. During the experiment, the forward speed of the machine was represented by the forward speed of the conveyor belt. The conversion relationship is expressed as follows:

$$N_P = \frac{60V_D}{S_Q N_Q} \cdot 1000 \tag{11}$$

where N_P is the rotational speed of the seed plate, [r/min]; V_D is the conveyor-belt speed, [m/s]; S_Q is the theoretical plant spacing, [mm]; and N_Q is the number of seed pickup spoons, [pcs].

Based on the mechanism analysis, DEM simulation, and production requirements, the main factors affecting the operational quality and suitable seeding range of the spoon-clamp precision garlic seeding device are seed plate speed and seed pickup spoon diameter. Bench tests were conducted to verify the effects of these two structural and operational parameters and to determine suitable parameter combinations for the tested garlic varieties.

Division of Sections and Variable Calculation

The measured spacing between adjacent garlic cloves was recorded as x_i, and the reference (theoretical) plant spacing was recorded as X_{ref}. The samples were divided into intervals with a step of $0.1X_{ref}$. The dimensionless spacing ratio for each observation was calculated using Equation (12).

$$X_i = \frac{x_i}{X_{ref}} \tag{12}$$

where X_i is the dimensionless spacing ratio; x_i is the measured spacing between adjacent garlic cloves, [mm]; and X_{ref} is the reference (theoretical) plant spacing, [mm].

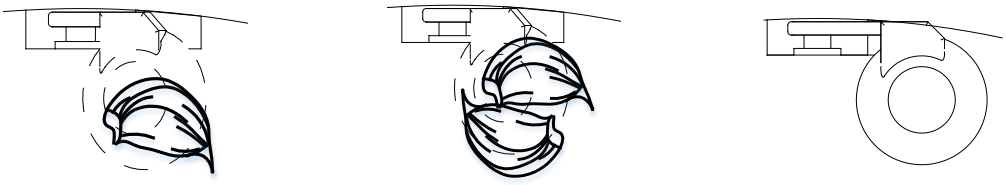
The spacing of the tested garlic seed samples was divided into qualified intervals, reseeding intervals, and miss-seeding intervals. The division methods for each interval are as follows:

$$\begin{cases} \boldsymbol{n}_1' = \sum \boldsymbol{n}_i (\boldsymbol{X}_i \in \{0.0-0.5\}) \Rightarrow Reseeing\ Interval \\ \boldsymbol{n}_2' = \sum \boldsymbol{n}_i (\boldsymbol{X}_i \in \{0.5-1.5\}) \Rightarrow Qualified\ Interval \\ \boldsymbol{n}_3' = \sum \boldsymbol{n}_i (\boldsymbol{X}_i \in \{1.5-2.5\}) \Rightarrow Miss-Seeding\ Interval \\ \boldsymbol{n}_4' = \sum \boldsymbol{n}_i (\boldsymbol{X}_i \in \{2.5-3.5\}) \\ \boldsymbol{n}_5' = \sum \boldsymbol{n}_i (\boldsymbol{X}_i \in \{3.5-+\infty\}) \\ \boldsymbol{N} = \boldsymbol{n}_1' + \boldsymbol{n}_2' + \boldsymbol{n}_3' + \boldsymbol{n}_4' + \boldsymbol{n}_5' \quad \Rightarrow Number\ of\ Interval \end{cases} \tag{13}$$

The qualified count, reseeding count, and miss-seeding count of the measured garlic seed hill spacing can be expressed by Equation (14) as follows:

$$\begin{cases} \text{Qualified Count:}\ \ n_1 = N - 2n_2 \\ \text{Reseeding Count:}\ \ n_2 = n_1' \\ \text{Miss-seeding Count:}\ \ n_0 = n_3' + 2n_4' + 3n_5' \\ \text{Number of Intervals:}\ \ N' = n_2' + 2n_3' + 3n_4' + 4n_5' \\ \text{Average Qualified Spacing:}\ \ \bar{X} = \dfrac{\sum n_i X_i}{n_2} \qquad Xi \in \{> 0.5 \sim \leq 1.5\} \end{cases} \tag{14}$$

where n'_j (j = 1,…,5) is the number of observations in the *j-th* spacing interval; n_i is the frequency in interval i; X_i is the dimensionless spacing ratio; N is the total number of observations; n_1, n_2, and n_0 are the qualified, reseeding, and miss-seeding counts, respectively; N' is the equivalent total interval count; and $\bar{X}$ is the mean qualified spacing ratio.



Calculation Methods for Seeding Performance Evaluation Indicators

Qualified Seeding Index, Miss-seeding Index, Reseeding Index, and Qualified Plant Spacing Index. The calculation methods for each performance indicator of the garlic seeding device in this study are shown in Equation (15) as follows:

$$\begin{cases} Qualified\ Seeding\ Index:\ \ \boldsymbol{S}_0 = \dfrac{\boldsymbol{n}_n}{\boldsymbol{N}'} \times 100\% \\ Qualified\ Plant\ Spacing\ Index:\ \ \boldsymbol{S} = \dfrac{\boldsymbol{n}_1}{\boldsymbol{N}'} \times 100\% \\ Reseeding\ Index:\ \ \boldsymbol{D} = \dfrac{\boldsymbol{n}_2}{\boldsymbol{N}'} \times 100\% \\ Miss-seeding\ Index:\ \ \boldsymbol{M} = \dfrac{\boldsymbol{n}_0}{\boldsymbol{N}'} \times 100\% \end{cases} \tag{15}$$

where S_0 is the qualified seeding index, [%]; S is the qualified plant spacing index, [%]; D is the reseeding index, [%]; M is the miss-seeding index, [%]; n_n is the single-seed pickup count, [pcs]; n_1 is the qualified single-seed discharge count, [pcs]; n_2 is the count of two or more seeds discharged, [pcs]; n_0 is the miss-seeding count, [pcs]; and N' is the total number of hill-spacing intervals in the sample, [pcs].

The evaluation criteria were as follows. In the single-factor tests of seed plate speed and seed pickup spoon diameter, the seed pickup spoon was judged as qualified if it held only one garlic clove after passing through the seed box, as shown in Fig. 11(a). If it held two or more garlic cloves, it was judged as reseeding, as shown in Fig. 11(b). If it did not hold any garlic clove, it was judged as miss-seeding, as shown in Fig. 11(c).

a) Qualified *b) Reseeding* *c) Miss-seeding*

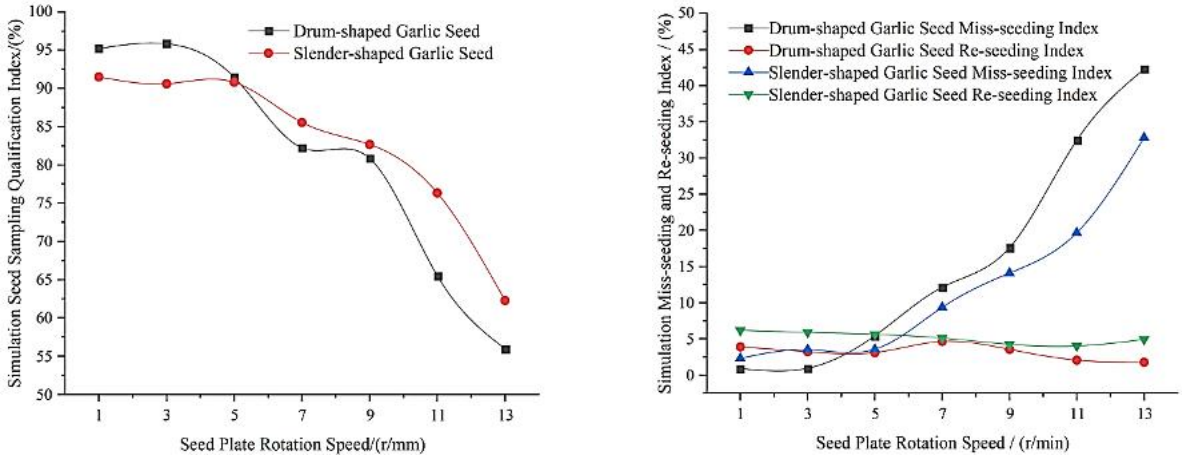
RESULTS



Simulation Results and Analysis

Seed plate speed and seed pickup spoon diameter were used as experimental factors, while qualified seeding index, reseeding index, and miss-seeding index were used as evaluation indicators. Single-factor DEM simulations were conducted for drum-shaped garlic cloves, represented by “Acheng Purple Garlic” and “Nong’an Purple Garlic”, and slender garlic cloves, represented by “Zhaozhou White Garlic”. These simulations were used to analyze the effect of each factor on seeding performance. Based on the structural dimensions of the seed metering device and the agronomic requirements for garlic seeding, the seed plate speeds were set to 1, 3, 5, 7, 9, 11, and 13 r/min. The seed pickup spoon diameter was fixed at 30 mm for the single-factor simulation on seed plate speed. The simulation results are shown in Table 3.

Table 3

Virtual simulation scheme and results for seed plate speed

Test Number	Operating Speed [r/min]	Drum-shaped			Slender

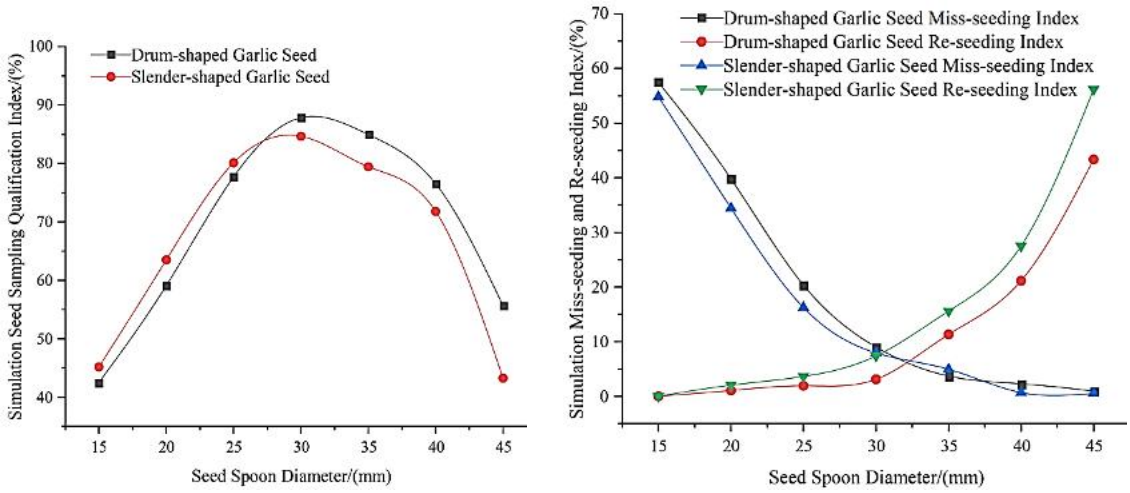
a) Simulation of qualified index *b) Simulation of reseeding and miss-seeding indices*

Fig. 12 – Single-factor simulation test of the rotation speed of seed metering plate



As shown in Fig. 12, the virtual simulation results showed that the qualified seeding index of both garlic-clove types first remained relatively stable and then decreased as seed plate speed increased. At low to medium speeds, the seed pickup spoon had sufficient contact time with the seed population, and the clamping mechanism could complete stable pickup and carrying. When the speed exceeded the suitable range, the contact time between the spoon and garlic cloves decreased. Collision disturbance also increased, which led to unstable pickup and higher miss-seeding. Under simulation conditions, the qualified seeding index was relatively high within 1–7 r/min, while the miss-seeding index increased continuously at higher speeds. The reseeding index was less affected by seed plate speed.

The seed pickup spoon diameters were set to 15, 20, 25, 30, 35, 40, and 45 mm. Other experimental conditions were fixed at a seed plate speed of 5 r/min for the single-factor simulation on seed pickup spoon diameter. The simulation results are shown in Table 4.

Table 4

Virtual simulation scheme and results for seed pickup spoon diameter

Test Number	Seed pickup spoon diameter [mm]	Qualified Index [%]	Drum-shaped Reseeding Index [%]	Miss-seeding Index [%]	Qualified Index [%]	Slender Reseeding Index [%]	Miss-seeding Index [%]
1	15	42.52	0	57.48	45.18	0	54.82
2	20	59.1	1.08	39.82	63.5	2.05	34.45
3	25	77.7	1.94	20.36	80.12	3.63	16.25
4	30	87.85	3.12	9.03	84.66	7.39	7.95
5	35	84.96	11.34	3.7	79.44	15.6	4.96
6	40	76.55	21.14	2.31	71.8	27.52	0.68
7	45	55.68	43.36	0.96	43.25	56.18	0.57

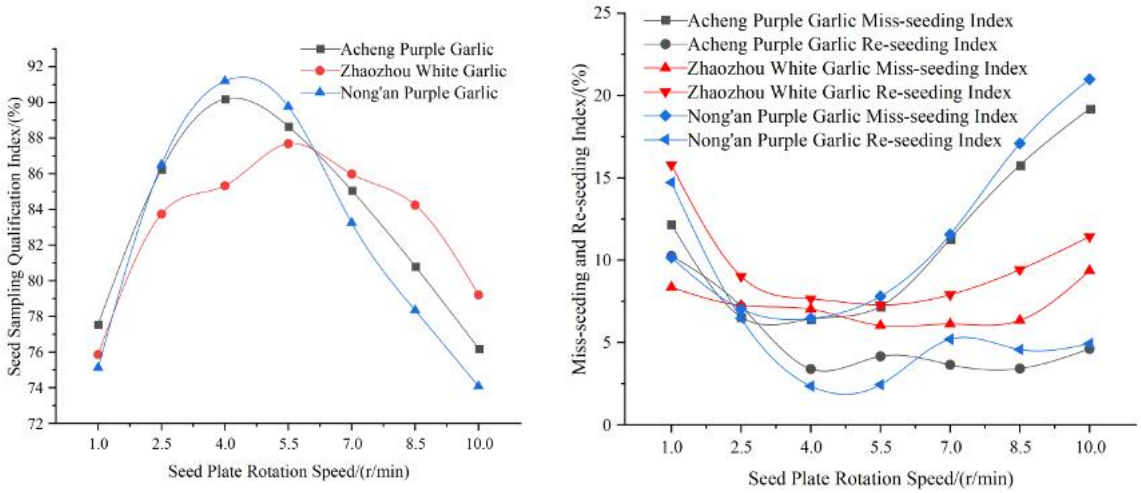
a) Simulation of qualified index *b) Simulation of reseeding and miss-seeding indices*

Fig. 13 – Single-factor simulation test of seed pickup spoon diameter

As shown in Fig.13, the qualified seeding index first increased and then decreased as seed pickup spoon diameter increased. A smaller spoon diameter reduced the effective contact area between the spoon and garlic clove, which resulted in a higher miss-seeding index. As the spoon diameter increased, the clove was more easily captured and carried. However, an excessively large spoon increased the probability of holding two or more cloves, and the reseeding index increased. The seed pickup spoon diameter should therefore match the size distribution of each garlic variety. Based on the single-factor simulation results, the suitable parameter range under DEM conditions was 1–7 r/min for seed plate speed and 25–35 mm for seed pickup spoon diameter.

Experimental Results and Analysis

"Acheng Purple Garlic", "Zhaozhou White Garlic", and "Nong'an Purple Garlic" were used as test materials to verify the influence of the selected factors on metering performance. Seed plate speed and seed pickup spoon diameter were taken as experimental factors. The qualified seeding index, miss-seeding index, reseeding index, and qualified plant spacing index were used as test indicators *(Xing et al., 2015)*. The seed plate speed ranged from 1 r/min to 10 r/min, and the seed pickup spoon diameter ranged from 20 mm to 44 mm.



Influence of Seed Plate Working Speed on Seeding Performance

With the seed pickup spoon diameter fixed at 32 mm, the seed plate speed was set to seven levels: 1, 2.5, 4, 5.5, 7, 8.5, and 10 r/min. Each level was tested three times. The average values of the qualified seeding index, miss-seeding index, and reseeding index were used for analysis. The single-factor bench-test plan and results for seed plate speed with the three garlic varieties are shown in Table 5.

Table 5

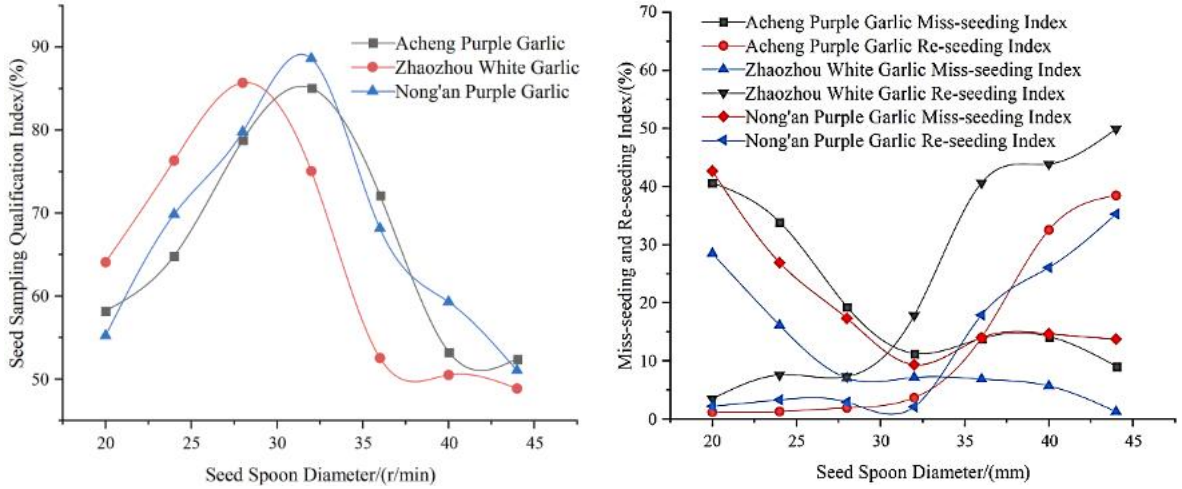
Single-factor test scheme and results for seed plate speed

Garlic Variety	Test Number	Seed Plate Rotation Speed [r/min]	Test Indicators [%]		
			Qualified seeding Index	Miss-seeding Index	Reseeding Index
Acheng Purple Garlic	1	1	77.56	12.18	10.26
	2	2.5	86.26	6.55	7.19
	3	4	90.19	6.42	3.39
	4	5.5	88.65	7.19	4.16
	5	7	85.06	11.3	3.64
	6	8.5	80.81	15.77	3.42
	7	10	76.21	19.19	4.61
Zhaozhou White Garlic	8	1	75.86	8.35	15.79
	9	2.5	83.74	7.25	9.01
	10	4	85.33	7.02	7.65
	11	5.5	87.69	6.03	7.28
	12	7	85.98	6.12	7.9
	13	8.5	84.24	6.34	9.42
	14	10	79.21	9.36	11.43
Nong'an Purple Garlic	15	1	75.12	10.16	14.72
	16	2.5	86.51	7.03	6.46
	17	4	91.20	6.45	2.35
	18	5.5	89.77	7.80	2.43
	19	7	83.25	11.56	5.19
	20	8.5	78.34	17.09	4.57
	21	10	74.08	20.99	4.93

a) Influence of seed plate rotation speed on qualified seeding index

b) Influence of seed plate rotation speed on miss-seeding and reseeding indices

Fig. 14 – Single-factor test result curve of the rotation speed of the seed metering plate



As shown in Fig. 14, the qualified seeding index of all three garlic varieties first increased and then decreased as seed plate speed increased. For "Acheng Purple Garlic" and "Nong'an Purple Garlic", the qualified index reached its maximum at 4 r/min. For "Zhaozhou White Garlic", the maximum value was obtained at 5.5 r/min. At a very low speed, the disturbance to the seed population was insufficient, which reduced the probability of stable single-clove pickup. At an excessively high speed, the spoon passed through the seed zone too quickly, and the cloves were more easily affected by collision and vibration. As a result, the miss-seeding index increased. The difference among varieties was mainly related to clove shape. The slender "Zhaozhou White Garlic" required a slightly higher speed to improve pickup probability, while the two drum-shaped varieties reached their suitable speed at 4 r/min.

Influence of Seed Pickup Spoon Diameter on Seeding Performance

Table 6

Single-factor test scheme and results for seed pickup spoon diameter

Garlic Variety	Test Number	Seed pickup spoon diameter [mm]	Test Indicators [%] Qualified seeding Index	Miss-seeding Index	Reseeding Index
Acheng Purple Garlic	1	20	58.21	40.64	1.15
	2	24	64.84	33.89	1.27
	3	28	78.78	19.32	1.9
	4	32	85.06	11.3	3.64
	5	36	72.15	13.84	14.01
	6	40	53.29	14.19	32.52
	7	44	52.46	9.1	38.44
Zhaozhou White Garlic	8	20	64.07	28.47	3.46
	9	24	76.32	16.12	7.56
	10	28	85.69	7.03	7.28
	11	32	75.05	7.14	17.81
	12	36	52.52	6.86	40.62
	13	40	50.49	5.66	43.85
	14	44	48.85	1.25	49.9
Nong'an Purple Garlic	15	20	55.21	42.64	2.15
	16	24	69.84	26.89	3.27
	17	28	79.78	17.32	2.9
	18	32	88.62	9.3	2.08
	19	36	68.15	13.99	17.86
	20	40	59.29	14.66	26.05
	21	44	51.02	13.72	35.26

a) Influence of seed pickup spoon diameter on qualified seeding index

b) Influence of seed pickup spoon diameter on miss-seeding and reseeding indices

Fig. 15 – Single-factor test result curve of seed pickup spoon diameter

As shown in Fig.15, the qualified seeding index of all three garlic varieties first increased and then decreased as seed pickup spoon diameter increased. The miss-seeding index decreased with increasing spoon diameter because the effective clamping and carrying area became larger. However, the reseeding index increased when the spoon diameter was too large, because two or more cloves could be picked up at the same time. The qualified seeding index reached its maximum at a spoon diameter of 32 mm for "Acheng Purple Garlic" and "Nong'an Purple Garlic", and at 28 mm for "Zhaozhou White Garlic". These results were consistent with the garlic-clove size differences measured in Table 1. Compared with the simulation results, the bench-test qualified indexes were lower because the real cloves had irregular surfaces, skin deformation, and non-uniform contact states. Therefore, the DEM simulation was used to determine the suitable parameter range, while the final parameter combination was verified by bench tests. Because the validation was conducted on a laboratory bench, field conditions such as vibration, soil resistance, ground-wheel slip, and non-uniform seed supply may affect the actual sowing performance. Further field validation and multi-factor optimization are needed in future work.

CONCLUSIONS

A spoon-clamp type garlic seed metering device was designed to improve the stability of single-clove pickup and carrying. The device integrates spoon pickup, spring-assisted clamping, seed cleaning, and controlled discharge. This structure is suitable for garlic cloves with irregular shapes and size variation.

DEM simulations were conducted to analyze the effects of seed plate speed and seed pickup spoon diameter. The qualified seeding index decreased at excessive seed plate speeds because seed pickup time was reduced and collision disturbance increased. Under simulation conditions, the suitable parameter range was 1–7 r/min for seed plate speed and 25–35 mm for seed pickup spoon diameter.

Bench tests verified the feasibility of the proposed mechanism under controlled test conditions. The suitable parameter combination was 4 r/min and 32 mm for “Acheng Purple Garlic” and “Nong’an Purple Garlic”, and 5.5 r/min and 28 mm for “Zhaozhou White Garlic”. Future work should focus on field validation, vibration adaptability, and multi-factor optimization of the garlic seed metering device.

ACKNOWLEDGEMENT

This study was funded by the Experimental Study on the Mechanism and Parameter Optimization of High-efficiency and Low-loss Screening of Trommel Screen of Flat Fritillary Harvester (XDB202401), and by the Heilongjiang Province “Double First-Class” Discipline Collaborative Innovation Achievement Projects of the Education Department of Heilongjiang Province (Grant Nos. LJGXCG2023–050 and LJGXCG2022–112).

ABSTRACT

Detasseling the female parent plants is a critical operation in hybrid corn seed production. This article systematically reviews global developments in mechanized detasseling technology for corn seed production. First, it provides an in-depth analysis of two key technologies supporting mechanized detasseling: the biomechanical characteristics of corn tassels and intelligent tassel-detection technologies based on machine vision and photoelectric sensing. Second, the current development of mechanized detasseling equipment is reviewed, and the technical parameters and field performance of representative domestic and international machines are compared in detail. The comparison identifies four major constraints limiting the wider adoption of this technology in China: an insufficient single-pass detasseling rate, poor coordination between machinery and agronomic practices, a high crop-damage rate, and low acceptance among farmers. Finally, three targeted optimization strategies are proposed: developing intelligent and precision detasseling equipment, promoting closer integration of agricultural machinery and agronomy, and strengthening field demonstration and extension activities. This review aims to provide a theoretical basis and practical reference for improving mechanized detasseling processes and supporting the development of more effective detasseling equipment.

摘要

母本去雄是制种玉米的核心生产环节。本文系统综述了全球制种玉米机械化去雄技术的发展动态。首先，深入分析了支撑机械化去雄的两大关键技术：雄穗生物力学特性研究与基于机器视觉、光电传感的智能识别技术。其次，梳理了机械化去雄装备的发展现状，详细对比了国内外主流机型的技术参数与作业性能。通过国内外发展现状比较，明确指出当前制约我国技术推广的四大瓶颈：一次性去净率不足、农机农艺不匹配、作业损伤率高以及农户接受度低。最后，针对性地提出三大优化策略：研发智能精细化装备、促进农机农艺深度融合、加强示范推广。本文旨在为优化机械去雄工艺与装备研发提供理论依据和参考。

INTRODUCTION

Corn can not only be used as a food crop, but also widely applied in various fields such as feed, food processing, medical and health care, light industry, chemical industry, and bioenergy *(Liu et al., 2024; Jahangirlou et al., 2023; Chukwutem et al., 2023)*. According to statistics from the Food and Agriculture Organization of the United Nations (FAO), corn has always been the second largest crop in terms of global cultivation area, second only to wheat. Its total yield and yield per unit area are higher than other major grains such as wheat and rice *(Rosegrant et al., 2009)*. High quality corn seeds are the foundation for ensuring high and stable yield of corn *(Singh et al., 2025)*. China's corn varieties are mainly hybrid varieties, and their hybrid advantage is mainly reflected in the first generation. From the second generation onwards, the advantage gradually decreases, so annual seed production is needed to maintain their potential for increased yield *(Wang et al., 2013; Su et al., 2003)*.

Seed production of corn refers to the process of selecting, breeding, producing, and processing high-quality seeds from superior species of corn through multiple techniques, such as selection, breeding, production, and processing, to be suitable for replanting, expansion, or sowing *(Wych et al., 1988; Liu et al., 2024)*. Compared to regular corn, seed corn has better economic benefits and the planting area has been increasing year by year in recent years *(Shahrokhi et al., 2024; Si et al., 2026)*.

Yang LI, lecturer; Yiteng LEI, Associate Professor; Luochuan XU, lecturer;Wei DONG, lecturer.

In China, the planting area of seed corn accounts for about 98% of the total planting area of corn *(Shi et al., 2014)*. Therefore, the sustained high yield and high quality of seed corn are of great significance for food security and economic stability *(Huang et al., 2024)*.

The removal of male parents is the core production process of seed corn. Timely and complete tassel removal effectively prevents self-pollination in seed-production fields, thereby ensuring the genetic purity and quality of the hybrid seed. It may also help reduce the risk of certain field diseases and pests *(Felkl et al., 1988; Darrah et al., 2019)*. Seed purity is a key indicator for evaluating the quality of corn hybrids *(Liu et al., 2024)*, and male removal is the most difficult and difficult key step to accurately control in the hybrid seed production process *(Liu et al., 2014; Tian et al., 2014)*. This article systematically analyzes the current development status of male elimination technology and equipment, identifies the main problems in male elimination operations, and proposes targeted improvement suggestions, in order to provide theoretical basis and reference for optimizing mechanical male elimination processes and equipment research and development.

AGRONOMY OF MALE REMOVAL IN CORN SEED PRODUCTION

To ensure the production of high-quality hybrid seed that meets purity standards, all tassels on the female parent plants must be removed before pollen shedding and preferably before full tassel emergence. The operation should follow the principles of timeliness, completeness, and thoroughness *(Tian et al., 2014; Moreira et al., 2010)*. According to the national standard *(GB/T 17315-2011)*, when the cumulative loose powder plant rate exceeds 1% during the entire male removal process, the seed field is scrapped. At present, there are two main methods for male removal in seed production of corn: manual male removal and mechanical male removal.

Manual detasseling commonly follows the principle of removing the tassels before they fully emerge from the leaf whorl. This operation may involve manually opening or removing the leaves enclosing the tassel, or removing one or two upper leaves before tassel emergence. Care must be taken to ensure that no tassel branches remain and that the plants are not broken or otherwise damaged during the operation *(Han et al., 2011; Czepak et al., 2019)*. Detasseling is preferably carried out in the morning and should be avoided on rainy days. It must be completed before the tassels fully emerge and begin shedding pollen *(Bai et al., 2022)*. The main advantage of manual detasseling is that it can reduce damage to the leaves and plants while allowing the operation to be performed at the most appropriate stage according to the growth condition of each plant *(Lu et al., 2010)*. However, it also has several evident disadvantages, including low working efficiency, high labour intensity, high production costs, unfavorable working conditions, and strong dependence on weather conditions *(Asefa et al., 2026; Han et al., 2011; Cui et al., 2010)*. In addition, manual detasseling generally requires five to seven repeated passes to meet pollination-control requirements. The first three or four passes mainly involve tassel removal, whereas the subsequent passes focus on identifying and removing missed or late-emerging tassels *(Tang et al., 2017; Fan et al., 2021)*.

Mechanical detasseling involves using a dedicated detasseling machine to remove tassels from the female parent plants. This method is particularly suitable for varieties with a relatively high number of upper leaves and a low ear position. The operation is generally initiated when approximately one-third of the tassel has emerged above the uppermost leaf.

During tassel removal, no more than two leaves should preferably be removed, with three leaves regarded as the maximum acceptable number *(Ghețe et al., 2020; Nicoletti et al., 2023)*. After mechanical detasseling, a timely manual follow-up inspection is required to remove missed tassels and any residual tassel branches *(Liu et al., 2010; Wu et al., 2013)*.

However, mechanical detasseling may cause substantial damage to the plants and consequently reduce yield. In addition, detasseling performance remains relatively unstable, with reported removal rates generally ranging from 80% to 90% *(Wilhelm et al., 1995; Wang et al., 2024; Prodanović et al., 2022)*.

Compared with manual detasseling, this method offers several important advantages, including high operational efficiency, less dependence on environmental and human factors, good maneuverability, suitability for large-scale field deployment, and improved working conditions for operators *(Sabljak et al., 2019)*. Therefore, the development and wider adoption of mechanical detasseling remain essential for promoting efficient and large-scale corn seed production *(Zhang et al., 2024; Ghimire et al., 2025)*.

RESEARCH STATUS OF DETASSELING TECHNIQUES FOR SEED PRODUCTION CORN

Mechanical Properties of Tassels

The mechanical properties of corn tassels in seed-production fields are key physical parameters for the design and optimization of detasseling equipment *(Jia et al., 1990)*, and have been studied for many years.

In 1990, American researchers *Jia et al.* pioneered the measurement of the manual pulling force required to remove tassels from different varieties of seed corn. They also analyzed the effects of gripping position, field location, and operating time on the pulling force. The results indicated that the average and maximum manual pulling forces for tassel removal were 58.3 N and 92.5 N, respectively. It was found that the corn variety, gripping position, and field location had a significant impact on the pulling force, whereas the time of day during which the operation was performed showed no significant effect *(Jia et al., 1990)*.

Subsequently, *Zhang et al.* conducted correlation and path analysis on nine stalk traits and the unit volume stalk rupture resistance (UVSRP) using a set of diallel cross combinations. The study found that the length of the tassel main axis showed a highly significant positive correlation with UVSRP, whereas the fresh weight of biomass below the ear, the length of the stalk below the ear, the fresh weight of the stalk, ear height, and the stalk length-to-thickness ratio exhibited highly significant negative correlations with UVSRP. Therefore, an appropriate tassel main axis length can serve as an important reference trait for breeding corn varieties with enhanced stalk lodging resistance *(Zhang et al., 2006)*. Wang conducted experimental and theoretical analyses on the tassel pulling force characteristics, plant elastic modulus, and spatial distribution traits of seed corn plants during the detasseling period. The study obtained the range of pulling forces for two inbred lines, Zheng 58 and PH6WC, at different growth stages, and determined their elastic modulus during detasseling as well as the natural spatial distribution patterns of the plants *(Wang et al., 2016)*. Jin further investigated the pulling force characteristics of tassels during the detasseling period, using Xianyu 335, a corn variety widely cultivated in Northeast China, as the research subject. The results showed that during the stage when the tassel had grown 5-10 cm and before pollen shedding, the maximum pulling force was 56.5 N, and the maximum cross-sectional area was 31.2 mm², with the pulling force being proportional to the cross-sectional area *(Jin et al., 2019)*.

Recently, *Ou et al.* systematically calibrated the physical property parameters of tassels in seed corn. Through mechanical tests, the bending modulus and shear strength were determined to be 46.41 MPa and 0.76 MPa, respectively. Furthermore, simulation tests involving rotary cutting components for tassel removal revealed that vertical feed cutting had the least impact on tassel bending deformation *(Ou et al., 2024)*.

Tassel recognition technology

With the advancement of agricultural modernization and intelligentization, the deep integration of computer technology into agricultural machinery and equipment has become a significant development trend *(Kasal et al., 2025; Rodene et al., 2024)*. Currently, achieving automatic recognition of corn tassels using advanced sensing technologies is a key link in enhancing the precision and intelligence of detasseling operations. Researchers both domestically and internationally have actively explored this direction, primarily focusing on two technical pathways: machine vision recognition and photoelectric sensing *(Shepard et al., 2024; Cao et al., 2025)*.

Machine vision recognition technology

Machine vision technology offers several advantages, including nondestructive operation, high accuracy and efficiency, substantial information-processing capacity, strong real-time performance, and flexibility. It has therefore received considerable attention and has been widely applied in precision *agriculture (Gong et al., 2007)*.

The earliest application of this technology to corn tassel recognition research in China was conducted by Tang Wenbing from China Agricultural University. Tang et al. designed and constructed a corn tassel recognition system based on binocular stereo vision, as shown in Figure 1. The hardware of the system primarily consisted of two CMOS color cameras of the same model, a pan-tilt, lenses, a conversion box, and a laptop computer. The workflow was as follows: first, preprocessing the captured images, using color features as the main basis for tassel extraction; then, obtaining the effective tassel regions through image segmentation techniques, and performing image matching based on the segmentation results using binocular stereo vision technology; finally, calculating depth information to determine the specific three-dimensional spatial position of the tassels *(Tang et al., 2011)*.

Kumar et al. proposed a novel method for corn ear detection based on k-means clustering and adaptive threshold segmentation. The study, focusing on the task of corn panicle detection in UAV images, developed a semi-automatic image annotation method to facilitate the rapid construction of labeled datasets for corn crops. A tool developed based on this method can be integrated with machine learning models to provide initial annotation results for given images and supports interactive user modification and refinement *(Kumar et al., 2021).*

Wang et al. compared three object detection models-Faster R-CNN, SSD, and YOLO_X-using UAV imagery and a transfer learning approach. The results showed that transfer learning significantly improved model performance, with YOLO_X performing the best, achieving a recognition precision of 97.16% and a mean average precision (mAP) of 93.60%. The study also found significant differences in detection adaptability across varieties, with Zhengdan 958 showing the best detection results. Moreover, as planting density increased, the mean absolute error of detection rose from 0.19 to 0.75. This research provides a reliable method for high-throughput detection of corn tassels in the field *(Wang et al., 2022)*.

Kurtulmuş et al. developed a corn tassel detection algorithm suitable for outdoor field environments. The algorithm utilizes color information and a Support Vector Machine (SVM) classifier for image binarization based on standard RGB images. It achieves tassel cutting position detection while effectively controlling the false positive rate. On the test set, the correct detection rate of this method reached 81.6% *(Kurtulmuş et al., 2014).*

National standards and seed purchasers impose stringent requirements on the tassel removal rate in seed corn production. Consequently, the identification of missed tassels has become a research hotspot *(Falahat et al., 2023; Ding et al., 2026). Li et al.* proposed a lightweight tassel detection model named MLCE-RTMDet. Based on the RTMDet-tiny architecture, this model employs MobileNetV3 as the backbone feature extraction network to reduce computational load and incorporates the CBAM attention mechanism to enhance multi-scale feature extraction capability for tassels, thereby mitigating the potential performance degradation associated with lightweight networks. Furthermore, the model utilizes EIOU Loss instead of GIOU Loss, further improving the accuracy of tassel detection. This research can provide effective technical support for detecting missed tassels after manual detasseling in corn seed production fields *(Li et al., 2024).*

Yang et al. integrated machine vision and UAV remote sensing technologies to collect visible-light images of corn during the tasseling stage. To construct a dataset and enhance model robustness, they employed the Segment Anything Model (SAM) for semi-automatic annotation and applied image augmentation techniques to simulate environmental variations. The study improved the YOLOv5 framework by introducing the lightweight MobileNetV3 network to reduce parameters and optimizing the network architecture for accurate detection of missed tassels. Experiments demonstrated that this method can automatically identify missed female tassels in the field, effectively evaluate detasseling performance, and provide precise location guidance for follow-up removal operations *(Yang et al., 2026)*.

Computer vision technology plays a central role in image recognition, and deep learning-based object detection algorithms (such as Faster R-CNN, SSD, and the YOLO series) have been widely applied to corn tassel recognition *(Duangpapeng et al., 2018; Alzadjali et al., 2021; Niu et al., 2024)*. Researchers train models using large, annotated datasets of tassel images, enabling the models to learn key information about tassel appearance, color distribution, and texture features. The trained models can then accurately identify tassels in new images captured by UAVs, providing reliable, high-throughput information on tasseling status for breeders *(Qi et al., 2025)*. However, the recognition accuracy of such models for small-target tassels remains insufficient, and their algorithmic performance requires further optimization.

Optoelectronic sensing recognition technology

Gu et al. designed an infrared detection-based corn detasseling machine, as shown in Figure 2. The machine mainly consists of a frame, a lifting device, a detasseling device, and an infrared detection unit. Its core innovation lies in the integration of an infrared detection unit in front of the detasseling unit, which contains multiple sets of infrared sensor pairs for precisely locating the height of the tassels. During field operation, when the top of the corn plant interrupts the optical path of the infrared sensor pairs, the control mechanism adjusts the working height of the hydraulic detasseling device in real time based on multiple height signals, thereby achieving precise alignment and adaptive control of the detasseling position *(Gu et al., 2013)*.

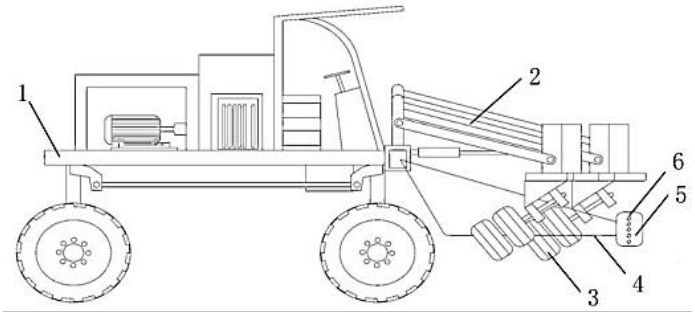

Fig. 2 - Infrared-guided corn detasseling machine *(Gu et al., 2013)*

1. Frame; 2. Lifting mechanism; 3. Profiling mechanism; 4. Connecting rod; 5. Infrared detection unit; 6. Infrared sensor

Liu et al. developed a height-adaptive corn detasseling device, as shown in Fig.3. The device primarily consists of a detasseling bracket and a control module. Two detasseling discs are mounted on the bracket, which is also equipped with a bracket hydraulic cylinder and a hydraulic cylinder for the sensor support rod. A reflector mechanism and a photoelectric sensor mechanism are installed at the front end of the bracket. During operation, the photoelectric sensor continuously detects tassel height and transmits the signal to the control module. The control module then actuates the bracket hydraulic cylinder to extend or retract, thereby adjusting the working height of the detasseling discs and profiling rollers. This enables the device to adapt to variations in corn tassel height during detasseling *(Liu et al., 2025)*.

Wang et al. designed a single-row profiling and lifting mechanism for corn detasseling, as shown in Fig.4. The device mainly consists of a hydraulic lifting cylinder, a parallel four-bar linkage, a hydraulic motor, and photoelectric sensors. The photoelectric sensors are installed at the front of the frame on both sides of the sensor mounting bracket. The detasseling wheels are mounted behind the sensors and connected to an electric push rod. The entire detasseling assembly is connected to the parallel four-bar linkage, whose vertical movement is controlled by the hydraulic cylinder. A displacement sensor is mounted on the hydraulic cylinder and connected to the piston rod to monitor changes in piston displacement and convert them into pulse signals. Based on the signals received from the photoelectric sensors and the displacement sensor, the controller regulates the extension and retraction of the hydraulic cylinder and electric push rod. This enables the detasseling unit to follow variations in tassel height and perform adaptive detasseling *(Wang et al., 2015)*.

KEY TECHNOLOGIES FOR MECHANIZED DETASSELING

Existing mechanized detasseling technologies can be classified into two categories according to the removal method: extraction-type and cutting-type systems. Extraction-type detasseling commonly uses rotating wheels, belts, or rollers to grip and pull the tassel, together with a portion of the upper stem and leaves, from the corn plant through a clamping and pulling action *(Costa et al., 2019)*. Cutting-type detasseling primarily uses reciprocating or rotating blades to remove the tassel and portions of the attached upper stem and leaves through a shearing action *(Zou et al., 2020)*.

Cutting-Type Detasseling Technology

Research on cutting-type corn detasseling technology began in developed countries as early as the 1970s. Gildersleeve et al. designed a clamping-and-cutting detasseling device, as shown in Fig.5. The device mainly consisted of a frame, hydraulic motor, flexible drive shaft, drive chain, fixed blade, clamping wheels, and related components. During operation, the hydraulic motor transmitted power through the flexible drive shaft and drive chain to a pair of clamping wheels, causing them to rotate in the same direction. Under the force of a tension spring, the left clamping wheel was pressed against the lower portion of the right clamping wheel, thereby creating frictional contact between them. As the machine advanced, corn plants were guided toward the center by a crop divider and entered the contact region between the clamping wheels. The tassels were then cut by the combined action of the clamping wheels and the fixed blade *(Gildersleeve et al., 1973)*.

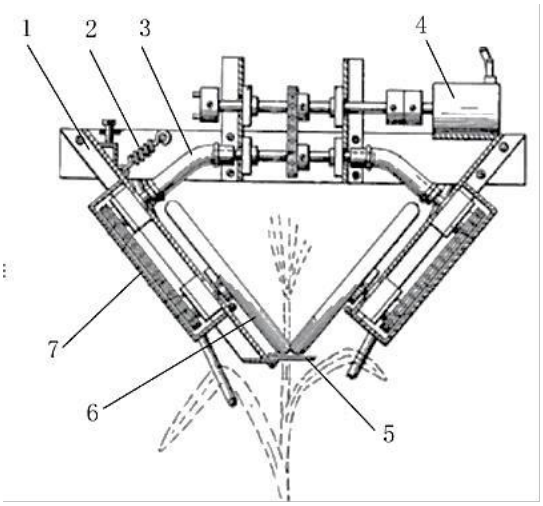

Fig. 5 - Clamping-and-cutting detasseling device *(Gildersleeve et al., 1973)*

1. Frame; 2. Tension spring; 3. Flexible drive shaft; 4. Hydraulic motor; 5. Fixed blade; 6. Clamping wheel; 7. Drive chain

Meiners et al. developed a horizontal cutting-type detasseling device, as shown in Fig.6. The device mainly consists of a drive belt, blades, guide rods, a crop divider, guide plates, and related components. During operation, corn plants are gathered toward the center by the crop divider and guided into the space formed between adjacent guide rods or between a guide rod and the protective shield. The tassels are then cut by blades arranged in a linear configuration. A notable feature of this device is that the multiple guide rods not only guide the plants but also help prevent leaves from entering the blade cutting zone, thereby reducing leaf damage and loss *(Meiners et al., 1973)*.

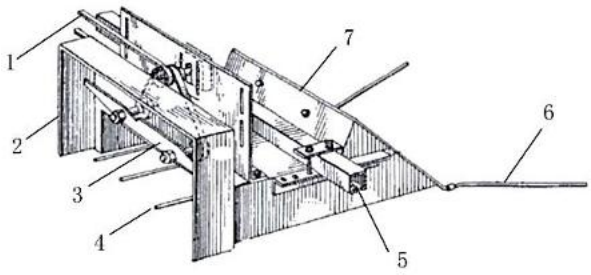

Fig. 6 - Horizontal cutting-type detasseling device (Meiners et al., 1973)

1. Drive belt; 2. Protective shield; 3. Blade; 4. Guide rod; 5. Frame; 6. Crop divider; 7. Guide plate

Grandinetti et al. designed an airflow-assisted corn detasseling device, as shown in Fig.7. The device mainly consists of a paddle wheel, a crop divider, air ducts and nozzles, an arcuate backing plate, and related components. During operation, the drive shaft rotates the paddle wheel to generate airflow, which is directed through the ducts and nozzles to separate the upper leaves. After the plants leave the airflow zone, the vertical plates maintain the leaves in the separated position. The tassel then enters the space between the two vertical plates and is snapped or cut off through the combined action of the paddle wheel, its blades, and the arcuate backing plate. The airflow system and vertical plates effectively separate the tassel from the upper leaves and prevent leaf rebound, thereby reducing damage to the upper leaves of the corn plants *(Meiners et al., 1990)*.

1. Air duct and nozzle 2. Vertical plate 3. Crop divider 4. Arcuate backing plate 5. Drive shaft 6. Paddle wheel 7. Frame

Based on the phenotypic characteristics of corn plants and the principles of manual detasseling, Song et al. proposed a downward cutting-and-rotating detasseling method designed to reduce damage to the leaves surrounding the tassel. To implement this method, they developed a compact corn detasseling device comprising an RGB camera, left and right gripping mechanisms (Claw-L and Claw-R), a sliding mechanism, and a rotating mechanism. The complete operating sequence of the device is illustrated in Fig.8. Field experiments showed that the device achieved a tassel-removal success rate of 88.33% *(Song et al., 2024)*.

Movement sequence of the two claws during detasseling; F. Device configuration upon completion of detasseling; G. Return of the device to its initial position; H. Removed corn tassel

Extraction-Type Detasseling Technology

In 1970, *Spry et al.* developed a belt-type extraction detasseling device, as shown in Fig.9. The device mainly consisted of a pressure wheel, a hydraulic motor, a leaf-pressing roller, and related components. During operation, as the implement advanced, corn plants were guided toward the center by a crop divider. Under the continuous action of the leaf-pressing roller, the tassel was separated from the surrounding leaves and then entered the gripping zone formed by two elastic belts. The tassel was gradually pulled from the plant and either discharged onto the ground or collected. A helical metal strip was mounted on the surface of the leaf-pressing roller to improve its gripping and downward-pressing performance *(Spry et al., 1970)*.

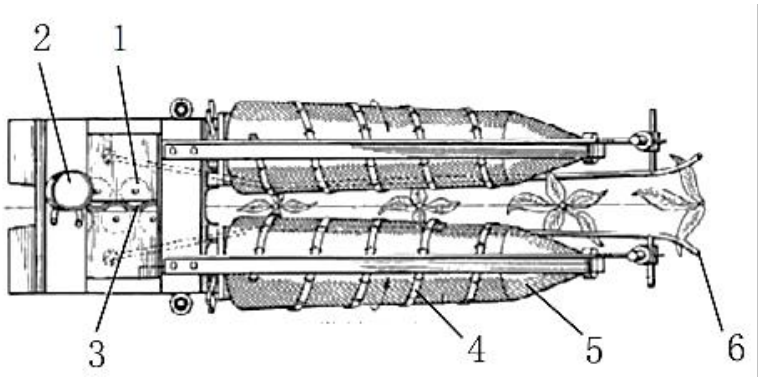

Fig. 9 - Belt-type extraction detasseling device *(Spry et al., 1970)*

1. Compression wheel; 2. Hydraulic motor; 3. Elastic belt; 4. Helical metal strip; 5. Leaf-pressing roller; 6. Crop divider

Kenneth et al. designed a pneumatic-wheel extraction detasseling device, as shown in Fig.10. The device primarily consists of a main frame, a support frame, a hydraulic motor, a drive shaft, a driven shaft, pneumatic rubber wheels, and related components. During operation, the drive wheel and driven wheel rotate in opposite directions, gripping and pulling the corn tassel together with a portion of the attached upper stem and leaves. The removed material is then discharged into the interrow space. The pneumatic rubber wheels provide flexible gripping, thereby improving the adaptability of the detasseling mechanism to variations in tassel size and position. In addition, the tread pattern on the wheel surfaces enhances gripping performance *(Kenneth et al., 1970)*.

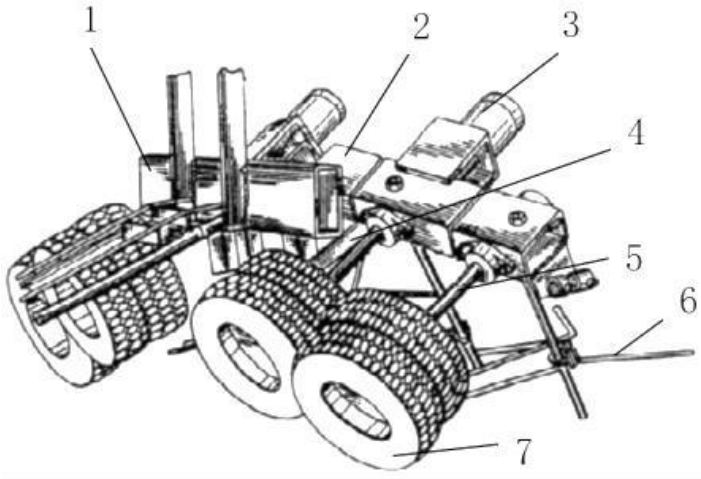

Fig. 10 - Pneumatic-wheel extraction detasseling device *(Kenneth et al., 1970)*

1. Frame; 2. Fixed frame; 3. Hydraulic motor; 4. Drive shaft; 5. Driven shaft; 6. Crop divider; 7. Pneumatic rubber wheel

Bourgoin developed a flexible-disk extraction detasseling unit, as shown in Fig.11. The unit mainly consists of a crop divider, two flexible disks, an opening roller, a pressure roller, and related components. During operation, as the detasseling unit advances, corn plants are guided toward the center by the crop divider and enter the V-shaped space formed by the two flexible disks. Under the combined effects of disk rotation and forward travel, the plants move progressively into the contact zone, where the gap between the disks gradually narrows until the disks come into full contact. The tassel is then firmly gripped by the flexible disks under the action of the pressure roller, pulled from the plant, and discharged forward. A limitation of this design is that the removed tassels may become entangled with or remain caught on the corn plants.

DEVELOPMENT STATUS OF MECHANIZED DETASSELING EQUIPMENT FOR CORN SEED PRODUCTION

Mechanized Detasseling Equipment Developed Outside China

Research on mechanized detasseling equipment for corn seed production began relatively early in other countries. In 1937, the first mechanized corn detasseling machine was developed in the United States. As shown in Fig.12, the machine featured a high-clearance chassis equipped with six operator platforms and supported by three ground wheels, allowing it to travel slowly between corn rows. However, tassel removal was still performed manually by workers standing on the platforms. Therefore, the machine essentially provided mechanized transport and elevation for manual detasseling rather than fully mechanized tassel removal *(Seeber et al., 1937)*. By 1950, a second-generation detasseling machine had been developed, as shown in Fig. 13 *(Hagle et al., 1950)*. Compared with the earlier model, it provided improved travel stability, operator safety, and field efficiency. Nevertheless, because the detasseling operation still depended heavily on manual labor and the level of automation remained limited, the machine was not widely adopted.

Fig. 12 - Early mechanically assisted corn detasseling machine *(Seeber et al., 1937)*

Fig. 13 - Second-generation mechanically assisted corn detasseling machine *(Hagle et al., 1950)*

In recent years, various corn detasseling machines have been widely adopted in Europe, the United States, and other regions as alternatives to manual labor. These machines are technologically mature, highly efficient, and adaptable to different field conditions. Representative models include the 204SP and DTB series manufactured by Hagie in the United States; the TS4, 5175, and 5180 manufactured by Oxbo in the United States; the PDF752D manufactured by Big John in the United States; the BD864 manufactured by Bourgoin in France; the FALCON 140 manufactured by Frema in France; and the S series manufactured by Castrix in Italy. The Hagie 204SP is one of the earliest commercially available self-propelled corn detasseling machines, as shown in Fig.14. It uses a four-wheel hydrostatic drive system and has a chassis ground clearance of 193 cm. Its track width can be adjusted from 214.6 to 304.8 cm, allowing operation at common corn row spacings of 51–76 cm. Depending on operational requirements, the front of the machine can be equipped with either extraction-type or cutting-type detasseling units. The operating height of these units can be adjusted over a range of 0–167.6 cm, and the machine can be configured to operate on 4 to 18 rows, in even-numbered configurations *(Ma et al., 2012)*.

Fig. 14 - Hagie 204SP self-propelled corn detasseling machine
(Ma et al., 2012)

Fig. 15 - Hagie DTB-series corn detasseling machine

In addition, the Hagie DTB-series corn detasseling machines have been well received because of their operational versatility. Machines in this series can also be readily converted for use as self-propelled sprayers, as shown in Fig. 15. Several other representative corn detasseling machines are presented in Fig.16, and their principal performance parameters are summarized in Table 1.

S4C	55.4/57.6	60	1600 ~ 2200	1600	4/6	3.4 ~ 4.8	1.8 ~ 2.3	≈95

Corn detasseling machines developed outside China are generally technologically mature. Their typical configurations include a self-propelled power unit, hydraulically driven working components, and cutting-type or pneumatic-wheel extraction-type detasseling mechanisms. These machines also commonly incorporate intelligent technologies, such as optical sensing for tassel detection and automatic height adjustment, to improve operating precision. However, this high level of technological integration also leads to substantial equipment costs, which typically exceed RMB 1 million per unit *(Liu et al., 2025)*. Such high prices significantly limit their adoption by farms in China, which generally operate on a smaller scale.

Mechanized Detasseling Equipment Developed in China

Research on corn detasseling machines in China began relatively late. During the early stages, development efforts focused primarily on importing and adapting foreign designs. One representative achievement was the 3QXZ-6 corn detasseler, developed by the Chinese Academy of Agricultural Mechanization Sciences in 2016. However, because of limitations in technological maturity and market adaptability at that time, the machine was not produced on a large scale *(Wang et al., 2016)*. At present, the corn detasseling machines that have entered mass production and practical use in China are mainly manufactured by Jiuquan Ouke Seed Machinery Co., Ltd. Representative models include the OK104-3CX and 3CX-6A corn detasseling machines, shown in Figs. 17 and 18, respectively. Together with the 3QXZ-6, these machines use both cutting-type and pneumatic-wheel extraction-type detasseling mechanisms. Their principal performance parameters are summarized in Table 2 *(Xu et al., 2015; Zhu et al., 2015; Feng et al., 2024)*.

Fig. 17 - OK104-3CX

Fig.18 - 3CX-6A

Table 2

Key specifications of three corn detasseling machines developed in China

Model	Rated power	Row spacing	Drive configuration	Track width	Ground clearance	Number of rows	Turning radius	Field capacity	Detasseling rate
	[KW]	[cm]	-	[cm]	[mm]	-	[m]	[ha/h]	[%]
3QXZ-6	88.2	60	self-propelled	2000～2600	1800	4/6	-	-	≈87.7

3CX-6A	120	-	self-propelled	1900～2300	1900	4/6	3.2～4	0.8～1.5	≥85

In July 2024, a fully electric corn detasseling robot independently developed by Xinjiang Jiuyu Technology Co., Ltd. was introduced and deployed for field operations in Guangming Village, Ergong Town, Changji City, as shown in Fig. 19. The robot integrates the BeiDou Navigation Satellite System with LiDAR point-cloud data and AI-based image-recognition algorithms to generate precise operating paths in real time. During operation, it detects the positions of the leaves and tassels and autonomously determines the required lowering distance of the detasseling actuators. The robot can accommodate corn plants ranging from 1.5 to 2.3 m in height, provides millimeter-level positioning accuracy, and achieves a tassel-removal rate of 90%. It can detassel four rows in a single pass, with a field capacity of 0.47–0.74 ha/h and an energy consumption of approximately 6 kWh/ha. Compared with conventional methods, the robot can reduce labor costs by more than RMB 40 per *mu* and substantially shorten the detasseling period. The deployment of this machine represents an important step toward the intelligent automation of detasseling operations in China's corn seed-production industry.

Fig. 19 - Fully electric corn detasseling robot

Corn detasseling equipment developed in Europe and the United States has established a relatively mature technological system characterized by high-powered self-propelled chassis, hydraulically driven cutting- or extraction-type working units, and basic optical height-profiling systems. Although this system provides high field efficiency, it is also associated with high equipment costs and limited adaptability to diverse agronomic practices. By contrast, although technological development in China began later, substantial progress has been made in lightweight machinery for small- and medium-sized fields and in intelligent recognition technologies based on machine vision and photoelectric sensing. Notable advances have also been achieved in fully electric drive systems and intelligent detasseling robots integrating the BeiDou Navigation Satellite System with AI-based technologies.

FACTORS LIMITING THE MECHANIZATION OF CORN DETASSELING

(1) Corn detasseling machinery continues to face important technical limitations. Although mainstream machines developed in China and other countries generally achieve satisfactory detasseling performance, they often fail to meet seed-purity requirements in a single pass. As a result, growers must rely on manual follow-up removal or repeated machine passes to eliminate missed tassels. The effective detasseling window is only 7–10 days. Manual inspection and removal are labor-intensive and inefficient and may not consistently ensure the required quality. Repeated passes by ground-based machinery, however, substantially increase operating costs and may cause soil compaction and crop damage. Therefore, the efficient and accurate detection and removal of missed tassels remains a central challenge in improving the quality and efficiency of detasseling operations.

(2) The requirements of agricultural machinery and agronomic practices remain insufficiently coordinated. The absence of unified standards for planting parameters, including row spacing and female-to-male row configuration, increases the difficulty of mechanized detasseling in corn seed production. China's principal corn seed-production areas are concentrated in regions such as Gansu and Xinjiang. In Gansu, however, fields are relatively fragmented, and plots larger than 30 *mu* account for less than 5% of the total cultivated area. This limits the ability of large detasseling machines to fully realize their field-efficiency advantages. In addition, the large number of corn varieties used for seed production results in substantial differences in tassel height and attachment strength. Even within the same field, individual plants may vary in height and morphology because of differences in seed vigor, water and nutrient availability, and localized soil conditions. These factors place greater demands on the adaptability and control accuracy of detasseling machinery.

(3) Mechanical damage caused by detasseling operations remains a significant problem. Manual detasseling can generally remove tassels from female parent plants with minimal damage to other plant tissues. In contrast, mechanical detasseling relies primarily on cutting or roller-clamping extraction mechanisms, which may tear or crush the leaves surrounding the tassel. This problem is particularly serious in varieties with relatively few leaves above the ear, because damage to these leaves can directly reduce photosynthetic capacity and impair assimilate transport, ultimately decreasing seed yield. Reported data indicate that mechanical detasseling may reduce the yield of such sensitive varieties by approximately 15%.

(4) Growers' acceptance of detasseling machinery remains relatively low. On the one hand, imported machines involve high purchase and maintenance costs, whereas the operating window for corn detasseling is short. Consequently, annual machine utilization is low and the investment payback period is long. On the other hand, although labor costs continue to rise, reaching approximately RMB 300 per worker per day, the advantages of existing machinery in terms of field efficiency and cost-effectiveness are not yet sufficiently pronounced. This is particularly true under complex agronomic conditions, where machine performance may remain unstable. In addition, traditional production practices continue to influence decision-making in some rural areas. Growers may therefore be cautious about adopting new technologies and may prefer to rely on experienced workers for detasseling operations.

OPTIMIZATION STRATEGIES FOR MECHANIZED CORN DETASSELING

(1) Promote the development of intelligent and precision detasseling equipment

Future research and development should focus on improving the overall performance of detasseling equipment. The primary objective should be to balance a high tassel-removal rate with a low plant-damage rate by minimizing mechanical damage to the leaves while maintaining effective detasseling performance. Efforts should also focus on improving equipment adaptability. Dedicated machine series and modular configurations should be developed for different production systems, including large-scale operations on expansive fields and fragmented production on small plots. The long-term goal is to develop a new generation of intelligent, precision detasseling equipment. Achieving this goal will require breakthroughs in key technologies, including intelligent tassel-recognition algorithms, high-precision height-profiling actuators, and adaptive control systems for complex field terrain. These developments are expected to address persistent limitations such as high plant-damage rates and large turning radii.

(2) Promote closer integration of agricultural machinery and agronomic practices

Efficient and stable mechanized detasseling requires coordinated optimization of agronomic standards and variety development. First, standardized planting protocols should be established and promoted to unify key agronomic parameters, including row spacing and female-to-male row ratios, thereby creating favorable conditions for mechanized operations. Second, breeding programs should target varieties with uniform plant height and ear position, together with tassel characteristics suitable for mechanical removal. Such varieties would provide stronger biological and agronomic support for mechanized detasseling. Finally, collaboration between agricultural machinery engineers and agronomists should be strengthened. A permanent, integrated mechanism for research, development, field validation, and extension should be established so that agronomic requirements guide machine design and machinery performance supports agronomic objectives. This coordinated approach will promote the systematic advancement and sustainable development of full-process mechanization in corn seed production.

(3) Strengthen demonstration, extension, and service support

First, the systematic development of high-standard farmland should be promoted. Land consolidation, field leveling, supporting farm roads, and improved field-layout planning can create more favorable operating conditions for mechanized detasseling and, ultimately, full-process mechanization. Second, an effective demonstration and extension system should be established. Large-scale growers, specialized cooperatives, and other qualified organizations should be selected and supported in establishing demonstration bases. Field comparison trials can then be used to clearly demonstrate the efficiency and economic benefits of mechanized detasseling, thereby increasing growers' awareness of and willingness to adopt the technology. Finally, new models of agricultural service provision should be actively explored. Cooperatives, agricultural enterprises, and other service providers should be encouraged to offer specialized contract detasseling services. Large-scale service operations can improve machinery utilization, spread investment and operating risks across multiple users, and support the development of a sustainable mechanism for technology adoption and expansion.

CONCLUSIONS

This paper systematically reviews and compares the historical development, current technological status, and equipment characteristics of mechanized detasseling for corn seed production worldwide. At present, the wider adoption of mechanized detasseling remains constrained by several factors, including insufficient single-pass tassel-removal rates, poor coordination between agricultural machinery and agronomic practices, high plant-damage rates, and limited economic viability. However, with continued advances in artificial intelligence, robotics, and precision agriculture, detasseling technology is expected to become increasingly intelligent, precise, and integrated. These developments may substantially reduce reliance on manual labor and create the conditions for mechanized detasseling to replace most, or potentially all, manual operations in corn seed production.

Keywords: *Benefit–Cost Ratio, Direct-Seeded Paddy, Economic Performance, Weeding Efficiency, Forward Speed, Mechanized Weeding*

ABSTRACT
Manual weeders reduce labour requirements compared with hand weeding but remain time-consuming and physically demanding in paddy cultivation. A rotary power weeder powered by a 4.5 hp single-cylinder, air-cooled engine and equipped with three rotary units was developed for direct-seeded paddy and evaluated under field conditions. The machine was tested at three forward speeds and compared with manual weeding using a khurpi. Weeding efficiency decreased with increasing forward speed, whereas plant damage and power requirement increased. The highest grain yield and benefit–cost ratio were obtained at 1.27 km h^{-1}, which was identified as the optimum operating speed. Field evaluation demonstrated that the developed machine reduced labour requirements, provided effective weed control, and improved the operational efficiency of mechanical weed management in direct-seeded paddy cultivation.

सारांश
मैनुअल वीडर हाथ से निराई की तुलना में श्रम की आवश्यकता को कम करते हैं, किंतु धान की खेती में ये अभी भी समय-साध्य एवं श्रमसाध्य बने रहते हैं। डायरेक्ट सीडेड धान के लिए 4.5 हार्सपावर एकल-सिलेंडर वायु-शीतित इंजन तथा तीन रोटरी इकाइयों से युक्त एक रोटरी पावर वीडर का विकास कर क्षेत्रीय परिस्थितियों में मूल्यांकन किया गया। मशीन का परीक्षण तीन अग्र गतियों पर किया गया तथा इसकी तुलना खुरपी द्वारा मैनुअल निराई से की गई। अग्र गति बढ़ने पर निराई दक्षता में कमी, जबकि पौधा क्षति एवं शक्ति आवश्यकता में वृद्धि पाई गई। सर्वाधिक उपज एवं लाभ–लागत अनुपात 1.27 किमी प्रति घंटा की गति पर प्राप्त हुआ, जिसे सर्वोत्तम कार्य गति पाया गया। क्षेत्रीय मूल्यांकन से श्रम आवश्यकता में कमी, प्रभावी खरपतवार नियंत्रण एवं धान की खेती में यांत्रिक निराई द्वारा बेहतर परिचालन दक्षता सिद्ध हुई।

INTRODUCTION
Paddy is the main crop of the Asia and the world with share 60% and 25% of its global production, respectively (*Timmer, 2010*). Paddy is cultivated in 43.86 million hectares in India with 104.80 million tonne production and 2.39 tonne/ha productivity (*Ministry of Agriculture & Farmers Welfare, 2022*). Bihar is progressing fast in paddy production with present productivity level 4.02 tonne/ha (Finance Department, 2023).

Intensive need of resources in traditional method of paddy cultivation has forced the scientists and policy makers for advocacy of direct seeded paddy cultivation. Paddy production by direct seeding method is adversely affected by the heavy infestation of weed resulting into reduction in grain yield 40-65% (*Farooq et. al., 2011b; Kumar et. al., 2016, Roy et. al., 2011*). Weeds reduce the yield between 40-65%. Weed eradication or its effect control is the critical challenge for the paddy growing farmers (*Sharma et. al., 1977*). Weeding alone contributes to one-third of the total cost of cultivation as the loss in total estimated cost of production of paddy (*Rangasamy et. al., 1993*). The loss of yield due to weed in direct seeding method may be up to 70-80% (*Singh et. al., 2007; Hussain et. al., 2008; Mahajan et. al., 2009*). Cultivation of direct seeded rice may give 27-30% more yield than the transplanted rice under effective weed management practices (*Mishra et. al., 2012*). Use of traditional tools and equipment for mechanical weeding increases the cost of operation besides enhanced drudgery, wastage of inputs as well as damage to the produce (*Shrivastava, 2000*).

Chemical weeding method is highly adopted practice by the farmers in paddy cultivation, where yield is reduced significantly in comparison to mechanical weeding method. Mechanical weeding method retards the growth rate of the weed without adversely affecting the growth of the plants (*Kwangwaropas, 1999*). However, hand held mechanical weeders or tools require lot of time, energy and labour (*Patel et. al., 2018*). Development of effective power weeder may reduce the time of weeding and associated drudgery to the operators in weeding operation. Power weeding in maize requires approximately 10 labour-hours per hectare, compared with 167 labour-hours per hectare for manual weeding using traditional tools (*Dixit and Syed, 2008*). Undoubtedly, power weeder is advantageous for the farmers on account of enhanced field capacity in comparison to all types of manually and animal driven weeders (*More et. al., 2020*).

Agricultural mechanization is essential for improving labour productivity and operational timeliness, particularly in weed management, which remains one of the most labour-intensive field operations (*Hunt, 2001*). In small and medium landholdings, tractor-mounted implements are often unsuitable due to economic and field constraints; consequently, self-propelled and engine-operated rotary power weeders have emerged as effective intermediate mechanization options (*FAO, 2011*). These machines perform shallow soil working and weed uprooting using rotary tools, offering higher field capacity, reduced drudgery and improved weeding efficiency compared with manual methods (*Manuwa, 2009; Tewari et al., 2014;Kumar et al., 2023*). Several studies have reported labour savings exceeding 60% and significant improvements in operational efficiency in row crops and horticultural systems (*Singh and Singh, 2012; Kumar, et al., 2026*). However, the performance of rotary power weeders is strongly influenced by design parameters, soil conditions and crop geometry, underscoring the need for systematic design and field-level performance evaluation (*Kepner et al., 2018*).

Manual weeding remains the most widely adopted method of weed control in India; however, it is highly labour-intensive, time-consuming, and significantly increases the cost of cultivation. Weeding requires approximately 900–1200 labour-hours per hectare, accounting for nearly 25% of the total labour requirement in crop production (*Nag and Dutta, 1979*). Delayed or inadequate weeding can reduce crop yield by 30–60% (*Singh, 1988*), while yield losses due to weeds alone have been reported to range from 16–42%, depending on crop and location, contributing nearly one-third of the cultivation cost (*Rangasamy et al., 1993*). In India, approximately ₹4.2 billion is spent annually on weed control, and nearly 40 million tonnes of major food grains are lost each year due to weed infestation (*Singh and Sahay, 2001*). Yield losses of 5–60% have been reported under different weed intensities and management conditions and may reach 80% when weeds are not controlled during the critical stage of crop growth (*Dutta, 1981; Goel et al., 2008; Paraforos, et al., 2018*).

Several mechanical weeders, including manual, push–pull, bullock-drawn, and self-propelled rotary weeders, have been developed to reduce labour dependency. However, their adoption remains limited due to labour scarcity, increasing wage rates, low field efficiency, dependence on optimum soil moisture, and inconsistent weed control performance. In particular, most commercially available self-propelled rotary weeders require multiple passes for inter-row weeding in wide-row crops, resulting in lower effective field capacity, increased fuel consumption, higher operational cost, and reduced overall productivity.

Despite these developments, limited research has focused on designing and evaluating a high-capacity rotary power weeder capable of simultaneously improving field capacity, field efficiency, weeding efficiency, and operational economy under wide-row crop conditions. Furthermore, comprehensive field performance evaluation considering operational parameters such as forward speed, field efficiency, fuel consumption, power requirement, and weeding effectiveness is scarce. This knowledge gap limits the optimization and wider adoption of rotary power weeders in Indian farming systems.

Therefore, the present study was undertaken to develop and evaluate an improved rotary power weeder with enhanced operational performance under field conditions. The study aims to optimize key operational parameters to improve weeding efficiency, reduce labour requirement and operating cost, minimize operator drudgery, and enhance crop productivity.

MATERIALS AND METHODS

The power weeder was developed in the Department of Farm Machinery and Power Engineering, College of Agricultural Engineering and Technology (CAET), Pusa. The design procedure is described below.

Drive Wheel

The design of the power weeder wheel is critical for ensuring effective traction, stability and soil engagement during operation. The wheel has a diameter of 44.80 cm and a hub bore diameter of 2.50 cm, providing sufficient clearance for mounting on the drive shaft while maintaining structural integrity.

The overall width of the wheel is 9.00 cm, with the spiked tread extending 7.00 cm, allowing adequate soil contact for propulsion and minimal slippage on soft or wet soils. The depth and geometry of the spikes, measured at 4.92 cm in height with a radial spacing of 6.45 cm, are designed to penetrate the soil effectively, loosening the top layer without causing excessive compaction. Triangular cut-outs on the wheel body reduce weight without compromising strength, while the rounded edges with radii R1.25 cm and R2.50 cm provide wear resistance and facilitate smooth rotation. The lateral thickness of the tines, ranging from 3.67 cm to 4.66 cm, ensures durability under repetitive loading and abrasive soil conditions as shown in fig. 1. Overall, the wheel design balances traction, mechanical strength and soil interaction to optimize the performance of the power weeder in various field conditions.

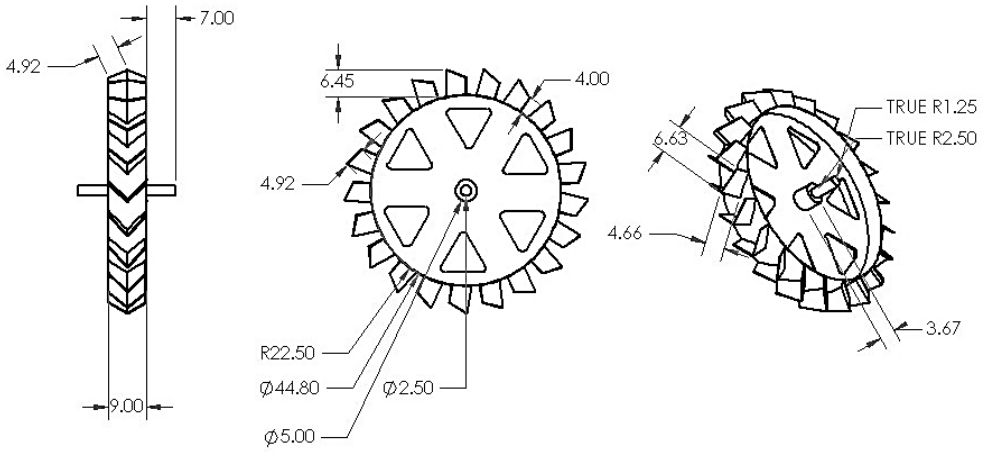

Fig. 1 - Different views of drive wheel

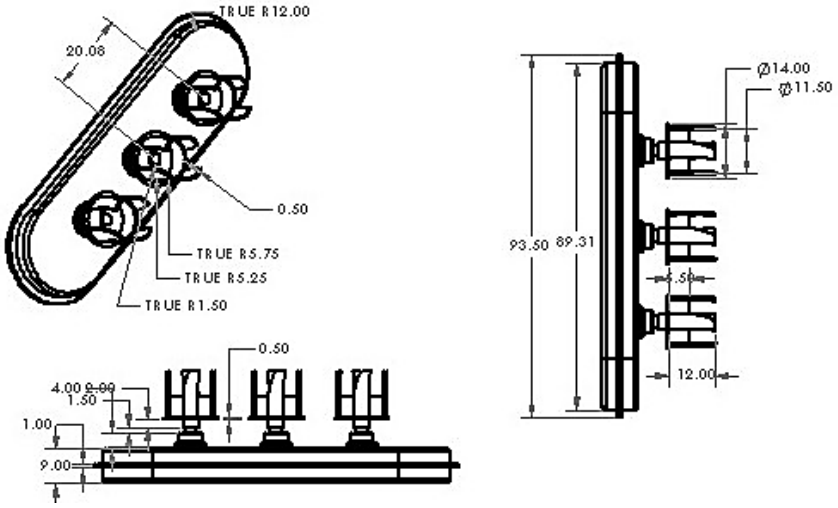
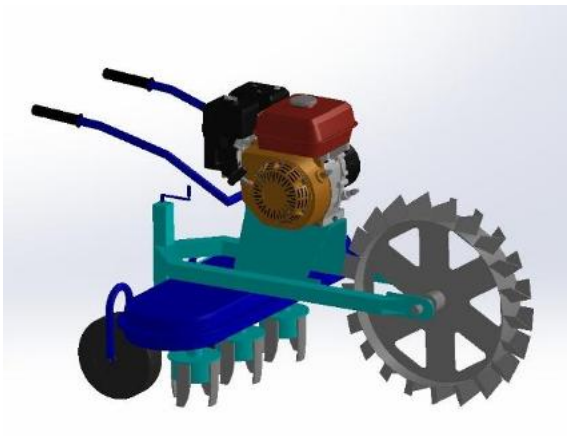
Vertical Rotary Blade

The power weeder blade design incorporates three rotary blades mounted on a 92.0 cm wide chain-driven assembly, with individual blade offset of 12.0 cm, ensuring balanced soil penetration and weed uprooting across varied field conditions. Key structural parameters include a 20.0 cm vertical height for the assembly, 9.50 cm and 4.0 cm horizontal spans for mounting stability, blade thickness of 0.5 cm, hub dimensions of 1.0 cm width by 12.0 cm length and a 12.0 cm base separation, which collectively optimize cutting width, torsional strength and minimal soil compaction during operation as shown in fig. 2. These dimensions support highly efficient weeding efficiency in multi-crop applications while maintaining operational safety and durability.





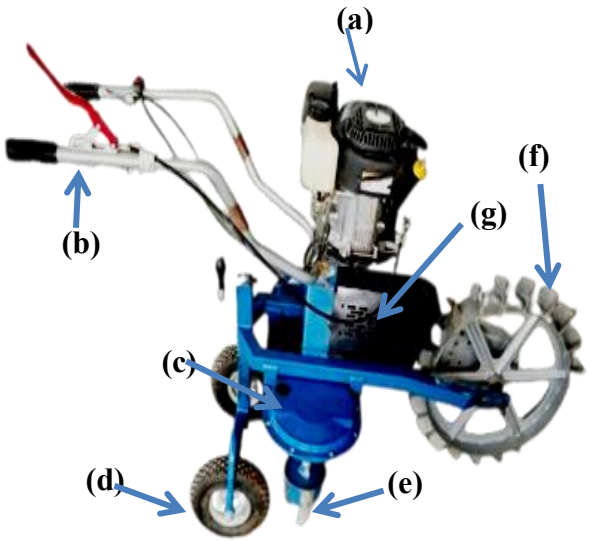


Fig. 2 - Different views of vertical rotary blade

Isometric view of the developed power weeder modeled in Solid Edge, illustrating the overall machine layout and spatial arrangement of major functional components and schematic diagram as shown in fig. 3. The view highlights the integration of the power unit, transmission system, rotary weeding mechanism and operator controls for design visualization and analysis.

Component of Power Paddy Weeder

The drive wheel generates power for the forward movement of the machine. The vertical rotor wheel has a conical-shaped blade that cuts the soil as it rotates and helps the machine achieve the desired working depth. The Gear Box-I multiplies the engine speed (rpm) and transmits it to the rotor shaft, while Gear Box-II reduces the engine speed and delivers a lower rpm (about 10) to the drive wheel. The depth control wheel maintains a uniform cutting depth across the field.

The engine supplies power to operate all the other components of the machine. The specifications of the developed power weeder are given in Table 1. The cost of the machine was considered as ₹90,000.00 per unit for the purpose of cost calculation.

	At the shank	:	40.67 (Average)

Experimental Field

The evaluation of developed paddy power weeder was carried out in the research farm of Dr. Rajendra Prasad Central Agricultural University in Kharif 2023. The experimental plot was located at Latitude 25°98' N, Longitude 85°67' E and altitude 53.0 meter above the mean sea level. The soil of the plot was calcareous sandy loam with pH 8.5, composed with 90.3% sand, 9.7% silt and clay, 10-12% $CaCO_3$, 0.06% organic matter. The bulk density of the experimental plot was 1.43g/cm^3. The Rajendra Bhagwati paddy variety was grown by direct seeding method in a plot having area 1200 m^{2}and size 40×30m (Table 2) under dry condition.

Experimental Procedure

The experiment was conducted under the Randomized Block Design by operating the power weeder at three variable speeds i.e. 1.10 km/h, 1.27 km/h and 1.45 km/h. Weeding by hand tool *Khurpi* was taken as check treatment in the present experiment. Data were recorded in five replications of each treatment. Machine, crop, and economic parameters were evaluated to assess the performance of the developed machine and its effects on paddy yield and production economics. The results were compared with the farmers' commonly adopted practice of manual weeding using a khurpi or trowel.

The average working depth was 27.7 mm, with an engine speed of 3600 rpm and a rotor speed of 545 rpm. During the field evaluation, operator feedback regarding ease of operation and machine vibration was recorded qualitatively at the end of each experimental run. The standard formulae adopted for calculating the performance parameters of the developed power weeder are presented in Table 3.

Table 3

Standard formulae used for evaluating the performance of a power weeder

No.	Parameter	Formula [Units]	Citation
1.	Theoretical field capacity (TFC)	$\text{TFC} = \frac{S \times W}{10}$ [ha h^{-1}]	*Kepner et al., 2018; Ragesh et al., 2018*
2.	Effective field capacity (EFC)	$EFC = \frac{Effective\ coverage\ area\ by\ the\ machine\ (m^2)}{Total\ time\ taken\ in\ in\ hour\ (t) \times 1000}$ [ha h^{-1}]	*Kepner et al., 2018; Ragesh et al., 2018*
3.	Field efficiency (FE)	$FE = \frac{Effective\ field\ capacity\ (ha/h)}{Theoretical\ field\ capacity\ (ha/h)} \times 100$ [%]	*Islam et al. 2017; Ragesh et al., 2018*
4.	Weeding efficiency (WE)	$WE = \frac{w_1 - w_2}{w_1} \times 100$ [%]	*Thorat et al. 2014; Ragesh et al., 2018*
5.	Performance index (PI)	$PI = \frac{Effective\ field\ capacity \times (100 - Damage\ factor) \times Weeding\ index}{Input\ power}$ [ha hp^{-1}h^{-1}]	*Thorat et al. 2014; Ragesh et al., 2018*

Assessment of Grain and Straw Yield

The grain yield was recorded by using a wire square of 1m^2 by throwing it randomly in each treatment. In each treatment grain yield was recorded at five different locations, treated as replications. The straw yield was worked out by considering the grain straw ratio 1:1.15 for Rajendra Bhagwati paddy variety. The evaluation of machine parameters, including theoretical and effective field capacities, field and weeding efficiencies, fuel consumption and power consumption, was carried out as per the methodology outlined by *Sanjay (2024)*. Whereas, the performance index of weeder was determined by method described by *Rangasamy et al. (1993.)*

Cost Economics of Paddy and Straw

It was taken as per local market rate available in Samastipur town of Bihar. The paddy and straw cost were Rs 19.00/kg and 1.50 Rs/ kg, respectively. The cost of machine was carried out as per the methodology mentioned by *Sanjay (2024).*

RESULTS AND DISCUSSIONS

The average data of the replications with regards to the field capacity and field efficiency of the machine in all the treatments is presented in Table 4 and at the end of the operation, the operator reported that the machine was easy to operate and produced minimal vibration.

Table 4

Determination of Field Capacity & Field Efficiency of the machine in different treatments

Treatments	TFC (ha/h)	Theoretical Time (h/ha)	No. of Turns	Turning time/ turn (s)	Turning time (h/ha)	Actual Time (h/ha)	AFC (ha/h)	Field Efficiency (%)
T_1	0.0825	12.12	39	16	1.44	13.56	0.074	89.69
T_2	0.0953	10.49	39	16	1.44	11.93	0.084	85.45
T_3	0.1087	9.20	39	19	1.72	10.92	0.092	84.63

From the data recorded in Table 3 above, it was observed that the highest field capacity was recorded in treatment T_3 (0.092 ha/h) followed by treatment T_2 (0.084 ha/h) & treatment T_1 (0.074 ha/h). The field efficiency of machine was found having antagonistic relationship with the field capacity. The field efficiency of machine was maximum 89.69% in treatment T_1 followed by treatment T_2 (85.45%) and the minimum in treatment T_3 (84.63%).

Since the actual field capacity (AFC) is not dependent on the theoretical field capacity, which in turn is influenced by the forward speed of the machine, the AFC was observed to increase with the increase in forward speed from treatment T1 (1.10 km/h) to treatment T3 (1.45 km/h) *(Kumar et al., 2018; Verma et al., 2020)*. When the machine speed was increased, operational control at the terminal points and near the headland required more time, resulting in higher turning time (*Bhoi & Dash, 2021*). Consequently, this adversely affected the overall field efficiency of the machine, which was found minimum (84.63%) in treatment T3 (*Ghosh et al., 2022; Yadav & Patel, 2023*). Field efficiency decreased with increasing forward speed because the actual field capacity did not increase proportionally with the theoretical field capacity. At higher operating speeds, turning losses at headlands, implement overlap, missed areas requiring correction, and time required for machine adjustments increased. In addition, higher speeds reduced the operator's ability to maintain precise machine guidance, resulting in greater operational inefficiencies. Consequently, the ratio of actual field capacity to theoretical field capacity declined, leading to a reduction in field efficiency.

The weeding efficiency of the machine as well as *khurpi* as control treatment was determined at 25 and 45 days after seeding (Table 5). There was a similar trend in variation of weeding efficiency of the machine both at 25 and 45 days after seeding (DAS).

Table 5

Determination of weeding efficiency (%) of machine in different treatments

Treatment	Forward speed of the machine (km/h)	Weeding at 25 DAS			Weeding at 45 DAS		
		Weed count/m² area before weeding	Weed count/m² area after weeding	Weeding efficiency (%)	Weed count/m² area before weeding	Weed count/m² area after weeding	Weeding efficiency (%)
T_1	1.10	134	18	86.57	63	7	88.89
T_2	1.27	169	23	86.39	63	8	87.30
T_3	1.45	161	27	83.23	60	10	83.33
T_4	-	152	7	95.39	66	3	95.45

At 25 days after seeding, the weeding efficiency in treatment T_1 and T_2 were 86.57% and 86.39%, respectively. In treatment T_3, the machine had exhibited lower weeding efficiency i.e. 83.23%. At 45 days after seeding, the weeding efficiency in treatment T_1 and T_2 were 88.89% and 87.30% respectively. However, the same was 83.33% in treatment T_3 at 45 days after seeding.

The manual weeding by *khurpi* in control treatment had registered highest weeding efficiency among all the treatments with values 95.39% and 95.45% at 25 and 45 days after seeding respectively.

The weeding efficiency of the machine at 45 DAS was found to be slightly higher, possibly due to the vigorous growth of paddy plants, which restricted the survival of weeds around the root zone (*Devi et al., 2021; Mehta et al., 2020*).

However, when the forward speed of the machine exceeded 1.27 km/h, there was a significant decline in the weeding efficiency of the vertical rotary weeder. This reduction occurred due to the smaller overlapping portion of the tilth soil during each blade rotation, which caused incomplete uprooting and allowed some weeds to survive within the tilled zone (*Rajendran & Manian, 2019; Dash et al., 2021; Singh et al., 2023*).

The plant damage reported in percentage (%) was increasing with increase in forward speed of the machine (Table 6). The trend in variation of plant damage by the machine recorded in different treatments had the antagonistic relationship with the performance index (Table 6).

The plant damage at 25 DAS was ranging between 2.63% to 2.98% in treatments from T_1 to T_3. However, at 45 DAS the same was minimum (5.34%) in treatment T_1, followed by treatment T_2 (5.81%) and treatment T_3 (6.78%) respectively. The power requirement of the machine for weeding was minimum 3.2 hp in treatment T_1 and maximum 4.1 hp in treatment T_3 followed by 3.8 hp in treatment T_2. However, the weeding efficiency of machine was increasing marginally in all the treatments at 45 DAS in comparison to weeding efficiency reported at 25 DAS. The performance index of the machine was maximum in treatment T_1, both at 25 DAS (190.19%) and 45 DAS (189.85%). The minimum performance index 181.98% was recorded at 25 DAS in treatment T_3 followed by 175.06% at 45 DAS.

Table 6

Determination of performance index of the machine

Treatments	AFC (ha/h)	Power (hp)	Weeding efficiency (%)		Plant damage (%)		Performance Index	
			At 25 DAS	At 45 DAS	At 25 DAS	At 45 DAS	At 25 DAS	At 45 DAS
T_1	0.0722	3.2	86.57	88.89	2.63	5.34	190.19	189.85
T_2	0.0825	3.8	86.39	87.30	2.46	5.81	182.94	178.52
T_3	0.0924	4.1	83.23	83.33	2.98	6.78	181.98	175.06

There was more plant damage in all the treatments at 45 DAS, probably due to the higher tillering per hill in the paddy crop, where plants often came in contact with the rotating blades, causing mortality during the forward movement of the machine (*Patel et al., 2020; Reddy et al., 2020*). The trend of increased plant damage percentage and decreased weeding efficiency with an increase in the forward speed of the machine resulted in the highest performance index in treatment T1 and the lowest in treatment T3 (*Kumar & Singh, 2022*).

The power requirement of the machine from treatment T1 to T3 was found to be in increasing order, primarily due to the higher operational speed during the weeding process (*Sharma et al., 2021*). Therefore, the observed increase in both plant damage percentage and power requirement for weeding from treatment T1 to T3 was responsible for the decreasing trend of the performance index of the machine across treatments (*Deshmukh & Tiwari, 2019*). Power requirement increased with increasing forward speed because the rotary blades engaged a larger volume of soil and weed biomass per unit time. This increased the soil-cutting force, draft resistance, and torque required to rotate the blades. Consequently, the engine was required to deliver higher power to overcome the increased operational load while maintaining the desired rotor speed. Additionally, the higher rate of soil fragmentation and biomass cutting at elevated forward speeds contributed to greater energy demand, resulting in an increase in power consumption.

The data of plant height recorded from 30 days after seeding in different treatments at successive interval of 15 days clearly indicates that the plant growth in all the treatments were symmetric and presented in Table 7. The plant height recorded at 45 days after seeding shown maximum growth of the crop (48.48 cm) in treatment T_1 and minimum (44.42 cm) in treatment T_4 (Control Treatment). However, after 60 days of seeding the plant height in treatment T_1, T_3 and T_4 were at par. In treatment T_1, there was maximum plant growth with crop height 780.8 mm.

Table 7

Measurement of plant height at different stages during crop growth

Treatments	Average of plant height after 30 days, mm	Average of plant height after 45 days, mm	Average of plant height after 60 days, mm
T_1	258.4	484.8	780.8
T_2	254.2	464.0	776.9
T_3	243.6	478.8	765.0
T_4	254.6	444.2	762.5

The weeding in paddy crop by machine had a positive effect on plant growth due to inter-row soil pulverization, which enhanced soil aeration and nutrient availability for the plants (*Deshmukh & Tiwari, 2019; Patel et al., 2020*). The change in machine speed had no significant impact on the extent of soil pulverization and therefore, only marginal variation was observed in plant height at 45 and 60 days after seeding across all treatments (*Kumar & Singh, 2022*).

The weeding by *khurpi* was also found to be equally effective because of its high weeding efficiency, coupled with improved soil aeration near the root zone of the plants (*Sharma et al., 2021*). The plant height in the control treatment at 45 and 60 DAS was statistically at par with the plant height in treatment T3, where the machine operated at a higher forward speed (1.45 km/h), indicating that increased speed did not significantly affect crop growth (*Reddy et al., 2020*).

The cost of cultivation of paddy crop by using power weeder and khurpi for weeding operation were worked out to determine the Benefit-cost ratio in all the treatments. The data with regards to B-C ratio in different treatments of machine operation and weeding by khurpi as control treatment is presented in Table 8.

Table 8

Economic assessment of Power Weeder vis-à-vis manual weeding in paddy crop

Treatments	Cost of common operation (Land preparation, Sowing, Irrigation & Harvesting and Threshing (Rs/ha)	Cost of weeding (Rs/ha)	Total Cost of cultivation (Rs/ha)	Cost of Produce (Rs/ha)			Benefit in cultivation in comparison to the traditional method (Rs/ha)	B-C ratio
	(1)	(2)	(3)=(1+2)	Grain (4)	Straw (5)	Total 6=(4+5)	(7)	(8)=(7/3)
T_1	16800	2974.57	19774.57	82608.2	7499.95	90108.15	70333.58	**3.56**
T_2	16800	2604.73	19404.73	83448.0	7576.20	91024.20	71619.47	**3.69**
T_3	16800	2326.30	19126.30	82239.6	7466.49	89706.09	70579.79	**3.69**
T_4	16800	9000.00	25800.00	81795.0	7426.12	89221.12	63421.12	**2.46**

From perusal of the data presented in the Table 7, it is evident that the benefit-cost ratio was in higher range (3.56 to 3.69) in weeding by machine from treatment T_1 to T_3, as compared to the manual weeding, by *Khurpi* (2.46). The B-C ratio was maximum in treatment T_2 and T_3 (3.69) and minimum (3.56) in treatment T_1, when the weeding was done by the use of power weeder. The weeding by *Khurpi* was found least economical on account of lowest B-C ratio among all the treatments.

The highest grain and straw yield were recorded in the paddy crop when weeding was done using a power weeder. This was probably due to the fact that the rotating blades pulverized the soil, leading to better aeration in the root zone and improved nutrient availability for plant growth and development (*Deshmukh & Tiwari, 2019; Singh et al., 2021*). In weeding by *Khurpi*, although the weeding efficiency was higher, the lower yield of the crop in comparison to machine weeding (treatments T_2 and T1) may be attributed to less soil pulverization, resulting in restricted aeration near the root zone of the plants (*Patel et al., 2020*). The highest B–C ratio in treatment T2, over treatments T1 and T3, was due to the higher yield of grain and straw in T1 compared to other machine operations. The lowest B–C ratio in the control treatment (T4) was mainly due to the reduced grain and straw yield and the higher cost of cultivation associated with *Khurpi* weeding, which required a large amount of manual labour for operation (*Kumar & Singh, 2022*).

CONCLUSIONS

The study evaluated the effect of forward speed of a rotary power weeder on field performance, crop yield and economic efficiency in paddy cultivation. Results revealed that an increase in forward speed enhanced the actual field capacity but led to higher plant damage, power requirement and a decline in field efficiency. The treatment operated at a moderate speed of 1.27 km h^{-1} (T_2) exhibited the most desirable combination of performance indicators, with superior weeding efficiency, lower crop damage and a balance between time efficiency and operational cost. Consequently, T_2 also recorded the highest grain and straw yields, resulting in the maximum benefit–cost ratio among all treatments. The findings suggest that maintaining an optimum forward speed of approximately 1.27 km h^{-1} ensures effective weed control, improved soil conditions and enhanced profitability in paddy cultivation. Adoption of rotary power weeders at this operational speed can significantly reduce labour dependency and promote sustainable mechanization in wetland paddy farming.

ABSTRACT

To address the high power consumption, limited load adaptability, and inadequate parameter matching of conventional axial-flow threshing devices, power-consumption tests were conducted on an axial-flow threshing device with adjustable threshing intensity using rice as the test material. The tests examined different threshing-intensity modes, separating-screen types, and operating parameters. The effects of these factors on no-load power consumption, effective power consumption, total power consumption, and mechanical efficiency were analyzed. The results showed that total power consumption was minimized when the threshing-intensity adjustment plates were fully open and the rectangular-hole separating screen was used. Total power consumption increased with increasing drum speed, deflector angle, and feed rate, but decreased with increasing concave clearance. Mechanical efficiency initially remained stable and then decreased as drum speed increased, whereas it increased with increasing deflector angle and feed rate. The specific threshing power consumption, expressed per unit feed rate, ranged from 4.4 to 5.2 kW/(kg/s). It increased with increasing drum speed, deflector angle, and feed rate, and decreased with increasing concave clearance. This study provides a reference for reducing power consumption and optimizing parameter matching in axial-flow threshing devices with adjustable threshing intensity.

摘要

针对传统轴流脱粒装置功耗偏高、负荷适应性差、参数匹配粗放等问题，以水稻为试验材料，在一种脱粒力度可调式轴流脱粒装置上，开展不同脱粒力度模式、分离筛板类型及不同工作参数条件下的脱粒功耗试验，分析各试验因素对空载功耗、有效功耗、总功耗及机械效率的影响规律。结果表明：脱粒力度调节板全部打开、采用长方形筛孔式分离筛板时总功耗最低；总功耗随滚筒转速、导流板角度、喂入量的增大而上升，随凹板筛间隙的增大而下降；机械效率随转速的升高先稳后降，随导流板角度及喂入量的增大而提高。装置单位喂入量脱粒功耗为 4.4～5.2 kW/(kg/s)，随滚筒转速、导流板角度、喂入速率的增加而升高，随凹板筛间隙的增大而降低。该研究可为脱粒力度可调式轴流脱粒装置低功耗优化与参数匹配提供参考。

INTRODUCTION

As the core working component of a grain combine harvester, the threshing device accounts for the highest proportion of the total power consumption of the whole machine. The characteristics of threshing power consumption directly affect the power matching, operating efficiency and performance, as well as fuel economy of the combine harvester *(Song et al., 2022; Li et al., 2011; Mousaviraad et al., 2020)*. In practical harvesting operations, operating parameters such as drum speed, concave clearance and feed rate jointly determine the threshing power consumption and the mechanical efficiency of the device *(Kiniulis et al. 2017; Qin et al., 2025; Yu et al., 2025)*. At present, harvesting equipment generally suffers from problems such as extensive parameter matching, high operating power consumption, large fluctuations in mechanical efficiency and poor load adaptability *(Lu et al., 2012; Chen et al., 2025; Vlăduț et al., 2022)*.

Yuejiang Teng, Lecturer, Ph.D.; Chengqian Jin, Prof., Ph.D.; Fuxiang Xie, Prof., Ph.D.; Jian Song, Prof., Ph.D.

Especially under complex field conditions with uneven feeding and drastic changes in crop moisture content, problems such as blockage, sharp increase in energy consumption, incomplete threshing or excessive grain damage frequently occur, which seriously restrict the upgrading and development of combine harvesters toward high efficiency, low consumption, intelligence and lightweight *(Jin et al., 2015; Ren et al., 2013; Steponavičius et al. 2023; Vlăduţ et al., 2023; Zhang et al., 2026)*.

In recent years, scholars worldwide have conducted extensive research on the structural optimization, parameter matching, and power consumption characteristics of axial-flow threshing devices. *Waree et al. (2016)* investigated the effects of structural parameters on the power consumption of an axial-flow corn threshing device using the response surface methodology. The results indicated that increasing the tine clearance, concave grate clearance, and concave clearance could significantly reduce threshing power consumption. Meanwhile, a power consumption prediction model with high fitting accuracy was established, which provided a theoretical basis for the low-energy structural parameter optimization of threshing devices. *Fan et al. (2022)* developed an adaptive feed-rate threshing clearance control system to address the excessive power consumption caused by non-adjustable threshing clearance under varying feed rates. Tests showed that the system could match the optimal threshing clearance, with the average power consumption increased by only 3.45%. The system significantly improved operating performance while maintaining basically stable energy consumption, providing a feasible approach for the energy-saving control of threshing devices. *Ali et al. (2024)* optimized the rotor structure of sunflower threshers to conduct experiments for energy consumption reduction. Their test results verified that rotor rotary speed and concave clearance exert remarkable impacts on the specific energy consumption during threshing operations. When adopting the tine-bar rotor under the working condition of 300 r/min rotor speed and 10 mm concave clearance, the specific energy consumption was reduced from 9.65 kWh/ton to 5.09 kWh/ton. This finding demonstrated that structural improvement of threshing rotors was an effective method to reduce the power consumption of threshing operations. *Xing et al. (2024)* designed a longitudinal-axial flow threshing device with a measurement and control system to tackle the high energy consumption and poor parameter matching of corn ear threshing under high moisture content. Parameter optimization tests were carried out with drum speed, concave clearance, and deflector angle as variables. A regression model of unit energy consumption was established and the optimal parameters were obtained. Results showed that the unit energy consumption was reduced by 14.74% after optimization with high model accuracy, offering a reference for the low-power consumption optimization of threshing devices.

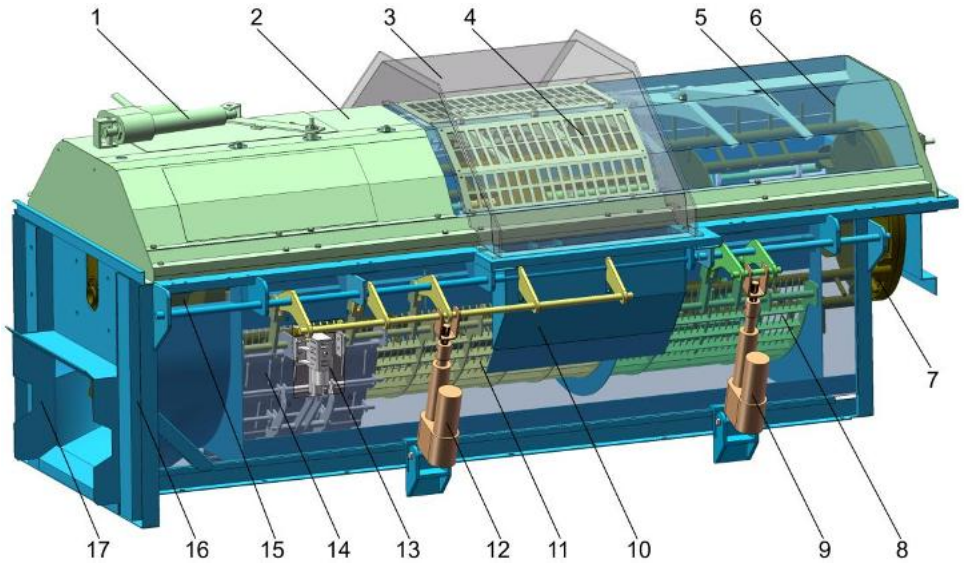
Most existing studies focused on threshing devices with fixed structures and single adjustment mode, and there is a lack of research on the power consumption characteristics of novel axial-flow threshing devices with adjustable threshing intensity, multi-mode switching and multi-parameter collaborative regulation *(Wang et al., 2025; Xie et al., 2021)*. In particular, studies on the variation laws of power consumption and mechanical efficiency under the coupling effects of different threshing intensity modes, separating screen types, concave clearance, deflector angle and other parameters are insufficient.

Therefore, this study took an axial-flow threshing device with adjustable threshing intensity as the research object. The device integrated an adjustable-intensity threshing concave, a 360° separation device, a concave clearance adjustment mechanism, and a deflector angle adjustment mechanism, which could realize the switching of four threshing intensity modes and multi-parameter collaborative regulation. Threshing power consumption tests were carried out under different threshing intensity modes, separating screen types, drum speeds, deflector angles, concave clearances and feed rates. The variation laws of no-load power consumption, effective threshing power consumption, total threshing power consumption and mechanical efficiency were systematically analyzed, and the influence mechanism of each parameter on threshing power consumption was revealed. This study could provide experimental evidence and theoretical support for the low-energy optimization and parameter matching of adjustable axial-flow threshing devices

MATERIALS AND METHODS

Structure of the longitudinal-axial flow threshing device with adjustable threshing intensity

The threshing intensity required during harvesting varies considerably among crop varieties, moisture contents, and feed-rate conditions. The complexity of practical threshing conditions therefore imposes greater requirements on the adaptability of the threshing device. To address these requirements, a longitudinal axial-flow threshing device with adjustable threshing intensity was designed, as shown in Fig. 1. The device mainly consists of a screw feeder, a trapezoidal threshing drum, an adjustable-intensity threshing concave, a 360° separation device, concave-clearance adjustment mechanisms, deflectors, and a deflector-angle adjustment mechanism.



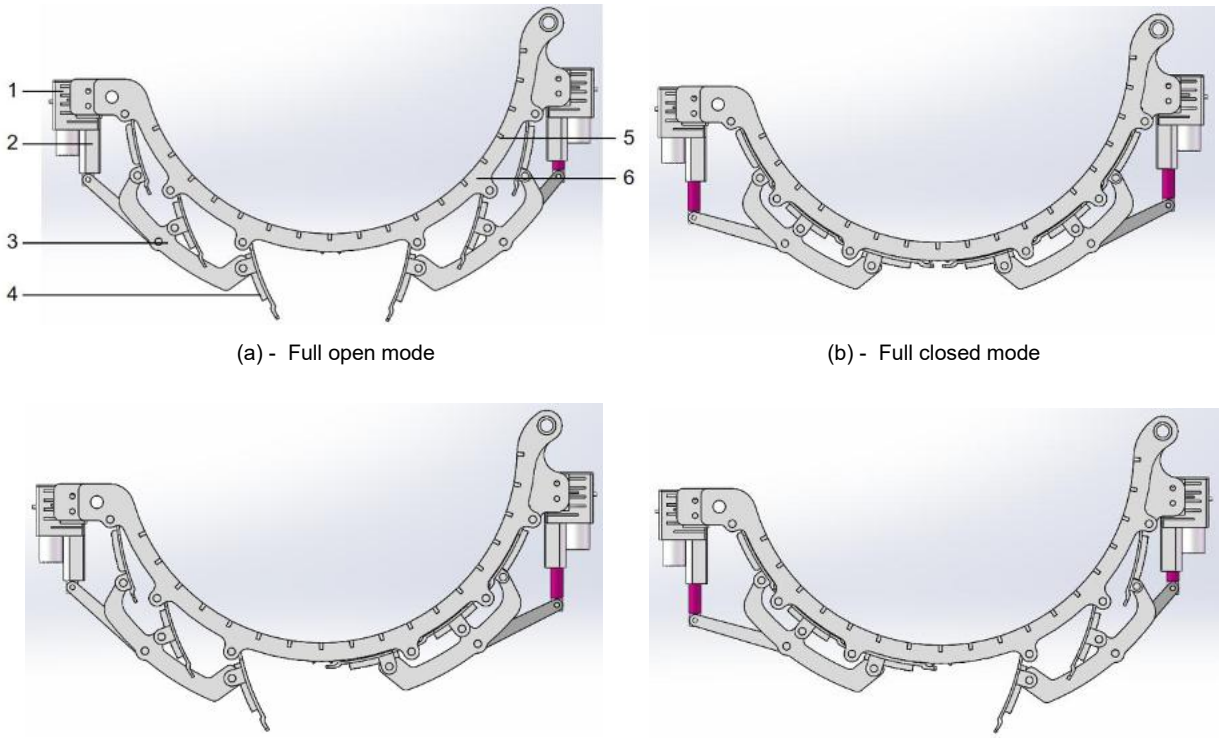


Fig. 1 - Structure of the longitudinal-axial flow threshing device with adjustable threshing intensity

1 – deflector angle adjustment mechanism; 2 – top cover; 3 – 360° separation device; 4 – upper sieve plate of 360° separation device; 5 – deflector; 6 – threshing element; 7 – trapezoidal threshing drum; 8 – separating concave; 9 – separating concave clearance adjustment mechanism; 10 – return plate of 360° separation device; 11 – threshing concave; 12 – threshing concave clearance adjustment mechanism; 13 – adjustable-intensity threshing concave; 14 – threshing-intensity adjustment plate; 15 – screw feeder;16 – frame; 17 – feed inlet

The structure of the adjustable-intensity threshing concave is shown in Fig. 2. It mainly consists of threshing intensity adjustment plates, transverse grids, concave bars, side arc plates, electric actuator mounts, electric actuators and transmission rods.

(a) - Full open mode

(b) - Full closed mode

(c) - Left open and right closed mode

(d) - Left closed and right open mode

Fig. 2 - Structure and operating modes of the adjustable-intensity threshing concave

1 – electric actuator mount; 2 – electric actuator; 3 – transmission rod; 4 – threshing-intensity adjustment plate; 5 – transverse partition plate; 6 – Side arc plate

The threshing-intensity adjustment plates were divided into left and right parts. Each part contained 9 adjustment plates arranged in 3 rows and 3 columns.

Each adjustment plate was hinged on one side to the concave frame, and the other side was uniformly controlled by an electric actuator through a transmission mechanism to switch between open and closed states. The left and right electric actuators were both fixed on the concave frame. According to the required threshing intensity during operation, the threshing-intensity adjustment plates could be adjusted to four modes: fully open, fully closed, left open and right closed (viewed from the rear of the threshing device), and left closed and right open (viewed from the rear of the threshing device), as shown in Fig. 2.

Test materials

Compared with other grains, rice grains and stems have higher moisture content, resulting in relatively high power consumption during threshing. Therefore, rice was selected as the test material in this study to investigate threshing power consumption. The relevant material properties of rice are listed in Table 1.

Table 1

Relevant material characteristic parameters of the test crop

Test crop	Plant height [mm]	Straw-to-grain ratio	Grain moisture content [%]	Stem moisture content [%]	Thousand-grain weight [g]	Yield per unit area [kg·hm^{-2}]
Rice	865	1:1.1	23.2	58.6	27.5	8960

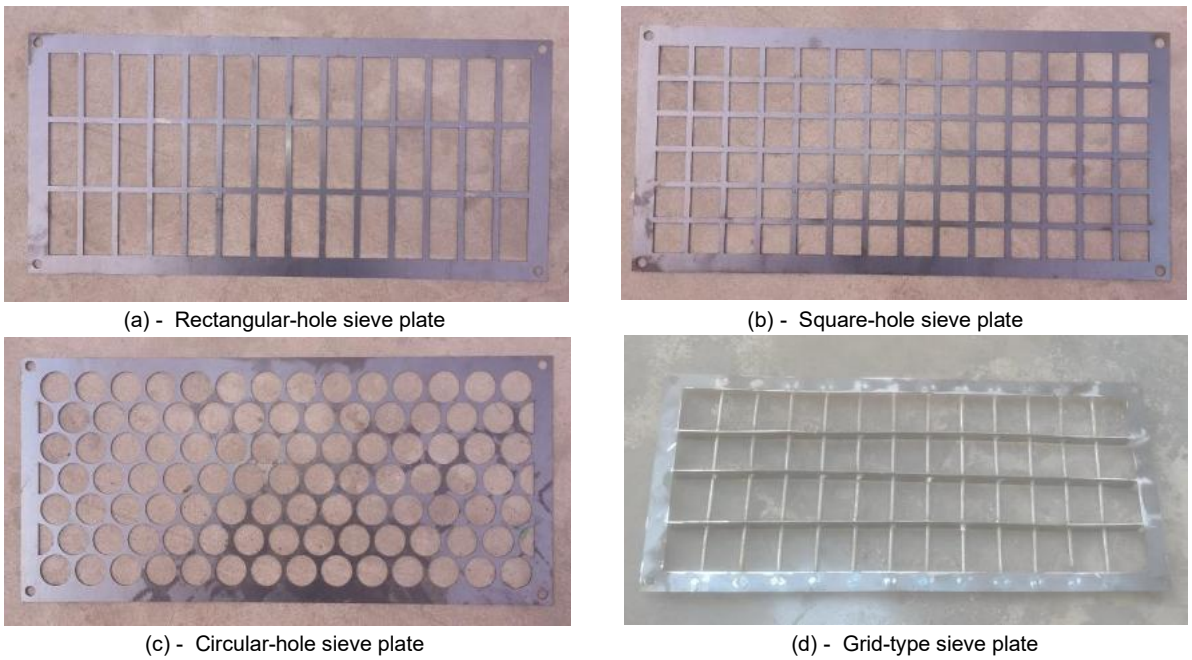
Test Method

The power consumption of the threshing device measured in the experiment included no-load power consumption, effective threshing power consumption, and total threshing power consumption. No-load power consumption referred to the power required to maintain the rotation of the threshing drum. Effective threshing power consumption was the power consumed for crop threshing. Total threshing power consumption, which is the sum of no-load power consumption and effective threshing power consumption, represented the total power required for the threshing operation of the device. The power consumption of the threshing device *(Wan et al., 2005; Zhang et al., 2010)* was calculated using Equation (1).

$$P=\frac{Mn}{9550} \tag{1}$$

where: P is power consumption of the threshing device, kW; M is torque acting on the threshing drum during operation, N·m; n is rotational speed of the threshing drum, r/min.

The experimental measurement equipment included a wireless torque measuring device, a data receiving device, a drum rotational speed measuring device, etc., as shown in Fig. 3. Before the experiment, the strain gauges of the torque acquisition device were adhered to the ground surface of the main shaft of the threshing drum with glue and fixed with adhesive tape. The wireless torque node and battery were also fixed on the main shaft of the threshing drum with adhesive tape. During the test, the torque data acting on the drum was transmitted to a computer through a wireless gateway. An encoder was installed at the rear of the threshing drum and connected to the main shaft of the drum via a coupling. The real-time rotational speed of the threshing drum could be measured by the encoder when the threshing device was in operation. The threshing power consumption could be obtained by substituting the torque and rotational speed parameters into Equation (1).



(a) - Data receiving and processing device

(b) - Drum torque acquisition device

(c) - Drum rotational speed measurement device

Fig. 3 - Equipment used to measure threshing power consumption

To investigate the influence laws of different structural parameters of the threshing device on its power consumption, comparative experiments were carried out on the threshing power consumption under different switching modes of the adjustable threshing force concave sieve (as shown in Fig. 2) and different types of separation sieve plates at the upper part of the 360°separation device (as shown in Fig. 4), respectively.

(a) - Rectangular-hole sieve plate (b) - Square-hole sieve plate

(c) - Circular-hole sieve plate (d) - Grid-type sieve plate

Fig. 4 - Different types of sieve plates used in the upper separation device

The basic operating parameters of the threshing device were set as follows *(Jiang et al., 2025; Zhou et al., 2022; Liu et al., 2025)*: drum rotational speed of 900 r/min, deflector angle of 60°, concave sieve clearance of 20 mm, and Feed rate of 4 kg/s. In the comparative experiment of threshing power consumption under different switching modes of the adjustable threshing force concave sieve, the upper part of the 360° separation device was equipped with a rectangular-hole separation sieve plate. In the comparative experiment of threshing power consumption with different types of separation sieve plates for the 360° separation device, the threshing force adjustment plates were fully opened.

To investigate the influence law of operating parameters on the threshing power consumption of the threshing device, single-factor tests were conducted by selecting rotational speed of the threshing drum, deflector angle, concave sieve clearance and feed rate as influencing factors. During the experiments, the threshing force adjustment plates were fully opened, and the upper part of the 360° separation device was equipped with a rectangular-hole separation sieve plate. The adjustment method of the operating parameters is shown in Fig. 5. The level coding design of the experimental influencing factors is presented in Table 2.

0.5	950	65	25	4.5
1	1000	70	30	5

RESULTS AND DISCUSSION

The results of the comparative tests on threshing power consumption under the different operating modes of the adjustable-intensity threshing concave are shown in Fig. 6. Among the four modes, total threshing power consumption was lowest, at 27.14 kW, when the threshing-intensity adjustment plates were fully open, and highest, at 27.67 kW, when they were fully closed. When the adjustment plates were fully open, the effective separation area of the concave was larger, which reduced the amount of crop material retained in the threshing chamber and decreased threshing resistance. Consequently, total threshing power consumption was minimized. When viewed from the rear of the device toward the front, the threshing drum rotated counterclockwise. Under this direction of rotation, threshing resistance was lower in the left-open/right-closed mode than in the left-closed/right-open mode. Accordingly, the total threshing power consumption was lower in the left-open/right-closed mode.

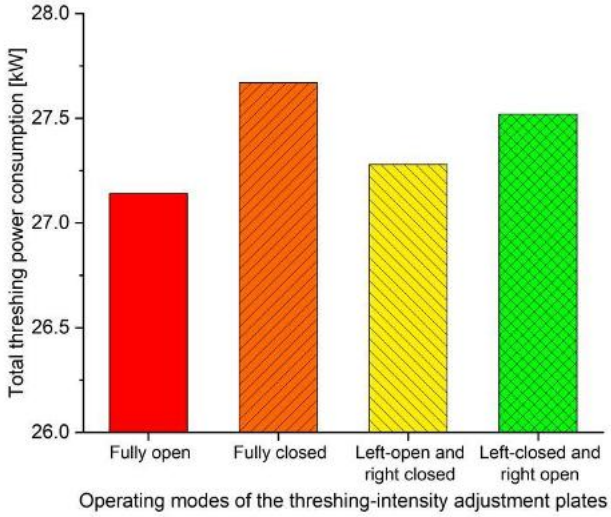

Fig. 6 - Comparison of total threshing power consumption among the operating modes of the threshing-intensity adjustment plates

The results of the comparative tests on threshing power consumption using different separation sieve plates in the 360° separation device are shown in Fig. 7.

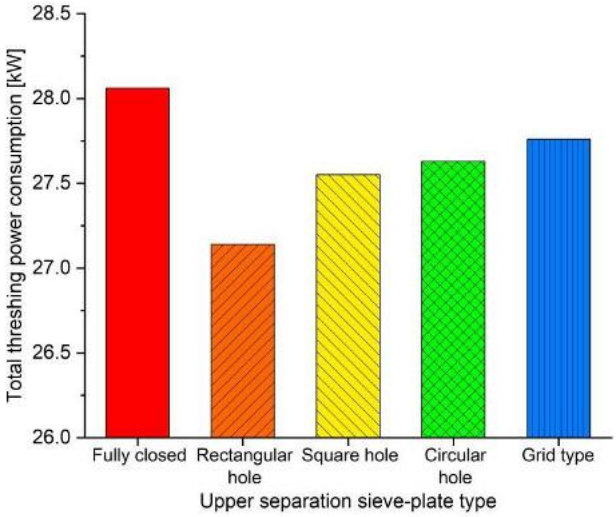

Fig. 7 - Comparison of total threshing power consumption among different upper separation sieve-plate types

As shown in Fig. 7, when the upper concave sieve of the 360° separation device was fully closed, the threshing power consumption was 28.06 kW, which was significantly higher than that under the open condition.

This phenomenon could be attributed to the reduced separation area of the concave sieve in the fully closed state, which prolonged the threshing and separation duration of crops in the threshing chamber and thus increases the threshing power consumption of the drum. The order of threshing power consumption for different types of separation sieve plates from low to high was as follows: rectangular-hole sieve plate, square-hole sieve plate, circular-hole sieve plate, and grid-type sieve plate. The underlying reason for this result was that, for separation sieve plates of the same overall size, the separation area of the rectangular-hole sieve plate was larger than that of the other types. Although the grid-type sieve plate also exhibited a large separation area in the front view, a considerable amount of threshed material exits the threshing chamber at a certain angle relative to the sieve plate during separation, and the protruding structure of the grid-type sieve plate impeded the separation process. Therefore, among the different types of separation sieve plates, the rectangular-hole sieve plate achieved the lowest total threshing power consumption of 27.14 kW.

The effects of drum rotational speed on the threshing power consumption and mechanical efficiency of the threshing device are depicted in Fig. 8. The no-load power consumption of the threshing device exhibited a gradual upward trend with increasing drum rotational speed, rising from approximately 7.32 kW at 800 r/min to about 9.21 kW at 1000 r/min. This phenomenon was attributed to the increased mechanical losses, such as bearing friction and air resistance, at higher drum speeds, which elevated the basic energy consumption required to maintain the idling of the drum. The effective threshing power consumption of the device increased continuously with the rise in drum rotational speed, from approximately 17.76 kW at 800 r/min to around 20.68 kW at 1000 r/min. The increased rotational speed intensified the impact and kneading actions of the threshing components on the crop materials, thereby raising the effective energy consumption for threshing, with a growth rate slightly higher than that of the no-load power consumption. As the sum of the no-load power consumption and the effective threshing power consumption, the total threshing power consumption also presented a linear increasing trend with the elevation of drum speed, increasing from about 25.08 kW at 800 r/min to roughly 29.89 kW at 1000 r/min. The overall variation trend was steady without drastic fluctuations, demonstrating the stable operation of the device within the tested rotational speed range.

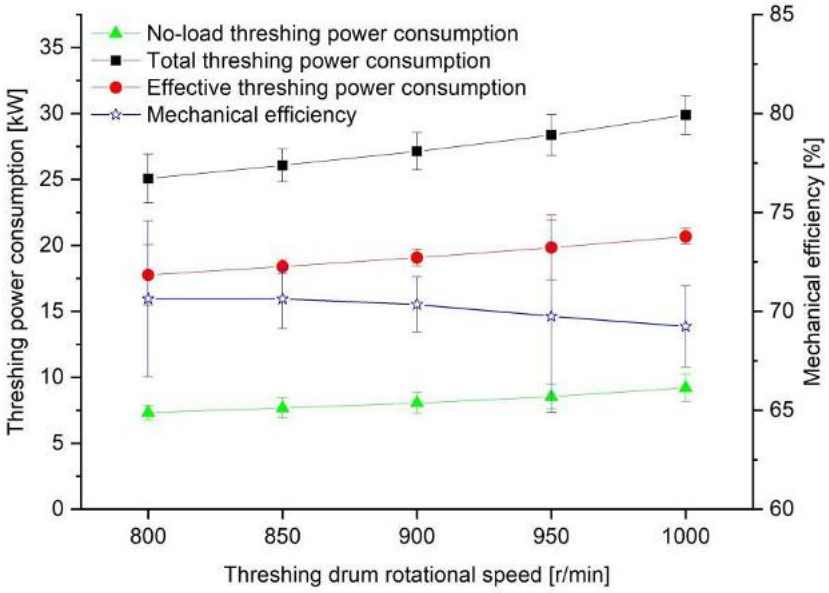

Fig. 8 - Effects of threshing-drum rotational speed on threshing power consumption and mechanical efficiency

As shown in Fig. 8, the mechanical efficiency of the threshing device remained relatively constant initially and then decreased as the drum rotational speed increased. Within the range of 800 ~ 900 r/min, the mechanical efficiency was stabilized at approximately 70.50%, indicating a high and stable energy utilization efficiency of the device in this speed interval. When the rotational speed exceeded 900 r/min, the mechanical efficiency began to decrease noticeably, dropping to about 69.76% at 950 r/min and further to 69.24% at 1000 r/min. The primary reason for the decline in mechanical efficiency was that the growth rate of no-load power consumption surpasses that of effective threshing power consumption at high speeds, with more energy dissipated in mechanical losses rather than being directly utilized for threshing operations, thus reducing the energy utilization efficiency.

The effects of deflector angle on the threshing power consumption and mechanical efficiency of the threshing device are illustrated in Fig. 9. The no-load power consumption remained basically stable at approximately 8.06 kW as the deflector angle increased from 50° to 70°.

This indicated that the variation in deflector angle exerted a negligible influence on mechanical losses during drum idling (such as bearing friction and air resistance), and the no-load power consumption was only determined by the inherent structure and operating state of the device. With the increase of the deflector angle, the effective threshing power consumption of the device exhibited a steady upward trend, rising gradually from approximately 18.68 kW at 50° to 19.60 kW at 70°. A larger deflector angle prolonged the residence time of crops in the threshing drum, promoted more uniform material distribution, and enhanced the interaction between threshing components and crops, thereby leading to a slight increase in effective threshing energy consumption. As the sum of no-load power consumption and effective threshing power consumption, the total threshing power consumption also increased slowly with the rise in deflector angle, from 26.74 kW at 50° to approximately 27.66 kW at 70°. The overall variation was gentle without obvious abrupt changes, demonstrating the stable operation of the device within the tested angle range.

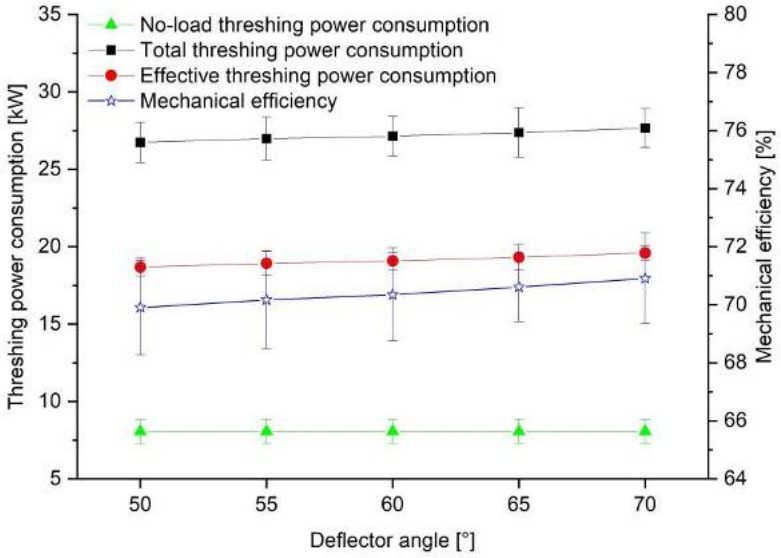

Fig. 9 - Effects of deflector angle on threshing power consumption and mechanical efficiency

As shown in Fig. 9, the mechanical efficiency of the threshing device displayed a continuous and steady upward trend with the increase in deflector angle, rising gradually from approximately 69.90% at 50° to about 70.91% at 70°. Although the increase amplitude was small, the trend was stable. The primary reason for the improved efficiency was that the growth rate of effective threshing power consumption was slightly higher than that of total power consumption, with more energy being efficiently utilized for threshing operations rather than mechanical losses, thus resulting in a slight optimization of energy utilization efficiency as the deflector angle increased.

The effects of concave sieve clearance on the threshing power consumption and mechanical efficiency of the threshing device are presented in Fig. 10. The no-load power consumption remained essentially constant at approximately 8.06 kW as the concave sieve clearance increased from 10 mm to 30 mm. This indicated that the adjustment of concave sieve clearance exerted no significant influence on the mechanical losses during drum idling, and the no-load power consumption was solely determined by the operating state of the device itself. The effective threshing power consumption of the device exhibited a gradual downward trend with the increase in concave sieve clearance, decreasing from 20.48 kW at 10 mm to 18.28 kW at 30 mm. A larger clearance weakened the squeezing and kneading interaction between the threshing components and the crop materials, and reduced the resistance of materials passing through the threshing zone, thereby lowering the effective energy consumption directly used for threshing operations. As the sum of the no-load power consumption and the effective power consumption, the total threshing power consumption also decreased steadily with the increase in clearance, from 28.54 kW at 10 mm to 26.34 kW at 30 mm. The overall variation was gentle without drastic fluctuations, indicating the stable operation of the device within the tested clearance range.

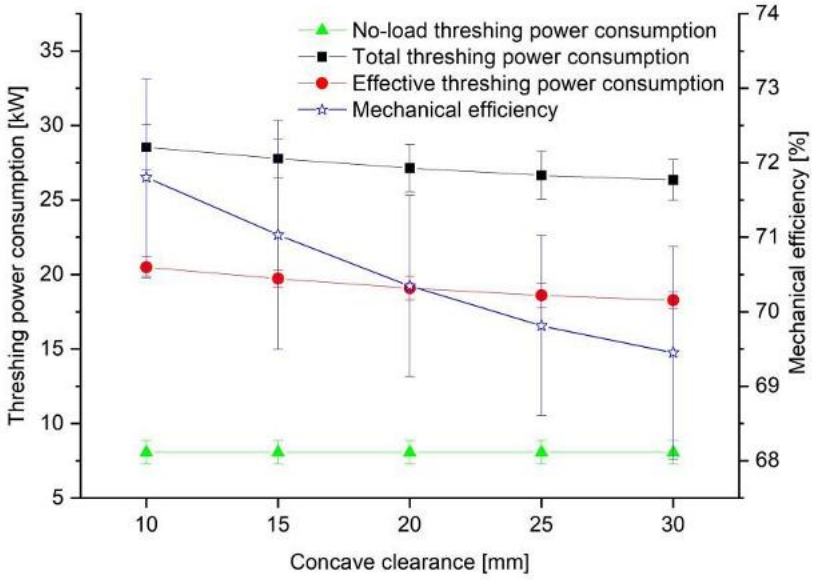

Fig. 10 - Effects of concave clearance on threshing power consumption and mechanical efficiency

As shown in Fig. 10, the mechanical efficiency of the threshing device decreased continuously as the concave clearance increased, declining from approximately 71.80% at 10 mm to 69.45% at 30 mm, a reduction of about 2.35 percentage points. This decrease occurred because effective threshing power consumption declined more rapidly than total power consumption. Consequently, a greater proportion of the total input power was associated with mechanical losses, such as those required to maintain drum rotation, rather than being used directly for threshing. Therefore, energy-use efficiency gradually decreased with increasing concave clearance.

The effects of feed rate on the threshing power consumption and mechanical efficiency of the device are illustrated in Fig. 11. Within the experimental range where the feed rate increased from 3.0 kg/s to 5.0 kg/s, the no-load power consumption remained stable at 8.06 kW without noticeable fluctuations. This indicated that the variation in feed rate exerted no significant influence on mechanical losses during drum idling. The no-load power consumption was determined only by the inherent structure and operating state of the device, independent of the working load, which conformed to the basic characteristics of the no-load power consumption of threshing devices. The effective threshing power consumption presented an approximately linear upward trend with the increase in feed rate, rising from about 13.98 kW at 3.0 kg/s to approximately 25.2 kW at 5.0 kg/s. The underlying reason was that a higher feed rate corresponded to a greater amount of crop material entering the threshing chamber per unit time, which synchronously enhanced the frequency and intensity of impact and kneading actions exerted by threshing components on the crop.

Consequently, the effective energy consumption directly employed for threshing operations increased substantially, with a stable growth rate and no obvious inflection point as the feed rate rose. As the sum of the no-load power consumption and the effective threshing power consumption, the total threshing power consumption exhibited a variation trend highly consistent with that of the effective threshing power consumption, increasing rapidly and approximately linearly from 22.04 kW at 3.0 kg/s to 33.26 kW at 5.0 kg/s. The continuous growth of total power consumption demonstrated that feed rate was a core sensitive factor affecting the overall energy consumption of the threshing device. The greater the operation load, the higher the energy consumption of the whole machine.

The mechanical efficiency of the threshing device increased continuously and rapidly with the rise in feed rate, from approximately 63.49% at 3.0 kg/s to 75.81% at 5.0 kg/s, with an increase of 12.32 percentage points, and the rising rate accelerated slightly with a higher feed rate. The essential reason was that the no-load power consumption remained constant. Meanwhile, the effective threshing power consumption increased linearly with feed rate. This led to a continuous rise in the proportion of effective threshing power consumption in total power consumption and a continuous decline in the proportion of mechanical losses. Therefore, energy utilization efficiency was significantly optimized. This regularity indicated that a proper increase in feed rate could considerably improve the energy utilization efficiency of threshing operations and reduce the energy consumption per unit grain mass. The premise was that the structural strength and threshing quality of the device were satisfied.

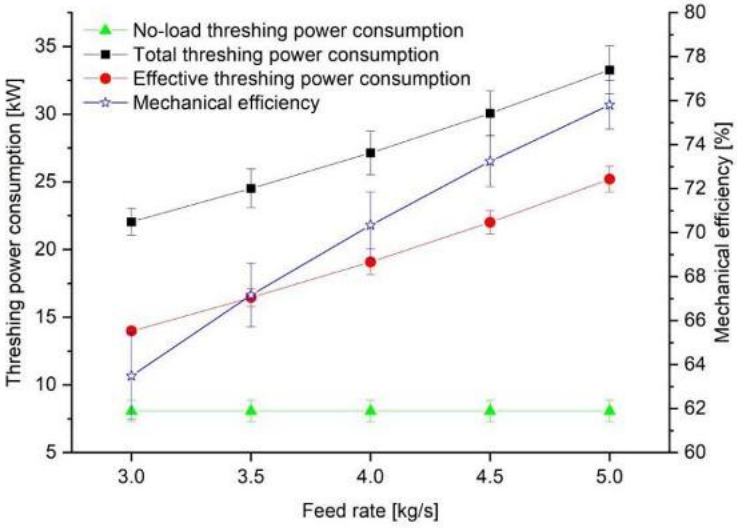

Fig. 11 - Effects of feed rate on threshing power consumption and mechanical efficiency

To further investigate the effects of operating parameters on the threshing power consumption of the device, the variation laws of these parameters on the threshing power consumption per unit feed rate of the threshing device were obtained, as shown in Fig. 12. The threshing power consumption per unit feed rate generally ranged from 4.4 kW/(kg/s) to 5.2 kW/(kg/s). It increased with the rise of drum rotational speed, deflector angle and feed rate, while decreasing with the increase of concave sieve clearance.

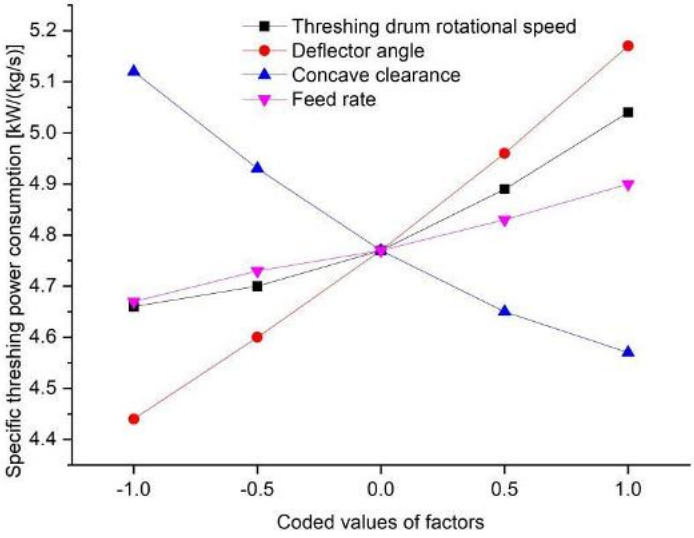

Fig. 12 - Effects of operating parameters on specific threshing power consumption

CONCLUSIONS

1) The effects of device structural parameters on the total threshing power consumption were clarified. Among the four modes of the threshing force adjustable concave sieve, the total threshing power consumption reached the minimum value of 27.14 kW when the threshing force adjustment plates were fully open, whereas the maximum value of 27.67 kW was obtained when the plates were fully closed. For different types of separation sieve plates on the upper part of the 360° separation device, the rectangular-hole sieve plate achieved the lowest total threshing power consumption of 27.14 kW.

2) Within the experimental range of drum rotational speed from 800 to 1000 r/min, with the increase of rotational speed, the no-load power consumption rose from 7.32 kW to 9.21 kW, the effective threshing power consumption increased from 17.76 kW to 20.68 kW, and the mechanical efficiency decreased from 70.63% to 69.24%. Within the deflector angle range of 50° to 70°, the no-load power consumption remained stable at 8.06 kW, the effective threshing power consumption increased from 18.68 kW to 19.60 kW, and the mechanical efficiency rose from 69.90% to 70.91%. Within the concave sieve clearance range of 10 to 30 mm, the no-load

power consumption was constant at 8.06 kW. The effective threshing power consumption decreased from 20.48 kW to 18.28 kW, and the mechanical efficiency dropped from 71.80% to 69.45%.

3) Within the feed rate range of 3.0 to 5.0 kg/s, with the increase of feed rate, the no-load power consumption remained stable at 8.06 kW, the effective threshing power consumption rose from 13.98 kW to 25.20 kW, and the mechanical efficiency increased from 63.49% to 75.81%. The threshing power consumption per unit feed rate of the device ranged from 4.4 kW/(kg/s) to 5.2 kW/(kg/s). It increased with the rise of drum rotational speed, deflector angle and feed rate, while decreasing with the increase of concave sieve clearance.

ABSTRACT

The soybean-maize strip intercropping mode has been widely popularized, yet existing plant protection machinery fails to dynamically adjust pesticide application according to crop zones, suffers from poor pesticide application accuracy, and is prone to causing crop damage. Aiming at the above problems, this study proposed a precise strip-zoning pesticide application method for soybean and maize and established an automatic strip-zoning pesticide application control system based on machine vision. Perspective transformation was adopted to correct image viewing angles; after subsequent processing via excess green binarization and opening-closing operations, a dynamic ROI (Region of Interest) positioning and recognition algorithm for crop rows based on the peak value method was applied. The least square method was used to extract crop row lines, the offset was calculated according to the geometric relationship of the centerlines of soybean and maize zones, and an automatic strip-zoning offset compensation model was constructed to achieve precise strip-zoning. Field experiment results show that: under conditions with little shadow and stable light, the recognition algorithm achieved the optimal performance with an accuracy of up to 92%. At operating speeds of 2–5 km/h, the automatic strip-zoning pesticide application control system had a mean strip-zoning deviation of ≤3.16 cm, with the proportion of deviations within 5 cm reaching 84% (up to 94%). Under wind speeds of 1.4–2.9 m/s, the maximum droplet drift deposition amount of the closed anti-drift device was 9.41 droplets per cm², delivering favorable strip-zoning pesticide application performance, which provides data support and a reference for field precision plant protection operations under the strip intercropping mode.

摘 要

大豆玉米带状复合种植模式广泛推广，但现有植保机械无法随作物带进行动态调整施药，且施药精度差，易造成伤害。针对上述问题，本文基于机器视觉，提出一种大豆玉米精准分带施药方法并搭建自动分带施药控制系统。采用透视变换校正图像视角，再经超绿二值化与开闭运算处理后，基于峰值法的作物行动态 ROI（Region of interesting）定位识别算法，采用最小二乘法提取作物行线，依据大豆玉米带中心线的几何关系计算偏移量并构建自动分带偏移补偿模型以实现精准分带。田间试验结果表明：在阴影少、光照稳定条件下，识别算法效果最佳，准确率可达 92%。自动分带施药控制系统在 2-5km/h 的速度下分带偏差均值≤3.16cm，5cm 内偏差占比达 84%（最高 94%）。1.4m/s~2.9m/s 风速条件下，封闭式防飘移装置的雾滴飘移沉积量最高为 9.41 个/cm2，具有较好的分带效果，为复合种植模式下的田间精准植保作业提供数据支撑与参考。

INTRODUCTION

Soybean and maize are important food crops, and efficient and precise plant protection operations constitute a key measure to improve their yield *(Cui et al., 2023; Zhang et al., 2025)*. At present, the mainstream pesticide application equipment for the soybean-maize strip intercropping mode is the traditional fixed zoned boom sprayer *(Khan et al., 2024; Zhang et al., 2024)*. Although it can realize zoned pesticide application to a certain extent, it is unable to perceive the dynamic information of field crop zones and achieve precise pesticide application when confronted with problems such as inconsistent inter-zone spacing and irregular sowing rows in the sowing process. Therefore, there is an urgent need to develop a technical scheme for field precision plant protection adapted to this cropping mode.

At present, scholars at home and abroad have carried out extensive research in the field of precision control such as crop row line extraction. *Zhao et al., (2016),* proposed an operation line extraction method suitable for wheat harvesting, which adopted the cross-correlation function method to detect the boundary points between the harvested area and the to-be-harvested area, and fitted the target line via the Hough transform. *Chen et al., (2019)* mapped the fitting straight lines obtained from different accumulation thresholds of the Hough transform to the parameter space, clustered the parameter space data by K-means clustering, and regarded the cluster centroids in the parameter space under the optimal accumulation threshold as the identified actual crop rows. *Chen et al., (2020)* adopted a median point Hough transform based on an optical system for navigation line fitting, which was 24 ms faster than the traditional Hough transform. In addition, *Yang et al., (2020),* used the least square method to obtain navigation lines in the dynamic ROI area on the basis of static ROI, with a recognition accuracy of 96%. *Liao. et al., (2019),* counted the pixel points of crop rows by sub-region and took them as candidate feature points, retained valid feature points based on the distance threshold, and performed straight line fitting on the feature points using the least square method, with an extraction accuracy of 95.6%. *Hossein et al., (2014),* extracted crop row center lines using the Hough transform and centroid image processing algorithm respectively, with the average time consumption of the two algorithms being 0.7 s and 0.4 s. *Montalvo et al., (2012),* proposed a crop row detection method based on the moving window method for maize fields with high weed density, which was superior to the traditional Hough transform in processing efficiency. However, the above methods are restricted by factors such as application scenarios and algorithm time consumption, and their robustness and accuracy need to be further improved. Meanwhile, all these studies are conducted for homogeneous crops, leading to poor applicability.

Aiming at the above problems, this study established an automatic strip-zoning pesticide application control system and proposed a dynamic ROI positioning and recognition algorithm for crop rows based on the peak value method, which fused perspective transformation, vertical projection, strip segmentation and the least square method for crop row fitting. Meanwhile, the offset was calculated according to the geometric relationship of the centerlines of soybean and maize zones, and an offset compensation model was constructed. The traditional PID control algorithm was introduced to enhance the regulation capability of the actuation output of the automatic strip-zoning pesticide application control system, thereby enabling rapid response and correction of deviations caused by changes in the field environment. Finally, the system was deployed on a strip-type boom sprayer to conduct field performance experiments. The results show that the recognition algorithm has a certain robustness under different light conditions. At different operating speeds, the system can effectively perform strip-zoning pesticide application and reduce crop phytotoxicity, which holds certain practical significance for strip-zoning pesticide application under the strip intercropping mode.

MATERIALS AND METHODS

1. Automatic Strip-zoning Pesticide Application Control System for Soybean-maize Intercropping Based on Machine Vision

1.1 Structural Composition of the Automatic Strip-zoning Pesticide Application Control System

The overall structure of the automatic strip-zoning boom sprayer for pesticide application based on machine vision is shown in Fig. 1, which is mainly composed of a power system, travel assembly, image acquisition and processing module, strip-zoning control module, and soybean-maize pesticide application module. The sprayer has a wheel base of 1.8 m and is powered by a single-cylinder diesel engine with a rated power of 14.7 kW, which can meet the requirements of normal field operations for the automatic strip-zoning pesticide application control system.

Fig. 1 - Structural Schematic Diagram of Automatic Strip-zoning Boom Sprayer

1 - Lateral adjustment spray boom mechanism; 2 - Soybean-maize pesticide application module; 3 - Travel assembly; 4 - Power system; 5 - Image acquisition and processing module

The structure of the automatic strip-zoning pesticide application control system is mainly composed of a lateral adjustment spray boom mechanism, a control unit and an image acquisition and processing module. Among them, the lateral adjustment spray boom mechanism consists of a middle spray boom frame, side spray boom frames and a lifting mechanism. One end of the central electric push rod is fixed to the lifting bracket, and the other end is connected to the middle spray boom frame. The sliders are arranged between the slide rails and the middle spray boom frame, and the two side spray boom frames are in sliding contact with the middle spray boom frame respectively, with a maximum operating width of 4.2 m. The control unit is mainly composed of a Delta PLC (Programmable Logic Controller), a Leadshine driver and a stepping push rod motor; the stepping push rod motor has a maximum stroke of 0.5 m and a maximum telescopic speed of 0.2 m/s. For the image acquisition and processing module, the acquisition device is an LT-USB 1080P depth camera (Lantian Technology Co., Ltd.), with a frame rate of 30 frames per second and a maximum video image resolution of 1920×1080. It is equipped with a 2.8–16 mm zoom lens and installed at a height of 1200 mm, which can effectively cover the target crop area. The built-in computer is configured with an Intel Core i5 processor, 16 GB of ROM, 512 GB of storage and 8 GB of RAM, which can basically meet the field operation requirements.

1.2 Working Principle of the Automatic Strip-zoning Pesticide Application Control System

As shown in Fig. 2, during field operation, the field crop row information (RGB images) collected by the LT-USB 1080P depth camera is transmitted to the upper computer via USB. The upper computer software calculates the lateral offset of the boom in real time and transmits it to the lower computer controller (PLC) through the RS485 serial port. The lower computer controller controls the left and right movement of the push rod motor via the Leadshine driver, and the Oedila rope displacement sensor feeds back the telescopic length of the push rod motor to the lower computer controller in real time, thereby achieving precise control of the boom's movement position. A speed sensor (E6B2-CWZ6C1000P incremental encoder, Omron Corporation) collects the operating speed of the sprayer in real time.

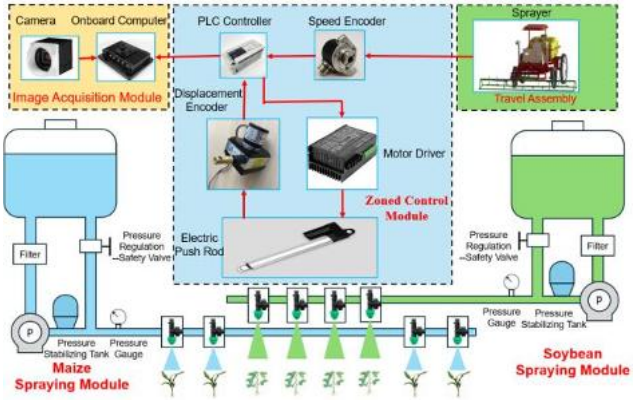

Fig. 2 - Flow Chart of Working Principle of Automatic Strip-Zoning Pesticide Application Control System

2. Recognition Method of Crop Zone Row Line Based on Machine Vision

Recognition of crop zone row lines is a prerequisite for achieving precision strip-zoning pesticide application. This paper adopts the peak value method for the fitting of soybean and maize crop zone row lines, and the specific process is illustrated in Fig. 3.

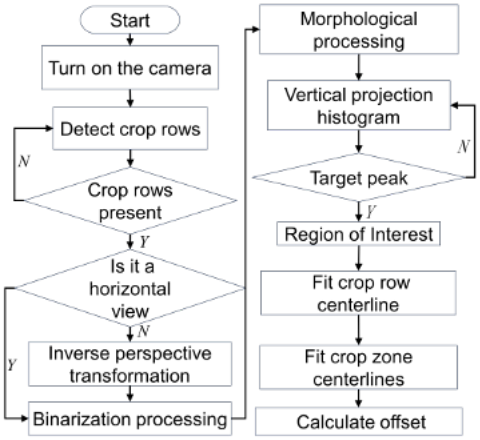

Fig. 3 - Flow Chart of Crop Zone Centerline Fitting

2.1 Image Acquisition and Preprocessing

2.1.1 Image Acquisition

Images were captured in a soybean-maize strip intercropping test field in Xinzheng City, Henan Province, with the shooting conducted from May to June 2025. The camera was mounted at a height of 1200 mm with an inclination angle of 30°. For subsequent research and analysis, soybean-maize videos with a resolution of 1280×720 pixels under different light conditions were selected, as shown in Fig. 4(a).

2.1.2 Image Preprocessing

2.1.2.1 Inverse Perspective Transformation

To maintain clear, parallel and equally wide boundaries of soybean and maize rows, effectively segment different crop zones, and avoid zonal segmentation errors caused by the convergence and overlap of distant crop zones in crop images, inverse perspective transformation was performed on the collected images *(Li et al., 2024; Tang et al., 2018; Zhao et al., 2019; Zhang et al., 2023)*.

As shown in Fig. 4, during plant protection operations, on the premise that the machine operates at a constant speed in a straight line while the camera angle and image size remain unchanged, four sets of valid pixel coordinates were selected from the image containing the target crop rows to form the boundary for inverse perspective transformation, and the target region was extracted accordingly. The inverse perspective transformation from Fig. 4(b) to Fig. 4(d) can be realized by means of the homography matrix (H matrix). From the transformation results, the crop rows are arranged in parallel without converging to infinity. This method can effectively reduce the computational complexity of the subsequent algorithm and facilitate the follow-up crop row line fitting *(Khan et al., 2024)*.

$$x' = H.x \tag{1}$$

where: H is the 3×3 homography matrix; x' is the corresponding plane coordinates in the transformed image, [Pixel]; x is the corresponding plane coordinates in the original image, [Pixel].

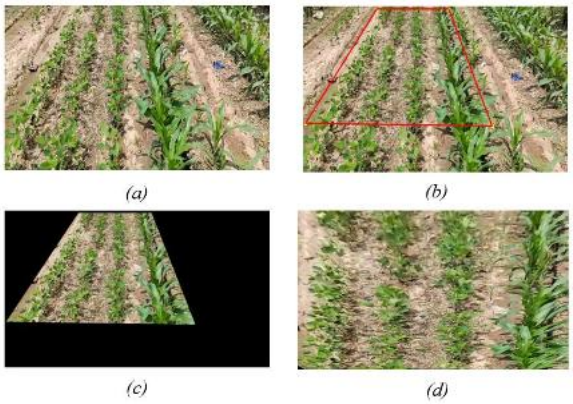

Fig. 4 - Inverse Perspective Transformation

(a) Original image; (b) Region division; (c) Region of Interest; (d) Perspective transformation

2.1.2.2 Image Segmentation

Segmenting crop regions from complex backgrounds such as soil and weeds is crucial for improving algorithm efficiency and achieving precision strip-zoning. Currently, image segmentation algorithms are mainly categorized into three types: color index-based segmentation, threshold-based segmentation, and deep learning-based segmentation *(Guerrero et al., 2013; Sun et al., 2022; Pérez-Ruíz et al., 2014; Jiang et al., 2014)*.

On this basis, this paper selected three typical segmentation algorithms, and ultimately determined the one with the optimal performance by comparing the time consumption and segmentation effectiveness of single-channel grayscale images under different climatic conditions.

(1) The VARI (Vegetation Index)-based image segmentation algorithm is mainly used to identify green vegetation regions from RGB images. Its core lies in utilizing the characteristic that the green component (*G*) is significantly higher than the red component (*R*), and reducing the impact of illumination intensity variations through normalization processing. The algorithm is presented as follows.

$$\begin{cases} VARI = (G - R) / D & (-1,1) \\ D = G + R - B & D \neq 0 \end{cases} \tag{2}$$

Based on this algorithm, green feature extraction was performed on the images, and the binarized images were further optimized via morphological operations, as shown in Fig. 5(b).

(2) An image preprocessing method based on the HSV color space. By adjusting the threshold ranges of hue, saturation and value, i.e., setting the values of the H, S and V channels within the green threshold range, the pixel values of green crops are enhanced while the non-green background is suppressed. To achieve effective segmentation of crop plants from the background, this paper combines the H and S channels: the green regions are filtered out by adjusting the threshold of the H channel, the S channel of the green regions is retained, and grayscale conversion is performed subsequently. The processing results are shown in Fig. 5(c).

(3) $2G\text{-}R\text{-}B$ based on the Excess Green Index is a green feature enhancement algorithm rooted in the RGB color space. It strengthens the weight of the green component and suppresses the red and blue components simultaneously, which makes the green regions more prominent after processing and facilitates subsequent segmentation and feature extraction. Its grayscale image is shown in Fig. 5(d).

$$ExG = 2G - R - B \tag{3}$$

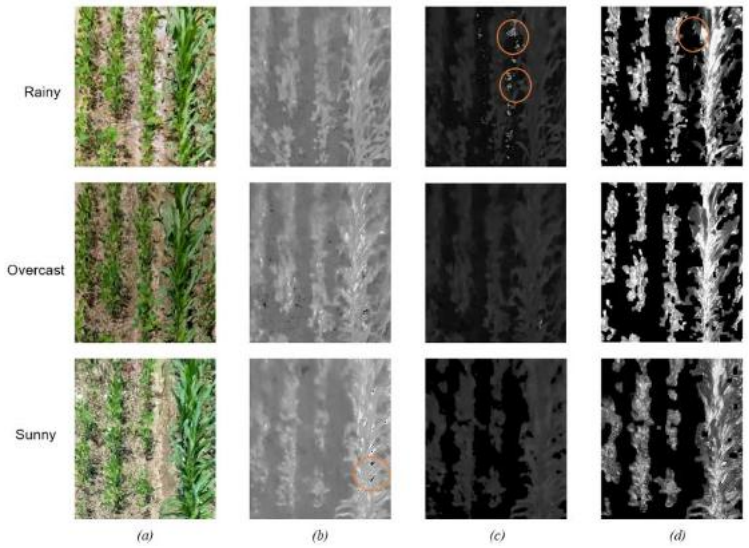

Fig. 5 - Grayscale Image Effect Comparison

(a) Original image; (b) VARI grayscale image; (c) HSV grayscale image; (d) 2G-R-B grayscale image

As shown in Fig. 5, a comparative analysis of the segmentation performance of the three different algorithms revealed that VARI could completely segment crops from the background under all three weather conditions, yet the resulting images were blurry with a time consumption of 201 ms. In comparison with the Excess Green algorithm, HSV leads to target loss and was prone to noise in rainy weather, which interfered with subsequent binarization processing. By contrast, the Excess Green-based segmentation algorithm could well preserve green crops; the time consumption of the Excess Green algorithm was 109 ms and that of the HSV algorithm is 98 ms. Considering the segmentation performance, time consumption and post-processing requirements comprehensively, the Excess Green algorithm was adopted as the preprocessing segmentation algorithm in this study. In view of the enhanced processing of green features by the Excess Green algorithm, to better constrain the range of green regions, this paper adopted the HSV threshold method in color space binarization for binarization processing, and the corresponding binary mask was generated by setting the threshold ranges of each HSV channel.

The expression is presented as follows.

$$\begin{cases} hsv\text{-}low = (H_{min},\ S_{min},\ V_{min}) \\ hsv\text{-}high = (H_{max},\ S_{max},\ V_{max}) \end{cases} \tag{4}$$

After completing the segmentation of the image foreground and background, there still exist noise and holes caused by interfering factors such as dew and shadows. These defects impair the image segmentation performance and hinder the subsequent detection of crop rows. In this study, morphological processing involving a closing operation followed by an opening operation was applied to the images, which can effectively fill gaps, eliminate noise, reduce interference from irrelevant detailed information, and enhance the algorithm's adaptability to complex environments.

Fig. 6 illustrates the corresponding processes of grayscale conversion, binarization and morphological processing.

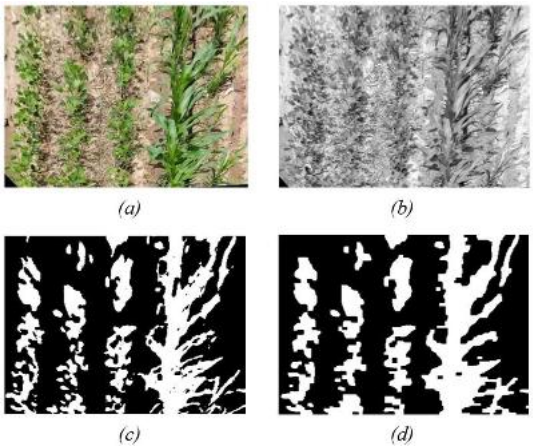

Fig. 6 - Binarization Processing Effect

(a) Original; (b) Grayscale; (c) Binarized; (d) Morphologically processed

2.2. Extraction of the Crop Zone Centerline

After acquiring the crop canopy characteristics, further post-processing is required for the preprocessed images to fit the geometric centerlines of the crop row canopy, laying a solid foundation for the extraction of the crop zone centerline.

2.2.1. Adaptive ROI Acquisition

The research object of this study is the test field under the soybean-maize strip intercropping mode. To achieve precision strip-zoning pesticide application, the recognition targets should be focused on the inter-zone areas between soybean zones and maize zones. In view of the complex field environment under the intercropping mode, which is likely to impair the algorithm recognition accuracy, this study adopts the peak value method to demarcate the ROI for the purpose of reducing interference from non-recognition areas *(Ota et al., 2022; Ramesh et al., 2016; Zhang et al., 2023)*. Given the known width (Width) and height (Height) of the preprocessed images, the expression for vertical projection is as follows:

$$S(j) = \sum_{i=1}^{H} P(i,j) \tag{5}$$

where: (i,j) is the pixel coordinates of the vertical projection, [Pixel]; $P(i,j)$ is the target pixel coordinates, [Pixel]; $S(j)$ is the cumulative value of target pixels in the j-th column, [Pixel].

Images are susceptible to noise caused by factors such as illumination and soil. To prevent minor wave crests from interfering with the subsequent identification of peak points, this study adopted mean filtering to perform denoising processing on the images.

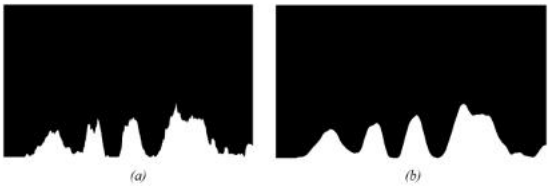

Fig. 7 - Vertical Projection Filtering Effect

(a) Before filtering; (b) After filtering

As shown in Fig. 7, four white vertical projections correspond to the position information of the four crop rows. Statistics of the cumulative pixel values and inspection of each contour are carried out on the vertical projection histogram. A height threshold T_k is set, which can filter out minor noise peaks. In this study, the height threshold is determined based on the mean value plus the standard deviation of the projection data.

Let the mean value be denoted as μ and the standard deviation as σ. The mean value represents the average value of each pixel array in the vertical projection, and the standard deviation characterizes the degree of dispersion of the array. In the vertical projection, the total pixel value of the "Target Peaks" (the columns corresponding to crop rows) is inevitably higher than the background mean value, while "noise" refers to random values that fluctuate slightly around the mean value. To obtain an optimal height threshold, 1σ and 2σ are selected to achieve a balance between the risk of peak missing and anti-noise capability. The expression is given as follows.

$$\mu + 1\sigma \le T_k \le \mu + 2\sigma \tag{6}$$

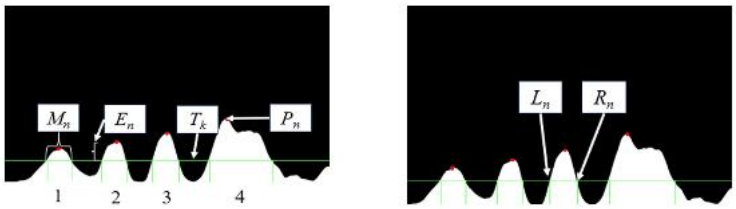

Fig. 8 - Algorithm Processing Effect

The research object of this study is limited to the adjacent vertical projection contours of soybean and maize, and valid contours are filtered out based on the global peak difference and peak width difference, for which the following expression is derived:

$$P_n = S(j)_{max} \tag{7}$$

where: $S(j)_{max}$ is the maximum cumulative value of target pixels, [Pixel].

Compare the M_n values of each contour from 1 to 4 and select the maximum value, then calculate the peak difference with its adjacent contour. The contour with the largest difference is retained to obtain the target contour, which narrows the ROI. To acquire complete crop rows, the peak values of the two contours are taken as reference points, with one target width ($\bar{M}$) expanded to the left and right respectively. The expression is as follows:

$$\bar{M} = \frac{1}{k}\sum_{i=1}^{n} M_i \tag{8}$$

where: k is the coefficient (related to crop growth conditions); n is the number of contours, which is known to be 2.

Analysis of program operation reveals that the value range of k is [2, 5]. The k value was screened using 200 images: different k coefficients were adopted with an increase step of 1, and the crop row retention effect was observed, from which it was concluded that k=3 meets the requirements. The positioning effect of the first ROI is shown in Fig. 9(a).

To extract the crop zone centerline and reduce the computational load of the recognition algorithm, a second ROI demarcation is performed for the soybean and maize row regions. On the basis of the first ROI, the rising edge boundaries and falling edge boundaries of the vertical projection contours of the soybean seedling rows and maize seedling rows were searched for and recorded. The ROI region was identified by acquiring the known height threshold T_k and boundary positioning points, as shown in Fig. 9(b).

Fig. 9 - ROI Localization Effect

(a) First ROI; (b) Second ROI

2.2.2. Crop Zone Centerline Fitting

As the core reference benchmark for an agricultural machinery vision plant protection system to complete offset detection and compensation, the crop zone centerline can clearly distinguish the spatial boundaries and central positions of soybean zones and maize zones, provide accurate displacement control commands for the automatic strip-zoning pesticide application control system, and ensure that operating components such as the spray boom and nozzles are accurately aligned with the crop zones. Its fitting process is illustrated in the figure below:

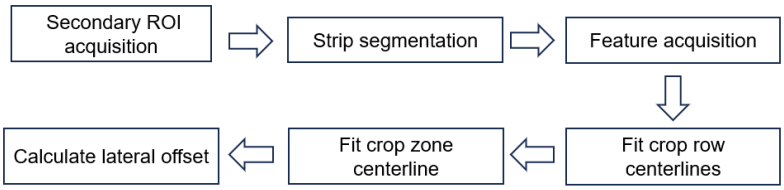

Fig. 10 - Flow Chart of The Crop zone Centerline Extraction

Strip segmentation was carried out on the basis of the second ROI. To reduce the computational load, the number of strips is set to N, and N is taken as 10 in this study. Vertical projection processing is performed on the pixels within each strip. Given the width W and height H of the ROI, the height of each strip is denoted by the mathematical expression ΔH. The mathematical expressions for the strips are given as follows.

$$S(j) = \sum_{i=1}^{\Delta H} P(i, j) \tag{9}$$

In the preprocessed images, the higher the leaf area ratio in the column direction, the larger the value of $S(j)$. The algorithm traverses $S(j)$ of each strip from left to right, excludes the values lower than the threshold, identifies the first and last qualified columns, and takes their average value to obtain the feature point ($\Delta H/2$, j). Subsequently, it traverses downward with a step size of ΔH within the ROI, collecting the feature points until all horizontal strips are completely traversed. The performance of the algorithm is shown in Fig. 11.

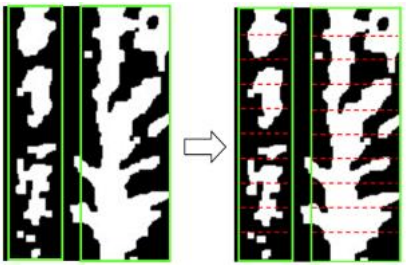

Fig. 11 - Strip Segmentation Effect

The crop row feature points obtained from each of the aforementioned strips are stored in a point set, and the fitting of the centerlines of soybean rows and maize rows is achieved based on the Least Squares Method *(Liao et al., 2019; McInnes et al., 2017; Ota et al., 2022; Vidovic et al., 2016; Yang et al., 2022)*. Ultimately, the crop zone centerline is derived by virtue of *the Parallel Centerline Principle*, with the results shown in Fig. 12.

Fig. 12 - Extraction Results of the Crop Zone Centerline

3. Realization of Offset Compensation Model and Strip-Zoning Control

3.1. Offset Calculation

3.1.1. Coordinate System Transformation

Coordinate System Transformation is a prerequisite for calculating the actual offset information of crop rows. To convert the identified row position information in the image into the actual displacement data in the world coordinate system, it is necessary to perform camera calibration and eliminate the errors caused by camera distortion.

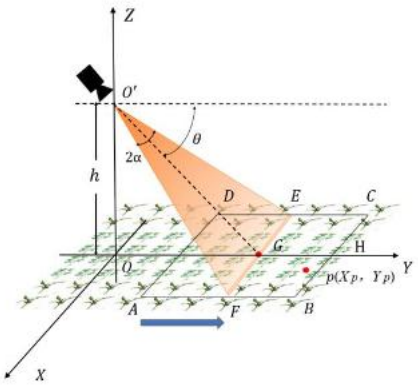

Fig. 13 - Geometric Relationship of the Camera Field of View in the World Coordinate System

As shown in Fig. 13, $ABCD$ in the figure represents the field of view (FOV) of the camera on the ground, point O' denotes the camera optical center, and point O is the projection coordinate of the camera on the ground, which also serves as the origin of the world coordinate system. Point P is the actual ground coordinate point corresponding to a pixel point p on the image, with the coordinate of (X_p,Y_p). G is the intersection point of the optical axis and the ground. The resolution of the industrial camera is $m \times n$, 2β is the vertical field of view angle ($\angle HO'O$), and 2α is the horizontal field of view angle ($\angle EO'F$). The calculation formulas are as follows:

$$\beta = arctan(\frac{Vc}{2f}) \tag{10}$$

$$\alpha = arctan(\frac{Vc'}{2f}) \tag{11}$$

where: β represents the half the vertical field of view angle, [°]; α represents the half the horizontal field of view angle, [°]; V_c is the sensor height, [mm]; V_c' is the sensor width, [mm].

From the camera sensor parameters, V_c is 2.92 mm, V_c' is 5.18 mm and f is 3.6 mm, from which β is calculated as 22.07 ° and α as 35.75 °.

Given a camera installation angle of 30°, the depression angle θ of the camera can be calculated as follows:

$$\theta = 30^\circ + \beta \tag{12}$$

θ is calculated as 52.07 °.

From the deduction based on the inverse perspective mapping formula, the corresponding coordinates of pixel point p in the world coordinate system can be obtained. Its expression is given as follows:

$$u = \frac{mY_p - htan\theta}{2Y_p tan\theta tan\alpha + 2htan\alpha} \tag{13}$$

$$v = \frac{nX_p}{2tan\alpha\sqrt{h^2 + Y_p^2}}\sqrt{1+\left(\frac{2utan\beta}{m}\right)^2} \tag{14}$$

where: u is the x-coordinate of point p on the image plane, [Pixel]; v is the y-coordinate of point p on the image plane, [Pixel].

Four coordinate systems are involved in the image processing process, namely the image coordinate system UO_0V, the image physical coordinate system XOY, the camera coordinate system $X_cO_cY_c$, and the world coordinate system $X_wO_wY_w$, as shown in Fig.15. The transformation relationship between the coordinates of any point in the image coordinate system and its corresponding coordinates in the world coordinate system is as follows:

$$Z_c\begin{bmatrix} u \\ v \\ 1 \end{bmatrix} = \begin{bmatrix} \frac{f}{dx} & 0 & 0 & 0 \\ 0 & \frac{f}{dy} & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}\begin{bmatrix} R & T \\ 0 & 1 \end{bmatrix}\begin{bmatrix} X_w \\ Y_w \\ Z_w \\ 1 \end{bmatrix} = M_1 M_2 \begin{bmatrix} X_w \\ Y_w \\ Z_w \\ 1 \end{bmatrix} \tag{15}$$

where: O_w-$X_wY_wZ_w$ is the world coordinate system, used to describe the camera position, [m]; O_c-$X_cY_cZ_c$ is the camera coordinate system, with the optical center as the origin, [m]; o-xy is the image coordinate system, with the midpoint of the imaging plane as the origin, [mm]; p is the point in the world coordinate system, i.e., a real physical point in the actual scene, [mm]; (u,v) are the coordinates of point p in the pixel coordinate system, [Pixel]; (x,y) are the coordinates of point p in the image coordinate system, [Pixel]; M_1 is the intrinsic parameter matrix ; M_2 is the extrinsic parameter matrix, which contains the rotation matrix R and the translation matrix T ; f is the camera focal length, i.e., [mm]. the distance between o and Oc, as shown in Fig. 14.

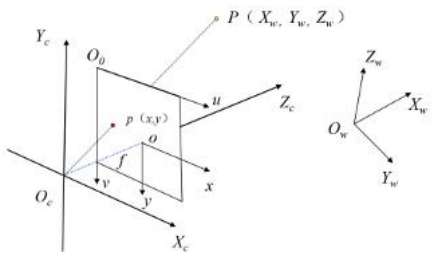

Fig. 14 - Schematic Diagram of Coordinate System Transformation

Two camera calibration methods based on OpenCV and MATLAB are currently available: the former is susceptible to image quality with relatively large calibration errors, while the latter requires manual extraction of corner points and features high accuracy with low calibration error. This study adopted the MATLAB-based calibration method: the calibration toolbox was invoked via the calib_gui command to import 20 calibration images, the checkerboard used had a square side length of 20 mm, and the results of corner point extraction are shown in Fig. 15.

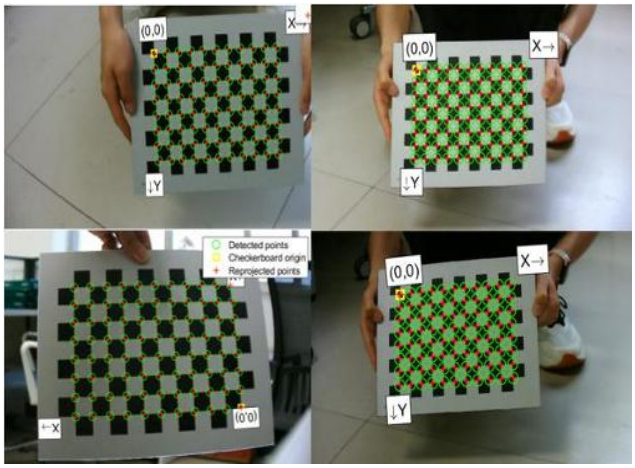

Fig. 15 - Corner Point Extraction Effect of the Calibration Board

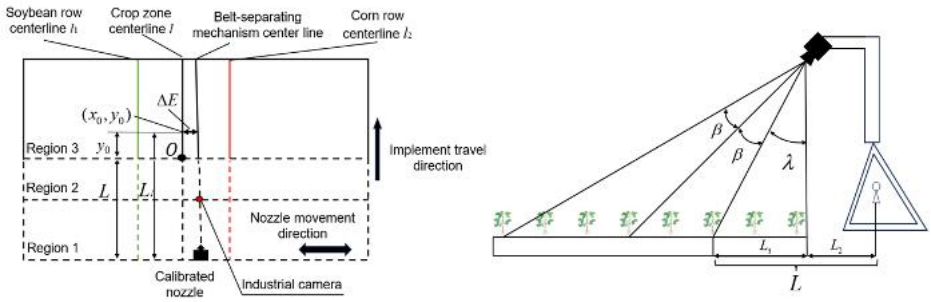
As shown in Table 1 are the intrinsic and extrinsic parameter matrices of the target camera obtained via the MATLAB calibration toolbox.

Table 1

Camera Calibration Results

Property	Parameter
K	[763.1029,0,0;0,762.2424,0;629.5229,345.8421,1]
Radial Distortion	[0.130846983244061, -0.150301138293976]
Tangential Distortion	[0,0]

3.1.2. Lateral Offset Compensation Control Variable



To achieve precise strip-zoning spraying, it is necessary to calculate the offset information of the crop zone centerline. The linear distance in the horizontal direction from the calibrated nozzle fixed on the anti-drift baffle to the crop zone centerline is defined as the offset. In the offset compensation model shown in Fig. 16(a), Zones 1 and 2 are the blind areas of the camera's field of view, among which Zone 1 refers to the area corresponding to the distance from the nozzle to the camera, and Zone 3 is the camera's field of view area. The crop zone centerline l: $Ax+By+C=0$ is derived from the soybean row centerline l_1: $Ax+By+C_1=0$ and the maize row centerline l_2: $Ax+By+C_2=0$ in accordance with the Parallel Centerline Principle. The point (x_0, y_0) represents the relative coordinate of a point on the crop zone centerline within Zone 3 with respect to the absolute coordinate system O, and ΔE denotes the actual lateral distance from this point to the nozzle, as given by the following formula:

$$\Delta E = \frac{\left|Ax_0 + By_0 + C\right|}{\sqrt{A^2 + B^2}} \tag{16}$$

The installation position coordinates and mounting angle of the industrial camera are shown in Fig. 16. The nozzle is fixed on the spray boom frame, and the actual distance L_1 from point (x_0, y_0) to the nozzle is jointly composed of y_0, L_2 and L_3, which can be expressed as:

$$\begin{cases} L_1 = y_0 + L \\ L = L_3 + L_2 \\ L_3 = h\tan\lambda \end{cases} \tag{17}$$

where: λ is the included angle between the lower boundary plane of the camera's field of view and the vertical direction, [°]; L_2 is the straight-line distance between the nozzle and the camera, [m]; L_3 is the straight-line distance between the camera and the field of view boundary, [m].

(a) *(b)*

Fig. 16 - Schematic Diagram of the Offset Compensation Model

(a) Top View; (b) Side View

When the automatic strip-zoning pesticide application control mechanism receives the execution signal, it cannot act immediately, and speed regulation control is thus required. The speed sensor mounted on the wheels captures the operating speed v_1, from which the safety boundary of the delayed execution time for the strip-zoning control system, t_1, is derived.

$$t_1 \leq \frac{L_1}{v_1} \tag{18}$$

Only when the time taken for the sprayer to operate a distance L satisfies the safety boundary condition can the row alignment mechanism complete the compensation for the offset ΔE. On this basis, an offset compensation model is established, yielding the response speed of the strip-zoning control mechanism as follows:

$$v_2 = \frac{\Delta E}{t_1} \tag{19}$$

To optimize the dynamic response characteristics of the offset compensation system, a position closed-loop control scheme based on a PD trajectory tracking strategy with PID control is designed in accordance with the established kinematic model of the row alignment mechanism (Fig. 16). This scheme is intended to significantly improve the response speed and accuracy of the system during target trajectory tracking by optimizing the controller design *(Ding et al., 2019; Han et al., 2022; Zheng et al., 2023)*. The expression is given as follows:

$$O_{pd} = K_p r + K_d \Delta r_0 + K_i \sum_{n=0}^{k} \Delta r_n \tag{20}$$

where: O_{pd} is the pulse output frequency, [Hz]; K_p is the proportional coefficient; K_d is the differential coefficient; K_i is the integral coefficient; Δr is the offset error, [mm]; Δr_0 is the offset error at the previous moment, [mm]; $\sum_{n=0}^{k} \Delta r_n$ is the cumulative offset error, [mm].

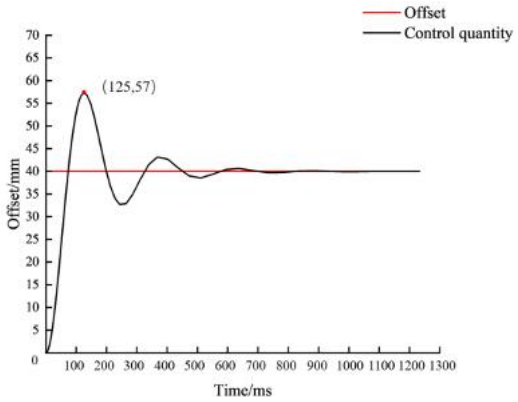


Fig. 17 - PD Control Curve

The results are shown in Fig. 17. When the target value was set to 40 mm, the maximum deviation of PD control reached 57 mm with a response time of 125 ms. To reduce the oscillation and instability phenomena occurring during the error adjustment process and enable the response speed of the actuator to be rapidly improved in a short time, the proportional coefficient K_p was determined as 2 and the differential coefficient K_d as 15 through manual tuning.

4 Experiment metrics and Determination Methods

4.1 Experiment metrics

This study selected the following core indicators to evaluate the system performance: mean recognition deviation and recognition accuracy reflect the recognition precision of the algorithm; mean deviation and the proportion of deviations within 50 mm reflect the strip-zoning accuracy of the system; droplet deposition density verifies the effect of strip-zoning pesticide application. The expressions are as follows:

$$\mu = \frac{1}{N}\sum_{i=1}^{N} x_i \tag{21}$$

$$P = \frac{N_{correct}}{N_{total}} \times 100\% \tag{22}$$

$$D = \frac{N_C}{S_T} \tag{23}$$

where: μ is the mean value of recognition deviation; $N_{correct}$ is the Number of correctly identified samples; N_{total} is the Total number of identified samples; D is the droplet deposition density, [droplet/cm²]; N_C is the number of droplets collected by the water-sensitive paper, [droplet]; S_T is the area of the water-sensitive test paper, [cm²].

4.2 Determination Methods

To verify the various performance metrics of the automatic strip-zoning pesticide application control system, the experiment was conducted in a soybean-maize strip intercropping test field in Xinzheng City, Henan Province (*34.3791°N, 113.6489°E*).

For the performance measurement of the recognition algorithm, light detection software was used to acquire field light intensity information at different time periods throughout the day, and videos of crop rows were collected and subjected to frame segmentation. The algorithm recognition system was applied to measure recognition deviations, with deviations exceeding 5 cm defined as recognition errors (*Wang, Q. et al., 2021; García et al., 2017*).

In the experiments for the system and droplet anti-drift performance, as is shown in Fig. 18, a strip intercropping plant protection sprayer was adopted, and the automatic strip-zoning pesticide application control system was mounted on the boom sprayer. A speed sensor was installed inside the sprayer's wheels, and a rope displacement sensor was fitted on the spray boom to measure the offset of the actuator. An industrial camera was installed at the front of the sprayer and positioned at the mid-stroke of the electric push rod. A calibrated nozzle was fixed inside the anti-drift device directly below the industrial camera to record the trajectory of the droplet strip. A rectangular area with a length of 20 m and a width equal to the inter-zone spacing was demarcated in the crop zone area; within this area, a piece of water-sensitive paper and a warning line of the same length as the area were laid every 40 cm as reference benchmarks. Meanwhile, water-sensitive test paper was laid on the canopies of soybean and maize plants (Fig. 22). During the experiment, the operating speed of the plant protection sprayer was controlled at 2 km/h, 3 km/h, 4 km/h and 5 km/h. After the system received control commands, the nozzles sprayed uniformly, and the droplet positions were visualized by utilizing the characteristic of water-sensitive paper turning red upon contact with water. The experiment wind speed was measured at 1.4–2.9 m/s. Upon completion of the experiment, the coordinate positions of droplet centers on the water-sensitive paper were manually recorded, and the number of blue spots on the surface of the water-sensitive test paper was counted to verify the overall performance of the automatic strip-zoning pesticide application control system.

Fig. 18 - Field Experiment

RESULTS

5. Field Experiment and Analysis

5.1. Performance Experiment of the Recognition Algorithm

To verify the robustness of the algorithm's recognition performance, this study conducted performance tests under different light intensities, with the mean recognition deviation and recognition accuracy adopted for evaluation.

The experimental results are shown in Table 2. The algorithm's recognition performance is dependent on light intensity: during the period of 14:30–16:30, the light was uniform and stable without direct strong light or shadow occlusion, and the crop row recognition accuracy reached the peak of the entire experiment period under both forward and backlighting conditions. The distinct crop-background feature boundaries facilitated target segmentation and contour extraction; during 9:30–14:30, the light intensity rose to the maximum, and local overexposure of images led to the loss of texture features in crop canopies and a decrease in the contrast between targets and the background, resulting in an increase in the mean recognition deviation and a subsequent decline in accuracy; during 16:30–18:30, the light intensity diminished, the area of shadows from crop canopies and the machine expanded with a complex distribution, and blurred pixel features caused a reduction in positioning accuracy, with the mean recognition deviation reaching 3.53 cm, which was significantly higher than that in the previous two periods. Overall, the recognition accuracy of the algorithm remained above 84% throughout the entire experiment period, indicating a certain level of its adaptability to the field environment.

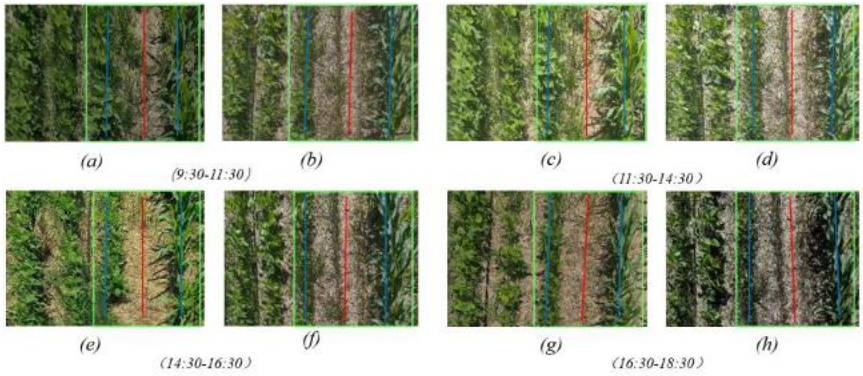

Fig. 19 - Light intensity experiment results

(a), (c), (e), (g)-- Frontlight; (b), (d), (f), (h)-- Backlight

Table 2

Light intensity experiment results

Time Interval	Light Intensity / Lux	Light Direction	Mean Recognition Deviation / cm	Recognition Accuracy / %
9:30-11:30	**1.66×10^4**	Frontlight	3.34	88
		Backlight	3.37	90
11:30-14:30	**1.79×10^4**	Frontlight	3.44	88
		Backlight	3.36	91
14:30-16:30	**1.39×10^4**	Frontlight	3.00	90
		Backlight	3.32	92
16:30-18:30	**1.15×10^4**	Frontlight	3.53	86
		Backlight	3.46	84

5.2. System Performance Experiment

To quantitatively analyze the real-time response characteristics of the visual recognition module and the automatic strip-zoning actuation mechanism, 20 groups of continuous and typically representative sample data were selected in this study while the sprayer was operating at an operating speed of 2 km/h, and the Trend Chart of Vision-Actuation Offset Variation (Fig. 20) was plotted accordingly.

As can be seen from Fig. 20, the strip-zoning actuation offset generally exhibits the characteristic of converging toward the visual recognition detection results. When the sprayer operated to Zone I, the crops grew uniformly with a reasonable planting density, and the crop row contours were clear and highly continuous. The automatic strip-zoning actuation mechanism featured a small displacement adjustment range and a rapid response, which reduced the offset to the minimum value of 0.3 cm throughout the entire operation process.

In contrast, when the sprayer operated to Zone II, the offset exhibited significant abnormal fluctuations, with the maximum offset reaching 4.9 cm, which was significantly higher than that in other operating areas.

This was due to the crop seedling absence in this zone, which led to the weakening of crop row contour features and the breakage of their continuity. This prevented the system's visual recognition module from accurately capturing the complete position of the crop zone centerline, which in turn caused a lag in the displacement adjustment of the automatic strip-zoning actuation mechanism and ultimately resulted in an increase in the offset.

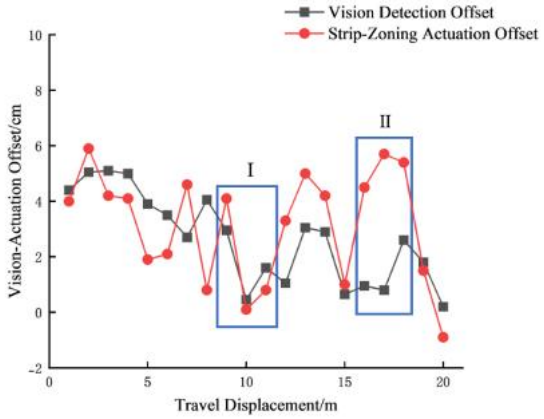

Fig. 20 - Trend Chart of Vision-Actuation Offset Variation

Meanwhile, the experiment set different operated speed gradients, and 50 groups of valid samples were selected for each gradient to plot the dynamic trend chart of the offset between the droplet zone center and the crop zone centerline (Fig. 21).

It can be seen from the trend characteristics in Fig. 21 that the offset exhibited a significant positive correlation with the increase in operating speed. The statistical characteristics of the crop zone trajectory offset under different speed gradients are shown in Table 3. Under the four operating speeds, the mean maximum deviation of the trajectory offset was all controlled within 50 mm. Among them, the mean offset fluctuated sharply at speeds of 2–4 km/h, with a maximum difference of 0.98 cm between adjacent speeds.

The main reasons are as follows: First, the nozzle and the boom frame are connected via a hinged joint. During the operating of the sprayer, the nozzle is prone to irregular lateral oscillation due to the unevenness of the field road surface and the inertial effect of the machine, which causes the droplet spray landing points to deviate from the preset area. Second, with the increase in the sprayer's operating speed, the video images collected by the system's visual recognition module suffer from insufficient resolution, which results in blurred boundary features between crop zones and a significant decline in contour recognizability. This makes it impossible to accurately extract the spatial position information of the inter-zone centerline, and thus the strip-zoning control actuation mechanism lacks a reliable visual perception basis for generating accurate offset compensation commands. This ultimately leads to continuous error accumulation, resulting in an obvious increasing trend of the mean offset with the rise in operating speed.

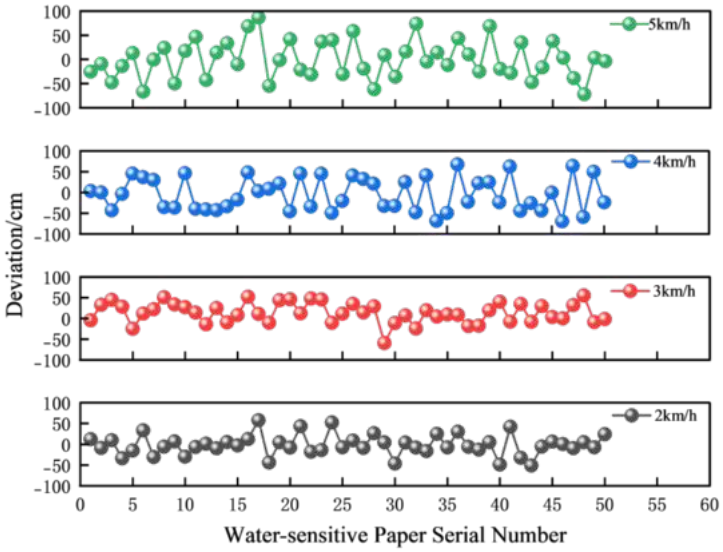

Fig. 21 - Deviation at Different Speeds

Table 3

Crop Strip Trajectory Deviation Statistics

Speed / km·h⁻¹	Mean Deviation / cm	Proportion of Deviations Within 50 mm / %
2	1.83	94.00
3	2.81	92.00
4	3.55	88.00
5	3.56	84.00

5.3 Drift Prevention Performance Experiment of Droplets

To further evaluate the strip-zoning effect of the automatic strip-zoning pesticide application control system, droplet cross-zone drift prevention performance experiment were conducted.

By calculating the droplet deposition density (Eq. 23), the deposition status of droplets per unit crop area can be determined *(Ma et al., 2023; Ni et al., 2020; Zhou et al., 2021)*. The results are shown in Tables 4 and 5.

Fig. 22 - Water-Sensitive Test Paper

Table 4

Maize Liquid Droplet Drift Deposition

Speed / km/h	Droplet Deposition Amount / (droplet /cm²)			Mean Droplet Deposition Amount / (droplet /cm²)
	1	2	3	
2	0.20	0.24	0.11	0.18
3	0.44	0.66	1.19	0.76
4	1.69	1.61	1.71	1.67
5	6.38	4.81	6.65	5.94

Table 5

Soybean Liquid Droplet Drift Deposition

Speed / km/h	Droplet Deposition Amount / (droplet /cm²)			Mean Droplet Deposition Amount / (droplet /cm²)
	1	2	3	
2	0.55	0.41	0.76	0.57
3	1.65	1.27	1.67	1.53
4	1.92	1.83	2.78	2.18
5	8.78	10.29	9.17	9.41

From the experimental results, the amount of droplet cross-zone drift is positively proportional to the operating speed, and the drift deposition amount of droplets is no more than 9.41 cm², which indicates that the system can effectively reduce droplet cross-zone drift.

CONCLUSIONS

(1) Taking soybean and maize under the strip intercropping mode as the research object, a crop row recognition algorithm and a strip-zoning spray control system were designed, and a vision-based strip-zoning pesticide application control system was established.

(2) Research is conducted on the crop row recognition method based on machine vision. A dynamic ROI positioning and crop row line extraction algorithm for soybean and maize crop rows based on the peak value method was proposed, and a strip-zoning offset compensation model was constructed accordingly.

(3) Field experiment results show that the light intensity at different times of the day causes slight fluctuations in the algorithm's recognition accuracy, while the recognition accuracy remains no less than 87% consistently. At operating speeds of 2 to 5 km/h, the mean strip-zoning deviation of the automatic strip-zoning pesticide application control system can be controlled within 3.61 cm, and the proportion of strip-zoning deviations within 5 cm reaches 84%, with a maximum of 94%. Under wind speeds of 1.4 to 2.9 m/s, the droplet drift deposition amount of the closed anti-drift device is directly proportional to the operating speed, with a maximum of 9.41 number/cm², which meets the plant protection operation standards for the soybean-maize strip intercropping mode. This study provides a practical technical reference for the development of precise plant protection operations under the soybean-maize intercropping mode.

Keywords: *furrowing tool; EDEM; response surface analysis; parameter optimisation.*

ABSTRACT
Mechanised furrowing and fertiliser application is an effective engineering solution for improving operational efficiency and reducing labour intensity in hilly and mountainous orchards. In this study, a systematic optimisation methodology for a disc-type furrowing tool is proposed by integrating discrete element method (DEM) simulations using EDEM with quadratic orthogonal regression experiments and response surface analysis. Key structural parameters, including bending radius, bending angle, and alpha angle, were selected as design variables, and their individual and interactive effects on furrowing power consumption were investigated. The results of the response surface analysis indicate that appropriate structural optimisation can significantly reduce trenching power consumption. The optimal structural parameters were determined as follows: bending radius of 36.79 mm, bending angle of 126.94°, and alpha angle of 43.65°. Under these conditions, the predicted power consumption was 0.85 kW, representing a reduction of 8.88% compared with the original tool design. Soil bin experiments were conducted to validate the DEM simulation results, and the experimental trends showed good agreement with the simulation predictions, demonstrating the reliability of the proposed optimisation approach. This study provides a practical reference for the engineering design and performance improvement of soil-engaging tools.

摘要
果园机械化开沟施肥技术是提高丘陵山区果园作业效率、降低劳动强度的关键手段之一。本文基于EDEM仿真技术，结合二次正交回归试验与响应曲面分析，优化了圆盘式开沟刀具的结构参数。研究重点分析了弯折半径、弯折角度和阿尔法角等关键参数，并通过响应曲面分析揭示了这些参数之间对开沟功耗的交互影响。优化结果表明，合理调整刀具结构能够显著降低开沟功耗，优化后的刀具参数为：弯折半径 X_1 = 36.79 mm、弯折角度 X_2 = 126.94°、阿尔法角 X_3 = 43.65°，优化后的功耗为 0.85 kW，相较未优化刀具，功耗降低了约 8.88%。土槽实验验证了仿真结果的准确性，为进一步优化开沟刀具提供了理论依据。

INTRODUCTION
Fertilisation is a fundamental management practice in orchard production because it directly influences tree growth, fruit yield, and fruit quality. In modern orchard management, strip fertilisation along the tree drip line is widely adopted to improve nutrient availability and root uptake. This practice requires efficient furrowing and subsequent backfilling to ensure uniform fertiliser placement and favourable soil conditions for root development *(Chen M. et al., 2024; Chen P. et al., 2024)*. However, conventional furrowing methods generally exhibit high energy consumption and low operational efficiency, particularly when traditional soil-engaging tools are employed. These limitations become more pronounced in hilly and mountainous orchards, where steep terrain, irregular planting layouts, and limited accessibility restrict the use of conventional agricultural machinery *(Fang et al., 2024; Jian et al., 2024)*. Consequently, fertilisation in these regions still relies heavily on manual labour, resulting in low productivity and high labour intensity. With the continuing shortage of agricultural labour, the development of efficient and energy-saving furrowing equipment has become an important prerequisite for improving the mechanisation of orchard fertilisation in hilly and mountainous areas.

As the key soil-engaging component of a furrowing machine, the structural design of the furrowing tool directly determines soil cutting performance, soil disturbance characteristics, and power consumption during operation *(Aikins et al., 2019; Madhusudan et al., 2024).* An appropriately designed tool not only improves trenching efficiency but also reduces energy consumption and enhances fertiliser placement quality, thereby improving both the economic and environmental sustainability of orchard production *(Wang et al., 2015; Yi et al., 2024).* These studies indicate that optimising the structural parameters of furrowing tools is an effective engineering approach for reducing power consumption and improving operational performance.

As a core component, tool structure significantly affects efficiency and energy demand. Extensive research has been conducted in this field. For instance, *Kang et al., (2016),* reduced power consumption by optimizing blade geometry, while *Yang et al., (2018)* developed a cut-and-throw furrowing tool tailored for tea plantations, thereby improving soil displacement performance. *Kim et al., (2021)* employed discrete element method simulations to optimise soil–tool interaction, achieving considerable reductions in power consumption and offering valuable guidance for tool design. Despite these advances, traditional furrowing tools still suffer from low efficiency and excessive power consumption when used in orchards located in hilly and mountainous regions—where high soil viscosity and sloughing are prevalent—indicating a clear need for further optimisation. Improving tool configuration is essential to enhance efficiency, reduce power consumption, and improve adaptability to diverse soils and fertilisation needs.

In this study, DEM simulations (EDEM) and soil trench tests were conducted to investigate the effects of bending radius, bending angle, and alpha angle on power consumption. A quadratic orthogonal regression model was established to optimise tool parameters.

MATERIALS AND METHODS

MAIN STRUCTURE AND PARAMETERS OF FURROWING TOOL

In this study, a disc-type furrowing cutter was adopted as the research object, and its structural design was developed based on the working principles of a wetland furrowing curved cutter, as illustrated in Figure 1. The tool mainly consists of a lateral cutting edge, a frontal cutting edge, a central shaft, and mounting apertures. The lateral cutting edge is formed along an Archimedean helix to facilitate soil cutting and conveyance, while the frontal cutting edge is designed with a circular arc profile to enhance soil penetration and stabilise the furrowing process *(Aikins et al., 2020; Amantayev et al., 2018; Barr et al., 2020; Mi et al., 2025).*

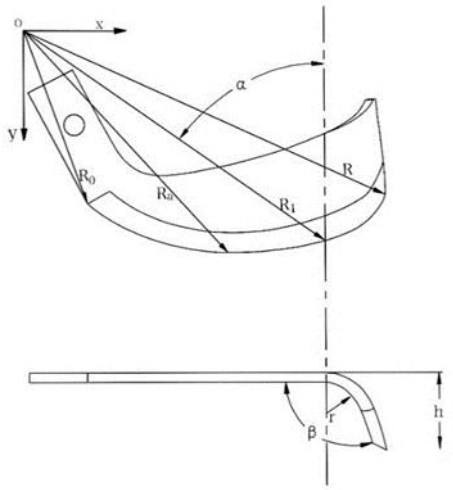

Fig. 1 - Tool structure diagram. O-centre of rotation

O-centre of rotation, R-radius of rotation, R_0-radius of the starting point of the side cutting edge, R_1-radius of the end point of the side cutting edge, R_α-radius of any point on the side cutting edge, α-angle between the end point of the side cutting edge and the bending line, r-bending radius, β-bending angle, h-working width.

The key structural parameters of the furrowing tool are listed in Table 1. These geometric parameters were obtained by measuring the manufactured prototype and were used to establish the three-dimensional model for DEM simulation.

Table 1

Main structural parameters of furrowing tool.

Parameter	Value
Radius of rotation [R]	245 mm
Bending radius [r]	45 mm
Bending angle [β]	145°
Alpha angle [α]	40°
Working width [h]	35 mm
Blade edge thickness	1.5 mm
Blade back thickness	5 mm
Working depth [H]	20 mm

Tool-soil coupling model based on EDEM

To ensure accuracy and reliability, a representative orchard soil from a hilly region was selected as the simulation medium. Measured soil properties were combined with literature values to define DEM input parameters *(Fang et al., 2016; HAO et al., 2023; Li et al., 2018; Liu et al., 2024; Liu et al., 2019; Zhu et al., 2020).* The soil is shaly and clayey, composed of fine particles that are difficult to measure directly at the particle scale. Thus, assumptions were made to balance computational efficiency and realistic soil behaviour. The Hertz–Mindlin with JKR model was used to simulate soil–soil and soil–tool interactions, with particle diameter set to 5 mm. Simulation parameters for the soil and tool are listed in Table 2.

Table 2

Tool-soil coupling model parameters

Parameter	Value	Parameter	Value
Machine forward speed [m/s]	0.3	Soil-soil recovery factor	0.28
Tool speed [rpm]	300	Soil- steel recovery factor	0.6
Soil density [kg/m³]	2500	Soil-soil static factor	0.5
Poisson's ratio for soil	0.32	Soil-steel static factor	0.5
Soil shear modulus [Pa]	1×10^{6}	Soil-soil rolling factor	0.37
Steel density [kg/m³]	7850	Soil-steel rolling factor	0.05
Shear modulus of steel [Pa]	7.962×10^{10}	Steel Poisson's ratio	0.3

Test equipment

The experimental system consisted of soil bin testing and processing equipment. The soil bin system included a P71 magnetic tachometer for speed measurement, an APN1211E-U power tester, a TAILI three-phase AC motor, and a TAILI S18 frequency converter. Processing equipment included a CNC machining centre (Huazhong CNC Co., Ltd.) for tool fabrication.

EDEM simulation test

A three-dimensional furrowing tool model was built in UG NX12 using the geometry and soil parameters from the previous section. The model was exported in STL format and imported into EDEM for simulation. The tool–soil coupling model was established by assigning material and contact properties to the tool and soil particles. Figure 2 shows the model generated using these methods and parameters.

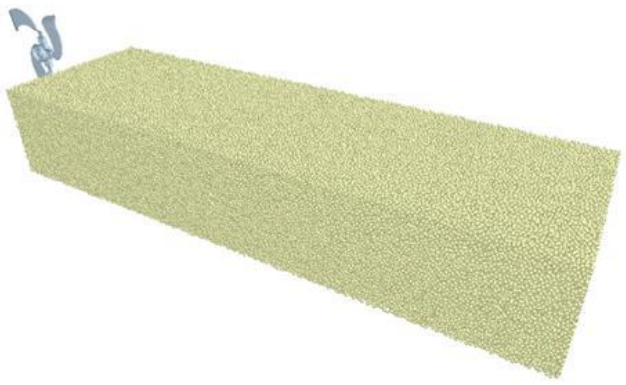

Fig. 1 - Tool-soil simulation model diagram

As EDEM does not directly provide tool power consumption as an output, the torque acting on the furrowing tool was first obtained from the simulation results and then converted into power consumption using the following Eq. 1:

$$P = \frac{T \cdot n}{9549} \quad (1)$$

where:

P-power consumption, [kW];

T-torque, [Nm];

n-tool speed, [rpm].

Soil bin experiment

To validate the EDEM simulation, a soil bin test bench was constructed. The soil bin measured 2500 × 600 × 500 mm, and the same disc-type tool as in the simulations was used. During testing, the tool was driven by an electric motor, and power consumption was recorded in real time. Each condition was repeated three times, and no-load power was subtracted to obtain net cutting power. Motor speed was controlled by a variable-frequency drive, while forward speed was manually adjusted. To reduce uncertainty, data were collected in the central region of the soil bin. Figure 3 shows the setup.

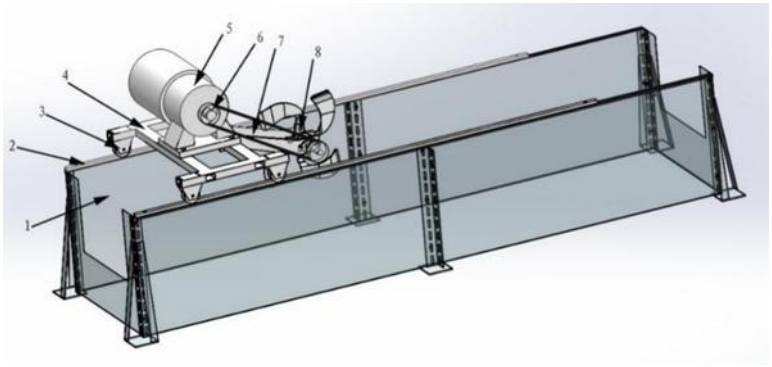

Fig. 2 - The schematic diagram of soil trough experimental scheme

1. soil tank; 2. guide rail; 3. pulley; 4. motor mounting; 5. motor; 6. chain drive; 7. tool arm; 8. cutter plate.

The constructed soil-tank experimental stand is illustrated inFig. **3** 3.

Fig. 3 - Soil trough test bench

Optimisation of furrowing tool parameters

This section optimises the parameters of the disc-type furrowing tool. Based on DEM simulations and soil bin tests, three parameters—bending radius (X_1), bending angle (X_2), and alpha angle (X_3)—were selected. The objective was to reduce power consumption and improve efficiency, thereby enhancing tool performance under typical orchard conditions.

Quadratic regression orthogonal experimental design

The orthogonal combination design includes a two-level test m_c, an asterisk test $2m_\gamma$ and zero-level experiment m_0. The total number of tests, n is calculated using the following Eq.(1):

$$n = m_c + 2m_\gamma + m_0 \quad (1)$$

In accordance with the orthogonality requirement, the arm length parameter, denoted as γ, must satisfy the following Eq. (2):

$$\gamma = \sqrt{\frac{\sqrt{(m_c + 2m_\gamma + m_0)m_c} - m_c}{2}} \quad (2)$$

The present experiment was a three-factor, two-level full-scale trial, which resulted in $\gamma = 1.353$.

In the context of the given factors, the arithmetic mean is defined as the zero level of factor x_j, denoted x_{j0}, where x_{j2} and x_{j1} represent the upper and lower levels of factor x_j, respectively. Let $x_{j\gamma}$ and $x_{-j\gamma}$ denote the upper and lower asterisk arm levels of factor x_j, respectively. These values correspond to the upper and lower levels of factor x_j(3).

$$x_{j0} = \frac{x_{j1} + x_{j2}}{2} = \frac{x_{j\gamma} + x_{-j\gamma}}{2} \quad (3)$$

Therefore, the variation in this factor is as Eq. (4):

$$\Delta_j = \frac{x_{j\gamma} - x_{j0}}{\gamma} \quad (4)$$

The factor levels and their corresponding coding results for this trial are shown in Table 3.

Table 3

Test factors and levels

coding	X_1 (bend radius)	X_2 (bending angle)	X_3 (Alpha angle)
γ (1.353)	58.53	145.15	46.77
1	55.00	142.50	45.00
0	45	135	40
-1	35.00	127.50	35.00
$-\gamma$ (-1.353)	31.47	124.85	33.23
Δ_j	3.6954	11.0864	3.6954

The quadratic regression orthogonal test design and the corresponding operating power consumption of the furrowing tool are presented in Table 4.

Table 4

Experimental arrangement and results

	X_1(Bending radius)	X_2(bending angle)	X_3(Alpha Angle)	Y（kW）

The objective was to minimize power consumption by optimising the structural parameters of the disc-type furrowing tool. A quadratic regression model was established to quantify the relationship between structural parameters and power consumption. The optimal parameters were obtained by solving the objective function in MATLAB.

RESULTS AND DISCUSSION

EDEM simulation results analysis

The torque acting on the disc-type furrowing tool during the furrowing process was obtained using the EDEM post-processing module, as shown inFig. 4. The mean torque was determined to be 29.79 Nm, and the corresponding furrowing power consumption was calculated to be 0.94 kW.

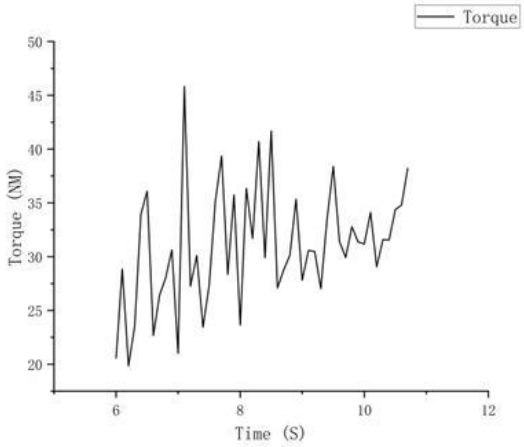

Fig. 4 - Tool furrowing torque diagram

The operation of the disc-type furrowing tool in the soil trench demonstrated its effectiveness in soil cutting and trench formation. During the furrowing process, the soil was lifted and displaced, with the majority returning to the trench, while a small portion of soil was ejected outside the simulation domain. This behaviour confirms the appropriateness of the tool's selected structural parameters for efficient trenching. The furrowing process is illustrated inFig. 5.

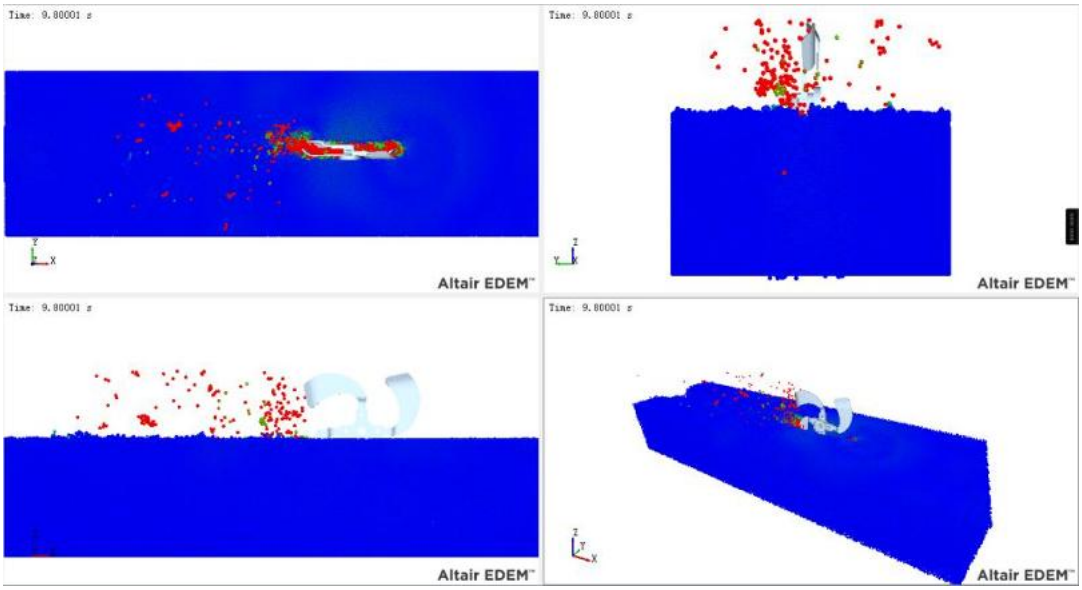

Fig. 5 - Schematic diagram of tool furrowing process

Comparative analysis of simulation test and soil tank test results

This section presents a comparative analysis of the simulation results and soil bin test data. Analysis of the soil bin experiments indicates that, during the furrowing process, the tool's lateral cutting edge initially engages and cuts the soil, followed by plastic deformation of the soil. As the disc-type furrowing tool rotates, the operating depth gradually increases, and the main cutting edge comes into contact with the soil, enlarging the contact area. This interaction results in shearing and extrusion of the soil, culminating in soil fragmentation, overturning, and partial ejection, thereby completing the furrowing and backfilling operations (Fig. **6**).

Fig. 6 - Effect diagram after furrowing

A detailed analysis of the soil bin test data indicated that the average power consumption of the disc-type furrowing tool was 1.07 kW. In comparison, the EDEM simulation predicted a furrowing power of 0.94 kW, yielding a relative error of 13.83%. The discrepancy can be attributed to fluctuations in the tool's forward speed, machining and assembly tolerances, and variations in soil properties. Nevertheless, this relative error is within an acceptable range for agricultural machinery, particularly for furrowing and tillage implements. These results demonstrate that the EDEM simulation can accurately predict the power consumption of the furrowing tool and can be effectively used to guide its structural optimisation.

Analysis of optimisation results of furrowing tool parameters

Quadratic regression orthogonal test results analysis

The results of the quadratic orthogonal regression experiments were imported into the statistical analysis software Design-Expert 13 for further evaluation. The outcomes of the analysis are summarised in Table **5**.

Table 5

Variance analysis

Source	Sum of Squares	df	Mean Square	F-value	p-value	VIF
Model	0.0196	9	0.0022	28.52	0.0001	1
A	0.0021	1	0.0021	27.70	0.0012	1
B	0.0107	1	0.0107	140.26	< 0.0001	1
C	0.0005	1	0.0005	6.19	0.0418	1
AB	0.0003	1	0.0003	4.28	0.0774	1
AC	0.0023	1	0.0023	29.63	0.0010	1
BC	0.0001	1	0.0001	0.8459	0.3883	1
A^2	0.0009	1	0.0009	11.62	0.0113	1
B^2	0.0011	1	0.0011	13.98	0.0073	1
C^2	0.0017	1	0.0017	22.18	0.0022	1

Note: $p \leq 0.01$ (highly significant), $p \leq 0.05$ (significant).

As shown in Table 5, the model has an F-value of 28.52, indicating statistical significance. The P-value indicates significance, with values < 0.05 denoting significant effects. Factors A, B, C, AC, and A^2, B^2, C^2 significantly affect power consumption. SS, DF, MS, and VIF denote sum of squares, degrees of freedom, mean square, and variance inflation factor, respectively; VIF = 1 indicates factor orthogonality.

ANOVA confirms that the model is statistically significant. Factor B (X_2) has the greatest effect, followed by C (X_3) and A (X_1). The interaction A × C also significantly affects power consumption. The analysis also yielded regression coefficients and model fit metrics.

The regression model is:

$$Y = +0.8770 + 0.0135 * X_1 + 0.0303 * X_2 - 0.0064 * X_3 + 0.0064 * X_1X_2 + 0.0168 * X_1X_3 + 0.0028 * X_2X_3 + 0.0115 * X_1^2 + 0.0126 * X_2^2 + 0.0159 * X_3^2 \quad (5)$$

Table 6

Fit degree analysis results

Std. Dev.	0.0087	R^2	0.9735
Mean	0.9045	Adjusted R^2	0.9393
C.V. %	0.9651	Predicted R^2	0.8023
		Adeq Precision	18.9286

The regression model exhibited an R^2 of 0.9735, an adjusted R^2 of 0.9393, and a P-value of 0.0001, indicating that the model fits the experimental data well, is highly reliable, and statistically significant. The predicted R^2 of 0.8023 is reasonably close to the adjusted R^2, with a difference of less than 0.2, further confirming the stability and predictive capability of the model.

Model adequacy was also evaluated using the Adeq Precision, which should ideally exceed 4. In this study, the Adeq Precision was 18.929, demonstrating that the model has sufficient signal strength and applicability. Additionally, the normality of the standardized residuals was assessed, showing that they approximately follow a normal distribution and converge along a standard normal probability plot, as illustrated in Fig. 7.

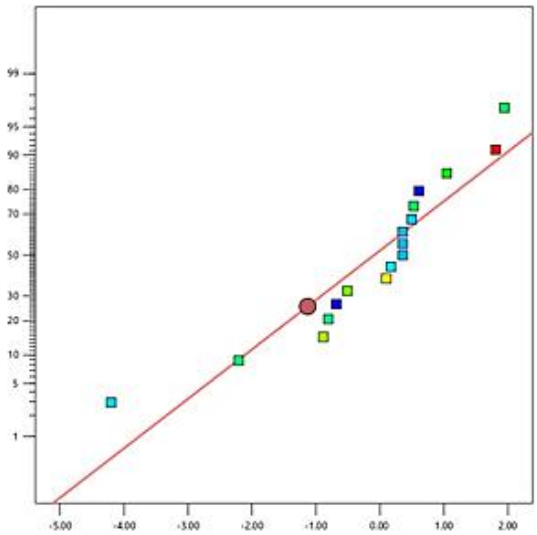

Fig. 7 - The distribution map of residual research

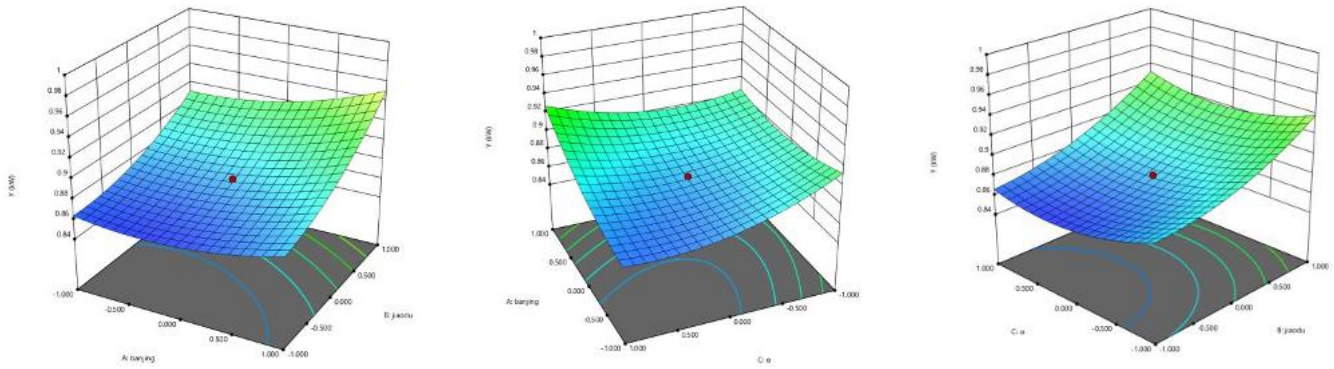

As shown in Fig. 7, the data points exhibit a linear trend and closely follow a normal distribution. This indicates a high degree of confidence in the predictive regression model and demonstrates strong agreement with the assumptions underlying the analysis of variance (ANOVA).

Optimisation analysis of tool structure parameters

The effect of tool structural parameters on furrowing power consumption.

Fig**. 8** illustrates the interaction effects of the disc-type furrowing tool's structural parameters on power consumption, as generated using Design-Expert 13. The figure indicates that an increase in the bending radius (X_1, factor A) leads to a gradual increase in furrowing power consumption, while an increase in the bending angle (X_2, factor B) also results in higher power consumption. In contrast, increasing the alpha angle (X_3, factor C) reduces furrowing power consumption.

Simulation analysis further revealed the underlying mechanisms of these effects. The bending radius strongly affects the tool–soil contact area and cutting characteristics. A smaller bending radius concentrates the cutting force and reduces the thickness of the soil layer being removed, but may increase soil reaction forces. Conversely, a larger bending radius allows deeper soil penetration but results in higher power consumption. The bending angle primarily influences the direction and efficiency of the shear force: smaller angles are more suitable for shallow cutting but may cause soil accumulation, whereas larger angles facilitate deeper cutting and improve the fragmentation of compacted soil layers. The alpha angle affects both the cutting depth and soil dispersion direction, with smaller angles promoting deeper penetration but increasing power requirements.

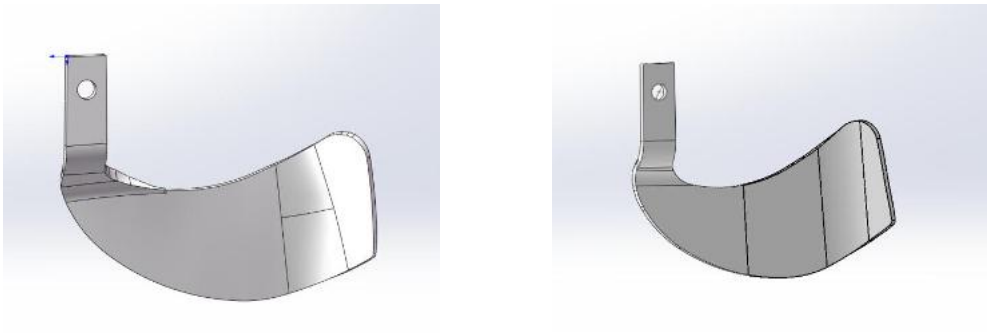
Fig. 8 - The interaction effect of tool structure parameters on power consumption

(a) The interaction between A (X1) and B (X2) on power consumption. (b) The interaction between C (X3) and B (X2) on power consumption. (c) The interaction between C (X3) and A (X1) on power consumption.

Optimisation of tool structure parameters

The objective of the optimisation was to minimise the furrowing power consumption by appropriately selecting the structural parameters of the disc-type furrowing tool. To achieve this, a regression model was established to quantify the relationship between the tool's structural parameters and power consumption, providing a quantitative foundation for optimisation.



The following constraints were applied during the optimisation process:

$$\begin{cases} X_1 = [-1.353, 1.353] \\ X_2 = [-1.353, 1.353] \\ X_3 = [-1.353, 1.353] \end{cases} \quad (6)$$

The objective function was solved using MATLAB, yielding the optimal solution as follows:

$$\begin{cases} X_1 = 36.7939 \\ X_2 = 126.938 \\ X_3 = 43.6471 \end{cases} \quad (7)$$

The optimised parameters were applied to the regression equation, resulting in a furrowing power of 0.853 kW.

(a) (b)

Fig. 10 - Comparison of cutting tools before and after optimisation.

(a) Optimizing the front tool. (b) Optimised tool.

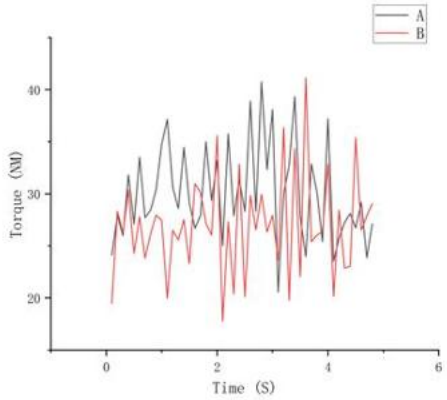


Fig. 11 - Comparison of furrowing torque before and after optimisation.

A Pre-optimisation torque. B Optimised furrowing torque

Simulation verification was performed to evaluate the furrowing power, which was determined to be 0.85 kW under the optimised tool parameters. The regression model predicted a furrowing power with a relative error of 0.6% compared to the simulation results. When compared with the pre-optimisation power of 0.94 kW, the optimised tool exhibited an 8.88% reduction in furrowing power consumption.

CONCLUSIONS

This study systematically optimised a disc-type furrowing tool using EDEM simulations combined with quadratic orthogonal regression. Results show that bending radius, bending angle, and alpha angle are key factors influencing furrowing power consumption. Response surface analysis revealed interactions: increasing bending radius or angle raises power, while increasing alpha angle reduces it. Tool optimisation reduced furrowing power by 8.88%.

Soil bin tests verified the simulation, showing a 13.8% relative error between experimental and simulated power. Discrepancies arose from soil property variations and experimental uncertainties. The error is acceptable for agricultural machinery, confirming the reliability of the EDEM simulation and structural optimisation approach.

Overall, this study offers a practical approach to improve open-furrow fertilisation in hilly orchards and a foundation for tool design and optimisation. Future work could refine soil parameters, improve model accuracy, and explore better tool configurations for more energy-efficient furrowing.

ABSTRACT

To address the issue of uneven fracture during the processing of Astragalus slices, this study first establishes a discrete element Bonding model for Astragalus roots, filling the gap in the calibration of its bonding parameters. Through uniaxial compression tests and multiple optimization experiments, the optimal parameters were determined, with simulation errors below 1.6% and validation errors for the fracture rate ≤ 12.7%, providing theoretical support for the development of processing equipment for Astragalus slices.

摘要

针对黄芪饮片加工断裂不均问题，本研究首次建立黄芪根离散元 Bonding 模型，填补其黏结参数标定空白。经单轴压缩试验与多组优化试验确定最优参数，仿真误差低于 1.6%，破碎率验证误差≤12.7%，可为黄芪饮片加工设备研发提供理论支撑。

INTRODUCTION

Astragalus membranaceus is a valuable traditional Chinese medicinal herb that functions in invigorating qi and enhancing body immunity. Its dried root has a long medicinal history and was incorporated into the medicine-food homologous catalogue in 2023, reflecting its significant medicinal value and industrial prospects (*Xi et al., 2023; Ji et al., 1998*). With the development of the modern Astragalus industry, promoting the mechanization and precision of processing operations such as root slicing and crushing has become essential. However, owing to the complex internal fibrous structure and unique mechanical properties of Astragalus root, uneven fractures and excessive powder production often occur during processing, which severely reduce the quality of prepared slices and production efficiency (*Duan, 2005*). The Discrete Element Method (DEM) coupled with the Bonding Model provides an effective means to simulate the bonding and fracture behaviors of granular materials and accurately reflect their mechanical responses, which has been widely applied in agricultural engineering (*Zhao et al., 2021; Zeng et al., 2021*). Nevertheless, existing DEM studies on Astragalus root lack accurate calibration of key Bonding Model parameters, including cohesion and elastic modulus, which limits the simulation accuracy of mechanical property evolution and fracture behaviors during processing. Therefore, calibrating these bonding parameters and establishing a high-precision DEM model is of great theoretical and practical importance for revealing tool-material interaction mechanisms, optimizing equipment design, and improving slice quality and active ingredient retention. Since DEM was proposed for soil mechanics by *Cundall et al.* (*1979*), it has been widely used in granular material operations such as mixing, conveying, filling and crushing (*Lu et al., 2015; Shen et al., 2016*). The Bonded Particle Model proposed by *Potyondy et al.* (*2004*) realizes fracture simulation via inter-particle bonding and has been widely adopted in agricultural research. Previous studies have completed bonding parameter calibration for various agricultural materials (e.g., coated fertilizer, garlic cloves, crop stems, corn ears) via mechanical tests such as uniaxial compression (*Du et al., 2022; Li et al., 2025; Xu et al., 2024; Gao et al., 2024; Xie et al., 2023; Li et al., 2025*). Relevant calibrations have also been conducted for banana stalks, walnuts and cotton seeds (*Zhang et al., 2023; Zhou et al., 2023; Hu et al., 2022*), and the model has been applied to analyze fracture mechanisms in Cyperus esculentus harvesting (*Zhu et al., 2022*).

[1] *Jun You, MA. Eng Stud.; Xin Du*, Lecturer Ph.D. Eng; Qixin Sun, Prof. Ph.D. Eng; Shufa Chen, Prof. Ph.D. Eng; Jingyi Mao, B.S Stud.*

These studies have promoted the application of the Bonding Model and parameter calibration in agricultural material processing. Building on existing research (*Du et al., 2022; Li et al., 2023; Xu et al., 2024; Gao et al., 2024; Xie et al., 2023; Li et al., 2025*), this study focuses on Astragalus root. Using the ultimate crushing load and displacement obtained from uniaxial compression tests, the Bonding Model parameters are optimized by combining the Plackett-Burman test, the Steepest Ascent test and the Box-Behnken test. The reliability of the calibrated parameters is verified through comparative tests between physical experiments and simulations.

This study aims to provide accurate basic parameters for DEM simulation of Astragalus processing equipment and support the intelligent development of related machinery. It fills the gap in DEM parameter calibration for Astragalus root and provides a new reference for mechanical simulation of granular traditional Chinese medicinal materials.

MATERIALS AND METHODS

Bonding Model

In discrete element numerical simulations, the bond-based contact model, designed by *Potyondy et al.* (*2004*), is a core method for studying material fracture. This model abstracts the interaction between particles as virtual connecting bonds, constructing a mechanical transmission network to simulate the fracture process. Although differing in theory and scale from the finite element method, it complements FEM in multi-physics field coupling. Bond elements possess multi-dimensional mechanical responses, undergoing tension, compression, torsion, and other deformations under load, following Hooke's law. The force-deformation relationship can be quantified using elastic moduli. When stress or torque exceeds a critical threshold, the bond breaks, simulating material crack propagation. The bonding contact model assumes that the bond between two particles is a virtual flat plate or cylinder, as illustrated in Figure 1.

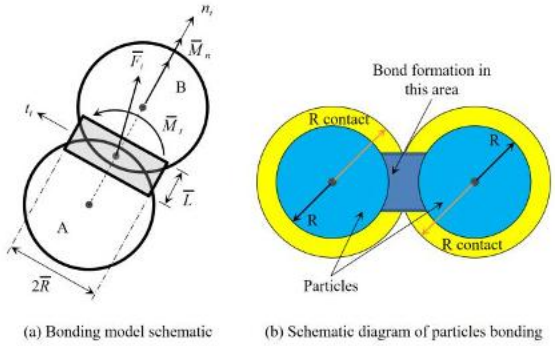

Fig. 1 - Schematic diagram of Bonding Model principle and particle bonding

During relative displacement between two particles, the plate or cylindrical structure is subjected to mechanical actions such as tension, bending, and shear. The force and moment increments on the bond are calculated as follows:

$$\begin{cases} \delta F_n = -v_n S_n A \delta t \\ \delta F_t = -v_t S_t A \delta t \\ \delta M_n = -\omega_n S_t J \delta t \\ \delta M_t = -\omega_t S_n \dfrac{J}{2} \delta t \end{cases} \quad (1)$$

$$\begin{cases} A = \pi R_B^2 \\ J = \dfrac{1}{2} \pi R_B^4 \end{cases} \quad (2)$$

where:

δF_n is the normal force, N; δF_t is the tangential force, N; v_n is the normal velocity, m/s; v_t is the tangential velocity, m/s; S_n is the normal stiffness, N/m; S_t is the tangential stiffness, N/m; δ_t is the simulation time step, s; A is the contact area between particles, m²; δM_n is the normal moment increment, N·m; δM_t is the tangential moment increment, N·m; ω_n is the normal angular velocity, rad/s; ω_t is the tangential angular velocity, rad/s; J is the particle moment of inertia, mm⁴; R_B is the bonded disk radius, mm.

Discrete Element Modeling of Astragalus Root Segment Particles

Astragalus roots from Dingxi, Gansu (density 0.912g/cm³) were cut into 37.5 mm-long uniform segments for geometric modeling. The Bonded Particle Method (BPM) (*Su et al., 2021*) was adopted to establish the discrete element model (DEM) for Astragalus root fracture analysis, where equal-diameter spherical particles are bonded to represent the root structure. A cylindrical bonding model was constructed, and 0.5 mm-radius spherical particles were finally selected for parameter calibration after comprehensive comparison of different particle sizes.

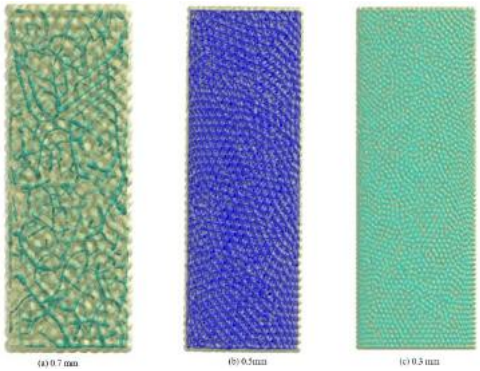

Fig. 2 - Filling diagrams using spherical particles of different diameters

Uniaxial Compression Test

Physical Experiment

Astragalus root segments with a diameter of 14 mm and length of 37.5 mm were selected. Uniaxial compression tests were performed on the segments using a universal testing machine. Loading was applied at a constant speed of 0.1 mm/s until specimen failure occurred. The loading process of a specimen during the uniaxial compression test is shown in Figure 3. The test was repeated 8 times, and the average displacement-load curve for the Astragalus segments is presented in Figure 4.

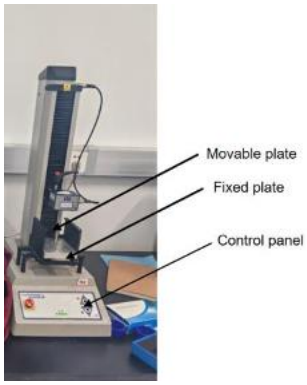

Fig. 3 - Universal testing machine

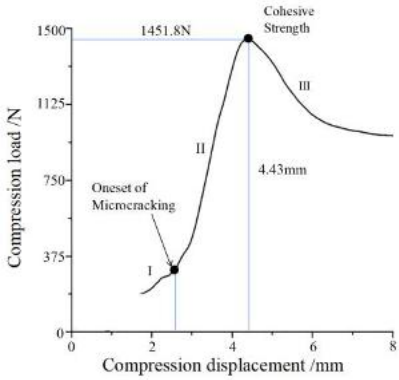

Fig. 4 - Displacement-load curve

Simulation Experiment

A uniaxial compression simulation model consistent with physical tests was established in EDEM 2022 (Figure 5). Material parameters are listed in Table 1. Simulation settings: total time 4 s, time step 8.5×10^{-6} s, data interval 0.01 s, grid size 3 times the radius of the smallest spherical particle.

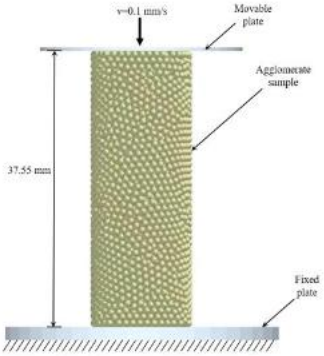

Fig. 5 - Uniaxial compression experiment simulation setup

Table 1

Physical property parameters of materials

Item	Parameter	Value
Astragalus	Poisson's Ratio	0.25
	Density (kg/m³)	912
	Shear Modulus (Pa)	2.17×10^{6}
Steel	Poisson's Ratio	0.3
	Density (kg/m³)	7850
	Shear Modulus (Pa)	8×10^{9}
Astragalus-Steel	Coefficient of Restitution	0.45
	Static Friction Coefficient	0.22
	Rolling Friction Coefficient	0.10
Astragalus-Astragalus	Coefficient of Restitution	0.51
	Static Friction Coefficient	0.43
	Rolling Friction Coefficient	0.15

Plackett-Burman Experimental Design

The Plackett-Burman design assesses factor significance by comparing two-level responses for each factor, taking ultimate crushing load (F_R) and displacement (L) as optimization objectives. Five factors (normal stiffness A, tangential stiffness B, critical normal stress C, critical tangential stress D, bonding radius E) were set at two levels. An 11-run design with 6 dummy terms for error analysis was used, and detailed factor levels are given in Table 2.

Table 2

Plackett-Burman experimental factor levels

No.	A	B	C	D	E
1	1.0×10^{7}	8.0×10^{6}	6.1×10^{6}	4.7×10^{6}	0.55
2	1.1×10^{7}	9.0×10^{6}	7.3×10^{6}	5.8×10^{6}	0.60

The simulation experimental design results are shown in Table 3.

Table 3

Plackett-Burman experimental design

No.	A	B	C	D	E	F_R/(N)	L/(mm)
1	1.1×10^{7}	9.0×10^{6}	6.1×10^{6}	5.8×10^{6}	0.60	1511	4.85
2	1.0×10^{7}	9.0×10^{6}	7.3×10^{6}	4.7×10^{6}	0.60	1484	5.05

Steepest Ascent Experimental Design

The Plackett-Burman results indicated that factor C had no significant effect on the experimental outcomes; therefore, C was fixed at 6.7×10^{6} Pa. A steepest ascent experiment was conducted to identify parameter combinations closer to the true values, with the experimental plan and results shown in Table 4.

Table 4

Steepest ascent experimental design

No.	A	B	D	E	F_R/(N)	L/(mm)

Box-Behnken Experimental Design

Design-Expert software was utilized to construct a Box-Behnken simulation experimental system for the significant contact parameters. The 7th level from the steepest ascent test was set as the central reference point (coded value 0). The 6th and 8th levels were defined as the low level (coded value -1) and high level (coded value +1), respectively, as shown in Table 5.

Table 5

Coding table for significant factor levels

Level	A	B	D	E
-1	6.25×10^6	9.15×10^6	8.00×10^6	0.625
0	5.40×10^6	9.28×10^6	8.55×10^6	0.635
+1	4.55×10^6	9.41×10^6	9.10×10^6	0.645

The experimental plan and results are shown in Table 6.

RESULTS AND ANALYSIS

Uniaxial Compression Test Results

As shown in Figure 4, the force-displacement curve of Astragalus root segments consists of three stages. Stage I involves local damage with rapid initial force growth followed by a slow increase, while the main body remains intact. Stage II is the main failure process: the load exceeds the bearing capacity, force peaks at the failure point. Stage III shows force decreasing with displacement, presenting oblique shear fracture.

The average ultimate crushing load of eight segments (14 mm diameter, 37.5 mm length) is 1451.8 N, with a corresponding ultimate displacement of 4.43 mm.

Plackett-Burman Test Significance Analysis

Design-Expert software was used to conduct ANOVA and t-tests (Table 7, Figure 6). For ultimate crushing load F_R, the influencing order was E > B > A > D > C; E, B and A posed significant effects (P<0.05) with all positive effect values, as confirmed by the Pareto chart. For ultimate crushing displacement L, the order was A > E > D > B > C; A, E and D showed significant effects (P<0.05), with positive effects for E, D, B, C and negative effect for A, as confirmed by the Pareto chart.

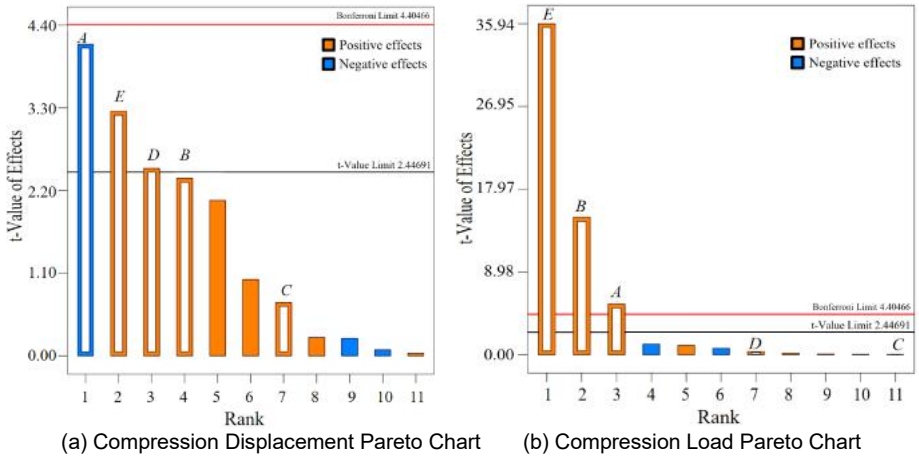

Table 7

Steepest Ascent Test Analysis

Combining the data in Table 4, it can be observed that the error between the simulated ultimate crushing load/displacement and the real values first decreased and then increased during the steepest ascent experiment. The 7th test group exhibited the highest agreement between the simulated F_R and L values and the real values.

Box-Behnken Test Significance Analysis and Parameter Optimization

Design-Expert 13 software was used to analyze the experimental data in Table 6. The ANOVA results are presented in Table 8. From Table 8, it can be seen that the quadratic regression models for both F_R and L were highly significant (P < 0.0001), and the lack-of-fit terms were not significant (P > 0.05), indicating high model accuracy. Factors A, B, and E were significant for both responses. For F_R, the order of influence was E > A > B. For L, the order of influence was also E > A > B.

The regression equations relating the factors to the ultimate crushing load F_R and ultimate crushing displacement L are:

$$\begin{cases} F_R = 1458 + 36.93A + 14.67B + 0.7667D + 39.44E + 2.6AB + 0.475AD - 9.47AE \\ \quad -2.63BD + 0.45BE + 0.25DE - 6.65A^2 + 1.92B^2 + 2.73D^2 - 4.31E^2 \\ L = 4.45 + 0.5033A + 0.1558B + 0.0317D + 0.4808E + 0.325AB + 0.005AD - 0.125AE \\ \quad -0.035BD + 0.1625BE - 0.025DE - 0.2067A^2 - 0.018B^2 - 0.1318D^2 - 0.003E^2 \end{cases} \quad (3)$$

To precisely determine the optimal parameter combination for each factor, the constraint range needed to be further narrowed. The target values for F_R and L were known to be 1451.8 N and 4.43 mm, respectively. Combining the data from Table 6, experimental runs 2, 11, 26, and 28 exhibited F_R and L values closest to the actual values. Based on the ANOVA results, since factor D had the lowest influence on both F_R and L, it was fixed at its central level (8.55×10^{6}Pa). The constraint ranges were set as follows:

$$\begin{cases} F = 1451.8\text{N} \\ L = 4.43\text{mm} \\ 4.55\times10^6\,\text{N/m}^3 \le A \le 6.25\times10^6\,\text{N/m}^3 \\ 9.15\times10^6\,\text{N/m}^3 \le B \le 9.41\times10^6\,\text{N/m}^3 \\ D = 8.55\times10^6\,Pa \\ 0.635 \le E \le 0.645 \end{cases} \quad (4)$$

Optimization solving was performed using Design-Expert 13. The optimal solution yielded values of A=5.3603×10^6 N/m³, B=9.23842×10^6 N/m³, D=8.55×10^6 Pa, E=0.635 mm. At this point, the predicted values for F_R and L were 1451.8 N and 4.38 mm, respectively. A simulation verification run using this parameter combination resulted in simulated F_R and L values of 1451.2 N and 4.31 mm, respectively. The relative errors compared to the real values were 0.04% and 1.6%, respectively.

As shown in Figure 7, the simulation results for load and displacement are generally consistent with the experimental data. The relative errors of the simulated values compared to the actual measurements are 0.04% and 1.6%, respectively. These findings suggest that the aforementioned parameters exhibit a high degree of reliability, thereby validating the applicability of the discrete element method for simulating the mechanical behavior of Astragalus roots.

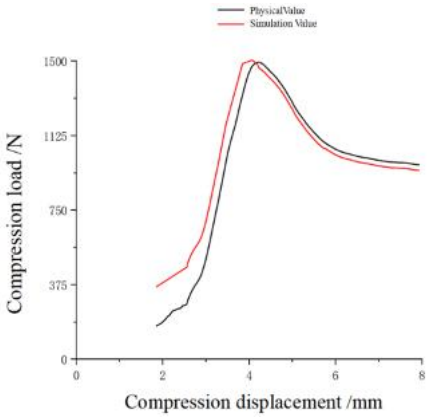

Fig. 7 - Deviation diagram of simulation value and test value

Verification test of the Bonding model breakage of Astragalus Root Granules

Experimental purpose

To verify the reliability of the parameter combination for the Astragalus root granule bonding model, this study simulated its actual crushing process in a hammer mill (including hammer impact, cavity wall extrusion and toothed ring shearing). The bond state and velocity distribution data were obtained to validate the model's characterization ability for Astragalus root crushing mechanics. The results provide theoretical support for the rotational speed optimization and structural improvement of traditional Chinese medicine hammer mills.

Test Equipment and Model Construction

Test equipment and materials

A small hammer-type pulverizer for Chinese medicinal materials (Figure 8) was used in the experiment. Its core parameters include a crushing chamber inner diameter of 165 mm and a screen mesh diameter of 0.5 mm. During operation, the high-speed rotating hammers impact and shear the material with toothed rings, and the screen controls the particle size. The experimental material was Astragalus roots from Dingxi, Gansu, cut into standard segments of 37.5 mm in length and 14 mm in diameter. Five intact and uniform segments were selected for the test.

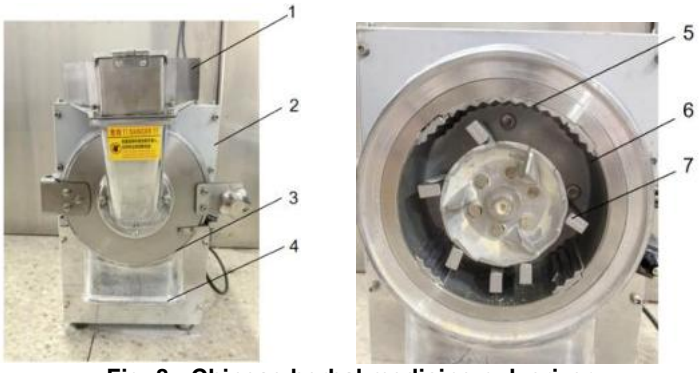

Fig. 8 - Chinese herbal medicine pulverizer

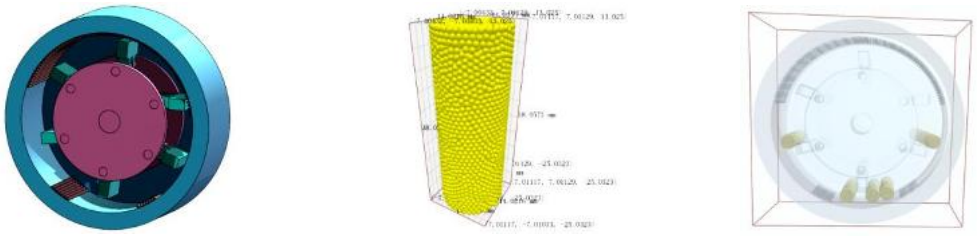
1. feed inlet; 2. electrical control box; 3. crushing chamber; 4. Discharge outlet; 5. toothed ring; 6. screen; 7. hammers

3D model and simulation Settings

The three-dimensional model of the inner wall of the crusher was constructed using SolidWorks 2024 (as shown in Figure 9a), including the crushing chamber, hammer pieces, toothed ring and other structures. The model was exported in .STL format and then imported into the Discrete element software EDEM 2022.

The virtual simulation test was conducted at the same rotor speed as the real test. The calculation formula for the particle breakage rate η of Astragalus root under each condition is:



$$\eta = \frac{m_1}{m_0} \times 100\% \tag{5}$$

In the formula:

m_1 represents the mass of the powder, (g)'

m_0-total mass of Astragalus membranaceus roots in the test, 20.5 g

A total of 7,200 1 mm-diameter Astragalus granules were bonded to construct the Astragalus root granule model using the bonding model (Figure 9b). According to the material parameters in Table 1, the Poisson's ratio, density and shear modulus of Astragalus granules and steel crushing components were defined, and the collision recovery coefficient, static and rolling friction coefficients between Astragalus and steel, as well as those between Astragalus granules were set. The crusher geometry and Astragalus root granule model were imported into the discrete element software (Figure 9c). The simulation was run for 30 s with a time step of 7.0×10^{-6} s and data saved every 0.01 s to reproduce the actual crushing process of Astragalus root.

(a) Three-dimensional model of the inner wall; (b) Astragalus Root Granules Bonding model; (c) Simulation diagram

Fig. 9 - Schematic diagram of simulation modeling for crushing Astragalus root

Test method

Real crushing experiment

A real crushing test of Astragalus roots was conducted using the traditional Chinese medicine hammer crusher shown in Figure 10. Before the test, the equipment was pre-started, and Astragalus roots were fed slowly after the rotor speed stabilized. In the crushing chamber, roots were crushed by hammer impact, chamber wall compression and inter-particle collision, with crushed products discharged from the lower outlet. During the test, samples from the outlet and chamber inner wall were collected every 5 seconds. Morphology photos were taken at 5, 10, 15, 20, 25 and 30 seconds (right side of Figure 10), and the test was terminated at 30 seconds.

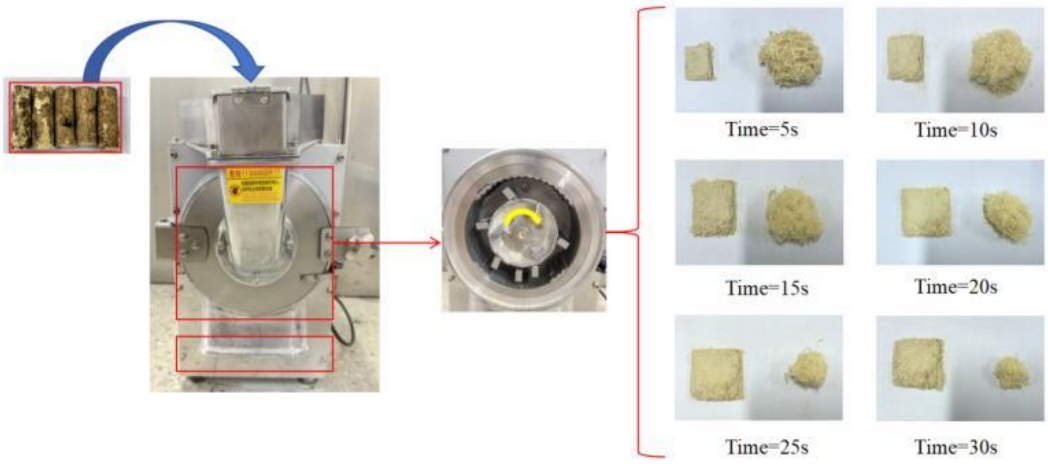


Fig. 10 - Bench test

Simulation crushing test

In EDEM 2022, rotor speed was set to 2840 r/min to match physical conditions. The discrete element model of Astragalus root particles, constructed based on the Bonding model, was imported to simulate the crushing process. Velocity field, vector distribution, and bond status evolution were recorded at 0, 5, 10, 15, 20, 25, and 30 s, with results shown in Figure 11.

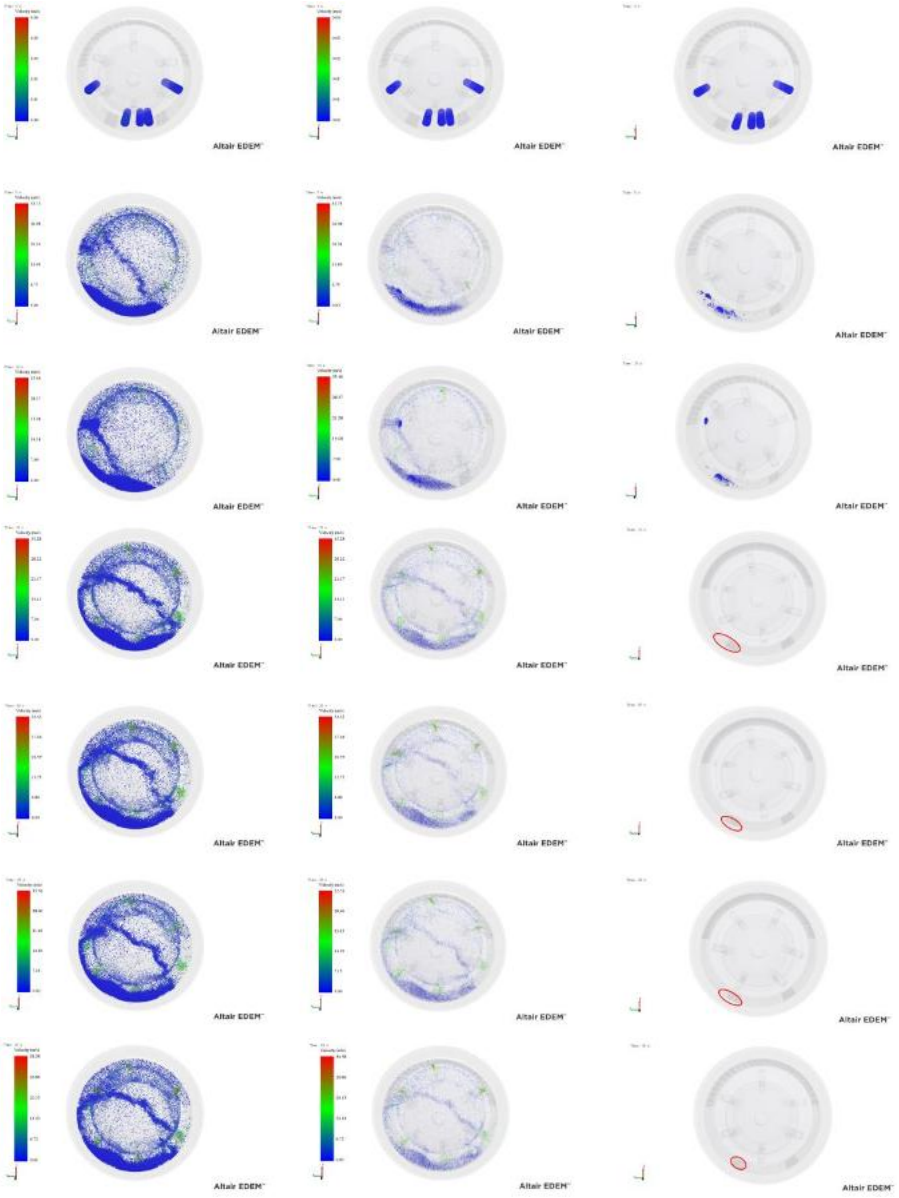

Fig. 11 - Simulation process of crushing Astragalus Root Granules

Test results

At a crusher speed of 2840 r/min, the error between the simulated and actual crushing rates of Astragalus root granules is 6.3%–12.7% as shown in Figure 12, which verifies the high accuracy of the calibrated bonding model parameters.

The crushing simulation presents three successive stages: initially, particles are agglomerated and static with complete bonds; subsequently, particles disperse and refine with increased velocity differences and large-scale bond breakage; finally, particles become fine and uniform, accompanied by a stable velocity field and nearly full bond dissociation.

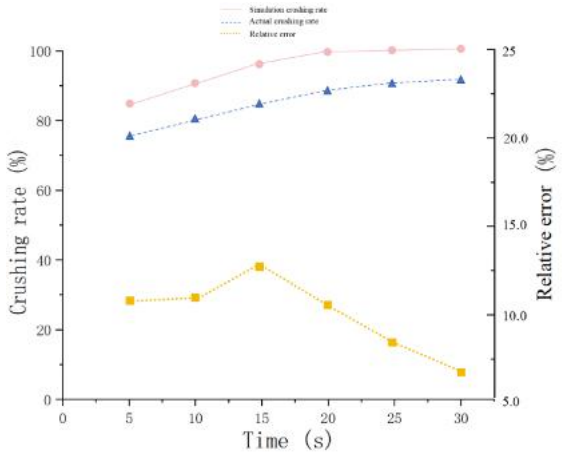

Fig. 12 - The breakage rate at different times

CONCLUSIONS

Uniaxial compression tests of Astragalus root segments were carried out to obtain its mechanical properties, with an ultimate crushing load of 1451.8 N and an ultimate crushing displacement of 4.43 mm. Significant factors were screened via the Plackett-Burman design, the parameter range was narrowed by the steepest ascent test, and the optimal Bonding Model parameters were determined by Box-Behnken optimization: normal stiffness per unit area 5.3603×10^{6} N/m³, shear stiffness per unit area 9.23842×10^{6} N/m³, critical shear stress 8.55×10^{6}Pa, bonded disk radius 0.635 mm. Uniaxial compression simulation verification shows that the relative errors of ultimate crushing load and displacement are only 0.04% and 1.6%, respectively. The parameters were applied to Astragalus root crushing simulation, accurately characterizing the evolution of velocity field, vector distribution and bond state, with a crushing rate error of 6.3%–12.7%, verifying their reliability. This study provides accurate parameter support for DEM simulation and intelligent design of Astragalus processing equipment, and offers a new reference for mechanical simulation of granular Chinese medicinal materials.

ABSTRACT

This study proposes a real-time method for detecting combine-harvester feed quantity based on multi-source information fusion and error correction, with the aim of addressing control delays caused by information lag. Field tests were conducted to obtain key parameters, including feeding-auger torque and threshing-drum torque, determine their relational weights, and establish a prediction model. The model achieved a maximum relative error of 9.64% and a mean relative error of 4.55%, meeting the requirements of practical field operation.

摘要

本研究旨在提出一种基于多信息融合与误差修正的联合收割机喂入量实时检测方法，以解决信息滞后导致的控制延迟问题。通过田间试验获取喂入搅龙转矩和脱粒滚筒转矩等关键参数，确定其关联权重，并建立预测模型。模型检测最大相对误差 9.64%，平均相对误差 4.55%，可满足实际作业需求。

INTRODUCTION

Combine harvesters possess the capability to carry out integrated multi-harvesting operations that encompass the direct harvesting of grain from the field. To maximize operational efficiency, parameters such as the feed quantity of the harvester and the width of the header have been progressively increasing in recent years (*Mathanker et al., 2015; Jiang et al., 2025; Chen et al., 2019*). Nevertheless, achieving an effective match between the separation, cleaning capabilities, and feed quantity of the harvester remains a pressing concern in practical operations. This is due to the challenges posed by excessive grain loss and high impurity content during the operational process. Consequently, it holds great significance to investigate a precise and efficient method for predicting the feed quantity of harvesters (*Li et al., 2024; Sun et al., 2022; Zhang et al., 2025*), which would facilitate comprehensive performance control and harvest loss reduction (*Wang et al., 2026*). The feed quantity of the harvester is defined as the total mass of harvested crops that are conveyed to the harvester feeding auger per unit time. The feed quantity is a crucial performance parameter of harvesters during harvesting operations, as it reflects the overall performance of the operation (*Li et al., 2026; Liang et al., 2024; Zhang et al., 2024*). The performance of the harvester can be affected by an excessive or insufficient feed quantity (*Saeys et al., 2009; Zhang et al., 2022*). A larger feed quantity, for instance, may cause the harvester to become overloaded, thus diminishing the overall performance of the operation, while increasing the rate of grain loss and damage. Conversely, a smaller feed quantity can lead to a significant decrease in operational efficiency and an increase in entrainment loss during operation, resulting in a reduced overall performance of the harvester. Consequently, accurate detection of the feed quantity of the harvester is highly significant and merits attention (*Wang et al., 2023; Abdeen et al., 2022; Chen et al., 2025; Yang et al., 2025*).

Four main approaches are currently used to detect or estimate combine-harvester feed quantity. The first estimates feed quantity by directly measuring the grain flow rate within the harvester *(Liu et al., 2018; Sangeetha et al., 2024)*. The second predicts feed quantity from the power consumption of the threshing mechanism. The third combines real-time grain-flow measurements with threshing-drum power consumption to improve feed-quantity estimation. The fourth predicts feed quantity by monitoring the torque and compressive force of key harvester components during operation *(Fricke et al., 2011; Ebrahimi et al., 2009; Wang et al., 2026)*.

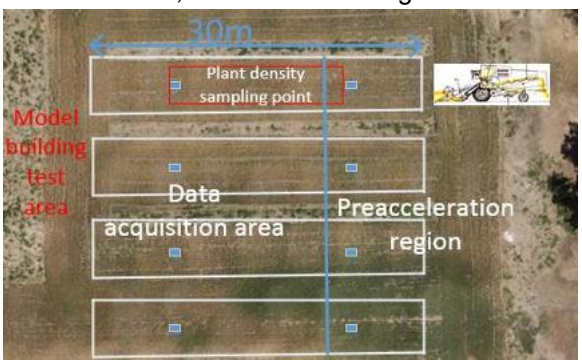
Firstly, the correlation weight is employed to scrutinize and define the correlation extent of every influential factor towards the forecasting of feed quantity. Subsequently, by scrutinizing the feed quantity time lag of the data samples procured from sensors that exert a significant impact on the indicators, a multi-information integration-based error correction technique is proposed to rectify the model. Finally, a field validation experiment is formulated and executed to authenticate the efficiency of the formulated feeding prediction model.

First, grey relational analysis was used to determine the relative influence of each factor on feed-quantity prediction. Next, the time delays in the sensor data associated with the parameters having the greatest influence on feed quantity were analyzed, and an error-correction method based on multi-source information fusion was developed to improve the prediction model. Finally, field-validation experiments were designed and conducted to evaluate the effectiveness of the proposed feed-quantity prediction model.

MATERIALS AND METHODS

Sample data acquisition test design

The field experiment was conducted at the wheat plantation base of Qingdao Jimo Shengfa Cooperative, using the GM series wheat combine harvesters of Lovol Geso as the experimental prototype. The experimental procedures were carried out in strict accordance with the national standard GB/T8097-2008 Equipment for Harvesting — Combine Harvesters — Test Procedure. According to this standard, the test plot was selected with a length of no less than 30 m and a width sufficient to accommodate the full working width of the header, ensuring stable and representative operating conditions. For each test run, the combine harvester was operated at a constant preset speed over a total distance of 30 m in a straight line. The first 10 m served as the preliminary acceleration and stabilization phase, during which no data were recorded. Once the harvester reached the steady operating state, data were collected over the remaining 20 m sampling distance. Each test condition was repeated three times, and the mean values of each parameter were used for subsequent analysis to minimize random experimental errors, as illustrated in Fig. 1.



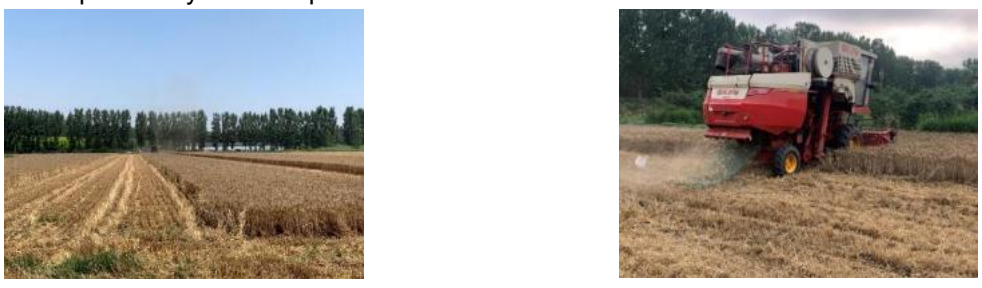


Fig. 1 - Schematic diagram of combine harvester field test scheme

Prior to the formal tests, a preliminary sampling survey of wheat crop properties was conducted within the test plot. Five representative 1 m × 1 m sampling areas were randomly selected to determine crop density, with the above-ground biomass harvested, oven-dried to constant weight at 105 °C, and weighed using an electronic balance (accuracy ±0.01 kg). The results indicated that the wheat had fully ripened, with a grain moisture content of 14.2% ± 0.5%, as measured by a grain moisture meter (PM-8188, Kett Electric Laboratory, Japan), which satisfied the harvesting standards specified in GB/T8097-2008. The test terrain was flat and the wheat growth was uniform with minimal weed presence, as illustrated in Fig. 2. These site conditions ensured the reliability and repeatability of the experimental data.

Fig. 2 - Wheat growth and field test

a) Field harvesting operation scene; b) Field harvesting operation scene

In the sampling area, a mesh collection bag was securely attached to the rear of the harvester to collect all impurities and threshed straw discharged during operation. After the harvester completed a 20 m test run, the contents of the bag were removed, sorted, and weighed, and a portion was retained as samples for subsequent tests. Ten tests were conducted following this procedure. For each test, the mean value of each performance index was used as the dataset for the corresponding group, as shown in Table 1.

Table 1

Field test data of operation parameters of key components of combine harvester

No.	Average feeding Quantity (kg/s)	Harvest speed (m/s)	Feeding auger torque(Nm)	Feeding auger rotation speed (r/min)	Threshing drum torque (Nm)	Threshing drum rotation speed (r/min)	Fan speed (r/min)

Analysis of the feed-quantity prediction model

Analysis of the relative influence of different factors

Feed quantity is affected by multiple operating parameters, and analyzing it on the basis of a single variable may introduce considerable uncertainty. Therefore, the grey relational weighting method was used to evaluate the relative influence of each factor on feed quantity and to clarify the effects of the different operating parameters. The procedure for determining the relational weights included establishing the reference sequence, normalizing the comparison sequences, calculating the relational coefficients between the reference and comparison sequences, and determining the grey relational grades. Feed quantity was selected as the reference sequence, while operating speed, feed-auger torque and rotational speed, and threshing-drum torque and rotational speed were used as the comparison sequences. The grey relational weighting method was then applied to determine the relative contribution of each factor to feed quantity, as shown in Fig. 3. The factors were ranked according to their relational weights as follows: harvester operating speed, 0.89; feeding auger torque, 0.84; and threshing drum torque, 0.72.

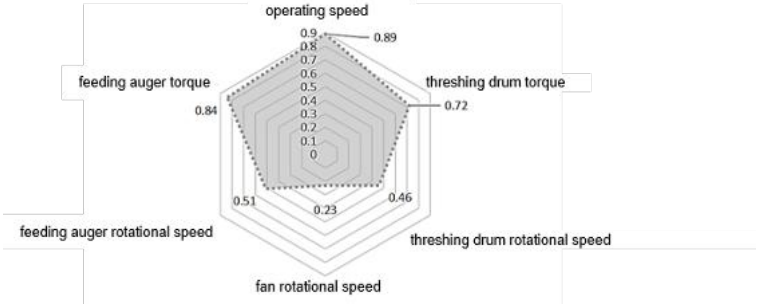

Fig. 3 - Influence weight of various factors on feed quantity

Analysis of the feed-quantity prediction model

Feed quantity is influenced not only by the operating parameters of the combine harvester but also by field crop characteristics, among which crop density is a key factor. To simplify the analysis and incorporate the measured crop-density data, crop density was divided into three categories: low, medium, and high. The corresponding ranges were 0.7~1.0kg/m^2, 1.0~1.3 kg/m^2, and 1.3~1.8 kg/m^2, respectively. By analyzing the relationship between the different crop-density ranges and feed quantity, a more accurate feed-quantity prediction model can be established.

Relationship between operating speed and feed quantity

Figure 4 presents the curve-fitting results based on the experimental data and shows the relationship between operating speed and feed quantity under low-, medium-, and high-crop-density conditions.

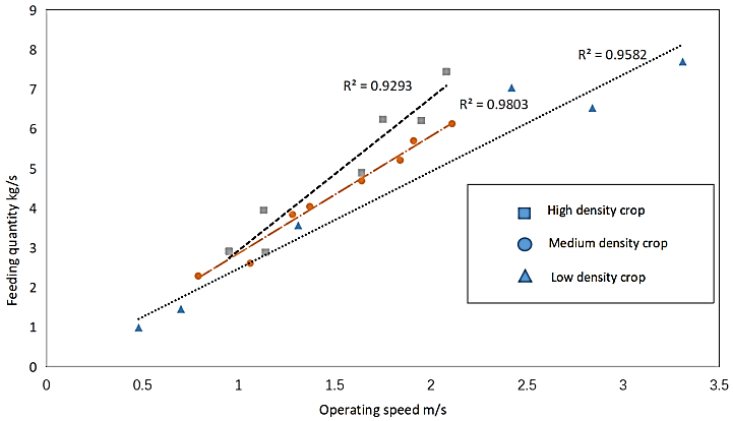

Fig. 4 - Regression curve between operating speed and feed quantity

The results shown in Fig. 4 indicate that, at the same operating speed, harvester feed quantity generally increased with crop density under low- and medium-speed conditions. However, under high-speed conditions, feed quantity was lower in the medium- and high-density crop regions than in the low-density crop region. To account for the combined effects of crop density and operating speed, their product was used as a composite influencing factor. A scatter plot describing the relationship between this factor and feed quantity is presented in Fig. 5.

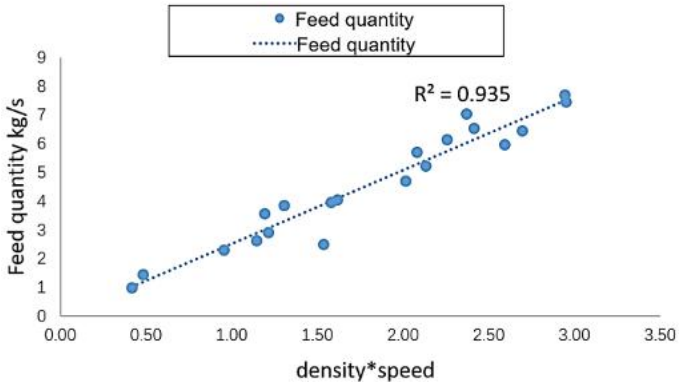

Fig. 5 - Regression relationship between the product of operating speed and wheat crop density and feed quantity

Table 2 presents the least-squares linear regression model for feed quantity, obtained by regressing harvester feed quantity against the product of operating speed and crop density.

Table 2

Regression relationship between the product of operating speed and wheat density and feed quantity

Model form	Regression equation	Coefficient of determination
y=a x+b	y=2.5668x+0.0632	0.935

Relationship between threshing-drum torque and feed quantity

Fig. 6 presents the curve-fitting results obtained from the experimental data and shows the relationship between threshing-drum torque and feed quantity under different crop-density conditions.

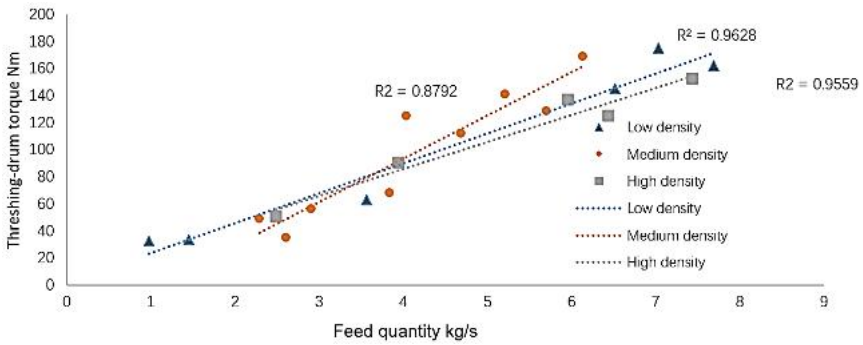

Fig. 6 - Relationship between threshing-drum torque and feed quantity under different crop-density conditions

As shown in Fig. 6, threshing-drum torque exhibited a strong linear relationship with feed quantity under low- and high-crop-density conditions. Under medium-crop-density conditions, the coefficient of determination was lower than those obtained for the other two density levels, although the linear relationship remained relatively strong. The corresponding regression models are presented in Table 3. These results indicate that a piecewise feed-quantity prediction model based on crop-density level is appropriate.

Table 3

Regression models relating feed quantity to threshing-drum torque under different crop-density conditions

Crop-density level	Model form	Regression equation	Coefficient of determination
Low density	y=a x+b	y=22.102x+34.83	0.9628
Medium density	y=a x+b	y=32.039x-34.837	0.8792
High density	y=a x+b	y=19.911x+34.83	0.9559

A multi-model regression analysis was conducted for the medium-crop-density condition to identify the most appropriate relationship between feed quantity and threshing-drum torque. The fitted models and their corresponding parameters are presented in Table 4, while the regression curves for the different model forms are shown in Fig. 7.

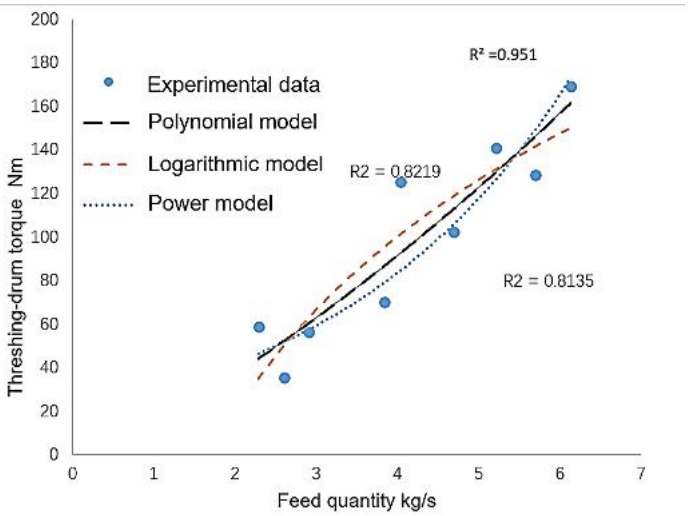

Fig. 7 - Regression curves relating feed quantity to threshing-drum torque using different model forms

As shown in Fig. 7, the quadratic model provided the best fit, with a higher coefficient of determination than the logarithmic and power models. Therefore, the quadratic model was selected to predict feed quantity under medium-crop-density conditions. The parameters and coefficients of determination of the fitted models are presented in Table 4.

Table 4

Comparison of regression models relating feed quantity to threshing-drum torque under medium-crop-density conditions

Crop-density level	Model form	Regression equation	Coefficient of determination
Low density	y=a x+b	y=22.102x+34.83	0.9628
Medium density	y=a x+b	y=32.039x-34.837	0.8792
High density	y=a x+b	y=19.911x+34.83	0.9559

In conclusion, linear regression models were suitable for describing the relationship between feed quantity and threshing-drum torque under low- and high-crop-density conditions, whereas a quadratic regression model was more appropriate under medium-crop-density conditions. The final piecewise prediction models are summarized in Table 5.

Table 5

Piecewise regression models relating feed quantity to threshing-drum torque

Crop-density level	Model form	Regression equation	Coefficient of determination
Low density	y=a x+b	y=22.102x+34.83	0.9628
Medium density	y=ax2+bx+c	y=1.3429x2+19.212x -6.7705	0.951
High density	y=a x+b	y=19.911x+34.83	0.9559

Analysis of the relationship between feeding-auger torque and feed quantity

Based on the experimental data, scatter plots were generated to illustrate the relationship between feeding-auger torque and feed quantity under different crop-density conditions. Regression analysis was then performed, and the fitted curves are presented in Fig. 8.

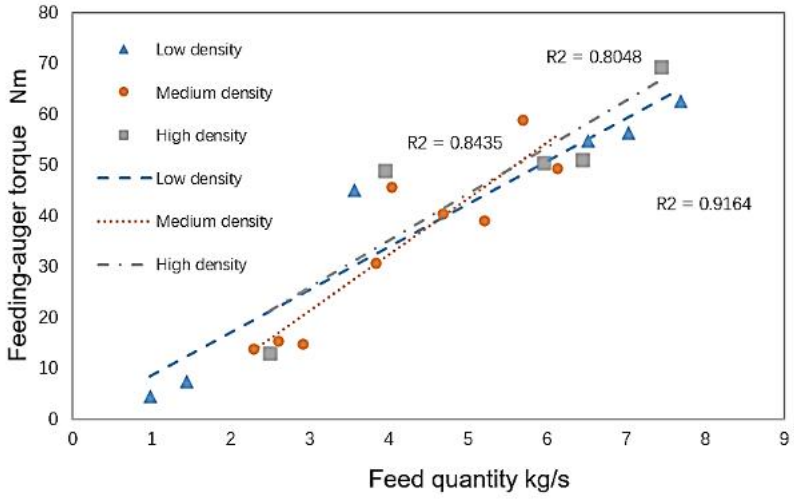

Fig. 8 - Regression curves relating feeding-auger torque to feed quantity under low-, medium-, and high-crop-density conditions

As shown in Fig. 8, feeding-auger torque exhibited a clear linear relationship with feed quantity under all three crop-density conditions. The strength of the relationship was highest under high-crop-density conditions, followed by medium- and low-crop-density conditions. The corresponding linear regression models are presented in Table 6.

Table 6

Linear regression models relating feeding-auger torque to feed quantity under different crop-density conditions

Crop-density level	Model form	Regression equation	Coefficient of determination
Low density	y=a x+b	y=22.102x+34.83	0.9628
Medium density	y=ax2+bx+c	y=1.3429x2+19.212x -6.7705	0.951
High density	y=a x+b	y=19.911x+34.83	0.9559

The analysis results indicated the presence of anomalous data points in the medium-crop-density dataset, which were attributed to irregular sensor measurements. After these anomalous points were removed, the remaining data exhibited a pronounced linear relationship between feeding-auger torque and feed quantity. Therefore, the valid samples obtained under medium-crop-density conditions were combined with those obtained under low-crop-density conditions for linear regression analysis. On this basis, the regression relationship for the medium-crop-density dataset was reconstructed, and the resulting fitted curve is presented in Fig. 9.

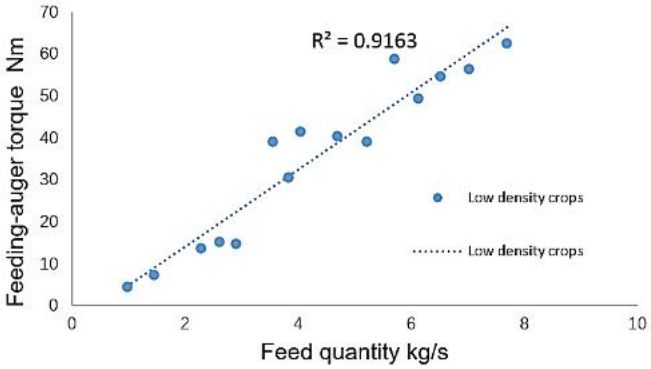

Fig. 9 - Regression relationship between feeding-auger torque and feed quantity under low-crop-density conditions

The data distribution for the high-crop-density condition was plotted, and regression analysis was performed. The resulting fitted curve is presented in Fig. 10.

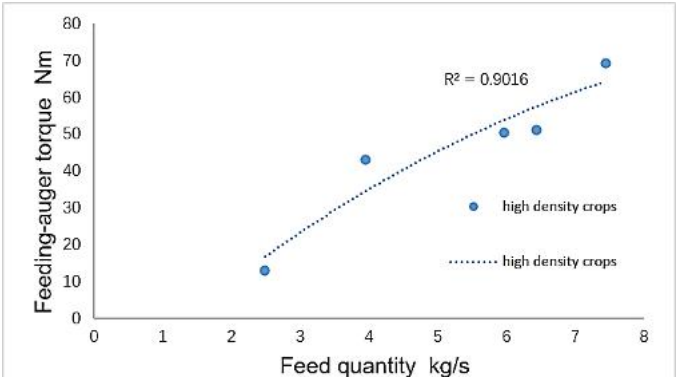

Fig. 10 - Regression relationship between feeding-auger torque and feed quantity under high-crop-density conditions

By comparing Figs. 9 and 10, it can be seen that different regression models were used to describe the relationship between feeding-auger torque and feed quantity under different crop-density conditions. A linear model was used for the combined low- and medium-crop-density data, whereas a quadratic model was used for the high-crop-density data. Both models exhibited relatively high coefficients of determination, indicating good fitting performance. In conclusion, the regression models describing the relationship between feed quantity and feeding-auger torque are presented in Table 7.

Table 7

Regression models relating feeding-auger torque to feed quantity under different crop-density conditions

Crop-density level	Model form	Regression equation	Coefficient of determination
Low and Medium density	y=a x+b	y = 9.1987x - 4.5299	0.9163
High density	y=ax2+bx+c	y=-0.7333x2+16.88x-20.796	0.9016

Analysis of the feed-quantity prediction model

During harvester operation, crop material passes through a series of conveying and processing stages. The wheat plants are first cut at the header and then enter the feeding auger, where they undergo initial compression before being transferred to the conveyor. The crop material is subsequently conveyed through the feeder house to the threshing drum, where threshing takes place. The straw is then separated and discharged, while the grain and impurities pass through the cleaning sieves. Finally, the cleaning system removes the remaining impurities and produces clean grain. Analysis of this material-flow process reveals a spatiotemporal delay between the feeding auger and the threshing drum during crop feeding. Consequently, the data collected from the different harvester components do not correspond to the same crop-material segment at the same instant and therefore cannot directly provide accurate real-time feedback on feed quantity for automatic harvester control.

To achieve spatiotemporal alignment between feed-quantity detection and the signals obtained from the feeding auger and threshing drum, and to reduce prediction delays caused by differences in material transport time, a model describing the crop-material conveying time through the harvester was established. The material-flow process is illustrated in Fig. 11.

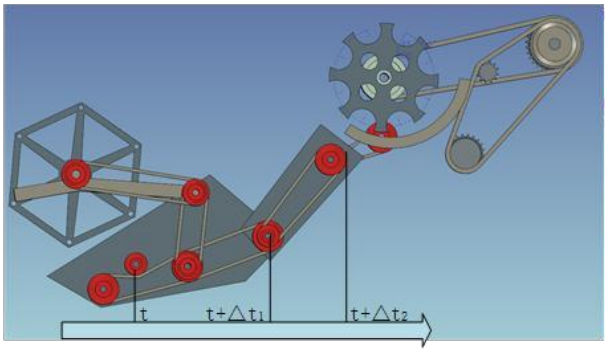

Fig. 11 - Crop-material conveying path through the combine harvester

As shown in Fig. 11, the crop-material conveying process begins when the crop enters the header and is subsequently transported from the feeding auger to the feeder house and then to the threshing drum. The transport time required for these two successive stages produces a delay in the crop-material flow. Neglecting frictional effects between the crop material and the conveying components, the time delay associated with crop transport from the feeding auger to the front end of the feeder house can be expressed by Eq. (1):

$$\Delta t_1 = \frac{L_1}{\omega_1 R_1} \tag{1}$$

where, L_1 is the effective conveying distance from the feeding auger to the front end of the feeder house, m; ω_1 is the rotational speed of the feeding auger, r/min; R_1 is the radius of the feeding-auger drive shaft, m.

The time delay associated with crop transport from the feeder house to the threshing drum was then analyzed and can be expressed by Eq. (2).

$$\Delta t_2 = \frac{L_2}{\omega_2 R_2} \tag{2}$$

where, L_2 is the effective conveying distance from the front end of the feeder house to the threshing drum, m; ω_2 is the rotational speed of the feeder-house conveyor drive shaft, r/min; R_2 is the radius of the feeder-house conveyor drive shaft, m.

Therefore, the total time delay required for the crop material to travel from the feeding auger to the threshing drum can be expressed by Eq. (3):

$$\Delta t = \Delta t_1 + \Delta t_2 = \frac{L_1}{\omega_1 R_1} + \frac{L_2}{\omega_2 R_2} = \frac{L_1 \omega_2 R_2 + L_2 \omega_1 R_1}{\omega_1 \omega_2 R_1 R_2} \tag{3}$$

Analysis of the crop-material transport delay from the header to the threshing drum indicates that, for a feed quantity $Q(t)$ entering the feeding system at time t, the corresponding operating parameters are the feeding-auger torque $T_1(t)$ and the threshing-drum torque $T_2(t + \Delta t_1 + \Delta t_2)$. The time shift in the threshing-drum torque signal results from the crop-material transport delays between the feeding auger, feeder house, and threshing drum.

By analyzing the relationships among key operating parameters, including feed quantity, operating speed, feeding-auger torque, and threshing-drum torque, this study determines the relative influence of each parameter and evaluates the time delay associated with the threshing-drum torque signal. On this basis, a multi-source information-fusion error-correction model based on relational weights is proposed for feed-quantity prediction. First, the pre-measured crop-density value is entered into the model. The real-time operating speed, feeding-auger torque, and threshing-drum torque are then integrated to obtain a preliminary estimate of feed quantity. Subsequently, the regression model relating threshing-drum torque to feed quantity is used to correct the error caused by the transport delay. The corrected value is then used as feedback to

refine the preliminary prediction. After the correction is completed, the model proceeds to the next feed-quantity prediction cycle.

First, the initial feed-quantity prediction model is formulated as:

$$Q(t) = \varphi_1 Q_1(T_1(t)) + \varphi_2 Q_v(v(t), \rho) + \Delta E(t) \tag{4}$$

where, φ_1 and φ_2 are the weighting coefficients of the prediction model, $Q(T_1)$ is the functional relationship between feed quantity and feeding-auger torque, $Q_v(v, \rho)$ is the functional relationship between feed quantity, operating speed, and crop density, $\Delta E(t)$ is the time-delay error-correction term.

The time-series error obtained from the current prediction cycle is used to correct the subsequent prediction, and the resulting correction term is denoted by $\Delta E(t)$.

First, the initial error sequence is defined as:

$$\Delta E^{(0)}(t) = \{e^{(0)}(t-nT), e^{(0)}(t-(n-1)T), e^{(0)}(t-(n-2)T), \cdots, e^{(0)}(t-(n-m)T), \cdots, e^{(0)}(t)\}$$

$$\begin{cases} n = 1, 2, 3, \ldots \\ m = 1, 2, 3, \ldots, n \end{cases} \tag{5}$$

where, T is the sampling interval of the threshing-drum torque signal. The sampling interval must be shorter than both transport-delay components, such that $T \leq \triangle t_1$ and $T \leq \triangle t_2$.

The elements of the initial error sequence are then expressed as:

$$\begin{aligned} e^{(0)}(t-(n-m)T) = \varphi_3 (Q_2(T_2(t-(n-m)T)) - Q(t-(n-m)\Delta t_1 T)) \\ - Q(t-(n-m)(\Delta t_1 + \Delta t_2)T)) \end{aligned} \tag{6}$$

where, $Q_2(T_2)$ is the functional relationship between threshing-drum torque and feed quantity, and φ_1, φ_2 and φ_3 are the relational weighting coefficients corresponding to operating speed, feeding-auger torque, and threshing-drum torque, respectively.

By applying the accumulated generating operation to △E(0)(t), the following accumulated sequence is obtained:

$$\begin{aligned} \Delta E^{(1)}(t) &= \left\{e^{(1)}(t-nT), e^{(1)}(t-(n-1)T), e^{(1)}(t-(n-2)T), \ldots, e^{(1)}(t-(n-m)T), \ldots, e^{(1)}(t)\right\} \\ e^{(1)}(t-(n-m)T) &= \sum_{i=1}^{m} e^{(0)}(t-(n-i)T) \end{aligned} \tag{7}$$

A first-order whitening differential equation is then established for the elements of the accumulated error sequence, as expressed in Eq. (8):

$$\frac{de^{(1)}}{dt} + ae^{(1)} = w \tag{8}$$

By discretizing Eq. 8, Eq. (9) is obtained:

$$\Delta^{(1)}(e^{(1)}(m+1)) + az^{(1)}(e(m+1)) = w \tag{9}$$

where, a and w are parameters to be determined.

The restored value of the sequence at time $m+1$ is then obtained by applying the inverse accumulated generating operation, as expressed in Eq. (10):

$$\begin{aligned} \Delta^{(1)}(e^{(1)}(m+1)) &= \Delta^{(0)}[e^{(1)}(m+1)] - \Delta^{(0)}[e^{(1)}(m)] = e^{(1)}(m+1) - e^{(1)}(m) = u^{(0)}(m+1) \\ z^{(1)}(e(m+1)) &= \frac{1}{2}(e^{(1)}(m+1) + e^{(1)}(m)) \end{aligned} \tag{10}$$

Substituting Eq. (10) into Eq. (9) yields Eq. (11):

$$e^{(0)}(m+1) = a[-\frac{1}{2}(e^{(1)}(m) + e^{(1)}(m+1))] + w \tag{11}$$

By expanding Eq. (11) in series form, Eq. (12) is obtained:

$$\begin{bmatrix} e^{(0)}(2) \\ e^{(0)}(3) \\ \cdot \\ \cdot \\ \cdot \\ e^{(0)}(m) \end{bmatrix} = \begin{bmatrix} -\frac{1}{2}(e^{(1)}(1)+e^{(1)}(2)) & 1 \\ -\frac{1}{2}(e^{(1)}(2)+e^{(1)}(3)) & 1 \\ \cdot & \cdot \\ \cdot & \cdot \\ \cdot & \cdot \\ -\frac{1}{2}(e^{(1)}(m-1)+e^{(1)}(m)) & 1 \end{bmatrix} \begin{bmatrix} a \\ w \end{bmatrix} \tag{12}$$

The auxiliary expressions are defined as follows:

$$Y = \begin{bmatrix} e^{(0)}(2) \\ e^{(0)}(3) \\ \cdot \\ \cdot \\ \cdot \\ e^{(0)}(m) \end{bmatrix} \tag{13}$$

$$B = \begin{bmatrix} -\frac{1}{2}(e^{(1)}(1)+e^{(1)}(2)) & 1 \\ -\frac{1}{2}(e^{(1)}(2)+e^{(1)}(3)) & 1 \\ \cdot & \cdot \\ \cdot & \cdot \\ \cdot & \cdot \\ -\frac{1}{2}(e^{(1)}(m-1)+e^{(1)}(m)) & 1 \end{bmatrix} \tag{14}$$

$$\Phi = [a \quad w]^T \tag{15}$$

Substituting Eqs. (13)–(15) into Eq. (12) yields the corresponding sequence:

$$Y = B\Phi \tag{16}$$

The parameter vector Φ can then be estimated using the least-squares method, as expressed in Eq. (17):

$$\Phi = [a, w]^T = (B^T B)^{-1} B^T Y \tag{17}$$

Accordingly, the time-response sequence can be derived as:

$$\hat{e}^{(1)}(m+1) = [e^{(1)}(1) - \frac{w}{a}]e^{-am} + \frac{w}{a} \tag{18}$$

By substituting Eq. (11), the restored original sequence is obtained as follows:

$$\hat{e}^{(0)}(m+1) = \hat{e}^{(1)}(m+1) - \hat{e}^{(1)}(m) = (1-e^{a})[e^{(1)}(1) - \frac{w}{a}]e^{-am} \tag{19}$$

For the known weighting-coefficient vector ϕ=[$\phi 1, \phi 2, \phi 3, \phi 4$], the grey relational grade vector is defined as shown in Eq. (20):

$$\hat{e}^{(0)}(m+1) = \hat{e}^{(1)}(m+1) - \hat{e}^{(1)}(m) = (1-e^{a})[e^{(1)}(1) - \frac{w}{a}]e^{-am} \tag{20}$$

The weighting coefficients corresponding to operating speed, feeding-auger torque, threshing-drum torque, and the fourth model parameter can then be determined as follows:

$$\varphi_k = \frac{\gamma_i}{\sum_{k=1}^{k=i} \gamma_k} \tag{21}$$

Experimental validation of the feed-quantity prediction model

The experiment was conducted at the wheat-growing base of Shengfa Cooperative in Jimo District, Qingdao. A modified GM-series combine harvester manufactured by Lovol was used, and the tested wheat cultivar was Jinan No. 17. Before the field tests, samples were collected from the experimental plot to determine key crop characteristics, including crop density and grain moisture content.

During each test, the harvester operated at a constant forward speed, while the crop material was fed manually to determine the actual feed quantity for the corresponding test plot. A total of 12 tests were conducted, and the validation results are presented in Table 8.

Table 8

Validation results for the feed-quantity prediction model

No.	Predicted feed quantity (kg/s)	Measured feed quantity (kg/s)	Absolute error	Relative error (%)
1	0.91	0.83	0.08	9.64
2	3.88	3.75	0.13	3.47
3	4.09	4.28	-0.19	4.44
4	1.5	1.65	-0.15	9.09
5	5.01	4.89	0.12	2.45
6	5.18	5.26	-0.08	1.52
7	3.38	3.16	0.22	6.96
8	5.72	5.9	-0.18	3.05
9	6.44	6.33	0.11	1.74
10	5.29	5.34	-0.05	0.94

After excluding the data from Tests 11 and 12, the maximum absolute error among the remaining samples was 0.22 kg/s, the maximum relative error was 9.64%, and the mean relative error was 4.33%. All relative errors were below 10%, indicating that the prediction model satisfied the specified measurement-error requirements.

In conclusion, the accuracy of detection and errors of the prediction model differ based on various feeding conditions. To analyze the variances in the feed quantity prediction models at different stages, the test data samples are divided into regions of low feed quantity, medium feed quantity, and high feed quantity. A comparative column chart is depicted in Fig. 12 to illustrate the differences.

Overall, the prediction accuracy and error varied under different feeding conditions. To evaluate the performance of the feed-quantity prediction model across different operating ranges, the validation samples were divided into low-, medium-, and high-feed-quantity groups. A comparative bar chart illustrating the prediction results and errors for these three groups is presented in Fig. 12.

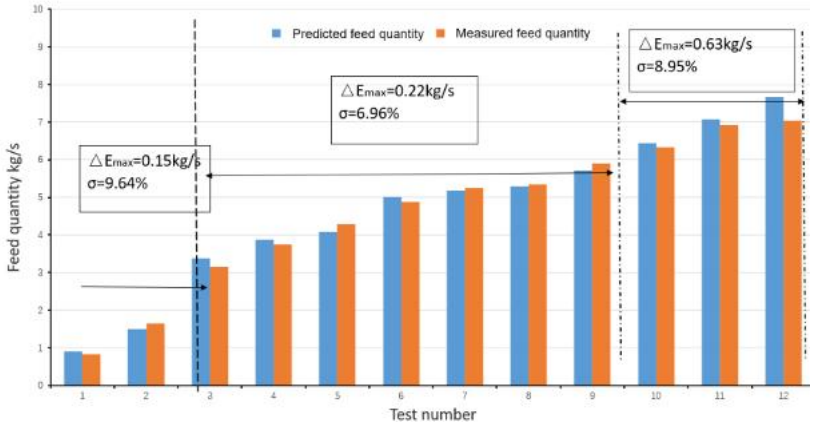

Fig. 12 - Comparison of measured and predicted feed quantities across different feed-quantity ranges

As shown in Fig. 12, the feed-quantity range was divided into three intervals: 0-3 kg/s, 3-6 kg/s, and 6-8 kg/s. The maximum relative errors in these intervals were 9.64%, 6.96%, and 8.95%, respectively. Comparison of the prediction results indicates that the model produced larger errors at low and high feed quantities, whereas its prediction performance was more accurate within the medium feed-quantity range.

CONCLUSIONS

(1) Grey relational weight analysis was used to determine the relative influence of the main operating parameters on feed quantity. Harvester operating speed had the highest relational weight (0.89), followed by feeding-auger torque (0.84) and threshing-drum torque (0.72). These results indicate that variations in feed quantity are primarily governed by changes in operating speed, whereas variations in feeding-auger and threshing-drum torque reflect the dynamic relationship between crop intake, material conveying, and threshing load.

(2) A piecewise modelling approach was adopted for different crop-density conditions. Under low- and high-crop-density conditions, feed quantity exhibited a strong linear relationship with threshing-drum torque, with coefficients of determination of R^2 = 0.9628 and 0.9559, respectively. Under medium-crop-density conditions, a quadratic model provided a better fit, with R^2 = 0.951. This result suggests that crop-flow and separation processes within the threshing system become more complex under medium-crop-density conditions and cannot be adequately described using a simple linear relationship.

(3) To compensate for the time delay in the signals collected from different harvester components, an error-corrected feed-quantity prediction model was developed. Field-validation results showed that, across the 12 test groups, the maximum absolute error was 0.63 kg/s, the maximum relative error was 9.64%, and the mean relative error was 4.55%. Further analysis by feed-quantity range showed that the maximum relative errors for the low (0–3 kg/s), medium (3–6 kg/s), and high (6–8 kg/s) ranges were 9.64%, 6.96%, and 8.95%, respectively. The model achieved the highest prediction accuracy within the medium feed-quantity range, whereas larger errors occurred at low and high feed quantities. These differences may be attributed to weaker sensor signals and a lower signal-to-noise ratio under low-feed conditions, as well as increased crop accumulation and greater torque fluctuations under high-feed conditions.

ABSTRACT

In greenhouse cultivation of cherry tomatoes, the accurate identification of pollination status is a key prerequisite for achieving automated robotic pollination. As the site of direct interaction during pollination, changes in the colour and morphology of the stigma most accurately indicate whether pollination has been successful. However, due to the minuscule size of the stigma and the extremely subtle visual differences among the three states—unpollinated, pollinated, and fruiting—combined with interference from fluctuating lighting conditions and complex backgrounds in greenhouse environments, traditional methods struggle to provide high-precision visual perception data for pollination robots. To address this issue, this paper proposes an improved model, YOLO11-RCSP, which focuses on the stigma as the core recognition object to achieve automatic classification of the three pollination states: introducing a novel attention mechanism, RFA (Receptive Field Attention), adding an enhancement module (CPA-Enhancer) to the original model, and incorporating SAConv switchable dilated convolutions. In addition, the loss function is improved using the Powerful-IoU method (adaptive penalty factor and gradient adjustment function based on anchor box quality). The precision rate of the improved model reached 88.40%, the recall rate reached 84.60%, and the average precision was 90.80% when the IoU was 0.50. The average precision ranged from 0.50 to 0.95, reaching 63.20%. These metrics represent improvements of 5.20%, 3.30%, 4.40%, and 5.30%, respectively, compared to the original YOLO11 network model, demonstrating stronger feature extraction capabilities and robustness. Ablation experiments further confirm that the attention mechanism and multi-scale optimization have a synergistic effect on enhancing the performance of stigma pollination status recognition. This research will be applied to pistil-level pollination status recognition tasks, helping to advance the development and application of pollination robots, and providing critical technical support for the development of automated pollination equipment in protected agriculture.

摘要

在圣女果温室栽培中，授粉状态的精准识别是实现机器人自动化授粉作业的核心前提。柱头作为授粉过程的直接作用部位，其颜色、形态变化能够最准确地反映授粉是否成功。然而柱头目标尺度微小，未授粉、授粉和结果三类状态的视觉差异极为细微，而且受温室环境中光照变化与复杂背景的干扰，传统方法难以为授粉机器人提供高精度的视觉感知决策依据。针对该问题，本文提出一个改进模型 YOLO11-RCSP，以柱头为核心识别对象，实现三类授粉状态的自动分类：引入一种新型的注意力机制 RFA（感受野注意力）；在原有模型中添加一种增强模块（CPA-Enhancer）；添加 SAConv 可切换空洞卷积；改进损失函数采用 Powerful-IoU(自适应惩罚因子和基于锚框质量的梯度调节函数) 的方法。改进后模型的准确率达到 88.40%，召回率达到 84.60%，平均精度在 IoU=0.50 时为 90.80%，在 0.50 至 0.95 的 IoU 平均精度达到 63.20%，各项指标相较于原 YOLO11 网络模型分别提高了5.20%，3.30%，4.40%，5.30%，拥有更强的特征提取能力和鲁棒性。消融实验进一步证实注意力机制与多尺度优化对提升柱头授粉状态识别性能具有协同效应。本研究将应用于柱头级别的授粉状态识别任务，有助于推动授粉机器人的研发与应用，为设施农业自动化授粉装备的研发提供关键技术支撑。

INTRODUCTION

Cherry tomatoes are an important fruit and vegetable crop widely cultivated in China's protected agriculture, known for their extensive planting area and significant economic benefits. According to statistics, the area under protected tomato cultivation in China has exceeded 1 million hectares, with cherry tomatoes being particularly favoured by the market due to their excellent taste and rich nutritional content. Cherry tomatoes are monoecious plants with unisexual flowers. In natural environments, pollination can be achieved through natural wind or insect vectors; however, in enclosed environments such as greenhouses, the absence of natural wind and insect activity leads to poor pollination, which can result in flower and fruit drop, as well as deformed fruit, severely affecting the yield and quality of cherry tomatoes *(Wang et al., 2016)*. Currently, greenhouse cherry tomato production primarily relies on manual pollination, bumblebee pollination or hormone-dipped flowers. Manual pollination is inefficient, labour-intensive and difficult to control for uniformity; bumblebee pollination is affected by environmental factors such as temperature and humidity within the greenhouse and is relatively costly *(Wang et al., 2013)*; hormone dipping, meanwhile, tends to increase the incidence of deformed fruit, severely affecting the economic efficiency of cherry tomato production. Consequently, pollination robots have emerged as a solution. Pollination robots can significantly reduce labour costs, accelerate pollination speed and improve cherry tomato pollination efficiency. However, the complex growing environment of greenhouse cherry tomatoes—characterised by small, numerous and overlapping flowers—complicates their identification and detection. This represents both a key challenge and a focal point in pollination robot research *(Hou et al., 2024)*.

In recent years, object detection methods based on deep learning have been widely used in crop detection, providing technical support for the precise localization and recognition of crops *(Kang et al., 2023; Hu et al., 2023; Jia et al., 2024)*. In the field of agricultural robot vision, most existing studies focus on fruit picking or flower localization, while studies related to pollination mostly take the whole flower as the recognition unit. To meet the demand for pollination detection of kiwifruit flowers, Pan et al. proposed a lightweight model KIWI-YOLO, which enhances the model's perception of flower contour details through a frequency-domain feature fusion module, and effectively recognized four states including bud, female flower, male flower, and successful pollination on a self-built kiwifruit flower dataset, with mAP@50 reaching 91.6% *(Pan et al., 2024)*. To solve the detection difficulty caused by the dense distribution of kiwifruit flowers in complex orchard environments, Tang et al. proposed an improved model YOLOv11-TYW based on the YOLOv11n architecture, which verified the applicability of the YOLOv11 architecture in orchard flower object detection tasks and provided a technical reference for flower recognition in subsequent pollination robots *(Tang et al., 2025)*.

Isabel Pinheiro et al. adopted deep learning methods to detect kiwifruit flowers and determine their gender to address the problems that kiwifruit is a dioecious plant with no nectar to attract pollinators and existing technologies lack gender-based flower detection methods; four pre-trained models including YOLOv5, YOLOv8, RT-DETR, and DETR were evaluated, K-fold cross-validation was used to test model performance, and a manually annotated kiwifruit flower gender classification dataset was constructed, among which the YOLOv5s model performed best with a detection accuracy of 97%, providing technical support for the precise operation of automated kiwifruit pollination robots *(Pinheiro et al., 2024)*. Manzoor et al. proposed an improved model based on YOLOv5s; by replacing the backbone network with MobileNetV3 and introducing Ghost convolutions from GhostNet, the model achieved a lightweight effect in apple blossom detection with about 85% reduction in model size and about 89% reduction in GFLOPs, while maintaining an accuracy of 90.6% and mAP@50 of 91.2%, verifying the applicability and lightweight potential of the YOLO series in flower detection for pollination scenarios *(Manzoor et al., 2024)*. Touko Mbouembe et al. proposed an improved YOLOv5s model, which significantly enhanced feature representation ability and detection robustness for occluded objects by integrating the SE attention mechanism, BiFPN multi-scale feature fusion network, CARAFE upsampling operator, and Soft-NMS algorithm *(Touko Mbouembe et al., 2024)*. However, using the whole flower as the recognition target has shortcomings: although the overall size of the flower is large, its morphological characteristics are affected by petal opening angles, variety differences, and environmental factors; the key changes determining successful pollination actually occur at the stigma level, such as stigma colour, surface gloss, and ovary expansion, and these subtle changes are often blocked by petals or disturbed by background in whole-flower images, making them difficult for models to capture accurately. Therefore, methods using the whole flower as the recognition object have obvious deficiencies in the accuracy and interpretability of pollination status recognition.

As the direct site of pollination, the stigma's colour and morphological changes most sensitively reflect whether pollination has been successful. Lorberboym et al. employed a YOLOv8 segmentation model to perform instance segmentation of cannabis stigmas, assessing flower maturity through the proportion of stigma colour, further demonstrating the potential of stigma visual analysis in automated agriculture *(Lorberboym et al., 2026)*.

The Swin Transformer proposed by *Gao et al.* utilises a hierarchical self-attention mechanism to construct robust multi-scale feature representations, offering a new approach to small-object detection in complex visual tasks *(Gao et al., 2024)*. Addressing the issues of low efficiency and high costs associated with manual saffron stigma harvesting, *Priyadharshini et al.* proposed a saffron harvesting system based on an autonomous mobile robot. This system utilises a CNN module to identify mature flowers and the position of their stigmas, and integrates a 6-degree-of-freedom robotic arm onto a mobile platform to achieve precise grasping and separation of the stigmas via vision-guided servo control *(Priyadharshini et al., 2023)*.

Yang et al. addressed the challenges of detecting the minute scale and difficult-to-identify rotational orientation of forsythia pistils by proposing the PSTL-Orient method to detect the area and orientation of rotating pistils. By combining servo technology with flower detection, they achieved precise autonomous pollen delivery to the pistils by a robot *(Yang et al., 2023)*.

However, the identification of stigmas presents multiple technical challenges: due to the minute scale of the stigma target, which occupies very few pixels in an image, traditional object detection methods struggle to effectively extract subtle features; the visual differences between the three states—unpollinated, pollinated and fruiting—are extremely subtle, manifesting only as gradual changes in stigma colour, glossiness and the morphology of the surrounding ovary; these differences require the model to possess a high level of discriminatory ability; lighting conditions in greenhouse environments are complex, with changes in the angle of light in the morning and evening, and fluctuations in brightness caused by shade net coverage, whilst the varied background further increases the difficulty of recognition.

Based on the above analysis, this paper proposes the YOLO11-RCSP method for identifying the pollination status of cherry tomato stigmas, based on an improved YOLO11. This is achieved by introducing a novel attention mechanism, RFA (Receptive Field Attention), adding an enhancement module (CPA-Enhancer) to the original model, adding SAConv switchable dilated convolutions, and improving the loss function by adopting Powerful-IoU (adaptive penalty factors and gradient adjustment functions based on anchor box quality). These four improvement strategies enable the model to adaptively cope with changes in greenhouse lighting and occlusion, whilst also allowing the receptive field to be adjusted according to stigma scale, balancing small-target details with large-scale context to enhance recognition accuracy and robustness. Validation results show that the model achieves a precision of 88.40% and a recall of 84.60%. The average precision at IoU=0.50 is 90.80%, and the average precision across the IoU range of 0.50 to 0.95 is 63.20%. Compared to the original YOLO11 network model, these metrics have improved by 5.20%,3.30%, 4.40% and 5.30% respectively compared to the original YOLO11 network model.

MATERIALS AND METHODS

MATERIALS

DATA AND ACQUISITION

The cherry tomato flower dataset used in this study was captured in an earthen-walled greenhouse at the Innovation and Entrepreneurship Practice Base of the School of Software Engineering, Shanxi Agricultural University, Shanxi Province, China, as shown in Figure 1.

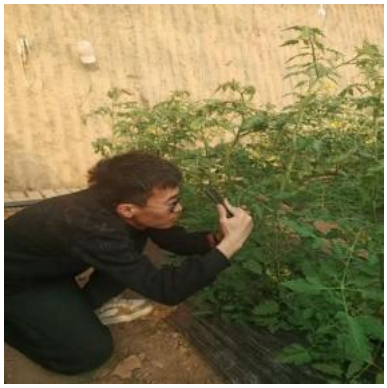

Fig. 1 - Scene of data capture

To enable the model to adapt to changes in stigma scale at different distances, three shooting distances were adopted: close-up (approximately 10–20 cm), medium (approximately 30–40 cm) and far (approximately 50–60 cm). The shooting angles included front, side and upward views to cover the various orientations a pollination robot might encounter during operation. Furthermore, to account for variations in greenhouse lighting conditions, data was collected during three time slots: 8:00–9:30 am, 12:00–1:30 pm and 3:30–5:00 pm. A total of 2,044 images of cherry tomato flowers were captured.

Photographs taken at the three different distances are shown in Figure 2:

Close-up *Medium range* *Long distance*

Fig. 2 - Images captured at different shooting distances

CONSTRUCTION OF THE DATASET

The 2,044 photographs collected were divided into training, validation and test sets in a ratio of 8:1:1, comprising 1,636 images in the training set, 204 in the validation set and 204 in the test set. Adhering to the principle of avoiding duplication and omissions, the LabelImg annotation tool was used to label the stigma of each image, categorising them into three states: unpollinated, pollinated and fruiting *(Li et al., 2024; Song et al., 2024; Sun et al., 2024)*. The specific data labels are shown in Figure 3.

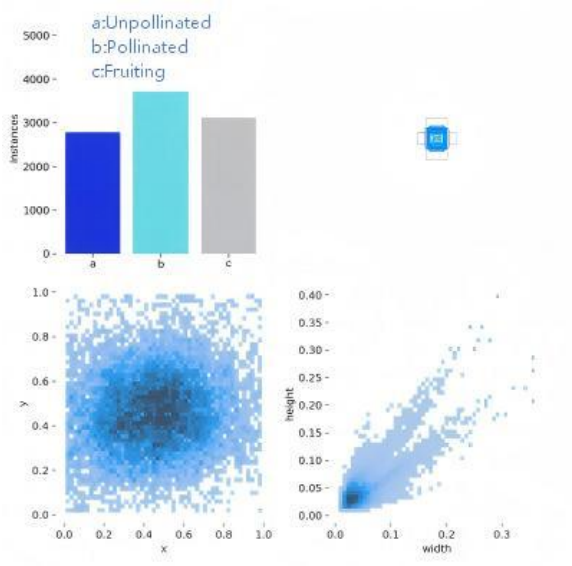

Fig. 3 - Data Labelling

IMPROVED METHOD

To address multiple technical challenges, including the minute scale of the stigma target, subtle visual differences between the three states, and complex lighting conditions in greenhouse environments, this paper proposes YOLO11-RCSP, a stigma pollination status recognition method based on an improved YOLO11. (1) Introducing RFAConv receptive field attention, which resolves the issue of parameter sharing by dynamically adjusting convolution kernel parameters, thereby enhancing the model's ability to perceive both local details and spatial context of the stigma; (2) Adding a CPA-Enhancer adaptive enhancement module to the original model, utilising thought chain prompts to encode degraded information, enabling the model to adaptively cope with changes in greenhouse lighting and occlusion; (3) Replacing the original C3k2 module with the

C3k2_SAConv module, which deeply integrates switchable dilated convolutions with C3k2, enabling the model to adaptively adjust the receptive field according to the scale of the stigma, balancing small-object details with large-scale context; (4) Modifying the loss function to Powerful-IoU, introducing an adaptive penalty factor and a gradient adjustment mechanism based on anchor box quality to improve small-object localisation accuracy and training stability. The diagram of the improved framework is shown in Figure 4.

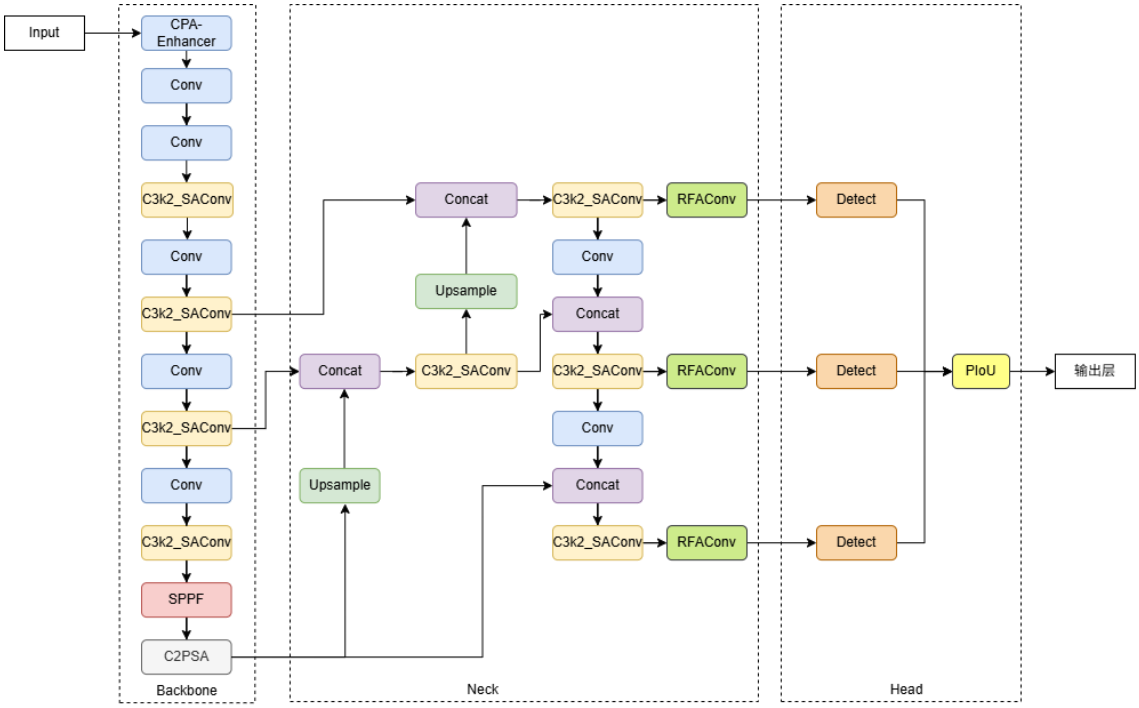

Fig. 4 - Diagram of the improved framework

RFACONV RECEPTIVE FIELD ATTENTION

The core idea of RFAConv is to introduce receptive field attention, allowing convolution kernel parameters to be dynamically adjusted based on the position and contextual information of the receptive field region, thereby addressing the issue of shared convolution kernel parameters *(Zhang et al., 2023)*. Unlike traditional spatial attention mechanisms, RFA not only focuses on spatial features within the image but also places greater emphasis on the spatial feature distribution within each receptive field. By dynamically weighting the importance of various features within the receptive field, it achieves the effect of 'different convolutional kernel parameters for different regions', as illustrated in Figure 5.

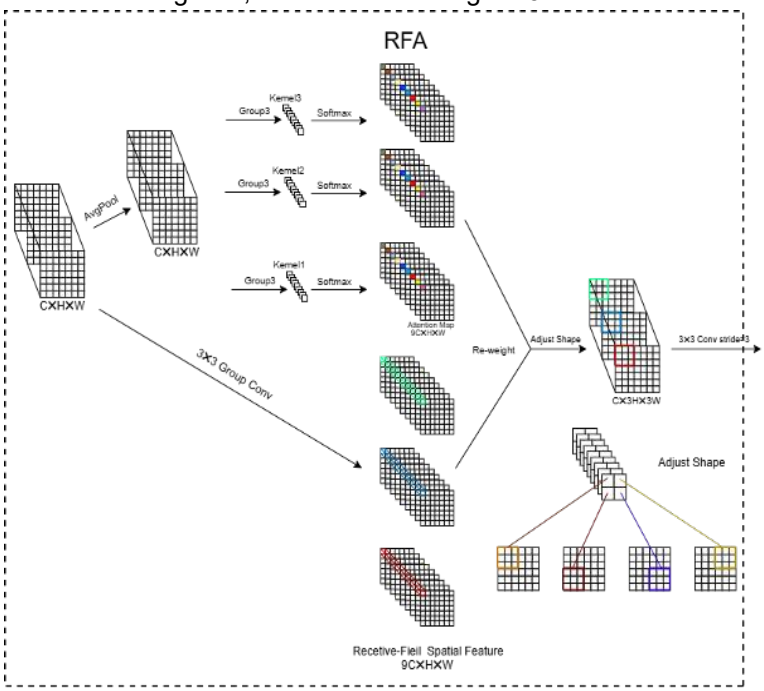

Fig. 5 - RFAConv architecture diagram

This study integrates the RFAConv module into the multi-scale feature fusion stage of YOLO11's neck network. This not only further enhances feature discrimination capabilities and strengthens the model's multi-scale perception but also controls computational overhead whilst improving performance. This design enables the model to dynamically adjust the size of the receptive field based on the scale characteristics of the stigmas in the input image. For smaller, unpollinated stigmas, the model assigns higher weights to branches with smaller receptive fields to preserve fine-scale details; for pollinated stigmas, it assigns higher weights to branches with medium and large receptive fields to capture broader spatial context.

CPA-ENHANCER MODULE

The CPA-Enhancer is specifically designed to enhance object detection performance under unknown degradation conditions. Its core innovation lies in utilising Chain of Thought (CoT) prompts to encode degradation-related information and gradually adjust the enhancement strategy under the step-by-step guidance of the CoT prompts, enabling the model to adaptively address unknown degradation types without prior knowledge of the degradation type *(Zhang et al., 2024)*.This is the first work to apply CoT prompts to object detection tasks; its modular design allows it to be seamlessly integrated into any general-purpose detector, achieving significant performance gains under various unknown degradation conditions. Its structure is shown in Figure 6.

The characteristics of the CPA-Enhancer module are well-suited to the requirements of this study. The identification of pollination status in tomato stigmas faces various complex factors, such as changes in greenhouse lighting and leaf occlusion, which traditional enhancement methods struggle to comprehensively address. Upon adding the CPA-Enhancer to the YOLO11 backbone network, the model can adaptively adjust its enhancement strategy based on the degraded features of the input image, thereby improving the robustness of detection for the small stigmas. Furthermore, as this module has a small number of parameters and low computational overhead, it effectively enhances the accuracy of pollination status recognition whilst maintaining YOLO11's real-time inference capability, providing a more reliable visual perception module for pollination robots.

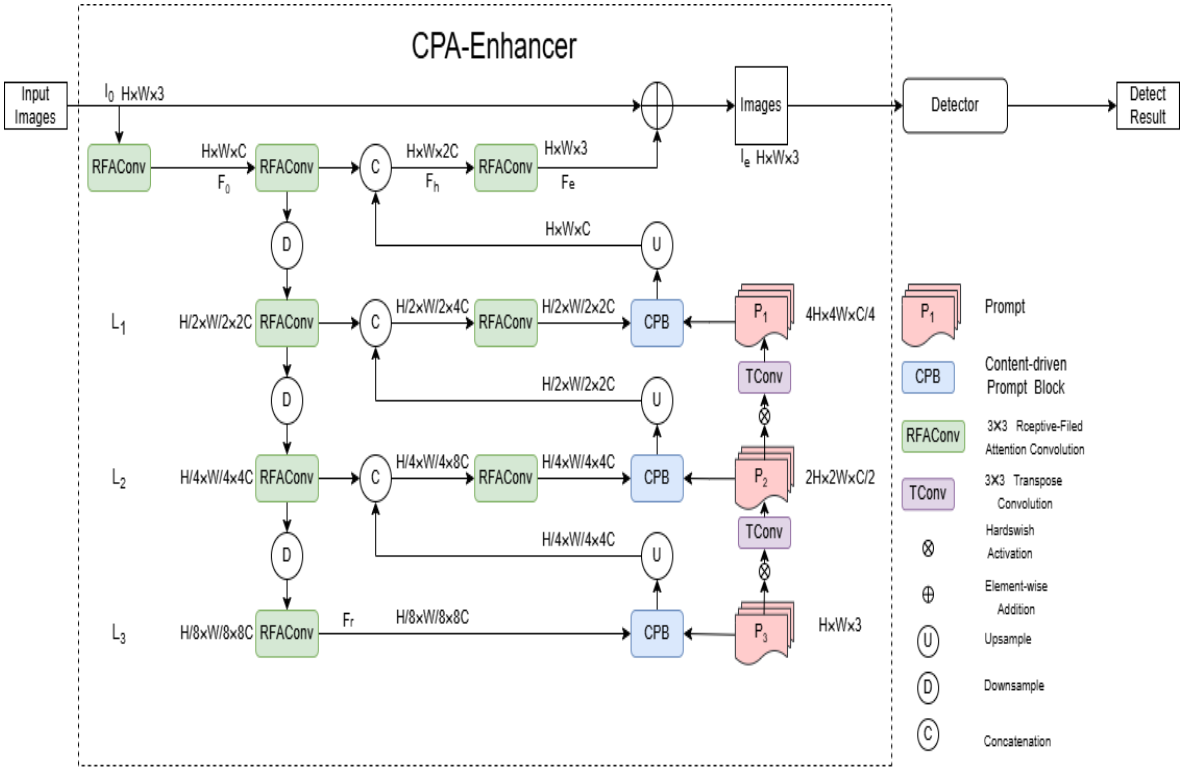

Fig. 6 - CPA-Enhancer architecture diagram

SACONV MODULE

SAConv is a convolutional operation capable of dynamically switching the stranding rate. Its core concept involves introducing a learnable routing mechanism that allows the convolutional kernel to select from or weight-blend multiple stranding rates *(Qiao et al., 2020)*.

This routing module first performs global average pooling on the input features, compressing them into a feature vector, then generates weight coefficients for each branch via two fully connected layers, and finally performs a weighted summation of the outputs from each branch. The expression is given by Eq. (1):

$$F_{out}=\sum_{i=1}^{3} \mathrm{comv}_{d_i}(F_{in}) \quad (1)$$

where '3' denotes the number of parallel dilated convolution branches configured in the SAConv module, i.e. three dilated convolution branches with different dilation rates; d_i is the dilation rate of the i-th branch; w_i is the weight coefficient generated by the dynamic routing module, satisfying Eq. (2):

$$\sum w_i=1 \quad (2)$$

This improvement enables the model to dynamically adjust the void ratio based on input features, allowing it to flexibly capture multi-scale context whilst preserving fine-grained details; its structure is shown in Figure 7.

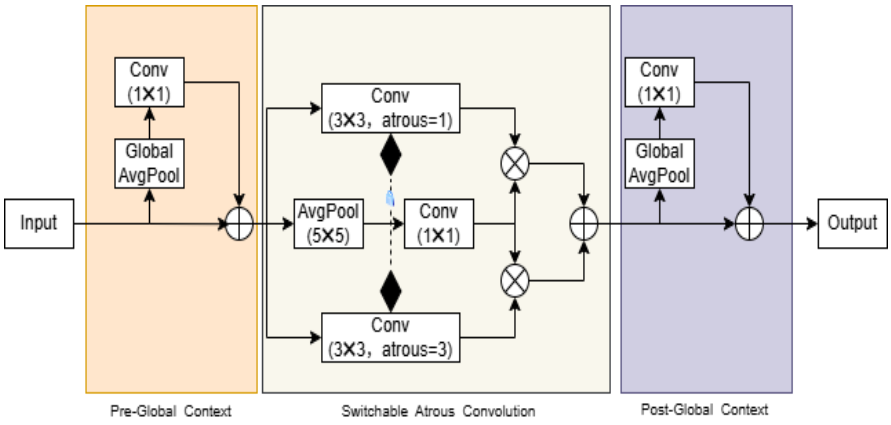

Fig. 7 - SAConv architecture diagram

Wang et al. integrated SAConv into YOLOv8n to construct the LSD-YOLO model, which was applied to the detection of surface diseases on lemons, thereby validating the effectiveness of this module in agricultural small-object detection tasks *(Wang et al., 2024)*. In this study, we propose the C3k2_SAConv module by deeply integrating the SAConv module with the C3k2 module. This enables the C3k2_SAConv module to retain the original lightweight advantages of C3k2 whilst enhancing the model's dynamic perception of features at different scales through the introduction of the SAConv module. It is particularly suitable for fine-grained recognition tasks, such as stigma detection, where scale varies significantly and the requirements for receptive fields change dynamically.

POWERFUL-IOU LOSS FUNCTION

Existing IoU-based loss functions first increase the size of the anchor boxes during regression to achieve overlap with the target box. Even when the area of the anchor box is already larger than that of the target box, this regression method is complex and slow, requiring more iterations to converge. Furthermore, their penalty terms contain unreasonable components that fail to accurately reflect the differences between the anchor and target boxes, and they do not fully account for the target size, which may lead to degradation in certain cases. To address issues such as anchor box enlargement, this paper proposes a size-adaptive penalty term that guides the anchor boxes to regress directly and efficiently. This paper combines this penalty term with a function that adjusts the gradient based on anchor box quality, resulting in a new IoU-based loss term called the Powerful-IoU (PIoU) loss.

PIoU is an improved bounding box regression loss function proposed by Liu et al., which has achieved superior performance compared to traditional loss functions such as CIoU and GIoU on mainstream detectors including YOLOv8 and DINO *(Liu et al., 2023)*. Its core innovation lies in the introduction of an adaptive penalty factor and a gradient adjustment mechanism based on anchor quality, enabling the model to dynamically adjust the loss contribution according to anchor quality, thereby enhancing its adaptability to small objects and high-precision localisation tasks. Its expression is given by Eq. (3):

$$L_{PIoU}=\gamma(1-IoU)^2 \quad (3)$$

Here, '$(1\text{-IOU})^2$' serves as the base loss term, assigning a higher loss weight to samples with low IoU; ` $\gamma$ ` acts as a gradient adjustment factor, dynamically adjusting the gradient contribution based on the quality of the anchor boxes.

This design enables PIoU to combine the dual advantages of rapid convergence and stable refinement, making it particularly suitable for the high-precision localisation requirements of small targets such as the stigma.

Evaluation Metrics

For object detection models, this paper primarily employs precision (P), recall (R), average precision (mAP@50), and mean average precision (mAP@50–95) as the main metrics for evaluating model performance. P represents the proportion of all targets correctly identified by the algorithm's bounding boxes, reflecting the model's accuracy; R represents the proportion of correctly identified samples out of the total number of samples; mAP@50 is a key metric reflecting the comprehensive performance of the detection model; mAP@50-95 denotes the average of the mean average precision across different IoU thresholds. The calculations for precision, recall, average precision and mean average precision are shown in Eqs. (4) to (7):

$$\mathrm{P}=\frac{TP}{TP+FP} \tag{4}$$

$$\mathrm{R}=\frac{TP}{TP+FN} \tag{5}$$

$$\mathrm{AP}=\int_0^1 P(r)dr \tag{6}$$

$$mAP=\frac{1}{C}\sum_{i=1}^{c} AP_i \tag{7}$$

TP denotes the number of correctly detected positive samples; FP denotes the number of incorrectly detected negative samples; FN denotes the number of missed positive samples; C represents the number of classes; AP_i represents the average precision of the i-th class.

EXPERIMENTAL ENVIRONMENT

For detailed experimental configuration parameters, see Table 1.

Table 1

Experimental Environment Configuration

Configuration Name	Version and Model
GPU Model and Quantity	NVIDIA GeForce RTX 4080
CPU Model	13th Gen Intel® Core™ i7-13700K
System Memory	32.0GB
Operating System	Windows 11 Home Chinese Edition (22H2 build)
Deep learning framework	Torch 2.2.0 + cu118
CUDA and cuDNN versions	CUDA 11.8 + cuDNN 8.9.7
Programming Languages and Dependencies	timm == 0.9.12, mmcv-full == 2.2.0, numpy=1.26.3

The training parameters are summarized in Table 2.

Table 2

Training Parameter Configuration

Parameter Name	Parameter Value
epoch	200
batch	8
workers	4
optimizer	SGD
size	640
patience	30
amp	False
iou	0.7
lr0	0.01
lrf	0.01

RESULTS AND DISCUSSION

To ensure the validity and reliability of both ablation and comparative experiments, this study strictly controlled extraneous variables by employing identical training configurations for all participating models, and fixed random seeds across all runs to eliminate stochastic fluctuations, thus ensuring that any observed performance variations arise exclusively from network architectural improvements.

ABLATION STUDIES

In the ablation experiments, individual modules (A, B, C, D) were incorporated into the base model to assess their impact on performance. A denotes the RFAConv module; B denotes the CPA-Enhancer module; C denotes the C3k2_SAConv module; D denotes the PIoU loss function. The results are shown in Table 2.

Table 2

Results of the ablation experiments

Model	Module				P	R	mAP@50	mAP@50–95	GFLOPs	FPS
	A	B	C	D						
1					0.832	0.813	0.864	0.579	6.3	210.1
2	√				0.826	0.817	0.87	0.574	14.8	37.7
3		√			0.83	0.819	0.867	0.6	9.6	10.3
4	√	√			0.843	0.829	0.882	0.614	13.87	8.4
5			√		0.84	0.833	0.881	0.568	5.9	93.6
6				√	0.832	0.813	0.865	0.581	6.3	207.1
7			√	√	0.867	0.807	0.878	0.569	5.9	97.6
8	√		√		0.855	0.821	0.868	0.576	14.6	33.8
9	√		√	√	0.838	0.827	0.878	0.584	14.6	33.9
10	√	√	√	√	0.884	0.846	0.908	0.632	13.75	36.3

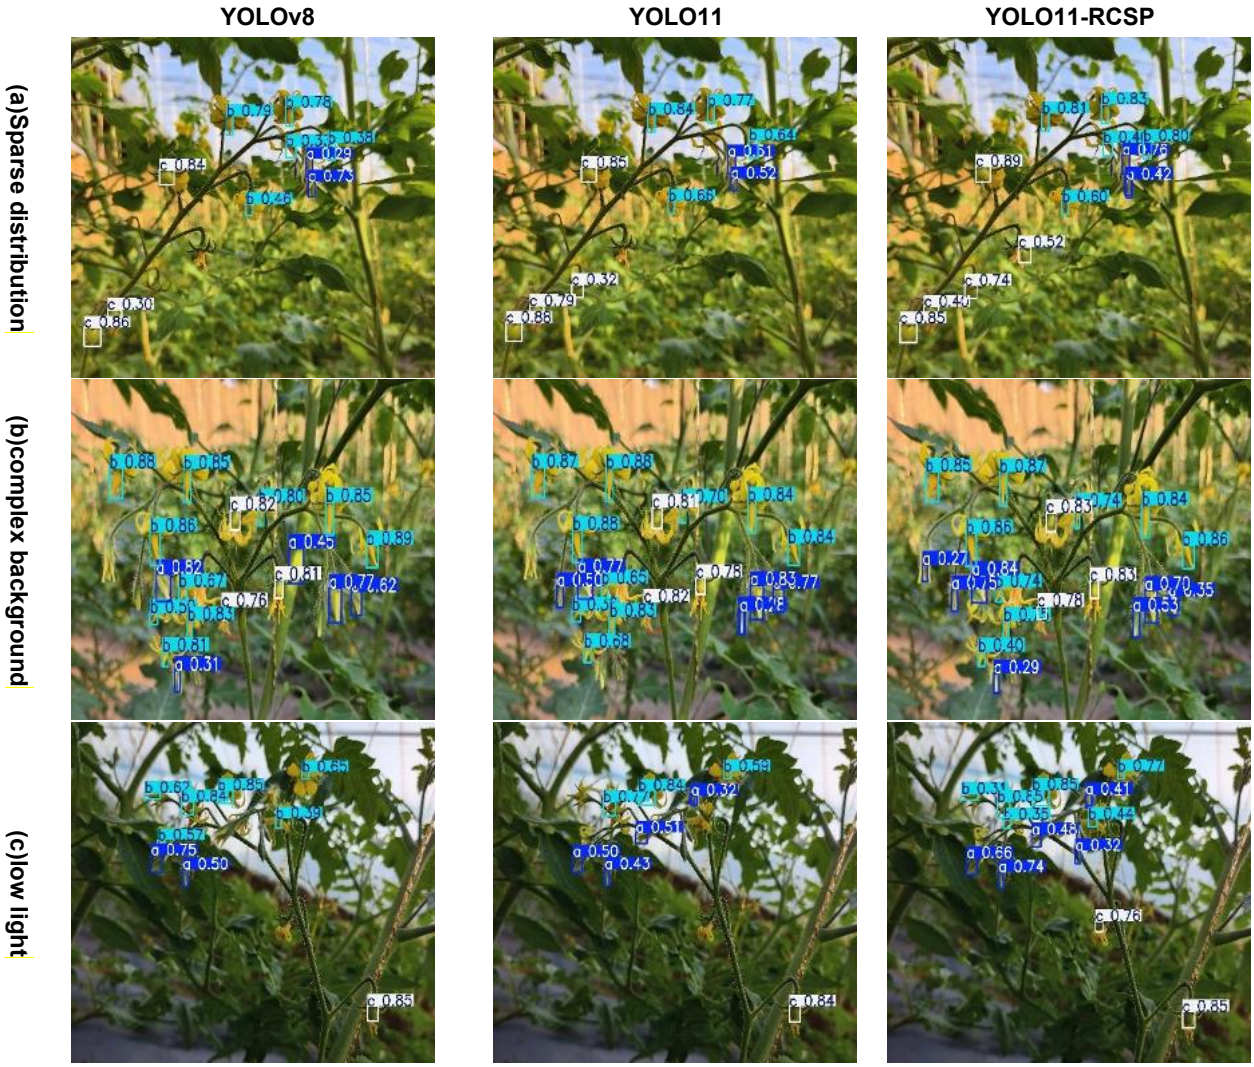
Based on the results of the comprehensive ablation experiments, the final improved scheme is Model 10: A+B+C+D. It achieved the best performance across core accuracy metrics such as precision, recall and mAP, significantly outperforming the baseline model and other module combinations, thereby fully validating the effectiveness of the multi-module joint optimisation strategy. However, compared to the baseline model, the computational cost of this scheme increased from 6.3 to 13.75, whilst inference speed decreased from 210.1 to 36.3. This change is primarily attributable to the inherent complexity of the introduced modules: RFAConv and C3k2_SAConv enhance feature representation capabilities but increase computational overhead; the serial processing mechanism of the CPA-Enhancer reduces real-time frame rates; and the PIoU loss function introduces additional floating-point operations. Nevertheless, these trade-offs do not detract from the value of the findings of this study. This study prioritises the improvement of detection accuracy; exchanging controllable computational redundancy for a 4.4% improvement in mAP@50 and a 5.3% improvement in mAP@50-95 represents a typical reasonable trade-off between accuracy and efficiency. Furthermore, compared to other high-accuracy combinations, such as Model 4, which achieves only 8.4 FPS, this approach maintains 36.3 FPS whilst achieving the highest accuracy, demonstrating a superior overall balance. Finally, the baseline model itself is designed to be extremely lightweight, with its 210 FPS far exceeding practical application requirements, whilst the computational load of this approach remains within an efficient and acceptable range, providing a clear direction for subsequent engineering optimisation. Therefore, variations in computational load and speed do not diminish the innovative contribution of this study at the algorithmic level; rather, they further highlight the significant advantages in terms of accuracy improvement.

MULTI-MODEL COMPARISON

To validate the superiority of YOLO11 in detecting the pollination status of cherry tomatoes, this paper trained seven models for detecting the pollination status of cherry tomato flowers using the same cherry tomato dataset under identical conditions. Precision (P), Recall (R), Average Precision (mAP@50) and Mean Average Precision (mAP@50-95) were adopted as the primary metrics for evaluating model performance. The comparison results are shown in Table 3.

Table 3

Comparison of model performance



Model	Precision (P)	Recall (R)	mAP@50	mAP@50–95	GFLOPs	FPS
YOLOv5	0.827	0.798	0.865	0.552	5.8	260.1
YOLOv6	0.834	0.796	0.855	0.533	11.5	242.8
YOLOv8	0.829	0.788	0.858	0.547	6.8	256.6
YOLOv9t	0.837	0.815	0.873	0.549	6.4	103.6
YOLOv10n	0.835	0.79	0.858	0.545	8.2	184.1
YOLO11	0.832	0.813	0.864	0.579	6.3	210.1
YOLO11-RCSP	0.884	0.846	0.908	0.632	13.75	36.3

As summarised in Table 3, which compares the results of several mainstream models on the same cherry blossom pollination dataset, the YOLO11-RCSP model proposed in this paper leads comprehensively across core accuracy metrics, achieving a precision of 88.4% and a recall of 84.6%, with mAP@50 and mAP@50-95 reaching as high as 90.8% and 63.2%, respectively, significantly outperforming six comparison models ranging from YOLOv5 to YOLO11. For example, compared to the original YOLO11, mAP@50 is improved by 4.4%, and mAP@50-95 by 5.3%; compared to the similarly performing YOLOv9t, mAP@50 is improved by 3.5%, fully demonstrating the significant advantage of this improved approach in detection accuracy. In terms of computational efficiency, YOLO11-RCSP achieves 13.75 GFLOPs and 36.3 FPS. Although this exceeds some lightweight models, the improvement in accuracy far outweighs the computational cost when compared to YOLOv6 and YOLOv10n. However, whilst YOLOv9t maintains 103.6 FPS, its mAP@50 and mAP@50-95 are both significantly lower than those of our model. The 36.3 FPS fully meets the real-time requirements of agricultural detection scenarios, whilst the 210.1 FPS of the baseline YOLO11 is over-engineered. Therefore, trading a moderate loss in efficiency for a significant gain in accuracy aligns with the core requirements for detection accuracy in practical applications, fully validating the superiority of YOLO11-RCSP in the comprehensive trade-off between accuracy and efficiency.

VISUALISATION

VISUAL ANALYSIS OF DETECTION RESULTS

In this experiment, the performance of the YOLO11-RCSP model and other models in the object detection task was evaluated using six sets of cherry tomato images with distinct characteristics, as shown in Figure 8.

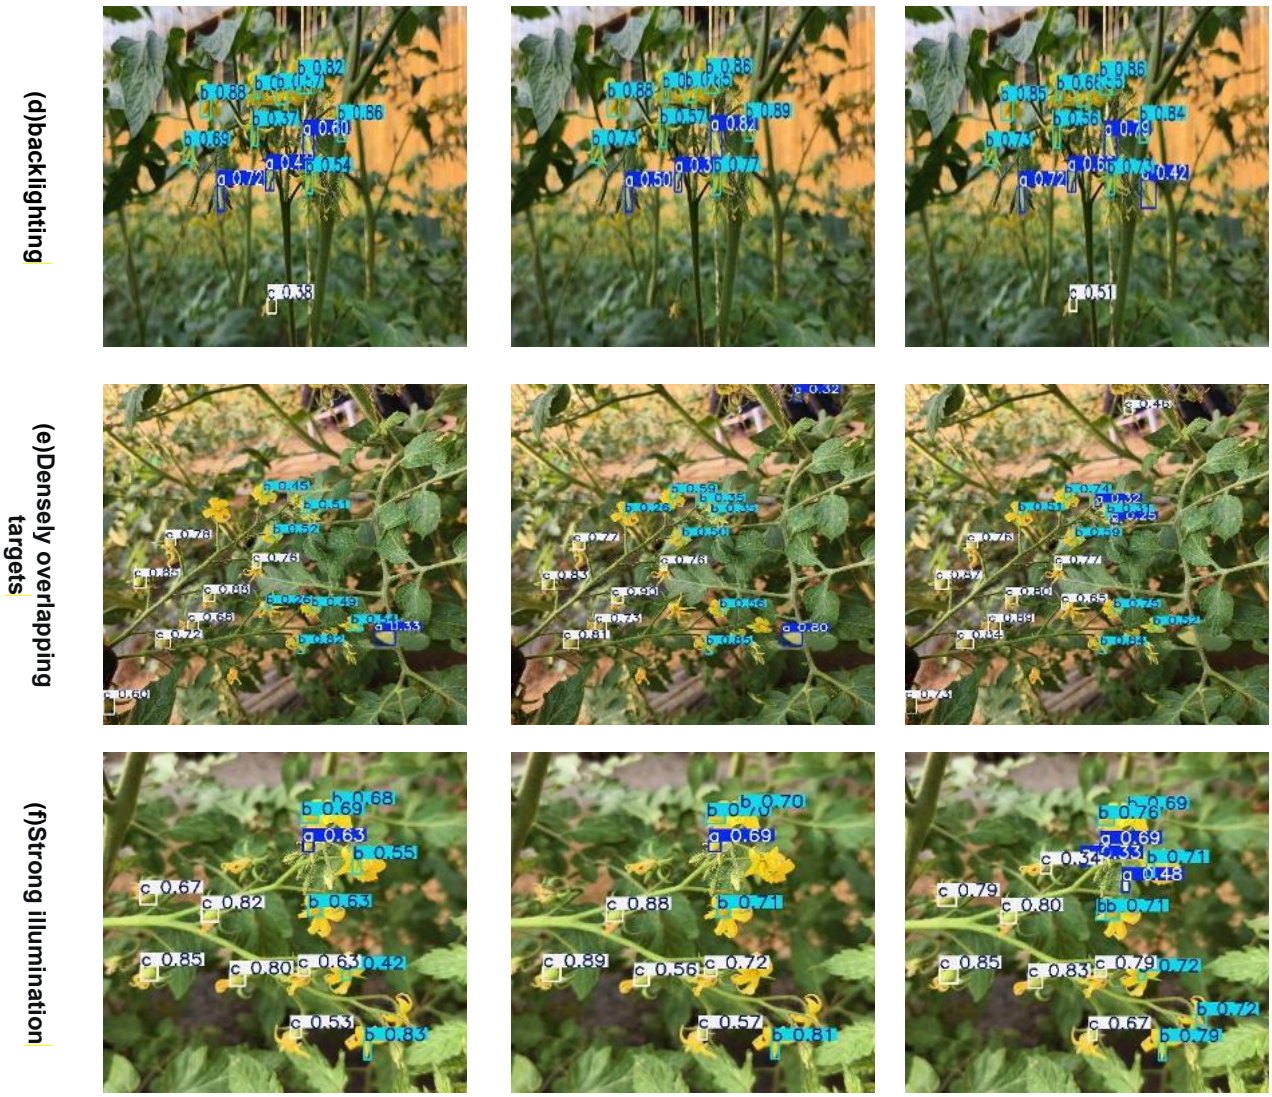


Fig. 8 - Detection comparison among different models and the improved model under various cherry tomato scenarios

The blue, green, and white bounding boxes indicate detected unpollinated styles, detected pollinated styles, and detected cherry tomato fruits, respectively.

In sparsely distributed and complex background scenarios, other models generally suffer from missed detections or misaligned bounding boxes. For example, YOLOv5 and YOLOv8 exhibit a weak response to unpollinated stigmas obscured by leaves, or fail to detect them entirely, whereas YOLO11-RCSP can accurately localise the stigma region, with bounding boxes closely matching the actual targets and a significantly higher accuracy rate than other models.

In scenes with dense targets, such as Column e, YOLOv6 and YOLOv9t exhibited overlapping detection boxes and false positives between multiple targets, misidentifying adjacent petals or ovaries as stigmas; whilst YOLOv10n and the original YOLOv11 detected most stigmas, their localisation accuracy was insufficient, and the detection boxes failed to tightly enclose the stigmas. In contrast, YOLO11-RCSP not only correctly detected all stigmas but also produced compact detection boxes with high accuracy.

In low-light images, the accuracy of other models generally declined, with some models even failing to detect stigmas, whilst YOLO11-RCSP maintained a high detection rate and localisation accuracy.

Visual Analysis of Heatmaps

In this experiment, to intuitively evaluate the areas of focus of different models regarding the pollination status of cherry tomato pistils, this study utilised the GradCAM method to generate heatmaps for each model and conducted a comparative analysis, as shown in Figure 9.

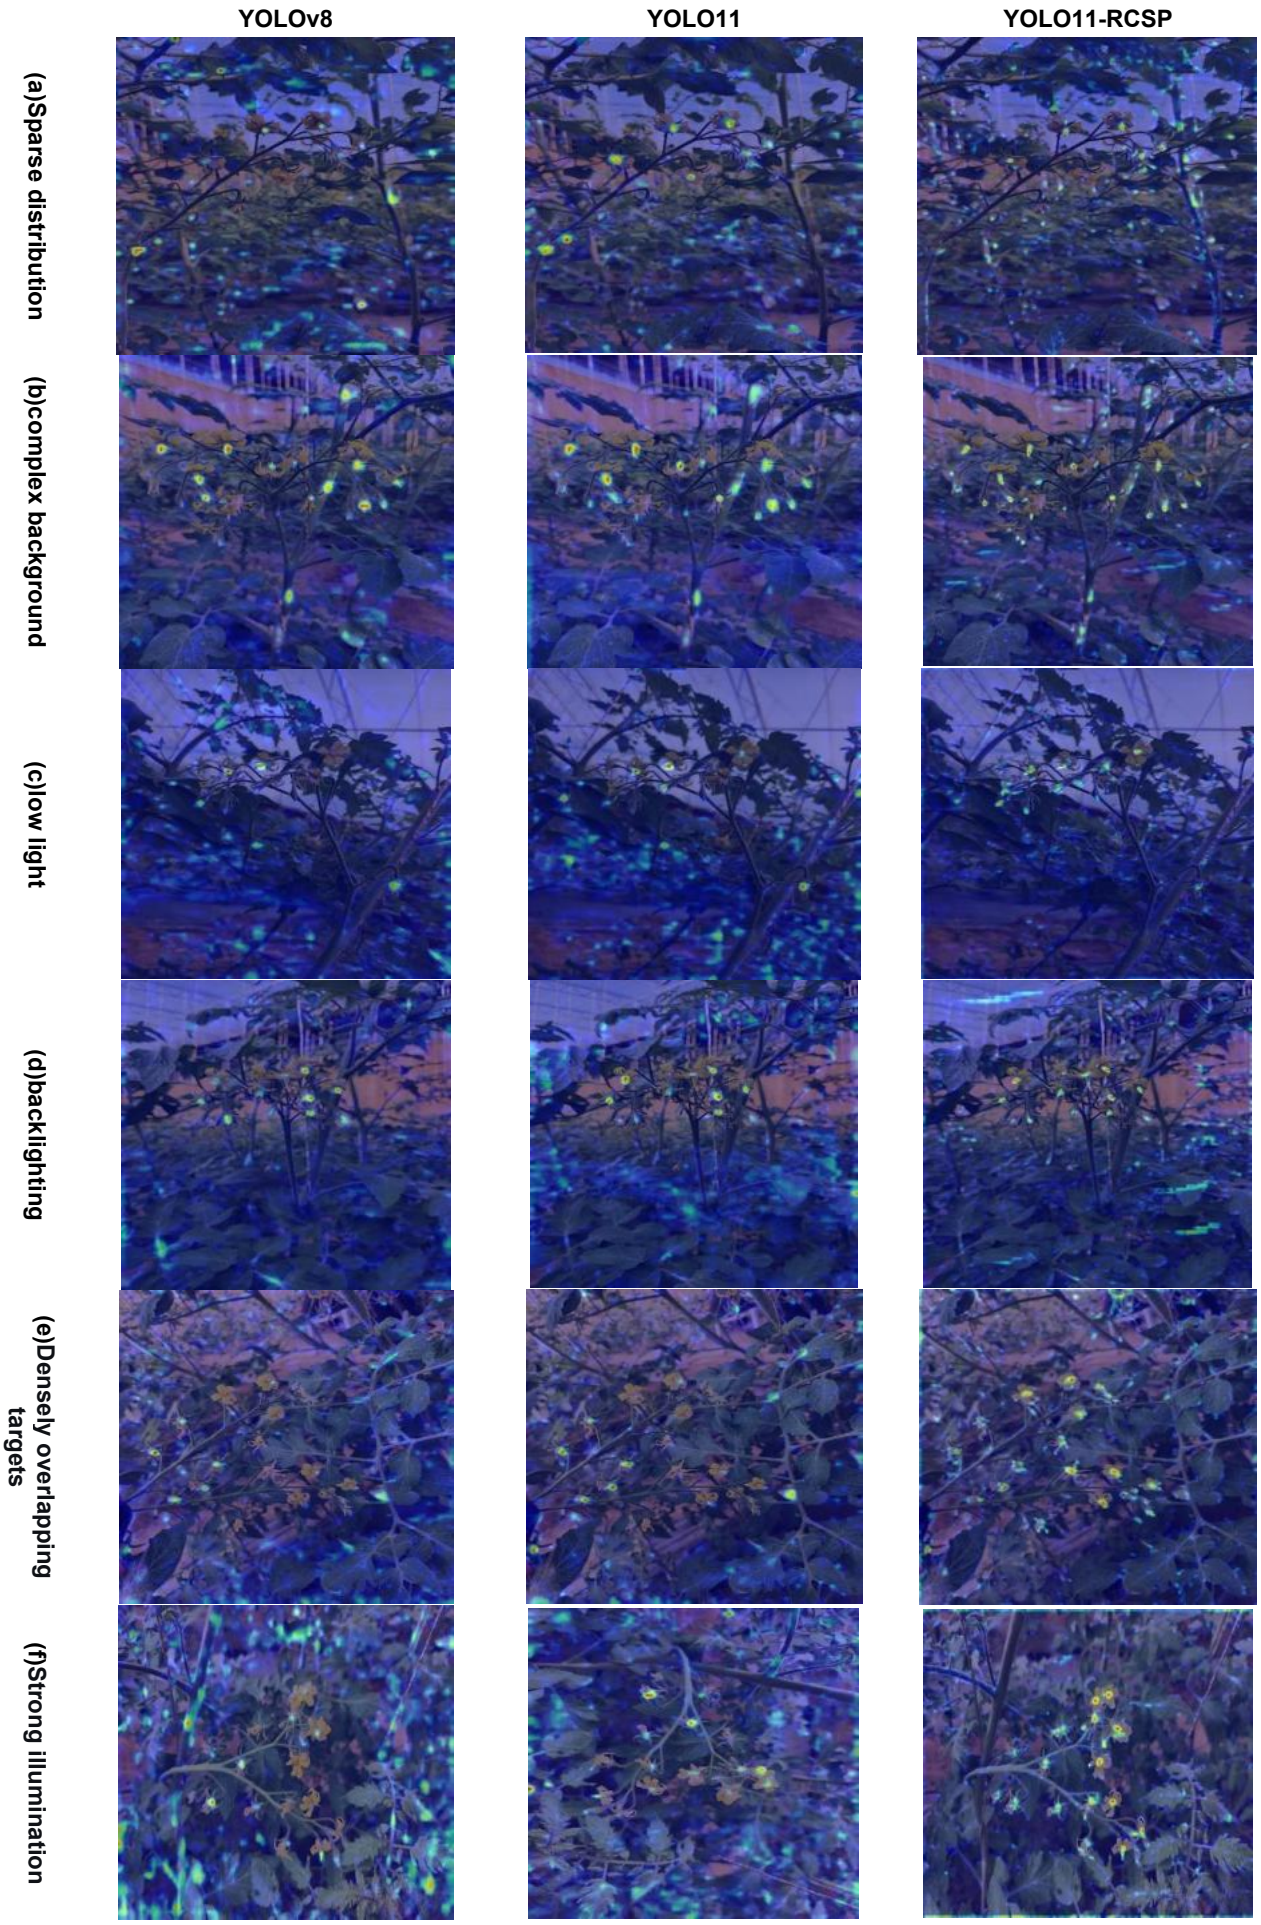

Fig. 9 - Comparison of heatmaps generated by different models and the improved model on various cherry tomato scenes

In scenarios featuring sparse cherry tomato distributions and complex backgrounds, the heatmaps demonstrate that the YOLO11-RCSP model focuses more accurately on the target regions compared to other models, effectively reducing unnecessary background activations. This indicates that the improved model can more effectively extract and focus on key features when handling complex backgrounds or sparse target distributions, exhibiting stronger robustness against interference.

For dense cherry tomato distributions, the YOLO11-RCSP model maintains high recognition accuracy even when targets are densely packed, accurately distinguishing individual targets and reducing false activations or missed detections. In contrast, other models are more susceptible to interference between targets in such scenarios, leading to a decline in detection performance.

Scene Application

Real-scene image collection was carried out in a ridge-planted facility tomato greenhouse using a DJI mobile phone gimbal combined with a smartphone, to verify the actual deployment effect of the model. During collection, the camera advanced uniformly along the planting ridges with wide-angle framing to include multiple tomato flowers in a single frame. By traversing each ridge, moving evenly and slightly adjusting the gimbal angle, repeated frames and overlapping regions were avoided, and the flowering and fruiting areas of the whole greenhouse were fully covered. A total of 218 field test images were obtained.

Inference deployment and acceleration of the optimal weight model best.pt were implemented based on PyTorch. A tomato flower detection system was constructed using Python and OpenCV, which enabled automatic image inference and detection. Unpollinated flowers, pollinated flowers and developed fruits were marked with bounding boxes of different colours, and quantity statistics and visual output were completed.

A field comparison test was conducted with reference to manually annotated ground truth. A total of 1530 valid targets were detected, including 445 unpollinated flowers, 820 pollinated flowers and 265 developed fruits, corresponding to the ground truth values of 454, 811 and 271 respectively. The results show that the model can accurately identify tomato organs at different developmental stages in the field environment with low quantity statistics error, and can provide intelligent support for flowering management, pollination effect evaluation and yield prediction of facility tomatoes.

CONCLUSIONS

To address the core requirement for the accurate recognition of stigma pollination status in cherry blossom pollination robots, along with technical challenges including the tiny size of stigma targets, subtle visual differences among three states, and complex lighting conditions in greenhouse environments, this paper proposes a YOLO11-RCSP model based on the improved YOLO11. The model incorporates four key enhancements: introducing RFAConv receptive field attention convolution to solve parameter sharing issues; adding a CPA-Enhancer adaptive enhancement module to improve adaptability to greenhouse lighting variations and occlusions; replacing the original C3k2 module with the C3k2_SAConv module to dynamically adjust the receptive field; and adopting the Powerful-IoU loss function to optimize small-object localization accuracy. On the self-built cherry tomato pistil dataset, the model achieves 88.40% precision, 84.60% recall, 90.80% mAP@50, and 63.20% mAP@50–95, representing improvements of 5.20%, 3.30%, 4.40%, and 5.30% respectively over the baseline YOLO11, and significantly outperforms mainstream detectors such as YOLOv5, YOLOv6, YOLOv8, YOLOv9t, and YOLOv10n, thereby validating the effectiveness and superiority of the proposed method.

Although the YOLO11-RCSP model has achieved significant improvements in detection accuracy, computational complexity has increased and inference speed has decreased following the model enhancements; whilst it meets real-time requirements, there is still room for optimisation. Future work will focus on model lightweighting and adaptive methods for cross-scenario data augmentation to further enhance the model's deployment efficiency and generalisation robustness.

This research is expected to be deployed in the visual perception module of a tomato pollination robot, enabling precise determination of pollination status and providing a basis for decision-making in automated pollination operations.

ACKNOWLEDGEMENT

This study received support from two projects: the Science and Technology Innovation Enhancement Project under the Scientific Research Initiatives of Shanxi Agricultural University (No. CXGC2025057), the Smart Agricultural Machinery and Rural Governance Project funded by the Shanxi Provincial Key Research and Development Project (No. 202202140601021). The authors express sincere gratitude for the financial and institutional support provided by these initiatives.

ABSTRACT

Accurate detection of grape diseases in controlled facility environments is of significant importance. In this study, a novel detection model, PWE-YOLO, is proposed based on YOLO v11. In this model, the C3k2 modules in the Neck network are replaced with C3k2-PConv modules, which maintain high-precision feature extraction while reducing model parameters and memory consumption. Furthermore, a WaveletPool module is introduced to replace all Conv modules in the model, except for the 0th and 1st layers, enhancing feature representation and detection accuracy for grape diseases while further reducing model parameters and floating-point operations. EMA attention modules are incorporated at the 17th and 24th layers to improve small-object detection capabilities, thereby increasing overall detection precision. Experimental results demonstrate that PWE-YOLO achieves a precision of 85.0%, recall of 83.6%, and mAP of 86.9%, with 1.96 × 10^6 parameters and 5.1 × 10^9 floating-point operations. Compared with the original YOLO v11 model, precision, recall, and mAP increase by 4.5, 1.4, and 1.9 percentage points, respectively, while parameters and floating-point operations decrease by 24.03% and 10.05%. Relative to YOLO v8, v9, v10, v12, and v13, precision improves by 2.2%, 5.3%, 3.3%, 2.2%, and 2.5%, recall by 6.0%, 2.8%, 5.2%, 8.8% and 3.8%, and mAP by 1.9%, 1.8%, 2.8%, 5.0%, and 2.3%, respectively, with corresponding reductions in model parameters and floating-point operations. These results indicate that PWE-YOLO not only provides high-accuracy detection for grape diseases but also reduces computational complexity, achieving a lightweight architecture and faster detection speed, making it suitable for deployment in resource-constrained target detection scenarios.

摘要

为实现设施环境中葡萄病害目标的准确检测，本文在 YOLO v11 的基础上，提出一种适用于设施环境葡萄病害目标检测模型 PWE-YOLO。将颈部网络中的 C3 2 模块替换为 C3 2-PConv 模块，在保持高精度特征提取能力的基础上，降低模型参数量和内存占用量；同时在模型中引入 WaveletPool 模块，替换模型中除第 0 层、第 1 层外的所有 Conv 模块，提高葡萄病害的特征表达能力与检测精度，进一步降低模型参数量和浮点运算量；且在模型的第 1 层和第 24 层中添加 EMA 注意力机制模块，增强模型对小目标的检测能力，提升模型的检测精度。结果显示，PWE-YOLO 模型的精确率为 85.0%、召回率为 83.6%、mAP 为 86.9%、参数量为 1.96×10^6、浮点运算量为 5.1×10^9。与原始 YOLO v11 模型相比，该模型的精确率、召回率和 mAP 分别提高 4.5、1.4、1.9 个百分点，参数量和浮点运算量分别降低 24.03%、10.05%。与 YOLO v8、YOLO v9、YOLO v10、YOLO v12、和 YOLO v13 模型相比，其精确率分别提高 2.2、5.3、3.3、2.2、和 2.5 个百分点，召回率分别提高 6.0、2.8、5.2、8.8、和 3.8 个百分点，mAP 分别提高 1.9、1.8、2.8、5.0、和 2.3 个百分比，参数量分别减少 34.88%、25.19%、2 .40%、21.91%和 20.00%，浮点运算量分别减少 3 .03%、52.34%、3 .80%、12.0 %和 1 . 4%。结果表明，本文提出的 PWE-YOLO 模型在葡萄病害检测任务中不仅能够提供高准确性的检测性能，同时也有效降低了计算复杂度，具有较轻的模型结构和较快的检测速度，适合应用于对计算资源要求较高的目标检测任务中。

INTRODUCTION

Grapes, as one of the most important economic crops worldwide, are known to be highly susceptible to fungal diseases, including downy mildew, powdery mildew, and gray mold, during their growth period. Premature leaf senescence and fruit rot are caused by these diseases, which severely affect yield and quality *(Rahman et al, 2024)*.

Haoyue Liu, M.Sc. Stud. Eng.; Benzhi Yang, M.Sc. Stud. Eng.; Mingyang Gao, M.Sc. Stud. Eng.; Dong Wang, M.Sc. Stud. Eng.; Longlong Ren Lecturer Ph.D. Eng; Yuepeng Song, Prof. Ph.D. Eng.

Therefore, early detection and effective control of these diseases are considered crucial for ensuring the sustainable development of the grape industry. However, in the early stages of infection, disease symptoms are often subtle and typically manifest as small spots or slight discoloration on leaves, which can be easily mistaken for leaf changes induced by environmental stress. Traditional manual identification methods are largely dependent on expert judgment, resulting in relatively low accuracy and making comprehensive monitoring in large-scale vineyards difficult to achieve *(Poblete-Echeverría et al, 2025)*.

In recent years, with the rapid advancement of computer vision and deep learning technologies, image recognition methods based on convolutional neural networks (CNNs) have made remarkable progress in crop disease detection *(Zhang et al, 2022)*. Among these methods, the YOLO series of algorithms has been extensively applied in agricultural settings, particularly for the identification and detection of grape diseases, due to its end-to-end architecture and high real-time performance. For example, Liu et al. proposed an improved CNN-based detection framework for multiple grape leaf diseases, in which preprocessing and data augmentation techniques were applied to simulate real-world environments, enhancing the model's robustness and generalization ability, and achieving a precision of 97.22% on the test set *(Liu et al, 2020)*. Zhen Yuanyuan et al. introduced the CBAM attention mechanism on top of the YOLOv8 model to enhance the feature representation of key disease spots on grape leaves, while the ShuffleNet V2 module was incorporated for network lightweight modification, which improved both detection accuracy and speed, achieving a mAP of 94.6% and an inference speed of 52.06 FPS *(Yang et al, 2024)*. Zhang et al. proposed the DLVTNet model, combining generative data augmentation with a lightweight Transformer, and achieved a precision of 98.48% on the grape leaf disease dataset *(Zhen et al, 2025)*. Fu et al. combined YOLO and Transformer concepts to develop the MHDI-DETR model, balancing computational efficiency and detection accuracy, and achieving a mAP of 92.6% in detecting grape leaf diseases such as black rot and black spot *(Fu et al, 2024)*. Zhang Lin et al. proposed a detection method combining StyleGAN2-ADA augmentation with an improved YOLOv7 model to enhance localization of small early-stage disease spots, and by utilizing attention mechanisms and feature fusion, the model was able to detect small targets effectively, achieving a mAP of 95.4%, a precision of 94.1%, and an inference speed of 77.12 FPS *(Zhang et al, 2025)*.

Nevertheless, existing studies remain limited, as deep network models typically involve large numbers of parameters and high computational complexity, which hinder efficient deployment on resource-constrained agricultural edge devices. To address these challenges, an early detection method for grape diseases based on PWE-YOLO is proposed in this study. The proposed model enhances detection accuracy for grape diseases, reduces model parameters and memory consumption, and improves detection speed. Notably, in resource-limited environments, the model demonstrates superior real-time detection and on-site deployment capabilities, thereby exhibiting increased practicality and robustness.

MATERIALS AND METHODS

Data Collection and Preprocessing

Image data were collected at the Yantai Academy of Agricultural Sciences, Fushan District, Yantai City (37.5076°N, 121.255°E), from September 2024 to August 2025. The images were captured under natural lighting conditions using an iPhone 15 Pro smartphone, which took multi-angle shots of grape leaves. A total of approximately 3,000 images were collected, covering both healthy leaves and five major disease types: downy mildew, powdery mildew, gray mold, canker, and Grapevine Leafroll-associated Virus (GLRaV) disease. To ensure sample diversity, the images were captured under varying lighting intensities, humidity levels, and leaf age stages. The collected images were manually screened to remove blurred and occluded samples, after which they were resized to 600×400 pixels and normalized to ensure consistency in input for model training. After screening, a final dataset consisting of 1,785 high-quality images was created. Table 1 presents the number of images for each disease category in the dataset.

Table 1

Number of images in grape disease dataset

Type	downy mildew	powdery mildew	gray mold	canker	GLRaV
Primitive	456	359	321	369	280

Disease annotation was performed using the LabelImg tool, with the annotation categories including five types: downy mildew, powdery mildew, gray mold, canker, and GLRaV; the annotation results are shown in Figure 1.

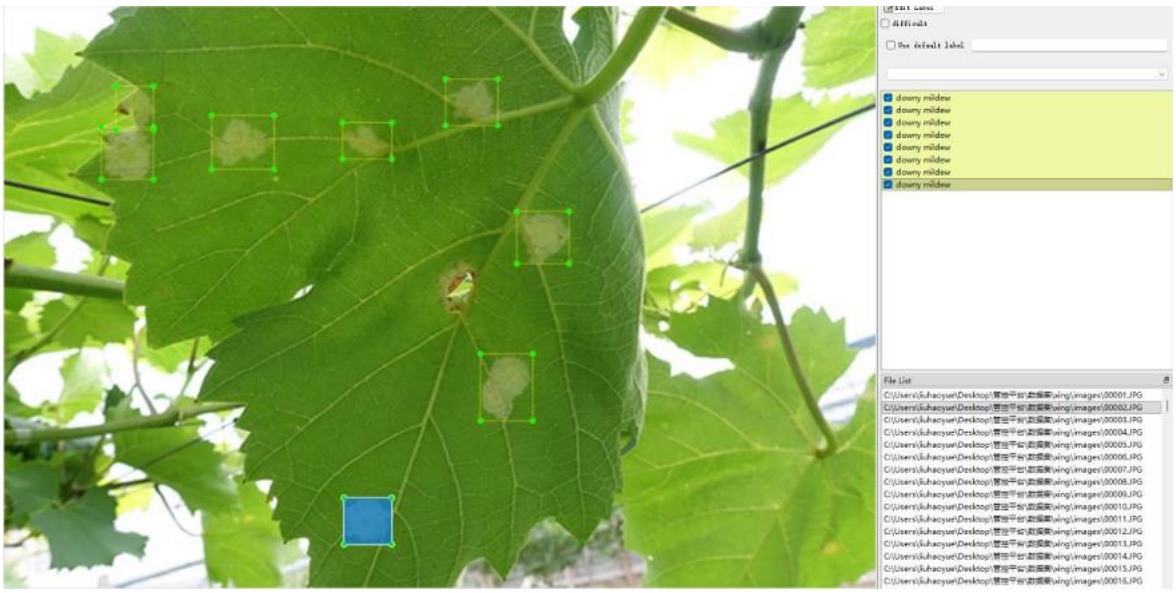

Fig. 1 - Annotation of the Grape Disease Dataset

The dataset was divided into training, validation, and test sets with a ratio of 70%, 20%, and 10%, respectively. To improve the model's robustness and generalization ability, data augmentation was applied to the images in the dataset. Specifically, six augmentation techniques were used: adding Gaussian noise, random rotation, random cropping, horizontal flipping, brightness adjustment, and Gaussian blur. For each original image, three techniques were randomly selected) from the six listed and applied in combination, repeated three times. This process produced three augmented samples per original image, effectively enlarging the dataset and improving the model's adaptability to complex imaging conditions. The dataset was ultimately expanded to 7,140 images, with 4,998 images in the training set, 1,428 in the validation set, and 714 in the test set. Representative examples of the augmented dataset images are shown in Figure 2.

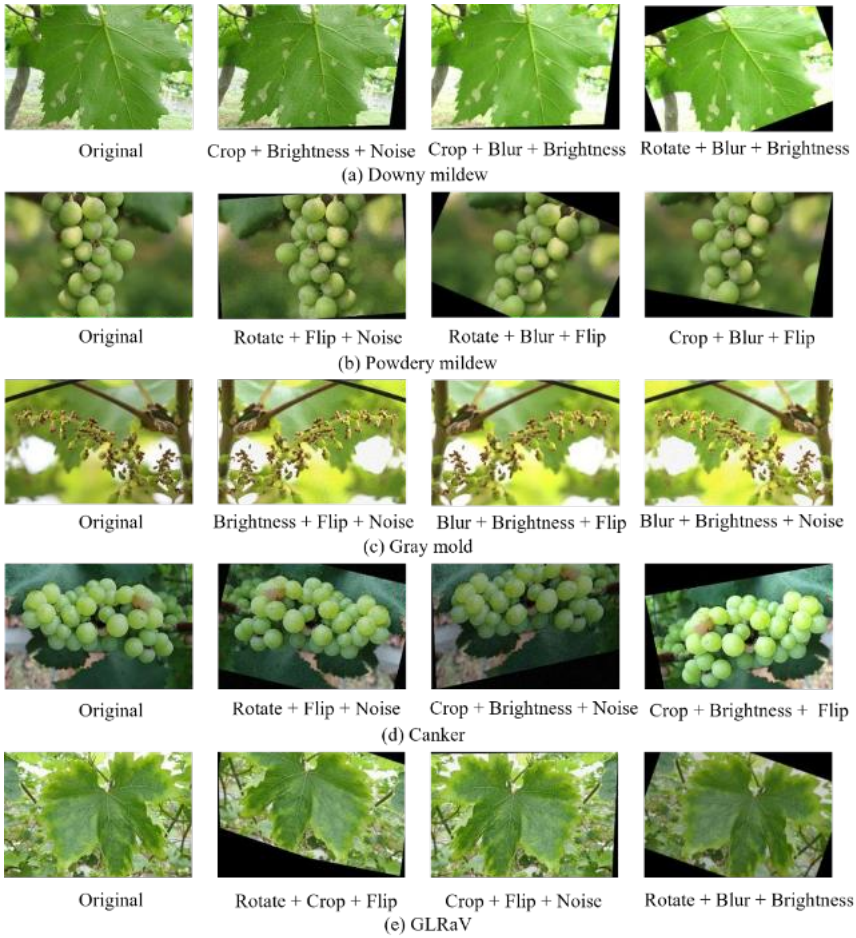

Fig. 2 - Image Examples of the Grape Disease Dataset

Construction of the PWE-YOLO-Based Grape Disease Detection Model

In agricultural object detection tasks, YOLO v11 adopts an efficient single-stage architecture and demonstrates strong small-object feature representation capabilities, enabling high-precision real-time detection of targets such as pests and diseases in complex scenarios, while maintaining a lightweight design and ease of deployment *(Badgujar et al, 2024)*. To enhance the detection performance of grape diseases in controlled environments, the YOLO v11 model was improved in this study.

First, the C3k2-PConv module was introduced to replace the C3k2 module in the Neck network. This modification reduces the model's parameter count and memory usage while preserving high-precision feature extraction capabilities. Consequently, real-time detection performance is improved, and model robustness and detection accuracy are simultaneously enhanced.

Second, the WaveletPool module was introduced to replace all Conv modules in the model, except for the 0th and 1st layers. This modification reduces the model's parameter count and floating-point operations, maintaining a lightweight architecture while effectively suppressing downsampling aliasing. Moreover, it enhances the retention of high-frequency features in disease regions, such as edges, patterns, and color variations, thereby improving feature representation and detection accuracy for early-stage grape diseases.

Finally, the EMA attention mechanism module was added to the 17th and 24th layers to mitigate background interference, enhance the model's robustness in complex environments, and improve precision and mAP values. The architecture of the proposed PWE-YOLO model is illustrated in Figure 3.

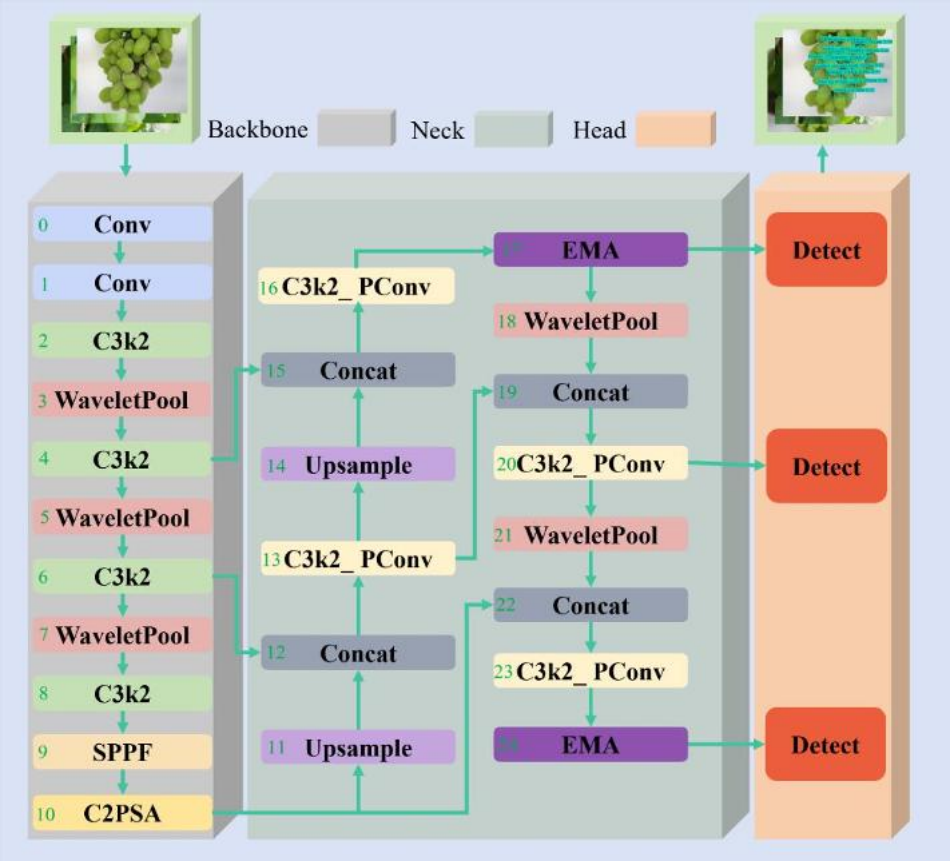

Fig. 3 - Architecture of the PWE-YOLO Model

C3k2-PConv Module

Partial Convolution (PConv) *(Chen et al, 2023)* performs convolution operations on the valid regions of the input feature map, reducing redundant computations and memory accesses, thereby improving the efficiency of spatial feature extraction *(Jiang et al, 2025)*. Unlike traditional convolution and depth/group convolutions, PConv applies the convolution kernel only to valid channels, leaving other channels unchanged. This approach reduces the number of floating-point operations, maintains high detection accuracy, reduces the model's parameter count, and increases computational speed *(Zhang and Zeng, 2024)*, The structure of PConv is illustrated in Figure 4. The C3k2 module extracts multidimensional features from the input image by combining convolutions at different levels. The C3 layer is generally used to capture feature information at multiple scales more effectively, thereby enhancing the model's ability to perceive complex image content *(Jin et al, 2025; Zhang et al, 2026)*.

The C3k2-PConv module combines the deep feature extraction capability of Convolutional Neural Networks (CNN) with the selective convolution ability of partial convolutions. Through flexible convolution kernel combinations and localized convolution operations, it enhances the processing of complex image content while effectively addressing the impact of missing or invalid data. The structure of the C3k2-PConv module is shown in Figure 5.

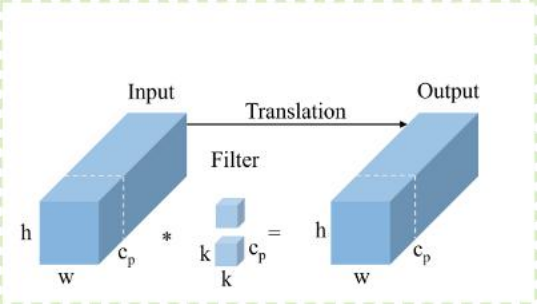

Fig. 4 - Architecture of the PConv Module

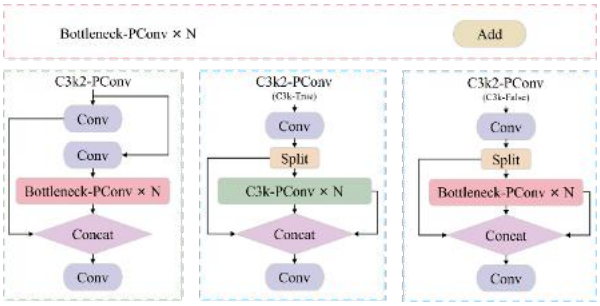

Fig. 5 - Architecture of the C3k2-PConv Module

For the early detection of grape diseases, the C3k2-PConv module substantially reduces the model's parameter count and memory usage while maintaining high-precision feature extraction capabilities, thereby enhancing real-time detection speed. Particularly in cases of feature loss or damaged regions caused by insufficient lighting or suboptimal shooting angles, C3k2-PConv performs convolution operations exclusively on valid regions, avoiding interference from missing or corrupted areas in the final detection results. Consequently, the module improves the model's robustness and detection accuracy under challenging imaging conditions.

WaveletPool Module

The WaveletPool module is an efficient downsampling method based on discrete wavelet transform *(Sun et al, 2022)*. By performing two-dimensional wavelet decomposition on the input feature map, the module extracts a low-frequency structural subband (LL) and three types of high-frequency detail subbands (LH, HL, HH), using the LL subband as the downsampling output. This approach reduces feature dimensionality while retaining key information such as edges and textures of the target *(Qu and Zhang, 2025; Xu and Wang, 2023)*. Compared with traditional max pooling or average pooling, WaveletPool module effectively suppresses aliasing in the downsampling process in the transform domain, preventing small target features from being overly smoothed or lost in deep networks. It is particularly suitable for small object recognition and detection tasks in agricultural scenarios characterized by significant scale variations and complex backgrounds *(Raj et al, 2025)*. Furthermore, WaveletPool features low computational cost and a lightweight structure, making it appropriate for deployment on mobile devices or in real-time detection systems. Its advantages in enhancing accuracy and feature stability have been validated in several lightweight detection networks. The structure of the WaveletPool module is shown in Figure 6.

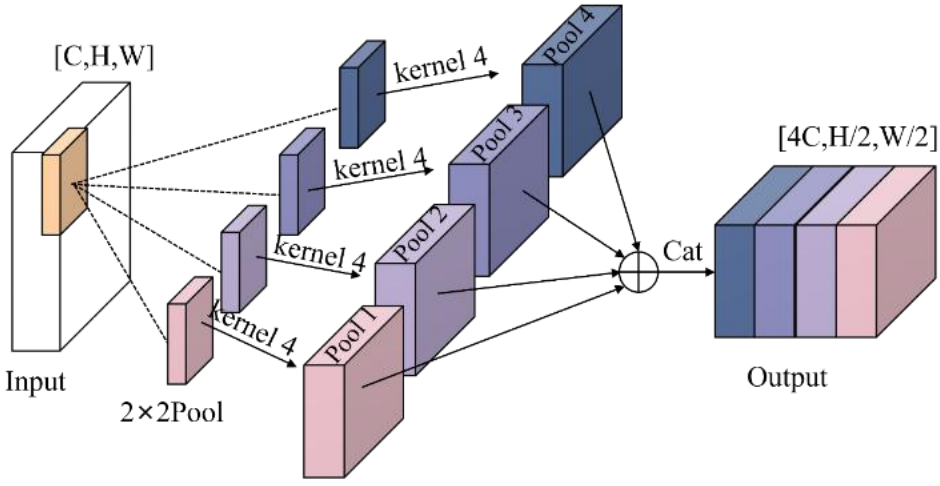

Fig. 6 - Architecture of the WaveletPool module

For grape disease detection tasks, the WaveletPool module, based on discrete wavelet transform, effectively suppresses aliasing during downsampling while maintaining the network's lightweight design, enhancing the retention of high-frequency features such as edges, patterns, and color variations in disease regions. This module stabilizes the model under conditions of low texture contrast, complex background lighting, and micro-scale variations in early-stage disease spots, thereby improving feature representation and detection accuracy for early-stage grape diseases.

EMA Attention Module

The EMA (Efficient Multi-scale Attention) *(Ouyang et al, 2023)* mechanism is an efficient feature extraction module designed to enhance the fusion of multi-scale features. Integrating the EMA attention mechanism into the YOLO model can improve the detection accuracy of agricultural targets, including crop diseases and small objects such as buds. The EMA module divides the input feature map into multiple sub-feature groups and utilizes parallel 1×1 and 3×3 convolution paths to extract fine-grained and large-scale features, respectively. The 1×1 path employs global average pooling and convolution operations to encode channel information, enhancing inter-channel interaction, while the 3×3 path captures broader spatial features, expanding the receptive field for feature extraction *(Li et al, 2025)*. This design allows the EMA attention mechanism to focus on target regions without compromising computational efficiency, improving robustness to small targets and complex backgrounds *(Williams et al, 2018)*. Following its integration, the YOLO model demonstrates enhanced capability in detecting small targets and handling complex backgrounds, thereby improving its suitability for agricultural application, effectively improving the detection of small objects such as buds and early-stage disease spots. The structure of the EMA attention mechanism is shown in Figure 7.

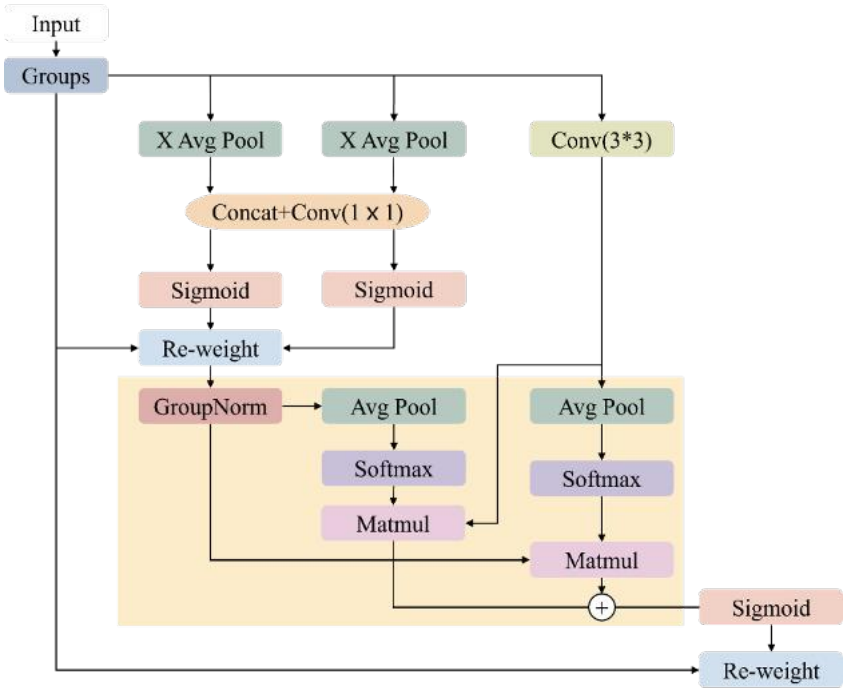

Fig. 7 - Architecture of the EMA module

In grape disease detection tasks, the EMA attention mechanism enhances the model's sensitivity to early-stage grape diseases, such as small lesions, through multi-scale feature extraction and information fusion. It effectively captures features at different scales via parallel 1×1 and 3×3 convolution paths, while reinforcing attention to small targets, thereby improving detection accuracy for small lesions. Additionally, EMA reduces background interference, enhancing model robustness in complex environments and enabling more accurate and stable early detection of grape diseases.

Model Deployment Methodology

The operating system used is Linux Ubuntu 22.04, with an Intel(R) Xeon(R) Platinum 8474C CPU model, an NVIDIA GeForce RTX 4090 GPU with 24GB of video memory. The programming language is Python 3.10, the deep learning framework is PyTorch 2.1.0, and the GPU acceleration library is CUDA 12.1.

RESULTS

Experimental Setup and Evaluation Metrics

To evaluate the performance of the network model in object detection tasks, Precision, Recall, mean Average Precision (mAP), the number of parameters, and the number of floating-point operations are used as the primary evaluation metrics *(Xie et al, 2025)*. During training, the input image size was set to 400 × 600 pixels, the number of epochs was set to 100, and the batch size was set to 64. The SGD optimizer was used for model optimization. The cache mechanism was enabled, the number of data loading workers was set to 8, and automatic mixed precision training was adopted.

Comparison Experiment of C3k2-PConv Module

To evaluate the performance of the C3k2-PConv module proposed in this study, alternative modules—C3k2-WTConv, C3k2-FasterBlock, and C3k2-RepVGG—were used to replace the corresponding module at the same position in the model, and comparison experiments were conducted. The results are summarized in Table 2.

Table 2

Effects of different C3k2 modules on detection performance

Model	P/%	R/%	mAP/%	Parameters	FLOPs
YOLO v11	80.5	82.2	85.0	2.58×10^6	6.3×10^9
YOLO v11-C3k2-PConv	81.5	82.7	85.7	2.37×10^6	5.9×10^9
YOLO v11-C3k2-WTConv	80.5	81.8	85.5	2.53×10^6	6.3×10^9
YOLO v11- C3k2-FasterBlock	82.0	82.5	85.1	2.54×10^6	6.2×10^9
YOLO v11-C3k2-RepVGG	80.9	82.5	85.2	2.60×10^6	6.4×10^9

As shown in the table, the YOLO v11-C3k2-PConv model achieves improvements of 1.0, 0.5, and 0.7 percentage points in Precision, Recall, and mAP, respectively, compared with the baseline YOLO v11 model, while reducing the number of parameters and floating-point operations by 8.1% and 6.3%, respectively. Compared with the other alternative modules, the YOLO v11-C3k2-PConv model exhibits slightly lower Precision than the YOLO v11-C3k2-FasterBlock model, but outperforms the remaining models across all other evaluation metrics. In particular, its Recall, mAP, number of parameters, and floating-point operations are superior to those of the alternative models, demonstrating a lower computational cost. These results suggest that the YOLO v11-C3k2-PConv model is well adapted to object detection tasks under constrained computational resources and demonstrates superior performance in the grape disease detection task evaluated in this study.

Comparison Experiment of WaveletPool Module

The performance of the WaveletPool module proposed in this study was evaluated by replacing it with alternative modules—SAConv, ContextGuided, and ADown—at the same position in the model, and comparison experiments were conducted. The results are summarized in Table 3.

Table 3

Comparison of detection results for different modules

Model	P/%	R/%	mAP/%	Parameters	FLOPs
YOLO v11	80.5	82.2	85.0	2.58×10^6	6.3×10^9
YOLO v11-WaveletPool	83.2	80.0	85.5	2.17×10^6	5.4×10^9
YOLO v11-SAConv	83.2	79.9	84.3	3.42×10^6	4.7×10^9
YOLO v11-ContextGuided	81.2	78.8	86.0	2.83×10^6	6.8×10^9
YOLO v11-ADown	83.0	80.0	83.7	2.11×10^6	5.3×10^9

As shown in the table, compared with the original YOLO v11 model, the YOLO v11-WaveletPool model exhibits a slight decrease in Recall, while Precision and mAP increase by 2.7 and 0.5 percentage points, respectively. Additionally, the number of parameters and floating-point operations decrease by 15.89% and 14.29%, respectively. Compared with the alternative modules, YOLO v11-WaveletPool demonstrates higher Precision and Recall. Although its mAP is slightly lower than that of the YOLO v11-ContextGuided model, it outperforms the other models in overall detection performance. In comparison with the YOLO v11-ADown model, the YOLO v11-WaveletPool model has slightly higher numbers of parameters and floating-point operations, but its Precision, Recall, and mAP remain superior. Moreover, the total number of parameters and floating-point operations in the YOLO v11-WaveletPool model is substantially lower than in the remaining models, contributing to better overall efficiency and detection performance.

Comparison Experiment of EMA Attention Module

The performance of the EMA attention mechanism proposed in this study was evaluated by integrating alternative attention mechanisms—including SCSA, MSDA, LSKA, iRMB, CGA, and SEAM—at the corresponding positions in the model. Performance comparisons were then conducted, and the results are presented in Figure 8.

As shown in Figure 8, compared with the baseline YOLO v11 model, the YOLO v11-EMA model achieves increases of 1.7, 0.4, and 0.7 percentage points in Precision, Recall, and mAP, respectively. Relative to the YOLO v11-MSDA model, the YOLO v11-EMA model exhibits a slightly lower Recall, while its Precision and mAP are improved by 0.4 and 1.2 percentage points, respectively. For the YOLO v11-iRMB model, although its mAP is comparable to that of the YOLO v11-EMA model, its Precision and Recall remain lower. Furthermore, compared with the YOLO v11-SCSA, YOLO v11-LSKA, YOLO v11-CGA, and YOLO v11-SEAM models, the YOLO v11-EMA model demonstrates superior performance in all three metrics. Collectively, these results indicate that the YOLO v11-EMA model exhibits the best overall performance in grape disease detection tasks.

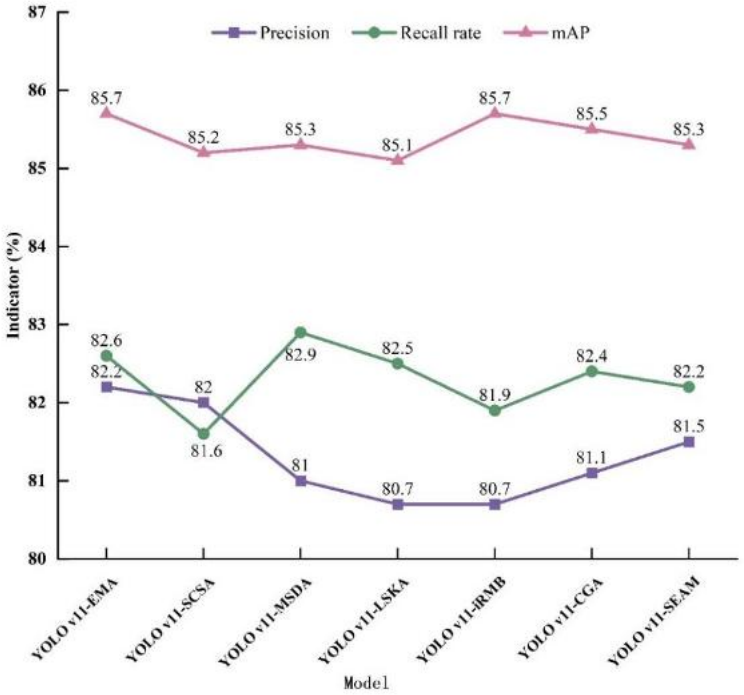

Fig. 8 - Comparative results of different attention modules

Ablation Experiment

The effectiveness of the improved PWE-YOLO model was evaluated through ablation experiments conducted on the custom-built grape disease dataset, with YOLO v11 serving as the baseline model. These experiments were designed to assess the impact of each individual module on overall model performance. The results of the ablation study are presented in Table 4, where "√" indicates the inclusion of a module and "×" indicates its exclusion. Here, P represents the C3k2-PConv module, W corresponds to the WaveletPool module, and E denotes the EMA attention mechanism.

Table 4

Results of ablation experiment

Model	WaveletPool	EMA	C3k2-PConv	P/%	R/%	mAP/%
YOLO v11	×	×	×	80.5	82.2	85.0
YOLO v11-P	×	×	√	81.5	82.7	85.7
YOLO v11-W	√	×	×	83.2	80.0	85.5
YOLO v11-E	×	√	×	82.2	82.6	85.7
YOLO v11-PW	√	×	√	83.9	83.2	85.8
YOLO v11-PE	×	√	√	84.5	83.4	86.6
YOLO v11-WE	√	√	×	83.3	83.1	86.4
PWE-YOLO	√	√	√	85.0	83.6	86.9

As presented in Table 4, the introduction of the C3k2-PConv module into the YOLO v11 model results in the YOLO v11-P model. Compared with the baseline YOLO v11 model, YOLO v11-P achieves improvements of 1.0, 0.5, and 0.7 percentage points in Precision, Recall, and mAP, respectively, while its number of parameters and floating-point operations are reduced by 8.13% and 6.35%, respectively. The integration of the WaveletPool module into YOLO v11 produces the YOLO v11-W model. Compared with YOLO v11, YOLO v11-W improves Precision and mAP by 2.7 and 0.5 percentage points, respectively, while its number of parameters and floating-point operations are reduced by 15.89% and 14.29%, respectively. Similarly, the addition of the EMA attention mechanism results in the YOLO v11-E model. Compared with the baseline model, YOLO v11-E achieves improvements of 1.7, 0.4, and 0.7 percentage points in Precision, Recall, and mAP, respectively, while its number of parameters and floating-point operations slightly increase. These results indicate that the individual incorporation of the C3k2-PConv, WaveletPool, and EMA modules can effectively enhance the detection performance of the model.

The simultaneous integration of the C3k2-PConv and WaveletPool modules into the YOLO v11 model produces the YOLO v11-PW model. Compared with the YOLO v11-P and YOLO v11-W models, YOLO v11-PW achieves improvements in Precision, Recall, and mAP, while its number of parameters and floating-point operations is significantly reduced relative to YOLO v11, YOLO v11-P, and YOLO v11-W. The combination of the C3k2-PConv module and the EMA attention mechanism results in the YOLO v11-PE model. YOLO v11-PE demonstrates enhanced Precision, Recall, and mAP compared with YOLO v11-P and YOLO v11-E, while its number of parameters and floating-point operations are reduced compared with YOLO v11 and YOLO v11-E, with a slight increase in floating-point operations relative to YOLO v11-P. Similarly, the integration of the WaveletPool module and the EMA attention mechanism yields the YOLO v11-WE model. Compared with YOLO v11-W and YOLO v11-E, YOLO v11-WE achieves improvements in Precision, Recall, and mAP, while its number of parameters and floating-point operations is significantly lower than in YOLO v11 and YOLO v11-E, with a slight increase in floating-point operations relative to YOLO v11-W.

The simultaneous integration of the C3k2-PConv module, the WaveletPool module, and the EMA attention mechanism into the YOLO v11 model produces the PWE-YOLO model. Compared with the baseline YOLO v11 model, PWE-YOLO achieves improvements of 4.5, 1.4, and 1.9 percentage points in Precision, Recall, and mAP, respectively, while reducing the number of parameters and floating-point operations by 24.03% and 10.05%, respectively. PWE-YOLO outperforms all other improved models across the evaluated metrics, demonstrating superior detection performance. The results of the ablation experiments confirm the effectiveness and rationality of the proposed design. By integrating the C3k2-PConv, WaveletPool, and EMA modules, the model's detection accuracy is effectively enhanced, while the computational cost is substantially reduced. These improvements make the proposed method particularly suitable for target detection tasks under constrained computational resources, highlighting its clear advantage for grape disease detection in controlled environments.

Comparative Experiment of Different Models

To further validate the advancement of the PWE-YOLO model proposed in this paper, a comparative experiment was conducted between the PWE-YOLO model and the YOLO v8 *(Ren et al, 2024)*, YOLO v9 *(Kalezhi and Shumba, 2025)*, YOLO v10 *(Zheng et al, 2025)*, YOLO v11, YOLO v12 *(Zhao et al, 2025)*, and YOLO v13 models. In the experimental design, all models were trained and tested under the same hardware and software environment to eliminate the influence of external environmental factors on the experimental results. The grape disease dataset constructed in this study was used, and reasonable hyperparameters were set to ensure the reliability and accuracy of the experimental results. The results are summarized in Table 5.

Table 5

Performance comparison of different models

Model	P/%	R/%	mAP/%	Parameters	FLOPs
YOLO v8	82.8	77.6	85.0	3.01×10^6	8.1×10^9
YOLO v9	79.7	80.8	85.1	2.62×10^6	10.7×10^9
YOLO v10	81.7	78.4	84.1	2.70×10^6	8.2×10^9
YOLO v11	80.5	82.2	85.0	2.58×10^6	6.3×10^9
YOLO v12	83.8	74.8	81.9	2.51×10^6	5.8×10^9
YOLO v13	83.5	79.8	84.6	2.45×10^6	6.2×10^9
PWE-YOLO	85.0	83.6	86.9	1.96×10^6	5.1×10^9

As shown in Table 5, the PWE-YOLO model achieves a Precision of 85.0%, Recall of 83.6%, and mAP of 86.9%, with a parameter count of 1.96×10^6 and floating-point operations of 5.1×10^9. Compared with YOLO v8, YOLO v9, YOLO v10, YOLO v11, YOLO v12, and YOLO v13, the Precision of PWE-YOLO increases by 2.2, 5.3, 3.3, 4.5, 2.2, and 2.5 percentage points, respectively; Recall increases by 6.0, 2.8, 5.2, 1.4, 8.8, and 3.8 percentage points, respectively; and mAP improves by 1.9, 1.8, 2.8, 1.9, 5.0, and 2.3 percentage points, respectively. In terms of computational complexity, PWE-YOLO demonstrates significant advantages over the compared models. The number of parameters is reduced by 34.88%, 25.19%, 27.40%, 24.03%, 21.91%, and 20.00%, respectively, while floating-point operations are decreased by 37.03%, 52.34%, 37.80%, 19.05%, 12.07%, and 17.74%, respectively. These results indicate that PWE-YOLO not only achieves higher accuracy in grape disease detection but also reduces computational complexity, featuring a lightweight architecture and faster inference speed. Overall, the proposed model demonstrates superior performance across Precision, Recall, and mAP, underscoring its effectiveness and suitability for real-time target detection in resource-constrained agricultural environments.

Analysis of Detection Results for Different Diseases

This study focuses on the recognition of multiple grape diseases, including downy mildew, powdery mildew, gray mold, canker, and Grapevine Leafroll-associated Virus (GLRaV) disease. Given the distinct manifestations of these diseases, the performance of the proposed PWE-YOLO model was evaluated separately for each disease type. To verify the recognition accuracy, comparative analyses were conducted between the original model and the improved PWE-YOLO model for all five disease categories.

Table 6

Comparison of model recognition accuracy for five diseases before and after improvement

Model	mAP (%)	Precision				
		downy mildew (%)	powdery mildew (%)	gray mold (%)	canker (%)	GLRaV (%)
YOLO v11	85.0	79.6	81.1	77.9	83.9	80.0
PWE-YOLO	86.9	84.8	85.5	82.2	87.0	85.5

Table 6 presents the recognition results for five grape diseases obtained using both the baseline YOLO v11 model and the improved PWE-YOLO model. The introduction of the C3k2-PConv module allows the model to perform convolution operations exclusively on valid regions during disease detection, effectively mitigating the impact of feature loss or damaged areas caused by insufficient lighting or unfavorable shooting angles. This approach prevents interference from missing regions in the final detection outcomes. The incorporation of the WaveletPool module enables effective suppression of downsampling aliasing while maintaining a lightweight network structure, significantly improving the retention of high-frequency features such as edges, patterns, and color variations in disease regions. Furthermore, the addition of the EMA attention mechanism enhances the model's focus on small targets, thereby increasing the detection accuracy of small lesions. As shown in Table 6, the integration of these three improvements leads to increases of 5.2, 4.4, 4.3, 3.1, and 5.5 percentage points in detection accuracy for the five grape diseases, respectively, compared with the baseline YOLO v11 model.

As shown in Table 6, through the three proposed improvements, the detection accuracy of the five grape diseases in the PWE-YOLO model increased by 5.2, 4.4, 4.3, 3.1, and 5.5 percentage points, respectively, compared with the original YOLO v11 model. These results indicate that the proposed PWE-YOLO model demonstrates superior performance across all disease types.

Analysis of Detection Results for Different Diseases

To comprehensively evaluate the detection performance of the proposed PWE-YOLO model, both PWE-YOLO and the baseline YOLO v11 models were applied to images from the test set. The visual detection results produced by the two models were compared, as illustrated in Figure 9.

The detection results are presented in Figure 9. For grape disease images with few targets, such as gray mold and Grapevine Leafroll-associated Virus (GLRaV) disease, the PWE-YOLO model accurately detects the disease regions, whereas the YOLO v11 model, although capable of detecting both diseases, exhibits slightly lower accuracy. For images containing multiple disease targets, such as downy mildew, powdery mildew, and canker, detection is challenged by overlapping symptoms and subtle disease manifestations, resulting in higher rates of missed and false detections.

Nevertheless, the PWE-YOLO model successfully detects a larger number of disease instances while maintaining lower rates of missed and false detections, whereas the YOLO v11 model exhibits missed detections for downy mildew and canker, and false detections for powdery mildew. These visualization results further validate the superiority and practical applicability of the PWE-YOLO model in grape disease detection tasks.

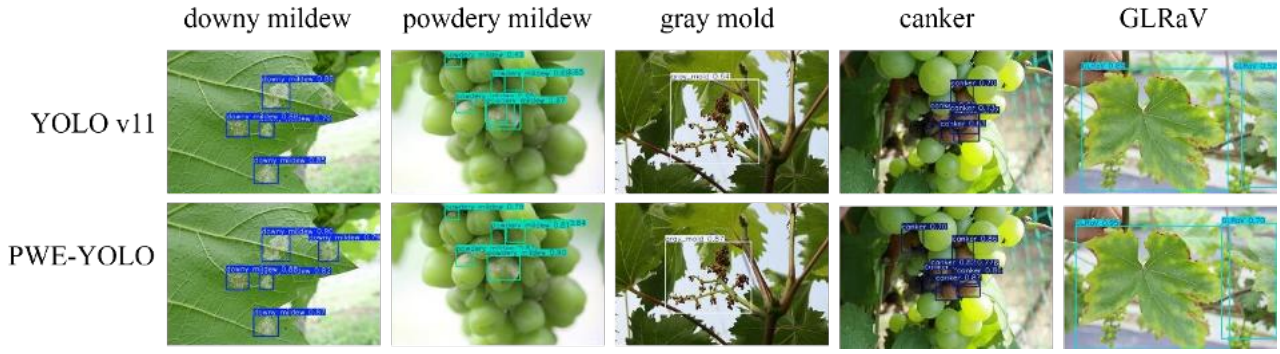

Fig. 9 - Detection results of different models

Practical Application in Vineyard Disease Inspection

To further demonstrate the practical applicability of the proposed method, a vineyard inspection robot platform was employed for field image acquisition. The platform consists of a mobile inspection robot, a robotic arm, and a depth camera mounted at the end of the robotic arm. During field operation, the robot moves along the vineyard rows, while the robotic arm adjusts the position and viewing angle of the camera to capture grape leaf images under natural environmental conditions. The acquired images are then input into the improved PWE-YOLO model for disease detection. The model outputs the disease category, confidence score, and location of the diseased region. Therefore, the integration of the inspection robot platform and the proposed detection model provides a feasible technical solution for intelligent grape disease monitoring, early warning, and precision vineyard management.

CONCLUSIONS

To achieve accurate detection of grape diseases in controlled environments, a PWE-YOLO model was proposed based on YOLO v11. By integrating the C3k2-PConv module, WaveletPool module, and EMA attention mechanism, the PWE-YOLO model improves detection accuracy, reduces floating-point operations and parameter count, and enhances inference speed.

The PWE-YOLO model achieves a Precision of 85.0%, Recall of 83.6%, and mAP of 86.9%, with a parameter count of 1.96×10^6 and floating-point operations of 5.1×10^9. Compared with the original YOLO v11 model, Precision, Recall, and mAP are improved by 4.5, 1.4, and 1.9 percentage points, respectively,

while the number of parameters and floating-point operations are reduced by 24.03% and 10.05%, respectively. Furthermore, when compared with YOLO v8, YOLO v9, YOLO v10, YOLO v11, YOLO v12, and YOLO v13, PWE-YOLO demonstrates clear advantages across multiple key metrics, including Precision, Recall, and mAP. In practical detection scenarios, PWE-YOLO effectively reduces missed detections, demonstrating its potential for real-time, accurate, and efficient grape disease monitoring in facility environments.

ABSTRACT

To address the challenges of low transplanting efficiency, poor planting accuracy, and high labor intensity associated with manual Panax notoginseng transplanting in the hilly and mountainous regions of Yunnan, as well as the limited adaptability of existing transplanting equipment to narrow ridged fields and steep, complex terrain, this study developed a self-propelled, fully electric tracked chassis tailored to the agronomic requirements of Panax notoginseng transplanting. The study included the overall structural design, selection and matching of the power battery and drive transmission system, and development of a dimensionless ratio-coefficient control model relating planting spacing to travel and transplanting speeds under the constraint of the manual seedling-feeding speed. An integrated electronic control system was developed to provide remote-controlled travel, speed-synchronized transplanting control, and straight-line deviation correction. The stability and dynamic performance of the chassis were analyzed theoretically and subsequently validated through field tests under multiple operating conditions. Theoretical results showed that the chassis had a maximum lateral roll angle of 39.19°, a maximum traction force of 7,524 N, and sufficient power reserve for operation on slopes of up to 25°. Field tests demonstrated that, after correction using the speed-adjustment coefficient, the straight-line deviation over a travel distance of 30 m was limited to within 1.1%, exceeding the requirements of the relevant national standard. The measured pivot-turning offset was approximately 191 mm, in close agreement with the theoretical value. Key performance indicators, including slope-climbing stability, ridge-travel stability, and motor thermal stability, all met the applicable national standards. The developed chassis effectively improves the adaptability of transplanting equipment for Panax notoginseng production in hilly and mountainous regions and significantly enhances the automation level and planting accuracy of transplanting operations. This study provides theoretical and technical support for the intelligent development of transplanting equipment for rhizomatous medicinal plants.

摘要

针对云南丘陵山区三七人工移栽效率低、栽植精度差、劳动强度大，且现有移栽装备难以适配垄上窄幅作业与陡坡复杂地形的产业痛点，本文设计一款适配三七移栽农艺需求的丘陵山区自走式纯电动履带底盘。完成整机结构方案设计、动力电池与驱动传动系统的选型匹配，基于人工投苗速度极限建立株距与行走-移苗速度的无量纲配比系数调控模型，开发集遥控行走控制、随速协同移栽控制、直线度纠偏控制于一体的电控系统，并开展整机稳定性与动力性能的理论计算，以及多工况田间性能验证试验。理论计算结果表明：该底盘横向极限倾翻角达 39.19°，最大牵引力 524 N，动力储备满足 25° 陡坡作业；田间试验结果显示：经速度修正系数纠偏后，整机 30 m 行程直线度误差可控制小于 1.1%，优于国家标准限值；原地转向中心偏移量实测约 191 mm，符合理论计算值；爬坡稳定性、垄上行驶稳定性及电机热稳定性等核心性能指标均满足相关国标要求。该底盘有效解决丘陵山区三七移栽的装备适配难题，显著提升移栽作业的自动化水平与栽植精度，可为根茎类中药材移栽装备的智能化升级提供理论与技术支撑。

INTRODUCTION

To address the practical challenges associated with manual transplanting of *Panax notoginseng* in the hilly and mountainous regions of Yunnan—including low efficiency, poor planting accuracy, and high labor intensity—as well as the limited adaptability of existing transplanting equipment to narrow ridges and steep, complex terrain *(Liu et al., 2025; Zhang, 2025; Zhu, 2025)*, an electric direct-drive, remote-controlled chassis is needed. The chassis should provide rapid dynamic response, stable operation *(Xu et al., 2023)*, and reliable remote-control capability, enabling it to operate effectively under narrow-width field conditions. By coordinating travel speed with the seedling-transplanting speed, the system can maintain accurate planting spacing and meet the operational requirements of ridged *Panax notoginseng* transplanting.

In the field of tracked chassis research, scholars worldwide have conducted extensive investigations, providing a solid theoretical and technical foundation for performance optimization. International studies have primarily focused on three directions: stability control, motion resistance analysis, and design evaluation versatility. *Rocha et al., (2023),* proposed an attitude controller integrating dual quaternions with the differential kinematics of a Stewart platform, enabling active track flap adjustments for terrain adaptation on rough ground. *Shafaei* & *Mousazadeh, (2023),* investigated the resistance characteristics of rubber track landing gears for autonomous towed robots, clarifying the effects of speed and load on resistance and suggesting optimization directions. *Dobretsov et al., (2021),* introduced a deterministic calculation method based on the Bernstein–Letoshnev relationship to effectively assess chassis–soil mechanical parameters. Validation using an eight-ton chassis demonstrated that this method outperforms stochastic approaches.

Chinese researchers have proposed various optimization strategies to address common challenges in the autonomous navigation and motion control of tracked chassis *(Liu et al., 2025; Zhao et al., 2024)*. *Qi et al., 2024,* developed a three-tangent path planning algorithm to mitigate the control deficiencies of single-side braking steering in tracked chassis, significantly improving path tracking stability and reducing steering control frequency. In response to the operational demands of complex environments such as hilly and mountainous regions and orchards, Chinese researchers have conducted targeted design and development efforts focusing on critical performance indicators, including trafficability and stability *(Chen et al., 2025; Zhang et al., 2025; Li et al., 2025; Wang et al., 2025)*. *Nie Jianjun et al., (2025),* designed an arch-shaped agricultural robot chassis with an adjustable posture tailored for hilly terrains, verifying its superior terrain adaptability and travel performance.

Addressing specific planting patterns and operational requirements, domestic researchers have also developed specialized chassis and their control systems *(Hao et al., 2024; Zhu et al., 2023)*. *Yu et al., (2025)*, tackling the challenges in rhizome transplanting of medicinal materials, designed an electronic control system for transplanters based on STM32 and fuzzy PID, validating its superior performance over traditional PID schemes, thereby providing theoretical and technical support for the mechanization of medicinal material transplanting. Additionally, some scholars have conducted foundational research on chassis performance prediction and validation, offering critical support for design optimization *(Liu et al., 2025)*. *Zhang et al., 2023*, addressing the performance deficiencies of a *Panax notoginseng* combined harvester chassis, investigated chassis trafficability under heavy clay soil conditions, providing theoretical references for the design of rhizomatous crop harvester chassis in hilly and mountainous regions.

In summary, the application of fully electric tracked chassis in the transplanting of rhizomatous medicinal materials remains underexplored. To address this gap, this study proposes a fully electric tracked chassis specifically designed for *Panax notoginseng* transplanting, integrating the characteristics of ridged planting and the steep terrain typical of hilly and mountainous regions. The chassis is tailored to the operational requirements of *Panax notoginseng* transplanting, with a core focus on the demanding conditions of low-speed, high-load operation. This capability to accommodate low travel speeds under substantial load during transplanting constitutes a key advantage distinguishing it from general-purpose chassis. To validate its performance under such conditions, a series of tests were conducted, including speed measurement, straight-line deviation correction, and pivot turning offset evaluation. Furthermore, a speed-synchronized control system was developed to precisely measure the travel speed of the transplanter. Using this measured speed as the target, a PID control algorithm was employed to regulate the seedling conveying belt motor, enabling coordinated control between the seedling conveying belt and travel motors, ultimately achieving precise transplanting.

MATERIALS AND METHODS

Test materials

The design, fabrication, and assembly of the chassis system and core working components of the *Panax notoginseng* transplanter developed in this study were completed by Sanniu Agricultural Machinery Manufacturing Co., Ltd. in Dingxi City, Gansu Province. After preliminary debugging and performance baseline tests of the prototype were conducted at the company's experimental field, comprehensive performance validation tests were carried out on January 19, 2026, at the Engineering Training Center of Kunming University of Science and Technology to fully verify the operational stability of the whole machine and optimize key working parameters.

Test equipment

All measuring instruments used in these tests were calibrated, with accuracy meeting the relevant requirements of the test specifications. Environmental parameter collection and measurement were strictly conducted in accordance with GB/T 5262—2008, "General Rules for Measuring Methods of Agricultural Machinery Test Conditions" *(General Administration of Quality Supervision, Inspection and Quarantine of P.R.China & Standardization Administration of P.R.China, 2008)*. The data obtained provide a reliable foundation for subsequent analysis of operational performance and optimization of key parameters.

Machine structure and working principle

Given the complex terrain of Yunnan's hilly and mountainous regions and the specific transplanting mode under *Panax notoginseng* shade shelters, the structural parameters of the tracked self-propelled transplanter chassis significantly affect critical performance metrics such as passability on sloping terrain *(Han et al., 2022)*. Through specialized chassis design, this study achieves a marked improvement in the trafficability of irregular pathways between planting ridges.

Table 1

Design Parameters of the Tracked Chassis

Parameters	Value	Parameters	Value
Overall length/mm	1400	Effective drive-wheel diameter/mm	150
Overall width/mm	1360	Total mass/kg	780
Overall height/mm	1050	Minimum ground clearance/mm	350
Track width/mm	230	Inner distance between tracks/mm	900
Idler wheel diameter/mm	150	Ground contact length/mm	850
Guide wheel diameter/mm	200	Maximum climbing angle/(°)	≥25

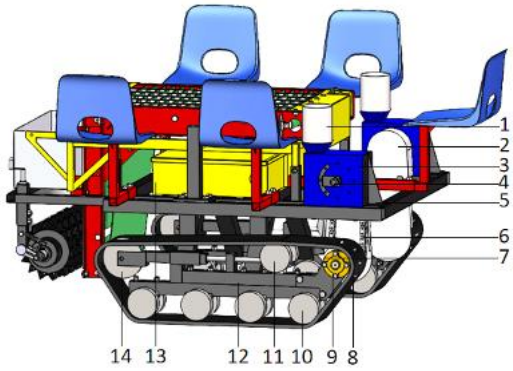

Fig. 1 - Schematic of the tracked chassis of the *Panax notoginseng* transplanter

1. Motor; 2. Chain guard; 3. NMRV110 gearbox; 4. Encoder; 5. Gearbox mounting plate; 6. Drive chain; 7. Track drive sprocket; 8. Track 9. FC207 bearing housing; 10. Idler wheel; 11. Drive wheel; 12. Chassis; 13. Battery box; 14. Guide wheel

The structure of the tracked chassis for the *Panax notoginseng* transplanter is illustrated in Figure 1. The machine employs a brushless DC motor coupled with an NMRV110 reducer, driving the tracked traveling mechanism via chain transmission. The power transmission path follows the sequence: motor, reducer, output shaft, sprocket and chain, drive wheel, and tracks, with assistance from supporting rollers and guide wheels to enable movement.

Given the operational demands of steep slopes in hilly regions, the electric chassis is required to achieve a climbing capability of no less than 25° and must not tip over when traversing laterally on slopes. The frame adopts a 1360 mm wide-base design with a low-center-of-gravity layout. Combined with the independent support on both sides of the tracks and the large ground contact area, this configuration significantly enhances anti-overturning capability and operational stability on complex slopes *(Mo, 2025; Mu et al., 2024; Quan & Ma, 2010)*.

Design and Selection of Key Chassis Components

To address the power requirements, agronomic compatibility, and intelligent control objectives for *Panax notoginseng* transplanting operations in the hilly and mountainous regions of Yunnan, this chapter focuses on the core working systems of the chassis. It presents the specialized design, parameter selection, and performance matching of the power battery system, drive motor system, and control system. These efforts ensure stable power output, precise coordination between travel and seedling transplanting operations, and flexible and reliable field maneuverability, thereby fully meeting the demands of narrow ridged field operations and steep, complex terrains.

Design and Selection of the Power Battery System

To meet the continuous operation and operational stability requirements of the traveling, transplanting, and electronic control systems of the *Panax notoginseng* transplanter, a dual-power supply architecture is adopted. The traveling power circuit is powered by a high-capacity battery pack consisting of sixteen 12 V/65 Ah lead-acid batteries configured in series-parallel to provide 48 V/260 Ah. The seedling transplanting power circuit is powered by a dedicated battery pack composed of two 12 V/20 Ah lead-acid batteries connected in series to supply 24 V/20 Ah, providing exclusive power to the seedling transplanting actuator. The control circuit employs an independent lithium battery module to deliver a stable 5 V power supply to controllers, sensors, and other components, achieving isolation between high-voltage and low-voltage electrical systems, thereby ensuring control accuracy and signal transmission stability. Under a rated operating voltage of 48 V supplied by the 260 Ah battery pack, the chassis operates in the field at full power of 4.4 kW. The endurance time of the traveling system is calculated using the following formula:

$$T = \frac{CkU}{P} \tag{1}$$

where: C — capacity of lead-acid battery pack (260 Ah)

U — rated voltage of travel motor (48 V)

P — actual power of travel motor (4400 W)

k — actual usable capacity factor of lead-acid batteries (0.8)

According to calculation, the full-power field operation duration of the chassis is approximately 2.3 hours.

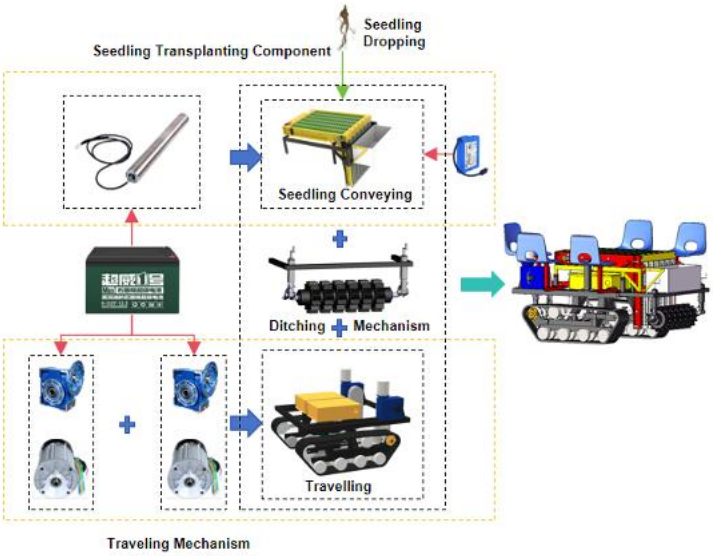

Fig. 2 - Schematic diagram of the power supply system for a transplanter

Design of the Drive Motor and Transmission System

The drive motor system serves as the power core for the chassis traveling and transplanting operations. Its parameter selection, transmission system matching, and coordinated design of operating speed directly determine the traction performance, climbing capability, and transplanting spacing accuracy of the whole machine.

Based on the agronomic requirements of *Panax notoginseng* transplanting and the limits of manual seedling feeding speed, this study completes the selection and design of the drive motor and transmission components, establishes a coordinated matching model for traveling and seedling transplanting speeds, thereby ensuring both dynamic performance and operational precision.

Coordinated Matching Model of Traveling and Seedling Transplanting Speeds under Manual Feeding Constraint

The transplanting operation of *Panax notoginseng* adopts a manual seedling feeding method, where the feeding rate serves as a critical constraint affecting the overall operating speed, seedling conveyor belt speed, and planting spacing. Experimental results indicate that the upper limit of manual feeding rate per person is 0.5 plants/s, with the machine employing four operators working simultaneously. Based on this constraint, a dimensionless ratio coefficient regulation model correlating planting spacing with traveling and seedling transplanting speeds was established, as illustrated in Figure 3.

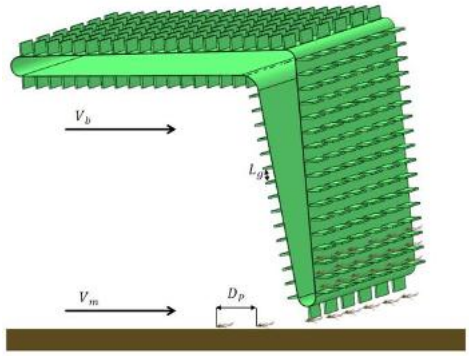

Fig. 3 - Schematic of seedling transplanting

The transplanting spacing is defined as the linear distance traveled by the transplanter along its direction of travel during the interval between the moment a preceding seedling drops into the planting soil and the moment the next seedling reaches the exit of the seedling conveyor belt. The underlying principle is illustrated in Figure 3.

The time interval for the subsequent seedling to reach the exit of the seedling conveyor belt can be expressed as $t=L_g/V_b$. Based on the physical definition of planting spacing D_p, the calculation formula for planting spacing can be derived as follows:

$$D_p=V_m t=V_m \frac{L_g}{V_b} \tag{2}$$

Introducing the dimensionless ratio coefficient $K=V_m/V_b$, which relates the traveling speed of the transplanter to the seedling conveyor belt speed, and substituting it into the above formula, the theoretical relationship between planting spacing and the ratio coefficient can be simplified as follows:

$$D_p=KL_g \tag{3}$$

where:

D_p— planting spacing (mm)

t — time interval for the next seedling to reach the outlet (min)

V_m — travel speed of transplanter (m/min)

V_b — conveying speed of seedling belt (m/min)

L_g — spacing between partition baffles on seedling conveyor belt (40 mm)

K — dimensionless matching coefficient between transplanter travel speed and seedling belt conveying speed (dimensionless)

To achieve convenient and precise regulation of *Panax notoginseng* transplanting spacing, the dimensionless ratio coefficient K is adopted as the core control parameter, addressing the limitations of traditional dual-speed synchronization methods. Based on the agronomic spacing requirement of Dp=80～200 mm for *Panax notoginseng* and the partition plate spacing Lg=40 mm on the seedling conveyor belt, the reasonable range of $K$is derived as 2～5, enabling precise matching of the corresponding planting spacing requirements.

In the control system, the operator only needs to set the target Kvalue, and the system automatically matches V_m and V_b to achieve single-parameter online regulation of planting spacing.

This approach simplifies operation, ensures regulation accuracy, and enhances equipment adaptability while precisely aligning with the limits of manual seedling feeding, thereby establishing an accurate correlation between operating speed and planting spacing.

Based on the limit of manual seedling feeding speed, the maximum allowable speed of the seedling conveyor belt is derived. Let the operation time be t, then the displacement of the seedling conveyor belt during time t is given by:

$$S_b = V_b t \tag{4}$$

Combined with the planting spacing D_p, the total number of seedlings planted within time t can be calculated as:

$$N = 6 \times \frac{S_b}{D_p} \tag{5}$$

Given that the maximum manual seedling feeding rate per person is 0.5 plants/s, equivalent to 30 plants/min, the number of seedlings fed per person within t minutes is less than $30t$, i.e., $N_S < 4 \times 30t$. Substituting $S_b = V_b t$ into the inequality and simplifying yields:

$$V_b < \frac{30 \times 4D_p}{6} = 20D_p \tag{6}$$

where:

N_s — total maximum fry output of four seedling distributors within a fixed time period (plant)

S_b — moving distance of seedling conveyor belt within a fixed time period (m)

t — operation assignment time (min)

6 — coefficient for simultaneous six-row transplanting (dimensionless)

4 — coefficient corresponding to four seedling planting units (dimensionless)

Based on the *Panax notoginseng* transplanting spacing control range of D_p=0.08～0.2 m, the constraint conditions for the seedling conveyor belt speed are derived as follows: when D_p=0.08 m, Vb<1.6 m/min; when D_p=0.2 m, V_b<4 m/min. These constraints ensure that the seedling conveyor belt speed matches the maximum manual seedling feeding rate, preventing missed placements or misalignment caused by excessive belt speed.

Combined with the previously derived formula for planting spacing $D_p = V_m L_g / V_b$, the calculation formula for the transplanter traveling speed can be rearranged to obtain:

$$V_m = \frac{D_p V_b}{L_g} \tag{7}$$

Under the constraint of the maximum manual seedling feeding rate, combined with the limit values of the seedling conveyor belt speed and the planting spacing range, the maximum traveling speed of the transplanter can be calculated as follows: when the planting spacing D_p=0.08 m, the maximum traveling speed is 3.2 m/min; when D_p=0.2 m, the maximum traveling speed is 20 m/min. The traveling speed of the transplanter must match the manual seedling feeding limit. In practical operation, a speed range of 3.2 m/min to 20m/min is recommended to accommodate the planting spacing requirement of 80 mm to 200 mm, ensuring coordinated matching among traveling speed, seedling feeding, and seedling conveying speed.

Matching Calculation of the Transmission Ratio for the Traveling System

Based on the design requirement of adopting the recommended speed range of 3.2~20 m/min in actual operation, and considering factors such as ground slip during tracked field operation and elastic slip in the chain transmission, sufficient margin is reserved for the theoretical traveling speed. Consequently, 22 m/min is ultimately determined as the theoretical maximum reference speed for the matching calculation of the sprocket-chain transmission ratio. The calculation formula for the straight-line traveling speed of the whole machine is:

$$V_m = \frac{\pi n_0 D(1-\delta)}{i_1 i_2} \tag{8}$$

where: V_m — theoretical maximum reference speed (22 m/min)

n_0 — rated speed of brushless DC motor (3000 r/min)

D — effective diameter of track driving wheel (0.15 m)

i_1 — reduction gear ratio (60)

i_2 — gear-chain transmission ratio (dimensionless)

δ— total slip coefficient of transmission system, including chain elastic slip and track-ground slip (0.26)

The calculated transmission ratio i_2≈0.79. Accordingly, the number of teeth on the driving sprocket of the reducer output shaft was selected as 15, and the number of teeth on the driven sprocket of the track drive wheel was selected as 19. This parameter matching scheme enables precise adaptation between the machine's traveling speed, the rated motor speed, and each stage of the transmission system, thereby effectively ensuring traveling stability and synchronization with seedling transplanting during field operations.

Control System Design

To ensure operational flexibility, accurate straight-line travel, and coordinated travel–transplanting performance during field operation of the *Panax notoginseng* transplanter, an electronic control system was developed that integrates remote travel control, speed-synchronized transplanting control, and straight-line deviation correction. The system enables remote control of chassis travel, steering, and emergency stopping, as well as real-time closed-loop coordination between seedling-conveying speed and travel speed. These functions improve the level of operational intelligence and enhance transplanting-spacing accuracy.

The control logic of the remote-control system for the tracked chassis is illustrated in Figure 4. Upon power-up, the system first initializes, followed by communication link verification of the wireless remote-control module, with the verification result indicated via an indicator light: if the module is not successfully connected, the light remains constantly on without flashing; if the connection is normal, the light flashes continuously, and the system enters the command-ready state. The remote controller issues three types of commands: travel commands control the chassis forward/backward movement, steering, and emergency stop; mode switching commands enable switching of operation modes such as cruise control; and motor correction coefficient commands adjust the track motor deviation correction parameters. After executing a command, the system verifies the completion status in real time; if incomplete, the command continues to execute, and upon completion, the control process terminates.

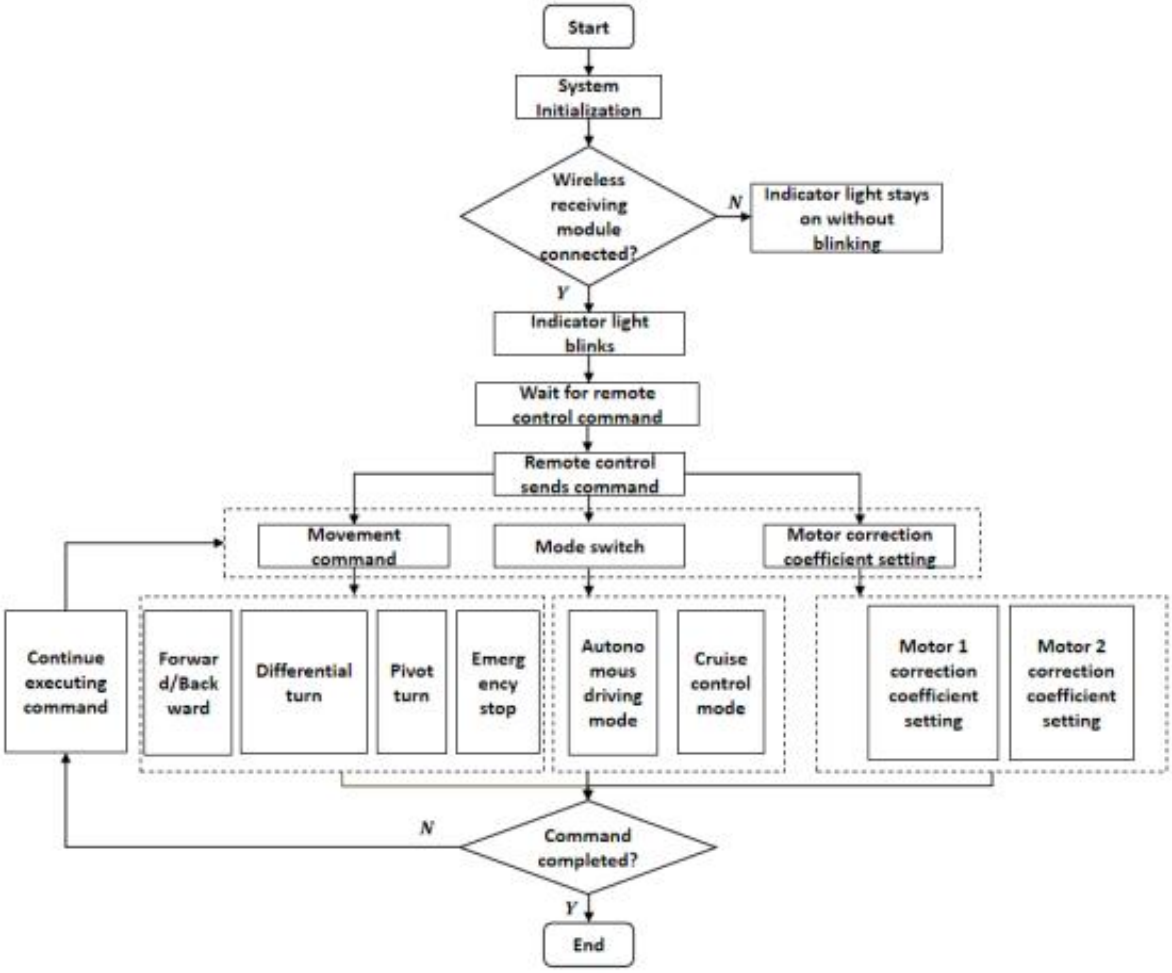

Fig. 4 - Control logic diagram of the remote control system

The speed-synchronized control system designed in this paper operates according to a three-stage architecture of "signal acquisition – main control processing-execution drive," with the core function of achieving real-time coordinated control between the seedling conveyor belt speed and the chassis traveling speed, thereby ensuring the stability and consistency of transplanting spacing. The schematic diagram of the control system is shown in Figure 5.

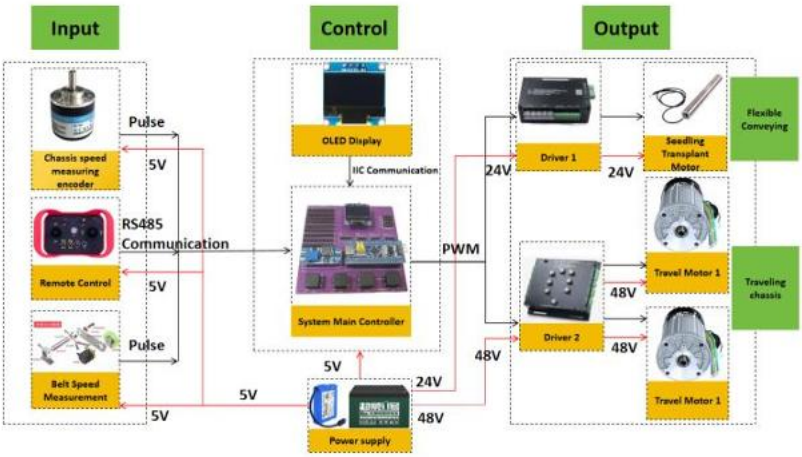

Fig. 5 - Schematic of the control system

During the signal acquisition stage, the chassis speed-measuring encoder and belt speed-measuring encoder at the input end collect pulse signals from one side of the traveling motor and seedling transplanting motor in real time with a sampling period of 100 ms. The remote controller synchronously transmits operation commands, such as travel control and transplanting operations, via the RS485 communication protocol. The aforementioned multi-source signals and commands are transmitted in real time to the system's main controller, providing the data foundation for subsequent coordinated computation.

During the main control processing and status display stage, the system's main controller, after receiving and parsing the multi-source signals, performs coordinated computation of the machine's operational logic and timing scheduling. The real-time speed feedback value of the traveling motor is multiplied by the preset dimensionless ratio coefficient K to serve as the target value for the PID control of the seedling transplanting motor speed, completing the core computation of speed-synchronized control. Simultaneously, operational status data—including real-time motor speeds, operation progress, and set planting spacing values—are transmitted to the OLED display via the IIC communication protocol, enabling real-time visualization of the machine's operating status.

Execution drive stage: The system's main controller outputs PWM speed regulation signals to the corresponding motor drivers, driving each actuator to complete the preset actions. The 24 V seedling transplanting motor driver controls the operation of the seedling transplanting motor, enabling gentle conveying of seedlings. The two 48 V traveling motor drivers independently control the two traveling motors, achieving traveling drive and differential steering control of the tracked chassis. Through closed-loop regulation using the speed-synchronized PID control algorithm, the real-time speed of the seedling transplanting motor continuously approaches the target speed, ultimately realizing precise matching between the chassis traveling speed and the seedling transplanting speed. This fundamentally ensures high consistency between the actual transplanting spacing and the preset value.

Straight-line deviation control is a key technical requirement in chassis design because it directly affects transplanting-row accuracy and helps prevent the machine from damaging the ridges or departing from the intended transplanting path. This study proposes a manual deviation-correction method based on a speed-correction coefficient. Straight-line travel is corrected by adjusting the rotational speeds of the left and right track motors.

The speed of a single track under the correction coefficient is calculated as follows:

$$\begin{cases} V_l = \dfrac{k_l n_1 \pi D(1-\delta)}{i_1 i_2} \\ V_r = \dfrac{k_r n_2 \pi D(1-\delta)}{i_1 i_2} \end{cases} \quad (9)$$

where:

V_l — corrected travel speed of the left track (m/min)

k_l — speed correction factor for left track motor (initial value = 1; manually adjustable via remote control) (dimensionless)

n_1 — rotational speed of left brushless DC motor before correction factor compensation (r/min)

D — effective diameter of track driving wheel (0.15 m)

δ — total slip coefficient of transmission system, including chain elastic slip and track-ground slip (0.26)

i_1 — reduction gear ratio (60)

i_2 — sprocket-chain transmission ratio (0.79)

V_r — corrected travel speed of the right track (m/min)

k_r — speed correction factor for right track motor (default value = 1; manually adjustable via remote control) (dimensionless)

n_2 — rotational speed of right brushless DC motor before correction factor compensation (r/min)

The specific deviation correction control logic is as follows: the motor speed is determined by the duty cycle of the PWM signal output by the main controller, with the duty cycle being positively correlated with the motor speed. By multiplying the correction coefficient by the current duty cycle, precise adjustment of the motor speed is achieved, thereby altering the traveling speed of the single-side track. When the transplanter deviates to the right, the correction coefficients are adjusted to increase the speed of the right traveling motor and decrease the speed of the left traveling motor （k_r>1, k_l<1）, generating a leftward corrective torque that returns the machine to the preset straight trajectory. Conversely, the reverse adjustment strategy is applied for trajectory correction. This approach ultimately ensures the straight-line traveling accuracy of the whole machine, meeting the field operation requirements for *Panax notoginseng* seedling transplanting.

Test method

The overall stability of the *Panax notoginseng* transplanter is not only crucial for the safety of the remote operator and seedling feeders but also plays a key role in improving transplanting quality. In this study, the maximum roll angle is adopted to evaluate the stability of the whole machine on ridges and under longitudinal operating conditions *(Jiang et al., 2023)*.

Lateral Stability Analysis

Under no-load condition, the force diagram of the *Panax notoginseng* transplanter when stationary or moving straight at a uniform speed on a transverse slope is illustrated in Figure 6.

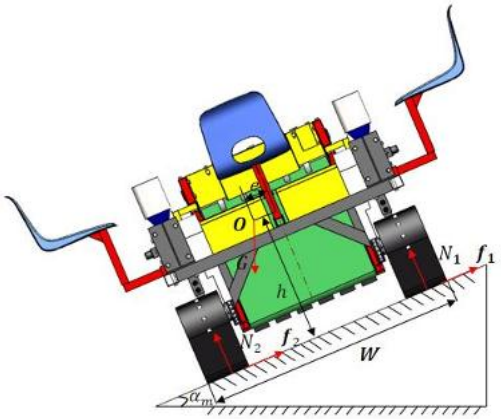

Fig. 6 - Schematic of lateral force analysis of crawler chassis for *Panax notoginseng* transplanter

The maximum roll angle α_m refers to the maximum slope angle at which the machine does not overturn when positioned on a transverse slope. According to the moment balance principle, when the machine is about to overturn about the edge of one track, the supporting force on that side becomes zero, and the moment of gravity about the pivot point is also zero.

Let the outer distance between the two tracks be W, the height of the center of mass be h, and the horizontal offset of the center of mass be e (positive to the left). The distances from the center of mass to the edges of the left and right tracks are then expressed as shown in Equation (10).

$$\begin{cases} L_L = \dfrac{W}{2} - e \\ L_R = \dfrac{W}{2} + e \end{cases} \tag{10}$$

where:

L_L — distance from mass center to the edge of left track (m)

L_R — distance from mass center to the edge of right track (m)

W — distance between outer edges of two tracks (m)

e — horizontal offset of mass center (m)

As shown in the figure, when the slope is inclined downward to the left, the critical condition for overturning about the left edge is as follows:

$$GL_L \cos \alpha_m = Gh \sin \alpha_m \tag{11}$$

The maximum roll angle formula can be derived as follows:

$$\alpha_m = \tan^{-1} \frac{\frac{W}{2} - e}{h} \tag{12}$$

If $W/2$-e≤0, the *Panax notoginseng* transplanter is already prone to overturning on level ground, and thus $\alpha_m=0$.

Based on theoretical calculations of relevant parameters for the *Panax notoginseng* transplanter and subsequent analysis using Equation (11), it can be determined that increasing the outer distance between the two tracks and lowering the height of the center of mass effectively enhances the lateral stability of the chassis. A larger maximum lateral roll angle α_m indicates superior lateral stability of the whole machine. Using the actual structural dimensions of the *Panax notoginseng* transplanter, the position of the center of mass was measured with SolidWorks software. The vertical distance from the center of mass to the ground was determined to be h=650 mm, the outer distance between the two tracks W=1360 mm, and the lateral offset of the center of mass relative to the longitudinal central plane e=150 mm. Substituting these parameters into the model yields a maximum lateral roll angle α_m=39.19° for the whole machine.

Ridging Stability Analysis

Deviation of the transplanter chassis or unevenness of the ridge may cause the tracks to ride onto the ridge slope, resulting in tilting of the transplanter and thereby increasing the risk of overturning. During *Panax notoginseng* transplanting operations, the ridge bottom width W_b is 850 mm, the ridge top width W_t is 720 mm, and the ridge height h ranges from 250 to 300 mm. The ridging state of the *Panax notoginseng* transplanter is illustrated in Figure 7.

(a)Normal Ridge Alignment (b)Abnormal Ridge-Straddling State

Fig. 7 - Schematic of ridge-riding state of *Panax notoginseng* transplanter

$$\alpha = \tan^{-1} \frac{2h}{W_b - W_t} \tag{13}$$

$$\alpha_t = \tan^{-1} \frac{2hh_0}{2hW_b - h_0(W_b - W_t)} \tag{14}$$

where:

α — slope angle of ridge side (\(^\circ\))

h — ridge height (mm)

W_b — base width of ridge (mm)

W_t — top width of ridge (mm)

h_0 — vertical distance between the bottom of side track and ridge bottom under tilting state of transplanter (mm)

α_t — tipping angle (°)

Under the limit state where h=h_0, the inclination angle of the transplanter reaches its maximum operational value. Substituting h=h_0=300 mm, W_b=850 mm, and W_t=720 mm into the calculation yields α=77.8° and α_t=20.9°. This critical roll angle is smaller than the previously calculated maximum lateral roll angle α_m=39.19◦. Therefore, even if the transplanter unexpectedly rides onto the ridge surface, there is no risk of overturning.

Theoretical Calculation of Dynamic Performance

When operating in hilly and mountainous regions, the chassis must not only meet the requirements for lateral and ridge stability but also possess sufficient power reserve to handle extreme steep slope conditions reaching up to 25° or more in certain areas of Yunnan Province (*Guo et al., 2025*). Based on the parameters of the drive motor and transmission system outlined in Section 2.2, a theoretical verification of the maximum traction force and climbing capability of the chassis is conducted, providing performance expectations for subsequent field climbing tests.

The whole machine adopts a dual-motor synchronous drive configuration. After two stages of transmission, the maximum traction force of the chassis can be calculated using the following formula:

$$\begin{cases} T_0 = \dfrac{9550 P_0}{n_0} \\ F_{max} = \dfrac{2 T_0 i_1 i_2 \eta}{r} \end{cases} \tag{15}$$

where: T_0 — rated torque of motor (N·m)

P_0 — rated power of motor (2.2 kW)

n_0 — rated rotational speed of motor (3000 r/min)

F_{max} — maximum traction force (N)

i_1 — transmission ratio of worm gear reducer (60)

i_2 — sprocket-chain transmission ratio (0.79)

η — total mechanical efficiency (0.85)

r — radius of driving wheel (0.075 m)

After calculation, the maximum traction force of the chassis is 7524 N, which meets the operational requirements of low-speed, high-load conditions.

Using the total resistance formula for slope traveling, the climbing capability under extreme operating conditions is verified for a design slope angle of 25°:

$$F_f = fG\cos\alpha + G\sin\alpha \tag{16}$$

where: F_f — maximum resistance force (N)

f — rolling resistance coefficient (0.15, dimensionless)

G — total gravity load (N)

α — slope inclination angle (25°)

The formula for the traction force reserve coefficient is given in Equation (17).

$$S = \frac{F_{max}}{F_f} \tag{17}$$

where: S — traction reserve coefficient (dimensionless)

F_{max} — maximum traction force of chassis (N)

F_f — maximum total running resistance on slope (N)

The total no-load mass of the whole machine is 780 kg, and the full-load mass is 1080 kg (including five operators). Calculations indicate that under full-load conditions, the maximum total resistance is approximately 5912 N, with a traction force reserve coefficient of about 1.27; under no-load conditions, the maximum total resistance is approximately 4270 N, with a traction force reserve coefficient of about 1.76. The traction force reserve is sufficient under all operating conditions, enabling stable adaptation to the steep slope requirements of ≥25° in the mountainous regions of Yunnan.

Steering Performance

Steering performance is a core indicator for the adaptability of the *Panax notoginseng* transplanter to narrow-row operations in mountainous areas, directly determining the machine's compatibility with complex terrain and its operational efficiency. This model adopts a pivot turning design, which fundamentally avoids issues such as damaging ridges or seedlings during turning. Therefore, the offset distance of the pivot turning center is selected as the key evaluation indicator for steering performance. During pivot turning of tracked vehicles in the field, longitudinal slip and lateral skid occur between the tracks and the ground due to soil characteristics, leading to deviations in the actual rotation center. Consequently, the calculation of the actual pivot turning center offset requires the introduction of correction terms for slip and skid. Based on the steering dynamics of tracked vehicles, the calculation formula (18) incorporating the effects of slip and skid is established.

$$R_{0,\delta}=\frac{Bk}{2(1-k)} \tag{18}$$

where: $R_{0,\delta}$ — actual offset of turning center under slipping turning condition (m)

B — track gauge of chassis (distance between centerlines of two tracks) (1.13 m)

k — steering slip coefficient (0.25, dimensionless)

Therefore, the theoretical offset distance of the pivot turning center during field operation is calculated to be 188 mm.

RESULTS AND ANALYSIS

Straight-line Traveling Speed Test

To verify the speed control accuracy of the traveling system and the reliability of the encoder speed measurement, and to provide data support for the coordinated matching between traveling speed and the seedling planting mechanism, a straight-line traveling speed test of the tracked chassis was conducted in accordance with GB/T 5668—2017, "Rotary Tillers"*(General Administration of Quality Supervision, Inspection and Quarantine of P.R.China & Standardization Administration of P.R.China, 2017)* .

The encoder is installed at the output shaft end of the traveling reducer, with a speed sampling period set to 100 ms. The output shaft speed is calculated by collecting the number of pulses per unit time, and the chassis traveling speed is estimated by combining transmission parameters, driving wheel dimensions, and slip rate correction. The speed measurement model is expressed as shown in Equation (19):

$$V_e=\frac{CN_0\pi D(1-\delta)}{Ni_2} \tag{19}$$

where: V_e — chassis travel speed calculated by encoder (m/min)

N_0 — encoder pulse count collected within 100 ms sampling period (1)

D — effective diameter of track driving wheel (0.15 m)

δ — total slip coefficient of transmission and travel system, including chain elastic slip and track-ground slip (0.26)

N — encoder resolution (10000 pulses per revolution)

i_2 — transmission ratio of sprocket-chain mechanism between reducer output shaft and driving wheel (0.79)

C — time conversion factor converting 100 ms sampling interval to minutes (600, dimensionless)

The test site was selected on a level and compacted field road surface within the Engineering Training Center of Kunming University of Science and Technology, with a road length of ≥30 m and longitudinal and transverse slopes of ≤1%, meeting the specifications for traveling performance testing of agricultural machinery.

During the test, the duty cycle of the PWM speed regulation signal for the traveling motor was set to 20%, 40%, 60%, 80%, and 100% via the remote controller, respectively, to control the whole machine to travel straight for 30 m at the corresponding set speeds. An electronic stopwatch was used to record the travel time for each pass. The test was repeated three times for each duty cycle parameter, and the arithmetic mean of the three measurements was taken to calculate the actual average traveling speed, which was then compared and analyzed with the speed synchronously measured by the encoder.

Table 2

Driving speed test results

Duty Cycle /%	Test No.	Time /s	Average Time /s	Actual Travel Speed (m/min)	Encoder-measured Travel Speed (m/min)
20	1	367.38	360.92	4.99	4.40
	2	357.36			
	3	358.02			
40	1	187.44	191.12	9.42	9.13
	2	197.22			
	3	188.7			
60	1	125.88	127.76	14.09	13.9
	2	127.50			
	3	129.90			

Duty Cycle /%	Test No.	Time /s	Average Time /s	Actual Travel Speed (m/min)	Encoder-measured Travel Speed (m/min)
80	1	97.38	96.06	18.74	17.85
	2	98.04			
	3	92.76			
100	1	83.92	83.47	21.56	21.32
	2	81.24			
	3	85.26			

The test results are presented in Table 2. The deviation between the encoder-measured speed and the actual average speed gradually decreases as the duty cycle increases. Under low-speed operating conditions, the deviation mainly arises from real-time fluctuations in track ground slip, elastic deformation of the transmission system, and differences in sampling scales between the long-stroke average speed and the short-period instantaneous speed. By calibrating and correcting the comprehensive slip rate coefficient, the encoder speed measurement can accurately approximate the actual traveling speed of the transplanter, thereby providing reliable data support for the coordinated speed control between traveling and seedling transplanting.

Straight-line deviation Test and Correction for the Transplanter During Traveling

The straight-line deviation test was conducted in accordance with the technical requirements and relevant test specifications for deviation under Clause 3.3.9 of the national standard GB/T 15370.4—2012, "Agricultural Tracked Tractors—Part 4: Technical Specifications for Belt Drive Tracked Tractors." The standard specifies that on a dry, hard, and level road surface with longitudinal and transverse slopes not exceeding 1%, the deviation of an agricultural tracked tractor over 100 m shall not exceed 6 m, which serves as the acceptance criterion for straight-line deviation *(General Administration of Quality Supervision, Inspection and Quarantine of P.R.China & Standardization Administration of P.R.China, 2012)*.

The straight-line deviation test of the transplanter was conducted by laying out a 30 m reference line in the test field, with marking points set every 5 m along the line. The initial position of the transplanter was aligned with the reference line, and the machine was driven at a uniform speed along the line. According to the aforementioned standard, the deviation over a 30 m travel distance shall not exceed 1.8 m, corresponding to a straight-line deviation of no more than 6%. The lateral deviation of the transplanter's traveling trajectory was measured using a tape measure. The field test setup for evaluating the straight-line deviation of the transplanter is shown in Figure 8.

Straight-line deviation is a core indicator for evaluating the degree of deviation, and its calculation expression is given as:

$$\gamma = \frac{max|y(x)-y_0(x)|}{L} \times 100\% \quad (20)$$

where: γ — straight-line deviation rate (%)

$y(x)$ — lateral coordinate of the actual travel path of the transplanter (dimensionless)

$y_0(x)$ — lateral coordinate of the ideal straight path, generally set to 0

L — straight-line test distance (30 m)

Fig. 8 - Straight-line travel deviation test of the transplanter

The straight-line traveling performance of the transplanter chassis directly determines the quality of ridged transplanting operations and the uniformity of plant distribution for *Panax notoginseng*. In this test, the straight-line deviation of the transplanter was measured under PWM duty cycles of 20%, 40%, 60%, 80%, and 100%, respectively. Through parameter calibration, the straight-line deviation was minimized as much as possible to enhance the precision and effectiveness of *Panax notoginseng* transplanting operations. The test results of the straight-line deviation before correction are shown in Table 3.

Table 3

Straight-line travel deviation of the transplanter before correction

Duty Cycle /%	Field Offset (Before Correction) /m			Mean straight-line deviation rate (Before Correction) /%
	Test 1	Test 2	Test 3	
20	1.63	1.67	1.72	5.58
40	2.23	1.92	2.13	6.98
60	2.16	2.09	2.2	7.17
80	2.06	2.45	2.36	7.63
100	2.48	2.39	2.56	8.26

As shown in the data in the table, the straight-line deviation of the transplanter gradually increases with the duty cycle, with most deviation values under each duty cycle exceeding the 6% limit specified in the national standard. If operated directly under such conditions, the transplanter would exhibit significant deviation during travel, leading to a high risk of the chassis riding onto the ridge. To avoid this problem, the remote operator would need to frequently apply minor steering corrections to maintain a stable travel path during operation. Therefore, this study introduces a straight-line deviation correction coefficient to address the issue of path deviation during transplanting operations. The straight-line deviation of the transplanter after correction is shown in Table 4, with the minimum value from three replicates used to determine the optimal correction coefficient.

Table 4

Straight-line travel deviation of the transplanter after correction

Duty Cycle /%	Lateral deviation after correction /m			Deviation rate corresponding to the minimum value /%
	Test 1	Test 2	Test 3	
20	0.32	0.26	0.29	0.87
40	0.34	0.24	0.28	0.8
60	0.45	0.38	0.25	0.83
80	0.78	0.43	0.32	1.07
100	0.32	0.47	0.36	1.07

Table 5

Correction coefficients of left and right motors under different duty cycles

Duty Cycle /%	Correction Parameters					
	Test 1		Test 2		Test 3	
	Right Motor	Left Motor	Right Motor	Left Motor	Right Motor	Left Motor
20	1	1.033	1	1.017	1	1.023
40	1	1.057	1	1.039	1	1.046
60	1	1.091	1	1.086	1	1.077
80	1	1.1	0.979	1.1	0.965	1.1
100	0.867	1.1	0.901	1.1	0.889	1.1

The correction coefficients for the left and right motors under different duty cycles are shown in Table 5. The test results indicate that the transplanter exhibits an overall leftward deviation when traveling on flat surfaces, which is attributed to the lower traveling speed of the left track compared to the right track. As the control duty cycle increases, the straight-line deviation of the whole machine tends to increase. To compensate for the speed difference between the two tracks and improve straight-line traveling accuracy, the correction coefficient for the left motor should be set greater than 1, while the correction coefficient for the right motor is either maintained at 1 or adjusted to less than 1.

The recommended correction coefficients for the left and right motors under different duty cycles are as follows: at 20% duty cycle, right motor 1, left motor 1.017; at 40% duty cycle, right motor 1, left motor 1.039; at 60% duty cycle, right motor 1, left motor 1.077; at 80% duty cycle, right motor 0.965, left motor 1.1; at 100% duty cycle, right motor 0.867, left motor 1.1.

Pivot Turning Center Offset Measurement

Steering performance is a core indicator of the field adaptability of tracked transplanters, directly determining the flexibility of inter-ridge turning and headland turning, as well as operational safety. This test was conducted in accordance with the steering performance test specifications for tracked tractors specified in GB/T 19040—2016, "Agricultural Tractors—Requirements for Steering" *(General Administration of Quality Supervision, Inspection and Quarantine of P.R.China & Standardization Administration of P.R.China, 2016)*. The pivot turning performance test of the transplanter was carried out on a typical soft field surface used for *Panax notoginseng* cultivation, where the track steering trajectory was measured and the turning center offset was determined.

(a) On-site turning test (b)Actual steering trajectory measurements

Fig. 9 - In-situ turning test of the transplanter

The test results indicate that the transplanter achieves stable pivot turning, with a measured turning center offset of approximately 191 mm, which is in close agreement with the previously calculated theoretical value. The turning accuracy and stability meet the operational requirements for *Panax notoginseng* transplanting in the field. The pivot turning test site and trajectory measurement results are shown in Figure 9.

Climbing Stability Test

In accordance with GB/T 3871.21—2015, "Agricultural Tractors—Test Procedures—Part 21: Stability" *(General Administration of Quality Supervision, Inspection and Quarantine of P.R.China & Standardization Administration of P.R.China, 2015)*, the climbing stability test of the *Panax notoginseng* transplanter was conducted. The test was performed on a slope with an inclination of 27°, and the machine was driven longitudinally and transversely on the slope at a travel speed of 10 m/min. The results showed that the transplanter successfully climbed the 27° slope during longitudinal travel and exhibited no instability or rollover during transverse travel on the 27° slope. The overall stability of the machine is excellent, meeting the operational requirements for ridged *Panax notoginseng* transplanting in the hilly and mountainous regions of Yunnan.

Fig.10 - Site of the vertical climb test

Fig.11 - Site of the lateral slope stability test

Ridged Traveling Stability Test

To verify the traveling stability of the transplanter under ridged slope conditions, a single-side ridge-crossing tilt travel test was conducted. One side of the transplanter's tracks was positioned to ride onto the ridge slope, and the machine was driven straight for 10 m along the ridge length at a uniform speed under different duty cycles. The traveling status of the whole machine was recorded, and no instability or overturning was observed throughout the process.

Fig.12 - On-ridge stability test

To verify the traveling stability of the transplanter under ridged slope conditions, a single-side ridge-crossing tilt travel test was conducted. The ridge parameters were fixed (ridge bottom width 850 mm, ridge top width 720 mm), and only the ridge height was varied to adjust the roll angle of the machine under different operating conditions. Three typical ridge heights for *Panax notoginseng* cultivation—200 mm, 250 mm, and 300 mm—were selected, corresponding to roll angles of 14.3°, 17.7°, and 20.9°, respectively, thereby establishing varying tilt operating conditions.

Table 6

Ridge-riding stability test results

Duty Cycle (%)	Working Condition Lateral Tilt Angle (°)		
	14.3	**17.7**	**20.9**
20	Pass	Pass	Pass
40	Pass	Pass	Pass
60	Pass	Pass	Pass
80	Pass	Pass	Pass
100	Pass	Pass	Pass

For each roll angle under different operating conditions, the transplanter was operated at five PWM speed regulation duty cycles of 20%, 40%, 60%, 80%, and 100%. The test was repeated three times for each condition, and the machine status was recorded. The test results are shown in Table 6. Under all combined conditions, the transplanter passed stably without overturning, verifying its traveling stability within this tilt range and across different operating parameters.

Motor Thermal Stability Test

Motor thermal stability is a core indicator determining the reliability of continuous field operation and the insulation service life of the transplanter's motors. In accordance with the mandatory requirements of Chapters 15 and 20 of GB/T 14711—2025, "General Requirements for Safety of Small and Medium-Sized Rotating Electrical Machines," concerning thermal testing and insulation structures, a thermal stability test was conducted on the variable-frequency speed-regulated brushless DC traveling motor with Class F insulation *(State Administration for Market Regulation & Standardization Administration of P.R.China, 2025)*. The test simulated load conditions of the transplanter under different operating speeds. The motor was operated continuously for 190 minutes under gradient PWM speed regulation duty cycles ranging from 20% to 90%, and the winding temperature was monitored in real time using a calibrated digital thermometer. Based on the heat resistance requirements for Class F insulation and accounting for a 20–30°C temperature margin between the motor housing and the winding, the evaluation criteria were established as follows: a safe operating range of 70°C to 90°C, and a forced shutdown protection threshold of 125°C to prevent insulation thermal aging.

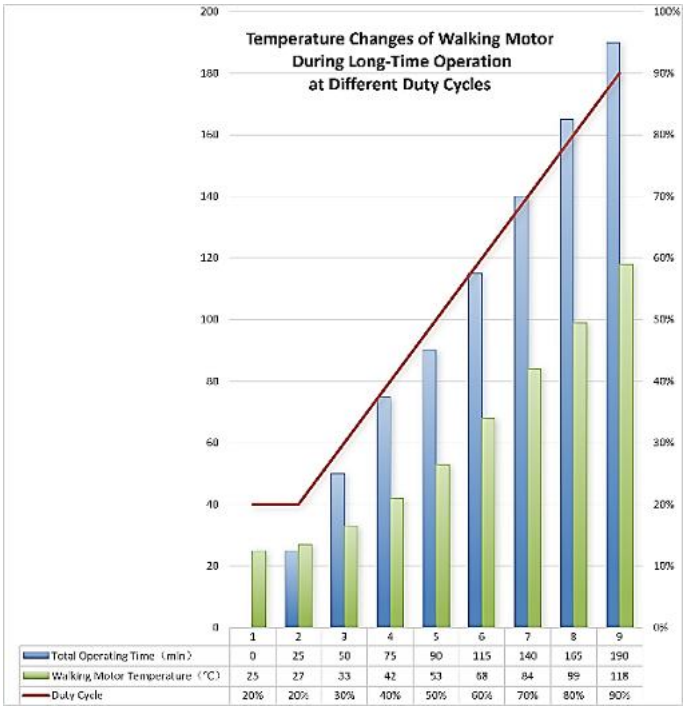

Fig.13 - Temperature change of driving motors under different duty cycle

The test results are shown in Figure 13: the motor temperature rise rate shows a clear positive correlation with the PWM duty cycle, consistent with the typical heating characteristics of small and medium-sized rotating electrical machines.

After 190 minutes of continuous operation, the final motor temperature reached 118°C, which did not reach the 125°C shutdown threshold, and remained within the safe operating range of 70°C to 90°C for most of the operation period. The test results meet the thermal safety requirements for continuous motor operation specified in GB/T 14711—2025, verifying that the traveling motor and transmission system possess good thermal stability and are capable of meeting the demands of prolonged continuous field operation for *Panax notoginseng* transplanting.

CONCLUSION AND DISCUSSION

An innovative design and theoretical modeling of a specialized tracked chassis for hilly and mountainous regions were completed. Addressing the complex agronomic requirements of ridged *Panax notoginseng* transplanting in Yunnan, the overall structure of a fully electric intelligent tracked chassis was designed. Based on the manual seedling feeding speed limit, a dimensionless ratio coefficient regulation model correlating

planting spacing with traveling and seedling transplanting speeds was innovatively established. This enabled precise matching of the transmission ratio and theoretical calculation of the overall machine stability, laying the theoretical foundation for subsequent control system development.

A coordinated control system for traveling and seedling transplanting, along with a straight-line deviation correction scheme, was developed. A speed-synchronized PID control system based on speed-measuring encoders was designed to achieve real-time coordinated control between seedling conveying speed and chassis traveling speed. A manual deviation correction method utilizing a speed correction coefficient was proposed, effectively addressing the issue of traveling deviation in tracked chassis. Field tests demonstrated that, after correction, the straight-line deviation of the whole machine over a 30 m travel distance was controlled to within 1.1%, which is superior to the national standard limit.

The key performance indicators of the whole machine were verified to meet the operational requirements of hilly and mountainous regions. The chassis achieved a maximum traction force of 7524 N, a maximum climbing angle of ≥25°, and a maximum lateral roll angle of 39.19°, with the pivot turning center offset closely matching the theoretical value. Performance indicators including slope climbing stability, ridged traveling stability, and motor thermal stability all satisfied the requirements of relevant national standards. This chassis effectively enhances the automation level and operational accuracy of *Panax notoginseng* transplanting in hilly and mountainous regions, providing technical support for the intelligent upgrade of transplanting equipment for rhizomatous medicinal herbs.

ACKNOWLEDGEMENT

We would like to thank all colleagues for their advice and support throughout the research process.

Keywords: *Fixed-wing UAV; Path planning; Improved DBO algorithm; Safe turning radius; Pitch angle; Overlap ratio; Coverage uniformity*

ABSTRACT
To address the contradiction between obstacle avoidance safety and irrigation operation quality in 3D path planning of fixed-wing UAVs for mountainous agricultural crop irrigation, this paper proposes a multi-strategy improved dung beetle optimization (MDBO) algorithm. First, safe turning radius and pitch angle constraints are embedded into the optimization objective to restrict flight attitude, ensure flight stability under complex mountain terrain, reduce collision risk, and maintain consistent spray deposition. Second, four improvement strategies, including Bernoulli chaotic mapping initialization, golden sine position update mechanism, dynamic adaptive weight, and adaptive Gaussian-Cauchy hybrid mutation perturbation, are integrated into the basic DBO algorithm to enhance global search capability, local exploitation accuracy and convergence performance. Comparative tests on 9 benchmark functions show that MDBO outperforms the basic DBO in convergence speed and solution stability. Furthermore, three irrigation performance indicators (coverage rate, overlap ratio and coverage uniformity) are constructed for posterior evaluation of spray distribution quality. Simulation experiments under three mountainous terrain scenarios verify that MDBO achieves better path accuracy, convergence performance and irrigation effect than traditional algorithms, and can meet the efficient irrigation path requirements of mountainous agricultural crops.

摘要
为解决固定翼无人机在山区农业作物灌溉三维路径规划中避障安全性与灌溉作业质量之间的矛盾，本文提出一种多策略改进的蜣螂优化（MDBO）算法。首先，将安全转弯半径和俯仰角约束嵌入优化目标函数中，以限制飞行姿态，确保复杂山地地形下的飞行稳定性，降低碰撞风险，并保持喷洒沉积的一致性。其次，将伯努利混沌映射初始化、黄金正弦位置更新机制、动态自适应权重以及自适应高斯-柯西混合变异扰动等四种改进策略融入基本 DBO 算法，以提升全局搜索能力、局部开发精度和收敛性能。在 9 个基准函数上的对比实验表明，MDBO 在收敛速度和解的稳定性方面优于基本 DBO 算法。此外，构建了三个灌溉性能指标（覆盖率、重叠率和覆盖均匀性），用于对喷洒分布质量进行后评估。在三种山地地形场景下的仿真实验验证了 MDBO 算法在路径精度、收敛性能和灌溉效果方面优于传统算法，能够满足山地农作物高效灌溉路径的需求。

INTRODUCTION
In agricultural and forestry mountainous planting scenarios, irrigation is a key link in ensuring crop yield *(Ma, 2025)*. However, mountainous crop areas are restricted by objective conditions such as complex terrain (with interlaced slopes and gullies) *(Hu, 2023)* and uneven crop distribution (fruit tree clusters, terraced crops). Traditional ground irrigation equipment struggles to access these areas, and manual irrigation faces the dilemma of low efficiency and high cost.

Against this background, fixed-wing UAVs, with the advantages of long endurance and wide coverage, have become an ideal carrier for irrigation in agricultural and forestry mountainous areas—by carrying spray or drip irrigation components, they can achieve large-area and efficient irrigation operations.

As one of the core issues in fixed-wing UAV irrigation operations, the quality of irrigation path planning *(Giagkiozis et al., 2015)* directly determines the irrigation effect: it is necessary to ensure that the path fully covers all areas to be irrigated, while avoiding obstacles such as fruit tree canopies and slope shoulders, and to maintain a stable flight process to prevent uneven irrigation caused by severe attitude changes. In agricultural aviation, flight stability and path smoothness are critical not only for geometry but also for spray deposition uniformity, droplet drift mitigation, and operational continuity. Studies on UAV-based spraying have shown that flight parameters such as altitude, velocity, and operational stability significantly influence droplet coverage, deposit consistency, and drift risk *(Wang et al., 2017; Wang et al., 2017; Pan et al., 2016)*. Furthermore, the spray distribution from a UAV is inherently non-uniform, and the coverage uniformity is critically affected by flight speed and pass width *(Nanavati et al., 2023)*. Therefore, optimizing path planning for irrigation requires not only obstacle avoidance and path length minimization but also consideration of spray coverage uniformity and overlap control.

In terms of flight parameter constraints *(Deng et al., 2022)*, in traditional path planning, UAVs are often simplified as point masses. However, fixed-wing UAVs have a large volume and may collide with obstacles during flight; moreover, they require long takeoff and landing distances. In addition, UAVs need to frequently adjust their flight trajectories between crops and slopes in agricultural and forestry mountainous areas. If parameter constraints are not fully considered in traditional planning, a series of problems are likely to occur: if the turning radius is too small, UAVs are prone to colliding with fruit trees or slope ridges; if the pitch angle fluctuates too much, it will lead to unstable flight altitude (excessively high altitude causes uneven diffusion of irrigation liquid/droplets, while excessively low altitude may scratch crops). Therefore, it is crucial to introduce constraints on the two flight parameters of safe turning radius and pitch angle in irrigation path planning for agricultural and forestry mountainous areas—which is also the key that distinguishes this scenario from ordinary mountain path planning, as the irrigation scenario has more prominent requirements for "path coverage integrity" and "flight attitude stability."

In terms of path planning algorithms, traditional path planning algorithms such as Dijkstra's algorithm *(Fadzli et al., 2015)*, artificial potential field (APF) method *(Zhou et al., 2015)*, and simulated annealing (SA) algorithm *(Zhu et al., 2006)* have the problem of slow convergence, making it difficult to adapt to the dynamically changing needs of crop distribution in agricultural and forestry mountainous areas. Although existing intelligent optimization algorithms such as the A* algorithm *(Wang et al., 2023)*, genetic algorithm (GA) *(Zhao et al., 2023)*, ant colony optimization (ACO) algorithm *(Wen et al., 2023)*, and particle swarm optimization (PSO) algorithm *(Chen et al., 2023)* have been applied in related fields, they still have the defect of being prone to falling into local optimality (e.g., only avoiding local fruit tree clusters while ignoring marginal irrigation areas). *Zhu et al., 2006,* proposed a path planning method for plant protection UAVs based on the genetic algorithm: by converting intra-regional operation paths and inter-regional scheduling paths into virtual nodes or arcs to construct a super network, it verified the feasibility of this method in the multi-plot path planning problem of UAV pesticide spraying. *Wang et al., (2023),* improved the ant colony algorithm by introducing a height factor, making the ant colony search more directional. *Zhao et al., (2023),* proposed an improved particle swarm UAV trajectory planning algorithm: by combining the "stepwise" adjustment strategy of inertia weight and the strategy of jumping out of local optimal solutions, it improved the optimality and real-time performance of the planning algorithm.

In the context of agricultural spraying operations, coverage path planning has been extensively studied. *Vazquez-Carmona et al., (2022),* proposed a CPP method for spraying drones that models the sprinkler footprint as a paraboloid and restricts flight within the region of interest to avoid collisions. *Plessen, (2025),* combined the traveling salesman problem with area coverage path planning for spot spraying, demonstrating that the inclusion of headland paths significantly reduces coverage gaps. *Meron et al., (2025),* employed high-resolution thermal and visible light imagery to quantify irrigation uniformity across surface, linear move, and solid-set irrigation systems, using the Crop Water Stress Index and Christiansen Uniformity Coefficient as evaluation metrics. *Cui et al., (2025),* utilized UAV multispectral imagery to estimate soil salinity under sunflower cover, demonstrating the feasibility of UAV-based monitoring for precision irrigation management.

Although the above algorithms can improve path planning performance to some extent, their application to mountainous crop irrigation remains limited when coverage continuity and terrain-adaptive flight stability must be considered simultaneously. For irrigation or spraying UAVs, trajectory optimization is not only a geometric problem; it also affects the continuity of the effective spray swath, local overlap/gap formation, and the stability of relative altitude above the crop canopy.

Existing studies on spraying path planning have shown that coverage-gap avoidance and area-coverage organization are essential for practical aerial application, rather than only minimizing route length. In addition, studies on UAV aerial spraying have reported that flight parameters such as height, velocity, and operational stability directly influence droplet coverage, deposit consistency, and drift risk.

Therefore, in the irrigation of mountain crops, a feasible approach should simultaneously meet the requirements of obstacle avoidance, fixed-wing kinematic constraints, and flight stability for irrigation. To address these challenges, the basic DBO framework was retained and enhanced by Bernoulli chaotic initialization, a golden sine strategy, dynamic adaptive weights, and an adaptive Gaussian-Cauchy mixed perturbation strategy, thereby proposing a multi-strategy DBO (MDBO). The optimization objective of this algorithm is to search for the shortest feasible path that satisfies the flight constraints such as smooth turning, stable pitch, and terrain adaptability, while ensuring the safety constraints. On this basis, this study introduces three irrigation performance indicators - coverage, repetition, and coverage uniformity - after the path planning is completed for posterior evaluation of the spray distribution quality of the optimized path. This design effectively overcomes the problems of local optimization and poor stability of fixed-wing unmanned aircraft in path planning in this scenario, and provides a quantitative evaluation basis for the applicability of the planned path for irrigation.

MATERIALS AND METHODS

Fixed-Wing UAV Path Planning Modelling

Mountain Modelling

To simulate the real mountainous irrigation environment, a 3D terrain model is constructed by superposition of multiple Gaussian hills, which can accurately reflect the elevation fluctuation characteristics of mountainous areas, as shown in Fig. 1.

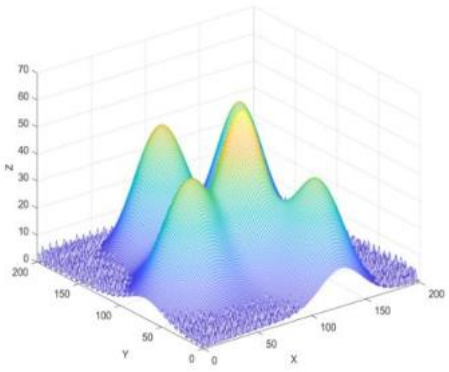

Fig. 1 - Mountain model

The mathematical expression is:

$$Z(x,y)=\sum_{i=1}^{N} h_i \exp[\left(\frac{x-x_{ic}}{x_{ir}}\right)^2-\left(\frac{y-y_{ic}}{y_{ir}}\right)^2 \tag{1}$$

where: N is the number of hills; h_i is the height; (x_{ic}, y_{ic}) is the center coordinate; x_{ir} is the gradient along the x-axis; and y_{ir} is the gradient along the y-axis.

Objective Function

Suppose that a fixed-wing UAV passes through N nodes during operation, with coordinate (x_1, y_1, z_1), (x_2, y_2, z_2), …, (x_N, y_N, z_N). The objective function consists of four core terms:

(1) The total length of the fixed-wing UAV path:

$$F_1=\sum_{i=1}^{N-1}\sqrt{dx_i^2+dy_i^2+dz_i^2} \tag{2}$$

where: F_1 represents the total length of the entire path, dx_i is the distance between two path nodes in the X-axis direction, dy_i is the distance between two path nodes in the Y-axis direction, dz_i is the distance between two path nodes in the Z-axis direction, and N represents the total number of path nodes.

(2) Path altitude of fixed-wing UAV:

$$F_2 = \sum_{i=1}^{N} \left| Z_i - \bar{Z} \right| \tag{3}$$

where: F_2 represents the path height, Z_i represents the z-coordinate of the i-th path point, $\bar{Z}$ represents the mean of all z-coordinates, and N represents the total number of path nodes.

(3) Safe turning radius for fixed-wing UAV:

$$F_3 = \sum_{i=1}^{N-2} \left(\cos\frac{\pi}{2} - \frac{dx_i \cdot dx_{i+1} + dy_i \cdot dy_{i+1} + dz_i \cdot dz_{i+1}}{\sqrt{dx_i^2 + dy_i^2 + dz_i^2} \cdot \sqrt{dx_{i+1}^2 + dy_{i+1}^2 + dz_{i+1}^2}} \right) \tag{4}$$

where: F_3 represents the safe turning radius, dx_i represents the variation of the i-th path segment on the x-coordinate, dy_i represents the variation of the i-th path segment on the y-coordinate, dz_i represents the variation of the i-th path segment on the z-coordinate, and dx_{i+1} represents the variation of the i+1st path segment on the x-coordinate, dy_{i+1} represents the variation of the i+1st path segment on the Y-coordinate, dz_{i+1} represents the variation of the i+1st path segment on the Z-coordinate, and N_2 represents the total number of path nodes.

(4) Pitch Angle of fixed-wing UAV flight:

$$F_4 = \tan^{-1}\left(\frac{dz}{\sqrt{dx^2 + dy^2}} \right) \tag{5}$$

where: F_4 represents the pitch Angle.

(5) Overall objective function expression:

$$F = \sum_{i=1}^{4} w_i \times F_i \tag{6}$$

where: $w_1 \sim w_4$ are weight coefficients, balancing path efficiency, flight safety and irrigation performance. The optimal weight combination is determined by ablation experiments.

Irrigation Performance Indicators

Different from ordinary path planning, irrigation path planning needs to evaluate the actual operation effect. Three quantitative indicators are proposed for posterior evaluation of spray distribution quality, which are not involved in the optimization process.

(1) Coverage rate: The proportion of grids sprayed at least once in the target area, reflecting the integrity of irrigation coverage.

$$CR = \frac{|\{(i,j) \mid c_{i,j} \geq 1\}|}{N_x \times N_y} \tag{7}$$

where: $c_{i,j}$ represents the coverage times of the grid (i,j), N_x and N_y represent the total number of grids in each dimension.

(2) Overlap ratio: The proportion of grids with spray times exceeding the ideal threshold, reflecting the degree of resource waste caused by repeated spraying.

$$OR = \frac{|\{(i,j) \mid c_{i,j} > c_{\text{ideal}}\}|}{N_x \times N_y} \tag{8}$$

where: c_{ideal} represents the ideal coverage threshold.

(3) Coverage uniformity: Quantifying the uniformity of spray distribution in the covered area. The closer the value is to 1, the more uniform the spray distribution.

$$U = 1 - \frac{\sigma(c_{\text{covered}})}{\mu(c_{\text{covered}})} \tag{9}$$

where: μ and σ represent the mean and standard deviation of the total number of times all covered grids have been covered, respectively.

Dung Beetle Optimization Algorithm

Dung Beetle Optimization Algorithm (DBO) is a novel population-based intelligence optimization algorithm inspired by social behaviors of dung beetles during the acquisition and handling of dung balls *(Xue et al., 2023)*.

As an innovative algorithm, dung beetles search rolling burying and guarding dung balls to implement the meta-heuristic as a means of dealing with complex optimization problems. More specifically, the DBO simulates 5 main behaviors of dung beetles — rolling of the ball, dance, mating, foraging and pill stealing *(Jin et al., 2023)*.

Rolling beetles move forward along a straight trajectory with the aid of light sources; dancing behavior adjusts moving direction when encountering obstacles; breeding beetles update positions within local optimal areas for oviposition; foraging beetles search for food near the global optimum with normal distribution perturbation; thief beetles compete for dung balls near the optimal food source to increase population diversity.

The basic DBO algorithm has fast initial convergence, but it still has limitations in solving complex 3D path planning problems: random initialization leads to insufficient population diversity, and population aggregation in the late iteration stage easily causes premature convergence and falls into local optimum. To address these defects, this paper improves the algorithm from four aspects to enhance its adaptability to mountainous irrigation path planning scenarios.

An Advanced Multiple Strategies Dung Beetle Optimization Algorithm

Aiming at the defects of basic DBO algorithm, four improvement strategies are integrated to construct a multi-strategy improved dung beetle optimization (MDBO) algorithm, so as to balance global exploration and local exploitation capability and avoid premature convergence.

Bernoulli Chaotic Mapping Strategy

Random initialization easily leads to uneven population distribution and insufficient diversity, limiting the early global search range. Chaotic mapping features ergodicity, randomness and regularity, which can generate initial populations with wider distribution and better diversity. In this paper, Bernoulli chaotic mapping is used to generate initial population positions *(Saito et al., 2016)*. The mapping expression is:

$$z_{n+1} = \begin{cases} \dfrac{z_n}{1-\beta}, & 0 \le z_n \le 1-\beta \\ \dfrac{z_n - (1-\beta)}{\beta}, & 1-\beta \le z_n \le 1 \end{cases} \tag{10}$$

where: $\beta \in (0,1)$.

Golden Sine Strategy

In the basic DBO algorithm, the position update of rolling beetles lacks sufficient information interaction with the optimal individual, which is easy to cause premature convergence. The golden sine algorithm combines the golden section ratio with the sine position update mechanism, which can effectively balance global exploration and local exploitation.

This paper introduces the golden sine strategy to optimize the position update of rolling beetles. The update formula is:

$$X_i^{t+1} = X_i^t \times |\sin(R_1)| + R_2 \times \sin(R_1) \times |x_1 \times P_i^t - x_2 \times X_i^t| \tag{11}$$

where: $R_1 \in (0, 2\pi)$, $R_2 \in (0, 2\pi)$, $x_1 = -\pi + (1-\tau) * 2\pi$, $x_2 = -\pi + (1-\tau) * 2\pi$, $\tau(\tau = (\sqrt{5}-1)/2)$.

In the second part of the position update expression, if $R_2 < ST$, the dung beetle gradually reduces its angle; otherwise $R_2 \geqslant ST$, the dung beetle has a random walk in normal distribution in the same region. While this design allows the algorithm to converge to the global best solution at the start of the fitness iteration, it also increases the potential to converge too quickly and get stuck at local optima. In order to remedy this defect, the present work proposed the golden sine, to optimize the DBO algorithm partition update mechanism. Below is the updated version of position update Equation:

$$X_{i,j}^{t+1} = \begin{cases} X_{ij}^t \times |sin(R_1)| + R_2 \times sin(R_1) \times |x_1 \times X_{best}^t - x_2 \times X_{ij}^t|, R_2 < ST \\ X_{i,j}^t + Q \cdot L, \qquad R_2 \ge ST \end{cases} \tag{12}$$

The improved position update scheme enhances algorithm performance in two aspects. First, all individuals interact with the current optimal individual per iteration to fully exploit optimal information, which

remedies the deficiency of inter-individual information exchange in the original DBO. Second, the golden sine strategy broadens the search range to avoid local optima, and the golden section coefficient fine-tunes the search distance and direction of dung beetles, thus achieving a balanced trade-off between global exploration and local exploitation.

Strategy For Dynamic Adaptability Weight

While, given many early iterations of the DBO algorithm, the algorithm may over-focus onto local areas, causing local convergence. To overcome this drawback, in this paper, the position update formula is changed by adding between its own position the global optimal solution from last generation, which means during the current position update, the position will be affected not only by itself but its optimal solution in the previous generation. Moreover, dynamic weight coefficient is proposed to improve global search ability in the early stage, whilst increasing local search and convergence processes in the latter stages by reducing adaptation. The new coefficient *w* and the new position update equations are as follows:

$$w = \frac{e^{2(1-t/iter_{max})} - e^{-2(1-t/iter_{max})}}{e^{2(1-t/iter_{max})} + e^{-2(1-t/iter_{max})}} \tag{13}$$

$$X_{i,j}^{t+1} = \begin{cases} (X_{i,j}^{t} + w(f_{j,g}^{t} - X_{i,j}^{t})) \cdot rand, R_2 < ST \\ \\ X_{i,j}^{t} + Q, \qquad\qquad R_2 \geq ST \end{cases} \tag{14}$$

where: $f_{j,g}^{t}$ is the j-th dimensional global optimal solution of the previous generation; Q is the stochastic number; $R_2 \in (0,1)$; and $ST \in (0.5,1)$.

Adaptive Gauss-Cauchy Mixed-Variance Perturbation Strategy

In later iterations, the basic DBO suffers from severe population aggregation around local optima. While accelerating convergence, this phenomenon sharply reduces population diversity, trapping the algorithm in local minima and even causing search stagnation. Mutation perturbation is a widely adopted technique to restore population diversity and assist the algorithm in escaping local optima *(Du et al., 2024)*.

Among common mutation operators, Gaussian mutation achieves fine local exploitation with small step sizes, whereas Cauchy mutation performs broader global exploration with larger step sizes but may generate lower-quality offspring. To fully leverage the strengths of both, this paper proposes an adaptive Gaussian-Cauchy hybrid mutation perturbation strategy. It only applies perturbation to the current best individual, and retains the mutated position only when its fitness is improved, thus effectively expanding population diversity while guaranteeing solution quality. The specific expression is given as follows:

$$H^b(t) = X^b(t) * (1 + \mu_1 * Gauss(\sigma) + \mu_2 * cauchy(\sigma)) \tag{15}$$

where: $\mu_1 = t / T_{max}$, $\mu_2 = 1 - t / T_{max}$, $X^b(t)$ indicates the individual's optimal position at the t-th iteration, $H^b(t)$ represents the position of the optimal position post a mixed Gauss-Cauchy perturbation, $Gauss(\sigma)$ is the Gaussian variational operator, and $cauchy(\sigma)$ is the Cauchy variational operator.

The strategy applies adaptive perturbation throughout iterations, with mutation modes dynamically tuned to the population distribution state. In early iterations, Cauchy distribution with large-amplitude perturbations is adopted for the widely dispersed population, which enhances population diversity, boosts global search capability, and prevents premature trapping in local optima. As iterations proceed and the population gradually converges, Gaussian distribution with small-amplitude perturbations dominates to perform precise local exploitation, accelerating convergence while maintaining algorithmic robustness in complex high-dimensional spaces. This adaptive switching mechanism effectively achieves a balanced trade-off between global exploration and local exploitation.

The mechanics and flow of this approach are encapsulated in the pseudo-code for the MDBO algorithm, which is detailed in Table 1 below.

Table 1

Pseudo-code for the MDBO algorithm

Pseudo-code for the MDBO algorithm
Inputs: maximum number of iterations T_{max} , population size N .
Output: optimal position X^b and its fitness value f_b .
1 Randomly initialize the dung beetle population, defining the relevant parameters
2 Initialization of population positions using Bernoulli's chaotic mapping
3 **while** $(t \le T_{max})$ **do**
4 **for** $i \leftarrow 1$ *to* N **do**
5 **if** $i ==$ Dung Beetle Roller **then**
5 $\delta = \text{rand}(1)$
6 **if** $\delta < 0.9$ **then**
7 Use the golden sine strategy to update the position of the rolling dung beetle;
8 **else**
9 Update the position of the rolling dung beetle;
10 **end if**
11 **end if**
12 **if** i ==Breeding Dung Beetles **then**
13 Update the location of breeding dung beetles;
14 **end if**
15 **if** i ==Foraging Dung Beetle **then**
16 The location of the foraging dung beetle was updated;
17 **end if**
18 **if** i ==Stealing Dung Beetles **then**
19 Updating the location of the stealing dung beetle using a equation that incorporates dynamic weighting factors;

29 $t = t + 1$
30 **end while**
31 **Return the** fitness value

Application of the MDBO Algorithm to Fixed-Wing UAV Path Planning

The procedure for applying the MDBO algorithm to fixed-wing UAV path planning is as follows:

Step1: Define start and end points, and construct a detailed map of complex mountain terrain;

Step2: Enter the objective function and associated parameters to guide the search;

Step3: Position the dung beetles using Bernoulli's chaotic mapping to ensure diverse starting points;

Step4: Calculate the fitness of each individual based on the objective function within the designated fitness landscape;

Step5: Apply the golden sine algorithm to adjust the positions of all dung beetles towards optimal paths;

Step6: Verify that no dung beetle exceeds the predefined map boundaries;

Step7: Modify current positions by integrating influences from both the previous positions and the current best solution using a dynamic adaptive weighting strategy;

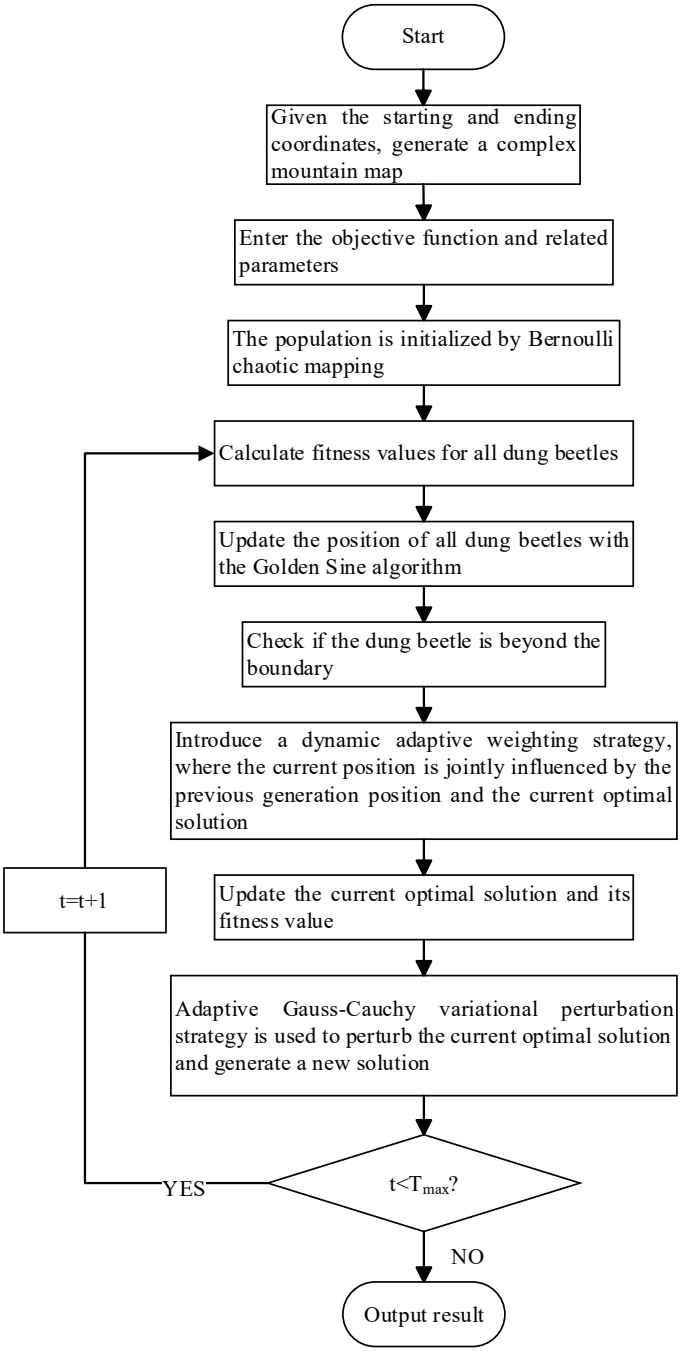
Step8: Refresh the best-known solution and its corresponding fitness score;

Step9: Employ an adaptive Gauss-Cauchy mixed-variance perturbation strategy to further refine the current best solution, creating potential new optimal paths;

Step10: Determine if the end condition is met; if not, loop back to Step 4; if yes, proceed to the final step;

Step11: Deliver the optimal path solution with its fitness value and conclude the algorithm.

Refer to the flowchart depicted in Fig. 2 for a graphical representation of the MDBO algorithm steps.



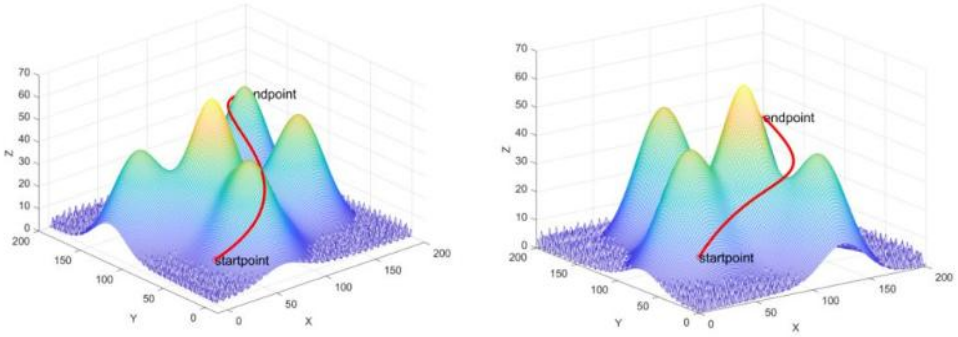


Fig. 2 - The flowchart of the MDBO algorithm

RESULTS

The experiments were conducted on a computer equipped with an Intel® Core™ i5-8250U processor operating at 1.60–1.80 GHz and 16 GB of RAM. The system ran the 64-bit version of Windows 11, and MATLAB R2022b was used for all simulations.

Security Constraints Impact Analysis

Safe turning radius and pitch angle are critical constraints for fixed-wing UAV path planning. Neglecting these constraints will induce excessively sharp turns and abrupt pitch maneuvers, which degrade flight efficiency, elevate collision risks and reduce spray uniformity in complex terrain. Comparative experiments with and without the above constraints are carried out, with results shown in Fig. 3. It is verified that introducing the constraints yields a smoother flight path with gentler turning and climbing maneuvers, thus effectively improving flight safety and operational reliability.

Performance Analysis of the Algorithm Using Benchmark Test Functions

To gauge the effectiveness of the modified MDBO algorithm, this research utilized nine benchmark test functions outlined in Table 2. These functions were used to test and compare the MDBO algorithm against the original DBO algorithm. The chosen benchmarks encompass single-peak, multi-peak, and fixed-dimension functions, providing a comprehensive evaluation across various optimization scenarios. For each algorithm, the testing conditions were standardized with a population size of 30 and a limit of 500 iterations.

Each algorithm was independently run 30 times on the nine benchmark test functions, and the optimal value, mean, and standard deviation of the function values were recorded. The computational results are displayed in Table 3. As shown in Table 3, the results of the comprehensive experiments across the nine test functions indicate that the MDBO algorithm achieves optimal values comparable to the DBO algorithm on the 7th and 8th functions. Additionally, for the 9th function, both algorithms yield identical results. For the remaining six functions, the MDBO algorithm demonstrates superior optimization accuracy compared to the DBO algorithm. Furthermore, in terms of computational stability, the MDBO algorithm exhibits a lower standard deviation over 30 runs, indicating higher consistency and enhanced search capability compared to the DBO algorithm.

Performance Analysis of the Algorithm Using Benchmark Test Functions

As the weight parameters of the multi-objective function directly determine path planning performance, this section adopts the single-factor control variable method in ablation experiments to analyze the influence law of each weight on fixed-wing UAV mountain irrigation path planning, and determines the optimal weight combination applicable to mountain agricultural irrigation scenarios.

The objective function consists of four core terms: path length, altitude fluctuation, turning radius constraint and pitch angle constraint, corresponding to weights w_1, w_2, w_3 and w_4 respectively. During the experiment, three weights are fixed at the final determined values, and only the target weight is adjusted within the range of [0, 1] with a step size of 0.1. Each parameter set undergoes 30 independent repeated experiments, and the error bars in the figures represent the standard deviation of results to quantify the operational stability of the algorithm.

Figs. 5–8 present the influence of each weight coefficient on path planning performance obtained via single-factor ablation experiments.

For the path length weight w_1 (Fig. 5): increasing w_1 within 0–0.3 significantly reduces altitude fluctuation, turning cost and pitch angle cost without notable path length degradation. At w_1 = 0.3, altitude fluctuation and pitch angle cost reach the global minimum, and turning cost stays within the optimal range. Values above 0.3 cause sharp deterioration of attitude-related indicators despite marginal reduction in path length, so w_1 = 0.3 is selected.

For the altitude fluctuation weight w_2 (Fig. 6): as w_2 rises from 0 to 0.3, altitude fluctuation drops sharply from 1200 m to 220 m, accompanied by optimized turning and pitch angle costs. When w_2 exceeds 0.3, altitude fluctuation oscillates without further improvement, while path length and attitude-related costs all deteriorate. Thus w_2 = 0.3 is adopted.

For the turning radius weight w_3 (Fig. 7): as a hard safety constraint for fixed-wing UAVs, insufficient turning radius directly leads to aerodynamic stall and crash. Increasing w_3 below 0.65 gradually optimizes turning cost without obvious degradation of other indicators, while values above 0.65 cause significant deterioration of path length, altitude fluctuation and pitch angle cost. Prioritizing flight safety, w_3 = 0.65 is determined.

For the pitch angle weight w_4 (Fig. 8): pitch angle cost keeps optimizing with the growth of w_4. Within the range of w_4 in [0.3, 1], pitch angle cost stabilizes in the optimal interval of 0.09–0.11, and no significant degradation occurs in path length, altitude fluctuation or turning cost. Given that pitch angle constraint directly determines operational feasibility, w_4 = 1.0 is chosen.

Based on the above experimental results, the final multi-objective weight combination applicable to mountain agricultural irrigation scenarios is determined as w_1 = 0.3, w_2 = 0.3, w_3 = 0.65, w_4 = 1.0.

Analysis Of Path Planning Simulation Results

To verify the robustness and effectiveness of the improved algorithms, this study conducted comparative experiments between the MDBO algorithm and several others, including PSO, COA, NGO, WOA, SSA, and DBO, in three mountainous environments with varying levels of complexity using MATLAB. The specific parameter settings for each algorithm are presented in Table 4.

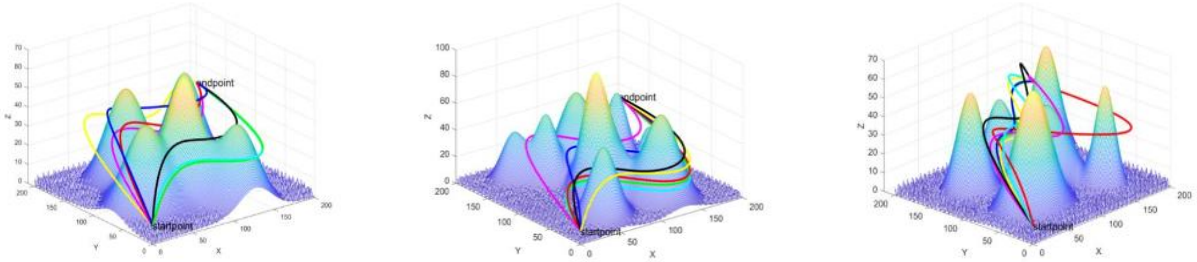

Table 4

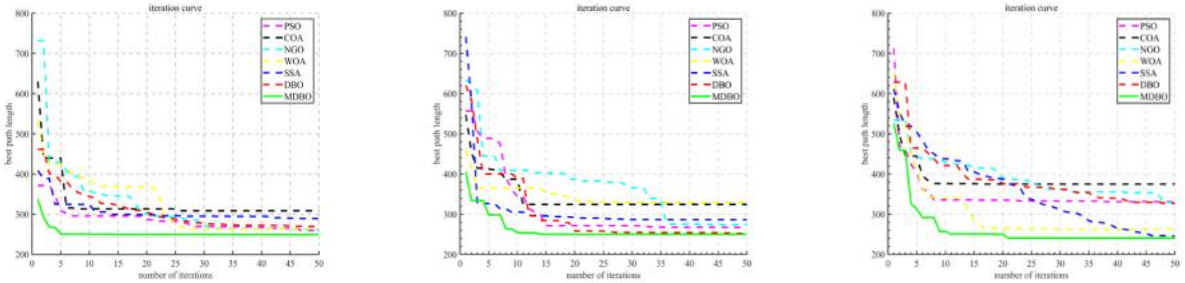
Parameter variable settings

Arithmetic	Algorithmic parameter	Numerical value
PSO	w	1
	c_1	1.5
	c_2	2.0
COA	w	Reduction from 1 to 0.1
	SF	1.5
NGO	w	Reduced linearly from 1 to 0.1
WOA	a	Decrease from 2 to 0
SSA	w	Reduced linearly from 1 to 0.1
	R	0.2
DBO	a	-1 or 1
	R	1(decreases linearly during iterations)
MDBO	R_1	$(0, 2\pi)$
	R_2	$(0, \pi)$
	τ	$(\sqrt{5}-1)/2$
	a	-1 or 1
	R	1(decreases linearly during iterations)



To ensure the neutrality of the experimental outcomes, the parameters for all tested algorithms were uniformly configured. The starting point was set at coordinates (0, 0, 10), while the endpoint was at (200, 200, 30). The experiments maintained a population size of 50 and were capped at a maximum of 50 iterations.

The evaluation of path optimization performance across three different mountainous terrains of increasing complexity is depicted in Figures 9 and 10. Figure 9 provides a visual comparison of the pathfinding results of each algorithm, and Figure 10 explores the correlation between the number of iterations and the achievement of optimal values.

Fig. 9 - Comparison of air path planning effects

(a) Map 1 (b) Map 2 (c) Map 3

Fig. 10 - The iterations vs optimal value curve

The iteration curves of three maps are shown in Fig. 10. The improved MDBO achieves faster convergence and stronger early exploration capability than the basic DBO. All algorithms tend to converge before the 8th iteration, while MDBO consistently yields the best convergence value at each iteration, with both higher convergence speed and solution accuracy than other comparison algorithms. The golden sine strategy accelerates convergence, the dynamic adaptive weight prevents premature local trapping, and the adaptive Gaussian-Cauchy hybrid mutation further helps the algorithm escape from local optima. The phenomenon that the basic DBO is easily trapped in local optima during iteration also verifies the effectiveness of the above improvements.

To eliminate the influence of randomness, 30 independent runs are conducted for each map. As shown in Table 5, the proposed MDBO outperforms all other algorithms in terms of maximum, minimum and average path length. More importantly, MDBO achieves the minimum standard deviation, indicating higher stability and consistency in path planning performance.

Ablation Experiment

The modified versions of the DBO algorithm are denoted in Table 6: DBO123 indicates the DBO algorithm equipped with the Bernoulli's chaotic mapping strategy, golden sine strategy and dynamic adaptive weighting strategy; DBO124 represents the DBO algorithm with the Bernoulli's chaotic mapping strategy, golden sine strategy and adaptive Gauss-Cauchy mixed-variance perturbation strategy; DBO234 means that the DBO algorithm uses golden sine strategy, dynamic adaptive weighting strategy and adaptive Gauss-Cauchy mixed-variance perturbation strategy.

Table 6

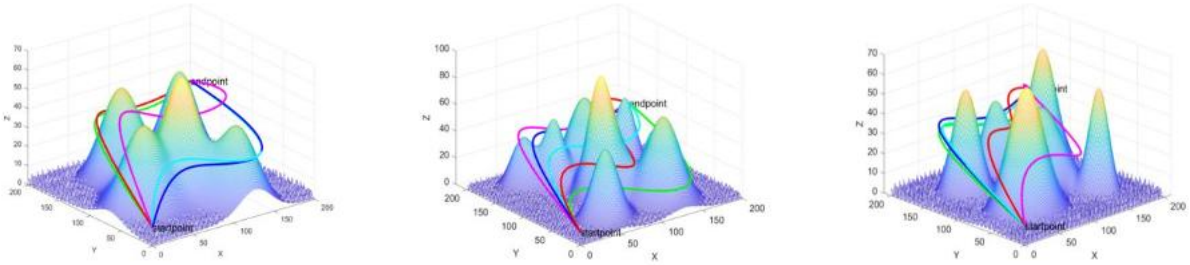
MDBO algorithm and its variants

Algorithm	Bernoulli's chaotic mapping	Golden sine	Dynamic adaptive weighting	Gauss-Cauchy mixed-variance perturbation
DBO123	√	√	√	
DBO124	√	√		√
DBO134	√		√	√
DBO234		√	√	√
MDBO	√	√	√	√

To confirm that simultaneously introducing the four strategies can improve the performance of the MDBO algorithm, a series of ablation experiments were designed. In three mountainous environments with different level of complexity, comparative experiments between MDBO with its variants DBO123, DBO124 and DBO234 were implemented using MATLAB. The parameter settings for all the experiments were the same, that is, the starting coordinate is (0,0,10), end coordinate is (200,200,30), population size 50 and maximum 50 iterations.

The path finding optimization of each algorithm across three mountain maps with varying levels of complexity is illustrated in Fig. 11 and Fig. 12. Fig. 11 presents a comparison of the path planning effectiveness, while Fig. 12 depicts the relationship between the number of iterations and the optimal values. A total of 30 experiments were conducted on each of the three maps, and the longest path, shortest path, average value, and standard deviation of the fixed-wing UAV in these experiments were statistically analyzed, as shown in Table 7.

Experimental results demonstrate that the complete MDBO algorithm outperforms all variant algorithms across all evaluation metrics, including maximum, minimum and mean path length, as well as standard deviation. Iteration curves further confirm that MDBO converges significantly faster on all test maps, and the synergy among multiple strategies substantially enhances its path planning capability in complex mountainous terrain.



These four complementary strategies empower MDBO to achieve superior 3D path planning for fixed-wing UAVs. Bernoulli mapping diversifies initial solutions, and the golden sine strategy accelerates convergence. Dynamic adaptive weights balance exploration and exploitation, while Gaussian-Cauchy hybrid mutation introduces stochastic perturbations to effectively escape local optima.

Evaluation of Irrigation Effectiveness

Spray distribution quality of five algorithms (DBO123, DBO124, DBO134, DBO234 and MDBO) is evaluated on Map 1, with 30 independent runs conducted for each algorithm. Table 8 presents the statistical results of three irrigation indicators — coverage rate, overlap ratio and coverage uniformity, including the maximum, minimum, mean and standard deviation across all runs.

As shown in Table 8, MDBO achieves the highest coverage rate with the smallest standard deviation, indicating both optimal coverage performance and operational stability. The overall coverage rate of all algorithms is relatively low, mainly because fixed start and end points restrict path freedom, making a single flight unable to cover the entire map area; the safe turning radius and pitch angle constraints further narrow the feasible path space. Even under these limitations, MDBO still realizes relatively optimal coverage performance.

In addition, MDBO obtains the lowest overlap ratio, verifying its superior ability to avoid excessive spraying and minimize resource waste while maintaining adequate coverage. It also delivers the highest coverage uniformity, demonstrating its advantage in achieving balanced spray distribution. Comprehensive analysis confirms that the proposed MDBO algorithm achieves excellent overall irrigation performance.

Table 8

The irrigation index results of each algorithm in Map 1

CONCLUSIONS

This study addresses the core challenge of balancing obstacle avoidance safety and irrigation effectiveness in 3D path planning of fixed-wing UAVs for mountainous agricultural irrigation, and proposes a multi-strategy improved DBO (MDBO) algorithm with embedded flight kinematic constraints. Safe turning radius and pitch angle constraints are introduced to stabilize flight attitude and maintain irrigation consistency. Four improvement strategies (Bernoulli chaotic mapping, golden sine mechanism, dynamic adaptive weight, adaptive Gaussian-Cauchy hybrid mutation) are integrated to balance global exploration and local exploitation capability. Benchmark function tests and scenario simulation experiments verify the effectiveness of the proposed method.

Three irrigation performance indicators are established for posterior evaluation of spray distribution quality. Simulation results demonstrate that MDBO achieves superior performance in both path length optimization and irrigation effect, which fully meets the efficient irrigation path demands of mountainous crops.

This study is limited to simulation environment without considering practical factors such as wind disturbance, sensor noise and environmental variability, and irrigation indicators are applied for post-evaluation rather than being incorporated into the optimization objective. Future research will embed irrigation indicators into the objective function to balance path efficiency and irrigation quality, and further validate the algorithm via hardware-in-the-loop simulation and field tests.

Keywords: *MATAG; smartphone; spectral signature; species detection*

ABSTRACT

Smartphones have become a convenient tool in agriculture due to their mobility, affordability, and capacity to enhance more efficient crop monitoring, including MATAG variety identification. Detecting MATAG hybrid varieties remains challenging because their morphological traits are difficult to differentiate macroscopically, but reflectance values can be generated using a spectral signature graph. This review aims to explore the development of an intelligent identification system for the MATAG variety based on spectral signature analysis using a smartphone device. It discusses characterisation of MATAG hybrids, spectral signature differences between each coconut species, the development of spectral signature libraries, and the potential of smartphone-spectral signature-based applications compared with manual inspection and laboratory analysis. It also highlights the mechanisms of MATAG variety detection based on spectral signature analysis using a smartphone and practical considerations for farmers. Case studies and testimonials from farmers on how smartphone devices have revolutionised crop monitoring practices were also discussed, together with the potential benefits of using this technology for the agricultural industry. It also elaborates on the opportunities and challenges of detecting MATAG variety using smartphone-spectral approaches, which will be a useful resource for app developers to solve the problems in the field. Overall, this review provides a comprehensive overview of smartphone-spectral signature integration for MATAG detection that eventually helps farmers in the plantation.

ABSTRAK

Telefon pintar telah menjadi alat yang mudah digunakan dalam pertanian kerana mobiliti, kemampuan dan keupayaannya untuk meningkatkan pemantauan tanaman yang lebih cekap, termasuk pengenalan kepelbagaian MATAG. Mengesan kepelbagaian hibrid MATAG kekal mencabar kerana ciri-ciri morfologinya sukar dibezakan melalui mikroskop, tetapi nilai pantulan dapat dijana menggunakan graf tanda tangan spektral. Ulasan artikel ini bertujuan untuk meneroka pembangunan sistem pengenalan pintar untuk kepelbagaian MATAG berdasarkan analisis tanda tangan spektral menggunakan peranti telefon pintar. Ia membincangkan ciri-ciri hibrid MATAG, perbezaan tanda tangan spektral antara setiap spesies kelapa, pembangunan perpustakaan tanda tangan spektral, dan potensi aplikasi berasaskan tanda tangan spektral telefon pintar berbanding dengan pemeriksaan manual dan analisis makmal. Ia juga menyoroti mekanisme pengesan kepelbagaian MATAG berdasarkan analisis tanda tangan spektral menggunakan telefon pintar dan pertimbangan praktikal bagi petani. Kajian kes dan testimoni daripada petani tentang bagaimana peranti telefon pintar telah merevolusi amalan pemantauan tanaman juga dibincangkan, bersama dengan faedah berpotensi menggunakan teknologi ini untuk industri pertanian. Ia juga membincangkan peluang dan cabaran mengesan kepelbagaian MATAG menggunakan pendekatan spektral telefon pintar, yang akan menjadi sumber berguna bagi pembangun aplikasi untuk menyelesaikan masalah di lapangan. Secara keseluruhan, artikel ini memberikan gambaran menyeluruh tentang integrasi tanda tangan spektral telefon pintar untuk mengesan MATAG yang akhirnya membantu petani di ladang.

1. INTRODUCTION

Coconut (*Cocos nucifera L.*) is one of the most important plantations, particularly in tropical countries. Indonesia, the Philippines, and India are the world's biggest coconut producers, accounting for up to 75% of global production (*Halim et al., 2018*). Almost every part of the coconut tree can be consumed for human benefit. There are three types of coconut trees: tall, dwarf, and hybrid. Hybrids have earlier flowering, higher fruit yield, higher copra production, and higher copra and oil quality than the parent. The most popular hybrid is the 'MATAG' cultivar. The 'MATAG' results from intervarietal crosses between 'Malayan Yellow Dwarf' or 'Malayan Red Dwarf' with 'Tagnanan Tall'. The MATAG could generate drinking fruit juice, whereas the husk fibres are denser and more suitable for coir production.

MATAG is also widely used in the industry of processing products. Therefore, the agro-based ministry of the respective countries is always trying to increase the amount of MATAG trees planted (*Halim et al., 2018*). Thus, seedling producers attempt to keep up with the high demand. However, MATAG plantations need help in producing uniform and high-quality seedlings, resulting in a shortage of plantations for farmers (*Hassan et al., 2021*). The reasons for this issue are a less true-to-type MATAG variety identification and poor seedling quality caused by non-systematic and imprecise nursery management, which enhances the inefficient distribution of water and nutrients to seedlings (*Yusof et al., 2017*).

The standard MATAG variety detection technique in coconut nurseries is expert visual assessment based on the parent's colour. This approach is time-consuming and prone to human error (*Bisi et al., 2020*). Therefore, the seedlings will be culled based on the assessor's visual ability and experience. MATAG variety detection could be improved using computer vision techniques, including machine learning and support vector machines (*Che'Ya et al., 2022*). The efficiency for plant species identification using machine learning could reach up to 99.8% (*Borraz-Martínez et al., 2022*). As a result, the cost of production can be reduced, and the nursery's output of high-quality MATAG seedlings could be increased.

Nevertheless, the differences between MATAG varieties are hard to distinguish by visual comparison due to their similar shapes and colours. Because different substances have specific spectral signatures and reflectance, remote sensing techniques can be used with high altitude imaging sensors to obtain spectral information of the Earth's surface, including MATAG varieties. Therefore, spectral signatures can identify each MATAG according to its unique value and characteristics, which are displayed through the spectral signature graph (*Ahansal et al., 2022*).

Some farmers cannot identify MATAG variety and their characteristics in the field because they need up-to-date data related to MATAG, including leaves information for sensor imagery such as its width, length, area, perimeter, area of white space, area of the bounding box, area of hull, the perimeter of the hull, colour, texture, morphology, and structure, as well as seedling information for spectral signature analysis such as only germinated, normal seedlings, and seedling age (*Zaki et al., 2023*). As an alternative, a spectral library can be developed to compare the reflectance of the MATAG variety and include other applications such as image processing, estimating the infestation percentage, identifying the trees' location, and providing information on managing crops from planting to harvesting (*Rosle et al., 2019*). The spectral signature graph can be stored in the library using an online database and a mobile app to avoid losing data and allow researchers to access it worldwide easily (*Roslin et al., 2021*). The apps could help the farmers to process the image on the sensor via smartphone and visualise the MATAG variety mapping in the nurseries.

Some digital databases of the spectral library for crop variety identification, including the Johns Hopkins Spectral Library, United States Geological Survey (USGS) Spectral Library, ASTER Spectral Library, MedSpec, Jet Propulsion Laboratory Spectral Library, and LILIAN, were inaccessible to the public (*Kokaly et al., 2017; Adam, 2012*). While general crop monitoring apps exist, none specifically address MATAG variety detection through spectral signatures. Developing a spectral library for the MATAG variety is a proactive starting point for storing spectral signatures for future usage. Therefore, this review aims to discuss and elaborate on developing an intelligent identification system for the Matag variety based on spectral signature analysis using a smartphone device. Rather than being separate approaches, smartphones, UAVs, and sensors form a complementary ecosystem. Data collected across different spatial and temporal scales are integrated, analysed, and communicated back to the farmer via the smartphone platform, creating a seamless workflow for precision MATAG detection and farm management.

2. CHARACTERISATION MATAG HYBRID

MATAG is currently the most commercialised coconut variety planted in Malaysia, followed by Aromatic Dwarf, known as PANDAN and other dwarf varieties. The name “MATAG” refers to a new hybrid coconut, based on the original coconut from Malaysia, which is Malayan Yellow Dwarf (MYD) or Malayan Red Dwarf (MRD), a female parent crossing with Tagnanan Tall coconut (from the Philippines) as a male parent. MATAG produces large, rounded fruits that mature rapidly and provide high yields. Due to the increasing demand for raw materials in cooking and virgin coconut oil, MATAG has been identified as a suitable source for commercial cultivation in several states in Malaysia (*Raj et al., 2024*). The main producing states are Johor, Perak, Selangor, and Kelantan, where the favourable climatic conditions are well suited to coconut cultivation (*Man and Shah et al., 2020*).

MATAG can reach a height of 15 m, has orange or green leaves, and may initiate to bloom mostly in the third year of cultivation. The MATAG is a new variety of coconut that can produce more coconuts annually than other hybrid or normal coconut trees, up to 40,000 coconuts per hectare. MATAG begins bearing fruit in the third year after planting and can be harvested at approximately 48 months *(DOA, 2016)*. Compared with other hybrid cultivars, MATAG produces a higher number of coconuts, typically about 10–22 fruits per bunch. MATAG has a high nut production rate, yielding approximately 25,000-30,000 nuts per hectare yearly, which is more than the other hybrid types (*PRESSREADER, 2016*). Its average output yield during the first six years of harvest is 18,467, compared to 5,050 nuts for Malayan Tall.

The benefits of MATAG coconuts include their ability to produce higher copra per yield, i.e., 53.9%, because they have thicker plump fruit than other hybrids such as Aromatic Green Dwarf (AGD), CAMMA, and normal coconuts (*Kingimi et al., 2023*). When compared to a normal coconut, the size of the coconut is also larger, which makes the copra thicker and, thus, increases the production of grated coconut and coconut milk (Fig. 1). The MATAG hybrid is more flexible in terms of suitability for both tender and dry nuts due to its ease of dehusking for dry nut purposes, larger nut size that results in a higher amount of water, and reduced husk thickness. In addition, the MATAG coconut’s flavour is tastier because the coconut water is sweeter than regular or other hybrid coconuts, making it more pleasant to drink.

Fig. 1 - Nursery centre for the MATAG variety at DoA, Jorak (Johor)

3. OVERVIEW OF MATAG VARIETY DETECTION BASED ON SPECTRAL SIGNATURE LIBRARIES

Plant pigments absorb light primarily within the photosynthetically active radiation range of 400–700 nm. For example, chlorophyll strongly absorbs blue-violet and red light while reflecting green light, which gives leaves their characteristic green appearance *(Virtanen et al., 2020)*. Carotenoids, in contrast, reflect light in the yellow, orange, and red regions of the spectrum while absorbing mainly blue-green and violet light *(Liu and Van Iersel, 2021)*. Different coconut cultivars often have similar shapes and colours, making visual

discrimination difficult. However, they can be differentiated and identified based on their distinctive spectral signatures. Each plant pigment exhibits a characteristic spectral response defined by its reflectance across different spectral bands. Plant spectral signatures generally show low reflectance in the visible region of the electromagnetic spectrum because photosynthetic pigments strongly absorb visible light *(Kutser et al., 2020)*.

Coconut tree fronds with varying degrees of Coconut Scale Insect (CSI) infestation are healthy (young), slightly healthy, moderately healthy, and severely infected. Therefore, the identification of CSI in spectral signatures, even at low level, can evaluate the efficacy of control measures (biological and chemical) (*Franco et al., 2018*). Furthermore, a previous study (*Noor Azmi et al., 2020*) found that various degrees of disease infestation on coconut can be differentiated based on spectral signature using 8-band Worldview-2 satellite imagery, with the NIR-1 and NIR-2 bands, followed by the Red Edge band.

Reflectance generally decreases across the measured wavelength range as leaf health declines from healthy to infected. However, the spectral curves may show substantial variability because infection affects only part of the leaf area, often up to 50%, and measurements may randomly include both infected and healthy tissue within the sensor's field of view *(Rodríguez Machado et al., 2020)*. These differences can be visualized using reflectance-wavelength curves. Reflectance is measured at discrete intervals over a specified wavelength range. The width of these intervals represents the spectral resolution of the sensor, while the reflectance recorded within each interval corresponds to an individual spectral band. A spectral signature is characteristic of a material because its reflectance and emittance properties vary with its physical condition and surrounding environment *(Meerdink et al., 2019)*.

The real-time monitoring of spectral signatures has been improved by using field-based devices. The portable spectrometer is a device that can measure the spectral signature of plants, in which the signature can be used to recognise the plant species. Accordingly, because reflectance readings rely on incident sunlight, the device can only capture valid spectral signatures throughout the day under a clear skyline view with no significant cloud cover or precipitation (*Musiol-ková et al., 2021*). This aspect is why comparing the spectral signature graph of the same plant species between earlier studies is challenging and depends on the sampling environment during the measurement, such as humidity, cloud cover, type temperature, wind speed and direction, and aerosols (*Torresani et al., 2024*) The other reasons are viewing geometry (fore optic degree and field of view or FOV and instantaneous-field-of-view or IFOV, fore optic height above terrain, and ground), and illumination geometry, such as date, azimuth and orientation, position and sun altitude, time, and smoke and haze (*Jafarbiglu and Pourreza, 2023*). Hence, different conditions that influence the spectra of vegetation are shown in Fig. 2.

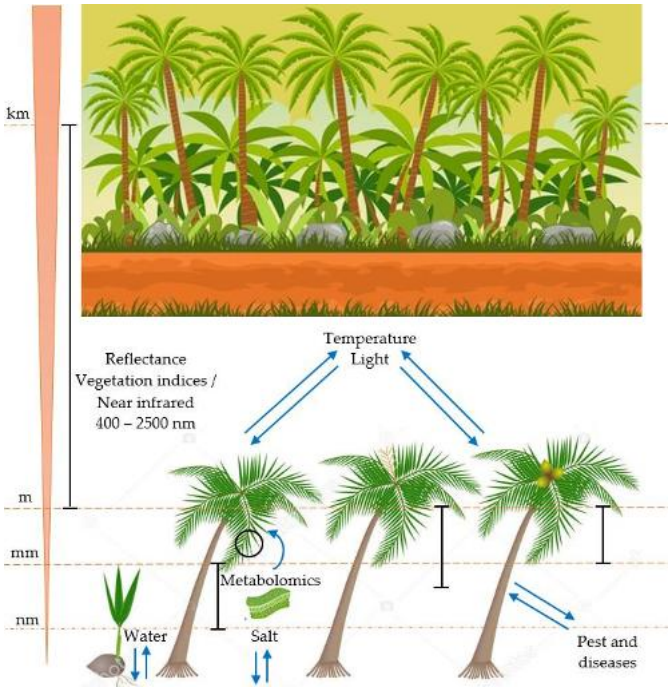

Fig. 2 - Different conditions which influence the spectra of vegetation

Plant reflectance can be measured using a handheld device, such as a spectroradiometer, to measure canopy spectral reflectance. These devices have developed into a helpful alternative for identifying or differentiating objects pertaining to spectral information using conventional methods, such as texture analysis and colour segmentation (*Soca-Muñoz et al., 2020*). Regarding vegetation, they can be used in the field to measure the spectral signatures of the visible light spectrum of various plant species, including different coconut species, i.e., MATAG. The spectral signature of the crop is attributed to low reflectance values in the visible zone of the electromagnetic spectrum due to significant light absorption by photosynthetic pigments (*Kutser et al., 2020*). The absorption maxima for chlorophyll a and b are in the blue (400 nm to 500 nm) and red (around 670 nm) zones, respectively, whereby carotenoids (i.e., xanthophylls and carotenes combined) absorb in the blue range as well (*Agostini et al., 2024*). Any disease that causes pigment degradation, chlorosis, or tissue necrosis may result in visible reflectance changes. Near-infrared (near-IR) reflectance values are high between 700 nm and 1000 nm. Hence, there is a need to develop a database to store spectral signature data. However, the database adopted from other studies requires an evaluation of dataset applicability for the specific task, such as detecting MATAG variety (*Imanian et al., 2021*). Furthermore, creating a large database of crop spectral signatures is difficult because it requires continuous monitoring of crops from seeding to harvesting.

For example, spectral signature libraries for agricultural research are accessible, such as the SPECCHIO Spectral online database held by the University of Zurich's Remote Sensing Laboratories in the Department of Geography (*SPECCHIO, 2022*). The library can display the spectral signature of significant crops such as wheat and potatoes. The database includes biophysical parameters of yields and soil characteristics. The library has been tested, but several things could be improved, including the lack of a multi-criteria query. A lengthy list containing hundreds of records is visualised for each search. Instead, it should be more systematic to include the crop's plantation date and location. Other agriculture libraries and databases are being developed. However, some are no longer available, such as the Vegetation Spectral Library, created with National Science Foundation funding by the Systems Ecology Laboratory at the University of Texas in El Paso (*Systems Ecology Laboratory, 2017*). Based on the published literature, no suitable library exists to be used for detecting MATAG. Hence, future studies are proposed to fill this limitation by developing a library specifically used to identify MATAG.

MATAG detection necessitates images during different growth stages, making fieldwork problematic in terms of labour and costly when using conventional visual assessment techniques based on the human eye (*Chu et al., 2025*). Conventional crop mapping is time-consuming and needs ongoing field research to validate and classify the images from RGB, multispectral, and hyperspectral sensors (*Zhang et al., 2025*). These problems can be solved by collecting spectral signatures for MATAG at various growth stages and mapping the reflectance of MATAG in the spectral signature library using sensors such as RGB and hyperspectral. Therefore, detecting MATAG using spectral signatures is highly desirable. The spectral signature can precisely map the MATAG variety as a spectral signature graph. Coconut species have specific spectral signatures with unique graph curves based on their characteristics. Then, a spectral library can compare the reflectance of MATAG in a field, estimating the infestation proportion (*Yang and Kong, 2017*). Moreover, it can identify plant locations through mapping coconut varieties. The spectral signature graph is stored in a digital database to prevent loss and provide easy access to researchers worldwide (*Rossel et al., 2016*). To the best of our knowledge, no study used spectral signatures to detect MATAG variety in any growing stages, starting from seeding, sprouting, growing, reaching maturity, and blooming. Only a few studies use the spectral signature analysis for coconut monitoring, and not specific for the detection of different coconut species (Table 1). Therefore, this approach could contribute to new knowledge and guide researchers to apply MATAG in the future.

Table 1

Investigate the potential use of high-resolution data for horticultural crop type classification and delineation using a semi-automatic classification method versus traditional visual interpretation techniques.	Plantations that were older and more mature were classified more accurately, whereas young and recently planted plantations (3 years or less) had poor classification accuracy due to a mixed spectral signature, wider spacing, and poor plantation stands.	*Hebbar et al. (2014)*

4. COMPARISON BETWEEN TRADITIONAL METHODS AND SMARTPHONE-SPECTRAL SIGNATURE-BASED APPROACHES FOR DETECTING MATAG HYBRID

Traditional methods of MATAG variety cultivation include visual inspection and laboratory analysis. These methods have both advantages and disadvantages. The collected data are manually recorded in notebooks or logbooks, making them simple to adopt and applicable to different age groups of farmers because they require no digital infrastructure. It uses basic tools such as measuring tapes, poles, and even binoculars to identify the characteristics of crop species. The farmers will also physically evaluate the seedling colour and seedling age using morphological observation, thus allowing for direct assessment and decision-making. Although it is inexpensive, monitoring is subjective and inconsistent. Only surface-level problems can be observed, resulting in a lack of precision and depth (*Mahant and Pal, 2025*). It is also time-consuming and labour-intensive to accurately identify different Matag variety species, as limited to the farmer's knowledge and experience (*Arumugam and Hatta, 2022*). It is unsuitable for large-scale operations due to the need for extensive skills by qualified experts, with significant resources. Data retrieval and aggregation are inefficient, with limited data integration possibilities. Manual data collection and interpretation using items such as magnifying glasses, soil kits, and moisture meters can be prone to errors (*Mihrete and Mihretu, 2025*). Furthermore, laboratory analysis is suitable for less common MATAG samples, is costly, takes a longer time to produce the results, and is not suitable for large-scale MATAG monitoring due to the requirement for laboratory facilities and qualified personnel.

The monitoring of MATAG has improved substantially as technology has become more sophisticated. Farmers can use smartphone devices as an interface to capture the high-resolution images and spectral data of MATAG seedlings collected from unmanned aerial vehicles (UAVs) equipped with cameras and sensors. Images of the trees are then analysed using artificial intelligence and machine learning algorithms by a mobile application (*Singh et al., 2021*). When reflectance data are collected using external devices such as a UAV, the processed reflectance data can be uploaded to a cloud database or server. These processed spectral datasets are then retrieved by the apps and displayed in a user-friendly interface for farmers (*Heim et al., 2024*). In this context, the smartphone serves mostly as the end-user platform, while external devices provide additional spectral information. This approach allows for the early identification of problems in the field, frequently before obvious signs occur. It also provides detailed aerial views, allowing for early detection of pest infestations, disease outbreaks, and nutrient deficits on the trees. Farmers can take a picture of an infected tree and send it to the mobile application, which can figure it out within minutes. It has user-friendly interfaces that include GPS mapping, automated alerts, data analytics, and cloud storage. It offers instructional tools and advice on best practices in the plantation. It can be used to detect diseases in real-time across large areas. It is portable since farmers may receive information directly (*Ibrahim et al., 2025*). However, the accuracy may vary based on the quality of the provided smartphone camera and sensors, as well as the specificity of the algorithms. The initial setup cost is high, and technical skills through training are required to configure, operate, and interpret the data efficiently. It also requires consistent internet connectivity (*Liu et al., 2023*).

MATAG variety identification can be monitored using spectral signature libraries, which analyse the specific wavelengths of light reflected by various plant tissues. These libraries store data on the spectral signatures of healthy and unhealthy coconut leaves, which can be utilised for determining disease transmission across large areas (*Roslin et al., 2021*). Mobile applications can be created to display the spectral signature of MATAG leaves through smartphones while also providing farmers with control measures of the disease. Smartphones can detect plant species using processed images from RGB, multispectral, or hyperspectral sensors, as well as an algorithm (*Che'Ya et al., 2022*). By connecting mobile devices with UAVs, images of

coconut tree crowns can be captured, and it is used to estimate total leaf area, number of bunches and fruits, and other phenotypic traits (*Arumugam and Md Hatta, 2022*). Such a connection can help to minimise data collection time and costs while also improving phenotyping data accuracy. Most smartphones are equipped only with RGB cameras. Hence, spectral signature analysis on smartphones is either limited to RGB-based indices or supported by add-on accessories (i.e., clip-on portable spectrometers) that increase the spectral range (*Schlemitz and Mezhuyev, 2024*). As an alternative, smartphones can be connected to external databases of pre-collected spectral libraries, which enables the phone to be utilised as the interface for spectral data visualisation and decision support.

While traditional methods for recognising MATAG diseases remain acceptable, smartphones with built-in cameras or that connect to external spectral sensors to evaluate the light reflected from coconut trees provide a more efficient, accurate, and cost-effective alternative. Smartphones can give precise data, detecting diseases that are invisible to the naked eye in real-time. Furthermore, smartphones are highly scalable, making them appropriate for large-scale plantations. Traditional approaches, on the other hand, have limited scalability due to labour constraints. Smartphones allow for seamless data integration, analysis, and storage, usually set up with cloud-based systems, whereas traditional methods rely on manual records that are difficult to analyse and prone to loss or damage. Traditional methods are less expensive initially. Despite the higher initial costs of smartphones, they provide better long-term cost reductions and benefits through optimised resource usage and increased yields, making them a good investment. Smartphones are designed to be user-friendly, but they need a certain amount of digital literacy, whereas traditional methods do not require technological proficiency but can be time-consuming and inconsistent (*Padhiary et al., 2025*). The combination of traditional and modern approaches might leverage the strengths of each to provide an efficient system for MATAG variety identification and farm management. The comparison between the advantages and disadvantages of traditional methods with smartphone-spectral signature-based approaches is presented in Fig. 3.

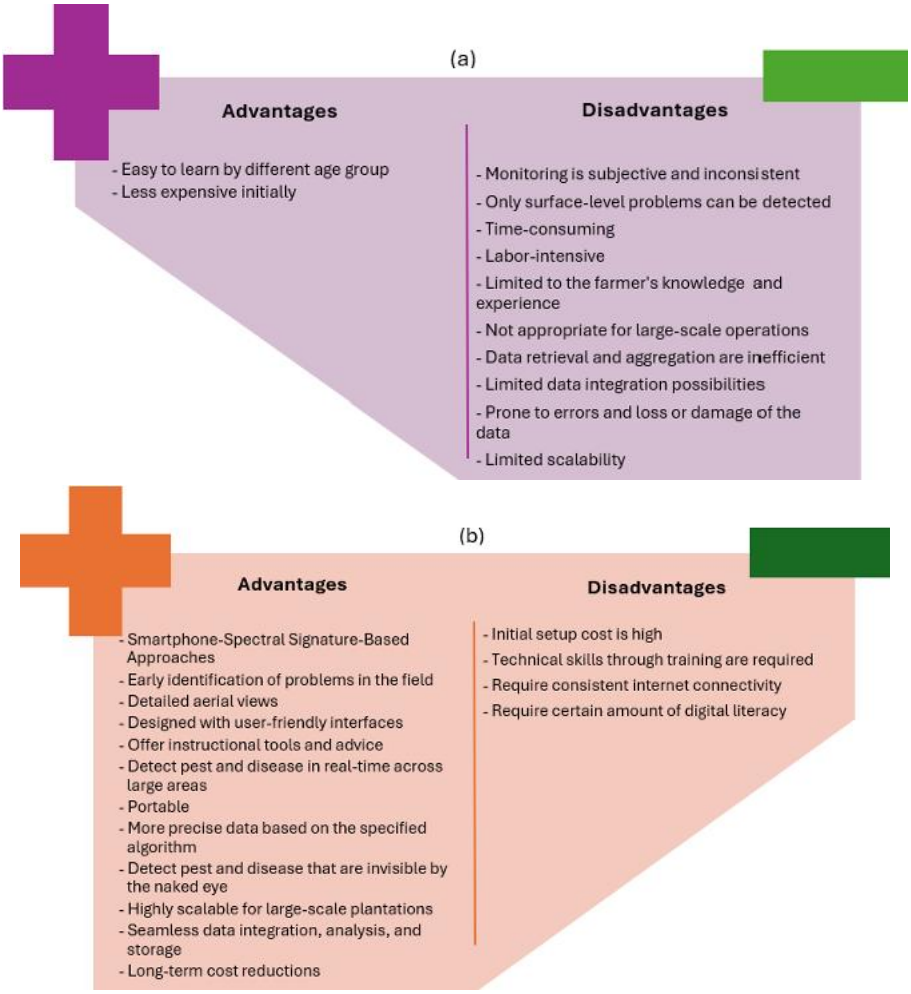

Fig. 3 - Advantages and Disadvantages between Traditional Methods (a) and Smartphone-Spectral Signature-Based Approaches (b) for Detecting MATAG Hybrid

5. MECHANISM OF MATAG VARIETY DETECTION BASED ON SPECTRAL SIGNATURE ANALYSIS USING A SMARTPHONE

5.1. Collection of Reflectance Data and Spectral Signatures

At first, the farmers need to ensure that the GPS in the smartphone is turned on to tag the location of the MATAG trees. After collecting the on-leaf surface of the seedlings, the reflectance of the spectral data is collected using a Handheld Spectroradiometer, under clear sky field conditions. It has a highly sensitive detector array with a low stray light grating, a built-in shutter, DriftLock dark current compensation, and second-order filtering, which produces a high signal-to-noise spectrum with second. Spectral data collection involves two primary steps, which include spectral sampling (Fig. 4) and spectral library compilation. During calibration, the white panel diffuses around 99% of incident light across its spectral range. Specifically, the reflectance value of the white reference panel is almost one for each wavelength (*Buddenbaum et al., 2019*). The MATAG trees should be chosen at random for 10 samples, with a spacing of 5 cm between the optical sensor and the sample. Accordingly, this method works to record data without inaccuracy or noise (*Che'Ya, 2016*). Reflectance data and spectral signature images for identifying MATAG species should be captured through RGB or hyperspectral sensors (*Strauss et al., 2021*).

The images are then divided into digital segments, and objects within the images are analysed using computer vision techniques such as machine learning and support vector machines. Hence, the spectral signature of a crop cannot be accurately assessed by parametric approaches such as regression or functional statistics. Non-parametric methods for hyperspectral spectroscopy include PCA, Fuzzy logic, SVM, CA, PLS, and NNs. Fisher's Linear Discriminant Analysis (LDA) classifies imaging and non-imaging hyperspectral data into two or more classes (*Golhani et al., 2018*). The generated images are examined for spectral signature differences among several MATAG types.

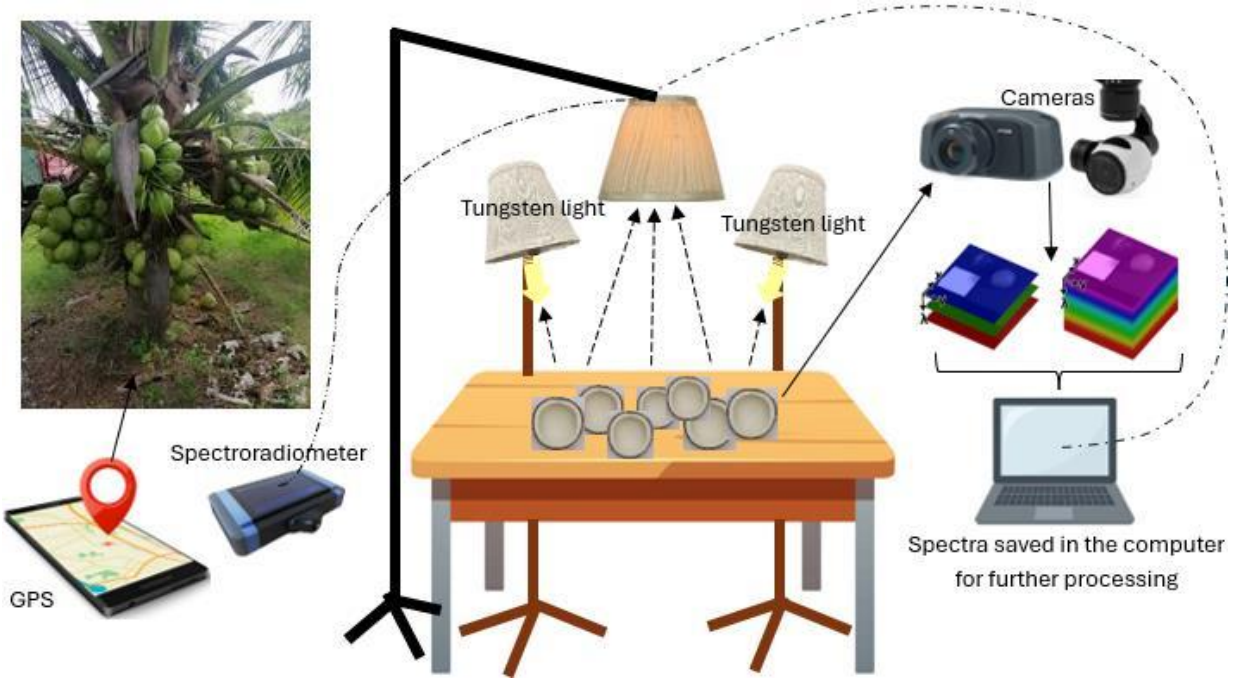

Fig. 4 - Configuration of spectral sampling in MATAG variety detection

5.2. Image Processing for Pest and Disease Monitoring Using the Mobile Application

Image preparation uses an algorithm incorporated into the system (*Miao et al., 2018*). The preprocessing phase ensures that the image collects only the analyses of hybrid components and excludes the other coconut species, also known as the separation technique. The colour of the images will be restored using colour constancy and uniformity (*Mendes et al., 2020*). The plant's various characteristics will next be retrieved and compared to the MATAG hybrid model to verify their uniqueness. The user receives findings that include the type of MATAG, the causing agent, a technique to control the infection, and prevention guidelines for overcoming the infection (*Ouhami et al., 2021*).

MATAG variety detection could be accomplished by capturing images of crops with seedlings using a camera. Under certain conditions, the camera may capture the image and detect the status of the plant

harbouring the different MATAG species based on light reflectance (*Areni, 2020*). Implementing hyperspectral sensors in smartphone devices is one way to improve the limits. A hyperspectral sensor can measure hundreds of electromagnetic spectrum bands within its range. The hyperspectral sensor's spectral bands monitor only a few nanometres of the electromagnetic spectrum, generating a wavelength with great spectral resolution (*Ko, 2019*). As a result, each pixel in a hyperspectral image acquires a specific set of data about the reflectance (or transmittance) of each spectral band (*Che'Ya, 2013*).

The total amount of these data is known as a spectral signature (or spectral profile), and it is captured by a non-imaging hyperspectral sensor (i.e., point spectroscopy) without the need for additional spatial information (*Park et al., 2020*). Hyperspectral sensors detect the spectral bands of each pixel in an image and merge the spectrum and spatial resolutions. As a result, each pixel in the image has a unique spectral signature, which comprises reflectance values for all spectrum bands detected by the hyperspectral sensor (*Hassanzadeh, 2020*). From another perspective, the final image is a hyperspectral data cube with two dimensions of spatial information and a single size for spectral information. In general, hyperspectral sensors can measure the NIR (700-1000 nm) and SWIR (1000-2500 nm) wavelengths of the electromagnetic spectrum (400-700 nm) (*Contreras, 2020*).

The interaction between spectral signature information and ground data demonstrated that the rate of MATAG variety detection in the crop may be predicted. Spectral reflectance can reveal species variances at specific wavelengths. *Roslin et al. (2021)* discovered that in the visible spectrum (450 nm to 700 nm), numerous weed spectral signatures were quite comparable, and several overlapped. Undoubtedly, not all MATAG have the same spectral signature on the coconut species, hence calibration and validation are still needed to identify MATAG. At the same time, in the infrared region (700 nm to 990 nm), different species' spectra are recognised by their wavelengths. Because each coconut has its own unique features, the significant bands for each species can be discovered in a specific region (710 nm to 750 nm), including MATAG. The damaged area could serve as an indicator for identifying MATAG species using spectral signatures. As a result, information on the spectral signature of the MATAG, as well as other sorts of pests and diseases, must be stored in a user-friendly manner.

The image data can be collected in red, green, and blue (RGB), and the MATAG will be identified based on its shape and colour using image processing. Thus, utilising a smartphone, the user can identify MATAG using apps connected to a cloud-based data processing machine. The spectroradiometer will capture spectral signatures (hyperspectral data) that can be used to classify MATAG. Thus, RGB, spectral, and hyperspectral information can be utilised to identify and refer to hyperspectral data. Certain smartphones only record RGB images. They can, however, process the RGB information and generate the results using artificial intelligence (AI) on the cloud server. The spectral signature of plants is already stored in the spectral library, which may be accessed if the user has a hyperspectral sensor and compares it to the spectral library in smartphone devices.

5.3. Generation of Spectral Signature Graph

The following subsection illustrates how spectral reflectance profiles can be analysed for MATAG and related coconut varieties. Applications for MATAG variety detection should rely on the ability to obtain a spectral signature that is related to tree features and plant health. Hence, a spectral signature graph could be associated with a variety of tree features, including age category, varietal difference, density, and shade composition (*Che'Ya et al., 2022a*). Other factors include healthy and unhealthy trees, with spectral signature values varying according to the types of MATAG hybrid. For data analysis, all raw data were sent to a computer. The data was saved in a Microsoft Excel file. In addition, the data should be arranged into 10 nm spectral bands, rather than its original 1 nm value (Fig. 5). The spectral signature may be seen in the spectral reflectance graph for each MATAG species. To further analyse subtle differences among coconut varieties, the first derivative of spectral reflectance is often used, as reported in a previous study (*Che'Ya et al., 2022c*). The general formula for calculating the first derivative between two adjacent reflectance values is given in Equation 1:

i. Visualising Spectral Reflectance. Construct a graphic illustration that shows spectral reflectance for MATAG.
ii. First Derivative Analysis. Use Equation (1) to calculate the first derivatives and then generate the spectral signature and first derivative graphs.

(1)

$$FD = \frac{R}{R} = \frac{Ry_2 - Ry_1}{\lambda x_2 - \lambda x_1}$$

where:

FD = First Derivative.

Ry_1, Ry_2= Reflectance of the first and second reflectance pairs n1 and n2.

λx_1, λx_2= Wavelength of first and second reflectance pairs n1 and n2.

n = Position of reflectance.

Fig. 5 presents an example of spectral reflectance profiles for MATAG seedlings. These curves can be further analysed using the derivative approach shown in Equation 1, which enhances the detection of small variations between overlapping spectra. The spectral reflectance profile of the three different coconut seedlings shows a similar trend. According to the graph, the spectral reflectance showed a low reflectance in the visible region with a small peak in the green region, and an increase begins at 680 nm. However, it is observed that numerous noises are clearer at certain points in the near-infrared region. The spectral data of the three coconut seedlings were similar in the visible region, and many overlapped each other. In the near-infrared region, the spectra of different seedlings also showed quite similar patterns, but they can be observed between 733 nm and 1000 nm. The reflectance of MRD coconut seedlings showed the highest NIR reflectance, and the lowest belongs to the reflectance of MATAG coconut seedlings. However, this study only detects and classifies MATAG coconut seedlings based on spectral data using a machine learning algorithm, without any integration with the mobile application. Future studies are needed to develop an intelligent identification system for the MATAG variety based on spectral signature analysis using a smartphone device.

5.4. Proposed Framework for Incorporating Spectral Libraries into Mobile Application
